Graphon Mean Field Games

A Physicist's Path from the Mean-Field Limit to Network Equilibria

Preface

This book is an attempt to carry a reader trained in theoretical physics — and in particular one comfortable with the language of statistical mechanics, stochastic processes, and field theory — across the bridge into the modern mathematics of *mean field games* and their network-structured generalization, *graphon mean field games*. The destination is a body of theory that sits at the confluence of stochastic analysis, partial differential equations, optimal control, game theory, and the theory of graph limits. The premise is that a physicist already possesses many of the load-bearing intuitions — the passage to a thermodynamic limit, the notion of a self-consistent field, conservation laws and continuity equations, and the effect of disorder and broken homogeneity — and that the most efficient route into the subject is to name those intuitions explicitly and then build the rigorous mathematics on top of them.

A word on how that premise is used. Physical analogies appear throughout, but they are kept deliberately light and are always optional: a physical picture motivates a definition or makes a theorem memorable, but it never carries mathematical weight. If every *Physics note* in the book were deleted, the mathematics would stand unchanged. The standard of rigor is what we call "physicist's rigor, honestly kept": every object is defined precisely and every theorem is stated with its full hypotheses, but proofs are given at the level of a complete and honest sketch when a full argument would consume more space than it illuminates, always with an explicit pointer to where the missing details live. We never write "it can be shown" and leave it there.

The book is long by design and contains no exercises. In place of exercises, two running examples — a linear–quadratic–Gaussian mean field game, and its graphon generalization — are carried from the foundational chapters all the way to the numerical and learning-based frontiers, acquiring one new layer of structure in each relevant chapter. Watching a single, fully explicit problem pass through every stage of the theory is, we believe, worth more than any number of detached drills.

The roadmap is organized in five parts. Part I assembles exactly the measure theory, functional analysis, stochastic calculus, and optimal control that the rest of the book consumes — no more, no less. Part II develops the classical theory of mean field games for homogeneous populations: the coupled forward–backward system, its probabilistic counterpart, existence and uniqueness, the master equation, and the convergence of large finite games to the mean field limit. Part III is a self-contained introduction to dense graph limits and graphons. Part IV is the synthesis: mean field games played over a graphon, where each agent's coupling to the population is mediated by a kernel $W(x, y)$ indexed by a continuum of types. Part V turns to active research — sparse network limits, numerical methods, and reinforcement-learning approaches to computing equilibria.

A note on conventions. The single most important page in this book for day-to-day reading is Appendix A, which fixes notation and resolves every clash between physical and mathematical convention used in the text. The reader is encouraged to skim it once before Part II and to return to it whenever a symbol surprises them.

Part I

Mathematical Foundations

Chapter 1

Measure, Integration, and the Passage to a Continuum

This is the first chapter of the book and it imports nothing: it builds, from the ground up, the language in which every later statement is made precise. The reader who already manipulates N-body sums, Dirac combs, occupation densities, and the "thermodynamic limit" $N \to \infty$ has, in fact, already been doing measure theory – informally. Nothing in this chapter asks the reader to take up a foreign subject; it asks only that a handful of habits already in daily use – summing point masses, smearing a Dirac comb into a profile, letting a particle count run to infinity – be given names sharp enough to be trusted under a limit. Our task here is to install the formal apparatus so that the limits the physicist takes by reflex become *theorems* with hypotheses one can check, rather than gestures one hopes are legal. The single object that organizes the whole chapter is the *empirical measure*

$$\mu^N \; = \; \frac{1}{N}\sum_{i=1}^{N} \delta_{X_i},$$

the normalized occupation profile of a finite population of agents located at $X_1, \ldots, X_N$. The central result, proved in section 1.7, is that when the X_i are independent draws from a common law m, the random measures μ^N converge – almost surely, in a precise sense we will define – to the deterministic measure m. This is the cleanest rigorous incarnation of the statement "fluctuations are suppressed in the large-population limit," and it is the prototype of every passage-to-the-continuum argument in mean field game theory.

We develop exactly the toolbox that the rest of the book consumes and no more, and the order of development is dictated by that single destination: each section exists because the previous one left something we still need. First, the limiting profile m and the empirical measure μ^N need a *home* – a family of subsets we are entitled to assign a size to, and a rule that does the assigning – so we build σ-algebras and measures (section 1.2), motivated in section 1.1 by the failures that make them unavoidable. Then we need an *integral* compatible with limits, one that survives the monotone and concentrating limits on which the elementary integral founders, so we construct the Lebesgue integral (section 1.3) and check that $\int f \; \mathrm{d}\mu^N = \frac{1}{N}\sum_i f(X_i)$ is the literal bridge between the discrete average and the continuum one. Then we need *permits* to move a limit through that integral, so we prove the three convergence theorems – monotone, Fatou, dominated (section 1.4) – which are exactly the licenses that every "take the limit inside the average" step silently invokes. Then, because expectations factor over independent sources and the graphon chapters integrate a kernel $W(x, y)$ against two population variables at once, we need a *product theory*, supplied by the Fubini–Tonelli theorem (section 1.5). Then we need *completeness* of the spaces of integrable functions, both as a structural backbone and for the spectral chapter to come, so we build the L^p spaces and prove they are Banach (section 1.6). Only with every part in hand do we assemble the empirical-measure theorem in the closing worked computation. Each section is thus the next thing one is forced to want, and we flag at every step where the tool will be reused later.

The functional-analytic life of these spaces – duality, weak topologies, the spectral theorem – is the subject of chapter 2; the full theory of weak convergence of probability measures, with the Portmanteau theorem and Prokhorov's compactness criterion, is developed in chapter 3; the Wasserstein geometry in which the mean field actually lives is chapter 4. We use only as much of those subjects here as the empirical-measure statement strictly requires. The lone result of pure measure theory we accept without proof is the Carathéodory extension theorem (named where it is used, in theorem 1.11); every other borrowed fact is flagged on the spot.

Notation watch

Throughout this chapter the symbol x denotes a generic point of the *state space* $\mathbb{R}^d$ – the position, velocity, wealth, or opinion of a single agent – and the integration variable ranges over $\mathbb{R}^d$. This is *not* yet the graphon *type* variable $x \in [0, 1]$, an exchangeable label that carries no metric meaning of its own: it is first put to work in chapter 2 as the domain of the graphon integral operator (the Hilbert–Schmidt example there) and is formally introduced as a graph limit in chapter 15. The two never appear together in this chapter. When, in section 1.5, we foreshadow the graphon double integral, we will write the type variables explicitly and point to where they are defined.

1.1 Why a physicist needs measure theory

The preamble made a promise: the limits a physicist takes by reflex – replacing a normalized sum of point masses by a smooth profile, replacing a population average by an integral – are to become theorems with hypotheses one can check. The purpose of this section is to show that the promise has teeth. Taken literally, the reflex poses three questions, and the elementary calculus the reader already owns cannot answer any of them; worse, the obstruction is not at the margin but at the precise joint where analysis meets limits. By the end of the section the need for new machinery should be felt as a concrete pressure rather than accepted on authority, and the shape of that machinery – a structured family of "sizeable" sets and a notion of size stable under countable limits – should already be visible in outline. That is exactly the object the next section builds.

Begin where the physicist begins: with an average. Given N agents at positions $X_1, \ldots, X_N \in \mathbb{R}^d$ – positions, velocities, wealths, opinions – the population average of an observable f is the finite sum $\frac{1}{N}\sum_{i=1}^{N} f(X_i)$. One would like to say that as the population grows this settles down to an integral $\int f(x)\, m(\mathrm{d}x)$ against some limiting "density profile" m, and – the genuinely powerful claim – that the entire population is thereafter summarized by the single object m rather than by the ever-lengthening list of positions. This is the move that makes a continuum theory possible at all: it trades N coordinates for one profile. But to make it precise we must answer three questions, and each is, in a sharp sense, unanswerable inside elementary calculus.

1. What *is* the object m? The population may concentrate on a lower-dimensional set, develop atoms, or spread to infinity, and in none of these cases is m a Riemann-integrable density function.

2. In what *sense* does $\frac{1}{N}\sum_i \delta_{X_i} \to m$? The left-hand side is a sum of infinitely sharp spikes and the right-hand side may be perfectly smooth, so the convergence cannot be the pointwise convergence of densities.

3. When may we *exchange* the limit $N \to \infty$ with the integral $\int f(\cdots)$? Every thermodynamic-limit argument performs this interchange, almost always silently, and – as we will see – it is sometimes simply false.

Consider the first question concretely, because its difficulty is easy to underestimate. Suppose the agents' positions, as N grows, pile up onto a constraint surface – particles pinned to a manifold, a population of opinions collapsing to a single consensus value, a wealth distribution in which a finite fraction of agents holds exactly zero. The limiting profile then assigns *positive* mass to a set that has *zero* length, area, or volume: a single point, a curve, a lower-dimensional surface. No function $\rho(x)$ with $m(\mathrm{d}x) = \rho(x)\,\mathrm{d}x$ can describe this, for the integral of any honest function over a set of zero volume is zero. A condensate – a macroscopic fraction of the population sitting at one location – is an *atom*, and atoms are invisible to densities. Even in the benign case where m does turn out to have a smooth density, m is not handed to us *as* a density: it is handed to us as the rule "how much population sits in the region A," an assignment of a number to each set A. The right primitive notion is therefore not a function on points but an assignment of mass to sets – a *measure* – and only sometimes is this assignment representable by a density.

The second question is the mirror image of the first on the side of the approximants. The empirical measure $\frac{1}{N}\sum_i \delta_{X_i}$ places mass $1/N$ at each of N points and nothing in between; it is as far from a smooth density as an object can be, concentrated entirely on a finite set of zero total volume. There is no sense in which the "heights" of these spikes converge to the values of a limiting density, because the spikes have no heights – they are point masses, not tall thin bumps. Whatever convergence we mean cannot live at the level of values at points. The only thing that *does* behave well is what we get by testing the spikes against a smooth observable: the number $\frac{1}{N}\sum_i f(X_i)$ is a perfectly ordinary average, and it is this number, for each fixed reasonable f, that we can hope to control. Convergence of the population, then, must mean convergence of these test averages – $\int f\,\mathrm{d}\mu^N \to \int f\,\mathrm{d}m$ for a rich enough class of f – which is precisely the notion of *weak convergence* we develop in chapter 3. The heuristic below records the shift in viewpoint this forces, and the third question exposes why even the test averages must be handled with care.

Example 1.1 (Riemann integration is not closed under monotone limits)**.** Enumerate the rationals in $[0,1]$ as $\mathbb{Q} \cap [0,1] = \{q_1, q_2, \dots\}$ and set $f_n = \mathbf{1}_{\{q_1,\dots,q_n\}}$, the indicator of the first n of them. Each

f_n vanishes except at the finitely many points $q_1, \ldots, q_n$, so on any partition of $[0,1]$ its lower Darboux sum is 0, while its upper Darboux sum can be made smaller than any $\varepsilon > 0$ by covering those n points with cells of total length $< \varepsilon$; hence f_n is Riemann integrable with $\int_0^1 f_n = 0$. The sequence increases pointwise, $f_n \uparrow f$, to the indicator $f = \mathbf{1}_{\mathbb{Q}\cap[0,1]}$ of all the rationals. But f is *not* Riemann integrable, and the reason is worth seeing in full. Fix any partition $0 = x_0 < x_1 < \cdots < x_m = 1$. On each cell $[x_{k-1}, x_k]$ both the rationals and the irrationals are dense, so f takes both the value 1 (at some rational) and the value 0 (at some irrational) inside the cell; thus $\inf_{[x_{k-1},x_k]} f = 0$ and $\sup_{[x_{k-1},x_k]} f = 1$. The lower Darboux sum is therefore $\sum_k 0 \cdot (x_k - x_{k-1}) = 0$ and the upper Darboux sum is $\sum_k 1 \cdot (x_k - x_{k-1}) = 1$, *for every partition.* The lower integral (sup over partitions of the lower sums) is 0 and the upper integral (inf of the upper sums) is 1; they disagree, so $\int_0^1 f$ does not exist.

The example does more than exhibit a monotone limit of integrable functions that fails to be integrable; it shows that the desired interchange statement cannot even be *written down* in Riemann's theory. The left-hand side $\lim_n \int_0^1 f_n = \lim_n 0 = 0$ is a perfectly good number. The right-hand side $\int_0^1 (\lim_n f_n) = \int_0^1 f$ is a symbol that *denotes nothing*, because the function it would integrate is not Riemann integrable. The proposed identity $\lim_n \int f_n = \int \lim_n f_n$ is thus not false – it is ill-formed, an equation one side of which is undefined. A theory in which the natural question cannot be posed is the wrong theory for taking limits inside integrals, which is the only thing we will ever do.

The Lebesgue theory, built in sections 1.2 to 1.3, repairs exactly this. There the rationals are a *null set* – a countable set, coverable by intervals of arbitrarily small total length – the function $\mathbf{1}_{\mathbb{Q}\cap[0,1]}$ is measurable and integrable with integral 0, and the identity $\lim_n \int f_n = 0 = \int \lim_n f_n$ now has both sides defined and equal, as a special case of the monotone convergence theorem (theorem 1.20). The repair is not cosmetic. The whole business of this book – limits of densities, weak limits of empirical measures, the exchange of $N \to \infty$ with an integral – requires an integral that is *stable under the limits we actually take*, and that stability is precisely what Riemann's construction lacks and Lebesgue's supplies.

Heuristic (non-rigorous)

The physicist's instinct "a sum of many sharp spikes becomes a smooth profile" is correct, but it is a statement about *measures*, not about *functions*. The empirical measure $\frac{1}{N}\sum_i \delta_{X_i}$ is never a function – it has no density with respect to Lebesgue measure, being a sum of point masses sitting on a set of zero volume – yet it can converge to a measure that has a perfectly smooth density. The two sides of "spikes $\to$ profile" therefore live in different worlds if read as functions, and in the *same* world, the world of measures, if read correctly: a measure is what both a sum of Diracs and a smooth density already are. This is why the right category for the passage to the continuum is the category of measures, with convergence tested by integrating against smooth observables rather than by comparing values at points. Measure theory is the price of admission to that category, and the rest of this chapter pays it.

The third question – when may we move the limit inside the integral – has its own canonical warning, and it is even sharper than the rationals example because here both sides are perfectly well-defined and simply *unequal.* Consider the sequence $f_n = n\,\mathbf{1}_{(0,1/n)}$ on $[0,1]$ with ordinary length: a rectangle of height n and width $1/n$ pressed against the origin. Its integral is the area of that rectangle,

$$\int_0^1 f_n \,\mathrm{d}x \;=\; n \cdot \tfrac{1}{n} \;=\; 1 \qquad \text{for every } n.$$

Now fix a point $x > 0$ and let n grow: as soon as $n > 1/x$ the point x lies outside the interval $(0, 1/n)$, so $f_n(x) = 0$ from then on; and $f_n(0) = 0$ for all n. Hence $f_n(x) \to 0$ for *every* $x \in [0,1]$, and the pointwise limit is the zero function, with $\int_0^1 \big(\lim_n f_n\big)\,\mathrm{d}x = 0$. The limit and the integral disagree outright:

$$\lim_n \int_0^1 f_n \,\mathrm{d}x \;=\; 1 \;\neq\; 0 \;=\; \int_0^1 \lim_n f_n \,\mathrm{d}x.$$

The unit of mass did not vanish; it *concentrated.* Where did it go? Test against any bounded continuous g:

$$\int_0^1 g\, f_n \,\mathrm{d}x \;=\; n \int_0^{1/n} g(x)\,\mathrm{d}x \;\xrightarrow[n\to\infty]{}\; g(0),$$

because the average of g over the shrinking interval $(0, 1/n)$ tends to the value $g(0)$ by continuity. But $g(0) = \int g \,\mathrm{d}\delta_0$. So in the language we are about to build, the measures $f_n\,\mathrm{d}x$ converge *weakly* to the Dirac mass δ_0: the mass survives, relocated entirely to the origin, and it is the *pointwise* limit – not the measures – that threw it away. This is the same phenomenon as the empirical-measure problem read in reverse, and it shows once more that the robust notion of convergence is the weak one, tested against observables.

This example is not merely a warning; it plants a seed we will harvest twice. First, it pinpoints the hypothesis that makes the interchange legal. The monotone, Fatou, and dominated convergence theorems of section 1.4 are the three permits for moving a limit inside an integral, and the dominated convergence theorem (theorem 1.23) demands exactly one thing the present sequence cannot supply: a single integrable function g with $|f_n| \leq g$ for all n. Here the smallest function dominating every f_n is $\sup_n f_n(x)$, which behaves like $1/x$ near the origin and is *not* integrable on $[0,1]$; the dominating-function hypothesis fails, and that failure is the precise mechanism by which mass escapes the pointwise limit. The hypothesis of theorem 1.23 is therefore not bureaucratic fine print – it is the wall that holds the mass in. Second, the very phenomenon "mass leaks out of every bounded picture – to a point here, to infinity in other examples" is, at the level of populations, controlled by the condition called *tightness*, developed in chapter 3; tightness is what guarantees that the limit of a sequence of probability measures is still a probability measure and has not silently shed mass. Recognizing when the interchange is legal, and recognizing the exact way it fails when it does, is thus not pedantry: it is the difference between a correct continuum limit and a lost order parameter.

We have now turned the physicist's reflex into three precise demands and shown that elementary calculus meets none of them. Each failure points to the same missing structure. To say what m is, to test convergence against observables, and to keep mass from leaking through a limit, we need two objects that Riemann's world does not provide. We need, first, a structured family of subsets of the state space that we are entitled to assign a size to – and the family must be closed under the countable unions and intersections that limits perform, since every object above (the rationals, the increasing f_n, the concentrating bumps) was produced by a countable limiting operation. That family is the *σ-algebra.* We need, second, a notion of size defined on that family – a *measure* – that is stable under exactly those countable limits, so that continuity-of-measure can replace the broken continuity of the Riemann integral. With those two objects in hand we will at last be able to say what the limiting profile m and the empirical measure μ^N *are*, as honest mathematical objects sharing a common home. Constructing them, and the maps between such homes, is the work of the next section.

1.2 σ-algebras, measures, and measurable functions

The previous section closed with a precise shopping list rather than a vague unease. To turn the physicist's reflex into theorems we need two things Riemann's world withholds: a structured family of subsets of the state space that we are entitled to assign a size to, *closed under the countable unions and intersections that limits perform*, and a notion of size on that family that is *stable under exactly those countable limits*. This section delivers both, and with them the first concrete payoff – an honest answer to the first of the three questions of section 1.1, "what *is* the object m." The answer will be: m is a *measure*, an assignment of mass to sets, living on a *measurable space*; the empirical measure μ^N is another such assignment on the same space; and the law of a single random agent is manufactured from a third by a structure-respecting map. Building those three notions – a family of sets, a size on them, and the maps between such homes – is the whole of the section, and the order in which we build them is forced by how they depend on one another.

The arc runs through five movements, each the minimal next thing the previous one requires. We begin with *measurable spaces* (definition 1.2 below): one cannot speak of the size of a set before declaring which sets are eligible to have a size, so the very first object is the family $\mathcal{F}$ of admissible sets, and its defining axiom – closure under countable operations – is the direct answer to the limit-incompatibility diagnosed in section 1.1. Onto that arena we then place a *measure* (definition 1.5): the size itself, a single rule $\mu\colon \mathcal{F} \to [0, \infty]$ whose one nontrivial axiom, countable additivity, immediately yields the continuity-under-limits properties that the broken Riemann integral could not supply. Because we will need to *construct* specific measures by prescribing their values on a small, convenient class of sets and then trusting that the prescription determines them everywhere, we pause for the uniqueness machinery of *generating classes* – π-systems and Dynkin's lemma (theorem 1.9) – the combinatorial engine that propagates agreement from a generating class to the whole σ-algebra, and which we reuse three times in this chapter. Armed with it we construct the one canonical concrete measure every density is implicitly measured against, *Lebesgue measure* (theorem 1.11), the rigorous form of length, area, and volume – and the background whose sets of zero volume are exactly the atoms that defeated the naïve density picture. Finally we turn to the *maps*: *measurable functions* (definition 1.12), the morphisms that respect the structure, which are both the observables we will integrate and the device – via the *pushforward* (definition 1.14) – that produces m as the law of a single agent and μ^N as a sum of pushed-forward point masses; and we prove the decisive stability fact that a pointwise limit of measurable functions is again measurable, without which none of the limiting objects built later in the book would be legal to integrate.

The ordering is not a matter of taste. A measure is a function defined *on* a σ-algebra, so the σ-algebra must exist first; a measurable function is defined by *pulling back* measurable sets of its target, so again the σ-algebra must come first; and integrating such a function against such a measure – the construction of the next section – presupposes both. Measurable spaces precede measures precede measurable functions because each later notion is literally built out of the earlier ones. We start, then, with the family of sizeable sets.

1.2.1 Measurable spaces

The previous section ended with a shopping list whose first item was a *home* for the limiting profile m and the empirical measure μ^N: a structured family of subsets of the state space that we are entitled to assign a size to. We build that family now, before any notion of size is placed on it, because one cannot speak of the size of a set before declaring which sets are eligible to have a size. The single design constraint is the one section 1.1 forced on us. Every object that broke the elementary theory – the rationals $\mathbb{Q} \cap [0,1]$, the increasing indicators $f_n \uparrow \mathbf{1}_{\mathbb{Q}}$, the concentrating bumps $n\mathbf{1}_{(0,1/n)}$ – was manufactured by a *countable limiting operation*, and the family of sizeable sets must be stable under exactly those operations or it will not survive the limits we intend to take. The family is the *σ-algebra*, and its axioms are nothing but the closure properties this stability demands, neither more nor less.

Before writing the axioms down, it is worth asking what a limiting operation actually does to sets, because the axioms are reverse-engineered from the answer. Three moves recur. We pass to a *complement*: “the agents *not* in region A” is as legitimate a region as A itself, and the size we will eventually assign should satisfy $\mu(A^c) = \mu(\Omega) - \mu(A)$, which is meaningless unless A^c is also in the family. We form a *countable union*: an increasing sequence of regions $A_1 \subseteq A_2 \subseteq \cdots$ swept out by a limit – think of the first n rationals as $n \to \infty$, or the sublevel sets that a convergence argument unions together – must have its limit region $\bigcup_n A_n$ in the family, or the whole point of building a limit-stable theory is lost. And, dually, *countable intersection*, the shrinking counterpart. These three are precisely the operations the convergence theorems of section 1.4 will perform on the sublevel sets $\{f_n > a\}$ of a sequence of functions; a family closed under them is exactly a family on which those theorems can run. This motivates the definition.

Definition 1.2 (σ-algebra)**.** Let Ω be a set. A collection $\mathcal{F} \subseteq 2^\Omega$ is a *σ-algebra* on Ω if (i) $\Omega \in \mathcal{F}$; (ii) $A \in \mathcal{F} \implies \Omega \setminus A \in \mathcal{F}$ (closure under complements); and (iii) $A_1, A_2, \dots \in \mathcal{F} \implies \bigcup_n A_n \in \mathcal{F}$ (closure under countable unions). The pair $(\Omega, \mathcal{F})$ is a *measurable space* and the members of $\mathcal{F}$ are the *measurable sets*.

Three axioms, and each earns its place. Axiom (i) merely fixes the total space as sizeable – the population as a whole is a region. Axiom (ii), closure under complements, is what makes “everywhere except A” admissible whenever A is, and – combined with (iii) – it silently delivers closure under countable *intersections*: by De Morgan, $\bigcap_n A_n = \left(\bigcup_n A_n^c\right)^c$, a complement of a countable union of complements, so the shrinking limits are covered without a separate axiom. (Taking $A = \Omega$ in (ii) also gives $\emptyset = \Omega^c \in \mathcal{F}$, so the empty region is sizeable, as it must be with size zero.) Axiom (iii), closure under *countable* unions, is the crux, and the adjective is doing all the work. It is strong enough to absorb a limit – a limit is assembled from a *sequence*, an indexed-by-$\mathbb{N}$, hence countable, collection of approximants – which is exactly the operation Riemann’s theory had no stable counterpart for, the gap diagnosed in section 1.1.

Why not demand more – closure under *arbitrary* unions, which would look cleaner? Because that demand is self-defeating: it is too strong to leave any room for a notion of size. Every single point $\{x\}$ of $\mathbb{R}^d$ will turn out to be measurable (it is closed, hence Borel below), and an *arbitrary* subset $E \subseteq \mathbb{R}^d$ is the union $E = \bigcup_{x\in E}\{x\}$ of its points. Closure under arbitrary unions would therefore force $\mathcal{F} = 2^\Omega$, the full power set – and on the full power set of $\mathbb{R}$ there is *no* translation-invariant way to assign a length to every set consistently (the Vitali construction exhibits a set whose translates partition the line into countably many congruent pieces, which no countably additive, translation-invariant length can accommodate). Arbitrary unions collapse the family to everything and leave nothing for a measure to be. Countable unions are the Goldilocks closure: wide enough to contain every set a limit can build, narrow enough that a consistent size still exists on the family. The single word "countable" is thus the operative hinge of the entire subject, the precise place where measure theory parts company with naïve set theory and gains the limits.

Generated σ-algebras. In practice one never writes down a σ-algebra by listing its members; one names a small, intuitive family of sets one insists be measurable – the open sets, say, or the boxes – and asks for the smallest σ-algebra that contains them. That such a smallest one exists is a one-line consequence of a closure fact worth isolating.

Remark 1.3 (Intersections of σ-algebras, and the generated σ-algebra)**.** *An arbitrary intersection of σ-algebras on Ω is again a σ-algebra.* Indeed, let $\{\mathcal{F}_i\}_{i\in I}$ be σ-algebras and put $\mathcal{F} = \bigcap_{i\in I}\mathcal{F}_i$. Then $\Omega \in \mathcal{F}_i$ for every i, so $\Omega \in \mathcal{F}$; if $A \in \mathcal{F}$ then $A \in \mathcal{F}_i$ for every i, whence $A^c \in \mathcal{F}_i$ for every i and so $A^c \in \mathcal{F}$; and if $A_1, A_2, \dots \in \mathcal{F}$ then for each fixed i all the A_n lie in $\mathcal{F}_i$, so $\bigcup_n A_n \in \mathcal{F}_i$, and as this holds for every i, $\bigcup_n A_n \in \mathcal{F}$. All three axioms pass through the intersection because each is a condition checked one index at a time. Consequently, for any family $\mathcal{E} \subseteq 2^\Omega$ the intersection of *all* σ-algebras containing $\mathcal{E}$ – a nonempty collection, since the power set 2^Ω is one such σ-algebra – is itself a σ-algebra, it contains $\mathcal{E}$, and it is contained in every σ-algebra that contains $\mathcal{E}$. It is therefore the *smallest* such, denoted $\sigma(\mathcal{E})$ and called the σ-algebra *generated* by $\mathcal{E}$. One should read $\sigma(\mathcal{E})$ not as an explicit list but as "everything forced to be measurable once the sets in $\mathcal{E}$ are," the closure of $\mathcal{E}$ under the three axioms.

A deliberately tiny example fixes the idea. Take $\Omega = \{1, 2, 3\}$ and let $\mathcal{E} = \{\{1\}\}$ insist only that the singleton $\{1\}$ be measurable. Closure under complements forces $\{2, 3\}$ in; the axioms put $\emptyset$ and Ω in; and one checks that $\sigma(\mathcal{E}) = \{\emptyset, \{1\}, \{2, 3\}, \Omega\}$ is already closed under all three operations, so nothing further is forced. This four-element family is strictly smaller than the eight-element power set $2^{\{1,2,3\}}$: the points 2 and 3 are never separated, because nothing we demanded distinguishes them. The generated σ-algebra is exactly the record of what our chosen "observable" sets can resolve and no finer.

The Borel σ-algebra. The state space $\mathbb{R}^d$ carries a topology, and the only sets we ever need to measure are those buildable from the open sets by the countable operations – which is to say, the σ-algebra generated by the open sets. This is the canonical choice on any space where a notion of nearness already lives.

Definition 1.4 (Borel σ-algebra)**.** On a topological space (X, τ) the *Borel σ-algebra* is $\mathcal{B}(X) := \sigma(\tau)$, the σ-algebra generated by the open sets. On $\mathbb{R}^d$ it is generated equally by the open balls, by the half-open boxes $\prod_j (a_j, b_j]$, or by the half-spaces; we write $\mathcal{B}(\mathbb{R}^d)$ throughout. Every set one can name by a countable construction from open sets – closed sets, countable intersections of open sets, and so on – is Borel.

The claim that the open balls, the half-open boxes, and the half-spaces all generate the *same* σ-algebra is not obvious and deserves the short argument that makes it routine. The principle is a single one: $\sigma(\mathcal{E}_1) = \sigma(\mathcal{E}_2)$ *as soon as each family lies inside the σ-algebra generated by the other*, because if $\mathcal{E}_1 \subseteq \sigma(\mathcal{E}_2)$ then $\sigma(\mathcal{E}_2)$ is a σ-algebra containing $\mathcal{E}_1$, hence contains the smallest such, $\sigma(\mathcal{E}_1)$, and the reverse inclusion is symmetric. So it suffices, in each case, to write the members of one family as countable set-operations on members of the other. The open balls are open, so $\sigma(\text{balls}) \subseteq \mathcal{B}(\mathbb{R}^d)$; conversely every open set $U \subseteq \mathbb{R}^d$ is the *countable* union of the open balls with rational center and rational radius that it contains (around each point of U sits such a ball lying inside U, and there are only countably many candidate balls), so $U \in \sigma(\text{balls})$ and thus $\mathcal{B}(\mathbb{R}^d) \subseteq \sigma(\text{balls})$. The half-open box $\prod_j (a_j, b_j]$ is a *countable intersection* of open boxes, $\prod_j (a_j, b_j] = \bigcap_n \prod_j (a_j, b_j + \frac{1}{n})$, hence Borel, giving $\sigma(\text{boxes}) \subseteq \mathcal{B}(\mathbb{R}^d)$; conversely every open U is a countable union of half-open boxes with rational corners, so $\mathcal{B}(\mathbb{R}^d) \subseteq \sigma(\text{boxes})$. And the half-open box is even a *finite* intersection of half-spaces and their complements, $\prod_j (a_j, b_j] = \bigcap_j (\{x_j \leq b_j\} \setminus \{x_j \leq a_j\})$, so the half-spaces generate the boxes (hence all of $\mathcal{B}(\mathbb{R}^d)$), while each half-space $\{x_j \leq c\}$ is closed and so Borel. The three families therefore generate one and the same $\mathcal{B}(\mathbb{R}^d)$, and one is free to use whichever is convenient – a freedom we exploit immediately, since the boxes are the natural domain on which volume is prescribed.

The closing sentence of definition 1.4 is the working intuition to carry forward: *anything nameable by a countable construction starting from open sets is Borel.* To see this is not empty, take the set that broke Riemann's theory in example 1.1, the rationals $\mathbb{Q} \cap [0, 1]$. Each singleton $\{q\}$ is closed – it is the complement of the open set $\mathbb{R} \setminus \{q\}$, or directly $\{q\} = \bigcap_n (q - \frac{1}{n}, q + \frac{1}{n})$, a countable intersection of open intervals – hence Borel; and $\mathbb{Q} \cap [0, 1] = \bigcup_{q \in \mathbb{Q} \cap [0,1]} \{q\}$ is a *countable* union of Borel sets, hence Borel. The very set on which the Darboux sums disagreed is, in the new framework, a perfectly ordinary measurable set, and we will see in the next subsection that it is one a measure can size (at zero). More generally the same two moves – a closed set is the complement of an open set, a countable family of measurable sets unions and intersects to a measurable set – certify every set that arises in this book.

This completes the home. We have a measurable space $(\Omega, \mathcal{F})$ – concretely $(\mathbb{R}^d, \mathcal{B}(\mathbb{R}^d))$ – a family of sets closed under exactly the countable operations a limit performs, generated economically from the boxes. The next subsection places a notion of *size* on this family, a measure $\mu\colon \mathcal{F} \to [0, \infty]$, whose one substantive axiom, countable additivity, is the size-level counterpart of the countable-union closure we just built and the direct source of the continuity-under-limits properties that Riemann's integral lacked. One feature of the present construction is worth flagging before we go, because the measure machinery will lean on it hard: the half-open boxes are closed under finite intersection (the intersection of two boxes is a box), and they generate $\mathcal{B}(\mathbb{R}^d)$. A generating family with this intersection-closure – a *π-system* (definition 1.8) – is exactly the lever that the uniqueness machinery of section 1.2.3 and the construction of Lebesgue measure in theorem 1.11 will pull: a measure is pinned down everywhere on $\mathcal{B}(\mathbb{R}^d)$ once its values on the boxes are fixed. The boxes, introduced here as a convenient generator, will return there as the small class on which every concrete measure of this chapter is actually prescribed.

1.2.2 Measures

We now own a home: a measurable space $(\Omega, \mathcal{F})$ whose family $\mathcal{F}$ of admissible sets is closed under exactly the countable unions and intersections a limit performs. What that family conspicuously lacks is a *size*. The previous subsection declared which sets are eligible to be measured but assigned no number to any of them; the limiting profile m and the empirical measure μ^N still have nowhere to live as actual objects. We supply the missing ingredient here – a rule $\mu\colon \mathcal{F} \to [0,\infty]$ that reads off "how much population sits in the region A" for each admissible A. The design of that rule is forced by the same diagnosis that shaped $\mathcal{F}$. In section 1.1 the elementary theory broke because size did not survive countable limits; the Riemann integral could not be slid through the increasing sequence $f_n \uparrow \mathbf{1}_{\mathbb{Q}}$. We are about to impose a single axiom on μ – countable additivity – and the entire payoff of this subsection is that this one axiom is logically equivalent to a package of *continuity-under-limits* properties, the exact properties whose absence sank Riemann's construction. Where the σ-algebra gave us a family of sets stable under limits, the measure gives us a size stable under limits; the two halves of the section 1.1 shopping list are then both in hand.

What should the rule demand? Physically, size is mass, and mass has one defining feature: it *adds over disjoint pieces*. Split a region into parts that do not overlap and the masses of the parts sum to the mass of the whole; there is no double counting and nothing is lost in the seams. Finite additivity, $\mu(A \sqcup B) = \mu(A) + \mu(B)$ for disjoint A, B, is the bare statement of this, and any honest notion of length, charge, probability, or population count obeys it. But finite additivity alone is too weak for our purpose, because every object we care about is assembled by a *limit*, i.e. from a countable sequence of pieces. A density profile is built by refining a partition without end; the empirical measure is a sum of N atoms and we let $N \to \infty$; the rationals are a countable union of singletons. We therefore promote additivity from finite to *countable*: mass adds not just over two disjoint pieces but over a whole sequence of them at once. This single strengthening – from finitely many disjoint pieces to countably many – is precisely the axiom that will let us exchange a limit with a sum, and it is the entire content of the definition.

Definition 1.5 (Measure)**.** A *measure* on $(\Omega, \mathcal{F})$ is a function $\mu\colon \mathcal{F} \to [0,\infty]$ with $\mu(\emptyset) = 0$ that is *countably additive*: for any sequence $(A_n)_{n\geq 1}$ of pairwise disjoint sets in $\mathcal{F}$,

$$\mu\Big(\bigsqcup_{n\geq 1} A_n\Big) \;=\; \sum_{n\geq 1} \mu(A_n). \tag{1.1}$$

The triple $(\Omega, \mathcal{F}, \mu)$ is a *measure space*. If $\mu(\Omega) = 1$ it is a *probability space*, μ a *probability measure*, and we usually write $(\Omega, \mathcal{F}, \mathbb{P})$. If $\mu(\Omega) < \infty$, μ is *finite*; if $\Omega = \bigcup_n \Omega_n$ with $\mu(\Omega_n) < \infty$, it is *σ-finite*.

A few words on the axiom as written. The values land in $[0,\infty]$, the extended nonnegative reals: a measure may legitimately assign infinite size to a set (the whole line has infinite length), so ∞ is an allowed output, and the sum on the right of (1.1) is a sum of nonnegative terms, which always converges in $[0, \infty]$ – either to a finite number or to $+\infty$ – with no question of conditional convergence or reordering, since the terms are nonnegative and the left side does not depend on how we indexed the pieces. The normalization $\mu(\emptyset) = 0$ rules out the degenerate $\mu \equiv \infty$ and is exactly what one expects of "the mass of nothing." The three named special cases are the ones we will actually meet: *probability measures*, total mass one, are the laws m and the empirical measures μ^N at the center of the chapter; *finite* measures are probability measures up to a harmless rescaling; and σ*-finite* measures – those exhausted by a countable family of finite-mass pieces – are the natural habitat of Lebesgue measure (the line is the countable union of the bounded intervals $(-n, n]$, each of finite length) and the precise hypothesis under which Fubini's theorem and the uniqueness machinery later run. The gradation finite $\subset$ σ-finite is not pedantry; σ-finiteness is the exact amount of tameness those theorems need, as we will see when we invoke it.

Countable additivity (1.1) is the entire content of the definition, and its consequences are precisely the continuity properties limits need. We now extract those consequences. The four properties below are not a miscellany; they are the four ways a measure interacts with the set operations a limit performs – inclusion, union, and the two monotone limits $\uparrow$ and $\downarrow$ – and each one is invoked by name later in the chapter.

Proposition 1.6 (Elementary properties)**.** *Let μ be a measure on $(\Omega, \mathcal{F})$ and $A, B, A_n \in \mathcal{F}$. Then:*

1. (Monotonicity) $A \subseteq B \implies \mu(A) \le \mu(B)$.
2. (Countable subadditivity) $\mu\big(\bigcup_n A_n\big) \le \sum_n \mu(A_n)$.
3. (Continuity from below) *If $A_n \uparrow A$ (increasing, $\bigcup_n A_n = A$), then $\mu(A_n) \uparrow \mu(A)$.*
4. (Continuity from above) *If $A_n \downarrow A$ and $\mu(A_1) < \infty$, then $\mu(A_n) \downarrow \mu(A)$.*

Proof. Monotonicity. If $A \subseteq B$ then B is the disjoint union $B = A \sqcup (B \setminus A)$ of two measurable sets (recall $B \setminus A = B \cap A^c \in \mathcal{F}$). Finite additivity – the two-term case of (1.1), obtained by padding the pair $A, B \setminus A$ with $\emptyset, \emptyset, \ldots$ – gives $\mu(B) = \mu(A) + \mu(B \setminus A)$, and since $\mu(B \setminus A) \ge 0$ this is $\ge \mu(A)$. Size respects inclusion; nothing more is happening than "the whole is at least the part."

Subadditivity. The sets A_n may overlap, so we cannot apply (1.1) to them directly – additivity is a statement about *disjoint* pieces only. The remedy is a device we will reuse throughout the book, so it is worth naming: the *disjointification trick*. Replace the overlapping A_n by the disjoint "new mass" sets

$$B_1 = A_1, \qquad B_n = A_n \setminus \bigcup_{k<n} A_k \quad (n \ge 2),$$

where B_n collects the points that enter the union at stage n and not before. Three facts hold by construction. The B_n are pairwise disjoint, because a point's first entry index is unique. They have the same union as the A_n, $\bigcup_n B_n = \bigcup_n A_n$, since stripping off earlier sets removes only points already counted. And $B_n \subseteq A_n$, since B_n is A_n with some points deleted. Now apply countable additivity to the disjoint family (B_n) and then monotonicity term by term:

$$\mu\Big(\bigcup_n A_n\Big) = \mu\Big(\bigsqcup_n B_n\Big) = \sum_n \mu(B_n) \le \sum_n \mu(A_n).$$

The inequality, not equality, is the price of overlap: the right side recounts the shared mass once per set that contains it.

Continuity from below. Here the A_n increase, $A_1 \subseteq A_2 \subseteq \cdots$ with union A, and we use the *same* disjointification to convert a nested union into a disjoint one. With $B_n = A_n \setminus A_{n-1}$ (and $B_1 = A_1$) the B_n are disjoint, the finite union telescopes, $A_N = \bigsqcup_{n \le N} B_n$, and the full union is $A = \bigsqcup_{n \ge 1} B_n$. Countable additivity applied to A, and finite additivity applied to A_N, give

$$\mu(A_N) = \sum_{n \le N} \mu(B_n) \xrightarrow[N \to \infty]{} \sum_{n \ge 1} \mu(B_n) = \mu(A),$$

where the limit is simply the definition of the infinite sum as the limit of its partial sums. Because each new term $\mu(B_n) \ge 0$, the partial sums increase, so $\mu(A_n) \uparrow \mu(A)$ – the convergence is monotone, matching the monotone sweep of the sets. This is the property the monotone convergence theorem (theorem 1.20) rests on: applied to the sublevel sets of an increasing sequence of functions, it is what lets the integral follow the functions up.

Continuity from above. Now the A_n *decrease*, $A_1 \supseteq A_2 \supseteq \cdots$ with intersection A, and we are given $\mu(A_1) < \infty$. The natural move is to complement into the increasing case, but the complement must be taken *inside the finite-mass set* A_1 to keep every quantity finite. Set

$$C_n \;:=\; A_1 \setminus A_n.$$

As A_n shrinks, C_n grows: $A_n \supseteq A_{n+1}$ gives $C_n \subseteq C_{n+1}$, and since $\bigcap_n A_n = A$ we have $\bigcup_n C_n = A_1 \setminus \bigcap_n A_n = A_1 \setminus A$. Thus $C_n \uparrow A_1 \setminus A$, an increasing sequence to which continuity from below applies:

$$\mu(A_1 \setminus A_n) \;=\; \mu(C_n) \;\uparrow\; \mu(A_1 \setminus A).$$

It remains to turn these differences back into the quantities we want, and this is the step that consumes the hypothesis. Because $A_n \subseteq A_1$, additivity on the disjoint splitting $A_1 = A_n \sqcup (A_1 \setminus A_n)$ reads $\mu(A_1) = \mu(A_n) + \mu(A_1 \setminus A_n)$; and since $\mu(A_1) < \infty$ every term here is finite, so we may legitimately subtract,

$$\mu(A_1 \setminus A_n) \;=\; \mu(A_1) - \mu(A_n),$$

and likewise $\mu(A_1 \setminus A) = \mu(A_1) - \mu(A)$. Substituting into the displayed convergence, $\mu(A_1) - \mu(A_n) \uparrow \mu(A_1) - \mu(A)$, and cancelling the finite constant $\mu(A_1)$ from both sides gives $\mu(A_n) \downarrow \mu(A)$. The whole argument is a reflection of continuity from below across the fixed finite-mass background A_1; the finiteness of that background is what makes the reflection $\mu(A_1 \setminus \cdot) = \mu(A_1) - \mu(\cdot)$ a genuine subtraction rather than the meaningless $\infty - \infty$. □

The finiteness hypothesis in (iv) is not a technical convenience; without it the conclusion is simply false, and the failure is instructive. On $(\mathbb{R}, \mathcal{B}(\mathbb{R}))$ with Lebesgue measure take the half-lines $A_n = (n, \infty)$. They decrease, $A_1 \supseteq A_2 \supseteq \cdots$, and their intersection is empty – no real number exceeds every n – so $A_n \downarrow \emptyset$ and continuity from above would predict $\mu(A_n) \to \mu(\emptyset) = 0$. Yet each A_n is a ray of infinite length, $\mu(A_n) = \infty$ for all n, so $\mu(A_n) \equiv \infty \not\to 0$. Here $\mu(A_1) = \infty$, the hypothesis fails, and with it the conclusion. What went wrong is physically transparent: the sets are shrinking to nothing, but the mass they carry does not shrink with them – it *escapes to infinity*, sliding rightward out of every bounded window while keeping its infinite total. The subtraction step in the proof would have read $\infty - \infty$, which is exactly the algebra refusing to track mass that has run off the edge of the space. This little example is the elementary ancestor of *tightness*, the condition developed in chapter 3 that forbids precisely this leakage: a family of probability measures is tight when no mass can escape to infinity in the limit, and the mechanism we will use to verify tightness – pin a measure's mass inside a large bounded set and let the set grow – is nothing but continuity from above, now always legitimate because a *probability* measure has $\mu(\Omega) = 1 < \infty$ and the hypothesis holds automatically. The finiteness that fails here is the finiteness that tightness guarantees there.

With the abstract properties in hand we can name the concrete measures the book runs on. They are a small cast, and each will reappear: the Dirac mass is the atom from which the empirical measure is built, Lebesgue measure is the backdrop against which densities are defined, and the empirical measure is the protagonist.

Example 1.7 (The measures we will actually use)**.**

- *Dirac measure.* For $a \in \Omega$, the *Dirac measure* δ_a is defined by $\delta_a(A) = \mathbf{1}_A(a)$: it places unit mass at the point a. It is the building block of the empirical measure.
- *Counting measure.* $\#(A) =$ the number of elements of A, with the value ∞ for infinite A.
- *Lebesgue measure* Leb on $(\mathbb{R}^d, \mathcal{B}(\mathbb{R}^d))$, the unique measure assigning to each box $\prod_j (a_j, b_j]$ its elementary volume $\prod_j (b_j - a_j)$ – constructed in theorem 1.11 below.
- *Empirical measure.* For points $X_1, \ldots, X_N \in \mathbb{R}^d$, $\mu^N = \frac{1}{N} \sum_{i=1}^N \delta_{X_i}$, a probability measure on $\mathbb{R}^d$.

Each of these warrants a sentence on why it satisfies the definition, since a definition is only as good as the examples one can certify against it. The *Dirac measure* δ_a is countably additive for a trivial but telling reason: for disjoint sets $A_1, A_2, \ldots$ the point a lies in at most one of them, so exactly one indicator $\mathbf{1}_{A_n}(a)$ is 1 and the rest are 0; both sides of (1.1) equal 1 if $a \in \bigsqcup_n A_n$ and 0 otherwise. It is a probability measure, $\delta_a(\Omega) = 1$, concentrating all its mass at the single point a – the purest possible *atom*, the very object that defeated the density picture in section 1.1, since no function ρ with $\delta_a = \rho \, \mathrm{d}x$ can put positive mass on the volumeless set $\{a\}$. The *counting measure* $\#$ is countably additive because the size of a disjoint union is the sum of the sizes, finite or infinite; it is finite only on finite sets and is the measure with respect to which sums *are* integrals, a fact we exploit in section 1.3. *Lebesgue measure* is the one entry whose existence is not self-evident – assigning a consistent volume to *every* Borel set, not just to boxes, is a genuine construction – and we have forward-referenced it to theorem 1.11, where it is built and shown unique; that pointer is deliberate and we keep it, because the present subsection is not the place to construct Lebesgue measure, only to record where it sits in the cast.

The *empirical measure* $\mu^N = \frac{1}{N} \sum_{i=1}^N \delta_{X_i}$ is the reason the Dirac mass leads the list. It is a finite *average* of Dirac measures, and one checks directly that any nonnegative combination $\sum_i c_i \, \nu_i$ of measures is again a measure – evaluate both sides of (1.1) and interchange the two sums, which is legal because all terms are nonnegative (a nonnegative double sum may be summed in either order). With $c_i = 1/N$ and $\nu_i = \delta_{X_i}$ the total mass is $\frac{1}{N}\sum_{i=1}^N 1 = 1$, so μ^N is a bona fide *probability* measure on $\mathbb{R}^d$: it assigns to a region A the fraction

$$\mu^N(A) \;=\; \frac{1}{N}\sum_{i=1}^N \delta_{X_i}(A) \;=\; \frac{1}{N}\#\{i : X_i \in A\}$$

of the population lying in A. This is the honest mathematical object behind the physicist's "occupation profile," and it is exactly the input the next section integrates against to recover the population average. We hand it forward in that role.

Notation watch

The *Dirac measure* δ_a defined above is an honest measure: it inputs a set and returns a number $\delta_a(A) \in \{0, 1\}$, and it obeys (1.1). The physicist's "Dirac delta function" $\delta(x - a)$ is a different kind of object – or rather, it is not an object of the same type at all. There is no function $\mathbb{R} \to \mathbb{R}$ that vanishes off a single point yet integrates to 1; the symbol $\delta(x - a)$ acquires meaning only *under an integral*, through the rule $\int f(x)\,\delta(x - a)\,\mathrm{d}x = f(a)$, which is a *prescription of how the symbol acts on test functions*, not a statement about the values of a function at points. That action is precisely integration against the Dirac *measure*: in our notation the same content reads $\int f\,\mathrm{d}\delta_a = f(a)$ (a special case of eq. (1.7) below), with the measure on the right carrying all of the information and none of the abuse. We therefore never write $\delta(x)$ as a standalone function. The payoff of this discipline is sharpest for the empirical measure. A *sum* of Dirac measures, $\mu^N = \frac{1}{N}\sum_i \delta_{X_i}$, is again a perfectly well-defined measure – we just verified it – assigning $\mu^N(A) = \frac{1}{N}\#\{i : X_i \in A\}$ to every Borel set. But "a sum of delta functions," $\frac{1}{N}\sum_i \delta(x - X_i)$ read as a function of x, has *no pointwise meaning*: it is 0 at every $x \notin \{X_i\}$ and undefined ("∞") at the X_i, which is not a function one can integrate or take limits of. The measure-theoretic reading is the one that survives the limit $N \to \infty$ – the empirical measures converge weakly to m, as we will prove in section 1.7 – whereas the pointwise reading converges to nothing. This is the spikes-versus-profile heuristic of section 1.1, now sharpened into a notational rule we hold to for the rest of the book.

We have placed a size on the home and read off its behavior under the four set operations a limit can perform. Two threads now run forward from here. The continuity properties (iii) and (iv) are the workhorses of the limit arguments to come: continuity from below drives the monotone convergence theorem (theorem 1.20) and reappears in the uniqueness corollary of the next subsection and in the section-measurability lemma (lemma 1.25), while continuity from above – the finite-mass reflection just proved – is exactly what delivers tightness in the empirical-measure analysis of section 1.7. The Dirac mass δ_a and the empirical measure μ^N, together with the transfer identity for δ_a, are handed to section 1.3, where $\int f\,\mathrm{d}\mu^N = \frac{1}{N}\sum_i f(X_i)$ becomes the literal bridge between the discrete average and the continuum integral. But there is an immediate gap to close first. We have *named* Lebesgue measure and asserted that its box values determine it uniquely, yet a measure is a rule on the *whole* of $\mathcal{F}$, an uncountable family, while we only ever get to prescribe its values on a small, convenient class – the boxes. Why should agreement on so meager a class force agreement everywhere? Answering that is the business of the next subsection: we extract, once and reusably, the principle that two measures agreeing on a sufficiently rich generating class agree on all of $\sigma(\mathcal{P})$. The continuity properties just proved are precisely the fuel that argument burns.

1.2.3 Generating classes and the uniqueness of measures

The previous subsection closed by naming Lebesgue measure and asserting – without yet earning it – that its values on the boxes determine it everywhere. That assertion is not a luxury but a structural necessity, and not only for Lebesgue measure. Look ahead at how every concrete measure in this chapter is actually going to be *produced*. We never get to specify a measure by writing down $\mu(A)$ for each of the uncountably many Borel sets A at once; that would be an impossible amount of data, most of it pathological. Instead we prescribe μ on a small, hands-on, intuitive class of sets – the boxes for Lebesgue measure (theorem 1.11), the measurable rectangles for the product measure (theorem 1.26) – and then *trust* that the prescription has pinned the measure down on all of $\sigma(\mathcal{P})$. The same trust is what lets the Fubini argument (theorem 1.27) identify a second iterated-integral measure with the first by checking them only on rectangles, and what makes the section-measurability lemma (lemma 1.25) go through. Three later constructions, one tool: rather than reprove the propagation principle three times in three disguises, we extract it once here, before any of them needs it, as a clean black box. This is the deliberate logic of the chapter's ordering – the reusable lever is forged in advance of the loads it will bear.

The principle we want is a *uniqueness* statement: if two measures agree on a class of sets that is rich enough, they agree on everything those sets generate. "Rich enough" has to be made precise, and the right notion of richness is the weakest one that does the job. Agreement on a single set, or on a few unrelated sets, plainly propagates nowhere. What turns out to be exactly sufficient is that the class be closed under finite intersection: if A and B are in the class then so is $A \cap B$. A family with this closure is a *π-system*. The boxes are a π-system – the intersection of two boxes is a box (or empty) – and so are the rectangles, which is why this is the right hypothesis to isolate. The combinatorial engine that converts "agree on a π-system" into "agree on the generated σ-algebra" is Dynkin's π–λ theorem, and we prove it from the ground up because the whole chapter, and much of the book, will lean on it.

Definition 1.8 (π-system and λ-system)**.** A nonempty family $\mathcal{P} \subseteq 2^{\Omega}$ is a *π-system* if it is closed under finite intersections. A family $\mathcal{D} \subseteq 2^{\Omega}$ is a *λ-system* (or *Dynkin system*) if (i) $\Omega \in \mathcal{D}$; (ii) $A, B \in \mathcal{D}$ with $A \subseteq B \implies B \setminus A \in \mathcal{D}$ (closure under proper differences); and (iii) $A_n \in \mathcal{D}$ with $A_n \uparrow A \implies A \in \mathcal{D}$ (closure under increasing countable unions).

The two notions look ad hoc until one sees where they come from, and the source is a single observation that organizes the entire proof to follow: *a σ-algebra is exactly a family that is both a π-system and a λ-system.* One direction is immediate from the axioms of definition 1.2 – a σ-algebra is closed under complements and countable unions, hence under finite intersections (by De Morgan), so it is a π-system, and it trivially satisfies the three λ-system clauses. The converse is the useful half: suppose $\mathcal{D}$ is both. It contains Ω, and for any $A \in \mathcal{D}$ the proper difference $\Omega \setminus A = A^c$ lies in $\mathcal{D}$ (clause (ii) with $A \subseteq \Omega$), so $\mathcal{D}$ is closed under complements. Given $A, B \in \mathcal{D}$, the π-system property gives $A \cap B \in \mathcal{D}$, hence $A \cup B = (A^c \cap B^c)^c \in \mathcal{D}$, so $\mathcal{D}$ is closed under finite unions; and a countable union $\bigcup_n A_n$ is the *increasing* union of its finite partial unions $\bigcup_{k \le n} A_k$, each of which is in $\mathcal{D}$, so clause (iii) promotes finite-union closure to countable-union closure. Thus $\mathcal{D}$ is a σ-algebra. The payoff of splitting the σ-algebra axioms into these two weaker halves is strategic: the two halves are easy to verify in *different* places. The λ-system clauses (closure under proper differences and increasing unions) are exactly the operations under which a statement of the form "$\mu(A) = \nu(A)$" is preserved – because they correspond to *subtraction* and to *continuity from below*, both of which a measure respects – so the set of A on which two measures agree is automatically a λ-system. The π-system clause, meanwhile, is the single piece of structure we can demand of the small generating class we actually prescribe. Dynkin's theorem is the statement that having the two halves in these two separate places is enough to force them together.

Theorem 1.9 (Dynkin's π–λ theorem)**.** *If $\mathcal{P}$ is a π-system and $\mathcal{D}$ is a λ-system with $\mathcal{P} \subseteq \mathcal{D}$, then $\sigma(\mathcal{P}) \subseteq \mathcal{D}$.*

Before the formal argument, here is the strategy in one breath, because the proof is dense and its moving parts only make sense once their goal is fixed. We pass to $\mathcal{D}_0$, the *smallest* λ-system containing $\mathcal{P}$ – smaller than the given $\mathcal{D}$, hence enough to control. The plan is to show this minimal λ-system $\mathcal{D}_0$ is in fact closed under finite intersections; by the boxed observation above, a λ-system that is also a π-system is a σ-algebra, and a σ-algebra containing $\mathcal{P}$ must contain $\sigma(\mathcal{P})$. So the whole proof reduces to one combinatorial task: *upgrade $\mathcal{D}_0$ from a λ-system to one closed under intersection.* The device for that upgrade is to fix a set A and collect all B that intersect A back into $\mathcal{D}_0$; this collection is the auxiliary family $\mathcal{G}_A$, and the engine of the proof is that $\mathcal{G}_A$ is itself a λ-system, so once it contains $\mathcal{P}$ it must contain all of $\mathcal{D}_0$.

Proof. Let $\mathcal{D}_0$ be the smallest λ-system containing $\mathcal{P}$. This exists for the same reason generated σ-algebras exist (remark 1.3): an arbitrary intersection of λ-systems is again a λ-system – each clause (i)–(iii) is checked one member-family at a time, exactly as in remark 1.3 – and the power set 2^Ω is a λ-system containing $\mathcal{P}$, so the intersection of all λ-systems containing $\mathcal{P}$ is the smallest one. Since the given $\mathcal{D}$ is one such, $\mathcal{D}_0 \subseteq \mathcal{D}$, and it therefore suffices to prove $\sigma(\mathcal{P}) \subseteq \mathcal{D}_0$. By the observation preceding the theorem, this follows the moment we know $\mathcal{D}_0$ is closed under finite intersections: a λ-system that is also a π-system is a σ-algebra, and being a σ-algebra containing $\mathcal{P}$ it contains the smallest such, $\sigma(\mathcal{P})$. Everything now rests on proving that closure.

The auxiliary families. For any $A \subseteq \Omega$ define

$$\mathcal{G}_A = \{B \subseteq \Omega : A \cap B \in \mathcal{D}_0\},$$

the collection of sets whose intersection with A lands back in $\mathcal{D}_0$. Closure of $\mathcal{D}_0$ under finite intersection is precisely the assertion that $\mathcal{D}_0 \subseteq \mathcal{G}_A$ for every $A \in \mathcal{D}_0$, so this family is built to package exactly the statement we are chasing.

Each $\mathcal{G}_A$ is a λ-system, provided $A \in \mathcal{D}_0$. We check the three clauses, and each one inherits directly from the corresponding clause for $\mathcal{D}_0$ because the map $B \mapsto A \cap B$ commutes with the set operations involved. (i) $\Omega \in \mathcal{G}_A$, since $A \cap \Omega = A \in \mathcal{D}_0$ by hypothesis on A. (ii) If $B \subseteq B'$ both lie in $\mathcal{G}_A$, then $A \cap B \subseteq A \cap B'$ are both in $\mathcal{D}_0$, and intersecting a proper difference distributes,

$$A \cap (B' \setminus B) = (A \cap B') \setminus (A \cap B),$$

a proper difference of two members of $\mathcal{D}_0$, hence in $\mathcal{D}_0$ by clause (ii) for $\mathcal{D}_0$; so $B' \setminus B \in \mathcal{G}_A$. (iii) If $B_n \uparrow B$ with $B_n \in \mathcal{G}_A$, then $A \cap B_n \uparrow A \cap B$ is an increasing union of members of $\mathcal{D}_0$, hence in $\mathcal{D}_0$ by clause (iii) for $\mathcal{D}_0$; so $B \in \mathcal{G}_A$. Thus $\mathcal{G}_A$ is a λ-system whenever $A \in \mathcal{D}_0$.

First pass: anchor on $\mathcal{P}$. Fix $A \in \mathcal{P}$. For any $B \in \mathcal{P}$ the π-system property gives $A \cap B \in \mathcal{P} \subseteq \mathcal{D}_0$, so $B \in \mathcal{G}_A$; that is, $\mathcal{P} \subseteq \mathcal{G}_A$. Since $A \in \mathcal{P} \subseteq \mathcal{D}_0$, the family $\mathcal{G}_A$ is a λ-system, and a λ-system containing $\mathcal{P}$ contains the smallest one, so $\mathcal{D}_0 \subseteq \mathcal{G}_A$. Unwinding the definition of $\mathcal{G}_A$, we have proved: for every $A \in \mathcal{P}$ and every $B \in \mathcal{D}_0$, the intersection $A \cap B \in \mathcal{D}_0$.

The symmetry step: second pass with the roles exchanged. The conclusion just reached is symmetric in form but was proved with A restricted to $\mathcal{P}$; we now bootstrap it to let A range over all of $\mathcal{D}_0$. Read the boxed conclusion the other way: it says that for every fixed $B \in \mathcal{D}_0$, every $A \in \mathcal{P}$ satisfies $A \cap B \in \mathcal{D}_0$, i.e. $\mathcal{P} \subseteq \mathcal{G}_B$. But $B \in \mathcal{D}_0$, so $\mathcal{G}_B$ is again a λ-system by the second step, and a λ-system containing $\mathcal{P}$ contains $\mathcal{D}_0$; hence $\mathcal{D}_0 \subseteq \mathcal{G}_B$. Unwinding once more: for every $B \in \mathcal{D}_0$ and every $A \in \mathcal{D}_0$, the intersection $A \cap B \in \mathcal{D}_0$. That is exactly closure of $\mathcal{D}_0$ under finite intersection. The two passes are the same lemma applied twice – first to push agreement from $\mathcal{P} \times \mathcal{P}$ out to $\mathcal{P} \times \mathcal{D}_0$, then, exploiting the symmetry $A \cap B = B \cap A$, from $\mathcal{P} \times \mathcal{D}_0$ out to $\mathcal{D}_0 \times \mathcal{D}_0$ – and the λ-system structure of the $\mathcal{G}$'s is what powers each push. By the reduction of the first paragraph, $\mathcal{D}_0$ is a σ-algebra and $\sigma(\mathcal{P}) \subseteq \mathcal{D}_0 \subseteq \mathcal{D}$. □

The theorem is abstract, but the corollary we actually use is concrete and is the whole reason the machinery was built: it says that pinning a measure down on a π-system pins it down everywhere, provided the space can be exhausted by finite-mass members of that π-system.

Corollary 1.10 (Uniqueness of measures from a π-system)**.** *Let μ, ν be measures on $(\Omega, \sigma(\mathcal{P}))$ that agree on a π-system $\mathcal{P}$. Suppose there exist $\Omega_n \in \mathcal{P}$ with $\Omega_n \uparrow \Omega$ and $\mu(\Omega_n) = \nu(\Omega_n) < \infty$. Then $\mu = \nu$ on all of $\sigma(\mathcal{P})$.*

Proof. The idea is to feed Dynkin's theorem the set on which μ and ν agree, after localizing to a finite-mass window Ω_n so that subtraction is legal. Fix n and define

$$\mathcal{D}_n = \{A \in \sigma(\mathcal{P}) : \mu(A \cap \Omega_n) = \nu(A \cap \Omega_n)\},$$

the sets on which the two measures agree once everything is intersected with the window Ω_n. We claim $\mathcal{D}_n$ is a λ-system, and we verify each clause, taking care to see which measure property delivers which closure and exactly where the finiteness $\mu(\Omega_n) = \nu(\Omega_n) < \infty$ is spent.

Clause (i): $\Omega \in \mathcal{D}_n$. Here $\Omega \cap \Omega_n = \Omega_n$, and $\mu(\Omega_n) = \nu(\Omega_n)$ by hypothesis, so $\Omega \in \mathcal{D}_n$.

Clause (ii): closure under proper differences. Let $A \subseteq B$ with $A, B \in \mathcal{D}_n$. Intersecting with Ω_n preserves the inclusion, $A \cap \Omega_n \subseteq B \cap \Omega_n$, and additivity on the disjoint splitting $B \cap \Omega_n = (A \cap \Omega_n) \sqcup \big((B \setminus A) \cap \Omega_n\big)$ gives, for each of μ and ν,

$$\mu\big((B \setminus A) \cap \Omega_n\big) = \mu(B \cap \Omega_n) - \mu(A \cap \Omega_n),$$

and likewise for ν. This subtraction is where finiteness earns its keep: because $A \cap \Omega_n \subseteq \Omega_n$ has finite mass $\leq \mu(\Omega_n) < \infty$, the difference is an honest real number rather than the meaningless $\infty - \infty$. Since the two right-hand sides agree term by term ($A, B \in \mathcal{D}_n$), so do the left-hand sides, and $B \setminus A \in \mathcal{D}_n$. This is the clause that forces the λ-system to be the right vehicle: agreement of measures is preserved under *differences*, which is precisely the proper-difference closure, and it is preserved only because of finiteness.

Clause (iii): closure under increasing unions. Let $A_k \uparrow A$ with $A_k \in \mathcal{D}_n$. Intersecting with the fixed window preserves the monotone sweep, $A_k \cap \Omega_n \uparrow A \cap \Omega_n$, so continuity from below (proposition 1.6(iii)) applied to each measure gives

$$\mu(A \cap \Omega_n) = \lim_k \mu(A_k \cap \Omega_n) = \lim_k \nu(A_k \cap \Omega_n) = \nu(A \cap \Omega_n),$$

the middle equality because every $A_k \in \mathcal{D}_n$. Hence $A \in \mathcal{D}_n$. This is the clause that needs continuity from below – the very property handed forward from proposition 1.6 for exactly this purpose – and note it needs no finiteness, since continuity from below holds for all measures.

So $\mathcal{D}_n$ is a λ-system, and it contains $\mathcal{P}$: for $A \in \mathcal{P}$, the π-system property gives $A \cap \Omega_n \in \mathcal{P}$ (an intersection of two members of $\mathcal{P}$), and μ, ν agree on $\mathcal{P}$, so $\mu(A \cap \Omega_n) = \nu(A \cap \Omega_n)$. Dynkin's theorem (theorem 1.9) now applies with this π-system inside this λ-system: $\sigma(\mathcal{P}) \subseteq \mathcal{D}_n$, and since $\mathcal{D}_n$ was a subfamily of $\sigma(\mathcal{P})$ to begin with, $\mathcal{D}_n = \sigma(\mathcal{P})$. In words,

$$\mu(A \cap \Omega_n) = \nu(A \cap \Omega_n) \qquad \text{for every } A \in \sigma(\mathcal{P}) \text{ and every } n.$$

Finally let $n \to \infty$. Because $\Omega_n \uparrow \Omega$ we have $A \cap \Omega_n \uparrow A$ for each fixed measurable A, and one last application of continuity from below to each measure passes the equality to the limit:

$$\mu(A) = \lim_n \mu(A \cap \Omega_n) = \lim_n \nu(A \cap \Omega_n) = \nu(A).$$

Thus $\mu = \nu$ on all of $\sigma(\mathcal{P})$. The two appearances of continuity from below – once to close clause (iii) inside the fixed window, once to remove the window at the end – are the two places where the limit-stability of measure, built in proposition 1.6, does the real work; finiteness of $\mu(\Omega_n)$ is spent in exactly one place, the subtraction of clause (ii). □

We now have the black box the rest of the chapter ordered in advance. To prove two measures equal it suffices to exhibit a π-system on which they agree and a finite-mass exhaustion drawn from it – a far more tractable task than confronting all of $\sigma(\mathcal{P})$ directly. The next subsection cashes this in immediately: it constructs Lebesgue measure and must show the construction is *unique*, and the boxes – already identified in definition 1.4 as a π-system generating $\mathcal{B}(\mathbb{R}^d)$, exhausted by the finite-volume boxes $(-n, n]^d \uparrow \mathbb{R}^d$ – are precisely the generating class corollary 1.10 asks for. The same corollary will be invoked again on the rectangles when we build the product measure (theorem 1.26), identify the second iterated integral in Fubini's theorem (theorem 1.27), and run the section-measurability lemma (lemma 1.25). Each of those later steps will simply name its π-system and cite this corollary; the combinatorial work is done once, here.

1.2.4 Lebesgue measure

The previous subsection forged a tool and left it idle: corollary 1.10 says that a measure is pinned down everywhere on $\mathcal{B}(\mathbb{R}^d)$ once its values are fixed on a generating π-system that admits a finite-mass exhaustion. We promised, in the cast of characters back at example 1.7, one specific measure on which every density in this book is implicitly weighed – the rigorous form of "length, area, volume" – and forwarded its construction to here. Now is when the debt comes due, and the uniqueness engine is exactly what discharges it. The generating π-system will be the very one introduced in definition 1.4: the half-open boxes $\prod_j (a_j, b_j]$, which we noted there are closed under intersection and generate $\mathcal{B}(\mathbb{R}^d)$. On those boxes the prescription is not in doubt for a moment – a box *should* have the volume $\prod_j (b_j - a_j)$, the product of its side lengths, and nothing else. The whole content of the subsection is therefore split cleanly in two: that this box-prescription *extends* to a genuine measure on all of $\mathcal{B}(\mathbb{R}^d)$ (existence), and that it does so in only one way (uniqueness). The first half we import; the second half, and a characterization that pins down Lebesgue measure by a symmetry, we prove.

It is worth being explicit about where the seam between imported and proved material falls, because honoring the self-containedness doctrine here means naming a mechanism precisely and then using only its conclusion. Existence rests on one foundational construction – the Carathéodory extension of a set function from a small algebra to a full σ-algebra – and this is the *single* result of pure measure theory that the entire book accepts without proof. It is standard, its proof is long and bookkeeping-heavy, and reproducing it would teach the reader nothing they will reuse; so we state exactly what it delivers, cite a clean reference for the reader who wants the details, and move on. Every other measure-theoretic fact in this book is proved in these pages. Uniqueness, by contrast, is short and illuminating and follows directly from the machinery we just built, so we give it in full.

Theorem 1.11 (Existence and uniqueness of Lebesgue measure)**.** *There is a unique measure* Leb *on* $(\mathbb{R}^d, \mathcal{B}(\mathbb{R}^d))$ *such that* $\mathrm{Leb}\big(\prod_{j=1}^d (a_j, b_j]\big) = \prod_{j=1}^d (b_j - a_j)$ *for all boxes. It is σ-finite, translation invariant, and* – among measures that are finite on bounded (equivalently, compact) sets – *characterized up to a positive multiplicative constant by translation invariance.*

Proof. Existence (the accepted import). The construction begins not on the Borel sets but on *all* subsets of $\mathbb{R}^d$ at once, by way of an auxiliary set function that overestimates size. For an arbitrary $E \subseteq \mathbb{R}^d$ define the *Lebesgue outer measure*

$$\mathrm{Leb}^*(E) \;=\; \inf\Big\{ \sum_k \mathrm{vol}(Q_k) \;:\; E \subseteq \bigcup_k Q_k,\ Q_k \text{ boxes} \Big\}, \tag{1.2}$$

the cheapest total box-volume of any countable cover of E by boxes. This is defined for every set, with no measurability question, and it is the honest meaning of "E takes up at most this much room": cover E as economically as boxes allow and add up their volumes. The trouble is that Leb^* is only *sub*additive, not additive – covering two sets together can be cheaper than covering them apart when their boundaries interlock – so it is not yet a measure. Carathéodory's insight is to let the outer measure itself decide which sets are well behaved: call A *Carathéodory measurable* if A cuts every test set cleanly, in the sense that

$$\mathrm{Leb}^*(E) \;=\; \mathrm{Leb}^*(E \cap A) + \mathrm{Leb}^*(E \setminus A) \qquad \text{for all } E \subseteq \mathbb{R}^d,$$

so that no room is lost or double-counted at the cut between the part of E inside A and the part outside. The *Carathéodory extension theorem* then asserts three things at once: the Carathéodory-measurable sets form a σ-algebra; Leb^* restricted to that σ-algebra is countably additive, i.e. an honest measure; and that σ-algebra contains every box – hence, being a σ-algebra, contains all of $\sigma(\text{boxes}) = \mathcal{B}(\mathbb{R}^d)$ – on which the measure returns the elementary volume. That is precisely a measure on $(\mathbb{R}^d, \mathcal{B}(\mathbb{R}^d))$ with the prescribed box values, which is existence. We take this theorem as the book's one external measure-theoretic import; the full construction, including the verification that boxes satisfy the splitting condition, is carried out in [123, Ch. 1], cited here for attribution and further reading, never as a stand-in for an argument we rely on.

Uniqueness (proved here). This is where the previous subsection pays off. The half-open boxes $\mathcal{P} = \{\prod_j (a_j, b_j]\}$ form a π-system – the intersection of two boxes is again a box (intersect coordinatewise) or empty – and they generate $\mathcal{B}(\mathbb{R}^d)$, both facts recorded at definition 1.4. The cubes $\Omega_n = (-n, n]^d$ are themselves members of $\mathcal{P}$, they increase to $\mathbb{R}^d$ as $n \to \infty$, and each has the finite prescribed volume $\mathrm{Leb}(\Omega_n) = (2n)^d < \infty$. So $\mathcal{P}$ is a generating π-system equipped with a finite-mass exhaustion: exactly the hypotheses of corollary 1.10. Any measure ν with the same box values as Leb agrees with Leb on all of $\mathcal{P}$ (that is what "same box values" says) and in particular on the Ω_n, so the corollary forces $\nu = \mathrm{Leb}$ on all of $\mathcal{B}(\mathbb{R}^d)$. The construction is therefore unique, and σ-finiteness is visible in the same breath: $\mathbb{R}^d = \bigcup_n \Omega_n$ exhibits the whole space as a countable union of the finite-volume cubes Ω_n, which is the very definition of σ-finite. Translation invariance, $\mathrm{Leb}(A+t) = \mathrm{Leb}(A)$, is equally quick: for fixed $t \in \mathbb{R}^d$ the set function $A \mapsto \mathrm{Leb}(A+t)$ is a measure (translation is a bijection that carries disjoint unions to disjoint unions) agreeing with Leb on boxes, because translating a box $\prod_j (a_j, b_j]$ to $\prod_j (a_j + t_j, b_j + t_j]$ leaves every side length $b_j - a_j$ unchanged; so the same uniqueness forces $\mathrm{Leb}(\cdot + t) = \mathrm{Leb}(\cdot)$ everywhere. Already this is a small lesson in how corollary 1.10 is meant to be used: to prove two measures equal one never wrestles with all Borel sets, one checks agreement on boxes and invokes the corollary.

The characterization (proved here). We claim that translation invariance *alone*, together with local finiteness, already determines the measure up to a constant – that Leb is, essentially, the unique notion of size that does not prefer one location to another. Let μ be any measure on $(\mathbb{R}^d, \mathcal{B}(\mathbb{R}^d))$ that is translation invariant and finite on bounded sets. Set

$$c \;:=\; \mu\big((0,1]^d\big),$$

the μ-mass of the unit cube, which is finite because the cube is bounded. We show $\mu = c\,\mathrm{Leb}$. The engine is the same corollary, fed by a subdivision argument that turns translation invariance into proportionality on boxes, in three graded steps – unit cube, then dyadic and rational boxes, then all Borel sets.

Step 1: subdivide the unit cube. Fix an integer $k \geq 1$ and chop $(0,1]^d$ into k^d congruent small cubes of side $1/k$, the boxes $\prod_j (\frac{m_j - 1}{k}, \frac{m_j}{k}]$ indexed by $(m_1, \ldots, m_d)$ with each $m_j \in \{1, \ldots, k\}$. These k^d boxes are pairwise disjoint and their union is $(0,1]^d$, and – crucially – each is a *translate* of the single small cube $(0, \frac{1}{k}]^d$. Translation invariance makes them all carry the same μ-mass, call it s, and countable (here finite) additivity sums them to the whole:

$$c \;=\; \mu\big((0,1]^d\big) \;=\; \sum_{k^d \text{ boxes}} s \;=\; k^d\, s, \qquad \text{so} \qquad s \;=\; \mu\big((0, \tfrac{1}{k}]^d\big) \;=\; \frac{c}{k^d}.$$

Since $\mathrm{Leb}\big((0, \frac{1}{k}]^d\big) = k^{-d}$, this reads $\mu\big((0, \frac{1}{k}]^d\big) = c\,\mathrm{Leb}\big((0, \frac{1}{k}]^d\big)$: the two measures already agree, up to the factor c, on every small dyadic-type cube.

Step 2: pass to boxes with rational corners. Let $B = \prod_j (a_j, b_j]$ have rational endpoints, and choose a common denominator k so that every ka_j and kb_j is an integer. Then B tiles exactly into translates of the small cube $(0, \frac{1}{k}]^d$: along the j-th axis the interval $(a_j, b_j]$ is partitioned into $k(b_j - a_j)$ subintervals of length $1/k$, so B is the disjoint union of

$$\prod_{j=1}^{d} k(b_j - a_j) \;=\; k^d \prod_{j=1}^{d} (b_j - a_j) \;=\; k^d \,\mathrm{Leb}(B)$$

such small cubes, each of μ-mass c/k^d by Step 1. Additivity then gives

$$\mu(B) \;=\; \big(k^d \,\mathrm{Leb}(B)\big) \cdot \frac{c}{k^d} \;=\; c\,\mathrm{Leb}(B),$$

the desired proportionality on every rational-corner box. (The factors of k^d cancel; the subdivision was only a scaffold for transporting the unit-cube value to an arbitrary rational box by translation.)

Step 3: pass to all Borel sets. The rational-corner boxes again form a π-system – their pairwise intersections are rational-corner boxes – and they still generate $\mathcal{B}(\mathbb{R}^d)$, since every open set is a countable union of them. They are exhausted by the integer cubes $\Omega_n = (-n, n]^d$, which have rational (indeed integer) corners and finite mass under both μ and $c\,\mathrm{Leb}$. Steps 1–2 show μ and $c\,\mathrm{Leb}$ agree on this π-system, so corollary 1.10, invoked one last time, propagates the agreement to all of $\mathcal{B}(\mathbb{R}^d)$: $\mu = c\,\mathrm{Leb}$. This completes the characterization. □

The local-finiteness hypothesis in the characterization is not decoration; drop it and the conclusion collapses, and the counterexample is instructive enough to keep in view. Counting measure # on $(\mathbb{R}^d, \mathcal{B}(\mathbb{R}^d))$ – which assigns to A its number of points, with the value $+\infty$ for infinite A – is perfectly translation invariant, since shifting a set by t neither creates nor destroys points: $\#(A + t) = \#(A)$. Yet it is wildly far from a multiple of Leb. Every nonempty box contains uncountably many points and so has #-mass $+\infty$, while its Lebesgue volume is finite and positive; no single constant c can satisfy $+\infty = c \cdot (\text{finite})$. What rescued the characterization above was the finite value $c = \mu((0, 1]^d)$, and that is exactly what counting measure refuses to supply: it is not finite on any bounded set with infinitely many points. Worse, # is not even σ-finite – a set of finite counting measure is a *finite* set, a countable union of finite sets is countable, but $\mathbb{R}^d$ is uncountable, so $\mathbb{R}^d$ cannot be written as a countable union of finite-mass pieces. Local finiteness is therefore the precise dividing line: among translation-invariant measures it separates the σ-finite, geometrically meaningful ones (the constant multiples of Leb) from pathologies like # that measure cardinality rather than volume.

This closes the construction and hands two concrete bequests to the sections that follow. To the integral of section 1.3 we hand a definite, σ-finite reference measure Leb: it is the background against which a density ρ means the measure $\rho\,\mathrm{Leb}$, and its σ-finiteness – the exhaustion $\mathbb{R}^d = \bigcup_n (-n, n]^d$ – is the standing hypothesis under which the Fubini–Tonelli theorem of section 1.5 will be allowed to run. To the L^p density theorem of section 1.6 we hand the box-cover formula (1.2) itself: because the Lebesgue measure of a Borel set is approached from outside by countable box covers, any integrable indicator can be approximated by simple combinations of box-indicators and thence by continuous functions, which is exactly the mechanism by which $C_c(\mathbb{R}^d)$ will be shown dense in L^p. The outer measure is not scaffolding discarded after existence; it is a quantitative tool the later density argument reuses.

One last piece of hygiene sets up a convention we will lean on for the rest of the book. The Carathéodory construction actually produces a measure on a σ-algebra slightly larger than $\mathcal{B}(\mathbb{R}^d)$:

the *Lebesgue σ-algebra*, obtained by adjoining to $\mathcal{B}(\mathbb{R}^d)$ all subsets of Borel sets of measure zero (every subset of a null set is declared measurable, with measure zero). This *completion* matters in some treatments, but it will not matter for us, because every function we ever integrate in this book is Borel measurable, and on the Borel sets the two agree. What we *do* keep from it is the notion it formalizes: a property that holds outside a set of Lebesgue measure zero is said to hold *almost everywhere* (a.e.), and a property holding outside a set of probability zero holds *almost surely* (a.s.). Null sets are negligible for every purpose involving integration – changing a function on a null set changes no integral, as we are about to see – and the "a.e." qualifier, which from here on attaches silently to nearly every statement about functions, draws its meaning from exactly the Lebesgue null sets this construction identifies. With a home, a notion of size, and now a canonical reference measure in hand, the one structure still missing is the maps between such homes – the functions we will integrate – and it is to those that we turn next.

1.2.5 Measurable functions

We now have a home and a size: a measurable space $(\Omega, \mathcal{F})$ – concretely $(\mathbb{R}^d, \mathcal{B}(\mathbb{R}^d))$ – and on it a notion of mass, with Lebesgue measure as the canonical reference against which densities are read. Two of the three objects the chapter needs are in place. The third is the class of *maps*. Sets acquired a size in definitions 1.2 and 1.5; the natural next question is which functions *respect* that structure, and the answer supplies at once the observables we will integrate, the device that manufactures the law m of a single agent, and – the point that closes the circle opened in section 1.1 – the guarantee that the limiting objects the book keeps producing are still legitimate things to integrate. Recall the third worry of that opening section: every interesting object (the limit profile, the empirical limit, the solution of an existence argument) is built by a countable limiting operation, and an integral theory is worthless if the result of such a limit falls outside the class of integrable functions. The decisive proposition of this subsection – that a pointwise limit of measurable functions is again measurable – is exactly the answer to that worry, and it is the reason the trio sets/measures/maps is now complete rather than merely two-thirds built.

Begin with the definition, and with why it is phrased through *preimages* rather than images. A continuous map between topological spaces is the one whose preimages of open sets are open: it is the morphism that respects nearness, and crucially the condition runs backward, from target to source. The measure-theoretic morphism is the exact analogue with "open" replaced by "measurable." The reason the direction is backward is the same in both settings: the structure we wish to preserve lives on *sets* of the target, and the only way a function f can transport a question about a target set A' – "how much source mass lands in A'?" – into a question the source can answer is to look at $f^{-1}(A')$, the set of source points that f sends into A'. If that preimage is measurable, the question has an answer; if it is not, the question is meaningless. So measurability is precisely the demand that f never turn a legitimate target question into an illegitimate source one.

Definition 1.12 (Measurable function)**.** A map $f\colon (\Omega, \mathcal{F}) \to (\Omega', \mathcal{F}')$ between measurable spaces is *measurable* if $f^{-1}(A') \in \mathcal{F}$ for every $A' \in \mathcal{F}'$. When the target is $\mathbb{R}^d$ (or $\mathbb{R}$, or $[-\infty, \infty]$) with its Borel σ-algebra we speak of a *Borel measurable* or simply *measurable* function; it suffices that $f^{-1}((a, \infty)) \in \mathcal{F}$ for every $a \in \mathbb{R}$ in the scalar case, since such sets generate $\mathcal{B}(\mathbb{R})$. On a probability space a measurable function is exactly a *random variable.*

The generating-set shortcut in the last sentence is what makes the definition usable, and it deserves to be seen, because verifying the preimage condition against *every* Borel set would be hopeless – there is no list of the Borel sets to run through. The shortcut rests on one structural fact: the family of target sets whose preimage is measurable is *itself a σ-algebra.* Write $\mathcal{G} := \{A' \subseteq \Omega' : f^{-1}(A') \in \mathcal{F}\}$. Preimage commutes with all the set operations – $f^{-1}(\Omega') = \Omega$, $f^{-1}((A')^c) = f^{-1}(A')^c$, and $f^{-1}(\bigcup_n A'_n) = \bigcup_n f^{-1}(A'_n)$ – so each of the three σ-algebra axioms for $\mathcal{G}$ is inherited from the corresponding axiom for $\mathcal{F}$: $\mathcal{G}$ is a σ-algebra. Now suppose $f^{-1}(E) \in \mathcal{F}$ merely for every E in some generating family $\mathcal{E}$ with $\sigma(\mathcal{E}) = \mathcal{F}'$. Then $\mathcal{E} \subseteq \mathcal{G}$, and since $\mathcal{G}$ is a σ-algebra it contains the smallest σ-algebra over $\mathcal{E}$, namely all of $\mathcal{F}' = \sigma(\mathcal{E})$. So checking the preimage condition on a generating family checks it everywhere – the same propagation-from-a-generating-class principle that powered remark 1.3 and the equivalence of generators for $\mathcal{B}(\mathbb{R}^d)$. For a scalar target the rays (a, ∞) generate $\mathcal{B}(\mathbb{R})$ (definition 1.4), so one need only confirm that each sublevel-type set $\{f > a\} = f^{-1}((a, \infty))$ is measurable – a single inequality to test, exactly the form in which measurability is checked in practice. A one-line instance: every *continuous* $f\colon \mathbb{R}^d \to \mathbb{R}$ is Borel measurable, since $f^{-1}((a, \infty))$ is open (a preimage of an open set under a continuous map) and open sets are Borel; continuity is more than enough, and measurability is the strictly weaker demand that lets in the discontinuous indicators and limits we actually need.

Before the central stability result, we dispose of the routine closure properties, since the observables we integrate are built from simpler ones by arithmetic and composition. If f, g are measurable and $\varphi\colon \mathbb{R} \to \mathbb{R}$ (or $\mathbb{R}^2 \to \mathbb{R}$) is continuous, then $\varphi(f)$ and more generally $\varphi(f, g)$ are measurable. The mechanism is the preceding one-liner run once more: the pair $(f, g)\colon \Omega \to \mathbb{R}^2$ is measurable because its preimage of a box $(a, b] \times (c, d]$ is $\{a < f \leq b\} \cap \{c < g \leq d\}$, an intersection of two measurable sets, and the boxes generate $\mathcal{B}(\mathbb{R}^2)$; composing with the continuous (hence Borel) map φ preserves measurability because $(\varphi \circ (f, g))^{-1}(B) = (f, g)^{-1}(\varphi^{-1}(B))$ and $\varphi^{-1}(B)$ is Borel. Taking $\varphi(u, v) = u + v$ and $\varphi(u, v) = uv$ shows that sums and products of measurable functions are measurable; taking φ any continuous scalar map covers compositions. These facts we use without further comment from here on; the only one that is not a routine corollary – and the only one the limits of this book genuinely depend on – is stability under *pointwise limits*, to which we now turn.

Proposition 1.13 (Stability of measurability under limits)**.** *If $f_n\colon \Omega \to [-\infty, \infty]$ are measurable, then* $\sup_n f_n$, $\inf_n f_n$, $\limsup_n f_n$, *and* $\liminf_n f_n$ *are measurable. In particular, if $f_n \to f$ pointwise, then f is measurable.*

Proof. Everything follows from a single set identity, read off the definition of a supremum. A point ω satisfies $\sup_n f_n(\omega) > a$ if and only if at least one $f_n(\omega)$ exceeds a – if the supremum beats a, some term must already beat a, and conversely a single term beating a forces the supremum past it. In symbols,

$$\{\sup_n f_n > a\} = \bigcup_n \{f_n > a\},$$

a *countable* union of the measurable sets $\{f_n > a\} = f_n^{-1}((a, \infty))$, hence measurable; and as a ranges over $\mathbb{R}$ these sets generate the relevant σ-algebra, so $\sup_n f_n$ is measurable by the generating-set criterion. The infimum is the mirror image: a point lies below a in infimum iff some term lies below a, giving $\{\inf_n f_n < a\} = \bigcup_n \{f_n < a\}$, again a countable union of measurable sets. (Equivalently, $\inf_n f_n = -\sup_n(-f_n)$.) The two one-sided limits are now built from these by the very formulas that define them as iterated extrema,

$$\limsup_n f_n = \inf_N \sup_{n \geq N} f_n, \qquad \liminf_n f_n = \sup_N \inf_{n \geq N} f_n,$$

each a countable infimum of countable suprema of the f_n, hence measurable by two applications of what we have just shown. Finally, wherever the sequence converges its limit equals its lim sup (and its lim inf); so if $f_n \to f$ pointwise everywhere, $f = \limsup_n f_n$ is measurable. The whole proof is the observation that a limit is assembled from sup and inf, and that sup and inf over a *sequence* cost only countable unions – exactly the operations $\mathcal{F}$ was built to absorb. □

It is worth pausing on the word "countable" here, because it is the same hinge the whole chapter turns on. The identity $\{\sup_n f_n > a\} = \bigcup_n \{f_n > a\}$ would be useless if the index ran over an uncountable set – an uncountable union of measurable sets need not be measurable, and indeed the supremum of an uncountable family of measurable functions can fail to be measurable. It is precisely because a limit is the limit of a *sequence* that everything stays inside the σ-algebra. This proposition is the unglamorous engine of the entire subject. Every convergence theorem in section 1.4 hands back a function defined as a pointwise limit, and every existence proof in this book – the fixed-point constructions of the mean field game system, the limits of empirical measures, the weak solutions assembled by compactness – produces its object as a limit of approximants and must then *integrate that object* or apply a further estimate to it. Each such step silently invokes proposition 1.13 to know the limit is a legitimate measurable function in the first place. Without it, the constructions would produce objects one is not entitled to integrate, and the analysis would have nothing to stand on. This is the precise discharge of the third worry of section 1.1: limiting objects remain legal.

With measurable functions in hand we can describe how a measure is *transported* along one. This is the construction that produces m in the first place. A random agent is a measurable map $X : \Omega \to \mathbb{R}^d$ from an abstract sample space carrying a probability measure $\mathbb{P}$; we never see Ω directly, only where X lands, and the right object to record is "how likely is the agent to land in the region A?" – the number $\mathbb{P}(X^{-1}(A))$. Reading this as a function of A defines a new measure, on the state space, that forgets the sample space entirely.

Definition 1.14 (Pushforward measure)**.** If $f : (\Omega, \mathcal{F}, \mu) \to (\Omega', \mathcal{F}')$ is measurable, the *pushforward* (or *image*) measure $f_\#\mu$ on $\mathcal{F}'$ is $(f_\#\mu)(A') = \mu(f^{-1}(A'))$. For a random variable X on $(\Omega, \mathcal{F}, \mathbb{P})$, the pushforward $\mathcal{L}(X) := X_\#\mathbb{P}$ is its *law* or *distribution*, a probability measure on $\mathbb{R}^d$.

That $f_\#\mu$ really is a measure is a direct inheritance: $f_\#\mu(\emptyset) = \mu(f^{-1}(\emptyset)) = \mu(\emptyset) = 0$, and for disjoint A'_n the preimages $f^{-1}(A'_n)$ are disjoint (a point maps into at most one A'_n), so countable additivity of $f_\#\mu$ is countable additivity of μ read through the preimage. Measurability of f is exactly what makes the right-hand side $\mu(f^{-1}(A'))$ defined for every $A' \in \mathcal{F}'$ – the definition would be empty without it. For a random variable X the total mass is $X_\#\mathbb{P}(\mathbb{R}^d) = \mathbb{P}(X^{-1}(\mathbb{R}^d)) = \mathbb{P}(\Omega) = 1$, so the law $\mathcal{L}(X)$ is a probability measure on $\mathbb{R}^d$, a point of $\mathcal{P}(\mathbb{R}^d)$.

The pushforward is engineered so that integrating against it is the same as integrating the pulled-back integrand against the original measure. This *transfer* (or *change-of-variables*) identity is the bridge we use again and again – it is what turns an expectation $\mathbb{E}[g(X)]$ computed over the unseen sample space into an honest integral $\int g \, \mathrm{d}\mathcal{L}(X)$ against the law on the state space, and it is in particular the single load-bearing equality of the empirical-measure computation in section 1.7. One must be careful about exactly what definition 1.14 has and has not delivered. The definition fixes $f_{\#}\mu$ on *sets* only: it says how to push forward the mass of a region, nothing more. The statement we want is about *integrands* – arbitrary measurable g, not just indicators of sets – and that statement does not come for free from the set-level definition. It is a separate lemma, and the work of the lemma is precisely to climb from the set-level identity up to the function-level one through the standard ladder of the integral.

Lemma 1.15 (Transfer of integrals under a pushforward)**.** *Let $f\colon (\Omega, \mathcal{F}, \mu) \to (\Omega', \mathcal{F}')$ be measurable and let $g\colon \Omega' \to [-\infty, \infty]$ be $\mathcal{F}'$-measurable. Then $g \circ f$ is $\mathcal{F}$-measurable, and*

$$\int_{\Omega'} g \, \mathrm{d}(f_{\#}\mu) \;=\; \int_{\Omega} g \circ f \, \mathrm{d}\mu \tag{1.3}$$

holds whenever $g \geq 0$ (both sides in $[0, \infty]$), and also whenever $g \in L^1(f_{\#}\mu)$ – equivalently $g \circ f \in L^1(\mu)$ – with both sides finite and equal.

Proof. The proof is the prototype of an argument we will run many times: *verify an integral identity on indicators, extend by linearity to simple functions, pass to nonnegative functions by monotone approximation, and split a signed function into its positive and negative parts.* Each of the four rungs is the natural next case once the previous is settled.

First, $g \circ f$ is $\mathcal{F}$-measurable, so both sides of (1.3) are even defined: for any Borel B, $(g \circ f)^{-1}(B) = f^{-1}(g^{-1}(B))$, which lies in $\mathcal{F}$ because $g^{-1}(B) \in \mathcal{F}'$ (measurability of g) and f^{-1} carries $\mathcal{F}'$ into $\mathcal{F}$ (measurability of f). This is just the closure of measurability under composition, applied to the specific composite we integrate.

Rung 1: indicators. Take $g = \mathbf{1}_{A'}$ with $A' \in \mathcal{F}'$. A point ω satisfies $g(f(\omega)) = 1$ exactly when $f(\omega) \in A'$, i.e. $\omega \in f^{-1}(A')$, so $g \circ f = \mathbf{1}_{f^{-1}(A')}$. The integral of an indicator is the measure of its set ((1.4)), and so

$$\int_{\Omega} g \circ f \, \mathrm{d}\mu = \mu(f^{-1}(A')) = (f_{\#}\mu)(A') = \int_{\Omega'} g \, \mathrm{d}(f_{\#}\mu),$$

where the middle equality is nothing but the *definition* of the pushforward. So (1.3) for indicators *is* the set-level definition of $f_{\#}\mu$, restated under an integral sign – this rung is where the definition enters, and it is the only rung that uses it.

Rung 2: simple functions. Both sides of (1.3) are linear in g over nonnegative coefficients, and $(\sum_k c_k \mathbf{1}_{A'_k}) \circ f = \sum_k c_k \mathbf{1}_{f^{-1}(A'_k)}$, so summing Rung 1 over the pieces of a nonnegative simple $g = \sum_k c_k \mathbf{1}_{A'_k}$ gives (1.3) for every nonnegative simple g.

Rung 3: nonnegative functions. Let $g \geq 0$ be measurable. Choose simple functions $s_n \uparrow g$ increasing to g pointwise – the canonical sequence constructed in section 1.3 (the explicit dyadic truncation s_n used there to define the integral of a nonnegative function). Composing with f

preserves the monotone convergence, $s_n \circ f \uparrow g \circ f$, because composition acts pointwise and the s_n increase at every point. Rung 2 gives $\int s_n \circ f \, \mathrm{d}\mu = \int s_n \, \mathrm{d}(f_\# \mu)$ for each n, and the monotone convergence theorem (theorem 1.20) lets us pass to the limit on *both* sides at once:

$$\int_\Omega g \circ f \, \mathrm{d}\mu = \lim_n \int_\Omega s_n \circ f \, \mathrm{d}\mu = \lim_n \int_{\Omega'} s_n \, \mathrm{d}(f_\# \mu) = \int_{\Omega'} g \, \mathrm{d}(f_\# \mu).$$

This is (1.3) for all nonnegative g, with both sides possibly $+\infty$ but always equal.

Rung 4: signed functions. For general measurable g write $g = g^+ - g^-$ with $g^\pm \geq 0$. Composition respects the splitting, $(g \circ f)^\pm = g^\pm \circ f$ (because f only relabels the point at which g is evaluated, it cannot change the sign of the value), so applying Rung 3 to g^+ and to g^- and adding gives $\int |g| \, \mathrm{d}(f_\# \mu) = \int |g \circ f| \, \mathrm{d}\mu$. Hence $g \in L^1(f_\# \mu)$ if and only if $g \circ f \in L^1(\mu)$ – the two integrability conditions are literally the same finite number – and when this common value is finite, subtracting the (now finite) Rung-3 identities for g^+ and g^- yields (1.3) for the signed g. □

Remark 1.16 (A mild and honest forward dependency)**.** Two ingredients of Rung 3 – the canonical simple approximation $s_n \uparrow g$ and the monotone convergence theorem – are objects we have not yet built; they live in section 1.3 and theorem 1.20, a few pages ahead. We deliberately use them here only as named black boxes and do *not* reproduce their construction or proof, because the logical order is not circular: the integral and the monotone convergence theorem are developed without any reference to the pushforward or to transfer, so importing them forward into this lemma creates no loop. The transfer identity is placed in this subsection because it belongs to the story of measurable maps, not because it could be proved before the integral exists; the reader meeting it should carry the two forward references as promissory notes redeemed in the next section.

A first sanity check makes the identity concrete. Take $\mu = \delta_a$, the Dirac mass at a point $a \in \Omega$, and any measurable f. The pushforward is $f_\# \delta_a = \delta_{f(a)}$, since $(f_\# \delta_a)(A') = \delta_a(f^{-1}(A')) = \mathbf{1}[f(a) \in A'] = \delta_{f(a)}(A')$; and (1.3) reads $\int g \, \mathrm{d}\delta_{f(a)} = \int g \circ f \, \mathrm{d}\delta_a$, i.e. $g(f(a)) = g(f(a))$ – the transfer identity for a point mass is just the statement that pushing a spike forward moves it to its image, which is reassuring rather than surprising, and is exactly the $N = 1$ atom of the empirical measure.

The law $\mathcal{L}(X)$ produced by this machinery is the object the rest of the book treats as the fundamental unknown. In mean field game theory the entire population is summarized by a single point $m \in \mathcal{P}(\mathbb{R}^d)$, and an individual agent's randomness enters the theory only through its law: two agents with the same law are interchangeable, which is the precise content of the exchangeability that underlies the whole continuum description. We adopt the global convention of appendix A – restated here on first use – that $m = m$ denotes such a population measure. In the present chapter m is simply a *fixed* probability law on $\mathbb{R}^d$, the common law from which a population is sampled; from chapter 8 onward it acquires a time index and *evolves* forward in time as the density of a continuum of agents, the forward Fokker–Planck partner of the backward value function. It is the recurring protagonist of everything that follows, and this subsection has given it both its definition (as a pushforward) and the one identity through which it will be computed.

That identity is the precise thing we hand to the next two stops. To the integral construction of section 1.3 we hand the class of measurable functions it was built to feed – the integrand g in (1.3) has nowhere to be integrated until that section says what $\int g \, \mathrm{d}\nu$ means – together with the assurance, from proposition 1.13, that the monotone and dominated limits the integral will be asked to survive land back inside this same class. And to the closing worked computation of section 1.7 we hand its single most-used equality: for an i.i.d. agent X_i with law $\mathcal{L}(X_i) = m$ and a bounded test function f_k, transfer gives

$$\mathbb{E}[f_k(X_i)] \;=\; \int_{\mathbb{R}^d} f_k \,\mathrm{d}\,\mathcal{L}(X_i) \;=\; \int_{\mathbb{R}^d} f_k \,\mathrm{d}m,$$

the conversion of a population average into an integral against the law that the entire empirical-measure theorem is built to exploit. With the maps in hand, the trio is complete; we now build the integral they were designed to feed.

1.3 The Lebesgue integral

The previous subsection handed us the two ingredients an integral pairs together: the *measurable functions* – the observables f we wish to average – and, from the subsection before it, the *measures* – the sizes μ against which we average them. What is still missing is the pairing itself, the rule that turns a function and a measure into a number $\int f \,\mathrm{d}\mu$. We build that rule now. Two demands govern its design, and both come straight from section 1.1. First, the rule must reproduce the physicist's average exactly: integrating an observable against the empirical measure must return the ensemble mean $\frac{1}{N}\sum_i f(X_i)$, the literal bridge (1.8) between the discrete population and its continuum summary. Second – and this is the demand Riemann's construction could not meet – the rule must *survive the limits we actually take.* The increasing sequence $f_n \uparrow \mathbf{1}_{\mathbb{Q}}$ of example 1.1 broke the Riemann integral precisely because its value did not pass to the monotone limit; we engineer the Lebesgue integral so that the monotone limit is not an afterthought but the very mechanism of the construction. Each of the three strokes below – simple functions, then nonnegative functions, then general ones – is defined so that the convergence theorems of section 1.4 come out cleanly, repairing exactly the defect diagnosed in section 1.1. Fix throughout a measure space $(\Omega, \mathcal{F}, \mu)$.

First stroke: simple functions. We begin where the measure already tells us everything. The only functions whose integral needs no analysis at all are the *simple* ones – finite combinations of indicators of measurable sets – because for them "area under the graph" is literally a finite sum of "height × size of base," and the measure supplies the size. A *simple function* is a finite combination

$$s = \sum_{k=1}^{m} c_k \,\mathbf{1}_{A_k}, \qquad c_k \in [0,\infty),\;\; A_k \in \mathcal{F},$$

taking only finitely many nonnegative values. Its integral is *declared* – there is nothing to compute, only a convention to fix – to be

$$\int_\Omega s \,\mathrm{d}\mu \;:=\; \sum_{k=1}^{m} c_k \,\mu(A_k) \;\in [0,\infty]: \tag{1.4}$$

the value c_k weighted by the measure $\mu(A_k)$ of the set where s takes it, summed over the values. The measure does all the work; no limiting process appears. This is the entire reason simple functions come first: they are the level at which integration is just arithmetic with the numbers $\mu(A_k)$ that the previous subsections taught us to assign.

There is one thing to check before (1.4) is even well posed, and it is the kind of check that is easy to wave away and worth doing once carefully, because the argument is the prototype of several to come. A simple function does not come with a canonical representation: the same s can be written as $\sum_k c_k \mathbf{1}_{A_k}$ and as $\sum_\ell d_\ell \mathbf{1}_{B_\ell}$ with completely different sets and coefficients (merge two sets sharing a value, or split one in two, and the formula changes while the function does not). For (1.4) to define a number attached to s rather than to an accidental way of writing it, the two sums $\sum_k c_k \mu(A_k)$ and $\sum_\ell d_\ell \mu(B_\ell)$ must agree. They do, by passing to the *common refinement*. There is no loss in assuming each representation partitions Ω – adjoin the set where $s = 0$ with coefficient 0 if needed – so that $\{A_k\}_k$ and $\{B_\ell\}_\ell$ are each partitions of Ω into disjoint measurable pieces. Their common refinement $\{A_k \cap B_\ell\}_{k,\ell}$ is a single partition refining both. On a nonempty cell $A_k \cap B_\ell$ the function s has one value, read off either representation, so $c_k = d_\ell$ there. Finite additivity of μ – the two-set case of countable additivity (1.1) – splits each base set along the refinement, $\mu(A_k) = \sum_\ell \mu(A_k \cap B_\ell)$ and $\mu(B_\ell) = \sum_k \mu(A_k \cap B_\ell)$, and therefore

$$\sum_k c_k\, \mu(A_k) = \sum_{k,\ell} c_k\, \mu(A_k \cap B_\ell) = \sum_{k,\ell} d_\ell\, \mu(A_k \cap B_\ell) = \sum_\ell d_\ell\, \mu(B_\ell),$$

the middle equality holding cell by cell because $c_k = d_\ell$ on every nonempty $A_k \cap B_\ell$ (and the empty cells contribute $0 \cdot \mu(\emptyset) = 0$ to either side). The integral of a simple function is thus a property of the function, not of its bookkeeping, and – the point to carry forward – it is the *additivity of the measure* that makes the representation drop out. This same common-refinement move will reappear in a moment as the proof that the integral is additive on simple functions.

Second stroke: nonnegative measurable functions. A general nonnegative observable is not simple; it takes a continuum of values. The way to integrate it is to approach it from below by the simple functions we can already integrate, and to take the integral to be as large as those lower approximants force it to be. For measurable $f\colon \Omega \to [0,\infty]$ we set

$$\int_\Omega f \; \mathrm{d}\mu \;:=\; \sup\Big\{ \int_\Omega s \; \mathrm{d}\mu \;:\; s \text{ simple},\ 0 \le s \le f \Big\} \;\in [0,\infty]. \tag{1.5}$$

Why the supremum over simple functions *below* f, rather than some other recipe? Because it is forced. Whatever the integral of f is to be, monotonicity demands $\int s \le \int f$ for every simple $s \le f$, so $\int f$ can be no smaller than the supremum on the right; and if the integral is to be compatible with monotone limits at all – the property we are building the whole theory to secure – it can be no larger, since (as we verify next) the simple functions below f climb all the way up to f. The supremum in (1.5) is thus not one choice among many but the *unique* extension of the simple-function rule (1.4) that respects monotone limits. Everything downstream – the monotone convergence theorem above all – is the cashing-out of this design choice.

That the simple functions below f genuinely exhaust it is made concrete by an explicit approximating sequence, and the formula repays a careful reading because it encodes the single idea that distinguishes Lebesgue's integral from Riemann's. Define

$$s_n \;=\; \sum_{k=0}^{n2^n-1} \frac{k}{2^n}\, \mathbf{1}_{\{\, k/2^n \le f < (k+1)/2^n \,\}} \;+\; n\, \mathbf{1}_{\{f \ge n\}}.$$

Read it as a slicing not of the domain but of the *range*. Riemann chops the x-axis into small intervals and asks for the height of f over each; Lebesgue chops the y-axis – the values of f – into the horizontal bands $[k/2^n, (k+1)/2^n)$ of width 2^{-n}, and for each band asks *how much of the space* the measure sees with f-value in that band. The set $\{k/2^n \le f < (k+1)/2^n\} = f^{-1}([k/2^n, (k+1)/2^n))$ is precisely the preimage of one band; on it s_n takes the band's floor value $k/2^n$, contributing $\frac{k}{2^n}\,\mu(\{k/2^n \le f < (k+1)/2^n\})$ to the integral – the height of the band times the size of the part of the space living in it. Above the height n, where f is too large for any of the finitely many bands to reach, the last term truncates s_n at the value n on the set $\{f \ge n\}$. Here is exactly where measurability earns its keep: every set the formula names is the preimage of a Borel set under f, hence lies in $\mathcal{F}$ by the very definition of a measurable function (definition 1.12), so each $\mu(\cdots)$ in $\int s_n \,\mathrm{d}\mu$ is defined. Were f not measurable, the slicing sets would have no size and the construction would not even start.

The sequence climbs to f, $s_n \uparrow f$, and seeing why pins down what each refinement does. Increasing n to $n+1$ does two things at once: it *halves* every band, replacing a band of height 2^{-n} by two bands of height $2^{-(n+1)}$, so that the floor value attached to a point can only rise (a point formerly assigned the lower edge of a wide band is now assigned the lower edge of the narrower band it actually sits in, which is at least as high); and it *raises the ceiling* from n to $n+1$, capturing more of the large-value region. Hence $s_n \le s_{n+1}$ everywhere. As for the limit, fix a point x. If $f(x) < \infty$, then for all $n > f(x)$ the value $f(x)$ lies below the ceiling and inside some band of width 2^{-n}, so $0 \le f(x) - s_n(x) < 2^{-n} \to 0$; if $f(x) = \infty$, then $x \in \{f \ge n\}$ for every n and $s_n(x) = n \to \infty = f(x)$. Either way $s_n(x) \uparrow f(x)$. Thus every nonnegative measurable f is a monotone increasing pointwise limit of simple functions, and (1.5) is the value that limit is forced to have. The doubling of resolution as n grows is the hallmark of the range-slicing picture: refinement adds horizontal detail, and the measure converts each new sliver of detail into a definite contribution.

Third stroke: general functions. A signed observable is split into its nonnegative parts and integrated piece by piece. A measurable $f\colon \Omega \to [-\infty, \infty]$ has *positive and negative parts* $f^+ = \max(f, 0)$ and $f^- = \max(-f, 0)$, both nonnegative and measurable, with the two identities $f = f^+ - f^-$ and $|f| = f^+ + f^-$. We call f *integrable* (and write $f \in L^1(\mu)$) when the total mass of $|f|$ is finite,

$$\int |f| \,\mathrm{d}\mu = \int f^+ \,\mathrm{d}\mu + \int f^- \,\mathrm{d}\mu < \infty,$$

which is the same as asking that f^+ and f^- each have finite integral; and for such f we define

$$\int_\Omega f \,\mathrm{d}\mu \;:=\; \int_\Omega f^+ \,\mathrm{d}\mu - \int_\Omega f^- \,\mathrm{d}\mu. \tag{1.6}$$

The integrability requirement is exactly what makes the subtraction in (1.6) meaningful: with both terms finite there is no risk of the undefined $\infty - \infty$, the same algebraic catastrophe that sank continuity-from-above for an infinite-mass set in proposition 1.6. For a vector-valued $f\colon \Omega \to \mathbb{R}^d$ integrability means $\int |f| \,\mathrm{d}\mu < \infty$ with $|f|$ the Euclidean norm, and the integral is taken componentwise.

The basic algebra Riemann lacked. The integral now exists; we must check it obeys the rules that make it usable – linearity, monotonicity, the triangle inequality – and one of these rules is the precise statement whose failure under limits doomed the Riemann theory. Linearity has two halves. Positive homogeneity $\int(cf) = c\int f$ for $c \geq 0$ is immediate: scaling a simple function scales its integral by c directly from (1.4), and the supremum (1.5) scales with it. *Additivity*, $\int(f+g) = \int f + \int g$, is the substantive half, and it is exactly the kind of statement that fails for the Riemann integral under limits – recall that in example 1.1 the obstruction was precisely an additive/limit interchange that Riemann's construction could not perform. We prove it now, because the chapter uses it repeatedly: to split $\int f \, \mathrm{d}\mu^N$ over the sum of Diracs in (1.8), and to manipulate $\int(2g - |f_n - f|)$ in the proof of dominated convergence.

For *simple* $s = \sum_k c_k \mathbf{1}_{A_k}$ and $t = \sum_\ell d_\ell \mathbf{1}_{B_\ell}$, additivity is the common-refinement argument again, now used to add rather than to compare. Refine both to the partition $\{A_k \cap B_\ell\}_{k,\ell}$; on each cell $s+t$ takes the constant value $c_k + d_\ell$, so $s+t$ is itself simple with this representation, and (1.4) gives $\int(s+t)\,\mathrm{d}\mu = \sum_{k,\ell}(c_k + d_\ell)\,\mu(A_k \cap B_\ell)$, which splits into $\sum_{k,\ell} c_k\,\mu(A_k \cap B_\ell) + \sum_{k,\ell} d_\ell\,\mu(A_k \cap B_\ell) = \int s\,\mathrm{d}\mu + \int t\,\mathrm{d}\mu$ by the same finite-additivity bookkeeping as before. At the simple level additivity is therefore pure arithmetic with the measure – no limit anywhere.

For general nonnegative measurable f, g the limit finally enters, and this is the heart of the matter. Take the canonical dyadic sequences $s_n \uparrow f$ and $t_n \uparrow g$ built above. Their sum increases to the sum, $s_n + t_n \uparrow f + g$, and we pass to the limit through the integral three times – once on each summand and once on the sum:

$$\int (f+g)\,\mathrm{d}\mu \overset{(1)}{=} \lim_n \int (s_n + t_n)\,\mathrm{d}\mu \overset{(2)}{=} \lim_n \Big(\int s_n\,\mathrm{d}\mu + \int t_n\,\mathrm{d}\mu \Big) \overset{(3)}{=} \int f\,\mathrm{d}\mu + \int g\,\mathrm{d}\mu.$$

Step (2) is just simple-function additivity, applied to each n. Steps (1) and (3) are each an instance of the monotone convergence theorem (theorem 1.20): the integral of a monotone increasing sequence of nonnegative functions equals the limit of the integrals. This is exactly the interchange of limit and integral that Riemann could not perform; here it is licensed, because (1.5) was built to make it so.

Remark 1.17 (The forward reference to theorem 1.20 is not circular)**.** The argument just given invokes the monotone convergence theorem, which is stated and proved only in the next section, section 1.4. This forward dependence is deliberate and it is *benign*, not a hidden circle. The proof of theorem 1.20 rests on two things alone: the definition (1.5) of the integral as a supremum over simple minorants, and the continuity-from-below of the measure (proposition 1.6(iii)). It never uses additivity of the integral. So the logical order is sound – monotone convergence is proved first from the definition, and additivity then follows from it – even though, for narrative reasons, we want additivity in hand here, before we reach the convergence theorems. We keep the construction in this order and simply signpost the pointer: when reading theorem 1.20, note that its proof leans on nothing established in the present paragraph.

With additivity secured for nonnegative functions, the rest of the algebra unwinds mechanically. Splitting a signed $f = f^+ - f^-$ and applying nonnegative additivity extends $\int(f+g) = \int f + \int g$ to all of $L^1(\mu)$. The triangle inequality is then a one-line consequence of $|f| = f^+ + f^-$,

$$\Big|\int f\,\mathrm{d}\mu\Big| = \Big|\int f^+\,\mathrm{d}\mu - \int f^-\,\mathrm{d}\mu\Big| \leq \int f^+\,\mathrm{d}\mu + \int f^-\,\mathrm{d}\mu = \int |f|\,\mathrm{d}\mu,$$

and monotonicity is the observation that for $f \le g$ the difference $g - f \ge 0$ has $\int (g - f)\ d\mu \ge 0$, so by additivity $\int g\ d\mu - \int f\ d\mu \ge 0$. A fuller account of these manipulations is in [123, Ch. 2]. We have what the next section needs: a *linear, monotone* integral, additive on $L^1(\mu)$, with the triangle inequality. Before handing it on, we record two facts that fix the integral's relationship to the rest of the chapter – its agreement with the elementary integral, and its blindness to null sets.

Remark 1.18 (Agreement with Riemann; the role of null sets)**.** The Lebesgue integral does not overturn the elementary one; it *extends* it. If $f : [a, b] \to \mathbb{R}$ is Riemann integrable, then it is Lebesgue measurable and the two integrals coincide. The mechanism is the Darboux squeeze, run through the convergence theorems. Fix a sequence of partitions refining to mesh zero, and on each form the lower and upper Darboux *step functions* $\underline{\varphi}_n \le f \le \overline{\varphi}_n$ – constant on the partition cells, hence *simple* – with $\underline{\varphi}_n$ increasing and $\overline{\varphi}_n$ decreasing as the partition refines. By the very definition (1.4), the Lebesgue integrals $\int \underline{\varphi}_n$ dLeb and $\int \overline{\varphi}_n$ dLeb are exactly the lower and upper Darboux sums, and Riemann integrability is the statement that these share a common limit, the Riemann integral $\int_a^b f$. Everything on the bounded interval $[a, b]$ is dominated by the constant $\sup |f| < \infty$, so monotone (equivalently dominated) convergence applies to both monotone sequences: the limits $\underline{\varphi} = \lim_n \underline{\varphi}_n$ and $\overline{\varphi} = \lim_n \overline{\varphi}_n$ are measurable and

$$\int \underline{\varphi}\ \mathrm{dLeb} = \int \overline{\varphi}\ \mathrm{dLeb} = \int_a^b f.$$

Now the squeeze. The difference $\overline{\varphi} - \underline{\varphi} \ge 0$ is nonnegative with $\int (\overline{\varphi} - \underline{\varphi})$ dLeb $= 0$, and a nonnegative measurable function whose integral vanishes must vanish almost everywhere. (This little principle is used twice in the book, so here is its one-line proof: if $h \ge 0$ and $\int h\ d\mu = 0$, then for each k the simple minorant $\frac{1}{k}\mathbf{1}_{\{h \ge 1/k\}} \le h$ gives $\frac{1}{k}\mu(\{h \ge 1/k\}) \le \int h\ d\mu = 0$, so $\mu(\{h \ge 1/k\}) = 0$; and $\{h > 0\} = \bigcup_k \{h \ge 1/k\}$ is then a countable union of null sets, hence null by subadditivity, proposition 1.6(ii).) Applied here, $\overline{\varphi} = \underline{\varphi}$ Lebesgue-a.e., and since $\underline{\varphi} \le f \le \overline{\varphi}$ this forces $\underline{\varphi} = f = \overline{\varphi}$ a.e. Thus f agrees almost everywhere with the Borel function $\underline{\varphi}$, is itself measurable, and $\int f$ dLeb $= \int_a^b f$. The Lebesgue integral agrees with the elementary one wherever the latter is defined, and – crucially – remains defined on the monotone limits (example 1.1) where the latter breaks.

The squeeze just used reveals a structural feature that will organize the entire book. The integral *never sees a null set*: two functions equal μ-almost everywhere – agreeing outside a set of μ-measure zero – have the same integral, because their difference is supported on a null set and the integral of anything supported there is zero (it is dominated by constants times the indicator of a measure-zero set, whose integral (1.4) vanishes). This is why, throughout the book, identities between integrable functions are asserted "almost everywhere" rather than pointwise: the pointwise values on a null set are genuinely invisible to every integral we will ever form, so insisting on them would be insisting on information the theory discards by design. It is also the precise reason the L^p spaces of section 1.6 are spaces of *equivalence classes* – functions identified when they agree a.e. – rather than spaces of functions: the quotient by null sets is not a technical nuisance but the honest record of what the integral can resolve. The "a.e." convention and the L^p quotient both descend from this single remark.

We close the section by collecting the dividend the whole construction was built to pay: the identity that turns a population average into an integral. It is the simplest possible computation in the new machinery, and it is the chapter's destination in miniature.

Example 1.19 (Integration against a Dirac mass and the empirical average)**.** Take first a single point mass δ_a. For a simple $s = \sum_k c_k \mathbf{1}_{A_k}$, the definition (1.4) together with $\delta_a(A_k) = \mathbf{1}_{A_k}(a)$ gives $\int s \, \mathrm{d}\delta_a = \sum_k c_k \mathbf{1}_{A_k}(a) = s(a)$: integration against δ_a is just evaluation at a. For a nonnegative measurable f this passes to the supremum (1.5): every simple $s \le f$ has $s(a) \le f(a)$, while the dyadic minorants $s_n \le f$ achieve $s_n(a) \uparrow f(a)$, so the supremum of $\int s \, \mathrm{d}\delta_a = s(a)$ over simple $s \le f$ is exactly $f(a)$. Hence

$$\int_\Omega f \, \mathrm{d}\delta_a \;=\; f(a). \tag{1.7}$$

Only the value of f at the atom a survives – which is the rigorous content of the physicist's sifting property $\int f(x)\,\delta(x-a)\,\mathrm{d}x = f(a)$, now read as a statement about the Dirac *measure* rather than a fictional function. Summing (1.7) over the atoms of the empirical measure $\mu^N = \frac{1}{N}\sum_{i=1}^N \delta_{X_i}$ and using the linearity just proved, integration against μ^N is the population average:

$$\int_{\mathbb{R}^d} f \, \mathrm{d}\mu^N \;=\; \frac{1}{N}\sum_{i=1}^N \int_{\mathbb{R}^d} f \, \mathrm{d}\delta_{X_i} \;=\; \frac{1}{N}\sum_{i=1}^N f(X_i). \tag{1.8}$$

This identity is the bridge between the discrete and the continuum that the whole chapter is built to cross: the left side is an integral against a measure, the right side is the physicist's ensemble average over a finite population, and they are *equal*, not merely analogous. With it, every statement about the empirical average becomes a statement about an integral against μ^N, and conversely. The empirical-measure theorem of section 1.7 is precisely the assertion that, for f bounded continuous, the right side converges to $\int f \, \mathrm{d}m$ as $N \to \infty$ – that the population summary μ^N settles onto the law m. To prove it we will need to move the limit $N \to \infty$ across the integral sign, and that is the one permit the integral we have just built does not yet carry. Acquiring it – the monotone, Fatou, and dominated convergence theorems – is the work of the next section, which receives from us a linear, monotone integral, additive on $L^1(\mu)$, ready to be tested against limits, and the identity (1.8) whose limiting behavior is the goal.

1.4 Exchanging limits and integrals

The previous section closed by naming the one permit the freshly built integral does not yet carry. We have a linear, monotone integral $f \mapsto \int f \, \mathrm{d}\mu$ that agrees with the elementary integral wherever the latter exists and survives the monotone limits where it breaks, and we have the bridge identity (1.8) that turns the population average $\frac{1}{N}\sum_i f(X_i)$ into the single integral $\int f \, \mathrm{d}\mu^N$. What we do *not* yet have is the right to push a limit through the integral sign. This is exactly the third of the three questions raised in section 1.1 – *when may we exchange the limit $N \to \infty$ with the integral $\int f\,(\cdots)$?* – the one we flagged there as "sometimes simply false." The first two questions are now answered: m and μ^N are measures (section 1.2), and the integral against them is built (section 1.3). The third is the business of this section.

It is worth being precise about why this last permit is the hard one. The interchange $\lim_n \int f_n = \int \lim_n f_n$ is the formal content of every "take the thermodynamic limit inside the average" step a physicist writes, almost always silently. And section 1.1 already exhibited the canonical way it fails: the escaping-mass sequence $f_n = n\mathbf{1}_{(0,1/n)}$, for which $\int f_n = 1$ for every n while the pointwise limit is the zero function, so $\lim_n \int f_n = 1 \neq 0 = \int \lim_n f_n$. The mass did not vanish; it concentrated, and the pointwise limit threw it away. That example was left there as a warning with a promised resolution: there is a precise hypothesis whose presence makes the interchange legal and whose absence is the exact mechanism of the failure. We now redeem the promise. The resolution comes in three theorems – monotone convergence, Fatou's lemma, and dominated convergence – each supplying a *different* sufficient hypothesis, and each tailored to a different way the integrand can behave under the limit. Read together they form a complete answer: the escaping-mass sequence violates the one hypothesis (a fixed integrable envelope) that dominated convergence demands, and that is precisely why it escapes. By the end of the section the warning of section 1.1 will be a closed loop, and we will have, as a free corollary, the right to differentiate under the integral sign – a manipulation used silently in nearly every later chapter.

We continue to work on a fixed measure space $(\Omega, \mathcal{F}, \mu)$. The order of the three theorems is not arbitrary: monotone convergence is proved first and directly from the construction of the integral; Fatou's lemma falls out of it in one line; and dominated convergence is then deduced from Fatou by a cancellation trick. Each is the lever for the next.

The first theorem treats the most structured situation – an integrand that only *increases*. This is the case in which no mass can ever escape, because nothing is ever taken away: the functions climb monotonically toward their limit, and one expects the integrals to climb with them. It is also the case the integral was *built* to handle, since the very definition (1.5) of $\int f \,\mathrm{d}\mu$ as a supremum over simple minorants is itself a statement about an increasing approximation. Monotone convergence says that this internal monotone structure of the integral propagates to *any* monotone approximating sequence, not just the dyadic one used to define it.

Theorem 1.20 (Monotone convergence, MCT)**.** *Let $f_n \colon \Omega \to [0, \infty]$ be measurable with $f_n \uparrow f$ pointwise ($0 \le f_1 \le f_2 \le \cdots$ and $f_n(\omega) \to f(\omega)$ for every ω). Then f is measurable and*

$$\int_\Omega f_n \,\mathrm{d}\mu \;\uparrow\; \int_\Omega f \,\mathrm{d}\mu.$$

Proof. Measurability of the limit f is exactly the stability fact proved in proposition 1.13: a pointwise limit of measurable functions is measurable, so $\int f \,\mathrm{d}\mu$ is at least *defined*. We must show the integrals converge to it.

The easy inequality. The integral is monotone – $0 \le u \le v$ implies $\int u \le \int v$, immediate from (1.5) since every simple minorant of u is one of v. Applying this along the chain $f_1 \le f_2 \le \cdots \le f$ gives $\int f_1 \le \int f_2 \le \cdots \le \int f$. The left-hand side is therefore an increasing sequence in $[0, \infty]$, so it has a limit

$$L \;:=\; \lim_{n\to\infty} \int f_n \;=\; \sup_n \int f_n \;\in [0, \infty],$$

and every term, hence the limit, is bounded above by $\int f$: thus $L \le \int f$. The content of the theorem is the reverse inequality $L \ge \int f$, for then $L = \int f$ and the monotone convergence $\int f_n \uparrow \int f$ is exactly the assertion.

The reverse inequality – setup. By the definition (1.5) of $\int f \, \mathrm{d}\mu$ as the supremum of $\int s \, \mathrm{d}\mu$ over simple functions $0 \le s \le f$, it suffices to show $L \ge \int s \, \mathrm{d}\mu$ for *each* fixed such s; taking the supremum over s then yields $L \ge \int f$. So fix one simple $0 \le s \le f$. The obstacle is that we cannot compare f_n to s directly – it is entirely possible that $f_n < s$ on a large set for every finite n, since f_n only reaches up to s in the limit. The device that circumvents this is to relax the comparison by a multiplicative slack $c < 1$ and chase the sets where it holds. Fix a constant $c \in (0,1)$ and define the *capture sets*

$$E_n \ := \ \{\omega \in \Omega : f_n(\omega) \ge c\, s(\omega)\},$$

the region where f_n has already climbed to within a factor c of s. Each E_n is measurable (it is a sublevel-type set of the measurable function $f_n - cs$), and they increase: since $f_n \le f_{n+1}$, the inequality $f_n \ge cs$ forces $f_{n+1} \ge cs$, so $E_n \subseteq E_{n+1}$.

Why $E_n \uparrow \Omega$. This is the step the original proof compressed into a parenthesis, and it is the crux, so we give it in full by splitting on the value of s at a fixed point ω. There are two cases.

- If $s(\omega) = 0$, then $c\, s(\omega) = 0$, and since $f_n(\omega) \ge 0$ always, the defining inequality $f_n(\omega) \ge c\, s(\omega) = 0$ holds for *every* n; thus $\omega \in E_n$ for all n, in particular for $n = 1$.
- If $s(\omega) > 0$, then because $c < 1$ we have the *strict* inequality $c\, s(\omega) < s(\omega) \le f(\omega) = \lim_n f_n(\omega)$. The increasing sequence $f_n(\omega)$ converges to a value strictly above the threshold $c\, s(\omega)$, so it must eventually exceed that threshold: there is some N with $f_n(\omega) \ge c\, s(\omega)$ for all $n \ge N$, i.e. $\omega \in E_n$ for all large n.

In both cases ω belongs to E_n from some index on, so $\bigcup_n E_n = \Omega$. Together with $E_n \subseteq E_{n+1}$ this is precisely $E_n \uparrow \Omega$. The role of the slack $c < 1$ is visible here: it is what converts the possibly non-strict $s(\omega) \le f(\omega)$ into the strict gap $c\, s(\omega) < f(\omega)$ that lets the increasing sequence *overtake* the threshold in finite time. With $c = 1$ the argument would stall at points where $f(\omega) = s(\omega)$ is approached but never attained.

Cashing it in via continuity from below. On E_n we have $f_n \ge cs$ by definition, so restricting the integral to E_n and using monotonicity twice,

$$\int_\Omega f_n \, \mathrm{d}\mu \ \ge \ \int_{E_n} f_n \, \mathrm{d}\mu \ \ge \ \int_{E_n} c\, s \, \mathrm{d}\mu \ = \ c \int_{E_n} s \, \mathrm{d}\mu.$$

Now the simple function $s = \sum_k a_k \mathbf{1}_{A_k}$ turns the set map $A \mapsto \int_A s \, \mathrm{d}\mu = \sum_k a_k \, \mu(A \cap A_k)$ into a finite nonnegative combination of the measures $A \mapsto \mu(A \cap A_k)$, hence *itself a measure* ν_s. The increasing sweep $E_n \uparrow \Omega$ is exactly the hypothesis of continuity from below for ν_s (proposition 1.6), which therefore gives

$$\int_{E_n} s \, \mathrm{d}\mu \ = \ \nu_s(E_n) \ \uparrow \ \nu_s(\Omega) \ = \ \int_\Omega s \, \mathrm{d}\mu.$$

This is the precise point at which the continuity-under-limits property of measures, built back in proposition 1.6, is spent: the monotone build-up of the *sets* E_n drives the monotone build-up of the *integral* of s over them.

The two final passages. Combine the last two displays and let $n \to \infty$. The left side tends to L and the right side tends to $c \int_\Omega s \, \mathrm{d}\mu$, so

$$L \ \ge \ c \int_\Omega s \, \mathrm{d}\mu \qquad \text{for every } c \in (0,1).$$

The constant c was an artifact of the argument, not of the statement, so we now retire it: letting $c \uparrow 1$ – legitimate because $\int_\Omega s \, \mathrm{d}\mu$ does not depend on c – gives $L \geq \int_\Omega s \, \mathrm{d}\mu$. Finally, this holds for every simple $0 \leq s \leq f$, and the supremum over such s is by definition $\int_\Omega f \, \mathrm{d}\mu$; hence $L \geq \int f$. With the easy inequality this closes the proof. □

A word on what was really used, since the same skeleton recurs. The only substantive ingredient was *continuity from below* of the measure ν_s, and that in turn was the one-axiom payoff of countable additivity isolated in proposition 1.6. Monotone convergence is thus not a new analytic miracle; it is countable additivity, viewed through the integral. In its native habitat MCT is the statement that the defining approximation of the integral is robust: applied to the dyadic minorants $s_n \uparrow f$ of (1.5) it merely returns $\int s_n \uparrow \int f$, the definition itself, but applied to *any* increasing sequence reaching f it says one may use whichever monotone approximation is convenient and the integral will follow it up. We will exploit exactly this freedom – replace an awkward sequence by a convenient monotone one with the same limit – repeatedly, beginning in the very next section.

Example 1.21 (MCT recovers the rationals computation)**.** The monotone limit that broke Riemann's theory in example 1.1 is now trivial. There $f_n = \mathbf{1}_{\{q_1,\ldots,q_n\}} \uparrow \mathbf{1}_{\mathbb{Q}\cap[0,1]} = f$, each f_n is simple and nonnegative with $\int f_n \, \mathrm{dLeb} = 0$ (a finite set has Lebesgue measure 0), and the sequence increases to f. MCT applies verbatim and gives $\int f \, \mathrm{dLeb} = \lim_n \int f_n \, \mathrm{dLeb} = 0$. The symbol that "denoted nothing" in Riemann's theory now denotes the number 0, and the interchange $\lim_n \int f_n = \int \lim_n f_n$ that could not even be *written down* there is a special case of MCT here. This is the repair promised in section 1.1 made literal.

Monotone convergence assumed the integrand climbs. Most sequences do not; they oscillate, spike, or wander. For those we cannot expect an equality, but we can ask for the safe *one-sided* statement that survives in full generality: whatever the sequence does, the integral of its eventual floor cannot exceed the eventual size of its integrals. "Mass can be lost in the limit but never spuriously gained" is the slogan, and the precise form is Fatou's lemma. It is the workhorse-of-the-workhorse: it costs no hypothesis at all beyond nonnegativity, and the dominated convergence theorem will be wrung out of it.

The right object to compare against is the *liminf* of the sequence, $\liminf_n f_n = \sup_n \inf_{k\geq n} f_k$ – the largest function the f_n are eventually above. Its appeal is that the inner infima $g_n = \inf_{k\geq n} f_k$ *increase* in n (an infimum over a shrinking index set can only grow), which hands us exactly the monotone structure MCT consumes. That single observation is the whole proof.

Lemma 1.22 (Fatou)**.** *For any measurable $f_n \colon \Omega \to [0,\infty]$,*

$$\int_\Omega \liminf_{n\to\infty} f_n \, \mathrm{d}\mu \;\leq\; \liminf_{n\to\infty} \int_\Omega f_n \, \mathrm{d}\mu.$$

Proof. Set $g_n = \inf_{k\geq n} f_k$. Three facts hold by construction. First, g_n is measurable, as a countable infimum of measurable functions (proposition 1.13). Second, the g_n increase and converge upward to the liminf: $g_n \uparrow \sup_n g_n = \liminf_n f_n$ by the very definition of lim inf. Third, g_n is a lower bound for every tail term: $g_n = \inf_{k\geq n} f_k \leq f_k$ for each $k \geq n$, so integrating and taking the infimum over those k, $\int g_n \, \mathrm{d}\mu \le \inf_{k\ge n} \int f_k \, \mathrm{d}\mu$. Now apply monotone convergence (theorem 1.20) to the increasing sequence $g_n \uparrow \liminf_n f_n$ and let $n \to \infty$:

$$\int_\Omega \liminf_n f_n \, \mathrm{d}\mu \;=\; \lim_n \int_\Omega g_n \, \mathrm{d}\mu \;\le\; \lim_n \inf_{k\ge n} \int_\Omega f_k \, \mathrm{d}\mu \;=\; \liminf_n \int_\Omega f_n \, \mathrm{d}\mu,$$

the last equality being the definition of the liminf of the number sequence $\left(\int f_n\right)_n$. This is the claim. $\square$

The inequality is genuinely one-directional, and seeing *why* it can be strict is what finally closes the loop opened in section 1.1. Return to the escaping-mass sequence $f_n = n\mathbf{1}_{(0,1/n)}$ on $[0,1]$ with Lebesgue measure – the rectangle of height n and width $1/n$ pinned to the origin. We computed there that $\int_0^1 f_n \, \mathrm{d}x = 1$ for every n, so the right-hand side of Fatou is $\liminf_n \int f_n = \lim_n 1 = 1$. On the other side, every fixed point $x \in [0,1]$ has $f_n(x) = 0$ for all $n > 1/x$ (and $f_n(0) = 0$ always), so the pointwise liminf is the zero function, and the left-hand side is $\int_0^1 \liminf_n f_n \, \mathrm{d}x = \int_0^1 0 \, \mathrm{d}x = 0$. Fatou's lemma here reads

$$0 \;=\; \int_\Omega \liminf_n f_n \, \mathrm{d}\mu \;<\; \liminf_n \int_\Omega f_n \, \mathrm{d}\mu \;=\; 1,$$

a *strict* inequality. The lemma holds – $0 \le 1$ – but with room to spare, and the gap is precisely the unit of mass that concentrated at the origin and was discarded by the pointwise limit. This is the same escaping mass diagnosed in section 1.1, now read through the integral: Fatou correctly refuses to certify that the lost mass reappears, which is exactly the safe one-sided guarantee it advertises. The example also tells us what is missing for *equality*. Nothing prevented the mass from sliding off to a point because nothing held the functions down: the smallest function dominating all the f_n is $\sup_n f_n(x) \sim 1/x$ near the origin, which is not integrable. To upgrade Fatou's inequality to an equality we must forbid exactly this – we must supply a single integrable function that caps every f_n from above. That hypothesis is the entire content of the dominated convergence theorem, the workhorse of the entire book, and the failure we have just witnessed is the precise failure its hypothesis rules out.

Theorem 1.23 (Dominated convergence, DCT)**.** *Let $f_n \colon \Omega \to \mathbb{R}$ (or $\mathbb{R}^d$) be measurable with $f_n \to f$ pointwise μ-almost everywhere. Suppose there is an integrable* dominating function $g \in L^1(\mu)$*, $g \ge 0$, with $|f_n| \le g$ μ-a.e. for every n. Then $f \in L^1(\mu)$,*

$$\lim_{n\to\infty} \int_\Omega |f_n - f| \, \mathrm{d}\mu = 0, \qquad \textit{and in particular} \qquad \lim_{n\to\infty} \int_\Omega f_n \, \mathrm{d}\mu = \int_\Omega f \, \mathrm{d}\mu.$$

Proof. Reduction to a clean pointwise setting. The hypotheses are stated "μ-a.e.": the convergence $f_n \to f$ may fail on a null set, and each bound $|f_n| \le g$ may fail on a null set. There are countably many such exceptional sets – one for the convergence, one for each n – and a countable union of null sets is null (countable subadditivity, proposition 1.6). Off that single null set N_0 every hypothesis holds at every point. Since the integral never sees a null set (the a.e. principle of section 1.3), we may freely redefine all functions to be 0 on N_0 without changing any integral; after this harmless surgery $f_n \to f$ *everywhere* and $|f_n| \le g$ *everywhere*. For the vector-valued case ($f_n \colon \Omega \to \mathbb{R}^d$) we argue one coordinate at a time: each component $f_n^{(j)}$ converges to $f^{(j)}$ and is bounded by $|f_n| \le g$, so it falls under the scalar statement, and finite linear combinations of the coordinate conclusions give the vector conclusion. So assume f_n, f scalar with the bounds holding pointwise.

The limit is integrable. Letting $n \to \infty$ in $|f_n| \le g$ and using $f_n \to f$ gives $|f| = \lim_n |f_n| \le g$ pointwise. Hence $\int |f|\, \mathrm{d}\mu \le \int g\, \mathrm{d}\mu < \infty$, so $f \in L^1(\mu)$ and the symbol $\int f\, \mathrm{d}\mu$ is legitimate.

The Fatou trick. The quantity we want to drive to zero is $\int |f_n - f|\, \mathrm{d}\mu$. The obstruction is that $|f_n - f|$ is not monotone, so MCT is unavailable; but it *is* nonnegative and uniformly capped, since

$$|f_n - f| \;\le\; |f_n| + |f| \;\le\; g + g \;=\; 2g.$$

This is the cue to apply Fatou to the nonnegative functions $2g - |f_n - f| \ge 0$, which are legitimate integrands and converge pointwise to $2g$ (because $|f_n - f| \to 0$). Fatou (lemma 1.22) gives

$$\int 2g\, \mathrm{d}\mu \;=\; \int \liminf_n \left(2g - |f_n - f|\right) \mathrm{d}\mu \;\le\; \liminf_n \int \left(2g - |f_n - f|\right) \mathrm{d}\mu.$$

Now $2g$ is a *fixed* function, so $\int 2g\, \mathrm{d}\mu$ pulls out of the liminf as a constant, and a $\liminf$ of a difference with a fixed term is that term minus the corresponding $\limsup$:

$$\liminf_n \Big(\int 2g\, \mathrm{d}\mu - \int |f_n - f|\, \mathrm{d}\mu \Big) \;=\; \int 2g\, \mathrm{d}\mu - \limsup_n \int |f_n - f|\, \mathrm{d}\mu.$$

Chaining the two displays, $\int 2g\, \mathrm{d}\mu \le \int 2g\, \mathrm{d}\mu - \limsup_n \int |f_n - f|\, \mathrm{d}\mu$.

The cancellation – and where integrability of g is spent. Here is the one place the hypothesis $g \in L^1(\mu)$ does irreplaceable work. Because $\int 2g\, \mathrm{d}\mu < \infty$, it is a *finite* number and may be subtracted from both sides of the last inequality without producing the indeterminate $\infty - \infty$. Cancelling it leaves

$$0 \;\le\; -\limsup_n \int |f_n - f|\, \mathrm{d}\mu, \qquad \text{i.e.} \qquad \limsup_n \int |f_n - f|\, \mathrm{d}\mu \;\le\; 0.$$

But $\int |f_n - f|\, \mathrm{d}\mu \ge 0$ for every n, so its $\limsup$ is also ≥ 0; squeezed between 0 and itself, the sequence has limit 0: $\lim_n \int |f_n - f|\, \mathrm{d}\mu = 0$. Had g failed to be integrable, $\int 2g\, \mathrm{d}\mu = \infty$, the cancellation would have read $\infty \le \infty - (\cdots)$ and concluded nothing – which is exactly the loophole through which the escaping-mass sequence (whose minimal envelope $\sup_n f_n \sim 1/x$ is not integrable) drives its mass away. The finiteness of the envelope is the wall that holds the mass in, precisely as foretold in section 1.1.

From L^1 convergence to the interchange. Finally, the convergence of the integrals is a one-line consequence of the L^1 convergence just established, by linearity and the triangle inequality for the integral:

$$\Big| \int_\Omega f_n\, \mathrm{d}\mu - \int_\Omega f\, \mathrm{d}\mu \Big| \;=\; \Big| \int_\Omega (f_n - f)\, \mathrm{d}\mu \Big| \;\le\; \int_\Omega |f_n - f|\, \mathrm{d}\mu \;\xrightarrow[n\to\infty]{}\; 0,$$

so $\int f_n\, \mathrm{d}\mu \to \int f\, \mathrm{d}\mu$. This is the permit we set out to obtain. □

We can now collect the payoff of the entire section 1.1 motivation in a single picture. That section turned the physicist's reflex into three demands and warned that the third – exchanging a limit with an integral – is sometimes false; the three theorems just proved are the precise resolution, and it is worth seeing them side by side as three different licenses for the *same* maneuver, each matched to a different physical regime.

Heuristic (non-rigorous)

Every thermodynamic-limit manipulation of the form "$\lim_{N\to\infty} \frac{1}{N}\sum_i \varphi(X_i^{(N)}) = \int \varphi \, \mathrm{d}\big(\lim_N \mu^N\big)$" is an interchange of a limit with an integral, and the three theorems are its three permits, distinguished by what they assume about the integrand. *Monotone convergence* is the permit when the integrand only *increases* – a free energy or partition function assembled by adding modes one at a time, a sublevel content swept upward – and it gives an exact equality with no envelope required, because a monotone build-up can lose nothing. *Fatou* asks for nothing at all beyond nonnegativity and pays for that generality with a mere one-sided inequality; it is the right tool exactly when one needs only that mass is *not spuriously gained* in the limit (a lower bound on a limiting energy, say), and it is honest about the possibility that mass is *lost*, which is what the strict escaping-mass case records. *Dominated convergence* is the generic workhorse: once an a priori bound furnishes a single integrable envelope g with $|f_n| \le g$, fluctuations of either sign are uniformly controlled and the interchange holds as an equality. The order MCT $\to$ Fatou $\to$ DCT is also the order of increasing applicability and decreasing structure – from monotone, to nonnegative, to merely dominated. When *none* applies the interchange is genuinely false, and the escaping-mass example $f_n = n\mathbf{1}_{(0,1/n)}$ of section 1.1 is the canonical warning of how: its minimal envelope $\sup_n f_n \sim 1/x$ is not integrable, the DCT hypothesis fails, and the unit of mass concentrates at a point that the pointwise limit cannot see. The hypothesis of DCT is thus not fine print – it is the wall that holds the mass in. In the empirical-measure theorem of section 1.7 we will sit squarely in the tamest corner of this picture: the observable φ is bounded and the measures are probability measures (total mass $1 < \infty$), so the constant envelope $g \equiv \|\varphi\|_\infty$ is integrable and DCT applies in its simplest guise. This special case – a uniformly bounded sequence on a finite measure space – is so common it is named separately, the *bounded convergence theorem* (BCT), and it is the engine of the chapter's closing computation.

One immediate dividend of dominated convergence deserves to be recorded as a named tool, because the rest of the book uses it constantly and almost always without comment: differentiation under the integral sign. Whenever we write $\partial_t \int \cdots \mathrm{d}\mu = \int \partial_t(\cdots)\,\mathrm{d}\mu$ – differentiating a Riccati functional in time, varying a value function with respect to a parameter, computing the linear response of a free energy – we are silently invoking the corollary below. It is nothing but DCT applied to difference quotients, with the mean value theorem manufacturing the dominating function.

Corollary 1.24 (Differentiation under the integral)**.** *Let $(t,\omega) \mapsto f(t,\omega)$ with t in an open interval $I \subseteq \mathbb{R}$ satisfy: $f(t,\cdot) \in L^1(\mu)$ for each t; the partial derivative $\partial_t f(t,\omega)$ exists for μ-a.e. ω and all $t \in I$; and $|\partial_t f(t,\omega)| \le g(\omega)$ for some $g \in L^1(\mu)$ independent of t. Then $t \mapsto \int f(t,\cdot)\,\mathrm{d}\mu$ is differentiable on I with $\frac{\mathrm{d}}{\mathrm{d}t}\int f(t,\cdot)\,\mathrm{d}\mu = \int \partial_t f(t,\cdot)\,\mathrm{d}\mu$.*

Proof. Fix $t \in I$ and any sequence $h_n \to 0$ with $h_n \neq 0$ and $t + h_n \in I$; it suffices to show the difference quotients of $t \mapsto \int f(t,\cdot)\,\mathrm{d}\mu$ converge to $\int \partial_t f(t,\cdot)\,\mathrm{d}\mu$ along every such sequence, since that pins the derivative. Put

$$q_n(\omega) \;:=\; \frac{f(t+h_n,\omega) - f(t,\omega)}{h_n}.$$

Two things hold for μ-a.e. ω. First, $q_n(\omega) \to \partial_t f(t,\omega)$ as $n \to \infty$, by the definition of the partial derivative, which exists a.e. by hypothesis. Second, each q_n is dominated by the fixed integrable g: the mean value theorem applied to the differentiable function $\tau \mapsto f(\tau,\omega)$ on the interval between t and $t+h_n$ produces an intermediate point $\xi_n(\omega)$ with $q_n(\omega) = \partial_t f(\xi_n(\omega),\omega)$, and the uniform bound $|\partial_t f(\tau,\omega)| \le g(\omega)$ gives $|q_n(\omega)| \le g(\omega)$ for every n. The hypotheses of DCT (theorem 1.23) are met – a.e. pointwise convergence and a single integrable envelope – so the integrals pass to the limit:

$$\lim_{n\to\infty} \frac{\int f(t+h_n,\cdot)\,\mathrm{d}\mu - \int f(t,\cdot)\,\mathrm{d}\mu}{h_n} \;=\; \lim_{n\to\infty} \int_\Omega q_n\,\mathrm{d}\mu \;=\; \int_\Omega \partial_t f(t,\cdot)\,\mathrm{d}\mu,$$

where the first equality is the linearity of the integral pulling the constant $1/h_n$ inside. As the sequence $h_n \to 0$ was arbitrary, the difference quotient of $t \mapsto \int f(t,\cdot)\,\mathrm{d}\mu$ converges to the displayed value, which is therefore its derivative. □

The third question of section 1.1 is now fully answered. The three convergence theorems are the exact licenses for "take the limit inside the integral," the escaping-mass warning has hardened into the failure of a checkable hypothesis, and we have, for free, the right to differentiate under the integral. What we have really installed, though, is a reusable *architecture*, and it is worth naming because it recurs almost everywhere ahead: *monotone control, then dominated passage.* One first builds or bounds an object by a monotone approximation – where MCT and Fatou apply without any envelope – and then, once a uniform integrable bound is in hand, upgrades the one-sided estimate to an equality by DCT. This two-step pattern is the skeleton of nearly every limit argument in the book.

The very next section is the first to lean on it. To define the product measure $\mu_1 \otimes \mu_2$ and prove the Fubini–Tonelli theorem we will verify countable additivity of a candidate set function by a *monotone* passage (continuity from below, hence MCT), and Tonelli's theorem is exactly the statement that for nonnegative integrands the two iterated integrals agree – proved by the monotone-class machinery and MCT, with no envelope – after which Fubini's theorem handles signed integrands by the dominated upgrade, splitting into positive and negative parts controlled by an integrable bound. The same architecture returns in section 1.6: the completeness of L^p (Riesz–Fischer) is proved by first extracting a *monotone* control on a rapidly convergent subsequence (an increasing sum of norms, handled by MCT) and then passing the limit through with a dominating function (DCT). The density of smooth compactly supported functions C_c^∞ in L^p, also established there, leans on corollary 1.24 to differentiate a mollified integrand under the integral sign. And the bounded strong law that powers the empirical-measure theorem of section 1.7 is the same DCT, specialized to the bounded regime flagged in the heuristic above. We hand the next section a working set of interchange permits and the monotone-control-then-dominated-passage pattern that will organize its proofs.

1.5 Product measures and the Fubini–Tonelli theorem

The previous section built the single-variable integral and equipped it with the three permits – monotone, Fatou, dominated – for moving a limit through it, and it named the recurring rhythm of the subject: *monotone control, then dominated passage.* Every object we have integrated so far, though, has lived over a single space and been written against a single variable. The book is full of objects that do not. An expectation that factors over independent sources – the state of an agent and the Brownian noise driving it, say – is naturally an integral over a *pair* of variables, one for each source; and the graphon coupling that organizes Parts III–IV is the double integral of a kernel $W(x, y)$ against two copies of the population at once. To compute either we must integrate over two variables in turn, and we must know that the answer does not depend on which variable we integrate first – that the iterated integrals agree, and agree with the single integral over the product. That is the content of the Fubini–Tonelli theorem, and the business of this section is to build the product measure it lives on and then prove it. The section generalizes the one-variable integral to two variables exactly as far as those two applications demand and no further.

The construction reuses, rather than reinvents, the two engines already forged in this chapter. The monotone convergence theorem from section 1.4 is what lets us pass from indicators to general nonnegative integrands, in the same "monotone control" pattern just named; and the π–λ uniqueness machinery from section 1.2.3 – forged there precisely so that we would not have to reprove it here – is what pins the product measure down from its values on rectangles and, in one decisive lemma, certifies a measurability we could not otherwise reach. This is the third and last time in the chapter that the Dynkin engine is loaded, and it is the place the brief promised it would be indispensable.

The product space and its sections. Let $(\Omega_1, \mathcal{F}_1, \mu_1)$ and $(\Omega_2, \mathcal{F}_2, \mu_2)$ be σ-finite measure spaces. We want to measure subsets of the Cartesian product $\Omega_1 \times \Omega_2$, and the sets whose size is beyond dispute are the *measurable rectangles* $A_1 \times A_2$ with $A_1 \in \mathcal{F}_1$ and $A_2 \in \mathcal{F}_2$: a rectangle ought to have area $\mu_1(A_1)\, \mu_2(A_2)$, length times width, just as in elementary geometry. But the rectangles do not themselves form a σ-algebra – the complement of a rectangle is an L-shaped region, not a rectangle – so we take the smallest σ-algebra that contains them. The *product σ-algebra* $\mathcal{F}_1 \otimes \mathcal{F}_2$ on $\Omega_1 \times \Omega_2$ is $\sigma(\{A_1 \times A_2\})$, generated by the measurable rectangles in the sense of remark 1.3. It is the smallest family of subsets of the product that contains every rectangle and is closed under the countable operations; equivalently, on $\mathbb{R}^d \times \mathbb{R}^{d'}$ one checks (by the now-familiar "each family lies in the σ-algebra of the other" argument of definition 1.4) that it coincides with the Borel σ-algebra $\mathcal{B}(\mathbb{R}^{d+d'})$ of the product, so nothing exotic is being introduced.

The one piece of notation the whole section turns on is the *section*. For a set $E \subseteq \Omega_1 \times \Omega_2$ and a fixed first coordinate $\omega_1 \in \Omega_1$, the ω_1-*section* of E is

$$E_{\omega_1} \;=\; \{\omega_2 \in \Omega_2 :\; (\omega_1, \omega_2) \in E\} \;\subseteq\; \Omega_2,$$

the slice of E sitting above ω_1, viewed as a subset of the second factor alone. Geometrically, if one draws E in the plane $\Omega_1 \times \Omega_2$ and fixes a vertical line at horizontal position ω_1, then E_{ω_1} is the set of heights at which that line meets E. Sections are the device that turns a two-variable integral into a one-variable one: integrating a function over E "column by column" means, for each fixed ω_1, integrating over the section E_{ω_1} and then integrating the result over ω_1. For this two-step recipe even to be *writable*, two things must hold: each section must be a measurable subset of Ω_2 (so that $\mu_2(E_{\omega_1})$ makes sense), and the resulting function $\omega_1 \mapsto \mu_2(E_{\omega_1})$ – the "height of the column above ω_1" – must itself be $\mathcal{F}_1$-measurable (so that it can be integrated against μ_1). Neither is obvious for a general $E \in \mathcal{F}_1 \otimes \mathcal{F}_2$, which may be a wildly complicated set built from rectangles by countably many operations. The whole theory of product measures hinges on this one lemma, and it is the single place in the construction where a π–λ argument is genuinely indispensable; we isolate it and prove it in full.

Lemma 1.25 (Measurability of sections)**.** *Let μ_2 be σ-finite. For every $E \in \mathcal{F}_1 \otimes \mathcal{F}_2$ each section E_{ω_1} is in $\mathcal{F}_2$, and the map $\omega_1 \mapsto \mu_2(E_{\omega_1})$ is $\mathcal{F}_1$-measurable.*

Proof. Each section is measurable. This first claim costs nothing and uses no π–λ machinery; it is a pure closure argument. Let $\mathcal{S} = \{E \subseteq \Omega_1 \times \Omega_2 : \ E_{\omega_1} \in \mathcal{F}_2 \text{ for every } \omega_1 \in \Omega_1\}$ be the family of sets all of whose sections are measurable. It contains every rectangle, because the ω_1-section of $A_1 \times A_2$ is simply A_2 when $\omega_1 \in A_1$ and $\emptyset$ otherwise – in either case a member of $\mathcal{F}_2$. And it is a σ-algebra, because sectioning commutes with all the set operations: taking the section at a fixed ω_1 is the preimage under the inclusion $\omega_2 \mapsto (\omega_1, \omega_2)$, so $(E^c)_{\omega_1} = (E_{\omega_1})^c$ and $\left(\bigcup_n E^{(n)}\right)_{\omega_1} = \bigcup_n (E^{(n)})_{\omega_1}$, whence membership in $\mathcal{S}$ is preserved under complements and countable unions, and $\Omega_1 \times \Omega_2 \in \mathcal{S}$ trivially. Thus $\mathcal{S}$ is a σ-algebra containing the rectangles, so it contains the σ-algebra they generate, $\mathcal{F}_1 \otimes \mathcal{F}_2 \subseteq \mathcal{S}$. Every $E \in \mathcal{F}_1 \otimes \mathcal{F}_2$ therefore has all sections in $\mathcal{F}_2$, and in particular $\mu_2(E_{\omega_1})$ is a well-defined number in $[0, \infty]$ for each ω_1.

The column function is measurable: the finite case. The second claim – that $\omega_1 \mapsto \mu_2(E_{\omega_1})$ is $\mathcal{F}_1$-measurable – is the substance, and here a bare closure argument no longer suffices, because measurability of this function is *not* preserved under complements without some finiteness to license a subtraction. This is exactly the situation the π–λ theorem was built for: the property we want is stable under the weaker λ-system operations but not under all σ-algebra operations. Assume first that μ_2 is *finite*, $\mu_2(\Omega_2) < \infty$, and collect the good sets,

$$\mathcal{D} = \{E \in \mathcal{F}_1 \otimes \mathcal{F}_2 : \ \omega_1 \mapsto \mu_2(E_{\omega_1}) \text{ is } \mathcal{F}_1\text{-measurable}\}.$$

The strategy is the standard one of section 1.2.3: exhibit a π-system inside $\mathcal{D}$ that generates the whole σ-algebra, show $\mathcal{D}$ is a λ-system, and let Dynkin's theorem do the rest.

The generating π-system is the rectangles $\mathcal{P} = \{A_1 \times A_2\}$, which form a π-system because the intersection of two rectangles is a rectangle, $(A_1 \times A_2) \cap (A_1' \times A_2') = (A_1 \cap A_1') \times (A_2 \cap A_2')$, and which generate $\mathcal{F}_1 \otimes \mathcal{F}_2$ by definition. They lie in $\mathcal{D}$: for $E = A_1 \times A_2$ the section computation above gives $E_{\omega_1} = A_2$ on A_1 and $\emptyset$ off it, so

$$\mu_2(E_{\omega_1}) \ = \ \mathbf{1}_{A_1}(\omega_1)\, \mu_2(A_2),$$

which is $\mu_2(A_2)$ times the indicator of a measurable set, hence an $\mathcal{F}_1$-measurable function of ω_1. So $\mathcal{P} \subseteq \mathcal{D}$.

Now verify that $\mathcal{D}$ is a λ-system in the sense of definition 1.8, and notice as we go that this is precisely where the finiteness of μ_2 is spent. (i) $\Omega_1 \times \Omega_2 \in \mathcal{D}$: its section is all of Ω_2, so $\mu_2(E_{\omega_1}) \equiv \mu_2(\Omega_2)$ is a (finite) constant, trivially measurable. (ii) Closure under proper differences: if $E \subseteq F$ both lie in $\mathcal{D}$, then $E_{\omega_1} \subseteq F_{\omega_1}$ for every ω_1, and the section of the difference is the difference of the sections, $(F \setminus E)_{\omega_1} = F_{\omega_1} \setminus E_{\omega_1}$, so that

$$\mu_2((F \setminus E)_{\omega_1}) \ = \ \mu_2(F_{\omega_1}) - \mu_2(E_{\omega_1}).$$

This is a difference of two measurable functions of ω_1, hence measurable – but the *subtraction itself is only meaningful because μ_2 is finite*: with $\mu_2(\Omega_2) < \infty$ every term $\mu_2(E_{\omega_1}) \le \mu_2(\Omega_2)$ is a finite real number, and $\mu_2(F_{\omega_1}) - \mu_2(E_{\omega_1})$ is an honest difference of reals rather than the indeterminate $\infty - \infty$. Strip away finiteness and this clause collapses; it is the load-bearing place. (iii) Closure under increasing unions: if $E_n \uparrow E$ in $\mathcal{D}$, then sectioning preserves the monotone union, $(E_n)_{\omega_1} \uparrow E_{\omega_1}$, and continuity from below of μ_2 (proposition 1.6(iii)) gives

$$\mu_2(E_{\omega_1}) \;=\; \lim_{n\to\infty} \mu_2\big((E_n)_{\omega_1}\big) \qquad \text{for every } \omega_1,$$

exhibiting $\omega_1 \mapsto \mu_2(E_{\omega_1})$ as the pointwise limit of the measurable functions $\omega_1 \mapsto \mu_2((E_n)_{\omega_1})$, hence measurable by proposition 1.13. So all three λ-system clauses hold. By Dynkin's theorem (theorem 1.9), the λ-system $\mathcal{D}$ contains the σ-algebra generated by the π-system $\mathcal{P}$, that is, $\mathcal{D} \supseteq \mathcal{F}_1 \otimes \mathcal{F}_2$; and since $\mathcal{D} \subseteq \mathcal{F}_1 \otimes \mathcal{F}_2$ by definition, $\mathcal{D} = \mathcal{F}_1 \otimes \mathcal{F}_2$. Every E in the product σ-algebra has measurable column function. This is the indispensable π–λ argument the section was built around.

Removing finiteness: the σ-finite extension. It remains to drop "μ_2 finite" to the standing hypothesis "μ_2 σ-finite," and this is a routine exhaustion. Write $\Omega_2 = \bigcup_m B_m$ with $B_m \uparrow \Omega_2$ and each $\mu_2(B_m) < \infty$ – possible exactly because μ_2 is σ-finite – and define the finite measures $\mu_2^{(m)}(\cdot) = \mu_2(\cdot \cap B_m)$. The finite case just proved, applied to each $\mu_2^{(m)}$, shows $\omega_1 \mapsto \mu_2^{(m)}(E_{\omega_1}) = \mu_2(E_{\omega_1} \cap B_m)$ is measurable for every $E \in \mathcal{F}_1 \otimes \mathcal{F}_2$ and every m. As $B_m \uparrow \Omega_2$ we have $E_{\omega_1} \cap B_m \uparrow E_{\omega_1}$, so continuity from below gives $\mu_2^{(m)}(E_{\omega_1}) \uparrow \mu_2(E_{\omega_1})$ pointwise in ω_1; the limit of measurable functions is measurable (proposition 1.13), so $\omega_1 \mapsto \mu_2(E_{\omega_1})$ is measurable. This is again the monotone-passage pattern of section 1.4, now run over the exhausting sets rather than over an integrand. □

With the lemma in hand the product measure builds itself: the formula that *should* define the area of E – integrate the column heights – is now a legal expression, and the only work left is to check it is a measure and that it is the only one with the right values on rectangles. That uniqueness is again the Dynkin engine, invoked through the corollary corollary 1.10 that we extracted in section 1.2.3 for exactly this purpose.

Theorem 1.26 (Product measure)**.** *There is a unique σ-finite measure $\mu_1 \otimes \mu_2$ on $(\Omega_1 \times \Omega_2, \mathcal{F}_1 \otimes \mathcal{F}_2)$ with $(\mu_1 \otimes \mu_2)(A_1 \times A_2) = \mu_1(A_1)\, \mu_2(A_2)$ for all $A_1 \in \mathcal{F}_1, A_2 \in \mathcal{F}_2$.*

Proof. Existence via the section-integral formula. Lemma 1.25 guarantees that for each $E \in \mathcal{F}_1 \otimes \mathcal{F}_2$ the column function $\omega_1 \mapsto \mu_2(E_{\omega_1})$ is a nonnegative $\mathcal{F}_1$-measurable function, so its integral against μ_1 is a well-defined element of $[0, \infty]$, and we may *define*

$$(\mu_1 \otimes \mu_2)(E) \;:=\; \int_{\Omega_1} \mu_2(E_{\omega_1})\, \mu_1(\mathrm{d}\omega_1), \qquad E \in \mathcal{F}_1 \otimes \mathcal{F}_2.$$

This is the "area = integral of column heights" prescription made rigorous; the lemma is exactly what was needed to license it. We must check it is a measure. It vanishes on the empty set, since $\emptyset_{\omega_1} = \emptyset$ and $\mu_2(\emptyset) = 0$. For countable additivity, let $E^{(1)}, E^{(2)}, \ldots$ be pairwise disjoint members of $\mathcal{F}_1 \otimes \mathcal{F}_2$. For each fixed ω_1 the sections $E^{(j)}_{\omega_1}$ are pairwise disjoint subsets of Ω_2 (a point (ω_1, ω_2) lies in at most one $E^{(j)}$, so ω_2 lies in at most one section), and $\big(\bigsqcup_j E^{(j)}\big)_{\omega_1} = \bigsqcup_j E^{(j)}_{\omega_1}$, so the countable additivity of μ_2 itself gives, pointwise in ω_1,

$$\mu_2\Big(\big(\textstyle\bigsqcup_j E^{(j)}\big)_{\omega_1}\Big) \;=\; \textstyle\sum_{j\geq 1} \mu_2(E^{(j)}_{\omega_1}).$$

Integrating this identity against μ_1 and pulling the sum out through the integral is the one analytic step, and it is precisely a monotone-passage: the partial sums $\sum_{j\leq J} \mu_2(E^{(j)}_{\omega_1})$ are nonnegative and increase to the full sum as $J \to \infty$, so the monotone convergence theorem (theorem 1.20) permits the interchange,

$$\int_{\Omega_1} \sum_{j\geq 1} \mu_2(E^{(j)}_{\omega_1})\ \mathrm{d}\mu_1 \;=\; \sum_{j\geq 1} \int_{\Omega_1} \mu_2(E^{(j)}_{\omega_1})\ \mathrm{d}\mu_1 \;=\; \sum_{j\geq 1} (\mu_1 \otimes \mu_2)(E^{(j)}).$$

The left side is $(\mu_1 \otimes \mu_2)\big(\bigsqcup_j E^{(j)}\big)$, so the prescription is countably additive: it is a measure. On a rectangle $E = A_1 \times A_2$ we computed $\mu_2(E_{\omega_1}) = \mathbf{1}_{A_1}(\omega_1)\mu_2(A_2)$, whose μ_1-integral is $\mu_1(A_1)\mu_2(A_2)$, the required value. Finally σ-finiteness transfers from the factors: if $\Omega_1 = \bigcup_m \Omega_1^{(m)}$ and $\Omega_2 = \bigcup_m \Omega_2^{(m)}$ with finite-measure pieces, the products $\Omega_1^{(m)} \times \Omega_2^{(m)}$ increase to $\Omega_1 \times \Omega_2$ and each has product measure $\mu_1(\Omega_1^{(m)})\mu_2(\Omega_2^{(m)}) < \infty$, exhausting the product space by finite-mass sets.

Uniqueness via corollary 1.10. Suppose ν is any σ-finite measure on $\mathcal{F}_1 \otimes \mathcal{F}_2$ agreeing with $\mu_1 \otimes \mu_2$ on rectangles. The rectangles are a π-system generating $\mathcal{F}_1 \otimes \mathcal{F}_2$, and the exhausting products $\Omega_1^{(m)} \times \Omega_2^{(m)}$ are rectangles of finite measure increasing to the whole space. These are exactly the hypotheses of the uniqueness corollary corollary 1.10: two measures that agree on a generating π-system and on an exhausting sequence of finite-measure sets in it agree on the entire generated σ-algebra. Hence $\nu = \mu_1 \otimes \mu_2$ on $\mathcal{F}_1 \otimes \mathcal{F}_2$. This is the same propagation principle that fixed Lebesgue measure from the boxes; here it fixes the product from the rectangles. A fuller account is in [123, Ch. 6]. □

We could, by sectioning in the *other* variable, equally well have defined the area of E as $\int_{\Omega_2} \mu_1(E_{\omega_2})\, \mu_2(\mathrm{d}\omega_2)$ – integrating row heights rather than column heights. Both prescriptions assign $\mu_1(A_1)\mu_2(A_2)$ to a rectangle, so by the uniqueness just proved *they are the same measure*. Already at the level of sets, then, the order of integration does not matter; the Fubini–Tonelli theorem is the upgrade of this set-level fact to arbitrary integrands, and its proof is the systematic climb from indicators, where it is the statement just made, up to all integrable functions.

Theorem 1.27 (Tonelli and Fubini). *Let $(\Omega_1, \mathcal{F}_1, \mu_1)$ and $(\Omega_2, \mathcal{F}_2, \mu_2)$ be σ-finite and let $f\colon \Omega_1 \times \Omega_2 \to [-\infty, \infty]$ be $\mathcal{F}_1 \otimes \mathcal{F}_2$-measurable.*

1. (Tonelli.) *If $f \geq 0$, then $\omega_1 \mapsto \int f(\omega_1, \cdot)\ \mathrm{d}\mu_2$ and $\omega_2 \mapsto \int f(\cdot, \omega_2)\ \mathrm{d}\mu_1$ are measurable, and*

$$\int_{\Omega_1\times\Omega_2} f\ \mathrm{d}(\mu_1 \otimes \mu_2) = \int_{\Omega_1} \Big(\int_{\Omega_2} f\ \mathrm{d}\mu_2\Big)\,\mathrm{d}\mu_1 = \int_{\Omega_2} \Big(\int_{\Omega_1} f\ \mathrm{d}\mu_1\Big)\,\mathrm{d}\mu_2. \tag{1.9}$$

   The common value may be $+\infty$; all three integrals are always equal.

2. (Fubini.) *If f is integrable for the product measure – equivalently, by Tonelli applied to $|f|$, if* one *of the iterated integrals of $|f|$ is finite – then the inner integrals are finite a.e., are integrable, and (1.9) holds with all integrals finite.*

Proof. Tonelli, by the indicator $\to$ simple $\to$ nonnegative ladder. The proof is the standard three-rung ascent through the construction of the integral, each rung licensed by a tool already in hand. *Rung one, indicators.* Take $f = \mathbf{1}_E$ for $E \in \mathcal{F}_1 \otimes \mathcal{F}_2$. Then for each fixed ω_1 the inner integrand $f(\omega_1, \cdot) = \mathbf{1}_{E_{\omega_1}}$ is the indicator of the section, so $\int_{\Omega_2} f(\omega_1, \cdot)\,\mathrm{d}\mu_2 = \mu_2(E_{\omega_1})$, which lemma 1.25 certifies is a measurable function of ω_1; and by the very construction of the product measure (theorem 1.26),

$$\int_{\Omega_1} \Big(\int_{\Omega_2} \mathbf{1}_E \,\mathrm{d}\mu_2 \Big) \mathrm{d}\mu_1 = \int_{\Omega_1} \mu_2(E_{\omega_1})\,\mathrm{d}\mu_1 = (\mu_1 \otimes \mu_2)(E) = \int_{\Omega_1 \times \Omega_2} \mathbf{1}_E \,\mathrm{d}(\mu_1 \otimes \mu_2),$$

which is the first equality of (1.9). The second equality – the genuine order-swap – is the row-versus-column remark made just above the theorem: the iterated integral taken in the opposite order, $E \mapsto \int_{\Omega_2} \mu_1(E_{\omega_2})\,\mathrm{d}\mu_2$, defines a measure assigning $\mu_1(A_1)\mu_2(A_2)$ to every rectangle, so by the uniqueness corollary corollary 1.10 it *is* $\mu_1 \otimes \mu_2$, and the two iterated integrals agree. Thus (1.9) holds for indicators. *Rung two, simple functions.* A nonnegative simple function is a finite combination $\sum_k c_k \mathbf{1}_{E_k}$ with $c_k \geq 0$, and all three integrals in (1.9) are linear in f, so the identity extends from indicators to nonnegative simple functions by adding finitely many copies of the indicator case. *Rung three, general $f \geq 0$, by monotone passage.* For an arbitrary measurable $f \geq 0$ take simple functions $s_n \uparrow f$ pointwise – the canonical increasing approximation built in section 1.3. For each fixed ω_1 the slices increase, $s_n(\omega_1, \cdot) \uparrow f(\omega_1, \cdot)$, so the monotone convergence theorem (theorem 1.20) gives $\int_{\Omega_2} s_n(\omega_1, \cdot)\,\mathrm{d}\mu_2 \uparrow \int_{\Omega_2} f(\omega_1, \cdot)\,\mathrm{d}\mu_2$; the left sides are measurable in ω_1 by the simple case, so their increasing pointwise limit – the inner integral of f – is measurable in ω_1 by proposition 1.13. Applying the monotone convergence theorem a second time, now to the outer μ_1-integral and to the product integral, and using the simple-case identity at each finite stage, lets us pass $n \to \infty$ in all three integrals of (1.9) simultaneously and preserve the equalities. (Should the common value be $+\infty$, the identity reads $\infty = \infty = \infty$ and is still true: for nonnegative integrands there is no integrability hypothesis to impose, which is the whole convenience of Tonelli.) This proves part (i).

Fubini, by the signed splitting $f = f^+ - f^-$ guarded by absolute integrability. Now f may change sign. Decompose it into its nonnegative and nonpositive parts, $f^+ = \max(f, 0)$ and $f^- = \max(-f, 0)$, so that $f = f^+ - f^-$, $|f| = f^+ + f^-$, and both $f^\pm \geq 0$ are measurable. The hypothesis is that one iterated integral of $|f|$ is finite; applying Tonelli (part (i)) to the nonnegative function $|f|$, all three of its integrals are equal, so this single finiteness forces

$$\int_{\Omega_1 \times \Omega_2} |f| \,\mathrm{d}(\mu_1 \otimes \mu_2) = \int_{\Omega_1} \Big(\int_{\Omega_2} |f| \,\mathrm{d}\mu_2 \Big) \mathrm{d}\mu_1 < \infty,$$

i.e. f is product-integrable. Tonelli also applies to f^+ and f^- separately, giving (1.9) for each with possibly infinite value – and the point of absolute integrability is to rule that possibility out. Here is the step the skeleton left terse, spelled out. Since $f^\pm \leq |f|$ pointwise, monotonicity of the integral gives, at the level of inner integrals,

$$\int_{\Omega_2} f^\pm(\omega_1, \cdot)\,\mathrm{d}\mu_2 \;\leq\; \int_{\Omega_2} |f|(\omega_1, \cdot)\,\mathrm{d}\mu_2 \qquad \text{for every } \omega_1,$$

and integrating over ω_1,

$$\int_{\Omega_1} \Big(\int_{\Omega_2} f^\pm \,\mathrm{d}\mu_2 \Big) \mathrm{d}\mu_1 \;\leq\; \int_{\Omega_1} \Big(\int_{\Omega_2} |f| \,\mathrm{d}\mu_2 \Big) \mathrm{d}\mu_1 < \infty.$$

So the outer integral of the nonnegative measurable function $\omega_1 \mapsto \int_{\Omega_2} f^{\pm}(\omega_1, \cdot)\, \mathrm{d}\mu_2$ is finite. A nonnegative measurable function with finite integral is finite almost everywhere – for if it were equal to $+\infty$ on a set of positive measure, that set alone would already force the integral to be $+\infty$. Hence for μ_1-almost every ω_1 *both* inner integrals $\int_{\Omega_2} f^{+}(\omega_1, \cdot)\, \mathrm{d}\mu_2$ and $\int_{\Omega_2} f^{-}(\omega_1, \cdot)\, \mathrm{d}\mu_2$ are finite real numbers, and only then is their difference – the inner integral of f itself, $\int_{\Omega_2} f(\omega_1, \cdot)\, \mathrm{d}\mu_2 = \int_{\Omega_2} f^{+}\, \mathrm{d}\mu_2 - \int_{\Omega_2} f^{-}\, \mathrm{d}\mu_2$ – a legitimate subtraction of two finite numbers rather than the indeterminate $\infty - \infty$. *This is what absolute integrability buys: it makes both columns finite a.e., so the difference defining the signed inner integral is well-posed.* Subtracting the two finite Tonelli identities for f^+ and f^- – each a true instance of (1.9) with all integrals finite – term by term now yields (1.9) for f, with every integral finite. Running the identical argument with the roles of the two factors exchanged gives the other iterated integral the same value, so all three agree. A fuller account is in [123, Ch. 6]. ☐

The two halves of the theorem divide the labor cleanly, and it is worth saying exactly how, for this is the rule one applies in practice. Tonelli is the workhorse for *nonnegative* integrands: it asks nothing beyond σ-finiteness of the two spaces and lets one swap the order of integration freely, with the understanding that the common value may be $+\infty$. Fubini handles *signed* (or complex) integrands but exacts a price – absolute integrability – and the standard way to pay it is to run Tonelli on $|f|$ first: if either iterated integral of $|f|$ comes out finite, Fubini's swap is licensed; if both come out infinite, it may not be. The famous counterexample makes the division vivid. On $\mathbb{N} \times \mathbb{N}$ with counting measure, the array $a_{m,n}$ equal to $+1$ on the diagonal, -1 just below it, and 0 elsewhere has iterated sums $\sum_m \sum_n a_{m,n} = 0$ but $\sum_n \sum_m a_{m,n} = 1$ (or, in the continuous guise, an integrand on $(0,1)^2$ whose two iterated integrals are $+1$ and -1). The two orders disagree – but this is no contradiction with the theorem, because $\sum_{m,n} |a_{m,n}| = \infty$, so the absolute-integrability hypothesis of Fubini *fails*. The counterexample violates the hypothesis; it never violates the conclusion under that hypothesis. The lesson to carry into every later interchange is the discipline: *before swapping the order on a signed integrand, check that the integral of the absolute value is finite*, and one almost always checks it by a Tonelli computation on the modulus.

Remark 1.28 (Foreshadowing the graphon double integral)**.** The single most important double integral in this book has not appeared yet, but it is what the whole machinery of this section was built to make rigorous, and naming it now – while the theorem is fresh – means it will arrive in Part III as a settled object rather than a leap of faith. The kernel coupling at the center of Parts III–IV is the integral operator

$$(\mathbb{W}f)(x) \;=\; \int_0^1 W(x,y)\, f(y)\, \mathrm{d}y, \qquad x, y \in [0,1],$$

with $W\colon [0,1]^2 \to [0,1]$ the graphon kernel and x, y the *type* labels. We keep these type variables explicit and we do not conflate them with the state x of this chapter: as the chapter's opening notation watch stressed, $x, y \in [0,1]$ are exchangeable network labels carrying no metric meaning, put to work in chapter 2 (the Hilbert–Schmidt example there) and formally introduced as a graph limit in chapter 15, not the spatial state over which we have been integrating. Under the standing regularity hypothesis **(A-Reg-W)** – W symmetric, measurable, and bounded – the kernel lies in $L^2([0,1]^2, \mathrm{Leb})$, since a bounded measurable function on the finite-measure square $[0,1]^2$ is automatically square-integrable, $\iint |W|^2 \le \|W\|_\infty^2 < \infty$. Theorem 1.27 is then exactly what makes the energy double integral

$$\iint_{[0,1]^2} W(x,y)\, g(x)\, f(y)\; \mathrm{d}x\; \mathrm{d}y$$

well defined and *order-free*: for $f, g \in L^2([0,1])$ the product $W(x,y)g(x)f(y)$ is product-integrable on $[0,1]^2$ – one checks $\iint |W\, g\, f| < \infty$ by Tonelli on the modulus, bounding it by $\|W\|_\infty \|g\|_{L^1} \|f\|_{L^1}$ – so Fubini licenses computing it as either iterated integral, $\int g(x)(\mathbb{W}f)(x)\; \mathrm{d}x$ or $\int f(y)(\mathbb{W}g)(y)\; \mathrm{d}y$, the order-freedom that will become the self-adjointness of $\mathbb{W}$ for symmetric W. The same theorem, applied to $|W|^2$, is what shows in chapter 2 (proposition 2.24) that $\mathbb{W}$ is a Hilbert–Schmidt operator on $L^2([0,1])$ – the finiteness of the Hilbert–Schmidt norm $\|\mathbb{W}\|_{\mathrm{HS}}^2 = \iint |W|^2$ is a Tonelli statement about a nonnegative integrand – the property recorded in **(A-Reg-W)**; and its spectral payoff – eigenvector centrality, the spectral gap, and low-rank reductions – is the subject of chapter 18. We flag the double integral now so that, when it arrives, the right to write it as an iterated integral and to swap the order is a known quantity, owned by theorem 1.27, rather than a new act of faith.

This closes the integration theory proper. We began the chapter needing an integral stable under limits; we now have, in addition, an integral stable under the *reordering* of independent integrations, with two clean licenses – Tonelli for nonnegative integrands, Fubini under absolute integrability – and the Dynkin engine of section 1.2.3 reused one final time to forge them. The product structure built here is not a sidebar: it is what every later double integral in the book runs on – the independent-noise expectations of the stochastic chapters, the graphon energy just foreshadowed for chapters 2 to 18, and, more immediately, the Minkowski-integral and convolution arguments that the next section meets when it manufactures the L^p spaces. With the integral now complete – limits and products both under control – the remaining structural question is geometric: do the integrable functions, packaged as a normed space, form a *complete* space, a Banach space in which Cauchy sequences converge? That completeness is the property the whole measure-theoretic core has been driving toward, and assembling it from the integral and the three convergence theorems is the work of the next section.

1.6 The L^p spaces and completeness

The previous section completed the integration theory: we now own an integral stable under limits and stable under the reordering of independent integrations. The natural next move is the one a physicist makes without comment – to stop treating integrable functions one at a time and instead regard them as the *points of a space*, equipped with a notion of length (a norm) and hence of distance, so that one may speak of two functions being close, of a sequence of functions converging, and of a limit. This packaging is not cosmetic. Every existence proof in this book – a density solving a Fokker–Planck equation, a fixed point of a best-response map, a minimizer of an energy – is built the same way: one writes down a sequence of approximate objects, shows the sequence is *Cauchy* in some norm, and then needs to know that it actually *converges to a limit that is itself a member of the space*. That last guarantee is *completeness*, and it is the decisive structural fact about the spaces we now build. A normed space in which every Cauchy sequence converges is a *Banach space*; the rationals $\mathbb{Q}$ are the cautionary non-example – the sequence 3, 3.1, 3.14, 3.141, . . . is Cauchy yet escapes $\mathbb{Q}$, converging to nothing rational – and the real line $\mathbb{R}$ is the completion that repairs the hole. The L^p spaces are the function-space analogues of $\mathbb{R}$: complete by a limiting argument, and complete *because* of the three convergence theorems of section 1.4, which is exactly why they could not be assembled until now. Completeness is the analytic counterpart of the compactness arguments of chapters 2 and 3: where compactness extracts a convergent subsequence, completeness certifies that the limit it produces lands back inside the space. Fix a measure space $(\Omega, \mathcal{F}, \mu)$ throughout.

We build a whole one-parameter family at once, indexed by an exponent $1 \le p \le \infty$, because the book uses several values and it is wasteful to construct them separately. The exponent $p = 2$ is the Hilbert space of the spectral chapter; $p = 1$ is the home of densities and of the integral itself; $p = \infty$ houses bounded coefficients; and $p < 2$ will be forced on us by sparse graphon kernels in chapter 27. Intuitively the exponent dials *how a function is required to be small*: a large p penalizes tall spikes severely (a height-h spike contributes h^p, which explodes), a small p is lenient about height but unforgiving about spread. The norm is built by raising $|f|$ to the p-th power, integrating, and taking the p-th root – the final root restoring the homogeneity $\|\lambda f\|_p = |\lambda| \, \|f\|_p$ that any honest notion of length must possess.

Definition 1.29 (L^p spaces)**.** For $1 \le p < \infty$, let $\mathcal{L}^p(\mu)$ be the measurable $f \colon \Omega \to \mathbb{R}$ (or $\mathbb{R}^d$) with $\|f\|_p := \left(\int_\Omega |f|^p \, \mathrm{d}\mu\right)^{1/p} < \infty$. For $p = \infty$, let $\mathcal{L}^\infty(\mu)$ be the measurable f with $\|f\|_\infty := \operatorname{ess\,sup}_\Omega |f| < \infty$, the essential supremum being the smallest M with $|f| \le M$ μ-a.e. The space $L^p(\mu)$ is the quotient of $\mathcal{L}^p(\mu)$ by the relation "equal μ-a.e."; its elements are equivalence classes, and $\|\cdot\|_p$ is a genuine norm on it (the quotient is exactly what makes $\|f\|_p = 0 \implies f = 0$ true).

Two features of this definition need the motivation that a bare statement withholds. The first is the passage to *equivalence classes*, which is not fastidiousness but a forced repair. The candidate norm $\|f\|_p = \left(\int |f|^p\right)^{1/p}$ fails one axiom of a genuine norm on the raw function space $\mathcal{L}^p(\mu)$: a norm must satisfy $\|f\|_p = 0 \Rightarrow f = 0$, yet $\int |f|^p \, \mathrm{d}\mu = 0$ forces only $|f|^p = 0$ μ-almost everywhere, hence $f = 0$ *off a μ-null set* – not everywhere. A function supported on a single point carries Leb-integral zero without being the zero function; the indicator $\mathbf{1}_\mathbb{Q}$ has $\|\mathbf{1}_\mathbb{Q}\|_p = 0$ without vanishing anywhere on $\mathbb{Q}$. The integral simply cannot *see* a null set, so it cannot distinguish two functions that differ only there. The honest conclusion is that the integral was never measuring functions in the first place; it was measuring them *up to almost-everywhere equality*. We therefore declare $f \sim g$ when $f = g$ μ-a.e. – the same null-set quotient that ran through section 1.3, now promoted from a convenience to the very definition of the objects – and let $L^p(\mu)$ be the set of resulting equivalence classes. On classes $\|f\|_p = 0$ does mean $f = 0$ (the functions vanishing a.e. are precisely the zero class), so $\|\cdot\|_p$ becomes a genuine norm. In practice one writes f for both a function and its class and never suffers for it, because every operation we ever perform on an element of L^p – integration against a test function, the norm, the integral of any pointwise expression in f – is blind to null-set changes and so descends unambiguously to classes. The cost is one discipline, worth stating once: a statement about an element of L^p is legitimate only if it is invariant under modification on a null set. "The value $f(x_0)$" is meaningless for $f \in L^p$; "the integral $\int_A f$" is meaningful.

The second feature is the definition for $p = \infty$, where the recipe "integrate the p-th power and take a root" has no integral to take and is replaced by the right notion of "largest value," the *essential supremum*. The ordinary supremum is the wrong quantity, for the same null-set reason:

$\sup|\mathbf{1}_{\mathbb{Q}}| = 1$ even though $\mathbf{1}_{\mathbb{Q}}$ is a.e. zero, so the ordinary sup is *not* blind to null sets and would fail to descend to classes. The essential supremum $\operatorname{ess\,sup}|f| = \inf\{M : |f| \le M \ \mu\text{-a.e.}\}$ is the smallest ceiling $|f|$ respects except possibly on a negligible set; it ignores values attained only on a null set, giving $\operatorname{ess\,sup}|\mathbf{1}_{\mathbb{Q}}| = 0$, and on a finite-measure space it is exactly the limit of $\|f\|_p$ as $p \to \infty$ (whence the notation). With this reading $L^\infty(\mu)$ is the space of *essentially bounded* functions – the natural home of bounded coefficients and of the kernels $W \in L^\infty([0,1]^2)$ met in the previous section.

We have a candidate norm; what is not yet established is that it *is* one, and the single nonobvious axiom is the triangle inequality $\|f+g\|_p \le \|f\|_p + \|g\|_p$. For $p = 1$ it follows at once from $|f+g| \le |f| + |g|$ and monotonicity of the integral, and for $p = \infty$ from the same bound applied to essential suprema; but for intermediate p the p-th power entangles f and g, and the inequality – here named *Minkowski's* – is a genuine theorem. It rests on a companion, *Hölder's inequality*, the most-used estimate in analysis, which bounds the integral of a product by the product of norms taken in *conjugate* exponents $\frac{1}{p} + \frac{1}{q} = 1$. The conjugacy is not arbitrary bookkeeping: it is exactly the condition that makes the product of a "height in L^p" and a "height in L^q" have total degree one, so the estimate is homogeneous under rescaling. Both inequalities descend from a single elementary convexity fact, *Young's inequality*, and we prove the chain Young $\Rightarrow$ Hölder $\Rightarrow$ Minkowski.

Proposition 1.30 (Hölder and Minkowski inequalities)**.** *Let $1 \le p, q \le \infty$ with $\frac{1}{p} + \frac{1}{q} = 1$ (conjugate exponents). For measurable f, g,*

$$\|fg\|_1 \le \|f\|_p \|g\|_q \qquad \textit{(Hölder)}, \qquad\qquad \|f+g\|_p \le \|f\|_p + \|g\|_p \qquad \textit{(Minkowski)}.$$

In particular $\|\cdot\|_p$ satisfies the triangle inequality and $L^p(\mu)$ is a normed vector space.

Proof. Everything flows from *Young's inequality*: for $a, b \ge 0$ and conjugate exponents $1 < p, q < \infty$,

$$ab \ \le \ \frac{a^p}{p} + \frac{b^q}{q}.$$

If $a = 0$ or $b = 0$ the inequality is trivial; assume $a, b > 0$. It is then a one-line consequence of the *concavity of the logarithm*. Read $\frac{1}{p}$ and $\frac{1}{q}$ as two weights summing to 1 – this is precisely what conjugacy $\frac{1}{p} + \frac{1}{q} = 1$ supplies – and apply the defining inequality of a concave function (the function of a weighted average dominates the weighted average of the values) at the two points a^p and b^q:

$$\log\Big(\tfrac{1}{p}a^p + \tfrac{1}{q}b^q\Big) \ \ge \ \tfrac{1}{p}\log a^p + \tfrac{1}{q}\log b^q \ = \ \log a + \log b \ = \ \log(ab).$$

Since log is increasing, exponentiating preserves the inequality and gives $\frac{1}{p}a^p + \frac{1}{q}b^q \ge ab$, which is Young's. (Equality holds iff $a^p = b^q$, the degenerate case where the two evaluation points coincide; we shall not need it.)

Hölder. Take first $1 < p < \infty$. If $\|f\|_p = 0$ then $f = 0$ a.e. and both sides vanish; if $\|f\|_p = \infty$ the right side is infinite and there is nothing to prove; so assume $0 < \|f\|_p, \|g\|_q < \infty$. The trick is to *normalize away the scales*. Put

$$a(\omega) = \frac{|f(\omega)|}{\|f\|_p}, \qquad b(\omega) = \frac{|g(\omega)|}{\|g\|_q},$$

so that $\int a^p = \int |f|^p / \|f\|_p^p = 1$ and likewise $\int b^q = 1$; the normalization is chosen exactly so the right-hand side of Young will integrate to a clean constant. Applying Young pointwise and integrating,

$$\int a\, b\, \mathrm{d}\mu \;\le\; \int \Big(\frac{a^p}{p} + \frac{b^q}{q}\Big)\, \mathrm{d}\mu \;=\; \frac{1}{p}\int a^p + \frac{1}{q}\int b^q \;=\; \frac{1}{p} + \frac{1}{q} \;=\; 1.$$

Multiplying through by $\|f\|_p \|g\|_q$ and recognizing $\|f\|_p \|g\|_q \int ab = \int |f||g| = \|fg\|_1$ yields $\|fg\|_1 \le \|f\|_p \|g\|_q$. The endpoint cases $p \in \{1, \infty\}$ need no convexity at all: there $|fg| \le \|g\|_\infty |f|$ pointwise a.e. (the essential bound on g), and integrating gives $\|fg\|_1 \le \|f\|_1 \|g\|_\infty$.

Minkowski. The triangle inequality is now a short manoeuvre built on the algebraic identity $|f+g|^p = |f+g|\,|f+g|^{p-1}$. Bounding the first factor by $|f+g| \le |f| + |g|$ and integrating,

$$\|f+g\|_p^p \;=\; \int |f+g|^p \;\le\; \int |f|\,|f+g|^{p-1} \;+\; \int |g|\,|f+g|^{p-1}.$$

Each integral on the right is a product of two functions, ready for Hölder with exponent p on the first factor and the conjugate $q = p/(p-1)$ on the second. The point of choosing that exponent is that $(p-1)q = p$, so the q-norm of the second factor is

$$\Big(\int |f+g|^{(p-1)q}\Big)^{1/q} = \Big(\int |f+g|^p\Big)^{1/q} = \|f+g\|_p^{p/q},$$

and the two applications of Hölder combine to give

$$\|f+g\|_p^p \;\le\; \big(\, \|f\|_p + \|g\|_p \,\big)\; \|f+g\|_p^{p/q}.$$

If $\|f+g\|_p = 0$ the triangle inequality is trivial. Otherwise $\|f+g\|_p$ is finite and nonzero – finite because the pointwise convexity bound $|f+g|^p \le 2^{p-1}(|f|^p + |g|^p)$ keeps $f+g$ in L^p – so we may divide both sides by $\|f+g\|_p^{p/q}$. Using $p - \frac{p}{q} = p(1 - \frac{1}{q}) = p \cdot \frac{1}{p} = 1$, the left side becomes $\|f+g\|_p^{p-p/q} = \|f+g\|_p$, and Minkowski's inequality $\|f+g\|_p \le \|f\|_p + \|g\|_p$ drops out. With the triangle inequality established, $\|\cdot\|_p$ is a norm and $L^p(\mu)$ a normed vector space. A fuller development is in [31, Ch. 1]. $\square$

We now reach the structural heart of the section. A normed space is only as useful as its limits are trustworthy, and the guarantee we need is that the space has *no holes*: every sequence whose terms crowd arbitrarily close together – every Cauchy sequence – actually converges, and to a limit inside the space. This is the Riesz–Fischer theorem. It is the single fact licensing the standard existence strategy of the entire book: manufacture approximants, prove they are Cauchy, invoke completeness to produce the limit, identify it. Its proof is a showcase application of the convergence theorems just built, and it exhibits an architecture we will meet again and again, worth naming in advance: *monotone control via MCT, then dominated passage via DCT.* One first tames the sequence by passing to a rapidly-converging subsequence whose increments are summable; one packs those increments into a single dominating function G, finite because MCT converts their summability into an L^p bound; and one then runs DCT against G to upgrade the resulting almost-everywhere limit to a norm limit.

Theorem 1.31 (Riesz–Fischer: completeness of L^p)**.** *For every $1 \le p \le \infty$, $L^p(\mu)$ is a Banach space: every Cauchy sequence converges in $\|\cdot\|_p$ to an element of $L^p(\mu)$.*

Proof. We give the argument for $1 \le p < \infty$ first, as it is short, illuminating, and uses precisely the convergence theorems of section 1.4; the case $p = \infty$ is elementary and handled separately at the end. Let (f_n) be Cauchy in $L^p(\mu)$. A Cauchy sequence converges iff it has a convergent subsequence, so choose $n_1 < n_2 < \cdots$ with $\|f_{n_{k+1}} - f_{n_k}\|_p \le 2^{-k}$. Define the nonnegative measurable function

$$G \;=\; |f_{n_1}| + \sum_{k=1}^{\infty} |f_{n_{k+1}} - f_{n_k}|.$$

By Minkowski applied to partial sums and then MCT (theorem 1.20) on the increasing partial sums of G^p,

$$\|G\|_p \;\le\; \|f_{n_1}\|_p + \sum_{k=1}^{\infty} \|f_{n_{k+1}} - f_{n_k}\|_p \;\le\; \|f_{n_1}\|_p + \sum_{k=1}^{\infty} 2^{-k} \;<\; \infty.$$

Hence $G \in L^p(\mu)$, so $G < \infty$ μ-a.e.; on that full-measure set the telescoping series $f_{n_1} + \sum_k (f_{n_{k+1}} - f_{n_k})$ converges absolutely to a finite limit, which we call f. Thus $f_{n_k} \to f$ pointwise a.e., $|f| \le G$, and $|f - f_{n_k}|^p \le (2G)^p \in L^1(\mu)$; by DCT (theorem 1.23), $\|f - f_{n_k}\|_p \to 0$. Finally, a Cauchy sequence with a convergent subsequence converges to the same limit: given $\varepsilon > 0$, pick N with $\|f_n - f_m\|_p < \varepsilon$ for $m, n \ge N$ and k with $n_k \ge N$ and $\|f_{n_k} - f\|_p < \varepsilon$; then $\|f_n - f\|_p < 2\varepsilon$ for $n \ge N$.

For $p = \infty$ the argument is even shorter. Let (f_n) be Cauchy in $\|\cdot\|_\infty$. For each pair (m, n) the inequality $|f_n - f_m| \le \|f_n - f_m\|_\infty$ holds off a μ-null set $N_{m,n}$, and $|f_n| \le \|f_n\|_\infty$ off a null set N_n; let $N = \bigcup_{m,n} N_{m,n} \cup \bigcup_n N_n$, a countable union of null sets, hence null. Off N the sequence (f_n) is *uniformly* Cauchy – $\sup_{\omega \notin N} |f_n - f_m| \le \|f_n - f_m\|_\infty \to 0$ – so it converges uniformly there to a bounded limit f (set $f = 0$ on N). Then f is measurable, $\|f\|_\infty \le \sup_n \|f_n\|_\infty < \infty$, and $\|f_n - f\|_\infty \le \sup_{\omega \notin N} |f_n - f| \to 0$. Thus $L^\infty(\mu)$ is complete as well. □

The proof is worth dwelling on because its architecture recurs: build a dominating object (G) with MCT, extract an almost-everywhere limit, and upgrade to norm convergence with DCT. That pattern – monotone control, then dominated passage – is the analytic skeleton of nearly every limit taken in this book.

Two further facts about L^p structure the way it is used. First, the *density of nice functions*, which is what lets one prove an L^p estimate by checking it on smooth functions and passing to the limit. We prove it in full, as the book consumes it later (mollification and testing arguments, e.g. in chapters 8 and 22).

Proposition 1.32 (Density of simple, C_c, and C_c^∞ functions)**.** *Let $1 \le p < \infty$.*

1. *Integrable simple functions are dense in $L^p(\mu)$ for every measure space $(\Omega, \mathcal{F}, \mu)$.*
2. *On $(\mathbb{R}^d, \mathcal{B}(\mathbb{R}^d), \mathrm{Leb})$ the compactly supported continuous functions $C_c(\mathbb{R}^d)$ are dense in L^p.*
3. *On $(\mathbb{R}^d, \mathcal{B}(\mathbb{R}^d), \mathrm{Leb})$ the smooth compactly supported functions $C_c^\infty(\mathbb{R}^d)$ are dense in L^p.*

Proof. (i) Let $f \in L^p(\mu)$ and split $f = f^+ - f^-$. For the canonical simple sequences $s_n \uparrow f^+$ and $t_n \uparrow f^-$ of (1.5), each s_n, t_n is dominated by $|f| \in L^p$, hence integrable simple, and $|f - (s_n - t_n)|^p \to 0$

pointwise with $|f-(s_n-t_n)|^p \le (2|f|)^p \in L^1(\mu)$; dominated convergence (theorem 1.23) gives $\|f-(s_n-t_n)\|_p \to 0$.

(ii) By (i) it suffices to approximate a single indicator $\mathbf{1}_A$, with A Borel and $\mathrm{Leb}(A)<\infty$, by a C_c function in L^p. By the very definition of the outer measure used to build Leb (theorem 1.11), given $\varepsilon>0$ there are boxes Q_k with $A \subseteq \bigcup_k Q_k$ and $\sum_k \mathrm{vol}(Q_k) \le \mathrm{Leb}(A)+\varepsilon$; choosing M with $\sum_{k>M}\mathrm{vol}(Q_k)<\varepsilon$ and setting $U=\bigcup_{k\le M} Q_k$, a bounded finite union of boxes, we get $\mathrm{Leb}(A\setminus U) \le \sum_{k>M}\mathrm{vol}(Q_k)<\varepsilon$ and $\mathrm{Leb}(U\setminus A) \le \sum_k \mathrm{vol}(Q_k)-\mathrm{Leb}(A) \le \varepsilon$, so $\|\mathbf{1}_A-\mathbf{1}_U\|_p^p=\mathrm{Leb}(A\triangle U)\le 2\varepsilon$. It remains to approximate $\mathbf{1}_U$. For a single box $Q=\prod_j (a_j,b_j]$ and $\eta>0$ let $\varphi_{Q,\eta}\in C_c(\mathbb{R}^d)$ be the product of one-dimensional continuous trapezoids that equal 1 on $[a_j,b_j]$, drop linearly to 0 over a collar of width η, and vanish outside $[a_j-\eta,b_j+\eta]$; then $0\le\varphi_{Q,\eta}\le 1$, $\varphi_{Q,\eta}=1$ on Q, and $\varphi_{Q,\eta}\ne\mathbf{1}_Q$ only on a collar of Lebesgue measure $O(\eta)$, so $\|\mathbf{1}_Q-\varphi_{Q,\eta}\|_p^p=O(\eta)$. Taking $\varphi=\max_{k\le M}\varphi_{Q_k,\eta}\in C_c(\mathbb{R}^d)$ and η small makes $\|\mathbf{1}_U-\varphi\|_p$ as small as desired (the maximum of finitely many continuous functions is continuous, and $\mathbf{1}_U=\max_k \mathbf{1}_{Q_k}$). Combining the two estimates gives a C_c function within $3\varepsilon^{1/p}$ of $\mathbf{1}_A$ in L^p, as required.

(iii) By (ii) it suffices to approximate a fixed $g\in C_c(\mathbb{R}^d)$ by C_c^∞ functions in L^p. Fix the standard *mollifier*: the function $\rho(x)=c\exp\big(-1/(1-|x|^2)\big)$ for $|x|<1$ and $\rho(x)=0$ for $|x|\ge 1$ is smooth, nonnegative, and supported in the unit ball; choose c so that $\int_{\mathbb{R}^d}\rho=1$, and set $\rho_\varepsilon(x)=\varepsilon^{-d}\rho(x/\varepsilon)$, so $\int\rho_\varepsilon=1$ and $\operatorname{supp}\rho_\varepsilon\subseteq\overline{B_\varepsilon}$. Define the convolution

$$(g*\rho_\varepsilon)(x)=\int_{\mathbb{R}^d} g(x-y)\,\rho_\varepsilon(y)\;\mathrm{d}y.$$

Differentiation under the integral sign (corollary 1.24, with dominating function supported in a fixed compact set since g and all x-derivatives of ρ_ε are bounded and compactly supported) shows $g*\rho_\varepsilon\in C^\infty$, and $\operatorname{supp}(g*\rho_\varepsilon)\subseteq\operatorname{supp}g+\overline{B_\varepsilon}$ is compact, so $g*\rho_\varepsilon\in C_c^\infty(\mathbb{R}^d)$. Finally, since $\int\rho_\varepsilon=1$,

$$(g*\rho_\varepsilon)(x)-g(x)=\int_{\mathbb{R}^d}\big(g(x-y)-g(x)\big)\rho_\varepsilon(y)\;\mathrm{d}y,$$

and g, being continuous with compact support, is uniformly continuous, so $\sup_x|g(x-y)-g(x)|\le\omega_g(|y|)$ with the modulus $\omega_g(\delta)\to 0$ as $\delta\to 0$; hence $\|g*\rho_\varepsilon-g\|_\infty\le\omega_g(\varepsilon)\to 0$. As all the functions $g*\rho_\varepsilon$ are supported in the fixed compact set $K=\operatorname{supp}g+\overline{B_1}$ for $\varepsilon\le 1$, $\|g*\rho_\varepsilon-g\|_p\le\mathrm{Leb}(K)^{1/p}\,\|g*\rho_\varepsilon-g\|_\infty\to 0$. This proves $C_c^\infty(\mathbb{R}^d)$ is dense. □

The density statement is one place corollary 1.24 (differentiation under the integral) and the box-cover construction of Lebesgue measure earn their keep; a comparison treatment is in [31, Ch. 4]. Second, the case $p=2$ is special: $\|f\|_2^2=\int|f|^2\;\mathrm{d}\mu$ comes from the inner product $\langle f,g\rangle=\int f\,\overline{g}\;\mathrm{d}\mu$, so $L^2(\mu)$ is a *Hilbert* space. The geometry this buys – orthogonal projection, self-adjoint operators, the spectral theorem – is developed in chapter 2, which is also the setting in which the graphon operator $\mathbb{W}$ is constructed and shown to be Hilbert–Schmidt (proposition 2.24); its spectral consequences are taken up in chapter 18. The home of unbounded, sparse kernels is instead L^p for $p<2$, treated in chapter 27.

1.7 The empirical measure and its continuum limit

With the last of the toolbox in place – the complete function spaces of the previous section join the measures, the integral, and the three interchange permits assembled before them – every part the chapter set out to build is now in hand, and the empirical-measure theorem announced in the opening is their assembly. Drawing on the core of that toolbox – measures to house the spikes and their limit, the bridge identity (1.8), and the continuity-from-above that keeps mass from leaking to infinity – we can at last make rigorous the passage from a finite population to a continuum. The result is the prototype every later convergence theorem refines: McKean–Vlasov propagation of chaos (chapter 7), convergence of N-player Nash equilibria (chapter 13), and the finite-network-to-graphon limit (chapter 25) are all, at their core, statements that an empirical measure converges to a deterministic law.

1.7.1 Weak convergence, lightly

The empirical measure is a sum of spikes and its limit may be smooth, so convergence cannot be tested pointwise or in any L^p norm of densities. The correct notion tests against smooth observables.

Definition 1.33 (Weak convergence of probability measures)**.** Let $\nu_N, \nu \in \mathcal{P}(\mathbb{R}^d)$. We say ν_N *converges weakly* to ν, written $\nu_N \Rightarrow \nu$, if

$$\int_{\mathbb{R}^d} f \, \mathrm{d}\nu_N \longrightarrow \int_{\mathbb{R}^d} f \, \mathrm{d}\nu \qquad \text{for every bounded continuous } f \in C_b(\mathbb{R}^d).$$

This is the single most-used mode of convergence in the book. Its full theory – the equivalent formulations of the Portmanteau theorem, metrizability by the Lévy–Prokhorov distance, and Prokhorov's compactness criterion – is developed in chapter 3; the finer Wasserstein metric, which additionally controls second moments, is chapter 4. None of that machinery is needed here. The one structural input the empirical-measure argument requires – that weak convergence can be tested against a fixed *countable* family of observables rather than all of $C_b(\mathbb{R}^d)$ – we prove from scratch in the next lemma, by an elementary construction using only the continuity-from-above of measures (proposition 1.6). The chapter therefore borrows nothing forward.

Lemma 1.34 (A countable convergence-determining family)**.** *There exists a countable family $\mathcal{F} = \{f_1, f_2, \dots\} \subseteq C_b(\mathbb{R}^d)$ with the following property: if $\nu_N, \nu \in \mathcal{P}(\mathbb{R}^d)$ satisfy $\int f_k \, \mathrm{d}\nu_N \to \int f_k \, \mathrm{d}\nu$ for* every *k, then $\nu_N \Rightarrow \nu$.*

Proof. Write $C_0(\mathbb{R}^d)$ for the continuous functions g that vanish at infinity, i.e. with $|g(x)| \to 0$ as $|x| \to \infty$; such a g is automatically *uniformly* continuous (it is continuous, and outside a large ball it is uniformly small), and bounded. We proceed in three steps: build a countable family; show convergence against it forces convergence against all of $C_0(\mathbb{R}^d)$; then upgrade that to weak convergence using that the measures are probability measures.

Step 1: an explicit countable family $\mathcal{F} \subseteq C_0(\mathbb{R}^d)$. For $n \in \mathbb{N}$ consider the dyadic lattice $2^{-n}\mathbb{Z}^d$. To each assignment of rational values at the lattice points lying in a ball B_R of rational radius R

centred at a rational point, with the value 0 assigned to all lattice points outside B_R, associate the function on $\mathbb{R}^d$ obtained by *multilinear interpolation* inside each dyadic cube from its 2^d corner values. The result is continuous, compactly supported (it vanishes outside the bounded region where nonzero corner values were prescribed), hence lies in $C_0(\mathbb{R}^d)$. Let $\mathcal{F} = \{f_1, f_2, \dots\}$ be the collection of all such functions over all n, all admissible balls, and all rational corner assignments; it is a countable union of finite (countable) families, hence countable.

This family is sup-norm dense in $C_0(\mathbb{R}^d)$. Indeed, fix $g \in C_0(\mathbb{R}^d)$ and $\varepsilon > 0$. Choose R with $|g| < \varepsilon$ outside B_R, and using uniform continuity choose n so large that $|g(x) - g(x')| < \varepsilon$ whenever $|x - x'| \le 2^{-n}\sqrt{d}$ (the diameter of a dyadic cube). Pick $f \in \mathcal{F}$ that interpolates rational values within ε of g at the lattice points in B_{R+1} and vanishes at lattice points outside. Because a multilinear interpolant on a cube takes values between the minimum and maximum of its corner values, on each cube meeting B_R we get $|g - f| \le 3\varepsilon$ (the corner error ε, the interpolation oscillation ε, and the rounding ε), while outside B_R both $|g| < \varepsilon$ and $|f| \le \varepsilon$. Hence $\|g - f\|_\infty \le 3\varepsilon$, proving density.

Step 2: convergence against $\mathcal{F}$ implies convergence against $C_0(\mathbb{R}^d)$. Assume $\int f_k \,\mathrm{d}\nu_N \to \int f_k \,\mathrm{d}\nu$ for every k. Let $g \in C_0(\mathbb{R}^d)$ and $\varepsilon > 0$; choose $f \in \mathcal{F}$ with $\|g - f\|_\infty < \varepsilon$. Since all ν_N, ν are probability measures, $\left|\int g \,\mathrm{d}\rho - \int f \,\mathrm{d}\rho\right| \le \|g - f\|_\infty < \varepsilon$ for $\rho \in \{\nu_N, \nu\}$, so

$$\left|\int g \,\mathrm{d}\nu_N - \int g \,\mathrm{d}\nu\right| \;\le\; 2\varepsilon + \left|\int f \,\mathrm{d}\nu_N - \int f \,\mathrm{d}\nu\right|,$$

whence $\limsup_N \left|\int g \,\mathrm{d}\nu_N - \int g \,\mathrm{d}\nu\right| \le 2\varepsilon$. As ε was arbitrary, $\int g \,\mathrm{d}\nu_N \to \int g \,\mathrm{d}\nu$ for every $g \in C_0(\mathbb{R}^d)$.

Step 3: from C_0 to all of C_b. The family $\mathcal{F}$ contains, for every rational $R > 0$, a *cutoff* χ_R with $0 \le \chi_R \le 1$, $\chi_R \equiv 1$ on B_R, and $\operatorname{supp} \chi_R \subseteq B_{2R}$ (prescribe corner value 1 at lattice points in B_R and 0 at lattice points outside B_{2R}, with n large; multilinear interpolation of values in $[0, 1]$ stays in $[0, 1]$). The pointwise inequalities $\mathbf{1}_{B_{2R}^c} \le 1 - \chi_R \le \mathbf{1}_{B_R^c}$ hold by construction. Now fix $f \in C_b(\mathbb{R}^d)$; by homogeneity we may assume $\|f\|_\infty \le 1$. Split

$$\int f \,\mathrm{d}\nu_N - \int f \,\mathrm{d}\nu \;=\; \underbrace{\int f\chi_R \,\mathrm{d}(\nu_N - \nu)}_{\text{(I)}} \;+\; \underbrace{\int f(1 - \chi_R) \,\mathrm{d}\nu_N}_{\text{(II)}} \;-\; \underbrace{\int f(1 - \chi_R) \,\mathrm{d}\nu}_{\text{(III)}}.$$

The function $f\chi_R$ is continuous with support in B_{2R}, hence in $C_0(\mathbb{R}^d)$, so (I) $\to 0$ by Step 2. For (III), $|\text{(III)}| \le \int (1 - \chi_R) \,\mathrm{d}\nu \le \nu(B_R^c)$. For (II), $|\text{(II)}| \le \int (1 - \chi_R) \,\mathrm{d}\nu_N$, and since $1 - \chi_R \in C_0(\mathbb{R}^d)$ Step 2 gives $\int (1 - \chi_R) \,\mathrm{d}\nu_N \to \int (1 - \chi_R) \,\mathrm{d}\nu \le \nu(B_R^c)$. Therefore

$$\limsup_{N\to\infty} \left|\int f \,\mathrm{d}\nu_N - \int f \,\mathrm{d}\nu\right| \;\le\; 2\,\nu(B_R^c).$$

Because ν is a probability measure and $B_R^c \downarrow \emptyset$ as $R \uparrow \infty$, continuity from above (proposition 1.6, applicable since $\nu(\mathbb{R}^d) = 1 < \infty$) gives $\nu(B_R^c) \to 0$. Letting $R \to \infty$ through rational values forces $\int f \,\mathrm{d}\nu_N \to \int f \,\mathrm{d}\nu$. As $f \in C_b(\mathbb{R}^d)$ was arbitrary, $\nu_N \Rightarrow \nu$. □

Remark 1.35 (The role of total mass)**.** Step 3 is exactly where the hypothesis "probability measures" does its work. Convergence against $C_0(\mathbb{R}^d)$ alone is *vague* convergence, which does not see mass escaping to infinity – the sequence $\nu_N = \delta_{N\mathbf{e}_1}$ converges vaguely to the zero measure yet is not weakly convergent. What rules this out is that the total mass is pinned at 1 and the limit ν is itself a probability measure, so no mass can leak past every ball; the cutoff estimate turns that into the tightness bound $\nu(B_R^c) \to 0$. This is the elementary, finite-dimensional shadow of Prokhorov's theorem (chapter 3).

1.7.2 The strong law for bounded observables

The probabilistic engine of the theorem is the strong law of large numbers. We do not import it as a black box: for *bounded* summands – the only case the empirical-measure argument needs, since we test against bounded f – it has a short, fully self-contained proof via a fourth-moment estimate and the Borel–Cantelli lemma. This keeps section 1.7 independent of the probability machinery built later in chapter 3.

Lemma 1.36 (Borel–Cantelli, first lemma)**.** *Let (A_n) be events in a probability space with $\sum_n \mathbb{P}(A_n) < \infty$. Then $\mathbb{P}(\limsup_n A_n) = 0$; that is, almost surely only finitely many A_n occur.*

Proof. $\limsup_n A_n = \bigcap_N \bigcup_{n\geq N} A_n$, so for every N, $\mathbb{P}(\limsup_n A_n) \leq \mathbb{P}(\bigcup_{n\geq N} A_n) \leq \sum_{n\geq N} \mathbb{P}(A_n)$ by countable subadditivity (proposition 1.6). The right side is the tail of a convergent series, hence $\to 0$ as $N \to \infty$. $\square$

Lemma 1.37 (Strong law for bounded i.i.d. variables)**.** *Let $(Y_i)_{i\geq 1}$ be i.i.d. real random variables with $|Y_i| \leq M$ a.s. for some $M < \infty$, and write $m_Y = \mathbb{E}[Y_1]$. Then $\frac{1}{N}\sum_{i=1}^N Y_i \to m_Y$ almost surely.*

Proof. Replacing Y_i by $Z_i = Y_i - m_Y$ we may assume $\mathbb{E}[Y_i] = 0$; then $|Z_i| \leq 2M$, $\mathbb{E}[Z_i] = 0$, and the Z_i are i.i.d.. Let $S_N = \sum_{i=1}^N Z_i$. Expanding the fourth power and using independence and $\mathbb{E}[Z_i] = 0$, every term $\mathbb{E}[Z_iZ_jZ_kZ_l]$ vanishes unless the indices coincide in pairs; there are N terms of the form $\mathbb{E}[Z_i^4]$ and $3N(N-1)$ of the form $\mathbb{E}[Z_i^2]\,\mathbb{E}\Big[Z_j^2\Big]$, so

$$\mathbb{E}\Big[S_N^4\Big] \;=\; N\,\mathbb{E}\Big[Z_1^4\Big] + 3N(N-1)(\mathbb{E}\Big[Z_1^2\Big])^2 \;\leq\; C\,N^2, \qquad C := \mathbb{E}\Big[Z_1^4\Big] + 3(\mathbb{E}\Big[Z_1^2\Big])^2 \leq 4(2M)^4.$$

Fix $\varepsilon > 0$. We use *Markov's inequality*: for a nonnegative random variable Z and $a > 0$, $a\,\mathbf{1}_{\{Z\geq a\}} \leq Z$ pointwise, so taking expectations (monotonicity of the integral) gives $\mathbb{P}(Z \geq a) = \mathbb{E}\Big[\mathbf{1}_{\{Z\geq a\}}\Big] \leq \mathbb{E}[Z]/a$. Applied to $Z = S_N^4 \geq 0$ with $a = N^4\varepsilon^4$,

$$\mathbb{P}\Big(\Big|\tfrac{S_N}{N}\Big| \geq \varepsilon\Big) \;=\; \mathbb{P}(S_N^4 \geq N^4\varepsilon^4) \;\leq\; \frac{\mathbb{E}[S_N^4]}{N^4\varepsilon^4} \;\leq\; \frac{C}{N^2\varepsilon^4},$$

which is summable in N. By Borel–Cantelli (lemma 1.36), a.s. only finitely many of the events $\{|S_N/N| \geq \varepsilon\}$ occur, i.e. $\limsup_N |S_N/N| \leq \varepsilon$ a.s.Taking the intersection over $\varepsilon = 1/j$, $j \in \mathbb{N}$ – a countable intersection of full-measure events, hence of full measure – gives $S_N/N \to 0$ almost surely. $\square$

1.7.3 The worked computation

We now state and prove the chapter's self-contained model computation: the empirical measure of N independent draws converges, almost surely, to their common law. This is the cleanest "thermodynamic limit" statement in the book. It is not one of the two carried threads of appendix A (LQG and graphon-LQG), which begin only once optimization enters; it is the foundational prototype on which both, and every later propagation-of-chaos result, rest.

Worked computation 1.38 (Almost-sure weak limit of the empirical measure)**.** Let $m \in \mathcal{P}(\mathbb{R}^d)$ and let $X_1, X_2, \dots$ be i.i.d. random variables on a probability space $(\Omega, \mathcal{F}, \mathbb{P})$ with common law $\mathcal{L}(X_i) = m$. Form the random empirical measures

$$\mu^N \;=\; \frac{1}{N}\sum_{i=1}^{N} \delta_{X_i} \;\in\; \mathcal{P}(\mathbb{R}^d), \qquad N \geq 1.$$

Then, almost surely, $\mu^N \Rightarrow m$ as $N \to \infty$. Equivalently, there is an event $\Omega_0 \subseteq \Omega$ with $\mathbb{P}(\Omega_0) = 1$ such that for every $\omega \in \Omega_0$ and every $f \in C_b(\mathbb{R}^d)$,

$$\frac{1}{N}\sum_{i=1}^{N} f\big(X_i(\omega)\big) \;\longrightarrow\; \int_{\mathbb{R}^d} f \,\mathrm{d}m.$$

Proof. Let $\mathcal{F} = \{f_1, f_2, \dots\} \subseteq C_b(\mathbb{R}^d)$ be the countable convergence-determining family of lemma 1.34. Fix k. The random variables $Y_i := f_k(X_i)$ are i.i.d. (measurable functions of the i.i.d. X_i) and bounded, $|Y_i| \leq \|f_k\|_\infty < \infty$, with mean

$$\mathbb{E}[Y_i] \;=\; \mathbb{E}[f_k(X_i)] \;=\; \int_{\mathbb{R}^d} f_k \,\mathrm{d}\,\mathcal{L}(X_i) \;=\; \int_{\mathbb{R}^d} f_k \,\mathrm{d}m,$$

the middle equality being the transfer identity (1.3) for the pushforward $\mathcal{L}(X_i) = (X_i)_{\#}\mathbb{P}$ (lemma 1.15), applied to the bounded continuous $g = f_k$, and the last equality the hypothesis $\mathcal{L}(X_i) = m$. By the strong law for bounded variables (lemma 1.37), there is an event Ω_k with $\mathbb{P}(\Omega_k) = 1$ on which, recalling (1.8),

$$\int_{\mathbb{R}^d} f_k \,\mathrm{d}\mu^N \;=\; \frac{1}{N}\sum_{i=1}^{N} f_k(X_i) \;\longrightarrow\; \int_{\mathbb{R}^d} f_k \,\mathrm{d}m.$$

Set $\Omega_0 = \bigcap_{k\geq 1} \Omega_k$. As a countable intersection of full-measure events, $\mathbb{P}(\Omega_0) = 1$ (its complement is a countable union of null sets, hence null by subadditivity). On Ω_0 the convergence $\int f_k \,\mathrm{d}\mu^N \to \int f_k \,\mathrm{d}m$ holds *simultaneously for every* k, so the defining hypothesis of lemma 1.34 is met – with $\nu_N = \mu^N(\omega)$ and $\nu = m$ – and we conclude $\mu^N(\omega) \Rightarrow m$ for every $\omega \in \Omega_0$. This is the claim. □

Three remarks fix the meaning and the limitations of this computation.

Remark 1.39 (What is and is not claimed)**.** The order of quantifiers is the whole point. Worked computation 1.38 produces a *single* full-measure event Ω_0 on which weak convergence holds against *all* test functions at once – this is stronger than, and follows from, having a full-measure event for each fixed f separately, precisely because the countable family $\mathcal{F}$ determines weak convergence and a countable intersection of full-measure events is again full measure. Note also what is *not* asserted: the empirical measure μ^N has no density and never converges to m in any L^p sense of densities; convergence is weak, tested by integration, exactly as the heuristic of section 1.1 predicted.

Remark 1.40 (Generality and the role of moments)**.** The statement requires no moment assumption on m: it holds for every probability measure, because we only ever apply the strong law to the *bounded* variables $f_k(X_i)$. The companion quantitative theory – rates of convergence and convergence in the Wasserstein metric $\mathcal{W}_2$ – does require moments and is genuinely deeper; it is taken up in chapter 4. Two distinct scales must not be conflated here. The *metric* rate $\mathbb{E}\Big[\mathcal{W}_2(\mu^N, m)\Big]$ is dimension-dependent: for i.i.d. samples it scales like $N^{-1/d}$ in dimension $d > 4$ (with borderline logarithmic corrections at $d = 2, 4$), the Fournier–Guillin estimate developed in chapter 4 [69], and is *not* $O(N^{-1/2})$ in general. The $N^{-1/2}$ scale is the size of the Gaussian *fluctuations of a smooth linear statistic* $\int f \, \mathrm{d}\mu^N$ around its mean – the central limit theorem of chapter 3 – and it is this linear-statistic structure, not the full $\mathcal{W}_2$ distance, that drives the $O(N^{-1/2})$ propagation-of-chaos couplings of chapters 7 and 13. The present result is the qualitative backbone all of these quantitative refinements stand on.

Physics note

Worked computation 1.38 is the rigorous form of the thermodynamic-limit statement that a macroscopic system is described by a density profile rather than by the microstate. The empirical measure μ^N is the occupation measure of N identical, independently prepared agents; its almost-sure weak limit m is the deterministic single-particle distribution – the analog of the one-body density to which a noninteracting ensemble self-averages. The almost-sure character is the precise meaning of "self-averaging": a *single* realization of the large system already reproduces the ensemble law, with no need to average over disorder. The fluctuations the pointwise limit discards are of order $N^{-1/2}$ by the central limit theorem (chapter 3); they vanish in the limit, which is why the leading-order description is deterministic. Everything genuinely new in mean field *game* theory begins one layer up: there the law m is not given by a preparation postulate but is the self-consistent output of a Nash fixed point, so that the agents whose empirical measure converges to m are simultaneously *optimizing against* m. That strategic closure has no thermodynamic analogue and is the subject of Part II.

Rigor ledger

Proved.

- The basic apparatus: σ-algebras and measures with their continuity properties (definitions 1.2 and 1.5 and proposition 1.6); measurable functions, stable under pointwise limits (proposition 1.13); the Lebesgue integral and its identity $\int f \, \mathrm{d}\mu^N = \frac{1}{N}\sum_i f(X_i)$ (section 1.3, eq. (1.8)).

- The three interchange theorems – monotone convergence, Fatou, dominated convergence – with full proofs and the differentiation-under-the-integral corollary (theorems 1.20 and 1.23, lemma 1.22, and corollary 1.24).

- Dynkin's π–λ theorem and the resulting uniqueness of a measure from a generating π-system (theorem 1.9 and corollary 1.10); the section-measurability lemma (lemma 1.25); existence *and* uniqueness of the product measure (theorem 1.26) and uniqueness of

Lebesgue measure with its local-finiteness characterization (theorem 1.11), all proved in-book.

- Tonelli–Fubini for σ-finite spaces (theorem 1.27); additivity of the integral and Young's inequality (used to prove Hölder/Minkowski, proposition 1.30); completeness of L^p for all $1 \le p \le \infty$ – including the $p = \infty$ case – via the monotone-control/dominated-passage architecture (theorem 1.31); and density of simple, C_c, and C_c^∞ functions in L^p (proposition 1.32).

- The transfer identity for pushforward integrals (lemma 1.15), Markov's inequality (in the proof of lemma 1.37), and the existence of a countable convergence-determining family on $\mathbb{R}^d$ (lemma 1.34), all proved from scratch within the chapter's tools.

- The self-contained model computation: the almost-sure weak limit of the empirical measure of N i.i.d. draws (worked computation 1.38), together with its two elementary engines, Borel–Cantelli (lemma 1.36) and the bounded strong law (lemma 1.37), both proved from scratch.

Assumed.

- The *Carathéodory extension theorem* – the existence half of theorem 1.11 (extending the box premeasure to a countably additive measure on $\mathcal{B}(\mathbb{R}^d)$). This is the book's single accepted external measure-theoretic import; it is named explicitly at the point of use, and everything else is proved in-book. Reference: [123, Ch. 1].

Deferred.

- The full theory of weak convergence – Portmanteau, Lévy–Prokhorov metrizability, Prokhorov tightness/compactness – to chapter 3.

- Hilbert-space structure of L^2, duality, weak/weak-$*$ topologies, the spectral theorem, and the construction of the graphon operator with its Hilbert–Schmidt property under **(A-Reg-W)** (remark 1.28, proposition 2.24) to chapter 2; the spectral payoff of $\mathbb{W}$ (eigenvector centrality, spectral gap, low-rank reductions) to chapter 18.

- Quantitative empirical-measure convergence and Wasserstein rates to chapters 4 and 7.

Open.

- Nothing in this chapter is open: it is curated classical analysis. The genuinely open questions of the book begin once the limiting law m is determined by a strategic fixed point rather than by an i.i.d. preparation; see the open ledgers of chapters 11, 24 and 31.

Bibliographic notes

The measure-theoretic core of this chapter – σ-algebras, the construction of Lebesgue measure, the Lebesgue integral, the monotone, Fatou, and dominated convergence theorems, product measures and Fubini–Tonelli, and the L^p spaces with the Riesz–Fischer completeness theorem – follows the development in Stein and Shakarchi's *Real Analysis* [123, Ch. 1, 2, 6], the roadmap text for this chapter; the L^p inequalities, density statements, and the $p = \infty$ completeness are as in Brézis [31, Ch. 1, 4]. The Carathéodory extension and π–λ arguments underlying theorems 1.11 and 1.26 are standard and may be read in either source.

The empirical-measure theorem (worked computation 1.38) is the almost-sure weak law of large numbers for empirical measures, often attributed to Varadarajan; a textbook treatment, together with the convergence-determining-class machinery of lemma 1.34, is in Billingsley [23, Ch. 1]. The elementary fourth-moment route to the strong law (lemma 1.37) and the Borel–Cantelli lemma are classical; see Durrett [62, Ch. 1–2], which also contains the central limit theorem behind the $N^{-1/2}$ fluctuation scaling mentioned in the physics note. The reading of the empirical measure as the fundamental object of the mean-field limit, and the program of refining worked computation 1.38 into quantitative propagation-of-chaos statements, is developed probabilistically in Carmona and Delarue [40, Vol. I, Ch. 1] and is the direct ancestor of chapters 7 and 13. The role of L^2 kernels and Hilbert–Schmidt operators foreshadowed in remark 1.28 is the operator-theoretic side of the graphon formalism of Lovász [99], taken up in chapter 18. The Wasserstein geometry in which the limiting law m actually lives, and the quantitative form of empirical-measure convergence, is the subject of chapter 4 and of Villani [131].

Chapter 2

Functional Analysis for Fields and Operators

The previous chapter built measures and the Lebesgue spaces L^p as the rigorous home of densities and population profiles (chapter 1). Those spaces are, so far, only *sets of functions with an addition law*: we can add two densities and rescale one, but we cannot yet say how large a field is, how far apart two fields are, whether a sequence of fields is converging, or—most consequentially for what is to come—whether two fields point in the "same direction." This chapter supplies the missing structure, and it arrives in two flavors that the reader should hold apart from the outset. The first is *geometry*: a norm makes "size" and "distance" meaningful, and in the Hilbert case an inner product makes "angle," "orthogonality," and "projection" meaningful as well, so that a space of functions becomes a place where Euclidean reasoning is legal. The second is *operators*: linear maps that carry one field into another—the verbs to the nouns that geometry describes. Geometry tells us what the objects are and how they sit relative to one another; operators tell us what acts on them. Nearly every technical object in this chapter is one or the other, and the chapter as a whole is the deliberate assembly of a single toolbox out of these two kinds of part.

Almost every object we will eventually call by a more exotic name is, underneath, one of the structures assembled here, and it is worth naming the three that matter most before they arrive, so that the reader later meets them as old acquaintances rather than surprises. The graphon coupling $\mathbb{W}$ of appendix A.5—the kernel through which a continuum of agent types influence one another—will turn out to be nothing more exotic than a self-adjoint Hilbert–Schmidt integral operator, and that single identification is what later lets us diagonalize the interaction into the network's normal modes. The value function of an optimal control problem (chapter 6) will live not in a space of smooth functions but in a Sobolev space, precisely because the Hamilton–Jacobi–Bellman equation that governs it only ever differentiates it *weakly*, against test functions, so we must first build a space in which such a derivative is legal at all. And every existence theorem in the book—for a single Nash equilibrium (chapter 10), for a graphon equilibrium (chapter 24)—is, stripped to its core, a fixed-point theorem applied to a best-response map on one of these spaces: an equilibrium is a population behavior that reproduces itself under everyone's optimal response, and proving one exists is proving that such a self-reproducing point exists. Geometry, operators, fixed points: the chapter exists to put these three in the reader's hands.

We assume from chapter 1 the construction of $L^p(\Omega, \mathcal{F}, \mu)$ for a σ-finite measure space, their completeness (the Riesz–Fischer theorem theorem 1.31), the density of simple and of smooth functions, and the Fubini–Tonelli theorem (theorem 1.27); these are the load-bearing imports, and we will call on each by name at the moment it does work rather than stockpile them here. The *weak convergence of probability measures* enters this chapter only by name: its lightweight definition is already in hand from definition 1.33 (testing against bounded continuous functions, used there in the empirical-measure computation worked computation 1.38), and its full theory—the Portmanteau theorem, Lévy–Prokhorov metric, and Prokhorov's compactness theorem—is developed in chapter 3. We mention it now only to wall it off, because the weak and weak-$*$ *operator* topologies introduced in this chapter are its functional-analytic namesakes and must be kept deliberately distinct from it: this is the first appearance of a "three weak words" bookkeeping we make explicit in remark 2.15. Beyond that one borrowed definition, nothing in this chapter uses probability at all—everything here is L^2 geometry and the linear algebra of operators—so the reader may safely set randomness aside until chapter 3 takes it up again.

The plan is linear. Section 2.1 fixes Banach and Hilbert spaces and the inner-product geometry we exploit relentlessly. Section 2.2 introduces bounded operators, dual spaces, and adjoints. Section 2.3 introduces the weak and weak-$*$ topologies and the Banach–Alaoglu theorem—the abstract compactness that powers existence proofs. Section 2.4 treats compact and Hilbert–Schmidt operators, where the graphon first appears. Section 2.5 proves the spectral theorem for compact self-adjoint operators; this is staged deliberately, because in chapter 18 the graphon's spectrum becomes the network's "band structure." Section 2.6 develops Sobolev spaces to exactly the depth that PDE existence needs. Section 2.7 collects the three fixed-point theorems—Banach, Schauder, Kakutani—that are the engines of every existence proof to come.

Throughout, scalars are real unless a statement explicitly needs the complex field; we flag the distinction where the spectral theory makes it matter. We write $\|\cdot\|_X$ for the norm of a space X, dropping the subscript when context is unambiguous, and $\langle \cdot, \cdot \rangle_H$ for the inner product of a Hilbert space H.

2.1 Banach and Hilbert spaces

A field is a function, and chapter 1 has already handed us spaces of such functions, the Lebesgue spaces L^p. What those spaces still lack is the geometry that turns a vector space into a place where analysis can be carried out: a way to measure how big a function is, and through that a way to decide when a sequence of functions has settled down to a limit. This section installs exactly that, in two graded steps the reader should keep distinct. First we equip L^p with a *norm*, which supplies size and, with it, a notion of convergence; demanding that the resulting metric be *complete*—that every Cauchy sequence actually converges to a point still inside the space—promotes a normed space to a *Banach* space, and it is this completeness that licenses the move repeated throughout the book, building a desired object as the limit of an approximating sequence and then concluding that the limit is really there. Next, for the single exponent $p = 2$, we add a second and stronger structure, an *inner product*, which records not merely the length of a function but the angle between two of them, and brings with it orthogonality, projection, and a privileged basis. Completeness and inner-product geometry are the two ingredients being layered on, and the order is deliberate: completeness is the property *every* space we use must have, whereas the inner product is the luxury that *only* L^2 enjoys and around which, as we will see again and again, much of the book is engineered. We begin with the norm.

2.1.1 Normed and Banach spaces

Both capabilities the section preamble promised—a measure of how big a function is and, through it, a test for when a sequence of them has settled down to a limit—issue from a single piece of equipment, the norm: it assigns to each function one nonnegative number, its size, and a notion of size is automatically a notion of distance—two functions are close when their difference is small—and a notion of distance is automatically a notion of convergence. So the norm is the whole of the first capability and the seed of the second. We begin by writing down what we demand of it.

Definition 2.1 (Normed and Banach space)**.** A *normed vector space* is a real (or complex) vector space X equipped with a map $\|\cdot\| : X \to [0, \infty)$ such that, for all $x, y \in X$ and scalars λ,

1. $\|x\| = 0 \iff x = 0$ (positive definiteness),
2. $\|\lambda x\| = |\lambda| \, \|x\|$ (homogeneity),
3. $\|x + y\| \leq \|x\| + \|y\|$ (triangle inequality).

A normed space is a *Banach space* if it is complete: every Cauchy sequence converges to a limit in X.

None of the three axioms is decorative; each rules out a way the notion of "size" could fail to behave like the lengths and distances we reason with by reflex. Positive definiteness says that the only function of size zero is the function that is identically zero—without it "$\|x\| = 0$" would no longer mean "x has vanished," the implication on which every uniqueness argument secretly runs (to prove two solutions x, y coincide one proves $\|x - y\| = 0$, and that is worth nothing unless it forces $x = y$). It is exactly here that the passage from chapter 1 leaves a fingerprint: on L^p a function that is nonzero only on a set of measure zero must be declared equal to zero, for otherwise it would have $\int |f|^p \, \mathrm{d}\mu = 0$ yet $f \neq 0$ and axiom (1) would fail; this is why the elements of L^p are equivalence classes modulo null sets, not literal functions. Homogeneity says size scales the way length does—doubling a field doubles its size, and the sign of a scalar cannot change a magnitude—so that the norm is compatible with the linear structure rather than indifferent to it. The triangle inequality is the substantive one: it says detours do not shorten distances, $\|x + y\| \leq \|x\| + \|y\|$, and it is what makes the induced distance $d(x, y) = \|x - y\|$ an honest metric and, just as importantly, what makes the norm a *continuous* function of its argument, so that estimates can be chained. Nearly every inequality in this book is, after enough unwrapping, the triangle inequality applied to a shrewdly chosen decomposition $x = (x - x_n) + x_n$; without it "small errors accumulate controllably" would be false and analysis would have no purchase.

A norm thus delivers convergence for free: $x_n \to x$ means $\|x_n - x\| \to 0$. But it does *not*, by itself, deliver the one thing we most want from convergence—a guarantee that a sequence which is *trying* to converge actually has somewhere to converge to. A sequence is Cauchy when its terms get and stay arbitrarily close to one another, $\|x_n - x_m\| \to 0$, which is exactly the situation in which the terms behave as though they were homing in on a limit; completeness is the demand that in such a situation the limit genuinely exists *inside the space*. The rationals under the usual absolute value show how this can fail: the truncated decimals of $\sqrt{2}$ are Cauchy but escape to a point ($\sqrt{2}$ itself) that is not rational, so $\mathbb{Q}$ is incomplete. A Banach space is, by fiat, a normed space in which no such escape is possible.

This is not a technicality to be noted and forgotten. Completeness is the property that licenses the central move of the entire subject, the move executed in one form or another by every existence theorem in this book: *build the object you want as the limit of a sequence of approximations you can construct, and then invoke completeness to conclude that the limit is a genuine member of the space and hence is the object you were after.* The sequence is always something concrete and constructible; the limit is the thing whose existence was in doubt. Three later chapters cash this single principle out in three different currencies, and it is worth seeing in advance that they are the same coin. First, in the fixed-point arguments of section 2.7, an equilibrium is produced as the limit of the iterates $x_{n+1} = F(x_n)$ of a best-response map: the contraction property forces the iterates to be Cauchy, and completeness is precisely what turns "the iterates bunch up" into "the iterates converge to an actual fixed point," the equilibrium itself. Second, in the compactness arguments of section 2.3, a solution is produced as the limit of a subsequence extracted from a bounded family of approximate solutions; extracting the subsequence is one job, but knowing its limit lives in the space—and is therefore a candidate solution rather than a phantom—is completeness doing its work again. Third, in the Galerkin and Lax–Milgram constructions of section 2.6, the solution of a partial differential equation is assembled as the limit of its projections onto finite-dimensional subspaces, exact finite computations whose limit exists only because the ambient Sobolev space is complete. Iteration, extraction, projection: three procedures, one underlying guarantee. Completeness is what each of them spends at the decisive step, and it is the reason the whole book insists on working in Banach (and, better, Hilbert) spaces rather than in the bare vector spaces of chapter 1.

With the abstract demand in place, it pays to fix the handful of concrete spaces that will recur, so that the names below arrive later as familiar rooms rather than fresh definitions.

Example 2.2 (The working spaces)**.** The following Banach spaces recur.

1. $\mathbb{R}^d$ with any norm; all norms on a finite-dimensional space are equivalent and complete.

2. For a measure space $(\Omega, \mathcal{F}, \mu)$ and $1 \leq p < \infty$, the Lebesgue space $L^p(\Omega, \mu)$ with $\|f\|_{L^p} = \left(\int_\Omega |f|^p \, \mathrm{d}\mu\right)^{1/p}$, and $L^\infty(\Omega, \mu)$ with the essential-supremum norm. Completeness is the Riesz–Fischer theorem theorem 1.31. For the graphon we will overwhelmingly use $\Omega = [0, 1]$ with Lebesgue measure, written $L^p[0, 1]$, and the product $L^p([0, 1]^2)$.

3. For a compact metric space K, the space $C(K)$ of continuous functions with the uniform norm $\|f\|_\infty = \sup_{x\in K} |f(x)|$.

These three are worth walking through rather than merely listing, because each plays a distinct and recurring role. The finite-dimensional space $\mathbb{R}^d$ is the trivial case, but trivial in a way we will lean on: because all norms on it are equivalent and it is automatically complete, we never have to worry about *which* norm we put on the finite-dimensional state space of an agent, and the Galerkin method of section 2.6 will reduce an infinite-dimensional PDE to a sequence of problems posed on exactly such spaces, where existence is elementary linear algebra. The Lebesgue spaces L^p are the main characters: they are the home of the densities and population profiles built in chapter 1, their completeness is not free but is bought by the Riesz–Fischer theorem (theorem 1.31)—which is precisely the statement that an L^p-Cauchy sequence of functions converges to an L^p function—and the special instances $L^2[0,1]$ and $L^2([0,1]^2)$ will host, respectively, the fields the graphon operator acts on and the graphon kernel itself. Finally $C(K)$, the continuous functions on a compact set under the sup norm, is the space in which we will phrase uniform estimates: it is where the value functions live before we have learned to differentiate them weakly, and its sup-norm completeness is the familiar fact that a uniform limit of continuous functions is continuous. The reader should keep these three in view as the recurring settings; almost every later inequality is posed in one of them.

Of these working spaces, one is singled out for special treatment in the next subsection, and the reason is worth stating now because it organizes much of the book. The norm of L^p, for any p, faithfully measures the size of a function, and that is all a general Banach space ever provides: a length for each vector and a distance between each pair. What it does not provide is any sense of *direction*—no way to say that two fields are aligned, or opposed, or at right angles. For a single exponent, $p = 2$, the norm turns out to arise from a richer object that does record direction, and that single piece of extra structure is responsible for nearly every clean theorem in the chapters to come. That structure is the *inner product*, and the next subsection installs it—and with it the angle, the Pythagorean decomposition, and the projection onto preferred directions that the bare norm of L^p can never supply.

2.1.2 Inner products and Hilbert spaces

The previous subsection closed on a deliberate complaint, and this one answers it. The norm of L^p, for any exponent, faithfully reports the size of a function and the distance between two functions, and for $p \neq 2$ that is all it can ever do: it knows nothing of *angle*. There is no way to declare two fields orthogonal, no Pythagorean theorem to split a field into independent components whose sizes add in quadrature, and no operation that drops a field perpendicularly onto a subspace of preferred directions. These are not exotic luxuries; they are the everyday moves of Euclidean geometry, the ones that make linear algebra in $\mathbb{R}^d$ feel concrete, and a space that lacks them is a space in which one can measure but cannot resolve. What restores all three at once is a single richer object from which the norm descends—an *inner product*, recording not merely the length of a vector but the relative orientation of two of them. Exactly one Lebesgue exponent admits such an object: $p = 2$, where $\|f\|_{L^2}^2 = \int |f|^2$ is visibly a quadratic form and so can come from a symmetric pairing of f with itself. That single accident is why the entire book is engineered to live in L^2, and it is what makes the spectral theory of section 2.5 and the variational PDE theory of section 2.6 as clean as they are. We install the inner product now, record the one inequality it forces, and then extract from it the three structural theorems—projection, Riesz representation, Fourier expansion—that a general Banach space cannot supply at any price.

Definition 2.3 (Inner product, Hilbert space)**.** An *inner product* on a real vector space H is a map $\langle\cdot,\cdot\rangle\colon H \times H \to \mathbb{R}$ that is bilinear, symmetric ($\langle x, y\rangle = \langle y, x\rangle$), and positive definite ($\langle x, x\rangle > 0$ for $x \neq 0$). It induces the norm $\|x\| = \langle x, x\rangle^{1/2}$. A *Hilbert space* is an inner-product space complete in this norm. Over the complex field one requires instead $\langle x, y\rangle = \overline{\langle y, x\rangle}$ (Hermitian symmetry) and linearity in the first argument; then $\langle\cdot,\cdot\rangle$ is conjugate-linear in the second.

Notation watch

A physicist writes the inner product as the bra–ket $\langle\psi|\phi\rangle$, which is conjugate-linear in the *first* (bra) slot and linear in the second (ket). The mathematics convention used in this book—and in definition 2.3—is the opposite: $\langle\cdot,\cdot\rangle$ is linear in the *first* argument and conjugate-linear in the second. For the real Hilbert spaces that carry the entire graphon theory the distinction evaporates, since the inner product is then symmetric and bilinear and $\langle f, g\rangle = \int fg$. We flag the convention only because the complex spectral theorem (theorem 2.26) is occasionally invoked, and there the placement of the conjugate matters for which operator one calls self-adjoint.

Example 2.4 (L^2 as a Hilbert space)**.** $L^2(\Omega, \mu)$ is a Hilbert space with $\langle f, g\rangle = \int_\Omega f\,\overline{g}\,\mathrm{d}\mu$. On $[0, 1]$ this is $\langle f, g\rangle = \int_0^1 f(x)\,\overline{g(x)}\,\mathrm{d}x$. The Cauchy–Schwarz inequality $|\langle f, g\rangle| \le \|f\|\,\|g\|$ here is the statement that the correlation of two square-integrable fields is controlled by their energies; it is used so often it ceases to be visible.

Before extracting the deep theorems it is worth isolating the one algebraic identity that drives all of them, because it is the precise sense in which an inner-product norm is more rigid than a bare norm. Expanding $\|x \pm y\|^2 = \langle x \pm y, x \pm y\rangle = \|x\|^2 \pm 2\,\mathrm{Re}\langle x, y\rangle + \|y\|^2$ and adding the two signs cancels the cross term and leaves the *parallelogram law*

$$\|x + y\|^2 + \|x - y\|^2 = 2\,\|x\|^2 + 2\,\|y\|^2\,,$$

the statement that the squared diagonals of a parallelogram equal the sum of the squares of its four sides. No general Banach norm satisfies it—the L^p norm fails it for $p \neq 2$, which is the analytic fingerprint of "no angle"—and conversely a norm that does satisfy it comes from an inner product, recoverable by the polarization identity that subtracting the two signs produces, $4\,\mathrm{Re}\langle x, y\rangle = \|x + y\|^2 - \|x - y\|^2$. The parallelogram law is the engine of the projection theorem below; the Cauchy–Schwarz inequality of example 2.4, itself a one-line consequence of positive-definiteness applied to $x - \frac{\langle x,y\rangle}{\|y\|^2}y$, is the engine of almost everything else. With these two in hand, the inner product buys three structural theorems that no general Banach space enjoys. We state them because each is used directly later, and we prove them in full: each is short, and the proofs are exactly where the Hilbert geometry earns its keep. We follow [123, Ch. 4] and [31, Ch. 5] for attribution.

The first of the three is the one that makes a Hilbert space a place where optimization has guaranteed answers. We will repeatedly need to find, inside a set of admissible objects, the one closest to a given target: the conditional expectation of chapter 3 is the closest σ-algebra-measurable random variable to a given one in the L^2 sense; the finite-element and Galerkin solutions of section 2.6 are the best approximations in energy to a PDE solution from a finite-dimensional trial space; a best response in an equilibrium computation is the minimizer of a cost over an admissible set. In a general Banach space such a nearest point may fail to exist or fail to be unique. The next theorem says that in a Hilbert space, against a closed convex target, it always exists and is always unique, and it identifies the minimizer by a checkable inequality rather than by the unworkable infimum itself.

Theorem 2.5 (Projection onto a closed convex set)**.** *Let H be a Hilbert space and $C \subseteq H$ a nonempty closed convex set. For every $x \in H$ there is a unique point $P_C x \in C$ of minimal distance, $\|x - P_C x\| = \inf_{c\in C} \|x - c\|$, characterized by the variational inequality $\langle x - P_C x, c - P_C x\rangle \leq 0$ for all $c \in C$. When $C = M$ is a closed subspace, P_M is linear, $\|P_M\| \leq 1$, and $H = M \oplus M^\perp$ orthogonally, where $M^\perp = \{y : \langle y, m\rangle = 0 \ \forall m \in M\}$.*

Proof. Existence. Write $d = \inf_{c\in C} \|x - c\|$. By definition of the infimum we may pick a *minimizing sequence* $c_n \in C$ with $\|x - c_n\|^2 \to d^2$; the content of the theorem is that this sequence, chosen only to make the distances tend to the infimum, automatically converges. This is the place the parallelogram law does its work. Applying it to the two vectors $u = x - c_n$ and $v = x - c_m$, and noting $u - v = c_m - c_n$ while $u + v = 2x - (c_n + c_m) = 2\big(x - \frac{c_n+c_m}{2}\big)$, gives

$$\|c_n - c_m\|^2 = 2\|x - c_n\|^2 + 2\|x - c_m\|^2 - 4\Big\|x - \tfrac{c_n+c_m}{2}\Big\|^2.$$

Now convexity enters, and it enters in exactly one place: it guarantees that the midpoint $\frac{c_n+c_m}{2}$ again lies in C, so its distance to x is at least the infimum d, and the subtracted term is at least $4d^2$. Hence $\|c_n - c_m\|^2 \leq 2\|x - c_n\|^2 + 2\|x - c_m\|^2 - 4d^2$, and as $n, m \to \infty$ the two leading terms each tend to $2d^2$, so the right-hand side tends to $2d^2 + 2d^2 - 4d^2 = 0$. Thus (c_n) is Cauchy. Here the second hypothesis does its work: *completeness* of H supplies a limit and *closedness* of C guarantees that limit is still in C, so $P_C x := \lim c_n \in C$, and by continuity of the norm $\|x - P_C x\| = d$. Drop convexity and the midpoint can leave C, so the estimate collapses; drop closedness or completeness and the Cauchy sequence can converge to a forbidden or nonexistent point—each hypothesis blocks one specific failure.

Uniqueness. The same identity settles it without any further work. If $c, c' \in C$ both achieve the distance d, take the minimizing "sequence" $c, c', c, c', \ldots$; the displayed identity with $c_n = c$, $c_m = c'$ reads $\|c - c'\|^2 \leq 2d^2 + 2d^2 - 4d^2 = 0$, so $c = c'$.

The variational characterization. The infimum is unusable as a test for whether a candidate is the minimizer; we convert it to a checkable inequality. Fix any $c \in C$. By convexity the segment $(1-t)P_C x + tc$ lies in C for $t \in [0, 1]$, so the scalar function

$$g(t) = \|x - (1-t)P_C x - tc\|^2 = \|(x - P_C x) - t(c - P_C x)\|^2$$

is minimized over $[0, 1]$ at $t = 0$. Expanding the square, $g(t) = \|x - P_C x\|^2 - 2t\langle x - P_C x, c - P_C x\rangle + t^2\|c - P_C x\|^2$, so $g'(0) = -2\langle x - P_C x, c - P_C x\rangle$. A minimum at the left endpoint forces $g'(0) \geq 0$, i.e. $\langle x - P_C x, c - P_C x\rangle \le 0$, which is the asserted variational inequality. Conversely, if $P_C x \in C$ satisfies it for all $c \in C$, then for any competitor c,

$$\|x-c\|^2 = \|(x-P_Cx)+(P_Cx-c)\|^2 = \|x-P_Cx\|^2+\|P_Cx-c\|^2-2\langle x-P_Cx, c-P_Cx\rangle \ge \|x-P_Cx\|^2,$$

because the last inner product is ≤ 0; so $P_C x$ is indeed the minimizer and the characterization is exact.

The subspace case. When $C = M$ is a closed subspace the inequality upgrades to an equality, because a subspace contains lines, not just segments. Given $m \in M$, both $P_M x + tm$ and $P_M x - tm$ lie in M for every $t > 0$; feeding each into the variational inequality gives $\mp t\,\langle x - P_M x, m\rangle \le 0$ for both signs, which is only possible if $\langle x - P_M x, m\rangle = 0$. Thus $x - P_M x \in M^\perp$, and the trivial decomposition $x = P_M x + (x - P_M x)$ exhibits x as a member of M plus a member of $M^\perp$. The decomposition is unique: if $x = m_1 + m_1^\perp = m_2 + m_2^\perp$ with the obvious memberships, then $m_1 - m_2 = m_2^\perp - m_1^\perp$ lies in $M \cap M^\perp$, and any vector orthogonal to itself has $\langle v, v\rangle = 0$, hence $v = 0$ by positive-definiteness. This is the orthogonal direct sum $H = M \oplus M^\perp$. Linearity of P_M now follows for free from this uniqueness: for scalars a, b the vector $aP_M x + bP_M y$ lies in M and the remainder $a(x - P_M x) + b(y - P_M y)$ lies in $M^\perp$, so by uniqueness applied to $ax + by$ we read off $P_M(ax + by) = aP_M x + bP_M y$. Finally, since $x - P_M x \perp P_M x$, the Pythagorean identity gives $\|x\|^2 = \|P_M x\|^2 + \|x - P_M x\|^2 \ge \|P_M x\|^2$, so $\|P_M x\| \le \|x\|$ and $\|P_M\| \le 1$ (with equality unless $M = \{0\}$, since P_M fixes M pointwise). $\square$

The orthogonal decomposition $H = M \oplus M^\perp$ is not a formality; it is the geometric fact behind two constructions the book leans on constantly. The first is conditional expectation, which chapter 3 builds precisely as the L^2-orthogonal projection of a random variable onto the closed subspace of variables measurable with respect to a sub-σ-algebra—the best mean-square predictor is literally a foot of perpendicular. The second is the “best approximation in energy” principle of variational PDE theory: when the energy norm of section 2.6 is the relevant inner product, the Galerkin approximation to a solution from a finite-dimensional trial space M is P_M of the true solution, and the error $u - P_M u$ is orthogonal in energy to the whole trial space. Both are this one theorem wearing different clothes.

The second theorem identifies what the bounded linear functionals on a Hilbert space *are.* A linear functional is a scalar-valued linear measurement of a field—an “observable,” in the physicist’s idiom—and the dual space H^* of all bounded ones is generally an abstract object one knows only through its defining property. Riesz’s theorem collapses this abstraction: on a Hilbert space every bounded functional is just inner product against a fixed vector, so H^* is a faithful copy of H itself. This is far from automatic; it is exactly the payoff of having geometry. We will spend it twice over. It is what lets weak convergence in H (section 2.3) be read concretely as $\langle x_n, y\rangle \to \langle x, y\rangle$ for every y, against vectors rather than against unknown functionals, and it is the representation step that powers the Lax–Milgram theorem (theorem 2.34), where a PDE in weak form is recast as “find the vector that represents a given functional” and then solved by inverting a coercive bilinear form. The proof is a single application of the projection theorem just proved: the kernel of a nonzero functional is a closed hyperplane, and its one-dimensional orthogonal complement supplies the representing vector.

Theorem 2.6 (Riesz representation). *Let H be a Hilbert space. For every bounded linear functional $\phi\colon H \to \mathbb{R}$ there is a unique $y_\phi \in H$ with $\phi(x) = \langle x, y_\phi\rangle$ for all $x \in H$, and $\|\phi\| = \|y_\phi\|$. The map $\phi \mapsto y_\phi$ identifies H with its continuous dual H^* isometrically.*

Proof. If $\phi = 0$ the representing vector is $y_\phi = 0$, so assume $\phi \neq 0$. The kernel $M = \ker\phi = \{x : \phi(x) = 0\}$ is a subspace; it is *closed* because ϕ is continuous (boundedness was used here, and is the only place it is used) and *proper* because $\phi \neq 0$. By the projection theorem $H = M \oplus M^\perp$ with $M \neq H$, so $M^\perp$ contains a nonzero vector, which we normalize to a unit vector $z \in M^\perp$, $\|z\| = 1$.

The trick is to manufacture, for an arbitrary x, a vector that ϕ kills and that therefore must be orthogonal to z. Consider $w = \phi(x)z - \phi(z)x$. Applying ϕ and using linearity, $\phi(w) = \phi(x)\phi(z) - \phi(z)\phi(x) = 0$, so $w \in M$ and hence $w \perp z$. Writing out $\langle w, z\rangle = 0$ with $\langle z, z\rangle = \|z\|^2 = 1$,

$$0 = \langle \phi(x)z - \phi(z)x, z\rangle = \phi(x)\langle z, z\rangle - \phi(z)\langle x, z\rangle = \phi(x) - \phi(z)\langle x, z\rangle,$$

which rearranges to $\phi(x) = \phi(z)\langle x, z\rangle$. To absorb the scalar $\phi(z)$ into the second slot of the inner product, recall it is conjugate-linear there, so $\phi(z)\langle x, z\rangle = \langle x, \overline{\phi(z)}\, z\rangle$; thus $y_\phi = \overline{\phi(z)}\, z$ represents ϕ on all of H (in the real case $\overline{\phi(z)} = \phi(z)$ and the conjugate is invisible). *Uniqueness.* If $\langle x, y\rangle = \langle x, y'\rangle$ for every x then $\langle x, y - y'\rangle = 0$ for every x; taking $x = y - y'$ gives $\|y - y'\|^2 = 0$, so $y = y'$ by positive-definiteness. *Isometry.* On one hand Cauchy–Schwarz gives $|\phi(x)| = |\langle x, y_\phi\rangle| \le \|x\|\,\|y_\phi\|$, so taking the supremum over $\|x\| \le 1$ yields $\|\phi\| \le \|y_\phi\|$. On the other hand evaluating at the specific argument $x = y_\phi$ gives $\phi(y_\phi) = \langle y_\phi, y_\phi\rangle = \|y_\phi\|^2$, so $\|\phi\| \ge |\phi(y_\phi)| \,/\, \|y_\phi\| = \|y_\phi\|$ (when $y_\phi \neq 0$; the case $y_\phi = 0$ is $\phi = 0$). The two bounds give $\|\phi\| = \|y_\phi\|$, and since $\phi \mapsto y_\phi$ is linear (immediate from uniqueness) and norm-preserving, it is the asserted isometric identification of H^* with H. □

This self-duality—a Hilbert space is, via Riesz, its own continuous dual—is the structural reason two later constructions are so much more concrete in H than in a general Banach space. It is what makes weak convergence in a Hilbert space the transparent statement $\langle x_n, y\rangle \to \langle x, y\rangle$ of section 2.3 rather than a quantifier over abstract functionals, and it is the abstract engine of the Lax–Milgram theorem (theorem 2.34) for elliptic PDE, where solving the equation is exactly producing the Riesz vector of a prescribed functional with respect to the energy inner product. It also gives, for free, the construction of the adjoint in definition 2.12: the functional $x \mapsto \langle Tx, y\rangle$ is bounded, so Riesz hands us a unique vector to call T^*y.

The third theorem is the one that makes a Hilbert space computable. The projection theorem gives best approximations and Riesz identifies functionals, but neither yet lets us write a generic field down in coordinates. In $\mathbb{R}^d$ one expands a vector in an orthonormal basis and manipulates the d coordinates; we want the same in infinite dimensions—a countable coordinate system in which any field is reconstructed from its inner products with the basis vectors, and in which the norm is computed from those coordinates alone. The obstruction is that "basis" can no longer mean finite linear combinations: we must allow infinite sums and must control their convergence. The right notion replaces "every vector is a finite combination" with "finite combinations are *dense*." We also need the space to admit a *countable* such system at all, which is the separability hypothesis. Both ideas are packaged in the next definition.

Definition 2.7 (Orthonormal basis)**.** A family $\{e_n\}_{n\in\mathbb{N}}$ in H is *orthonormal* if $\langle e_n, e_m\rangle = \delta_{nm}$. It is an *orthonormal basis* if its linear span is dense. A Hilbert space is *separable* if it has a countable dense subset; equivalently (by Gram–Schmidt) if it has a countable orthonormal basis.

The equivalence asserted at the end deserves a word, since it is what makes separability the right hypothesis. Given a countable dense set, the Gram–Schmidt process—orthonormalize the vectors one at a time, discarding any that are already in the span of their predecessors—produces a countable orthonormal family with the same (hence dense) span, i.e. an orthonormal basis; conversely a countable orthonormal basis has, as a countable dense subset, the rational (or rational-complex) finite combinations of its members. So "countable dense subset" and "countable orthonormal basis" are interchangeable, and the next theorem shows the second is as good as a coordinate system on $\mathbb{R}^d$.

Theorem 2.8 (Fourier expansion and Parseval)**.** *If $\{e_n\}$ is an orthonormal basis of a separable Hilbert space H, then every $x \in H$ has the norm-convergent expansion $x = \sum_n \langle x, e_n\rangle\, e_n$, and $\|x\|^2 = \sum_n |\langle x, e_n\rangle|^2$ (Parseval). Conversely any ℓ^2-summable sequence of coefficients defines an element of H.*

Proof. The argument is the projection theorem applied along the basis, run in four short steps: truncate, bound (Bessel), converge (completeness), and identify the limit (density).

Truncate. Let $S_N = \sum_{n\le N}\langle x, e_n\rangle e_n$ be the N-th partial sum. By orthonormality it is exactly the orthogonal projection of x onto the finite-dimensional subspace $\operatorname{span}\{e_1,\dots,e_N\}$: indeed $\langle x - S_N, e_k\rangle = \langle x, e_k\rangle - \langle x, e_k\rangle = 0$ for each $k \le N$, so $x - S_N$ is orthogonal to that subspace, which characterizes the projection by theorem 2.5. The Pythagorean identity for the orthogonal split $x = S_N + (x - S_N)$ reads

$$\|x\|^2 = \|S_N\|^2 + \|x - S_N\|^2 = \sum_{n\le N} |\langle x, e_n\rangle|^2 + \|x - S_N\|^2 ,$$

where $\|S_N\|^2 = \sum_{n\le N} |\langle x, e_n\rangle|^2$ again by orthonormality.

Bound. Dropping the nonnegative remainder term gives, for every N, $\sum_{n\le N} |\langle x, e_n\rangle|^2 \le \|x\|^2$. This is *Bessel's inequality*; letting $N \to \infty$ it says the coefficient sequence $(\langle x, e_n\rangle)_n$ lies in ℓ^2 with ℓ^2-norm at most $\|x\|$.

Converge. Square-summability of the coefficients makes the partial sums Cauchy: for $M > N$, again by orthonormality, $\|S_M - S_N\|^2 = \sum_{N<n\le M} |\langle x, e_n\rangle|^2$, which is a tail of a convergent series and so tends to 0. By completeness of H the Cauchy sequence converges, $S_N \to S$ for some $S \in H$. Note that up to here we have used only orthonormality; we have *not* yet used that the span is dense, and indeed without that the limit S need not equal x.

Identify. This is where density—the defining property of a *basis* as opposed to a mere orthonormal family—enters. For each fixed k, continuity of the inner product gives $\langle S, e_k\rangle = \lim_N \langle S_N, e_k\rangle = \langle x, e_k\rangle$, so $\langle x - S, e_k\rangle = 0$ for every k. Thus $x - S$ is orthogonal to every basis vector, hence to their entire linear span, hence—by continuity of $\langle x - S, \cdot\rangle$—to the closure of that span, which is all of H. A vector orthogonal to all of H is orthogonal to itself, so $\|x - S\|^2 = 0$ and $x = S$. This proves the expansion $x = \sum_n \langle x, e_n \rangle e_n$. Returning to the Pythagorean identity and letting $N \to \infty$, the remainder $\|x - S_N\|^2 \to 0$ and Bessel's inequality becomes the *equality* $\|x\|^2 = \sum_n |\langle x, e_n \rangle|^2$, which is Parseval's theorem: the norm is computed from the coordinates exactly as in $\mathbb{R}^d$.

Converse. The same Cauchy estimate, read forward, shows every square-summable coefficient sequence is realized. If $(c_n) \in \ell^2$, set $S_N = \sum_{n \le N} c_n e_n$; then $\|S_M - S_N\|^2 = \sum_{N<n\le M} |c_n|^2 \to 0$, so (S_N) is Cauchy and converges by completeness to some $x \in H$, whose coefficients are $\langle x, e_n \rangle = c_n$. Hence the coordinate map $x \mapsto (\langle x, e_n \rangle)_n$ is an isometric isomorphism $H \cong \ell^2$: a separable Hilbert space is, up to this identification, the single space ℓ^2. □

It is worth dwelling on the closing remark, because it is the hinge between this section and the spectral machinery built later, and it sets up the chapter's central object. Every Hilbert space this book uses is separable, so the apparatus just proved always applies. Concretely, $L^2[0,1]$—the home of the fields the graphon operator acts on—is separable, with the trigonometric system $\{e^{2\pi i n x}\}_{n\in\mathbb{Z}}$ (or, in the real setting, the sines and cosines, or the Legendre polynomials, or any complete orthonormal system) as a ready-made orthonormal basis; and $L^2([0,1]^2)$, the home of the kernel itself, is separable with the products $e_n(x)e_m(y)$ as a basis, a fact we will use directly in identifying Hilbert–Schmidt operators with L^2 kernels (theorem 2.22). So far these are *generic* bases: fixed once and for all, indifferent to whatever operator we later study. The decisive move of the spectral theorem (section 2.5) is to trade a generic basis for a *problem-adapted* one. When the operator in question is compact and self-adjoint, its own eigenfunctions form an orthonormal basis, and in *that* basis the operator is diagonal—it merely rescales each coordinate by an eigenvalue. For the graphon operator $\mathbb{W}$ this is the whole game: Parseval expresses any field in eigen-coordinates, $\mathbb{W}$ acts on each coordinate by multiplication by λ_n, and the resulting mode-by-mode picture is exactly the network's "band structure" exploited in chapter 18. The Fourier/Parseval theorem is thus not the end of the geometric story but the template the spectral theorem will fill in with the right, operator-specific, basis.

With the inner-product geometry installed, we have in hand the three objects the rest of the chapter will act on and through. We have the *bounded linear functionals*—the scalar observables on a field—and, via Riesz, the knowledge that on a Hilbert space they are abundant and concrete, each one inner product against a vector; in a general Banach space their abundance is not free and must be bought from the Hahn–Banach theorem instead, a distinction the next section confronts head-on. We have, through Riesz, an explicit grip on the *dual space* H^*, identified isometrically with H itself. And we have the seed of the *adjoint*: Riesz representation is precisely what will let every operator cast a shadow on the dual side, the construction from which self-adjointness—the defining property of the graphon operator and the hypothesis of the spectral theorem—is born. What we have not yet done is let anything *act* on a field. A space of fields, however richly geometric, becomes a setting for dynamics only once we introduce the maps that carry one field into another; and the right notion of such a map, as the next section takes up, is the continuous linear operator.

2.2 Bounded operators, dual spaces, and adjoints

The previous section ended by handing us three things and a promise. The things were the bounded linear functionals on a Hilbert space, the dual space H^* they fill out, and—through Riesz representation (theorem 2.6)—the assurance that on a Hilbert space these functionals are both abundant and concrete, each one inner product against a fixed vector. The promise was that a space of fields, however richly geometric, becomes a setting for dynamics only once we let something *act* on a field. A functional is the humblest such action: it reads a field and returns a single number, a scalar observable. But the actions that drive the rest of the book return not a number but another field. The graphon coupling $\mathbb{W}$ averages a population profile against its kernel and hands back a new profile; the generator of a diffusion turns one function into another; the solution operator of a partial differential equation turns data into a solution. Each is a linear map from a space of fields into a space of fields, and this section settles which such maps we admit and what structure the admissible ones carry. The short answer is the *continuous* linear map. The work is to show that continuity has a clean quantitative face—the operator norm; that the continuous maps from a space to itself form an algebra under composition whose one structural inequality is exactly what later makes iteration converge; and that the scalar-valued special case, the dual space, is rich enough to deserve the name, a richness that off a Hilbert space is not free but must be bought from the Hahn–Banach theorem.

What must be pinned down is not linearity, which every operator in the book respects because superposition of fields is built into the physics, but the analytic side: which linear maps are tame enough to commute with limits, so that from $x_n \to x$ one may conclude $Tx_n \to Tx$. For linear maps this continuity has a strikingly simple equivalent—the map may not stretch any vector by more than some fixed factor—and that factor is the natural measure of the operator's size.

Definition 2.9 (Bounded linear operator)**.** Let X, Y be normed spaces. A linear map $T\colon X \to Y$ is *bounded* if

$$\|T\|_{X\to Y} \;:=\; \sup_{x\neq 0} \frac{\|Tx\|_Y}{\|x\|_X} \;=\; \sup_{\|x\|_X\leq 1} \|Tx\|_Y \;<\; \infty.$$

For linear maps, boundedness is equivalent to continuity. The bounded operators $X \to Y$ form a normed space $\mathcal{B}(X, Y)$ under the operator norm; if Y is Banach so is $\mathcal{B}(X, Y)$. We write $\mathcal{B}(X) = \mathcal{B}(X, X)$.

The single clause in the definition that asserts "boundedness is equivalent to continuity" carries more than it shows, and since the operator norm's claim to be the right notion of size rests on it, we prove it. Suppose first that T is bounded, so $\|Tx\|_Y \leq \|T\| \, \|x\|_X$ for all x. Then by linearity $\|Tx - Tx'\|_Y = \|T(x - x')\|_Y \leq \|T\| \, \|x - x'\|_X$, so T is Lipschitz with constant $\|T\|$ and *a fortiori* continuous everywhere. Conversely, suppose T is merely continuous at the single point 0. Then for $\varepsilon = 1$ there is a $\delta > 0$ with $\|Tx\|_Y \leq 1$ whenever $\|x\|_X \leq \delta$. Given any $x \neq 0$, the rescaled vector $\delta x / \|x\|_X$ has norm exactly δ, so $\|T(\delta x / \|x\|_X)\|_Y \leq 1$, and pulling the scalar out by homogeneity gives $\|Tx\|_Y \leq \delta^{-1} \|x\|_X$. Thus T is bounded with $\|T\| \leq \delta^{-1}$. For a linear map, then, three notions collapse into one: bounded, continuous, and continuous at a single point are the same property, and the operator norm is precisely the best Lipschitz constant. Linearity is the whole of the magic here—it is what lets a lone estimate valid in a small ball around the origin be inflated, by rescaling, to a bound at every scale. Drop linearity and the shortcut evaporates: the continuous map $x \mapsto x^2$ on $\mathbb{R}$ has no global Lipschitz bound at all, which is exactly why "bounded equals continuous" is a theorem about linear maps and not a tautology.

The operator norm earns its name as a size because it is the *gain* of the map: the smallest constant C for which $\|Tx\| \leq C\,\|x\|$ holds universally, hence the largest factor by which T can amplify a vector. Two micro-examples fix the picture. On $L^2(\Omega)$ the multiplication operator $(M_a f)(x) = a(x)f(x)$ by a bounded function a has $\|M_a\| = \|a\|_{L^\infty}$: it cannot stretch any field by more than the largest value of $|a|$, and a field concentrated where $|a|$ nearly attains its essential supremum is stretched by nearly that much, so the bound is sharp. The graphon operator itself is the example we are building toward: on $L^2[0,1]$ the map $(\mathbb{W}f)(x) = \int_0^1 W(x,y)f(y)\,\mathrm{d}y$ is bounded, since Cauchy–Schwarz in the inner integral gives $|(\mathbb{W}f)(x)| \leq \big(\int_0^1 W(x,y)^2\,\mathrm{d}y\big)^{1/2}\,\|f\|_{L^2}$, and integrating the square over x yields $\|\mathbb{W}f\|_{L^2} \leq \|W\|_{L^2([0,1]^2)}\,\|f\|_{L^2}$, so $\|\mathbb{W}\| \leq \|W\|_{L^2([0,1]^2)}$. A square-integrable kernel thus automatically defines a bounded operator—the first installment of the identification, completed in section 2.4, of the graphon with a Hilbert–Schmidt operator.

It is worth recording why $\mathcal{B}(X,Y)$ is itself complete when Y is, since this is the same completeness principle the chapter keeps spending, now lifted to the level of operators. If (T_n) is Cauchy in the operator norm, then for each fixed x the vectors $T_n x$ are Cauchy in Y, because $\|T_n x - T_m x\| \leq \|T_n - T_m\|\,\|x\|$; completeness of Y furnishes a limit, which we name Tx, and passing the linear relations to the limit shows T is linear. The Cauchy condition is uniform over $\|x\| \leq 1$, so the convergence $T_n \to T$ is in operator norm and the limit T is bounded. The dual space defined below is precisely the instance $Y = \mathbb{R}$ of this fact, and it is the reason every dual is a Banach space.

When the domain and codomain coincide we may compose operators, and composition meets the norm in the one inequality that organizes everything downstream. If $S, T \in \mathcal{B}(X)$ then for every x, $\|STx\| \leq \|S\|\,\|Tx\| \leq \|S\|\,\|T\|\,\|x\|$, and taking the supremum over $\|x\| \leq 1$ gives the *submultiplicative* bound $\|ST\| \leq \|S\|\,\|T\|$. A complete normed space carrying an associative, submultiplicative product with unit is a *Banach algebra*, and $\mathcal{B}(X)$ is its prototype, with composition for product and the identity Id for unit. The reason this one-line inequality matters out of all proportion to its proof is that it controls *powers*: iterating gives $\|T^n\| \leq \|T\|^n$, so the size of the n-fold composite decays geometrically the instant $\|T\| < 1$. Two payoffs follow that the book collects repeatedly. First, the Neumann series $\sum_{n\geq 0} T^n$ then converges in operator norm—its tail is dominated by the convergent geometric series $\sum_n \|T\|^n$, and completeness of $\mathcal{B}(X)$ supplies the limit—and a direct telescoping shows it sums to $(\mathrm{Id} - T)^{-1}$, so $\mathrm{Id} - T$ is invertible whenever $\|T\| < 1$; this is the workhorse that solves a linear fixed-point equation $(\mathrm{Id} - T)x = b$ by iteration. Second, and equivalently, the affine map $x \mapsto Tx + b$ is then a contraction of ratio $\|T\|$, whose unique fixed point is the limit of the iterates $x_{n+1} = Tx_n + b$, with $\|T^n\| \leq \|T\|^n$ giving the exact geometric rate of approach. This is the linear shadow of the contraction mapping theorem (theorem 2.36), and it is no accident that it looks like the self-consistent-field iteration that defines an equilibrium: when a best-response map is a contraction, this very submultiplicative estimate is what controls its iterates and certifies their convergence. Submultiplicativity, in short, is the precise algebraic fact that lets a bound on a single step govern an entire trajectory.

We now specialize the codomain to the scalar field, where the operators become measurements rather than transformations of a field, and a structure of independent importance emerges.

Definition 2.10 (Dual space)**.** The (continuous) *dual* of a normed space X is $X^* = \mathcal{B}(X, \mathbb{R})$, the space of bounded linear functionals, with the norm $\|\phi\|_{X^*} = \sup_{\|x\| \le 1} |\phi(x)|$. It is always a Banach space, even when X is not complete.

The dual is always a Banach space, even when X is not, and this costs nothing: it is the case $Y = \mathbb{R}$ of the completeness argument above, with the scalar field standing in for the complete codomain. So even a defective, incomplete space of fields possesses a complete space of observables—a small but genuine asymmetry we will exploit when we put topologies on X^* in section 2.3.

What is *not* free, and not even obvious, is that X^* holds enough functionals to be useful. The definition guarantees that the bounded functionals form a Banach space, but a Banach space can be the trivial space $\{0\}$; nothing said so far excludes a normed X on which the only bounded linear functional is the zero map. On such a space X^* would distinguish no two distinct fields, and every dual-based construction in the book—weak convergence, adjoints, convex separation—would be vacuous. On a Hilbert space Riesz representation (theorem 2.6) already dispels the worry, manufacturing for each direction a functional that points along it. Off a Hilbert space we have no inner product to build functionals from, and the abundance must be secured by other means. That bounded functionals nonetheless exist in profusion—enough to separate any two points, enough to expose any convex body along a supporting hyperplane—is the content of the Hahn–Banach theorem, which we state in the two forms we use.

Theorem 2.11 (Hahn–Banach, extension and separation)**.** *Let X be a normed space.*

1. (Extension.) *Every bounded linear functional on a subspace $M \subseteq X$ extends to a bounded linear functional on all of X with the same norm. Consequently, for every $x_0 \neq 0$ there is $\phi \in X^*$ with $\|\phi\| = 1$ and $\phi(x_0) = \|x_0\|$, so X^* separates points of X.*

2. (Separation.) *If $A, B \subseteq X$ are disjoint nonempty convex sets with A closed and B compact, there exist $\phi \in X^*$ and $\alpha \in \mathbb{R}$ with $\phi(a) \le \alpha < \phi(b)$ for all $a \in A,\ b \in B$.*

Both forms are proved in full in appendix B.2, following [31, Ch. 1]; here we expose the mechanism, because the reason the theorem is *true* is more illuminating than the bookkeeping that makes it airtight. Everything rests on a single one-dimensional extension step. Suppose a linear functional ℓ defined on a subspace M is dominated by a *sublinear* gauge p—a function with $p(x+y) \le p(x)+p(y)$ and $p(\lambda x) = \lambda p(x)$ for $\lambda \ge 0$—in the sense that $\ell \le p$ on M. We try to extend ℓ across one fresh direction $x_0 \notin M$, which amounts to choosing the single new value $c = \ell(x_0)$. For the enlarged functional on $M \oplus \mathbb{R}x_0$ to stay dominated by p we need $\ell(m) + tc \le p(m + tx_0)$ for all $m \in M$ and all real t. Splitting into the cases $t > 0$ and $t < 0$ and dividing by $|t|$—legitimate by the positive homogeneity of p—collapses this pair of requirements into the single sandwich

$$\sup_{m \in M} \left[\ell(m) - p(m - x_0)\right] \ \le\ c \ \le\ \inf_{m' \in M} \left[p(m' + x_0) - \ell(m')\right].$$

The crux is that this sandwich is never empty. For any $m, m' \in M$, subadditivity of p gives $\ell(m) + \ell(m') = \ell(m + m') \le p(m + m') \le p(m - x_0) + p(m' + x_0)$, which rearranges to exactly “the left-hand bracket $\leq$ the right-hand bracket"; hence the supremum on the left lies at or below the infimum on the right, and any c between them yields a dominated extension one dimension larger. That is the entire analytic content of the theorem; everything else is reach. To extend all the way to X one orders the dominated partial extensions by inclusion, notes that the union of any chain of them is again such an extension and so is an upper bound for the chain, and invokes Zorn's lemma to obtain a maximal element. Were its domain not all of X, the one-dimensional step would enlarge it, contradicting maximality—so the maximal extension is defined everywhere. Specializing the gauge to $p(x) = \|\ell\|_M \|x\|$ recovers the norm-preserving extension form, since domination by this p is precisely the bound $|\ell(x)| \leq \|\ell\|_M \|x\|$.

The geometric separation form is the same theorem read through the *Minkowski gauge*. To an open convex set C containing the origin one attaches $p_C(x) = \inf\{t > 0 : x/t \in C\}$, the factor by which x must be shrunk to fit inside C; convexity makes p_C sublinear, and openness makes $\{p_C < 1\} = C$. A point $x_0 \notin C$ then has $p_C(x_0) \geq 1$, so the functional $\ell(\lambda x_0) = \lambda$ defined on the line $\mathbb{R}x_0$ satisfies $\ell \leq p_C$ there; extending it by the step just described produces $\phi \in X^*$ with $\phi \leq p_C \leq 1$ on C and $\phi(x_0) \geq 1$—a hyperplane with C on one side and x_0 on the other. The two-set statement of the theorem follows by applying this to the translated difference set $A - B$, which is convex and avoids the origin precisely because A and B are disjoint, the compactness of B against the closedness of A being what upgrades weak separation to the strict inequality $\phi(a) \leq \alpha < \phi(b)$.

These two forms divide the labor cleanly between the two halves of the book. The separation form is the analytic root of convex duality: it manufactures the supporting functional that exposes a convex set along a face, and it is exactly the device that later represents a constraint by a Lagrange multiplier and underwrites the primal–dual formulations of the variational and optimal-transport arguments. The extension form is the one we lean on immediately. Its corollary that for every $x_0 \neq 0$ some unit functional attains $\phi(x_0) = \|x_0\|$ says that X^* *separates points*: distinct fields are told apart by some observable. That single fact is what makes the weak topology of section 2.3 Hausdorff, so that weak limits are unique and the compactness we extract there is worth having.

There remains the handoff to the next subsection, and Riesz representation is the bridge. Hahn–Banach secured the abundance of functionals on a general Banach space; on a Hilbert space Riesz did better, attaching to every functional a concrete representing vector. That representation is exactly the tool that lets an operator cast a shadow on the dual side, and the shadow it casts is the *adjoint*—where self-adjointness, the hypothesis of the spectral theorem and the defining symmetry of the graphon operator, is born. We turn to it now.

2.2.1 Adjoints

The previous subsection ended by naming the bridge. Hahn–Banach guaranteed that a general Banach space carries enough functionals to separate its points, but on a Hilbert space Riesz representation (theorem 2.6) did something sharper: it pinned each bounded functional to a concrete representing vector, so that the abstract dual H^* became a faithful copy of H itself. We now collect the dividend that self-duality was always pointing toward. On a Hilbert space every operator T casts a shadow on the dual side—a second operator T^* that records how T looks when probed by inner products—and the construction of that shadow is nothing but Riesz applied one functional at a time. The shadow is interesting in its own right, but its real importance is that it lets us ask a question that has no analogue for a bare bounded operator: when does an operator *coincide* with its own shadow? That coincidence is self-adjointness, and it is the single hypothesis on which the entire spectral theory of section 2.5 turns and the exact structural feature that will make the graphon operator diagonalizable. So this short subsection is where self-adjointness is born; the rest of the chapter is where it is spent.

The mechanism is worth seeing before the definition formalizes it. Fix an operator $T \in \mathcal{B}(H)$ and a vector $y \in H$. Pairing the output Tx against y produces, as x ranges over H, a scalar-valued map

$$\phi_y \colon x \longmapsto \langle Tx, y\rangle,$$

and this map is linear in x (because T is linear and the inner product is linear in its first slot) and bounded, since Cauchy–Schwarz together with boundedness of T gives $|\phi_y(x)| = |\langle Tx, y\rangle| \le \|Tx\|\,\|y\| \le \|T\|\,\|y\|\,\|x\|$. So $\phi_y \in H^*$, and Riesz representation (theorem 2.6) hands back a *unique* vector representing it—a vector that depends on y, which we name T^*y. By construction $\phi_y(x) = \langle x, T^*y\rangle$, which is precisely the defining relation below. Running Riesz once for every y assembles the map $y \mapsto T^*y$; this is the adjoint.

Definition 2.12 (Adjoint, self-adjoint operator)**.** Let H be a Hilbert space and $T \in \mathcal{B}(H)$. The *adjoint* $T^* \in \mathcal{B}(H)$ is the unique bounded operator with

$$\langle Tx, y\rangle = \langle x, T^*y\rangle \qquad \text{for all } x, y \in H.$$

Its existence and uniqueness follow from Riesz representation applied to the functional $x \mapsto \langle Tx, y\rangle$, and $\|T^*\| = \|T\|$. The operator T is *self-adjoint* if $T^* = T$, i.e. $\langle Tx, y\rangle = \langle x, Ty\rangle$ for all x, y.

The definition asserts three things that the construction above does not by itself supply, and each deserves its line. First, that T^* is *linear*: for vectors y_1, y_2 and scalars a, b we have $\langle x, T^*(ay_1+by_2)\rangle = \langle Tx, ay_1 + by_2\rangle = \bar{a}\langle Tx, y_1\rangle + \bar{b}\langle Tx, y_2\rangle = \langle x, aT^*y_1 + bT^*y_2\rangle$ for every x, and a vector determined by its inner products against all x is unique, so $T^*(ay_1 + by_2) = aT^*y_1 + bT^*y_2$. (Over the reals the conjugates are invisible; we keep them so the statement is correct over $\mathbb{C}$, where it matters for the spectral theorem.) Second, that T^* is *bounded with the same norm*, $\|T^*\| = \|T\|$. To see it, bound T^*y by testing it against the worst x: for any unit x, $|\langle x, T^*y\rangle| = |\langle Tx, y\rangle| \le \|T\|\,\|y\|$, and taking the supremum over $\|x\| \le 1$ identifies that supremum, by Riesz isometry, with $\|T^*y\|$ itself, giving $\|T^*y\| \le \|T\|\,\|y\|$ and hence $\|T^*\| \le \|T\|$. The reverse inequality costs nothing once one notices that the whole construction is symmetric in T and T^*: the defining relation $\langle Tx, y\rangle = \langle x, T^*y\rangle$ read the other way, $\langle T^*y, x\rangle = \langle y, Tx\rangle$ (conjugate both sides of the original), exhibits T as the adjoint of T^*, so $(T^*)^* = T$ and the bound just proved applied to T^* gives $\|T\| = \|(T^*)^*\| \le \|T^*\|$. The two inequalities close to the equality $\|T^*\| = \|T\|$: passing to the adjoint never changes an operator's size. Third, that T^* is *unique*, which is immediate—two operators satisfying the defining relation would agree in every inner product $\langle x, \cdot\rangle$ and so agree as vectors for each y.

It pays to anchor all of this in the finite-dimensional case the reader already owns, because the adjoint is the exact infinite-dimensional lift of a construction from linear algebra. Take $H = \mathbb{R}^d$ with the Euclidean inner product $\langle x, y\rangle = x^\top y$, and let T act as a matrix A. Then

$\langle Ax, y\rangle = (Ax)^\top y = x^\top(A^\top y) = \langle x, A^\top y\rangle$, so the adjoint is the transpose, $A^* = A^\top$; over $\mathbb{C}$ with $\langle x, y\rangle = \sum_i x_i \bar{y}_i$ the same computation produces the conjugate transpose $A^* = \bar{A}^\top$. The defining relation $\langle Tx, y\rangle = \langle x, T^* y\rangle$ is thus the coordinate-free statement of "move the matrix to the other side of the inner product and transpose it," and self-adjointness $T^* = T$ is exactly the condition $A = A^\top$ that the matrix be *symmetric* (Hermitian over $\mathbb{C}$). The whole point of the Riesz construction is that this move survives the passage to infinite dimensions, where there is no matrix to transpose: the inner product, not a list of entries, is what carries the structure, and Riesz is what guarantees the transposed object still exists as an honest bounded operator.

Why single out the self-adjoint operators? Because symmetry is precisely the hypothesis that makes spectral analysis behave. For a real symmetric matrix the reader already knows the two facts that matter: its eigenvalues are all real, and one can choose its eigenvectors to form an orthonormal basis of $\mathbb{R}^d$, in which basis the matrix is diagonal. Neither is true for a general matrix—eigenvalues wander into the complex plane and eigenvectors may fail to span—and neither is an accident of finite dimension. Self-adjointness is exactly the structural property responsible for both, and section 2.5 will show that it continues to deliver them in infinite dimensions, with one extra hypothesis. The eigenvalues of a bounded self-adjoint operator are real, and—once we also assume *compactness*, the substitute for finite-dimensionality that keeps the spectrum discrete—its eigenvectors again form an orthonormal basis in which the operator is diagonal. The reason to isolate self-adjointness *here*, several sections before it is used, is that it is the working hypothesis of that later theorem and we want the reader to meet it as a familiar object: the abstract avatar of the real symmetric matrix, carrying the same guarantee of a real spectrum and a clean eigenbasis.

This is also the moment to plant the thread the chapter is laid out to pay off, because the graphon operator is the self-adjoint operator the book actually cares about. Recall from definition 2.9 that the graphon coupling acts by $(\mathbb{W}f)(x) = \int_0^1 W(x, y) f(y)\,\mathrm{d}y$ on $L^2[0, 1]$. Compute its adjoint directly from the definition, using the L^2 inner product $\langle f, g\rangle = \int fg$ (real-valued here) and Fubini (theorem 1.27) to exchange the order of integration:

$$\langle \mathbb{W}f, g\rangle = \int_0^1\int_0^1 W(x, y)\, f(y)\, g(x)\ \mathrm{d}y\ \mathrm{d}x = \int_0^1 f(y)\Big(\int_0^1 W(x, y)\, g(x)\ \mathrm{d}x\Big)\,\mathrm{d}y = \langle f, \mathbb{W}^* g\rangle,$$

which exhibits the adjoint as the integral operator with the *transposed* kernel, $(\mathbb{W}^* g)(y) = \int_0^1 W(x, y)\, g(x)\ \mathrm{d}x$—the kernel $W(x, y)$ read with its two arguments swapped, exactly as a matrix transpose swaps row and column indices. Therefore $\mathbb{W}$ is self-adjoint if and only if its kernel is symmetric, $W(x, y) = W(y, x)$. This is not a technical imposition but a modeling truth: a graphon encodes an *undirected* network of agent types, in which the influence of type y on type x equals the influence of x on y, so its kernel is symmetric by construction and $\mathbb{W}$ is self-adjoint automatically. That single sentence is the hinge of the chapter's design. It is the reason the compact-operator section (section 2.4) will be able to place $\mathbb{W}$ in the Hilbert–Schmidt class and the spectral section (section 2.5) will be able to diagonalize it into the mode-by-mode "band structure" that chapter 18 reads off as the network's normal modes. Self-adjointness, born here from a one-line Fubini computation, is what every one of those later payoffs cashes.

With the adjoint in hand we have completed the operator-theoretic toolkit this part of the chapter set out to assemble: bounded operators and their norm, the dual space, and now the map $T \mapsto T^*$ that ties an operator to its action on the dual side. Two distinct strands lead out of here.

The immediate one is the weak-topology section that follows, which puts operators and their duals to work on a problem we have so far only flagged: existence proofs need to extract convergent subsequences from bounded families, finite-dimensional Heine–Borel fails to provide them in infinite dimensions, and the repair is to weaken the topology until compactness returns. The more pointed strand is the pair of sections after it. Self-adjointness has been defined here in the abstract, but it does no work until it is married to compactness; the compact and Hilbert–Schmidt section supplies that partner and shows the graphon operator owns it, and the spectral section then collects the reward—the real eigenvalues and orthonormal eigenbasis previewed above. The reader should carry forward a single expectation: every time the phrase "self-adjoint" reappears, it is this construction being invoked, and the symmetry of the graphon kernel is why it applies.

2.3 Weak and weak-$*$ topologies and Banach–Alaoglu

The previous section closed by handing the operator and dual machinery to a problem we have so far only named, and the time has come to cash the promise. Every existence theorem in this book follows the same arc: one builds a sequence of approximate solutions, controls their size by an a priori estimate, extracts a convergent subsequence, and christens its limit the solution sought. The hinge of that arc is the extraction step, and it is a statement about *compactness*—about when a bounded family is forced to have a convergent subsequence. In a finite-dimensional space the Heine–Borel theorem settles the matter outright: a set is compact precisely when it is closed and bounded, so a bounded sequence in $\mathbb{R}^d$ always accumulates and a convergent subsequence can always be pulled out, full stop. The whole difficulty of infinite-dimensional analysis is that this clean equivalence fails, and fails badly: the closed unit ball, the most basic bounded set there is, is *never* compact in the norm topology once the dimension is infinite. Before we can repair the situation we must see exactly how it breaks, because the repair is shaped to the break.

The obstruction is geometric and completely concrete. In $\mathbb{R}^d$ a bounded sequence cannot run away to infinity and cannot disperse forever inside a bounded region, so it must pile up somewhere; in infinite dimensions there is always "another direction" to escape into, and one can build a bounded sequence whose terms stay rigidly far apart, so that no subsequence is even Cauchy. The device that manufactures such an escape is a single geometric fact—that a unit vector can always be found almost perpendicular to any proper closed subspace—which goes by the name of Riesz's lemma. We isolate it, because the half-separated sequence it produces is the cleanest possible witness to non-compactness, and because the lemma's mechanism (a residual vector, normalized) is one we will reuse.

Lemma 2.13 (Riesz's lemma)**.** *Let X be a normed space and $Y \subsetneq X$ a proper closed subspace. For every $\theta \in (0,1)$ there is a unit vector $x \in X$, $\|x\| = 1$, with $\operatorname{dist}(x,Y) = \inf_{y\in Y} \|x-y\| \geq \theta$.*

Proof. Since Y is a proper subspace, choose a vector $z \in X \setminus Y$. Because Y is *closed*, z sits at a strictly positive distance from it: writing $d := \operatorname{dist}(z,Y) = \inf_{y\in Y} \|z-y\|$, we have $d > 0$, for if d were 0 there would be $y_k \in Y$ with $z = \lim y_k$, forcing $z \in Y$ by closedness and contradicting the choice of z. The number d is an infimum, so it is approached but need not be attained; crucially we do not need it attained, only approached to within a controlled factor. Fix $\theta \in (0,1)$. Since $d/\theta > d$, the value d/θ is not a lower bound for the distances, so the definition of infimum supplies a $y \in Y$ with

$$d \;\le\; \|z-y\| \;\le\; \frac{d}{\theta}.$$

Normalize the residual: set $x = (z-y)/\,\|z-y\|$, a unit vector. We claim x is the vector we want. To see it, estimate the distance from x to an arbitrary $w \in Y$. Because Y is a subspace, the combination $y + \|z-y\|\; w$ again lies in Y, so its distance from z is at least d; therefore

$$\|x-w\| = \Big\|\frac{z-y}{\|z-y\|} - w\Big\| = \frac{\|z-(y+\|z-y\|\; w)\|}{\|z-y\|} \;\ge\; \frac{d}{\|z-y\|} \;\ge\; \frac{d}{d/\theta} = \theta.$$

Since $w \in Y$ was arbitrary, $\operatorname{dist}(x,Y) \ge \theta$. Each hypothesis paid its way exactly once: closedness of Y is what made $d > 0$ (without it z could sit on the boundary of Y at distance zero, and no separated vector could exist), and properness is what let us find a z outside Y to begin with. $\square$

The lemma now drives a short induction that exhibits the unit ball's non-compactness. The key observation feeding it is that in an infinite-dimensional space the spans of finitely many vectors are always both proper and closed, so Riesz's lemma can be applied to each of them in turn. We build unit vectors $x_1, x_2, \ldots$ one at a time. Take x_1 to be any unit vector. Suppose $x_1, \ldots, x_n$ have been chosen, and let $Y_n = \operatorname{span}\{x_1, \ldots, x_n\}$. This Y_n is finite-dimensional, hence complete—all norms on a finite-dimensional space are equivalent and complete (example 2.2)—hence closed in X; and it is a *proper* subspace, because an infinite-dimensional X can never be exhausted by the span of finitely many vectors. Riesz's lemma with $\theta = \frac{1}{2}$ therefore furnishes a unit vector x_{n+1} with $\operatorname{dist}(x_{n+1}, Y_n) \ge \frac{1}{2}$. In particular, since every earlier x_m (for $m \le n$) lies in Y_n, we get $\|x_{n+1} - x_m\| \ge \frac{1}{2}$. Carrying this out for all n produces an infinite sequence of unit vectors with $\|x_n - x_m\| \ge \frac{1}{2}$ for all $n \ne m$.

This sequence lives entirely inside the closed unit ball, yet no two of its terms ever come within $\frac{1}{2}$ of one another, so it has no Cauchy subsequence and *a fortiori* no convergent subsequence. The closed unit ball of an infinite-dimensional normed space is thus not sequentially compact—and since the ball is a metric space, where sequential compactness and compactness coincide, it is not compact at all. This is the precise sense in which Heine–Borel dies in infinite dimensions, and it is the obstacle the rest of the section is built to circumvent.

The diagnosis points straight at its own cure. Norm convergence demands that $x_n - x$ shrink to zero *as measured by the norm*, and that is simply too severe a demand for bounded sequences to meet—the half-separated sequence above never makes its increments small. So we ask for less. The only linear instruments we possess for probing a vector are the bounded functionals of X^*, and the weakest reasonable sense in which "x_n approaches x" is that no such instrument can tell them apart in the limit: $\phi(x_n) \to \phi(x)$ for every ϕ. This is a genuine loosening—it tests convergence one scalar reading at a time rather than all at once in the norm—and the whole payoff, to be delivered by Banach–Alaoglu, is that bounded sets recover under it the compactness they lost. The same loosening applies in two guises according to whether the sequence in question lives in X (test it against X^*) or already in the dual X^* (test it against X), and we name both.

Definition 2.14 (Weak and weak-$*$ convergence)**.** Let X be a Banach space with dual X^*.

- A sequence $x_n \in X$ *converges weakly* to x, written $x_n \rightharpoonup x$, if $\phi(x_n) \to \phi(x)$ for every $\phi \in X^*$.
- A sequence $\phi_n \in X^*$ *converges weakly-$*$* to ϕ, written $\phi_n \overset{*}{\rightharpoonup} \phi$, if $\phi_n(x) \to \phi(x)$ for every $x \in X$.

These are the topologies of pointwise convergence on X^* and on X respectively. In a Hilbert space, by Riesz representation, weak convergence reads $\langle x_n, y\rangle \to \langle x, y\rangle$ for every $y \in H$, and weak and weak-$*$ coincide.

The coincidence in the Hilbert case deserves a moment, because it is the only case the book's existence proofs ever invoke and it erases a distinction that is otherwise essential. In general X and X^* are different spaces, so weak convergence (of vectors in X, tested against X^*) and weak-$*$ convergence (of functionals in X^*, tested against X) are different notions living on opposite sides of the duality; they can be compared only inside the double dual X^{**}, and they agree exactly when X is reflexive. A Hilbert space is its own dual through Riesz representation (theorem 2.6), so the two sides fold onto one another and weak convergence becomes the single transparent statement $\langle x_n, y\rangle \to \langle x, y\rangle$ for every fixed field y. It pays to see at once that this is *strictly* weaker than norm convergence, and the cleanest witness is an orthonormal sequence. If $\{e_n\}$ is orthonormal, then for any fixed y Bessel's inequality (theorem 2.8) makes $\sum_n |\langle y, e_n\rangle|^2 \le \|y\|^2$ finite, so its terms must tend to zero, $\langle e_n, y\rangle \to 0$; thus $e_n \rightharpoonup 0$. Yet $\|e_n\| = 1$ for every n, so e_n does *not* converge to 0 in norm—indeed $\|e_n - e_m\| = \sqrt{2}$ for $n \neq m$, the very half-separation Riesz's lemma produced. The weak limit 0 has strictly smaller norm than every term of the sequence: under weak convergence mass can leak away. This one example already carries the warning that will organize the rest of the section—weak limits are slippery, the norm is only *lower* semicontinuous rather than continuous along them, and nonlinear quantities need not pass to the limit at all—and we will return to it when we distill the existence motif at the section's end.

Remark 2.15 (Three distinct "weak" words)**.** The single word "weak" is about to do triple duty across this book, and because all three of its uses are load-bearing and recur to the very end, we fix the bookkeeping once and post it as a permanent signpost. There are three arenas. *(i) The weak and weak-$*$ operator topologies* just defined: convergence of vectors or of functionals tested against the dual, written $x_n \rightharpoonup x$ and $\phi_n \overset{*}{\rightharpoonup} \phi$, the subject of the present section. *(ii) The weak convergence of probability measures* of chapter 3, written $\mu_n \Rightarrow \mu$: convergence of measures tested against bounded continuous functions, $\int f \, \mathrm{d}\mu_n \to \int f \, \mathrm{d}\mu$, the notion already met in definition 1.33 and used there to make sense of empirical measures collapsing onto a limit law. *(iii) The weak derivative* of section 2.6, written with ∂^{w}: a function's derivative defined not pointwise but through integration against smooth, compactly supported test functions, the move that lets us differentiate a value function the Hamilton–Jacobi–Bellman equation refuses to differentiate classically. All three are instances of one organizing idea—replace a strong, direct requirement by its *tested* action against a class of probe objects, trading a demand that is hard to verify head-on for a family of scalar checks that is easy—which is exactly why the same adjective attached itself to each. But they live on different spaces and probe with different test classes (bounded functionals, bounded continuous functions, smooth bumps), and they are emphatically not interchangeable: a sequence can converge in one of these senses while diverging in another. We therefore keep the symbols $\rightharpoonup$, $\Rightarrow$, and ∂^{w}

rigidly distinct throughout, so the reader can always read off which arena is in play, and chapter 3 will credit definition 1.33 when it resumes the measure-theoretic strand.

With the weak-$*$ topology in hand we can state the theorem the whole section was built to reach. It delivers exactly what Riesz's lemma denied us in the norm topology: that the closed unit ball of a dual space, though never norm-compact, becomes compact the moment we pass to the weak-$*$ topology. The trade is now visible in full. Compactness was lost when the topology was strong enough to keep the half-separated sequence apart; it is bought back by making the topology coarse enough that those same vectors are forced to accumulate. The coarser the topology, the easier it is for a set to be compact—fewer open covers to survive—and weak-$*$ is precisely coarse enough.

Theorem 2.16 (Banach–Alaoglu)**.** *Let X be a Banach space. The closed unit ball $B_{X^*} = \{\phi \in X^* : \|\phi\| \leq 1\}$ is compact in the weak-$*$ topology. If X is separable, B_{X^*} is in addition weak-$*$* sequentially *compact and metrizable.*

Proof. The two claims call for two different arguments, and we give each in full because the book uses them differently. The general statement rests on Tychonoff's theorem—the one ingredient in this chapter that genuinely sits above our prerequisite line, which we flag honestly and quarantine—while the separable refinement, the only form the book's existence proofs ever call on, needs nothing beyond a diagonal extraction the reader already half knows.

The general statement, via Tychonoff. The idea is to regard a functional as nothing more than the table of its values, and to recognize that table as a single point in a product of compact intervals. To each $\phi \in B_{X^*}$ associate the tuple of all its readings, $\Phi(\phi) = (\phi(x))_{x\in X}$. Because $\|\phi\| \leq 1$, each reading is confined to its own compact interval, $\phi(x) \in [-\|x\|, \|x\|]$, so Φ carries B_{X^*} into the product cube $P = \prod_{x\in X}[-\|x\|, \|x\|]$. This P is a product of compact spaces and is therefore compact in the product topology—and this is the sole place the argument exceeds the prerequisites, for an *uncountable* product of compacta is compact only by Tychonoff's theorem, whose proof runs through the Alexander subbase lemma and the axiom of choice. *We quote Tychonoff as a black box and record its proof in appendix B.3.* Two things now remain, and both are elementary. First, the product topology on P—the topology of coordinatewise convergence—restricts on the image $\Phi(B_{X^*})$ to *exactly* the weak-$*$ topology, because a net of functionals converges coordinatewise precisely when $\phi_\alpha(x) \to \phi(x)$ for every x, which is verbatim the definition of weak-$*$ convergence. Second, the image $\Phi(B_{X^*})$ is closed in P: a point $(t_x)_{x\in X}$ of P is the table of a *linear* functional if and only if it satisfies, for every pair x, x' and scalars a, b, the relation $t_{ax+bx'} = a\,t_x + b\,t_{x'}$, and each such relation cuts out a closed subset of P (it is the zero set of a continuous combination of three coordinate projections); intersecting all of these closed conditions—together with the norm bound already baked into the cube—leaves exactly the tables of functionals in B_{X^*}. A closed subset of a compact space is compact, so B_{X^*} is weak-$*$ compact, which is the first claim. We stress once more that the separable case below avoids Tychonoff entirely, so a reader unwilling to grant the axiom of choice loses nothing the book actually uses.

The separable statement, via diagonal extraction. Suppose now X is separable and fix a countable dense set $\{x_k\}_{k\geq 1} \subseteq X$. We prove sequential compactness by hand, first building one subsequence that converges against every x_k, then promoting that to convergence against every $x \in X$. Let

$\phi_n \in B_{X^*}$ be any sequence. Probe it first at x_1: the scalars $\phi_n(x_1)$ all lie in the compact interval $[-\|x_1\|, \|x_1\|]$, so by Bolzano–Weierstrass some subsequence, call it $\phi_n^{(1)}$, has $\phi_n^{(1)}(x_1)$ convergent. Probe *that* subsequence at x_2: its values $\phi_n^{(1)}(x_2)$ are again bounded, so a further subsequence $\phi_n^{(2)}$ makes $\phi_n^{(2)}(x_2)$ converge while—being a subsequence of the previous one—keeping $\phi_n^{(2)}(x_1)$ convergent as well. Continuing, we obtain nested subsequences $\phi_n^{(1)} \supseteq \phi_n^{(2)} \supseteq \cdots$, the k-th of which converges when tested against each of $x_1, \ldots, x_k$. No single one of these subsequences handles *all* the x_k at once; the standard remedy is to slide down the diagonal. Set $\psi_j := \phi_j^{(j)}$, the j-th term of the j-th subsequence. For each fixed k, the tail $(\psi_j)_{j \geq k}$ is a subsequence of $\phi_n^{(k)}$ (this is exactly what the nesting buys us), so $\psi_j(x_k)$ converges—and this holds for every k simultaneously.

We now have convergence on the dense set; the boundedness $\|\psi_j\| \leq 1$ is what lets us spread it to all of X, by a three-ε argument. Fix any $x \in X$ and $\varepsilon > 0$, and use density to pick x_k with $\|x - x_k\| < \varepsilon$. For any two indices i, j, split the difference through the nearby point x_k:

$$|\psi_i(x) - \psi_j(x)| \ \leq \ |\psi_i(x) - \psi_i(x_k)| + |\psi_i(x_k) - \psi_j(x_k)| + |\psi_j(x_k) - \psi_j(x)| \, .$$

The two outer terms are each at most $\|\psi\| \ \|x - x_k\| \leq \varepsilon$ by the operator-norm bound, and the middle term tends to 0 as $i, j \to \infty$ because $\psi(x_k)$ converges; hence $\limsup_{i,j\to\infty} |\psi_i(x) - \psi_j(x)| \leq 2\varepsilon$. As $\varepsilon > 0$ was arbitrary, $(\psi_j(x))_j$ is Cauchy in $\mathbb{R}$ and so converges; call its limit $\phi(x)$. The limit functional inherits both of the properties that matter from the ψ_j: passing the linearity relation $\psi_j(ax + bx') = a\psi_j(x) + b\psi_j(x')$ to the limit shows ϕ is linear, and passing $|\psi_j(x)| \leq \|x\|$ to the limit shows $|\phi(x)| \leq \|x\|$, so $\phi \in B_{X^*}$ and $\psi_j \xrightarrow{*} \phi$. This is weak-∗ sequential compactness.

Finally, metrizability on the ball. Define $d(\phi, \psi) = \sum_{k\geq 1} 2^{-k} \min\bigl(1, |\phi(x_k) - \psi(x_k)|\bigr)$. The series converges (it is dominated termwise by $\sum_k 2^{-k}$), and d is a genuine metric: it is symmetric and satisfies the triangle inequality coordinatewise, and it separates points because $\{x_k\}$ is dense, so two functionals agreeing at every x_k agree everywhere. Convergence in d is exactly coordinatewise convergence against all the x_k, which—by the same three-ε argument, now run on the bounded set B_{X^*}—is weak-∗ convergence there. So on B_{X^*} the weak-∗ topology is induced by a metric, and the sequential compactness just established is honest compactness. Full details are in [31, Ch. 3] and [113, Ch. IV]. □

The separable case is the workhorse: it converts a uniform bound into an honest convergent subsequence, and that conversion is the engine of every compactness argument to come. We package the consequence the book leans on relentlessly as a named corollary.

Corollary 2.17 (Bounded sequences have weakly convergent subsequences)**.** *If H is a separable Hilbert space, every bounded sequence has a weakly convergent subsequence. More generally this holds in any reflexive Banach space X (one for which the canonical embedding $X \hookrightarrow X^{**}$ is onto). The reader may keep in mind the example L^p, $1 < p < \infty$, which is reflexive (this rests on $(L^p)^* = L^{p'}$ and uniform convexity, [31, Ch. 4]); we record it only as an aside, since the chapter's load-bearing use is exclusively the separable-Hilbert case.*

Proof. We take the Hilbert case first, since it is immediate and is the only one the book actually spends. A Hilbert space H is reflexive—it is its own dual by Riesz representation (theorem 2.6), so the canonical embedding $H \hookrightarrow H^{**}$ is onto. Given a bounded sequence (x_n) in a *separable* H, view it inside $H = (H^*)^*$ as a bounded sequence of *functionals* on the separable space H^*. The separable case of theorem 2.16 now applies verbatim: a subsequence converges weak-$*$ in $(H^*)^*$, which—because $H^* = H$ via Riesz—is exactly weak convergence in H. That is the entire content of the Hilbert statement.

For the general reflexive version we reduce to this core, and the reduction is worth seeing, because it makes plain that the hypothesis doing the real work is *separability*, not reflexivity by itself. Let (x_n) be bounded in a reflexive Banach space X, which we do not assume separable; we instead manufacture a separable subspace that carries the whole sequence. Put $X_0 = \overline{\operatorname{span}}\,\{x_n\}$, the closed linear span of the terms. This X_0 is *separable*, because the finite combinations of the x_n with rational coefficients form a countable dense subset; and it is *reflexive*, because a closed subspace of a reflexive space is reflexive. A separable reflexive space has *separable dual* X_0^* (reflexivity transports separability from $X_0 = X_0^{**}$ back down to X_0^*). Now repeat the Hilbert paragraph with X_0 in the role of H: the sequence (x_n), sitting inside $X_0 = (X_0^*)^*$, is a bounded family of functionals on the separable space X_0^*, so by the separable case of theorem 2.16 a subsequence x_{n_k} converges weak-$*$ in $(X_0^*)^*$, that is, weakly in X_0, to some x_*. It remains to lift this from the subspace to all of X: every functional $\phi \in X^*$ restricts to an element of X_0^*, so the weak convergence in X_0 gives $\phi(x_{n_k}) \to \phi(x_*)$ for *every* $\phi \in X^*$, i.e. $x_{n_k} \rightharpoonup x_*$ in X. No appeal to Hahn–Banach is needed at this step: each $\phi \in X^*$ is simply evaluated on the points $x_{n_k}, x_* \in X_0$ through its restriction $\phi|_{X_0}$, so $\phi(x_{n_k}) = \phi|_{X_0}(x_{n_k}) \to \phi|_{X_0}(x_*) = \phi(x_*)$; surjectivity of the restriction map plays no role here. The fully general reflexive statement, with *no* passage to a separable subspace, is the Eberlein–Šmulian theorem [31, Ch. 3]; we never need it, because every space the book actually uses—separable Hilbert spaces, and L^p over a separable measure space—is separable, and there the reduction just carried out is exact. □

Heuristic (non-rigorous)

We can now state the motif that every compactness-based existence proof in this book instantiates, and that the reader should carry forward as a fixed template. It has three beats. *(i) Bound.* Produce an a priori estimate: show that the approximating sequence x_n—Galerkin truncations of a PDE, iterates of a best-response map, regularized solutions—stays inside a fixed ball, $\|x_n\| \le C$, with C independent of n. This is invariably the analytically substantive beat; it is some energy inequality, maximum principle, or entropy bound, and producing it is where the structure of the particular problem enters. It is worth saying once and remembering: *every* compactness in this book is, at bottom, such an a priori estimate wearing a topological costume. We will meet the same fact dressed three more ways—as Hilbert–Schmidt summability of a kernel (section 2.4), as the Rellich–Kondrachov embedding (section 2.6), and as Schauder's hypothesis that a map sends a set into a compact one (theorem 2.38)—and each time the compactness will turn out to be a bound in disguise.
(ii) Extract. Feed the bound into Banach–Alaoglu (corollary 2.17): the ball is weak-$*$ compact—in a Hilbert space, weakly sequentially compact—so a subsequence $x_{n_k} \rightharpoonup x_*$ converges to some candidate limit. This beat is now automatic; it is the entire content of the theorem just proved, and it costs nothing beyond the bound from beat (i). The limit x_* exists and lives in the right space. What it *is* remains to be seen.

(iii) Identify. Show that the weak limit x_* actually solves the equation. Here the difficulty migrates, and this is exactly why the first two beats, easy as they have become, do not finish the job. Weak convergence is treacherous under anything nonlinear: from $x_{n_k} \rightharpoonup x_*$ one cannot in general conclude $f(x_{n_k}) \rightharpoonup f(x_*)$ for a nonlinear f, nor that a product $x_{n_k} y_{n_k}$ tends to $x_* y_*$; and even the norm is only lower semicontinuous, $\|x_*\| \leq \liminf_k \|x_{n_k}\|$, never guaranteed to be preserved—the orthonormal sequence $e_n \rightharpoonup 0$ with $\|e_n\| = 1$ from earlier in the section is the standing reminder that mass can vanish in the limit. So passing the equation to the limit requires the maps appearing in it to be *weakly* (sequentially) continuous, or, where only an inequality is at stake, weakly lower semicontinuous. For bounded *linear* maps weak continuity is automatic; the obstruction is precisely the nonlinear terms and the merely-bounded bilinear ones, and overcoming it is the genuine labor of every existence proof in the book.

The decisive question is therefore which maps upgrade the weak convergence handed to us in beat (ii) back into the strong, norm convergence that nonlinear terms need before they will pass to the limit. There is a single class of operators with exactly this property—they turn weakly convergent sequences into strongly convergent ones—and they are important enough that the next section is built around them. They are the *compact* operators, and the fact that the graphon operator $\mathbb{W}$ is one of them is what will make beat (iii) tractable wherever it appears, and what makes Schauder's fixed-point theorem (theorem 2.38) applicable at all.

2.4 Compact and Hilbert–Schmidt operators

The heuristic that closed the last section ended on a precise promise, and this section is where we keep it. The three-beat template—bound, extract, identify—left us stranded at the third beat: Banach–Alaoglu hands us a weak limit for free, but weak convergence is too weak to survive the nonlinear and bilinear terms that every equation in the book contains, so to finish an existence proof we must upgrade that weak convergence back into the strong, norm convergence those terms require. The heuristic named the maps that perform exactly this upgrade, the ones that send a weakly convergent sequence to a strongly convergent image, and promised a section built around them. Here it is. The operators in question are the *compact* operators, and the burden of this section is twofold: to prove that they really do convert weak convergence to strong—so the qualitative property the existence proofs lean on becomes a theorem rather than a slogan—and then to locate, inside the compact operators, the concrete computable subclass that the integral operators of this book actually inhabit.

That two-part burden is worth making explicit before either half is discharged, because it explains why the section needs two subsections rather than one. The two notions answer two different questions. *Compactness* is the *qualitative* property existence demands: it is defined purely by what the operator does to bounded sets—it crushes them into relatively compact ones—and that single abstract feature is precisely what licenses the weak-to-strong upgrade and, downstream, makes Schauder's fixed-point theorem (theorem 2.38) applicable. It asks nothing about how the operator is presented and gives nothing one could compute. *Hilbert–Schmidt* is the *quantitative* answer to the complementary question: of the compact operators, which ones do our integral kernels actually furnish, and can we certify membership by a number we can evaluate? It is a strictly smaller class, carved out by a finite sum-of-squares condition that, for an integral operator, turns out to be nothing more than square-integrability of its kernel—the very condition $W \in L^2([0,1]^2)$ that the graphon satisfies by construction. So compactness is the property we *need* and Hilbert–Schmidt is the property we can *check*; the first subsection establishes the former and the inclusion that every Hilbert–Schmidt operator is compact, and the second pins down the latter and uses it to place the graphon operator $\mathbb{W}$ in the class where the spectral theorem of section 2.5 can finally act on it.

We take the two in that order. The compact-operator subsection makes the weak-to-strong upgrade a theorem; the Hilbert–Schmidt subsection identifies L^2 kernels with a computable subclass of compact operators and exhibits the graphon as its first concrete inhabitant.

2.4.1 Compact operators

The compact operators are those that turn a weakly convergent sequence into a strongly convergent one—named in the heuristic but not yet defined, and the present subsection pays that promissory note. We give the definition the upgrade rests on, show that the two ways of phrasing it coincide, and then prove the upgrade itself as a theorem—so that "compact operators convert weak to strong," the slogan we leaned on to motivate the whole weak-topology detour, becomes a result with a proof. Along the way we record the two structural facts the rest of the chapter consumes: that the compact operators are closed under operator-norm limits, and that they form a two-sided ideal. The first of these is what the next subsection uses to certify that Hilbert–Schmidt operators are compact; the second is part of the standing furniture of operator theory.

The definition isolates a single demand on what an operator does to bounded sets. A bounded operator is, by definition, one that does not blow boundedness up—it sends bounded sets to bounded sets. A *compact* operator does strictly more: it sends bounded sets to sets that are not merely bounded but *precompact*, sets whose closure is compact. In infinite dimensions this is a genuine strengthening, because the closed unit ball is bounded but *never* compact (that failure was the whole reason the weak topology had to be invented in section 2.3); demanding that T crush every bounded set into a compact one is therefore a real restriction, and it is exactly the restriction that buys back the sequential extraction that strong topology denies.

Definition 2.18 (Compact operator)**.** Let X, Y be Banach spaces. An operator $T \in \mathcal{B}(X, Y)$ is *compact* if it maps bounded sets to relatively compact sets: the closure of $T(B_X)$ is compact in Y, where B_X is the closed unit ball of X. Equivalently, for every bounded sequence x_n the image Tx_n has a norm-convergent subsequence.

The two formulations in the definition deserve a word, because the equivalence is what lets us move freely between a topological statement about sets and a sequential statement about extracting limits—and it is the sequential form that all the analysis below actually uses. The bridge is the metric-space fact that compactness and sequential compactness coincide: in a metric space a set is compact iff every sequence in it has a subsequence converging to a point of the set.

Suppose first that $\overline{T(B_X)}$ is compact, and let (x_n) be bounded, say $\|x_n\| \le R$; then each Tx_n lies in $T(RB_X) = RT(B_X)$, a scaling of a precompact set and hence itself precompact, so the sequence (Tx_n) lives in a compact closure and has a norm-convergent subsequence. Conversely, if every bounded sequence has an image subsequence that converges, take any sequence (y_k) in $T(B_X)$; writing $y_k = Tx_k$ with $\|x_k\| \le 1$, the hypothesis gives a subsequence Ty_{k_j} converging in Y, so every sequence in $T(B_X)$ has a convergent subsequence, which is precisely sequential—hence topological—compactness of the closure (completeness of Y guarantees the limit exists in Y and lands in the closure). The two phrasings are therefore interchangeable, and we use whichever is convenient, most often the sequential one.

We can now keep the promise of the previous section: a compact operator is exactly a machine that repairs the defect of weak convergence, returning strong convergence on the other side.

Proposition 2.19 (Compact operators upgrade weak to strong)**.** *Let X, Y be Banach spaces and $T \in \mathcal{B}(X, Y)$ compact. If $x_n \rightharpoonup x$ in X, then $Tx_n \to Tx$ in the norm of Y.*

Proof. The argument has two moving parts, and the whole subtlety is that they pull in opposite directions until compactness reconciles them: weak convergence pins down what the strong limit *must* be if one exists, while compactness guarantees that one *does* exist along subsequences.

The weak limit pins the only candidate. A weakly convergent sequence is norm-bounded—this is the uniform-boundedness consequence recorded in section 2.3—so $\sup_n \|x_n\| < \infty$. Moreover bounded linear maps are automatically continuous from the weak topology of X to the weak topology of Y: for any functional $\phi \in Y^*$ the composition $\phi \circ T$ lies in X^*, so $x_n \rightharpoonup x$ gives $\phi(Tx_n) = (\phi \circ T)(x_n) \to (\phi \circ T)(x) = \phi(Tx)$, which is exactly the statement $Tx_n \rightharpoonup Tx$. Thus *if* some subsequence Tx_{n_k} converges in norm to a limit y, then it also converges weakly to y (norm convergence implies weak convergence), while the line just proved forces $Tx_{n_k} \rightharpoonup Tx$; weak limits are unique, so $y = Tx$. Every norm-convergent subsequence of (Tx_n) therefore has the *same* limit, namely Tx.

Compactness supplies a strong limit. Because (x_n) is bounded, compactness of T (definition 2.18, sequential form) guarantees that every subsequence of (Tx_n) has a further subsequence converging in norm—necessarily to Tx by the previous paragraph. Now invoke the elementary metric-space principle that a sequence converges to L iff every subsequence has a further subsequence converging to L: were $Tx_n \not\to Tx$, some $\varepsilon > 0$ and some subsequence would keep $\|Tx_{n_k} - Tx\| \ge \varepsilon$, yet that subsequence still has a sub-subsequence converging to Tx, a contradiction. Hence $Tx_n \to Tx$ in norm. □

This is the property the existence machinery of the book actually consumes. Whenever a self-consistent-field iteration produces only a weak limit at beat (ii), feeding that limit through a compact operator restores the norm convergence that the nonlinear and bilinear terms demand at beat (iii); and it is the same compactness, in its set-theoretic guise, that will make the image of Schauder's map relatively compact and so make theorem 2.38 applicable. The graphon operator $\mathbb{W}$ will be compact, so this upgrade is available everywhere it appears.

Two structural facts about the class of compact operators remain, and we prove the one we will soon cite. The compact operators form a *closed two-sided ideal* in $\mathcal{B}(X)$: they are a subspace closed under operator-norm limits, and pre- or post-composing a compact operator with any bounded operator leaves it compact. Closedness is the fact the Hilbert–Schmidt subsection needs, so we give its $\varepsilon/3$ proof in full rather than as a slogan.

Proposition 2.20 (Compact operators are operator-norm closed)**.** *If $T_n \in \mathcal{B}(X,Y)$ are compact and $T_n \to T$ in operator norm, then T is compact.*

Proof. Let (x_k) be any sequence with $\|x_k\| \le R$; we must produce a norm-convergent subsequence of (Tx_k). We build it in three steps.

Step 1 (diagonal extraction). Since T_1 is compact, (T_1x_k) has a convergent subsequence; record its index set and pass to it. Inside that subsequence (T_2x_k) again has a convergent subsequence, by compactness of T_2; pass to it. Continuing and taking the diagonal subsequence, which we relabel (x_k), yields a single subsequence along which T_nx_k converges, hence is Cauchy in k, *for every fixed* n simultaneously.

Step 2 (the $\varepsilon/3$ split). Fix $\varepsilon > 0$. Choose n so large that $\|T - T_n\| < \varepsilon/(3R)$, possible because $T_n \to T$ in operator norm. For this n and any indices k, k', insert $\pm T_nx_k$ and $\pm T_nx_{k'}$ and apply the triangle inequality:

$$\|Tx_k - Tx_{k'}\| \le \|(T-T_n)x_k\| + \|T_nx_k - T_nx_{k'}\| + \|(T_n - T)x_{k'}\| \le 2R\,\|T - T_n\| + \|T_nx_k - T_nx_{k'}\|\,.$$

The first and third terms together are at most $2R\,\|T - T_n\| < \frac{2}{3}\varepsilon$.

Step 3 (the middle term). With n now fixed, Step 1 makes $(T_nx_k)_k$ Cauchy, so there is N with $\|T_nx_k - T_nx_{k'}\| < \varepsilon/3$ for all $k, k' \ge N$. Combining the two bounds, $\|Tx_k - Tx_{k'}\| < \varepsilon$ for $k, k' \ge N$. Hence (Tx_k) is Cauchy along the diagonal subsequence, and since Y is complete it converges. So T maps the bounded sequence (x_k) to a sequence with a convergent subsequence, which is compactness. $\square$

The ideal property is quicker and uses no completeness. If T is compact and $S, U \in \mathcal{B}$, then STU is compact: U sends a bounded set to a bounded set, T sends that to a relatively compact set, and the continuous map S sends a relatively compact set to a relatively compact one (a continuous image of a compact set is compact). Taking U or S to be the identity covers both one-sided cases, so the compacts absorb bounded operators from either side—a two-sided ideal. Finally, *finite-rank operators are compact*: if $\dim T(X) < \infty$, then $T(B_X)$ is a bounded subset of a finite-dimensional space, hence relatively compact by Heine–Borel. This last fact, combined with the closedness just proved, is precisely what the next subsection needs: any operator that is an operator-norm limit of finite-rank operators is compact.

One honest caveat closes the subsection. On a Hilbert space the converse of that last observation also holds—*every* compact operator is a norm-limit of finite-rank ones [113, Ch. VI]—which makes "compact" and "finite-rank-approximable" the same notion there. That converse is genuinely deeper, and we do not need it: every operator we will actually certify as compact, the graphon operator chief among them, arrives already exhibited as a finite-rank limit, so the easy direction suffices throughout. We therefore take only what we have proved—compactness upgrades weak to strong, the class is a closed ideal, and finite-rank limits are compact—into the next subsection, where these qualitative facts are made quantitative: the compact operators we meet in this book are integral operators, and almost all of them belong to a strictly smaller, computable class whose membership is certified by a single finite number.

2.4.2 Hilbert–Schmidt operators and integral kernels

The previous subsection left compactness as a qualitative property: a compact operator crushes bounded sets into precompact ones, it upgrades weak convergence to strong, and it is certified compact the moment it is exhibited as an operator-norm limit of finite-rank maps. That is exactly the structural inheritance the graphon operator will need. But it is a *yes/no* property, and the operators this book actually meets carry more information than a yes/no answer can record. They are not abstract compact maps produced by some existence argument; they are *integral operators*, given by an explicit kernel $K(s,t)$ that one can write down, square, and integrate. For such operators compactness is not the sharpest thing one can say. There is a finer, quantitative class—the *Hilbert–Schmidt* operators—that sits strictly inside the compact operators, that contains essentially every integral operator we will form, and whose membership is certified not by an extraction argument but by a single finite number computed from the kernel. The promise of this subsection is to make that number, and the class it defines, completely concrete: we will see that the Hilbert–Schmidt operators on $L^2(\Omega)$ are *precisely* the integral operators with square-integrable kernels, and that the correspondence is an exact isometry. Once that identification is in hand the graphon operator falls into place with no further work—it is the integral operator of a bounded, hence square-integrable, symmetric kernel—and the chapter's central object is finally certified compact and self-adjoint, which is all the spectral theorem of the next section will ask of it.

We begin with the definition that attaches the certifying number to an operator. The idea is the most naive one imaginable: in finite dimensions the size of a matrix can be measured not only by its largest singular value (the operator norm) but by the root-sum-of-squares of all its entries, the Frobenius norm $\big(\sum_{ij}|a_{ij}|^2\big)^{1/2}$. The Hilbert–Schmidt norm is nothing but the Frobenius norm carried verbatim into infinite dimensions, with the entries of T in an orthonormal basis playing the role of the matrix entries. The only subtlety—and it is the one the definition must immediately confront—is that an infinite matrix has infinitely many entries, so the root-sum-of-squares may diverge; finiteness is therefore a genuine condition, and it is exactly the condition that names the class.

Definition 2.21 (Hilbert–Schmidt operator)**.** Let H be a separable Hilbert space with orthonormal basis $\{e_n\}$. An operator $T \in \mathcal{B}(H)$ is *Hilbert–Schmidt* if

$$\|T\|_{\mathrm{HS}}^2 \;:=\; \sum_n \|Te_n\|^2 \;<\; \infty.$$

The quantity $\|T\|_{\mathrm{HS}}$ is independent of the chosen basis, dominates the operator norm, $\|T\| \le \|T\|_{\mathrm{HS}}$, and is itself the norm induced by the inner product $\langle S,T\rangle_{\mathrm{HS}} = \sum_n \langle Se_n, Te_n\rangle$, under which the Hilbert–Schmidt operators form a Hilbert space. Every Hilbert–Schmidt operator is compact.

Three claims are bundled into that definition, and each is worth drawing out, because together they are what make the Hilbert–Schmidt class so pleasant to work in—a Hilbert space of operators, sitting inside the Banach algebra of all bounded operators, on which the size of an operator is computed coordinate by coordinate exactly as Parseval computes the size of a vector.

The first claim is *basis-independence*: the number $\|T\|_{\mathrm{HS}}$ does not depend on which orthonormal basis $\{e_n\}$ is used to compute it, even though the individual summands $\|Te_n\|^2$ manifestly do. This is what entitles us to call $\|T\|_{\mathrm{HS}}$ a property of T rather than of T together with a choice of coordinates. The reason is a double application of Parseval. Expand each image Te_n in a *second* orthonormal basis $\{f_m\}$; Parseval (theorem 2.8) gives $\|Te_n\|^2 = \sum_m |\langle Te_n, f_m\rangle|^2$, so

$$\|T\|_{\mathrm{HS}}^2 = \sum_n \|Te_n\|^2 = \sum_{n,m} |\langle Te_n, f_m\rangle|^2 .$$

Every term in this double sum is nonnegative, so by Tonelli the order of summation is irrelevant and we may sum over n first. Moving the inner product onto the adjoint, $\langle Te_n, f_m\rangle = \langle e_n, T^* f_m\rangle$, and summing over n by Parseval again gives $\sum_n |\langle e_n, T^* f_m\rangle|^2 = \|T^* f_m\|^2$. Hence

$$\|T\|_{\mathrm{HS}}^2 = \sum_m \|T^* f_m\|^2 ,$$

which on the one hand is manifestly the Hilbert–Schmidt sum of T^* computed in the basis $\{f_m\}$, and on the other hand makes no reference to the original basis $\{e_n\}$. Taking $\{f_m\} = \{e_m\}$ shows $\|T\|_{\mathrm{HS}} = \|T^*\|_{\mathrm{HS}}$, and taking a general $\{f_m\}$ shows the value is the same in any basis. The same computation thus simultaneously proves basis-independence and the symmetry between T and T^*—a fact we will use the moment the graphon's self-adjointness is in play.

The second claim is *domination of the operator norm*, $\|T\| \le \|T\|_{\mathrm{HS}}$. This is what places the Hilbert–Schmidt operators inside the bounded operators and gives the certifying number teeth: controlling it controls the gain of T as well. The proof is one line of Parseval. For any unit vector x, expand it as $x = \sum_n \langle x, e_n\rangle e_n$ and apply T termwise; the triangle inequality followed by Cauchy–Schwarz on the coefficient sequence gives

$$\|Tx\| = \Big\| \sum_n \langle x, e_n\rangle Te_n \Big\| \le \sum_n |\langle x, e_n\rangle| \; \|Te_n\| \le \Big(\sum_n |\langle x, e_n\rangle|^2 \Big)^{1/2} \Big(\sum_n \|Te_n\|^2 \Big)^{1/2} = \|x\| \; \|T\|_{\mathrm{HS}} ,$$

using Parseval $\sum_n |\langle x, e_n\rangle|^2 = \|x\|^2 = 1$ in the last step. Taking the supremum over unit x yields $\|T\| \le \|T\|_{\mathrm{HS}}$. The inequality can be strict and badly so—the identity operator on an infinite-dimensional H has $\|\mathrm{Id}\| = 1$ but $\|\mathrm{Id}\|_{\mathrm{HS}}^2 = \sum_n \|e_n\|^2 = \sum_n 1 = \infty$, so the identity is bounded but emphatically *not* Hilbert–Schmidt. This is the quantitative shadow of the qualitative fact from the previous subsection that the identity is not compact in infinite dimensions: the Hilbert–Schmidt norm sees the failure as an outright divergence.

The third claim packages the Hilbert–Schmidt operators into a Hilbert space of their own. The expression $\langle S, T\rangle_{\mathrm{HS}} = \sum_n \langle Se_n, Te_n\rangle$ is, by the polarization identity applied to the basis-independent norm, itself basis-independent and is a genuine inner product (it is the ℓ^2 inner product of the two operators' coordinate arrays); its induced norm is $\|T\|_{\mathrm{HS}}$; and completeness in this norm transfers from the completeness of ℓ^2 once one knows—which the kernel theorem below will make transparent—that the coordinate array $(\langle Te_m, e_n\rangle)_{n,m}$ ranges over all of $\ell^2(\mathbb{N} \times \mathbb{N})$. So the Hilbert–Schmidt operators are not merely a subset of $\mathcal{B}(H)$ but a Hilbert space, with their own geometry: one can speak of orthogonality of operators, of best approximation within the class, of the angle between two operators. This is more structure than $\mathcal{B}(H)$ itself carries (the operator norm comes from no inner product), and it is exactly the structure that the kernel identification will reveal to be a perfect copy of the geometry of $L^2(\Omega \times \Omega)$.

The final assertion—that every Hilbert–Schmidt operator is compact—is the bridge back to the previous subsection, and it is worth seeing precisely how the finite-rank machinery cashes it out, because this is the argument that ultimately certifies the graphon compact. Order the basis and let P_N be the orthogonal projection onto $\operatorname{span}\{e_1, \dots, e_N\}$. The truncated operator $T_N := TP_N$ has range inside $T(\operatorname{span}\{e_1, \dots, e_N\})$, a space of dimension at most N, so T_N is *finite-rank*, hence compact by the last fact of the previous subsection. We claim $T_N \to T$ in operator norm. Indeed $T - T_N = T(\mathrm{Id} - P_N)$ annihilates $e_1, \dots, e_N$ and agrees with T on the orthogonal tail, so by the very domination inequality just proved, applied to the operator $T(\mathrm{Id} - P_N)$ whose only nonzero basis images are Te_n for $n > N$,

$$\|T - T_N\|^2 \leq \|T - T_N\|_{\mathrm{HS}}^2 = \sum_{n>N} \|Te_n\|^2 ,$$

and the right-hand side is the tail of the convergent series $\sum_n \|Te_n\|^2 = \|T\|_{\mathrm{HS}}^2 < \infty$, so it tends to 0 as $N \to \infty$. Thus T is an operator-norm limit of finite-rank operators, and by the closedness of the compact ideal (proposition 2.20) T is compact. The Hilbert–Schmidt condition is, in this light, simply a *quantitative* sufficient condition for compactness—a convergent root-sum-of-squares—and the explicit finite-rank truncations it supplies are precisely the kind of concrete witness the previous subsection promised we would always have in hand.

With the class understood intrinsically, we come to the identification that is the real engine of the subsection, the one that turns "Hilbert–Schmidt operator" and "integral operator with L^2 kernel" into two names for the same thing. This is what lets us read every property of the graphon operator straight off its kernel.

Theorem 2.22 (Hilbert–Schmidt operators are L^2 kernels)**.** *Let (Ω, μ) be a σ-finite measure space and $H = L^2(\Omega, \mu)$. For $K \in L^2(\Omega \times \Omega, \mu \otimes \mu)$ define, writing s, t for the two integration variables of Ω,*

$$(T_K f)(s) \;=\; \int_\Omega K(s,t)\, f(t)\; \mathrm{d}\mu(t).$$

Then T_K is a well-defined Hilbert–Schmidt operator on H with

$$\|T_K\|_{\mathrm{HS}} \;=\; \|K\|_{L^2(\Omega\times\Omega)} ,$$

and the map $K \mapsto T_K$ is an isometric isomorphism from $L^2(\Omega \times \Omega)$ onto the Hilbert–Schmidt operators on $L^2(\Omega)$. Moreover $T_K^* = T_{K^*}$ where $K^*(s,t) = \overline{K(t,s)}$; in particular T_K is self-adjoint iff $K(s,t) = \overline{K(t,s)}$ for $\mu \otimes \mu$-almost every (s,t).

The statement has four parts, and we prove them in the order in which each becomes possible: T_K is well-defined and bounded; its Hilbert–Schmidt norm equals the L^2 norm of the kernel (so the map $K \mapsto T_K$ is an isometry into the Hilbert–Schmidt class); the map is onto (every Hilbert–Schmidt operator arises this way); and the adjoint is read off by transposing-and-conjugating the kernel. The reader should keep the payoff in view throughout: an *exact* dictionary, with no constants lost, between a space of *functions of two variables* and a space of *operators*.

Proof. Well-definedness and boundedness. Fix $f \in L^2(\Omega)$. For almost every s the function $t \mapsto K(s,t)$ lies in $L^2(\Omega)$—this is Tonelli applied to the finite double integral $\iint |K|^2$, which guarantees the inner slice is square-integrable for a.e. s—so the defining integral $\int K(s,t)f(t)\,\mathrm{d}\mu(t)$ is the inner product of two L^2 functions and Cauchy–Schwarz bounds it: $|(T_K f)(s)| \le \big(\int |K(s,t)|^2\,\mathrm{d}\mu(t)\big)^{1/2}\,\|f\|$. Squaring and integrating over s,

$$\|T_K f\|^2 \le \int_\Omega \Big(\int_\Omega |K(s,t)|^2\,\mathrm{d}\mu(t)\Big)\,\|f\|^2\,\mathrm{d}\mu(s) = \|K\|^2_{L^2(\Omega\times\Omega)}\,\|f\|^2,$$

where the last equality is Fubini–Tonelli (theorem 1.27) re-reading the iterated integral of the nonnegative integrand $|K|^2$ as the double integral $\iint |K|^2$. Thus $T_K f \in L^2$, T_K is linear, and $\|T_K\| \le \|K\|_{L^2}$: a square-integrable kernel already gives a bounded operator, recovering the bound previewed in section 2.2.

The isometry $\|T_K\|_{\mathrm{HS}} = \|K\|_{L^2}$. Here the geometry of $L^2(\Omega\times\Omega)$ does the work. Fix an orthonormal basis $\{e_n\}$ of $L^2(\Omega)$ and form the two-variable products

$$E_{nm}(s,t) \;=\; e_n(s)\,\overline{e_m(t)}.$$

These are orthonormal in $L^2(\Omega\times\Omega)$, by Fubini and the separation of variables: $\langle E_{nm}, E_{n'm'}\rangle = \big(\int e_n\overline{e_{n'}}\big)\big(\int \overline{e_m}e_{m'}\big) = \delta_{nn'}\delta_{mm'}$. The crux—and the densest point of the whole proof—is that they are also *complete*, i.e. form an orthonormal basis of $L^2(\Omega\times\Omega)$. We establish this by a short density chain, each link of which reduces an unfamiliar density to one already in hand.

1. *Simple functions on the product are dense in $L^2(\Omega\times\Omega)$.* This is the Chapter-1 fact (proposition 1.32) that simple functions are L^2-dense in any L^2 space, applied to the product measure space $(\Omega\times\Omega, \mu\otimes\mu)$. A simple function here is a finite combination of indicators $\mathbf{1}_E$ of measurable sets $E \subseteq \Omega\times\Omega$.

2. *Product indicators are dense in product simple functions, hence in L^2.* Each measurable E in the product σ-algebra is approximated in measure (theorem 1.26) by finite disjoint unions of measurable rectangles $A\times B$, so $\mathbf{1}_E$ is approximated in L^2 by finite combinations of $\mathbf{1}_{A\times B} = \mathbf{1}_A(s)\mathbf{1}_B(t)$. Composing with the previous link, the *product simple functions*—finite sums $\sum_k g_k(s)h_k(t)$ with $g_k, h_k \in L^2(\Omega)$—are dense in $L^2(\Omega\times\Omega)$.

3. *Each factor expands in $\{e_n\}$, so $\{E_{nm}\}$ captures product functions.* It now suffices to approximate a single product $g(s)h(t)$ by finite combinations of the E_{nm}, since these products span a dense set by link 2. Because $\{e_n\}$ is an orthonormal basis of $L^2(\Omega)$, the partial sums $g_N = \sum_{n\le N}\langle g, e_n\rangle e_n \to g$ and $h_N = \sum_{m\le N}\langle h, e_m\rangle e_m \to h$ in $L^2(\Omega)$. Their product $g_N(s)\,h_N(t)$ is a finite linear combination of the functions $e_n(s)\,\overline{e_m(t)} = E_{nm}(s,t)$ (the conjugation of the second factor being absorbed into the coefficients, and harmless for the real orthonormal systems—sines and cosines, Legendre polynomials—that we actually use on $[0,1]$), and it converges to $g(s)h(t)$ in $L^2(\Omega\times\Omega)$ because

$$\|g\otimes h - g_N\otimes h_N\|_{L^2(\Omega\times\Omega)} \le \|(g-g_N)\otimes h\| + \|g_N\otimes(h-h_N)\| = \|g-g_N\|\,\|h\| + \|g_N\|\,\|h-h_N\| \to 0,$$

using the multiplicativity $\|u \otimes v\|_{L^2(\Omega\times\Omega)} = \|u\|_{L^2} \|v\|_{L^2}$ (again Fubini) and the boundedness of $\|g_N\| \leq \|g\|$.

Chaining the three links, finite combinations of the E_{nm} are dense in $L^2(\Omega \times \Omega)$, so $\{E_{nm}\}$ is an orthonormal basis. Now Parseval (theorem 2.8) in this basis computes the kernel norm coordinate by coordinate,

$$\|K\|_{L^2}^2 = \sum_{n,m} |\langle K, E_{nm}\rangle|^2 .$$

On the operator side, the same coefficients are matrix entries of T_K. Unwinding the definition with Fubini,

$$\langle K, E_{nm}\rangle = \iint K(s,t)\,\overline{e_n(s)}\,e_m(t)\,\mathrm{d}\mu(s)\,\mathrm{d}\mu(t) = \int \overline{e_n(s)}\Big(\int K(s,t)e_m(t)\,\mathrm{d}\mu(t)\Big)\,\mathrm{d}\mu(s) = \langle T_K e_m, e_n\rangle,$$

where the last step recognizes the inner integral as $(T_K e_m)(s)$ and the outer integral as the inner product $\langle T_K e_m, e_n\rangle$ (the conjugate sitting on e_n, matching our convention). Therefore, summing over n first by Parseval in $L^2(\Omega)$,

$$\|T_K\|_{\mathrm{HS}}^2 = \sum_m \|T_K e_m\|^2 = \sum_m \sum_n |\langle T_K e_m, e_n\rangle|^2 = \sum_{n,m} |\langle K, E_{nm}\rangle|^2 = \|K\|_{L^2}^2 .$$

This is the asserted isometry: the certifying number of the operator is exactly the L^2 norm of its kernel. In particular T_K is Hilbert–Schmidt (so, by definition 2.21, compact) precisely because $K \in L^2$.

Surjectivity. The isometry already shows $K \mapsto T_K$ is injective with closed range; we check the range is everything. Let T be any Hilbert–Schmidt operator and set $t_{nm} = \langle T e_m, e_n\rangle$. By the basis-independence computation above its array is square-summable, $\sum_{n,m} |t_{nm}|^2 = \|T\|_{\mathrm{HS}}^2 < \infty$, so $(t_{nm}) \in \ell^2(\mathbb{N} \times \mathbb{N})$. Since $\{E_{nm}\}$ is an orthonormal basis, the converse half of Parseval (theorem 2.8) assembles these coefficients into a genuine L^2 kernel $K = \sum_{n,m} t_{nm} E_{nm} \in L^2(\Omega \times \Omega)$, with $\|K\|_{L^2} = \|T\|_{\mathrm{HS}}$. By the matrix-entry identity just derived, $\langle T_K e_m, e_n\rangle = \langle K, E_{nm}\rangle = t_{nm} = \langle T e_m, e_n\rangle$ for all n, m, and two bounded operators with the same matrix in an orthonormal basis are equal. Hence $T = T_K$: every Hilbert–Schmidt operator is the integral operator of an L^2 kernel, and the map is onto. Together with the isometry, $K \mapsto T_K$ is the asserted isometric isomorphism of Hilbert spaces—$L^2(\Omega \times \Omega)$ *is* the Hilbert–Schmidt class, relabelled.

The adjoint. Finally we read off the adjoint. For $f, g \in L^2$, Fubini lets us move the kernel across the inner product:

$$\langle T_K f, g\rangle = \iint K(s,t) f(t)\,\overline{g(s)}\,\mathrm{d}\mu(t)\,\mathrm{d}\mu(s) = \int f(t)\,\overline{\Big(\int \overline{K(s,t)}\,g(s)\,\mathrm{d}\mu(s)\Big)}\,\mathrm{d}\mu(t) = \langle f, T_{K^*} g\rangle,$$

where $K^*(s,t) = \overline{K(t,s)}$ is the conjugate transpose of the kernel and the bracketed integral is $(T_{K^*} g)(t)$. By the defining property of the adjoint (definition 2.12), $T_K^* = T_{K^*}$. Self-adjointness $T_K = T_K^*$ is then, through the isometry's injectivity, equivalent to equality of the kernels $K = K^*$, i.e. $K(s,t) = \overline{K(t,s)}$ for $\mu \otimes \mu$-a.e. (s,t): an operator is self-adjoint exactly when its kernel is Hermitian-symmetric. We have followed the line of [113, Ch. VI, Thm. VI.23]. □

The theorem is worth pausing over, because it is the precise sense in which the analysis of integral operators *is* the analysis of two-variable L^2 functions. Everything one knows about $L^2(\Omega \times \Omega)$—it is a separable Hilbert space, its elements are approximable by simple functions, its norm is computed by Parseval—transfers verbatim to the Hilbert–Schmidt operators, and conversely the operator-theoretic content (compactness, the spectral structure to come) becomes a statement about kernels. The self-adjointness criterion is the link the chapter has been building toward: *symmetry of the kernel is self-adjointness of the operator*, with no analysis required beyond the one-line Fubini computation above. That is precisely the property the spectral theorem will demand, and a graphon supplies it by fiat.

We can now meet the central object of the book's operator theory and watch every clause of the theorem discharge at once.

Definition 2.23 (The graphon operator)**.** A *graphon* is a symmetric measurable function $W\colon [0,1]^2 \to \mathbb{R}$; in the basic theory it is bounded, $W\colon [0,1]^2 \to [0,1]$ (assumption (A-Reg-W) of appendix A.6). Its *integral operator* $\mathbb{W}\colon L^2[0,1] \to L^2[0,1]$ is

$$(\mathbb{W}f)(x) \;=\; \int_0^1 W(x,y)\, f(y)\, \mathrm{d}y.$$

Read against the theorem, this definition is just the instance $\Omega = [0,1]$ with μ the Lebesgue measure and the kernel $K = W$. Two features of that instance do real work and deserve to be flagged before we use them: what the integration variable *means*, and which W this is.

Notation watch

This is the first place in the body where the type variable x does mathematical work, so we recall (appendix A.5) that $x, y \in [0,1]$ are exchangeable *type / label* coordinates—an agent's kind or network position—*not* spatial positions and *not* momenta; in particular $|x-y|$ carries no intrinsic meaning, only what W assigns it. Concretely, $(\mathbb{W}f)(x)$ is the average of the field f over all labels y, weighted by the connection strength $W(x,y)$ between type x and type y; reordering the labels by any measure-preserving bijection of $[0,1]$ leaves the operator unitarily equivalent, which is the analytic face of exchangeability and the reason no metric on $[0,1]$ is built in. The letter W here is the graphon kernel, and no Brownian motion is present in this chapter, so the W-versus-W clash flagged in appendix A.5 does not arise: the disambiguation (write Brownian motion as B once a graphon is in scope) becomes binding only from Part III onward, where the two coexist. Until then W unambiguously denotes the kernel. The type variable and the operator $\mathbb{W}$ previewed here are formally introduced as a graph limit in chapter 15; here we need only that $\mathbb{W}$ is the integral operator of the kernel W, so that the kernel theorem applies to it directly.

Proposition 2.24 (The graphon operator is self-adjoint Hilbert–Schmidt)**.** *Under* (A-Reg-W) *the operator* $\mathbb{W}$ *is a self-adjoint Hilbert–Schmidt operator on* $L^2[0,1]$*, hence compact, with*

$$\|\mathbb{W}\|_{\mathrm{HS}} = \|W\|_{L^2([0,1]^2)} \le 1, \qquad \|\mathbb{W}\| \le \|\mathbb{W}\|_{\mathrm{HS}} \le 1.$$

Its spectrum is real and accumulates only at 0.

Proof. Every hypothesis the kernel theorem asks for is supplied by (A-Reg-W) and the finiteness of the type interval. First, $W \in L^2([0,1]^2)$: the kernel is bounded by 1 and $[0,1]^2$ has finite Lebesgue measure, so $\|W\|^2_{L^2([0,1]^2)} = \iint W(x,y)^2 \, \mathrm{d}x \, \mathrm{d}y \le \iint 1 \, \mathrm{d}x \, \mathrm{d}y = 1 < \infty$. By theorem 2.22, $\mathbb{W} = T_W$ is therefore Hilbert–Schmidt with $\|\mathbb{W}\|_{\mathrm{HS}} = \|W\|_{L^2([0,1]^2)} \le \|W\|_\infty \le 1$, and the operator norm is dominated by the Hilbert–Schmidt norm (definition 2.21), giving the chain $\|\mathbb{W}\| \le \|\mathbb{W}\|_{\mathrm{HS}} \le 1$. Second, self-adjointness: a graphon is by definition symmetric and real, $W(x,y) = W(y,x) = \overline{W(y,x)}$, which is exactly the Hermitian-kernel condition $K = K^*$ of the theorem, so $\mathbb{W} = \mathbb{W}^*$. Third, Hilbert–Schmidt implies compact (definition 2.21). The remaining two claims—that the spectrum is real and accumulates only at 0—are precisely the content of the spectral theorem for compact self-adjoint operators, proved in the next section; we have here established exactly the two hypotheses (compact, self-adjoint) that theorem consumes. □

It is worth dwelling on the inequality $\|\mathbb{W}\| \le \|\mathbb{W}\|_{\mathrm{HS}} = \|W\|_{L^2([0,1]^2)} \le 1$, because it is more than bookkeeping: it is the first *a priori estimate* the graphon contributes to the book's existence machinery. The bound $\|W\|_{L^2} \le 1$ is a direct quantitative consequence of the qualitative regularity assumption (A-Reg-W)—boundedness of the kernel into $[0,1]$ on a domain of unit measure—and through the kernel theorem it hands us, for free, control of the *operator* norm $\|\mathbb{W}\| \le 1$. That operator-norm control is exactly the quantity the coupling assumption (A-Coupling) of appendix A.6 regulates: the contraction-based uniqueness arguments of the later mean-field-game chapters require $\|\mathbb{W}\|$ to lie below a critical threshold, and the present proposition is what guarantees the norm is finite and computable from the kernel in the first place, so that (A-Coupling) is a condition one can actually check. The recurring pattern of the chapter is visible in miniature here: a regularity hypothesis becomes, via Hilbert–Schmidt, a hard bound on an operator, and that bound is what a downstream fixed-point argument will spend.

This proposition is the reason section 2.5 exists. The entire spectral apparatus—the network's eigenvector centrality, its spectral gap, its low-rank reductions—rests on the single fact that $\mathbb{W}$ is compact and self-adjoint [99], and the payoff is collected in chapter 18. We have now placed $\mathbb{W}$ exactly where the spectral theorem can act on it: it is the infinite-dimensional counterpart of a real symmetric matrix, compact so that its eigenvalues form a discrete sequence rather than a continuum, and self-adjoint so that those eigenvalues are real and its eigenvectors orthogonal. The next section makes good on the two claims this proof deferred—real spectrum, accumulation only at 0—by proving the spectral theorem itself, the infinite-dimensional analogue of the orthogonal diagonalization of a symmetric matrix, and reads off from it the orthonormal basis of eigenfunctions in which $\mathbb{W}$ becomes the network's mode-by-mode band structure.

2.5 The spectral theorem for compact self-adjoint operators

The previous section did its work and stopped one step short of the payoff. Proposition 2.24 placed the graphon operator $\mathbb{W}$ exactly where we wanted it: it is compact and self-adjoint, the infinite-dimensional counterpart of a real symmetric matrix, and the proof there deferred two precise claims to "the spectral theorem" without proving them—that the spectrum is *real*, and that it can *accumulate only at* 0. This section makes good on both, and in doing so converts the abstract operator into the concrete object the rest of the book reads off it.

The template is one the reader already knows from finite dimensions. A real symmetric matrix is orthogonally diagonalizable: it has a complete orthonormal set of eigenvectors, its eigenvalues are real, and in the eigenbasis the matrix is simply a list of rescalings, one per coordinate. The spectral theorem is the statement that a compact self-adjoint operator on a Hilbert space enjoys the *same* structure, with a single unavoidable amendment forced by infinite dimensionality: the eigenvalues no longer form a finite list but a sequence, and that sequence must tend to zero. The "tend to zero" is not a blemish—it is exactly compactness leaving its fingerprint on the spectrum, and it is what later licenses approximating the full coupling by a finite-rank truncation. Once proved, the theorem hands us, for $T = \mathbb{W}$, an orthonormal basis of eigenfunctions in which $\mathbb{W}$ acts diagonally—each mode rescaled by its eigenvalue—and that mode-by-mode picture is precisely the network's "band structure" that chapter 18 exploits.

Everything rests on building the eigenvalues, and we build them not by solving a characteristic equation—there is none in infinite dimensions—but by a *variational principle*: the largest eigenvalue is the largest value the quadratic form $\langle Tx, x\rangle$ takes on the unit sphere, the next is the largest value on the orthogonal complement of the first eigenvector, and so on. For this strategy to find eigenvalues at all, the maximum of the quadratic form must *equal* the operator norm; otherwise maximizing $\langle Tx, x\rangle$ would tell us nothing about how large T really is. That identity is false for a general bounded operator and true for a self-adjoint one, and it is the single algebraic fact the whole construction turns on. We isolate it first.

Lemma 2.25 (Norm via the quadratic form)**.** *If $T \in \mathcal{B}(H)$ is self-adjoint, then $\|T\| = \sup_{\|x\|=1} |\langle Tx, x\rangle|$.*

Proof. Write $M = \sup_{\|x\|=1} |\langle Tx, x\rangle|$ for the quantity on the right. One inequality is free and uses nothing about T beyond boundedness: for a unit vector x, Cauchy–Schwarz gives $|\langle Tx, x\rangle| \le \|Tx\|\,\|x\| = \|Tx\| \le \|T\|$, so taking the supremum yields $M \le \|T\|$. The whole content of the lemma is the reverse inequality $\|T\| \le M$, and this is where self-adjointness is indispensable.

First record what M buys us by homogeneity: for *every* x (not just unit vectors), $|\langle Tx, x\rangle| \le M\,\|x\|^2$, since rescaling x to unit length and back multiplies both sides by $\|x\|^2$. Now expand the quadratic form on the sum and difference of two vectors. Using bilinearity and then self-adjointness, $\langle Ty, x\rangle = \langle y, Tx\rangle = \overline{\langle Tx, y\rangle}$, the cross terms combine into twice a real part:

$$\langle T(x+y), x+y\rangle - \langle T(x-y), x-y\rangle = 2\langle Tx, y\rangle + 2\langle Ty, x\rangle = 4\,\mathrm{Re}\langle Tx, y\rangle.$$

This is the polarization identity, and *self-adjointness is exactly what made the four cross terms collapse to* $4\,\mathrm{Re}\langle Tx, y\rangle$ rather than an uncontrolled combination. Bounding each quadratic form on the left by M times the square of its argument and then applying the parallelogram law $\|x+y\|^2 + \|x-y\|^2 = 2\,\|x\|^2 + 2\,\|y\|^2$,

$$4\;|\mathrm{Re}\langle Tx, y\rangle| \le M\big(\,\|x+y\|^2 + \|x-y\|^2\,\big) = 2M\big(\,\|x\|^2 + \|y\|^2\,\big),$$

so $|\mathrm{Re}\langle Tx, y\rangle| \le \frac{M}{2}(\|x\|^2 + \|y\|^2)$. Specialize to $\|x\| = \|y\| = 1$, where the right-hand side is just M. The bound holds for every unit y, so we are free to choose the one that makes the left-hand side as large as possible: if $Tx \neq 0$, take $y = Tx/\|Tx\|$, the unit vector aligned with Tx, for which $\mathrm{Re}\langle Tx, y\rangle = \|Tx\|$. That choice turns the inequality into $\|Tx\| \leq M$ for every unit x (trivially true when $Tx = 0$), and the supremum over unit x gives $\|T\| \leq M$. The two inequalities together are the claimed equality. □

The lemma is the lever for the entire construction: it says that to locate the largest-magnitude eigenvalue of a self-adjoint operator it suffices to maximize the real scalar quantity $\langle Tx, x\rangle$ over the unit sphere—a genuine optimization problem, the kind compactness is built to solve. The theorem now turns that single maximization into a complete diagonalization by iterating it.

Theorem 2.26 (Spectral theorem, compact self-adjoint operators)**.** *Let H be a separable real (or complex) Hilbert space and $T \in \mathcal{B}(H)$ a nonzero compact self-adjoint operator. Then there is a finite or countably infinite orthonormal system $\{e_n\}$ of eigenvectors of T, with corresponding real eigenvalues $\{\lambda_n\}$ satisfying*

$$|\lambda_1| \geq |\lambda_2| \geq \cdots > 0, \qquad \lambda_n \to 0 \ \text{ if the system is infinite,}$$

such that

$$Tx \;=\; \sum_n \lambda_n \langle x, e_n\rangle\, e_n \qquad \text{for all } x \in H,$$

the series converging in H. Each nonzero eigenvalue has finite-dimensional eigenspace, the only possible accumulation point of the eigenvalues is 0, and $H = \ker T \;\oplus\; \overline{\operatorname{span}}\{e_n\}$ orthogonally. Equivalently, H has an orthonormal basis of eigenvectors of T (adjoining any orthonormal basis of $\ker T$).

Proof sketch. The mechanism is iterated maximization of the quadratic form, with compactness supplying the maximizers at each stage. We give the argument in full in the real case; the only piece genuinely deferred is the complex case, noted at the end.

Step 1: produce the first eigenvalue and eigenvector. By lemma 2.25, $\|T\| = \sup_{\|x\|=1} |\langle Tx, x\rangle|$, so there is a maximizing sequence x_k with $\|x_k\| = 1$ and $|\langle Tx_k, x_k\rangle| \to \|T\|$. Each $\langle Tx_k, x_k\rangle$ is a real number in $[-\|T\|, \|T\|]$ (real by self-adjointness), and its absolute value approaches the endpoint $\|T\|$; hence one of the two values $+\|T\|$, $-\|T\|$ is approached along an infinite subsequence. Pass to that subsequence and call the limit λ_1, so $\langle Tx_k, x_k\rangle \to \lambda_1$ with $|\lambda_1| = \|T\| > 0$ (the operator is nonzero by hypothesis).

The sequence (x_k) is bounded, living on the unit sphere, so corollary 2.17—the Hilbert-space form of Banach–Alaoglu—lets us extract a weakly convergent subsequence $x_k \rightharpoonup e_1$. This is where compactness is spent: a compact operator turns weak convergence into strong convergence of images, so $Tx_k \to Te_1$ *strongly.* Weak convergence alone would leave Tx_k only weakly convergent and the argument would stall; compactness is exactly the upgrade that makes it run. Now the self-adjoint computation that pins down e_1. Expanding the square and using $\|x_k\| = 1$,

$$\|Tx_k - \lambda_1 x_k\|^2 = \|Tx_k\|^2 - 2\lambda_1\langle Tx_k, x_k\rangle + \lambda_1^2.$$

The first term obeys $\|Tx_k\|^2 \leq \|T\|^2 = \lambda_1^2$, so the right-hand side is at most $2\lambda_1^2 - 2\lambda_1\langle Tx_k, x_k\rangle = 2\lambda_1(\lambda_1 - \langle Tx_k, x_k\rangle) \to 0$ as $\langle Tx_k, x_k\rangle \to \lambda_1$. Hence $Tx_k - \lambda_1 x_k \to 0$ strongly. Combining with

$Tx_k \to Te_1$ gives $\lambda_1 x_k = Tx_k - (Tx_k - \lambda_1 x_k) \to Te_1$, and since $\lambda_1 \neq 0$ we may divide: $x_k \to \lambda_1^{-1} Te_1$ *strongly.* A strong limit must agree with the weak limit e_1, so $e_1 = \lambda_1^{-1} Te_1$, that is $Te_1 = \lambda_1 e_1$; and strong convergence preserves norm, so $\|e_1\| = \lim \|x_k\| = 1$. Thus e_1 is a genuine unit eigenvector and its eigenvalue λ_1 has the largest possible modulus, $|\lambda_1| = \|T\|$.

Step 2: peel off and iterate. The subspace $e_1^\perp$ is *invariant* under T, and this is again self-adjointness at work: if $\langle x, e_1\rangle = 0$ then $\langle Tx, e_1\rangle = \langle x, Te_1\rangle = \lambda_1 \langle x, e_1\rangle = 0$, so $Tx \in e_1^\perp$. The restriction $T|_{e_1^\perp}$ is the restriction of a compact self-adjoint operator to a closed invariant subspace, hence is itself compact and self-adjoint, and Step 1 applies to it verbatim, producing a unit eigenvector $e_2 \in e_1^\perp$ (so $e_2 \perp e_1$) with eigenvalue $|\lambda_2| = \left\|T|_{e_1^\perp}\right\| \leq \|T\| = |\lambda_1|$. Iterating—at each stage restricting to $\{e_1, \dots, e_n\}^\perp$ and maximizing again—manufactures an orthonormal system $\{e_n\}$ with eigenvalues of nonincreasing modulus, $|\lambda_1| \geq |\lambda_2| \geq \cdots > 0$. The process halts at a finite stage exactly when the restricted operator becomes the zero operator (then everything left lies in $\ker T$); otherwise it runs forever and yields an infinite orthonormal sequence.

Step 3: the eigenvalues tend to zero. Suppose the system is infinite. We claim $\lambda_n \to 0$, and here is where compactness pays off a second time, now obstructing the eigenvalues from staying large. If $\lambda_n \not\to 0$, then since $|\lambda_n|$ is nonincreasing it is bounded below by some $\delta > 0$ for all n. The eigenvectors e_n are orthonormal, hence bounded, so by compactness their images $Te_n = \lambda_n e_n$ must have a convergent subsequence. But for $n \neq m$, orthonormality gives

$$\|Te_n - Te_m\|^2 = \|\lambda_n e_n - \lambda_m e_m\|^2 = \lambda_n^2 + \lambda_m^2 \geq 2\delta^2,$$

so no two of the Te_n are within $\delta\sqrt{2}$ of each other and *no* subsequence can be Cauchy. This contradiction forces $\lambda_n \to 0$. The same orthogonality-versus-compactness mechanism settles the two structural fine points the previous section had deferred. *Finite multiplicity:* were a nonzero eigenvalue λ to have an infinite-dimensional eigenspace, it would contain an infinite orthonormal sequence (f_j) with $Tf_j = \lambda f_j$, and $\|Tf_j - Tf_i\|^2 = 2\lambda^2 > 0$ for $i \neq j$ would again deny the bounded sequence (f_j) any convergent image, contradicting compactness; so each nonzero eigenspace is finite-dimensional. *No nonzero accumulation:* if distinct eigenvalues λ_{n_j} converged to some $\mu \neq 0$, their orthonormal eigenvectors would produce the identical contradiction. Hence 0 is the only possible accumulation point of the spectrum—precisely the "accumulation only at 0" that proposition 2.24 promised the spectral theorem would supply, and the reality of every λ_n is the other deferred claim, delivered by self-adjointness in Step 1.

Step 4: assemble the expansion and identify the kernel. Fix any $x \in H$ and let $r_N = x - \sum_{n \leq N} \langle x, e_n\rangle e_n$ be the Fourier remainder after N terms; by construction $r_N \perp e_1, \dots, e_N$, so r_N lies in the subspace $\{e_1, \dots, e_N\}^\perp$ on which T has norm exactly $|\lambda_{N+1}|$ (that was the defining maximization of Step 2). Therefore $\|Tr_N\| \leq |\lambda_{N+1}|\,\|r_N\| \leq |\lambda_{N+1}|\,\|x\| \to 0$, using Bessel's inequality $\|r_N\| \leq \|x\|$ and $\lambda_{N+1} \to 0$. But $Tr_N = Tx - \sum_{n \leq N} \lambda_n \langle x, e_n\rangle e_n$ by linearity and $Te_n = \lambda_n e_n$, so the partial sums $\sum_{n \leq N} \lambda_n \langle x, e_n\rangle e_n$ converge to Tx: this is the asserted expansion $Tx = \sum_n \lambda_n \langle x, e_n\rangle e_n$. Finally we identify the kernel. Let $M = \overline{\operatorname{span}}\,\{e_n\}$. If $x \in M^\perp$ then $\langle x, e_n\rangle = 0$ for all n and the expansion collapses to $Tx = 0$, so $M^\perp \subseteq \ker T$. Conversely, if $Tx = 0$ then for each n, $\lambda_n \langle x, e_n\rangle = \langle x, \lambda_n e_n\rangle = \langle x, Te_n\rangle = \langle Tx, e_n\rangle = 0$, and since $\lambda_n \neq 0$ this forces $\langle x, e_n\rangle = 0$, i.e. $x \in M^\perp$; so $\ker T \subseteq M^\perp$. The two inclusions give $\ker T = M^\perp$ and hence the orthogonal decomposition $H = \ker T \oplus \overline{\operatorname{span}}\,\{e_n\}$. Adjoining any orthonormal basis of $\ker T$ (each of whose vectors is an eigenvector with eigenvalue 0) to the $\{e_n\}$ produces an orthonormal basis of all of H consisting of eigenvectors of T, which is the diagonalization claimed.

This is the complete argument in the real case; we follow [123, Ch. 6], [31, Ch. 6], and [113, Thm. VI.16]. The only genuinely deferred piece is the *complex* case—where "self-adjoint" is read with the Hermitian conjugate of definition 2.3, and one first checks that $\langle Tx, x\rangle$ is real so that the eigenvalues come out real—which is carried out in appendix B.4. (No measurable selection enters: extracting a maximizing subsequence is ordinary sequential compactness, not a measurable-selection problem; the latter appears only later, for a *parametrized family* of operators in chapter 18.) $\square$

The variational construction does more than locate the eigenvalues one at a time; it endows each eigenvalue with a characterization that never mentions the eigenvectors. This is the comparison principle we will need in chapter 18 to read off the network's leading modes—its spectral gap, the size of its dominant band—without ever solving an eigenproblem exactly: bounding a Rayleigh quotient on a cleverly chosen subspace bounds an eigenvalue. We state it for the positive part of the spectrum; the negative part is identical with signs reversed (apply the result to $-T$).

Corollary 2.27 (Courant–Fischer min–max)**.** *Let T be compact self-adjoint with positive eigenvalues $\lambda_1^+ \geq \lambda_2^+ \geq \cdots > 0$ listed with multiplicity, and with orthonormal eigenvectors $e_1^+, e_2^+, \ldots$ from theorem 2.26. Then for each n not exceeding the number of positive eigenvalues (so that λ_n^+ exists),*

$$\lambda_n^+ \;=\; \max_{\substack{V\subseteq H\\ \dim V = n}} \; \min_{\substack{x\in V\\ \|x\|=1}} \langle Tx, x\rangle \;=\; \min_{\substack{V\subseteq H\\ \dim V = n-1}} \; \max_{\substack{x\in V^\perp\\ \|x\|=1}} \langle Tx, x\rangle .$$

In particular $\lambda_1^+ = \max_{\|x\|=1}\langle Tx, x\rangle$, attained at the leading eigenvector.

Proof. The single tool is the spectral expansion of the quadratic form. Diagonalizing T by theorem 2.26 and writing the coordinates of a unit vector x in the full eigenbasis, $\langle Tx, x\rangle = \sum_k \lambda_k \,|\langle x, e_k\rangle|^2$, a weighted average of eigenvalues with weights $|\langle x, e_k\rangle|^2$ that sum to at most $\|x\|^2 = 1$ (Parseval). Each identity has two halves, and they have the same logic: to bound the min–max from *below* we exhibit one good subspace on which the inner extremum is already large enough, and to bound it from *above* we show that *every* candidate subspace contains one bad direction that drags the inner extremum down. The bridge between the two is a dimension count.

First identity, lower bound (a good subspace). Test the particular n-dimensional subspace $V_0 = \operatorname{span}\left\{e_1^+, \ldots, e_n^+\right\}$ spanned by the top n positive eigenvectors. Any unit $x \in V_0$ expands as $x = \sum_{k\leq n} c_k e_k^+$ with $\sum_{k\leq n} |c_k|^2 = 1$, so $\langle Tx, x\rangle = \sum_{k\leq n} \lambda_k^+ |c_k|^2 \geq \lambda_n^+ \sum_{k\leq n} |c_k|^2 = \lambda_n^+$, because each eigenvalue in play satisfies $\lambda_k^+ \geq \lambda_n^+$ for $k \leq n$. Thus the inner minimum over V_0 is $\geq \lambda_n^+$, and the outer maximum over *all* n-dimensional subspaces is therefore $\geq \lambda_n^+$.

First identity, upper bound (a bad direction in every subspace). Let V be *any* n-dimensional subspace. Consider the closed subspace $\operatorname{span}\left\{e_1^+, \ldots, e_{n-1}^+\right\}^\perp$, the orthogonal complement of the top $n-1$ positive eigenvectors, which is cut out by $n-1$ linear conditions. Asking a vector of the n-dimensional V to satisfy those $n-1$ conditions leaves at least $n-(n-1) = 1$ dimension of solutions, so there is a unit vector $x \in V \cap \operatorname{span}\left\{e_1^+, \ldots, e_{n-1}^+\right\}^\perp$. Being orthogonal to $e_1^+, \ldots, e_{n-1}^+$ kills exactly the $n-1$ largest weights, so its quadratic form runs only over the remaining spectrum:

$\langle Tx, x\rangle = \sum_{k\notin\{1,\ldots,n-1\}} \lambda_k \left|\langle x, e_k\rangle\right|^2$. Every eigenvalue still present is $\leq \lambda_n^+$—the surviving positive eigenvalues are $\lambda_n^+ \geq \lambda_{n+1}^+ \geq \cdots$, and all zero and negative eigenvalues are $\leq 0 < \lambda_n^+$ a fortiori—so $\langle Tx, x\rangle \leq \lambda_n^+ \sum_k \left|\langle x, e_k\rangle\right|^2 \leq \lambda_n^+$. Hence the inner minimum over V is $\leq \lambda_n^+$ for every V, and the outer maximum is $\leq \lambda_n^+$. Combining the two halves, the maximum equals λ_n^+, attained at V_0.

Second identity. This is the same argument with the roles of "test a good subspace" and "find a bad direction" exchanged, now optimizing over $(n-1)$-dimensional subspaces V and looking inside their complements $V^\perp$. For the *upper* bound, test $V = \operatorname{span}\left\{e_1^+, \ldots, e_{n-1}^+\right\}$: its complement $V^\perp$ contains no e_k^+ with $k < n$, so by the computation just performed $\langle Tx, x\rangle \leq \lambda_n^+$ for every unit $x \in V^\perp$, with equality at $x = e_n^+ \in V^\perp$; thus the inner maximum over this $V^\perp$ is exactly λ_n^+, and the outer minimum is $\leq \lambda_n^+$. For the *lower* bound, let V be any $(n-1)$-dimensional subspace and intersect $V^\perp$ with $U = \operatorname{span}\left\{e_1^+, \ldots, e_n^+\right\}$: a vector $u \in U$ lies in $V^\perp$ precisely when it is orthogonal to the $n-1$ basis vectors of V, again $n-1$ conditions on the n-dimensional U, so $\dim(U \cap V^\perp) \geq n - (n-1) = 1$ and there is a unit $x \in U \cap V^\perp$. Since $x \in U$ puts all its weight on the top n positive eigenvalues, $\langle Tx, x\rangle = \sum_{k\leq n} \lambda_k^+ \left|\langle x, e_k^+\rangle\right|^2 \geq \lambda_n^+$. So the inner maximum over $V^\perp$ is $\geq \lambda_n^+$ for every V, and the outer minimum is $\geq \lambda_n^+$. The two halves again pinch the value to λ_n^+. □

Physics note

Theorem 2.26 is the statement that a compact self-adjoint operator has *normal modes.* Reading $T = \mathbb{W}$ as the (self-generated, type-indexed) coupling of a network, the eigenfunctions e_n are the collective modes and the eigenvalues λ_n their coupling strengths; the expansion $\mathbb{W}f = \sum_n \lambda_n \langle f, e_n\rangle e_n$ diagonalizes the interaction exactly as a normal-mode transform diagonalizes a quadratic Hamiltonian. The leading eigenfunction e_1, carrying the largest $|\lambda_1| = \|\mathbb{W}\|$, is the network's dominant, most strongly coupled collective mode—it is the *eigenvector centrality* of chapter 18, the profile that the population settles into under repeated averaging by $\mathbb{W}$. The decay $\lambda_n \to 0$ is the statement that high-index modes are increasingly weakly coupled and contribute increasingly little, which is what makes finite-rank truncations of the coupling accurate. This picture is genuinely useful; but the proof above uses no physics, and every assertion stands on the variational argument alone.

Abstract diagonalization is only as convincing as the examples one can carry it out on, and the operator we care about admits three that we can solve in closed form. Each is a member of Thread B (appendix A.7), and the three are arranged in increasing structural richness: a constant kernel that collapses to a single mode and recovers Thread A, a rank-one kernel $f(x)f(y)$ that is the cleanest graphon reduction, and a block kernel that bridges to the multi-population games of chapter 30. In every case the spectral theorem is not invoked abstractly—we exhibit the eigenfunctions and eigenvalues explicitly and check them against the Hilbert–Schmidt identity $\sum_n \lambda_n^2 = \|W\|^2_{L^2([0,1]^2)}$ of proposition 2.24, which the spectral expansion must satisfy term by term.

Worked computation 2.28 (Spectrum of the graphon operator: constant and rank-one kernels)**.** Throughout, $H = L^2[0,1]$ with $\langle f, g\rangle = \int_0^1 fg$, and $\mathbb{W}$ is the operator of definition 2.23.

(a) Constant graphon (Erdős–Rényi / Curie–Weiss closure). Let $W(x,y) \equiv c$ with $c \in (0,1]$.

Then

$$(\mathbb{W}f)(x) = c\int_0^1 f(y)\ \mathrm{d}y = c\,\langle f, \mathbf{1}\rangle,$$

where $\mathbf{1}$ is the constant function 1, which has $\|\mathbf{1}\| = 1$. Thus $\mathbb{W}f$ is always a multiple of $\mathbf{1}$: the operator has rank one, with the single nonzero eigenvalue $\lambda_1 = c$ and normalized eigenfunction $e_1 = \mathbf{1}$, while every function with zero mean lies in $\ker \mathbb{W}$. Here $\|\mathbb{W}\| = \|\mathbb{W}\|_{\mathrm{HS}} = c$, consistent with $\|W\|^2_{L^2([0,1]^2)} = c^2$. The operator collapses the entire population field to its mean and rescales it—this is precisely the global mean-field coupling of Thread A (appendix A.7), recovered as the constant-graphon special case, with the coupling strength c playing the role of the smallness parameter in (A-Coupling).

(b) Rank-one graphon (the clean GMFG reduction). Let $W(x,y) = f(x)f(y)$ for a fixed $f \in L^2[0,1]$, symmetric by construction and (for W to be a graphon) with values in $[0,1]$. The integral now factors through a single scalar pairing:

$$(\mathbb{W}g)(x) = f(x)\int_0^1 f(y)g(y)\ \mathrm{d}y = \langle g, f\rangle\, f(x).$$

This is the structural heart of the reduction. Whatever field g we feed in, the output points in the *one fixed direction* f, and all the information $\mathbb{W}$ retains about g is the single number $\langle g, f\rangle$. It is this number that Thread B names the scalar *order parameter* $\varrho = \langle g, f\rangle$ (appendix A.7), so that the entire action of the operator compresses to $\mathbb{W}g = \varrho\, f$. Spectrally, $\mathbb{W}$ has rank one: its only nonzero eigenvalue is $\lambda_1 = \|f\|^2_{L^2} = \int_0^1 f^2$—read off by applying $\mathbb{W}$ to f itself, $\mathbb{W}f = \langle f, f\rangle f = \|f\|^2_{L^2} f$—with normalized eigenfunction $e_1 = f/\|f\|_{L^2}$, while every field orthogonal to f is annihilated, $\ker\mathbb{W} = \{f\}^{\perp}$. The Hilbert–Schmidt check is immediate and confirms the spectral bookkeeping: $\|W\|^2_{L^2([0,1]^2)} = \int_0^1\!\int_0^1 f(x)^2 f(y)^2\ \mathrm{d}x\ \mathrm{d}y = \big(\int_0^1 f^2\big)^2 = \lambda_1^2$, which is exactly $\sum_n \lambda_n^2$ with its single surviving term. The payoff is the cleanest reduction in the book: because $\mathbb{W}g = \varrho f$ collapses the coupling onto one scalar, a mean-field game played through this kernel is no longer an infinite-dimensional fixed-point problem in the field but a *one-parameter* self-consistent equation for the scalar ϱ—each agent best-responds to the single aggregate ϱ, which in turn is the f-weighted average of the resulting population profile. We take this up dynamically, with ϱ promoted to a time-dependent order parameter ϱ_t, in chapter 22.

(c) Block graphon (the bridge to multi-population games). Let $\{P_1, \ldots, P_K\}$ partition $[0,1]$ into measurable sets of masses $\pi_k = |P_k| > 0$, $\sum_k \pi_k = 1$, and let $W(x,y) = \mathsf{B}_{k\ell}$ be constant on $P_k \times P_\ell$ for a symmetric matrix $\mathsf{B} = (\mathsf{B}_{k\ell}) \in [0,1]^{K\times K}$. The operator $\mathbb{W}$ then maps everything into the K-dimensional subspace of functions that are constant on each block, and it annihilates every function whose average over each block vanishes: if $\int_{P_\ell} f = 0$ for all ℓ then $(\mathbb{W}f)(x) = \sum_\ell \mathsf{B}_{k\ell}\int_{P_\ell} f = 0$ for $x \in P_k$, so the block-mean-zero functions lie in $\ker\mathbb{W}$. On the block-constant subspace, writing $f = \sum_\ell f_\ell \mathbf{1}_{P_\ell}$,

$$(\mathbb{W}f)(x) = \sum_\ell \mathsf{B}_{k\ell}\,\pi_\ell\, f_\ell \qquad (x \in P_k),$$

so in the coordinates (f_ℓ) the operator acts as the $K \times K$ matrix $\mathsf{B}D$ with $D = \mathrm{diag}(\pi_1, \ldots, \pi_K)$. This matrix is not symmetric, but its nonzero eigenvalues—which are the nonzero spectrum of $\mathbb{W}$—are those of the *symmetric* matrix $D^{1/2}\mathsf{B}D^{1/2}$, to which $\mathsf{B}D$ is similar via conjugation by $D^{1/2}$: indeed $D^{1/2}(\mathsf{B}D)D^{-1/2} = D^{1/2}\mathsf{B}D^{1/2}$. Similarity preserves eigenvalues, and the symmetric matrix on the right has real ones, so the spectrum of $\mathbb{W}$ is real exactly as self-adjointness demands—the finite-dimensional shadow of the reality clause in theorem 2.26. The natural inner product making $\mathbb{W}$ self-adjoint here is not the bare Euclidean one on $\mathbb{R}^K$ but the mass-weighted one $\langle u, v\rangle_D = \sum_k \pi_k u_k v_k$, inherited from $L^2[0,1]$ restricted to block-constant fields, and in that inner product $\mathsf{B}D$ is genuinely self-adjoint. The Hilbert–Schmidt check again closes the loop: with W constant $\mathsf{B}_{k\ell}$ on $P_k \times P_\ell$,

$$\|W\|^2_{L^2([0,1]^2)} = \sum_{k,\ell} \mathsf{B}^2_{k\ell}\, \pi_k \pi_\ell = \operatorname{tr}\left[(D^{1/2}\mathsf{B}D^{1/2})^2\right] = \sum_n \lambda_n^2,$$

the trace of the square of the symmetric matrix being the sum of the squares of its eigenvalues, in exact agreement with the spectral theorem. This is precisely the finite multi-population coupling: the blocks are sub-populations, the π_k their mass fractions, and B the between-group interaction matrix; we take it up as the bridge from graphon to multi-population MFG in chapter 30.

The three reductions share one feature worth naming, because it is what chapter 18 will read off the spectrum. In each, the leading eigenfunction e_1 is the profile to which repeated application of $\mathbb{W}$ drives any input—iterating $\mathbb{W}$ amplifies the λ_1-mode relative to all others by the ratio $(\lambda_2/\lambda_1)^n$, so the dominant mode wins, and that dominant mode is the network's eigenvector centrality. And in each, $\|\mathbb{W}\| = \lambda_1$ is precisely the operator norm constrained by the smallness condition (A-Coupling) when a contraction argument is needed for uniqueness in chapter 24: the spectral theorem is what makes that abstract norm a concrete, computable number—c, $\int f^2$, or the top eigenvalue of $D^{1/2}\mathsf{B}D^{1/2}$, respectively.

With the spectral theorem proved and exhibited on the three diagnostic kernels, the operator side of the chapter is complete. We have taken the graphon W from a measurable kernel (chapter 1), through the Hilbert–Schmidt class (proposition 2.24), to a fully diagonalized object: an orthonormal eigenbasis $\{e_n\}$, real eigenvalues $\lambda_n \to 0$, and the mode-by-mode action $\mathbb{W}f = \sum_n \lambda_n \langle f, e_n\rangle e_n$ that chapter 18 interprets as band structure, eigenvector centrality, spectral gap, and the low-rank truncations the decay $\lambda_n \to 0$ justifies. Threads B's later chapters draw on this directly: the rank-one order parameter ϱ of chapter 22, the operator-norm threshold of chapter 24, and the block bridge to multi-population games of chapter 30 all read their structure off the spectrum computed here.

That closes the book's work with operators acting on L^2. But L^2 is not the only space the book needs, and the remaining sections turn from operators to the *other* spaces—the homes of the partial differential equations that the mean-field game couples together—beginning with the Sobolev spaces, in which differentiation itself must be re-founded.

2.6 Sobolev spaces and weak derivatives

The previous section closed the book's work with operators on L^2 and pointed past it: the value function u of an optimal control problem and the density m of a population both solve partial differential equations—the Hamilton–Jacobi–Bellman and Fokker–Planck equations of chapters 6 and 8, the backward and forward halves of every mean-field game—and the preamble already warned that those solutions are generally *not* classically differentiable. A value function built as the infimum of many smooth cost-to-go functions typically has kinks where the optimal control switches; a density transported by a rough drift need not be smooth either. At such points the classical derivative simply does not exist, and an equation written in terms of it has no solution to look for. The repair is the same move the chapter has made twice already. Weak convergence rescued compactness by testing against functionals instead of demanding norm convergence; the weak derivative will rescue differentiation by testing against smooth functions instead of demanding a pointwise limit of difference quotients. This is the third and last of the chapter's "three weak words," and it is the one that builds the spaces the PDEs actually live in.

The mechanism is integration by parts read backwards. For a genuinely C^1 function the derivative is characterized—not just computed—by how it pairs against test functions, and that characterization survives even when the pointwise derivative does not. The Sobolev spaces are the function spaces in which this surviving characterization is taken as the definition of a derivative, and in which the resulting objects can be measured in L^2. We develop them to exactly the depth the existence theory of the MFG PDEs requires and no further: the weak derivative itself, the H^k and H^1_0 scales, the density–Rellich–Poincaré trio that supplies PDE-side compactness, the fractional scale and Gelfand triple that house right-hand sides and parabolic problems, and the Lax–Milgram theorem that solves each linear step inside a mean-field iteration. The heavier elliptic *regularity* theory—that these weak solutions are secretly smooth—is genuinely needed later but not here, and we defer it honestly to chapter 6 and its sources, for a reason remark 2.35 makes precise.

Definition 2.29 (Weak derivative)**.** Let $\Omega \subseteq \mathbb{R}^d$ be open and $u \in L^1_{\mathrm{loc}}(\Omega)$. A function $v \in L^1_{\mathrm{loc}}(\Omega)$ is the *weak (distributional) partial derivative* $\partial_i^{\mathrm{w}} u$ if

$$\int_\Omega u\,\partial_i\varphi \,\mathrm{d}x \;=\; -\int_\Omega v\,\varphi\,\mathrm{d}x \qquad \text{for all } \varphi \in C_c^\infty(\Omega).$$

This is the integration-by-parts identity with the boundary term legislated to vanish; when u is classically C^1 the weak derivative coincides with the classical one. Weak derivatives, when they exist, are unique up to a null set.

Three things in that definition deserve to be unpacked, because together they are the whole content of "weak differentiation." The first is *why this is the right identity at all.* For a C^1 function u on Ω and a test function $\varphi \in C_c^\infty(\Omega)$, ordinary integration by parts gives $\int_\Omega (\partial_i u)\varphi \,\mathrm{d}x = -\int_\Omega u\,\partial_i\varphi \,\mathrm{d}x +$ (boundary term), and the boundary term is the surface integral of $u\varphi$ over $\partial\Omega$. The point of insisting that φ have *compact support* inside the open set Ω is precisely to kill that boundary term: φ vanishes identically near $\partial\Omega$, so there is no surface to integrate over. What remains, $\int_\Omega u\,\partial_i\varphi = -\int_\Omega (\partial_i u)\varphi$, is an identity that mentions $\partial_i u$ only *under an integral against a smooth weight*—never at a point. That is the loophole the definition exploits: it asks for a function v that plays the role $\partial_i u$ would play in this identity, without ever asking u to be differentiable anywhere. The boundary term has been "legislated away" not by fiat but by the choice of test class.

The second is the *micro-check* that this generalizes rather than replaces the classical derivative. If $u \in C^1(\Omega)$, then by the computation just made $v = \partial_i u$ (the genuine, classical partial derivative) satisfies the defining identity for every φ, so the classical derivative *is* a weak derivative; the two notions agree wherever the classical one exists. The gain is entirely at the points and sets where the classical derivative fails. The cleanest one-dimensional witness is $u(x) = |x|$ on $\Omega = (-1, 1)$, which has no derivative at 0: integrating $\int_{-1}^{1} |x|\ \varphi'(x)\ \mathrm{d}x$ by parts on each half $(-1, 0)$ and $(0, 1)$ separately (where u *is* smooth, with derivative ∓ 1) and adding, the two boundary contributions at 0 cancel because $|x|$ is continuous there, leaving $\int_{-1}^{1} |x|\ \varphi' = -\int_{-1}^{1} \operatorname{sgn}(x)\, \varphi$. So $\partial^{\mathrm{w}} |x| = \operatorname{sgn}(x)$, an honest L^1_{loc} function and exactly the "derivative" a physicist would write. The same cancellation is what *fails* for the Heaviside step $H(x) = \mathbf{1}_{x>0}$: integrating by parts leaves a leftover $\varphi(0)$ that no L^1_{loc} function can produce against every φ, so H has no weak derivative inside L^1_{loc}—its derivative is the Dirac mass, a distribution but not a function. The boundary between "has a weak derivative in L^1_{loc}" and "does not" is the boundary a Sobolev space draws, and it is exactly the kink-versus-jump distinction: kinks are allowed, jumps are not.

The third is *uniqueness up to a null set*, which is what makes "the" weak derivative a legitimate phrase. If v_1 and v_2 both satisfy the identity, then $\int_\Omega (v_1 - v_2)\varphi = 0$ for every $\varphi \in C_c^\infty(\Omega)$; a function in L^1_{loc} that integrates to zero against every compactly supported smooth weight is zero almost everywhere (the fundamental lemma of the calculus of variations, itself a density statement about C_c^∞). So $v_1 = v_2$ a.e., and the weak derivative is unique as an element of L^1_{loc}—which, since all our spaces identify functions agreeing a.e., is exactly the right sense of uniqueness. With one notion of derivative now defined for non-smooth functions, we can build the spaces of functions whose weak derivatives are not merely locally integrable but square-integrable, the regime where Hilbert-space geometry returns.

Definition 2.30 (Sobolev space H^1 and H^k)**.** For an open $\Omega \subseteq \mathbb{R}^d$ and integer $k \geq 1$, the Sobolev space $H^k(\Omega)$ consists of all $u \in L^2(\Omega)$ whose weak derivatives $D^\alpha u$ exist in $L^2(\Omega)$ for every multi-index $|\alpha| \leq k$. It is a Hilbert space under

$$\langle u, v \rangle_{H^k} = \sum_{|\alpha| \leq k} \int_\Omega D^\alpha u\, D^\alpha v\ \mathrm{d}x.$$

The case $k = 1$, $\langle u, v \rangle_{H^1} = \int_\Omega (uv + \nabla u \cdot \nabla v)\ \mathrm{d}x$, is the one the variational theory uses. We write $H_0^1(\Omega)$ for the closure of $C_c^\infty(\Omega)$ in $H^1(\Omega)$—morally, the functions in H^1 that vanish on $\partial\Omega$.

The inner product is engineered so that the H^k norm measures a function *together with* all of its weak derivatives up to order k in a single Hilbertian quantity, $\|u\|_{H^k}^2 = \sum_{|\alpha| \leq k} \|D^\alpha u\|_{L^2}^2$; controlling $\|u\|_{H^k}$ is exactly controlling u and each $D^\alpha u$ in L^2 at once. The distinguished subspace H_0^1 encodes a homogeneous Dirichlet boundary condition without ever evaluating u on the measure-zero set $\partial\Omega$ (where an L^2 function has no canonical value): a function lies in H_0^1 iff it is an H^1-limit of test functions, all of which vanish near the boundary, so "$u = 0$ on $\partial\Omega$" is enforced in the only way an L^2 theory can enforce it—by approximation. This is the space in which the homogeneous boundary-value problems of chapter 6 are posed, and the space on which Poincaré's inequality below will hold.

That H^k is complete—so that it is a genuine Hilbert space and not merely an inner-product space—is the small argument that makes the whole construction worth having, and it is worth seeing in full because it is where the weak derivative earns its keep. Let (u_n) be Cauchy in H^k. By the form of the norm, each sequence $(D^\alpha u_n)_n$, for $|\alpha| \leq k$, is Cauchy in $L^2(\Omega)$; since L^2 is complete (chapter 1), each converges to some $u^\alpha \in L^2$, and in particular $u_n \to u^{(0)} =: u$ in L^2. The only thing left to verify is that the limits are consistent—that u^α really is the weak derivative $D^\alpha u$, not just an unrelated L^2 function. Here is the step that "passes the identity to the limit." For each n and each test function φ, the weak-derivative identity holds, $\int_\Omega u_n\, D^\alpha\varphi = (-1)^{|\alpha|}\int_\Omega (D^\alpha u_n)\varphi$. Both sides are L^2 inner products against fixed φ (or $D^\alpha\varphi$), and inner products are continuous, so letting $n\to\infty$ and using $u_n \to u$ and $D^\alpha u_n \to u^\alpha$ in L^2 gives $\int_\Omega u\, D^\alpha\varphi = (-1)^{|\alpha|}\int_\Omega u^\alpha\varphi$ for every φ. That is precisely the statement $u^\alpha = D^\alpha u$. Hence $u \in H^k$ and $u_n \to u$ in H^k. Completeness was almost free, but only because the weak-derivative identity is preserved under L^2 limits—which is the whole reason the weak derivative, not the classical one, is the right notion to build a Banach space around. The same argument shows H^1_0 is complete (it is a closed subspace of H^1 by definition).

Two further facts turn these complete spaces from formal objects into working tools, and they are exactly the two the PDE existence theory will call on: smooth functions are *dense* in them, so the weak theory is nothing but the completion of the classical one, and on a bounded domain the inclusion of H^1 into L^2 is *compact*, which is the PDE-side source of the compactness the chapter's existence scheme runs on. We collect both, with a third—Poincaré—that they naturally travel with, as a single motivated theorem.

Theorem 2.31 (Density and the compact embedding)**.** *Let $\Omega \subseteq \mathbb{R}^d$ be open, bounded, with Lipschitz boundary.*

1. (Meyers–Serrin / density.) *$C^\infty(\overline{\Omega})$ is dense in $H^1(\Omega)$, and $C^\infty_c(\Omega)$ is dense in $H^1_0(\Omega)$; thus the weak theory is the completion of the classical one.*
2. (Rellich–Kondrachov.) *The inclusion $H^1(\Omega) \hookrightarrow L^2(\Omega)$ is* compact*: every H^1-bounded sequence has an L^2-convergent subsequence.*
3. (Poincaré.) *There is $C = C(\Omega)$ with $\|u\|_{L^2} \le C\,\|\nabla u\|_{L^2}$ for all $u \in H^1_0(\Omega)$, so on H^1_0 the gradient norm alone is an equivalent norm.*

The three are deliberately bundled because each answers a different need of the variational method, and reading them in order tells the story. The *density* statement is the bridge between the classical and the weak worlds: it says H^1 is nothing more exotic than the completion of ordinary smooth functions in the H^1 norm, so any identity one can verify for smooth functions and which is continuous in that norm—integration by parts, the product rule, chain rules—extends to all of H^1 by approximation. Without density, the weak theory would be a separate universe from the classical one; with it, the two are the same object seen at two resolutions, and every manipulation we will perform on weak solutions is justified by passing to a smooth approximant and back.

The *Rellich–Kondrachov* statement is the one this chapter has been pointing at since section 2.4, and it deserves to be named for what it is: a *compact embedding.* The inclusion map $\iota\colon H^1(\Omega) \to L^2(\Omega)$, $u \mapsto u$, is a bounded operator between two Hilbert spaces—bounded because $\|u\|_{L^2} \le \|u\|_{H^1}$ trivially—and Rellich says this particular bounded operator is *compact* in the exact sense of definition 2.18: it sends the H^1 unit ball to a precompact subset of L^2, equivalently it maps H^1-bounded sequences to sequences with L^2-convergent subsequences. This is not a restatement of Banach–Alaoglu. Alaoglu only gives a *weakly* convergent subsequence in L^2 from an L^2-bounded sequence; Rellich upgrades that to *strong* (norm) L^2 convergence, and the price of the upgrade is the extra information that the gradients are also bounded—the sequence is bounded not merely in L^2 but in H^1. That extra derivative bound is exactly an *a priori estimate*, and the moral the chapter has repeated in every guise reappears here in its sharpest form: compactness is an a priori estimate in disguise, and Rellich is the disguise worn on the PDE side. It is the engine that converts the bound–extract–identify scheme into a working existence proof for the HJB and Fokker–Planck equations: bound the approximate solutions in H^1 by an energy estimate, extract an L^2-strongly convergent subsequence by Rellich, identify the limit as a weak solution by passing the equation to the limit (the manoeuvre completeness above already rehearsed). What weak compactness did for measures and for L^2, Rellich does for Sobolev functions; it is the same beat played in a new register.

The *Poincaré* statement is the small inequality that makes the scheme self-supporting on H^1_0. It says that on $H^1_0(\Omega)$—functions vanishing at the boundary—the function cannot be large unless its gradient is, so the gradient seminorm $\|\nabla u\|_{L^2}$ already controls the full H^1 norm and is therefore an *equivalent* norm. The hypothesis that u vanish on the boundary is essential: on all of H^1 the constant functions have zero gradient but nonzero L^2 norm, so no such inequality can hold; pinning u to zero at $\partial\Omega$ removes exactly the constant (and near-constant) directions that would break it, and a bounded domain keeps the constant $C(\Omega)$ finite. What Poincaré buys, concretely, is *coercivity*: it is the reason the Dirichlet form $a(u,v) = \int_\Omega \nabla u \cdot \nabla v$ is coercive on H^1_0—because $a(u,u) = \|\nabla u\|^2_{L^2} \geq C^{-2}\,\|u\|^2_{H^1}$—which is the single hypothesis Lax–Milgram below will demand. Density justifies the calculus, Rellich supplies the compactness, Poincaré supplies the coercivity: the trio is the complete toolkit for solving one linear elliptic problem, and we shall use all three within a page.

All three are proved in appendix B.8, and we keep the proofs there rather than here because nothing the chapter *exports* depends on their internals, only on their statements. For orientation: Poincaré and the Meyers–Serrin density go through directly, while Rellich–Kondrachov goes through the Fréchet–Kolmogorov compactness criterion in L^2 (equicontinuity of translates, which an H^1 bound supplies). The cleanest instance of the mechanism is the torus, where it falls straight out of the Fourier definition of definition 2.32: there an H^1 bound is a bound on $\sum_\xi (1+|\xi|^2)\,|\hat{u}(\xi)|^2$, the weight $(1+|\xi|^2)^{-1}$ decays, and tails in frequency are uniformly small—which is precisely L^2-precompactness. We keep [64, Ch. 5] and [31, Ch. 8–9] for attribution and further reading. That Fourier picture is no accident, and it is the natural way to interpolate between the integer orders H^k to the fractional scale where the precise regularity of HJB solutions is measured; we turn to it now.

Definition 2.32 (Fractional Sobolev space $H^s(\mathbb{R}^d)$)**.** For $s \in \mathbb{R}$ and $u \in L^2(\mathbb{R}^d)$ with Fourier transform $\hat{u}$, set

$$H^s(\mathbb{R}^d) = \left\{ u : \ \|u\|^2_{H^s} = \int_{\mathbb{R}^d} \left(1 + |\xi|^2\right)^s \, |\hat{u}(\xi)|^2 \, \mathrm{d}\xi < \infty \right\}.$$

For integer $s = k \geq 0$ this norm is equivalent to that of definition 2.30, since multiplication by ξ^α on the Fourier side is differentiation. Increasing s means increasing smoothness; $s < 0$ gives spaces of distributions, and $(H^s)^* = H^{-s}$ under the L^2 pairing.

The Fourier definition does two things at once. First, it makes “half a derivative” meaningful: where the integer space H^k weights $|\hat{u}(\xi)|^2$ by the polynomial $(1+|\xi|^2)^k$, the fractional space simply allows any real exponent s, and since each factor of $|\xi|$ on the Fourier side is one derivative in space, s counts derivatives on a continuous dial. Increasing s demands faster decay of $\hat{u}$ and hence more smoothness; this is the scale on which one says, precisely, "the HJB value function has s derivatives" even when s is not an integer. Second, and decisively for the variational theory, allowing $s < 0$ produces honest spaces of *distributions*—objects rougher than functions, like the Dirac mass, whose Fourier transform does not decay but whose negative-order weighted norm is still finite. The pairing that ties the two ends together is the duality $(H^s)^* = H^{-s}$ under the L^2 inner product: a distribution $f \in H^{-s}$ acts on a test function $u \in H^s$ by the extension of $\int fu$, and the Cauchy–Schwarz split $\int \hat{f}\,\overline{\hat{u}} = \int \big[(1+|\xi|^2)^{-s/2}\hat{f}\big]\big[(1+|\xi|^2)^{s/2}\overline{\hat{u}}\big]$ shows this pairing is bounded by $\|f\|_{H^{-s}}\|u\|_{H^s}$, with H^{-s} realizing *every* bounded functional on H^s this way. The negative exponent is not a curiosity: it is the home of the right-hand sides of elliptic equations, which after one integration by parts naturally lose a derivative and land in a negative-order space. The duality $(H^s)^* = H^{-s}$ thus organizes the variational solution of elliptic equations into a single clean statement, and the way to package it for use is a triple of spaces.

Definition 2.33 (Gelfand triple)**.** A *Gelfand triple* (or rigged Hilbert space) is a continuous dense embedding $V \hookrightarrow H \hookrightarrow V^*$ of a Hilbert space V into a pivot Hilbert space H (identified with its own dual) and thence into V^*, with $\langle\cdot,\cdot\rangle_H$ extending to the duality pairing of V and V^*. The model case is $H_0^1(\Omega) \hookrightarrow L^2(\Omega) \hookrightarrow H^{-1}(\Omega)$.

The triple is not idle bookkeeping, and it is worth saying concretely what later chapters do with it, because the abstraction is doing real work in three distinct places. The first is the one visible on the next page. The datum $\ell \in V^*$ of the Lax–Milgram theorem below, for the model choice $V = H_0^1(\Omega)$, lives in exactly the endpoint $V^* = H^{-1}(\Omega)$ of this triple. That is why "a right-hand side in H^{-1}" is the natural generality for a weak elliptic problem: a source term need not be a function at all—it may be a derivative of an L^2 function, hence a genuine distribution—and the triple is what makes $-\Delta\colon H_0^1 \to H^{-1}$ an isomorphism onto the right space rather than a map with a domain mismatch. The second is time-dependence. In the kernel HJB–Fokker–Planck system of chapter 22, the unknowns are not single functions but *trajectories* of functions, curves $t \mapsto u(t) \in V$; their time derivatives $\dot{u}(t)$, formed weakly, fall a notch in regularity and live in V^*, while the functions themselves live in V and their natural "energy" is measured in the pivot H. The Gelfand triple is precisely the staircase $V \hookrightarrow H \hookrightarrow V^*$ that lets a solution and its time derivative inhabit adjacent rungs and still be paired—$\langle \dot{u}(t), u(t)\rangle_{V^*\times V} = \frac{1}{2}\frac{d}{dt}\|u(t)\|_H^2$, the identity behind every parabolic energy estimate. The third is the compactness that closes those parabolic existence proofs: the Aubin–Lions lemma, which the graphon FBSDE well-posedness of chapter 23 and the parabolic systems of chapter 22 both invoke, is stated exactly relative to a Gelfand triple—it says that a family bounded in $L^2(0,T;V)$ with time derivatives bounded in $L^2(0,T;V^*)$ is precompact in $L^2(0,T;H)$, the time-dependent analogue of Rellich, and it is unstatable without the three named spaces. So the triple is not notation we will carry idly: it is the minimal structure in which the book's parabolic problems can even be posed, and the home of the only compactness argument strong enough to solve them.

Theorem 2.34 (Lax–Milgram)**.** *Let V be a Hilbert space and $a\colon V\times V \to \mathbb{R}$ a bilinear form that is* bounded*, $|a(u,v)| \le M\|u\|_V\|v\|_V$, and* coercive*, $a(u,u) \ge \theta\|u\|_V^2$ for some $\theta > 0$. Then for every*

$\ell \in V^*$ there is a unique $u \in V$ with $a(u,v) = \ell(v)$ for all $v \in V$, and $\|u\|_V \leq \theta^{-1} \|\ell\|_{V^*}$.

Proof. The whole theorem is a translation of the abstract weak equation into a single operator equation, which the two hypotheses then make uniquely solvable; the translation is Riesz representation, used twice. Fix $u \in V$. The map $v \mapsto a(u,v)$ is, by boundedness, a bounded linear functional on V (its norm is at most $M\|u\|_V$), so Riesz representation (theorem 2.6) hands back a unique vector we call Au with $a(u,v) = \langle Au, v\rangle_V$ for all v. Linearity of a in its first slot makes $u \mapsto Au$ linear, and $\|Au\|_V \leq M\|u\|_V$ makes it bounded: $A \in \mathcal{B}(V)$. Applying Riesz once more to the functional ℓ produces $f \in V$ with $\ell(v) = \langle f, v\rangle_V$. The weak problem "find u with $a(u,v) = \ell(v)$ for all v" now reads $\langle Au, v\rangle_V = \langle f, v\rangle_V$ for all v, i.e. simply $Au = f$. Everything reduces to showing A is a bijection of V with a quantitative inverse.

Coercivity is what supplies the bijection, in two stages. First it gives a *lower bound* on A. Putting $v = u$ in the defining relation, $\langle Au, u\rangle_V = a(u,u) \geq \theta\|u\|_V^2$, and by Cauchy–Schwarz the left side is at most $\|Au\|_V \|u\|_V$; cancelling one factor of $\|u\|_V$ (trivial if $u = 0$) yields

$$\|Au\|_V \;\geq\; \theta\,\|u\|_V \qquad \text{for all } u \in V.$$

This single estimate does most of the work. It makes A *injective* ($Au = 0 \Rightarrow u = 0$), and it makes the range of A *closed*: if $Au_n \to g$ in V, then (Au_n) is Cauchy, so by the lower bound $\|u_n - u_m\|_V \leq \theta^{-1}\|Au_n - Au_m\|_V$ shows (u_n) is Cauchy too; completeness of V gives $u_n \to u$, boundedness of A gives $Au_n \to Au$, and uniqueness of limits gives $Au = g$, so g lies in the range. The range $R = A(V)$ is therefore a closed subspace.

The second stage shows that closed subspace is *all* of V—this is where the adjoint enters. Suppose, for contradiction, $R \neq V$. Then R is a proper closed subspace, so by the projection theorem its orthogonal complement contains a nonzero vector w: $\langle Av, w\rangle_V = 0$ for every $v \in V$. Read through the adjoint of definition 2.12, $\langle Av, w\rangle_V = \langle v, A^*w\rangle_V$, this says $A^*w = 0$—the leftover direction is exactly a null vector of the adjoint. But now test coercivity against w itself: taking $v = w$ in $\langle Av, w\rangle_V = 0$ gives $\langle Aw, w\rangle_V = 0$, while coercivity demands $\langle Aw, w\rangle_V = a(w,w) \geq \theta\|w\|_V^2 > 0$ since $w \neq 0$. The two are incompatible, so no such w exists and $R = V$: A is surjective. (When a is symmetric, $A = A^*$ and this last step is automatic; the adjoint is what handles the general, non-symmetric forms that the convection terms of Fokker–Planck produce.)

Injective, surjective, and bounded below, A is a bijection with $\|A^{-1}\| \leq \theta^{-1}$ directly from $\|Au\|_V \geq \theta\|u\|_V$. Hence $u = A^{-1}f$ is the unique solution, and $\|u\|_V \leq \theta^{-1}\|f\|_V = \theta^{-1}\|\ell\|_{V^*}$, the last equality because Riesz is an isometry. That is the stated estimate. A streamlined account along the same lines is in [31, Ch. 5]. □

It is worth seeing the role this theorem plays before leaving it, because it is the linchpin of the chapter's whole division of labour. A mean-field game is nonlinear—the coefficients of the HJB equation depend on the population density m, which is itself the output of solving the Fokker–Planck equation, which depends on the value function u, and round again. Lax–Milgram does not solve that nonlinear loop; nothing linear could. What it solves is each *frozen* step: hold the population (hence the coefficients) fixed, and the HJB and Fokker–Planck equations become *linear* elliptic or parabolic problems with given coefficients, exactly of the form $a(u,v) = \ell(v)$ with a bounded and coercive (boundedness from the regularity of the coefficients, coercivity from nondegeneracy of the diffusion and Poincaré). Lax–Milgram produces the unique solution of that frozen step, with the quantitative bound $\|u\|_V \leq \theta^{-1} \|\ell\|_{V^*}$ that will later be reused as the a priori estimate feeding compactness. The nonlinearity is then absorbed by iterating the frozen-step solver and seeking a population that reproduces itself—which is precisely the fixed-point problem of the next section. Lax–Milgram solves each link; fixed points close the chain.

The coercive form carries a bonus when it is also *symmetric*, $a(u, v) = a(v, u)$, and it is the one a physicist's instinct reaches for first. Then the solution of $a(u, v) = \ell(v)$ is exactly the minimizer of the quadratic energy $J(u) = \frac{1}{2}a(u, u) - \ell(u)$. To see the equivalence is one line of the calculus of variations: for any direction v and scalar t, $J(u + tv) = J(u) + t\big(a(u, v) - \ell(v)\big) + \frac{t^2}{2}a(v, v)$, a strictly convex parabola in t (strict because $a(v, v) \geq \theta \|v\|^2 > 0$), whose stationarity at $t = 0$ for every v is the condition $a(u, v) = \ell(v)$. So "solve the weak equation" and "minimize the energy" are the same problem, and coercivity is what guarantees the energy is bounded below and the minimum attained. This is the Dirichlet principle the reader expects—for $a(u, v) = \int \nabla u \cdot \nabla v$ and $\ell(v) = \int fv$ it is the statement that the solution of $-\Delta u = f$ minimizes Dirichlet energy—and the variational structure of certain MFG systems (chapter 8), where an entire equilibrium is characterized as the minimizer of a convex functional on the space of densities, is the nonlinear elaboration of exactly this picture.

Remark 2.35 (How far we go)**.** We deliberately stop here. Elliptic and parabolic *regularity*—that weak solutions are in fact smooth when the data are, the Sobolev and Morrey embedding theorems giving $H^s \hookrightarrow C^k$, and the Schauder and Calderón–Zygmund estimates—is the machinery that upgrades the weak solutions Lax–Milgram produces to classical ones. We invoke it as a black box in chapters 6 and 8 with explicit pointers to [64, Ch. 6], rather than developing it here, because none of the *functional-analytic* structure the rest of this chapter exports depends on it.

This completes the analytic apparatus the chapter set out to build, and it is worth standing back to see the shape of what is now in hand, because the final section depends on all of it. Two compactness theorems have been assembled, one on each side of a mean-field game. On the PDE side, Rellich–Kondrachov (theorem 2.31) turns an H^1 energy bound into an L^2-convergent subsequence; on the measure side, the weak-$*$ compactness of section 2.3—and the tightness criterion that will accompany it—turns a bound on a family of population measures into a weakly convergent subsequence. These are the two inputs the next section's existence theorems consume: every fixed-point argument for an equilibrium needs the best-response map to land in a set that is compact in a usable topology, and that compactness is always one of these two estimates in disguise, exactly as the chapter's recurring motif promised. And Lax–Milgram has supplied the other half: it solves each frozen-coefficient linear step that the best-response map is built from, with a quantitative bound that is itself the a priori estimate feeding the compactness. The division of labour is now fully drawn. Lax–Milgram solves one linear problem; fixed points glue the solved problems into a self-consistent equilibrium. It remains only to supply the gluing, and that is the business of the three fixed-point theorems—Banach, Schauder, Kakutani—to which we turn, recognizing the self-consistent loop they govern as the same self-reproduction picture the mean-field idea has worn since the start.

2.7 Fixed-point theorems: the engines of existence

Every equilibrium in this book is a fixed point. An agent best-responds to the population; the population is the aggregate of best responders; an equilibrium is a population that reproduces itself under this loop. Formalizing "reproduces itself" as $\Phi(m) = m$ for a best-response map S on a suitable space, existence of an equilibrium becomes existence of a fixed point. Three theorems supply fixed points under three different trade-offs between what one assumes about the map and what one concludes.

Heuristic (non-rigorous)

The physical reflex is the self-consistent field: guess a mean field, compute the best response to it, read off the new mean field it generates, and iterate $m^{(0)} \mapsto m^{(1)} = \mathsf{S}(m^{(0)}) \mapsto m^{(2)} = \mathsf{S}(m^{(1)}) \mapsto \cdots$, hoping for a fixed point. The three theorems below are precisely the three rigorous guarantees one can attach to this iteration. *Banach* (contraction) says: if the map shrinks distances, the iteration converges geometrically to the unique fixed point—this is convergence *and* uniqueness, but it demands a smallness/contraction hypothesis (in the graphon theory, smallness of $\|\mathbb{W}\|$, (A-Coupling)). *Schauder* says: if the map is merely continuous and lands in a compact convex set, a fixed point exists—this is existence without uniqueness and without convergence of the naive iteration, and it is what one uses when no smallness is available. *Kakutani* extends this to *set-valued* best responses, for when the best response is not unique and one must allow a convex set of optimal replies.

Theorem 2.36 (Banach contraction principle)**.** *Let (X, d) be a nonempty complete metric space and $\mathsf{S}\colon X \to X$ a* contraction*: there is $\kappa \in [0, 1)$ with $d(\mathsf{S}x, \mathsf{S}y) \le \kappa\, d(x, y)$ for all x, y. Then S has a unique fixed point x_*, and for every x_0 the iterates $x_{n+1} = \mathsf{S}x_n$ converge to it with $d(x_n, x_*) \le \dfrac{\kappa^n}{1-\kappa}\, d(x_1, x_0)$.*

Proof. The iterates are Cauchy: $d(x_{n+1}, x_n) \le \kappa^n d(x_1, x_0)$, and summing the geometric series bounds $d(x_{n+p}, x_n) \le \frac{\kappa^n}{1-\kappa} d(x_1, x_0)$. Completeness gives a limit x_*; continuity of the contraction (it is Lipschitz) gives $\mathsf{S}x_* = \lim \mathsf{S}x_n = \lim x_{n+1} = x_*$. If x_*, x_*' are both fixed, $d(x_*, x_*') = d(\mathsf{S}x_*, \mathsf{S}x_*') \le \kappa\, d(x_*, x_*')$ forces $d(x_*, x_*') = 0$. □

This is the only one of the three that yields uniqueness and a constructive, convergent algorithm, which is why every *uniqueness* theorem in the book that is not monotonicity-based (chapters 11 and 24) ultimately reduces best response to a contraction under a smallness hypothesis. Its limitation is exactly that hypothesis: when the coupling is not small the map need not contract, and one must trade uniqueness for the weaker existence guarantees that compactness provides. The bridge is the finite-dimensional fixed-point theorem of Brouwer, which we state as the seed.

Theorem 2.37 (Brouwer)**.** *Every continuous map of a nonempty compact convex subset of $\mathbb{R}^d$ into itself has a fixed point.*

Brouwer's theorem sits above our prerequisite line, so we do not take it on faith: an elementary and fully self-contained proof, via Sperner's combinatorial lemma, is given in theorem B.13, with [79, Ch. 1] for the degree-theoretic and simplicial-approximation routes as further reading. Its infinite-dimensional extension is the workhorse of MFG existence.

Theorem 2.38 (Schauder)**.** *Let C be a nonempty closed convex subset of a Banach space X and $\mathsf{S}\colon C \to C$ a continuous map whose image $\mathsf{S}(C)$ is relatively compact. Then S has a fixed point. (Equivalently: any continuous self-map of a nonempty compact convex set has a fixed point.)*

Proof sketch. The mechanism is to approximate the infinite-dimensional problem by finite-dimensional ones to which Brouwer applies, then pass to the limit using compactness. Since $K = \overline{\mathsf{S}(C)}$ is compact, for each $\varepsilon > 0$ it has a finite ε-net $\{y_1, \ldots, y_N\} \subseteq K$. The Schauder projection $P_\varepsilon z = \frac{\sum_j \theta_j(z)\, y_j}{\sum_j \theta_j(z)}$, with $\theta_j(z) = \max(0, \varepsilon - \|z - y_j\|)$, maps K continuously into the finite-dimensional convex hull $C_\varepsilon = \operatorname{conv}\{y_1, \ldots, y_N\}$ and moves each point by less than ε. Because every $y_j \in K = \overline{\mathsf{S}(C)} \subseteq C$ and C is convex, the hull $C_\varepsilon \subseteq C$; hence $P_\varepsilon \circ \mathsf{S}$ is a continuous self-map of the finite-dimensional compact convex set C_ε (S maps $C_\varepsilon \subseteq C$ into $\mathsf{S}(C) \subseteq K$, and P_ε maps K back into C_ε), so Brouwer (theorem 2.37) gives a fixed point $x_\varepsilon \in C_\varepsilon$ with $\|\mathsf{S}x_\varepsilon - x_\varepsilon\| = \|\mathsf{S}x_\varepsilon - P_\varepsilon \mathsf{S}x_\varepsilon\| < \varepsilon$. Letting $\varepsilon \to 0$, compactness of K extracts a convergent subsequence $\mathsf{S}x_\varepsilon \to x_*$, whence $x_\varepsilon \to x_*$ as well, and continuity of S gives $\mathsf{S}x_* = x_*$. The argument is carried out in full in theorem B.14; see also [79, Ch. II] and [31, Ch. 11]. □

Schauder is the theorem behind the existence proofs of chapters 10 and 24: the best-response map is shown continuous, and the relatively compact image is produced by an a priori estimate (tightness in chapter 3 on the measure side, the Rellich–Kondrachov compactness of theorem 2.31 on the PDE side). It gives existence with no uniqueness and no algorithm—which is honest, because mean field games genuinely can have multiple equilibria (chapter 11). When the best response is not single-valued—when an agent is indifferent among several optimal replies—one needs a set-valued refinement.

Definition 2.39 (Upper hemicontinuity)**.** A set-valued map $\mathsf{S}\colon C \rightrightarrows C$ (assigning to each x a subset $\mathsf{S}(x) \subseteq C$) is *upper hemicontinuous with closed graph* if its graph $\{(x, y) : y \in \mathsf{S}(x)\}$ is closed in $C \times C$; concretely, $x_n \to x$, $y_n \in \mathsf{S}(x_n)$, $y_n \to y$ imply $y \in \mathsf{S}(x)$.

A word on the name. Having a closed graph and being upper hemicontinuous in the standard sense (preimages of open sets pull back to open sets under the upper inverse) are not equivalent for arbitrary correspondences. They *do* coincide in the only setting we use, where the target C is compact and the values $\mathsf{S}(x)$ are closed (hence compact): there a closed graph is exactly upper hemicontinuity. We verify and invoke the closed-graph form throughout because it is what the fixed-point argument actually checks, and we keep the name "upper hemicontinuous" to match the literature.

Theorem 2.40 (Kakutani–Fan–Glicksberg)**.** *Let C be a nonempty compact convex subset of a locally convex space (e.g. a Banach space, or a convex weak-$*$ compact set of measures), and $\mathsf{S}\colon C \rightrightarrows C$*

an upper hemicontinuous set-valued map with closed graph such that every value $\mathsf{S}(x)$ *is nonempty, convex, and closed. Then* S *has a fixed point: some* $x_* \in C$ *with* $x_* \in \mathsf{S}(x_*)$*.*

The proof reduces the set-valued problem to the single-valued Schauder theorem by an approximate-selection construction. For each $\varepsilon > 0$, cover the compact C by finitely many balls $B(x_i, \varepsilon)$, take a continuous partition of unity $\{\psi_i\}$ subordinate to this cover, choose one value $z_i \in \mathsf{S}(x_i)$ at each centre, and set $f_\varepsilon = \sum_i \psi_i\, z_i$. This $f_\varepsilon : C \to C$ is continuous and single-valued (a convex combination of points of C, which is convex), and it is an ε-approximate selection of S in the sense that its graph lies within ε of the graph of S. Schauder (theorem 2.38) applied to f_ε on the compact convex C yields a fixed point $x_\varepsilon = f_\varepsilon(x_\varepsilon)$; letting $\varepsilon \to 0$, compactness extracts $x_\varepsilon \to x_*$, and the closed graph together with convexity of the values forces $x_* \in \mathsf{S}(x_*)$ in the limit. The full argument—including the approximate-selection lemma and the closed-graph passage to the limit—is carried out in theorem B.16; see also [79, Ch. II]. Kakutani is what licenses *relaxed* or *mixed* equilibria in chapter 10, where the optimal control need not be unique and the best response is the (convex) set of all optimal replies. The convexity of the values is the crucial hypothesis and the reason relaxed controls—probability measures over actions—are introduced: convexifying the action set is what makes the best-response correspondence convex-valued.

Notation watch

The three theorems sit in a strict logical hierarchy of hypothesis strength, and it is worth fixing which is which to avoid over-claiming. Banach needs a metric *contraction* and delivers the most (unique fixed point, convergent iteration). Schauder needs only *continuity plus compactness* and delivers existence of a (possibly non-unique) fixed point with no algorithm. Kakutani needs *upper hemicontinuity plus convex values plus compactness* and delivers existence for set-valued maps. A common error is to invoke “Schauder” for a map that is continuous but whose image is not relatively compact; without the compactness input the theorem is false in infinite dimensions (the identity map on the unit ball has no fixed point). The compactness input is never free—it is always an a priori estimate in disguise.

Rigor ledger

Rigor ledger

Proved (in full or by complete sketch with the mechanism named).

- Hilbert-space geometry: projection onto closed convex sets, Riesz representation, Parseval (theorems 2.5, 2.6 and 2.8); stated with proofs cited.
- Banach–Alaoglu and the extraction of weakly convergent subsequences from bounded sequences in reflexive/Hilbert spaces (theorem 2.16 and corollary 2.17), proved via Tychonoff.
- Identification of Hilbert–Schmidt operators with L^2 kernels and the self-adjoint Hilbert–Schmidt structure of the graphon operator (theorem 2.22 and proposition 2.24).

- The spectral theorem for compact self-adjoint operators and the Courant–Fischer min–max (theorem 2.26 and corollary 2.27), with a complete variational-construction sketch; the explicit spectra of the constant and rank-one graphon operators (worked computation 2.28).
- The Banach contraction principle in full (theorem 2.36); Lax–Milgram by a complete sketch (theorem 2.34).

Imported from chapter 1 (proved there, used here).

- Completeness of L^p (theorem 1.31), density of simple and smooth functions, and Fubini–Tonelli (theorem 1.27); the lightweight definition of weak convergence of probability measures (definition 1.33).
- Standing assumption (A-Reg-W) of appendix A.6, used to make $\mathbb{W}$ self-adjoint Hilbert–Schmidt.

Proved in-book in appendix B (stated here with body sketch where given).

- Hahn–Banach extension and separation (theorem 2.11), via Zorn's lemma and the Minkowski gauge: appendix B.2.
- Tychonoff's theorem for the product of compact intervals underlying Banach–Alaoglu (theorem 2.16), via the Alexander subbase lemma: appendix B.3. The separable case used throughout the book needs no Tychonoff and is proved in the body.
- Brouwer's theorem (theorem 2.37) via Sperner's lemma (theorem B.13); the Schauder and Kakutani–Fan–Glicksberg theorems (theorems 2.38 and 2.40), with body sketches and the full arguments in theorems B.14 and B.16.
- Meyers–Serrin density, the Rellich–Kondrachov compact embedding, and the Poincaré inequality (theorem 2.31): appendix B.8.

Deferred (named destination).

- The complex case of the spectral theorem: appendix B.4 (the real case is proved in full in the body).
- Elliptic/parabolic regularity (Sobolev/Morrey embeddings, Schauder estimates) that upgrades weak to classical solutions: invoked in chapters 6 and 8, sources [64, Ch. 6].
- The spectral payoff—eigenvector centrality, spectral gap, operator-norm thresholds, low-rank reductions of $\mathbb{W}$: chapter 18 (static games chapter 20, GMFG existence and the critical coupling chapter 24).

Open (genuinely, beyond this book's scope).

- No claim in this chapter is open; it is classical functional analysis. The open questions it *feeds* are downstream: sharp operator-norm thresholds for GMFG uniqueness (chapter 24) and the spectral theory of *unbounded* (L^p, $p < \infty$) graphon operators where $\mathbb{W}$ is no longer Hilbert–Schmidt (chapter 27).

Bibliographic notes

The Hilbert-space material of sections 2.1 and 2.2—inner products, projection, Riesz representation, orthonormal bases—follows [123, Ch. 4], the roadmap's designated source, supplemented by [31, Ch. 5–6] and the physicist-friendly [113, Ch. II]. The weak and weak-$*$ topologies and Banach–Alaoglu (section 2.3) are treated in [31, Ch. 3] and [113, Ch. IV]; [50] is a good alternative reference for the duality theory and the Hahn–Banach theorem. Compact and Hilbert–Schmidt operators and the spectral theorem (sections 2.4 and 2.5) are in [123, Ch. 6], [31, Ch. 6], and [113, Ch. VI]; the variational construction of the eigenvalues and the min–max principle are classical. That the graphon is exactly a self-adjoint Hilbert–Schmidt operator, and the spectral reading of network structure that this enables, is the operator-theoretic core of graph-limit theory [99, Ch. 7.5], collected in chapter 18. The Sobolev-space theory of section 2.6—weak derivatives, the H^s scale, Rellich–Kondrachov, Lax–Milgram—follows [31, Ch. 8–9] and [64, Ch. 5], which are also the sources for the deferred elliptic regularity. The three fixed-point theorems of section 2.7 are developed, with the finite-dimensional-approximation proofs sketched here given in full, in [79, Ch. I–II]; their use as the engines of mean-field-game existence follows [36] and [40, Vol. I], and in the graphon setting [34, 108].

Chapter 3

Probability and Weak Convergence of Measures

The previous two chapters built the two pillars on which this one stands, and it is worth recalling not merely their contents but their purpose, because every instrument assembled here is welded out of them. From chapter 1 we import the measure-theoretic apparatus: σ-algebras as the bookkeeping of events, the Lebesgue integral as the universal averaging operation, the monotone and dominated convergence theorems (theorem 1.20, theorem 1.23) that license the exchange of a limit with an integral, the Fubini–Tonelli theorem (theorem 1.27) that disentangles a joint integral into iterated ones, and the picture of the empirical measure $\mu^N = \frac{1}{N}\sum_{i=1}^{N} \delta_{X_i}$ as the rigorous occupation profile of a finite ensemble — the histogram that records *where* the agents are without recording *which* agent is where. From chapter 2 we import Hilbert-space geometry: closed subspaces, orthogonal projection onto a closed convex set as the unique nearest-point map, and the duality between a Banach space and its continuous dual. The first pillar tells us how to integrate; the second tells us how to project. This chapter welds the two into the single instrument the rest of the book uses more than any other: a *topology on the space of probability measures* in which the empirical measure of a large population converges to a deterministic limit, a precise accounting of the residual fluctuations around that limit, and — the projection pillar's contribution — the conditional expectation the stochastic chapters demand.

The reason this matters can be stated before any formalism, and it is the whole motivation for the chapter. A mean field game confronts an N-player problem in which every agent's optimal behaviour depends on what all the others do; with the coupling fully retained the problem is intractable as N grows. The mean field idea is to replace it, in the limit $N \to \infty$, by a problem with a single *representative* agent who best-responds not to the other agents individually but to a *measure* m summarizing the population's state, with the closing consistency requirement that when every agent plays this best response the population they generate is again m. Two phrases in this story must be given precise meaning, and supplying that meaning is what the chapter does. First, "the population converges to a measure": the object that converges is the empirical measure μ^N, itself a *random point in the space of probability measures*, and to say it settles down to a deterministic m we need a notion of *convergence of measures*. Second, "the finite game is well approximated by the limit game": this demands control of the discrepancy between μ^N and m, and an elementary variance computation (carried out at the end of section 3.1) already shows that discrepancy is of typical size $N^{-1/2}$, with — as the central limit theorem will sharpen — a Gaussian profile.

Concretely, four tools do this work, and the reader should keep each tool's downstream consumer in view from the start. *(i) Weak convergence*, with the Portmanteau theorem as its working characterization, is the right notion of "the population converges to a measure"; it is the topology in which the existence arguments operate. *(ii) Tightness together with Prokhorov's theorem* is the compactness theory that extracts a limit from a sequence of measures when no limit is given in advance; it is the engine of the existence proofs in chapter 10 and chapter 24, where an equilibrium is obtained as a subsequential limit of approximate ones. *(iii) The characteristic-function route to the central limit theorem* pins the $N^{-1/2}$ Gaussian fluctuation scale, the quantity that chapter 7 (propagation of chaos) and chapter 13 (fluctuation analysis) make their business. *(iv) Conditional expectation as an orthogonal projection* — where the second pillar finally pays off — is the prerequisite for the filtrations and backward stochastic equations of chapter 5 and chapter 9. These are not a generic probability refresher; they are exactly the pieces of probability the mean field and graphon mean field theories consume, curated to that end. And, honouring the self-containedness demanded in chapter 1, *every named theorem among them is proved here, not cited*: Portmanteau, Prokhorov, the Skorokhod representation, the central limit theorem, and the projection theorem for conditional expectation all receive complete in-book proofs.

A word on the setting before we begin. Throughout, the state space of a single agent is a complete separable metric (*Polish*) space, most often $\mathbb{R}^d$; Polishness is precisely what makes tightness and the Skorokhod representation available, and we flag each place it is used. The type variable $x \in [0,1]$ of the graphon chapters plays no role here — this chapter concerns the law of a *single* agent's state, not the network of types — and no standing assumption from the thread specification is invoked, because this is a foundations chapter and its theorems hold in the generality stated. The order of march follows the order of the four tools, and each later section opens by saying where in this march we stand: we begin (section 3.1) with the objects — probability spaces, random variables, expectation, independence; build weak convergence and prove Portmanteau, the metrization, and the Skorokhod representation that make it a usable topology (section 3.2); develop tightness and prove Prokhorov (section 3.3); quantify the $N^{-1/2}$ fluctuations through characteristic functions and the central limit theorem (section 3.4); pause to record two concentration tools — the Borel–Cantelli lemmas and the Azuma–Hoeffding inequality — that the later chapters draw on (section 3.5); and close with conditional expectation as projection (section 3.6).

3.1 Probability spaces, expectation, and independence

With the four-tool itinerary fixed, we start at the bottom, with the objects themselves, and in doing so redeem the preamble's central promise: that this chapter makes good on the slogan "every probabilistic quantity is an integral" by welding the measure theory of chapter 1 into probability. The recollection that follows is short, but it turns on a single conceptual move — the one a physicist most needs to internalize. A random variable is not a number equipped with a "spread"; it is a *measurable function on a sample space.* And every probabilistic quantity built from it — the probability of an event, a mean, a variance, a correlation — is an *integral* of such a function against a measure. Once that identification is in hand, the whole convergence apparatus of chapter 1 (the monotone and dominated convergence theorems, Fubini–Tonelli) transfers to probability with no further work, and the remainder of this section is the harvest.

Definition 3.1 (Probability space)**.** A *probability space* is a triple $(\Omega, \mathcal{F}, \mathbb{P})$ where Ω is a set (the sample space), $\mathcal{F}$ is a σ-algebra of subsets of Ω (the events), and $\mathbb{P} : \mathcal{F} \to [0, 1]$ is a measure with $\mathbb{P}(\Omega) = 1$. A property that holds for all ω outside a set $N \in \mathcal{F}$ with $\mathbb{P}(N) = 0$ is said to hold *almost surely* (a.s.).

The structure is *exactly* that of chapter 1, specialized to total mass one; nothing is added, and one thing is fixed. The normalization $\mathbb{P}(\Omega) = 1$ is the entire difference between a general measure and a probability measure, and it is what licenses the two probabilistic readings we will lean on: $\mathbb{P}(A)$ is the "chance" of the event A, a number in $[0, 1]$ rather than an arbitrary nonnegative quantity, and $\mathbb{E}[X]$ (defined below) is a genuine *average* — each outcome weighted by how likely it is — rather than an unnormalized total. Everything underneath, from countable additivity to the monotone and dominated convergence theorems, is the measure theory already in hand, inherited verbatim. The almost-sure language of definition 3.1 is the probabilistic name for "up to a $\mathbb{P}$-null set"; it is the equivalence under which we tacitly identify random variables throughout, exactly as chapter 1 identifies functions that agree almost everywhere.

Definition 3.2 (Random variable and its law)**.** Let $(S, \mathcal{S})$ be a measurable space. An *S-valued random variable* is a measurable map $X : (\Omega, \mathcal{F}) \to (S, \mathcal{S})$, i.e. $X^{-1}(B) \in \mathcal{F}$ for every $B \in \mathcal{S}$. Its *law* (or *distribution*) is the push-forward measure

$$\mathcal{L}(X) \;=\; \mathbb{P} \circ X^{-1} \;:=\; \mu_X, \qquad \mu_X(B) = \mathbb{P}(X \in B), \quad B \in \mathcal{S},$$

a probability measure on $(S, \mathcal{S})$. When S is a metric space we always take $\mathcal{S} = \mathcal{B}(S)$, the Borel σ-algebra.

The law μ_X *forgets the sample space entirely.* Nothing in μ_X remembers which $\omega \in \Omega$ produced which value; it records only how the unit mass of $\mathbb{P}$ is spread over the state space S. This forgetting is not a loss but the whole point: Ω is an auxiliary scaffold, chosen for convenience and never canonical, whereas μ_X is the invariant content. It is the law, not the sample space, that survives into every limit theorem of this chapter, and it is the law on which the entire mean field theory is built — the mean field m *is* a law, a point of $\mathcal{P}_2(\mathbb{R}^d)$ in the sense of chapter 4, and the empirical occupation profile μ^N is a (random) law as well. Because the sample space is disposable, two random variables with the same law are interchangeable for every purpose this book cares about; we write $X \overset{d}{=} Y$, call them *equal in distribution*, and allow them to live on entirely different probability spaces. This is precisely why weak convergence, the subject of section 3.2, will be phrased as a convergence of laws rather than of the variables themselves: the variables may not even share a home.

The single quantity we extract from a real random variable more than any other is its average. A physicist reads $\mathbb{E}[X]$ as "the value of X averaged over the ensemble of outcomes, each weighted by its probability," and the next definition makes exactly this precise by declaring the average to *be* the Lebesgue integral of chapter 1: built first for $X \geq 0$, where the integral is the supremum of the integrals of simple functions beneath X and so is always defined in $[0, \infty]$, and then for signed X by subtracting the contributions of its positive and negative parts.

Definition 3.3 (Expectation as integration)**.** For a real random variable $X \geq 0$ the *expectation* is the Lebesgue integral $\mathbb{E}[X] = \int_\Omega X \, \mathrm{d}\mathbb{P} \in [0, \infty]$. For general real X, X is *integrable* if $\mathbb{E}[|X|] < \infty$, and then $\mathbb{E}[X] = \int_\Omega X^+ \, \mathrm{d}\mathbb{P} - \int_\Omega X^- \, \mathrm{d}\mathbb{P}$. We write $X \in L^p(\Omega, \mathcal{F}, \mathbb{P})$, $p \geq 1$, when $\mathbb{E}[|X|^p] < \infty$.

Because the expectation is *literally* an integral against $\mathbb{P}$, every theorem of chapter 1 applies to it verbatim — this is the dividend of insisting that a random variable is a measurable function rather than a number with a spread. Two consequences are used on nearly every page that follows: the change-of-variables formula, which moves a computation off the abstract space Ω and onto the concrete state space S where the law lives, and the convergence theorems, which let us exchange a limit with an expectation. We record both here in probabilistic dress.

Lemma 3.4 (Change of variables; convergence under the integral)**.** *Let X be an S-valued random variable with law μ_X and let $f : S \to \mathbb{R}$ be Borel measurable.*

1. (Transport of the integral.) *If $f \geq 0$ or $f(X)$ is integrable, then*

$$\mathbb{E}[f(X)] \;=\; \int_S f \, \mathrm{d}\mu_X. \tag{3.1}$$

2. (Dominated convergence.) *If $X_n \to X$ a.s. and $|X_n| \leq Y$ a.s. with $\mathbb{E}[Y] < \infty$, then $\mathbb{E}[X_n] \to \mathbb{E}[X]$. If instead $0 \leq X_n \uparrow X$ a.s., then $\mathbb{E}[X_n] \uparrow \mathbb{E}[X]$ (monotone convergence).*

Proof. Part (1) is the pushforward transfer formula of chapter 1 (lemma 1.15), re-derived here in probabilistic notation by the *standard machine*: establish the identity for indicators, extend it by linearity to simple functions, by monotone convergence to nonnegative functions, and by a difference to integrable ones. We run the four steps because the same ladder reappears, unannounced, in almost every later proof.

Indicators. Let $f = \mathbf{1}_B$ with $B \in \mathcal{S}$. Then $f(X) = \mathbf{1}\{X \in B\} = \mathbf{1}_{X^{-1}(B)}$, an indicator on Ω, so by the definition of the integral of an indicator and of the law μ_X (definition 3.2),

$$\mathbb{E}[\mathbf{1}_B(X)] = \mathbb{P}(X^{-1}(B)) = \mathbb{P}(X \in B) = \mu_X(B) = \int_S \mathbf{1}_B \, \mathrm{d}\mu_X.$$

Thus (3.1) holds when f is an indicator.

Simple functions. Let $f = \sum_{k=1}^r c_k \, \mathbf{1}_{B_k}$ with $c_k \geq 0$ and $B_k \in \mathcal{S}$. Both sides of (3.1) are linear in f — the left side by linearity of the integral over Ω, the right side by linearity of the integral of a simple function over S (eq. (1.4)) — so the indicator case applied termwise gives $\mathbb{E}[f(X)] = \sum_k c_k \, \mu_X(B_k) = \int_S f \, \mathrm{d}\mu_X$.

Nonnegative functions. Let $f \geq 0$ be Borel. By the standard approximation of measurable functions in chapter 1 there are simple functions s_n with $0 \leq s_n \uparrow f$ pointwise on S; composing with X preserves the monotone increase, $0 \leq s_n(X) \uparrow f(X)$ pointwise on Ω. Applying the monotone convergence theorem (theorem 1.20) on $(\Omega, \mathcal{F}, \mathbb{P})$ to the left and on $(S, \mathcal{S}, \mu_X)$ to the right, with the simple-function identity in the middle,

$$\mathbb{E}[f(X)] = \lim_n \mathbb{E}[s_n(X)] = \lim_n \int_S s_n \, \mathrm{d}\mu_X = \int_S f \, \mathrm{d}\mu_X.$$

Integrable functions. For a general Borel f write $f = f^+ - f^-$ with $f^\pm \geq 0$. The nonnegative case applied to $|f| = f^+ + f^-$ gives $\mathbb{E}[|f(X)|] = \int_S |f| \, \mathrm{d}\mu_X$, so the hypothesis $\mathbb{E}[|f(X)|] < \infty$ is exactly $\int_S |f| \, \mathrm{d}\mu_X < \infty$ and renders both $\int_S f^+ \, \mathrm{d}\mu_X$ and $\int_S f^- \, \mathrm{d}\mu_X$ finite. Subtracting the nonnegative identity for f^- from that for f^+ yields (3.1) for f.

Part (2) is the convergence machinery of chapter 1 read on the probability space, with no new idea. If $X_n \to X$ a.s. and $|X_n| \leq Y$ a.s. with $\mathbb{E}[Y] < \infty$, then Y is an integrable dominating function, and the dominated convergence theorem (theorem 1.23) applied to (X_n) on $(\Omega, \mathcal{F}, \mathbb{P})$ gives $\mathbb{E}[X_n] = \int_\Omega X_n \, \mathrm{d}\mathbb{P} \to \int_\Omega X \, \mathrm{d}\mathbb{P} = \mathbb{E}[X]$. If instead $0 \leq X_n \uparrow X$ a.s., the monotone convergence theorem (theorem 1.20) delivers $\mathbb{E}[X_n] \uparrow \mathbb{E}[X]$. The almost-sure qualifiers are harmless: altering each X_n on a $\mathbb{P}$-null set changes none of the integrals, by the very definition of the Lebesgue integral. □

Formula (3.1) is the bridge we cross constantly, and it is worth saying exactly what it buys. Its left-hand side lives on the abstract, inaccessible space Ω, which we never describe; its right-hand side lives on the concrete state space S — usually $\mathbb{R}^d$ — where f is an explicit function and μ_X an explicit distribution. The identity therefore lets every later computation be carried out on S against the law, never needing to mention Ω at all. A tiny instance fixes the idea: with $f(x) = x$ the formula reads $\mathbb{E}[X] = \int_S x \, \mathrm{d}\mu_X(x)$, the familiar statement that the mean is the integral of the value against the distribution; and if X takes finitely many values $x_1, \ldots, x_r$ with probabilities $p_k = \mathbb{P}(X = x_k)$, then $\mu_X = \sum_k p_k \, \delta_{x_k}$ and the integral collapses, by the Dirac evaluation (1.7), to $\mathbb{E}[X] = \sum_k x_k \, p_k$ — the elementary weighted-average formula, recovered as a special case rather than posited. The same bridge with $f(x) = x^2$, with $f(x) = e^{itx}$, and with $f(x) = \mathbf{1}_{\{x>a\}}$ produces, respectively, the second moment, the characteristic function of section 3.4, and a tail probability, each as a single integral against μ_X; these are the three computations the rest of the chapter actually performs.

Two such integrals earn their own names, because they are the L^2 data of a random variable and the L^2 geometry of chapter 2 will return for them in force when we reach conditional expectation. For $X, Y \in L^2(\Omega, \mathcal{F}, \mathbb{P})$ the *variance* and *covariance* are the special cases

$$\operatorname{Var}(X) = \mathbb{E}\Big[(X - \mathbb{E}[X])^2\Big], \qquad \operatorname{Cov}(X, Y) = \mathbb{E}[(X - \mathbb{E}[X])(Y - \mathbb{E}[Y])].$$

Read geometrically, these are nothing but the squared norm and the inner product of the *centered* variables in the Hilbert space L^2: $\operatorname{Var}(X) = \|X - \mathbb{E}[X]\|_{L^2}^2$ and $\operatorname{Cov}(X, Y) = \langle X - \mathbb{E}[X]\,, Y - \mathbb{E}[Y] \rangle_{L^2}$. They are finite precisely because $X, Y \in L^2$ — this is where the square-integrability hypothesis is spent — and the Cauchy–Schwarz inequality (proposition 1.30 with $p = q = 2$) both guarantees the covariance exists and gives the bound $|\operatorname{Cov}(X, Y)| \leq \sqrt{\operatorname{Var} X}\,\sqrt{\operatorname{Var} Y}$. Reading variance and covariance as L^2 geometry is not a flourish: it is the very viewpoint under which conditional expectation becomes an orthogonal projection in section 3.6, and it is why "uncorrelated" will turn out to mean "orthogonal."

Expectation is now pinned down as integration against the law, and with it the L^2 bookkeeping of fluctuations. The next structural ingredient the limit theorems require is the encoding of "no interaction" between random variables. It is this notion — independence — that makes the law of large numbers and the central limit theorem run, and, fittingly, it is expressed through the very integral pairing just established: independence will be the statement that the expectation of a product *factorizes* into the product of expectations.

3.1.1 Independence

Expectation is now the integral pairing $\mathbb{E}[f(X)] = \int_S f \, \mathrm{d}\mu_X$ of (3.1), and the L^2 data of a random variable read off as the geometry of that pairing. With this in hand we can give precise meaning to the one structural relation between several random variables that the limit theorems require: that they do *not* interact. "No interaction" is a physical phrase, and the task is to translate it into a statement about the integral pairing just established. The translation is the cleanest possible: two variables fail to interact when the expectation of their product *splits* into the product of their expectations, so that knowing one carries no information about the average of the other. This is independence, and the whole engine of the law of large numbers and the central limit theorem turns on it. It is, moreover, the exact structural fact at stake in the mean field programme: a mean field limit *manufactures* independence asymptotically — this is propagation of chaos (chapter 7), the statement that any fixed finite group of agents becomes independent as $N \to \infty$ — while the coupling in an N-player game *destroys* it at finite N, every agent's state depending on every other's through the shared population. The residual dependence is precisely what section 3.4 will weigh, and the $N^{-1/2}$ that measures it is already visible, as we will see, in a one-line variance computation.

We give the definition in its most structural form, at the level of σ-algebras, and then unfold it into the two working forms one actually computes with.

Definition 3.5 (Independence)**.** Sub-σ-algebras $\mathcal{F}_1, \ldots, \mathcal{F}_k \subseteq \mathcal{F}$ are *independent* if for all $A_i \in \mathcal{F}_i$,

$$\mathbb{P}\Big(\bigcap_{i=1}^{k} A_i\Big) = \prod_{i=1}^{k} \mathbb{P}(A_i).$$

Random variables $X_1, \ldots, X_k$ are independent if the generated σ-algebras $\sigma(X_1), \ldots, \sigma(X_k)$ are. An infinite family is independent if every finite subfamily is. The variables are *independent and identically distributed* (i.i.d.) if they are independent and share a common law. We write $X \perp\!\!\!\perp \mathcal{G}$ when $\sigma(X)$ and the σ-algebra $\mathcal{G}$ are independent.

The definition is phrased through σ-algebras because that is the form that composes cleanly — $\sigma(X_i)$ records *everything* measurable about X_i, so factorization of probabilities across the $\sigma(X_i)$ says no event decided by one variable shifts the odds of any event decided by another. But it is not the form one verifies or computes with. There are two equivalent working forms, and tracing the equivalence is worthwhile because the bridge between them is exactly the Fubini–Tonelli theorem of chapter 1, the same disentangling of a joint integral into iterated ones that the chapter preamble flagged as imported machinery.

The first working form is a statement about the joint law on the product space. The variables $X_1, \ldots, X_k$ assemble into a single S^k-valued variable $(X_1, \ldots, X_k)$, whose law $\mu_{(X_1,\ldots,X_k)}$ is a probability measure on S^k; its one-dimensional marginals are the individual laws μ_{X_i}. Then $X_1, \dots, X_k$ are independent *iff* this joint law is the product measure

$$\mu_{(X_1,\dots,X_k)} \;=\; \mu_{X_1} \otimes \cdots \otimes \mu_{X_k}, \tag{3.2}$$

the unique measure on S^k assigning mass $\prod_i \mu_{X_i}(B_i)$ to each rectangle $B_1 \times \cdots \times B_k$. That this is the same condition as definition 3.5 is immediate on rectangles — the event $\{X_i \in B_i \ \forall i\} = \bigcap_i \{X_i \in B_i\}$ has probability $\prod_i \mathbb{P}(X_i \in B_i) = \prod_i \mu_{X_i}(B_i)$ exactly when the $\sigma(X_i)$ factorize — and rectangles form an intersection-stable generating class for the product σ-algebra, so agreement there forces agreement everywhere by the uniqueness lemma for measures (corollary 1.10). This is the cleanest formulation, but it lives on S^k and speaks of sets.

The second working form lives back on the level of expectations, where we actually integrate. When the relevant products are integrable, $X_1, \dots, X_k$ are independent iff

$$\mathbb{E}\Big[\textstyle\prod_{i=1}^k f_i(X_i)\Big] = \displaystyle\prod_{i=1}^k \mathbb{E}[f_i(X_i)] \qquad \text{for all bounded measurable } f_i : S \to \mathbb{R}. \tag{3.3}$$

This is the form the limit theorems consume, and it is *exactly* the product-measure form (3.2) read through Fubini–Tonelli. Indeed, transporting the expectation to the product space by the change-of-variables formula (3.1) and then, *because* the joint law is a product, iterating the integral via Fubini–Tonelli (theorem 1.27),

$$\mathbb{E}\Big[\textstyle\prod_{i=1}^k f_i(X_i)\Big] = \displaystyle\int_{S^k} \prod_{i=1}^k f_i(x_i) \; \mathrm{d}(\mu_{X_1} \otimes \cdots \otimes \mu_{X_k})(x_1, \dots, x_k) = \prod_{i=1}^k \int_S f_i \; \mathrm{d}\mu_{X_i} = \prod_{i=1}^k \mathbb{E}[f_i(X_i)]\,.$$

The middle equality is the entire content: Fubini–Tonelli is the theorem that licenses splitting an integral against a product measure into a product of one-dimensional integrals, and it is precisely the integrability of $\prod_i |f_i(X_i)|$ — guaranteed here by boundedness of the f_i — that its hypotheses demand. Conversely, taking $f_i = \mathbf{1}_{B_i}$ in (3.3) returns the rectangle identity and hence definition 3.5, so the three forms are genuinely one notion wearing three costumes: σ-algebra factorization for structure, product law for cleanliness, expectation factorization for computation, with Fubini the hinge between the last two.

The single scalar consequence we extract is the one that already encodes the fluctuation scale. Specializing (3.3) to $k = 2$ and to the *centered* test functions $f_1(x) = x - \mathbb{E}[X_i]$, $f_2(x) = x - \mathbb{E}[X_j]$ (legitimate whenever $X_i, X_j \in L^2$, where these products are integrable) gives, for $i \neq j$,

$$\mathrm{Cov}(X_i, X_j) = \mathbb{E}[(X_i - \mathbb{E}[X_i])(X_j - \mathbb{E}[X_j])] = \mathbb{E}[X_i - \mathbb{E}[X_i]]\; \mathbb{E}[X_j - \mathbb{E}[X_j]] = 0,$$

since each centered factor has mean zero. So independent variables are *uncorrelated*: in the L^2 geometry of section 3.1 their centered versions are mutually orthogonal. The converse fails, and it is worth one concrete witness rather than a bare warning. Let X be standard Gaussian and set $Y = X^2$. Then $\mathrm{Cov}(X, Y) = \mathbb{E}[X^3] - \mathbb{E}[X]\,\mathbb{E}[X^2] = 0 - 0 \cdot 1 = 0$ by the vanishing of the odd moments of a symmetric law, yet Y is a deterministic function of X — about as dependent as two variables can be, since X determines Y outright. Vanishing covariance probes only the second-order, linear relationship and is blind to the quadratic dependence here; the pair (X, X^2) is of course not jointly Gaussian, and the one setting where uncorrelated does force independent is precisely a *jointly* Gaussian vector, whose dependence is entirely carried by its covariance matrix.

The reason uncorrelatedness is worth isolating is that it is all one needs for the identity that seeds the entire fluctuation story: the additivity of variance. If $X_1, \dots, X_N$ are independent — indeed merely pairwise uncorrelated — with finite variances, then

$$\operatorname{Var}\Big(\sum_{i=1}^N X_i\Big) = \sum_{i=1}^N \operatorname{Var}(X_i). \tag{3.4}$$

The computation is short and the cross-term cancellation is the whole point, so we show it in full. Writing $\bar{X}_i = X_i - \mathbb{E}[X_i]$ for the centered variables, so that $\sum_i X_i - \mathbb{E}[\sum_i X_i] = \sum_i \bar{X}_i$, and expanding the square of the sum,

$$\operatorname{Var}\Big(\sum_{i=1}^N X_i\Big) = \mathbb{E}\Bigg[\Big(\sum_{i=1}^N \bar{X}_i\Big)^2\Bigg] = \mathbb{E}\Bigg[\sum_{i=1}^N\sum_{j=1}^N \bar{X}_i\bar{X}_j\Bigg] = \sum_{i=1}^N\sum_{j=1}^N \mathbb{E}\Big[\bar{X}_i\bar{X}_j\Big] = \sum_{i=1}^N\sum_{j=1}^N \operatorname{Cov}(X_i, X_j),$$

the third equality by linearity of expectation across the N^2 terms. Now split the double sum into its diagonal $i = j$ and off-diagonal $i \neq j$ parts:

$$\sum_{i,j} \operatorname{Cov}(X_i, X_j) = \underbrace{\sum_{i=1}^N \operatorname{Cov}(X_i, X_i)}_{=\sum_i \operatorname{Var}(X_i)} + \underbrace{\sum_{i\neq j} \operatorname{Cov}(X_i, X_j)}_{=0},$$

and the off-diagonal block vanishes term by term because each $\operatorname{Cov}(X_i, X_j) = 0$ for $i \neq j$ — this is exactly where independence (through uncorrelatedness) is spent, and without it the discarded cross-terms would survive and could be of either sign. What remains is the diagonal $\sum_i \operatorname{Var}(X_i)$, which is (3.4).

Innocuous as it looks, (3.4) already contains the seed of the $N^{-1/2}$ law that organizes the entire fluctuation analysis of this book. Take the X_i i.i.d. with common variance σ^2. The sum has variance $\operatorname{Var}(\sum_i X_i) = N\sigma^2$, growing *linearly* in N: the random contributions, being uncorrelated, neither systematically reinforce nor cancel but accumulate additively. The empirical average $\bar{X}_N = \frac{1}{N}\sum_i X_i$ then has variance

$$\operatorname{Var}(\bar{X}_N) = \frac{1}{N^2}\operatorname{Var}\Big(\sum_{i=1}^N X_i\Big) = \frac{N\sigma^2}{N^2} = \frac{\sigma^2}{N},$$

the factor N^{-2} coming from pulling the constant $1/N$ out of the variance twice. So the variance of the average shrinks like $1/N$, and its standard deviation — the typical size of a fluctuation of $\bar{X}_N$ about its mean — like $\sigma/\sqrt{N}$. This $N^{-1/2}$ is the rate at which the empirical average of a non-interacting ensemble concentrates on its mean, and read on the empirical measure μ^N it is the rate at which the population profile settles onto the deterministic mean field m. At this stage it is only a statement about the second moment; section 3.4 promotes it, through the characteristic function, from variance bookkeeping into the full distributional statement that the rescaled fluctuation $\sqrt{N}(\bar{X}_N - \mathbb{E}[X_1])$ is asymptotically Gaussian — the central limit theorem.

With independence installed and the fluctuation scale already in view, the static catalogue of probabilistic objects is complete: we have sample spaces, laws, expectation-as-integration, the L^2

geometry of fluctuations, and the encoding of non-interaction. Every one of these is an object attached to a *fixed* law. But the mean field story is not about a fixed law; it is about a *sequence* of them — the empirical measures μ^N as N grows — and the assertion that this sequence converges to m. What survives into that limit is, as we stressed for the law itself, not the sample space but the law, and so the question that now organizes the rest of the chapter is dynamic rather than static: in *what sense* does a sequence of laws converge? Answering it requires choosing a topology on the space of probability measures, and the next section builds exactly that topology, together with the theorem — Portmanteau — that makes it usable.

3.2 Weak convergence and the Portmanteau theorem

The previous section closed by isolating what survives the passage to a limit. A random variable's sample space is disposable scaffolding; the invariant content, the thing that reappears in every limit theorem and on which the entire mean field theory is built, is its *law*. The mean field assertion "the population converges to a measure" is therefore, stripped to its mathematical core, the assertion that a sequence of laws — the empirical measures μ^N as N grows — converges to a deterministic law m. To make that assertion mean something we must say in *what sense* a sequence of probability measures converges, and that is a choice of topology on the space of all of them. Choosing and mastering that topology is the business of this section and the two that follow; it is the single piece of apparatus the rest of the book leans on more than any other, because every existence proof, every propagation-of-chaos statement, and every fluctuation theorem is ultimately a convergence statement in it.

We fix the setting once and for all. Let (S, d) be a metric space carrying its Borel σ-algebra $\mathcal{B}(S)$ — the reader may keep the concrete case $S = \mathbb{R}^d$ in mind throughout, since that is the single agent's state space in nearly every application, though separability and, later, completeness are the only structural facts we will actually use. Write $C_b(S)$ for the space of bounded continuous real-valued functions on S, $U_b(S) \subseteq C_b(S)$ for the bounded *uniformly* continuous ones, and $\mathcal{P}(S)$ for the set of Borel probability measures on S. These function classes are the test objects against which we will probe a measure: a probability measure μ is examined not by listing the μ-mass of every set — there are far too many sets — but by recording the averages it assigns to a rich enough family of functions, and $C_b(S)$ and $U_b(S)$ are the two families that turn out to be rich enough. We abbreviate that averaging by the *integral pairing*

$$\mu(f) \;:=\; \int_S f \,\mathrm{d}\mu, \qquad f \in C_b(S),\ \mu \in \mathcal{P}(S),$$

which is exactly the expectation $\mathbb{E}[f(X)]$ of (3.1) when μ is the law of X. This pairing $\mu \mapsto \mu(f)$ is the lens through which a measure is viewed for the remainder of the chapter, and weak convergence will be nothing other than convergence of every such reading. The notation $\mu(f)$ for $\int f \,\mathrm{d}\mu$ is used without further comment from here on.

The development proceeds in three movements, and it is worth naming them in advance so the reader sees the shape of the argument rather than meeting each piece cold. The *first* movement (section 3.2.1) steps back to the random variables themselves and sorts out the four standard senses in which a sequence X_n can converge — almost surely, in probability, in L^p, and in distribution — arranging them into a strict hierarchy. This is the orientation that prevents the most common confusions, and it earns its place here because the fourth and weakest mode, convergence in distribution, is precisely convergence of *laws*: it is the one mode that compares random variables through their laws alone, demands no common sample space, and is therefore the only one that can survive the mean field limit, where the coupling between agents makes almost-sure or L^p statements about individual trajectories hopeless. Locating it among its stronger cousins is what motivates singling it out for deep study. The *second* movement (section 3.2.2) makes that mode precise as the *weak convergence* of measures — $\mu_n(f) \to \mu(f)$ for every $f \in C_b(S)$ — and immediately confronts the awkwardness of the definition: testing against *all* bounded continuous functions is clean to state but unwieldy to verify and to exploit, since one cannot test directly against the indicator of an event. The Portmanteau theorem is the resolution, assembling five mutually equivalent characterizations — in terms of continuous tests, uniformly continuous tests, closed sets, open sets, and continuity sets — each tuned to a different use, and we prove it in full because it is the workhorse of every later chapter. The same movement shows that, when S is separable, weak convergence is not merely a convergence class but a genuine *metric* topology, exhibited through one explicit metric; this metrization is what licenses the constant use of sequential and subsequence arguments that the compactness theory of section 3.3 will demand. The *third* movement (section 3.2.3) supplies the bridge back from measures to random variables: Skorokhod's representation theorem realizes any weakly convergent sequence of laws as a sequence of random variables on one common probability space that converges *almost surely*. This is the device that lets us import the powerful pointwise convergence theorems of chapter 1 into the weak-convergence world, and it is the technical engine behind many of the later limit arguments.

We begin, then, with the first movement: before topologizing the laws we ask how the random variables underneath them converge, so as to place weak convergence correctly among the modes it is the weakest of.

3.2.1 Modes of convergence

We have just fixed the two test classes $C_b(S)$ and $U_b(S)$ and announced that a measure will be probed through the integral pairing $\mu \mapsto \mu(f)$; the plan is to declare a sequence of laws convergent when every such reading converges. Before we topologize the laws, however, it pays to drop back one level and ask the more elementary question the whole programme rests on: in what sense can the *random variables* themselves converge? There is not one answer but four, and they are genuinely different. Sorting them out now is not a digression but the orientation that fixes the target: the weakest of the four will turn out to be convergence of laws — the very thing the pairing $\mu(f)$ is built to detect — and seeing it sit at the bottom of a strict hierarchy is what explains why it, and not its stronger cousins, is the notion the mean field limit forces upon us. Keeping the four straight also heads off the most common errors, because the implications between them run one way only and the reverse implications fail in ways worth seeing concretely.

Let us name the four and say in words what each demands, since the formal statement that follows compresses them. *Almost-sure* convergence is the strongest and the most intuitive: for almost every outcome ω the numerical sequence $X_n(\omega)$ converges to $X(\omega)$ in the ordinary sense, so the trajectories settle down individually. *Convergence in probability* relaxes this to a statement about the bulk: the probability that X_n strays from X by more than a fixed tolerance ε tends to zero, but on the small bad set the discrepancy is uncontrolled and may be enormous, and that bad set is allowed to *move* with n rather than shrinking onto one fixed null set. *Convergence in L^p* measures closeness by an average of the p-th power of the error, so it controls the typical magnitude of the discrepancy but is sensitive to rare events carrying large values — a vanishing probability multiplying a huge value can keep an L^p distance from converging. Finally, *convergence in distribution* asks only that the laws converge: the histograms $\mathcal{L}(X_n)$ approach $\mathcal{L}(X)$, with no requirement that the variables be close, or even defined on the same probability space. The first three compare X_n to X *pathwise*, outcome by outcome, and so presuppose a common sample space; the fourth compares them only through their laws and so does not. This last distinction is the one that will matter most, and we return to it once the hierarchy is established.

Lemma 3.6 (Hierarchy of modes)**.** *Let X_n, X be S-valued random variables on a common probability space. Consider:* (a) $X_n \to X$ *almost surely;* (b) $X_n \to X$ *in probability, i.e.* $\mathbb{P}(d(X_n, X) > \varepsilon) \to 0$ *for every $\varepsilon > 0$;* (c) $X_n \to X$ *in L^p (for real-valued X_n), i.e.* $\mathbb{E}[|X_n - X|^p] \to 0$*;* (d) $X_n \to X$ *in distribution, i.e.* $\mathcal{L}(X_n) \to \mathcal{L}(X)$ *in the sense of definition 3.7 below. Then* (a)⇒(b)*,* (c)⇒(b)*, and* (b)⇒(d)*. Moreover* (b)⇒(a) along a subsequence*. None of the reverse implications holds in general; but if the limit X is a.s. a constant, then* (d)⇒(b)*.*

The lemma asserts a single chain, (a) ⇒ (b) ⇒ (d) with (c) ⇒ (b) feeding in from the side, so that both almost-sure and L^p convergence are strictly stronger than convergence in probability, which is in turn strictly stronger than convergence in distribution. Two of the four arrows are one-line consequences of machinery already in hand; the third, (b) ⇒ (d), is the only substantive one and is where the function classes of the previous section earn their keep; and the partial converses — recovery of almost-sure convergence along a subsequence, and the full converse when the limit is constant — are the refinements the later chapters actually invoke. We take the arrows in that order.

Proof. (a)⇒(b). Fix $\varepsilon > 0$ and consider the indicator $\mathbf{1}\{d(X_n, X) > \varepsilon\}$. If $X_n \to X$ almost surely then for almost every ω one has $d(X_n(\omega), X(\omega)) \to 0$, so eventually $d(X_n(\omega), X(\omega)) \le \varepsilon$ and the indicator is 0 from some n on; thus $\mathbf{1}\{d(X_n, X) > \varepsilon\} \to 0$ a.s.. These indicators are bounded by the constant 1, an integrable dominating function on a probability space, so dominated convergence (lemma 3.4) lets us pass the limit through the expectation: $\mathbb{P}(d(X_n, X) > \varepsilon) = \mathbb{E}[\mathbf{1}\{d(X_n, X) > \varepsilon\}] \to 0$. As ε was arbitrary, this is (b). The mechanism is worth registering: it is exactly the dominated convergence theorem of chapter 1, applied to indicators, that converts a pathwise statement into a statement about probabilities.

(c)⇒(b). This is Markov's inequality and nothing more. The event $\{|X_n - X| > \varepsilon\}$ is contained in the event where $|X_n - X|^p > \varepsilon^p$, and on that event the integrand $|X_n - X|^p$ exceeds ε^p, so

$$\varepsilon^p\, \mathbb{P}(\, |X_n - X| > \varepsilon) \le \mathbb{E}[|X_n - X|^p\ \mathbf{1}\{|X_n - X| > \varepsilon\}] \le \mathbb{E}[|X_n - X|^p]\,,$$

whence $\mathbb{P}(|X_n - X| > \varepsilon) \le \varepsilon^{-p}\mathbb{E}[|X_n - X|^p] \to 0$. Convergence of the p-th-power average therefore forces convergence in probability, with an explicit rate.

(b)⇒(d). This is the one arrow that is not a formality, and the reason is structural, so we pause on it. The Portmanteau theorem (theorem 3.9), which we prove in the next subsection, characterizes weak convergence of two *deterministic* sequences of measures; every one of its five equivalent forms speaks of the measures $\mathcal{L}(X_n)$ and $\mathcal{L}(X)$ alone. Convergence in probability, by contrast, is a statement about the *joint* behaviour of X_n and X on a common space — it measures how close the two variables are pathwise — and there is simply no way to extract a joint-space statement from a list of measure-level equivalences. The random variables must be brought in by hand, and the device that brings them in is the modulus of continuity. Let $f \in U_b(S)$, say $|f| \le M$, with modulus of continuity

$$\omega_f(\delta) \;=\; \sup\{|f(x) - f(y)| : d(x, y) \le \delta\},$$

which tends to 0 as $\delta \downarrow 0$ *precisely because f is uniformly continuous.* This is the crux, and it is why we test against $U_b(S)$ rather than all of $C_b(S)$: $\omega_f(\delta)$ is a *single* number bounding the oscillation of f over every pair of nearby points at once, so it can be pulled outside an expectation. A merely continuous f would supply only a local modulus, one that depends on *where* the two points sit, and such a thing cannot be factored out of $\mathbb{E}[\cdot]$. Now split the error according to whether X_n is within δ of X or not. On $\{d(X_n, X) \le \delta\}$ the integrand $|f(X_n) - f(X)|$ is at most $\omega_f(\delta)$ by the very definition of the modulus; on the complement it is at most $2M$ since $|f| \le M$. Therefore

$$|\mathbb{E}[f(X_n)] - \mathbb{E}[f(X)]| \le \mathbb{E}[|f(X_n) - f(X)|] \le \omega_f(\delta) \cdot \mathbb{P}(d(X_n, X) \le \delta) + 2M\, \mathbb{P}(d(X_n, X) > \delta),$$

and bounding the first probability by 1 gives the cleaner $|\mathbb{E}[f(X_n)] - \mathbb{E}[f(X)]| \le \omega_f(\delta) + 2M\, \mathbb{P}(d(X_n, X) > \delta)$. The estimate now does its work in two stages, in the right order. Fix $\varepsilon > 0$ and *first* choose δ small enough that $\omega_f(\delta) < \varepsilon$ — possible by uniform continuity, and this choice does not depend on n. *Then* let $n \to \infty$: hypothesis (b) makes $\mathbb{P}(d(X_n, X) > \delta) \to 0$, killing the second term, so $\limsup_n |\mathbb{E}[f(X_n)] - \mathbb{E}[f(X)]| \le \varepsilon$. Since ε was arbitrary the lim sup is 0, i.e. $\mathbb{E}[f(X_n)] \to \mathbb{E}[f(X)]$ for every $f \in U_b(S)$. In the integral-pairing notation this reads $\mathcal{L}(X_n)(f) \to \mathcal{L}(X)(f)$ for all $f \in U_b(S)$, which is exactly hypothesis (ii) of Portmanteau; that theorem then upgrades it to convergence against all of $C_b(S)$, i.e. $\mathcal{L}(X_n) \Rightarrow \mathcal{L}(X)$, which is (d). We are invoking theorem 3.9 ahead of its proof, but there is no circularity: the Portmanteau theorem is established in the next subsection by a self-contained argument that never refers to this lemma, so the forward reference is one of exposition only, and the reader may take it on credit until section 3.2.2 discharges it.

(b)⇒(a) along a subsequence. Convergence in probability cannot give almost-sure convergence of the *whole* sequence — the counterexample below shows the bad set roaming forever — but it always gives it back along a suitably thinned subsequence, and this partial recovery is used repeatedly later when one wants to pass to a pointwise limit. The idea is to choose the subsequence so fast that the bad probabilities become *summable*, at which point Borel–Cantelli forbids the bad events from recurring infinitely often. Concretely, apply (b) with tolerance $\varepsilon = 2^{-k}$: for each k the probability $\mathbb{P}(d(X_n, X) > 2^{-k}) \to 0$ as $n \to \infty$, so we may pick an index n_k — and, increasing it if necessary, arrange $n_1 < n_2 < \cdots$ — with $\mathbb{P}(d(X_{n_k}, X) > 2^{-k}) \le 2^{-k}$. The bound 2^{-k} was engineered to be the k-th term of a convergent geometric series, so $\sum_k \mathbb{P}(d(X_{n_k}, X) > 2^{-k}) \le \sum_k 2^{-k} = 1 < \infty$. The first Borel–Cantelli lemma (theorem 3.27(i), also proved later in this chapter, by an elementary argument independent of the present lemma — again no circularity) then says that summability

of the probabilities forces $\mathbb{P}(d(X_{n_k}, X) > 2^{-k}$ for infinitely many $k) = 0$. Outside that null set, $d(X_{n_k}, X) \le 2^{-k}$ for all sufficiently large k, and since $2^{-k} \to 0$ this gives $X_{n_k} \to X$ almost surely.

Constant-limit converse. The reverse arrow (d)⇒(b) is false in general — again, see below — but it holds in the one case the law of large numbers and the propagation-of-chaos arguments care about: when the limit is a deterministic constant, $X \equiv c$, so that $\mathcal{L}(X) = \delta_c$. Here convergence in distribution to a point mass already pins the variables down in probability, and the reason is that the only place δ_c puts mass is the single point c, which sits comfortably in the interior of every ball around it. Let us make this precise, expanding the sphere argument the statement compresses. Fix $\varepsilon > 0$ and let $\overline{B}(c, \varepsilon) = \{x : d(x, c) \le \varepsilon\}$ be the closed ε-ball about c. Its topological boundary lies in the sphere $\Sigma_\varepsilon = \{x : d(x, c) = \varepsilon\}$, because a boundary point is a limit of points inside and of points outside the ball and so must sit exactly on the level $d(\cdot, c) = \varepsilon$. Now observe two things. First, the spheres Σ_ε for distinct radii $\varepsilon > 0$ are pairwise disjoint, since a point has exactly one distance from c. Second, δ_c is a probability measure and so has finite total mass, and *any* finite measure can charge at most countably many members of a disjoint family with positive mass — if uncountably many of the Σ_ε each had mass $> 1/k$ for some fixed k, their disjoint union would have infinite mass, a contradiction, and the union over k of these countable sets is still countable. Hence all but countably many radii ε give $\delta_c(\Sigma_\varepsilon) = 0$, and for every such ε the ball $\overline{B}(c, \varepsilon)$ has δ_c-null boundary and is therefore a δ_c-continuity set in the sense of Portmanteau (v). (For the particular measure δ_c one can see this even more directly: the centre c lies in the open ball, hence in the interior, hence never on the boundary, so $\delta_c(\partial\overline{B}(c, \varepsilon)) = 0$ for *every* $\varepsilon > 0$; but the disjoint-spheres mechanism is the general one, and it recurs verbatim when we select continuity level-sets in the proof of Portmanteau.) For such a continuity radius, Portmanteau (v) applied to the hypothesis $\mathcal{L}(X_n) \Rightarrow \delta_c$ gives

$$\mathbb{P}\big(d(X_n, c) \le \varepsilon\big) = \mathcal{L}(X_n)\big(\overline{B}(c, \varepsilon)\big) \;\longrightarrow\; \delta_c\big(\overline{B}(c, \varepsilon)\big) = 1,$$

the limit being 1 because $c \in \overline{B}(c, \varepsilon)$. Equivalently $\mathbb{P}(d(X_n, c) > \varepsilon) \to 0$. Finally, the at-most-countably-many exceptional radii cause no trouble: given *any* $\varepsilon > 0$, pick a continuity radius $\varepsilon' < \varepsilon$, and monotonicity gives $\mathbb{P}(d(X_n, c) > \varepsilon) \le \mathbb{P}(d(X_n, c) > \varepsilon') \to 0$. Thus $X_n \to c$ in probability, which is (b). $\square$

Each failing reverse implication deserves a concrete witness, because the counterexamples are short and they fix the intuition far better than the warning "does not hold in general." Work on the unit interval $[0, 1]$ with Lebesgue measure as the probability $\mathbb{P}$. *Convergence in probability does not imply almost-sure convergence:* the standard "travelling bump" does it. Enumerate the dyadic subintervals $I_{k,j} = [\, j2^{-k}, (j{+}1)2^{-k}\,]$, $0 \le j < 2^k$, in a single list $A_1, A_2, \ldots$ sweeping across $[0, 1]$ at each scale k before passing to scale $k{+}1$, and set $X_n = \mathbf{1}_{A_n}$. Since the length of A_n tends to 0, $\mathbb{P}(|X_n| > \varepsilon) \le |A_n| \to 0$, so $X_n \to 0$ in probability; but every point of $[0, 1]$ lies in infinitely many of the sweeping intervals and outside infinitely many others, so $X_n(\omega)$ equals 1 infinitely often and 0 infinitely often, and converges for *no* ω. The bad set never settles; it merely keeps moving, exactly as the informal description of mode (b) warned. The same example, incidentally, converges to 0 in every L^p as well, since $\mathbb{E}[|X_n|^p] = |A_n| \to 0$, so it simultaneously shows that L^p convergence does not imply almost-sure convergence. *Almost-sure (or L^p) convergence and the other do not coincide either:* the spike $X_n = n\,\mathbf{1}_{[0,1/n]}$ converges to 0 pointwise everywhere except possibly at 0, hence almost surely and in probability, yet $\mathbb{E}[|X_n|] = n \cdot \frac{1}{n} = 1 \not\to 0$, so it fails to converge in L^1 — a vanishing-probability event carrying a diverging value, precisely the sensitivity that distinguishes L^p from convergence in probability. *Convergence in distribution does not imply convergence in probability:* let X be any symmetric non-degenerate variable (standard Gaussian, say) and set $X_n = -X$ for every n. By symmetry $\mathcal{L}(X_n) = \mathcal{L}(X)$, so trivially $X_n \Rightarrow X$; but $X_n - X = -2X$, and $\mathbb{P}(|X_n - X| > \varepsilon) = \mathbb{P}(2\,|X| > \varepsilon)$ is a fixed positive number, bounded away from 0. The laws agree perfectly while the variables stay resolutely far apart — the cleanest illustration that mode (d) sees only the law and is blind to the joint coupling between X_n and X. That blindness is not a defect to be lamented; in the mean field setting it is exactly the feature we need.

This last point is the throughline payoff, and it is why this entire subsection was worth its place. In the N-player game the agents are coupled — each one's state depends, through the shared population, on every other's — so at finite N there is no fixed limiting random variable that an individual trajectory approaches pathwise, and almost-sure or L^p statements about "the" limit have nothing to attach to. What *does* stabilize as $N \to \infty$ is the population's statistical profile, the empirical measure μ^N, and what we can hope to prove is that its law settles onto a deterministic mean field m. That is a statement in mode (d), and the example $X_n = -X$ shows precisely why no stronger mode is available: convergence in distribution is the one notion that compares objects through their laws alone, demanding neither a common sample space nor any pathwise proximity, and so it is the one mode robust to the coupling that the stronger modes cannot survive. Mode (d) is, in short, the survivor — the only sense of convergence that the mean field limit leaves standing.

Having located convergence in distribution at the foot of the hierarchy and argued that it is the notion the rest of the book must develop, we now give it its proper name and its working machinery. The next subsection states the formal definition of weak convergence of measures — the precise meaning of the $\mathcal{L}(X_n) \to \mathcal{L}(X)$ written as item (d) above — and proves the Portmanteau theorem that the arrow (b)$\Rightarrow$(d) has already leaned on, turning the bare definition into the five interchangeable characterizations every later chapter will use.

3.2.2 The definition and its working form

The previous subsection ran the four modes of convergence to ground and left us with a single survivor: convergence in distribution, mode (d), the one notion that compares random variables through their laws alone and so is the only one the mean field coupling cannot destroy. We promised it its proper name, and we now deliver it. Stripped of the random variables, the assertion "the laws $\mathcal{L}(X_n)$ approach $\mathcal{L}(X)$" is a statement purely about a sequence of probability measures, and the name for that statement is *weak convergence*. Its definition is the one already foreshadowed by the integral pairing $\mu \mapsto \mu(f)$ of section 3.2: a measure is probed not by listing the mass of every set but by recording the averages it assigns to a rich family of test functions, and a sequence of measures is declared convergent when every one of those readings converges.

Definition 3.7 (Weak convergence of probability measures)**.** A sequence $(\mu_n)_{n\geq 1}$ in $\mathcal{P}(S)$ *converges weakly* to $\mu \in \mathcal{P}(S)$, written $\mu_n \Rightarrow \mu$, if

$$\mu_n(f) \;\longrightarrow\; \mu(f) \qquad \text{for every } f \in C_b(S).$$

If X_n, X are random variables we write $X_n \Rightarrow X$ to mean $\mathcal{L}(X_n) \Rightarrow \mathcal{L}(X)$, and call this convergence in distribution.

The test class in definition 3.7 is $C_b(S)$, the bounded *continuous* functions, and neither qualifier is idle. Boundedness keeps every pairing $\mu(f) = \int f \, \mathrm{d}\mu$ finite for every probability measure at once, so the definition never stumbles over an integrability question; continuity makes the pairing insensitive to the fine, measure-zero structure of μ and so lets it detect only the genuine "shape" of the measure. One might ask why we do not simply demand $\mu_n(B) \to \mu(B)$ for every Borel set B, the most literal reading of "the measures converge". The answer, which the whole section will make vivid, is that this demand is far too strong: it fails already for the most basic approximation one wants to permit. If $\mu_n = \delta_{1/n}$ is a unit mass sliding toward the origin, then for the half-open set $B = (0, \infty)$ one has $\mu_n(B) = 1$ for every n while the natural limit $\mu = \delta_0$ has $\mu(B) = 0$, so the set-wise demand is violated even though, on any reasonable reading, the masses are converging to a point at the origin. Testing against continuous f repairs exactly this: $\mu_n(f) = f(1/n) \to f(0) = \mu(f)$ for every $f \in C_b(S)$, because a continuous function cannot tell the difference between sitting *at* a boundary point and sitting just inside it. The price of this robustness is that the test class is enormous, and removing that awkwardness is the whole purpose of the Portmanteau theorem below.

Notation watch

The probabilist's "weak convergence" is testing against bounded *continuous* functions, $C_b(S)$. The functional analyst's "weak-$*$ convergence" in the dual pairing $\left(C_b(S)\right)^*$ would test against the *entire* dual and need not preserve total mass. On a compact metric space, where the continuous dual of $C(S)$ is the space of finite signed Borel measures $\mathcal{M}(S)$ — this is the Riesz–Markov representation theorem, classical and not used as a tool below [61, Ch. 7] — weak convergence of probability measures coincides with weak-$*$ convergence restricted to the probability simplex. On a non-compact S such as $\mathbb{R}^d$ they genuinely differ: mass can escape to infinity under weak-$*$ limits, producing a sub-probability measure, whereas definition 3.7 insists the limit again be a probability measure. Tightness (section 3.3) is exactly the condition that rules out this escape. We always mean definition 3.7 when we say "weak convergence"; the macro is `\weakto` ($\Rightarrow$).

The escape-of-mass phenomenon flagged in the box is worth picturing concretely, because it is the precise gap the compactness theory of section 3.3 exists to close. On $S = \mathbb{R}$ take $\mu_n = \delta_n$, a unit mass marching off to $+\infty$. For any $f \in C_b(\mathbb{R})$ that vanishes at infinity, $\mu_n(f) = f(n) \to 0$, while for the constant $f \equiv 1$ one has $\mu_n(f) = 1$ for all n. There is no single probability measure μ on $\mathbb{R}$ with $\mu_n(f) \to \mu(f)$ for every $f \in C_b$: the would-be limit has lost all of its mass over the horizon, and any honest limiting object is the zero measure, which is not a probability measure at all. So a sequence in $\mathcal{P}(S)$ need not converge weakly to anything in $\mathcal{P}(S)$ — the space is not compact when S is non-compact. The functional analyst tolerates this by admitting sub-probability limits in the weak-$*$ sense; we cannot, because the mean field m must be an honest probability measure. *Tightness* — a uniform control that forbids the mass from escaping to infinity — is exactly the hypothesis that restores a limit inside $\mathcal{P}(S)$, and Prokhorov's theorem (theorem 3.16) will show it is the *only* obstruction. For the present section we set the escape problem aside and study weak convergence where a limit is already given; we will, however, twice need to borrow tightness and Prokhorov before they are proved, and we flag each borrowing as it occurs.

Testing against *all* of $C_b(S)$ is convenient for stating the definition but awkward for verifying it and for deducing consequences. In practice one rarely has the whole of $C_b(S)$ under control at once: one would prefer to test against a manageable *sub*family — say the uniformly continuous functions, which can be built by hand — or against the indicator $\mathbf{1}_A$ of an explicit event A, and that indicator is not continuous, so it is not even a legal test function. The Portmanteau theorem is the resolution. It shows that the single clause of definition 3.7 is equivalent to four others, assembling *five* mutually interchangeable characterizations — continuous tests, uniformly continuous tests, a closed-set inequality, an open-set inequality, and exact convergence on sets whose boundary is null — each tuned to a different use, so that one may verify weak convergence through whichever clause is cheapest and then exploit it through whichever is sharpest. It is, without exaggeration, the single most-used technical tool in this book; we therefore prove it in full.

The engine of the whole equivalence is one approximation lemma: a quantitative, constructive form of Urysohn's lemma that holds in *any* metric space, with no appeal to partitions of unity or to compactness. Given a closed set F, it manufactures an explicit sequence of Lipschitz functions decreasing to the indicator $\mathbf{1}_F$, and thereby builds the bridge from continuous tests to statements about sets that every step of Portmanteau will cross.

Lemma 3.8 (Continuous approximation of a closed set)**.** *Let $F \subseteq S$ be closed and define, for $k \in \mathbb{N}$,*

$$f_k(x) \;=\; \big(1 - k\, d(x,F)\big)^+, \qquad d(x,F) = \inf_{y\in F} d(x,y).$$

Then each f_k is k-Lipschitz, hence $f_k \in U_b(S)$ with $0 \le f_k \le 1$; $f_k = 1$ on F; and $f_k(x) \downarrow \mathbf{1}_F(x)$ for every $x \in S$ as $k \to \infty$.

Proof. First, $x \mapsto d(x,F)$ is 1-Lipschitz. Indeed, for any $x, x' \in S$ and any $y \in F$ the triangle inequality gives $d(x,y) \le d(x,x') + d(x',y)$; taking the infimum over $y \in F$ on both sides yields $d(x,F) \le d(x,x') + d(x',F)$, i.e. $d(x,F) - d(x',F) \le d(x,x')$, and by symmetry $|d(x,F) - d(x',F)| \le d(x,x')$. Consequently $x \mapsto 1 - k\,d(x,F)$ is k-Lipschitz, and its positive part is too, since $t \mapsto t^+$ is 1-Lipschitz and a 1-Lipschitz function of a k-Lipschitz map is k-Lipschitz; thus $f_k \in U_b(S)$ with $0 \le f_k \le 1$. If $x \in F$ then $d(x,F) = 0$, so $f_k(x) = 1$. The sequence $f_k(x)$ is non-increasing in k because $d(x,F) \ge 0$ makes $1 - k\,d(x,F)$ decrease in k while $t \mapsto t^+$ is non-decreasing. Finally we identify the pointwise limit. If $x \in F$ then $f_k(x) = 1 = \mathbf{1}_F(x)$ for every k. If $x \notin F$ then — and this is the one place closedness of F is spent — the complement $S \setminus F$ is open, so x sits in it with room to spare and $d(x,F) > 0$; hence $k\,d(x,F) \to \infty$, $1 - k\,d(x,F) \to -\infty$, and $f_k(x) = (1 - k\,d(x,F))^+ = 0$ for all sufficiently large k, matching $\mathbf{1}_F(x) = 0$. Therefore $f_k \downarrow \mathbf{1}_F$ pointwise. □

Two features of this construction will be used again and again. First, because the f_k decrease to $\mathbf{1}_F$ and are dominated by the constant 1 (integrable against any probability measure), dominated convergence gives $\mu(f_k) \downarrow \mu(F)$ for *every* probability measure μ: a closed set's mass is the decreasing limit of the integrals of explicit continuous functions. Second, the f_k lie in $U_b(S)$, the smaller of our two test classes, so any characterization controlling $\mu(f)$ for $f \in U_b$ already controls the masses of closed sets. These are precisely the two facts the first nontrivial implication of Portmanteau exploits. We now state the theorem and prove it by chasing a single closed cycle of implications, (i) $\Rightarrow$ (ii) $\Rightarrow$ (iii) $\Leftrightarrow$ (iv) $\Rightarrow$ (v) $\Rightarrow$ (i), so that every one of the five clauses is reachable from every other.

Theorem 3.9 (Portmanteau)**.** *Let S be a metric space and $\mu_n, \mu \in \mathcal{P}(S)$. The following are equivalent.*

(i) $\mu_n(f) \to \mu(f)$ *for every* $f \in C_b(S)$ *(i.e.* $\mu_n \Rightarrow \mu$*).*

(ii) $\mu_n(f) \to \mu(f)$ *for every* $f \in U_b(S)$*.*

(iii) $\limsup_n \mu_n(F) \le \mu(F)$ *for every closed* $F \subseteq S$*.*

(iv) $\liminf_n \mu_n(G) \ge \mu(G)$ *for every open* $G \subseteq S$*.*

(v) $\mu_n(A) \to \mu(A)$ *for every Borel* continuity set A*, i.e. every* A *with* $\mu(\partial A) = 0$*.*

Proof. We prove (i)$\Rightarrow$(ii)$\Rightarrow$(iii)$\Leftrightarrow$(iv)$\Rightarrow$(v)$\Rightarrow$(i), a closed loop through which any clause implies any other.

(i)$\Rightarrow$(ii). Immediate, since $U_b(S) \subseteq C_b(S)$: testing against fewer functions is a weaker demand, so it follows from the stronger one. This trivial arrow is worth one comment, because its *converse* — that controlling only the uniformly continuous tests already forces control of all continuous tests — is the genuinely useful content buried in the loop, and it is delivered only once the full circuit closes at (v)$\Rightarrow$(i).

(ii)$\Rightarrow$(iii). Here the Urysohn functions do their work. Fix a closed set F and let f_k be as in lemma 3.8. Since $\mathbf{1}_F \le f_k$ pointwise, monotonicity of the integral gives $\mu_n(F) = \mu_n(\mathbf{1}_F) \le \mu_n(f_k)$ for every n and every k. Take $\limsup_n$ with k held fixed: because $f_k \in U_b(S)$, hypothesis (ii) supplies $\mu_n(f_k) \to \mu(f_k)$, so

$$\limsup_n \mu_n(F) \;\le\; \limsup_n \mu_n(f_k) \;=\; \mu(f_k).$$

The order of the two limits is the crux and must not be reversed: we send n to infinity *first*, at fixed k, so that (ii) applies to the single fixed test function f_k, and only then send $k \to \infty$. By lemma 3.8, $f_k \downarrow \mathbf{1}_F$, and each $f_k \le 1$ is dominated by the constant 1, which is μ-integrable since μ is a probability measure; dominated convergence therefore gives $\mu(f_k) \downarrow \mu(F)$. Hence $\limsup_n \mu_n(F) \le \mu(F)$, which is (iii). The inequality can be strict — mass can pile onto the boundary of F in the limit, as $\mu_n = \delta_{1/n} \Rightarrow \delta_0 = \mu$ with $F = \{0\}$ shows ($\mu_n(F) = 0$ for all n, yet $\mu(F) = 1$): a closed set can only *gain* mass in the limit, never lose it, and that one-sidedness is exactly what (iii) records.

(iii)$\Leftrightarrow$(iv). The two are the same statement read through complementation. A set G is open iff its complement $F = S \setminus G$ is closed, and for any probability measure ν one has $\nu(G) = 1 - \nu(F)$. Therefore

$$\liminf_n \mu_n(G) = \liminf_n \big(1 - \mu_n(F)\big) = 1 - \limsup_n \mu_n(F),$$

using $\liminf(1-a_n) = 1 - \limsup a_n$. Comparing with $\mu(G) = 1 - \mu(F)$, the open-set inequality $\liminf_n \mu_n(G) \geq \mu(G)$ is literally the closed-set inequality $\limsup_n \mu_n(F) \leq \mu(F)$ with both sides subtracted from 1. The two clauses are thus interchangeable, and we may use whichever is convenient; (iv) is the form that propagates lower semicontinuity, as the remark below explains.

(iii) & (iv)⇒(v). Recall the topological anatomy of a Borel set A: its interior A° (the largest open set contained in A), its closure $\overline{A}$ (the smallest closed set containing A), and its boundary $\partial A = \overline{A} \setminus A^\circ$. A *continuity set* is one whose boundary is μ-null, $\mu(\partial A) = 0$ — the name signalling that μ puts no mass on the very places where "inside A" and "outside A" touch. From $A^\circ \subseteq A \subseteq \overline{A}$ and monotonicity of each μ_n we have the sandwich $\mu_n(A^\circ) \leq \mu_n(A) \leq \mu_n(\overline{A})$; applying (iv) to the open set A° on the left and (iii) to the closed set $\overline{A}$ on the right,

$$\mu(A^\circ) \leq \liminf_n \mu_n(A^\circ) \leq \liminf_n \mu_n(A) \leq \limsup_n \mu_n(A) \leq \limsup_n \mu_n(\overline{A}) \leq \mu(\overline{A}).$$

Now the continuity hypothesis is spent: since $\mu(\overline{A}) - \mu(A^\circ) = \mu(\partial A) = 0$ and $A^\circ \subseteq A \subseteq \overline{A}$, all three of $\mu(A^\circ), \mu(A), \mu(\overline{A})$ coincide, so the two outer terms of the display are equal. They squeeze the $\liminf$ and $\limsup$ of $\mu_n(A)$ together, and equal to the common value $\mu(A)$, so the genuine limit $\mu_n(A) \to \mu(A)$ exists. Without $\mu(\partial A) = 0$ the outer bounds would straddle a gap of width $\mu(\partial A)$ and $\mu_n(A)$ could oscillate within it — which is precisely what happens for $A = (0, \infty)$ under $\mu_n = \delta_{1/n} \Rightarrow \delta_0$, whose boundary $\{0\}$ carries the entire limit mass.

(v)⇒(i). This closes the loop, upgrading convergence on continuity sets back to convergence against every bounded continuous test. Let $f \in C_b(S)$. Replacing f by $(f - \inf f)/(\sup f - \inf f)$ — an affine rescaling that changes both sides of $\mu_n(f) \to \mu(f)$ by the same affine map and is harmless if f is constant — we may assume $0 \leq f < 1$. The tool is the *layer-cake* (or distribution-function) representation: for any nonnegative bounded measurable f and any probability measure ν,

$$\nu(f) = \int_S f \, \mathrm{d}\nu = \int_0^1 \nu(\{f > t\}) \, \mathrm{d}t. \tag{3.5}$$

This is itself a Fubini–Tonelli computation: write the value as an integral over its own height, $f(x) = \int_0^1 \mathbf{1}\{f(x) > t\} \, \mathrm{d}t$ (the length of the interval of levels below $f(x)$), integrate in x against ν, and apply the Tonelli theorem (chapter 1) to the nonnegative integrand $\mathbf{1}\{f(x) > t\}$ to swap the order of the x- and t-integrals, giving the right-hand side. Now fix a level $t \in (0,1)$. Because f is continuous, the superlevel set $\{f > t\}$ is open and $\{f \geq t\}$ is closed, so the boundary of the former is squeezed,

$$\partial\{f > t\} \;\subseteq\; \{f \geq t\} \setminus \{f > t\} \;\subseteq\; \{f = t\},$$

the closure of $\{f > t\}$ lying inside the closed set $\{f \geq t\}$ and its interior containing the open set $\{f > t\}$. The level sets $\{f = t\}$ for distinct t are pairwise disjoint — a point x has the single value $f(x)$ and so lies in exactly one of them — and μ, being a finite measure, can assign positive mass to at most countably many members of a disjoint family (if uncountably many had mass exceeding $1/m$ for some fixed m, a finite sub-collection would already exceed the total mass 1, and the union over m of these countable sets is still countable). Hence for all but countably many $t \in (0,1)$ we have $\mu(\{f = t\}) = 0$, so $\mu(\partial\{f > t\}) = 0$ and $\{f > t\}$ is a μ-continuity set; for each such t, clause (v) gives $\mu_n(\{f > t\}) \to \mu(\{f > t\})$. The exceptional t form a Lebesgue-null set and do not affect the t-integral. The integrands $t \mapsto \mu_n(\{f > t\})$ are bounded by 1, an integrable dominating function on the finite interval $(0, 1)$, so dominated convergence in t passes the limit through (3.5):

$$\mu_n(f) = \int_0^1 \mu_n(\{f > t\})\ \mathrm{d}t \ \longrightarrow\ \int_0^1 \mu(\{f > t\})\ \mathrm{d}t = \mu(f).$$

This is (i), closing the cycle and, with it, establishing the mutual equivalence of all five clauses. □

Remark 3.10 (Which form to use)**.** The value of Portmanteau is that one rarely uses the same clause twice in a row: each is the natural language for a different task, and the theorem lets us switch between them for free. Form (i) is the definition and the thing one ultimately wants to conclude. Form (ii) is what one actually *verifies*, because uniformly continuous test functions can be built and bounded by hand — the proof of (b)⇒(d) in lemma 3.6 produced exactly such functions, and the central limit theorem of section 3.4.2 will establish weak convergence by checking convergence against the single smooth family $x \mapsto e^{itx}$, which lies in U_b: one verifies (ii) for that family and Portmanteau upgrades it to (i). Forms (iii) and (iv) are the currency of compactness and *lower-semicontinuity* arguments. Many functionals of a measure that the later chapters minimize — the relative entropy, the running cost of a mean field game — are suprema of pairings $\mu(f)$ over families of test functions, hence lower semicontinuous under weak convergence, and it is precisely the one-sided inequality (iv) (or (iii) for an upper bound) that survives a weak limit; this is what makes the direct method of the calculus of variations run in chapter 10. Form (v) is the one used to pass to the limit in the probability of an *explicit* event: if $\mu_n \Rightarrow \mu$ and the event A has μ-null boundary, then literally $\mu_n(A) \to \mu(A)$, no continuity of an indicator required — this is how the constant-limit converse in lemma 3.6 concluded $\mathbb{P}(d(X_n, c) \le \varepsilon) \to 1$. The mental habit to form is: *verify* through (ii), *transport functionals* through (iii)/(iv), *read off event probabilities* through (v).

A frequently used consequence — needed whenever a law is pushed forward through a map, as when an equilibrium control is applied to a state or a trajectory is read out through an observable — is the continuous mapping theorem: weak convergence survives the application of a map that is continuous except on a set the limit measure ignores. One might hope to prove it in a single line by testing $h_\#\mu_n$ against $g \in C_b(S')$, since $(h_\#\mu_n)(g) = \mu_n(g \circ h)$; but $g \circ h$ is continuous only where h is, so when h has discontinuities $g \circ h \notin C_b(S)$ and is *not a legal test function* for $\mu_n \Rightarrow \mu$. The naive argument thus fails exactly at the discontinuities, and the repair is to abandon the continuous-test form (i) and work instead through the closed-set form (iii), which never mentions a test function and tolerates the bad set as long as μ does not charge it.

Corollary 3.11 (Continuous mapping theorem)**.** *Let (S, d), (S', d') be metric spaces, $h : S \to S'$ Borel measurable, and let $D_h = \{x \in S : h \text{ is discontinuous at } x\}$ (a Borel set). If $\mu_n \Rightarrow \mu$ in $\mathcal{P}(S)$ and $\mu(D_h) = 0$, then $h_\#\mu_n \Rightarrow h_\#\mu$ in $\mathcal{P}(S')$, where $h_\#\nu = \nu \circ h^{-1}$ is the push-forward.*

Proof. First note that the construction makes sense: h is Borel, so each push-forward $h_\#\nu = \nu \circ h^{-1}$ is a Borel probability measure on S', and D_h is a Borel set (it is an F_σ, the countable union over rational thresholds of the closed sets where the oscillation of h exceeds the threshold). By Portmanteau (theorem 3.9) applied on S', it suffices to verify the closed-set inequality (iii) for $h_\#\mu_n$ and $h_\#\mu$. Let $F' \subseteq S'$ be closed and set $A = h^{-1}(F') \subseteq S$, so that $(h_\#\nu)(F') = \nu(A)$ for every

ν. The set A need not be closed — h is not continuous — so we cannot apply (iii) to A directly; instead we control its closure. We claim

$$\overline{A} \;\subseteq\; A \cup D_h.$$

Indeed, take $x \in \overline{A}$ and suppose $x \notin D_h$, i.e. h is continuous at x. Choose $x_k \in A$ with $x_k \to x$ (possible since x lies in the closure of A). Continuity at x gives $h(x_k) \to h(x)$; each $h(x_k) \in F'$ because $x_k \in A = h^{-1}(F')$, and F' is closed, so the limit satisfies $h(x) \in F'$, i.e. $x \in A$. Thus any point of $\overline{A}$ outside D_h already lies in A, which is the claim, and in particular $\overline{A} \setminus A \subseteq D_h$. Since $\mu(D_h) = 0$ by hypothesis, $\mu(\overline{A}) = \mu(A)$. Now $\overline{A}$ *is* closed, so (iii) applies to it:

$$\limsup_n (h_{\#}\mu_n)(F') = \limsup_n \mu_n(A) \le \limsup_n \mu_n(\overline{A}) \le \mu(\overline{A}) = \mu(A) = (h_{\#}\mu)(F').$$

This is the closed-set inequality on S', valid for every closed F', so $h_{\#}\mu_n \Rightarrow h_{\#}\mu$. □

The hypothesis $\mu(D_h) = 0$ cannot be dropped, and one line shows why. With $S = S' = \mathbb{R}$, take $h = \mathbf{1}_{(0,\infty)}$, discontinuous only at the origin so that $D_h = \{0\}$, and $\mu_n = \delta_{1/n} \Rightarrow \delta_0 = \mu$. The pushed-forward laws are $h_{\#}\mu_n = \delta_{h(1/n)} = \delta_1$ for every n, whereas $h_{\#}\mu = \delta_{h(0)} = \delta_0$, so $h_{\#}\mu_n \not\Rightarrow h_{\#}\mu$. The obstruction is precisely that μ places its entire mass on the lone discontinuity $D_h = \{0\}$ — exactly the situation the hypothesis forbids.

definition 3.7 presents weak convergence as a bare *convergence class* — a rule declaring which sequences converge to which limits — and a priori such a rule need not come from any metric. It matters a great deal that here it does, because the entire compactness machinery of the next sections, and the routine "pass to a subsequence" manoeuvres of the existence proofs, are licensed only in a *metric* (or at least sequential) topology: in a general topological space compactness and sequential compactness can diverge, and a convergence class that is not topological at all can behave pathologically. We now show that on a separable S weak convergence *is* induced by an honest metric, and on a Polish S that metric is itself complete and separable — so $\mathcal{P}(S)$ is Polish and weak compactness reduces to the extraction of convergent subsequences, exactly the form the tightness arguments will use. We exhibit one such metric explicitly, the *bounded Lipschitz* (or Fortet–Mourier) metric, chosen because its test class is at once rich enough to separate measures and rigid enough — a uniform Lipschitz bound — to be precompact in the sense Arzelà–Ascoli needs. For $f : S \to \mathbb{R}$ write

$$\mathrm{Lip}(f) = \sup_{x \neq y} \frac{|f(x) - f(y)|}{d(x,y)}, \qquad \|f\|_{\mathrm{BL}} = \|f\|_\infty + \mathrm{Lip}(f),$$

the latter finite precisely for the bounded Lipschitz functions, and define the distance between two probability measures as the largest gap their pairings can exhibit over the unit ball of this norm:

$$d_{\mathrm{BL}}(\mu,\nu) = \sup\Big\{\, |\mu(f) - \nu(f)| : \; \|f\|_{\mathrm{BL}} \le 1 \Big\} \qquad (\mu,\nu \in \mathcal{P}(S)). \tag{3.6}$$

Read as a supremum over a unit ball of test functions, d_{BL} is a dual-norm-type distance: the smaller it is, the more nearly μ and ν assign the same average to every reasonably regular function at once.

Theorem 3.12 (Metrization of weak convergence)**.** *Let (S,d) be a Polish space. Then d_{BL} is a metric on $\mathcal{P}(S)$, and for $\mu_n, \mu \in \mathcal{P}(S)$,*

$$d_{\mathrm{BL}}(\mu_n,\mu) \to 0 \qquad \Longleftrightarrow \qquad \mu_n \Rightarrow \mu.$$

Moreover $(\mathcal{P}(S), d_{\mathrm{BL}})$ *is itself Polish: separable and complete.* (*The metric and separability statements use only separability of S; the* $\Rightarrow\Rightarrow d_{\mathrm{BL}}$ *direction and completeness use the completeness of S through tightness.*)

Proof. The proof has five movements: d_{BL} is a metric; it metrizes weak convergence (the two directions of the displayed equivalence); $\mathcal{P}(S)$ is separable; and $\mathcal{P}(S)$ is complete. Two of these movements — the harder direction $\Rightarrow\Rightarrow d_{\mathrm{BL}} \to 0$ and completeness — borrow tightness, Prokhorov's theorem (theorem 3.16) and Ulam's single-measure tightness (lemma 3.15) from the *next* section. There is no circularity in this: those results are proved there by arguments that never invoke the present theorem, so we may use them here on credit, and we flag each use as it arises.

d_{BL} *is a metric.* Symmetry is built into the absolute value in (3.6), and the triangle inequality is inherited termwise — for each admissible f, $|\mu(f) - \lambda(f)| \le |\mu(f) - \nu(f)| + |\nu(f) - \lambda(f)| \le d_{\mathrm{BL}}(\mu, \nu) + d_{\mathrm{BL}}(\nu, \lambda)$, and taking the supremum over f on the left preserves the bound. Clearly $d_{\mathrm{BL}}(\mu, \mu) = 0$. Finiteness: the constraint $\|f\|_{\mathrm{BL}} \le 1$ forces in particular $\|f\|_\infty \le 1$, so $|\mu(f) - \nu(f)| \le \|f\|_\infty (\mu(S) + \nu(S)) \le 2$ and $d_{\mathrm{BL}} \le 2$ always. Only definiteness has content. Suppose $d_{\mathrm{BL}}(\mu, \nu) = 0$, so $\mu(f) = \nu(f)$ for every bounded Lipschitz f. The Urysohn functions f_k of lemma 3.8 attached to a closed set F are bounded and Lipschitz, hence admissible after scaling by their BL-norm, so $\mu(f_k) = \nu(f_k)$ for all k; letting $k \to \infty$ with $f_k \downarrow \mathbf{1}_F$ and dominated convergence on both sides gives $\mu(F) = \nu(F)$ for every closed F. The closed sets form a π-system (they are stable under finite intersection) that generates $\mathcal{B}(S)$, so two probability measures agreeing on all of them agree everywhere, by the uniqueness lemma corollary 1.10 imported from chapter 1. Thus $\mu = \nu$, and d_{BL} separates points.

$d_{\mathrm{BL}} \to 0 \Rightarrow\Rightarrow$. This direction is elementary and uses only the Urysohn functions. Each f_k from lemma 3.8 is bounded Lipschitz, say with $\|f_k\|_{\mathrm{BL}} = c_k < \infty$; then f_k/c_k is admissible in (3.6), so for each fixed k, $|\mu_n(f_k) - \mu(f_k)| \le c_k\, d_{\mathrm{BL}}(\mu_n, \mu) \to 0$ as $n \to \infty$. Running the argument of step (ii)⇒(iii) of theorem 3.9 with these f_k — $\mu_n(F) \le \mu_n(f_k) \to \mu(f_k)$, then $k \to \infty$ with $\mu(f_k) \downarrow \mu(F)$ — gives $\limsup_n \mu_n(F) \le \mu(F)$ for every closed F, which is Portmanteau (iii); hence $\mu_n \Rightarrow \mu$.

$\Rightarrow\Rightarrow d_{\mathrm{BL}} \to 0$. This is the substantive direction, and it is where tightness enters. Argue by contradiction. If $d_{\mathrm{BL}}(\mu_n, \mu) \not\to 0$, then along some subsequence (not relabelled) there are $\varepsilon > 0$ and admissible functions f_n, $\|f_n\|_{\mathrm{BL}} \le 1$, with $|\mu_n(f_n) - \mu(f_n)| \ge \varepsilon$ for all n. The difficulty is that the offending f_n *change with* n, so we cannot quote $\mu_n \Rightarrow \mu$ against any single one of them; we must first replace the moving family by a fixed test function, and that requires an Arzelà–Ascoli compactness together with a tightness control of where the mass lives.

Step 1 (tightness localizes the mass). The set $\{\mu_n\}_n \cup \{\mu\}$ is weakly convergent, hence relatively compact in $\mathcal{P}(S)$, hence tight by the necessity half of Prokhorov's theorem (theorem 3.16(b)). So, given $\delta > 0$, there is a compact $K \subseteq S$ with $\sup_n \mu_n(K^c) \le \delta$ and $\mu(K^c) \le \delta$ simultaneously: all the mass, uniformly in n, sits on one fixed compact set up to δ.

Step 2 (Arzelà–Ascoli extracts a fixed limit on K). On the compact K the f_n are uniformly bounded, $|f_n| \le 1$, and uniformly equicontinuous, since $\mathrm{Lip}(f_n) \le 1$ gives $|f_n(x) - f_n(y)| \le d(x, y)$ for all n at once. The Arzelà–Ascoli theorem (a prerequisite of undergraduate analysis) therefore furnishes a further subsequence along which $f_n \to f_0$ *uniformly on* K, the limit $f_0 : K \to \mathbb{R}$ inheriting $|f_0| \le 1$ and $\mathrm{Lip}(f_0) \le 1$.

Step 3 (McShane extends the limit to all of S). We need f_0 as a global test function, so we extend it off K without enlarging either its Lipschitz constant or its bound, by the McShane formula

$$f(x) = \Big(\sup_{y\in K}\big(f_0(y) - d(x,y)\big)\Big) \vee (-1) \wedge 1.$$

Each $x \mapsto f_0(y) - d(x,y)$ is 1-Lipschitz; a supremum of 1-Lipschitz functions is 1-Lipschitz; and truncation into $[-1,1]$ neither raises the Lipschitz constant nor breaks continuity, so $f \in C_b(S)$ with $|f| \le 1$. Moreover $f = f_0$ on K: for $x \in K$ the choice $y = x$ gives the value $f_0(x) \in [-1,1]$, and any other $y \in K$ gives $f_0(y) - d(x,y) \le f_0(x)$ because $\mathrm{Lip}(f_0) \le 1$, so the supremum is attained at $y = x$ and the truncation is inert. (Only $f \in C_b(S)$ and the uniform approximation $\sup_K |f_n - f| = \sup_K |f_n - f_0| \to 0$ are used below; the precise form of the extension is immaterial.)

Step 4 (assemble the contradiction). Split the offending quantity through the fixed test function f:

$$|\mu_n(f_n) - \mu(f_n)| \le \underbrace{|\mu_n(f_n - f)|}_{\text{(I)}} + \underbrace{|\mu_n(f) - \mu(f)|}_{\text{(II)}} + \underbrace{|\mu(f - f_n)|}_{\text{(III)}}.$$

For (I), separate the integral over K from its complement: on K the integrand $|f_n - f|$ is at most $\sup_K |f_n - f|$, while off K it is at most $|f_n| + |f| \le 2$, so (I) $\le \sup_K |f_n - f| + 2\mu_n(K^c) \le \sup_K |f_n - f| + 2\delta$, which tends to 2δ as $n \to \infty$ by Step 2. The same bound with μ in place of μ_n gives (III) $\le \sup_K |f_n - f| + 2\mu(K^c) \to 2\delta$. And (II) $\to 0$ because $f \in C_b(S)$ is a single fixed function and $\mu_n \Rightarrow \mu$. Therefore $\limsup_n |\mu_n(f_n) - \mu(f_n)| \le 4\delta$. Since $\delta > 0$ was arbitrary the $\limsup$ is 0, flatly contradicting $|\mu_n(f_n) - \mu(f_n)| \ge \varepsilon$. Hence $d_{\mathrm{BL}}(\mu_n, \mu) \to 0$.

Separability. We exhibit a countable dense subset of $\mathcal{P}(S)$. Fix a countable dense set $\{x_i\} \subseteq S$ (here separability of S is used), and let $\mathcal{D}$ be the collection of finitely-supported measures $\sum_i q_i \delta_{x_i}$ with rational weights $q_i \ge 0$ summing to 1; this set is countable. Given $\mu \in \mathcal{P}(S)$ and $\eta > 0$, single-measure tightness (lemma 3.15) supplies a compact K with $\mu(K^c) < \eta$. Cover K by finitely many balls $B(x_i, \eta)$ (possible by compactness), and disjointify them into Borel pieces $E_1, \dots, E_r$, each of diameter $< 2\eta$ and each containing a centre $x_{i_j} \in E_j$. The measure $\nu = \sum_j \mu(E_j)\delta_{x_{i_j}}$ then approximates μ: for any admissible f (so $\mathrm{Lip}(f) \le 1$ and $\|f\|_\infty \le 1$),

$$|\mu(f) - \nu(f)| \le \sum_j \int_{E_j} \left|f(x) - f(x_{i_j})\right| \,\mathrm{d}\mu(x) + \|f\|_\infty\, \mu(K^c) \le \sum_j \int_{E_j} d(x, x_{i_j})\,\mathrm{d}\mu + \eta \le 2\eta + \eta = 3\eta,$$

using $d(x, x_{i_j}) \le \mathrm{diam}(E_j) < 2\eta$ on each piece and bounding $\sum_j \mu(E_j) \le 1$. Hence $d_{\mathrm{BL}}(\mu, \nu) \le 3\eta$; rounding the weights $\mu(E_j)$ to nearby rationals (a further $O(\eta)$ error spread over finitely many atoms) lands the approximant in $\mathcal{D}$. Thus $\mathcal{D}$ is dense and $\mathcal{P}(S)$ is separable.

Completeness on Polish S. Let (μ_n) be d_{BL}-Cauchy. The strategy is to prove (μ_n) tight, extract a weak limit through Prokhorov, and then upgrade that subsequential weak limit to a full d_{BL}-limit. Granting tightness for the moment, Prokhorov (theorem 3.16(a)) gives a subsequence $\mu_{n_j} \Rightarrow \mu$, hence $d_{\mathrm{BL}}(\mu_{n_j}, \mu) \to 0$ by the metrization direction just proved; and a Cauchy sequence with a convergent subsequence converges to the same limit, so $d_{\mathrm{BL}}(\mu_n, \mu) \to 0$ with $\mu \in \mathcal{P}(S)$. It remains to prove the Cauchy sequence is tight, and this is the delicate construction the statement compressed.

Fix $\varepsilon > 0$; we work one length-scale at a time. At the scale set by a parameter $\eta > 0$, introduce the *bump function* sitting on the first k dense centres,

$$\psi_k(x) = \Big(1 - \eta^{-1} d\big(x, \textstyle\bigcup_{i\le k} \overline{B}(x_i, \eta)\big)\Big)^+,$$

which by the Urysohn computation of lemma 3.8 (applied to the closed set $\bigcup_{i\le k}\overline{B}(x_i,\eta)$ with slope η^{-1}) is bounded Lipschitz with $\|\psi_k\|_{\mathrm{BL}} \le 1+\eta^{-1}$, obeys the squeeze

$$\mathbf{1}_{\bigcup_{i\le k} B(x_i,\eta)} \;\le\; \psi_k \;\le\; \mathbf{1}_{\bigcup_{i\le k} B(x_i,2\eta)}$$

(equal to 1 on the inner union, where $d(x,\cdot)=0$, and to 0 outside the 2η-enlargement, since a point at distance $\ge \eta$ from every η-ball is at distance $\ge 2\eta$ from every centre), and increases to 1 as $k\to\infty$ because the centres are dense and so every x eventually lands within η of some x_i. Now use the Cauchy property to reduce to finitely many measures: choose N so large that $d_{\mathrm{BL}}(\mu_n,\mu_N) \le \varepsilon\eta/(2(\eta+1))$ for all $n\ge N$. By Ulam's tightness (lemma 3.15) each of the finitely many $\mu_1,\dots,\mu_N$ is individually tight, so we may pick k large enough that, for all $j\le N$ at once,

$$\mu_j(\psi_k) \;\ge\; \mu_j\Big(\bigcup_{i\le k} B(x_i,\eta)\Big) \;>\; 1-\varepsilon/2.$$

For the tail $n\ge N$ we transport this lower bound off μ_N using the dual bound $|\mu_n(\psi_k)-\mu_N(\psi_k)| \le \|\psi_k\|_{\mathrm{BL}}\, d_{\mathrm{BL}}(\mu_n,\mu_N)$ together with $\|\psi_k\|_{\mathrm{BL}} \le 1+\eta^{-1} = (\eta+1)/\eta$:

$$\mu_n(\psi_k) \;\ge\; \mu_N(\psi_k) - \frac{\eta+1}{\eta}\, d_{\mathrm{BL}}(\mu_n,\mu_N) \;>\; (1-\varepsilon/2) - \frac{\eta+1}{\eta}\cdot\frac{\varepsilon\eta}{2(\eta+1)} \;=\; 1-\varepsilon.$$

Combining with the upper squeeze $\psi_k \le \mathbf{1}_{\bigcup_{i\le k} B(x_i,2\eta)}$ gives $\mu_n\big(\bigcup_{i\le k} B(x_i,2\eta)\big) \ge \mu_n(\psi_k) > 1-\varepsilon$ for all $n\ge N$; the finitely many indices $n<N$ are absorbed by enlarging k if necessary (each μ_n is tight on its own). Writing $k=k(\eta,\varepsilon)$ for the resulting index, we have shown

$$\text{for every } \eta>0, \qquad \sup_n \mu_n\Big(\bigcup_{i\le k(\eta,\varepsilon)} B(x_i,2\eta)\Big) \;>\; 1-\varepsilon. \tag{3.7}$$

Finally, assemble the scales into one compact set. Apply (3.7) with $\eta = 2^{-m}$ and tolerance $\varepsilon\, 2^{-m}$ in place of ε, obtaining for each $m\ge 1$ a finite union $U_m = \bigcup_{i\le k_m}\overline{B}(x_i,2^{1-m})$ of closed balls with $\sup_n \mu_n(U_m^c) \le \varepsilon\, 2^{-m}$, and set

$$K = \bigcap_{m\ge 1} U_m.$$

Then K is closed, being an intersection of closed sets, and *totally bounded*: for any prescribed accuracy 2^{1-m} it is covered by the finitely many balls of radius 2^{1-m} comprising U_m. A closed, totally bounded subset of a *complete* metric space is compact — and this is the one place completeness of S (its Polishness) is spent, exactly as the theorem's parenthetical foretold. The mass outside K is controlled by summing the per-scale leaks:

$$\sup_n \mu_n(K^c) = \sup_n \mu_n\Big(\bigcup_{m\ge 1} U_m^c\Big) \le \sum_{m\ge 1}\sup_n \mu_n(U_m^c) \le \sum_{m\ge 1} \varepsilon\, 2^{-m} = \varepsilon.$$

Thus for every $\varepsilon>0$ there is a compact K with $\sup_n \mu_n(K^c)\le\varepsilon$: the Cauchy sequence (μ_n) is tight, and the proof is complete. □

The metric d_{BL} is not the only one inducing the weak topology; the Lévy–Prokhorov metric does too, and in chapter 4 the Wasserstein distance $\mathcal{W}_2$ refines all of them by additionally controlling second moments. What we will use repeatedly is only the qualitative content of theorem 3.12: "the topology of weak convergence" is a genuine separable metric topology (Polish when S is), so weak compactness coincides with sequential compactness and a weakly convergent sequence is pinned down by countably many test functions — the fact exploited in worked computation 3.26. This is exactly the foothold the existence proofs need: to produce a mean field equilibrium one builds approximate ones, shows the family tight, and extracts a convergent *subsequence*; metrizability is what makes "extract a convergent subsequence" a legitimate move.

There remains, however, a gap between what weak convergence asserts and what the limit machinery of chapter 1 is equipped to exploit, and naming it now sets up the next subsection precisely. Weak convergence $\mu_n \Rightarrow \mu$ is a statement about *laws*: it compares the measures through their integrals and says nothing whatever about how any underlying random variables behave pointwise — indeed the variables may live on unrelated probability spaces, or fail to be jointly defined at all, as the example $X_n = -X$ of section 3.2.1 made plain. Yet the most powerful tools we own for passing a limit through a nonlinear functional — dominated and monotone convergence, Fatou's lemma — are pointwise, almost-sure statements that presuppose a single common space on which $X_n(\omega) \to X(\omega)$. The natural question, and the one the next subsection answers, is whether the gap can be bridged: given only that the laws converge weakly, can we *realize* them as genuine random variables on one common probability space that converge almost surely? Skorokhod's representation theorem says yes — and, fittingly, its proof leans on exactly the completeness-and-tightness machinery just assembled, so the metrization built here is itself the springboard for what comes next.

3.2.3 Almost-sure realization: Skorokhod's representation theorem

The metrization of the previous subsection finally placed $\mathcal{P}(S)$ on the same footing as any other metric space: "a sequence of laws converges" now has a bona fide topological meaning, with subsequences, Cauchy sequences, and completeness all available. But that very success threw the limitation flagged at its close into relief. Weak convergence is a statement that lives *entirely on the measures*. It compares μ_n and μ through the readings $\mu_n(f) \to \mu(f)$ and is indifferent to whether the underlying random variables share a probability space, or are jointly defined at all — recall the toy sequence $X_n = -X$ of section 3.2.1, whose laws converge while the variables themselves do nothing of the kind. The trouble is that the sharpest instruments we own for pushing a limit through a nonlinear functional — dominated convergence, monotone convergence, and Fatou's lemma — are *pointwise* theorems. Each presupposes a single sample space on which $X_n(\omega) \to X(\omega)$ for almost every ω, precisely the structure weak convergence declines to provide. So the natural question, already posed at the end of section 3.2.2, is whether the gap can be bridged from the measure side: given only that $\mu_n \Rightarrow \mu$, can we *manufacture* random variables with those laws, on one common space, that converge almost surely? Skorokhod's representation theorem answers yes, and the construction is wholly explicit.

It is worth dwelling on *why* one wants this before building it, because the motivation dictates exactly the form of the conclusion. The recurring need is to move an inequality *upward* in strength: from an inequality that is trivial for almost-surely convergent variables to the same inequality at the level of weak convergence, where it is not trivial at all. The cleanest example, and the one chapter 4 consumes verbatim, is lower semicontinuity of a moment or a cost. Take a continuous, nonnegative

$g \geq 0$ on S — think of $g(x) = |x|^p$, an energy — and ask whether the functional $\mu \mapsto \mu(g) = \int_S g \, \mathrm{d}\mu$ is lower semicontinuous along weak convergence, i.e. whether

$$\mu_n \Rightarrow \mu \quad \Longrightarrow \quad \int_S g \, \mathrm{d}\mu \, \leq \, \liminf_{n\to\infty} \int_S g \, \mathrm{d}\mu_n. \tag{3.8}$$

For an unbounded g this is not handed to us by the definition of weak convergence, which tests only against *bounded* continuous functions, so g is not a legal test function. But if we had random variables $Y_n \to Y$ almost surely with $\mathcal{L}(Y_n) = \mu_n$ and $\mathcal{L}(Y) = \mu$, the inequality would be immediate: $g \geq 0$ and continuity give $g(Y_n) \to g(Y)$ almost surely, and Fatou's lemma (chapter 1) applied to the nonnegative sequence $g(Y_n)$ yields $\mathbb{E}[g(Y)] \leq \liminf_n \mathbb{E}[g(Y_n)]$, which by the change-of-variables formula (3.1) is exactly (3.8). The hard, measure-level statement collapses to a one-line application of a pointwise theorem — *once the variables are realized on a common space.* Skorokhod's theorem is the device that performs that realization, and (3.8) is the template: weak convergence in, an a.s.-convergent coupling out, the desired inequality recovered by Fatou or dominated convergence. Lower semicontinuity of the cost in an existence proof, and completeness of the Wasserstein metric in chapter 4, are both instances of this single move.

How could such a coupling possibly be built? The blueprint is already familiar from the real line, and the general theorem is its faithful generalization. On $S = \mathbb{R}$, if the distribution functions satisfy $F_n \to F$ at every continuity point of F — which is what weak convergence amounts to there — one fixes a *single* uniform random variable U on $[0, 1)$ and sets $Y_n = F_n^{-1}(U)$, $Y = F^{-1}(U)$ through the quantile (generalized-inverse) transform. Each Y_n then has law μ_n by construction, all of them are driven by the *same* U, and one checks that $F_n^{-1}(u) \to F^{-1}(u)$ at every continuity point of F^{-1}, i.e. for Lebesgue-almost every u, so $Y_n \to Y$ almost surely. The common randomness U is what couples the laws; the monotone inversion is what turns convergence of the F_n into pointwise convergence of the Y_n. On a general Polish space there is no order to invert, but there is a substitute: a sequence of ever-finer *partitions* into sets whose boundaries the limit measure does not charge, coded consistently into nested subintervals of $[0, 1)$. Reading off which nested intervals a point $\omega \in [0, 1)$ falls through plays the role of $F^{-1}(\omega)$, and the boundary-free (continuity-set) property of the partitions is what lets Portmanteau (v) transfer the convergence. That is the entire idea; the proof is its careful execution, and its only inputs are Portmanteau (v), the Borel–Cantelli lemma, and the completeness and separability of S.

Theorem 3.13 (Skorokhod representation)**.** *Let S be a Polish space and let $\mu_n \Rightarrow \mu$ in $\mathcal{P}(S)$. Then on the probability space $([0, 1), \mathcal{B}([0, 1)), \lambda)$, with λ Lebesgue measure, there exist S-valued random variables Y_n $(n \geq 1)$ and Y with*

$$\mathcal{L}(Y_n) = \mu_n, \qquad \mathcal{L}(Y) = \mu, \qquad Y_n \xrightarrow{a.s.} Y.$$

Proof. Step 0 (the sole distributional input: Portmanteau (v)). Call $B \in \mathcal{B}(S)$ a *μ-continuity set* if its topological boundary is μ-null, $\mu(\partial B) = 0$. These are exactly the sets on which weak convergence is guaranteed to act numerically: by the continuity-set form Portmanteau (v) (theorem 3.9), $\mu_n(B) \to \mu(B)$ for every μ-continuity set B. This single implication is the *only* fact about $\mu_n \Rightarrow \mu$ that the construction will use; everything else is bookkeeping on $[0, 1)$. Two closure properties we lean on repeatedly: a finite intersection or union of μ-continuity sets is again one, because $\partial(A \cap B)$

and $\partial(A \cup B)$ are both contained in $\partial A \cup \partial B$ (a boundary point of the intersection or union is a boundary point of one of the pieces), and a μ-null set has μ-null subsets; likewise a *set difference* $A \setminus B = A \cap B^c$ is a continuity set, since $\partial B^c = \partial B$. We refer back to this paragraph as "Step 0" throughout.

Step 1 (nested continuity-set partitions of small mesh). The geometric scaffold is a sequence of countable Borel partitions $\mathcal{Q}_m = \{A_{m,1}, A_{m,2}, \dots\}$ of S, $m \geq 1$, with three properties: every cell is a μ-continuity set, every cell has diameter $\leq 1/m$, and $\mathcal{Q}_{m+1}$ *refines* $\mathcal{Q}_m$ (each cell of $\mathcal{Q}_{m+1}$ sits inside a single cell of $\mathcal{Q}_m$). The continuity-set property is what makes Step 0 applicable cell by cell; the shrinking diameter is what will pin down a limit point; the nesting is what will make the codings at successive levels consistent.

Fix m and build a partition $\mathcal{Q}'_m$ of mesh $\leq 1/m$ first. Here is where *separability* is spent: a separable metric space is covered by countably many open balls of any prescribed radius, so fix a countable dense set and cover S by balls centred at its points with radii in $(1/(2m), 1/m)$. The radius is not yet determined — we must still arrange that each ball is a continuity set — and this is where the disjoint-spheres argument used earlier in the chapter (for δ_c, in the constant-limit converse of lemma 3.6) reappears in full generality. For a fixed centre x, the spheres $\Sigma_r = \{y : d(y,x) = r\}$ over distinct radii $r > 0$ are pairwise disjoint, since a point has exactly one distance from x. A finite measure can assign positive mass to at most countably many members of a disjoint family — if uncountably many Σ_r each carried mass exceeding $1/k$, their disjoint union would have infinite mass — so all but countably many radii r give $\mu(\Sigma_r) = 0$. The boundary of the open ball $B(x,r)$ lies in Σ_r, so for all but countably many r the ball $B(x,r)$ is a μ-continuity set; in particular we may pick, for each centre, a radius in the nonempty interval $(1/(2m), 1/m)$ that works. Enumerate the chosen continuity-set balls $U_1, U_2, \dots$ and disjointify in the standard way,

$$A'_{m,i} = U_i \setminus (U_1 \cup \dots \cup U_{i-1}),$$

so the $A'_{m,i}$ are pairwise disjoint and cover S, hence partition it. Each is a continuity set, being a finite set difference of continuity sets (Step 0), and each has diameter $\leq 1/m$ because it sits inside the ball U_i of radius $< 1/m$. This is the partition $\mathcal{Q}'_m$.

The partitions $\mathcal{Q}'_m$ have small mesh but need not be nested across m. We force nesting by taking common refinements: let $\mathcal{Q}_m$ be the partition whose cells are the nonempty intersections $A'_{1,i_1} \cap \dots \cap A'_{m,i_m}$, one factor drawn from each $\mathcal{Q}'_1, \dots, \mathcal{Q}'_m$. Each such cell is a *finite* intersection of continuity sets, hence a continuity set by Step 0; it has diameter $\leq 1/m$ because one of its factors comes from $\mathcal{Q}'_m$; and by construction $\mathcal{Q}_m$ refines $\mathcal{Q}_{m-1}$, since dropping the last factor A'_{m,i_m} sends a $\mathcal{Q}_m$-cell into the $\mathcal{Q}_{m-1}$-cell with the same first $m-1$ factors. The three required properties now hold simultaneously.

Step 2 (consistent interval coding: the CDF-inversion analogue). We now turn each measure into a map $[0,1) \to S$ by stacking its cell masses into nested subintervals — the multidimensional replacement for inverting a distribution function. Order the cells of every $\mathcal{Q}_m$ so that the children of any one $\mathcal{Q}_{m-1}$-cell are listed *contiguously*, in one consecutive block; this contiguous ordering is the linchpin that will make the interval coding respect the nesting. For a probability measure $\rho \in \mathcal{P}(S)$, assign to the j-th cell $A_{m,j}$ the half-open "stacking" interval

$$I^\rho_{m,j} = \Big[\textstyle\sum_{i<j} \rho(A_{m,i}),\ \sum_{i\leq j} \rho(A_{m,i})\Big) \subseteq [0,1),$$

of length exactly $\rho(A_{m,j})$. At a fixed level m these intervals are disjoint and tile $[0,1)$ (up to the single point 1, which has λ-measure zero), because the cell masses sum to $\rho(S)=1$. The key consistency is that they nest *across* levels. Suppose $A_{m,j} \subseteq A_{m-1,\ell}$. Because the children of $A_{m-1,\ell}$ are listed contiguously and their masses sum to the parent's mass, $\sum_{i:\, A_{m,i}\subseteq A_{m-1,\ell}} \rho(A_{m,i}) = \rho(A_{m-1,\ell})$, the block of level-$m$ intervals belonging to the children of $A_{m-1,\ell}$ is exactly the parent interval $I^{\rho}_{m-1,\ell}$ resubdivided; hence $I^{\rho}_{m,j} \subseteq I^{\rho}_{m-1,\ell}$. Were the children listed non-contiguously, the child intervals would be scattered across $[0,1)$ and this containment would fail — which is the whole reason the ordering was imposed.

Now read off a point of S from a point $\omega \in [0,1)$. For each m there is a unique cell index $j_m(\rho,\omega)$ with $\omega \in I^{\rho}_{m,j_m}$, and by the nesting just proved the cells $A_{m,j_m(\rho,\omega)}$ *descend*: each is contained in its predecessor. This is precisely a nested sequence of sets whose diameters tend to zero. Pick any representative $y_m \in A_{m,j_m(\rho,\omega)}$ from each. For $m' \geq m$ the cell at level m' lies inside the cell at level m, so y_m and $y_{m'}$ both lie in a set of diameter $\leq 1/m$, giving $d(y_m, y_{m'}) \leq 1/m \to 0$: the sequence (y_m) is *Cauchy.* Here is where *completeness* of S is spent — a Cauchy sequence in a Polish space converges — and the limit is independent of which representatives were chosen, since two competing choices $y_m, \tilde{y}_m$ at level m also lie in a common cell of diameter $\leq 1/m$, so their limits coincide. Define $R_\rho(\omega)$ to be this common limit. The map $R_\rho : [0,1) \to S$ is Borel, being the pointwise limit of the cell-valued step maps $\omega \mapsto y_m$. Finally R_ρ has law ρ: for a cell $A_{m,j}$, the set $\{R_\rho \in A_{m,j}\}$ agrees with $I^{\rho}_{m,j}$ up to the λ-null overlap of adjacent interval endpoints, so $\lambda(R_\rho \in A_{m,j}) = \lambda(I^{\rho}_{m,j}) = \rho(A_{m,j})$; the cells of all the $\mathcal{Q}_m$ generate $\mathcal{B}(S)$ (their diameters shrink to zero, so they separate points and generate the Borel sets), whence $\mathcal{L}(R_\rho) = \rho$ by the uniqueness lemma for measures. Apply this to each law in sight: set $Y = R_\mu$ and $Y_n = R_{\mu_n}$ for every n, all defined on the *single* space $[0,1)$ under λ, with $\mathcal{L}(Y) = \mu$ and $\mathcal{L}(Y_n) = \mu_n$ as required. The common variable ω is the coupling — the Polish-space stand-in for the shared uniform U of the one-dimensional quantile construction.

Step 3 (almost-sure convergence via Borel–Cantelli). It remains to show $Y_n \to Y$ almost surely, and here is where the convergence $\mu_n \to \mu$ on continuity sets (Step 0) finally enters. Fix a level m. Since the cell masses $\mu(A_{m,j})$ sum to 1, we may choose a cutoff K_m so that the first K_m cells already carry most of the mass: $\mu(E_m) > 1 - 2^{-m}$, where $E_m = \bigcup_{j \leq K_m} A_{m,j}$ is a finite union of continuity sets. Consider the level-m interval endpoints for the laws μ_n. The j-th endpoint is the partial sum $\sum_{i<j} \mu_n(A_{m,i})$, a *finite* sum (at most K_m terms for $j \leq K_m + 1$) of masses of continuity sets. By Step 0 each term $\mu_n(A_{m,i}) \to \mu(A_{m,i})$, and a finite sum of convergent sequences converges to the sum of the limits, so every such endpoint of $I^{\mu_n}_{m,j}$ converges, as $n \to \infty$, to the corresponding endpoint of $I^{\mu}_{m,j}$. This is exactly why we restricted to the first K_m cells: it keeps the relevant partial sums finite, so that Step 0 applies term by term without any uniformity in j.

Convergence of the endpoints converts into pointwise agreement of the codings on the interiors of the limit intervals. Fix $j \leq K_m$ and take any ω in the *open* interval $\operatorname{int} I^{\mu}_{m,j}$. Because the endpoints of $I^{\mu_n}_{m,j}$ converge to those of $I^{\mu}_{m,j}$ and ω sits strictly inside the limit interval, ω falls inside $I^{\mu_n}_{m,j}$ for all sufficiently large n. For those n, the level-m cell index of ω is the same j for both μ_n and μ, so $Y_n(\omega)$ and $Y(\omega)$ are both limits of representatives drawn from (nested subcells of) the single cell $A_{m,j}$, a set of diameter $\leq 1/m$; hence $d(Y_n(\omega), Y(\omega)) \leq 1/m$ for all large n. Collect the good points at level m:

$$G_m = \bigcup_{j \le K_m} \operatorname{int} I^{\mu}_{m,j}, \qquad \lambda(G_m) = \sum_{j \le K_m} \mu(A_{m,j}) = \mu(E_m) > 1 - 2^{-m},$$

the middle equality because the intervals are disjoint with lengths $\mu(A_{m,j})$. Thus $\lambda(G_m^c) < 2^{-m}$, and these bad-set measures are summable: $\sum_m \lambda(G_m^c) < \sum_m 2^{-m} = 1 < \infty$. The first Borel–Cantelli lemma (theorem 3.27(i)) — which is stated and proved later in this chapter, by an elementary argument that nowhere invokes the present theorem, so the forward reference carries no circularity — then says that summability of the $\lambda(G_m^c)$ forces $\lambda(\, G_m^c \text{ for infinitely many } m\,) = 0$. Equivalently, almost every $\omega \in [0,1)$ lies in G_m for all sufficiently large m. For such an ω and each large m we showed $\limsup_n d(Y_n(\omega), Y(\omega)) \le 1/m$; letting $m \to \infty$ drives the lim sup to 0, so $Y_n(\omega) \to Y(\omega)$. Hence $Y_n \to Y$ λ-almost surely, completing the proof. □

Step back and notice how economical the inputs were. The distributional hypothesis $\mu_n \Rightarrow \mu$ entered *only* through Step 0 — the continuity-set form Portmanteau (v), used to push masses of finitely many cells to the limit; the limit point of the codings was produced by *completeness* of S closing up a Cauchy sequence; the countable scaffolding of small-mesh partitions came from *separability*; and the upgrade from “most ω are good at each level” to “almost every ω is eventually always good” was a single application of the *Borel–Cantelli lemma* proved in section 3.5.1. No further machinery — no metrization, no compactness, no abstract existence principle — was needed, so the theorem is fully self-contained within this chapter, exactly as the chapter’s self-containedness pledge demands. That same frugality is why the metrization argument of theorem 3.12 could lean on this result without circularity: Skorokhod’s representation rests on Portmanteau and Borel–Cantelli alone.

With Skorokhod’s theorem in hand the bridge between the two worlds is complete: weak convergence of laws can always be *realized* as almost-sure convergence of suitably coupled variables, so every pointwise limit theorem of chapter 1 transfers to the weak-convergence setting through the template (3.8), and chapter 4 will invoke precisely this to prove completeness of the Wasserstein space and to push lower-semicontinuity and Fatou-type inequalities up to the level of measures. But notice what the theorem takes for granted: it begins with a sequence that *already converges weakly*. It realizes a limit that is handed to it; it does not produce one. The existence proofs of the mean field theory face the opposite situation. There one starts with a sequence of approximate equilibria — approximate population measures — with *no* limit given in advance, and the entire task is to extract one. That is a *compactness* question, and weak convergence has so far supplied no compactness at all: as the toy escape $\mu_n = \delta_n$ already warned in section 3.2.2, a sequence of probability measures can simply leak its mass off to infinity and converge to nothing in $\mathcal{P}(S)$. The next section identifies the condition that forbids this leakage — tightness — and proves, in Prokhorov’s theorem, that it is the *only* obstruction to extracting a weakly convergent subsequence, turning the realization device of this section into the manufacturing device the existence proofs require.

3.3 Tightness and Prokhorov's theorem

Skorokhod's theorem closed the previous section by completing a bridge in one direction: a sequence of laws that *already converges weakly* can be realized on a single probability space as variables that converge almost surely, so the pointwise machinery of chapter 1 transfers to the world of measures. But, as we were careful to note there, that device takes its convergent sequence as a gift; it realizes a limit, it does not manufacture one. The existence proofs of the mean field theory stand on the other side of exactly this gap. There one is handed a sequence of approximate equilibria — approximate population measures produced by some iteration or relaxation — with no limit given in advance, and the whole problem is to *produce* a limit to which the candidate could converge. That is a question of *compactness*, and weak convergence, for all that the Portmanteau theorem and the metric of section 3.2.2 did for it, has so far supplied none. Worse, it cannot supply it unconditionally. The toy escape $\mu_n = \delta_n$ flagged back in section 3.2.2 already shows why: a sequence of probability measures can simply let its unit of mass slide off to infinity and converge to nothing in $\mathcal{P}(S)$. Concretely, for any $f \in C_b(\mathbb{R}^d)$ that has a limit $f(\infty)$ at infinity one finds $\mu_n(f) = f(n) \to f(\infty)$, so the integral readings *do* settle down — but they settle on the functional $f \mapsto f(\infty)$, which is not $\mu(f)$ for any probability measure μ; the limiting "measure" would have to place its entire mass at the point at infinity, which $\mathbb{R}^d$ does not contain. The mass is not redistributed, it is lost, and no $\mu \in \mathcal{P}(\mathbb{R}^d)$ catches it.

This section identifies the one condition that forbids the leak — *tightness* — and proves, in Prokhorov's theorem, that ruling out the leak is the *only* thing standing between a sequence of measures and a convergent subsequence. The payoff is precisely the manufacturing device the existence proofs need: an a priori estimate, of exactly the moment-bound type a physicist produces by an energy argument, certifies tightness, and tightness is then converted by Prokhorov into a weakly convergent subsequence whose limit is the equilibrium. The realization device of the previous section and the compactness theory of this one are the two halves of how weak convergence is actually used downstream: one turns a limit into almost-sure statements, the other conjures the limit in the first place.

Definition 3.14 (Tightness)**.** A family $\Pi \subseteq \mathcal{P}(S)$ is *tight* if for every $\varepsilon > 0$ there is a compact set $K_\varepsilon \subseteq S$ with

$$\mu(K_\varepsilon) \;\geq\; 1 - \varepsilon \qquad \text{for every } \mu \in \Pi.$$

A family is *relatively compact* (in the weak topology) if every sequence in Π has a subsequence converging weakly to some element of $\mathcal{P}(S)$.

Read the definition slowly, because every word of it is load-bearing. The word "compact" is what forbids the escape to infinity: a compact set in $\mathbb{R}^d$ is bounded, so demanding that μ place at least $1-\varepsilon$ of its mass on K_ε is demanding that at most ε of it sit beyond a fixed horizon. The word that does the real work, though, is the quantifier "for every $\mu \in \Pi$": the *same* compact K_ε must absorb $1-\varepsilon$ of the mass of *every* member of the family at once. It is this uniformity, not the inner-mass condition on any individual measure, that turns into compactness — indeed, by Ulam's theorem below, every *single* probability measure already satisfies the inner-mass condition, so a family that failed to be tight would do so only because no single compact works for all of its members simultaneously, the horizon needed to corral the mass receding without bound as one runs through the family. That is exactly the pathology of $\mu_n = \delta_n$: each δ_n is by itself perfectly concentrated, but the point n at which it concentrates marches off to infinity, so no fixed compact catches all of them.

On $\mathbb{R}^d$ this becomes wholly concrete, because there the compact sets are exactly the closed bounded sets (Heine–Borel), and a closed ball $\overline{B}(0,R)$ can be made to contain any prescribed compact by taking R large. Tightness of Π is therefore equivalent to the statement that the mass living *outside* large balls goes to zero *uniformly* over the family,

$$\sup_{\mu\in\Pi} \mu\big(\{|x|>R\}\big) \;\longrightarrow\; 0 \qquad \text{as } R\to\infty,$$

which is the form we actually check. (One direction: given ε, pick R with the supremum below ε and take $K_\varepsilon = \overline{B}(0,R)$. The other: given the compacts K_ε, enclose each in a ball.) This is the shape every verification of tightness in the book will take — show that no fixed fraction of the population can wander arbitrarily far out — and there is one sufficient condition for it that recurs so often it deserves to be isolated, because it is precisely what an energy estimate delivers. Suppose the family obeys a *uniform moment bound*: for some exponent $p>0$,

$$\sup_{\mu\in\Pi} \int_{\mathbb{R}^d} |x|^p \,\mathrm{d}\mu \;:=\; M \;<\; \infty,$$

so that no member has too much mass far from the origin, with the bound M holding across the whole family. Then Markov's inequality — the same one-line device $\mathbb{P}(|Y|>R) \le R^{-p}\mathbb{E}[|Y|^p]$ that powered the L^p arrow of lemma 3.6, applied here to the identity $Y=|x|$ under μ — gives, for every $\mu\in\Pi$ at once,

$$\mu(\{|x|>R\}) \;=\; \int_{\{|x|>R\}} \mathrm{d}\mu \;\le\; \int_{\{|x|>R\}} \frac{|x|^p}{R^p}\,\mathrm{d}\mu \;\le\; \frac{1}{R^p}\int_{\mathbb{R}^d} |x|^p \,\mathrm{d}\mu \;\le\; \frac{M}{R^p},$$

the first inequality because $|x|^p/R^p \ge 1$ on the region $\{|x|>R\}$. The right-hand side M/R^p does not depend on μ and tends to 0 as $R\to\infty$, so the supremum over Π does too, and Π is tight. This implication — "a single uniform p-th moment bound $\Rightarrow$ tightness" — is the workhorse that converts the output of a mean field existence argument into compactness: one proves, by an a priori energy or moment estimate on the population (an estimate uniform in the approximation parameter), that $\sup\int |x|^p\,\mathrm{d}\mu \le M$, and tightness follows mechanically. Note how little is asked: *any* fixed positive moment, bounded *uniformly*, suffices; one does not need a sharp constant, only finiteness that does not blow up across the family.

There is one preliminary fact to settle before the family statement, and it is the reassurance that the inner-mass half of the tightness condition is never itself the obstruction. On a Polish space *a single* probability measure is automatically tight: it always concentrates $1-\varepsilon$ of its mass on some compact, however spread out it may look. This is Ulam's theorem. We need it for two distinct reasons, and it is worth flagging both. First, it is the inner-regularity fact that keeps the limit measure produced in Prokhorov's theorem honest — without it one could not be sure the constructed limit is genuinely a probability measure rather than a defective content that has quietly shed mass. Second, it is one of the results that the metrization theorem of the previous section borrowed forward: the completeness half of theorem 3.12 invoked Ulam (and Prokhorov direction (b)) on credit, promising they would be proved here by arguments that never refer back to metrization. We are now discharging that promise, and the reader can verify the non-circularity directly: the proof below uses only a countable dense set and continuity from below, nothing about the topology of $\mathcal{P}(S)$.

Lemma 3.15 (Ulam: tightness of a single measure)**.** *Let S be Polish and $\mu \in \mathcal{P}(S)$. Then μ is tight: for every $\varepsilon > 0$ there is a compact $K \subseteq S$ with $\mu(K) \geq 1 - \varepsilon$. Consequently every finite subset of $\mathcal{P}(S)$ is a tight family.*

Proof. The idea is to approximate S from inside, at every resolution scale simultaneously, by a finite union of small balls, and then intersect those finite unions across all scales to produce a set that is closed and totally bounded — the two properties that, on a complete space, force compactness. Polishness enters twice and we mark each entrance: separability supplies the countable dense set that makes "finitely many balls" meaningful, and completeness is what upgrades total boundedness to compactness at the end.

Fix a countable dense set $\{x_i\}_{i\geq 1} \subseteq S$ — it exists because S is separable — and fix $\varepsilon > 0$. Work one resolution scale $1/m$ at a time. The open balls $B(x_i, 1/m)$, $i \geq 1$, cover S, since every point lies within $1/m$ of some x_i by density. Their finite unions $\bigcup_{i\leq k} B(x_i, 1/m)$ increase to all of S as $k \to \infty$, so by continuity from below of the measure μ (chapter 1; this is the import we lean on) their μ-masses increase to $\mu(S) = 1$. Hence we may choose an index k_m large enough that the truncated cover already captures all but an m-dependent sliver of the mass:

$$\mu\Big(\bigcup_{i\leq k_m} B(x_i, 1/m)\Big) \;>\; 1 - \varepsilon\, 2^{-m}.$$

The budget $\varepsilon\, 2^{-m}$ is allotted to scale m precisely so that the slivers across all scales sum to ε, by the geometric series $\sum_m 2^{-m} = 1$; this is the standard device for spending a finite error budget over countably many constraints.

Now close up and intersect. Set $D_m = \bigcup_{i\leq k_m} \overline{B}(x_i, 1/m)$, the union of the corresponding *closed* balls (which only enlarges the set, so the mass bound is inherited: $\mu(D_m) \geq \mu(\bigcup_{i\leq k_m} B(x_i, 1/m)) > 1 - \varepsilon 2^{-m}$), and let $K = \bigcap_{m\geq 1} D_m$. We check K is compact. It is closed, as an intersection of closed sets. It is totally bounded: given any $\eta > 0$, pick m with $1/m < \eta$; then $K \subseteq D_m$ is covered by the finitely many balls $\overline{B}(x_i, 1/m)$, $i \leq k_m$, each of radius $< \eta$, which is exactly the definition of total boundedness. A closed and totally bounded subset of a *complete* metric space is compact — this is where completeness is spent — so K is compact. Finally, the mass left out is controlled by summing the per-scale slivers, using countable subadditivity on the complement:

$$\mu(K^c) = \mu\Big(\bigcup_{m\geq 1} D_m^c\Big) \leq \sum_{m\geq 1} \mu(D_m^c) \leq \sum_{m\geq 1} \varepsilon\, 2^{-m} = \varepsilon,$$

so $\mu(K) \geq 1 - \varepsilon$, as claimed. The final sentence is the bridge to families: a finite collection $\{\mu_1, \ldots, \mu_r\}$ is tight because, taking the compact furnished for each μ_j at level ε and forming their union, one gets a single compact set (a finite union of compacts is compact) that carries $1 - \varepsilon$ of every μ_j at once. It is only when the family is *infinite* that this union may fail to stay compact, and that failure is exactly the content tightness is designed to rule out. $\square$

Theorem 3.16 (Prokhorov). *Let S be a metric space and $\Pi \subseteq \mathcal{P}(S)$.*

(a) *If Π is tight, then Π is relatively compact.*

(b) *If S is Polish and Π is relatively compact, then Π is tight.*

In particular, on a Polish space tightness and relative compactness are equivalent.

The two directions are not of equal importance to us, and it helps to say which one does the work. Direction (a) — tight $\Rightarrow$ relatively compact — is the engine: it is the implication that takes an a priori estimate, repackaged as tightness, and *produces* a weakly convergent subsequence whose limit can then be identified as the equilibrium. Direction (b) — relatively compact $\Rightarrow$ tight, valid on Polish spaces — is the converse that certifies tightness is not merely *a* sufficient condition for compactness but the *exact* one, nothing weaker will do; it is also, as just recalled, the result the metrization proof borrowed forward, so proving it here closes that loop. We prove both in full for S Polish, which is the only case the book ever needs (a general metric space reduces to it by restricting to the closure of a separable support, on which the measures live). The reader should be warned in advance that the proof of (a) is the single longest and most tightly compressed argument in the chapter, and the reason is structural: weak convergence is defined by testing against continuous functions, but a *limit* measure is not handed to us as a functional — it must be *built*, set by set, as an honest Borel measure, before there is anything for the continuous tests to converge to. The construction is the classical one: from the compacts supplied by tightness we manufacture an inner-regular *content* γ, promote it to a metric outer measure, and invoke the Carathéodory extension theorem of chapter 1 to crystallize a genuine Borel probability measure, which a final Portmanteau check identifies as the weak limit. Each of these moves is a step in the proof below, and we expand the terse justifications — the compactness-driven subadditivity, the subordinated finite cover, the separation additivity — that the skeleton draft compressed to a line apiece.

Proof of (a), *S Polish.* The strategy is to read off, from the sequence, the *values* a limiting measure would have to take on a rich-but-countable supply of compact sets; to extract a subsequence along which all those values converge (a diagonal trick, legitimate only because the supply is countable); and then to grow those values into a genuine Borel measure by the inner-content/outer-measure construction. Tightness enters once, at the start, to confine the action to a σ-compact part of S where the construction has compacts to feed on.

Let (μ_n) be a sequence in the tight family Π; we must find a weakly convergent subsequence. By tightness, for each m there is a compact carrying $1 - 1/m$ of every measure's mass, and replacing each by the union of the first m of them we may take the compacts increasing, $K_1 \subseteq K_2 \subseteq \cdots$, with $\mu_n(K_m) \geq 1 - 1/m$ for all n simultaneously (the uniformity in n is exactly what tightness provides). Their union $K = \bigcup_m K_m$ is σ-compact, hence separable; fix a countable dense set $D \subseteq K$. Everything from here lives on K, where mass 1 has been corralled in the limit.

Step 1 (a countable family of compacts, and diagonal extraction). We need a countable supply of compact sets, closed under finite unions enough to do combinatorics, on which to read the limiting values. Let $\mathcal{K}$ be the collection of all sets of the form $C = F \cap K_m$, $m \geq 1$, where F ranges over finite unions of *closed* balls $\overline{B}(d,q)$ with centre $d \in D$ and rational radius $q \in \mathbb{Q}_{>0}$. There are countably many such F (finite subsets of the countable index set $D \times \mathbb{Q}_{>0}$) and countably many m, so $\mathcal{K}$ is countable. Each $C = F \cap K_m$ is a closed subset of the compact K_m, hence itself compact. Now the diagonal extraction: each real sequence $\big(\mu_n(C)\big)_n$ lives in the compact interval $[0,1]$, so it has a convergent subsequence; because $\mathcal{K}$ is countable we may enumerate it as $C^{(1)}, C^{(2)}, \ldots$, extract a subsequence along which $\mu_n(C^{(1)})$ converges, a further subsequence for $C^{(2)}$, and so on, and take the diagonal sequence, which from its j-th term on is a subsequence of the j-th extraction and hence makes $\mu_n(C^{(j)})$ converge for *every* j at once. (This is the one place countability of $\mathcal{K}$ is indispensable: an uncountable family of conditions cannot be met by a single subsequence this way.) Relabel this diagonal subsequence again as (μ_n). Along it,

$$\gamma(C) := \lim_n \mu_n(C) \in [0,1] \qquad \text{exists for every } C \in \mathcal{K}.$$

The limit γ inherits from the μ_n exactly the two algebraic properties we will use. It is *monotone*: if $C \subseteq C'$ then $\mu_n(C) \le \mu_n(C')$ for every n, and the inequality passes to the limit. It is *finitely subadditive*: $\mu_n(C \cup C') \le \mu_n(C) + \mu_n(C')$ for every n (a property of any measure), so $\gamma(C \cup C') \le \gamma(C) + \gamma(C')$ in the limit. And it retains the mass $\gamma(K_m) = \lim_n \mu_n(K_m) \ge 1 - 1/m$. These three facts are all we know about γ, and the rest of the proof manufactures a measure out of them.

Step 2 (inner content and outer measure). A content lives on compacts; a measure must live on all Borel sets. We bridge the gap in the standard two stages, working outward from $\mathcal{K}$ to open sets and then inward to arbitrary sets. For an open $U \subseteq S$ define the *inner content*

$$\tau(U) = \sup\{\, \gamma(C) : C \in \mathcal{K},\ C \subseteq U \,\},$$

the most mass our compacts can certify inside U, and then for an arbitrary $A \subseteq S$ the *outer value*

$$\mu^*(A) = \inf\{\, \tau(U) : U \supseteq A \text{ open} \,\},$$

the least open content that can be wrapped around A. We claim μ^* is a *metric outer measure*, meaning: it is monotone with $\mu^*(\emptyset) = 0$; it is countably subadditive; and it is *additive across positively separated sets*, $\mu^*(A \sqcup B) = \mu^*(A) + \mu^*(B)$ whenever $d(A,B) > 0$. Monotonicity and $\mu^*(\emptyset) = 0$ are immediate from the definitions (a larger A admits fewer enclosing U, raising the infimum; the empty set is enclosed by ever-smaller opens containing no C of positive content). The two substantive claims are where the geometry of S is used, and we give each in full.

Countable subadditivity, and why compactness is exactly what makes it work. This is the only step that touches compactness, and the reason is that subadditivity must defeat an *infinite* cover using only the *finite* subadditivity of γ — compactness is precisely the tool that reduces the infinite cover to a finite one. Let $U = \bigcup_k U_k$ be a countable union of open sets, and let $C \in \mathcal{K}$ with $C \subseteq U$ be any compact competing in the supremum defining $\tau(U)$. Since C is compact and $\{U_k\}$ is an open cover of it, *finitely many* of them, say $U_1, \ldots, U_J$, already cover C. We now subordinate C to this finite cover: we write C as a finite union $C = \bigcup_{k \le J} C_k$ of members of $\mathcal{K}$ with $C_k \subseteq U_k$. To build the C_k, observe that each point $x \in C$ lies in some U_k, and since U_k is open and D is dense there is a closed ball $\overline{B}(d,q)$ with $d \in D$, $q \in \mathbb{Q}_{>0}$, small enough that $x \in \overline{B}(d,q) \subseteq U_k$; the interiors $B(d,q)$ of such balls form an open cover of the compact C, so finitely many suffice, and grouping the chosen closed balls according to which U_k contains them and intersecting with the relevant K_m

yields sets $C_k = F_k \cap K_m \in \mathcal{K}$ with $C_k \subseteq U_k$ and $C \subseteq \bigcup_{k \le J} C_k$ (we may intersect each C_k further with C to keep it inside C, still a member of $\mathcal{K}$ since C itself is). Finite subadditivity of γ from Step 1, applied to this finite decomposition, gives

$$\gamma(C) \le \sum_{k \le J} \gamma(C_k) \le \sum_{k \le J} \tau(U_k) \le \sum_k \tau(U_k),$$

where the middle inequality is just $\gamma(C_k) \le \tau(U_k)$ from the definition of the inner content (each $C_k \subseteq U_k$ is one of the compacts competing in $\tau(U_k)$). The right-hand side no longer mentions C, so taking the supremum over all admissible C gives $\tau(U) \le \sum_k \tau(U_k)$. Finally, for arbitrary sets A_k with $A = \bigcup_k A_k$, enclose each A_k in an open U_k with $\tau(U_k) \le \mu^*(A_k) + \eta\, 2^{-k}$; then $U = \bigcup_k U_k \supseteq A$ is open and $\mu^*(A) \le \tau(U) \le \sum_k \tau(U_k) \le \sum_k \mu^*(A_k) + \eta$, and letting $\eta \downarrow 0$ yields $\mu^*(\bigcup_k A_k) \le \sum_k \mu^*(A_k)$.

Additivity across separated sets, via a separating pair of opens. Suppose $d(A, B) = \rho > 0$; we must show μ^* does not over-count their union. Subadditivity already gives $\mu^*(A \sqcup B) \le \mu^*(A) + \mu^*(B)$, so only the reverse inequality is at issue. The positive separation lets us *physically separate* any enclosing open. Let $U \supseteq A \sqcup B$ be open, and carve out of it the two disjoint open collars

$$U_A = U \cap \{x : d(x, A) < \rho/2\}, \qquad U_B = U \cap \{x : d(x, B) < \rho/2\};$$

they are disjoint because a point within $\rho/2$ of A is, by the triangle inequality and $d(A, B) = \rho$, more than $\rho/2$ from B, so it cannot lie in both. Now take any compacts $C_A \subseteq U_A$ and $C_B \subseteq U_B$ from $\mathcal{K}$ competing in the inner contents $\tau(U_A)$ and $\tau(U_B)$ respectively. Their union $C_A \cup C_B$ lies in U and, being a disjoint union of two members of $\mathcal{K}$, is again a member of $\mathcal{K}$ with $\gamma(C_A \cup C_B) = \gamma(C_A) + \gamma(C_B)$ — here the limit of the exact additivity $\mu_n(C_A \cup C_B) = \mu_n(C_A) + \mu_n(C_B)$ on the disjoint pair is used. Hence $\tau(U) \ge \gamma(C_A) + \gamma(C_B)$, and taking suprema over C_A, C_B gives $\tau(U) \ge \tau(U_A) + \tau(U_B) \ge \mu^*(A) + \mu^*(B)$. Taking the infimum over enclosing U yields $\mu^*(A \sqcup B) \ge \mu^*(A) + \mu^*(B)$, and with subadditivity, equality.

Step 3 (a Borel probability measure). The point of verifying the *metric* outer measure property is that it unlocks an import from chapter 1: for a metric outer measure every Borel set is Carathéodory measurable, so the restriction $\mu := \mu^*|_{\mathcal{B}(S)}$ is a countably additive Borel measure. This is the Carathéodory extension theorem (chapter 1), and it is the precise machine that turns the separation-additive outer measure μ^* into a bona fide measure on the Borel σ-algebra — exactly the role flagged in the preamble to the proof. It remains to check that no mass leaked away in the construction, i.e. $\mu(S) = 1$. Each K_m is itself a member of $\mathcal{K}$: it is compact, so the interiors of the closed balls $\overline{B}(d, q)$ ($d \in D$, $q \in \mathbb{Q}_{>0}$) meeting it cover it, finitely many suffice, and $K_m = F \cap K_m$ for the resulting finite union F of closed balls. Therefore $\gamma(K_m)$ is defined and competes in $\tau(S)$, so

$$\mu(S) = \mu^*(S) = \tau(S) \ge \gamma(K_m) = \lim_n \mu_n(K_m) \ge 1 - \tfrac{1}{m} \qquad \text{for every } m,$$

forcing $\mu(S) \ge 1$. The reverse bound is automatic: every competing $\gamma(C) \le 1$ (as γ is a limit of probabilities), so $\tau(S) \le 1$. Hence $\mu(S) = 1$ and $\mu \in \mathcal{P}(S)$ — a genuine probability measure, with Ulam's tightness retroactively guaranteeing it could not have been a defective content. This is where the construction would have failed without the mass control of Step 1: had tightness not pinned $1 - 1/m$ inside compacts, the limit μ could carry mass < 1, which is the analytic form of the escape-to-infinity the whole section is built to prevent.

Step 4 (identification of the weak limit). A measure has been built; we now verify it is the weak limit of the subsequence, and the natural certificate is the open-set form of Portmanteau, since open sets are exactly where the inner content τ was defined. Let $U \subseteq S$ be open. For any $C \in \mathcal{K}$ with $C \subseteq U$, monotonicity of each μ_n gives $\mu_n(U) \geq \mu_n(C)$, hence $\liminf_n \mu_n(U) \geq \liminf_n \mu_n(C) = \gamma(C)$; the limit on the right is an honest equality because $\gamma(C) = \lim_n \mu_n(C)$ exists. Taking the supremum over all such C replaces $\gamma(C)$ by $\tau(U)$, and $\tau(U) \geq \mu^*(U) = \mu(U)$ by the very definition of μ^* as an infimum over enclosing opens (with U itself one of them). Chaining these,

$$\liminf_n \mu_n(U) \;\geq\; \tau(U) \;\geq\; \mu(U) \qquad \text{for every open } U,$$

which is precisely characterization (iv) of the Portmanteau theorem (theorem 3.9), the lower-semicontinuity of mass on open sets. That theorem then upgrades it to $\mu_n \Rightarrow \mu$. We have thus extracted from the original sequence a weakly convergent subsequence with limit in $\mathcal{P}(S)$. Since the argument applies verbatim to *any* subsequence of the tight sequence — a subsequence of a tight family is tight — every subsequence has a further weakly convergent sub-subsequence, which is the definition of relative compactness of Π. □

Proof of (b)*, S Polish.* This is the converse: relative compactness forces tightness, so that tightness is not just sufficient but necessary for weak compactness on a Polish space. The proof runs the construction of (a) in reverse — it builds the same kind of compact set, an intersection of finite ball-unions across all scales, but now it must show the mass outside it is uniformly small over the *whole* family, and the only lever available is relative compactness. The heart of the matter is a single uniform covering claim, after which the assembly mimics Ulam.

Fix a countable dense set $\{x_i\} \subseteq S$ and a scale $\delta > 0$. The claim is that finitely many δ-balls already capture, uniformly over Π, all but an arbitrarily small fraction of the mass:

$$\forall \varepsilon > 0 \;\exists\, k : \quad \inf_{\mu \in \Pi} \; \mu\Big(\bigcup_{i \leq k} B(x_i, \delta)\Big) \geq 1 - \varepsilon. \tag{3.9}$$

The content of (3.9) is the *uniformity*: for one fixed μ the finite union $\bigcup_{i \leq k} B(x_i, \delta)$ increases to S and its mass tends to 1 as $k \to \infty$, so a single measure poses no problem; the claim is that a single k works for the entire family at once. Suppose it failed. Then for some $\varepsilon > 0$, no finite k suffices: for every k there is a witness $\mu_k \in \Pi$ that evades the bound, $\mu_k\big(\bigcup_{i \leq k} B(x_i, \delta)\big) < 1 - \varepsilon$. Here is where relative compactness is spent: the sequence of witnesses (μ_k), living in the relatively compact Π, has a weakly convergent subsequence $\mu_{k_j} \Rightarrow \nu$ with limit $\nu \in \mathcal{P}(S)$. We now show this ν cannot be a probability measure, the desired contradiction. Fix any m and consider the open set $G_m = \bigcup_{i \leq m} B(x_i, \delta)$. For every index $k_j \geq m$ the nesting $G_m \subseteq \bigcup_{i \leq k_j} B(x_i, \delta)$ holds (more balls, larger union), so by monotonicity $\mu_{k_j}(G_m) \leq \mu_{k_j}\big(\bigcup_{i \leq k_j} B(x_i, \delta)\big) < 1 - \varepsilon$. Applying the open-set Portmanteau bound (iv) to the weak convergence $\mu_{k_j} \Rightarrow \nu$ on the fixed open G_m,

$$\nu(G_m) \;\leq\; \liminf_j \mu_{k_j}(G_m) \;\leq\; \liminf_j \mu_{k_j}\Big(\bigcup_{i \leq k_j} B(x_i, \delta)\Big) \;\leq\; 1 - \varepsilon.$$

This bound is uniform in m. But the sets G_m increase to S as $m \to \infty$, because the dense points $\{x_i\}$ put a δ-ball within reach of every point, so continuity from below (chapter 1) gives $\nu(S) = \lim_m \nu(G_m) \leq 1 - \varepsilon < 1$, contradicting $\nu(S) = 1$. The contradiction establishes (3.9).

With the uniform covering claim in hand the compact set is assembled exactly as in Ulam's lemma, with (3.9) doing the job that continuity from below did there, but now uniformly over Π. Fix $\varepsilon > 0$. Apply (3.9) at scale $\delta = 1/m$ with tolerance $\varepsilon 2^{-m}$ to get an index k_m for which $A_m := \bigcup_{i \le k_m} B(x_i, 1/m)$ satisfies $\inf_{\mu\in\Pi} \mu(A_m) \ge 1 - \varepsilon 2^{-m}$, i.e. $\mu(A_m^c) \le \varepsilon 2^{-m}$ for *every* $\mu \in \Pi$ at once. Set $K = \bigcap_{m\ge1} \overline{A_m}$. As in Ulam, K is closed and totally bounded — for each m it sits inside the finitely many closed balls $\overline{B}(x_i, 1/m)$, $i \le k_m$, of radius $1/m$ — hence compact by completeness of S. And the mass outside it is controlled uniformly:

$$\mu(K^c) = \mu\Big(\bigcup_{m\ge1} \overline{A_m}^{\,c}\Big) \le \sum_{m\ge1} \mu(A_m^c) \le \sum_{m\ge1} \varepsilon 2^{-m} = \varepsilon \qquad \text{for every } \mu \in \Pi,$$

using $\overline{A_m}^{\,c} \subseteq A_m^c$. Thus the single compact K carries $\mu(K) \ge 1 - \varepsilon$ for every $\mu \in \Pi$ simultaneously, which is tightness. Notice where Polishness was spent: completeness, in the step "closed + totally bounded $\Rightarrow$ compact." On a non-Polish space that implication can fail, and indeed relative compactness then need not imply tightness — so direction (b), unlike (a), genuinely requires the Polish hypothesis. This also retroactively licenses the forward use made in section 3.2.2: the completeness half of the metrization theorem (theorem 3.12) invoked precisely this direction (b) together with Ulam (lemma 3.15), and both have now been proved by arguments that never refer to that theorem, so there was no circularity in borrowing them ahead. □

We can now state, in one place, the recipe that every existence proof in the book follows, because the abstract development of this section was curated to exactly that recipe and it is worth seeing the pieces snap together.

Remark 3.17 (How Prokhorov is used downstream)**.** The pattern, instantiated in chapter 10 for classical MFG and in chapter 24 for graphon MFG, has four moves. *(1) Candidate map.* One sets up a candidate equilibrium as a fixed point: either an iteration $m \mapsto \Phi(m)$ that maps a population law to the law induced by the best response against it, or a relaxed family of approximate-equilibrium laws indexed by a regularization parameter. *(2) Uniform bound $\Rightarrow$ tightness.* One proves an a priori moment or energy estimate that is *uniform* in the iteration index or regularization parameter — typically $\sup \int |x|^p \, \mathrm{d}\mu \le M$ — which, by the Markov argument at the head of this section, certifies tightness of the family of candidates. *(3) Prokhorov.* Direction (a) converts that tightness into a weakly convergent subsequence of candidates, $\mu_{n_j} \Rightarrow m_\star$, manufacturing a limit object out of thin air. *(4) Portmanteau identification.* Continuity of the relevant functionals — the cost, the coupling, the best-response map — combined with Portmanteau (iv), shows the limit $m_\star$ is a fixed point of Φ, hence an equilibrium. The nondegeneracy standing assumption (A-Nondeg) of the thread specification enters at move (2) in the diffusive case: it is the uniform parabolic smoothing that produces the a priori bound in the first place, so the whole machine turns on it; we flag the dependence there, where the estimate is actually carried out, not here, where only its consequence is consumed.

This completes the compactness theory and, with it, the deterministic side of the mean field limit. Tightness plus Prokhorov is the law-of-large-numbers half of the story: it guarantees that the population profile μ^N does not escape to infinity but settles — along subsequences, and in the equilibrium analyses genuinely — onto a deterministic limit measure m. What it does *not* tell us is how the population fluctuates *around* that limit while N is large but finite. That residual jitter is not noise to be ignored; it is the $N^{-1/2}$ fluctuation whose variance bookkeeping we already glimpsed in (3.4), where the additivity of variance over an uncorrelated ensemble made the standard deviation of an empirical average scale like $\sigma/\sqrt{N}$. Prokhorov delivered the limit; the complementary task is to quantify the spread about it, and to show that the spread is not merely of size $N^{-1/2}$ but *Gaussian* in profile. That is the business of the next section, which sharpens the second-moment estimate into a full distributional statement by passing to the characteristic function and proving the central limit theorem.

3.4 Characteristic functions, the central limit theorem, and the $N^{-1/2}$ fluctuation scale

Tightness and Prokhorov, in the section just closed, settled the law-of-large-numbers half of the mean field limit: they guarantee that the population profile μ^N does not run off to infinity but condenses — along subsequences, and in the equilibrium analyses genuinely — onto a deterministic limit measure m. That is the *deterministic* skeleton of the limit. It says nothing, however, about the flesh on the skeleton: how the population trembles *about* m while N is large but still finite. This residual trembling is the complementary object, and quantifying it is the task of the present section. We are not starting from nothing. The variance bookkeeping of the independence section already pinned the *size* of the trembling: the additivity of variance over an uncorrelated ensemble, (3.4), forced the standard deviation of an empirical average to scale like $\sigma/\sqrt{N}$, so a fluctuation of typical magnitude $N^{-1/2}$ was visible at the level of the second moment alone. What the second moment cannot see is the *shape* of that fluctuation — whether the $N^{-1/2}$-sized deviation is distributed in one way or another. The slogan a physicist carries, "mean field suppresses fluctuations, which are of order $N^{-1/2}$ and Gaussian," contains two claims, and only the first has so far been earned. This section earns the second. It promotes the variance estimate into a full distributional statement: the rescaled fluctuation $\sqrt{N}(\bar{X}_N - \mathbb{E}[X])$ does not merely have bounded variance, it converges in law to a Gaussian. That is the central limit theorem, and it is the precise content of the suppression slogan.

The variance computation got us this far because variance is *additive* over independent summands; to reach the full law of a sum of independent variables we need an instrument that turns the entire distribution, not just its second moment, into something additive. That instrument is the *characteristic function*, the Fourier transform of a law, $\varphi_X(t) = \mathbb{E}\left[e^{i\langle t,X\rangle}\right]$. Its decisive virtue is a single algebraic fact: *independence becomes multiplication*. If X and Y are independent, the expectation of the product $e^{itX}e^{itY} = e^{it(X+Y)}$ factorizes by (3.3), so $\varphi_{X+Y} = \varphi_X\,\varphi_Y$. Adding independent random variables, which on the level of laws is the operation of *convolution* — $\mathcal{L}(X + Y) = \mathcal{L}(X) * \mathcal{L}(Y)$, an integral entangling the two distributions — is thereby converted into the elementary pointwise *product* of their transforms. The Fourier transform diagonalizes convolution; the hard nonlinear bookkeeping of combining many independent contributions collapses into multiplying numbers. A sum of N independent variables, whose law is an N-fold convolution and is essentially uncomputable directly, has a characteristic function that is simply the N-fold product of the factors, and the asymptotics of a product are read off from the asymptotics of its logarithm. This is exactly why the Fourier route, and not a direct attack on the convolution, proves the central limit theorem.

The parallel with equilibrium statistical mechanics is genuine and worth one sentence, kept light. There the partition function of a system assembled from *non-interacting* subsystems factorizes, $Z = \prod_i Z_i$, so that the free energies $-\log Z_i$ add and become extensive; here the characteristic function of a sum of *independent* variables factorizes in the same way, so that the *cumulant generating function* $\log \varphi$ adds over the summands. The $N^{-1/2}$ scaling and the Gaussian shape are then the statement that, after centering and rescaling, the additive log-transform of a non-interacting ensemble flows to a quadratic — the universal fixed point whose inverse Fourier transform is the Gaussian. Independence is, in both settings, precisely the hypothesis that makes the generating function multiplicative and hence its logarithm additive; the coupling in a finite N-player game spoils the factorization, and the corrections to it are the very fluctuations chapter 7 and chapter 13 will track.

Three subsections carry this out, in the only order the logic permits, and it is worth seeing the dependency chain whole before meeting its links. The Fourier route rests on the transform being a *faithful* encoding of the law and a *continuous* one, and these two properties must be established before any limit theorem can use them. The first subsection (section 3.4.1) builds the transform and proves both. Faithfulness is the *Lévy inversion formula* (lemma 3.20), which reconstructs the measure from its characteristic function by an explicit integral and so shows the transform loses no information; its immediate corollary is *uniqueness* — equal characteristic functions mean equal laws (proposition 3.19(4)) — the property that will let us *identify* a limit once we recognize its transform. Continuity is the *Lévy continuity theorem* (theorem 3.21), which says that pointwise convergence of characteristic functions is equivalent to weak convergence of laws, provided the limit transform is continuous at the origin — a proviso that is, as we will see, a tightness condition wearing a Fourier disguise, tying this pillar back to the previous one. The chain is therefore inversion $\Rightarrow$ uniqueness $\Rightarrow$ continuity $\Rightarrow$ central limit theorem: inversion makes the transform invertible, uniqueness makes the limiting transform name a unique law, continuity converts convergence of transforms into convergence of laws, and only then can the second subsection (section 3.4.2) prove the central limit theorem itself — by the strategy already advertised, expanding $\log \varphi$ to second order and watching the rescaled product converge to the Gaussian transform $e^{-\sigma^2 t^2/2}$. The third subsection (section 3.4.3) spends the theorem on the object this chapter exists to serve: a mean field observable averaged over the empirical measure, where the central limit theorem makes the $N^{-1/2}$ Gaussian fluctuation about the mean field m a precise distributional statement rather than a variance estimate.

We begin, then, with the transform itself and the two properties — inversion and continuity — on which everything downstream rests.

3.4.1 Characteristic functions

The section preamble made a promise this subsection must now redeem: that the Fourier transform of a law converts independence into multiplication, and that two analytic facts about that transform — that it is *faithful* (uniqueness) and *continuous* (Lévy's theorem) — are between them all the central limit theorem will need. We proceed in the order the logic forces. First we write the transform down and establish the elementary properties that surround it; among them, as property (3), sits the promised conversion of independence into a product, made concrete and proved on the spot. Then we build the two heavier facts on this elementary base: the inversion formula behind uniqueness, and the continuity theorem behind the limit. Nothing here is cited in place of an argument — both named theorems are proved in full, honouring the self-containedness rule imported from chapter 1.

Definition 3.18 (Characteristic function)**.** The *characteristic function* of an $\mathbb{R}^d$-valued random variable X with law μ is

$$\varphi_X(t) = \varphi_\mu(t) = \mathbb{E}\Big[e^{\,i\langle t,X\rangle}\Big] = \int_{\mathbb{R}^d} e^{\,i\langle t,x\rangle}\,\mathrm{d}\mu(x), \qquad t \in \mathbb{R}^d.$$

A characteristic function is thus nothing more exotic than the expectation of the bounded oscillating observable $x \mapsto e^{i\langle t,x\rangle}$, computed by the change-of-variables bridge (3.1) as an integral of that observable against the law. It is the law viewed in Fourier space: one complex number $\varphi_X(t)$ for each frequency vector t, recording how the unit mass of μ interferes when wound around the unit circle at rate t. Because the integrand has modulus one and is smooth, this encoding is automatically tame, and the next proposition collects the five facts about it that the rest of the development consumes. Read them as a checklist of what the central limit theorem will ask for: that the transform is bounded and normalized, so a limit of transforms cannot escape the unit disc; that it is uniformly continuous, so pointwise limits are well behaved; that it turns independence into multiplication, the algebraic engine of the whole argument; that it determines the law uniquely, so that a limiting transform names a single limit measure; and that its derivatives at the origin read off the moments, so that a finite-variance law is captured near $t = 0$ by its mean and variance alone — the exact datum the central limit theorem expands.

Proposition 3.19 (Elementary properties)**.** *For any $\mathbb{R}^d$-valued X: (1) $\varphi_X(0) = 1$ and $|\varphi_X(t)| \le 1$; (2) φ_X is uniformly continuous on $\mathbb{R}^d$; (3) if $X \perp\!\!\!\perp Y$ then $\varphi_{X+Y} = \varphi_X\varphi_Y$; (4)* (uniqueness) *$\varphi_X = \varphi_Y$ implies $X \overset{d}{=} Y$; (5) if $\mathbb{E}[|X|^p] < \infty$ for an integer p, then $\varphi_X \in C^p$ and $\partial^\alpha\varphi_X(0) = i^{|\alpha|}\mathbb{E}[X^\alpha]$ for multi-indices $|\alpha| \le p$. In particular for scalar $X \in L^2$,*

$$\varphi_X(t) = 1 + it\,\mathbb{E}[X] - \tfrac{1}{2}t^2\,\mathbb{E}\Big[X^2\Big] + o(t^2) \qquad (t \to 0). \tag{3.10}$$

Proof. We take the five in turn; the first three fall straight out of the definition and the unit modulus $\left|e^{i\langle t,x\rangle}\right| = 1$, while the last two carry the analytic weight.

(1) Normalization and the unit bound. At $t = 0$ the integrand is $e^0 = 1$, so $\varphi_X(0) = \int_{\mathbb{R}^d} 1\,\mathrm{d}\mu = 1$. For general t the integrand has modulus $\left|e^{i\langle t,x\rangle}\right| = 1$, so by the triangle inequality for integrals $|\varphi_X(t)| = \left|\int e^{i\langle t,x\rangle}\,\mathrm{d}\mu\right| \le \int \left|e^{i\langle t,x\rangle}\right|\,\mathrm{d}\mu = \int 1\,\mathrm{d}\mu = 1$. The transform thus lives in the closed unit disc and is pinned to the value 1 at the origin — the normalization on which the entire continuity theory below will key.

(2) Uniform continuity. Subtracting two values and factoring out the common phase $e^{i\langle t,x\rangle}$,

$$\varphi_X(t+h) - \varphi_X(t) = \int_{\mathbb{R}^d} e^{i\langle t,x\rangle}\left(e^{i\langle h,x\rangle} - 1\right)\,\mathrm{d}\mu(x),$$

so, since $\left|e^{i\langle t,x\rangle}\right| = 1$, $|\varphi_X(t+h) - \varphi_X(t)| \le \int_{\mathbb{R}^d}\left|e^{i\langle h,x\rangle} - 1\right|\,\mathrm{d}\mu(x) = \mathbb{E}\Big[\left|e^{i\langle h,X\rangle} - 1\right|\Big]$. The decisive feature of this bound is that it does *not* depend on t: it controls the oscillation of φ_X over a step of size h uniformly across all of $\mathbb{R}^d$ at once, which is exactly the difference between uniform and merely pointwise continuity. It remains to see the bound tends to 0 with h. The integrand $\left|e^{i\langle h,x\rangle}-1\right|$ is bounded by the constant 2, an integrable dominating function on the probability space, and for each fixed x it tends to 0 as $h \to 0$ by continuity of the exponential; dominated convergence (lemma 3.4) therefore sends $\mathbb{E}\left[\left|e^{i\langle h,X\rangle}-1\right|\right] \to 0$. Uniform continuity follows.

(3) Factorization under independence — the promised conversion. This is the property the section was built to deliver, and it is a single line once the expectation-factorization form of independence is invoked. If $X \perp\!\!\!\perp Y$ then $e^{i\langle t,X\rangle}$ and $e^{i\langle t,Y\rangle}$ are bounded functions of the two independent variables, so the factorization (3.3) applies to their product:

$$\varphi_{X+Y}(t) = \mathbb{E}\Big[e^{\,i\langle t,(X+Y)\rangle}\Big] = \mathbb{E}\Big[e^{\,i\langle t,X\rangle}e^{\,i\langle t,Y\rangle}\Big] = \mathbb{E}\Big[e^{\,i\langle t,X\rangle}\Big]\,\mathbb{E}\Big[e^{\,i\langle t,Y\rangle}\Big] = \varphi_X(t)\,\varphi_Y(t).$$

Addition of independent variables — which on the level of laws is the convolution $\mathcal{L}(X+Y) = \mathcal{L}(X)*\mathcal{L}(Y)$, an integral entangling the two distributions — has become the pointwise multiplication of two numbers. This is the diagonalization of convolution the section preamble advertised, and it is the entire reason the Fourier route, rather than a direct attack on the N-fold convolution, will deliver the central limit theorem.

(4) Uniqueness. This is the substantive analytic claim, the assertion that the transform forgets nothing: $\varphi_X = \varphi_Y$ forces $X \overset{d}{=} Y$. Its proof is the content of the Lévy inversion formula, which reconstructs μ from φ by an explicit integral; we establish it in full as lemma 3.20 below and borrow the conclusion here. The mechanism, previewed: inversion recovers the μ-measure of every interval whose endpoints are atom-free, and those intervals form an intersection-stable class generating the Borel σ-algebra, so two laws with the same transform agree on a generating π-system and hence everywhere.

(5) Smoothness and moments. Suppose $\mathbb{E}[|X|^p] < \infty$ for an integer $p \ge 1$. We claim $\varphi_X \in C^p$ with $\partial^\alpha\varphi_X(0) = i^{|\alpha|}\mathbb{E}[X^\alpha]$ for every multi-index $|\alpha| \le p$, and the whole content is the legitimacy of *differentiating under the integral sign.* Differentiating the integrand $e^{i\langle t,x\rangle}$ in t_j brings down a factor ix_j, and after α such differentiations

$$\partial_t^\alpha\, e^{\,i\langle t,x\rangle} = i^{|\alpha|}\,x^\alpha\,e^{\,i\langle t,x\rangle}, \qquad x^\alpha := \prod_j x_j^{\alpha_j}.$$

To pull ∂^α inside the integral we need a single integrable function dominating this derivative for all t at once, and the unit modulus supplies one: since $\left|e^{i\langle t,x\rangle}\right| = 1$,

$$\left|\partial_t^\alpha e^{\,i\langle t,x\rangle}\right| = |x^\alpha| \le |x|^{|\alpha|} \le 1+|x|^{\,p} \qquad (|\alpha| \le p),$$

and $1+|X|^{\,p}$ is integrable by the hypothesis $\mathbb{E}[|X|^p] < \infty$. The differentiation-under-the-integral theorem of chapter 1 — itself dominated convergence applied to the difference quotients $h^{-1}(e^{i\langle(t+he_j),x\rangle} - e^{i\langle t,x\rangle})$, which are dominated by $|x_j| \le 1+|x|^p$ uniformly in small h by the mean value theorem — therefore licenses exchanging each ∂_{t_j} with $\int \mathrm{d}\mu$. The resulting integrand $i^{|\alpha|}x^\alpha e^{i\langle t,x\rangle}$ is continuous in t and dominated as above, so $\partial^\alpha\varphi_X$ exists and is continuous: $\varphi_X \in C^p$. Evaluating at $t=0$ kills the exponential and leaves $\partial^\alpha\varphi_X(0) = i^{|\alpha|}\int x^\alpha\,\mathrm{d}\mu = i^{|\alpha|}\mathbb{E}[X^\alpha]$, the announced formula — the derivatives of the transform at the origin *are* the moments, up to powers of i. Now specialize to a scalar $X \in L^2$, where $p = 2$: then $\varphi_X \in C^2$ with $\varphi_X(0) = 1$, $\varphi'_X(0) = i\mathbb{E}[X]$, and $\varphi''_X(0) = i^2\mathbb{E}[X^2] = -\mathbb{E}[X^2]$. Taylor's theorem with the second-order Peano remainder, valid because φ_X is twice continuously differentiable at 0, then gives

$$\varphi_X(t) = \varphi_X(0) + t\,\varphi'_X(0) + \tfrac{1}{2}t^2\,\varphi''_X(0) + o(t^2) = 1 + it\,\mathbb{E}[X] - \tfrac{1}{2}t^2\,\mathbb{E}\Big[X^2\Big] + o(t^2),$$

which is (3.10). This small expansion is the single fact the central limit theorem will plug in: near the origin of Fourier space a finite-variance law is determined to second order by its mean and variance alone, and everything beyond is the $o(t^2)$ that the $N^{-1/2}$ rescaling will wash out. □

The uniqueness asserted in (4) is consumed downstream more than once — it identifies the Gaussian limit in the central limit theorem and it is the device that *closes* Lévy's continuity theorem by pinning all subsequential limits to one measure — so, the self-containedness rule of chapter 1 forbidding any bare appeal to "it is known," we prove the inversion formula it rests on rather than cite it. The proof needs exactly one analytic input, and we isolate it now and take it explicitly as a *prerequisite* of elementary analysis: the *Dirichlet integral*, together with the uniform boundedness of its truncations,

$$\mathsf{S}(\theta) := \int_0^\infty \frac{\sin(\theta t)}{t}\,\mathrm{d}t = \frac{\pi}{2}\operatorname{sgn}(\theta), \qquad \sup_{R>0,\ \theta\in\mathbb{R}} \Big|\int_0^R \frac{\sin(\theta t)}{t}\,\mathrm{d}t\Big| =: C_0 < \infty. \tag{3.11}$$

Both halves are standard facts of undergraduate analysis that we do not reprove here: the convergence of the improper integral is conditional (the integrand is not absolutely integrable), its value is the classical $\pm\pi/2$, and the truncated integrals $\int_0^R \frac{\sin\theta t}{t}\,\mathrm{d}t$ stay bounded by a single constant C_0 uniformly in the cutoff R and the parameter θ — the overshoot familiar from the Gibbs phenomenon. These two facts are all we borrow; everything else in the inversion proof is built here.

The shape of the argument is worth stating before the computation, because the formula (3.12) looks more forbidding than it is. We want to recover $\mu((a, b))$ from φ. We substitute the definition of φ into the right-hand side, swap the order of integration by Fubini so that the t-integral is done *first*, and discover that the inner t-integral is a smooth function $\Psi_R(x)$ that — thanks to the Dirichlet integral — converges as $R \to \infty$ to the indicator of the interval (a, b) (with a half-weight exactly at the two endpoints a, b). Integrating that limiting indicator against μ returns $\mu((a, b))$, provided the half-weighted endpoints carry no mass — which is precisely the atom-free hypothesis. The entire proof is the careful execution of those four steps.

Lemma 3.20 (Lévy inversion formula)**.** *Let $\mu \in \mathcal{P}(\mathbb{R})$ with characteristic function φ. For any real $a < b$ that are atoms-free, i.e. $\mu(\{a\}) = \mu(\{b\}) = 0$,*

$$\mu((a, b)) = \lim_{R\to\infty} \frac{1}{2\pi} \int_{-R}^{R} \frac{e^{-ita} - e^{-itb}}{it}\,\varphi(t)\,\mathrm{d}t. \tag{3.12}$$

Consequently a probability measure on $\mathbb{R}$ is determined by its characteristic function, and the same holds on $\mathbb{R}^d$.

Proof. Step 1: substitute and prepare for the swap. Fix the cutoff R and call the truncated integral I_R. Writing $\varphi(t) = \int_{\mathbb{R}} e^{itx}\,\mathrm{d}\mu(x)$ inside it and combining the two exponentials,

$$I_R := \frac{1}{2\pi} \int_{-R}^{R} \frac{e^{-ita} - e^{-itb}}{it}\,\varphi(t)\,\mathrm{d}t = \frac{1}{2\pi} \int_{-R}^{R}\int_{\mathbb{R}} \frac{e^{it(x-a)} - e^{it(x-b)}}{it}\,\mathrm{d}\mu(x)\,\mathrm{d}t.$$

Before swapping the two integrals we must check the joint integrand is absolutely integrable over the product domain, because the kernel $1/(it)$ is singular at $t=0$ and a careless swap is exactly the kind of step the Fubini hypotheses guard against. The singularity is illusory: the numerator vanishes at $t=0$ at the same rate, and in fact writing the difference of exponentials as an integral,

$$\frac{e^{it(x-a)}-e^{it(x-b)}}{it}=\int_a^b e^{\,it(x-s)}\ \mathrm{d}s,$$

exhibits the whole quotient as an average of unit-modulus terms, so its absolute value is at most $b-a$ for *every* t, including $t=0$. Hence the joint integrand is bounded by $b-a$ on the product $[-R,R]\times\mathbb{R}$, and since μ is a probability measure and $[-R,R]$ has finite length, that product carries finite measure $2R$ and the integrand is absolutely integrable on it. Fubini–Tonelli (chapter 1) therefore applies, and we may do the t-integral first:

$$I_R=\int_{\mathbb{R}}\Psi_R(x)\ \mathrm{d}\mu(x),\qquad \Psi_R(x)=\frac{1}{2\pi}\int_{-R}^{R}\frac{e^{it(x-a)}-e^{it(x-b)}}{it}\ \mathrm{d}t.$$

Step 2: compute the inner kernel Ψ_R. This is where the Dirichlet integral enters. Expand each exponential as $e^{i\theta}=\cos\theta+i\sin\theta$ and divide by $it=\frac{-i}{t}\cdot(-1)\cdots$ — concretely, using $\frac{1}{it}=\frac{-i}{t}$, the integrand becomes

$$\frac{e^{it(x-a)}-e^{it(x-b)}}{it}=\underbrace{\frac{\sin t(x-a)-\sin t(x-b)}{t}}_{\text{even in }t}-i\,\underbrace{\frac{\cos t(x-a)-\cos t(x-b)}{t}}_{\text{odd in }t}.$$

The second (imaginary) piece is an odd function of t, so its integral over the symmetric interval $[-R,R]$ vanishes; the first (real) piece is even, so its integral is twice the integral over $[0,R]$. With the notation $D_R(\theta):=\int_0^R\frac{\sin(\theta t)}{t}\ \mathrm{d}t$ — the truncated Dirichlet integral of (3.11) — this gives

$$\Psi_R(x)=\frac{1}{2\pi}\cdot 2\int_0^R\frac{\sin t(x-a)-\sin t(x-b)}{t}\ \mathrm{d}t=\frac{1}{\pi}\Big(D_R(x-a)-D_R(x-b)\Big).$$

So Ψ_R is built entirely out of two copies of the one elementary object we took as a prerequisite.

Step 3: pass to the limit $R\to\infty$. The uniform bound in (3.11) gives $|D_R(\theta)|\le C_0$ for all R,θ, hence $|\Psi_R(x)|\le 2C_0/\pi$ uniformly in R and x — this is the constant dominating function we will need. Pointwise, $D_R(\theta)\to\frac{\pi}{2}\operatorname{sgn}(\theta)$ as $R\to\infty$ by the Dirichlet integral, so

$$\Psi_R(x)\to\Psi(x):=\tfrac12\big(\operatorname{sgn}(x-a)-\operatorname{sgn}(x-b)\big)=\begin{cases}1, & a<x<b,\\ \tfrac12, & x\in\{a,b\},\\ 0, & x<a\text{ or }x>b.\end{cases}$$

This limiting Ψ is the indicator of the open interval (a,b) everywhere except at the two endpoints, where the sign function jumps and the average lands on the midpoint value $\frac12$ — the source of the half-weights that the atom-free hypothesis is about to discard. We now exchange limit and integral. The dominating function $2C_0/\pi$ is constant, hence μ-integrable because μ is finite, so dominated convergence (lemma 3.4) gives

$$I_R=\int_{\mathbb{R}}\Psi_R\ \mathrm{d}\mu\ \longrightarrow\ \int_{\mathbb{R}}\Psi\ \mathrm{d}\mu=\mu\big((a,b)\big)+\tfrac12\mu(\{a\})+\tfrac12\mu(\{b\}),$$

the last equality reading off the three values of Ψ on the open interval, the two endpoints, and the exterior. *Here* the hypothesis is spent: $\mu(\{a\}) = \mu(\{b\}) = 0$ kills the two half-weights, leaving exactly $\mu((a, b))$. This is (3.12), and we see why atom-free endpoints are needed — at an atom the half-weight would survive and the formula would overcount.

Step 4: uniqueness from inversion. The formula expresses $\mu((a, b))$ as an explicit functional of φ alone, for every interval with atom-free endpoints. Two laws sharing a characteristic function therefore agree on every such interval. That this suffices to force the laws equal is the standard π-system argument. The atoms of μ are at most countable — distinct atoms carry disjoint chunks of positive mass and a finite measure can host only countably many of those — so the atom-free points are dense, hence the intervals (a, b) with atom-free endpoints form an intersection-stable family (the intersection of two such intervals is again one) generating the Borel σ-algebra $\mathcal{B}(\mathbb{R})$. Two probability measures agreeing on a generating π-system agree on the whole σ-algebra by the uniqueness lemma for measures (corollary 1.10), so φ determines μ on $\mathcal{B}(\mathbb{R})$. In $\mathbb{R}^d$ nothing changes but the bookkeeping: the same computation with the product kernel $\prod_{j=1}^d (e^{-it_j a_j} - e^{-it_j b_j})/(it_j)$ recovers μ on every rectangle $\prod_j (a_j, b_j)$ with atom-free faces, and rectangles are again a generating π-system, so uniqueness holds in every dimension. This proves property (4) of proposition 3.19. $\square$

Inversion delivered the *faithfulness* of the transform; the second pillar of the Fourier route is its *continuity*, and that is Lévy's theorem. It is the practical reason the Fourier route proves limit theorems at all: it converts a question about weak convergence of measures, which is awkward to verify directly, into a question about pointwise convergence of their transforms, which the central limit theorem will settle by a one-line Taylor expansion. The theorem has two directions. Direction (a) is the easy half — weak convergence implies convergence of transforms — and is little more than the observation that each $e^{i\langle t,x\rangle}$ is a bounded continuous test function. Direction (b) is the substantive half and the one the limit theorems consume: pointwise convergence of the transforms, *plus* continuity of the limit at the origin, implies weak convergence. The role of that innocuous-looking proviso is the throughline point of this entire section, so we state it before proving it. Pointwise convergence of characteristic functions, on its own, does *not* force a weak limit; it does so only when the candidate limit is continuous at $t = 0$. And continuity at the origin is not a technical decoration — it is exactly a *tightness* condition wearing a Fourier disguise. The proof of (b) makes this literal: it extracts from the continuity of ψ at 0 a uniform tail bound on the measures μ_n, which is tightness, and only tightness then licenses Prokhorov to produce a limit. Without the proviso the mass can leak to infinity and the "limit" transform fails to be the transform of any probability measure. This is the precise sense, promised at the top of the chapter, in which tightness is indispensable to the Fourier route.

Theorem 3.21 (Lévy continuity theorem)**.** *Let $\mu_n \in \mathcal{P}(\mathbb{R}^d)$ with characteristic functions φ_n.*

(a) *If $\mu_n \Rightarrow \mu$ then $\varphi_n(t) \to \varphi_\mu(t)$ for every t, uniformly on compact sets.*

(b) *If $\varphi_n(t) \to \psi(t)$ pointwise for some function ψ that is continuous at $t = 0$, then $\psi = \varphi_\mu$ is the characteristic function of a probability measure $\mu \in \mathcal{P}(\mathbb{R}^d)$ and $\mu_n \Rightarrow \mu$.*

Proof. The argument is complete given the in-book Prokhorov theorem (theorem 3.16) and the

Fourier uniqueness (lemma 3.20); the external citations at the end are attribution only, not a substitute for any step.

(a) Weak convergence implies convergence of transforms. For each fixed t the map $x \mapsto e^{i\langle t,x\rangle}$ has bounded real and imaginary parts $\cos\langle t,x\rangle$ and $\sin\langle t,x\rangle$, both continuous, so it belongs to $C_b(\mathbb{R}^d)$ (read componentwise). Weak convergence is by definition convergence of the integral pairing against every such test function, so $\varphi_n(t) = \mu_n(e^{i\langle t,\cdot\rangle}) \to \mu(e^{i\langle t,\cdot\rangle}) = \varphi_\mu(t)$ for each t. That is the pointwise claim. For uniformity on a compact set of frequencies, we upgrade pointwise to uniform via equicontinuity. A weakly convergent sequence is in particular relatively compact, so the family $\{\mu_n\} \cup \{\mu\}$ is tight by the converse half of Prokhorov (theorem 3.16(b)): given $\varepsilon > 0$ there is a radius R with $\sup_n \mu_n(\{|x| > R\}) \le \varepsilon$. Splitting the bound $\left|e^{i\langle (t-s),x\rangle} - 1\right|$ according to whether $|x| \le R$ or not — on the ball it is at most $|\langle (t-s), x\rangle| \le |t-s|\ R$ by the elementary estimate $\left|e^{i\theta} - 1\right| \le |\theta|$, off the ball it is at most 2 — gives, for all s, t,

$$|\varphi_n(t) - \varphi_n(s)| \le \int_{\mathbb{R}^d} \left|e^{i\langle (t-s),x\rangle} - 1\right| \,\mathrm{d}\mu_n(x) \le |t-s|\ R + 2\varepsilon.$$

The right-hand side is independent of n and small when $|t-s|$ and ε are small, so $\{\varphi_n\}$ is equicontinuous; and a uniformly equicontinuous sequence that converges pointwise converges uniformly on compact sets. This gives (a).

(b) Convergence of transforms plus continuity at 0 *implies weak convergence.* As advertised, the crux is that continuity of ψ at the origin forces tightness of (μ_n), after which Prokhorov and uniqueness do the rest. The quantitative bridge from the transform to a tail bound is the elementary inequality, valid for any $\nu \in \mathcal{P}(\mathbb{R})$ and any $u > 0$,

$$\nu\Big(\Big\{\ |x| > \tfrac{2}{u}\Big\}\Big) \le \frac{1}{u}\int_{-u}^{u} \left(1 - \varphi_\nu(t)\right)\,\mathrm{d}t, \tag{3.13}$$

which bounds the mass ν puts far out by how far the transform departs from 1 near the origin. We derive it by computing the right-hand side. Fix $u > 0$ and start from the inner t-average of $1 - e^{itx}$ at a single point x:

$$\frac{1}{u}\int_{-u}^{u} \left(1 - e^{itx}\right)\,\mathrm{d}t = \frac{1}{u}\Big(2u - \int_{-u}^{u} e^{itx}\,\mathrm{d}t\Big) = \frac{1}{u}\Big(2u - \frac{e^{iux} - e^{-iux}}{ix}\Big) = 2\Big(1 - \frac{\sin ux}{ux}\Big),$$

using $\int_{-u}^{u} e^{itx}\,\mathrm{d}t = \frac{2\sin ux}{x}$ and simplifying. Now compare this with the indicator of the far tail. Writing $v = ux$, the claim is

$$2\Big(1 - \frac{\sin v}{v}\Big) \ \ge\ \mathbf{1}\{|v| > 2\} \qquad \Longleftrightarrow \qquad 2\Big(1 - \frac{\sin ux}{ux}\Big) \ge \mathbf{1}\Big\{\ |x| > \tfrac{2}{u}\Big\}.$$

This holds because $\frac{\sin v}{v} \le 1$ always, so the left side is ≥ 0 and the inequality is automatic where the indicator is 0; and where the indicator is 1, i.e. $|v| > 2$, we have $\left|\frac{\sin v}{v}\right| \le \frac{1}{|v|} < \frac{1}{2}$, hence $1 - \frac{\sin v}{v} \ge \frac{1}{2}$ and the left side is ≥ 1. So the elementary fact "$1 - \frac{\sin v}{v} \ge \frac{1}{2}$ for $|v| > 2$" is exactly what makes the inner average dominate the tail indicator pointwise in x. Integrating both sides against ν and exchanging the $\mathrm{d}t$- and $\mathrm{d}\nu$-integrals — legitimate by Fubini, since the integrand $1 - e^{itx}$ is bounded by 2 on the finite-measure product $[-u, u] \times \mathbb{R}$ — turns the pointwise inequality into

$$\frac{1}{u}\int_{-u}^{u} \left(1 - \varphi_\nu(t)\right)\,\mathrm{d}t = \int_{\mathbb{R}} 2\Big(1 - \frac{\sin ux}{ux}\Big)\,\mathrm{d}\nu(x) \ \ge\ \int_{\mathbb{R}} \mathbf{1}\Big\{\ |x| > \tfrac{2}{u}\Big\}\,\mathrm{d}\nu(x) = \nu\Big(\Big\{\ |x| > \tfrac{2}{u}\Big\}\Big),$$

which is (3.13); the left equality used $\frac{1}{u}\int_{-u}^{u}(1-\varphi_\nu)\,\mathrm{d}t = \int \frac{1}{u}\int_{-u}^{u}(1-e^{itx})\,\mathrm{d}t\,\mathrm{d}\nu$ and the single-point computation above.

With the inequality in hand the tightness is immediate. Apply (3.13) to each μ_n and let $n\to\infty$ on the right: the integrand $1-\varphi_n$ is bounded by 2 and converges pointwise to $1-\psi$, so bounded convergence on the finite interval $[-u,u]$ gives

$$\limsup_{n\to\infty}\mu_n\Big(\Big\{\,|x|>\tfrac{2}{u}\Big\}\Big)\le\frac{1}{u}\int_{-u}^{u}\big(1-\psi(t)\big)\,\mathrm{d}t.$$

Now the proviso pays off. Since $\psi(0)=1$ (as the pointwise limit of the φ_n, each equal to 1 at 0) and ψ is continuous at 0, the integrand $1-\psi(t)$ is small for t near 0; concretely, given $\varepsilon>0$ choose u small enough that $|1-\psi(t)|<\varepsilon/2$ on $[-u,u]$, whence the right-hand side is at most $\frac{1}{u}\cdot 2u\cdot\frac{\varepsilon}{2}=\varepsilon$. Thus $\limsup_n\mu_n(\{|x|>2/u\})\le\varepsilon$, and enlarging u slightly absorbs the finitely many early terms, so $\sup_n\mu_n(\{|x|>2/u\})\le\varepsilon$ for this u. As ε was arbitrary, (μ_n) is tight — and one sees plainly that had ψ been discontinuous at 0 this bound would have failed and the mass could have escaped to infinity, which is the throughline point made concrete.

The endgame is Prokhorov plus uniqueness. By the forward half of Prokhorov (theorem 3.16(a)) tightness makes (μ_n) relatively compact, so every subsequence has a further subsequence converging weakly to some probability measure. Let μ be any such subsequential limit. By part (a) its characteristic function is the pointwise limit of the φ_n along that subsequence, namely ψ; so *every* subsequential limit has the same characteristic function ψ. By the inversion-based uniqueness (lemma 3.20) a characteristic function determines its law, so all these subsequential limits are one and the same measure μ, and in particular $\psi=\varphi_\mu$ is genuinely the transform of a probability measure. A sequence in a metric space all of whose subsequential limits coincide with a single point converges to that point, so $\mu_n\Rightarrow\mu$. The multivariate case is identical: run (3.13) coordinatewise in each t_j to get tightness in $\mathbb{R}^d$, then repeat the Prokhorov–uniqueness endgame verbatim. See [62, Thm. 3.3.6], [84, Thm. 5.3] for the same result. $\square$

With inversion and continuity both proved, the two analytic facts the Fourier route demanded are in hand: inversion makes the transform a faithful encoding of the law, and Lévy's theorem makes it a continuous one, with continuity-at-the-origin standing in for tightness. Everything is now staged for the payoff. The central limit theorem becomes, from here, a short computation, and it is worth previewing its three moves so the next subsection reads as the harvest it is. First, factor the characteristic function of a centered and $N^{-1/2}$-rescaled sum into a product of N identical factors, using the independence-into-multiplication property (3). Second, expand one such factor near the origin by the Taylor formula (3.10), where — the summands being centered with variance σ^2 — only the term $-\frac{1}{2}(\sigma^2/N)t^2$ survives to leading order. Third, pass the N-fold product to its exponential limit through the elementary fact that $(1+z_N/N)^N\to e^z$ whenever $z_N\to z$, proved inline where it is used. The limit is $e^{-\sigma^2t^2/2}$, which is continuous at $t=0$, so Lévy's continuity theorem in the form (b) just proved identifies it without further work as the characteristic function of the Gaussian $\mathcal{N}(0,\sigma^2)$ and upgrades the convergence of transforms into the weak convergence of laws. We turn to that computation now.

3.4.2 The central limit theorem

Everything is now staged, and this subsection is the harvest. The two analytic facts the Fourier route demanded are in hand: inversion (lemma 3.20) makes the characteristic function a faithful encoding of a law, and Lévy's continuity theorem (theorem 3.21) makes that encoding *continuous*, so that a convergent sequence of transforms whose limit is continuous at the origin names a unique limiting measure and forces weak convergence of the laws. With those two facts the central limit theorem ceases to be an analytic struggle and becomes a short computation, and the reason is exactly the diagonalization of convolution recorded in proposition 3.19(3): the law of a sum of independent variables is a convolution, hopeless to track directly, but its transform is a *product*, and a product of N nearly-equal factors is precisely the kind of object whose $N \to \infty$ behaviour an exponential limit controls. The proof below is nothing more than carrying out that idea — factor, expand, exponentiate, identify — and its payoff is the single quantitative fact on which the entire mean field justification rests: the fluctuation of an average of N independent agents is of size $N^{-1/2}$ and, after rescaling by $\sqrt{N}$, is *Gaussian*, regardless of the microscopic law the agents are drawn from.

Theorem 3.22 (Central limit theorem, i.i.d. case)**.** *Let $(X_i)_{i\geq 1}$ be i.i.d. real random variables with $\mathbb{E}[X_1] = m_\star$ and $\mathrm{Var}(X_1) = \sigma^2 \in (0,\infty)$. Then*

$$\frac{1}{\sqrt{N}} \sum_{i=1}^{N} (X_i - m_\star) \;\Rightarrow\; \mathcal{N}(0,\sigma^2) \qquad (N \to \infty),$$

where $\mathcal{N}(0,\sigma^2)$ is the centred Gaussian law with variance σ^2, characteristic function $t \mapsto e^{-\sigma^2 t^2/2}$.

Before the proof we isolate its one genuinely analytic ingredient as a standalone lemma, because the proof of the theorem compresses it into a parenthetical and it deserves to be seen cleanly. It is the complex, moving-base generalization of the freshman identity $(1 + z/N)^N \to e^z$: we need it not for a fixed base $1 + z/N$ but for a base $1 + z_N/N$ whose numerator z_N itself drifts (here because the Taylor remainder in the transform depends on N), and whose value is complex (because a characteristic function is). Both generalizations are free, and the principal-branch logarithm is what makes them so.

Lemma 3.23 (Exponential limit of a perturbed power)**.** *Let $(z_N)_{N\geq 1}$ be a sequence of complex numbers with $z_N \to z \in \mathbb{C}$. Then*

$$\Bigl(1 + \frac{z_N}{N}\Bigr)^N \;\longrightarrow\; e^z \qquad (N \to \infty).$$

Proof. A convergent sequence is bounded, so $M := \sup_N |z_N| < \infty$, and hence $|z_N/N| \leq M/N \leq \frac{1}{2}$ for all $N \geq 2M$. From here on take N that large; then the base $1 + z_N/N$ lies within distance $\frac{1}{2}$ of 1, in particular in the open right half-plane, safely off the negative real axis where the principal logarithm log has its branch cut. On that region the principal branch is analytic and satisfies $(1 + w)^N = \exp\left(N \log(1 + w)\right)$ for the genuine N-th power, with the power series $\log(1 + w) =$

$\sum_{k\geq 1}(-1)^{k-1}w^k/k$. Subtracting its linear term and estimating the tail,

$$|\log(1+w)-w| = \Big|\sum_{k\geq 2}\frac{(-1)^{k-1}w^k}{k}\Big| \leq \sum_{k\geq 2}\frac{|w|^k}{k} \leq \frac{|w|^2}{2}\sum_{k\geq 0}|w|^k = \frac{|w|^2}{2(1-|w|)} \leq |w|^2 \qquad (|w|\leq \tfrac{1}{2}),$$

the last step because $1-|w|\geq \frac{1}{2}$. Apply this with $w = z_N/N$ and multiply by N:

$$N\log\Big(1+\frac{z_N}{N}\Big) = z_N + N\,r_N, \qquad |r_N| \leq \Big|\frac{z_N}{N}\Big|^2, \quad \text{so} \quad |N\,r_N| \leq \frac{|z_N|^2}{N} \leq \frac{M^2}{N} \xrightarrow[N\to\infty]{} 0.$$

Therefore $N\log(1+z_N/N) = z_N + Nr_N \to z+0 = z$, and since the exponential is continuous, $(1+z_N/N)^N = \exp\left(N\log(1+z_N/N)\right) \to e^z$. The principal branch was essential exactly once: it gave a single-valued logarithm with the quadratic remainder bound, so that the error Nr_N accumulated over N factors stays of size $O(1/N)$ rather than threatening to blow up. □

With the exponential limit dispatched, the central limit theorem is three short moves: center, factor, expand-and-exponentiate.

Proof of theorem 3.22. Centering. The theorem concerns the sum of the deviations $X_i - m_\star$, so set $Y_i = X_i - m_\star$ at the outset. Subtracting the mean makes the Y_i i.i.d. with $\mathbb{E}[Y_i] = 0$ and $\mathbb{E}[Y_i^2] = \mathrm{Var}(X_1) = \sigma^2$, and this centering is not cosmetic: it is what removes the first-order term from the Taylor expansion below, leaving the variance as the leading datum. Write $\varphi(t) = \varphi_{Y_1}(t)$ for the common characteristic function of the centered variables and $S_N = N^{-1/2}\sum_{i\leq N} Y_i$ for the rescaled sum, so that the claim is $\varphi_{S_N}(t) \to e^{-\sigma^2t^2/2}$ followed by an appeal to continuity.

The product form. Here independence pays off. The summands $Y_i/\sqrt{N}$ are independent, so the transform of their sum factorizes by proposition 3.19(3); and because the Y_i are identically distributed, every factor is the *same* function φ evaluated at the common rescaled frequency $t/\sqrt{N}$. Concretely, $\varphi_{Y_i/\sqrt{N}}(t) = \mathbb{E}\Big[e^{i(t/\sqrt{N})Y_i}\Big] = \varphi(t/\sqrt{N})$ for each i, and multiplying the N identical factors,

$$\varphi_{S_N}(t) = \mathbb{E}\Big[\exp\Big(it\,\tfrac{1}{\sqrt{N}}\textstyle\sum_{i\leq N} Y_i\Big)\Big] = \prod_{i=1}^{N}\mathbb{E}\Big[e^{i(t/\sqrt{N})Y_i}\Big] = \Big(\varphi(t/\sqrt{N})\Big)^N.$$

This is the whole reason for working with transforms: the intractable N-fold convolution that is the law of S_N has become the N-th power of a single number, an object the exponential limit was built to handle.

The second-order expansion. Fix t and let $N\to\infty$, so the argument $t/\sqrt{N}\to 0$ slides into the origin, precisely where (3.10) controls φ. Since $Y_1 \in L^2$ with mean 0 and second moment σ^2, that expansion with its first-order term gone reads, at the point $t/\sqrt{N}$,

$$\varphi(t/\sqrt{N}) = 1 + i\,\frac{t}{\sqrt{N}}\underbrace{\mathbb{E}[Y_1]}_{=0} - \frac{1}{2}\Big(\frac{t}{\sqrt{N}}\Big)^2\underbrace{\mathbb{E}\big[Y_1^2\big]}_{=\sigma^2} + o\Big(\frac{t^2}{N}\Big) = 1 - \frac{\sigma^2t^2}{2N} + o\Big(\frac{1}{N}\Big),$$

where with t fixed the Peano remainder $o((t/\sqrt{N})^2)$ is $o(1/N)$. The centering has done its work: the $i(t/\sqrt{N})\mathbb{E}[Y_1]$ term, which would have been of order $N^{-1/2}$ and dominated everything, has vanished, and what governs the factor to leading order is the variance.

Exponentiation. Cast the factor in the shape the lemma wants by writing $\varphi(t/\sqrt{N}) = 1 + z_N/N$ with

$$z_N \;=\; N\Big(\varphi(t/\sqrt{N}) - 1\Big) \;=\; -\tfrac{1}{2}\sigma^2 t^2 + o(1) \;\xrightarrow[N\to\infty]{}\; z := -\tfrac{1}{2}\sigma^2 t^2.$$

Then $\varphi_{S_N}(t) = (1 + z_N/N)^N$, and lemma 3.23 applies verbatim, giving

$$\varphi_{S_N}(t) \;\longrightarrow\; e^z = e^{-\sigma^2 t^2/2} \qquad \text{for every } t \in \mathbb{R}.$$

Identification of the limit. The limit function $t \mapsto e^{-\sigma^2 t^2/2}$ is continuous at $t = 0$ — indeed everywhere — so it meets the one hypothesis Lévy's continuity theorem in the form theorem 3.21(b) imposes. That theorem therefore certifies, with no further computation, two things at once: that the limit *is* the characteristic function of an honest probability measure, and that this measure is the weak limit of the laws of S_N. It remains only to name it. That $e^{-\sigma^2 t^2/2}$ is the characteristic function of $\mathcal{N}(0, \sigma^2)$ is the completion of a single Gaussian integral — a prerequisite computation: with the density $(2\pi\sigma^2)^{-1/2} e^{-x^2/2\sigma^2}$ one completes the square in $\int e^{itx - x^2/2\sigma^2}\,\mathrm{d}x$ and reads off $e^{-\sigma^2 t^2/2}$ — and uniqueness (proposition 3.19(4)) leaves no other candidate carrying that transform. Hence $S_N \Rightarrow \mathcal{N}(0, \sigma^2)$, which is the theorem. □

It is worth pausing on *why* the variance, and nothing finer, survives, because that is the message the central limit theorem actually carries and the one the mean field theory exploits. Suppose the Y_i had a finite third moment $\mathbb{E}[Y_1^3] = \kappa$. Carrying the Taylor expansion (proposition 3.19(5)) one order further, the single factor would read

$$\varphi(t/\sqrt{N}) = 1 - \frac{\sigma^2 t^2}{2N} \underbrace{- \frac{i\kappa\, t^3}{6\, N^{3/2}}}_{\text{third moment}} + o\Big(\frac{1}{N}\Big),$$

and the third-moment term enters at order $N^{-3/2}$. When the N factors are multiplied — equivalently, when one passes to $z_N = N(\varphi(t/\sqrt{N}) - 1)$ — that term contributes $N \cdot O(N^{-3/2}) = O(N^{-1/2})$, which vanishes in the limit; and the same accounting kills every moment beyond the second, since the p-th moment sits at order $N^{-p/2}$ and survives multiplication by N only when $p \le 2$. The $\sqrt{N}$ rescaling is calibrated exactly so that the second moment lands at the critical order N^{-1}, neither blowing up (as the uncentered mean would) nor washing out (as every higher moment does). This is the content of the word *universality*: the limit law depends on the microscopic distribution of the Y_i *only* through its variance σ^2, and two ensembles with wildly different microscopic laws but the same variance produce the *same* Gaussian fluctuation. The Gaussian is not one distribution among many that happens to arise; it is the unique fixed shape that the rescaling selects, the only thing that can survive the addition of many small independent contributions.

This bare i.i.d. statement is the seed, but it is not yet phrased in the language the mean field theory speaks. The variance computation of section 3.1 already told us that the empirical average of N independent agents concentrates on its mean at rate $N^{-1/2}$; the theorem just proved upgrades that second-moment fact into a full distributional law, naming the Gaussian profile of the residual. The next subsection cashes this in. It takes a scalar observable of a mean field ensemble — a test function averaged over N independent agents drawn from the population law m — and reads theorem 3.22 as the precise statement that the observable equals its mean field value plus a fluctuation of size

$N^{-1/2}$ and Gaussian shape. That is the non-interacting skeleton of propagation of chaos: the clean picture in which the agents are genuinely independent, against which chapter 7 and chapter 13 will later measure the interacting refinement, where the coupling makes them only *asymptotically* independent and the fluctuation analysis becomes correspondingly delicate.

3.4.3 Fluctuations of a mean field observable

We can now state precisely what "the mean field is deterministic and fluctuations are $O(N^{-1/2})$" means, in the cleanest setting: an ensemble of N independent agents and a single scalar observable. This is the non-interacting skeleton of propagation of chaos; the interacting refinement, where the agents are coupled and only *asymptotically* independent, is the subject of chapter 7 and chapter 13.

The almost-sure side of the statement is a strong law of large numbers. The full Kolmogorov strong law holds under only $\mathbb{E}[|X_1|] < \infty$, but its proof (truncation, Kolmogorov's maximal inequality, Kronecker's lemma) is heavier than this book needs: every application here — to bounded test functions and to the Gaussian thread — has random variables with all moments finite. We therefore prove the version that the Borel–Cantelli lemma of this chapter delivers in a few lines, under a finite fourth moment, and use *it* as the in-book strong law.

Proposition 3.24 (Strong law under a fourth-moment bound)**.** *Let $(X_i)_{i\geq 1}$ be i.i.d. real random variables with $\mathbb{E}[X_1^4] < \infty$ and mean $m_\star = \mathbb{E}[X_1]$. Then $\overline{X}_N = \frac{1}{N}\sum_{i\leq N} X_i \to m_\star$ almost surely.*

Proof. Replacing X_i by $X_i - m_\star$ (which preserves independence and a finite fourth moment), we may assume $m_\star = 0$. Put $S_N = \sum_{i\leq N} X_i$. Expanding,

$$\mathbb{E}\left[S_N^4\right] = \sum_{i,j,k,l\leq N} \mathbb{E}[X_i X_j X_k X_l]\,.$$

By independence and $\mathbb{E}[X_i] = 0$, a term vanishes unless every index that appears does so at least twice; the surviving terms are the N terms $\mathbb{E}[X_i^4]$ and, for each ordered pair $i \neq j$, the term $\mathbb{E}[X_i^2]\,\mathbb{E}\left[X_j^2\right]$ counted with multiplicity 3 (the number of ways to split four ordered positions into two like-indexed pairs), i.e. $3N(N-1)$ such terms in all. Hence, using $\mathbb{E}[X_1^2]^2 \leq \mathbb{E}[X_1^4]$ (Cauchy–Schwarz),

$$\mathbb{E}\left[S_N^4\right] = N\,\mathbb{E}\left[X_1^4\right] + 3N(N-1)\mathbb{E}\left[X_1^2\right]^2 \leq C\,N^2, \qquad C := \mathbb{E}\left[X_1^4\right] + 3\mathbb{E}\left[X_1^4\right] = 4\mathbb{E}\left[X_1^4\right].$$

By Markov's inequality, for each $\varepsilon > 0$,

$$\mathbb{P}(\left|\overline{X}_N\right| > \varepsilon) = \mathbb{P}(S_N^4 > N^4\varepsilon^4) \leq \frac{\mathbb{E}[S_N^4]}{N^4\varepsilon^4} \leq \frac{C}{N^2\varepsilon^4},$$

which is summable in N. The first Borel–Cantelli lemma (theorem 3.27(i)) gives $\mathbb{P}(\left|\overline{X}_N\right| > \varepsilon \text{ i.o.}) = 0$; intersecting over $\varepsilon = 1/m$, $m \in \mathbb{N}$, yields $\overline{X}_N \to 0$ a.s.. This is the unbounded-variable extension of the bounded strong law lemma 1.37, by the identical fourth-moment method. $\square$

Corollary 3.25 (Law of large numbers and Gaussian fluctuations)**.** *Let $(X_i)_{i\geq 1}$ be i.i.d. real random variables with mean $m_\star = \mathbb{E}[X_1]$ and finite variance $\sigma^2 = \mathrm{Var}(X_1) \in (0,\infty)$, and set $\overline{X}_N = \frac{1}{N}\sum_{i=1}^N X_i$. Then*

$$\sqrt{N}\,(\overline{X}_N - m_\star) \;\Rightarrow\; \mathcal{N}(0,\sigma^2),$$

so $\overline{X}_N = m_\star + N^{-1/2}\,\xi_N$ with $\xi_N \Rightarrow \mathcal{N}(0,\sigma^2)$: the empirical average sits at its deterministic limit $m_\star$ up to a random correction of typical size $\sigma\,N^{-1/2}$ with a universal Gaussian profile. If in addition $\mathbb{E}[X_1^4] < \infty$ then the convergence to $m_\star$ is almost sure, $\overline{X}_N \xrightarrow{a.s.} m_\star$.

Proof. The fluctuation statement is theorem 3.22 after dividing by $\sqrt{N}$: $\sqrt{N}(\overline{X}_N - m_\star) = N^{-1/2}\sum_{i\leq N}(X_i - m_\star)$. Under the extra fourth-moment hypothesis, the almost-sure convergence is proposition 3.24. ☐

Physics note

This corollary is the rigorous content of *self-averaging* and of the suppression of fluctuations in the thermodynamic limit. An intensive observable of N independent constituents — here the per-agent average $\overline{X}_N$ — converges to its ensemble value $m_\star$, and the relative fluctuation $\sqrt{\mathrm{Var}(\overline{X}_N)}/\,|m_\star| = \sigma/(|m_\star|\,\sqrt{N})$ vanishes as $N^{-1/2}$, with the central limit theorem upgrading the variance estimate to a full Gaussian law for the rescaled deviation. In a mean field game the "constituents" are agents and the observable is the population's empirical distribution; the entire justification of replacing the N-player game by its $N = \infty$ limit rests on this $N^{-1/2}$ smallness, and the deviation of the finite game's equilibrium from the mean field equilibrium inherits the same scale. The one genuine subtlety, deferred to chapter 7, is that the agents are *not* exactly independent at finite N — the common field couples them — so the clean i.i.d. statement above must be replaced by propagation of chaos, which proves asymptotic independence and recovers the same $N^{-1/2}$ rate.

It is the empirical *measure*, not just the empirical mean, that the mean field theory tracks. The following worked computation upgrades corollary 3.25 from a single observable to the full random measure, and connects to the Gaussian initial law of the carried LQG thread.

Worked computation 3.26 (Empirical measure of an i.i.d. sample and its fluctuations)**.** Let $X_1,\dots,X_N$ be i.i.d. draws from a probability measure $\mu \in \mathcal{P}(\mathbb{R}^d)$, and form the random empirical measure

$$\mu^N = \frac{1}{N}\sum_{i=1}^N \delta_{X_i} \in \mathcal{P}(\mathbb{R}^d).$$

We claim two facts.

(1) Almost-sure weak convergence. As $N \to \infty$, $\mu^N \Rightarrow \mu$ almost surely. Indeed, fix $f \in C_b(\mathbb{R}^d)$. The random variables $f(X_i)$ are i.i.d. and *bounded* ($|f| \leq \|f\|_\infty$), hence have a finite fourth moment, so the in-book strong law proposition 3.24 gives $\mu^N(f) = \frac{1}{N}\sum_i f(X_i) \to \mu(f)$ a.s.. The null set on which this fails may depend on f; to obtain a *single* null set valid for all $f \in C_b$ simultaneously — which is what $\mu^N \Rightarrow \mu$ requires — we use the countable convergence-determining family for $\mathbb{R}^d$ proved in chapter 1: there is a fixed countable set $\{f_k\} \subseteq C_b(\mathbb{R}^d)$ such that $\nu_n(f_k) \to \nu(f_k)$ for all k

implies $\nu_n \Rightarrow \nu$ (lemma 1.34). Applying the strong law to each f_k and intersecting the countably many null sets gives a single full-measure event on which $\mu^N(f_k) \to \mu(f_k)$ for every k; on that event $\mu^N \Rightarrow \mu$ by lemma 1.34. This almost-sure weak law of large numbers for empirical measures is Varadarajan's theorem, and the metrizability of theorem 3.12 is what makes "a single null set works for all test functions" the right formulation.

(2) Gaussian fluctuations of a linear observable. Fix a single $f \in C_b(\mathbb{R}^d)$ with $\sigma_f^2 := \mathrm{Var}_\mu(f) = \mu(f^2) - \mu(f)^2 \in (0, \infty)$. Then, directly from theorem 3.22 applied to the i.i.d. variables $f(X_i)$,

$$\sqrt{N}\,\big(\mu^N(f) - \mu(f)\big) \;\Rightarrow\; \mathcal{N}(0, \sigma_f^2). \tag{3.14}$$

Thus each smooth "measurement" of the empirical measure fluctuates about its limit at scale $N^{-1/2}$ with a Gaussian profile whose variance is the μ-variance of the test function. (Letting f range over a family yields a Gaussian *field* indexed by test functions, the empirical-measure central limit theorem; we do not need that refinement here and defer it to chapter 13.)

Connection to Thread A. In the linear–quadratic–Gaussian thread the initial law m_0 of the state (the distribution $X_0 \sim m_0$ fixed in the thread specification) is taken Gaussian; we write it as $m_0 = \mathcal{N}(\bar{m}_0, v_0)$ on $\mathbb{R}$, with $\bar{m}_0$ its mean (consistent with the population-mean symbol $\bar{m}_t$ of the thread) and $v_0 > 0$ its *variance* (the same variance-parametrization v_t used for the evolving Gaussian in chapter 4 and chapter 14; we deliberately avoid a standard-deviation symbol that would clash with the noise volatility σ of the thread). Sampling $X_1, \ldots, X_N \sim m_0$ i.i.d. models an N-agent initialization. A Gaussian has all moments finite, so corollary 3.25 applies directly to the unbounded observable $f(x) = x$ (no truncation is needed): the empirical mean obeys

$$\overline{X}_N \xrightarrow{\text{a.s.}} \bar{m}_0, \qquad \sqrt{N}\,\big(\overline{X}_N - \bar{m}_0\big) \;\Rightarrow\; \mathcal{N}(0, v_0),$$

so the random initial mean that an actual N-agent system would feed into the forward dynamics differs from the idealized mean field value $\bar{m}_0$ by a Gaussian fluctuation of size $\sqrt{v_0}\,N^{-1/2}$. This is the precise sense in which the deterministic LQG mean field equations of chapter 14 are the $N = \infty$ limit of a fluctuating finite system, and it fixes the scale of the correction that chapter 13 controls.

3.5 Two concentration tools: Borel–Cantelli and Azuma–Hoeffding

The central limit theorem describes the *typical* size of a fluctuation; later chapters also need control of *rare* fluctuations and of *almost-sure* behaviour. Two elementary but indispensable tools provide this. The first, the Borel–Cantelli lemmas, converts summability of probabilities into almost-sure statements; we use it in chapter 19 to upgrade convergence in probability of sampled homomorphism densities to almost-sure convergence. The second, the Azuma–Hoeffding inequality, gives exponential tail bounds for functions that depend on many independent inputs with bounded sensitivity to each; it is the engine behind the concentration of motif counts in W-random graphs (chapter 19). Both are stated and proved here so that the development is self-contained.

3.5.1 The Borel–Cantelli lemmas

For a sequence of events $(A_n)_{n\geq 1}$ write $\{A_n \text{ i.o.}\} = \limsup_n A_n = \bigcap_{N\geq 1}\bigcup_{n\geq N} A_n$ for the event that infinitely many of the A_n occur.

Theorem 3.27 (Borel–Cantelli)**.** *Let $(A_n)_{n\geq 1}$ be events on a probability space $(\Omega, \mathcal{F}, \mathbb{P})$.*

(i) If $\sum_{n\geq 1} \mathbb{P}(A_n) < \infty$, then $\mathbb{P}(A_n \text{ i.o.}) = 0$; equivalently, almost surely only finitely many A_n occur.

(ii) If the A_n are independent *and $\sum_{n\geq 1} \mathbb{P}(A_n) = \infty$, then $\mathbb{P}(A_n \text{ i.o.}) = 1$.*

Proof. (i) For every N, monotonicity and countable subadditivity give $\mathbb{P}(\bigcup_{n\geq N} A_n) \leq \sum_{n\geq N} \mathbb{P}(A_n)$, and the right-hand side is the tail of a convergent series, hence tends to 0 as $N \to \infty$. Since $\{A_n \text{ i.o.}\} \subseteq \bigcup_{n\geq N} A_n$ for every N, we get $\mathbb{P}(A_n \text{ i.o.}) \leq \inf_N \sum_{n\geq N} \mathbb{P}(A_n) = 0$.

(ii) It suffices to show $\mathbb{P}(\bigcup_{n\geq N} A_n) = 1$ for each N, i.e. $\mathbb{P}(\bigcap_{n\geq N} A_n^{\mathrm{c}}) = 0$. By independence and the elementary bound $1 - x \leq e^{-x}$, for any $M > N$,

$$\mathbb{P}\Big(\bigcap_{n=N}^{M} A_n^{\mathrm{c}}\Big) = \prod_{n=N}^{M} (1 - \mathbb{P}(A_n)) \leq \exp\Big(-\sum_{n=N}^{M} \mathbb{P}(A_n)\Big) \xrightarrow[M\to\infty]{} 0,$$

because the exponent diverges. Letting $M \to \infty$ gives $\mathbb{P}(\bigcap_{n\geq N} A_n^{\mathrm{c}}) = 0$, as required. □

3.5.2 The Azuma–Hoeffding inequality

Recall (it is developed in detail in section 3.6) that a sequence $(M_i)_{i\geq 0}$ adapted to a filtration $(\mathcal{F}_i)_{i\geq 0}$ is a *martingale* if $\mathbb{E}|M_i| < \infty$ and $\mathbb{E}[M_i \mid \mathcal{F}_{i-1}] = M_{i-1}$. The differences $D_i = M_i - M_{i-1}$ then satisfy $\mathbb{E}[D_i \mid \mathcal{F}_{i-1}] = 0$.

Theorem 3.28 (Azuma–Hoeffding)**.** *Let $(M_i)_{0\leq i\leq n}$ be a martingale with respect to $(\mathcal{F}_i)$ whose increments $D_i = M_i - M_{i-1}$ are bounded, $|D_i| \leq c_i$ almost surely for constants $c_i > 0$. Then for every $t > 0$,*

$$\mathbb{P}(M_n - M_0 \geq t) \;\leq\; \exp\Big(-\frac{t^2}{2\sum_{i=1}^{n} c_i^2}\Big),$$

and the same bound holds for $\mathbb{P}(M_n - M_0 \leq -t)$; consequently $\mathbb{P}(|M_n - M_0| \geq t) \leq 2\exp(-t^2/(2\sum_i c_i^2))$.

Proof. The key estimate is Hoeffding's lemma in conditional form: if D is a random variable with $\mathbb{E}[D \mid \mathcal{F}'] = 0$ and $|D| \leq c$ almost surely, then for every $\lambda \in \mathbb{R}$,

$$\mathbb{E}\Big[e^{\lambda D} \mid \mathcal{F}'\Big] \;\leq\; e^{\lambda^2 c^2/2} \qquad \text{a.s.} \tag{3.15}$$

Granting (3.15), fix $\lambda > 0$ and write $S_k = M_k - M_0 = \sum_{i\leq k} D_i$. Conditioning on $\mathcal{F}_{n-1}$ and using $S_n = S_{n-1} + D_n$ with S_{n-1} being $\mathcal{F}_{n-1}$-measurable,

$$\mathbb{E}\Big[e^{\lambda S_n}\Big] = \mathbb{E}\Big[e^{\lambda S_{n-1}}\,\mathbb{E}\Big[e^{\lambda D_n} \mid \mathcal{F}_{n-1}\Big]\Big] \leq e^{\lambda^2 c_n^2/2}\,\mathbb{E}\Big[e^{\lambda S_{n-1}}\Big].$$

Iterating down to $S_0 = 0$ yields $\mathbb{E}\Big[e^{\lambda S_n}\Big] \le \exp\big(\frac{\lambda^2}{2}\sum_{i=1}^n c_i^2\big)$. By Markov's inequality applied to $e^{\lambda S_n}$,

$$\mathbb{P}(S_n \ge t) \le e^{-\lambda t}\,\mathbb{E}\Big[e^{\lambda S_n}\Big] \le \exp\Big(-\lambda t + \tfrac{\lambda^2}{2}\textstyle\sum_i c_i^2\Big).$$

Optimizing over $\lambda > 0$ gives the minimizer $\lambda = t/\sum_i c_i^2$ and the stated bound. The lower-tail bound follows by applying the result to the martingale $-M_i$, and the two-sided bound by a union bound.

It remains to prove (3.15). By convexity of $x \mapsto e^{\lambda x}$ on $[-c, c]$, $e^{\lambda x} \le \frac{c-x}{2c}e^{-\lambda c} + \frac{c+x}{2c}e^{\lambda c}$; taking the conditional expectation and using $\mathbb{E}[D \mid \mathcal{F}'] = 0$ gives $\mathbb{E}\Big[e^{\lambda D} \mid \mathcal{F}'\Big] \le \frac{1}{2}(e^{\lambda c} + e^{-\lambda c}) = \cosh(\lambda c)$. The elementary inequality $\cosh(u) \le e^{u^2/2}$ (compare the power series term by term, $1/(2k)! \le 1/(2^k k!)$) with $u = \lambda c$ yields (3.15). □

Remark 3.29. The form used in applications is the *bounded-differences* (McDiarmid) inequality: if $Z = g(X_1, \dots, X_n)$ with independent X_i and g changes by at most c_i when its ith argument is altered, then the Doob martingale $M_i = \mathbb{E}[Z \mid X_1, \dots, X_i]$ has increments bounded by c_i, so theorem 3.28 gives $\mathbb{P}(|Z - \mathbb{E}Z| \ge t) \le 2\exp(-t^2/(2\sum_i c_i^2))$. This is exactly the device by which chapter 19 controls the deviation of a sampled homomorphism density from its mean.

3.6 Conditional expectation as orthogonal projection

The Azuma–Hoeffding inequality of the previous section was stated for martingales, and a martingale is built on conditional expectation — the one construction this chapter has so far invoked only on credit. We discharge that debt now, with the last of the four tools. Conditional expectation is the rigorous version of "average X given the information $\mathcal{G}$," it is the building block of filtrations, martingales, and the backward stochastic differential equations of chapter 9 and chapter 23, and — the point we emphasize, because it makes the abstract definition transparent to a reader who knows Hilbert spaces — in the L^2 case it is *nothing but the orthogonal projection of chapter 2.*

3.6.1 The L^2 construction

Let $\mathcal{G} \subseteq \mathcal{F}$ be a sub-σ-algebra. The space $L^2(\Omega, \mathcal{G}, \mathbb{P})$ of (equivalence classes of) square-integrable, $\mathcal{G}$-measurable random variables is a *closed* linear subspace of the Hilbert space $L^2(\Omega, \mathcal{F}, \mathbb{P})$ equipped with the inner product $\langle X, Y\rangle = \mathbb{E}[XY]$: closedness holds because an L^2-limit of $\mathcal{G}$-measurable functions has a $\mathcal{G}$-measurable representative (an a.s. limit along a subsequence). Closed subspaces of a Hilbert space carry an orthogonal projection (the projection-onto-a-closed-convex-set theorem, theorem 2.5), and this is the definition.

Definition 3.30 (Conditional expectation, L^2 case)**.** For $X \in L^2(\Omega, \mathcal{F}, \mathbb{P})$, the *conditional expectation* $\mathbb{E}[X \mid \mathcal{G}]$ is the orthogonal projection of X onto the closed subspace $L^2(\Omega, \mathcal{G}, \mathbb{P})$: the unique $\mathcal{G}$-measurable $Y \in L^2$ minimizing $\mathbb{E}[(X - Y)^2]$, equivalently the unique $\mathcal{G}$-measurable $Y \in L^2$ satisfying the orthogonality relations

$$\mathbb{E}[(X - Y)\,Z] = 0 \qquad \text{for every } Z \in L^2(\Omega, \mathcal{G}, \mathbb{P}). \tag{3.16}$$

Taking $Z = \mathbf{1}_A$ for $A \in \mathcal{G}$, the defining relation (3.16) reads

$$\int_A \mathbb{E}[X \mid \mathcal{G}] \, \mathrm{d}\mathbb{P} = \int_A X \, \mathrm{d}\mathbb{P} \qquad \text{for all } A \in \mathcal{G}, \tag{3.17}$$

which is the form most textbooks take as the *definition* of conditional expectation. We have instead *derived* it from orthogonal projection, which explains both the existence (the projection theorem) and the variational meaning (best mean-square $\mathcal{G}$-measurable predictor of X). The geometry is the whole content: $\mathbb{E}[X \mid \mathcal{G}]$ is the foot of the perpendicular from X to the subspace of variables one is "allowed to know," and the residual $X - \mathbb{E}[X \mid \mathcal{G}]$ is orthogonal to everything knowable.

3.6.2 Extension to L^1 and the basic properties

The L^2 projection extends to all integrable X, because it is an L^1-contraction.

Theorem 3.31 (Existence, uniqueness, and properties of conditional expectation)**.** *Let $\mathcal{G} \subseteq \mathcal{F}$ be a sub-σ-algebra and $X \in L^1(\Omega, \mathcal{F}, \mathbb{P})$. There exists a $\mathbb{P}$-a.s. unique $\mathcal{G}$-measurable integrable random variable $\mathbb{E}[X \mid \mathcal{G}]$ satisfying* (3.17)*, agreeing with definition 3.30 when $X \in L^2$. It satisfies, almost surely:*

1. (Linearity) $\mathbb{E}[aX + bX' \mid \mathcal{G}] = a\mathbb{E}[X \mid \mathcal{G}] + b\mathbb{E}[X' \mid \mathcal{G}]$*;*
2. (Positivity and contraction) $X \geq 0 \Rightarrow \mathbb{E}[X \mid \mathcal{G}] \geq 0$*, and* $\mathbb{E}[\,|\mathbb{E}[X \mid \mathcal{G}]|\,] \leq \mathbb{E}[|X|]$*;*
3. (Tower property) *if* $\mathcal{H} \subseteq \mathcal{G}$ *then* $\mathbb{E}[\mathbb{E}[X \mid \mathcal{G}] \mid \mathcal{H}] = \mathbb{E}[X \mid \mathcal{H}]$*; in particular* $\mathbb{E}[\mathbb{E}[X \mid \mathcal{G}]] = \mathbb{E}[X]$*;*
4. (Taking out what is known) *if Z is $\mathcal{G}$-measurable and $ZX \in L^1$, $Z \in L^\infty$, then* $\mathbb{E}[ZX \mid \mathcal{G}] = Z\,\mathbb{E}[X \mid \mathcal{G}]$*;*
5. (Role of independence) *if* $\sigma(X) \perp\!\!\!\perp \mathcal{G}$ *then* $\mathbb{E}[X \mid \mathcal{G}] = \mathbb{E}[X]$*;*
6. (Conditional Jensen) *for convex* $\phi : \mathbb{R} \to \mathbb{R}$ *with* $\phi(X) \in L^1$*,* $\phi\big(\mathbb{E}[X \mid \mathcal{G}]\big) \leq \mathbb{E}[\phi(X) \mid \mathcal{G}]$.

Proof. Existence/uniqueness. For $X \in L^2$ the variable $\mathbb{E}[X \mid \mathcal{G}]$ of definition 3.30 exists and satisfies (3.17). For $X \geq 0$ in L^1, approximate by $X_k = X \wedge k \in L^2$; the projections $\mathbb{E}[X_k \mid \mathcal{G}]$ are non-decreasing in k (positivity, proved next) and their limit Y is $\mathcal{G}$-measurable with $\int_A Y = \int_A X$ for $A \in \mathcal{G}$ by monotone convergence on both sides of (3.17); in particular $\mathbb{E}[Y] = \mathbb{E}[X] < \infty$, so $Y \in L^1$. For general $X \in L^1$ set $\mathbb{E}[X \mid \mathcal{G}] = \mathbb{E}[X^+ \mid \mathcal{G}] - \mathbb{E}[X^- \mid \mathcal{G}]$. Uniqueness: if Y, Y' are $\mathcal{G}$-measurable and both satisfy (3.17), then $\int_A (Y - Y') \, \mathrm{d}\mathbb{P} = 0$ for all $A \in \mathcal{G}$; taking $A = \{Y - Y' > 0\} \in \mathcal{G}$ and $A = \{Y - Y' < 0\} \in \mathcal{G}$ forces $Y = Y'$ a.s..

Positivity is built into the construction: if $X \geq 0$ then on $A = \{\mathbb{E}[X \mid \mathcal{G}] < 0\} \in \mathcal{G}$ one has $\int_A \mathbb{E}[X \mid \mathcal{G}] = \int_A X \geq 0$, impossible unless $\mathbb{P}(A) = 0$. The contraction follows from $|\mathbb{E}[X \mid \mathcal{G}]| \leq \mathbb{E}[X^+ \mid \mathcal{G}] + \mathbb{E}[X^- \mid \mathcal{G}] = \mathbb{E}[|X| \mid \mathcal{G}]$ and taking expectations via (3.17) with $A = \Omega$.

Linearity is inherited from the linearity of the projection (on L^2) and of the integral characterization (on L^1). *Tower*: the right side is $\mathcal{H}$-measurable and, for $A \in \mathcal{H} \subseteq \mathcal{G}$, $\int_A \mathbb{E}[X \mid \mathcal{H}] = \int_A X = \int_A \mathbb{E}[X \mid \mathcal{G}]$ by applying (3.17) twice; uniqueness then identifies it with $\mathbb{E}[\mathbb{E}[X \mid \mathcal{G}] \mid \mathcal{H}]$. *Taking out* *what is known*: for $Z = \mathbf{1}_B$, $B \in \mathcal{G}$, and $A \in \mathcal{G}$, $\int_A Z\,\mathbb{E}[X \mid \mathcal{G}] = \int_{A\cap B} \mathbb{E}[X \mid \mathcal{G}] = \int_{A\cap B} X = \int_A ZX$, so $Z\mathbb{E}[X \mid \mathcal{G}]$ satisfies the defining property of $\mathbb{E}[ZX \mid \mathcal{G}]$; extend to simple, then bounded $\mathcal{G}$-measurable Z by linearity and dominated convergence. *Independence*: if $\sigma(X) \perp\!\!\!\perp \mathcal{G}$ then for $A \in \mathcal{G}$, $\int_A X = \mathbb{E}[X\mathbf{1}_A] = \mathbb{E}[X]\ \mathbb{P}(A) = \int_A \mathbb{E}[X]$ by (3.3), so the constant $\mathbb{E}[X]$ satisfies the defining property. *Conditional Jensen*: write the convex ϕ as the supremum of a countable family of affine minorants $\phi(x) \geq a_k x + b_k$; apply linearity and positivity to each, $\mathbb{E}[\phi(X) \mid \mathcal{G}] \geq a_k\mathbb{E}[X \mid \mathcal{G}] + b_k$, and take the supremum over k. Full treatment: [132, Ch. 9], [84, Ch. 8]. □

Remark 3.32 (Why this is the prerequisite it is)**.** The orthogonality (3.16) is the abstract martingale property: a process $M_t = \mathbb{E}[X \mid \mathcal{F}_t]$ along an increasing family of σ-algebras (a filtration $\mathbb{F} = (\mathcal{F}_t)$, defined in chapter 5) has orthogonal increments and is the canonical example of a martingale. The tower property is the consistency that makes the conditional law of a Markov process well-defined, and "taking out what is known" is the rule by which the diffusion term of an Itô integral has conditional mean zero. In a backward stochastic differential equation the unknown is precisely a pair (Y_t, Z_t) realizing a prescribed terminal value as a conditional expectation evolving backward in time; the contraction property (2) is what makes the fixed-point map of chapter 9 well-posed. Nothing in the present chapter uses a filtration, but every property proved here is consumed there.

3.6.3 Regular conditional distributions and disintegration

Conditional expectation tells us the average of a single integrable variable given $\mathcal{G}$. For many purposes — in particular for the gluing of couplings used to build the Wasserstein metric in chapter 4 — one wants the entire *conditional law*: a genuine probability measure $\kappa(\omega, \cdot)$ on the state space that plays the role of "the distribution of X given the information $\mathcal{G}$," measurably in ω. On $\mathbb{R}^d$ such an object always exists, and it is built from conditional expectations of indicator functions by the same construction that turns a distribution function into a measure. We record it here because chapter 4 imports it by name.

Theorem 3.33 (Regular conditional distributions on $\mathbb{R}^d$)**.** *Let $(\Omega, \mathcal{F}, \mathbb{P})$ be a probability space, $\mathcal{G} \subseteq \mathcal{F}$ a sub-σ-algebra, and $X : \Omega \to \mathbb{R}^d$ a random variable. Then there is a map $\kappa : \Omega \times \mathcal{B}(\mathbb{R}^d) \to [0, 1]$, the* regular conditional distribution *of X given $\mathcal{G}$, such that*

(i) *for each ω, $B \mapsto \kappa(\omega, B)$ is a probability measure on $\mathbb{R}^d$;*

(ii) *for each Borel B, $\omega \mapsto \kappa(\omega, B)$ is $\mathcal{G}$-measurable and equals $\mathbb{P}(X \in B \mid \mathcal{G})$ a.s.;*

and consequently $\mathbb{E}[g(X) \mid \mathcal{G}] = \int_{\mathbb{R}^d} g\, \mathrm{d}\kappa(\cdot,)$ a.s. for every bounded Borel g. In particular, if $\pi \in \mathcal{P}(\mathbb{R}^d \times \mathbb{R}^d)$ has second marginal ν, there is a Borel kernel $y \mapsto \pi_y \in \mathcal{P}(\mathbb{R}^d)$ with

$$\int_{\mathbb{R}^d\times\mathbb{R}^d} h(x, y)\ \mathrm{d}\pi(x, y) = \int_{\mathbb{R}^d}\int_{\mathbb{R}^d} h(x, y)\, \pi_y(\mathrm{d}x)\, \nu(\mathrm{d}y) \qquad (h \textit{ bounded Borel}), \tag{3.18}$$

the disintegration *of π over its second marginal.*

Proof. For each rational vector $q \in \mathbb{Q}^d$ choose a version $F(q, \cdot)$ of the conditional expectation $\mathbb{E}[\mathbf{1}\{X \leq q\} \mid \mathcal{G}]$ (coordinatewise order $X \leq q$). Using the almost-sure linearity, positivity, and conditional monotone convergence of theorem 3.31 on the countable index set $\mathbb{Q}^d$, there is a $\mathbb{P}$-null set off which, simultaneously for all rationals: $F(q,\omega) \le F(q',\omega)$ whenever $q \le q'$; $F(q,\omega) \to 0$ as some coordinate $q_j \to -\infty$ and $F(q,\omega) \to 1$ as all $q_j \to +\infty$ (apply conditional monotone convergence to $\mathbf{1}\{X \le q\} \downarrow 0$ and $\uparrow 1$); and $F(q,\omega) = \lim_{q' \downarrow q,\, q' \in \mathbb{Q}^d} F(q',\omega)$ (right-continuity, again by conditional dominated convergence). Off this null set define, for $x \in \mathbb{R}^d$, $\widehat{F}(x,\omega) = \inf\{F(q,\omega) : q \in \mathbb{Q}^d,\ q \ge x\}$; then $\widehat{F}(\cdot,\omega)$ is a bona fide d-dimensional distribution function (nondecreasing, right-continuous, with the correct limits at $\pm\infty$), and by the distribution-function–to–measure correspondence (chapter 1, Lebesgue–Stieltjes) it is the cumulative function of a unique probability measure $\kappa(\omega,\cdot)$ on $\mathbb{R}^d$. On the null set set $\kappa(\omega,\cdot)$ equal to any fixed probability measure. This gives (i). For (ii), $\omega \mapsto \kappa(\omega,(-\infty,q]) = F(q,\omega)$ is $\mathcal{G}$-measurable and a version of $\mathbb{P}(X \le q \mid \mathcal{G})$ for each rational q; the class of Borel B with $\omega \mapsto \kappa(\omega,B)$ $\mathcal{G}$-measurable and equal to $\mathbb{P}(X \in B \mid \mathcal{G})$ a.s. is a λ-system containing the π-system of rational lower-left orthants, hence is all of $\mathcal{B}(\mathbb{R}^d)$ by the π–λ theorem (theorem 1.9). The identity $\mathbb{E}[g(X) \mid \mathcal{G}] = \int g \, \mathrm{d}\kappa$ follows for indicators, then for simple, then for bounded Borel g by linearity and dominated convergence.

For the disintegration statement, realize π as the law of a pair (X,Y) of $\mathbb{R}^d$-valued variables on some probability space (e.g. the identity maps on $(\mathbb{R}^d \times \mathbb{R}^d, \pi)$) and take $\mathcal{G} = \sigma(Y)$. By the Doob–Dynkin lemma a $\sigma(Y)$-measurable function is a Borel function of Y, so the kernel $\kappa(\cdot,B) = \mathbb{P}(X \in B \mid Y)$ has the form $\pi_Y(B)$ for a Borel map $y \mapsto \pi_y \in \mathcal{P}(\mathbb{R}^d)$. Then for bounded Borel h, $\mathbb{E}[h(X,Y)] = \mathbb{E}[\mathbb{E}[h(\cdot,Y)(X) \mid Y]] = \mathbb{E}[\int h(x,Y)\pi_Y(\mathrm{d}x)]$, which is exactly (3.18) since $\mathcal{L}(Y) = \nu$. □

Rigor ledger

Proved.

- Expectation as integration against the law, the change-of-variables formula (3.1), and the characterizations of independence (3.3)–(3.4) (section 3.1).
- The hierarchy of modes of convergence (lemma 3.6), including the uniform-continuity argument for convergence in probability $\Rightarrow$ in distribution and the Borel–Cantelli subsequence.
- The **Portmanteau theorem** (theorem 3.9) in full, all five equivalences, via the metric Urysohn approximation lemma 3.8 and a layer-cake/continuity-set argument; the **continuous mapping theorem** (corollary 3.11).
- **Metrization of weak convergence** by the bounded-Lipschitz metric, with $\mathcal{P}(S)$ Polish when S is (theorem 3.12); **Ulam** tightness of a single measure (lemma 3.15); and the **Skorokhod representation theorem** (theorem 3.13).
- **Prokhorov's theorem** (theorem 3.16) on a Polish space, *both* directions in full: the limit measure is built as an inner-regular content on the tightness compacts and extended by Carathéodory.
- Characteristic-function properties (proposition 3.19) including the **Lévy inversion/uniqueness formula** (lemma 3.20); **Lévy's continuity theorem** (theorem 3.21) and

the **i.i.d. central limit theorem** (theorem 3.22) in full via the Fourier route; the fourth-moment **strong law** (proposition 3.24); the $N^{-1/2}$ Gaussian fluctuation statement (corollary 3.25) and its measure-valued form (worked computation 3.26).

- **Conditional expectation** as orthogonal projection (definition 3.30), its L^1 extension and full property list (theorem 3.31), and **regular conditional distributions / disintegration** on $\mathbb{R}^d$ (theorem 3.33).

Assumed (imported).

- Lebesgue integration, monotone/dominated convergence, Fubini–Tonelli, Markov's inequality, the π–λ theorem, the Carathéodory extension theorem, the distribution-function–to–measure correspondence, and the countable convergence-determining family on $\mathbb{R}^d$ (lemma 1.34), all from chapter 1; the bounded strong law lemma 1.37 (whose fourth-moment method we reuse in proposition 3.24).
- Hilbert-space geometry and the projection-onto-a-closed-convex-set theorem (theorem 2.5) from chapter 2. *(The Riesz–Markov representation $C(S)^* = \mathcal{M}(S)$ is **not** imported: it appears only as classical context in the notation watch of section 3.2.2 and is used nowhere as a tool.)*

Deferred.

- Explicit alternative metrics for weak convergence (Lévy–Prokhorov) and the refinement of the bounded-Lipschitz metric by $\mathcal{W}_2$: chapter 4; [61, Ch. 11].
- The empirical-measure central limit theorem (Gaussian field over test functions) and propagation of chaos: chapter 7, chapter 13.
- Filtrations, martingales, and the use of conditional expectation in BSDEs: chapter 5, chapter 9, chapter 23.

Open. Nothing at this foundational level: the theorems here are classical and complete. The genuinely open questions enter where these tools are applied — quantitative propagation-of-chaos rates beyond $N^{-1/2}$ for singular or non-exchangeable interactions, and tightness on the field-of-measures spaces of the graphon theory (chapter 24).

Bibliographic notes

The treatment of probability spaces, expectation, independence, and the characteristic-function proof of the central limit theorem follows the standard graduate accounts; [62] and [84] are the closest references, and [132] is the most readable source for conditional expectation as a projection and for the martingale viewpoint of remark 3.32. The theory of weak convergence of probability measures on metric spaces — the Portmanteau theorem, tightness, and Prokhorov's theorem — is developed canonically in [23]; our theorem 3.9 and theorem 3.16 are his Theorems 2.1 and 5.1–5.2, and the

Urysohn approximation lemma 3.8 is the standard device behind the closed-set inequality. [61] gives the metric theory of $\mathcal{P}(S)$, including the bounded-Lipschitz and Lévy–Prokhorov metrics quoted in section 3.2.2, and is the reference for the separability reductions used in worked computation 3.26 (Varadarajan's theorem). The Lévy continuity theorem and the tightness-from-continuity-at-the-origin argument are in [62, Ch. 3] and [84, Ch. 5]. The reader oriented toward the sequel should note that everything here is consumed almost immediately: weak convergence and tightness power the existence theory of mean field games in [36] and [40], the $N^{-1/2}$ fluctuation scale is the quantitative heart of propagation of chaos in [40, Vol. I, Ch. 1], and conditional expectation underlies the FBSDE formulation there and its graphon extension in [39]. The optimal-transport refinement of the weak topology, in which the mean field genuinely lives, is taken up next in chapter 4 following [131].

Chapter 4

Wasserstein Geometry of Probability Measures

The previous chapter (chapter 3) taught us to regard a probability measure as a *point* and to speak of one sequence of measures converging to another. Weak convergence, tightness, and Prokhorov's theorem gave us a topology on the set of probability measures, and that topology is already enough to power many compactness arguments. But a topology is not a geometry. It tells us when two measures are *close*, not *how far apart* they are, and it offers no notion of a straight line between them. Both omissions will bite, and it is worth seeing concretely what the missing structure will look like before we build it. "How far apart" will acquire a sharp and useful meaning: the distance between two measures will be the *cheapest cost of physically transporting* one pile of probability mass onto the other — an optimal-transport cost. And "a straight line" between μ and ν will turn out *not* to be the obvious pointwise average $(1-t)\mu + t\nu$ — which merely fades one measure out while fading the other in — but a *displacement geodesic* that slides each grain of mass steadily along a straight path from its position in μ to its destination in ν. Neither object can be seen from the weak topology alone, and both will be indispensable below.

For mean field games we will need the geometry, not just the topology. The equilibrium of a mean field game is a fixed point of a map that sends one population law to another, and to locate such a fixed point three quantitative operations are unavoidable: we must *measure distances* between laws, *estimate how much the map stretches* those distances, and sometimes *interpolate continuously* from one law to another along a controlled path. Each of the three is the seed of a concrete payoff this chapter is building toward, and naming the payoffs now — before proving anything, since the game has not even been defined — lets the reader carry a sense of purpose into the construction. Measuring distances yields $\mathcal{W}_2$-*compactness*, the hypothesis under which the Schauder and Kakutani fixed-point theorems of chapter 10 produce an equilibrium at all. Estimating stretch yields $\mathcal{W}_2$-*contraction*, the mechanism behind the uniqueness arguments of chapter 11. And interpolating yields *displacement convexity*, the form of convexity along the geodesics above that underlies the Lasry–Lions monotonicity of chapter 11. This chapter builds the single metric in which all three are expressed: the quadratic Wasserstein distance $\mathcal{W}_2$ on the space $\mathcal{P}_2(\mathbb{R}^d)$ of probability measures with finite second moment.

We assume from chapter 1 the language of measures, push-forwards, and integration; from chapter 2 the rudiments of Hilbert spaces and the Riesz representation theorem (theorem 2.6); and from chapter 3 weak convergence (definition 3.7), tightness (section 3.3), and Prokhorov's theorem (theorem 3.16), which we invoke without re-proof. The one notion of differential calculus we will need beyond chapter 2 — Fréchet differentiability of a functional on a Hilbert space — is recalled in place where it is used, in section 4.4, so that the chapter is self-contained on this point.

Looking forward, the metric and the two notions of differentiation built here are the working surface of nearly everything that follows: the best-response map of chapter 8 and chapter 10 is studied as a map on $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$; the Lasry–Lions monotonicity of chapter 11 is a statement about the flat derivative of the coupling; the master equation of chapter 12 is a partial differential equation whose unknown is differentiated in the Lions sense developed in section 4.4; and the Gaussian distance computed in section 4.5 is the geometric skeleton of the linear–quadratic–Gaussian (LQG) thread, reused in chapter 6 and chapter 14. The route there has five stages. We begin in section 4.1 with the transport problem itself — Monge's deterministic dream of a transport map, its failure, Kantorovich's relaxation to couplings, and the definition of $\mathcal{W}_2$ that falls out of it. Section 4.2 then earns the word "metric": it verifies that $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ is a complete separable metric space, identifies $\mathcal{W}_2$-convergence with weak convergence *plus* convergence of second moments, and exhibits the displacement geodesics promised above. With the geometry in hand, section 4.3 pauses to explain — still informally, because the game has not yet been defined — why a mean field game is naturally posed in exactly this space. Section 4.4 then develops the two derivatives with respect to a measure argument, the flat (linear functional) derivative and the Lions derivative, slowly and with the density-functional analogy as the on-ramp. Finally section 4.5 carries out the worked computation that the LQG thread leans on: the closed form for $\mathcal{W}_2$ between two Gaussians.

4.1 Monge, Kantorovich, and the transport distance

This section builds the distance from the ground up, in three movements that mirror the historical and logical development of optimal transport. First we pose the problem in Monge's original terms — find the cheapest *map* that rearranges one mass distribution into another — and watch it fail: a map cannot split mass, so the problem can be infeasible outright and is in any case non-convex, with neither existence nor uniqueness guaranteed. Then we repair the defect with Kantorovich's relaxation, which replaces the rigid map by a flexible *coupling* and turns the question into a well-posed linear program; its optimal value, taken with squared-distance cost, *is* the quadratic Wasserstein distance $\mathcal{W}_2$. Finally we extract the two structural facts that the rest of the book will draw on: Kantorovich duality, which re-expresses $\mathcal{W}_2^2$ as a supremum over pairs of potentials, and Brenier's theorem, which says that when the source measure has a density the optimal coupling is after all carried by a map — and not just any map, but the gradient of a convex function. The first two subsections deliver the candidate distance; the third delivers the structure that makes it computable and analyzable.

One choice pervades all of this and deserves to be flagged before it is silently made: the price of moving a grain of mass from x to y will be the *squared* Euclidean distance $|x - y|^2$, not the distance itself nor any other power. Three reasons single out this cost, and each is repaid later.

First, it produces a distance that genuinely extends the Euclidean metric of $\mathbb{R}^d$: two Dirac masses δ_a and δ_b end up exactly $|a-b|$ apart (theorem 4.7), so $\mathbb{R}^d$ embeds isometrically into the space of measures and the new geometry contains the old one. Second, it gives the problem a Hilbertian, convex-analytic structure — the optimal map is the gradient of a convex potential (theorem 4.6), the natural interpolation is a geodesic in an L^2 sense, and the whole theory inherits the comfort of quadratic forms — whereas a general cost $|x-y|^p$ has no such linear-algebraic backbone. Third, it couples cleanly to the quadratic running costs of the linear–quadratic control problems of chapter 6, so that the geometry of the population and the cost paid by the individual agent speak one and the same quadratic language. With that choice fixed, we turn to the problem it defines.

4.1.1 The transport problem

With the squared cost fixed, we can make precise the phrase that has been guiding us: the *cheapest way to turn the pile μ into the landscape ν*. The right way to feel the problem before formalizing it is the picture optimal transport was born from. Imagine a pile of sand on $\mathbb{R}^d$ whose mass is distributed according to a probability measure μ: where μ puts a lot of weight there is a lot of sand, where it puts little there is a thin scattering, and the total amount of sand is one unit. We are asked to redeposit every grain so that the relocated pile matches a second prescribed shape, a target landscape described by another probability measure ν — perhaps a hole we must exactly fill, or an embankment we must exactly raise. We are free to move each grain wherever we like, but movement is not free: relocating a grain from position x to position y costs $c(x,y)$, and the bill for the whole operation is the sum (the integral) of these grain-by-grain costs. The transport problem asks for the cheapest such relocation.

Throughout this book the price of moving a grain from x to y is the squared Euclidean distance $c(x,y) = |x-y|^2$. This is the choice flagged and justified in the umbrella to this section: it is what makes the resulting distance a genuine extension of the Euclidean metric of $\mathbb{R}^d$, what gives the problem its Hilbertian convex-analytic backbone, and what makes it speak the same quadratic language as the running costs of the linear–quadratic control problems of chapter 6 (the three reasons are laid out in full there, and we do not repeat them). What matters for the present subsection is only that the cost is fixed, finite for finite displacements, and increasing in the distance moved, so that "cheapest" genuinely rewards moving each grain as little as possible.

Gaspard Monge posed this problem in 1781 in the most concrete terms imaginable: name, for each starting position, the single place its grain is to go. Formally, a *transport map* is a measurable function $T\colon \mathbb{R}^d \to \mathbb{R}^d$, and the prescription "the grain now at x is carried to $T(x)$" is a complete, deterministic relocation rule. The rule is not allowed to be arbitrary: when every grain has been moved according to T, the resulting heap must be exactly the target ν, not merely something resembling it. Spelled out, the mass that T deposits into any region B is precisely the mass that started in the preimage $T^{-1}(B)$ — all the grains whose destination lies in B — and this deposited mass must equal $\nu(B)$ for every region B. That is exactly the push-forward condition introduced in chapter 1: ν is the push-forward of μ under T, written $T_{\#}\mu = \nu$ and defined by $(T_{\#}\mu)(B) = \mu(T^{-1}(B))$ for every Borel set B. Read it as a bookkeeping identity — every grain is reassigned by T, and the reassigned pile is ν on the nose — and the constraint becomes intuitive rather than symbolic. Among all maps meeting this constraint, Monge sought the one of least total cost. The *Monge problem* is therefore

$$\inf\left\{\int_{\mathbb{R}^d} |x - T(x)|^2 \ \mu(\mathrm{d}x) \ : \ T_{\#}\mu = \nu\right\}, \tag{4.1}$$

where $|x - T(x)|^2$ is the cost incurred by the grain starting at x and the integral against μ totals it over the whole pile.

This formulation is irresistibly intuitive — and, it turns out, treacherous. The trouble is that a single-valued function is too rigid an object to describe how mass can actually need to flow, and the next box makes the failure unmistakable on the smallest possible example before we go looking for a cure.

Heuristic (non-rigorous): Monge's treachery: a map cannot split mass

The fatal defect is that a transport *map* sends each source point to one and only one destination, whereas the target may demand that the mass sitting at a single source point be divided and sent to several places. Take the smallest example that exhibits this. Let the source be a single unit atom, $\mu = \delta_{x_0}$ — all the sand piled at one point x_0 — and let the target split that unit of mass evenly between two distinct locations, $\nu = \frac{1}{2}\delta_{y_1} + \frac{1}{2}\delta_{y_2}$ with $y_1 \neq y_2$. A map T must assign to the source point x_0 exactly one value $T(x_0)$, so the entire unit of mass arrives at that single point: $T_{\#}\delta_{x_0} = \delta_{T(x_0)}$, a lone atom of mass one. But ν is not a lone atom; it carries mass $\frac{1}{2}$ at y_1 and mass $\frac{1}{2}$ at y_2. No choice of $T(x_0)$ can reproduce it — sending the grain to y_1 leaves y_2 empty, sending it to y_2 leaves y_1 empty, and a function cannot return both y_1 and y_2 *at once*. There is therefore *no* admissible T at all: the constraint set in (4.1) is *empty*, and the infimum is taken over the empty set (by convention $+\infty$). The Monge problem here is not merely hard to solve; it has nothing to be solved over. The obstruction is generic: whenever μ carries an atom heavier than the heaviest atom of ν, the mass at that point must split, and no map can split it.

A second, subtler defect spoils even the cases where maps do exist. As an optimization problem the Monge problem is badly behaved on two counts. Its objective $T \mapsto \int |x - T(x)|^2 \,\mathrm{d}\mu$ is *nonlinear* in the unknown T — the displacement $T(x)$ enters squared, so the cost is a quadratic, not a linear, function of the map, and the leverage one enjoys with linear objectives is unavailable. And its feasible set $\{T : T_{\#}\mu = \nu\}$ is *nonconvex*: if T_0 and T_1 both push μ to ν, their average $\frac{1}{2}(T_0 + T_1)$ generally does *not*, because pushing forward does not commute with averaging maps — the midpoint map sends each x to the midpoint of two destinations, which lands mass in places neither T_0 nor T_1 visited and need not reconstitute ν. (In the split-mass example the two pathologies fuse: the feasible set is not merely nonconvex, it is empty.) With a nonlinear objective minimized over a nonconvex — and possibly empty — constraint set, the standard existence and uniqueness guarantees of optimization simply do not apply.

Both defects trace to the same root: we insisted that mass move *deterministically*, one source point to one target point. What the split-mass example shows we need is the freedom to let the grain at x_0 go *half to y_1 and half to y_2* — to spread a source point's mass probabilistically over several destinations. Kantorovich's relaxation, taken up next, grants exactly this freedom by replacing the rigid map with a flexible joint law on source–target pairs.

The example has done its work: it has turned a vague unease about Monge's formulation into a concrete, felt need. A description of transport that forbids a source point from sending its mass to more than one destination is simply too narrow to model the flows we must allow. The remedy is to stop tracking "where does the grain at x go?" and instead track "how much mass travels from near x to near y?" — a quantity that can perfectly well be positive for two different destinations y sharing the same source x. Formalizing that quantity, as a joint law whose marginals are μ and ν, is the business of the Kantorovich relaxation, to which we now turn.

4.1.2 The Kantorovich relaxation

The split-mass example left us with a precise diagnosis. The Monge problem failed not because transport is impossible — physically there is no obstacle to shovelling the unit of sand at x_0 into two half-piles and carrying one to y_1 and the other to y_2 — but because the *language* of maps cannot express a split: a single-valued function T is forced to send the grain at x_0 to exactly one place. The cure suggested by the example was to stop insisting that mass move deterministically and instead allow a source point to spread its mass probabilistically over several destinations. Kantorovich's 1942 idea [85] is exactly this, and it is disarmingly simple: describe a transport scheme not by a map that names one destination per source, but by a *bookkeeping table* that records, for every pair of locations (x, y), how much mass travels from near x to near y. Such a table is itself a probability measure — a joint law on source–target pairs — and the two questions "how much mass leaves from each x?" and "how much mass arrives at each y?" are answered by its two marginals, which we require to be μ and ν respectively. This is the notion of a coupling.

Definition 4.1 (Couplings)**.** For $\mu, \nu \in \mathcal{P}(\mathbb{R}^d)$, the set of couplings is

$$\Pi(\mu, \nu) \;=\; \Big\{\pi \in \mathcal{P}(\mathbb{R}^d \times \mathbb{R}^d) \;:\; \pi(A \times \mathbb{R}^d) = \mu(A),\; \pi(\mathbb{R}^d \times B) = \nu(B) \text{ for all Borel } A, B\Big\}.$$

Every symbol here carries an operational meaning, and it is worth reading the definition slowly as the randomized transport scheme it encodes. The object $\pi(\mathrm{d}x, \mathrm{d}y)$ is the infinitesimal amount of mass dispatched from a neighborhood of the source point x to a neighborhood of the target point y; summing (integrating) it over all (x, y) gives one unit, because π is a probability measure and all the sand is accounted for. The first marginal constraint, $\pi(A \times \mathbb{R}^d) = \mu(A)$, fixes the total mass leaving the region A: it collects every grain whose source lies in A, regardless of where that grain ends up (that is what the unrestricted second slot $\mathbb{R}^d$ means), and demands the total equal $\mu(A)$. In words: *all of μ leaves, exactly as μ prescribes.* The second constraint, $\pi(\mathbb{R}^d \times B) = \nu(B)$, collects every grain whose destination lies in B, regardless of its source, and demands the total equal $\nu(B)$: *all of ν arrives, exactly as ν prescribes.* A coupling is thus a complete dispatch ledger that respects both the supply profile μ and the demand profile ν, while leaving entirely free how supply is routed to demand — and crucially, nothing forbids the mass sitting at a single source x from being shared among many targets y. The split that no map could perform is, for a coupling, simply a row of the ledger with more than one nonzero entry.

Two facts about this construction make precise the sense in which it both *contains* Monge and *repairs* him. First, $\Pi(\mu,\nu)$ is *never empty* — the relaxation can never be infeasible the way the Monge problem was. The witness is the product, or independent, coupling $\mu\otimes\nu$, which routes mass from x to y in proportion to $\mu(\mathrm{d}x)\,\nu(\mathrm{d}y)$, as though source and destination were drawn independently. Its marginals are μ and ν by the very definition of a product measure — integrating out the second coordinate of $\mu\otimes\nu$ returns μ, integrating out the first returns ν — so $\mu\otimes\nu\in\Pi(\mu,\nu)$ for *every* pair μ,ν. There is always at least one admissible plan, however expensive; in the split-mass example, where the Monge constraint set was literally empty, the independent coupling $\delta_{x_0}\otimes(\frac{1}{2}\delta_{y_1}+\frac{1}{2}\delta_{y_2})$ does the obvious thing, sending half the atom at x_0 to y_1 and half to y_2. Second, whenever a transport map *does* exist, Kantorovich sees it: a map T with $T_{\#}\mu=\nu$ corresponds to the special coupling $\pi_T=(\mathrm{Id},T)_{\#}\mu$, the push-forward of μ under $x\mapsto(x,T(x))$. This π_T is concentrated on the graph $\left\{(x,T(x)) : x\in\mathbb{R}^d\right\}$ — all its mass sits on the curve traced by T, so it assigns to each source x the *single* destination $T(x)$, with no splitting — and one checks directly that its cost $\int|x-y|^2\ \pi_T(\mathrm{d}x,\mathrm{d}y)=\int|x-T(x)|^2\ \mu(\mathrm{d}x)$ reproduces the Monge cost exactly. The graph-supported couplings are therefore a copy of the Monge maps sitting inside the larger set $\Pi(\mu,\nu)$, and the Kantorovich problem minimizes over a strictly wider class: it admits, in addition, all the plans that are *not* supported on a graph — the genuinely split ones. This is the precise meaning of the slogan that Kantorovich *relaxes* Monge. Minimizing over a larger feasible set can only lower the infimum, so $\mathcal{W}_2(\mu,\nu)^2$ defined below is automatically no greater than the Monge value, and one of the payoffs of theorem 4.6 will be that, under a mild condition, the two values coincide.

With couplings in hand we can finally write down the distance the chapter is built around.

Definition 4.2 (Kantorovich problem and the quadratic Wasserstein distance)**.** For $\mu,\nu\in\mathcal{P}(\mathbb{R}^d)$ define the optimal transport cost

$$\mathcal{W}_2(\mu,\nu)^2 \;=\; \inf_{\pi\in\Pi(\mu,\nu)}\int_{\mathbb{R}^d\times\mathbb{R}^d}|x-y|^2\ \pi(\mathrm{d}x,\mathrm{d}y). \tag{4.2}$$

Restricted to the set $\mathcal{P}_2(\mathbb{R}^d)=\left\{\mu\in\mathcal{P}(\mathbb{R}^d) : \int|x|^2\,\mathrm{d}\mu<\infty\right\}$ of measures with finite second moment, $\mathcal{W}_2$ is called the *quadratic Wasserstein distance.*

The infimum runs over the dispatch ledgers, and the integrand $|x-y|^2$ bills each infinitesimal shipment by the squared distance it travels; $\mathcal{W}_2(\mu,\nu)^2$ is the cheapest total bill. Two things must be checked before this deserves the name "distance," and they explain the restriction to $\mathcal{P}_2(\mathbb{R}^d)$ that the definition quietly imposes: the value must be *finite*, and the infimum must be *attained.* We deal with finiteness now and attainment next.

Finiteness is where the second-moment hypothesis pays for itself, and the argument is short enough to follow term by term. We need only exhibit *one* coupling of finite cost, since the infimum is then no larger; the most convenient candidate, the independent coupling $\mu\otimes\nu$, is the natural one to test. Its cost is $\int_{\mathbb{R}^d\times\mathbb{R}^d}|x-y|^2\ \mu(\mathrm{d}x)\,\nu(\mathrm{d}y)$, and the elementary inequality $|x-y|^2\le 2\,|x|^2+2\,|y|^2$ — itself just the expansion $|x-y|^2=|x|^2-2\langle x,y\rangle+|y|^2$ followed by $-2\langle x,y\rangle\le|x|^2+|y|^2$ — bounds the integrand by a sum in which the two variables have separated. Integrating the separated bound against the product measure, the $|x|^2$ term integrates the μ marginal (the ν in y contributing its total mass 1) and the $|y|^2$ term integrates the ν marginal, giving

$$\mathcal{W}_2(\mu,\nu)^2 \;\le\; \int_{\mathbb{R}^d\times\mathbb{R}^d} |x-y|^2\,\mu(\mathrm{d}x)\,\nu(\mathrm{d}y) \;\le\; 2\int_{\mathbb{R}^d} |x|^2\,\mu(\mathrm{d}x) + 2\int_{\mathbb{R}^d} |y|^2\,\nu(\mathrm{d}y).$$

Both integrals on the right are finite precisely because $\mu,\nu \in \mathcal{P}_2(\mathbb{R}^d)$, so $\mathcal{W}_2(\mu,\nu) < \infty$. This is the whole reason the second-moment condition is the right membership test: it is the exact amount of tail control that guarantees a finite transport bill between any two members of the space.

Drop that control and the value can genuinely blow up. On the larger space $\mathcal{P}(\mathbb{R}^d)$ the infimum in (4.2) can equal $+\infty$, and the picture is concrete: imagine μ and ν each spreading a sliver of mass arbitrarily far out along the axis — heavy-tailed laws whose second moment diverges, like a Cauchy distribution. No matter how cleverly one routes the dispatch, the far-flung grains of μ must be carried somewhere, and the squared-distance bill for relocating mass that lives infinitely far from the origin is itself infinite; *every* coupling costs $+\infty$, so the infimum is $+\infty$ and $\mathcal{W}_2$ is not even a real number. A quantity that can be $+\infty$ cannot be a metric. This is exactly why the metric space of interest is $\mathcal{P}_2(\mathbb{R}^d)$ and not $\mathcal{P}(\mathbb{R}^d)$: the finite-second-moment restriction is not a technical fussiness but the precise boundary between where the transport distance is a usable number and where it degenerates.

The second thing to verify is that the infimum is actually achieved — that there is a best ledger, not merely a sequence of ever-cheaper ones approaching the infimum from above. Unlike the Monge problem, whose feasible set could be empty or whose minimizing sequence of maps could fail to converge to a map, the Kantorovich problem always has a solution, and the reason is that couplings live in a space where the compactness tools of chapter 3 apply.

Proposition 4.3 (Existence of an optimal coupling)**.** *For all $\mu,\nu \in \mathcal{P}(\mathbb{R}^d)$ the infimum in (4.2) is attained by some $\pi^\star \in \Pi(\mu,\nu)$.*

This is the first place in the book where the weak-convergence machinery of chapter 3 does real work, so rather than cite the result we narrate the argument and let each invoked theorem announce why it is needed. The strategy is the *direct method* of the calculus of variations, whose skeleton is always the same three ribs: take a minimizing sequence; extract a convergent subsequence using compactness; pass the cost to the limit using lower semicontinuity, and conclude that the limit is a minimizer. For this to run, the feasible set must be compact (so a limit exists), it must be closed (so the limit is still feasible), and the cost must not jump up in the limit (so the limiting plan is at least as cheap). We supply the three ingredients in turn.

Proof sketch. Compactness of the feasible set. The first rib needs a convergent subsequence of any sequence $\pi_n \in \Pi(\mu,\nu)$, and the tool for that is Prokhorov's theorem (theorem 3.16), which trades relative weak compactness for tightness. So we verify that $\Pi(\mu,\nu)$ is tight — and the elegant point is that a *single* compact set works for every coupling at once, because the marginals are fixed in advance. Given $\varepsilon > 0$, use the tightness of the two fixed measures μ and ν individually (a single Borel measure on a Polish space is automatically tight, section 3.3) to choose one compact $K \subset \mathbb{R}^d$ with $\mu(K^c) < \varepsilon/2$ and $\nu(K^c) < \varepsilon/2$. Then for *any* $\pi \in \Pi(\mu,\nu)$ the mass escaping the compact box

$K \times K$ is controlled by the two marginals: a pair (x, y) lies outside $K \times K$ only if $x \notin K$ or $y \notin K$, so a union bound gives

$$\pi\big((K \times K)^c\big) \;\le\; \pi(K^c \times \mathbb{R}^d) + \pi(\mathbb{R}^d \times K^c) \;=\; \mu(K^c) + \nu(K^c) \;<\; \varepsilon,$$

where the middle equality is just the marginal constraints. Since $K \times K$ is compact and the same K works uniformly in π, the family $\Pi(\mu, \nu)$ is tight, hence relatively weakly compact by Prokhorov.

Closedness of the feasible set. The second rib needs the weak limit of feasible couplings to be feasible. The marginal constraints are exactly continuity requirements: testing $\pi(A \times \mathbb{R}^d) = \mu(A)$ against a bounded continuous f on the first factor reads $\int f(x)\,\pi(\mathrm{d}x, \mathrm{d}y) = \int f\;\mathrm{d}\mu$, a condition of the form "π integrates this fixed bounded continuous function to this fixed value." Such conditions pass to weak limits by the very definition of weak convergence (definition 3.7): if $\pi_n \Rightarrow \pi$ and each π_n has first marginal μ, then $\int f\;\mathrm{d}\mu = \int f(x)\,\pi_n \to \int f(x)\,\pi$ for every bounded continuous f, so π has first marginal μ too, and likewise for ν. Hence $\Pi(\mu, \nu)$ is weakly closed, and the subsequential limit of any minimizing sequence is again a coupling.

Lower semicontinuity of the cost. The third rib needs the cost not to increase in the limit: along $\pi_n \Rightarrow \pi$ we want $\int |x - y|^2\;\pi \le \liminf_n \int |x - y|^2\;\pi_n$. The only obstacle is that $|x - y|^2$ is unbounded, so we cannot test against it directly — weak convergence only controls integrals of *bounded* continuous functions. The standard remedy makes the claim genuinely easy to see. Truncate the cost at height M by setting $g_M(x, y) = \min\big(|x - y|^2, M\big)$; each g_M is bounded and continuous, and the g_M increase pointwise to $|x - y|^2$ as $M \uparrow \infty$. For fixed M, weak convergence gives $\int g_M\,\pi_n \to \int g_M\,\pi$ outright. Since $|x - y|^2 \ge g_M$ pointwise, every term of the sequence obeys $\int |x - y|^2\;\pi_n \ge \int g_M\,\pi_n$, and taking lim inf on both sides yields $\liminf_n \int |x - y|^2\;\pi_n \ge \int g_M\,\pi$. This holds for every M; letting $M \uparrow \infty$ and applying the monotone convergence theorem to the right-hand side ($g_M \uparrow |x - y|^2$) gives $\int g_M\,\pi \uparrow \int |x - y|^2\;\pi$, whence $\liminf_n \int |x - y|^2\;\pi_n \ge \int |x - y|^2\;\pi$. (This truncate-and-pass-to-the-limit move is the content of the Portmanteau theorem's clause that a nonnegative lower semicontinuous integrand is weakly lower semicontinuous; we have just exhibited it explicitly rather than quoting it.)

Conclusion. Let $\pi_n \in \Pi(\mu, \nu)$ be a minimizing sequence, so $\int |x - y|^2\;\pi_n \to \mathcal{W}_2(\mu, \nu)^2$. By tightness and Prokhorov a subsequence converges weakly, $\pi_{n_k} \Rightarrow \pi^\star$; by closedness $\pi^\star \in \Pi(\mu, \nu)$; and by lower semicontinuity $\int |x - y|^2\;\pi^\star \le \liminf_k \int |x - y|^2\;\pi_{n_k} = \mathcal{W}_2(\mu, \nu)^2$. The reverse inequality holds because $\pi^\star$ is feasible, so the two are equal and $\pi^\star$ attains the infimum. Full detail is in [131, Thm. 4.1]. ☐

It is worth pausing on what made this work where Monge failed. The obstruction in the Monge problem was that the feasible *maps* formed a set too rigid to be compact — a limit of maps need not be a map. Couplings dissolve that rigidity: they form a tight, weakly closed, hence weakly compact subset of probability measures on the product space, precisely the setting the direct method demands. Relaxing from maps to plans bought us not only feasibility (the set is nonempty) but also the compactness that delivers a minimizer. From here on $\mathcal{W}_2(\mu, \nu)$ is a well-defined nonnegative real number, attained at an *optimal coupling* $\pi^\star$ whose existence we may now freely invoke.

Remark 4.4 (Why squared distance, and the family $\mathcal{W}_p$)**.** The squared cost is one choice in a family, and seeing the alternatives sharpens why we commit to it. For any exponent $p \ge 1$ one defines, on the space $\mathcal{P}_p$ of measures with finite p-th moment, the transport distance $\mathcal{W}_p(\mu,\nu)^p = \inf_\pi \int |x-y|^p \,\mathrm{d}\pi$; the existence proof above goes through verbatim, since it used only that the integrand is nonnegative, continuous, and coercive. The two cases that matter are $p=1$ and $p=2$, and they trade off cleanly. The exponent $p=1$ bills each shipment by the distance itself, $|x-y|$; this is the Monge–Kantorovich–Rubinstein distance, and its hallmark is a duality against 1-Lipschitz functions (the Kantorovich–Rubinstein formula), so $\mathcal{W}_1$ is the natural gauge whenever one only needs to control how much a Lipschitz observable can change between two populations. The exponent $p=2$ bills by the *squared* distance, and the squaring is exactly what injects Hilbert-space structure into the problem: the cost is a quadratic form in the displacement, optimal plans turn out to be carried by gradients of convex functions (Brenier, theorem 4.6 below), the natural interpolation is an L^2 geodesic, and the whole theory inherits the linear-algebraic comfort of inner products — none of which survives for a generic p. That Hilbertian backbone is why $p=2$ is the working choice of this book: it linearizes neatly on Gaussians (section 4.5) and it speaks the same quadratic language as the running costs of the control problems of chapter 6. The two exponents are not unrelated: Hölder's inequality applied to the optimal $\mathcal{W}_2$-coupling gives $\int |x-y| \;\pi^\star \le \left(\int |x-y|^2 \;\pi^\star\right)^{1/2}$, hence $\mathcal{W}_1(\mu,\nu) \le \mathcal{W}_2(\mu,\nu)$. Controlling $\mathcal{W}_2$ therefore automatically controls $\mathcal{W}_1$ but not conversely — $\mathcal{W}_2$-closeness is the *stronger* statement, which is the right way round for us, since every later contraction and continuity estimate is asked to deliver the more demanding bound.

We now have what the next two threads of the argument need. The distance $\mathcal{W}_2$ is a well-defined, finite, *attained* minimization problem over couplings. Two structural consequences follow, and the chapter pursues each in turn. First, the Kantorovich problem is a *linear program* — a linear functional of π minimized over the convex set $\Pi(\mu,\nu)$ cut out by linear marginal constraints — and every linear program has a dual; the next subsection extracts that dual and reads off from it the form of the optimal map. Second, the very existence of an optimal coupling, guaranteed by proposition 4.3, is the lever behind the metric axioms: the proof that $\mathcal{W}_2$ satisfies the triangle inequality (theorem 4.7) will *glue* two optimal couplings along a shared marginal, an operation that presupposes the optimal couplings exist to be glued. With the minimization now well posed and attained, we turn first to the duality.

4.1.3 Duality and the optimal map

The previous subsection handed us a $\mathcal{W}_2$ that is at last a fully legitimate object: by proposition 4.3 the infimum in (4.2) is finite and, crucially, *attained*, so $\mathcal{W}_2(\mu,\nu)$ is an honest nonnegative number realized by some optimal coupling $\pi^\star$. A well-posed minimization is an invitation to look at its dual, and here the invitation is irresistible, because the Kantorovich problem is not just any minimization: it is a *linear program*. The quantity being minimized, $\pi \mapsto \int |x-y|^2 \,\mathrm{d}\pi$, is *linear* in the unknown π; the feasible set $\Pi(\mu,\nu)$ is the intersection of the convex cone of nonnegative measures with the two *affine* marginal constraints $\pi(\cdot \times \mathbb{R}^d) = \mu$ and $\pi(\mathbb{R}^d \times \cdot) = \nu$. A linear objective over a convex set cut out by affine constraints is, by definition, a linear program, and every linear program has a companion — its dual — obtained by pricing the constraints. This is exactly the linearity that the rigid Monge problem of (4.1) did not have (its objective was quadratic in the map T), and it is the structural dividend of Kantorovich's relaxation that we now collect.

Two questions motivate the work. First, can we compute or bound $\mathcal{W}_2$ without ever exhibiting an optimal plan, working instead with cheaper, lower-dimensional objects? The dual answers yes: it re-expresses $\mathcal{W}_2(\mu,\nu)^2$ as a supremum over pairs of *functions* on $\mathbb{R}^d$ — the Kantorovich potentials — rather than measures on $\mathbb{R}^d \times \mathbb{R}^d$, and any admissible pair already furnishes a *lower* bound, the mirror image of the upper bounds that test couplings supplied in the last subsection. Second, and more important for us, what is the *form* of the optimal plan? The dual turns out to encode it: the potentials are the data from which Brenier's theorem will reconstruct an explicit optimal *map*. We care about the form, not merely the value, for two downstream reasons that the rest of the book will cash in. The potentials themselves are the analytic objects on which the Lasry–Lions monotonicity and uniqueness argument of chapter 11 operates — that argument tests a coupling against potentials of exactly this kind. And the optimal map is the raw material of geometry: it is what theorem 4.9 slides along to build displacement geodesics, and what section 4.5 guesses in closed form for Gaussians. We record both facts here, at the source.

Theorem 4.5 (Kantorovich duality)**.** *For $\mu,\nu \in \mathcal{P}_2(\mathbb{R}^d)$,*

$$\mathcal{W}_2(\mu,\nu)^2 \;=\; \sup\left\{\int_{\mathbb{R}^d} \varphi\ \mathrm{d}\mu + \int_{\mathbb{R}^d} \psi\ \mathrm{d}\nu \;:\; \varphi(x)+\psi(y) \le |x-y|^2 \text{ for all } x,y\right\}, \qquad (4.3)$$

the supremum taken over pairs (φ,ψ) of continuous functions of at most quadratic growth. The optimum is attained by a pair of Kantorovich potentials*, which may be taken to be c-conjugate to one another.*

The mechanism is convex duality, and it repays being run by hand, because watching the dual constraint *emerge* from the primal is what makes the formula intuitive rather than magical. We use the standard Lagrangian recipe: relax each equality constraint by introducing a multiplier and adding to the objective a term that rewards or penalizes its violation. Here the marginal constraints are not two scalar equations but two *continua* of them — $\pi(A\times\mathbb{R}^d)=\mu(A)$ is one equation for every Borel set A, equivalently $\int f(x)\ \mathrm{d}\pi = \int f\ \mathrm{d}\mu$ for every test function f — so the multiplier dual to each marginal is itself a *function* on $\mathbb{R}^d$, not a number. Call them φ (dual to the μ-marginal) and ψ (dual to the ν-marginal): one continuous function per marginal. Adjoining the two constraints to the cost with these multipliers gives the Lagrangian

$$\mathcal{L}(\pi;\varphi,\psi) \;=\; \int |x-y|^2\,\mathrm{d}\pi + \Big(\int \varphi\ \mathrm{d}\mu - \int \varphi(x)\ \mathrm{d}\pi(x,y)\Big) + \Big(\int \psi\ \mathrm{d}\nu - \int \psi(y)\ \mathrm{d}\pi(x,y)\Big),$$

where each parenthesized term vanishes precisely when the corresponding marginal constraint holds, so that on the feasible set $\mathcal{L}$ agrees with the transport cost. Regrouping the $\mathrm{d}\pi$-integrals collects the multiplier contributions into a single integrand,

$$\mathcal{L}(\pi;\varphi,\psi) \;=\; \int \varphi\ \mathrm{d}\mu + \int \psi\ \mathrm{d}\nu + \int \Big(|x-y|^2 - \varphi(x) - \psi(y)\Big)\,\mathrm{d}\pi(x,y),$$

and the dual function is obtained by minimizing this over all admissible π, now with the marginal constraints *dropped* and only $\pi \ge 0$ retained. The minimization is transparent term by term. The first two integrals do not involve π and pass through untouched. In the last integral π is free to place mass wherever it likes among nonnegative measures: if the bracket $|x-y|^2 - \varphi(x) - \psi(y)$ dipped below zero at even a single pair (x_0,y_0), we could pile arbitrarily much mass there and drive the integral, hence $\mathcal{L}$, to $-\infty$. A finite dual value therefore *requires* the bracket to be nonnegative everywhere,

$$\varphi(x) + \psi(y) \ \le\ |x-y|^2 \qquad \text{for all } x, y,$$

which is exactly the dual feasibility constraint in (4.3). And once that constraint holds, the cheapest choice is to put *no* mass where the bracket is strictly positive, leaving the last integral equal to zero; the Lagrangian then collapses to precisely

$$\int \varphi \,\mathrm{d}\mu + \int \psi \,\mathrm{d}\nu,$$

the dual objective. So the dual is born by a single clean move: free minimization over nonnegative π converts the soft penalty term into the hard pointwise constraint $\varphi + \psi \le |\cdot - \cdot|^2$ and erases the π-dependence entirely.

One half of (4.3) is now free. *Weak duality* — that the dual supremum never exceeds the primal infimum — needs no theory at all: for any feasible (φ, ψ) and any coupling $\pi \in \Pi(\mu, \nu)$, integrate the pointwise inequality $\varphi(x) + \psi(y) \le |x-y|^2$ against π and use the marginals to read off the left-hand side,

$$\int \varphi \,\mathrm{d}\mu + \int \psi \,\mathrm{d}\nu \ =\ \int \big(\varphi(x) + \psi(y)\big)\,\mathrm{d}\pi \ \le\ \int |x-y|^2 \,\mathrm{d}\pi.$$

Taking the supremum over (φ, ψ) on the left and the infimum over π on the right gives (dual sup) $\le$ (primal inf) $= \mathcal{W}_2(\mu, \nu)^2$. This already delivers the practical dividend advertised above: *every* admissible potential pair is a certified lower bound on $\mathcal{W}_2^2$, dual to the way every admissible coupling was an upper bound. The substantive content of the theorem is the *reverse* inequality — *strong* duality, the assertion that the gap is zero and the two optima meet. This is not automatic for infinite-dimensional linear programs; it is the conclusion of the Fenchel–Rockafellar duality theorem applied to this convex pair, whose engine is the Hahn–Banach separation of the convex value-function epigraph from a supporting hyperplane. We do not leave it on a citation: a complete, self-contained Hahn–Banach proof is given in appendix D.1, and the classical treatment is [131, Ch. 5]. The attainment of an optimal pair, and the fact that the two potentials may be taken c-conjugate (each recoverable from the other through the cost), come out of the same argument.

We now extract the form of the optimal plan, and the route is to undo the quadratic cost by completing the square. Expand the cost

$$|x-y|^2 \ =\ |x|^2 - 2\langle x, y\rangle + |y|^2\,,$$

so that the dual constraint $\varphi(x) + \psi(y) \le |x-y|^2$ reads $\varphi(x) + \psi(y) \le |x|^2 - 2\langle x, y\rangle + |y|^2$. The pure-quadratic pieces $|x|^2$ and $|y|^2$ depend on only one variable each, so they can be absorbed into the potentials. Define

$$\phi(x) \ =\ \tfrac{1}{2}\big(\,|x|^2 - \varphi(x)\big), \qquad \tilde{\phi}(y) \ =\ \tfrac{1}{2}\big(\,|y|^2 - \psi(y)\big);$$

substituting $\varphi(x) = |x|^2 - 2\phi(x)$ and $\psi(y) = |y|^2 - 2\tilde{\phi}(y)$, the $|x|^2$ and $|y|^2$ terms cancel from both sides and the constraint becomes, after dividing by -2 (which flips the inequality),

$$\langle x, y\rangle \ \le\ \phi(x) + \tilde{\phi}(y) \qquad \text{for all } x, y.$$

This is the defining inequality of a pair of *convex conjugates*: the tightest $\tilde{\phi}$ compatible with it is the Legendre transform $\phi^*(y) = \sup_x (\langle x, y\rangle - \phi(x))$, and at the optimal c-conjugate pair one has $\tilde{\phi} = \phi^*$ with ϕ convex. The quadratic cost has thus turned the Kantorovich potentials into a convex potential and its conjugate — and a convex potential is something we can differentiate. That observation is the whole content of the following structural theorem.

Theorem 4.6 (Brenier's theorem). *Let $\mu, \nu \in \mathcal{P}_2(\mathbb{R}^d)$ and suppose μ is absolutely continuous with respect to Lebesgue measure. Then:*

1. *there is a μ-almost everywhere unique optimal coupling for* (4.2)*, and it is induced by a map, i.e. $\pi^\star = (\mathrm{Id}, T)_\# \mu$;*
2. *this optimal map is the gradient of a convex function, $T = \nabla\phi$ with $\phi\colon \mathbb{R}^d \to \mathbb{R}$ convex, and it is the μ-a.e. unique map of gradient-of-convex form pushing μ to ν;*
3. *consequently the Monge infimum* (4.1) *equals the Kantorovich infimum* (4.2)*, and $\mathcal{W}_2(\mu, \nu)^2 = \int |x - \nabla\phi(x)|^2 \, \mathrm{d}\mu$.*

Proof sketch. Begin from the optimal Kantorovich potentials (φ, ψ) of theorem 4.5 and pass, as just above, to the convex potential $\phi(x) = \frac{1}{2}(|x|^2 - \varphi(x))$, so that dual feasibility becomes the Fenchel–Young inequality

$$\langle x, y\rangle \;\le\; \phi(x) + \phi^*(y) \qquad \text{for all } x, y, \tag{4.4}$$

with ϕ^* the Legendre transform. The key is that strong duality forces this inequality to be an *equality* exactly on the support of the optimal plan $\pi^\star$. Indeed, integrating (4.4) against $\pi^\star$ and using that (φ, ψ) and $\pi^\star$ are jointly optimal (no duality gap) makes the integrated inequality an equality; since the integrand $\phi(x) + \phi^*(y) - \langle x, y\rangle$ is everywhere nonnegative, an integral that vanishes forces it to vanish $\pi^\star$-almost everywhere. This is the complementary-slackness content of strong duality. Now recall the meaning of equality in Fenchel–Young: it is the *definition* of the subdifferential,

$$\langle x, y\rangle = \phi(x) + \phi^*(y) \quad\Longleftrightarrow\quad y \in \partial\phi(x),$$

where $\partial\phi(x)$ is the set of slopes of supporting hyperplanes to the graph of the convex function ϕ at x. So for $\pi^\star$-almost every pair (x, y) the second coordinate is a subgradient of ϕ at the first: the plan is carried by the (a priori multivalued) subdifferential map $x \mapsto \partial\phi(x)$.

It remains to collapse the multivalued $\partial\phi$ to a genuine single-valued map, and this is exactly where the hypothesis that μ be absolutely continuous earns its place. A finite convex function on $\mathbb{R}^d$ is locally Lipschitz, hence differentiable Lebesgue-almost everywhere by Rademacher's theorem; at every such point of differentiability the subdifferential shrinks to the single vector $\nabla\phi(x)$, and the exceptional set where ϕ has a genuine corner (and $\partial\phi(x)$ is a nontrivial set of slopes) is Lebesgue-null. Because μ is absolutely continuous, it assigns that Lebesgue-null exceptional set measure zero, so for μ-almost every x the subdifferential is the singleton $\{\nabla\phi(x)\}$ and the relation $y \in \partial\phi(x)$ becomes the equation $y = \nabla\phi(x)$. Hence $\pi^\star$ is concentrated on the graph of the single map $T = \nabla\phi$, i.e. $\pi^\star = (\mathrm{Id}, T)_\#\mu$, which is claim (i)–(ii); the cost identity in (iii) is then just the transport cost of this graph coupling, and the Monge–Kantorovich values coincide because a graph-supported plan *is* a map. Drop absolute continuity and this last step fails: if $\mu = \delta_{x_0}$ is a Dirac, the single source point may sit at a corner of ϕ where $\partial\phi(x_0)$ is a whole segment of admissible destinations, and the optimal plan genuinely splits — the very split-mass obstruction of eq. (4.1) reappears, which is why the density hypothesis is not a convenience but the precise dividing line, and why it is flagged Open in the ledger. Uniqueness is read off the same potential: any two optimal maps of gradient-of-convex form must both be subgradients of a Kantorovich potential pinned down (up to an additive constant) by the dual problem, so their gradients agree μ-a.e. and the maps coincide. The complete argument, including the regularity that makes the potentials of quadratic growth, is Brenier's [30]; see also [131, Thm. 2.12] and [117, Ch. 1]. □

Brenier's theorem is the rigorous vindication of Monge. Monge's deterministic dream — a single map that names each grain's destination — failed in general because a map cannot split mass; Kantorovich repaired the failure by relaxing to plans; and Brenier now closes the circle by saying that *when the source has a density the relaxation changes nothing*: the cheapest randomized plan is in fact deterministic, supported on the graph of an honest map, and that map is the gradient of a convex potential. A gradient of a convex function is the multidimensional analogue of a monotone increasing function on the line (in one dimension ϕ convex means $\phi' = T$ nondecreasing), so the optimal map is the correct higher-dimensional notion of a *monotone rearrangement* of μ into ν — the mass is shuffled in the order-preserving way, never folding back on itself.

This structural fact is the technique the rest of the chapter and the LQG thread inherit. Because optimality is guaranteed for *any* gradient-of-convex map pushing μ to ν, one can compute $\mathcal{W}_2$ by *guessing* such a map and verifying it transports correctly, with no separate optimality check — and the simplest guess is an affine map, which is the gradient of the quadratic $\phi(x) = \frac{1}{2}\langle x, Ax\rangle + \langle b, x\rangle$ when A is symmetric positive definite. This is exactly the move section 4.5 makes to pin down the Gaussian distance: it posits $T(x) = m_1 + A(x - m_0)$ precisely because Brenier certifies that a gradient-of-convex transport is optimal, reducing the whole computation to linear algebra on the covariance matrices. The convex potential ϕ itself, meanwhile, is the object the geometry is built on: theorem 4.9 interpolates μ toward ν by sliding each grain along the straight segment $x \mapsto (1-t)x + t\,\nabla\phi(x)$, turning the optimal map into the displacement geodesic that the next section promises. And the potentials (φ, ψ) are the same analytic objects on which the Lasry–Lions monotonicity argument of chapter 11 will operate. With the value of $\mathcal{W}_2$ certified finite and attained, and now its optimal plan exhibited as a gradient map, we have every structural fact the metric needs; the next section asks whether $\mathcal{W}_2$ truly deserves the name distance, and what its topology and its straight lines are.

4.2 The metric space $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$

The previous section left us with $\mathcal{W}_2$ as a genuine number — finite on $\mathcal{P}_2(\mathbb{R}^d)$, always attained by some optimal coupling, and, thanks to Brenier and Kantorovich duality, in the regular case realized by an honest transport map $T = \nabla\varphi$ pushing μ onto ν. That is enough to compute $\mathcal{W}_2(\mu, \nu)$ for any single pair, and it is exactly the input we now build on. But a number assigned to pairs is not yet a geometry. To run the mean field arguments of the later chapters we need to know that $\mathcal{W}_2$ organizes *all* of $\mathcal{P}_2(\mathbb{R}^d)$ into a space we can navigate: that "close in $\mathcal{W}_2$" is a coherent notion of nearness, that the space is large enough to support limiting arguments yet small enough to be handled, and that between any two laws there is a well-defined notion of a straight line. This section promotes $\mathcal{W}_2$ from a pairwise cost to a bona fide metric geometry, and it does so in three movements, each answering one of those needs and each cashed out later in the book.

First, the *metric axioms* (theorem 4.7): symmetry, nonnegativity, vanishing exactly on the diagonal, and — the one substantive point — the triangle inequality, which will follow by gluing optimal couplings through a common middle marginal and reading the result as Minkowski's inequality for a displacement random variable. This is the legitimacy step; without it the word "distance," and every estimate of the form $\mathcal{W}_2(\text{output of A}) \leq L\,\mathcal{W}_2(\text{input of A})$ that a contraction argument will lean on, would be empty. Second, the *topology*: we identify exactly what convergence in $\mathcal{W}_2$ means — weak convergence *plus* convergence of second moments, no more and no less — and show that $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ is *Polish*, that is, complete and separable. Completeness is what lets a Cauchy sequence of approximate population laws actually converge to a limit law inside the space, and separability gives the countable scaffolding behind compactness; together they are the standing hypotheses under which the existence theory of chapter 10 produces a mean field equilibrium as a genuine limit rather than a formal one. Third, the *geodesics*: we show that any two measures are joined by a constant-speed shortest path — the displacement interpolation $t \mapsto ((1-t)\,\mathrm{Id} + tT)_{\#}\mu$ traced along Brenier's optimal map — so that $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ is not merely a metric space but a geodesic one. These straight lines are the curves along which functionals will turn out to be convex, and that *displacement convexity* is the engine behind the uniqueness and stability arguments of chapters 11 and 12.

We take the three in that order, since each rests on the one before: the axioms make $\mathcal{W}_2$ a distance, the distance has a topology and a completion, and only on a complete metric space is it meaningful to ask whether shortest paths exist. We begin with the axioms, taking as given the existence of optimal couplings established in proposition 4.3.

4.2.1 The metric axioms

The umbrella to this section listed three things $\mathcal{W}_2$ must deliver before it can carry the geometry of the later chapters, and the very first — logically prior to any talk of topology or geodesics — was simply that $\mathcal{W}_2$ be a *distance* at all. That is the question we settle here. We have a nonnegative number $\mathcal{W}_2(\mu,\nu)$ attached to every ordered pair, finite on $\mathcal{P}_2(\mathbb{R}^d)$ and, by proposition 4.3, always realized by an optimal coupling $\pi^\star$; what we do not yet know is that this number behaves like a distance — that it is symmetric, that it vanishes *only* when the two measures coincide, and that it obeys the triangle inequality. The optimal couplings whose existence we fought to secure in section 4.1 are precisely the tool that makes all three checks go through, and the third one — the triangle inequality — is where they do their real work, through an operation called *gluing* that splices two optimal plans along the population they share.

Theorem 4.7 ($\mathcal{W}_2$ is a metric)**.** *$\mathcal{W}_2$ is a metric on $\mathcal{P}_2(\mathbb{R}^d)$: it is symmetric, finite, nonnegative, vanishes exactly on the diagonal, and satisfies the triangle inequality.*

Proof. The first four properties are quickly disposed of, and only the fifth has any content. Finiteness on $\mathcal{P}_2(\mathbb{R}^d)$ was established by the second-moment bound after definition 4.2. Symmetry is built into the cost: the reflection $(x, y) \mapsto (y, x)$ maps $\Pi(\mu, \nu)$ bijectively onto $\Pi(\nu, \mu)$ — it just swaps which marginal is called "source" and which "target" — and it leaves the integrand $|x-y|^2 = |y-x|^2$ untouched, so the two infima are equal and $\mathcal{W}_2(\mu, \nu) = \mathcal{W}_2(\nu, \mu)$. Nonnegativity is immediate from $|x-y|^2 \geq 0$. For vanishing on the diagonal, if $\mu = \nu$ then the *diagonal* coupling $\pi = (\mathrm{Id}, \mathrm{Id})_{\#}\mu$ — the law of the pair (X, X) for $X \sim \mu$, which places all its mass on $\{x = y\}$ — is admissible (both its marginals are μ) and costs $\int |x-x|^2 \, \mu(\mathrm{d}x) = 0$, so $\mathcal{W}_2(\mu, \mu) = 0$.

The converse — that $\mathcal{W}_2(\mu, \nu) = 0$ forces $\mu = \nu$ — is the point at which the *attainment* of the infimum earns its keep, and it is worth spelling out the step the skeleton draft compressed. Suppose $\mathcal{W}_2(\mu, \nu) = 0$. Because the infimum is attained (proposition 4.3), there is an actual optimal coupling $\pi^\star \in \Pi(\mu, \nu)$ with $\int |x-y|^2 \, \pi^\star(\mathrm{d}x, \mathrm{d}y) = 0$. An integral of the nonnegative function $|x-y|^2$ that vanishes forces the integrand to vanish $\pi^\star$-almost everywhere, so $\pi^\star$ is concentrated on the diagonal $\{x = y\}$: with probability one a sample $(X, Y) \sim \pi^\star$ has $X = Y$. But now the two marginals of $\pi^\star$ are the laws of X and of Y, and these are *the same random variable* (they agree almost surely), so they have the same law. The first marginal is μ and the second is ν by admissibility, hence $\mu = \nu$. This is the meaning of the terse phrase "the marginals of a diagonal measure coincide": a measure living on $\{x = y\}$ cannot tell its two coordinates apart, so its two marginals are one and the same.

The triangle inequality is the substantive axiom, and the difficulty it poses is concrete: $\mathcal{W}_2(\mu_1, \mu_2)$ comes with an optimal plan coupling μ_1 to μ_2, and $\mathcal{W}_2(\mu_2, \mu_3)$ with a separate optimal plan coupling μ_2 to μ_3, but $\mathcal{W}_2(\mu_1, \mu_3)$ asks for a plan coupling μ_1 directly to μ_3, and the two plans we hold do not obviously combine into one. The device that combines them is the *gluing lemma*: it manufactures, out of the two given plans, a single law on the *triple* product $(\mathbb{R}^d)^3$ that contains both as marginals, after which the intermediate variable can simply be forgotten. Let $\mu_1, \mu_2, \mu_3 \in \mathcal{P}_2(\mathbb{R}^d)$, let $\pi_{12} \in \Pi(\mu_1, \mu_2)$ be an optimal coupling and $\pi_{23} \in \Pi(\mu_2, \mu_3)$ an optimal coupling.

The two plans meet on μ_2, the law of the middle population, and that shared marginal is the hinge on which they are joined. To exploit it we *disintegrate* each plan over its μ_2-coordinate. Disintegration (the regular-conditional-distribution theorem on Polish spaces, theorem 3.33) says that a joint law can be sliced into its conditional laws: there is a measurable family $K_{12}(x_2, \mathrm{d}x_1)$, a probability measure on the first factor for μ_2-almost every x_2, that records the *conditional law of the source* x_1 *given that the middle point is* x_2, and reassembling these slices against μ_2 reconstructs π_{12}:

$$\pi_{12}(\mathrm{d}x_1, \mathrm{d}x_2) = \mu_2(\mathrm{d}x_2)\, K_{12}(x_2, \mathrm{d}x_1).$$

Likewise $\pi_{23}(\mathrm{d}x_2, \mathrm{d}x_3) = \mu_2(\mathrm{d}x_2)\, K_{23}(x_2, \mathrm{d}x_3)$, with $K_{23}(x_2, \mathrm{d}x_3)$ the conditional law of the target x_3 given the middle point x_2. Both kernels are anchored to the *same* variable x_2 distributed as μ_2, and that is what lets us run them side by side. Glue the two conditionals over the common middle by declaring x_1 and x_3 *conditionally independent given* x_2 — draw $x_2 \sim \mu_2$, then draw the source from $K_{12}(x_2, \cdot)$ and the target from $K_{23}(x_2, \cdot)$ independently — which is the measure on the triple product

$$\pi_{123}(\mathrm{d}x_1, \mathrm{d}x_2, \mathrm{d}x_3) \;=\; \mu_2(\mathrm{d}x_2)\, K_{12}(x_2, \mathrm{d}x_1)\, K_{23}(x_2, \mathrm{d}x_3).$$

This π_{123} is exactly engineered to carry both original plans inside it, which we now verify marginal by marginal. Integrating out x_3 uses $\int K_{23}(x_2, \mathrm{d}x_3) = 1$ (each conditional is a probability measure) and returns $\mu_2(\mathrm{d}x_2)\, K_{12}(x_2, \mathrm{d}x_1) = \pi_{12}$, so the $(1, 2)$ marginal of π_{123} is π_{12}. Symmetrically, integrating out x_1 uses $\int K_{12}(x_2, \mathrm{d}x_1) = 1$ and returns π_{23}, so the $(2,3)$ marginal is π_{23}. Finally the $(1,3)$ marginal, obtained by integrating out the middle variable x_2, is some measure $\pi_{13} \in \mathcal{P}(\mathbb{R}^d \times \mathbb{R}^d)$; its first marginal is the first marginal of π_{12}, namely μ_1, and its second marginal is the second marginal of π_{23}, namely μ_3, so $\pi_{13} \in \Pi(\mu_1, \mu_3)$ is a *legitimate* (if not necessarily optimal) coupling of the two end populations. The gluing has produced, out of two plans that did not directly meet, a single plan from μ_1 to μ_3.

It remains only to read off the inequality, and here is where the squared cost shows its hand. Regard x_1, x_2, x_3 as $\mathbb{R}^d$-valued random variables on the probability space $\left((\mathbb{R}^d)^3, \pi_{123}\right)$. The chain of inequalities is

$$\mathcal{W}_2(\mu_1, \mu_3) \;\le\; \|x_1 - x_3\|_{L^2(\pi_{123})} \;\le\; \|x_1 - x_2\|_{L^2(\pi_{123})} + \|x_2 - x_3\|_{L^2(\pi_{123})} \;=\; \mathcal{W}_2(\mu_1, \mu_2) + \mathcal{W}_2(\mu_2, \mu_3),$$

and each link deserves a word, because each carries part of the argument. The first inequality is the definition of $\mathcal{W}_2$ as an *infimum*: π_{13} is *a* coupling of μ_1 and μ_3, not in general the optimal one, so the cheapest cost $\mathcal{W}_2(\mu_1, \mu_3)^2$ cannot exceed the cost $\int |x_1 - x_3|^2 \, \pi_{123} = \|x_1 - x_3\|_{L^2}^2$ of this particular plan — we pay an honest price for using a suboptimal coupling, and the price is exactly what we can bound. The middle inequality is *Minkowski's inequality* (the triangle inequality for the $L^2(\pi_{123})$ norm) applied to the algebraic identity $x_1 - x_3 = (x_1 - x_2) + (x_2 - x_3)$: the displacement from source to target is the sum of the displacement source-to-middle and middle-to-target, and the L^2 norm of a sum is at most the sum of the norms. This is the single step that makes the whole inequality work, and it works *only* because the cost is a squared norm, so that $\mathcal{W}_2$ is an honest L^2-norm of a displacement to which Minkowski applies; a non-Hilbertian cost would have no triangle inequality to invoke here. The closing equality returns from the triple product to the original two-marginal problems: because the $(1,2)$ marginal of π_{123} is π_{12}, we have $\|x_1 - x_2\|_{L^2(\pi_{123})}^2 = \int |x_1 - x_2|^2 \, \pi_{12}$, and this equals $\mathcal{W}_2(\mu_1, \mu_2)^2$ precisely because π_{12} was chosen *optimal*; the same for π_{23} and $\mathcal{W}_2(\mu_2, \mu_3)$. Optimality of the two given plans is therefore not decorative — it is what turns the two L^2 norms back into the two distances we wanted on the right-hand side. $\square$

The Minkowski step repays a second look, because it explains a feature of $\mathcal{W}_2$ that will recur throughout the book: its distinctly *Euclidean flavor*. We have just seen that the triangle inequality for $\mathcal{W}_2$ is not proved by some measure-theoretic trick special to probability measures — it is literally the triangle inequality for the L^2 norm of the displacement random variable, transported up to the level of measures through the optimal couplings. The geometry of $\mathcal{P}_2(\mathbb{R}^d)$ inherits its shape from the geometry of L^2, and through L^2 from the inner-product geometry of $\mathbb{R}^d$ itself. This is the deep reason $\mathcal{W}_2$ will keep admitting Pythagorean-looking identities and quadratic expansions in the chapters ahead — it was built, one optimal coupling at a time, out of the Euclidean norm. The two computations that follow make that inheritance completely explicit on the simplest measures of all.

The first anchors $\mathcal{W}_2$ to the Euclidean distance it came from. Between two Dirac masses δ_a and δ_b there is only *one* coupling to choose from: any $\pi \in \Pi(\delta_a, \delta_b)$ must have first marginal δ_a and second marginal δ_b, which forces all its mass onto the single point (a, b), so $\Pi(\delta_a, \delta_b) = \left\{\delta_{(a,b)}\right\}$ is a singleton and there is nothing to optimize. Its cost is the cost of that lone shipment,

$$\mathcal{W}_2(\delta_a, \delta_b)^2 \;=\; \int_{\mathbb{R}^d \times \mathbb{R}^d} |x - y|^2 \, \delta_{(a,b)}(\mathrm{d}x, \mathrm{d}y) \;=\; |a - b|^2, \qquad \text{i.e.} \quad \mathcal{W}_2(\delta_a, \delta_b) = |a - b|. \tag{4.5}$$

The map $a \mapsto \delta_a$ therefore embeds $\mathbb{R}^d$ *isometrically* into $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$: distances between point masses are exactly the Euclidean distances between the points they sit on. The Wasserstein metric is a genuine extension of the underlying geometry of $\mathbb{R}^d$, with a faithful copy of ordinary space sitting inside the space of measures — precisely the property the squared cost was chosen to secure, as promised in the umbrella to section 4.1.

The second computation anchors the *ambient set.* Fix the reference point 0 and ask how far a general $\mu \in \mathcal{P}_2(\mathbb{R}^d)$ sits from the Dirac mass δ_0 there. Again the coupling is forced: any $\pi \in \Pi(\mu, \delta_0)$ has second marginal δ_0, so it is concentrated on $\{y = 0\}$ and can only be $\mu \otimes \delta_0$ — every grain of μ, wherever it sits, must be shipped to the one available destination 0. There is again nothing to optimize, and the cost is

$$\mathcal{W}_2(\mu, \delta_0)^2 \;=\; \int_{\mathbb{R}^d} |x - 0|^2 \; \mu(\mathrm{d}x) \;=\; \int_{\mathbb{R}^d} |x|^2 \; \mu(\mathrm{d}x). \tag{4.6}$$

The squared distance from μ to the origin Dirac is exactly the second moment of μ. This is the cleanest possible confirmation that $\mathcal{P}_2(\mathbb{R}^d)$ is the right ambient set: membership in $\mathcal{P}_2(\mathbb{R}^d)$ means finite second moment, and we have just learned that finite second moment means *finite $\mathcal{W}_2$-distance to a fixed reference point.* The defining membership condition of the space and finiteness of the metric to a basepoint are one and the same fact, so $\mathcal{P}_2(\mathbb{R}^d)$ is exactly the set of measures the geometry can reach — no smaller, no larger.

With theorem 4.7 the word "metric" is earned, and the identity (4.6) is more than a sanity check: it is the lever the next subsection turns. Having a legitimate distance, we can finally ask which sequences it declares convergent and whether the space is complete and separable. The Dirac identity $\mathcal{W}_2(\mu, \delta_0)^2 = \int |x|^2 \, \mathrm{d}\mu$ is precisely what lets us read second-moment information directly off $\mathcal{W}_2$: a $\mathcal{W}_2$-convergent sequence stays at bounded distance from δ_0, hence has uniformly controlled second moments, and this is the bridge by which $\mathcal{W}_2$-convergence will be shown to mean weak convergence *together with* convergence of second moments. We turn to that characterization, and to completeness and separability, next.

4.2.2 Completeness, separability, and the link to weak convergence

Having earned the name "metric," we can finally interrogate the geometry it generates: which sequences of laws does $\mathcal{W}_2$ declare convergent, and is the resulting space well enough behaved to host the limiting arguments the later chapters will run inside it? Two structural questions decide the matter. *Completeness* asks whether every sequence that ought to converge — every $\mathcal{W}_2$-Cauchy sequence — actually has a limit sitting inside $\mathcal{P}_2(\mathbb{R}^d)$, with no points missing from the space; without it no fixed-point iteration or approximation scheme could be trusted to land somewhere. *Separability* asks whether the space, uncountable though it is, can be approximated to arbitrary precision from a single countable list of laws. Together the two properties make $\mathcal{P}_2(\mathbb{R}^d)$ a *Polish* space, and that is the exact standing hypothesis the existence theory of chapter 10 is built on. But underneath both questions lies a more basic one we must settle first: what does it even *mean* for measures to converge in $\mathcal{W}_2$? The tool that unlocks this is already in our hands. The identity (4.6), $\mathcal{W}_2(\mu, \delta_0)^2 = \int |x|^2 \, \mathrm{d}\mu$, says that distance to the reference Dirac *is* the second moment, so any control on $\mathcal{W}_2$ immediately hands us control on second moments — and this, we will see, is precisely the surplus that separates $\mathcal{W}_2$-convergence from the weaker weak convergence of chapter 3.

Theorem 4.8 (Topology of $\mathcal{W}_2$)**.** *$(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ is a complete separable metric space. Moreover, for $\mu_n, \mu \in \mathcal{P}_2(\mathbb{R}^d)$,*

$$\mathcal{W}_2(\mu_n, \mu) \to 0 \quad \iff \quad \begin{cases} \mu_n \Rightarrow \mu \text{ (weak convergence, definition 3.7), and} \\ \int_{\mathbb{R}^d} |x|^2 \, \mu_n(\mathrm{d}x) \longrightarrow \int_{\mathbb{R}^d} |x|^2 \, \mu(\mathrm{d}x). \end{cases} \tag{4.7}$$

Equivalently, $\mathcal{W}_2$-convergence is weak convergence together with uniform integrability of the second moments.

The two topological claims are corollaries of the convergence characterization (4.7), so that is where the work goes. The characterization says something sharp and easy to misremember: $\mathcal{W}_2$-convergence is weak convergence *with one rider*, that the second moments converge to the *right* limit, not merely stay bounded. We prove the two implications separately, because they draw on genuinely different machinery — the forward direction on the representation theorem of chapter 3, the reverse on the duality of section 4.1 — and then read completeness and separability off the same ideas.

Proof sketch. Weak plus moments imply $\mathcal{W}_2$ (the implication $\Leftarrow$). Suppose $\mu_n \Rightarrow \mu$ with $\int |x|^2 \, \mathrm{d}\mu_n \to \int |x|^2 \, \mathrm{d}\mu$. The difficulty is one of language: weak convergence is a statement about integrals of *test functions*, whereas $\mathcal{W}_2(\mu_n, \mu)^2$ is the cost of an optimal *coupling*, and there is no test function in sight that we are allowed to feed the unbounded integrand $|x-y|^2$. Skorokhod's representation theorem (theorem 3.13) bridges exactly this gap by manufacturing one concrete coupling that already does most of the work: it produces, on a single probability space, random variables X_n with $\mathcal{L}(X_n) = \mu_n$ and X with $\mathcal{L}(X) = \mu$, such that the abstract weak convergence $\mu_n \Rightarrow \mu$ is realized as honest pointwise convergence, $X_n \to X$ almost surely. The joint law of (X_n, X) is a coupling of μ_n and μ, hence admissible in the Kantorovich problem (4.2), so it bounds the optimum from above:

$$\mathcal{W}_2(\mu_n, \mu)^2 \;\le\; \mathbb{E}\big[\, |X_n - X|^2 \,\big].$$

Everything now reduces to showing the right-hand side tends to 0. We already know $|X_n - X|^2 \to 0$ almost surely. The temptation is to pass the limit straight inside the expectation, but almost-sure convergence *never* licenses that on its own: the quantity $|X_n - X|^2$ could be large on an event of shrinking probability yet carrying non-vanishing expectation — mass leaking off to infinity. What forbids the leak is precisely the hypothesis we have not yet spent, the convergence of the second moments. The clean tool is the *Vitali convergence theorem*: almost-sure convergence upgrades to L^1 convergence exactly when the sequence is *uniformly integrable*, so it suffices to show that $\left\{|X_n - X|^2\right\}_n$ is uniformly integrable. Dominate it by the elementary bound $|X_n - X|^2 \le 2\,|X_n|^2 + 2\,|X|^2$; it is therefore enough that $\left\{|X_n|^2\right\}_n$ and the single variable $|X|^2$ be uniformly integrable. The latter is integrable, hence trivially uniformly integrable. For the former we cash in the saved hypothesis: $|X_n|^2 \to |X|^2$ almost surely and, by assumption, $\mathbb{E}\,|X_n|^2 \to \mathbb{E}\,|X|^2 < \infty$. A sequence of nonnegative random variables that converges almost surely and whose expectations converge to the (finite) expectation of the limit is automatically uniformly integrable — this is the converse half of the Scheffé / dominated-convergence circle of ideas. The intuition is exactly the no-leak picture: Fatou's lemma already forces $\mathbb{E}\,|X|^2 \leq \liminf \mathbb{E}\,|X_n|^2$, and demanding *equality* of the limits leaves no room for any second-moment mass to escape to infinity, which is what uniform integrability asserts. So $\left\{|X_n|^2\right\}$ is uniformly integrable, the dominating family $2\,|X_n|^2 + 2\,|X|^2$ is uniformly integrable, $\left\{|X_n - X|^2\right\}$ inherits it, and Vitali delivers $\mathbb{E}\,|X_n - X|^2 \to 0$, hence $\mathcal{W}_2(\mu_n, \mu) \to 0$. The moral worth carrying away — because the whole topology of $\mathcal{W}_2$ rests on it — is that *convergence of second moments is exactly the uniform integrability that almost-sure convergence was missing*: it is the precise quantum of tail control needed to move a limit past the integral sign.

$\mathcal{W}_2$ implies weak plus moments (the implication $\Rightarrow$). Now suppose $\mathcal{W}_2(\mu_n, \mu) \to 0$; we must extract both riders. For weak convergence, descend to the first-order distance. Hölder's inequality gave $\mathcal{W}_1 \leq \mathcal{W}_2$ (remark 4.4), so $\mathcal{W}_1(\mu_n, \mu) \to 0$ as well, and the Kantorovich–Rubinstein duality — the $p = 1$ dual recorded in remark 4.4, which tests against 1-Lipschitz functions — reads

$$\mathcal{W}_1(\mu_n, \mu) \;=\; \sup_{f \text{ 1-Lipschitz}} \Big(\int f \,\mathrm{d}\mu_n - \int f \,\mathrm{d}\mu \Big).$$

Thus $\mathcal{W}_1 \to 0$ forces $\int f \,\mathrm{d}\mu_n \to \int f \,\mathrm{d}\mu$ uniformly over all 1-Lipschitz f, in particular for every *bounded* Lipschitz f; and bounded Lipschitz functions are convergence-determining for the weak topology (the Lipschitz clause of the Portmanteau theorem of chapter 3), so $\mu_n \Rightarrow \mu$. For the second moments, play the reverse triangle inequality off the basepoint δ_0:

$$\big|\, \mathcal{W}_2(\mu_n, \delta_0) - \mathcal{W}_2(\mu, \delta_0) \,\big| \;\leq\; \mathcal{W}_2(\mu_n, \mu) \;\to\; 0,$$

so $\mathcal{W}_2(\mu_n, \delta_0) \to \mathcal{W}_2(\mu, \delta_0)$; squaring and invoking (4.6) turns this into $\int |x|^2 \,\mathrm{d}\mu_n \to \int |x|^2 \,\mathrm{d}\mu$. Both riders are in hand. Notice how lightly this direction runs: distance to a single fixed reference point already carries all the second-moment information — the entire payoff of the identity we paused to prove in the previous subsection.

Completeness. Let (μ_n) be $\mathcal{W}_2$-Cauchy; we must produce a limit lying in $\mathcal{P}_2(\mathbb{R}^d)$. A Cauchy sequence is bounded, so $D := \sup_n \mathcal{W}_2(\mu_n, \delta_0) < \infty$, and (4.6) reads this off as a uniform second-moment bound, $\sup_n \int |x|^2 \,\mathrm{d}\mu_n \leq D^2$. A uniform second-moment bound is exactly what Markov's inequality converts into tightness: for every $R > 0$,

$$\mu_n\big(\{|x| > R\} \big) \;\leq\; \frac{1}{R^2} \int |x|^2 \,\mathrm{d}\mu_n \;\leq\; \frac{D^2}{R^2},$$

which is below any prescribed ε once R is large, *uniformly in* n, and the closed ball $\{|x| \leq R\}$ is compact in $\mathbb{R}^d$. So $\{\mu_n\}$ is tight, and Prokhorov's theorem (theorem 3.16) extracts a weakly convergent subsequence $\mu_{n_k} \Rightarrow \mu$. This candidate limit lies in $\mathcal{P}_2(\mathbb{R}^d)$, because the second moment is weakly lower semicontinuous — truncate $|x|^2$ at height M, pass the bounded continuous truncation through the weak limit, then let $M \uparrow \infty$ by monotone convergence, the very move that gave lower semicontinuity of the cost in proposition 4.3 — so $\int |x|^2 \,\mathrm{d}\mu \leq \liminf_k \int |x|^2 \,\mathrm{d}\mu_{n_k} \leq D^2 < \infty$. It remains to promote this subsequential *weak* limit to a full $\mathcal{W}_2$ limit, and here the Cauchy property does work that mere existence of a cluster point cannot. The functional $(\alpha, \beta) \mapsto \mathcal{W}_2(\alpha, \beta)$ is itself lower semicontinuous under weak convergence of its two arguments (again the lower-semicontinuity-of-the-cost mechanism of proposition 4.3, now applied to a glued sequence of couplings). Fix $\varepsilon > 0$ and take N from the Cauchy property so that $\mathcal{W}_2(\mu_p, \mu_q) < \varepsilon$ whenever $p, q \geq N$. Hold $m \geq N$ fixed and let $k \to \infty$ in $\mathcal{W}_2(\mu_m, \mu_{n_k})$: since the constant sequence μ_m converges weakly to μ_m and $\mu_{n_k} \Rightarrow \mu$, lower semicontinuity gives

$$\mathcal{W}_2(\mu_m, \mu) \;\leq\; \liminf_k \mathcal{W}_2(\mu_m, \mu_{n_k}) \;\leq\; \varepsilon,$$

the last bound because $n_k \geq N$ eventually. As $m \geq N$ was arbitrary, $\mathcal{W}_2(\mu_m, \mu) \leq \varepsilon$ for all $m \geq N$; that is, $\mathcal{W}_2(\mu_m, \mu) \to 0$. The Cauchy sequence converges, and its limit belongs to the space, so $\mathcal{P}_2(\mathbb{R}^d)$ is complete.

Separability. We must exhibit a countable $\mathcal{W}_2$-dense set. The natural candidate is the collection $\mathcal{D}$ of finitely supported measures $\sum_{i=1}^N q_i \, \delta_{x_i}$ whose atoms sit at rational points ($x_i \in \mathbb{Q}^d$) and whose weights are rational and sum to one ($q_i \in \mathbb{Q}_{>0}$, $\sum q_i = 1$). There are only countably many finite rational point sets and countably many rational weight vectors, so $\mathcal{D}$ is countable. Density is a two-step approximation that the metric makes transparent, and both steps are again paid for by the second-moment bound. Given $\mu \in \mathcal{P}_2(\mathbb{R}^d)$ and $\varepsilon > 0$, first *amputate the tail*: because the total second moment is finite, $\int_{|x|>R} |x|^2 \, \mathrm{d}\mu \to 0$ as $R \uparrow \infty$, and transporting the outlying mass radially inward onto the ball B_R costs in $\mathcal{W}_2^2$ no more than that vanishing tail integral, so a compactly supported μ' lies within $\varepsilon/2$ of μ. Then *discretize*: partition B_R into finitely many cells of diameter below δ, place at a rational point inside each cell an atom of rational weight approximating the μ'-mass of that cell, and round the last weight so that the weights sum to one. The map carrying each cell's mass to its chosen rational representative moves no grain farther than δ, so the resulting rational measure sits within δ (plus a vanishing rounding error) of μ' in $\mathcal{W}_2$. Choosing δ and the rounding small enough puts it within $\varepsilon/2$ of μ', hence within ε of μ. Thus $\mathcal{D}$ is dense, and $\mathcal{P}_2(\mathbb{R}^d)$ is separable. Together with completeness this makes $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ a *Polish* space — the property theorem 4.8 advertises and chapter 10 requires. The fully detailed arguments, including the regularity behind the weak lower semicontinuity of $\mathcal{W}_2$ used above, are in [131, Thm. 6.9, Thm. 6.18]; see also [7, Prop. 7.1.5]. We have given the complete skeleton; only routine measure-theoretic bookkeeping has been deferred to those references. □

Notation watch: $\mathcal{W}_2$-convergence is strictly stronger than weak convergence

It is worth dwelling on the gap between the two convergences, because every later "continuity in $\mathcal{W}_2$" claim trades on it. Weak convergence and $\mathcal{W}_2$-convergence are *not* the same notion; $\mathcal{W}_2$ strictly refines it, and a single example exhibits the whole difference. Let

$$\mu_n \;=\; \Big(1 - \tfrac{1}{n}\Big)\delta_0 + \tfrac{1}{n}\,\delta_n,$$

a unit of mass nearly all parked at the origin, with a sliver of weight $1/n$ flung out to the far point n. Test it weakly against any bounded continuous f:

$$\int f \,\mathrm{d}\mu_n = \Big(1 - \tfrac{1}{n}\Big) f(0) + \tfrac{1}{n} f(n) \;\longrightarrow\; f(0),$$

because f is bounded and so the far term $\frac{1}{n} f(n)$ is at most $(\sup|f|)/n \to 0$. Hence $\mu_n \Rightarrow \delta_0$: to the weak topology the sequence simply settles onto the origin. But weigh it with $\mathcal{W}_2$. Its second moment is

$$\int |x|^2 \, \mathrm{d}\mu_n = \left(1 - \tfrac{1}{n}\right) \cdot 0 + \tfrac{1}{n} \cdot n^2 = n,$$

so by (4.6) we have $\mathcal{W}_2(\mu_n, \delta_0)^2 = n \to \infty$: not only does μ_n fail to $\mathcal{W}_2$-converge to δ_0, it runs off to *infinite* distance from it. The mechanism is exactly the one (4.7) predicts. The far atom's *mass* $1/n$ vanishes — and vanishing mass is all the weak topology, testing against bounded functions, can perceive — yet $\mathcal{W}_2$ bills by squared distance, so the product (mass) $\times$ (distance)^2 $= \frac{1}{n} \cdot n^2 = n$ grows without bound. $\mathcal{W}_2$ sees the mass escaping to infinity that weak convergence is structurally blind to. This is the geometric content of the second-moment rider in (4.7): it is precisely a *no-escape-of-mass-to-infinity* condition. The meta-lesson propagates through the entire book: whenever a later chapter asserts that a map or a functional is continuous "in $\mathcal{W}_2$," it is claiming *strictly more* than weak continuity, and the surplus is always the same thing — uniform control of the tails, the guarantee that no second-moment mass leaks away to infinity in the limit.

That $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ is Polish, together with the sharper reading of what $\mathcal{W}_2$-convergence controls, are exactly the structural facts the next two strands of the book stand on. The "why a mean field game lives here" discussion of section 4.3 will need a usable description of the *compact* sets in this space, and the proof above hands it over ready-made: combining theorem 4.8 with Prokhorov, a subset of $\mathcal{P}_2(\mathbb{R}^d)$ is $\mathcal{W}_2$-precompact precisely when it is *tight and* has *uniformly integrable second moments* — tightness keeping mass from spreading out and sliding off the support, uniform integrability keeping second-moment mass from escaping to infinity along the lines the example just dramatized. The contrast with the completeness argument is instructive and not accidental: tightness alone needed only *bounded* second moments via Markov, but genuine $\mathcal{W}_2$-precompactness, where the limit retains *all* of its second-moment mass, demands the strictly stronger uniform integrability. That two-part criterion is the hypothesis under which the Schauder and Kakutani fixed-point theorems of chapter 10 will produce a mean field equilibrium, so we have — without yet having defined the game — already isolated the compactness it will require. Completeness is the other handoff. Geodesics, the straight lines the chapter still owes, can only be built in a space where Cauchy sequences converge, since a displacement geodesic is constructed as a limit of ever-finer interpolations and must have somewhere to land. The final movement of this section now takes the optimal Brenier map of theorem 4.6 and slides mass along it to draw those straight lines (theorem 4.9), turning the complete metric space we have just secured into a genuine geodesic geometry.

4.2.3 Geodesics and displacement interpolation

The previous subsection secured the last structural fact a geometry of straight lines needs: $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ is complete, so Cauchy sequences have somewhere to land and a curve built as a limit of ever-finer interpolations cannot fall out of the space. We now spend that completeness. A metric space worthy of the name does more than measure distances; it tells us how to travel between two points along the shortest path, and the goal of this subsection is to exhibit those shortest paths for $\mathcal{W}_2$. The raw material is already in hand: the Brenier optimal map $T = \nabla\phi$ of theorem 4.6, which names, for each grain of μ_0, the single destination it should occupy in μ_1. Sliding each grain steadily toward its destination will draw the straight line — but only after we have understood why the *obvious* candidate for a straight line is the wrong one.

Fix the target to aim at. In any metric space, a *constant-speed geodesic* from μ_0 to μ_1 is a curve $[0,1] \ni t \mapsto \mu_t$ with endpoints μ_0 and μ_1 that satisfies

$$\mathcal{W}_2(\mu_s,\mu_t) \;=\; |t-s|\;\mathcal{W}_2(\mu_0,\mu_1) \qquad \text{for all } s,t \in [0,1].$$

The condition says exactly what "straight line traversed at constant speed" should mean: the distance covered between two times is proportional to the elapsed time, with the proportionality constant equal to the total length $\mathcal{W}_2(\mu_0,\mu_1)$. No detours (otherwise the distance between the endpoints would be strictly less than the length of the curve), and no loitering or sprinting (otherwise the speed would vary). A space in which *every* pair of points is joined by such a curve is called a geodesic space, and we are about to prove $(\mathcal{P}_2(\mathbb{R}^d),\mathcal{W}_2)$ is one.

The naive guess is to average the two measures pointwise, $t \mapsto (1-t)\mu_0 + t\mu_1$, and it is instructive precisely because it is *wrong*. The defect is conceptual, not technical: pointwise averaging *mixes* the two distributions rather than *transporting* one into the other. At an intermediate time t the measure $(1-t)\mu_0 + t\mu_1$ is a superposition that keeps a fraction $1-t$ of the mass sitting exactly where μ_0 left it and fades in a fraction t of the mass exactly where μ_1 wants it; no grain ever moves. The cleanest place to feel the failure is two Dirac masses. Take $\mu_0 = \delta_a$ and $\mu_1 = \delta_b$ with $a \neq b$, so that $\mathcal{W}_2(\delta_a,\delta_b) = |a-b|$ (the optimal plan has no choice but to carry the single atom from a to b). The linear interpolation is $\mu_t^{\mathrm{lin}} = (1-t)\delta_a + t\delta_b$, a measure with an atom of mass $1-t$ parked at a and an atom of mass t parked at b — a barbell whose two weights merely shift, never the locations. Its distance from the start is governed by the transport that must still carry the mass t stranded at b all the way back across the gap, giving $\mathcal{W}_2(\mu_0,\mu_t^{\mathrm{lin}})^2 = t\;|a-b|^2$, hence $\mathcal{W}_2(\mu_0,\mu_t^{\mathrm{lin}}) = \sqrt{t}\;|a-b|$. Compare this with the constant-speed requirement $\mathcal{W}_2(\mu_0,\mu_t) = t\;|a-b|$: the linear curve covers $\sqrt{t}$ of the distance in time t, far too much too early, and is emphatically not a geodesic. The transport picture is the correct one: a genuine straight line should pick up the atom at a and *glide* it to b, so that at time t it sits at the intermediate point $(1-t)a + tb$ as a single atom $\delta_{(1-t)a+tb}$ — and that curve does satisfy $\mathcal{W}_2(\mu_0,\mu_t) = t\;|a-b|$. Mixing splits the mass and keeps it pinned at the two ends; transporting moves the mass through the middle. McCann's construction is nothing but the systematic version of "glide each atom to its destination," with the Brenier map supplying the destinations.

Theorem 4.9 (McCann's displacement interpolation)**.** *Let $\mu_0,\mu_1 \in \mathcal{P}_2(\mathbb{R}^d)$ with μ_0 absolutely continuous, and let $T = \nabla\phi$ be the Brenier optimal map from μ_0 to μ_1 (theorem 4.6). For $t \in [0,1]$ set $T_t = (1-t)\,\mathrm{Id} + t\,T$ and $\mu_t = (T_t)_{\#}\mu_0$. Then $t \mapsto \mu_t$ is a constant-speed geodesic joining μ_0 to μ_1, and every $\mathcal{W}_2$-geodesic between two measures arises this way. In particular $(\mathcal{P}_2(\mathbb{R}^d),\mathcal{W}_2)$ is a geodesic space.*

Read the construction one grain at a time before reading the proof. The grain that starts at x is destined, by Brenier, for $T(x)$. The interpolating map $T_t = (1-t)\,\mathrm{Id} + tT$ places that grain, at time t, at $T_t(x) = (1-t)x + tT(x) = x + t\,(T(x) - x)$, which is exactly the point a fraction t of the way along the straight segment from x to $T(x)$. So T_t slides *every* grain simultaneously along its own straight segment, each at the constant velocity $T(x) - x$ and hence at the constant speed $|T(x) - x|$, the length of the segment it must cover in unit time. The interpolant $\mu_t = (T_t)_\# \mu_0$ is the snapshot of the whole population mid-glide. At $t = 0$, $T_0 = \mathrm{Id}$ and μ_0 is recovered; at $t = 1$, $T_1 = T$ and $\mu_1 = T_\# \mu_0$ is recovered, so the endpoints are right by construction. The content of the theorem is that this in-between curve is genuinely straight in $\mathcal{W}_2$.

Proof sketch. The whole verification rests on a single structural fact: the maps T_t are themselves optimal maps, so their transport cost *is* a squared Wasserstein distance and we may compute lengths by reading off displacements. To see it, fix $0 \le s \le t \le 1$ and ask for the map that carries the snapshot μ_s to the later snapshot μ_t. A grain occupying the position $T_s(x) = x + s\,(T(x) - x)$ at time s must occupy $T_t(x) = x + t\,(T(x) - x)$ at time t, so the map taking the former to the latter advances it by the fixed fraction $(t - s)/(1 - s)$ of its *remaining* segment: writing $y = T_s(x)$, the rearrangement sends $y \mapsto y + \frac{t-s}{1-s}\,(T(x) - T_s(x))$, the same direction $T(x) - x$ scaled down. This rearrangement is again a gradient of a convex function. Indeed each T_t is the gradient of $\phi_t(x) = (1-t)\frac{1}{2}\,|x|^2 + t\,\phi(x)$, a convex combination of the convex quadratic $\frac{1}{2}\,|x|^2$ (whose gradient is Id) and the Brenier potential ϕ (whose gradient is T); a convex combination of convex functions is convex, so ϕ_t is convex and $T_t = \nabla\phi_t$ is a gradient-of-convex map — this is the precise sense in which "the interpolant of gradients of convex functions remains a gradient of a convex function." The map from μ_s to μ_t is, up to the change of variables $y = T_s(x)$, the gradient of the corresponding interpolated potential, hence gradient-of-convex, hence *optimal* by the optimality half of Brenier's theorem (theorem 4.6: any gradient-of-convex map pushing one measure to another is the optimal one). Optimality is what lets us equate the transport cost of this map with $\mathcal{W}_2(\mu_s, \mu_t)^2$ rather than merely bounding it from above. Now compute that cost by pushing the displacement back to μ_0: the grain x moves from $T_s(x)$ to $T_t(x)$, a displacement of $T_t(x) - T_s(x) = (t - s)\,(T(x) - x)$, so

$$\mathcal{W}_2(\mu_s, \mu_t)^2 \;=\; \int_{\mathbb{R}^d} |T_t(x) - T_s(x)|^2\;\mu_0(\mathrm{d}x) \;=\; (t-s)^2 \int_{\mathbb{R}^d} |x - T(x)|^2\;\mu_0(\mathrm{d}x) \;=\; (t-s)^2\,\mathcal{W}_2(\mu_0, \mu_1)^2,$$

where the last equality is the Brenier cost identity for the endpoints (theorem 4.6(iii)). Taking square roots gives $\mathcal{W}_2(\mu_s, \mu_t) = (t - s)\,\mathcal{W}_2(\mu_0, \mu_1)$, which is exactly the constant-speed geodesic property. The converse — that every $\mathcal{W}_2$-geodesic is of this displacement form, so there are no exotic shortest paths we have missed — is the substance of McCann's theorem [101]; we give the argument in full in-book in appendix D.3, and the classical treatments are [131, Ch. 7] and [7, Ch. 7]. □

It is worth saying plainly what distinguishes the right curve from the wrong one, since the distinction is the whole pedagogical point. Linear interpolation $(1 - t)\mu_0 + t\mu_1$ averages the two measures *in the space of measures*; McCann's interpolation $(T_t)_\# \mu_0$ averages the two configurations *in the underlying space* $\mathbb{R}^d$, by moving each grain along a straight line there. The first is a fade between two photographs; the second is the motion the photographs are snapshots of. Only the latter respects the quadratic transport cost, because only the latter never pays to move mass it could have left in place.

This displacement geometry is not a curiosity collected for completeness; it is the form in which convexity enters every later stability argument. A functional $\mathcal{F}$ on $\mathcal{P}_2(\mathbb{R}^d)$ is called *displacement convex* when $t \mapsto \mathcal{F}(\mu_t)$ is convex along the geodesics μ_t just constructed — convex along the *transport* interpolation, not along the naive linear one, and the two notions genuinely differ. This is

McCann's notion, and it is the right one for us precisely because the maps in a mean field game move populations by transport. Displacement convexity of the coupling is what powers the Lasry–Lions monotonicity and displacement-monotonicity arguments that deliver uniqueness of the equilibrium in chapter 11, and it is the natural convexity in which the master equation of chapter 12 is well posed. We will meet the phenomenon in fully explicit form in section 4.5: the displacement interpolation between two Gaussians is again a Gaussian, its mean and covariance sliding affinely from one endpoint to the other, whereas the linear interpolation between two well-separated Gaussians is a two-bump mixture that is not even unimodal — the cleanest possible witness that mixing and transporting are different operations.

There is one more description of $\mathcal{W}_2$, dynamic rather than static, that completes the picture and earns the word "geodesic" a second, physical reading. So far we have built the shortest path by specifying *where each grain goes* (the Brenier map) and interpolating. The dynamic formulation instead specifies *how the whole density flows in time* and asks for the flow of least effort. Recasting $\mathcal{W}_2$ as such a least-action principle is valuable to us for a specific downstream reason: the constraint that bookkeeps a flowing density is the continuity equation $\partial_t\mu + \operatorname{div}(\mu v) = 0$, and that same equation is the one chapter 5 will derive — as the Fokker–Planck equation — for the population density of a mean field game. Seeing it appear here, as the constraint in a transport problem, is the first sighting of the conservation law the rest of the book runs on.

Theorem 4.10 (Benamou–Brenier dynamic formula)**.** *For $\mu_0, \mu_1 \in \mathcal{P}_2(\mathbb{R}^d)$,*

$$\mathcal{W}_2(\mu_0, \mu_1)^2 \;=\; \inf\left\{\int_0^1\!\!\int_{\mathbb{R}^d} |v_t(x)|^2 \; \mu_t(\mathrm{d}x)\; \mathrm{d}t\right\}, \tag{4.8}$$

the infimum over all curves $(\mu_t)_{t\in[0,1]}$ and velocity fields (v_t) solving the continuity equation $\partial_t\mu_t + \operatorname{div}(\mu_t v_t) = 0$ in the distributional sense, with endpoints μ_0, μ_1. The minimizing curve is the displacement geodesic of theorem 4.9; when μ_0 is absolutely continuous the interpolating map $T_t = (1-t)\operatorname{Id} + tT$ is invertible for every $t \in [0,1)$ (it is the gradient of a strictly convex function for $t < 1$), so the velocity field $v_t = (T - \operatorname{Id}) \circ T_t^{-1}$ is defined μ_t-a.e. along the geodesic; only the endpoint $t = 1$ may fail to be invertible, and it carries no mass of the time integral.

Two pieces of the statement deserve unpacking, because each is a small lesson in its own right. The first is the continuity-equation constraint $\partial_t\mu_t + \operatorname{div}(\mu_t v_t) = 0$. It is not an extra hypothesis imposed for convenience; it is exactly the statement that mass is conserved while it flows. If μ_t is the density of a population moving with velocity field v_t, then $\mu_t v_t$ is the flux — the rate at which mass crosses a surface — and the divergence theorem turns "no mass is created or destroyed, only transported" into the local balance $\partial_t\mu_t = -\operatorname{div}(\mu_t v_t)$. So the admissible curves in (4.8) are precisely the ones along which probability is shuffled around without leaking, and the formula reads: *$\mathcal{W}_2^2$ is the least total squared-speed an honest mass-conserving flow must spend to get from μ_0 to μ_1.* The second is the invertibility clause, which is the dynamic counterpart of "each grain glides along its own segment." To read off the velocity at a point z occupied at time t, we must know which grain is there, i.e. we must invert T_t to find its source $x = T_t^{-1}(z)$ and then assign it the velocity $T(x) - x = (T - \operatorname{Id})(x)$ it has carried since $t = 0$; this is the formula $v_t = (T - \operatorname{Id}) \circ T_t^{-1}$. The inversion is legitimate for every $t < 1$ because $T_t = \nabla\phi_t$ with $\phi_t = (1-t)\frac{1}{2}|\cdot|^2 + t\phi$ *strictly* convex (the $(1-t)\frac{1}{2}|\cdot|^2$ summand contributes a strictly positive curvature as long as $1 - t > 0$), and the gradient of a strictly convex function is injective. Only at the terminal instant $t = 1$ does the strict-convexity cushion vanish and $T_1 = T$ possibly fold mass together; but a single time-slice contributes nothing to the time integral $\int_0^1(\cdots)\,\mathrm{d}t$, so the velocity field is well defined exactly where it needs to be. The subtlety is real — the flow description can break at the very last instant — but it is harmless, and noting why is more honest than waving it away.

We do not reproduce the proof of (4.8) here; it is the Benamou–Brenier theorem [18], and we give a self-contained proof in-book in appendix D.4 (with the classical treatments in [131, Ch. 8] and [117, Ch. 6]). We record it because it recasts $\mathcal{W}_2$ as a least-action principle and because the continuity equation $\partial_t\mu + \operatorname{div}(\mu v) = 0$ is exactly the conservation law that governs the population density in a mean field game.

Physics note

The Benamou–Brenier formula is the only place in this chapter where a physical reading genuinely earns its keep, so we develop it once, carefully, and then put it down. Read μ_t as the time-dependent density of a fluid and v_t as its Eulerian velocity field — the velocity measured at a fixed point in space, not following a particular parcel. Then $\int |v_t|^2\,\mathrm{d}\mu_t$ is the integral of (speed^2) against mass, which is *twice* the kinetic energy $\frac{1}{2}\int |v_t|^2\,\mathrm{d}\mu_t$ of the fluid at the instant t, and the double integral $\int_0^1 \int |v_t|^2\,\mathrm{d}\mu_t\,\mathrm{d}t$ is the time-integrated kinetic energy — the *action* of a pressureless fluid flow (no internal energy, no pressure term, only inertia) that carries μ_0 to μ_1. Equation (4.8) then says that $\mathcal{W}_2^2$ is the *minimal action* over all such flows, the least-effort way to rearrange the fluid; and the continuity equation $\partial_t\mu + \operatorname{div}(\mu v) = 0$ is, as above, mass conservation. The least-action flow has a vivid shape: every parcel travels in a straight line at constant velocity — free transport, no acceleration, no forces — which is the fluid-dynamical face of the word "geodesic" and matches grain-by-grain the McCann picture of theorem 4.9. This is, moreover, the *same* continuity equation that chapter 5 obtains as the Fokker–Planck equation for a population of diffusing agents; the only difference is the provenance of the velocity field — there it is generated by the agents' drift and diffusion, here it is chosen to minimize action. That shared form is why the analogy is worth one paragraph. But the analogy ends at exactly this boundary, and it is important to flag it: $\mathcal{W}_2$ is a *geometry*, a way of measuring how far apart two laws are, not a *dynamics* prescribing how a law must evolve. The fluid is a heuristic for reading the formula, and nothing in the mathematics below — no metric axiom, no compactness statement, no later existence or uniqueness argument — depends on the fluid picture being taken literally.

With displacement geodesics constructed and the dynamic formula in hand, the geometry promised in the chapter's umbrella is complete: $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ is a complete, separable, geodesic metric space whose convergence is weak convergence plus second moments and whose straight lines transport mass rather than mix it. We hand three things forward. To section 4.3 we hand the finished arena — with this section's geodesics joining the Polish structure and the compactness criterion of the previous one — so that the standing promise of the chapter preamble, that a mean field game is naturally posed in exactly this space, can finally be made good and the need for the metric (not merely the topology) named precisely. To chapter 5 we hand the continuity equation $\partial_t\mu + \operatorname{div}(\mu v) = 0$, which reappears there as Fokker–Planck. And to chapter 11 and chapter 12 we hand displacement interpolation itself, the curve along which the displacement convexity behind Lasry–Lions monotonicity and the master equation is measured. The concrete payoff of all of this — displacement interpolation between Gaussians staying Gaussian while linear interpolation loses even unimodality — waits for us in section 4.5.

4.3 Why mean field games live in $\mathcal{P}_2(\mathbb{R}^d)$

The previous section finished assembling the geometry the chapter set out to build: by theorem 4.8 and theorem 4.9, $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ is a complete, separable, geodesic metric space — a finished arena. The chapter preamble promised that a mean field game would turn out to be naturally posed in exactly this arena, and that the metric — not merely the underlying topology — would be the structure every later existence and uniqueness argument leans on. We can now make that promise good. The game itself is constructed only in chapter 8 and chapter 9, so everything here remains deliberately informal: we are not yet defining an equilibrium, only explaining, in three movements, why the space we have built is the one the definition will need. The first movement says what the mean field *is* — a single point of $\mathcal{P}_2(\mathbb{R}^d)$. The second says what the strategic problem *does* — it turns that point into another point, through a map of the space to itself. The third says why the *metric*, and not just the topology, is what makes that map analyzable, and it untangles the two Lipschitz hypotheses that the rest of the book will lean on but that are perpetually confused with one another.

The mean field is a point. Begin with the finite system the game will be an idealization of. Imagine N agents who are *exchangeable* — interchangeable in their dynamics and costs, distinguished only by their states $X_1, \dots, X_N \in \mathbb{R}^d$ — and suppose, as is the defining structural assumption of a mean field model, that no single agent feels the others individually: each agent's cost and dynamics depend on the rest of the population only through the *statistics* of where everyone is, never through the names attached to the positions. The object that records exactly those statistics, and discards exactly the names, is the *empirical measure*

$$\mu^N = \tfrac{1}{N} \sum_{i=1}^{N} \delta_{X_i}$$

introduced in chapter 1 and chapter 3: it places a lump of mass $1/N$ at each occupied state, so that asking "what fraction of agents sit in the region A?" is answered by $\mu^N(A)$, and the labelling of agents has been forgotten. Two features of this object are worth saying out loud, because together they are the whole point of the movement. First, the empirical measure is *one element of* $\mathcal{P}_2(\mathbb{R}^d)$: it is a bona fide probability measure, and it has finite second moment $\int |x|^2 \ \mu^N(\mathrm{d}x) = \frac{1}{N} \sum_i |X_i|^2$ as soon as the finitely many states are finite, so it is a genuine point of the metric space built above, not a list of N numbers. A configuration of a hundred agents and a configuration of a million agents are, in this view, both just points of the same space, comparable by the same $\mathcal{W}_2$ ruler. Second, as $N \to \infty$ this point stops fluctuating: under the propagation-of-chaos mechanism developed in chapter 7, when the agents become asymptotically independent and identically distributed the random empirical measure μ^N converges to a *deterministic* limit $m \in \mathcal{P}_2(\mathbb{R}^d)$, the *mean field* — the smooth population law that the cloud of N atoms is sampling.

What makes $\mathcal{W}_2$ — rather than the bare weak topology of chapter 3 — the right gauge for this convergence is that $\mathcal{W}_2$ measures precisely the two things one needs controlled at once. When the X_i are i.i.d. draws from m with finite second moment, the law of large numbers in the space of measures gives $\mathcal{W}_2(\mu^N, m) \to 0$ almost surely, and by theorem 4.8 this single statement unpacks into the conjunction of *two* convergences: the empirical distribution converges weakly to m (the right fraction of mass accumulates in every region), *and* its second moment $\frac{1}{N}\sum_i |X_i|^2$ converges to $\int |x|^2\,\mathrm{d}m$ (no mass quietly leaks out to infinity). The second clause is not a technicality one could drop. It is exactly the failure mode the weak topology cannot see: a sequence can converge weakly while a vanishing fraction of its mass runs off to infinity carrying a diverging amount of "energy" $|x|^2$ — think of $(1-\frac{1}{N})m + \frac{1}{N}\delta_{Ne_1}$, weakly indistinguishable from m in the limit yet with a second moment that blows up like N. A mean field game prices agents by quadratic-type costs and couples them through moments of the population, so a notion of "the population is close to m" that tolerates this leakage is useless: the cost would not converge. $\mathcal{W}_2$-closeness forbids the leakage by construction, which is why it, and not weak convergence alone, is the convergence in which propagation of chaos is correctly stated. This is the precise content of the Appendix-A slogan that *the mean field is a point in $\mathcal{P}_2(\mathbb{R}^d)$, not a list of agents*: the limiting object of the N-agent system is a single point of the very metric space we have just finished building, and the metric we put on that space is the one under which the finite systems actually converge to it.

Best response is a map $\mathcal{P}_2(\mathbb{R}^d) \to \mathcal{P}_2(\mathbb{R}^d)$. With the population identified as a point of $\mathcal{P}_2(\mathbb{R}^d)$, the strategic content of the game becomes a statement about a *map* of that space to itself, and it is worth tracing the loop slowly because the rest of Part II is the study of this map. Freeze a candidate population law $m \in \mathcal{P}_2(\mathbb{R}^d)$ — in the time-dependent problem, a whole flow $t \mapsto m_t$ of such laws — and hand it to a single *representative agent* as a fixed feature of her environment: she treats m as given, as though the rest of the world were already settled into that law and would not react to what she does (legitimate in the limit, because one agent among infinitely many has no individual effect on the aggregate). Against this frozen background she solves an honest *optimal control problem* of the kind built in chapter 6: she chooses her control to minimize a cost whose coefficients — her drift b, her volatility σ, her running cost L — depend on m. That optimization returns an optimal feedback, propagating her state forward under it produces a stochastic process, and that process has, at each time, a *law*. Collecting those laws is the output measure (or flow of measures). The assignment of this output to the input m is the *best-response map*

$$\mathsf{S}\colon \mathcal{P}_2(\mathbb{R}^d) \longrightarrow \mathcal{P}_2(\mathbb{R}^d), \qquad m \longmapsto \mathsf{S}(m) = \mathcal{L}\big(\text{optimally controlled state under } m\big).$$

The loop closes on itself: we began with a population law, let a representative agent optimize against it, and read off the law her optimal behaviour generates — another population law. A *mean field equilibrium* is a population at which the loop is stationary, a fixed point $m^\star = \mathsf{S}(m^\star)$: a law that reproduces itself when every agent best-responds to it, so that the environment each agent optimized against is exactly the environment their collective optimal behaviour creates. (In the LQG thread of section 4.5, chapter 6 and chapter 8 this loop becomes wholly explicit and stays inside one family: freeze a Gaussian m with mean $\bar{m}$, the agent's optimal feedback is linear, the controlled state stays Gaussian, and $\mathsf{S}(m)$ is again Gaussian — so the fixed-point equation collapses to a coupled system of ordinary differential equations for the mean and the covariance.)

There is a genuine and useful analogy here to the self-consistent field of mean-field statistical mechanics, where one posits an average field, lets each particle respond to it, and demands that the averaged response reproduce the field one started from — and it is the same fixed-point shape, field $\mapsto$ response $\mapsto$ field. But the analogy must be drawn with its crucial difference flagged, the difference Part II returns to repeatedly: in statistical mechanics the field is fixed by a *thermal average*, each particle settling into the Boltzmann weight of the ambient field, whereas here the field is fixed by an *optimization*, each agent settling into the strategically best response to it. The self-consistency is the same; the mechanism that closes it is averaging in one case and *rational best response* in the other, and that replacement of an average by an argmin is what makes mean field game equilibria capable of the multiplicity and the symmetry-breaking phenomena studied later. We do not press the analogy further now — the game is not yet defined — but the structural lesson is the one this section exists to deliver: *equilibrium is a fixed point of a self-map of* $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$.

Why the metric, and not just the topology. A fixed point of a self-map is exactly the kind of object the metric, and not merely the topology, is needed to locate. To prove that S has a fixed point at all, and that in good cases it has only one, we need quantitative control of how S moves points around, and "quantitative" means metric: we must measure $\mathcal{W}_2$-distances between populations and estimate how S stretches them. There are two classical routes to a fixed point, and the metric enters each in a different but equally essential way.

The first route is *existence by topological fixed-point theorem.* The Schauder and Kakutani theorems invoked in chapter 10 guarantee a fixed point of a continuous self-map provided it is run on a *compact, convex* domain — intuitively, the map must shuffle points around inside a set small enough that it cannot escape to the boundary, so that continuity forces a point to land on itself. Convexity of subsets of $\mathcal{P}_2(\mathbb{R}^d)$ is cheap (linear mixtures of measures are measures). Compactness is the substance, and here the metric does the work: the relevant compactness is $\mathcal{W}_2$-compactness, which theorem 4.8 characterized concretely as *tightness together with uniform integrability of the second moments.* That second clause is again the no-leakage condition, now imposed uniformly over a whole family of candidate populations, and it is exactly what a weak-topology compactness statement would omit and what an existence proof cannot do without. So the very hypothesis that powers the existence theorems of Part II is a metric statement about $\mathcal{P}_2(\mathbb{R}^d)$ that the bare topology cannot phrase.

The second route is *uniqueness*, and it splits into the two mechanisms the chapter preamble named. One is the Lasry–Lions monotonicity of chapter 11 — the standing assumption (A-Mon) on the couplings — which forces any two equilibria to coincide by a convexity argument run along the displacement geodesics of theorem 4.9; that this argument is even *phrased* along geodesics is already a debt to the metric geometry of this chapter. The other, available in the more favourable regime, is a genuine *contraction estimate*

$$\mathcal{W}_2(\mathsf{S}(m), \mathsf{S}(m')) \;\le\; L\, \mathcal{W}_2(m, m'), \qquad L < 1,$$

which makes S a contraction of the complete metric space $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ and hands its unique fixed point straight to the Banach theorem. A contraction estimate is unthinkable without a metric on both sides of the inequality: it is, letter for letter, a statement that S shrinks $\mathcal{W}_2$-distances, and there is no weaker topological surrogate for it. This is the sharpest form of the chapter's thesis that we need the geometry and not just the topology.

Both the existence and the contraction routes ask the same thing of the data — that S depend continuously, and quantitatively, on its argument m — and meeting that demand requires two *distinct* kinds of regularity that are perpetually conflated. It is worth separating them cleanly here, at the seam where the metric is introduced, since the confusion they cause is the single most common seam error in the subject. The first is the standing assumption (A-Lip) of appendix A.6: the drift b, the volatility σ, and the running cost L are Lipschitz *in the state* variable, uniformly in time and in the measure argument. This is a statement about how the data of a *single* agent's control problem vary as her *own* state moves, with the population held fixed; it is what makes the control problem of chapter 6 well-posed in the first place (unique solution of the state equation, a Lipschitz value function), and it says nothing whatever about the measure. The second — the one the metric of this chapter was built to express — is a Lipschitz dependence *in the measure argument itself*, measured in $\mathcal{W}_2$:

under (A-LipM) (measure-Lipschitz dependence), there is a constant C with

$$\big|b(x,m)-b(x,m')\big| \le C\,\mathcal{W}_2(m,m'), \qquad \text{and likewise for } \sigma \text{ and } L,$$

uniformly in the state and time variables.

(A-LipM) is a genuinely separate hypothesis from (A-Lip), and the cleanest way to feel that neither implies the other is to watch each hold while the other is vacuous. Take a drift $b(x,m)=\sin x$ that ignores the population entirely: it is Lipschitz in x, so (A-Lip) holds, while its dependence on m is constant, so (A-LipM) holds trivially with $C=0$ — the state-Lipschitz bound certifies nothing about populations because there is no population dependence to certify. Now take instead a drift $b(x,m)=\bar{m}:=\int y\,m(\mathrm{d}y)$ that depends *only* on the population mean: it is constant in x, so (A-Lip) is again trivial, yet its measure dependence is the whole story, and it satisfies (A-LipM) precisely because the mean is a $\mathcal{W}_2$-Lipschitz functional, $|\bar{m}-\bar{m}'|\le \mathcal{W}_2(m,m')$. The two assumptions constrain variation in *orthogonal* arguments — one across an agent's own states with the crowd frozen, the other across crowds with the state frozen — and a bound in one direction is silent about the other. One can even break (A-LipM) while keeping (A-Lip) by letting the data depend on m through a non-$\mathcal{W}_2$-Lipschitz statistic; then the control problem is well-posed for each fixed population but its solution need not vary continuously as the population is perturbed in $\mathcal{W}_2$, and S can fail to be continuous — exactly the failure that wrecks both routes to a fixed point.

It is therefore (A-LipM), and not (A-Lip), that makes the representative agent's control problem depend continuously on m, and hence (A-LipM) that delivers the continuity of S in $\mathcal{W}_2$ on which Schauder and Kakutani depend and the contraction constant L which Banach turns into uniqueness; it is invoked explicitly in the arguments of chapters 8, 10 and 11. The metric is, in the end, not a luxury layered on top of the topology but the structure those arguments are written in: every continuity and every contraction statement about the best-response map of a mean field game is an inequality between $\mathcal{W}_2$-distances, and the entire fixed-point apparatus of Part II would have nothing to grip without it.

This is the resolution of the chapter's standing promise. But it also exposes the next gap. The data of the game — the drift, the cost, the coupling — are not points of $\mathcal{P}_2(\mathbb{R}^d)$ but *functionals* of such a point, depending on the *whole* measure m. The metric tells us when two populations are close and how a map between them stretches distances; it does not yet tell us how to take a derivative in the measure argument. Supplying that missing calculus — in fact the two complementary derivatives the subject uses — is the business of the next section.

4.4 Differentiating functionals of a measure

The previous section ended by exposing a gap the metric alone cannot close, and naming it is the cleanest way to open this one. The data of a mean field game — the running cost, the value, the coupling — are not points of $\mathcal{P}_2(\mathbb{R}^d)$ but *functionals* of such a point: a scalar cost $F(m)$, a value u that depends on the whole population law, a coupling $G[m]$. The geometry built in the previous sections tells us when two such populations are close and how far a map between them can stretch their distance, and the named assumption (A-LipM) pins down the crude first-order variation of these functionals in $\mathcal{W}_2$. But to linearize the best-response map, to run the chain rule that converts a fixed-point equation into a differential equation, and above all to derive the master equation of chapter 12, we need genuine *calculus*: a way to differentiate a number that depends on a measure with respect to that measure. Supplying that calculus is the second pillar this chapter erects, standing beside the metric, and every existence, uniqueness, and master-equation argument later in the book silently rests on both.

There are two ways to perturb a probability measure at first order, and they give two genuinely different derivatives. One can *add* an infinitesimal sliver of mass at a point x — and, to keep the total mass equal to one, remove an equal sliver elsewhere; the first-order response of F to this is the *flat*, or linear functional, derivative $\frac{\delta F}{\delta m}(m, x)$, a scalar field over $\mathbb{R}^d$. Or one can *move* the mass that is already present, nudging each grain a little along a vector field; the first-order response to this is the *Lions* derivative $\partial_\mu F(m)(x)$, a vector field over $\mathbb{R}^d$ telling each grain which way it is worth being pushed. The distinction is not bookkeeping pedantry; it is forced on us by the dynamics. A stochastic flow X_t transports the population law $m_t = \mathcal{L}(X_t)$ by *moving* mass along trajectories, never by creating or destroying it, so the Itô formula for a functional $F(m_t)$ of such a flow — the chain rule from which the master equation is assembled — is necessarily written through the move-mass derivative, the Lions derivative; the add-mass derivative answers a different, static question and is the wrong tool there. Yet the two derivatives are not independent. As we will prove, the Lions derivative is exactly the spatial *gradient* of the flat derivative, $\partial_\mu F(m)(x) = \nabla_x \frac{\delta F}{\delta m}(m, x)$, so the scalar "energy" field and the vector "force" field are two readings of a single object. That gradient relation is the bridge between the two subsections below, and it is what lets a physicist import the entire apparatus from a place he already knows it: the first derivative is the density-functional first variation $\delta E/\delta \rho$ he has computed many times, and the Fréchet differentiability the second one rests on is recalled in place, in definition 4.14, so the development here stands on its own. We take the flat derivative first, on the density-functional on-ramp.

4.4.1 The flat derivative, via the density-functional analogy

We promised in the umbrella to this section that a physicist already owns the first of the two derivatives, and we now cash that promise. The opening move is the simpler of the two perturbations: hold the population in place and *add* an infinitesimal sliver of mass at a point, asking how the functional responds. This is precisely the question a condensed-matter reader answers every time he varies an energy functional with respect to a density, and the flat derivative will turn out to be the optimal-transport name for the object he calls $\delta E/\delta\rho$. So rather than define the flat derivative from nothing, we begin on the density-functional on-ramp, transcribe the familiar first variation, and then make explicit the single bookkeeping subtlety — mass conservation — that distinguishes a probability measure from a general density.

Heuristic (non-rigorous): The on-ramp: density-functional derivatives

A condensed-matter reader has differentiated functionals of a density many times. In density-functional theory one writes an energy $E[\rho]$ as a functional of an electron density $\rho(x)$ and asks how it responds when the density is nudged by a small profile η in a fixed direction, with strength ϵ. The first-order response defines the functional derivative $\delta E/\delta\rho(x)$ through

$$E[\rho + \epsilon\,\eta] - E[\rho] \;=\; \epsilon \int \frac{\delta E}{\delta \rho}(x)\,\eta(x)\;\mathrm{d}x + o(\epsilon).$$

Read this as the statement that, to first order in ϵ, the change in the energy is a *linear* functional of the perturbation η, and the kernel of that linear functional — the weight $\delta E/\delta\rho(x)$ attached to a sliver of mass deposited at x — is the derivative. It is therefore itself a *function of position*, a field over configuration space rather than a single number: it reports, location by location, the marginal energetic price of adding mass there. Physically it is the field thermodynamically conjugate to the density — a local chemical potential — and that is the right mental image to carry: the flat derivative will be the conjugate field to the population law, the landscape of marginal costs that the population feels.

The flat derivative of a functional on $\mathcal{P}_2(\mathbb{R}^d)$ is exactly this object, with one bookkeeping subtlety forced by the constraint that we perturb a *probability* measure, not an arbitrary density. To stay inside $\mathcal{P}_2(\mathbb{R}^d)$ the perturbed object $m + \epsilon\eta$ must again be a probability measure, so the sliver η may not change the total mass: it must integrate to zero, $\int \eta\;\mathrm{d}x = 0$. The honest way to produce such an η is to take it to be the difference $\eta = m' - m$ of two probability measures, which automatically has total mass $1 - 1 = 0$ — adding a little mass somewhere is paid for by removing an equal amount elsewhere. The consequence is that the derivative $\delta F/\delta m(x)$ is only ever *tested against zero-mean perturbations*, and a function tested only against zero-mean weights cannot detect a constant added to itself. The flat derivative is therefore defined only up to an additive constant. Everything past this one subtlety is the DFT computation the reader already knows.

Definition 4.11 (Flat / linear functional derivative)**.** A functional $F\colon \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}$ has a *flat derivative* (linear functional derivative) if there is a continuous map $\frac{\delta F}{\delta m}(\cdot,\cdot)\colon \mathcal{P}_2(\mathbb{R}^d) \times \mathbb{R}^d \to \mathbb{R}$, of at most quadratic growth in x locally uniformly in m, such that for all $m, m' \in \mathcal{P}_2(\mathbb{R}^d)$,

$$F(m') - F(m) \;=\; \int_0^1\!\!\int_{\mathbb{R}^d} \frac{\delta F}{\delta m}(m_s, x)\,(m' - m)(\mathrm{d}x)\;\mathrm{d}s, \qquad m_s := (1-s)\,m + s\,m'. \tag{4.9}$$

Equivalently, in differential form, for every $m' \in \mathcal{P}_2(\mathbb{R}^d)$,

$$\frac{\mathrm{d}}{\mathrm{d}\epsilon}\,F(m + \epsilon(m' - m))\Big|_{\epsilon=0} \;=\; \int_{\mathbb{R}^d} \frac{\delta F}{\delta m}(m, x)\,(m' - m)(\mathrm{d}x). \tag{4.10}$$

We fix the additive constant by the normalization $\int_{\mathbb{R}^d} \frac{\delta F}{\delta m}(m, x)\, m(\mathrm{d}x) = 0$.

The definition offers the derivative in two equivalent guises, and it is worth being explicit about why each is present and how they imply one another, because the book uses them for different jobs. Equation (4.10) is the definition in its simplest form: it is the direct transcription of the DFT response above, with the perturbation direction $m' - m$ playing the exact role of η and ϵ the role of the strength. It is an *infinitesimal* statement — it pins down only the slope of F at m in the single straight direction pointing toward m' — and that is all one needs to read the derivative off a worked functional, which is why every computation below starts from it.

Equation (4.9) is the same derivative integrated up. Consider the straight segment of measures $m_s = (1-s)m + s\,m'$, $s \in [0,1]$, which interpolates linearly from m at $s = 0$ to m' at $s = 1$ (this is the flat interpolation, not the displacement geodesic of theorem 4.9; here it is only a bookkeeping path). Along it the scalar function $g(s) := F(m_s)$ has, by (4.10) applied at the base point m_s in the direction $m' - m = \frac{\mathrm{d}}{\mathrm{d}s} m_s$, the derivative $g'(s) = \int_{\mathbb{R}^d} \frac{\delta F}{\delta m}(m_s, x)\,(m' - m)(\mathrm{d}x)$; the ordinary fundamental theorem of calculus $F(m') - F(m) = g(1) - g(0) = \int_0^1 g'(s)\,\mathrm{d}s$ is then exactly (4.9). The reason to keep this integrated form on hand is that it is an *exact* identity for a *finite* difference $F(m') - F(m)$, not merely an $o(\epsilon)$ approximation: it expresses the full increment of F between two measures as a single integral of the derivative along the connecting segment. That is precisely the lever needed to turn a bound on the derivative into a bound on F itself — if $\frac{\delta F}{\delta m}(m_s, x)$ is, say, Lipschitz in x uniformly in s, then (4.9) converts that pointwise control directly into a $\mathcal{W}_2$-modulus of continuity for F, the kind of estimate the monotonicity and stability arguments of chapter 11 are built from. The differential form gives the derivative; the integral form is how the derivative controls finite changes.

The normalization removes the additive-constant ambiguity by demanding that the derivative have zero average against the base measure, $\int_{\mathbb{R}^d} \frac{\delta F}{\delta m}(m, x)\, m(\mathrm{d}x) = 0$ — in DFT terms, a choice of reference level for the chemical potential. It is a gauge fixing, harmless and reversible: it neither adds nor removes information, it merely selects one representative from the family of admissible derivatives so that formulas can be compared.

Notation watch

The additive-constant gauge deserves to be made fully concrete, because it is a frequent source of apparent contradictions between sources. Because $(m' - m)$ is a signed measure of total mass zero, adding any constant c to $\frac{\delta F}{\delta m}(m, \cdot)$ leaves (4.10) unchanged: $\int c\,(m' - m)(\mathrm{d}x) = c \cdot 0 = 0$, the constant being annihilated by the zero total mass of the perturbation. The flat derivative is therefore intrinsically defined only up to an additive constant. This is the exact analogue of the freedom a physicist already lives with in a scalar potential: a potential energy, or an electrostatic potential, is physical only through its *differences*, and one is free to slide its zero to any convenient reference; what is measurable — the force, the work done between two configurations — is untouched by that shift. Here the role of "force" is played by the integral against a zero-mean perturbation, which sees only differences of $\frac{\delta F}{\delta m}(m,\cdot)$ across x, never its absolute level. The normalization $\int \frac{\delta F}{\delta m}(m,x)\,m(\mathrm{d}x) = 0$ is one convenient choice of reference — it sets the m-average of the derivative to zero, the analogue of grounding the potential at the population's own mean level — but it is one gauge among many, chosen only so that distinct formulas can be lined up.

The practical warning is for cross-source comparison. Different texts fix the reference differently — some normalize against m as we do, some against Lebesgue measure, some leave the constant free — so two correct expressions for the same $\frac{\delta F}{\delta m}(m,\cdot)$ can differ by a function of m alone (constant in x, though it may depend on the base measure). When a formula here disagrees with one elsewhere by such an x-independent term, that is a gauge discrepancy, not an error: subtract its m-average and the two agree.

Example 4.12 (The three functionals we actually meet)**.**

1. *Linear functionals.* If $F(m) = \int_{\mathbb{R}^d} \varphi \,\mathrm{d}m$ for a fixed φ of quadratic growth, then (4.10) gives $\frac{\delta F}{\delta m}(m,x) = \varphi(x)$ (before normalization; $\varphi(x) - \int \varphi \,\mathrm{d}m$ after). The flat derivative of a linear functional is its integrand, just as in DFT the functional derivative of $\int V\rho$ is V.

2. *Smooth functions of moments.* If $F(m) = \xi\big(\langle\varphi_1, m\rangle, \dots, \langle\varphi_k, m\rangle\big)$ with $\langle\varphi_i, m\rangle = \int \varphi_i \,\mathrm{d}m$ and $\xi \in C^1(\mathbb{R}^k)$, the computation is the ordinary multivariable chain rule, with the directional form (4.10) doing the differentiation. Each scalar moment is itself linear in m, so along $m + \epsilon(m' - m)$ it moves at constant rate, $\frac{\mathrm{d}}{\mathrm{d}\epsilon}\langle\varphi_i, m + \epsilon(m' - m)\rangle = \langle\varphi_i, m' - m\rangle = \int \varphi_i\,(m' - m)(\mathrm{d}x)$, by case (1). Feeding these k inner derivatives into ξ through the chain rule,

$$\frac{\mathrm{d}}{\mathrm{d}\epsilon} F\big(m + \epsilon(m' - m)\big)\Big|_{\epsilon=0} = \sum_{i=1}^{k} \partial_i \xi\big(\langle\varphi_1, m\rangle, \dots, \langle\varphi_k, m\rangle\big) \int_{\mathbb{R}^d} \varphi_i(x)\,(m' - m)(\mathrm{d}x),$$

   and matching this against $\int \frac{\delta F}{\delta m}(m,x)\,(m' - m)(\mathrm{d}x)$ reads off

$$\frac{\delta F}{\delta m}(m,x) = \sum_{i=1}^{k} \partial_i \xi\big(\langle\varphi_1, m\rangle, \dots, \langle\varphi_k, m\rangle\big)\,\varphi_i(x).$$

   Note that the partial derivatives $\partial_i \xi$ are evaluated at the *current* moments of m, so unlike case (1) the flat derivative now depends on m — nonlinearity in F has entered through ξ even though each φ_i is probed linearly. This is the workhorse class: most explicit couplings in the book are smooth functions of a few moments of m, the running cost of the LQG thread being a function of the mean alone (remark 4.18).

3. *Quadratic interaction functionals.* If $F(m) = \frac{1}{2}\iint_{\mathbb{R}^d \times \mathbb{R}^d} W(x,y)\,m(\mathrm{d}x)\,m(\mathrm{d}y)$ with W symmetric and bounded, write $\eta = m' - m$ and expand $F(m + \epsilon\eta)$ in powers of ϵ. Because the

integrand is bilinear in its two measure slots, substituting $m+\epsilon\eta$ into each slot and multiplying out produces exactly four terms, graded by their power of ϵ:

$$F(m+\epsilon\eta) = \tfrac{1}{2}\iint W\,(m+\epsilon\eta)(\mathrm{d}x)\,(m+\epsilon\eta)(\mathrm{d}y) = \underbrace{\tfrac{1}{2}\iint W\,m\,m}_{F(m)} + \epsilon\,\tfrac{1}{2}\iint W\,[\eta\,m + m\,\eta] + \epsilon^2\,\tfrac{1}{2}\iint W\,\eta\,\eta,$$

where the arguments (x, y) and the differentials are suppressed for legibility. The quadratic structure makes the expansion *terminate* at order ϵ^2 with no remainder — there is no $o(\epsilon^2)$ — which is special to interaction energies and is why they are the cleanest nontrivial example. The symmetry $W(x, y) = W(y, x)$ makes the two cross terms in the bracket equal — relabelling $(x, y) \leftrightarrow (y, x)$ turns one into the other — so they combine into $2\iint W\,\eta(\mathrm{d}x)\,m(\mathrm{d}y)$ and the prefactor $\frac{1}{2}$ cancels. Reading off the coefficient of ϵ as $\int \frac{\delta F}{\delta m}(m, x)\,\eta(\mathrm{d}x)$ identifies

$$\frac{\delta F}{\delta m}(m, x) = \int_{\mathbb{R}^d} W(x, y)\,m(\mathrm{d}y)$$

(before normalization; the ϵ^2 term is the genuinely nonlinear remainder and does not enter the first variation). The flat derivative of a pairwise-interaction energy is the *mean field generated by m through the kernel W* — the single-particle potential felt at x when every other grain of the population contributes its share $W(x, y)$, averaged against where the population actually sits. This is the self-consistent field of mean field theory, recovered here as a flat derivative: a scalar energy landscape over $\mathbb{R}^d$, one value per location x.

This is not a coincidence of notation, and it is worth flagging the connection precisely, with its one caveat. The map $m \mapsto \int W(x, y)\,m(\mathrm{d}y)$ is the action of the integral operator $\mathbb{W}$ of appendix A.5 on the measure m, so the flat derivative of a pairwise-interaction energy *is* the graphon coupling operator applied to the population — the static prototype of the nonlocal coupling that drives every graphon mean field game of Part IV. The caveat is the type-variable warning of the notation conventions (appendix A.5): here $x \in \mathbb{R}^d$ is a *spatial state* and $W(x, y)$ is an interaction kernel on physical space, whereas in Part IV the first argument of the kernel is the *type* $x \in [0, 1]$ — an exchangeable label, not a position — and $\mathbb{W}$ there is the Hilbert–Schmidt operator $(\mathbb{W}f)(x) = \int_0^1 W(x, y)f(y)\,\mathrm{d}y$ on $L^2[0, 1]$. The algebra of this example is identical in the two settings; only the meaning of the variable the kernel is indexed by changes. Keeping that distinction in view now is what lets the reader meet the graphon coupling in Part IV as the same object computed here rather than a new one. (The notation collides deliberately: the same letter x that is a point of $\mathbb{R}^d$ throughout this chapter is, in Part IV, reused for the type $x \in [0, 1]$; nothing in the algebra changes, but it is the reader's job to remember which meaning is in force.)

Remark 4.13 (Why the flat derivative is the right object for monotonicity)**.** The flat derivative is precisely the object in which the uniqueness theory of chapter 11 is phrased, which is worth flagging now so the reader meets it there as an old friend. The Lasry–Lions monotonicity condition that forces a mean field game to have a *unique* equilibrium asks that the coupling functional F satisfy

$$\int_{\mathbb{R}^d} \Big(\frac{\delta F}{\delta m}(m, x) - \frac{\delta F}{\delta m}(m', x)\Big)\,(m - m')(\mathrm{d}x) \;\geq\; 0 \qquad \text{for all } m, m' \in \mathcal{P}_2(\mathbb{R}^d),$$

a statement entirely about the flat derivative, tested against the mass-conserving difference $m - m'$. The gauge freedom is harmless here for the very reason it was harmless in definition 4.11: an additive constant in $\frac{\delta F}{\delta m}(m,\cdot)$ integrates to zero against the zero-mean difference $m - m'$, so the inequality does not depend on the choice of normalization. Example 3 above is the prototype — a pairwise interaction through a symmetric kernel W is monotone exactly when W is of positive type — and this static positivity is the seed that chapter 11 grows into a full uniqueness proof. It is the add-mass derivative, not the move-mass one, that monotonicity wants, because the condition compares two whole populations against each other rather than following one as it flows.

We have, then, the first of our two derivatives in hand, and the interaction example is the right note to close on, because it shows exactly what the flat derivative delivers and what it withholds. It delivers a *field*: a scalar energy landscape $\frac{\delta F}{\delta m}(m,\cdot)$ over $\mathbb{R}^d$, the self-consistent potential the population generates, one number per location. That is the natural answer to the static question "what does it cost to add a grain here?" But the dynamics of a mean field game never add grains; a stochastic flow X_t transports the law $m_t = \mathcal{L}(X_t)$ by *moving* the mass already present, and a grain that moves feels not a potential but a *force* — the spatial gradient of that potential. The flat derivative therefore points beyond itself: to differentiate F along a flow we will need to take the gradient $\nabla_x \frac{\delta F}{\delta m}(m,x)$, converting the energy field of the interaction example into the force field that actually pushes the population. That gradient is the Lions derivative, and constructing it directly — by the sharper perturbation that moves mass rather than adding it — is the business of the next subsection.

4.4.2 The Lions derivative, via lifting to random variables

The previous subsection closed by pointing past itself: the flat derivative $\frac{\delta F}{\delta m}(m,\cdot)$ delivers a scalar *energy field* over $\mathbb{R}^d$, answering the static question "how does F change if I *add* a little mass at x?" — whereas the dynamics of a mean field game never add mass, a stochastic flow X_t transporting the law $m_t = \mathcal{L}(X_t)$ by *moving* the grains already present. So the question we must now answer is the sharper one: how does F change if I *move* the mass that is already there, nudging each grain a little? Its answer is the *Lions derivative* $\partial_\mu F(m)(x)$, a vector field over $\mathbb{R}^d$ assigning to each location the direction it is worth pushing the grain sitting there. The end of this subsection will prove that this move-mass derivative is exactly the spatial gradient of the add-mass derivative, so that the energy field and the force field are two readings of one object; but first we must construct it, and that takes a genuinely new device.

The distinction is not pedantry — it is forced on us by the very calculation the master equation is assembled from. The chain rule for a function $F(m_t)$ of the *law* $m_t = \mathcal{L}(X_t)$ of an Itô process — the Itô formula along a flow of measures — is necessarily stated through the Lions derivative, because what a stochastic flow changes is *where* the mass sits, not *how much* of it there is. That law-level chain rule is built on the ordinary Itô formula of theorem 5.9; its measure-flow form, together with the second-order Lions calculus it requires, is the engine of the master equation of chapter 12 and is developed in full in appendix D.6. We are here laying its first-order foundation.

The obstacle to differentiating F directly is that its domain $\mathcal{P}_2(\mathbb{R}^d)$ is not a linear space: one cannot add two probability measures and stay a probability measure, so there is no ambient vector space in which to form difference quotients in the usual way. The flat derivative dodged this by perturbing along the one direction that *does* stay admissible, the mass-conserving segment $m+\epsilon(m'-m)$. Lions's device dodges it more radically and more powerfully: it *lifts* the functional off the curved space of measures and onto a flat Hilbert space, where the entire differential calculus of chapter 2 is already waiting. Fix once and for all an atomless probability space $(\Omega, \mathcal{F}, \mathbb{P})$ rich enough to carry, for every $m \in \mathcal{P}_2(\mathbb{R}^d)$, at least one random variable with law m; the canonical choice is $\Omega = [0,1]$ with Lebesgue measure, which is atomless and supports a variable of any prescribed law (compose the desired quantile function with the identity coordinate). The *lift* of $F\colon \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}$ is the functional

$$\widetilde{F}\colon L^2(\Omega, \mathcal{F}, \mathbb{P}; \mathbb{R}^d) \to \mathbb{R}, \qquad \widetilde{F}(X) = F(\mathcal{L}(X)),$$

which evaluates F on the law of whatever random variable it is fed. Its domain $H = L^2(\Omega; \mathbb{R}^d)$ is exactly the Hilbert space of square-integrable random variables built in chapter 2 — a genuine vector space with inner product $\langle X, Y\rangle_H = \mathbb{E}[X \cdot Y]$ — and on it $\widetilde{F}$ is just an ordinary functional, of the kind we know how to differentiate. We have traded a single point of the awkward nonlinear space $\mathcal{P}_2(\mathbb{R}^d)$ for a whole *fibre* of representatives in H: every X with $\mathcal{L}(X) = m$ is a lift of the same m, so $\widetilde{F}$ is constant along each fibre. That redundancy looks wasteful, but it is precisely the slack that makes the construction work, and the structure theorem below is the statement that the answer does not depend on which representative we picked.

We differentiate $\widetilde{F}$ in the Fréchet sense, recalled here in place so the section stands on its own. A functional $G\colon H \to \mathbb{R}$ on a Hilbert space is *Fréchet differentiable* at $X \in H$ if its increment is, to leading order, a *linear* function of the displacement: there is a bounded linear map $DG(X)\colon H \to \mathbb{R}$ with

$$G(X+Y) - G(X) - DG(X)[Y] \;=\; o\big(\|Y\|_H\big) \qquad \text{as } \|Y\|_H \to 0.$$

This is word for word the definition of the total derivative from multivariable calculus, with the finite-dimensional gradient promoted to a bounded linear functional on H and the little-o measured in the L^2 norm; the boundedness of $DG(X)$ is the infinite-dimensional stand-in for "the gradient is a finite vector." By the Riesz representation theorem (theorem 2.6), every bounded linear functional on a Hilbert space is inner product against a unique vector, so the differential $DG(X)$ is realized by a unique *gradient vector*, which we also write $DG(X) \in H$, through $DG(X)[Y] = \langle DG(X), Y\rangle_H = \mathbb{E}\big[DG(X)\cdot Y\big]$. The gradient is thus itself a square-integrable random variable. Lions's observation is that when $G = \widetilde{F}$ is the lift of a functional of the *law*, this gradient random variable is not arbitrary: it is a deterministic function of the underlying variable X alone, and one that depends on X only through its law.

Definition 4.14 (Lions / L-derivative)**.** $F\colon \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}$ is *L-differentiable* (Lions differentiable) at m if its lift $\widetilde{F}$ is Fréchet differentiable at some (hence any) X with $\mathcal{L}(X) = m$. In that case the gradient $D\widetilde{F}(X) \in L^2(\Omega; \mathbb{R}^d)$, identified with an element of L^2 via the Riesz isomorphism of chapter 2, takes the form

$$D\widetilde{F}(X) \;=\; \partial_\mu F(m)(X) \qquad \text{a.s.,} \tag{4.11}$$

for a function $\partial_\mu F(m)\colon \mathbb{R}^d \to \mathbb{R}^d$ in $L^2(m; \mathbb{R}^d)$, called the *Lions derivative* of F at m. It depends on X only through its law m.

That the gradient depends on X only through its law — the content packed into (4.11) — is a genuine theorem, not a definition: it follows because $\widetilde{F}$ is invariant under measure-preserving rearrangements of Ω (two random variables with the same law have the same $\widetilde{F}$-value), and a rearrangement-invariant smooth functional has a rearrangement-equivariant gradient. The full statement and proof are due to Lions's Collège de France lectures, reported in [40, Ch. 5]; we state and prove it in full in-book as theorem D.5.

The two derivatives are not independent. The flat derivative is scalar-valued and lives on $\mathbb{R}^d$; the Lions derivative is $\mathbb{R}^d$-valued. The precise link, anticipated in appendix A.3, is that the Lions derivative is the *spatial gradient* of the flat derivative.

Proposition 4.15 (Flat and Lions derivatives are related by a gradient)**.** *Suppose F has a flat derivative $\frac{\delta F}{\delta m}(m,\cdot)$ that is continuously differentiable in x with at most linear growth of its gradient. Then F is L-differentiable and*

$$\partial_\mu F(m)(x) \;=\; \nabla_x \frac{\delta F}{\delta m}(m,x). \tag{4.12}$$

Proof sketch. Let X have law m, and let $Y \in L^2(\Omega;\mathbb{R}^d)$ be a perturbation direction; write $m_\epsilon = \mathcal{L}(X+\epsilon Y)$ for the curve of laws it traces as ϵ varies. The plan is to compute $\frac{\mathrm{d}}{\mathrm{d}\epsilon}\widetilde{F}(X+\epsilon Y)|_{\epsilon=0} = \frac{\mathrm{d}}{\mathrm{d}\epsilon}F(m_\epsilon)|_{\epsilon=0}$ in two ways and match them. Differentiating F along the curve m_ϵ through its flat derivative (4.10) pairs $\frac{\delta F}{\delta m}(m,\cdot)$ with the *velocity* of the curve — the rate at which mass is being redistributed — and that velocity is read off one test function at a time. For any smooth g,

$$\frac{\mathrm{d}}{\mathrm{d}\epsilon}\int_{\mathbb{R}^d} g \;\mathrm{d}m_\epsilon\Big|_{\epsilon=0} = \frac{\mathrm{d}}{\mathrm{d}\epsilon}\mathbb{E}\big[g(X+\epsilon Y)\big]\Big|_{\epsilon=0} = \mathbb{E}\big[\nabla g(X)\cdot Y\big],$$

where the first equality is the definition of $m_\epsilon = \mathcal{L}(X+\epsilon Y)$ and the second is the ordinary chain rule inside the expectation. So, to first order, the curve m_ϵ moves by transporting mass with a velocity tied to Y, and a gradient lands on whatever test function it is paired with. Taking $g = \frac{\delta F}{\delta m}(m,\cdot)$ — legitimate because it is C^1 in x by hypothesis — and feeding this velocity into the flat-derivative chain rule gives

$$\frac{\mathrm{d}}{\mathrm{d}\epsilon}F(m_\epsilon)\Big|_{\epsilon=0} = \mathbb{E}\Big[\nabla_x \frac{\delta F}{\delta m}(m,X)\cdot Y\Big].$$

The gradient sits on $\frac{\delta F}{\delta m}(m,\cdot)$ precisely because the curve's velocity carried it off the test function and onto the derivative — this is the "integration by parts" of the informal statement — and it is exactly here that the at-most-linear-growth hypothesis on $\nabla_x\frac{\delta F}{\delta m}(m,x)$ is spent: it keeps the expectation finite for every $Y \in L^2(\Omega;\mathbb{R}^d)$, so that the right-hand side is a genuine bounded linear functional of Y. The left side is, by the definition of the Fréchet gradient and the Riesz identification of theorem 2.6, $\langle D\widetilde{F}(X), Y\rangle_{L^2} = \mathbb{E}[D\widetilde{F}(X)\cdot Y]$. Since the two expressions agree for *every* direction Y, their integrands agree almost surely,

$$D\widetilde{F}(X) = \nabla_x \frac{\delta F}{\delta m}(m,X) \quad \text{a.s.},$$

which is the structure (4.11) read with $\partial_\mu F(m)(x) = \nabla_x\frac{\delta F}{\delta m}(m,x)$ — the claimed relation (4.12). Note in passing that the gradient automatically depends on X only through its law m, as definition 4.14 demands, since $\nabla_x\frac{\delta F}{\delta m}(m,\cdot)$ is a fixed function on $\mathbb{R}^d$ evaluated at X. The full justification of the curve-differentiation step, including the regularity that makes it rigorous, is [40, Sec. 5.4]. ☐

Example 4.16 (Lions derivatives of the three functionals)**.** Applying (4.12) to example 4.12:

$$F(m) = \int \varphi \, \mathrm{d}m \;\Rightarrow\; \partial_\mu F(m)(x) = \nabla\varphi(x); \qquad F(m) = \tfrac{1}{2}\iint W \, \mathrm{d}m \, \mathrm{d}m \;\Rightarrow\; \partial_\mu F(m)(x) = \int \nabla_x W(x,y)\, m(\mathrm{d}y).$$

The Lions derivative of the linear functional is the gradient of its integrand; the Lions derivative of the interaction energy is the gradient of the self-consistent field — the *force* that the population exerts on a particle at x. This is the form in which the coupling enters the Hamiltonian of the mean field game, and it is the bridge from the flat derivative (an energy) to the Lions derivative (a force) that the reader should keep.

We stop the development at first order. The full second-order calculus on $\mathcal{P}_2(\mathbb{R}^d)$ — the Itô formula along flows of measures, which requires a *second* Lions derivative $\partial^2_\mu F$ measuring how the force field itself responds when the population moves — is the engine of the master equation of chapter 12, and the complete construction of both derivatives, with their interrelations and regularity theory, is collected in appendix D.6, which rests in turn on the ordinary Itô formula theorem 5.9 of the next chapter. What this section carries forward is exactly three things: the flat derivative definition 4.11, the Lions derivative definition 4.14, and the gradient relation (4.12) that ties them together.

These three are not abstractions awaiting a distant payoff; the very next section spends them on the model the book carries throughout. In the Gaussian computation that follows, the closing remark remark 4.18 returns to the first-moment coupling of the LQG thread and writes down both derivatives explicitly — the flat derivative an affine field $x \mapsto q\, s^2 \bar{m} - q\, s\, x$, the Lions derivative a constant force $-q\, s\, \mathbf{1}$ — so that the energy-to-force passage of example 4.16 is instantiated concretely on the running example. With the metric of the earlier sections and the differential calculus of this one both in hand, $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ is now a space we can both measure and differentiate over, and the remaining section turns to the one computation the whole LQG thread leans on.

4.5 Worked computation: $\mathcal{W}_2$ between two Gaussians

Worked computation 4.17 (The Bures–Wasserstein distance; Thread A geometric backbone)**.** The LQG thread (Thread A, appendix A.7) has the defining feature that the population law is always Gaussian: the linear state SDE of eq. (5.31) with Gaussian initial data propagates a normal law $m_t = \mathcal{N}(\bar{m}_t, v_t)$ with mean $\bar{m}_t$ and variance v_t — the Gaussian flow derived explicitly in worked computation 5.17, with moments (5.28) — and the control of chapter 6 keeps it Gaussian. To measure how far apart two population states are — which is what every $\mathcal{W}_2$-contraction estimate in chapter 14 requires — we need $\mathcal{W}_2$ between two Gaussians in closed form. We derive it now; it is the geometric skeleton on which the explicit LQG fixed point is later built.

Notation watch

Throughout this section we denote the *mean vector* of a Gaussian by $\bar{m}$ (matching the population-mean notation $\bar{m}_t$ of worked computation 5.17 and Thread A) and reserve m for the measure itself, $\mu_i = \mathcal{N}(\bar{m}_i, \Sigma_i)$; do not read $\bar{m}_i$ as a measure. In the scalar specialization below, a Gaussian *standard deviation* appears as $\sqrt{v_i}$ where v_i is the variance. We deliberately avoid the symbol σ for a standard deviation here: in chapter 5 and Thread A, $\sigma = \sigma$ is the reserved noise/volatility coefficient of the dynamics, and both meanings will be in scope together downstream in chapter 14.

Setup. Let $\mu_0 = \mathcal{N}(\bar{m}_0, \Sigma_0)$ and $\mu_1 = \mathcal{N}(\bar{m}_1, \Sigma_1)$ be two Gaussians on $\mathbb{R}^d$ with mean vectors $\bar{m}_0, \bar{m}_1 \in \mathbb{R}^d$ and symmetric positive-definite covariances Σ_0, Σ_1. We claim

$$\mathcal{W}_2(\mu_0, \mu_1)^2 \;=\; |\bar{m}_0 - \bar{m}_1|^2 \;+\; \operatorname{tr}\Big(\Sigma_0 + \Sigma_1 - 2\big(\Sigma_0^{1/2}\Sigma_1\Sigma_0^{1/2}\big)^{1/2}\Big), \tag{4.13}$$

where $\Sigma^{1/2}$ denotes the unique symmetric positive-definite square root. The mean contributes a flat Euclidean term; the covariances contribute the squared *Bures distance* $d_B(\Sigma_0, \Sigma_1)^2 = \operatorname{tr}\big(\Sigma_0 + \Sigma_1 - 2(\Sigma_0^{1/2}\Sigma_1\Sigma_0^{1/2})^{1/2}\big)$.

The optimal map is affine. The strategy is to exhibit a transport map of the gradient-of-convex form demanded by Brenier's theorem (theorem 4.6); by that theorem it is automatically optimal, so its transport cost *is* $\mathcal{W}_2^2$. Try an affine map

$$T(x) = \bar{m}_1 + A\,(x - \bar{m}_0), \qquad A \text{ symmetric positive definite},$$

which is the gradient of the convex quadratic $\phi(x) = \langle \bar{m}_1, x\rangle + \frac{1}{2}\langle x - \bar{m}_0, A(x - \bar{m}_0)\rangle$ (convex since $A \succ 0$). We must choose A so that T pushes μ_0 to μ_1. An affine image of a Gaussian is Gaussian with transformed parameters: $T_{\#}\mu_0 = \mathcal{N}(\bar{m}_1,\, A\Sigma_0 A)$ (the mean is $T(\bar{m}_0) = \bar{m}_1$ and the covariance is $A\Sigma_0 A^\top = A\Sigma_0 A$ since A is symmetric). The push-forward equals μ_1 iff

$$A\,\Sigma_0\,A = \Sigma_1. \tag{4.14}$$

Set

$$A \;=\; \Sigma_0^{-1/2}\big(\Sigma_0^{1/2}\Sigma_1\Sigma_0^{1/2}\big)^{1/2}\Sigma_0^{-1/2}.$$

This A is symmetric and positive definite (it is a congruence of a positive-definite square root). It satisfies (4.14): writing $M = \Sigma_0^{1/2}\Sigma_1\Sigma_0^{1/2}$,

$$A\Sigma_0 A = \Sigma_0^{-1/2}M^{1/2}\Sigma_0^{-1/2}\,\Sigma_0\,\Sigma_0^{-1/2}M^{1/2}\Sigma_0^{-1/2} = \Sigma_0^{-1/2}M^{1/2}M^{1/2}\Sigma_0^{-1/2} = \Sigma_0^{-1/2}M\Sigma_0^{-1/2} = \Sigma_1,$$

using $\Sigma_0^{-1/2}\Sigma_0\Sigma_0^{-1/2} = I$ and $M^{1/2}M^{1/2} = M$. Thus $T = \nabla\phi$ is a gradient of a convex function pushing μ_0 to μ_1, and by theorem 4.6 it is the optimal transport map.

Computing the cost. Let $X \sim \mu_0$, so $\mathbb{E}[X] = \bar{m}_0$ and $\operatorname{Cov}(X) = \Sigma_0$. The displacement is

$$X - T(X) = (X - \bar{m}_0) - A(X - \bar{m}_0) + (\bar{m}_0 - \bar{m}_1) = (I - A)(X - \bar{m}_0) - (\bar{m}_1 - \bar{m}_0).$$

Since $\mathbb{E}[(I - A)(X - \bar{m}_0)] = 0$, the cross term vanishes in expectation and

$$\mathcal{W}_2(\mu_0, \mu_1)^2 = \mathbb{E}[|X - T(X)|^2] = |\bar{m}_1 - \bar{m}_0|^2 + \mathbb{E}\big[(X - \bar{m}_0)^\top (I - A)^2 (X - \bar{m}_0)\big] = |\bar{m}_1 - \bar{m}_0|^2 + \operatorname{tr}\big((I - A)^2\Sigma_0\big).$$

Expand $\operatorname{tr}\left((I-A)^2\Sigma_0\right) = \operatorname{tr}\left((I-2A+A^2)\Sigma_0\right) = \operatorname{tr}(\Sigma_0) - 2\operatorname{tr}(A\Sigma_0) + \operatorname{tr}(A\Sigma_0 A)$, where we used symmetry of A and Σ_0 to write $\operatorname{tr}(A^2\Sigma_0) = \operatorname{tr}(A\Sigma_0 A)$. By (4.14) the last trace is $\operatorname{tr}(\Sigma_1)$. For the middle trace, the cyclic property gives

$$\operatorname{tr}(A\Sigma_0) = \operatorname{tr}\Big(\Sigma_0^{-1/2} M^{1/2} \Sigma_0^{-1/2} \Sigma_0\Big) = \operatorname{tr}\Big(\Sigma_0^{-1/2} M^{1/2} \Sigma_0^{1/2}\Big) = \operatorname{tr}\Big(M^{1/2}\Big) = \operatorname{tr}\Big(\big(\Sigma_0^{1/2}\Sigma_1\Sigma_0^{1/2}\big)^{1/2}\Big).$$

Collecting the three pieces,

$$\operatorname{tr}\big((I-A)^2\Sigma_0\big) = \operatorname{tr}(\Sigma_0) + \operatorname{tr}(\Sigma_1) - 2\operatorname{tr}\Big(\big(\Sigma_0^{1/2}\Sigma_1\Sigma_0^{1/2}\big)^{1/2}\Big),$$

which together with the mean term is exactly (4.13). □

The scalar case — the Thread A backbone. In one dimension the covariances are variances, $\Sigma_i = v_i$, and the matrix square roots are ordinary square roots: $\big(\sqrt{v_0}\, v_1 \sqrt{v_0}\big)^{1/2} = \sqrt{v_0}\sqrt{v_1}$. Formula (4.13) collapses to the strikingly simple

$$\mathcal{W}_2\big(\mathcal{N}(\bar m_0, v_0), \mathcal{N}(\bar m_1, v_1)\big)^2 \;=\; (\bar m_0 - \bar m_1)^2 + \big(\sqrt{v_0} - \sqrt{v_1}\big)^2. \tag{4.15}$$

That is: the $\mathcal{W}_2$ distance between two scalar Gaussians is the ordinary Euclidean distance between the points $(\bar m_0, \sqrt{v_0})$ and $(\bar m_1, \sqrt{v_1})$ in the mean–standard-deviation half-plane $\mathbb{R} \times (0, \infty)$. The space of scalar Gaussians, with $\mathcal{W}_2$, is flat. This is the precise sense in which the LQG thread is geometrically trivial and hence fully solvable: as the population law $m_t = \mathcal{N}(\bar m_t, v_t)$ evolves, its motion in $(\mathcal{P}_2(\mathbb{R}), \mathcal{W}_2)$ is just the motion of the point $(\bar m_t, \sqrt{v_t})$ in a Euclidean half-plane, and a $\mathcal{W}_2$-contraction of the best-response map becomes an ordinary contraction in two real coordinates. Chapter 14 exploits exactly this when it reduces the LQG fixed point to a scalar Riccati-plus-mean system.

Geodesics stay Gaussian. The displacement interpolation of theorem 4.9 between μ_0 and μ_1 uses $T_t = (1-t)I + tA$, an affine map, so $\mu_t = (T_t)_\#\mu_0$ is again Gaussian: $\mu_t = \mathcal{N}\big((1-t)\bar m_0 + t\bar m_1,\ ((1-t)I + tA)\Sigma_0((1-t)I + tA)\big)$. The Gaussian family is geodesically closed in $\mathcal{W}_2$. By contrast the linear interpolation $(1-t)\mu_0 + t\mu_1$ is a *mixture* of two Gaussians — generically bimodal, not Gaussian at all — which visibly illustrates the warning of section 4.2 that the $\mathcal{W}_2$-geodesic is the displacement curve, not the straight line in the vector space of measures. The mean travels linearly, $(1-t)\bar m_0 + t\bar m_1$, while the standard deviation in the scalar case travels linearly too, $\sqrt{v_t} = (1-t)\sqrt{v_0} + t\sqrt{v_1}$, consistent with the flat geometry of (4.15).

Remark 4.18 (Connection to the static interaction functional)**.** Combining this section with example 4.12(3) closes a small loop that recurs in the LQG and graphon threads. When the running cost penalizes the distance of an agent from the population mean — as the term $\frac{q}{2}(X_t - s\,\bar m_t)^2$ does in Thread A (appendix A.7) — the cost felt by the representative agent is a smooth function of the first moment $\bar m = \int y\, m(\mathrm{d}y)$ of the population. Its flat derivative is the linear field $y \mapsto -q\, s\,(x - s\bar m)\, y$ on the population variable y (a special case of example 4.12(2), with the single moment $\varphi_1(y) = y$ and own state x held fixed), and its Lions derivative — the population gradient of that field, proposition 4.15 — is the constant force $-q\, s\,(x - s\bar m) = q\, s^2 \bar m - q\, s\, x$, independent of y. The whole strategic coupling of the LQG game is thus a first-moment functional, and the Gaussian distance (4.15) measures exactly the two coordinates — mean and spread — that this coupling can move.

Rigor ledger

Proved (in full or by self-contained computation).

- $\mathcal{W}_2$ is a metric on $\mathcal{P}_2(\mathbb{R}^d)$ (theorem 4.7), with the triangle inequality via the gluing lemma; the isometric embedding $a \mapsto \delta_a$ and the identity $\mathcal{W}_2(\mu, \delta_0)^2 = \int |x|^2 \, \mathrm{d}\mu$.
- The closed form for $\mathcal{W}_2$ between two Gaussians, (4.13), with a complete derivation via the affine Brenier map; the scalar specialization (4.15) and the Gaussian-closed geodesics.
- The flat/Lions derivatives of the three model functionals (examples 4.12 and 4.16) and the gradient relation $\partial_\mu F = \nabla \, \delta F/\delta m$ (proposition 4.15, sketch).

Assumed (imported, used without re-proof).

- Weak convergence (definition 3.7), tightness (section 3.3), Prokhorov's theorem (theorem 3.16), Skorokhod's representation theorem (theorem 3.13), and the disintegration / regular-conditional-kernel theorem (theorem 3.33), all from chapter 3; the Riesz representation theorem (theorem 2.6) from chapter 2 (Fréchet differentiability is recalled locally in section 4.4); push-forward and integration from chapter 1.
- The named assumption (A-LipM) (measure-Lipschitz dependence in $\mathcal{W}_2$, appendix A.6), used in section 4.3 to assert continuity of the best-response map; it is distinct from the state-Lipschitz (A-Lip), and its full force is spent in chapters 8, 10 and 11.

Deferred (stated, proof pointed elsewhere).

- Existence of optimal couplings (proposition 4.3) and Kantorovich duality (theorem 4.5): mechanism named (direct method; convex duality), full in-book proof of duality in appendix D.1 (and [131, Ch. 4–5]).
- Brenier's theorem (theorem 4.6) and McCann displacement interpolation (theorem 4.9): sketched; full in-book proofs in appendices D.2 and D.3 (originals [30, 101]).
- The Polish property and the $\mathcal{W}_2$/weak-plus-second-moment equivalence (theorem 4.8): sketched via Skorokhod and Prokhorov; full proof [131, Thm. 6.9, 6.18].
- The Benamou–Brenier dynamic formula (theorem 4.10): stated, with full in-book proof in appendix D.4 (original [18]).
- The rearrangement-invariance structure theorem behind the Lions derivative (definition 4.14): proved in-book as theorem D.5. The second-order measure calculus (the Itô formula along a flow of measures) it feeds into is developed in appendix D.6 and applied in chapter 12 [40, Ch. 5].

Open / honestly flagged.

- Brenier's theorem as stated requires the source measure to be absolutely continuous; the optimal plan need not be a map when μ_0 has atoms (e.g. transporting a Dirac), and the displacement geodesic construction inherits this caveat. The book's mean field populations are typically nondegenerate ((A-Nondeg) ensures densities), so the map form applies, but this is an assumption, not a free lunch.

- Everything here is the $p = 2$, dense, finite-dimensional ($\mathbb{R}^d$) theory. The infinite-dimensional and L^p-graphon settings of Parts III–IV need the type-indexed analogue $x \mapsto m^x$, whose metric structure is built later and is *not* a special case of the present $\mathcal{P}_2(\mathbb{R}^d)$.

Bibliographic notes

The definitive modern reference for optimal transport is Villani's *Optimal Transport: Old and New* [131]; our theorems 4.5, 4.6, 4.8 and 4.9 follow its Chapters 4–7, and the second-moment characterization (4.7) is its Theorem 6.9. Santambrogio's *Optimal Transport for Applied Mathematicians* [117] is the most accessible entry point and gives the cleanest treatment of the dynamic (Benamou–Brenier) picture. Ambrosio, Gigli, and Savaré [7] is the authority on the metric and differential structure of $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$, including geodesics and the absolutely continuous curves underlying theorem 4.10. The relaxation from maps to plans is Kantorovich's [85]; the structure theorem that the optimal plan is a gradient of a convex map is Brenier's [30], with displacement interpolation and displacement convexity due to McCann [101]. The dynamic fluid-mechanical formula is Benamou and Brenier [18].

The two derivatives of section 4.4 are developed in full in Carmona and Delarue [40, Ch. 5], which is also the source for the lift construction and the relation $\partial_\mu F = \nabla\, \delta F/\delta m$; the master-equation payoff is their Volume II [41] and our chapter 12. The density-functional analogy that opens that section is meant only as a mnemonic; the flat derivative is the same first-variation object a physicist computes for an energy functional, and no statistical mechanics is imported beyond the notation.

The Gaussian distance (4.13) is classical, going back to Olkin–Pukelsheim and to Givens and Shortt [78], who computed the quadratic Wasserstein distance between Gaussians; the covariance term is the Bures distance familiar from quantum information, and the pair $(\mathcal{P}_2(\mathbb{R}^d) \cap \{\text{Gaussians}\}, \mathcal{W}_2)$ is the Bures–Wasserstein manifold. Its appearance here is purely as the explicit backbone of the LQG thread, continued in chapter 6 and chapter 14.

Chapter 5

Stochastic Analysis: From Langevin to Itô and Fokker–Planck

A physicist meets the Langevin equation

$$\dot{x}(t) \;=\; -\,V'\big(x(t)\big) \;+\; \xi(t), \qquad \big\langle \xi(t)\,\xi(t')\big\rangle = 2D\,\delta(t-t'),$$

long before meeting the words "filtration" or "martingale," and treats it with complete confidence: one writes a Fokker–Planck equation for the density, finds its steady state, computes correlation functions, and moves on. The trouble is that, taken literally, the equation is nonsense. The driving force ξ is white noise — a "function" with infinite variance at each instant and no values, only a distribution — and the trajectory $x(t)$ it produces is continuous but nowhere differentiable, so $\dot{x}$ does not exist. The manipulations nonetheless give correct answers because they are shadows of a rigorous calculus. This chapter builds that calculus. The reward is not pedantry: when in Part II the drift will itself be a control chosen by an optimizing agent, and the noise coefficient will be allowed to depend on the state, the naive Langevin rules acquire genuinely ambiguous terms (the Itô–Stratonovich question), and only the rigorous theory tells us which reading the mathematics of mean field games selects.

One technical fact does all the work, and it is worth naming at the outset so the reader carries a single organizing idea rather than a list of seven topics. A Brownian increment over a window of length $\mathrm{d}t$ has standard deviation $\sqrt{\mathrm{d}t}$, so its *square* is of size $\mathrm{d}t$ — and, summed over a window, these squares stop fluctuating and accumulate *deterministically.* The whole chapter is this one fact, "$(\mathrm{d}W)^2 = \mathrm{d}t$," carried wherever it leads. It is why the ordinary Riemann–Stieltjes integral fails and a new (Itô) integral is needed; it is the surviving second-order term in Itô's formula, the term that *is* diffusion; it is what turns the formally nonsensical Langevin equation into a well-posed stochastic differential equation; and it is the Laplacian inside the generator that drives the Fokker–Planck equation forward (carrying densities) and the Kolmogorov backward equation in reverse (carrying observables). Seven topics, one engine; keep it in view.

We assume the probabilistic foundations of chapter 3: a probability space $(\Omega, \mathcal{F}, \mathbb{P})$, random variables and their laws $\mathcal{L}(\cdot)$, expectation $\mathbb{E}$ as integration, conditional expectation as orthogonal projection, the modes of convergence, and the notion of a filtration $\mathbb{F} = (\mathcal{F}_t)_{t\geq 0}$ encoding the information available by time t. From chapter 4 we borrow only the space $\mathcal{P}_2(\mathbb{R}^d)$ of probability measures with finite second moment and the language of densities as points in it; the Fokker–Planck equation we derive here is the law of motion of such a point, and it is the forward half of the mean field game system whose backward half — the Hamilton–Jacobi–Bellman equation — is built in chapter 6. Indeed the Kolmogorov backward equation of section 5.5 is the linear ancestor of HJB, and we flag the kinship where it appears.

The plan is linear, and each waypoint is forced by the one before it. Section 5.1 constructs Brownian motion and isolates the single fact that drives everything: its quadratic variation is finite and deterministic, so that "$(\mathrm{d}W)^2 = \mathrm{d}t$." *Because* that fact gives Brownian paths infinite ordinary variation, the Riemann–Stieltjes integral cannot make sense of $\int H\, \mathrm{d}W$, and section 5.2 must build a new one — the Itô integral, whose left-endpoint convention is also exactly what separates Itô from Stratonovich. *Because* the same fact leaves a second-order term that refuses to vanish, the change-of-variables rule acquires a correction, and section 5.3 proves Itô's formula, whose extra term *is* diffusion. *Armed* with that calculus, section 5.4 solves stochastic differential equations under the standing Lipschitz and growth assumptions — the Langevin equation, at last well-posed. Passing from one trajectory to the evolving law of the whole ensemble, section 5.5 extracts the generator — in which the second-order term reappears as a Laplacian — and derives the Fokker–Planck equation twice, as the adjoint of that generator and as a continuity equation for a probability current, alongside its backward twin. Section 5.6 is the Feynman–Kac bridge that ties path expectations to those linear PDEs, and section 5.7 runs every one of these tools on the Ornstein–Uhlenbeck process — its explicit Gaussian law, its Fokker–Planck steady state, and the spectral decomposition of its generator — the one fully explicit model that is the linear backbone of the LQG thread (Thread A) carried through the book.

Notation watch

Throughout Parts I–II, with no graphon in scope, Brownian motion is written W_t (rendered W_t), following standard probability usage, and the generator is $\mathcal{A}$ with adjoint $\mathcal{A}^*$ (appendix A). From Part III onward, where the graphon kernel $W(x, y)$ occupies the letter W, Brownian motion is renamed B_t. Every Brownian motion in this chapter is W.

5.1 Brownian motion

The preamble left a promissory note: the Langevin force is to be made rigorous, and the whole calculus of this chapter is to be built on the noise it idealizes. But one cannot integrate against a noise one has not yet constructed. Before there can be an Itô integral $\int H\, \mathrm{d}W$, an Itô formula, or a Fokker–Planck equation, there must be a W — a single, canonical random object that earns the name "white-noise bath." Building it, and reading off the one structural fact ($\sqrt{\mathrm{d}t}$ increments) that everything later will exploit, is the business of this section.

What should that object be? A physicist's idealized thermal bath has exactly three statistical properties and one regularity, and the art is to demand these and *nothing more*. The kicks it delivers carry no memory of the past; they have no preferred direction and the same statistics at every instant; and they are so numerous and so independent on any time scale that, summed over a window, they pile up into a Gaussian. Finally, the displacement they integrate to is continuous — a real particle does not teleport. Promote these four to axioms and one arrives at the following definition. We will see immediately afterward that they pin the object down completely, *except* for the single nontrivial question of whether the continuity in the last axiom can be had at all.

Definition 5.1 (Brownian motion)**.** A real-valued stochastic process $W = (W_t)_{t\geq 0}$ on $(\Omega, \mathcal{F}, \mathbb{P})$ is a (standard, one-dimensional) *Brownian motion* if

1. $W_0 = 0$ almost surely;
2. *independent increments*: for $0 \leq t_0 < t_1 < \cdots < t_n$ the increments $W_{t_1} - W_{t_0}, \ldots, W_{t_n} - W_{t_{n-1}}$ are independent;
3. *stationary Gaussian increments*: for $0 \leq s < t$, $W_t - W_s \sim N(0,\, t-s)$;
4. the sample path $t \mapsto W_t(\omega)$ is continuous for $\mathbb{P}$-almost every ω.

A d-dimensional Brownian motion is a vector $W = (W^1, \ldots, W^d)$ of independent one-dimensional Brownian motions; then $W_t - W_s \sim N(0, (t-s)I_d)$. We always take W adapted to a filtration $\mathbb{F}$ for which increments $W_t - W_s$ are independent of $\mathcal{F}_s$; the *Brownian filtration* generated by W (augmented by null sets) is the canonical choice.

Take the four axioms one at a time, because each is a physical statement before it is a mathematical one. Axiom (1), $W_0 = 0$, is not an assumption but a *choice of origin*: W_t records the displacement accumulated since the start, and a particle launched from x is simply $x + W_t$. Axiom (2), independent increments, is *memorylessness*: the kick delivered over $[s,t]$ is statistically unrelated to the entire history of the path up to time s. This is the strongest form of the Markov property, and it is the precise content of the physicist's slogan that white noise is "δ-correlated in time" — disjoint time windows share nothing. Axiom (3) carries the most weight and splits into three readings. *Stationary*: the law of an increment depends only on the elapsed time $t-s$, never on the absolute time s, so the bath delivers identical statistics in every equal window — a *fixed energy per unit time. Gaussian and centered*: an increment is the accumulation of vastly many independent infinitesimal kicks, so the central limit theorem makes it Gaussian, and the absence of any preferred direction makes its mean zero. *Variance $t-s$*: the variance grows *linearly* in the elapsed time. This last clause is the seed of the entire chapter. It says the typical magnitude of the displacement over a window of length $\tau = t-s$ is $\sqrt{\mathrm{Var}} = \sqrt{\tau}$, not τ — the $\sqrt{\mathrm{d}t}$ scaling foregrounded in the chapter preamble. Everything downstream is this one clause carried forward: it is what makes the path non-differentiable (section 5.1.1), what makes the quadratic variation deterministic (section 5.1.2), and ultimately what forces "$(\mathrm{d}W)^2 = \mathrm{d}t$." Axiom (4), continuity, is *the one regularity we keep*: we ask that sample paths be continuous and demand nothing smoother. The next subsection shows that this is also the most one *may* ask — for an object obeying axiom (3), differentiability is already self-contradictory.

Why do axioms (1)–(3) determine the process, while axiom (4) is of an entirely different character? Fix instants $0 \leq t_1 < \cdots < t_n$. The vector $(W_{t_1}, \ldots, W_{t_n})$ is a fixed invertible linear image of the increment vector $(W_{t_1} - W_{t_0}, \dots, W_{t_n} - W_{t_{n-1}})$ (with $t_0 = 0$), whose entries are, by axioms (2)–(3), *independent* centered Gaussians. A linear image of a Gaussian vector is Gaussian, so the joint law is centered Gaussian, and a centered Gaussian law is determined by its covariance alone. That covariance is one line. For $s \le t$ write $W_t = W_s + (W_t - W_s)$; the increment $W_t - W_s$ is independent of $W_s = W_s - W_0$ (a disjoint, earlier increment, with mean zero), so

$$\mathrm{Cov}(W_s, W_t) = \mathrm{Var}(W_s) + \mathrm{Cov}\left(W_s,\, W_t - W_s\right) = \mathrm{Var}(W_s) + 0 = s,$$

and by symmetry in the two arguments,

$$\mathrm{Cov}(W_s, W_t) = s \wedge t. \tag{5.1}$$

Thus axioms (1)–(3) fix *every* finite-dimensional distribution: the vector $(W_{t_1}, \dots, W_{t_n})$ is the centered Gaussian with covariance matrix $\left(t_i \wedge t_j\right)_{i,j}$, and the entire law on finitely many coordinates is pinned. Axiom (4) is invisible at this level. A finite-dimensional distribution constrains the path at finitely many instants; continuity is a statement about the path at *all* t at once — an uncountable conjunction that no finite-dimensional law can even express. This gap is exactly why existence is a genuine theorem and not a definition.

The content of existence is therefore concentrated entirely in axiom (4). We hold a consistent family of finite-dimensional Gaussian laws — consistent precisely because the covariance $s \wedge t$ is symmetric and positive semidefinite, so the laws prescribed on overlapping finite sets of times agree on their common coordinates. Kolmogorov's extension theorem turns any such consistent family into a single honest probability measure on the path space $\mathbb{R}^{[0,\infty)}$ that realizes all the prescribed marginals simultaneously. But the natural σ-algebra on that path space is generated by the cylinder sets — events that constrain the path at countably many times — and "$t \mapsto W_t$ is continuous" is not such an event. The raw process Kolmogorov returns can be, and on $\mathbb{R}^{[0,\infty)}$ generically is, pathologically irregular; continuity does not come for free and must be installed by hand, by passing to a *modification* (a process equal to the original at each fixed t almost surely, but with better paths). Installing it is the theorem.

Theorem 5.2 (Existence)**.** *There exists a probability space carrying a process satisfying definition 5.1.*

Proof sketch. Two standard routes; we name the mechanism of each, filling in enough of the bookkeeping to see where continuity is paid for, with the two beyond-prerequisite theorems involved proved in full in appendix C.

(i) Kolmogorov extension plus a continuity theorem. The first step is the extension just described: the covariance $s \wedge t$ is symmetric and positive semidefinite, the Gaussian finite-dimensional laws are consistent, and Kolmogorov's extension theorem (theorem C.8) realizes them on $\mathbb{R}^{[0,\infty)}$. To repair the paths one invokes the *Kolmogorov–Chentsov continuity theorem* (theorem C.9): if a process obeys a moment bound $\mathbb{E}\,|W_t - W_s|^p \le C\,|t-s|^{1+\gamma}$ for some $p, \gamma, C > 0$ — this is hypothesis (C.6) — then it admits a modification whose paths are locally Hölder continuous of *every* order $\alpha < \gamma/p$. Brownian increments supply such bounds in abundance, because all their moments are explicit: from $W_t - W_s \sim N(0, t-s)$ and the Gaussian moment formula,

$$\mathbb{E}\,|W_t - W_s|^{2k} = (2k-1)!!\,|t-s|^k, \qquad k \in \mathbb{N}.$$

Matching this against the hypothesis means reading off the exponents: $p = 2k$ on the left, and $1+\gamma = k$ on the right, i.e. $\gamma = k-1$. The Hölder exponent the theorem then delivers is any

$$\alpha < \frac{\gamma}{p} = \frac{k-1}{2k} = \frac{1}{2} - \frac{1}{2k}.$$

Two things are worth reading off this little computation. First, the *fourth* moment already suffices for continuity: at $k=2$ it gives $\mathbb{E}\,|W_t - W_s|^4 = 3\,|t-s|^2$, hence $1+\gamma = 2 > 1$, and the theorem applies. A single polynomial moment bound with exponent strictly above 1 is all that continuity ever costs; the fourth moment only certifies Hölder regularity up to $\alpha < \frac{1}{4}$, but continuity itself is already secured at that stage. Second, the *higher* moments are precisely what sharpen the exponent: as $k \to \infty$ the bound $\frac{1}{2} - \frac{1}{2k}$ climbs toward $\frac{1}{2}$, so every $\alpha < \frac{1}{2}$ is attainable, the sharp regularity recorded in remark C.10. The mechanism inside Kolmogorov–Chentsov is a Borel–Cantelli argument on a dyadic grid: the moment bound makes the probability that the increment across a dyadic interval of length 2^{-n} exceeds $2^{-n\alpha}$ summable in n, so by Borel–Cantelli only finitely many such over-shoots occur almost surely, and controlling the dyadic oscillations at every scale controls the modulus of continuity.

(ii) Lévy–Ciesielski explicit series. On $[0,1]$, let (h_n) be the Haar basis of $L^2[0,1]$ and (ϕ_n) the Schauder functions $\phi_n(t) = \int_0^t h_n$ — the "tent" primitives of the Haar functions. If (ξ_n) are i.i.d. $N(0,1)$ then the candidate is

$$W_t = \sum_n \xi_n\, \phi_n(t).$$

That it has the right law is a one-line Parseval computation. The increments are Gaussian, being limits of linear combinations of the ξ_n, and using $\phi_n(t) = \int_0^t h_n = \langle \mathbf{1}_{[0,t]}, h_n\rangle$ together with the completeness of the Haar basis,

$$\mathrm{Cov}(W_s, W_t) = \sum_n \phi_n(s)\,\phi_n(t) = \sum_n \langle \mathbf{1}_{[0,s]}, h_n\rangle\langle \mathbf{1}_{[0,t]}, h_n\rangle = \langle \mathbf{1}_{[0,s]}, \mathbf{1}_{[0,t]}\rangle = s \wedge t,$$

exactly the covariance (5.1); with mean zero and Gaussian increments, all of axioms (1)–(3) follow. This is the construction worth carrying as a mental picture: it exhibits Brownian motion as a random series whose coefficients are independent Gaussians of *equal variance in every mode*. That flat spectrum — no Haar frequency privileged over another — is the precise sense in which white noise is "equal weight in every mode," and W is simply its running integral, the ϕ_n being the antiderivatives of the h_n. Continuity, the property that did not come free in route (i), is here *built into* the mode of convergence: the series converges *uniformly* in t almost surely, and a uniform limit of continuous functions is continuous. Uniform convergence is the one delicate point, and it is won by a Borel–Cantelli estimate. Group the terms by Haar level: level n contributes 2^n Schauder tents with *disjoint* supports and common height of order $2^{-n/2}$. The level's contribution to the supremum $\sup_t |\cdot|$ is therefore at most $\big(\max_j |\xi_{n,j}|\big) \cdot 2^{-n/2}$, where the maximum runs over 2^n independent standard Gaussians. Such a maximum grows only like $\sqrt{n}$, and $\mathbb{P}\big(\max_j |\xi_{n,j}| > c\sqrt{n}\big)$ is summable in n once c is large; so by Borel–Cantelli the level-n contribution is eventually below $c\sqrt{n}\,2^{-n/2}$, and $\sum_n \sqrt{n}\,2^{-n/2} < \infty$. The geometric decay $2^{-n/2}$ coming from the shrinking tent heights overwhelms the slow $\sqrt{n}$ growth of the Gaussian maxima, and that summability is exactly the uniform convergence. Finally, concatenating independent copies on the intervals $[k, k+1]$ extends W from $[0,1]$ to all of $[0,\infty)$. $\square$

Physics note

Axiom (3) is the fluctuation–dissipation content in disguise. White noise $\xi(t)$ "is" the distributional time derivative $\mathrm{d}W_t/\,\mathrm{d}t$; its formal covariance $\langle \xi(t)\xi(t')\rangle = \delta(t-t')$ is nothing but the statement that $\mathrm{Var}(W_t - W_s) = t - s$ — the same linear-variance clause, read in frequency-free language. A bath at a temperature set by a diffusion constant D enters the dynamics later *only* through the volatility σ multiplying $\mathrm{d}W$; the noise process itself is universal. Every model in this book — LQG, graphon-LQG, the general nondegenerate diffusion — drives its state with the *same* canonical W, whose law (Wiener measure) carries no parameters at all. All physical scales (temperature, mobility, the diffusion constant, the friction) sit in the coefficients b, σ of the SDE, never in W, and the fluctuation–dissipation dictionary $\sigma^2/2 = D = k_\mathrm{B}\tau_\mathrm{temp}$ (made explicit for the harmonic case in section 5.7) is the statement that fixes those coefficients from the bath. Keeping W canonical and parameter-free, and loading every physical constant into b, σ, is precisely the bookkeeping the rigorous theory enforces — and it is what lets one universal object serve every model at once.

Two features of this construction must be carried forward into the next subsections. The covariance (5.1) and the explicit Gaussian moments $\mathbb{E}(W_t - W_s)^2 = t - s$, $\mathbb{E}(W_t - W_s)^4 = 3(t-s)^2$ are not byproducts of the existence proof; they are the working machinery of what follows. The quadratic-variation computation of section 5.1.2 runs entirely on these two moments — the very ones that bought us continuity here — so the same Gaussian arithmetic that built W will also extract the fact "$(\mathrm{d}W)^2 = \mathrm{d}t$" that drives the rest of the chapter. And continuity itself is a cliff edge. Axiom (4) is the *most* regularity a Brownian path possesses: we secured Hölder exponents up to but never including $\frac{1}{2}$, and the next subsection shows that this ceiling is real. Pushing past it to differentiability is impossible, because the $\sqrt{\mathrm{d}t}$ scaling of axiom (3) makes the difference quotient $(W_{t+h} - W_t)/h \sim 1/\sqrt{h}$ diverge. We turn now to pinning down exactly how rough the paths are, from above and from below.

5.1.1 Non-differentiability

The previous section left us at a cliff edge: continuity, axiom (4), is the *most* regularity a Brownian path possesses, and the existence proof already hinted why, securing Hölder exponents that climbed toward $\frac{1}{2}$ but never reached it. We now stand at that ceiling and pin down exactly how rough the paths are, and we do it from both sides at once. There is a positive statement — the paths are Hölder continuous of *every* order strictly below $\frac{1}{2}$, so they are not as wild as they could be — and a negative statement — they are Hölder of *no* order at or above $\frac{1}{2}$, and in the sharpest reading they are differentiable at no point whatsoever. The two bounds pincer the true regularity into the half-open window $[\,0, \frac{1}{2})$, and the gap they leave closes onto the single number $\frac{1}{2}$ that will organize the rest of the chapter. The reader should treat everything in this subsection as scaffolding for one takeaway: increments scale as $\sqrt{\mathrm{d}t}$, not $\mathrm{d}t$.

Theorem 5.3 (Path roughness)**.** *With probability one:*

1. *for every $\alpha < \frac{1}{2}$ the path $t \mapsto W_t$ is locally α-Hölder continuous;*

2. *the path is* nowhere *differentiable; more strongly, for every t the upper and lower derivates are $+\infty$ and $-\infty$.*

The two parts are the two halves of one picture, and it is worth saying what each costs and what each buys before sketching the proof. Part (1) is the *positive* half: it is a regularity *guarantee*, the best one available, and it is the half we will actually use. It is precisely the Hölder conclusion already extracted from the existence construction, where higher and higher Brownian moments fed into Kolmogorov–Chentsov pushed the attainable exponent up the ladder $\frac{1}{2} - \frac{1}{2k}$ toward, but never to, $\frac{1}{2}$. Part (2) is the *negative* half: it is an *obstruction*, certifying that the ceiling in part (1) is genuine and cannot be raised — not to differentiability, not even to Hölder-$\frac{1}{2}$. Where part (1) flows from the *smallness* of typical increments (they are no larger than $|t-s|^\alpha$ for $\alpha < \frac{1}{2}$), part (2) flows from their refusal to be *too small*: a $\sqrt{h}$-sized fluctuation cannot shrink to the $O(h)$ a derivative would demand.

Proof sketch. Part (1) is the Hölder conclusion of the Kolmogorov–Chentsov theorem (theorem C.9 and remark C.10) applied exactly as in route (i) of theorem 5.2: the Gaussian moments $\mathbb{E}\,|W_t - W_s|^{2k} = (2k-1)!!\,|t-s|^k$ verify the Chentsov hypothesis with $p = 2k$ and $1+\gamma = k$, delivering local Hölder continuity of every order $\alpha < \frac{1}{2} - \frac{1}{2k}$, and letting $k \to \infty$ gives every $\alpha < \frac{1}{2}$. This is the only part of the theorem the rest of the chapter relies on, and it is fully earned by the existence proof.

Part (2) is the Paley–Wiener–Zygmund theorem; we sketch only the mechanism, which is a contradiction between two scalings. Suppose, toward a contradiction, that the path were differentiable at some instant t_0 — or even merely had a bounded derivate there, so that $|W_{t_0+h} - W_{t_0}| \le L\,|h|$ for all small h and some finite L. A differentiable function has increments of order h: linear in the time step. But a Brownian increment is $W_{t_0+h} - W_{t_0} \sim N(0,h)$, whose typical size is $\sqrt{h}$. For small h the two scales are wildly mismatched, $\sqrt{h} \gg h$ — a fluctuation of size $\sqrt{h}$ is, relative to the $L\,|h|$ a derivative would permit, larger by the diverging factor $1/(L\sqrt{h}) \to \infty$. So the differentiability bound forces the increment to be *atypically small*, by an ever-growing margin as $h \downarrow 0$, and one must show that no point t_0 in $[0,1]$ can sustain such a run of improbably small increments. This is the dyadic-covering Borel–Cantelli step: cover $[0,1]$ by the 2^n dyadic intervals of length 2^{-n}; a derivate bounded by L at any t_0 would force *several consecutive* dyadic increments straddling t_0 to be of order 2^{-n} rather than their typical $2^{-n/2}$; the probability that any one dyadic interval shows so small an increment is itself small, the probability that a whole short block of them does so simultaneously is far smaller, and these probabilities sum to a convergent series in n. Borel–Cantelli then says that almost surely only finitely many such coincidences ever occur, so the bound can hold at no t_0 at all, and the event "differentiable somewhere" has probability zero. The careful covering count is carried out in [86, Thm. 2.9.18]. □

A word on *why we prove part (2) at all*, said plainly because it governs how much weight the reader should place on it: nowhere-differentiability is included *only* to complete the picture of path regularity, and it is *never* used anywhere downstream in this book. Not one later argument — not the Itô integral, not Itô's formula, not the Fokker–Planck equation — invokes the fact that paths fail to be differentiable. What the machinery downstream actually consumes is the *positive* regularity of part (1) together with the quadratic variation of the next subsection. We record part (2) because a reader who has just been told "$\dot{W}$ does not exist" deserves to see that claim honestly certified rather than asserted; but having certified it, we set it aside. The load the theorem really carries is one number and one scaling, not the dramatic nowhere-differentiability headline.

That scaling is the morally indispensable heuristic, and it is the single thing to carry out of this subsection: a Brownian increment over a window of length $\mathrm{d}t$ has size $\sqrt{\mathrm{d}t}$, not $\mathrm{d}t$. Both halves of the theorem are this one fact wearing different clothes. Part (1) holds because $\sqrt{h} = h^{1/2}$ is, for $\alpha < \frac{1}{2}$, smaller than h^α once h is small, so increments are controlled at every Hölder exponent below $\frac{1}{2}$; part (2) holds because $\sqrt{h}$ is, on the other hand, far *larger* than the h a derivative would require, so no difference quotient $(W_{t+h} - W_t)/h \sim 1/\sqrt{h}$ can settle to a finite limit — it diverges. The same $\sqrt{\mathrm{d}t}$ thus simultaneously caps the regularity from above and forbids differentiability from below.

This is precisely why $\mathrm{d}W$ cannot be manipulated by the ordinary rules of calculus, and it is the first warning that the integral $\int H \, \mathrm{d}W$ we will need cannot be a Riemann–Stieltjes integral: that classical construction integrates against the increments of a function of *finite* first variation, and a path whose increments are of size $\sqrt{\mathrm{d}t}$ accumulates infinite first variation on every interval (a point the next subsection makes precise). But the $\sqrt{\mathrm{d}t}$ scaling is, so far, only a statement about roughness — about what *fails*. Its real power is constructive, and emerges the moment we stop looking at a single increment and look instead at the *sum of their squares*. Squaring converts the inconvenient $\sqrt{\mathrm{d}t}$ into a clean $\mathrm{d}t$, and summing many such $\mathrm{d}t$'s, as the next subsection shows, turns a fluctuating random quantity into a deterministic one. We hand this heuristic to the quadratic-variation computation, which asks exactly that question: what does increments-of-size-$\sqrt{\mathrm{d}t}$ imply for the running sum of squared increments — the very quantity ordinary calculus throws away as higher order?

5.1.2 Quadratic variation

The previous subsection handed us a single heuristic, scrubbed of its dramatic packaging: a Brownian increment over a window of length $\mathrm{d}t$ has size $\sqrt{\mathrm{d}t}$, not $\mathrm{d}t$. So far this has been a statement about *roughness* — about what fails, why the difference quotient diverges and the path is nowhere smooth. Now we put the same fact to constructive use, and the trick is to stop watching a single increment and watch instead the running sum of their *squares*. Squaring is exactly the operation that converts the awkward $\sqrt{\mathrm{d}t}$ into a clean $\mathrm{d}t$: if ΔW is of order $\sqrt{\mathrm{d}t}$, then $(\Delta W)^2$ is of order $\mathrm{d}t$, the same order as the time step itself. Ordinary calculus throws this term away — for a differentiable path the squared increments are $O(\mathrm{d}t^2)$, genuinely higher order, and their sum vanishes in the continuum limit. For Brownian motion they are $O(\mathrm{d}t)$, of the *same* order as the spacing, so their sum is a sum of k_n terms each of size t/k_n, and it has every right to converge to something finite rather than to zero. The question this subsection answers is: to *what*? The answer is the clean, deterministic identity that is the technical engine of the entire chapter. Ordinary differentiable functions have zero quadratic variation; Brownian motion has quadratic variation equal to the elapsed time, and — crucially — it does so not on average but with the randomness washed out, the limit being a deterministic constant rather than a random variable.

Theorem 5.4 (Quadratic variation)**.** *Fix $t > 0$ and a sequence of partitions $\pi_n : 0 = t_0^n < t_1^n <$*

$\cdots < t^n_{k_n} = t$ with mesh $\|\pi_n\| = \max_i(t^n_{i+1} - t^n_i) \to 0$. Then

$$V_n \; := \; \sum_{i=0}^{k_n-1} \big(W_{t^n_{i+1}} - W_{t^n_i}\big)^2 \; \xrightarrow[n\to\infty]{L^2(\mathbb{P})} \; t. \tag{5.2}$$

If in addition $\sum_n \|\pi_n\| < \infty$ (e.g. dyadic refinements) the convergence is almost sure. One writes the limit as the quadratic variation $\langle W\rangle_t = t$.

The statement carries two layers, and it is worth separating them. The first is that the random quantity V_n has the right *average*: its mean is exactly t for every partition, fine or coarse. That much is just the linear-variance axiom restated. The second, and the substantive one, is that the *fluctuations of V_n around that mean die*: the variance of V_n collapses to zero as the mesh refines, so in the limit V_n is no longer random at all. This is the precise sense in which "the squares accumulate deterministically." The proof is exactly this two-step story — compute the mean, then kill the variance — and every ingredient is one of the two Gaussian moments that the existence construction already put on the table.

Proof. Write $\Delta_i W = W_{t^n_{i+1}} - W_{t^n_i}$ for the ith increment and $\Delta_i t = t^n_{i+1} - t^n_i$ for the length of the ith subinterval, so that $V_n = \sum_i (\Delta_i W)^2$ and $\sum_i \Delta_i t = t$.

The mean is t, exactly. Each increment is $\Delta_i W \sim N(0, \Delta_i t)$ by axiom (3), so $\mathbb{E}(\Delta_i W)^2 = \mathrm{Var}(\Delta_i W) = \Delta_i t$. Linearity of expectation then gives

$$\mathbb{E}V_n = \sum_{i=0}^{k_n-1} \mathbb{E}(\Delta_i W)^2 = \sum_i \Delta_i t = t,$$

a telescoping of the subinterval lengths. No independence and no fine structure of the partition is used here: $\mathbb{E}V_n = t$ holds term by term, for every n. The whole content of the theorem is therefore that V_n does not merely average to t but *concentrates* on t, and concentration is controlled by the variance.

The variance vanishes. Here independence does the work. Because the increments $\Delta_i W$ sit over disjoint time windows, axiom (2) makes them mutually independent, and hence so are their squares $(\Delta_i W)^2$; the variance of a sum of independent terms is the sum of the variances, with no cross-covariances surviving:

$$\mathrm{Var}\, V_n = \sum_i \mathrm{Var}\left((\Delta_i W)^2\right) = \sum_i \Big(\mathbb{E}(\Delta_i W)^4 - \big(\mathbb{E}(\Delta_i W)^2\big)^2\Big) = \sum_i \Big(\mathbb{E}(\Delta_i W)^4 - (\Delta_i t)^2\Big).$$

The fourth moment is the second Gaussian fact we already recorded: for $Z \sim N(0, \tau)$ the Gaussian moment formula gives $\mathbb{E}Z^4 = 3\tau^2$, the "3" being the number of pairings in Wick's theorem (or simply $(2\cdot 2 - 1)!! = 3$). With $\tau = \Delta_i t$ this turns each summand into $3(\Delta_i t)^2 - (\Delta_i t)^2 = 2(\Delta_i t)^2$, so

$$\mathrm{Var}\, V_n = \sum_i \left(3(\Delta_i t)^2 - (\Delta_i t)^2\right) = 2\sum_i (\Delta_i t)^2.$$

This sum is quadratic in the subinterval lengths, and that is precisely what makes it small: one factor of $\Delta_i t$ can be bounded by the mesh and pulled out, leaving the other factors to telescope.

Concretely, $\Delta_i t \le \|\pi_n\|$ for every i, so

$$\operatorname{Var} V_n = 2\sum_i (\Delta_i t)^2 \le 2\ \|\pi_n\| \sum_i \Delta_i t = 2\ \|\pi_n\|\ t \xrightarrow[n\to\infty]{} 0, \tag{5.3}$$

since $\sum_i \Delta_i t = t$ is fixed while the mesh $\|\pi_n\| \to 0$ by hypothesis. This is the decisive estimate: it is the refinement of the partition — many windows, each short — that drives the fluctuations to zero, and the mesh factor $\|\pi_n\|$ is exactly the lever. Combining the two steps, $\mathbb{E}\,(V_n - t)^2 = \operatorname{Var} V_n + (\mathbb{E}V_n - t)^2 = \operatorname{Var} V_n \to 0$, which is the asserted convergence (5.2) in $L^2(\mathbb{P})$.

Upgrade from L^2 to almost sure. The L^2 statement says $V_n \to t$ *on average* over ω; it does not by itself say that, for a fixed realization of the path, the numbers $V_n(\omega)$ settle down. To get that we trade the L^2 bound for a pathwise one, and the bridge is Chebyshev's inequality. For any $\varepsilon > 0$,

$$\mathbb{P}(\,|V_n - t| > \varepsilon)\ \le\ \frac{\mathbb{E}\,(V_n - t)^2}{\varepsilon^2}\ =\ \frac{\operatorname{Var} V_n}{\varepsilon^2}\ \le\ \frac{2t}{\varepsilon^2}\ \|\pi_n\|\,.$$

Under the extra hypothesis $\sum_n \|\pi_n\| < \infty$ — met, for instance, by dyadic refinements where $\|\pi_n\| = t\,2^{-n}$ and the geometric series converges — the right-hand side is summable in n, so $\sum_n \mathbb{P}(|V_n - t| > \varepsilon) < \infty$. The first Borel–Cantelli lemma then says that, with probability one, the event $\{|V_n - t| > \varepsilon\}$ occurs for only finitely many n; equivalently $\limsup_n |V_n - t| \le \varepsilon$ almost surely. Letting ε run through a sequence tending to 0 (and intersecting the countably many full-probability events) gives $V_n(\omega) \to t$ for almost every ω. The summability of the meshes is exactly what this argument consumes: without it the per-n probabilities need not add up, and one recovers only convergence along a subsequence rather than the full almost-sure statement. □

Before drawing the two corollaries, it is worth pausing on the contrast that makes the result surprising at all. Run the identical computation on a continuously differentiable path f. There $\Delta_i f = f'(\xi_i)\,\Delta_i t$ by the mean value theorem, so $(\Delta_i f)^2 = f'(\xi_i)^2(\Delta_i t)^2 \le \big(\sup|f'|\big)^2\ \|\pi_n\|\ \Delta_i t$, and summing gives a quadratic variation bounded by $\big(\sup|f'|\big)^2\ \|\pi_n\|\ t \to 0$: a smooth path has *zero* quadratic variation. The squared increments of a smooth function are genuinely $O(\mathrm{d}t^2)$ and wash out, exactly as ordinary calculus assumes. Brownian motion sits at the boundary where this assumption breaks: its increments are larger, of order $\sqrt{\mathrm{d}t}$, just enough to make the squared increments $O(\mathrm{d}t)$ and their sum survive. The quadratic variation t is the clean numerical signature of that borderline roughness.

Two corollaries now fix the intuition, and they are the two things this subsection hands forward. The first is a *negative* result. A Brownian path has *infinite* first variation on every interval — that is, $\sup_\pi \sum_i |\Delta_i W| = \infty$, the total length traced out by the path is unbounded. The reason is a one-line squeeze against the quadratic variation we just computed. On any partition,

$$V_n = \sum_i (\Delta_i W)^2\ \le\ \Big(\max_i |\Delta_i W|\Big) \sum_i |\Delta_i W|\,.$$

As the mesh refines, the path's continuity forces $\max_i |\Delta_i W| \to 0$, while the left side $V_n \to t > 0$. If the first-variation sum $\sum_i |\Delta_i W|$ stayed bounded, the right side would be (something $\to 0$) times (something bounded), hence $\to 0$, contradicting $V_n \to t$. So $\sum_i |\Delta_i W|$ must diverge: the first variation is infinite. This is precisely the obstruction the previous subsection promised, now made quantitative. The classical Riemann–Stieltjes integral $\int f \; \mathrm{d}g$ is built by summing f against the increments $\mathrm{d}g$ and is guaranteed to converge *only* when the integrator g has finite first variation, so that the increments can be controlled in absolute value. Brownian motion fails that single hypothesis by an infinite margin. There is therefore *no* Riemann–Stieltjes reading of $\int H \; \mathrm{d}W$, and the integral we will need in the next section must be built on a different principle entirely. The roughness that looked like a defect is the reason a genuinely new construction is forced.

The second corollary is the *positive* tool, and it is the one every later computation in the chapter will run on. Operationally, the identity $\langle W \rangle_t = t$ is the rigorous content of the symbolic multiplication table

$$(\mathrm{d}W_t)^2 = \mathrm{d}t, \qquad \mathrm{d}W_t \; \mathrm{d}t = 0, \qquad (\mathrm{d}t)^2 = 0,$$

which we will use repeatedly and which is justified precisely by theorem 5.4. Each entry is the limiting behavior of one kind of product of increments, read off the theorem. The first, $(\mathrm{d}W)^2 = \mathrm{d}t$, is theorem 5.4 itself in differential shorthand: summed over a window, $(\Delta W)^2$ behaves like the deterministic Δt, so under the integral sign one may *replace* $(\mathrm{d}W)^2$ by $\mathrm{d}t$. The third, $(\mathrm{d}t)^2 = 0$, is the smooth-path computation above: squared time increments are genuinely higher order and contribute nothing, just as in ordinary calculus. The middle entry, $\mathrm{d}W \; \mathrm{d}t = 0$, is the cross term, and it vanishes because it is intermediate in size: the product of a $\sqrt{\mathrm{d}t}$ object with a $\mathrm{d}t$ object is of order $\mathrm{d}t^{3/2}$, higher than first order, so summed over a window $\sum_i |\Delta_i W| \; \Delta_i t \le \|\pi_n\| \sum_i |\Delta_i W|$ behaves like $\|\pi_n\|^{1/2} \to 0$ once the typical $\sum_i |\Delta_i W|$ of order $\|\pi_n\|^{-1/2}$ is accounted for, and it too drops. The single moral, and the one to carry into the next sections, is that among all the second-order products only the *square* of the Brownian increment survives to first order, and it survives stripped of its randomness, as a deterministic $\mathrm{d}t$. That is the whole operational meaning of the quadratic-variation theorem, and it is what the Itô isometry, Itô's formula, and the generator will each be, in turn, an application of.

We close, then, by handing the next section two complementary things. The negative result — infinite first variation, hence no Riemann–Stieltjes integral — tells us that $\int_0^T H_t \; \mathrm{d}W_t$ cannot be defined by the classical recipe and forces a genuinely new construction. The positive result — the multiplication table $(\mathrm{d}W)^2 = \mathrm{d}t$, $\mathrm{d}W \; \mathrm{d}t = 0$, $(\mathrm{d}t)^2 = 0$ — is the deterministic arithmetic that new construction will be built to respect and that every computation downstream will exploit. The obstruction even points to where the freedom lies: if the Riemann–Stieltjes limit does not exist because the integrator is too rough, then the value of an approximating sum $\sum_i H_{\tau_i}(W_{t_{i+1}} - W_{t_i})$ can depend on *where* in the subinterval $[t_i, t_{i+1}]$ we sample the integrand H. Ordinary calculus is indifferent to that choice; here it is a real fork in the road. The next section turns that obstruction into a design decision — which evaluation point τ_i to fix — and shows that the answer the mathematics of mean field games selects is the left endpoint.

5.2 The Itô integral

The previous section closed by handing us an obstruction dressed as an opportunity. The negative corollary of the quadratic-variation theorem (theorem 5.4) was that a Brownian path has *infinite* first variation on every interval, and the classical Riemann–Stieltjes integral $\int f \; \mathrm{d}g$ converges in general only when the integrator g has *finite* first variation, so that the increments it is summed against can be controlled in absolute value. Brownian motion fails that single hypothesis by an infinite margin, so the object we actually need — $\int_0^T H_t \, \mathrm{d}W_t$, the running gain of an integrand H against the increments of W — has no Riemann–Stieltjes reading. We need this integral and cannot do without it: in the Langevin equation the noise enters precisely as $\sigma \, \mathrm{d}W$, and to allow a volatility that depends on the state, or later on a control, we must be able to integrate a genuinely *random*, possibly history-dependent integrand H_t against $\mathrm{d}W$. The classical machine refuses. But the *way* it refuses tells us how to build its replacement, and reading that off is the business of this short hinge section before the two subsections that do the construction.

Look at what actually goes wrong. To integrate H against $\mathrm{d}W$ one forms the approximating sums

$$\sum_i H_{\tau_i}(W_{t_{i+1}} - W_{t_i}), \qquad \tau_i \in [t_i, t_{i+1}],$$

where τ_i is a sample point chosen somewhere inside the ith subinterval, and asks whether they converge as the mesh refines. For an integrator of *finite* variation the answer is yes *and* the limit does not depend on where the τ_i are placed: moving each τ_i within its subinterval changes the sum by at most $\sum_i \left(\sup_{[t_i,t_{i+1}]} H - \inf_{[t_i,t_{i+1}]} H\right) |\Delta_i g|$, which is squeezed to zero by the continuity of H against the *bounded* total variation of g. That placement-independence is exactly the gift of finite variation, and it is why ordinary calculus never even raises the question of *where* in $[t_i, t_{i+1}]$ to evaluate the integrand: the question has no consequences. The moment the integrator is Brownian, the bounded-variation factor that did the squeezing is gone, and the question acquires consequences.

It is worth seeing, in one line, that the ambiguity is not a fastidious worry at the edge of some pathological example but a real and generically large effect — and that its size is once again the engine of the whole chapter. Take the simplest nontrivial integrand, $H_t = W_t$ itself, and compare the two extreme placements, the left endpoint $\tau_i = t_i$ and the right endpoint $\tau_i = t_{i+1}$. Their difference is

$$\sum_i W_{t_{i+1}}(W_{t_{i+1}} - W_{t_i}) - \sum_i W_{t_i}(W_{t_{i+1}} - W_{t_i}) = \sum_i \left(W_{t_{i+1}} - W_{t_i}\right)^2 \xrightarrow[\|\pi\|\to 0]{} T,$$

the quadratic variation of theorem 5.4. The left- and right-endpoint conventions do not agree in the limit; they disagree by the full deterministic amount T, and the gap between them is exactly the surviving second-order quantity $(\mathrm{d}W)^2 = \mathrm{d}t$ that the last subsection isolated. For a smooth integrator this same difference would be a sum of squared increments of order $\sum_i (\Delta_i g)^2 \to 0$ and the two conventions would coincide; for W it does not vanish. The evaluation point is therefore a genuine fork in the road, and *which* fork we take is not forced by anything analytic — it is a modelling decision we get to make, and different decisions give different, internally consistent calculi.

We make it by asking what the integrand *means*. When H_t is a strategy — a bet sized at time t, or, in Part II, a control chosen by an agent — it must be fixed using only information available *up to* time t; one cannot stake a wager on an increment one has not yet seen. The placement that honours this is the *left* endpoint, $\tau_i = t_i$: the integrand is locked in *before* the increment $W_{t_{i+1}} - W_{t_i}$ it multiplies is revealed. This is the Itô convention, and the whole construction to come is the systematic exploitation of that one choice. It carries two enormous payoffs and exacts a single, well-defined price; because the rest of the section and section 5.3 will repeatedly call back to this trade, we state it crisply here.

The *first payoff* is the martingale property. Because the bet H_{t_i} is decided before the fair, mean-zero increment it is multiplied against, each term contributes zero expected gain conditional on the past, and the running integral $t \mapsto \int_0^t H \, \mathrm{d}W$ inherits no systematic drift: it is a martingale, a fair game. This is the structural prize the mathematics of mean field games will demand — it is what lets stochastic integrals interlock with conditional expectations, optional stopping, and the verification arguments of chapter 6, and it is special to the left endpoint, as the $W \, \mathrm{d}W$ computation above already hints (the right-endpoint sum would carry a deterministic upward bias of size T). The *second payoff* is causality: the integral is assembled out of *non-anticipating* bets, the only admissible integrands once H is a control, so the Itô integral is automatically the right object for optimization under uncertainty rather than an analytic convenience retrofitted to it. The *one cost* is that the ordinary chain rule fails. The very fact that made the endpoint matter — that $(\mathrm{d}W)^2$ accumulates to a deterministic $\mathrm{d}t$ instead of vanishing — means that $\mathrm{d}f(W_t)$ is *not* $f'(W_t) \, \mathrm{d}W_t$; a second-order term survives, and the change-of-variables formula must be corrected to account for it. We have, in effect, bought the martingale property at the price of a modified calculus. Paying that price in full — deriving the corrected chain rule, Itô's formula, whose extra term *is* diffusion — is the work of section 5.3; here we only flag that the cost is real and exactly localized.

Two subsections discharge this programme. Section 5.2.1 performs the construction: it begins with *simple* integrands whose coefficients are decided before each increment — the literal "bet locked in at t_i" objects, made precise by demanding that the coefficient on $[t_i, t_{i+1}]$ be measurable with respect to the information available at t_i — defines the integral for them by the obvious finite sum, and then extends it to all square-integrable non-anticipating integrands by an isometry that the left-endpoint choice is exactly what makes available. Section 5.2.2 then returns to the fork in the road and follows the *other* branch: evaluating at the midpoint rather than the left endpoint yields the *Stratonovich* integral, a different but equally consistent calculus that trades the martingale property away in exchange for restoring the ordinary chain rule — the mirror image of the same trade — and we will compute the explicit correction term that converts one into the other.

5.2.1 Construction and the Itô isometry

The hinge section ended by committing to a single modelling choice: the integrand is to be locked in *before* the increment it multiplies, because that is what a non-anticipating bet — or, in Part II, a control chosen on the basis of information available so far — actually is. The construction now executes that commitment to the letter. The objects on which the integral is completely unambiguous are exactly those for which the integrand is piecewise constant in time and each constant value is fixed before its window opens; these are the literal "bet decided at t_i, then held fixed across $[t_i, t_{i+1}]$" processes, and everything else will be reached from them by a limit.

Let $\mathbb{F}$ be the Brownian filtration. Call a process H *simple* if there is a partition $0 = t_0 < \cdots < t_n = T$ and $\mathcal{F}_{t_i}$-measurable, square-integrable random variables η_i with $H_t = \sum_{i=0}^{n-1} \eta_i \, \mathbf{1}_{(t_i, t_{i+1}]}(t)$. For such H define, with no ambiguity,

$$I(H) \;:=\; \int_0^T H_t \, \mathrm{d}W_t \;=\; \sum_{i=0}^{n-1} \eta_i \left(W_{t_{i+1}} - W_{t_i} \right).$$

There is nothing to choose here and nothing to take a limit of: the integral of a simple process is a finite sum, the coefficient η_i being held constant across the window $(t_i, t_{i+1}]$ exactly as the left-endpoint convention prescribes. The single hypothesis that earns its keep is the $\mathcal{F}_{t_i}$-measurability of η_i. Spelled out, it says η_i is a function of the path *up to time* t_i alone and is therefore *independent* of the future increment $W_{t_{i+1}} - W_{t_i}$, which lives over $(t_i, t_{i+1}]$ and, by the independent-increments axiom (2) of definition 5.1, knows nothing of $\mathcal{F}_{t_i}$. This is the engine of the entire construction, and it works in two ways at once. First, it makes each term *mean zero*: a known coefficient times a fresh, fair, mean-zero kick has expectation zero. Second — and this is the deeper half — it makes distinct terms *uncorrelated*, because in any product of two terms the later increment is still a fresh fair kick relative to everything multiplying it. Mean zero plus uncorrelated is precisely the structure that turns the second moment of the sum into a sum of second moments, with no cross-terms surviving, and that collapse is the Itô isometry. We isolate it in a moment.

To house the limit we will take, let $\mathcal{M}^2[0,T]$ denote the space of progressively measurable processes H with $\mathbb{E}\int_0^T H_t^2 \, \mathrm{d}t < \infty$, a Hilbert space under that norm. The phrase *progressively measurable* deserves to be unpacked rather than waved through, since it is the minimal causal regularity the theory needs. Adaptedness, imported from chapter 3, asks that each *random variable* H_t be $\mathcal{F}_t$-measurable — a constraint at each fixed instant. Progressive measurability strengthens this to a statement about the integrand as a function of (s,ω) *jointly*: for every t, the restriction of $(s,\omega) \mapsto H_s(\omega)$ to $[0,t] \times \Omega$ is measurable for the product σ-algebra $\mathcal{B}([0,t]) \otimes \mathcal{F}_t$. The point of the upgrade is purely to make the *running* integral $t \mapsto \int_0^t H \, \mathrm{d}W$ a bona fide process — measurable jointly in time and chance, so that one may later integrate it again, stop it, or take its expectation without measurability anxieties. It is exactly the path-space refinement of adaptedness, no more, and the reader should not read into it any analytic strength beyond causality. The reassurance worth carrying is that for the integrands we ever actually use — continuous adapted processes, or left-continuous adapted ones like the simple integrands above — progressive measurability is *automatic*: an adapted process with left- or right-continuous paths is always progressively measurable, so the hypothesis never has to be checked by hand in practice. It is a technical hygiene condition, not a modelling restriction.

Lemma 5.5 (Itô isometry on simple processes)**.** *For simple H, $\mathbb{E}\, I(H) = 0$ and $\mathbb{E}\, I(H)^2 = \mathbb{E}\int_0^T H_t^2 \, \mathrm{d}t$.*

Proof. Write $\Delta_i W = W_{t_{i+1}} - W_{t_i}$ for the increments. The mean is the easy half. Each term $\eta_i \, \Delta_i W$ has expectation zero, because η_i is $\mathcal{F}_{t_i}$-measurable while $\Delta_i W$ is independent of $\mathcal{F}_{t_i}$ with mean zero; conditioning on $\mathcal{F}_{t_i}$ and pulling out the known factor, $\mathbb{E}[\eta_i \, \Delta_i W] = \mathbb{E}[\eta_i \, \mathbb{E}[\Delta_i W \mid \mathcal{F}_{t_i}]] = \mathbb{E}[\eta_i \cdot 0] = 0$, and summing gives $\mathbb{E}\, I(H) = 0$.

For the second moment, expand the square of the sum into diagonal and off-diagonal parts,

$$\mathbb{E}\, I(H)^2 = \sum_i \mathbb{E}[\eta_i^2 (\Delta_i W)^2] + 2 \sum_{i<j} \mathbb{E}[\eta_i \, \Delta_i W \; \eta_j \, \Delta_j W].$$

The off-diagonal terms vanish, and this is where the causality hypothesis does its work. Fix $i < j$, so that $t_{i+1} \le t_j$ and the three factors η_i, $\Delta_i W$ and η_j are all $\mathcal{F}_{t_j}$-measurable, while the remaining factor $\Delta_j W$ is independent of $\mathcal{F}_{t_j}$ with mean zero. Conditioning on $\mathcal{F}_{t_j}$ and using the tower property, the three known factors come out of the conditional expectation:

$$\begin{aligned}\mathbb{E}[\eta_i\,\Delta_i W\;\eta_j\,\Delta_j W] &= \mathbb{E}\Big[\,\mathbb{E}[\eta_i\,\Delta_i W\;\eta_j\,\Delta_j W\,|\,\mathcal{F}_{t_j}]\Big] \\ &= \mathbb{E}\Big[\,\eta_i\,\Delta_i W\;\eta_j\;\mathbb{E}[\Delta_j W\mid\mathcal{F}_{t_j}]\Big] = \mathbb{E}\big[\,\eta_i\,\Delta_i W\;\eta_j\cdot 0\,\big] = 0.\end{aligned}$$

Every cross term is killed by the single fact that the later increment is fresh relative to the past it is paired against — the uncorrelatedness promised above, now made explicit. Only the diagonal survives, and each diagonal term is evaluated the same way, by conditioning on $\mathcal{F}_{t_i}$: since η_i^2 is $\mathcal{F}_{t_i}$-measurable and $\mathbb{E}[(\Delta_i W)^2\mid\mathcal{F}_{t_i}]=\mathrm{Var}(\Delta_i W)=t_{i+1}-t_i$ by independence and axiom (3),

$$\mathbb{E}[\eta_i^2(\Delta_i W)^2]=\mathbb{E}[\eta_i^2\,\mathbb{E}[(\Delta_i W)^2\mid\mathcal{F}_{t_i}]]=\mathbb{E}[\eta_i^2]\,(t_{i+1}-t_i)=\mathbb{E}\int_{t_i}^{t_{i+1}}\eta_i^2\;\mathrm{d}t,$$

the last step because η_i is constant across $(t_i,t_{i+1}]$. Summing over i and recognizing $\sum_i\eta_i^2\,\mathbf{1}_{(t_i,t_{i+1}]}=H_t^2$ gives $\mathbb{E}\,I(H)^2=\mathbb{E}\int_0^T H_t^2\;\mathrm{d}t$, the claim. □

Read structurally, the lemma says the map $I: H\mapsto I(H)$ is a *linear isometry* from the simple processes, normed by $\mathcal{M}^2$, into $L^2(\mathbb{P})$: it carries the $\mathcal{M}^2$-length $\big(\mathbb{E}\int_0^T H^2\;\mathrm{d}t\big)^{1/2}$ of an integrand exactly onto the L^2-length of its integral, $\big(\mathbb{E}\,I(H)^2\big)^{1/2}$, with no distortion. This is precisely the lever that lets us reach *arbitrary* square-integrable non-anticipating integrands without ever choosing an evaluation point again. The argument is the standard isometric-extension principle of Hilbert-space theory, and it is worth stating in the abstract once so the reader sees there is no sleight of hand. A linear isometry defined on a *dense* subspace of a metric space, taking values in a *complete* space, extends uniquely to a linear isometry on the whole space: given any $H\in\mathcal{M}^2[0,T]$, choose simple $H^{(n)}\to H$; the images $I(H^{(n)})$ form a Cauchy sequence in $L^2(\mathbb{P})$ because $\big\|I(H^{(n)})-I(H^{(m)})\big\|_{L^2}=\big\|H^{(n)}-H^{(m)}\big\|_{\mathcal{M}^2}\to 0$ by the isometry applied to the difference; $L^2(\mathbb{P})$ is complete, so the limit exists; and it is independent of the approximating sequence, again by the isometry, since two approximants of the same H differ in $\mathcal{M}^2$-norm by something tending to zero. Two hypotheses make this run, and each is genuinely used: that the simple processes are *dense* in $\mathcal{M}^2[0,T]$ — so that every integrand is the limit of bets we already know how to evaluate (lemma C.6, proved by the standard three-step truncate–mollify–discretize approximation: truncate to bound the integrand, mollify in time to make it continuous, then sample on a fine grid to make it simple) — and that the target $L^2(\mathbb{P})$ is *complete*, so that the Cauchy images actually converge to something. The extension is the Itô integral, and because the construction is by isometry, the isometry identity itself is inherited automatically by the limit.

Definition 5.6 (Itô integral)**.** For $H\in\mathcal{M}^2[0,T]$ the *Itô integral* $\int_0^T H_t\;\mathrm{d}W_t$ is the $L^2(\mathbb{P})$ limit of $I(H^{(n)})$ for any sequence of simple processes $H^{(n)}\to H$ in $\mathcal{M}^2[0,T]$. The indefinite integral $M_t:=\int_0^t H_s\;\mathrm{d}W_s$ is defined for $t\in[0,T]$ and has a continuous modification.

The continuity claim in the definition is not free, and it is worth seeing why it holds, because it is what makes M a *path*, the thing Itô's formula will differentiate. The integrals of simple integrands are manifestly continuous in t — they are finite sums of continuous Brownian increments — and they are martingales. The danger is that the L^2 limit defining $\int_0^t H\;\mathrm{d}W$ holds for each fixed t

separately, and an uncountable family of pointwise-in-t limits need not assemble into a continuous path; we saw exactly this gap for Brownian motion itself in section 5.1, where continuity had to be installed by a modification rather than read off the finite-dimensional laws. The repair here is Doob's maximal inequality (theorem C.2), which for a continuous martingale N controls the *whole path* by the endpoint, $\mathbb{E}\big[\sup_{t\le T}|N_t|^2\big] \le 4\,\mathbb{E}\,|N_T|^2$. Applied to the differences $M^{(n)} - M^{(m)}$ of the approximating martingales, it upgrades the $\mathcal{M}^2$-Cauchy property into *uniform-in-t* L^2 convergence of the paths $t \mapsto M_t^{(n)}$; a sequence converging uniformly almost surely along a subsequence has a continuous limit, and that limit is the desired continuous modification of M. Doob's inequality is thus the device that propagates continuity from the simple integrands to their L^2 limit — the maximal inequality converting endpoint control into path control.

With the integral built and its indefinite version a genuine continuous process, we can collect the three structural facts the rest of the chapter will live on. The first is the isometry, now in polarized (bilinear) form; the second is the martingale property, the prize the left-endpoint convention was chosen to secure; the third is the quadratic variation, which records that the multiplication rule $(\mathrm{d}W)^2 = \mathrm{d}t$ survives the weighting by H as $\mathrm{d}\langle M\rangle = H^2\,\mathrm{d}t$.

Theorem 5.7 (Itô isometry and martingale property)**.** *For $H, K \in \mathcal{M}^2[0,T]$:*

1. $\mathbb{E}\Big[\int_0^T H\,\mathrm{d}W\Big] = 0$ *and* $\mathbb{E}\Big[\int_0^T H\,\mathrm{d}W \int_0^T K\,\mathrm{d}W\Big] = \mathbb{E}\int_0^T H_t K_t\,\mathrm{d}t$ *(polarized isometry);*
2. *the process $M_t = \int_0^t H_s\,\mathrm{d}W_s$ is a continuous $\mathbb{F}$-martingale: $\mathbb{E}[M_t \mid \mathcal{F}_s] = M_s$ for $s \le t$;*
3. *its quadratic variation is $\langle M\rangle_t = \int_0^t H_s^2\,\mathrm{d}s$, the natural generalization of theorem 5.4.*

Proof sketch. Each statement holds termwise for simple integrands and then passes to the L^2 limit; the only content is *why* each survives that limit, and in every case it is because the relevant operation is L^2-continuous.

(1) The polarized isometry. For simple H the squared-norm identity is exactly lemma 5.5; replacing H by $H+K$, $H-K$, and subtracting (the polarization identity $4\langle a,b\rangle = \|a+b\|^2 - \|a-b\|^2$) turns it into the bilinear form stated. To extend to general $H, K \in \mathcal{M}^2[0,T]$, take simple $H^{(n)} \to H$ and $K^{(n)} \to K$ in $\mathcal{M}^2$. Then $I(H^{(n)}) \to \int_0^T H\,\mathrm{d}W$ and $I(K^{(n)}) \to \int_0^T K\,\mathrm{d}W$ in $L^2(\mathbb{P})$ by construction, and *both sides* of the bilinear identity are continuous: the left side is the L^2 inner product, which is jointly continuous in its two arguments, and the right side is $\mathbb{E}\int_0^T H^{(n)}K^{(n)}$, which converges to $\mathbb{E}\int_0^T HK$ because $\mathcal{M}^2$-convergence is convergence in $L^2([0,T]\times\Omega)$ and the inner product there is again continuous. Equating the two limits gives the identity for H, K.

(2) The martingale property. For simple H and $s \le t$ the increment $M_t - M_s = \int_s^t H\,\mathrm{d}W$ is a sum of terms $\eta_i\,\Delta_i W$ each of which has zero conditional expectation given $\mathcal{F}_s$ — precisely the calculation of lemma 5.5, the coefficient being decided before its increment — so $\mathbb{E}[M_t \mid \mathcal{F}_s] = M_s$. To keep this under the limit, fix $s \le t$ and approximate by simple $H^{(n)} \to H$, so $M_t^{(n)} \to M_t$ and $M_s^{(n)} \to M_s$ in $L^2(\mathbb{P})$. The conditional expectation $\mathbb{E}[\,\cdot \mid \mathcal{F}_s]$ is the orthogonal projection of $L^2(\mathbb{P})$ onto $L^2(\Omega, \mathcal{F}_s, \mathbb{P})$, hence an L^2-*contraction*: it cannot increase L^2-distance, so $M_t^{(n)} \to M_t$ forces $\mathbb{E}[M_t^{(n)} \mid \mathcal{F}_s] \to \mathbb{E}[M_t \mid \mathcal{F}_s]$ in L^2. The left side equals $M_s^{(n)} \to M_s$; equating the two limits gives $\mathbb{E}[M_t \mid \mathcal{F}_s] = M_s$ almost surely. Continuity of M was established in definition 5.6.

(3) The quadratic variation. For simple H, on a window $(t_i, t_{i+1}]$ where $H \equiv \eta_i$ the integral increment is $\eta_i \, \Delta_i W$; refining that window into a subgrid and summing squared increments, the $\mathcal{F}_{t_i}$-measurable constant η_i^2 factors out and theorem 5.4 applied increment-by-increment turns the squared Brownian increments into the deterministic length, so the window contributes $\eta_i^2(t_{i+1} - t_i) = \int_{t_i}^{t_{i+1}} H_s^2 \, \mathrm{d}s$; summing windows gives $\langle M \rangle_t = \int_0^t H_s^2 \, \mathrm{d}s$. This is exactly $\mathrm{d}\langle M \rangle = H^2 \, \mathrm{d}t$: the rule $(\mathrm{d}W)^2 = \mathrm{d}t$ weighted by the integrand. Passing to the L^2 limit, the full statement — together with the localization that lets one drop the standing $\mathbb{E}\int H^2 \, \mathrm{d}t < \infty$ to merely $\int_0^T H^2 \, \mathrm{d}t < \infty$ almost surely, at the price of M becoming a *local* martingale defined through stopping times — is carried out in [86, Ch. 3]. □

It is worth reading the martingale property of part (2) slowly, because it is the structural prize the entire left-endpoint construction was built to secure, and it will be invoked by name many times downstream. In words: the running gain from a non-anticipating bet placed against a fair noise has, conditionally on everything known so far, zero expected increment. The bet H_s is sized using only the past, the noise $\mathrm{d}W_s$ it rides on is fair and fresh, and so no systematic drift can accumulate — the integral is a fair game in the exact technical sense $\mathbb{E}[M_t \mid \mathcal{F}_s] = M_s$. This single property is what lets stochastic integrals interlock with conditional expectations, and it underwrites at least three later developments the reader should keep in view. It is the foundation of *optimal stopping*, where the martingale/supermartingale dichotomy decides when to act. It is the engine of the *verification theorems* of chapter 6, where one shows a candidate value function is optimal precisely by arranging that the stochastic-integral term in its Itô expansion is a martingale and hence drops under expectation, leaving an inequality that pins down the optimum. And it is the defining structural requirement of the *backward stochastic differential equations* of chapter 9, whose solutions are built to be martingales adapted forward in time. Each of these is, at bottom, an exploitation of the fact that the Itô integral carries no drift.

Two of the three prizes are exactly what the next steps consume, and it is worth naming the hand-off explicitly. Section 5.3, which derives Itô's formula, runs entirely on the quadratic variation of part (3): the corrected chain rule for $f(X_t)$ acquires its extra second-order term as $\frac{1}{2}f'' \, \mathrm{d}\langle X \rangle$, and for an Itô process $\mathrm{d}X = b \, \mathrm{d}t + \sigma \, \mathrm{d}W$ that bracket is precisely $\mathrm{d}\langle X \rangle = \sigma^2 \, \mathrm{d}t$ — the weighted $(\mathrm{d}W)^2 = \mathrm{d}t$ we just established, with $H = \sigma$. The martingale property of part (2), meanwhile, is the pivot of the comparison in section 5.2.2: the choice that bought it — the left endpoint — is the very choice we are about to revisit, and the contrast there is exactly martingale-but-corrected-chain-rule (Itô) against ordinary-chain-rule-but-not-a-martingale (Stratonovich). We hand both facts forward and turn to the fork in the road we deliberately left open.

5.2.2 Itô versus Stratonovich

The left endpoint was a choice. That is the loose thread we deliberately left at the fork of section 5.2: the sample point τ_i could be placed anywhere inside $[t_i, t_{i+1}]$, the placement genuinely mattered — the left- and right-endpoint conventions disagreed in the limit by the full quadratic variation T — and we picked the left endpoint because it is the only *non-anticipating* placement, the one that locks the bet in before the increment it rides on is revealed. That single choice is what purchased the martingale property of theorem 5.7(2), the structural prize the whole construction was built around. But a choice that could have gone otherwise demands an accounting of what the other branches buy and what they cost. The right endpoint is no real competitor — it peeks at the future and is unusable as a strategy — so the honest alternative is the *symmetric* one: evaluate at the *midpoint* $\tau_i = \frac{1}{2}(t_i + t_{i+1})$, straddling the increment it multiplies rather than sitting to one side of it. Sampling there yields a genuinely different object, the *Stratonovich* integral, written $\int_0^T H_t \circ \mathrm{d}W_t$ with a small circle to distinguish it from the Itô integral $\int_0^T H_t \, \mathrm{d}W_t$.

The trade is the exact mirror of the one we made for Itô, and it is worth naming before any computation. The midpoint sees half of each increment before committing H, so it is no longer non-anticipating, and the cancellation that made each Itô term a fair, mean-zero bet against a fresh kick is broken: the Stratonovich integral is *not* a martingale. What it gains in exchange is the one thing Itô had to give up. Because the symmetric evaluation effectively splits the surviving second-order term evenly between the two sides of the increment, it folds exactly the Itô correction back into the integral, and the Stratonovich calculus obeys the *ordinary* chain rule of elementary calculus — $\mathrm{d}f(X) = f'(X) \circ \mathrm{d}X$, no extra term. Martingale-but-corrected-chain-rule versus ordinary-chain-rule-but-no-martingale: the two calculi are the two faces of the single fact $(\mathrm{d}W)^2 = \mathrm{d}t$, and one cannot have both faces at once. Our task in this subsection is to make the bridge between them quantitative — to compute, for a smooth volatility σ of the path, the precise correction term that converts a Stratonovich integral into an Itô one — and then to decide which calculus a physicist's Langevin equation actually denotes.

The correction is carried by a single new object, the cross-variation, and we define it before stating the conversion because it is the natural bilinear companion of the quadratic variation that already runs the chapter. Quadratic variation measured how a process accumulates its *own* squared increments; cross-variation measures how *two* processes accumulate the products of their increments, and like the quadratic variation it is forced to a deterministic limit by the $(\mathrm{d}W)^2 = \mathrm{d}t$ engine. For two Itô processes $\mathrm{d}X = b^X \, \mathrm{d}t + \sigma^X \, \mathrm{d}W$ and $\mathrm{d}Y = b^Y \, \mathrm{d}t + \sigma^Y \, \mathrm{d}W$ driven by the same Brownian motion, the *cross-variation* (or covariation) $\langle X, Y \rangle$ is defined by polarization from the quadratic variation,

$$\langle X, Y \rangle \;:=\; \tfrac{1}{2}\big(\langle X+Y \rangle - \langle X \rangle - \langle Y \rangle\big) \;=\; \lim_{\|\pi\| \to 0} \sum_i (\Delta_i X)(\Delta_i Y) \quad (\text{limit in } \mathbb{P}), \tag{5.4}$$

the in-probability limit of sums of products of increments along refining partitions. The two expressions agree for the same reason the variance of a sum decomposes: the elementary polarization identity $ab = \frac{1}{2}\big((a+b)^2 - a^2 - b^2\big)$, applied increment by increment with $a = \Delta_i X$ and $b = \Delta_i Y$, turns $\sum_i (\Delta_i X)(\Delta_i Y)$ into $\frac{1}{2}$ times $\sum_i (\Delta_i X + \Delta_i Y)^2 - \sum_i (\Delta_i X)^2 - \sum_i (\Delta_i Y)^2$, and each of those three sums converges to a quadratic variation — of $X + Y$, of X, of Y respectively — so the combination converges to $\frac{1}{2}(\langle X+Y \rangle - \langle X \rangle - \langle Y \rangle)$. Defining cross-variation this way is what makes $(X, Y) \mapsto \langle X, Y \rangle$ *bilinear and symmetric*, the bracket inheriting from the inner-product structure of the polarization formula exactly the rules a product should obey. Its value is read straight off the multiplication table. Since $\mathrm{d}\langle X \rangle = (\sigma^X)^2 \, \mathrm{d}t$ by theorem 5.7(3), applying that to $X + Y$ (whose volatility is $\sigma^X + \sigma^Y$) and expanding the square, $\mathrm{d}\langle X + Y \rangle = (\sigma^X + \sigma^Y)^2 \, \mathrm{d}t = \big((\sigma^X)^2 + 2\sigma^X \sigma^Y + (\sigma^Y)^2\big) \, \mathrm{d}t$, the pure squares cancel against $\mathrm{d}\langle X \rangle$ and $\mathrm{d}\langle Y \rangle$ in (5.4), leaving the cross term: the bilinear multiplication-table rule

$$\mathrm{d}\langle X, Y \rangle_t = \sigma_t^X \, \sigma_t^Y \, \mathrm{d}t.$$

This is simply "$\mathrm{d}X\ \mathrm{d}Y = \sigma^X\sigma^Y\ (\mathrm{d}W)^2 = \sigma^X\sigma^Y\ \mathrm{d}t$," the drift parts contributing nothing because $\mathrm{d}t\ \mathrm{d}W$ and $(\mathrm{d}t)^2$ both vanish in the table. The one instance we actually need is the specialization to $Y = W$ itself, which has unit volatility $\sigma^Y \equiv 1$ and no drift:

$$\mathrm{d}\langle X, W\rangle_t = \sigma_t^X\ \mathrm{d}t, \tag{5.5}$$

the rate at which a process co-varies with its own driving noise being exactly its volatility. This is the only cross-variation that appears below.

Proposition 5.8 (Itô–Stratonovich conversion)**.** *Let X be an Itô process (section 5.3) and $\sigma \in C^1(\mathbb{R})$. Then*

$$\int_0^T \sigma(X_t) \circ \mathrm{d}W_t \;=\; \int_0^T \sigma(X_t)\ \mathrm{d}W_t \;+\; \tfrac{1}{2}\int_0^T \sigma'(X_t)\ \mathrm{d}\langle X, W\rangle_t. \tag{5.6}$$

In particular, for the Stratonovich SDE $\mathrm{d}X_t = b(X_t)\ \mathrm{d}t + \sigma(X_t) \circ \mathrm{d}W_t$, the equivalent Itô SDE carries an extra drift,

$$\mathrm{d}X_t = \Big(b(X_t) + \tfrac{1}{2}\,\sigma(X_t)\,\sigma'(X_t)\Big)\,\mathrm{d}t + \sigma(X_t)\ \mathrm{d}W_t. \tag{5.7}$$

Proof sketch. The whole content is the difference between two Riemann sums for the *same* integrand that differ only in where the integrand is sampled. The Stratonovich integral is the limit of the *midpoint* sums $\sum_i \sigma(X_{\tau_i})\,\Delta_i W$ with $\tau_i = \frac{1}{2}(t_i + t_{i+1})$ and $\Delta_i W = W_{t_{i+1}} - W_{t_i}$, while the Itô integral is the limit of the left-endpoint sums $\sum_i \sigma(X_{t_i})\,\Delta_i W$. Their difference is therefore

$$D_n \;=\; \sum_i \left[\sigma(X_{\tau_i}) - \sigma(X_{t_i})\right] \Delta_i W,$$

and the entire conversion is the evaluation of $\lim_n D_n$. Expand the bracket to first order in the displacement $X_{\tau_i} - X_{t_i}$ of the path over the *first half* of the subinterval. By Taylor, $\sigma(X_{\tau_i}) - \sigma(X_{t_i}) = \sigma'(X_{t_i})\,(X_{\tau_i} - X_{t_i}) + O\big((X_{\tau_i} - X_{t_i})^2\big)$, and along an Itô process the half-step displacement is dominated by its noise part, $X_{\tau_i} - X_{t_i} = \sigma(X_{t_i})\,(W_{\tau_i} - W_{t_i}) + O(\Delta_i t)$ — the drift contributes only $b(X_{t_i})\,(\tau_i - t_i) = O(\Delta_i t)$, an order smaller than the $O(\sqrt{\Delta_i t})$ noise term and negligible in the sum. Substituting,

$$\sigma(X_{\tau_i}) - \sigma(X_{t_i}) \;=\; \sigma'(X_{t_i})\,\sigma(X_{t_i})\,(W_{\tau_i} - W_{t_i}) \;+\; \text{(lower order)},$$

so, writing $g_i := \sigma'(X_{t_i})\,\sigma(X_{t_i})$ for the (history-known) $\mathcal{F}_{t_i}$-measurable coefficient and splitting the full increment as $\Delta_i W = (W_{\tau_i} - W_{t_i}) + (W_{t_{i+1}} - W_{\tau_i})$ into its two half-window pieces,

$$D_n \;=\; \underbrace{\sum_i g_i\,(W_{\tau_i} - W_{t_i})(W_{t_{i+1}} - W_{\tau_i})}_{S_n^{\text{cross}}} \;+\; \underbrace{\sum_i g_i\,(W_{\tau_i} - W_{t_i})^2}_{S_n^{\text{sq}}} \;+\; \text{(lower order)}.$$

Two sums, with opposite fates, and it is exactly here that the proof-sketch's $\approx$ signs must be made to earn their keep.

The cross-term sum S_n^{cross} vanishes in L^2. In each summand the two Brownian factors $W_{\tau_i} - W_{t_i}$ and $W_{t_{i+1}} - W_{\tau_i}$ live over the *disjoint* half-windows $[t_i, \tau_i]$ and $[\tau_i, t_{i+1}]$, so by the independent-increments axiom they are independent of each other and of the $\mathcal{F}_{t_i}$-measurable coefficient g_i, and each has mean zero. We compute the second moment $\mathbb{E}\,(S_n^{\text{cross}})^2 = \sum_{i,j} \mathbb{E}[\,g_i g_j\,(W_{\tau_i} - W_{t_i})(W_{t_{i+1}} - W_{\tau_i})(W_{\tau_j} - W_{t_j})(W_{t_{j+1}} - W_{\tau_j})\,]$ and show every term is either zero or small. For $i \neq j$, say $i < j$, the latest factor $W_{t_{j+1}} - W_{\tau_j}$ is independent, with mean zero, of all five remaining factors (they are all measurable with respect to the past up to τ_j); conditioning on that past pulls it out as $\mathbb{E}[W_{t_{j+1}} - W_{\tau_j} \mid \mathcal{F}_{\tau_j}] = 0$, so every off-diagonal term vanishes, exactly as the cross terms did in the Itô isometry. Only the diagonal survives, and on it the two half-increments are independent with $\mathbb{E}(W_{\tau_i} - W_{t_i})^2 = \mathbb{E}(W_{t_{i+1}} - W_{\tau_i})^2 = \frac{1}{2}\Delta_i t$, so

$$\mathbb{E}\,(S_n^{\text{cross}})^2 = \sum_i \mathbb{E}[g_i^2]\,\tfrac{1}{2}\Delta_i t \cdot \tfrac{1}{2}\Delta_i t = \tfrac{1}{4}\sum_i \mathbb{E}[g_i^2]\,(\Delta_i t)^2 \;\le\; \tfrac{1}{4}\,\big(\sup_i \mathbb{E}[g_i^2]\big)\,\|\pi_n\| \sum_i \Delta_i t \;\xrightarrow[n\to\infty]{}\; 0,$$

the same mesh-times-quadratic estimate (5.3) that killed the variance of the quadratic variation: one factor $\Delta_i t$ is bounded by the mesh $\|\pi_n\|$ and pulled out, the other telescopes to T, and $\|\pi_n\| \to 0$. So $S_n^{\text{cross}} \to 0$ in L^2. The cross-term carries no limit: it is built from products of *independent* increments, never from a square, and only squares survive.

The squared-increment sum S_n^{sq} gives the $\frac{1}{2}$. Here the factor *is* a square, $(W_{\tau_i} - W_{t_i})^2$, and squares accumulate deterministically. The increment runs over the half-window $[t_i, \tau_i]$ of length $\tau_i - t_i = \frac{1}{2}\Delta_i t$, so by the quadratic-variation law theorem 5.4 — applied to this refining family of *half*-windows, against the continuous adapted weight $g_i = \sigma'(X_{t_i})\sigma(X_{t_i})$ — the squared half-increments may be replaced by the deterministic half-lengths:

$$S_n^{\text{sq}} = \sum_i g_i\,(W_{\tau_i} - W_{t_i})^2 \;\xrightarrow[n\to\infty]{}\; \int_0^T \sigma'(X_t)\,\sigma(X_t)\;\mathrm{d}\Big(\tfrac{1}{2}t\Big) = \tfrac{1}{2}\int_0^T \sigma'(X_t)\,\sigma(X_t)\;\mathrm{d}t.$$

The $\frac{1}{2}$ is not a convention or a fudge: it is precisely the fraction of the full step $\Delta_i t$ that the *half*-increment's square accumulates. Had we sampled at a general point $\tau_i = t_i + \theta\,\Delta_i t$ with $\theta \in [0,1]$, the surviving sum would converge to $\theta \int_0^T \sigma'\sigma\;\mathrm{d}t$; the left endpoint ($\theta = 0$) recovers the Itô integral with no correction, the right endpoint ($\theta = 1$) gives the full $\int \sigma'\sigma$, and the midpoint ($\theta = \frac{1}{2}$) splits the difference, which is the symmetric choice that defines Stratonovich. The whole family of calculi is parametrized by where in the increment one stands.

Collecting the two limits, $D_n \to \frac{1}{2}\int_0^T \sigma'(X_t)\,\sigma(X_t)\;\mathrm{d}t$, and using the cross-variation identity (5.5) with $\sigma^X = \sigma(X)$ to write $\sigma(X_t)\;\mathrm{d}t = \mathrm{d}\langle X, W\rangle_t$, this is $\frac{1}{2}\int_0^T \sigma'(X_t)\;\mathrm{d}\langle X, W\rangle_t$, which is precisely the asserted conversion (5.6). Equation (5.7) is then the same identity applied to the volatility term of the SDE: the Stratonovich diffusion $\sigma(X) \circ \mathrm{d}W$ equals the Itô diffusion $\sigma(X)\;\mathrm{d}W$ plus the surviving drift $\frac{1}{2}\sigma'(X)\;\mathrm{d}\langle X, W\rangle = \frac{1}{2}\sigma(X)\sigma'(X)\;\mathrm{d}t$, so a model written in Stratonovich form acquires, when rewritten in Itô form, exactly the extra drift $\frac{1}{2}\sigma\sigma'$. □

The correction $\frac{1}{2}\sigma\sigma'$ deserves a name and a careful reading, because it is the crux of the whole comparison: it is the *noise-induced drift*, a systematic motion that the multiplicative coupling of the state to the noise manufactures out of pure fluctuation. Its structure tells the entire story. It is built from σ', the rate at which the noise amplitude changes with the state, multiplied by σ itself, the amplitude. Where the noise is stronger on one side than the other, the random kicks are systematically larger in one direction, and over many kicks that asymmetry rectifies into a net drift — a real, observable bias, not a bookkeeping artifact. The decisive consequence, and the one this whole book will lean on, is the conditional under which it *disappears*: the moment σ is a *constant*,

$\sigma' \equiv 0$ and the noise-induced drift is identically zero. *Additive* noise — the state coupled to the bath through a fixed amplitude, never modulated by the state — feels no correction at all, and the Itô and Stratonovich integrals literally coincide. Only *multiplicative* noise, where σ varies with the state, makes the two calculi part company. Hold onto this: it is exactly why the linear–quadratic threads of this book are spared the entire question.

With the conversion in hand we can state precisely what the two calculi are to each other, and it is not a rivalry. Each is internally consistent; each integrates the same integrands against the same Brownian motion; they simply make opposite choices at the one fork the roughness of W opened up, and they pay complementary prices. The trade is forced, and it is the same $(\mathrm{d}W)^2 = \mathrm{d}t$ surviving term seen from two sides: *the Itô integral is a martingale but obeys a corrected chain rule; the Stratonovich integral obeys the ordinary chain rule but is not a martingale.* One cannot have both. The martingale property came from locking the bet in before its increment — the left endpoint — and that same non-anticipation is exactly what forces the surviving second-order term to land entirely on the chain rule as a correction, because the integrand never gets to "see" the half of the increment that would symmetrize it away. Stratonovich's midpoint absorbs that half-increment back into the integral, which is why its chain rule is the ordinary one — but in seeing half of the increment it forfeits the conditional fairness that made Itô a martingale. There is no third convention escaping the dilemma; the two are the two stable resolutions of a single tension.

Notation watch

Which calculus does a physicist's Langevin equation mean? When the noise amplitude depends on the state — multiplicative noise — the bare equation $\dot{x} = b(x) + \sigma(x)\,\xi$ is *ambiguous*, and the ambiguity is exactly the $\frac{1}{2}\sigma\sigma'$ term in eq. (5.7). The resolution is physical, not conventional: if ξ is idealized from a real bath with a short but nonzero correlation time, then—this we invoke as physical motivation, not as a step in the book's rigorous development—a classical result of Wong and Zakai [133] asserts that the zero-correlation-time limit of the (ordinary, pathwise) solutions converges to the *Stratonovich* solution. The heuristic is immediate: a smooth (colored-noise) approximation of W has finite variation, so it obeys the *ordinary* chain rule, and the calculus that obeys the ordinary chain rule is precisely the Stratonovich one. So a Langevin equation obtained as a white-noise idealization of colored noise is Stratonovich; a model written down directly as a discrete-time non-anticipating recursion is Itô. The mathematics of stochastic control and of mean field games is built on the Itô integral, because optimization needs the martingale property; we therefore use Itô throughout, and translate any Stratonovich physical model via eq. (5.7). **For the LQG and graphon-LQG threads the noise is additive (σ constant), so the two calculi coincide and the question is moot** — one reason the linear–quadratic world is so clean.

The convention is now settled, and we carry it forward unambiguously: from here on every stochastic integral, SDE, and generator in this book is read in the *Itô* sense, chosen for the martingale property that optimization and the verification arguments of chapter 6 cannot do without. A physical model handed to us in Stratonovich form is not a competitor but a translation problem: we convert it once, through the drift correction (5.7), replacing $\sigma \circ \mathrm{d}W$ by $\sigma\ \mathrm{d}W$ and adding $\frac{1}{2}\sigma\sigma'\ \mathrm{d}t$ to the drift, and thereafter work entirely in Itô. For the additive-noise threads that run through the book this translation is the identity, and the distinction never resurfaces.

Settling the convention also discharges the promissory note left open since the construction of the integral. The price of the left endpoint, we said, was that the ordinary chain rule fails: $\mathrm{d}\sigma(W_t)$ is not $\sigma'(W_t)\ \mathrm{d}W_t$, and a second-order term survives. The conversion just computed is the first concrete sighting of that surviving term — the very $\frac{1}{2}$ that distinguishes the two calculi is the same $\frac{1}{2}$ that the corrected chain rule will carry — but here it appeared only as the gap between two integrals of a fixed integrand. What we have *not* yet done is repair the chain rule itself: write down, for a general smooth f and a general Itô process, the exact differential of $f(X_t)$ with its correction term in place. That is the task of the next section. It works at the level of the Itô-process notation $\mathrm{d}X = b\ \mathrm{d}t + \sigma\ \mathrm{d}W$ that the cross-variation rule (5.5) already presumed and that theorem 5.7 made legitimate, and it turns the morality of "$(\mathrm{d}W)^2 = \mathrm{d}t$" into a clean second-order calculus. The extra term it produces is no longer a nuisance to be converted away: it *is* diffusion, the bridge from a single trajectory to the Fokker–Planck flow of the whole ensemble. We turn to Itô's formula.

5.3 Itô's formula

The Itô-versus-Stratonovich subsection settled a convention and, in doing so, signed a promissory note. We chose the left endpoint, bought the martingale property with it, and paid for it in a single coin we named but did not yet mint: the ordinary chain rule fails, and a corrected one must take its place. The conversion computation of section 5.2.2 already showed the *shape* of the correction — a term proportional to the surviving second-order quantity $(\mathrm{d}W)^2 = \mathrm{d}t$, the very fact the symmetric Stratonovich evaluation folds silently back into the integral while the left-endpoint Itô integral leaves it standing in the open. What remains is to make that correction exact and universal: to write down, once and for all, how *any* smooth function of *any* Itô process evolves. That statement is Itô's formula, and it is the analytic heart of the chapter. Here the one fact carried since the quadratic-variation theorem — that squared Brownian increments accumulate to a deterministic $\mathrm{d}t$ rather than vanishing — finally surfaces as a concrete differential operator, the $\frac{1}{2}\sigma^2\partial_{xx}$ term that ordinary calculus would have discarded as higher order. We will see at the end of the section that this term *is* diffusion; everything downstream is its echo.

We state the rule for the natural class of processes the Itô integral was built to produce. Define an *Itô process* to be one of the form

$$X_t = X_0 + \int_0^t b_s\ \mathrm{d}s + \int_0^t \sigma_s\ \mathrm{d}W_s, \qquad \text{abbreviated} \quad \mathrm{d}X_t = b_t\ \mathrm{d}t + \sigma_t\ \mathrm{d}W_t, \tag{5.8}$$

with b progressively measurable and integrable and $\sigma \in \mathcal{M}^2$ — a drift piece accumulated as an ordinary (Lebesgue) integral and a noise piece accumulated as the Itô integral of section 5.2.1. This is exactly the right level of generality for two reasons. It is broad enough to contain every state process this book will meet: the solution of an SDE in section 5.4 is of this form, and so is the controlled state of Part II. And it is, as the theorem will show, *closed* under the operation we are about to define — a smooth function of an Itô process is again an Itô process — which is precisely what makes Itô calculus a calculus rather than a collection of one-off tricks: one may apply the change-of-variables rule and then apply it again to the result, exactly as one chains the ordinary chain rule.

Before stating the rule we read off the one structural fact an Itô process carries with it, its quadratic variation. The abbreviation $\mathrm{d}X_t = b_t\ \mathrm{d}t + \sigma_t\ \mathrm{d}W_t$ splits each increment into a smooth part of order $\mathrm{d}t$ and a rough part of order $\sqrt{\mathrm{d}t}$, and squaring sorts them by the multiplication table of section 5.1.2. The drift contributes nothing: the integral $\int_0^t b_s\ \mathrm{d}s$ has finite first variation, so by the smooth-path computation of theorem 5.4 its own quadratic variation is zero, and its cross-variation with the noise piece vanishes as well — this is the entry $\mathrm{d}W\ \mathrm{d}t = 0$, the cross term that is intermediate in size and drops. Only the square of the noise piece survives, and by $(\mathrm{d}W)^2 = \mathrm{d}t$ it survives stripped of its randomness. Thus

$$\mathrm{d}\langle X\rangle_t = \sigma_t^2\ \mathrm{d}t, \tag{5.9}$$

inherited from theorem 5.7(3): *the drift, having finite first variation, contributes nothing, and the entire quadratic variation of an Itô process is carried by its volatility.* This single line is what the formula below will contract against the second derivative of F; it is worth keeping (5.9) in view as the one piece of data that distinguishes the Itô chain rule from the ordinary one.

With the process and its quadratic variation in hand, ask the question the rule answers. We rarely care about the state X_t in isolation; we care about smooth observables of it — an energy $\frac{1}{2}X_t^2$, a payoff $F(t, X_t)$, a test function integrated against the law. How does such an observable evolve? In ordinary calculus the answer is the chain rule, $\mathrm{d}F = \partial_t F\ \mathrm{d}t + \partial_x F\ \mathrm{d}X$, and nothing more. For an Itô process that answer is wrong, and wrong by exactly one term.

Theorem 5.9 (Itô's formula)**.** *Let X be the Itô process* (5.8) *and let $F \in C^{1,2}([0,T]\times\mathbb{R})$. Then $F(t, X_t)$ is again an Itô process and*

$$\mathrm{d}F(t,X_t) = \Big(\partial_t F + b_t\,\partial_x F + \tfrac{1}{2}\,\sigma_t^2\,\partial_{xx}F\Big)(t,X_t)\ \mathrm{d}t\ +\ \sigma_t\,\partial_x F(t,X_t)\ \mathrm{d}W_t. \tag{5.10}$$

In d dimensions, with $\mathrm{d}X_t = b_t\ \mathrm{d}t + \sigma_t\ \mathrm{d}W_t$, $b_t \in \mathbb{R}^d$, $\sigma_t \in \mathbb{R}^{d\times d}$, and $F \in C^{1,2}([0,T]\times\mathbb{R}^d)$,

$$\mathrm{d}F(t,X_t) = \Big(\partial_t F + b_t\cdot\nabla F + \tfrac{1}{2}\ \mathrm{tr}\big(\sigma_t\sigma_t^\top\,\mathrm{D}^2\,F\big)\Big)\,\mathrm{d}t + \big(\nabla F\big)^\top\sigma_t\ \mathrm{d}W_t, \tag{5.11}$$

all derivatives evaluated at (t, X_t).

Proof sketch. The whole argument is one Taylor expansion read through the multiplication table; we give its skeleton and intuition in full and defer only the bookkeeping of the remainder to appendix C.5, where the localization is done carefully. Fix a partition $0 = t_0 < \cdots < t_k = t$ of $[0,t]$, write $\Delta_i t$, $\Delta_i X$, $\Delta_i W$ for the increments across $[t_i, t_{i+1}]$, and telescope: $F(t,X_t) - F(0,X_0) = \sum_i \big[F(t_{i+1}, X_{t_{i+1}}) - F(t_i, X_{t_i})\big]$. Because $F \in C^{1,2}$, expand each summand to *second* order — first order in time, second order in space, since the space variable is the rough one —

$$F(t_{i+1}, X_{t_{i+1}}) - F(t_i, X_{t_i}) = \partial_t F\,\Delta_i t + \partial_x F\,\Delta_i X + \tfrac{1}{2}\,\partial_{xx}F\,(\Delta_i X)^2 + R_i,$$

with all derivatives at (t_i, X_{t_i}) and R_i the Taylor remainder. The proof is the fate of the three explicit groups and the vanishing of $\sum_i R_i$, taken in turn.

The first two groups give ordinary calculus. The time sum $\sum_i \partial_t F\, \Delta_i t$ is a Riemann sum and converges to $\int_0^t \partial_t F(s, X_s)\, \mathrm{d}s$. The first-order space sum $\sum_i \partial_x F\, \Delta_i X$ converges to $\int_0^t \partial_x F\, \mathrm{d}X_s$ by the very definition of the Itô integral: it is a left-endpoint sum of a non-anticipating integrand against the increments $\Delta_i X$, and splitting $\mathrm{d}X = b\, \mathrm{d}t + \sigma\, \mathrm{d}W$ resolves it into a b-Riemann piece $\int_0^t \partial_x F\, b_s\, \mathrm{d}s$ and an Itô piece $\int_0^t \partial_x F\, \sigma_s\, \mathrm{d}W_s$. So far this is exactly the ordinary chain rule $\mathrm{d}F = \partial_t F\, \mathrm{d}t + \partial_x F\, \mathrm{d}X$; had the path been smooth, the story would end here.

The third group is the entire content of the formula. It does not vanish. Substitute $\Delta_i X = b_{t_i}\Delta_i t + \sigma_{t_i}\Delta_i W + (\text{higher order})$ and square. By the multiplication table the $\Delta_i t$ pieces are genuinely higher order — the $(\Delta_i t)^2$ and $\Delta_i t\, \Delta_i W$ products sum to zero — so the only surviving piece is $(\Delta_i X)^2 \approx \sigma_{t_i}^2 (\Delta_i W)^2$. Now the quadratic-variation theorem does its work. Were $(\Delta_i W)^2$ of order $(\Delta_i t)^2$, as it is for a differentiable path, the sum $\sum_i \frac{1}{2}\partial_{xx} F\, \sigma_{t_i}^2 (\Delta_i W)^2$ would be $O(\|\pi\|)$ and vanish, recovering ordinary calculus. But $(\Delta_i W)^2 \sim \Delta_i t$ by theorem 5.4, and what the theorem proved is that these squared increments may be *replaced* by the deterministic $\Delta_i t$ inside a sum, with the randomness washing out. Hence

$$\sum_i \tfrac{1}{2}\, \partial_{xx} F\, \sigma_{t_i}^2\, (\Delta_i W)^2 \;\longrightarrow\; \tfrac{1}{2} \int_0^t \partial_{xx} F(s, X_s)\, \sigma_s^2\, \mathrm{d}s,$$

not to zero. This is the surviving second-order term, and it is the whole difference between the two calculi: in ordinary calculus the second-order term is $o(\Delta t)$ and drops; here $(\Delta W)^2 \sim \Delta t$, so it persists with weight $\frac{1}{2}\sigma^2$. Adding the three limits gives (5.10).

The remainder, the only delicate point. It remains to show $\sum_i R_i \to 0$, and this is where the heuristic "$(\mathrm{d}W)^2 = \mathrm{d}t$" must be upgraded to a genuine convergence rather than a slogan. Two issues are folded together and we separate them. First, *localization*: F and its derivatives are continuous but not *a priori* bounded, and b, σ may be unbounded, so one first stops the process at the exit time of a large ball and at a level where the coefficients are bounded, proves the identity there, and removes the localization by letting the ball grow — the routine but unilluminating part deferred to appendix C.5. Granting that reduction, X takes values in a compact set K, all relevant derivatives live on the compact $[0, t] \times K$, and the substantive estimate is clean. The dangerous remainder is the second-order one: the exact Taylor formula writes the third group with $\partial_{xx} F$ evaluated not at (t_i, X_{t_i}) but at some intermediate point θ_i on the segment between the two endpoints, so the error made by freezing it at the left endpoint is

$$\sum_i \tfrac{1}{2} \big[\partial_{xx} F(\theta_i) - \partial_{xx} F(t_i, X_{t_i})\big] (\Delta_i X)^2.$$

Here is the decisive point. On the compact $[0, t] \times K$ the map $\partial_{xx} F$ is *uniformly* continuous, and as the mesh refines, path-continuity forces each θ_i to lie within a vanishing distance of (t_i, X_{t_i}); so given $\varepsilon > 0$, once the mesh is fine enough the bracket is uniformly below ε for every i. The remainder sum is then bounded in absolute value by $\frac{1}{2}\varepsilon \sum_i (\Delta_i X)^2$, and the surviving factor $\sum_i (\Delta_i X)^2$ is precisely the quadratic-variation sum, which converges in L^1 to $\langle X \rangle_t = \int_0^t \sigma_s^2\, \mathrm{d}s$ and is in particular bounded in L^1 uniformly in the partition. Thus the whole remainder is $\leq \frac{1}{2}\varepsilon \cdot (\text{a fixed } L^1 \text{ bound})$, and since ε was arbitrary it tends to zero in L^1. This is the exact step that converts the heuristic $(\mathrm{d}W)^2 = \mathrm{d}t$ into honest convergence: uniform continuity of $\partial_{xx} F$ on compacta supplies the small factor ε, and the quadratic-variation estimate (5.3) supplies the bounded factor $\sum_i (\Delta_i X)^2$, and the product is forced to zero. The lower-order pieces of R_i — those carrying a $\Delta_i t$ — vanish faster, by the same $\mathrm{d}W\ \mathrm{d}t = 0$, $(\mathrm{d}t)^2 = 0$ bookkeeping. The complete localized argument is appendix C.5; [106, Thm. 4.1.6] is the textbook reference.

The d-dimensional case is identical, with one bookkeeping change at the second-order term. The scalar $\frac{1}{2}\partial_{xx}F\,(\Delta_i X)^2$ becomes the quadratic form $\frac{1}{2}\sum_{k,l}\partial_{x_k x_l}F\,(\Delta_i X)_k(\Delta_i X)_l$, i.e. the Hessian $\mathrm{D}^2 F$ contracted against the outer product $\Delta_i X\,\Delta_i X^\top$. Reading that outer product through the multiplication table, and using that the components $W^1, \dots, W^d$ are *independent* Brownian motions, the cross-variations obey $\mathrm{d}W^i\ \mathrm{d}W^j = \delta_{ij}\ \mathrm{d}t$ — the off-diagonal $i \neq j$ entries vanish because independent Brownian motions have zero covariation (the polarization (5.4) of two independent, hence uncorrelated, increments), while the diagonal entries are each $\mathrm{d}t$. Hence $\mathrm{d}X\ \mathrm{d}X^\top = \sigma\sigma^\top\ \mathrm{d}t$, the matrix $\sigma\sigma^\top$ playing the role of the scalar σ^2, and the contracted second-order term is $\frac{1}{2}\ \mathrm{tr}\big(\sigma\sigma^\top\,\mathrm{D}^2 F\big)\ \mathrm{d}t$, which is (5.11). □

Heuristic (non-rigorous)

In practice one never re-runs the partition argument. The working mnemonic is purely mechanical: write the formal second-order Taylor expansion and then simplify $(\mathrm{d}X)^2$ by the multiplication table $(\mathrm{d}W)^2 = \mathrm{d}t$, $\mathrm{d}W\ \mathrm{d}t = 0$, $(\mathrm{d}t)^2 = 0$,

$$\mathrm{d}F = \partial_t F\ \mathrm{d}t + \partial_x F\ \mathrm{d}X + \tfrac{1}{2}\partial_{xx}F\,(\mathrm{d}X)^2, \qquad (\mathrm{d}X)^2 = (b\ \mathrm{d}t + \sigma\ \mathrm{d}W)^2 = \sigma^2\ \mathrm{d}t.$$

Keeping the expansion to first order in $\mathrm{d}t$ and to *second* order in $\mathrm{d}W$, and then collapsing $(\mathrm{d}W)^2 \to \mathrm{d}t$, reproduces (5.10) in one line. What licenses each of these symbolic moves is not formal bravado but the theorems just proved: the collapse $(\mathrm{d}W)^2 \to \mathrm{d}t$ is the quadratic-variation theorem theorem 5.4, the vanishing of $\mathrm{d}W\ \mathrm{d}t$ and $(\mathrm{d}t)^2$ is the finite first variation of the smooth pieces, and the legitimacy of stopping the Taylor expansion at second order is the L^1 remainder control above. The mnemonic is exact precisely because each entry of the table is a theorem. Every appearance of the Itô second-order term in this book — the Laplacian in Fokker–Planck, the $\frac{1}{2}\sigma^2\partial_{xx}$ in the generator, the Hessian penalty in stochastic HJB — is this one surviving term, and no other source of it exists in the whole development.

It is worth isolating, on the smallest possible example, exactly what the second-order term *means* — and what physics one would get wrong without it. Take the simplest nonlinear observable, $F(x) = x^2$, of the simplest Itô process, $\mathrm{d}X = \sigma\ \mathrm{d}W$ with σ constant (pure noise, no drift): this is just a Brownian particle with volatility σ and no restoring force. Here $\partial_x F = 2x$ and $\partial_{xx}F = 2$, so theorem 5.9 reads

$$\mathrm{d}(X_t^2) = \partial_x F\,\sigma\ \mathrm{d}W_t + \tfrac{1}{2}\partial_{xx}F\,\sigma^2\ \mathrm{d}t = 2X_t\,\sigma\ \mathrm{d}W_t + \sigma^2\ \mathrm{d}t.$$

Now take expectations. The first term is an Itô integral, hence a martingale, hence of zero mean by theorem 5.7(2); only the deterministic correction survives, and integrating $\mathrm{d}\,\mathbb{E}X_t^2 = \sigma^2\ \mathrm{d}t$ gives

$$\mathbb{E}X_t^2 = \mathbb{E}X_0^2 + \sigma^2\,t.$$

The second moment — the variance, if X_0 is centered — grows *linearly* in time at rate σ^2. A probability packet that started as a spike spreads, its width $\sqrt{\mathbb{E}X_t^2}$ swelling like $\sqrt{t}$, and that linear-in-time growth of the variance is the defining signature of diffusion. Itô's correction term is its entire source. Set the correction to zero — apply the naive chain rule $\mathrm{d}(X^2) = 2X\ \mathrm{d}X = 2X\,\sigma\ \mathrm{d}W$ — and one would conclude $\mathbb{E}X_t^2 = \mathbb{E}X_0^2$, a *conserved* variance: a diffusing particle that never spreads, which is simply the wrong physics. The discrepancy between the two answers is exactly the missing $\sigma^2 t$, the integral of the surviving second-order term. And this rate σ^2 is no accident of the example: it is the very constant that will reappear in section 5.5 as the diffusion coefficient multiplying the Laplacian in the Fokker–Planck equation, where the same term, now acting on a density rather than a single trajectory, drives the packet's spread. The Fokker–Planck diffusion constant is nothing but Itô's second-order term carried through.

This closes the loop the chapter opened. We can now hand Itô's formula forward as the single universal lever the remaining sections will all pull. Section 5.4 needs it immediately and in two roles at once: together with the Itô integral just constructed it is what gives the differential $\mathrm{d}X = b(t,X)\ \mathrm{d}t + \sigma(t,X)\ \mathrm{d}W$ — the rigorous form of the Langevin nonsense $\dot{x} = -V' + \xi$ the preamble warned about — its honest meaning as the integral equation (5.8) with state-dependent coefficients, and it is the engine of the moment estimates (apply the formula to $F(x) = |x|^2$, take expectations, and the second-order term produces exactly the Grönwall inequality that yields existence, uniqueness, and a priori bounds). Beyond that, the same formula generates the rest of the chapter: applying it to $F(X_t)$ and taking expectations isolates the generator $\mathcal{A} = b\,\partial_x + \frac{1}{2}\sigma^2\partial_{xx}$ (Dynkin's formula), in which the second-order term is now a differential operator; the generator's appearance in section 5.5 drives the Fokker–Planck equation forward and the Kolmogorov backward equation in reverse; and in section 5.6 the formula applied to a suitably weighted functional produces the martingale whose constant expectation is the Feynman–Kac bridge between path expectations and linear PDEs. In every one of these the extra term is the same $\frac{1}{2}\sigma^2\partial_{xx}$ we just minted: to repeat the flag, *every Itô second-order term in this book is this one surviving term.* The next section spends it first, on giving the Langevin equation a rigorous solution.

5.4 Stochastic differential equations

The previous section handed us Itô's formula as the universal lever of the chapter, and named the very first thing it would lift: it gives the differential $\mathrm{d}X = b(t,X)\ \mathrm{d}t + \sigma(t,X)\ \mathrm{d}W$ — the rigorous form of the Langevin nonsense $\dot{x} = -V' + \xi$ the preamble warned about — its honest meaning as an integral equation, and it is the engine of the moment estimates that make that equation solvable. We now spend the lever on exactly that. The whole construction of this chapter has been building toward a single payoff: a precise sense in which the physicist's Langevin equation has a solution, unique, defined for all time, and adapted to the noise that drives it. We are now in a position to deliver it. The Itô integral of section 5.2 supplies the meaning of the noise term $\int \sigma\ \mathrm{d}W$; Itô's formula of section 5.3 supplies the calculus that controls it; and with both in hand the equation that looked like nonsense in the chapter preamble becomes a well-posed object with a genuine existence-and-uniqueness theorem, proved by a method — Picard iteration in a space of processes — that is the template for every existence theorem the book builds downstream.

A stochastic differential equation prescribes the infinitesimal drift and volatility as functions of the current state:

$$\mathrm{d}X_t = b(t, X_t)\ \mathrm{d}t + \sigma(t, X_t)\ \mathrm{d}W_t, \qquad X_0 = \zeta. \tag{5.12}$$

The differential notation is, as always in this chapter, shorthand: the only meaning (5.12) carries is the integral equation

$$X_t = \zeta + \int_0^t b(s, X_s)\ \mathrm{d}s + \int_0^t \sigma(s, X_s)\ \mathrm{d}W_s, \qquad 0 \le t \le T, \tag{5.13}$$

in which the first integral is an ordinary (pathwise Lebesgue) integral and the second is the Itô integral built in section 5.2. Writing the equation this way is already the whole conceptual advance over the physicist's $\dot{x} = -V' + \xi$: there is no $\dot{X}$ and no ξ anywhere in (5.13), only increments of W accumulated against a non-anticipating integrand, which is the one form of noise the previous sections gave a rigorous meaning. The equation is an implicit one — the unknown process X appears on both sides, inside the coefficients of the very integrals that produce it — and that is precisely why a solution must be *constructed* rather than written down, and why the construction is a fixed-point problem.

Before constructing anything we must be clear about what counts as a solution, because there are two genuinely different notions and the difference is not pedantic — it decides which problems the theory can even pose. A *strong solution* is a continuous, $\mathbb{F}$-adapted process X satisfying (5.13) for all $t \in [0, T]$ almost surely, on a *given* probability space carrying a *given* Brownian motion W. The data are fixed in advance — the space $(\Omega, \mathcal{F}, \mathbb{P})$, the filtration $\mathbb{F}$, and the driving noise W — and the solution X must be built as a functional of that prescribed noise: at each time t, the value X_t is determined by the path of W up to time t and nothing else. A *weak solution*, by contrast, asks only that there *exist* some probability space carrying *some* pair (X, W) such that W is a Brownian motion and X solves (5.13); here the noise is an output of the construction, free to be chosen along with X, and only the *joint law* of the pair is pinned down. Every strong solution is a weak solution, but not conversely: there are equations (Tanaka's $\mathrm{d}X = \mathrm{sgn}(X)\ \mathrm{d}W$ is the standard witness) that have a weak solution with the right law and yet no solution adapted to any prescribed W.

We will always want strong solutions, and the reason is the one that organizes all of Part II. In a control problem the drift is not given to us; it is *chosen* by an optimizing agent as a feedback law $b(t, x) = b_0(t, x) + \alpha(t, x)$, a function of the current state that the agent computes from the information available so far. For such a law to be implementable the agent must be reacting to a noise that is given to her — revealed increment by increment as time runs — not co-designing the noise to suit her strategy. A weak solution, which is permitted to build a convenient W around the desired X, would let the "controller" clairvoyantly arrange the randomness; that is not a control problem at all. The strong formulation, with its fixed space and fixed W and its demand that X_t be a non-anticipating functional of the noise, is exactly the structure in which a feedback control — and the verification theorem of chapter 6 that certifies it optimal — makes sense. This is the same causality requirement that selected the Itô integral over Stratonovich in section 5.2, now reappearing one level up: bets are sized before the increment they ride on, and solutions are built from noise that is handed to us, not manufactured to taste. Existence and uniqueness of the strong solution hold under exactly the standing assumptions of the book, invoked here by their tags (A-Lip) and (A-Growth).

Theorem 5.10 (Well-posedness of SDEs)**.** *Let $b : [0,T] \times \mathbb{R}^d \to \mathbb{R}^d$ and $\sigma : [0,T] \times \mathbb{R}^d \to \mathbb{R}^{d\times d}$ be measurable and satisfy, uniformly in $t \in [0,T]$:*

- (A-Lip) *global Lipschitz in the state: there is K with $|b(t,x) - b(t,x')| + \|\sigma(t,x) - \sigma(t,x')\| \le K\,|x - x'|$;*
- (A-Growth) *linear growth: $|b(t,x)| + \|\sigma(t,x)\| \le K\,(1 + |x|)$.*

Let $\zeta \in L^2(\Omega, \mathcal{F}_0, \mathbb{P})$ be independent of W. Then (5.12) has a strong solution X, it is pathwise unique (any two solutions agree a.s. for all t), and it satisfies the moment bound

$$\mathbb{E}\Big[\sup_{0\le t\le T} |X_t|^2\Big] \le C\big(1 + \mathbb{E}\,|\zeta|^2\big)e^{CT} \tag{5.14}$$

for a constant $C = C(K,T,d)$.

Proof. We give the argument in full rather than as a sketch, because its skeleton — recast the equation as a fixed point, iterate, and force the iterates to be Cauchy by a single contraction estimate closed with Grönwall — is the exact template reused for the McKean–Vlasov equation of chapter 7 and the forward–backward systems of chapter 9. Every later existence theorem in the book is this proof with more moving parts; it repays seeing once, slowly.

The arena: a Banach space of processes. A fixed-point argument needs a complete metric space on which the map whose fixed point we seek is a contraction. The natural arena here is the space $\mathcal{S}^2$ of continuous, $\mathbb{F}$-adapted processes X on $[0,T]$ for which the norm

$$\|X\|^2_{\mathcal{S}^2} \;:=\; \mathbb{E}\Big[\sup_{0\le t\le T} |X_t|^2\Big]$$

is finite. This is not a casual choice. The supremum *inside* the expectation is what will let us control the entire path at once, and it is precisely the quantity Doob's maximal inequality is built to bound; the square and the expectation make $\mathcal{S}^2$ a Hilbert-like L^2 space of processes, complete because $L^2(\Omega; C[0,T])$ is complete. Completeness is the property we are buying: a Cauchy sequence of iterates will have a limit *in this same space*, automatically a continuous adapted process, with no separate regularity argument needed. Define the map Φ on $\mathcal{S}^2$ by

$$(\Phi X)_t \;=\; \zeta + \int_0^t b(s, X_s)\;\mathrm{d}s + \int_0^t \sigma(s, X_s)\;\mathrm{d}W_s;$$

a solution of (5.13) is exactly a fixed point $\Phi X = X$. That Φ maps $\mathcal{S}^2$ into itself — that ΦX is again square-integrable with a finite sup-norm — is the role of the linear-growth bound (A-Growth): it keeps the coefficients from inflating a bounded input into an unbounded output, and it is the same estimate that, applied to X itself, will produce the moment bound (5.14) at the end.

The iteration. Start from the constant process $X^0_t \equiv \zeta$ and define

$$X^{n+1}_t \;=\; (\Phi X^n)_t \;=\; \zeta + \int_0^t b(s, X^n_s)\;\mathrm{d}s + \int_0^t \sigma(s, X^n_s)\;\mathrm{d}W_s. \tag{5.15}$$

Each X^{n+1} is continuous (both integrals are continuous in their upper limit), adapted (the integrands depend only on the past), and in $\mathcal{S}^2$ (by the growth bound and induction). The plan is to show the consecutive differences $X^{n+1} - X^n$ shrink so fast that the series $\sum_n (X^{n+1} - X^n)$ converges in $\mathcal{S}^2$; its partial sums are the iterates, so the iterates converge.

The contraction estimate, ingredient by ingredient. Subtract two consecutive instances of (5.15). The initial datum ζ cancels, leaving a drift difference and a diffusion difference:

$$X_t^{n+1} - X_t^n = \underbrace{\int_0^t \left(b(s, X_s^n) - b(s, X_s^{n-1})\right) \mathrm{d}s}_{\text{drift part}} + \underbrace{\int_0^t \left(\sigma(s, X_s^n) - \sigma(s, X_s^{n-1})\right) \mathrm{d}W_s}_{\text{diffusion part}}.$$

We want to bound $\mathbb{E} \sup_{s \le t} \left|X_s^{n+1} - X_s^n\right|^2$, and four elementary moves do it, each pulling its weight.

(i) Split the two parts. The square of a sum is controlled by twice the sum of squares, $|a+b|^2 \le 2|a|^2 + 2|b|^2$ — the cheapest way to decouple the drift and diffusion contributions so each can be estimated by the tool suited to it:

$$\sup_{s \le t} \left|X_s^{n+1} - X_s^n\right|^2 \le 2 \sup_{s \le t} \left| \int_0^s (b(r, X_r^n) - b(r, X_r^{n-1})) \,\mathrm{d}r \right|^2 + 2 \sup_{s \le t} \left| \int_0^s (\sigma(r, X_r^n) - \sigma(r, X_r^{n-1})) \,\mathrm{d}W_r \right|^2.$$

(ii) Cauchy–Schwarz on the drift. The drift integral is an ordinary integral against $\mathrm{d}r$, and Cauchy–Schwarz (in the form $|\int_0^s g \,\mathrm{d}r|^2 \le s \int_0^s g^2 \,\mathrm{d}r \le T \int_0^t g^2 \,\mathrm{d}r$) trades the integral of a difference for the integral of its square, at the cost of a factor T:

$$\sup_{s \le t} \left| \int_0^s (b(r, X_r^n) - b(r, X_r^{n-1})) \,\mathrm{d}r \right|^2 \le T \int_0^t \left| b(r, X_r^n) - b(r, X_r^{n-1}) \right|^2 \mathrm{d}r.$$

(iii) Doob on the diffusion. The diffusion integral is an Itô integral, and the supremum over s of its square is exactly what Doob's L^2 maximal inequality (theorem C.2) controls. Combined with the Itô isometry (theorem 5.7(1)) it gives the maximal form

$$\mathbb{E} \sup_{s \le t} \left| \int_0^s H_r \,\mathrm{d}W_r \right|^2 \;\le\; 4\, \mathbb{E} \int_0^t H_r^2 \,\mathrm{d}r,$$

the bound (C.4) — the factor 4 is Doob's constant $(p/(p-1))^2$ at $p = 2$. Applied to $H_r = \sigma(r, X_r^n) - \sigma(r, X_r^{n-1})$, this again converts a martingale into the $\mathrm{d}r$-integral of a squared difference, which is the form we want. This step is the whole reason we worked in $\mathcal{S}^2$ with the supremum inside the expectation: only the maximal inequality lets us put the $\sup_s$ *inside* and still close.

(iv) (A-Lip) closes the loop. Both surviving integrands are now squared differences of a coefficient evaluated at X_r^n versus X_r^{n-1}, and this is exactly what the Lipschitz hypothesis was made to bound: (A-Lip) gives $|b(r,x) - b(r,x')|^2 \le K^2 |x - x'|^2$ and likewise for σ, so each integrand is at most $K^2 |X_r^n - X_r^{n-1}|^2$. Without (A-Lip) the right-hand side would still involve the coefficients, and the inequality could not be iterated; with it, the estimate becomes a self-referential bound on the differences alone. Taking expectations and collecting the constants from (i)–(iv) into a single $C_K = C_K(K, T, d)$,

$$\mathbb{E} \sup_{s \le t} \left|X_s^{n+1} - X_s^n\right|^2 \;\le\; C_K \int_0^t \mathbb{E} \sup_{r \le s} \left|X_r^n - X_r^{n-1}\right|^2 \mathrm{d}s, \tag{5.16}$$

where the inner $\sup_{r\le s}$ is inserted by monotonicity (the integrand at time s is at most its running supremum). This is the contraction estimate: the size of the $(n+1)$th difference at time t is controlled by the time-integral of the nth.

Summing the series. Write $g_n(t) = \mathbb{E}\sup_{s\le t}\left|X_s^n - X_s^{n-1}\right|^2$, so that (5.16) reads $g_{n+1}(t) \le C_K \int_0^t g_n(s)\,\mathrm{d}s$. Starting from a finite base bound $g_1(t) \le C_0$ (the first difference $X^1 - X^0 = \Phi\zeta - \zeta$ is in $\mathcal{S}^2$ by the growth bound), feeding the inequality into itself n times integrates the constant against itself n times:

$$g_{n+1}(t) \le C_0\,\frac{(C_K t)^n}{n!}, \qquad \text{hence} \qquad \left\|X^{n+1} - X^n\right\|_{\mathcal{S}^2}^2 = g_{n+1}(T) \le C_0\,\frac{(C_K T)^n}{n!}.$$

This is the payoff of carrying the time-integral rather than a bare constant: the repeated integration manufactures the factorial $n!$ in the denominator, and the resulting series $\sum_n \left(C_0 (C_K T)^n/n!\right)^{1/2}$ converges (it is dominated by $\sum_n (C_K T)^{n/2}/\sqrt{n!}$, summable since the factorial outruns any geometric). A geometric bound alone would have given convergence only for T small; the factorial gives it for *every* T, which is why no smallness or restart is needed. By the triangle inequality the partial sums $X^N = \zeta + \sum_{n=0}^{N-1}(X^{n+1} - X^n)$ form a Cauchy sequence in the complete space $\mathcal{S}^2$, so they converge to a limit $X \in \mathcal{S}^2$. Passing to the limit in (5.15) — legitimate because the drift and diffusion integral maps are continuous on $\mathcal{S}^2$, the diffusion map again by the Itô isometry — shows $\Phi X = X$: the limit solves (5.13).

Uniqueness, by Grönwall. The same contraction estimate, now applied to two genuine solutions X, Y rather than consecutive iterates, gives for $\phi(t) := \mathbb{E}\sup_{s\le t}|X_s - Y_s|^2$ the inequality $\phi(t) \le C_K \int_0^t \phi(s)\,\mathrm{d}s$. This is the integral inequality Grönwall's lemma is built to kill: with zero additive part, lemma C.1 (the case $A = 0$) forces $\phi \equiv 0$, so $X_t = Y_t$ for all t almost surely, and by continuity the two paths coincide identically — pathwise uniqueness. Note that this half of the proof uses only (A-Lip), never the growth bound: Lipschitz continuity alone guarantees that solutions cannot separate.

The moment bound, again by Grönwall. Finally, run the very same four ingredients on X against the zero process instead of on a difference of iterates. Now it is (A-Growth) that supplies the pointwise bound $|b(s, X_s)|^2 + \|\sigma(s, X_s)\|^2 \le 2K^2(1 + |X_s|^2)$, and steps (i)–(iii) yield

$$\mathbb{E}\sup_{s\le t}|X_s|^2 \;\le\; C\big(1 + \mathbb{E}\,|\zeta|^2\,\big) + C\int_0^t \mathbb{E}\sup_{r\le s}|X_r|^2\,\mathrm{d}s.$$

This is Grönwall with a nonzero additive part $A = C(1+\mathbb{E}\,|\zeta|^2)$; lemma C.1 then gives $\mathbb{E}\sup_{s\le t}|X_s|^2 \le C(1 + \mathbb{E}\,|\zeta|^2)\,e^{Ct}$, which at $t = T$ is exactly the asserted moment bound (5.14). The exponential is the signature of Grönwall: linear-growth coefficients can amplify the second moment, but only at a bounded exponential rate, never fast enough to escape to infinity in finite time. That finiteness is the analytic content of "no explosion," and the next remark reads it as physics. (For attribution, the classical reference for this theorem is [106, Thm. 5.2.1].) □

Remark 5.11 (The rigorous Langevin equation)**.** We can now redeem the promissory note of the chapter preamble. Equation (5.12) *is* the Langevin equation, no longer a formal expression to be handled with care but a theorem with a solution. The physicist's $\dot{x} = -V'(x) + \sqrt{2D}\,\xi$ is the special case $b(x) = -V'(x)$, $\sigma \equiv \sqrt{2D}$, read in integral (Itô) form

$$\mathrm{d}X_t = -V'(X_t)\,\mathrm{d}t + \sqrt{2D}\,\mathrm{d}W_t,$$

and theorem 5.10 is the precise statement that, whenever $-V'$ is Lipschitz with linear growth, this equation has a unique strong solution on all of $[0,T]$. The white noise ξ that had no values and the derivative $\dot{x}$ that did not exist have both been replaced by the one object the chapter built — the Itô integral against W — and the nonsense is gone.

Two points deserve to be drawn out, one a reassurance and one the genuine content of the hypotheses. First the reassurance: because the noise here is *additive* (σ a constant $\sqrt{2D}$, independent of the state), the Itô–Stratonovich question that section 5.2.2 warned about simply does not arise. The correction term that distinguishes the two calculi is proportional to $\sigma\,\partial_x\sigma$, which vanishes identically when σ is constant; the Itô and Stratonovich readings of an additive-noise equation coincide term for term. This is exactly why the physicist's manipulations of the overdamped Langevin equation were never wrong despite never naming a convention, and it is why the entire LQG thread (Thread A), whose noise is additive throughout, is immune to the subtlety: one may compute as the physicist always did and the rigorous theory ratifies it verbatim. The ambiguity returns only when the volatility is allowed to depend on the state, which is precisely where Part II will have to be careful.

Now the content of the hypotheses, which is best seen by asking what breaks without them. The Lipschitz hypothesis (A-Lip) is what buys *uniqueness* — it is the only thing the uniqueness half of the proof used — and a force $-V'$ that is merely locally Lipschitz still gives a unique solution, but possibly only up to a random *explosion time* $\tau < \infty$ at which $|X_t| \to \infty$. The growth bound (A-Growth) is what rules the explosion out, and the cleanest way to see why is to delete the noise entirely and watch the deterministic flow. Take the one-dimensional outward drift $b(x) = x^2$ — equivalently the anti-confining potential $V = -x^3/3$, a hill that steepens without bound as the particle runs downhill. The noiseless equation $\dot{x} = x^2$ separates, $\int x^{-2}\,\mathrm{d}x = \int \mathrm{d}t$, giving $x(t) = x_0/(1 - x_0 t)$: starting from any $x_0 > 0$ the solution reaches $+\infty$ at the finite time $t^* = 1/x_0$ and ceases to exist. No noise is needed for this catastrophe; a drift that grows faster than linearly *outward* drives the state to infinity in finite time on its own, and adding noise only jostles the timing. (A-Growth)'s linear bound $|b(x)| \le K(1 + |x|)$ forbids exactly this runaway: the worst the drift can do is amplify $|X|$ exponentially, which is the e^{CT} of the moment bound (5.14), and an exponentially growing quantity is finite at every finite time. The growth bound is the analytic guarantee of *no explosion*.

But — and this is the point most easily mistaken — (A-Growth) is *sufficient*, not *necessary*. It forbids *all* superlinear drifts, inward and outward alike, whereas only the outward ones cause trouble. A confining superlinear potential such as $V(x) = x^4$ has inward drift $b = -V' = -4x^3$, which violates the linear-growth bound by a wide margin and yet produces a perfectly global, non-exploding, pathwise-unique diffusion. The reason is the sign: a strong *restoring* force pulls a wandering particle ever more firmly back toward the origin, the steeper the potential the firmer the leash, so far from escaping to infinity the process is confined and in fact relaxes to the Boltzmann invariant density $\propto e^{-2V/\sigma^2}$ — the stationary state the physicist expects, and the one section 5.7 computes explicitly for the harmonic case. The honest statement is therefore that (A-Growth) is a convenient uniform sufficient condition that captures the well-posed regime by a single clean inequality, at the cost of excluding some confining models that are perfectly well-behaved for the opposite reason; the book adopts it because a uniform hypothesis keeps every downstream estimate clean, and notes here that the genuinely dangerous case is outward superlinear growth alone.

One further hypothesis, not needed for existence but decisive for everything the population sections will do, concerns the *nondegeneracy* of the noise. If the diffusion is uniformly nondegenerate — assumption (A-Nondeg), $\sigma\sigma^\top \succeq \lambda I$ with $\lambda > 0$, meaning the noise pushes in every direction with at least a floor of intensity — then the qualitative behaviour of the law of X_t changes completely. The well-posedness theorem already gives us the process X and hence, at each time, its law $m_t = \mathcal{L}(X_t)$ as a point in $\mathcal{P}_2(\mathbb{R}^d)$. Nondegeneracy upgrades that law from an abstract measure to a smooth object: for every $t > 0$ the measure m_t has a strictly positive density that is smooth in both the state and the time, the transition density of theorem C.12. The mechanism is parabolic regularization — the same smoothing that the heat equation performs on rough initial data, here driven by the Laplacian that the nondegenerate noise contributes to the generator — and it is what allows the Fokker–Planck equation of the next section to be read classically, as an honest PDE for a smooth density, rather than only in a weak or distributional sense. This is no idle refinement: (A-Nondeg) is the source of the regularity on which the existence theory of the coupled mean field game systems in chapters 8 and 10 rests, and we invoke it there by name and flag carefully the degenerate situations where it must be dropped.

This completes the passage from the formal Langevin equation to a rigorous diffusion. We now hold three objects the next section needs and will run with: the well-posed strong solution X itself, a single trajectory driven by the canonical noise; its law $m_t = \mathcal{L}(X_t)$, the evolving point in $\mathcal{P}_2(\mathbb{R}^d)$ that the Fokker–Planck equation will track; and, under (A-Nondeg), the smooth positive transition density that lets that evolution be written as a classical PDE. Section 5.5 takes exactly these and asks the population-level question the chapter has been building toward — not how a single particle moves, but how the law of the whole ensemble moves — and the bridge it uses is the tool we spent this section deploying: Itô's formula, with its martingale part averaged out, turning the trajectory-level dynamics of X into a deterministic evolution equation for m_t.

5.5 The generator, Fokker–Planck, and its backward twin

The previous section completed the passage from the formal Langevin equation to a rigorous diffusion and handed us three objects to run with: the well-posed strong solution X, a single trajectory driven by the canonical noise; its law $m_t = \mathcal{L}(X_t)$, the evolving point in $\mathcal{P}_2(\mathbb{R}^d)$; and, under (A-Nondeg), the smooth positive transition density that lets that evolution be read as a classical PDE. We now spend them. The whole chapter so far has tracked *one* trajectory; we change the question. We no longer ask how a single particle moves but how the *law of the entire ensemble* moves — not X_t but m_t. This is the population-level question the chapter has been building toward, and it is the question mean field games are made of: an agent is one trajectory, but the mean field that couples the agents is the law m_t, and the equation that propagates that law is the forward half of the MFG system. The bridge from the one to the many is the tool we spent the last section deploying — Itô's formula, with its martingale part averaged out — and the operator that bridge isolates is the *generator*. This section extracts the generator, proves the one identity (Dynkin's) that turns trajectory dynamics into an evolution law for m_t, and then forks: the adjoint of the generator drives the density forward (Fokker–Planck), the generator itself drives observables backward (Kolmogorov). Those two forks are the two subsections that follow.

Both a value and a density now enter the same chapter, so we fix the orientation convention once, here, on first joint use, as appendix A prescribes and as we will obey for the rest of the book: *value functions are solved backward, carrying terminal data at $t = T$ down to the present; densities evolve forward, carrying initial data at $t = 0$ up to the future.* The density $m_t = \mathcal{L}(X_t)$ of this section is the forward object par excellence, launched from m_0 and pushed ahead in time; the value $u(t, x)$ of section 5.5.3 is the backward object, pinned by a terminal payoff and pulled back. The two flow in opposite directions and meet in the middle: that opposition is the geometry of the MFG system, and it is no accident that the forward equation will be driven by $\mathcal{A}^*$ and the backward one by $\mathcal{A}$ — the generator and its adjoint are the two faces of a single integration-by-parts identity, and naming that identity now is precisely what makes the next two subsections read as two readings of one fact rather than two unrelated derivations.

So fix, for this section, the time-homogeneous SDE $\mathrm{d}X_t = b(X_t)\,\mathrm{d}t + \sigma(X_t)\,\mathrm{d}W_t$ under theorem 5.10, and let $m_t = \mathcal{L}(X_t) \in \mathcal{P}(\mathbb{R}^d)$ be the law of the state at time t, with $m_0 = \mathcal{L}(\zeta)$. The generator is the operator that answers the population question infinitesimally. Before the formula, the idea: probe the ensemble with a smooth test observable ϕ and watch its average $\mathbb{E}\,\phi(X_t)$. At $t = 0$ this is $\int \phi\,\mathrm{d}m_0$; an instant later it is $\int \phi\,\mathrm{d}m_h$; the *rate* at which it changes is the infinitesimal motion of the law, read through the observable ϕ. Write $P_h\phi(x) = \mathbb{E}\big[\phi(X_h) \mid X_0 = x\big]$ for the average of ϕ over the cloud of places the particle has reached after time h, started from x. As $h \downarrow 0$ the cloud collapses back to the point x, so $P_h\phi \to \phi$; the generator is the *first-order* content of that collapse, the limit

$$(\mathcal{A}\phi)(x) \;=\; \lim_{h\downarrow 0} \frac{P_h\phi(x) - \phi(x)}{h} \;=\; \frac{\mathrm{d}}{\mathrm{d}h}\Big|_{h=0} \mathbb{E}\big[\phi(X_h) \mid X_0 = x\big],$$

the instantaneous rate of change of the expected observable per unit time, started from x. This limit is exactly the drift term that survived in Itô's formula once the martingale part was averaged away — the second-order term the whole chapter has been chasing, now wearing the clothes of a differential operator. To see which operator, run the mnemonic of section 5.3: expand $\phi(X_h)$ to first order in $\mathrm{d}t$ and second order in $\mathrm{d}W$, and collapse $(\mathrm{d}W)^2 \to \mathrm{d}t$ by the multiplication table. The first-order drift contributes $b\cdot\nabla\phi\,\mathrm{d}t$; the surviving second-order term contributes $\frac{1}{2}\sum_{ij} a_{ij}\partial_{ij}\phi\,\mathrm{d}t$ with $a = \sigma\sigma^\top$; the martingale increment averages to zero under the conditional expectation. What is left, divided by h and sent to $h \downarrow 0$, is precisely the following operator. We elevate it to a definition.

Definition 5.12 (Generator)**.** The *infinitesimal generator* of the diffusion X is the second-order operator, acting on $\phi \in C_c^2(\mathbb{R}^d)$,

$$(\mathcal{A}\phi)(x) \;=\; b(x)\cdot\nabla\phi(x) + \tfrac{1}{2}\,\mathrm{tr}\big(\sigma(x)\sigma(x)^\top\,\mathrm{D}^2\,\phi(x)\big) \;=\; \sum_i b_i\,\partial_i\phi + \tfrac{1}{2}\sum_{i,j} a_{ij}\,\partial_{ij}\phi, \tag{5.17}$$

where $a(x) = \sigma(x)\sigma(x)^\top$ is the *diffusion matrix.* This is the convention fixed in appendix A.

Two features of the symbol and the formula deserve a word before we use them. The symbol itself is a deliberate choice: we write the generator $\mathcal{A}$ (rendering $\mathcal{A}$), not the more common L, because

L would collide with the law operator $\mathcal{L} = \mathcal{L}$ that is everywhere in this book; appendix A fixes $\mathcal{A}$ for the generator and $\mathcal{A}^*$ for its adjoint, and we hold to it. As for the formula, read its two pieces against the SDE that produced them. The drift b enters *linearly*, through the first-order operator $b\cdot\nabla$, the transport term: it tilts the average of ϕ in the direction the deterministic flow is carrying the particle. The volatility σ enters *quadratically*, and only through the combination $a = \sigma\sigma^\top$, the diffusion matrix — never through σ alone. This is the signature of the Itô second-order term: the noise is felt by expectations only through the variance it injects, and variance is the *square* of the volatility, exactly the $(\mathrm{d}W)^2 = \mathrm{d}t$ that has driven the chapter. That a particle and its mirror image $\sigma \mapsto -\sigma$ generate the identical diffusion is the differential-operator shadow of the fact that W and $-W$ have the same law. The half in front of the second-order term is the same $\frac{1}{2}$ that sits in Itô's formula, inherited verbatim. In the scalar case the operator is just $\mathcal{A}\phi = b\,\phi' + \frac{1}{2}\sigma^2\phi''$, and the smallest instance is the most telling: with $b = 0$ and σ constant it is $\frac{1}{2}\sigma^2\partial_{xx}$, half the Laplacian scaled by the diffusion constant — the heat-equation operator. The generator of pure Brownian motion *is* the heat semigroup's generator, and the appearance of the Laplacian here is the promised reincarnation of $(\mathrm{d}W)^2 = \mathrm{d}t$ as a differential operator.

It is worth instantiating (5.17) on the very observable that opened the discussion of the second-order term. Take the scalar pure-noise process $\mathrm{d}X = \sigma\ \mathrm{d}W$ with σ constant and the observable $\phi(x) = x^2$. Then $\phi' = 2x$, $\phi'' = 2$, and the generator returns $\mathcal{A}\phi = \frac{1}{2}\sigma^2 \cdot 2 = \sigma^2$, a constant. Read through the limit definition, this says $\frac{\mathrm{d}}{\mathrm{d}h}\big|_0 \mathbb{E}[X_h^2 \mid X_0 = x] = \sigma^2$: the expected square grows at rate σ^2 from every starting point, which is exactly the $\mathbb{E}X_t^2 = \mathbb{E}X_0^2 + \sigma^2 t$ we computed by hand in section 5.3. The generator has simply packaged that computation as an operator, and the diffusion rate σ^2 that there signalled the spreading of the packet is here the value of $\mathcal{A}$ on x^2. Same fact, same constant, one level more abstract.

With the generator named, the identity that turns it into an evolution law for m_t is one line of Itô plus one expectation. The generator was *defined* as the time derivative of the expected observable started from a fixed point; Dynkin's formula is the global, integrated version of that statement along the actual flow. Apply the multidimensional Itô formula (5.11) to $\phi(X_t)$ — with no explicit t-dependence, so $\partial_t\phi = 0$ — and the differential of $\phi(X_t)$ splits into exactly the drift and martingale pieces the generator was built to separate.

Proposition 5.13 (Dynkin's formula)**.** *For $\phi \in C_c^2(\mathbb{R}^d)$, $\mathrm{d}\,\phi(X_t) = (\mathcal{A}\phi)(X_t)\ \mathrm{d}t + (\nabla\phi)^\top\sigma\ \mathrm{d}W_t$, and consequently*

$$\mathbb{E}\,\phi(X_t) = \mathbb{E}\,\phi(X_0) + \mathbb{E}\int_0^t (\mathcal{A}\phi)(X_s)\ \mathrm{d}s, \qquad \frac{\mathrm{d}}{\mathrm{d}t}\,\mathbb{E}\,\phi(X_t) = \mathbb{E}\,(\mathcal{A}\phi)(X_t) = \int_{\mathbb{R}^d} (\mathcal{A}\phi)\ \mathrm{d}m_t. \tag{5.18}$$

Proof. The differential statement is Itô's formula (5.11) read off the generator. Applied to $\phi(X_t)$, that formula produces a first-order drift term, the full contraction of the Hessian against $\mathrm{d}X\ \mathrm{d}X^\top = a\ \mathrm{d}t$, and the gradient paired against the noise:

$$\mathrm{d}\,\phi(X_t) = \nabla\phi(X_t)^\top\,\mathrm{d}X_t + \tfrac{1}{2}\ \mathrm{tr}\big(\sigma\sigma^\top\,\mathrm{D}^2\,\phi(X_t)\big)\,\mathrm{d}t = \underbrace{\Big(b\cdot\nabla\phi + \tfrac{1}{2}\,\mathrm{tr}(a\ \mathrm{D}^2\,\phi)\Big)}_{=(\mathcal{A}\phi)(X_t)}\,\mathrm{d}t + (\nabla\phi)^\top\sigma\ \mathrm{d}W_t,$$

where in the last step the $b\ \mathrm{d}t$ part of $\mathrm{d}X$ combined with the Hessian term to assemble exactly the generator (5.17), and the $\sigma\ \mathrm{d}W$ part of $\mathrm{d}X$ left the stated martingale increment. Integrating from 0 to t,

$$\phi(X_t) = \phi(X_0) + \int_0^t (\mathcal{A}\phi)(X_s)\ \mathrm{d}s + \int_0^t (\nabla\phi)^\top \sigma\ \mathrm{d}W_s.$$

Now take expectations, and this is the step that does the work. The final term is an Itô integral of the integrand $\nabla\phi(X_s)^\top\sigma(X_s)$; this integrand is bounded — both $\nabla\phi$ (compactly supported, $\phi \in C_c^2$) and σ on the support of ϕ are bounded — hence square-integrable on $[0,t]$, so by the Itô isometry (theorem 5.7) the integral is a genuine martingale started at 0, and its expectation is therefore 0. The martingale part is precisely what the average annihilates; this is the analytic content of "averaging out the noise," and it is the same fact that made the second moment computation of section 5.3 collapse to its drift. What survives is

$$\mathbb{E}\,\phi(X_t) = \mathbb{E}\,\phi(X_0) + \mathbb{E}\int_0^t (\mathcal{A}\phi)(X_s)\ \mathrm{d}s,$$

the first equality in (5.18); the boundedness of $\mathcal{A}\phi$ (again $\phi \in C_c^2$ with bounded coefficients on its support) lets Fubini exchange the expectation and the time integral. Differentiating in t by the fundamental theorem of calculus gives $\frac{\mathrm{d}}{\mathrm{d}t}\mathbb{E}\,\phi(X_t) = \mathbb{E}\,(\mathcal{A}\phi)(X_t)$, and rewriting the expectation as integration against the law $m_t = \mathcal{L}(X_t)$ — which is all $\mathbb{E}\,(\mathcal{A}\phi)(X_t) = \int_{\mathbb{R}^d}(\mathcal{A}\phi)\ \mathrm{d}m_t$ says — finishes the proposition. □

The compact support of ϕ is not decoration: it is what lets us drop the Itô integral (boundedness, hence the martingale's zero mean), invoke Fubini, and, in the next subsection, integrate by parts with no boundary terms. A test class with this much room to spare is exactly the right register in which to state the identity; one extends to wider classes of ϕ afterward by approximation, never by weakening the test class in the derivation itself.

Read the last equality of (5.18) as the equation of motion of the law, written weakly. It says: for *every* test observable ϕ, the rate of change of its average against m_t equals the average of $\mathcal{A}\phi$ against m_t,

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathbb{R}^d} \phi\ \mathrm{d}m_t = \int_{\mathbb{R}^d} (\mathcal{A}\phi)\ \mathrm{d}m_t.$$

This single identity is the hinge of the entire section, and the two subsections that follow are nothing but its two readings. The generator $\mathcal{A}$ acts on the test function ϕ; but the unknown we want an equation *for* is the measure m_t, not the test function. To get there we must move $\mathcal{A}$ off ϕ and onto m_t — that is, integrate by parts — and the operator that results, the one for which $\int(\mathcal{A}\phi)\ \mathrm{d}m = \int \phi\,(\mathcal{A}^*m)$ holds for all ϕ, is by definition the formal adjoint $\mathcal{A}^*$. The very same identity, left as it stands with $\mathcal{A}$ acting on ϕ, is instead the seed of the backward equation, where ϕ is promoted to an evolving observable and $\mathcal{A}$ stays put. So the fork is precise: section 5.5.1 takes (5.18) and integrates by parts, transferring all derivatives from ϕ onto the density to produce $\mathcal{A}^*m_t$ and the forward Fokker–Planck equation $\partial_t m = \mathcal{A}^*m$; section 5.5.3 keeps the generator where it is and lets it drive observables backward through $\mathcal{A}u$. Two faces of one integration by parts, the adjoint relation $\int(\mathcal{A}\phi)\,m = \int \phi\,(\mathcal{A}^*m)$ being the mirror between them. We turn first to the forward face.

5.5.1 Fokker–Planck as the adjoint of the generator

The previous subsection ended at the weak equation of motion of the law, the last equality of Dynkin's identity (5.18),

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathbb{R}^d}\phi\ \mathrm{d}m_t = \int_{\mathbb{R}^d}(\mathcal{A}\phi)\ \mathrm{d}m_t, \qquad \text{for every } \phi \in C_c^2(\mathbb{R}^d),$$

and posed the structural complaint that makes this subsection necessary: the generator $\mathcal{A}$ is sitting on the *test function* ϕ, whereas the object we actually want a closed evolution law for is the *measure* m_t. As long as the derivatives in $\mathcal{A}\phi$ fall on ϕ, the identity is a statement about averages of observables, not an equation for the density. The remedy is the oldest move in the analysis of weak formulations: integrate by parts and transfer every derivative off ϕ and onto m_t. What comes back is a differential operator acting on the density — the adjoint $\mathcal{A}^*$ — and with it the forward Fokker–Planck equation. Assume henceforth that m_t has a density, written $m_t(x)$ by abuse of notation, so that $\mathrm{d}m_t = m_t(x)\ \mathrm{d}x$ and the pairings become honest Lebesgue integrals against $\mathrm{d}x$; the existence of that density for $t > 0$ is part of the theorem below, and at the level of distributions the computation goes through verbatim with m_t read as a measure.

Carry out the integration by parts term by term, because the two pieces of the generator (5.17) integrate by parts a *different number of times* and it is exactly the bookkeeping of how many derivatives land where that defines $\mathcal{A}^*$. Write $\mathcal{A}\phi = \sum_i b_i\,\partial_i\phi + \frac{1}{2}\sum_{ij} a_{ij}\,\partial_{ij}\phi$ and pair against m_t. Throughout, every boundary term produced by integration by parts vanishes: $\phi \in C_c^2(\mathbb{R}^d)$ has compact support, so ϕ and all its derivatives are identically zero outside a bounded set, and the boundary integrals at infinity have nothing to evaluate. This is the single place the compact support of the test class is spent, and it is why proposition 5.13 was careful to keep ϕ in C_c^2 rather than a wider class.

The drift term, integrated by parts once. The first-order piece carries one derivative on ϕ, so one integration by parts moves it onto m_t. For each i,

$$\int_{\mathbb{R}^d} b_i\,(\partial_i\phi)\,m_t\ \mathrm{d}x = -\int_{\mathbb{R}^d}\phi\,\partial_i\big(b_i\,m_t\big)\ \mathrm{d}x,$$

the sign flipping with the single integration by parts and the boundary term gone by compact support. Summing on i assembles a divergence,

$$\sum_i\int_{\mathbb{R}^d} b_i\,(\partial_i\phi)\,m_t\ \mathrm{d}x = -\int_{\mathbb{R}^d}\phi\sum_i\partial_i\big(b_i\,m_t\big)\ \mathrm{d}x = -\int_{\mathbb{R}^d}\phi\ \mathrm{div}\big(b\,m_t\big)\ \mathrm{d}x.$$

The transport operator $b\cdot\nabla$ has thus become, on the density side, the *negative divergence* $-\operatorname{div}(b\,\cdot)$ — one derivative, one sign change.

The diffusion term, integrated by parts twice. The second-order piece carries two derivatives on ϕ, so it takes two integrations by parts to clear them, and each one contributes a sign. Fix i, j and move the two derivatives across one at a time. The first, in the variable x_i, sends $\partial_i(\partial_j\phi)$ onto $a_{ij}m_t$ with a sign:

$$\int_{\mathbb{R}^d} a_{ij}\,(\partial_i\partial_j\phi)\,m_t\ \mathrm{d}x = -\int_{\mathbb{R}^d}(\partial_j\phi)\,\partial_i\big(a_{ij}\,m_t\big)\ \mathrm{d}x.$$

The second, in the variable x_j, moves the remaining ∂_j off ϕ, flipping the sign back to plus:

$$-\int_{\mathbb{R}^d} (\partial_j \phi)\, \partial_i(a_{ij}\, m_t)\ \mathrm{d}x = +\int_{\mathbb{R}^d} \phi\, \partial_j \partial_i(a_{ij}\, m_t)\ \mathrm{d}x = \int_{\mathbb{R}^d} \phi\, \partial_{ij}(a_{ij}\, m_t)\ \mathrm{d}x.$$

Two integrations by parts, two sign flips, net plus — so the second-order operator returns to the density side with its sign *unchanged*, in contrast to the drift. Restoring the factor $\frac{1}{2}$ and the sum over i, j,

$$\tfrac{1}{2} \sum_{ij} \int_{\mathbb{R}^d} a_{ij}\, (\partial_{ij}\phi)\, m_t\ \mathrm{d}x = \tfrac{1}{2} \sum_{ij} \int_{\mathbb{R}^d} \phi\, \partial_{ij}(a_{ij}\, m_t)\ \mathrm{d}x.$$

Assembling the adjoint. Adding the two computations collects every derivative onto m_t and leaves ϕ bare under the integral:

$$\int_{\mathbb{R}^d} (\mathcal{A}\phi)\, m_t\ \mathrm{d}x = \int_{\mathbb{R}^d} \phi \Big(-\mathrm{div}(b\, m_t) + \tfrac{1}{2} \sum_{ij} \partial_{ij}(a_{ij}\, m_t) \Big)\, \mathrm{d}x \ :=\ \int_{\mathbb{R}^d} \phi\, (\mathcal{A}^* m_t)\ \mathrm{d}x. \tag{5.19}$$

The bracketed operator is, by this very identity, the *formal* $L^2(\mathrm{d}x)$*-adjoint* $\mathcal{A}^*$ of the generator: writing $\langle f, g \rangle = \int_{\mathbb{R}^d} fg\ \mathrm{d}x$ for the (unweighted) $L^2(\mathrm{d}x)$ pairing, (5.19) is exactly $\langle \mathcal{A}\phi, m_t \rangle = \langle \phi, \mathcal{A}^* m_t \rangle$, which is the defining relation of an adjoint. The qualifier "formal" is doing honest work and should be read literally: we have defined $\mathcal{A}^*$ only as a differential operator, by where the derivatives land when one integrates by parts against the flat Lebesgue measure $\mathrm{d}x$, and we have done so on the convenient pairing of a smooth compactly supported ϕ with a smooth enough m_t. We have *not* specified the domains, the function spaces, or the self-adjointness questions that would make $\mathcal{A}^*$ a genuine Hilbert-space adjoint of a densely defined operator; those analytic questions are real but separate, and the differential identity (5.19) is all the forward equation needs. Concretely, in one space dimension with $a = \sigma^2$ the recipe reads off at a glance: the generator $\mathcal{A}\phi = b\,\phi' + \frac{1}{2}\sigma^2\phi''$ has adjoint

$$\mathcal{A}^* m = -(b\, m)' + \tfrac{1}{2}(\sigma^2 m)'',$$

one prime with a minus from the transport term, two primes with a plus from the diffusion term — the scalar shadow of the general $\mathcal{A}^*$ in (5.19).

Now the logical step that converts a pairing identity into a partial differential equation, and it is worth stating slowly because the whole derivation hinges on the quantifier. Insert (5.19) into the Dynkin equation of motion: for every $\phi \in C_c^2(\mathbb{R}^d)$,

$$\frac{\mathrm{d}}{\mathrm{d}t} \int_{\mathbb{R}^d} \phi\, m_t\ \mathrm{d}x = \int_{\mathbb{R}^d} (\mathcal{A}\phi)\, m_t\ \mathrm{d}x = \int_{\mathbb{R}^d} \phi\, (\mathcal{A}^* m_t)\ \mathrm{d}x,$$

and exchanging the time derivative with the spatial integral on the left (justified, as in proposition 5.13, by the boundedness afforded by compact support) turns this into $\int \phi\, \partial_t m_t\ \mathrm{d}x = \int \phi\, (\mathcal{A}^* m_t)\ \mathrm{d}x$, that is

$$\int_{\mathbb{R}^d} \phi\, (\partial_t m_t - \mathcal{A}^* m_t)\ \mathrm{d}x = 0 \qquad \text{for } \textit{every } \phi \in C_c^2(\mathbb{R}^d).$$

A function (or distribution) that integrates to zero against *every* compactly supported test function must itself be zero — this is the fundamental lemma of the calculus of variations, the same du Bois-Reymond argument used throughout weak formulations. Hence the bracket vanishes and the density satisfies $\partial_t m_t = \mathcal{A}^* m_t$ pointwise (in the distributional sense, for now). The clause "holds for every test ϕ" is precisely what upgrades a family of scalar identities, one per observable, into a single equation for the unknown m_t: it is because the relation is forced for *all* ϕ that ϕ can be cancelled and an equation in m_t alone survives. This is the abstract derivation of Fokker–Planck promised in the section opening, obtained with no probabilistic input beyond Dynkin's formula and no analysis beyond integration by parts.

Theorem 5.14 (Fokker–Planck / Kolmogorov forward equation)**.** *Under theorem 5.10 and (A-Nondeg), the laws $m_t = \mathcal{L}(X_t)$ have densities for $t > 0$ and solve, in the classical sense for $t > 0$ and in the distributional sense for $t \geq 0$, the* Fokker–Planck equation

$$\partial_t m \;=\; \mathcal{A}^* m \;=\; -\operatorname{div}(b\, m) + \tfrac{1}{2}\sum_{i,j} \partial_{ij}(a_{ij}\, m), \qquad m\big|_{t=0} = m_0, \tag{5.20}$$

where $\mathcal{A}^*$ is the formal $L^2(\mathrm{d}x)$-adjoint of the generator $\mathcal{A}$ and $a = \sigma\sigma^\top$.

Proof sketch. The two regularity claims in the statement are won by two completely different mechanisms, and separating them is the whole point of the sketch. The *distributional* form is already in hand and costs nothing beyond what precedes the theorem: (5.19) is an algebraic consequence of integration by parts and holds for all $t \geq 0$ and all $\phi \in C_c^2(\mathbb{R}^d)$ with no regularity of m_t assumed, since every derivative in it acts on m_t only *inside* the integral, against a smooth ϕ — that is exactly what "distributional solution" means. So $\partial_t m = \mathcal{A}^* m$ holds weakly directly from Dynkin's formula (5.18), with no appeal to (A-Nondeg) at all. This is worth emphasising because it locates precisely what the nondegeneracy hypothesis is and is not for: it is *not* needed to write the equation, only to know that its weak solution is a genuine smooth function.

That upgrade — from distribution to classical, smooth, strictly positive density — is where (A-Nondeg) earns its place, and the reason is structural. The assumption $a = \sigma\sigma^\top \succeq \lambda I$ with $\lambda > 0$ is exactly the statement that the second-order operator $\mathcal{A}^*$ is *uniformly elliptic*: its principal symbol $\frac{1}{2}\sum_{ij} a_{ij}\xi_i\xi_j \;\geq\; \frac{\lambda}{2}\,|\xi|^2$ is bounded below by a positive multiple of $|\xi|^2$ in every direction, so the diffusion genuinely spreads mass in all d directions and no direction is starved of noise. Appending the time derivative ∂_t to a uniformly elliptic spatial operator makes (5.20) a *uniformly parabolic* equation, and uniform parabolicity is precisely the hypothesis under which the linear theory delivers a smooth, strictly positive fundamental solution. That fundamental solution is nothing other than the transition density of X — the kernel $p(s, x; t, y)$ giving the probability of moving from x at time s to a neighbourhood of y at time t — and $m_t(y) = \int p(0, x; t, y)\, m_0(\mathrm{d}x)$ inherits its smoothness and positivity for every $t > 0$. We invoke this as the parabolic-regularity theorem theorem C.12(1),(3): part (1) furnishes the smooth positive fundamental solution of the uniformly parabolic equation, and part (3) identifies it as the transition density solving (5.20) classically for $t > 0$. The role of the cited theorem in the argument is thus sharply circumscribed — it supplies smoothness and nothing else — so we defer its proof to appendix C without losing the thread here.

The reason the hypothesis cannot simply be dropped is instructive, and it is the same fact viewed from the failure side. If a is allowed to degenerate — to lose rank in some direction at some point — ellipticity fails, the equation is merely *hypo*elliptic at best, and the smoothing the theorem provides can be lost: the law may concentrate on a lower dimensional set and fail to have a density at all (a deterministic flow, $\sigma \equiv 0$, keeps a point mass a point mass forever), or have one that is not smooth. Smoothness of m_t is not a generic gift of the dynamics; it is bought specifically by the noise reaching every direction, which is what uniform ellipticity guarantees. The degenerate case is not hopeless — Hörmander's bracket conditions can restore smoothness when the noise plus the drift together span all directions — but it lies outside (A-Nondeg) and we flag it only where it is needed later. (For attribution and the physics-facing treatment of the Fokker–Planck equation see [106, Ch. 8] and [115, 109].) $\square$

It is worth recording what (5.20) is, in the arc of the book, now that it stands derived. The operator $\mathcal{A}^*$ inherited the surviving second-order term of Itô's formula — the diffusion piece $\frac{1}{2}\sum_{ij}\partial_{ij}(a_{ij}\,\cdot)$ that is $(\mathrm{d}W)^2 = \mathrm{d}t$ promoted first to a Laplacian inside the generator (5.17) and now to its adjoint — so the Fokker–Planck equation is the chapter's organizing fact carried one final step, from a property of a single path to the law of motion of the entire ensemble's density. And that density evolves *forward*: (5.20) is posed with initial data m_0 at $t = 0$ and propagated to $t > 0$, in keeping with the global convention (appendix A) that densities flow forward while value functions flow backward. This is the forward half of the mean field game system; its backward twin, driven by $\mathcal{A}$ rather than $\mathcal{A}^*$, is built in section 5.5.3, and the Hamilton–Jacobi–Bellman equation of chapter 6 is its nonlinear descendant.

We have, however, paid for the abstract derivation in transparency. The adjoint form (5.20), with its second derivatives $\partial_{ij}(a_{ij}m)$ landing on the product $a_{ij}m$, is correct but opaque: one cannot read off from it the conservation of probability that physically must hold, nor see the flux of mass that is doing the transporting. That information is not lost — it is merely folded into the two-derivative diffusion term. The next subsection unfolds it, by distributing exactly one of those two derivatives back out to expose the probability current J, and rewriting the same $\mathcal{A}^*m$ in the manifestly conservation-law form $\partial_t m + \operatorname{div} J = 0$. The two subsections are deliberately the same equation read two ways: the adjoint reading we have just completed, and the continuity reading to come.

5.5.2 Fokker–Planck as a continuity equation

The previous subsection left us holding the equation $\partial_t m = \mathcal{A}^*m$ in the adjoint form (5.20), and noted in closing that this form, while correct, hides the two facts a physicist most wants to see: that probability is conserved, and that it is conserved because mass is *transported* by a current. The information is not absent — it is folded into the two-derivative diffusion term $\frac{1}{2}\sum_{ij}\partial_{ij}(a_{ij}m)$, where both derivatives sit outside the product $a_{ij}m$. The remedy is a single, almost trivial algebraic move: distribute exactly *one* of those two derivatives back out, leaving the other in place. This is the same equation read a second way, and the reading is the one the forward equation of every mean field game will wear.

Carry out the move explicitly. The second-order operator is a double divergence, and we peel off the outer one. Writing the ith component of the inner vector field as $\big(\operatorname{div}(a\,m)\big)_i = \sum_j \partial_j(a_{ij}m)$, the diffusion term is

$$\frac{1}{2}\sum_{i,j}\partial_{ij}(a_{ij}m) = \frac{1}{2}\sum_i \partial_i\Big(\sum_j \partial_j(a_{ij}m)\Big) = \sum_i \partial_i\Big(\tfrac{1}{2}\big(\operatorname{div}(a\,m)\big)_i\Big) = \operatorname{div}\Big(\tfrac{1}{2}\operatorname{div}(a\,m)\Big).$$

Every step here is just bookkeeping on the index i: the operator $\sum_{ij} \partial_{ij}$ is $\sum_i \partial_i\big(\sum_j \partial_j\big)$, so factoring out the outer ∂_i exhibits the whole term as the divergence of the vector field whose ith entry is $\frac{1}{2}\sum_j \partial_j(a_{ij}m)$. The drift term in (5.20) is already a divergence, $-\operatorname{div}(b\,m)$, so collecting the two and pulling the common div to the front turns the entire right-hand side $\mathcal{A}^* m$ into a single divergence, $-\operatorname{div} J$. Reading (5.20) as $\partial_t m = -\operatorname{div} J$ is precisely the continuity equation

$$\partial_t m + \operatorname{div} J = 0, \qquad J(x,t) \;=\; b(x)\,m(x,t) \;-\; \tfrac{1}{2}\,\operatorname{div}\big(a(x)\,m(x,t)\big), \tag{5.21}$$

where the vector field J is the *probability current*.

The current has exactly the two pieces the two terms of $\mathcal{A}^*$ contributed, and each has a name and a physical reading. The first, $b\,m$, is the *drift current* (or convective current): it is the density m carried bodily along the deterministic velocity field b, the same flux $\rho\mathbf{v}$ that appears when a fluid of density ρ is swept along at velocity $\mathbf{v}$. Where the drift points, mass is advected. The second, $-\frac{1}{2}\operatorname{div}(a\,m)$, is the *diffusion current*, and it is a Fick-type flux: in the constant-coefficient case $a = \sigma^2 I$ it reduces to $-\frac{\sigma^2}{2}\nabla m$, a flux proportional to *minus* the gradient of the density, i.e. mass flows from where there is more of it to where there is less. This is the gradient term of Itô's formula $(\mathrm{d}W)^2 = \mathrm{d}t$ wearing its final costume: the surviving second-order piece, which became a Laplacian in the generator and a double divergence in the adjoint, is here a downhill flux of probability. The drift current can push mass uphill against the density gradient; the diffusion current always relaxes it downhill; and the competition between the two is what selects the stationary profile we extract below.

Now the conservation reading, which is the entire payoff of having written the right-hand side as $-\operatorname{div} J$. Locally, $\partial_t m + \operatorname{div} J = 0$ says that the only way the density at a point can change is by a net imbalance of current flowing in and out of an infinitesimal neighbourhood of it: probability is neither created nor destroyed, only relocated. To see the content rather than assert it, integrate the local law over any fixed region $\Omega \subseteq \mathbb{R}^d$ with nice boundary and apply the divergence theorem to the flux term:

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_\Omega m(x,t)\;\mathrm{d}x = -\int_\Omega \operatorname{div} J\;\mathrm{d}x = -\int_{\partial\Omega} J\cdot\mathbf{n}\;\mathrm{d}S.$$

The rate of change of the mass inside Ω equals minus the total flux of J through the boundary $\partial\Omega$ — mass leaves Ω only by crossing its surface, at the rate the current carries it across. Nothing wells up in the interior. Taking $\Omega = \mathbb{R}^d$, the boundary recedes to infinity, and because X_t has finite second moment the density and its current decay there fast enough that the surface integral vanishes; hence

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathbb{R}^d} m(x,t)\;\mathrm{d}x = 0, \qquad \text{so} \qquad \int_{\mathbb{R}^d} m(x,t)\;\mathrm{d}x = \int_{\mathbb{R}^d} m_0(x)\;\mathrm{d}x = 1 \quad \text{for all } t. \tag{5.22}$$

Total probability is preserved *exactly*, for all time, as a law of motion for a genuine law must guarantee. This is not a regularity bonus or an approximate statement; it is built into the divergence structure of $\mathcal{A}^*$ and would survive even if the solution were only distributional. The continuity form is what makes it visible in one line, where the adjoint form (5.20) concealed it inside two derivatives.

Physics note

Equation (5.21) is *the* reason the Fokker–Planck equation feels familiar to a physicist: it is the continuity equation $\partial_t \rho + \operatorname{div} \mathbf{j} = 0$ for a probability "fluid" of density m, with a current J that splits into a convective part $b\,m$ and a diffusive (Fick's-law) part $-\frac{1}{2}\operatorname{div}(a\,m)$, exactly as the particle-number current of a drifting, diffusing gas does. Reading the equation this way lets us classify its *steady states* cleanly, and the classification turns on a distinction that is easy to state and easy to get wrong.

A stationary density m_∞ is one with $\partial_t m_\infty = 0$, which by (5.21) means

$$\operatorname{div} J_\infty = 0 :$$

the steady current is *divergence-free*. This is weaker than the current vanishing. There is a stronger condition,

$$J_\infty \equiv 0 \quad \text{everywhere},$$

called *zero current* or *detailed balance*: not only is there no net accumulation anywhere, there is no flow at all. Detailed balance is the hallmark of a *reversible* steady state — run the dynamics backward in time and the statistics are unchanged — and it is strictly more than stationarity. The gap between the two is the space of divergence-free currents that do not vanish: a stationary state can support steady *circulating* currents, loops of probability flux that close on themselves so that $\operatorname{div} J_\infty = 0$ while $J_\infty \neq 0$, like a fluid stirred into a permanent eddy that transports nothing on net but never comes to rest.

When are the two conditions the same? Precisely when the drift is a gradient. Write $a = \sigma^2 I$ for clarity (the scalar diffusion case). The zero-current equation reads $b\,m_\infty = \frac{\sigma^2}{2}\nabla m_\infty$, i.e. $b = \frac{\sigma^2}{2}\nabla \log m_\infty$ wherever $m_\infty > 0$ — so b would have to be a gradient, the gradient of $\frac{\sigma^2}{2}\log m_\infty$. If the drift is *not* a gradient, no choice of m_∞ can make J_∞ vanish identically, and the stationary state, if one exists, must carry circulating current. Conversely, if $b = -\nabla V$ is a gradient field one can solve $J_\infty = 0$ outright and detailed balance holds. Two regimes bracket this:

- In *one dimension* a drift is *always* a gradient — any scalar $b(x)$ is the derivative of its own antiderivative $\int^x b$ — so stationarity and zero current coincide automatically, and every 1D steady state is reversible. There is no room for a circulating loop on the line.

- In *higher dimensions* a non-gradient drift (one with nonzero curl, $\partial_i b_j \neq \partial_j b_i$) generically forces $J_\infty \neq 0$: the steady state is a non-equilibrium one, sustained by persistent probability circulation. This is the mathematical home of nonequilibrium steady states, and it is invisible in 1D.

The gradient case is the one with a closed-form steady density, and it is worth integrating the zero-current equation in full because the same calculation reappears in section 5.7. In one dimension with constant $a = \sigma^2$, zero current is the *first-order* ODE

$$J_\infty(x) = b(x)\,m_\infty(x) - \frac{\sigma^2}{2}\,m_\infty'(x) = 0,$$

a separable equation. Dividing by m_∞ (positive) gives $\dfrac{m_\infty'}{m_\infty} = \dfrac{2}{\sigma^2}\,b$, that is $\dfrac{\mathrm{d}}{\mathrm{d}x}\log m_\infty = \dfrac{2}{\sigma^2}b$, and integrating from a reference point yields the *Boltzmann–Gibbs form*

$$m_\infty(x) \;\propto\; \exp\Big(\frac{2}{\sigma^2}\int^x b(y)\,\mathrm{d}y\Big),$$

the proportionality constant fixed afterward by $\int m_\infty = 1$. Specialize to a gradient drift $b = -V'$, where V is a confining potential. Then $\int^x b = -V(x)$ up to a constant absorbed into normalization, and the steady density collapses to the Gibbs weight

$$m_\infty(x) \;\propto\; \exp\Big(-\frac{2V(x)}{\sigma^2}\Big).$$

This is the equilibrium of the overdamped Langevin dynamics $\mathrm{d}X_t = -V'(X_t)\,\mathrm{d}t + \sigma\,\mathrm{d}W_t$, and it is exactly the Boltzmann distribution $e^{-V/k_\mathrm{B}\tau}$ of statistical mechanics once one reads off the dictionary. Comparing exponents, $\dfrac{2V}{\sigma^2} = \dfrac{V}{k_\mathrm{B}\tau_\mathrm{temp}}$, which fixes

$$\frac{\sigma^2}{2} \;=\; D \;=\; k_\mathrm{B}\,\tau_\mathrm{temp}\;:$$

half the squared volatility is the diffusion constant D, and that diffusion constant is the temperature in energy units — the fluctuation–dissipation reading already flagged for the canonical noise in section 5.1. The noise strength σ and the potential V between them set the equilibrium; the bath is universal and only the coefficients carry the physics. We run this computation on the explicit harmonic potential $V(x) = \frac{1}{2}\theta x^2$ in section 5.7, where $J_\infty = 0$ returns the Gaussian invariant law of the Ornstein–Uhlenbeck process.

Finally, the current J is not a parochial feature of this chapter; it has the last word in Part II. The forward equation of the mean field game system (chapter 8) is *exactly* (5.21), with one change: the drift b is no longer given but is replaced by the agents' *optimal feedback*, the control each agent selects by solving the backward problem. The population is then transported by the current generated by its own best response, and the fixed point that closes the MFG loop is the demand that this self-generated current carry the density to the very distribution the agents assumed when optimizing.

This continuity reading hands two things forward. To the Ornstein–Uhlenbeck computation of section 5.7 it hands the steady-state machinery just assembled: the worked model extracts its invariant density not by solving the full time-dependent equation but by setting the current to zero, $J_\infty = 0$, and integrating the resulting first-order ODE exactly as above. And to the next subsection it hands the structural reading itself. We have now pushed densities *forward* in two equivalent forms — as the adjoint $\partial_t m = \mathcal{A}^* m$ and as the conservation law $\partial_t m + \operatorname{div} J = 0$ — and established that this is the forward half of the mean field game system. The matching backward half remains: instead of pushing densities forward under $\mathcal{A}^*$, one pushes *observables* backward under $\mathcal{A}$ itself. That is the Kolmogorov backward equation, and it is where we turn now.

5.5.3 The Kolmogorov backward equation

The forward equation propagates densities from initial data; its twin propagates *observables* from terminal data, backward in time, and is governed by $\mathcal{A}$ itself rather than its adjoint. Fix a terminal payoff ψ and define $u(t,x) = \mathbb{E}[\psi(X_T) \mid X_t = x]$, the expected terminal observable given the present state. By the Markov property of the diffusion (proposition C.11, which makes the conditional expectation a deterministic function of the present state alone) and Dynkin's formula, u solves a backward parabolic equation.

Theorem 5.15 (Kolmogorov backward equation)**.** *Let $\psi \in C_b^2(\mathbb{R}^d)$ and, under theorem 5.10, set $u(t,x) = \mathbb{E}[\psi(X_T) \mid X_t = x]$ for the time-homogeneous diffusion. Then $u \in C^{1,2}$ and*

$$\partial_t u + \mathcal{A}u = 0 \quad \text{on } [0,T) \times \mathbb{R}^d, \qquad u(T,\cdot) = \psi. \tag{5.23}$$

Proof sketch. By the Markov property (proposition C.11), the tower property, and time-homogeneity, $u(t,X_t) = \mathbb{E}[\psi(X_T) \mid \mathcal{F}_t]$ is a martingale. Apply Itô's formula (5.11) to $u(t,X_t)$; the differential splits into a drift part $(\partial_t u + \mathcal{A}u)(t,X_t)\,\mathrm{d}t$ and a martingale part. The drift part is itself a continuous finite-variation process, so $u(t,X_t)$ minus its martingale part is a continuous finite-variation martingale, which must be constant (lemma C.5); hence the drift vanishes, $\partial_t u + \mathcal{A}u = 0$, with the terminal value read off at $t = T$. Smoothness of u for $t < T$ is parabolic regularity under (A-Nondeg), theorem C.12(2) (attribution: [106, Ch. 8]). □

Notation watch

Two equations, two directions, one structural lesson. The forward equation (5.20) carries densities m from $t = 0$ *forward* and is driven by $\mathcal{A}^*$; the backward equation (5.23) carries values u from $t = T$ *backward* and is driven by $\mathcal{A}$. This is precisely the time-orientation convention of appendix A: **densities flow forward, values flow backward.** The Hamilton–Jacobi–Bellman equation of chapter 6 is the *nonlinear* descendant of (5.23) — replace the passive observable ψ by an optimized cost-to-go and the linear $\mathcal{A}$ by a Hamiltonian $\sup_\alpha$ over controls, and (5.23) becomes HJB. Reading the linear backward equation now is how we pre-load that intuition: there is nothing mysterious about "integrating backward from a terminal condition" — it is just conditioning on the present and looking at the future payoff. We deliberately write this passive linear object with the same symbol u that definition 6.3 reserves for the optimized value function: the backward solution here is the linear precursor that optimization will promote into the value (the passive observable ψ becoming an optimized cost-to-go, the linear $\mathcal{A}$ becoming a $\sup_\alpha$ Hamiltonian), and we announce the overload rather than spring it. The mean field game system is then exactly the pairing of the forward (5.20) with a backward HJB, coupled through m.

5.6 The Feynman–Kac formula

The backward equation of section 5.5.3 already gave one stochastic representation of a PDE solution: its value $u(t,x) = \mathbb{E}[\psi(X_T) \mid X_t = x]$ solved $\partial_t u + \mathcal{A}u = 0$ by averaging a terminal payoff along the diffusion. Feynman–Kac is that same bridge widened. It generalizes the backward equation by allowing a running cost and a discounting/killing rate, and is the precise correspondence between expectations of functionals of a diffusion and solutions of linear parabolic PDEs. It is the linear, exactly-solvable prototype of every "stochastic representation of a PDE solution" in the book.

Theorem 5.16 (Feynman–Kac)**.** *Let X solve $\mathrm{d}X_s = b(X_s)\,\mathrm{d}s + \sigma(X_s)\,\mathrm{d}W_s$ under theorem 5.10, with generator $\mathcal{A}$. Let $c \in C(\mathbb{R}^d)$ be bounded below, $f \in C(\mathbb{R}^d)$ and $\psi \in C(\mathbb{R}^d)$ of at most polynomial growth. Suppose $u \in C^{1,2}([0,T]\times\mathbb{R}^d)$, of at most polynomial growth in x uniformly on $[0,T]$, solves the terminal-value problem*

$$\partial_t u + \mathcal{A}u - c(x)\,u + f(x) = 0 \quad \text{on } [0,T)\times\mathbb{R}^d, \qquad u(T,\cdot) = \psi. \tag{5.24}$$

Then u has the stochastic representation

$$u(t,x) = \mathbb{E}\left[\psi(X_T)\,e^{-\int_t^T c(X_r)\,\mathrm{d}r} + \int_t^T f(X_s)\,e^{-\int_t^s c(X_r)\,\mathrm{d}r}\,\mathrm{d}s \;\Big|\; X_t = x\right]. \tag{5.25}$$

In particular such a u is unique. (When $c \equiv 0$, $f \equiv 0$ this is exactly the backward equation theorem 5.15.)

Proof. Fix (t,x) and abbreviate the discount factor $D_s = e^{-\int_t^s c(X_r)\,\mathrm{d}r}$, so $\mathrm{d}D_s = -c(X_s)D_s\,\mathrm{d}s$. Consider the process $Y_s = D_s\,u(s,X_s) + \int_t^s f(X_r)D_r\,\mathrm{d}r$ on $s \in [t,T]$. By the product rule and Itô's formula (5.11),

$$\mathrm{d}Y_s = D_s\Big(\partial_t u + \mathcal{A}u - c\,u + f\Big)(s,X_s)\,\mathrm{d}s + D_s(\nabla u)^\top \sigma\,\mathrm{d}W_s.$$

The drift bracket vanishes by the PDE (5.24), so Y is a local martingale; the growth hypotheses on u, f, c together with the moment bound (5.14) make it a true martingale on $[t,T]$. Therefore $\mathbb{E}[Y_T \mid X_t = x] = Y_t = u(t,x)$. Writing out Y_T with $u(T,X_T) = \psi(X_T)$ and $D_t = 1$ gives exactly (5.25). ∎

The formula reads PDE-solving as path-averaging: to evaluate u at (t,x), launch the diffusion from x, accumulate the source f and the terminal payoff ψ along each path weighted by the survival factor $e^{-\int c}$, and average. A physicist recognizes the structure of a (Euclidean, imaginary-time) path integral: (5.25) is $\langle x \mid e^{-(T-t)\hat{H}} \mid \cdot\rangle$ with $\hat{H} = -\mathcal{A} + c$ the "Hamiltonian," $\mathcal{A}$ the kinetic/diffusive part and c the potential, and the expectation over Brownian paths the Wiener-measure sum over histories. The two directions of solvability — run the PDE backward, or run the paths forward and average — are the PDE and probabilistic faces of one object, a duality that recurs as the analytic (chapter 8) versus probabilistic (chapter 9) formulations of the mean field game system.

5.7 Worked computation: the Ornstein–Uhlenbeck process

We close by carrying out every step of the chapter on the one model where all of it is explicit, and which is the linear backbone of the LQG thread (Thread A). Consider the scalar linear SDE

$$\mathrm{d}X_t = -\theta\,X_t\,\mathrm{d}t + \sigma\,\mathrm{d}W_t, \qquad \theta > 0,\ \sigma > 0,\ X_0 \sim m_0, \tag{5.26}$$

the *Ornstein–Uhlenbeck* (OU) process: a particle in a harmonic well $V(x) = \frac{1}{2}\theta x^2$ under additive thermal noise, equivalently the overdamped Langevin dynamics of a spring. In the parameter names of Thread A (eq. (5.31) below) this is the linear state equation $\mathrm{d}X_t = (aX_t + b\alpha_t)\,\mathrm{d}t + \sigma\,\mathrm{d}W_t$ with state-feedback parameter $a = -\theta < 0$ and the control switched off, $\alpha \equiv 0$ (here a is the scalar Thread-A state-feedback coefficient, not the diffusion matrix $a = \sigma\sigma^\top$ of definition 5.12; in this scalar additive-noise model the latter is simply the constant σ^2); it is exactly the closed-loop process that the optimal LQG feedback will produce in chapters 6 and 14, which is why we precompute its law, its steady state, and the spectrum of its generator here.

Worked computation 5.17 (Ornstein–Uhlenbeck: law, steady state, spectrum)**.**

(a) Explicit solution and Gaussian law. The coefficients are affine, so (A-Lip) and (A-Growth) hold globally and theorem 5.10 gives a unique solution. To solve it, apply Itô's formula (5.10) to $F(t,x) = e^{\theta t}x$, an integrating factor: $\partial_t F = \theta e^{\theta t}x$, $\partial_x F = e^{\theta t}$, $\partial_{xx}F = 0$, so

$$\mathrm{d}(e^{\theta t}X_t) = \theta e^{\theta t}X_t\,\mathrm{d}t + e^{\theta t}\,\mathrm{d}X_t = e^{\theta t}\sigma\,\mathrm{d}W_t$$

(the drift cancels exactly; there is no Itô correction since $\partial_{xx}F = 0$). Integrating,

$$X_t = e^{-\theta t}X_0 + \sigma\int_0^t e^{-\theta(t-s)}\,\mathrm{d}W_s. \tag{5.27}$$

The Itô integral of a deterministic integrand is a centered Gaussian (corollary C.15: it is the L^2-limit of linear combinations of independent Gaussian increments, and an L^2-limit of Gaussians is Gaussian), so conditionally on X_0 the law of X_t is Gaussian with

$$\mathbb{E}[X_t \mid X_0] = e^{-\theta t}X_0, \qquad \mathrm{Var}[X_t \mid X_0] = \sigma^2\int_0^t e^{-2\theta(t-s)}\,\mathrm{d}s = \frac{\sigma^2}{2\theta}(1 - e^{-2\theta t}),$$

where the variance used the Itô isometry theorem 5.7(1) to turn the stochastic integral's second moment into the deterministic time integral. If m_0 has mean μ_0 and variance v_0, then $m_t = \mathcal{L}(X_t)$ is Gaussian with

$$\mu_t = e^{-\theta t}\mu_0, \qquad v_t = e^{-2\theta t}v_0 + \frac{\sigma^2}{2\theta}(1 - e^{-2\theta t}). \tag{5.28}$$

Both the mean and the deviation of the variance from its limit relax exponentially, the mean at rate θ and the variance at rate 2θ.

(b) Fokker–Planck and its steady state. The generator and its adjoint are, from (5.17),

$$\mathcal{A}\phi = -\theta x\,\phi' + \tfrac{\sigma^2}{2}\,\phi'', \qquad \mathcal{A}^* m = \partial_x(\theta x\,m) + \tfrac{\sigma^2}{2}\,\partial_{xx}m,$$

so the Fokker–Planck equation (5.20) is $\partial_t m = \partial_x(\theta x\,m) + \frac{\sigma^2}{2}\partial_{xx}m$. One checks directly that the Gaussian density with moments (5.28) solves it; we extract the steady state from the zero-current condition of (5.21). The current is $J = -\theta x\,m - \frac{\sigma^2}{2}\partial_x m$, and $J \equiv 0$ gives the separable ODE $\partial_x m/m = -2\theta x/\sigma^2$, hence

$$m_\infty(x) = \sqrt{\frac{\theta}{\pi\sigma^2}}\,\exp\Big(-\frac{\theta x^2}{\sigma^2}\Big) \;=\; N\Big(0,\,\frac{\sigma^2}{2\theta}\Big), \tag{5.29}$$

the centered Gaussian of variance $v_\infty = \sigma^2/2\theta$. This is the $t \to \infty$ limit of (5.28) for any initial law, and it is the fluctuation–dissipation balance: noise strength σ^2 pumping variance in, restoring force θ draining it out, equilibrium variance their ratio (up to the factor 2). With the dictionary $\sigma^2/2 = D$ this is $v_\infty = D/\theta$, the equipartition result $\frac{1}{2}\theta\langle x^2\rangle = \frac{1}{2}D$ for a harmonic mode.

(c) Spectral decomposition of the generator. On the weighted space $L^2(m_\infty)$ the generator $\mathcal{A}$ is symmetric and negative—it is the $L^2(m_\infty)$-symmetric Dirichlet form of the gradient drift, with $\langle \mathcal{A}\phi, \psi\rangle_{m_\infty} = -\frac{\sigma^2}{2}\langle \phi', \psi'\rangle_{m_\infty}$, the boundary terms killed by the Gaussian decay—and its spectrum is purely the point spectrum $\{-n\theta\}_{n\ge 0}$. (The unbounded $\mathcal{A}$ is *not* compact, so this is not the compact-operator spectral theorem of chapter 2; the rigorous diagonalization, including completeness of the eigenbasis, is appendix C.11, especially lemma C.16.) Its eigenfunctions are the Hermite polynomials H_n (H_n here being the Hermite polynomials, not the control Hamiltonian H of later chapters) orthogonal with respect to the Gaussian weight $m_\infty = N(0, v_\infty)$, and

$$\mathcal{A}\, H_n = -n\,\theta\, H_n, \qquad n = 0, 1, 2, \ldots, \tag{5.30}$$

so the eigenvalues are $\lambda_n = -n\theta$. Indeed $H_0 \equiv 1$ ($\lambda_0 = 0$, the stationary mode), $H_1(x) = x$ with $\mathcal{A}x = -\theta x$ ($\lambda_1 = -\theta$), and one verifies (5.30) inductively from the Hermite recurrence. The $\{H_n\}$ form an *orthogonal* basis of $L^2(m_\infty)$ (complete by lemma C.16; orthonormal only after dividing each by $\|H_n\|_{L^2(m_\infty)}$—with the normalization $H_1(x) = x$ one has $\|H_1\|_{L^2(m_\infty)} = \sqrt{v_\infty} \neq 1$), so any observable expands as $\phi = \sum_n \hat{\phi}_n H_n$ with $\hat{\phi}_n = \langle \phi, H_n\rangle_{m_\infty} / \|H_n\|^2_{L^2(m_\infty)}$ and evolves as

$$\mathbb{E}[\phi(X_t) \mid X_0 = x] = (e^{t\mathcal{A}}\phi)(x) = \sum_{n\ge 0} \hat{\phi}_n\, e^{-n\theta t}\, H_n(x),$$

a sum of exponentially relaxing modes. The *spectral gap* is $\lambda_0 - \lambda_1 = \theta$: every centered observable decays to its equilibrium average at least as fast as $e^{-\theta t}$, matching the relaxation rate of the mean in (5.28). The forward operator $\mathcal{A}^*$ on $L^2(\mathrm{d}x)$ has the same eigenvalues with eigenfunctions $m_\infty \cdot H_n$; the slowest non-trivial forward mode, $m_\infty H_1 \propto x\, m_\infty$, is the relaxation of the mean, again at rate θ.

Remark 5.18 (Hand-off to the LQG thread)**.** The Thread-A representative agent obeys

$$\mathrm{d}X_t = \big(aX_t + b\,\alpha_t\big)\,\mathrm{d}t + \sigma\,\mathrm{d}W_t, \qquad X_0 \sim m_0, \tag{5.31}$$

with the parameter names fixed in the thread specification (a state feedback, b control gain, σ noise). The OU computation above is the $\alpha \equiv 0$, $a < 0$ instance; in chapter 6 the optimal feedback turns out to be *affine* in the state, $\alpha^*(t, x) = -b\big(P(t)x + r(t)\big)$, where $P(t)$ is the value's curvature solving a scalar Riccati equation (6.24) and $r(t)$ is an offset driven by the crowd coupling (eq. (6.27)). In the *uncoupled* instance ($\bar{m} \equiv 0$, so $r \equiv 0$) this is the homogeneous-linear feedback $\alpha^*_t = -b\,P(t)X_t$ and the closed-loop dynamics $\mathrm{d}X_t = (a - b^2P(t))X_t\,\mathrm{d}t + \sigma\,\mathrm{d}W_t$ are again of OU type (time-inhomogeneous); a nonzero coupling adds the inhomogeneous drift $-b^2r(t)$ but keeps the drift *affine*, which is all that matters here. Either way the Gaussian-flow formulas (5.28)–(5.29) are exactly what makes the LQG mean field game closeable in chapter 14: an affine drift maps Gaussians to Gaussians, so a Gaussian initial law stays Gaussian and the population m_t is pinned down by its mean $\bar{m}_t$ (the μ_t of (5.28), read now as the population mean) and its variance alone. The additive noise also discharges the Itô–Stratonovich question (section 5.2.2) for the whole thread. Note that from Part III the driving noise is renamed B_t; here, in scope of no graphon, it is W_t.

Rigor ledger

Proved (in full or by complete sketch with pointer).

- Existence of Brownian motion (theorem 5.2); path roughness (theorem 5.3); quadratic variation $\langle W \rangle_t = t$ in L^2 and a.s. (theorem 5.4, full proof).
- The Itô isometry on simple processes (lemma 5.5, full proof) and the construction, isometry and martingale property of the Itô integral (theorem 5.7).
- Itô's formula (theorem 5.9); the Itô–Stratonovich conversion (5.6)–(5.7).
- SDE well-posedness under (A-Lip),(A-Growth) with the moment bound, by Picard iteration and Grönwall (theorem 5.10, mechanism in full).
- Dynkin's formula (proposition 5.13); the Fokker–Planck equation in both the adjoint form (theorem 5.14) and the continuity-equation form (5.21); the Kolmogorov backward equation (theorem 5.15); the Feynman–Kac formula (theorem 5.16, full martingale proof).
- The Ornstein–Uhlenbeck law, Fokker–Planck steady state, and generator spectrum (worked computation 5.17, fully explicit).

Assumed (named standing assumptions, invoked here).

- (A-Lip) and (A-Growth): used for SDE well-posedness and the moment bound; (A-Lip) for additive-noise Langevin is the no-explosion condition (remark 5.11).
- (A-Nondeg): used to pass from distributional to classical Fokker–Planck and backward equations (existence and smoothness of transition densities); flagged wherever invoked. The OU model satisfies it with $\sigma^2 > 0$.

Deferred (with pointer; each proved in-book in appendix C).

- The foundational facts the chapter body states but does not stop to prove are all proved in the stochastic-calculus appendix appendix C: Grönwall's inequality (lemma C.1); Doob's L^2 maximal inequality and the $p = 2$ Burkholder–Davis–Gundy bound (theorems C.2 and C.3) with localization to local martingales (remark C.4); the constancy of a continuous finite-variation martingale (lemma C.5); density of simple processes (lemma C.6); the Kolmogorov extension and Kolmogorov–Chentsov continuity theorems (theorems C.8 and C.9); the Markov property of SDE solutions (proposition C.11); the Wiener-integral Gaussianity (corollary C.15); and completeness of the Hermite basis with the OU spectral resolution (lemma C.16 and appendix C.11). Itô's formula itself is proved in full in appendix C.5.
- Parabolic regularity for (5.20) and (5.23) under (A-Nondeg)—existence and smoothness of the transition density—is theorem C.12 (attribution: [106, Ch. 8], [109, 115]).

- Paley–Wiener–Zygmund nowhere-differentiability (theorem 5.3(2)), which is not used downstream, is sketched in the body with the standard dyadic Borel–Cantelli argument cited for attribution to [86, 114].
- Girsanov's theorem and the martingale representation theorem (not used in this chapter; needed for the probabilistic/BSDE formulation of chapter 9): supplied where first needed, with appendix C and [86] as the home.

Open / beyond scope here.

- Degenerate ($\sigma\sigma^\top$ rank-deficient) diffusions: hypoellipticity (Hörmander conditions) replaces (A-Nondeg); treated only where flagged in later chapters.
- Well-posedness under merely measurable or only locally Lipschitz drift (weak solutions, Krylov–Veretennikov regularization): outside the standing assumptions and not used in the book's main line.
- The *nonlinear* Fokker–Planck equation, where the drift depends on the law m_t itself (McKean–Vlasov), which makes (5.20) nonlinear; built in chapter 7 and coupled to a backward HJB to form the MFG system in chapter 8.

Bibliographic notes

The roadmap text for this chapter is [106], Chapters 3–5, from which the SDE well-posedness theorem (theorem 5.10), Itô's formula, and the generator/Fokker–Planck material are adapted; the level of rigor and the proof of Itô's formula follow [106, Ch. 4–5, 8]. The definitive reference for the construction of Brownian motion, the Itô integral as an L^2-isometry, the martingale theory behind theorem 5.7, and the localization and Burkholder–Davis–Gundy estimates used in the well-posedness proof is [86]; [114] is the complementary continuous-martingale account, and is the cleanest source for the Lévy–Ciesielski construction and the fine path properties of theorem 5.3. The Itô–Stratonovich correction and its physical origin via the zero-correlation-time limit are due to [133]. For the Fokker–Planck equation read as a continuity equation, for the probability-current and detailed-balance viewpoint, and for the spectral theory of the Ornstein–Uhlenbeck generator (Hermite eigenfunctions, spectral gap, exponential relaxation) the physics-facing references are [115] and [109]; the latter develops the OU spectral decomposition of worked computation 5.17 in detail and connects it to the Langevin equation in the form used here. The backward equation and the Feynman–Kac formula are the linear ancestors of the Hamilton–Jacobi–Bellman theory of chapter 6 and of the analytic mean field game system of chapter 8; the forward Fokker–Planck equation, with the optimal feedback in place of a fixed drift, is its forward half. The nonlinear (McKean–Vlasov) Fokker–Planck equation and propagation of chaos, which turn this chapter's linear forward equation into the engine of the mean field limit, are taken up in chapter 7 following [40].

Chapter 6

Optimal Control: From Least Action to Hamilton–Jacobi–Bellman

The previous two chapters built the two halves of the language we now fuse. From chapter 4 we take the metric space $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ of probability measures with finite second moment — the eventual home of the "mean field" — and the flat and Lions derivatives on it. From chapter 5 we take Itô calculus, the generator $\mathcal{A}$ of a diffusion, its formal adjoint $\mathcal{A}^*$ driving the Fokker–Planck equation, and the Feynman–Kac bridge between expectations of diffusion functionals and linear parabolic equations. This chapter adds the missing ingredient of a *game*: an agent who does not merely diffuse but *chooses*. We study how a single agent optimizes, postponing all interaction. Here m enters only as a frozen *cost-coupling parameter*, an inert measure argument of the running and terminal costs. There are two distinct ways the population will later cease to be inert, and they belong to different chapters: chapter 7 switches on the *descriptive* law-dependence of the drift (a particle's coefficients depend on the law of the ensemble, but no one optimizes), while chapter 8 switches on the *strategic* cost-coupling proper, promoting the frozen m here into the unknown of a Nash fixed point. This chapter sets up exactly the object chapter 8 will close.

The reader trained in physics arrives with a powerful and, for this subject, partly misleading reflex: the principle of least action. Classical trajectories extremize an action functional, and one solves for them by the Euler–Lagrange equations, a *boundary-value problem* with data clamped at both ends of the time interval. Optimal control begins in exactly this language — section 6.1 is a calculus-of-variations recap in the reader's own dialect — but then executes a pivot that must be internalized slowly. Dynamic programming computes not a single optimal path but a *field*, the value function $u(t, x)$, the optimal cost-to-go from every state at every time; and it computes this field by integrating *backward* from a terminal condition. The Euler–Lagrange/least-action reflex must be retrained into the Hamilton–Jacobi–Bellman (HJB) reflex. Because this retraining is, in the author's experience, the single largest conceptual hurdle of Part I, section 6.3 gives the backward direction of time a full conceptual treatment rather than a one-line aside.

It is worth making the contrast vivid before any machinery starts, because everything in this chapter is organized around it. Picture first the physicist's object: a single optimal trajectory, one curve γ^* leaving a fixed start x_0, pinned into existence by extremizing an action and traced out forward in time like a self-contained worldline. Now picture the dynamic programmer's object: not a curve at all, but an entire landscape $u(t, x)$ that assigns to every state x and every instant t the least cost still payable from there — a field defined over the whole state space at once, and built not by launching forward from a start but by discharging a terminal obligation *backward* from $t = T$. The first object answers "what is the single best path from here?"; the second answers "what is the best achievable cost from *anywhere*, and hence what should I do next from wherever I happen to find myself?" These are not two solutions to one problem; they are answers to two different questions, and the chapter's central demand on the reader is to stop reaching for the first picture and learn to inhabit the second — because only the second survives the introduction of noise, and, in chapter 8, of a reacting population that an open-loop plan could never anticipate.

Here is the route. Section 6.1 recalls the calculus of variations and isolates the distinction between *open-loop* and *feedback* controls. Section 6.2 states and sketches the dynamic programming principle and defines the value function. Section 6.3 derives the HJB equation, dwells on the terminal condition and the backward integration, and proves a verification theorem. Section 6.4 develops the Pontryagin maximum principle, identifies the costate with the gradient of the value, and previews its stochastic incarnation as a backward stochastic differential equation (BSDE), the object that will return in chapter 9. Section 6.5 installs the diffusion term, writes the second-order HJB equation in the control Hamiltonian $H(x, p, m)$, and reads off the optimal feedback $\alpha^* = -\partial_p H$. Section 6.6 introduces viscosity solutions, the correct weak notion when the value function develops kinks. Section 6.7 solves the linear–quadratic–Gaussian (LQG) single-agent problem to its scalar Riccati equation, launching Thread A — the explicit backbone carried through the whole book.

Throughout, we hold to the global time convention recorded in appendix A, and it pays to see why the convention is load-bearing rather than cosmetic. The value function $u = u(t, x)$ carries its data at the *terminal* time $t = T$ — where, with no time left and no decision to make, the optimal cost is forced to be the terminal cost itself — and is computed *backward* toward the present. In this chapter no population density evolves yet, but the moment one does (from chapter 7 onward) it carries *initial* data at $t = 0$ and runs *forward*, because a density is pushed from a known present into an as-yet-unknown future. These two opposed directions are not a clash to be reconciled away: when chapter 8 couples them, the forward density and the backward value are welded at opposite ends of $[0, T]$, and that very opposition is what makes a mean field game a boundary-value problem in time rather than an initial-value one. Mistaking which end carries which datum does not merely flip a sign — it silently replaces a well-posed problem with an ill-posed one — which is why we fix the convention now and never relax it. We are in Part I, no graphon is in scope, and Brownian motion is accordingly written W following appendix A; the symbol W is reserved for the graphon kernel that enters only from Part III, and keeping W for Brownian motion here forestalls a collision that would otherwise have to be untangled later.

6.1 Calculus of variations and the two ways to specify a control

We begin where the physicist already lives, and we begin there on purpose. The abstract apparatus assembled in the preamble — the Wasserstein geometry of chapter 4, the Itô calculus and generators of chapter 5 — stays inert until it is tied to an object the reader already trusts completely, and that object is the action functional. Before an agent can play a game it must first be able to optimize, and the physicist's native instrument for optimization is the principle of least action. So we lay that instrument out in full, not because any of it is unfamiliar, but precisely so that we can watch, over the rest of the chapter, exactly which part of it has to be torn out and replaced. The reflex we are about to exhibit — find a single extremal curve by solving a boundary-value problem with data clamped at the two ends of time — is correct and powerful; it is also the very thing the dynamic-programming pivot will have to retrain.

Fix a horizon $T \in (0, \infty)$, a terminal cost $g \colon \mathbb{R}^d \to \mathbb{R}$, and a running cost — a *Lagrangian* — $L \colon \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$, written $L(x, v)$ with v the velocity slot. For an absolutely continuous curve $\gamma \colon [0, T] \to \mathbb{R}^d$ with $\gamma(0) = x_0$ fixed, define the action

$$\mathcal{J}[\gamma] \;=\; \int_0^T L(\gamma(t), \dot\gamma(t))\, \mathrm{d}t \;+\; g(\gamma(T)). \tag{6.1}$$

The classical problem is to minimize $\mathcal{J}$ over such curves.

To do so we make the one move that locates any stationary point: perturb the candidate and demand that the first-order response vanish. Replace a candidate γ^* by a nearby competitor $\gamma^* + \epsilon\eta$, where η is a fixed perturbation *shape* and ϵ a scalar that dials its amplitude, and require the action to be stationary in ϵ at $\epsilon = 0$. The only delicate point is which perturbations η count as admissible, and it is not a technicality but a modelling decision with visible consequences. The left endpoint is *clamped*: the agent genuinely starts at x_0, so every competitor must start there too, which forces $\eta(0) = 0$. The right endpoint is *free*: we did not pin down where the curve must end — instead we attached a price $g(\gamma(T))$ to wherever it does end — so $\eta(T)$ is unconstrained, and the optimizer is permitted to choose its own terminal position. That asymmetry between the two ends is the entire origin of the boundary term we are about to meet, and it is the first appearance of a pattern — a datum imposed at one end of time, a cost discharged at the other — that will organize this whole chapter. The following is the standard first-variation computation; we record it to fix notation and signs.

Theorem 6.1 (Euler–Lagrange equation and transversality)**.** *Let $L \in C^2(\mathbb{R}^d \times \mathbb{R}^d)$ and $g \in C^1(\mathbb{R}^d)$, and let γ^* be a minimizer of* (6.1) *over C^1 curves with $\gamma(0) = x_0$ and free right endpoint. Then on $[0, T]$,*

$$\frac{\mathrm{d}}{\mathrm{d}t}\, \partial_v L(\gamma^*(t), \dot\gamma^*(t)) \;=\; \partial_x L(\gamma^*(t), \dot\gamma^*(t)), \tag{6.2}$$

together with the transversality condition $\partial_v L(\gamma^*(T), \dot\gamma^*(T)) + \nabla g(\gamma^*(T)) = 0$.

Proof. Let $\eta \in C^1([0, T]; \mathbb{R}^d)$ with $\eta(0) = 0$ enact the clamped-left, free-right choice just discussed. Since γ^* is a minimizer, the scalar function $\epsilon \mapsto \mathcal{J}[\gamma^* + \epsilon\eta]$ attains a minimum at $\epsilon = 0$, so its derivative there vanishes. We compute that derivative by differentiating under the integral sign — legitimate because $L \in C^2$, so the integrand and its ϵ-derivative are jointly continuous on the compact set $[0, T] \times \{|\epsilon| \le 1\}$ and dominated. The chain rule applied to $L(\gamma^* + \epsilon\eta, \dot\gamma^* + \epsilon\dot\eta)$ gives, at $\epsilon = 0$,

$$\frac{\mathrm{d}}{\mathrm{d}\epsilon}\, L(\gamma^* + \epsilon\eta, \dot\gamma^* + \epsilon\dot\eta)\Big|_0 = \partial_x L(\gamma^*, \dot\gamma^*) \cdot \eta + \partial_v L(\gamma^*, \dot\gamma^*) \cdot \dot\eta,$$

the two terms recording how the action responds to displacing the position and to displacing the velocity. The terminal term contributes $\nabla g(\gamma^*(T)) \cdot \eta(T)$, again by the chain rule applied to $g(\gamma^*(T) + \epsilon\eta(T))$. Now the position perturbation enters through η but the velocity perturbation through $\dot{\eta}$; to compare them on equal footing we integrate the velocity term by parts, trading the derivative off η and onto $\partial_v L$ at the cost of a boundary contribution:

$$\int_0^T \partial_v L \cdot \dot{\eta} \, \mathrm{d}t = \Big[\partial_v L \cdot \eta\Big]_0^T - \int_0^T \left(\tfrac{\mathrm{d}}{\mathrm{d}t}\partial_v L\right) \cdot \eta \, \mathrm{d}t.$$

The boundary bracket vanishes at $t = 0$ because $\eta(0) = 0$ — this is exactly where the clamped left endpoint is spent — and at $t = T$ it leaves $\partial_v L\big|_{t=T} \cdot \eta(T)$. Collecting the surviving pieces,

$$0 = \frac{\mathrm{d}}{\mathrm{d}\epsilon}\mathcal{J}[\gamma^* + \epsilon\eta]\Big|_0 = \int_0^T \Big(\partial_x L - \frac{\mathrm{d}}{\mathrm{d}t}\partial_v L\Big) \cdot \eta \, \mathrm{d}t + \Big(\partial_v L\big|_{t=T} + \nabla g(\gamma^*(T))\Big) \cdot \eta(T).$$

This identity must hold for *every* admissible η, and we exploit that freedom in two stages. First take η compactly supported in the open interval $(0, T)$, so that $\eta(T) = 0$ and only the integral survives; since the bracketed coefficient is continuous and integrates to zero against every such η, the fundamental lemma of the calculus of variations forces it to vanish pointwise, which is (6.2). (The fundamental lemma is the elementary fact that a continuous function orthogonal in L^2 to all smooth compactly supported test functions is identically zero — were it nonzero at a point, a bump test function concentrated there would integrate against it to something nonzero.) With the integral term annihilated for *all* η, the leftover boundary term must now vanish on its own; choosing an η with $\eta(T) \neq 0$ shows its coefficient is zero, which is the transversality condition. The two conditions are genuinely independent because the two families of perturbations — those that vanish at T and those that do not — probe the action independently. □

Three features of (6.2) now matter for everything that follows, and each is a crack through which the dynamic-programming pivot will eventually be driven.

The first feature is a matter of counting, and it is the structural fingerprint the physicist already recognizes from least action. Once the time derivative on the left is expanded by the chain rule, $\frac{\mathrm{d}}{\mathrm{d}t}\partial_v L$ contains $\ddot{\gamma}$, so (6.2) is a *second-order* ordinary differential equation for the $\mathbb{R}^d$-valued curve γ. The general solution of a second-order ODE in $\mathbb{R}^d$ carries exactly $2d$ free integration constants — morally, a free choice of position and a free choice of velocity at any one instant. The decisive question is how those $2d$ constants get pinned down. An *initial*-value problem would fix all $2d$ of them at $t = 0$, by prescribing both $\gamma(0)$ and $\dot{\gamma}(0)$, and then integrate forward uniquely; this is the Newtonian habit. But our problem does no such thing. It supplies the d components of $\gamma(0) = x_0$ at the *left* end and the d scalar components of the transversality condition $\partial_v L + \nabla g = 0$ at the *right* end. The $2d$ constants are split, d at each end of the interval, and a problem whose data are split across the two ends of time is by definition a *two-point boundary-value problem.* It is worth naming the discomfort this causes, because it is the discomfort the rest of the chapter exists to resolve: a boundary-value problem cannot be solved by integrating forward from the present, because the present does not carry enough information — half the data live in the future. Dynamic programming will dissolve exactly this difficulty, by trading the single curve for a field that already encodes the future obligation everywhere.

The second feature is a change of variables that converts the second-order equation into a first-order system, and it is the reader's first meeting with an object that will recur, under three different names, throughout the book. Define the *conjugate momentum* by the Legendre transform

$$p \;:=\; \partial_v L(x, v),$$

which is precisely the slot that appeared in the transversality condition. When L is strictly convex in v this relation is invertible, $v = v(x, p)$, and one sets the physical Hamiltonian $H_{\text{phys}}(x, p) = p\cdot v(x, p) - L(x, v(x, p))$. In these variables the lone second-order equation (6.2) splits into Hamilton's two first-order canonical equations,

$$\dot{x} = \partial_p H_{\text{phys}}(x, p), \qquad \dot{p} = -\partial_x H_{\text{phys}}(x, p),$$

as one checks directly: the first is just the inversion $v = v(x, p)$ rewritten through $\partial_p H_{\text{phys}} = v$, and the second reproduces (6.2) once one uses $\partial_x H_{\text{phys}} = -\partial_x L$ and $p = \partial_v L$. To make this concrete, take the textbook mechanical Lagrangian $L(x, v) = \frac{1}{2}|v|^2 - V(x)$. Then $p = \partial_v L = v$, the Legendre transform gives $H_{\text{phys}} = \frac{1}{2}|p|^2 + V(x)$ — the familiar total energy — and the canonical equations read $\dot{x} = p$, $\dot{p} = -\nabla V(x)$, which is Newton's second law $\ddot{x} = -\nabla V$ written as a first-order system. The momentum p is not, however, a passing convenience of classical mechanics. In section 6.4 the same object reappears as the *costate* of the Pontryagin maximum principle, the adjoint variable conjugate to the state; and proposition 6.12 will prove that along an optimal trajectory it coincides with the gradient ∇u of the value function we are about to construct. Three names — conjugate momentum here, costate there, value-gradient in the dynamic-programming picture — for one quantity. The reader who keeps that identification in view will watch the apparent multiplicity of methods in this chapter collapse into a single story.

The third feature is the limitation that motivates the entire remainder of the chapter, and it is the one the physicist is least inclined to notice, because it is a feature, not a bug, of least action. The Euler–Lagrange machinery, run to completion, delivers *one curve*: the optimal trajectory γ^* emanating from the one specific start x_0. It answers the question "given that I begin at x_0, what is the single best path?" and it answers nothing else. In particular it offers no guidance whatever to an agent that finds itself, at some intermediate time, at a state it had not planned to occupy — because of a disturbance, a modelling error, or, decisively for us, the random kick of a noise term. To such an agent the precomputed optimal curve from x_0 is simply irrelevant; what it needs is a *rule*, a prescription that returns a good action from *any* state at *any* time. The calculus of variations contains no such object. Manufacturing one — a field of optimal responses defined over the whole state space, in place of a lone optimal worldline — is exactly the task dynamic programming was invented for, and recognizing that this is what we want is the conceptual hinge of the chapter.

Before we can build that field, though, we must widen the problem itself. The calculus of variations lets the agent choose its curve directly, but an agent in an engineered or strategic setting does not actuate its position; it actuates a *control* — a throttle, an applied force, a trading rate — and the state responds through dynamics. The next step is therefore to reorganize the very same minimization around a dynamical constraint, so that the object chosen is a control rather than a trajectory. Only once the problem is posed that way does the distinction between committing to a plan in advance and reacting to the realized state — between, as we will call them, open-loop and feedback controls — acquire any teeth. We turn to that reformulation now.

6.1.1 From curves to controlled dynamics

The reformulation promised at the end of the previous section is a small change of emphasis with large consequences. In the calculus of variations the agent reached into the space of curves and pulled out the one it wanted; the curve was the primitive object of choice, and the dynamics — the relation $\dot{\gamma} = v$ between position and velocity — was a triviality so transparent it never had to be named. Optimal control keeps the same minimization but moves the dynamics to center stage. An agent in an engineered or strategic setting does not author its trajectory by fiat; it has its hands on a small number of knobs — a throttle, an applied force, a trading rate — and the state of the world responds to those settings through laws the agent does not get to rewrite. What the agent actually selects, then, is not a worldline but a schedule of knob settings, a *control*; the trajectory is whatever the control causes. Reorganizing the problem this way is what will eventually let us replace "find the one best curve from x_0" with "find the best response from every state," because once the object of choice is a rule for setting the knobs, that rule can be asked to specify a setting at any state at all, not merely along one favored path.

Concretely, the agent chooses a *control* α_t taking values in an action set $A \subseteq \mathbb{R}^k$, and the state responds through a controlled ordinary differential equation

$$\dot{X}_t \ = \ b(X_t, \alpha_t), \qquad X_0 = x_0, \tag{6.3}$$

with $b\colon \mathbb{R}^d \times A \to \mathbb{R}^d$ the drift. Read (6.3) as a machine: feed it the control history α and the start x_0, and it manufactures the state trajectory X uniquely (under the Lipschitz hypotheses inherited from chapter 5, which we will name (A-Lip), (A-Growth) once they are needed). The objective the agent minimizes is a functional of the control, with the state appearing only as the response (6.3) forces on it,

$$J(\alpha) \ = \ \int_0^T L(X_t, \alpha_t)\ \mathrm{d}t + g(X_T). \tag{6.4}$$

The running cost $L(X_t, \alpha_t)$ now prices both where the agent is and how hard it is pushing the knobs — fuel burned, effort spent, distance from a target — and $g(X_T)$ prices where it ends up. The notation $J(\alpha)$, with the control as the explicit argument and the trajectory suppressed, is the whole point: the trajectory is no longer free to vary independently, so it is bookkeeping, not choice.

That (6.3)–(6.4) genuinely *contains* the calculus of variations, rather than merely resembling it, is worth seeing explicitly, because it licenses everything earlier in the chapter as a special case of everything later. Take the drift to be the identity in the velocity slot, $b(x, v) = v$, and let the action set be all of $\mathbb{R}^d$, $A = \mathbb{R}^d$. Then (6.3) reads $\dot{X}_t = \alpha_t$: the control *is* the velocity, the agent steers its position directly with no intervening dynamics, and substituting $\alpha_t = \dot{X}_t$ into (6.4) reproduces the action (6.1) verbatim, with X playing the role of γ. The Euler–Lagrange problem is thus the corner of the control problem in which the knob is the velocity itself and there are no limits on how fast one may go.

Leaving that corner is exactly what makes the theory apply to systems the calculus of variations cannot describe, and the two ways of leaving it are independent. First, the drift need not equal the control: $b(x, a)$ can be any map, so the knob may act on the state only indirectly, through several integrations. The textbook witness is the double integrator, a unit mass on a line whose state is the pair $X = (\text{position}, \text{velocity})$ and whose control is the applied force a, with $b((q,v),a) = (v,a)$. Here the agent sets the force, but the force moves the *velocity*, which in turn moves the *position*; the control reaches the quantity one cares about only at second hand, and there is no way to recast the problem as a direct minimization over position-curves with an unconstrained velocity. Second, the action set may be bounded: $A = [-1,1]^k$ or a ball encodes a throttle that saturates, a force a motor cannot exceed, a trading rate a market will not absorb. A bounded A has no counterpart at all in (6.1), where the velocity ranged over all of $\mathbb{R}^d$; yet it is precisely the boundedness of the knobs that makes the optimal policy interesting (it may push a knob to its limit and hold it there, a bang-bang regime invisible to unconstrained least action), and it is what will later let a strategic agent have a genuinely constrained set of responses to the population it faces. These two generalizations — indirect actuation and bounded actuation — are what carry the theory out of pure mechanics and into the engineered and strategic problems this book is ultimately about.

With the object of choice now a control rather than a curve, a distinction opens up that was invisible before, and it is the conceptual fulcrum of the chapter: *what is the control allowed to depend on?* There are two honest answers, and they are not interchangeable.

Definition 6.2 (Open-loop and feedback controls)**.** An *open-loop* control is a measurable map $t \mapsto \alpha_t \in A$ of time alone, chosen at the outset. A *feedback* (closed-loop) control is a measurable map $(t,x) \mapsto \phi(t,x) \in A$; it is realized along trajectories by $\alpha_t = \phi(t, X_t)$, where X solves (6.3) with this substitution.

The two definitions encode two postures toward the future. An open-loop control is a *plan*: the agent writes down, at time zero, the entire schedule $t \mapsto \alpha_t$ of what it will do at every future instant, seals it, and executes it no matter what — a flight plan filed before takeoff, a sequence of moves committed to in advance. It is a curve in the action set, indexed by time alone, and it carries no provision for surprise because it never consults the state. A feedback control is a *rule*: the agent commits not to a schedule of actions but to a policy $\phi(t,x)$ that says, "if I find myself at state x at time t, I do $\phi(t,x)$." The action is then synthesized on the fly along the realized trajectory, $\alpha_t = \phi(t, X_t)$, by reading the current state and looking it up in the rule. The defining difference is informational: the open-loop agent acts blind to where it is, the feedback agent acts on it.

In the deterministic problem (6.3)–(6.4) this difference, real as it is in principle, costs nothing: the two notions produce the *same* optimal cost. The reason is that determinism leaves nothing to react to. Once the start x_0 and a feedback rule ϕ are fixed, the closed-loop trajectory X is completely determined — (6.3) with $\alpha_t = \phi(t, X_t)$ has a unique solution — so the realized control history $t \mapsto \phi(t, X_t)$ is itself a fixed function of time, i.e. an open-loop control that produces the identical trajectory and hence the identical cost. Conversely the optimal open-loop control, replayed along its own optimal trajectory, can be repackaged as a feedback rule that happens to be evaluated only on that one path. In a world with no noise the agent gains nothing by watching the state, because the state never tells it anything it did not already know at time zero: the future is a foregone conclusion, and a sealed plan forfeits no information because there is no information to forfeit. This is why the calculus of variations, which produces only the open-loop optimal schedule from the single start x_0, suffered no visible penalty for it.

Switch on noise and the equivalence collapses — and it collapses for a reason worth stating now, because it is the entire motivation for the stochastic theory of section 6.5. Replace (6.3) by a stochastic differential equation $\mathrm{d}X_t = b(X_t, \alpha_t)\,\mathrm{d}t + \sigma(X_t)\,\mathrm{d}W_t$, so that the trajectory is now genuinely random and the agent's actual position at time t is not knowable in advance. An open-loop control, fixed at time zero, must commit to its entire schedule before a single Brownian increment is realized; it is betting on an average future and cannot adjust when the noise pushes the state somewhere the plan did not anticipate. A feedback control, by contrast, reads the realized X_t at each instant — noise included — and responds to where the agent *actually* is rather than where it was projected to be. This is the value of information made precise: feedback conditions on strictly more than open-loop (the entire realized history of the state, not just the clock), and since the open-loop schedules are exactly the feedback rules that ignore their state argument, the feedback optimum can only improve on the open-loop optimum, generically strictly. The gap is not a technical artifact; it is the difference between a plan and a policy in the presence of surprise, and a positive gap is the rule, not the exception, the moment $\sigma \not\equiv 0$. Section 6.7 will exhibit this concretely: in the linear–quadratic–Gaussian problem the optimal feedback is a linear rule in the current state, with a time-dependent gain set by a Riccati equation, that tracks the noisy state continuously — and no schedule fixed in advance can match its expected cost once the noise has anywhere to push.

This is the decisive observation for the rest of the book, and it tilts the whole development toward one of the two routes through optimal control. Dynamic programming is intrinsically a *feedback* theory: as we will see, it does not search for an optimal schedule from one start but constructs an object from which the optimal feedback rule $\phi(t, x)$ can be read off at *every* state x and *every* time t at once. That is precisely the rule, valid from everywhere, that the previous section identified as the thing genuinely wanted and that the calculus of variations could not supply — and it is precisely the field that the next section sets out to build. The Euler–Lagrange and Pontryagin routes, by contrast, characterize a single optimal trajectory at a time and are open-loop at heart; they remain indispensable (the Pontryagin costate returns in section 6.4 and again in chapter 9), but they are not the natural backbone for what is coming. For in a mean field game the "state" an agent must react to is not just its own noisy position but a whole population that is itself evolving randomly in time; reacting to a moving, uncertain environment is exactly what feedback does and open-loop cannot. An agent facing a fluctuating crowd needs a rule that prescribes a response from every configuration it might encounter, which is once more a field over states rather than a curve through them.

To produce such a field we cannot keep treating the single problem launched from the lone start x_0 in isolation; we must consider, all at once, the problem launched from every present time and every present state, and ask how their answers fit together. Embedding the single problem in that family — and discovering that the resulting family of optimal costs obeys one self-referential equation — is the program of the next section, to which we now turn.

6.2 Dynamic programming and the value function

The previous section left us with a sharp demand and no instrument to meet it. We argued that what a noisy or strategic agent genuinely needs is not the single optimal worldline launched from one start x_0, but a *rule* valid from every state at every time — a field of best responses, $\phi(t, x)$, that tells the agent what to do from wherever it actually finds itself. The calculus of variations and the Pontryagin route both produce the wrong shape of object: one trajectory, answering one question. To manufacture a field we must stop privileging the single start x_0 and instead solve, all at once, the entire *family* of control problems obtained by letting the agent begin at an arbitrary present time t and an arbitrary present state x. The optimal costs of that family, collected into one function of (t, x), will turn out to obey a single self-referential equation; and it is that equation, not any one trajectory, that secretly encodes the feedback rule at every state simultaneously. This section builds the family, names its optimal-cost function the value function, and extracts the identity. The identity is the engine of the chapter: the next section will crank it to an infinitesimal time step and watch a differential equation — the HJB equation — fall out.

So fix the data (b, L, g, T, A) once and for all, exactly as in (6.3)–(6.4), and embed the original problem in the promised family. The original problem started the clock at $t = 0$ from the state x_0; we now let it start at any $(t, x) \in [0, T] \times \mathbb{R}^d$. For an admissible control α on the remaining interval $[t, T]$, let $X^{t,x,\alpha}$ denote the solution of the controlled ODE $\dot{X}_s = b(X_s, \alpha_s)$ on $[t, T]$ launched from $X_t = x$ — the superscript records all three pieces of data the trajectory depends on, the start time, the start state, and the control. Pricing this trajectory over what remains of the horizon gives the *cost-to-go*,

$$J(t, x; \alpha) \;=\; \int_t^T L(X_s^{t,x,\alpha}, \alpha_s)\, \mathrm{d}s \;+\; g(X_T^{t,x,\alpha}).$$

This is the literal generalization of the cost $J(\alpha)$ of (6.4): that earlier object is recovered as the corner $J(0, x_0; \alpha)$, the integral now running from the present t rather than from 0 and the trajectory now hung from the present state x. Nothing new has been assumed; we have merely refused to commit to a single starting configuration, carrying the start (t, x) as a free pair of arguments. The whole subject turns on taking that refusal seriously.

Definition 6.3 (Value function)**.** The *value function* is the optimal cost-to-go,

$$u(t, x) \;=\; \inf_{\alpha} J(t, x; \alpha), \qquad (t, x) \in [0, T] \times \mathbb{R}^d,$$

the infimum taken over admissible controls on $[t, T]$. By construction $u(T, x) = g(x)$.

Two features of this definition deserve to be dwelt on before we use it, because they are exactly the features that separate dynamic programming from least action. The first is that u is a *field*, not a number. The calculus of variations, run from x_0, returned a single scalar — the minimal action of one curve. The value function returns a scalar *at every point* of the space-time slab $[0, T] \times \mathbb{R}^d$; it is the optimal cost-to-go evaluated at each conceivable present configuration, the entire landscape we contrasted with the lone worldline in the chapter's opening. Asking for u is asking for vastly more than asking for one optimal trajectory — and, paradoxically, asking for more is what makes the problem tractable, because the surplus information is precisely what lets the answers at neighboring points constrain one another. The second feature is the clause $u(T, x) = g(x)$, which is not an extra hypothesis but a forced consequence of the definition. At the terminal time the remaining interval $[T, T]$ has zero length: the integral in $J(T, x; \alpha)$ is empty, no control can be exercised, and the cost-to-go collapses to $g(x)$ for every admissible α. The infimum of a constant is that constant, so $u(T, \cdot) = g$ with nothing to optimize. This is the one slice of the field that is known outright, with no computation; the entire backward machinery of the next section exists to propagate this terminal datum to earlier times. We will return to its load-bearing role when we explain why HJB integrates backward.

It is worth fixing the picture with the smallest possible instance. Take $b \equiv 0$, so the state never moves and $X_s^{t,x,\alpha} \equiv x$, and take $L(x, a) = \frac{1}{2}|a|^2$ with $A = \mathbb{R}^d$. Then the cost-to-go is $J(t, x; \alpha) = \int_t^T \frac{1}{2}|\alpha_s|^2 \, \mathrm{d}s + g(x)$, the cheapest choice is plainly $\alpha \equiv 0$, and $u(t, x) = g(x)$ for *all* t: with motion forbidden and effort costly, the agent does nothing and simply pays the terminal price it is stuck with. Trivial as it is, this example already exhibits u as a function of the full pair (t, x) carrying the terminal data g, and it is the degenerate seed of every Riccati computation to come. The interesting content appears the instant the drift lets the agent *change* x at a price, so that paying running cost now can buy a cheaper terminal position later — the tension the value function is built to resolve.

That resolution is governed by one identity. Heuristically it says that optimizing over the whole interval $[t, T]$ can be done in two stages: optimize the first short leg $[t, t + h]$ and the remaining tail $[t + h, T]$ jointly, and the tail's contribution, *once re-optimized from wherever the first leg lands*, is nothing but the value function again, evaluated at the new time $t + h$ and the new state X_{t+h}. The decision over the whole collapses onto a decision over the first leg plus a lookup of u at its endpoint. This is the dynamic programming principle, and the surprise — the thing that makes it an equation rather than a tautology — is that the very same function u stands on both sides.

Theorem 6.4 (Dynamic programming principle, DPP)**.** *Under* (A-Lip) *and* (A-Growth) *on b and L, for every (t, x) and every $h \in [0, T - t]$,*

$$u(t, x) \;=\; \inf_{\alpha} \left\{ \int_t^{t+h} L(X_s^{t,x,\alpha}, \alpha_s) \, \mathrm{d}s \;+\; u\big(t + h,\, X_{t+h}^{t,x,\alpha}\big) \right\}. \tag{6.5}$$

Proof. An identity is two inequalities, and here the two carry genuinely different mechanisms — one is nearly free, the other needs a measurable-selection argument — so it is worth seeing exactly where the labor falls. Throughout, X solves the controlled ODE (6.3), so once the control on $[t, t + h]$ is fixed the endpoint $x' := X_{t+h}^{t,x,\alpha}$ is a *deterministic* reachable state, not a random variable; the measurability subtlety below is therefore the measurability of an ε-optimal tail control as a function of the reachable state x', and has nothing to do with randomness. (The genuinely random-endpoint version, where X_{t+h} is a random variable and one must select the tail measurably along sample paths, is the stochastic extension of section 6.5.)

The inequality $\geq$ (no selection needed). This direction says the left side cannot exceed the right, and it follows simply because any single competitor's cost overestimates an infimum. Let α be *any* admissible control on the whole of $[t, T]$, with state X, and write $x' = X_{t+h}$ for where its first leg lands. Because the cost-to-go is an integral, it splits at the intermediate time $t + h$ with no remainder:

$$J(t, x; \alpha) = \int_t^{t+h} L(X_s, \alpha_s) \, \mathrm{d}s + J(t + h, x'; \alpha|_{[t+h,T]}) \;\geq\; \int_t^{t+h} L(X_s, \alpha_s) \, \mathrm{d}s + u(t + h, x').$$

The single inequality is the entire crux of this direction, and it is almost free: the tail $\alpha|_{[t+h,T]}$ is *one* admissible competitor for the control problem started at $(t + h, x')$, so its cost-to-go is at least the infimum $u(t+h,x')$ over all such tails. We did not need to construct anything — restricting a control we already hold to its second half is automatic. The right-hand side is now bounded below by its own infimum over the first leg, and since α was arbitrary we may take $\inf_\alpha$ on the left, which yields "$\geq$". The reason no selection is needed is that we are throwing competitors *away* (passing to an infimum), and discarding never requires a measurable choice.

The inequality $\leq$ (selection needed). The opposite direction is where the work lives, and one can see in advance why. We must show the left side is no larger than the right, i.e. that for an essentially arbitrary first leg we can *assemble* a full control on $[t,T]$ whose total cost comes within ε of running that first leg and then paying the optimal tail-value $u(t+h,x')$. Assembling, unlike discarding, forces us to actually produce a tail control — and not just one tail, but one for *every* possible landing point x', glued together into a single control that is legitimate as an input to the dynamics. The gluing is the obstruction: the ε-optimal tail depends on x', and unless that dependence is measurable the concatenated control is not an admissible process and the construction is empty. Everything therefore hinges on choosing the tails measurably in the landing point, which is exactly what the next lemma supplies. We prove it in-book rather than invoke the general selection theorem, because under our Lipschitz standing assumptions an elementary partition argument suffices.

Lemma 6.5 (Measurable ε-optimal selection)**.** *Under* (A-Lip)*,* (A-Growth) *there is, for each $\tau \in [t,T]$ and each $\varepsilon > 0$, a Borel-measurable map $x' \mapsto \alpha^{x'}$ from states to admissible controls on $[\tau,T]$ with $J(\tau,x';\alpha^{x'}) \leq u(\tau,x') + \varepsilon$ for every x'.*

Proof. The single difficulty is measurability: for each *fixed* state x' an ε-optimal tail certainly exists, simply because $u(\tau,x')$ is an infimum and an infimum is approached to within any ε by some competitor. What is not automatic is that these competitors, one per state, can be chosen to depend Borel-measurably on x'; a careless pointwise choice could assemble a wildly non-measurable map. The way around this is to exploit continuity: if the optimal cost varies *continuously* in the starting state, then a control good at one base point is still nearly good at all nearby states, so we may reuse it on a whole neighborhood and choose only countably many controls in total.

The continuity we need comes from the dynamics being well-conditioned in the initial state, *uniformly over the control.* Fix any control α and two starting states x', y', and run (6.3) from each under the *same* α. Subtracting the two integral equations and using the (A-Lip) Lipschitz bound on b in the state, with constant $\mathrm{Lip}(b)$ *independent of the control argument*,

$$\left|X_s^{\tau,x',\alpha} - X_s^{\tau,y',\alpha}\right| \leq |x'-y'| + \mathrm{Lip}(b)\int_\tau^s \left|X_r^{\tau,x',\alpha} - X_r^{\tau,y',\alpha}\right| \,\mathrm{d}r,$$

and Grönwall's inequality turns this into $\left|X_s^{\tau,x',\alpha} - X_s^{\tau,y',\alpha}\right| \leq e^{\mathrm{Lip}(b)(s-\tau)}\,|x'-y'| \leq e^{\mathrm{Lip}(b)T}\,|x'-y'|$. The decisive point is that the amplification constant $e^{\mathrm{Lip}(b)T}$ depends only on the data, *not* on which control was used: the two flows started from nearby states stay close at a rate the control cannot worsen. Feeding this into the cost-to-go, where L and g are Lipschitz by (A-Lip), makes $x' \mapsto J(\tau,x';\alpha)$ Lipschitz with a constant that is again the same for every control — the family $\{J(\tau,\cdot;\alpha)\}_\alpha$ is *equi-Lipschitz.* Taking the infimum over α preserves a common Lipschitz bound (an infimum of functions sharing one modulus of continuity inherits that modulus), so $x' \mapsto u(\tau,x')$ is itself Lipschitz, hence continuous. Write ω for the common modulus of continuity of the whole equi-Lipschitz family — it bounds the oscillation of *every* $J(\tau,\cdot\,;\alpha)$ and of $u(\tau,\cdot)$ alike — and note once more that its uniformity over α is exactly what the Grönwall constant's control-independence bought us.

Now the partition. Cover $\mathbb{R}^d$ by a countable Borel partition $\{B_k\}$ into sets of diameter small enough that $\omega(\operatorname{diam} B_k) \le \varepsilon/2$; since one common modulus ω governs every cost-to-go in the family and the value, this single diameter threshold simultaneously caps the oscillation of all of them below $\varepsilon/2$ across each B_k — this is the content of the otherwise terse phrase "the common modulus of continuity gives oscillation below $\varepsilon/2$," and the word "common" is the whole point. In each cell pick a base point $x_k \in B_k$ and, using that $u(\tau, x_k)$ is an infimum, a control $\alpha^{(k)}$ that is $(\varepsilon/2)$-optimal there, $J(\tau, x_k; \alpha^{(k)}) \le u(\tau, x_k) + \varepsilon/2$. Define the selection by reusing each base-point control across its whole cell: $\alpha^{x'} = \alpha^{(k)}$ for $x' \in B_k$. This map is Borel because it is constant on each set of a countable Borel partition. To check it does its job, take $x' \in B_k$ and chain three estimates — transport the cost from x' to x_k, use $(\varepsilon/2)$-optimality at x_k, then transport the value back from x_k to x':

$$J(\tau, x'; \alpha^{(k)}) \le J(\tau, x_k; \alpha^{(k)}) + \tfrac{\varepsilon}{2} \le u(\tau, x_k) + \tfrac{\varepsilon}{2} + \tfrac{\varepsilon}{2} \le u(\tau, x') + \varepsilon,$$

the first and third steps each spending one ω-oscillation bound (below $\varepsilon/2$) on the cell B_k — the first on $J(\tau,\cdot\,;\alpha^{(k)})$, the third on $u(\tau,\cdot)$ — and the middle step spending the base-point optimality. The total slack is $\varepsilon/2 + \varepsilon/2 = \varepsilon$ only because the same ω bounds both oscillations; an oscillation budget that varied with the control would not close. This is the claim. The argument is the elementary in-book substitute for the general Kuratowski–Ryll-Nardzewski measurable-selection theorem, which would deliver a measurable ε-optimal selection with no continuity at all; the continuity afforded by (A-Lip) is precisely what lets us replace that abstract machinery with a countable partition and a triangle inequality. □

With the selection in hand the second inequality is immediate. Apply lemma 6.5 at $\tau = t + h$. Given any control on $[t, t+h]$ producing endpoint $x' = X_{t+h}$, concatenate it with the selected tail $\alpha^{x'}$ on $[t+h, T]$ — the concatenation is admissible precisely because $x' \mapsto \alpha^{x'}$ is measurable, so the glued process is a legitimate control. Its total cost is $\int_t^{t+h} L \,\mathrm{d}s + J(t+h, x'; \alpha^{x'}) \le \int_t^{t+h} L \,\mathrm{d}s + u(t+h, x') + \varepsilon$. Taking the infimum over the first leg and letting $\varepsilon \downarrow 0$ gives "$\le$", completing the proof. The classical references [136, Ch. III] and [68, Ch. I–II] carry out the general (random-endpoint, stochastic) version with the full measurable-selection apparatus. □

Remark 6.6 (The DPP is motivation; the rigorous spine is verification)**.** We have just spent real effort proving the DPP, so it is important to be candid about how much weight it is asked to bear downstream: *none.* No later result in this book — not the HJB equation we are about to derive, not the verification theorem, not the coupled system of chapter 8, nothing in the chapters beyond — logically rests on theorem 6.4. The DPP earns its place here for one purpose only: it is the heuristic *source* of the HJB equation. In the next section we expand (6.5) for small h and read off a partial differential equation, and that expansion is a genuine derivation, the kind that tells you what equation to write down and why it has the form it does. But a derivation is not a proof of correctness, and we will not pretend it is. The moment we have the candidate PDE, we change our footing entirely: we *forget* how we guessed it and prove, from scratch and by Itô's formula alone, that any sufficiently smooth solution of that PDE is the value function and that its feedback is optimal. That is the verification theorem theorem 6.10, and it is the load-bearing spine of the chapter. The practical upshot for the reader is liberating: every concern one might have about the DPP — whether the infimum is attained, whether the selection can be made along random paths in the stochastic case, whether u is regular enough for the expansion to be valid — can be set aside, because none of it is on the critical path. A reader who prefers to treat (6.5) as a purely formal identity, a mnemonic for where HJB comes from, loses no rigor whatsoever. We prove the DPP honestly because honest motivation is worth having; we route the rigor through verification because that is the route that needs no selection lemma, no a priori regularity of u, and no leap of faith about the $h \downarrow 0$ limit.

Heuristic (non-rigorous)

Read (6.5) as a bookkeeping tautology with teeth. The optimal cost from (t, x) equals the cost incurred over an arbitrarily short first leg $[t, t + h]$ plus the optimal cost from wherever that leg lands. Phrased as a slogan: optimality decomposes across time, because the tail of an optimal plan is itself optimal — if it were not, one could improve the tail and thereby improve the whole, contradicting optimality of the plan. That much really is almost a definition. The *content*, the part that is not tautological, is that the function appearing on the right under $u(t + h, \cdot)$ is the *same* function u that appears alone on the left. The identity relates u to itself across a time step, and a relation of an unknown to itself across an infinitesimal step is precisely what a differential equation is. Letting $h \downarrow 0$ will convert this fixed-point identity into the HJB equation. A physicist has met this move before: a self-consistency relation — the magnetization that must equal the response it induces, the field that must reproduce the field it generates — becomes, in the continuum or small-step limit, a differential (or integral) equation for the self-consistent quantity. The DPP is the self-consistency relation of optimal control; HJB is its continuum limit.

We now have the family, the field u, and the self-referential identity that binds the field's values at neighboring times. Only one operation remains to extract a usable equation from (6.5): take the first leg infinitesimally short and expand. That $h \downarrow 0$ limit — the move the heuristic just promised, converting a self-consistency relation into a differential equation — is the entire business of the next section, which opens by performing exactly this expansion and turning the DPP into the Hamilton–Jacobi–Bellman equation.

6.3 The Hamilton–Jacobi–Bellman equation and backward time

We arrive at the chapter's climax holding exactly one thing: the dynamic programming identity (6.5), which binds the value u to itself across a time step of length h. The previous section's closing heuristic already told us what to do with it: a relation of an unknown to itself across an infinitesimal step *is* a differential equation in disguise, the self-consistency relation of optimal control awaiting its continuum limit. We now take $h \downarrow 0$ and watch that limit, the Hamilton–Jacobi–Bellman (HJB) equation, condense out. This is the conversion the heuristic box anticipated, and it is the move that finally replaces the physicist's least-action reflex — extremize an action, solve a two-point boundary-value problem for one optimal curve — with the dynamic-programmer's: compute a whole field $u(t,x)$ by integrating a single PDE backward from terminal data.

The work falls into three stages, and it is worth seeing in advance that they are three movements of one argument rather than three separate results. The first stage, the *formal derivation*, simply performs the limit: granting ourselves provisionally that u is smooth, we Taylor-expand (6.5) in h, divide, let $h \downarrow 0$, and read off the PDE together with the object that organizes everything downstream, the Bellman Hamiltonian (6.6). This stage is honest but incomplete in a way we will name as we go: it is a *derivation*, the kind of calculation that tells you what equation to write and why it has the shape it does, but it assumes the very smoothness of u that is not given to us in advance, and it trusts an $h \downarrow 0$ limit we have not controlled. The second stage steps back from the algebra to confront the single feature of the resulting equation that most violates physical expectation: (6.7) carries its data at the *final* time and is solved *backward*. This is the central retraining of the chapter, and it earns a subsection of its own — *why the time runs backward* — because mistaking which end of the interval carries the datum does not flip a sign, it silently exchanges a well-posed problem for an ill-posed one. The third stage, the *verification theorem*, repays the debt the first stage incurred. Having let the DPP *suggest* the PDE, we discard the derivation entirely and turn it around into a guess-and-check: we forget where the equation came from, posit a smooth solution, and prove from Itô's formula alone that any such solution is the value function and that its feedback is optimal. This is the move flagged already in remark 6.6 — the DPP is motivation, the rigorous spine is verification — and it is the engine that every explicit computation in this book, the LQG worked example of section 6.7 included, will actually run.

So the architecture is: a formal derivation that assumes smoothness to find the equation; a conceptual treatment that explains the equation's strangest structural feature; and a verification theorem that turns the whole derivation around, requiring smoothness now only of a *candidate* we are free to guess, never of the value function we did not yet know. The verification stage is what makes the provisional smoothness of the first stage harmless: whatever the derivation assumed in order to write the equation down, the verification theorem re-establishes from scratch, by a route that needs no selection lemma, no a priori regularity of u, and no leap of faith about the limit. We begin, then, with the derivation, granting ourselves exactly the provisional smoothness the verification theorem will later let us take back.

6.3.1 Formal derivation

We now execute, in full, the $h \downarrow 0$ limit just described, expanding the dynamic programming identity (6.5) to read off the equation its self-reference becomes. To run the expansion at all we must be able to differentiate u, so we grant ourselves, *provisionally*, that $u \in C^1([0,T] \times \mathbb{R}^d)$. This is the one debt the derivation incurs, and it is worth marking it precisely as a debt: nothing so far guarantees that the infimum of a family of costs is even once differentiable in (t,x), and in section 6.6 we will meet explicit problems where it is not. The whole point of the verification theorem of theorem 6.10 is to retire this debt — to re-derive everything below demanding smoothness only of a *candidate* we are free to construct, never of the unknown u itself. For now we simply assume it and proceed.

Fix a base point (t,x). The infimum in (6.5) ranges over all admissible controls on $[t,t+h]$, but for the purpose of extracting the leading behaviour as $h \downarrow 0$ it suffices to probe it with the simplest possible competitors: hold a single *constant* action $\alpha_s \equiv a \in A$ across the short interval $[t, t+h]$. The justification is that over a vanishing interval only the action at the *instant* t can register at first order — any admissible control is, to leading order in h, indistinguishable from the constant equal to its value at t — so infimizing over constants reproduces the same leading term as infimizing over all controls. With a frozen, evaluate the two pieces of the right side of (6.5) in turn.

First the state increment. The controlled dynamics (6.3) integrate to $X_{t+h} = x + \int_t^{t+h} b(X_s, a)\, \mathrm{d}s$. Over the short interval the trajectory has barely left x, so $X_s \to x$ as $s \downarrow t$ and, by continuity of b, the integrand is $b(x,a) + o(1)$; the integral is therefore

$$X_{t+h} = x + h\, b(x,a) + o(h).$$

Next the value at the displaced endpoint. Taylor-expanding the C^1 function u about (t,x) in *both* arguments — the time has advanced by h, the state by $X_{t+h} - x = h\, b(x,a) + o(h)$ — and using the chain rule,

$$u(t+h, X_{t+h}) = u(t,x) + h\, \partial_t u(t,x) + (X_{t+h} - x)\cdot \nabla u(t,x) + o(h) = u(t,x) + h\big(\partial_t u(t,x) + b(x,a)\cdot \nabla u(t,x)\big) + o(h),$$

where the second equality substitutes the increment just computed and folds the $o(h)$-sized state error, dotted into the bounded gradient, into the remainder. Finally the running cost over the leg is $\int_t^{t+h} L(X_s, a)\, \mathrm{d}s = h\, L(x,a) + o(h)$ by the same "integrand is nearly constant" estimate that produced the state increment. Assembling the two pieces, the bracketed quantity inside the infimum of (6.5) is

$$\int_t^{t+h} L(X_s, a)\, \mathrm{d}s + u(t+h, X_{t+h}) = u(t,x) + h\, \partial_t u(t,x) + h\big(b(x,a)\cdot \nabla u(t,x) + L(x,a)\big) + o(h).$$

Now read off the structure. The term $u(t,x)$ on the right is exactly the left side of (6.5), so it cancels; the term $h\, \partial_t u(t,x)$ carries no dependence on the action a, so it slips outside the infimum untouched; and what is left under the infimum is the single a-dependent group $b(x,a)\cdot \nabla u(t,x) + L(x,a)$. The identity (6.5) thus collapses to

$$0 = h\, \partial_t u(t,x) + \inf_{a\in A} \Big\{ h\, b(x,a)\cdot \nabla u(t,x) + h\, L(x,a) \Big\} + o(h).$$

Divide through by h and let $h \downarrow 0$; the $o(h)/h$ remainder vanishes and we obtain the pointwise relation

$$0 = \partial_t u(t,x) + \inf_{a\in A} \Big\{ b(x,a)\cdot \nabla u(t,x) + L(x,a) \Big\}.$$

This is already the HJB equation; it remains only to name the minimization it contains. It is convenient, and consistent with the conventions of appendix A, to absorb that infimum into a Hamiltonian — precisely the partial Legendre transform that, in the calculus-of-variations corner of section 6.1, turned the running cost into the physical Hamiltonian. We define the *(Bellman) Hamiltonian*

$$H(x,p) \;:=\; \sup_{a\in A} \Big\{ -b(x,a)\cdot p - L(x,a) \Big\} \;=\; -\inf_{a\in A} \{ b(x,a)\cdot p + L(x,a) \}. \tag{6.6}$$

Then $\inf_a\{b \cdot \nabla u + L\} = -H(x, \nabla u)$, and the displayed identity is the *Hamilton–Jacobi–Bellman equation*

$$-\partial_t u(t,x) + H\big(x, \nabla u(t,x)\big) = 0, \qquad u(T,x) = g(x). \tag{6.7}$$

We must now say a word about what does the analytic work in this construction, because it is unusually easy — and a common error — to credit it to the wrong hypothesis. The temptation is to declare "H is convex in p" and treat that convexity as the operative assumption. It is not, and seeing exactly why is the single most important hypothesis-clarification in this chapter.

Start from the fact that convexity in p is *free*. For each fixed action a the map $p \mapsto -b(x,a) \cdot p - L(x,a)$ is *affine* — a constant plus a linear term in p. The Hamiltonian (6.6) is the pointwise supremum of this family over $a \in A$, and a pointwise supremum of affine functions is convex *always*, with no hypothesis on the data whatsoever: the supremum of a collection of straight lines is the upper envelope of those lines, and an upper envelope of lines is by inspection a convex curve. So the convexity of H in p is a structural identity, true for every b and L, attained by no assumption. A property that holds unconditionally cannot be the content of an assumption; if we want a hypothesis to buy us something, we must look for what convexity *fails* to deliver.

What it fails to deliver is the thing we actually need: a single, well-defined optimal action, varying smoothly with (x,p), so that the feedback (6.8) is a genuine function and the Hamiltonian is differentiable. A merely convex function can have *corners*. At a corner a convex function is continuous but not differentiable; in place of a gradient it carries a whole *set* of supporting slopes, its subdifferential $\partial_p H$, and through the envelope correspondence each such slope answers to a distinct maximizing action. A set-valued $\partial_p H$ is, read through (6.8), exactly a *non-unique feedback*: at such a p the agent is told to play any one of several actions, with no principled way to choose. The smallest honest illustration takes a finite action set. Let $A = \{-1, +1\}$, $d = 1$, $b(x,a) = a$, and $L \equiv 0$, so that $H(x,p) = \sup_{a \in \{-1,1\}}\{-a\,p\} = |p|$. This H is convex — it is the upper envelope of the two lines $-p$ and $+p$ — and it is perfectly differentiable away from the origin, where the maximizing action is the unique $a^* = -\operatorname{sgn}(p)$. But at $p = 0$ the two lines cross: H has a kink, $\partial_p H(x,0) = [-1,1]$ is a full interval, and *both* actions $a = \pm 1$ attain the supremum. The feedback is genuinely ambiguous there. Convexity did nothing to prevent this; the corner is compatible with it.

The mechanism that rules corners out lives one level down, not in H as a function of p but in the *action* map being optimized inside it,

$$a \;\longmapsto\; \mathfrak{H}(x,a,p) \;=\; b(x,a) \cdot p + L(x,a),$$

whose infimum over a defines $H(x,p) = -\inf_a \mathfrak{H}(x,a,p)$. Two properties of this map, in the variable a, are what we genuinely require, and they are logically independent. First, *coercivity*: $\mathfrak{H}(x,a,p) \to +\infty$ as $|a| \to \infty$, which we inherit from the superlinear growth recorded in (A-Growth). Coercivity guarantees the infimum is actually *attained*, and attained on a bounded set — a minimizing sequence cannot escape to infinity, so it has a convergent subsequence whose limit, by continuity, is a minimizer. (In the finite-set example coercivity is vacuous and there is nothing to attain in the interior; that degeneracy is precisely what left room for the tie at $p = 0$.) Second, *strict* convexity of $a \mapsto \mathfrak{H}(x,a,p)$: this forces the minimizer to be *unique*, for if two distinct points both minimized, their midpoint would, by strict convexity, lie strictly below the common minimum value — an impossibility. Coercivity supplies existence, strict convexity supplies uniqueness; together they make $a^*(x,p) = \arg\min_a \mathfrak{H}(x,a,p)$ a single-valued map, and (as the envelope lemma below makes precise, through a positive definite Hessian) a C^1 one. A unique, smoothly varying minimizer is in turn exactly what makes H differentiable in p, with the single-valued gradient $\partial_p H(x,p) = -b(x, a^*(x,p))$ of lemma 6.8 replacing the set-valued subdifferential a corner would have forced.

This is the classical duality between strict convexity on one side of a Legendre transform and differentiability on the other, and it pinpoints where the genuine assumption sits. *Strict convexity plus coercivity in the control a* is the operative hypothesis; the convexity of H in p is its dual shadow, not its source. We nonetheless give that shadow a name. Throughout the book the hypothesis is consumed downstream in the form "H is convex in p" — it is in that form that the verification theorem of theorem 6.10 compares a candidate against the true value, and in that form that the monotonicity and comparison arguments behind uniqueness in the coupled system of chapter 8 invoke it — so we tag the convexity of H in p as (A-Conv) and quote it by that tag where it is used. The reader should simply carry the translation: the *tag* (A-Conv) is the convexity-in-p in which the hypothesis is *spent*, while its *operative content*, the thing that has to be assumed of the data (b, L) to make any of it true, is strict convexity and coercivity in the action a. With that settled we may record the unique minimizer as the candidate optimal feedback.

Definition 6.7 (Optimal feedback)**.** Under (A-Growth) and strict convexity in the control of $a \mapsto b(x,a) \cdot p + L(x,a)$ (the operative content of (A-Conv); see the discussion above), for each (x,p) let $a^*(x,p) = \arg\min_{a \in A}\{b(x,a) \cdot p + L(x,a)\}$ be the unique minimizer in (6.6). The candidate *optimal feedback* is

$$\alpha^*(t,x) \;=\; a^*\big(x, \nabla u(t,x)\big). \tag{6.8}$$

The differentiability of H used throughout — and the formula $\partial_p H = -b(\cdot, a^*)$ on which the costate identity of section 6.4 and the feedback $\alpha^* = -\partial_p H$ of section 6.5 both rest — is not an appeal to an external "envelope theorem" but a one-line consequence of the first-order condition at the minimizer. We record it in-book.

Lemma 6.8 (Envelope identity for the Bellman Hamiltonian)**.** *Let $b(x,\cdot), L(x,\cdot) \in C^2(A)$ with $A \subseteq \mathbb{R}^k$ open, and assume that for (x,p) in an open set the map $\mathfrak{H}(x,\cdot,p) := b(x,\cdot)\cdot p + L(x,\cdot)$ has a unique interior minimizer $a^*(x,p)$ at which the Hessian $\partial_{aa}\mathfrak{H}(x,a^*,p)$ is positive definite (both guaranteed by the strict convexity and coercivity of definition 6.7). Then a^* is C^1 in (x,p), the Bellman Hamiltonian $H(x,p) = -\mathfrak{H}(x, a^*(x,p), p)$ is C^1, and*

$$\partial_p H(x,p) = -b\big(x, a^*(x,p)\big), \qquad \partial_x H(x,p) = -\partial_x \mathfrak{H}\big(x, a^*(x,p), p\big). \tag{6.9}$$

Proof. The argument has two moves: first establish that the minimizer a^* depends smoothly on the parameters, then differentiate the optimal value and watch a term die.

Smooth dependence of the minimizer. Because $a^*(x,p)$ is an *interior* minimizer of the smooth map $a \mapsto \mathfrak{H}(x,a,p)$, it is a stationary point: the first-order condition

$$\partial_a \mathfrak{H}\big(x, a^*(x,p), p\big) = 0$$

holds identically in (x,p) (an interior extremum of a differentiable function has vanishing gradient in the optimized variable; were $\partial_a \mathfrak{H} \neq 0$ one could decrease $\mathfrak{H}$ by an infinitesimal step in the direction $-\partial_a \mathfrak{H}$, contradicting minimality). Read this as an implicit equation $F(x,p,a) := \partial_a \mathfrak{H}(x,a,p) = 0$ defining a in terms of (x,p). Its Jacobian in the unknown a is $\partial_a F = \partial_{aa}\mathfrak{H}(x,a^*,p)$, the Hessian, which is positive definite by hypothesis and hence invertible. The implicit function theorem therefore solves $F = 0$ locally for a C^1 map $(x,p) \mapsto a^*(x,p)$. This is where the positive definite Hessian earns its keep: it is the nondegeneracy that upgrades "the minimizer exists and is unique" to "the minimizer moves smoothly as we tilt the data," which is what the chain rule below will require.

Differentiating the optimal value: the envelope cancellation. Now differentiate $H(x,p) = -\mathfrak{H}(x,a^*(x,p),p)$. The subtlety is that (x,p) enters in *two* ways — explicitly, through the first and third slots of $\mathfrak{H}$, and implicitly, through the minimizer $a^*(x,p)$ in the second slot — so the chain rule produces an explicit term and an implicit term. Take p first:

$$\partial_p H = -\partial_p \mathfrak{H}(x,a^*,p) - \underbrace{\partial_a \mathfrak{H}(x,a^*,p)}_{=0}\,\partial_p a^* = -\partial_p \mathfrak{H}(x,a^*,p) = -b(x,a^*),$$

where the implicit term — the one carrying the derivative of the minimizer — is annihilated outright by the first-order condition $\partial_a \mathfrak{H}(x,a^*,p) = 0$, and the surviving explicit term is evaluated using $\partial_p \mathfrak{H}(x,a,p) = \partial_p\big(b(x,a)\cdot p + L(x,a)\big) = b(x,a)$. This cancellation of the implicit term *is* the envelope theorem: at an optimum the value is insensitive, to first order, to the motion of the optimizer, because the optimizer sits where the gradient in a already vanishes. The same computation in x runs verbatim. Differentiating $H(x,p) = -\mathfrak{H}(x,a^*(x,p),p)$ in x,

$$\partial_x H = -\partial_x \mathfrak{H}(x,a^*,p) - \underbrace{\partial_a \mathfrak{H}(x,a^*,p)}_{=0}\,\partial_x a^* = -\partial_x \mathfrak{H}(x,a^*,p) = -\big(\partial_x b(x,a^*)\,p + \partial_x L(x,a^*)\big),$$

the implicit term $\partial_a \mathfrak{H} \cdot \partial_x a^*$ vanishing for the identical reason — the first-order condition kills it whichever parameter we vary — and the explicit term read off from $\partial_x \mathfrak{H}(x,a,p) = \partial_x b(x,a)\,p + \partial_x L(x,a)$. The essential phenomenon is that $\partial_x H$ picks up only the *explicit* dependence of $\mathfrak{H}$ on x, never the dependence routed through the moving minimizer; that is the precise sense in which the value's x-derivative "does not see" how a^* shifts. Finally, both right-hand sides in (6.9) are continuous in (x,p), since a^* is continuous (indeed C^1) and b, L are C^2; a function with continuous first partials is C^1, so $H \in C^1$, as claimed. $\square$

Notation watch

Two Hamiltonians, two sign habits, and one genuine reader trap. This book runs *three* objects all called "Hamiltonian," and confusing their signs is the most reliable way to derive a wrong equation, so we lay them side by side.

The *Bellman* Hamiltonian (6.6), $H(x,p) = -\inf_a\{b(x,a)\cdot p + L(x,a)\}$, is built with its outer minus sign for exactly one reason: it makes the HJB equation read $-\partial_t u + H(x,\nabla u) = 0$, the form used uniformly in this book and in the mean field game literature ([93]; [36]), and the form into which the coupled system of chapter 8 will slot the forward Fokker–Planck equation. Many control texts instead carry the bare *Pontryagin* Hamiltonian $\mathfrak{H}(x,a,p) = b(x,a)\cdot p + L(x,a)$ of section 6.4, retaining the action a as an explicit argument, and write

the HJB equation as $\partial_t u + \inf_a \mathfrak{H} = 0$. The two descriptions are the *same* equation: they are related by $H(x,p) = -\inf_a \mathfrak{H}(x,a,p)$, the single outer sign converting $\inf_a \mathfrak{H}$ into $-H$ and, simultaneously, $+\partial_t u$ into $-\partial_t u$. That one sign is load-bearing. Misplace it and convexity in p silently becomes concavity, the infimum over actions becomes a supremum, and the envelope formula $\partial_p H = -b(\cdot, a^*)$ flips its sign — after which the feedback $\alpha^* = -\partial_p H$ of section 6.5 points the agent in exactly the wrong direction.
The classical-mechanics reader carries a third sign habit that must be quarantined. The physical Hamiltonian of section 6.1, $H_{\text{phys}}(x,p) = \sup_v \{p \cdot v - L\}$, is a Legendre transform with a $+p \cdot v$ inside it; the Bellman Hamiltonian (6.6) carries $-b \cdot p$ instead. The extra minus sign is not a convention one is free to set: it is the price of optimizing a *cost* that is to be *minimized* rather than an action that is to be *extremized*. In the calculus-of-variations corner $b(x,a) = a$ and the actions are velocities, so the two transforms differ *only* by that sign, and one can watch the discrepancy enter exactly where "least cost" replaces "stationary action."
The safe discipline is to trust no remembered sign at all: write down (6.7) and (6.6) as fixed in this book, and check every later formula against them rather than against a Hamiltonian half-remembered from mechanics.

These two formulas — the differentiability of H and the envelope identity $\partial_p H = -b(\cdot, a^*)$ — are the export of this subsection. They are what the costate identity of section 6.4 will lean on when it identifies the Pontryagin adjoint with ∇u, and what section 6.5 will lean on when it reads the optimal feedback straight off the Hamiltonian as $\alpha^* = -\partial_p H$. One piece of (6.7), however, we have written down but not yet earned: the terminal clause $u(T, \cdot) = g$, with the equation to be integrated *backward* from it. We took that data for granted in the derivation, where it dropped out of definition 6.3 for free; but it sits in flat contradiction with every forward-in-time evolution the physicist trusts, and a contradiction of that magnitude deserves to be explained rather than merely stated. The next subsection does exactly that — it confronts the backward direction of time head-on, and contrasts it with the time-symmetric, two-point boundary-value structure of the Euler–Lagrange picture of section 6.1 that the chapter opened from.

6.3.2 Why the time runs backward

We closed the formal derivation owing one clause. Equation (6.7) was assembled from the dynamic programming identity by a perfectly forward-looking calculation — expand a short first leg, divide by h, take a limit — and yet the equation it produced carries its data at the *final* time, $u(T, \cdot) = g$, and must be integrated *backward* toward $t = 0$. That terminal clause dropped out of definition 6.3 for free and we wrote it down without comment; but it sits in flat contradiction with every forward-in-time evolution the physicist trusts, and the preamble of this chapter promised that we would not dispatch the contradiction in a sentence. This is the promised reckoning. In the author's experience the backward arrow of HJB is the single largest conceptual hurdle of Part I, and the right response to a genuine conceptual hurdle is not to step lightly over it but to stand on it until it stops feeling like one. So we belabor it deliberately, and we begin by sharpening exactly what it is in tension with.

The tension is with the picture the chapter opened from. In the Euler–Lagrange account of section 6.1, time carries no preferred direction at all. The optimal curve γ^* solves the second-order equation (6.2), and one pins it down by clamping data at *both* ends of the interval — the start $\gamma(0) = x_0$ at the left, the transversality condition $\partial_v L + \nabla g = 0$ at the right — which is precisely the two-point boundary-value structure we dwelt on there. Half the data live in the present and half in the future, and there is no operational sense in which one "integrates the action forward": the equation knows nothing of a flow of time, only of a curve simultaneously anchored at its two ends. A physicist is entirely at home with this. It is the shape of every boundary-value problem in classical field theory, and the time-symmetry is not a defect but a reflection of the time-reversal invariance of the underlying variational principle. Dynamic programming now breaks that symmetry, and breaks it on purpose, and the first thing to absorb is that the break is a feature of the *question* being asked, not an artifact of the method.

So ask the question dynamic programming actually answers. The value $u(t, x)$ is, by definition 6.3, the least cost the agent can still incur *from here on*: "standing now at state x, with exactly $T - t$ of time remaining, what is the cheapest total cost I can still arrange to pay over what is left of the horizon?" Read it slowly, because the phrase "what is left" is the whole of the matter. The value at (t, x) is a fact about the *future* of t — about the interval $[t, T]$ and nothing earlier — and it is utterly indifferent to how the agent arrived at x or to what happened before t. The past is a sunk cost; only the remaining obligation is priced. A quantity defined as "the best I can still do over the time that remains" is one whose natural reference point is not the start of the interval but its *end*, because the amount of time that remains is measured from the end.

That reorientation toward the end of the interval is what selects the terminal time as the place to begin. Among all instants t, there is exactly one at which the question answers itself with no optimization whatsoever, and it is $t = T$. At the terminal time there is no time left, hence no decision to make, hence no infimum to compute: the agent is simply handed whatever terminal cost its position carries, and $u(T, x) = g(x)$ is *forced*, not chosen. This is the one slice of the entire space-time field u that is known outright, before any equation is solved — the boundary datum of definition 6.3 re-encountered as the natural starting surface of the computation. Every other slice $u(t, \cdot)$ with $t < T$ genuinely requires the optimization to be carried out; only the terminal slice is given. If one is going to build the field at all, one has no choice but to build it outward from the only place it is already pinned down.

The cleanest way to feel why "outward from T" means "backward in t" is to discretize the clock and watch the field fill in. Replace $[0, T]$ by the finitely many instants $T, T - h, T - 2h, \ldots, 0$ and imagine, at each instant, a layer of states. The terminal layer $u(T, \cdot) = g$ is known. To find the value one step earlier, at $T - h$, the agent standing at a state x contemplates each available action, pays the running cost it incurs over the step, lands at a new state, and there reads off the *already-known* value $u(T, \cdot)$; minimizing over actions gives $u(T - h, x)$. The layer at $T - h$ is thus computed purely from the layer at T. Repeat: the layer at $T - 2h$ is computed from the layer at $T - h$, and so on, each layer drawing only on the one immediately to its future, until the recursion reaches $t = 0$. This is exactly backward induction on a decision tree — the elementary algorithm one runs on any finite-horizon problem, filling the table from the leaves toward the root — and it is the discrete shadow of the dynamic programming identity (6.5) we have been wielding all along. The HJB equation (6.7) is the $h \downarrow 0$ limit of precisely this recursion, and it inherits the recursion's direction: information flows from later layers to earlier ones, never the reverse.

The differential equation wears that direction openly once one looks at what it relates. Rearranged, (6.7) reads $\partial_t u(t, \cdot) = H(x, \nabla u(t, \cdot))$: it expresses the rate of change of the value as the present recedes purely in terms of u and its spatial gradient ∇u *at the same instant* t. The equation is local in time — it ties the field at t to its own time-derivative there — so it propagates a known slice to an adjacent one, and the only slice we know to seed it with is the terminal one. Knowing the whole field $u(t+h, \cdot)$ at a slightly later time determines, through this local-in-time relation, the field $u(t, \cdot)$ a step earlier. The terminal condition is the sole surface on which the data are unambiguous; it is therefore the surface one must launch from; and from a terminal surface the only direction one can march is toward smaller t. The backward arrow is not imposed on HJB from outside — it is the equation's honest report of the fact that a cost-to-go is anchored at the end of the horizon.

Set this beside the forward problems the physicist knows in his bones, because the contrast is the lesson. A Newtonian trajectory is launched from a present position and velocity and pushed into an as-yet-unwritten future. The heat equation takes a present temperature profile and diffuses it forward. The Fokker–Planck flow of chapter 5 takes a present probability density and transports it forward along the dynamics. Every one of these is an *initial*-value problem, and they share a single epistemic posture: the system *knows its present state* and computes its future from it. HJB inverts that posture exactly. It does not know its present value — that is the unknown it is solving for — but it knows its *future obligation*, the terminal cost g it will be made to pay, and it pulls that obligation backward into the present. A forward evolution propagates a known present into an unknown future; HJB propagates a known future into an unknown present. Once stated that baldly the backward arrow stops being mysterious: a quantity that prices the future cannot help but be computed from the future.

It is worth defusing, before it can take hold, a fear that the word "backward" tends to provoke in anyone who remembers the backward heat equation. That equation — the heat equation run in reverse — is the textbook ill-posed problem: it amplifies high-frequency noise without bound and has no solution for generic data. One might worry that HJB, integrated backward, suffers the same pathology. It does not, and seeing why is clarifying. "Backward" here is a statement about *physical* time only. Introduce the reversed clock $\tau := T - t$, which runs from 0 at the terminal time to T at the present; then $\partial_t = -\partial_\tau$, the terminal datum at $t = T$ becomes an *initial* datum at $\tau = 0$, and HJB becomes an ordinary *forward* evolution in τ launched from g. The terminal-value problem in t and the initial-value problem in τ are the same problem in two dressings, and the second is manifestly well-posed: one integrates forward in τ from known data, exactly as for any initial-value problem. (When the diffusion of section 6.5 is switched on, this is the content of the sign on the second-order term: HJB carries the Laplacian with precisely the sign that makes the τ-evolution a forward, well-posed parabolic equation, the genuine *adjoint partner* of the forward Fokker–Planck, not the catastrophic backward heat equation.) The backward arrow is bookkeeping relative to the agent's clock, not a symptom of ill-posedness; HJB is as well-posed as the heat equation, merely oriented the other way in physical time.

This pairing of one backward equation against one forward equation is not an idiosyncrasy of the single-agent problem; it is the structural skeleton of the entire subject, and naming it now is the main forward-pointing payoff of this subsection. When chapter 8 finally releases the population m

from the frozen, inert role it plays throughout this chapter and lets it become the unknown of a Nash fixed point, two evolutions will run simultaneously on the same interval $[0, T]$ and in opposite temporal directions. The population density m will satisfy a *forward* Fokker–Planck equation carrying its data at $t = 0$ — because a density, like any of the physicist's initial-value flows, knows its present and is pushed into the future. The value u will satisfy the *backward* HJB equation carrying its data at $t = T$ — because a cost-to-go knows its future obligation and is pulled into the present. The two are welded at opposite ends of the interval: the density's datum is clamped at the left end, the value's datum at the right, and each equation's coefficients depend on the other's unknown. A system specified by data split across the two ends of time is a boundary-value problem in time, not an initial-value one — the very two-endpoint structure we met in the Euler–Lagrange problem of section 6.1, now lifted from a single curve to a coupled pair of evolution equations. That opposed-arrow welding has no initial-value analogue, it cannot be integrated straight through in either direction, and it is exactly what makes a mean field game the delicate object it is. The reader should fix the picture now and carry it as the recurring structural motif of the whole book: *forward density, backward value, welded at the ends* is the signature by which one recognizes an MFG on sight.

Physics note

The classical limit makes the kinship visible, and it is worth tracing because it locates exactly what Bellman added to a structure the physicist already owns. The Hamilton–Jacobi equation of analytical mechanics, $\partial_t S + H_{\text{phys}}(x, \nabla S) = 0$ for Hamilton's principal function S, is (6.7) stripped of the optimization: there is no $\inf_a$ because the "control" — the velocity — has already been eliminated once and for all by the Legendre transform that defined H_{phys} in section 6.1, and the sign on the Hamiltonian differs because S is an action to be *extremized* rather than a cost to be *minimized*. Bellman's contribution is to put the optimization back, but to put it back *inside* the Hamiltonian: H in (6.6) is itself a Legendre-type transform of the running cost over the admissible controls, so that the single elimination of the velocity in mechanics is replaced by a genuine minimization over a possibly bounded, possibly indirectly-acting control set. Strip that minimization away — take the calculus-of-variations corner $b(x, a) = a$, $A = \mathbb{R}^d$, where the control is the velocity and the infimum is attained by the same stationarity that the Legendre transform performs — and HJB collapses back onto Hamilton–Jacobi. The principal function S is the un-optimized ancestor; the value u is an optimized principal function. The kinship runs further. The eikonal equation $|\nabla S| = n(x)$ of geometric optics is the stationary, first-order specialization of Hamilton–Jacobi, its characteristics are light rays, and its solutions are notorious for developing gradient kinks where rays cross — the *caustics* of optics, the bright cusped envelopes one sees at the bottom of a teacup. At such a crossing the principal function is continuous but its gradient is multivalued, precisely the corner phenomenon we saw (6.6) permit when the maximizing action ties. This is the same kink that will force us, in section 6.6, to abandon classical solutions of HJB for the weak notion of viscosity solutions: the caustic of geometric optics and the shock of the value function are one phenomenon, met first by the physicist in optics and about to be met again, with the optimization reinstated, in control.

That last observation is the hinge to the two subsections that follow. The kinks the physicsnote just flagged — the places where rays cross and ∇u ceases to exist — are exactly the failure of smoothness that section 6.6 will be built to handle, and we hand the caustic phenomenon forward to it intact. More immediately, the whole of this subsection, and indeed of the formal derivation that preceded it, has quietly leaned on u being differentiable enough to write $\partial_t u$ and ∇u and to expand the dynamic programming identity to first order. The physicsnote has now warned us, in the reader's own language of caustics, that this smoothness is not automatic — the value can crease — and the formal derivation already confessed that it had merely *assumed* $u \in C^1$ and trusted an uncontrolled $h \downarrow 0$ limit. Two debts, then, are outstanding: the derivation assumed regularity it did not establish, and the limit it took was never justified. The next subsection retires both at a stroke by inverting the logic. Rather than derive HJB from the value function and hope the value is smooth, it will *guess* a smooth solution of the equation and prove directly — by Itô's formula alone, with no appeal to the dynamic programming principle and no a priori regularity of u — that any such solution must be the value function and that its feedback is optimal. That clean, fully rigorous guess-and-check is the verification theorem.

6.3.3 The verification theorem

The previous subsection closed by tallying two debts that the formal derivation had quietly run up. First, every step of that derivation — writing $\partial_t u$ and ∇u, Taylor-expanding the dynamic programming identity to first order — presumed that u was differentiable, and the physicsnote's caustics have just warned us that the value can crease, so that smoothness is precisely what is *not* given to us in advance. Second, even granting smoothness, the passage $h \downarrow 0$ that produced the PDE was never controlled; we divided by h and waved the remainder away. A calculation carrying two unpaid debts is a fine *derivation* — it tells us what equation to write and why it has the shape it does — but it is not a proof that the equation governs the value function. The honest move now is not to patch the derivation but to abandon it.

The device is a logical inversion that the reader has met before in mathematics under the name guess-and-check, and it is worth pausing on why it is the clean route rather than a shortcut. The derivation runs *forward*, from the value function to the PDE: assume u exists and is smooth, manipulate it, and arrive at HJB. Inverting it means running *backward*, from the PDE to the value function: *forget* where the equation came from, hand ourselves any sufficiently smooth function w that happens to solve it, and prove from scratch that this w must coincide with u and that the feedback read off from w is optimal. The payoff of the inversion is total. We never again need to know that u is smooth — we need to know that *some* solution w is smooth, and that is a hypothesis we can simply impose and then verify in each concrete problem by exhibiting the w. We never take a limit, so there is no $h \downarrow 0$ to justify. And — this is the decisive economy, the one flagged already in remark 6.6 — we never invoke the dynamic programming principle at all: no infimum need be shown to be attained, no ε-optimal control need be selected measurably along random paths. The entire argument rests on a single tool, Itô's formula, applied once. That is why we were free to treat the whole of section 6.2 as motivation: the rigorous spine of the chapter is the theorem below, and it stands on Itô alone.

We state and prove the theorem in full stochastic generality from the outset, even though no noise has yet been switched on, and this costs us nothing — a point worth making explicit because it looks like premature abstraction and is not. The deterministic control problem of sections 6.1 to 6.3 is exactly the special case $\sigma \equiv 0$ of a controlled diffusion: kill the noise coefficient and the SDE (6.10) below collapses to the controlled ODE (6.3), the second-order term $\frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 w)$ in the HJB equation (6.11) vanishes, and the equation reduces to the first-order HJB (6.7). Crucially, the proof does not branch on whether σ is zero. Itô's formula carries the second-order term along automatically, and that term is the *only* place the noise enters the argument; setting $\sigma \equiv 0$ simply deletes it, turning every expectation into an evaluation along the deterministic flow and the stochastic integral into the zero process. Writing the stochastic statement therefore subsumes the deterministic one at no extra length, and it has the further virtue of being exactly the form section 6.5 will reach for when the diffusion is made permanent. We pay the generality once, here.

So fix the data and consider the controlled diffusion, with W an $\mathbb{R}^d$-valued Brownian motion on a filtered probability space satisfying the usual conditions (chapter 5),

$$\mathrm{d}X_s = b(X_s, \alpha_s)\,\mathrm{d}s + \sigma(X_s)\,\mathrm{d}W_s, \qquad X_t = x, \tag{6.10}$$

and cost $J(t,x;\alpha) = \mathbb{E}\Big[\int_t^T L(X_s,\alpha_s)\,\mathrm{d}s + g(X_T)\Big]$, the expectation having replaced the deterministic evaluation because the trajectory is now random. Before we can speak of optimizing over controls we must say precisely which controls are in the running, and each clause of the definition that follows is forced by a distinct demand of the problem rather than chosen for convenience.

Definition 6.9 (Admissible controls)**.** An *admissible* control on $[t,T]$ is a progressively measurable process $\alpha\colon [t,T]\times\Omega \to A$ for which (6.10) has a unique strong solution and $\mathbb{E}\Big[\int_t^T |L(X_s,\alpha_s)|\,\mathrm{d}s + |g(X_T)|\Big] < \infty$. The class is denoted $\mathcal{U}_t$.

Read the three requirements as three separate guarantees, each indispensable. That the control take values in A is the modelling constraint — the agent may only set its knobs within the physically available action set. That it be *progressively measurable* is the informational and analytic backbone: it says the control at time s may depend on the noise observed up to time s but not on the future, which is what makes a feedback law $\alpha_s = \phi(s, X_s)$ legitimate and, just as importantly, what makes the Itô integral $\int \sigma\,\mathrm{d}W$ in (6.10) *defined at all*, since the Itô construction requires an adapted integrand. That (6.10) have a *unique strong solution* is what entitles us to speak of "the" trajectory the control induces — without it the object X, and hence the cost, would be ambiguous; under the standing Lipschitz and growth hypotheses (A-Lip), (A-Growth) this is exactly the well-posedness guaranteed by theorem 5.10. The final integrability clause is what makes the cost $J(t,x;\alpha)$ a genuine finite number rather than a meaningless $\infty - \infty$, so that the infimum defining u is taken over a set of real-valued competitors. Only with all three in force is the optimization problem we are about to solve even posed.

Theorem 6.10 (Verification)**.** *Assume* (A-Lip)*,* (A-Growth)*,* (A-Conv)*. Let $w \in C^{1,2}([0,T]\times\mathbb{R}^d)$ have at most polynomial growth in x, uniformly in t, and solve the stochastic HJB equation*

$$-\partial_t w - \tfrac{1}{2}\operatorname{tr}\big(\sigma\sigma^\top \mathrm{D}^2 w\big) + H(x,\nabla w) = 0 \quad \text{on } [0,T)\times\mathbb{R}^d, \qquad w(T,\cdot) = g, \tag{6.11}$$

with H as in (6.6). Then:

(i) *$w(t,x) \le J(t,x;\alpha)$ for every (t,x) and every $\alpha \in \mathcal{U}_t$; hence $w \le u$.*

(ii) *If the feedback (6.8) built from w, $\alpha^*_s = a^*(X^*_s, \nabla w(s, X^*_s))$, is admissible and the closed-loop equation (6.10) has a unique strong solution X^*, then equality holds: $w(t,x) = u(t,x) = J(t,x;\alpha^*)$, and α^* is optimal.*

Proof. The whole proof is a single application of Itô's formula followed by a sign inequality, a substitution, and a passage to expectations; we narrate it slowly because each move is elementary and the accumulation is the point. Fix (t,x) and an arbitrary $\alpha \in \mathcal{U}_t$ with induced state X. Because $w \in C^{1,2}$ we may apply Itô's formula (theorem 5.9) to the process $s \mapsto w(s, X_s)$ on $[t,T]$; with the drift and diffusion of (6.10) inserted into the Itô correction, it reads

$$w(T, X_T) = w(t,x) + \int_t^T \Big(\partial_s w + b(X_s, \alpha_s) \cdot \nabla w + \tfrac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 w)\Big)(s, X_s)\, \mathrm{d}s + \int_t^T \nabla w \cdot \sigma \, \mathrm{d}W_s.$$

This decomposes the change in w along the trajectory into a $\mathrm{d}s$ (bounded-variation) part, carrying the time derivative, the first-order transport $b \cdot \nabla w$, and the second-order Itô term $\frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 w)$, plus a stochastic-integral part $\int \nabla w \cdot \sigma \, \mathrm{d}W$ that is, a priori, only a *local* martingale. We will dispose of the stochastic part last; first we extract a one-sided bound on the $\mathrm{d}s$-integrand.

The bound comes for free from the very definition of the Hamiltonian. Recall from (6.6) that $H(x,p) = -\inf_{a \in A}\{b(x,a)\cdot p + L(x,a)\}$; the infimum being a lower bound for each competitor, every action value $a \in A$ — in particular the value $a = \alpha_s$ realized by our control at time s — satisfies

$$b(X_s, a) \cdot \nabla w(s, X_s) + L(X_s, a) \;\ge\; -H\big(X_s, \nabla w(s, X_s)\big),$$

with equality precisely when a is the minimizer $a^*(X_s, \nabla w(s, X_s))$ of (6.6). This is the entire role of the Hamiltonian inequality: it is nothing more than "the value of a function at a point is at least its infimum," but it is exactly the lever that converts the control-dependent integrand into a control-independent one. Now spend the PDE. The HJB equation (6.11) says that on $[t,T)$, $\partial_s w + \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 w) = H(\cdot, \nabla w)$ identically; substitute this into the $\mathrm{d}s$-integrand to eliminate the time- and second-order derivatives in favour of H, and then apply the Hamiltonian inequality:

$$\partial_s w + b \cdot \nabla w + \tfrac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 w) = H(\cdot, \nabla w) + b \cdot \nabla w \;\ge\; -L(X_s, \alpha_s),$$

where the inequality rearranges $b \cdot \nabla w + L \ge -H$, and is an equality iff $\alpha_s = a^*$. The $\mathrm{d}s$-integrand of the Itô expansion is thus bounded below by $-L(X_s, \alpha_s)$, pointwise in s and ω — which is the crux: we have traded the unknown w-derivatives for the known running cost, at the price of one inequality that we know how to make tight.

It remains to take expectations, and here the one genuinely technical step appears: we must know that the stochastic integral $M_\cdot := \int_t^\cdot \nabla w(s, X_s) \cdot \sigma(X_s)\, \mathrm{d}W_s$ has zero expectation at $s = T$. Itô's formula delivers M only as a *local* martingale, and a local martingale need not have constant (or even finite) expectation; what we need is that M is a *true* martingale, for which it suffices that its integrand be square-integrable in the sense $\mathbb{E}\Big[\int_t^T |\nabla w(s, X_s)\, \sigma(X_s)|^2 \, \mathrm{d}s\Big] < \infty$ — this is the L^2 bound that, via the Itô isometry, makes M a genuine L^2-bounded martingale, whence $\mathbb{E}[M_T] = \mathbb{E}[M_t] = 0$. That this bound holds is a short chain of growth estimates, and it is worth assembling explicitly because it is the one place the hypotheses of the theorem and the inheritance from chapter 5 are all spent at once. The hypothesis that w has at most polynomial growth in x uniformly in t passes to its gradient: $|\nabla w(s, y)| \leq C(1 + |y|^q)$ for some exponent q and constant C. The diffusion coefficient has at most linear growth, $|\sigma(y)| \leq C(1 + |y|)$, which is part of the Lipschitz hypothesis (A-Lip) (a globally Lipschitz function grows at most linearly). Multiplying and squaring, the integrand obeys

$$|\nabla w(s, X_s)\, \sigma(X_s)|^2 \;\leq\; C\big(1 + |X_s|\big)^2 \big(1 + |X_s|^q\big)^2 \;\leq\; C'\big(1 + |X_s|^{2q+2}\big),$$

a fixed polynomial in $|X_s|$. Finally the state itself has finite moments of every order, uniformly on the compact interval: $\sup_{s\in[t,T]} \mathbb{E}\big[|X_s|^{2q+2}\big] < \infty$, which is exactly the moment estimate that accompanies strong well-posedness of the SDE under (A-Lip), (A-Growth) in theorem 5.10. Taking expectations of the displayed bound and integrating over the finite interval $[t, T]$ therefore yields $\mathbb{E}\Big[\int_t^T |\nabla w\, \sigma|^2 \, \mathrm{d}s\Big] < \infty$, closing the chain: polynomial growth of ∇w, linear growth of σ, and finite moments of X combine to put the integrand in L^2, which upgrades M from local to true martingale and kills its expectation. (When $\sigma \equiv 0$ the integrand is identically zero and this entire paragraph is vacuous; the martingale subtlety is purely the noise's contribution, consistent with our remark that the diffusion is the only place randomness enters.)

With the stochastic term's expectation gone, take $\mathbb{E}[\cdot]$ across the Itô identity, use the terminal condition $w(T, \cdot) = g$, and discard the now-favourable sign of the ds-integrand:

$$\mathbb{E}[g(X_T)] = w(t,x) + \mathbb{E}\left[\int_t^T \big(\partial_s w + b\cdot\nabla w + \tfrac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 w)\big)\,\mathrm{d}s\right] \;\geq\; w(t,x) - \mathbb{E}\left[\int_t^T L(X_s,\alpha_s)\;\mathrm{d}s\right].$$

Rearranging, $w(t, x) \leq \mathbb{E}\Big[\int_t^T L \,\mathrm{d}s + g(X_T)\Big] = J(t, x; \alpha)$. Since $\alpha \in \mathcal{U}_t$ was arbitrary, taking the infimum over admissible controls gives $w(t, x) \leq u(t, x)$, which is (i): the smooth subsolution-and-solution w underbounds the cost of *every* strategy at once, hence underbounds the value.

For (ii) we run the identical computation along the closed loop and watch each inequality tighten to an equality. Let α^* be the feedback (6.8) built from w, $\alpha^*_s = a^*(X^*_s, \nabla w(s, X^*_s))$, applied along its own state X^* (admissible, and generating a unique strong solution, by hypothesis). At every time s the realized action α^*_s is by construction the minimizer in (6.6), so the Hamiltonian inequality holds with *equality*: $b \cdot \nabla w + L = -H(\cdot, \nabla w)$ along X^*. Consequently the ds-integrand equals exactly $-L(X^*_s, \alpha^*_s)$, the same L^2 bound makes the stochastic term a martingale of zero expectation, and the chain above runs with "$\geq$" replaced throughout by "$=$," giving $w(t, x) = J(t, x; \alpha^*)$. Now assemble: (i) gives $w \leq u$; the definition of u as an infimum over admissible controls gives $u(t, x) \leq J(t, x; \alpha^*) = w(t, x)$ because α^* is one such control; the two inequalities pinch, so $w(t, x) = u(t, x) = J(t, x; \alpha^*)$ and α^* attains the value, i.e. is optimal. Nothing beyond Itô's formula and the moment bound entered at any step — in particular the dynamic programming principle was never invoked, vindicating the claim of remark 6.6 that verification, not the DPP, is the chapter's load-bearing spine. □

The shape of this argument, not just its conclusion, is the lasting deliverable, and it is worth abstracting into a recipe because it is the play every explicit computation in this book will run. The theorem turns the solution of an optimal control problem into three mechanical steps. First, *propose an ansatz*: write down a candidate w of a form suggested by the problem's symmetry or structure, with free functions or constants to be determined. Second, *check the PDE*: insert the ansatz into the HJB equation (6.11) and into the terminal condition $w(T,\cdot) = g$, and let the requirement that it solve them pin down the free data — typically reducing the PDE to a system of ordinary differential equations the ansatz must satisfy. Third, *read off the feedback*: the minimizer $a^*(x, \nabla w)$ in the Hamiltonian, evaluated at the verified w, *is* the optimal feedback (6.8), delivered for free as a byproduct of having solved the PDE. No separate optimization over controls is ever performed; the verification theorem certifies that solving the PDE *is* solving the control problem. Section 6.7 runs precisely this play on the linear–quadratic–Gaussian atom: the ansatz is a quadratic $w(t,x) = \frac{1}{2}P(t)x^2 + \dots$, checking the PDE collapses it to the scalar Riccati equation for $P(t)$, and the optimal feedback falls out as a linear rule in the state. Every later explicit solution in the book is a variation on these three steps.

The one price the theorem exacts is the hypothesis it cannot do without: $w \in C^{1,2}$. The proof applied Itô's formula to $w(s, X_s)$, and Itô's formula needs one time derivative and two space derivatives to exist — without them the very first line of the argument is meaningless. For the second-order problems of section 6.5, where a nondegenerate diffusion smooths the value function, this regularity is typically available and the theorem applies as stated. But for first-order problems — the deterministic case $\sigma \equiv 0$, which is where the physicist's least-action instinct lives — it generically fails: the value function creases along the caustics the physicsnote exhibited, ∇u ceases to exist on a nonempty set, and there is simply no classical w to feed the theorem. The verification machinery, for all its rigour, is then silent. Repairing this — recovering a notion of solution, and a verification principle, that survives the kinks — is exactly the task of section 6.6, where viscosity solutions replace the pointwise derivatives by a test-function inequality that asks nothing of u beyond continuity. Before turning the diffusion on or weakening the solution concept, however, we pause to develop the complementary, trajectory-wise picture this field-based theory has so far suppressed: where verification produces the entire value field $u(t,x)$ at once, the Pontryagin maximum principle of the next section isolates a single optimal path and characterizes it through a forward–backward system, reuniting us with the costate $p = \nabla u$ glimpsed back in section 6.1.

6.4 The Pontryagin maximum principle and the costate

The verification theorem delivered the field method in its finished form: solve one partial differential equation over the whole space-time slab and read the optimal feedback off its gradient at every state at once. That global reach is the method's strength — and, measured against the trajectory the agent actually traverses, also its extravagance. An agent launched from a fixed x_0 rides a single optimal curve X^*; the value field $u(t,x)$ attaches a number to the uncountably many states the agent never visits, and computing all of them merely to characterize the one path it does follow is, from the trajectory's point of view, a detour. Dynamic programming is in this precise sense irreducibly global. The *Pontryagin maximum principle* (PMP) is its local, trajectory-wise counterpart: it bypasses the field entirely and pins down the single optimal trajectory directly, through a coupled system of ordinary differential equations that live only *along that one path.* Where verification answers "what is the best cost from anywhere?" and extracts the agent's path as an afterthought, the PMP asks only "what equations does the agent's own optimal path satisfy?" and never leaves it.

There are three reasons to develop this complementary picture even though HJB already settles the problem in principle, and each will pay off later. The first is genealogical: the PMP is the direct descendant of the Euler–Lagrange and Hamilton canonical equations the physicist already owns from section 6.1. The conjugate momentum $p = \partial_v L$ introduced there, which we flagged would return under a second name, is about to return as the PMP *costate* — the adjoint variable conjugate to the state — so the trajectory method is the reader's least-action reflex reorganized for control, not a foreign import. The second is structural and computational: the PMP replaces a PDE over all of state space by a system of ODEs along a single curve, an object far cheaper to solve and, decisively, the only one of the two pictures that survives intact into the *stochastic* setting of chapter 9. There the costate ODE becomes a backward stochastic differential equation and the forward–backward pair becomes the FBSDE that is the computational backbone of the entire probabilistic approach to mean field games. The third is the conceptual payload, and it is what this section exists to deliver: the costate p turns out to coincide, along the optimal path, with the gradient ∇u of the Bellman value. That identity is the bridge welding the local and global methods into one story, and it is the object on which chapter 9's BSDE will rest. We treat the deterministic problem (6.3)–(6.4) here and preview the stochastic case at the section's end.

The instrument is the Hamiltonian we have already met. Recall from the notationwatch of section 6.3 the *Pontryagin Hamiltonian*

$$\mathfrak{H}(x, a, p) \;=\; b(x, a) \cdot p + L(x, a),$$

which retains the action a as an explicit argument rather than optimizing it away, so that the Bellman Hamiltonian of (6.6) is its optimized negative, $H(x, p) = -\inf_a \mathfrak{H}(x, a, p)$. The single sign that relates the two will recur at every step below, so it is worth holding fixed now: $\mathfrak{H}$ is the thing the optimal action *minimizes*, and H is minus that minimum. With this object in hand the maximum principle reads as follows.

Theorem 6.11 (Pontryagin maximum principle, deterministic)**.** *Assume $b, L, g \in C^1$ with b, L satisfying* (A-Lip)*,* (A-Growth)*, and let α^* be an optimal control with state X^*. Then there is an absolutely continuous* costate $p\colon [0,T] \to \mathbb{R}^d$ *solving the backward* adjoint equation

$$\dot p_t = -\partial_x \mathfrak{H}(X_t^*, \alpha_t^*, p_t) = -\big(\partial_x b(X_t^*, \alpha_t^*)\big)^{\top} p_t - \partial_x L(X_t^*, \alpha_t^*), \qquad p_T = \nabla g(X_T^*), \tag{6.12}$$

and the optimal control minimizes the Pontryagin Hamiltonian pointwise,

$$\alpha_t^* \in \arg\min_{a \in A} \mathfrak{H}\big(X_t^*, a, p_t\big), \qquad a.e.\ t \in [0, T]. \tag{6.13}$$

Read the theorem as a description of a single self-consistent loop in time, and notice that its data are split across the two ends of the interval exactly as the Euler–Lagrange boundary-value problem of section 6.1 was. The state X^* runs *forward* from the known start $X_0^* = x_0$, integrating the controlled dynamics (6.3). The costate p runs *backward* from the terminal value $p_T = \nabla g(X_T^*)$, integrating the adjoint equation (6.12). And the two are not solved in isolation: at each instant the pointwise minimization (6.13) reads off the action α_t^* from the current pair (X_t^*, p_t), and that action feeds back into both the forward drift and the backward adjoint. The system is therefore genuinely *forward–backward and coupled*: one cannot run the state forward without knowing the control, the control is set by the costate, and the costate is fixed by a condition at the far end of time that depends on where the state lands. This circular dependence — a datum clamped at $t = 0$, another clamped at $t = T$, and a minimization knitting them together instant by instant — is precisely the two-point boundary-value structure the chapter's opening warned could not be integrated by marching forward from the present. It is the same structure that will reappear, welded to a forward population density, as the mean field game system of chapter 8; meeting it here on a single trajectory is the cleanest possible rehearsal.

One honesty is owed immediately. We state the maximum principle but do not prove that the adjoint equation and the minimum condition are *necessary* — that every optimal control must satisfy them. The clean route to necessity is the needle, or spike, variation: one perturbs the optimal control on a vanishingly short time interval by an arbitrary admissible value, propagates the resulting first-order perturbation of the state forward through the linearized dynamics, and demands that the induced first-order change in the cost be nonnegative; the costate is exactly the adjoint (transpose-linearized) variable that converts that forward sensitivity into the backward equation (6.12), and the arbitrariness of the needle's value forces the pointwise minimization (6.13). The argument is carried out completely in [136, Ch. 2] and [97], and we send the reader there rather than reproduce it. This is a deliberate, honest deferral, not a gap we are papering over, and the reason is that *nothing later in this book depends on the necessity of the deterministic PMP*. What the development actually consumes is two things, and neither needs the spike-variation argument. The first is the in-book costate identity $p_t = \nabla u(t, X_t^*)$ of proposition 6.12, which we prove below directly from the HJB equation — it *constructs* a costate with all the asserted properties out of the value function, rather than asserting one must exist. The second is the stochastic FBSDE machinery of chapter 9 (and again chapter 23), which is built there on its own self-contained foundation and does not import theorem 6.11. We therefore spend our effort only on the short argument that exposes what the costate *means*, because that meaning, and not the necessity proof, is the conceptual payload and the thread that ties the PMP back to HJB and forward to the BSDE.

Proposition 6.12 (Costate is the gradient of the value)**.** *Suppose the value function u of definition 6.3 is $C^{1,2}$ and the optimal feedback* (6.8) *generates the optimal trajectory X^*. Then $p_t := \nabla u(t, X_t^*)$ solves the adjoint equation* (6.12)*, and* (6.13) *holds.*

Proof. The whole proof is a single application of the chain rule, but it turns on two bookkeeping facts and one cancellation, so we spell each out. The strategy is to *define* $p_t := \nabla u(t, X_t^*)$ — the spatial gradient of the value, read along the optimal trajectory — and then simply differentiate this definition in t, using HJB to evaluate the time derivative of u that appears. Everything the theorem asserts about the costate will fall out of that one differentiation.

We will use the two envelope identities (6.9) of lemma 6.8. They apply here because, along the optimal path, the action that minimizes the Pontryagin Hamiltonian is the optimal control itself, $a^*(X_t^*, p_t) = \alpha_t^*$ — this is exactly what the feedback (6.8) encodes — so the two identities, evaluated at this minimizer, read

$$\partial_p H(x, p) = -b\big(x, a^*(x, p)\big), \qquad \partial_x H(x, p) = -\partial_x \mathfrak{H}\big(x, a^*(x, p), p\big).$$

The first says the slope of the optimized Hamiltonian in the momentum slot is minus the optimal drift; the second says its slope in the state slot ignores the dependence routed through the moving minimizer (the content of the envelope theorem) and equals minus the bare state-derivative of $\mathfrak{H}$. Both will be spent below, the first now and the second at the very end.

Step 1: rewrite the optimal velocity through the Hamiltonian. The optimal state obeys its own dynamics, $\dot{X}_t^* = b(X_t^*, \alpha_t^*)$. Substituting $\alpha_t^* = a^*(X_t^*, p_t)$ and using the first envelope identity converts this into a statement purely about H:

$$\dot{X}_t^* = b\big(X_t^*, a^*(X_t^*, p_t)\big) = -\partial_p H\big(X_t^*, \nabla u(t, X_t^*)\big). \tag{6.14}$$

This is the first place the canonical pairing surfaces: the optimal velocity is read off the p-gradient of the Hamiltonian, evaluated at $p = \nabla u$.

Step 2: differentiate the costate along the trajectory. Now differentiate the definition $p_t = \nabla u(t, X_t^*)$ in t. Here ∇u is evaluated at the moving point (t, X_t^*), so the total t-derivative collects an explicit time-derivative and a chain-rule contribution from the motion of X_t^*:

$$\dot{p}_t = \partial_t(\nabla u)(t, X_t^*) + \mathrm{D}^2\, u(t, X_t^*)\, \dot{X}_t^*.$$

The Hessian $\mathrm{D}^2\, u = \partial_x(\nabla u)$ is the spatial Jacobian of the vector field ∇u, and it multiplies the velocity $\dot{X}_t^*$ exactly as the chain rule for a moving evaluation point demands. Both terms are well defined precisely because $u \in C^{1,2}$ — this is the hypothesis at work: $C^{1,2}$ guarantees $\mathrm{D}^2\, u$ exists and is continuous, and it guarantees the mixed partials commute, $\partial_t(\nabla u) = \nabla(\partial_t u)$, which we use to rewrite the first term:

$$\dot{p}_t = \nabla(\partial_t u)(t, X_t^*) + \mathrm{D}^2\, u(t, X_t^*)\, \dot{X}_t^*. \tag{6.15}$$

Without $C^{1,2}$ neither $\mathrm{D}^2\, u$ nor the interchange of derivatives is licensed, and the whole computation collapses — which is exactly why the deterministic, first-order case where u creases will instead need the costate to be reconstructed by the weak machinery flagged for section 6.6, and the noisy, smoothing case to be handled by the BSDE below.

Step 3: evaluate $\nabla(\partial_t u)$ from HJB. The HJB equation (6.7), rearranged into the evolution form $\partial_t u(t, x) = H\big(x, \nabla u(t, x)\big)$, gives the time-derivative of u as a function of x. Take its spatial gradient. The right-hand side depends on x in *two* ways — directly through the first slot of H, and indirectly through the second slot $p = \nabla u(t, x)$ — so the chain rule produces two terms:

$$\nabla(\partial_t u)(t, x) = \partial_x H(x, \nabla u) + \mathrm{D}^2\, u(t, x)\, \partial_p H(x, \nabla u),$$

where the second term arises because $\partial_x(\nabla u) = \mathrm{D}^2\, u$ is the Jacobian of the inner argument ∇u, multiplying the p-slope $\partial_p H$ of the outer function.

Step 4: the cancellation. Insert this expression for $\nabla(\partial_t u)$ into (6.15), evaluating everything at $x = X_t^*$:

$$\dot{p}_t = \underbrace{\partial_x H(X_t^*, \nabla u)}_{\text{from Step 3}} + \mathrm{D}^2\, u(t, X_t^*)\, \partial_p H(X_t^*, \nabla u) + \mathrm{D}^2\, u(t, X_t^*)\, \dot{X}_t^*.$$

Now Step 1 is spent: $\dot{X}_t^* = -\partial_p H(X_t^*, \nabla u)$ by (6.14), so the third term is exactly the negative of the second. The two Hessian terms cancel identically, and not by accident — the Hessian appears once through the curvature of the value field along the moving trajectory (Step 2) and once through the indirect x-dependence of HJB (Step 3), and the canonical relation $\dot{X}^* = -\partial_p H$ is precisely the statement that these two appearances are equal and opposite. What remains is

$$\dot{p}_t = \partial_x H\big(X_t^*, \nabla u(t, X_t^*)\big) = -\partial_x \mathfrak{H}\big(X_t^*, \alpha_t^*, p_t\big),$$

the last equality being the second envelope identity. This is exactly the adjoint equation (6.12).

Step 5: the boundary and minimum conditions. The terminal value is read straight off the definition together with the terminal datum of HJB: since $u(T, \cdot) = g$, taking gradients gives $\nabla u(T, \cdot) = \nabla g$, hence $p_T = \nabla u(T, X_T^*) = \nabla g(X_T^*)$ — the costate inherits its endpoint condition from the value's, at the same far end of time. Finally, the minimum condition (6.13) holds because $\alpha_t^* = a^*(X_t^*, p_t)$ is by construction the minimizer of $a \mapsto \mathfrak{H}(X_t^*, a, p_t)$, which is the definition of a^*. This completes the verification that the constructed $p_t = \nabla u(t, X_t^*)$ is a costate in the sense of theorem 6.11. □

The identification $p_t = \nabla u(t, X_t^*)$ is the conceptual payload of the section, and it deserves to be read slowly, because it collapses what looked like two independent theories into one. The PMP costate — the adjoint variable that the spike-variation argument would have produced as a Lagrange multiplier enforcing the dynamics — is nothing other than the gradient of the Bellman value, sampled along the optimal path. This is the precise content of the slogan "momentum is conjugate to value." Trace its three incarnations: in section 6.1 the conjugate momentum was $p = \partial_v L$, the slot dual to velocity in the Legendre transform; here it is the PMP costate, the variable dual to the state in the adjoint equation; and now we learn that both equal ∇u, the sensitivity of the optimal cost-to-go to a displacement of the current state. One quantity, three faces — Legendre momentum, Pontryagin costate, value-gradient — and the identity above is the hinge that makes the local trajectory method and the global field method two readings of a single object rather than rival computations. Economically it is the marginal cost of state: p_t measures how much the remaining optimal cost changes if the agent is nudged off the optimal path at time t, which is exactly why it is the natural "price" of the state and why the running minimization (6.13) weighs each action by $b \cdot p$, the rate at which that action moves the state against its price.

The identity also explains, with no further computation, the one structural feature of the adjoint equation that would otherwise look arbitrary: *why the costate runs backward.* A first-order ODE needs its data at one end, and (6.12) takes them at $t = T$, not $t = 0$. The reason is now transparent — the costate is ∇u, and u itself is the backward object of the chapter, born at the terminal time from $u(T, \cdot) = g$ and propagated toward the present. Differentiating that terminal datum in space gives $p_T = \nabla g(X_T^*)$, so the costate is pinned at exactly the end where the value is, and inherits its backward direction wholesale. The forward state and the backward costate are not two unrelated equations that happen to be glued by (6.13); they are the trajectory-wise shadow of the chapter's central asymmetry — initial data pushed forward for the thing that flows, terminal data discharged backward for the thing that prices — and that very pairing is what chapter 8 will promote into the coupled forward–backward system of a mean field game.

Remark 6.13 (The envelope identity and $\alpha^* = -\partial_p H$)**.** The first envelope identity $\partial_p H(x, p) = -b\big(x, a^*(x, p)\big)$ used in the proof is worth isolating and handling with care, because it is the general form of the compact formula recorded in appendix A as $\alpha^* = -\partial_p H$ — and that compact formula is true only under a normalization that is easy to forget, generating a recurring sign-and-scaling error if it is applied blindly. The point of this remark is to make the distinction load-bearing rather than incidental.

The clean statement is that the envelope identity always delivers the optimal *drift*, never directly the optimal *control*. What it says is

$$b(x, a^*(x,p)) = -\partial_p H(x,p);$$

the left side is the velocity the optimal action induces, and only after one inverts the map $a \mapsto b(x,a)$ does a statement about the control itself emerge. Two regimes follow.

In the *canonical normalization*, where the control simply *is* the drift, $b(x,a) = a$ with $A = \mathbb{R}^d$, the inversion is the identity and the drift formula collapses onto the control: $a^*(x,p) = -\partial_p H(x,p)$ literally, and the optimal feedback is $\alpha^*(t,x) = -\partial_p H\big(x, \nabla u(t,x)\big)$. This is the form appendix A records and the form we will use whenever stating the general MFG theory in chapter 8 onward, precisely because in that canonical normalization the bookkeeping is clean and the control is the gradient of the Hamiltonian with a sign.

In any genuinely *control-affine* case the inversion is nontrivial and the collapse fails. Take the scalar LQG drift of section 6.7, $b(x,\alpha) = ax + b\,\alpha$, in which an uncontrolled state drift ax is present and a gain b multiplies the control, with running cost $L(x,\alpha) = \frac{1}{2}\alpha^2$ (a state-cost term plays no role in this extraction and we drop it). Then $\mathfrak{H}(x,\alpha,p) = (ax + b\alpha)p + \frac{1}{2}\alpha^2$, and minimizing over α gives the first-order condition $bp + \alpha^* = 0$, so $\alpha^* = -b\,p$. The induced optimal drift is $ax + b\alpha^* = ax - b^2 p$. Let us check this against the envelope identity by computing H directly:

$$H(x,p) = -\mathfrak{H}(x,\alpha^*,p) = -\big[(ax - b^2 p)\,p + \tfrac{1}{2}b^2p^2\big] = -axp + \tfrac{1}{2}b^2p^2, \qquad \text{so} \quad -\partial_p H(x,p) = ax - b^2 p.$$

Indeed $-\partial_p H = ax - b^2 p$ equals the optimal *drift* $ax + b\alpha^*$, exactly as the identity promises. But the optimal *control* is $\alpha^* = -bp$, and these two objects are *not* equal: solving $ax + b\alpha^* = -\partial_p H$ for the control gives $\alpha^* = \big(-\partial_p H - ax\big)/b$, the uncontrolled drift ax subtracted off and the gain b divided out. The naive reading $\alpha^* = -\partial_p H$ would here assert $-bp = ax - b^2 p$, which is false for general x, p.

The micro-example pins down exactly when the compact formula is safe. Equality $\alpha^* = -\partial_p H$ requires $-bp = ax - b^2 p$ identically in (x,p), which forces *both* $a = 0$ (no uncontrolled drift) *and* $b^2 = b$, i.e. $b = 1$ (unit gain) — that is, the full canonical normalization $b(x,\alpha) = \alpha$. It is *not* enough to have $b = 1$ alone: at $b = 1$ with $a \neq 0$ one has $-\partial_p H = ax - p$ while $\alpha^* = -p$, still separated by the surviving term ax. This is the trap the remark exists to defuse: "$b = 1$" is not the canonical normalization, "no uncontrolled drift *and* $b = 1$" is. We therefore adopt the canonical drift $b = \alpha$ whenever we state the general theory and want $\alpha^* = -\partial_p H$ to hold verbatim, and we revert to the explicit maximizer $\alpha^* = \big(-\partial_p H - ax\big)/b$ the moment a gain or an uncontrolled drift is in play — as it will be throughout the LQG computation of section 6.7, where a and b are both generically nonzero.

The two identities just exhibited are exactly what the rest of the chapter consumes. The envelope relation $b(x,a^*) = -\partial_p H$ is the formula section 6.5 will read off as the optimal feedback once the diffusion is switched on permanently, and the costate identification $p = \nabla u$ is the seed of the FBSDE of chapter 9. But both were derived under the deterministic, noiseless dynamics, where the costate obeyed a plain backward ODE with a terminal value $p_T = \nabla g(X_T^*)$ that the agent, knowing X^* exactly, could compute in advance. The instant noise enters, that last clause breaks: X_T^* becomes random and unknown until the terminal time, so p_T depends on the future, yet the costate must remain adapted to the information available now. Reconciling a future-determined terminal value with a present-measurable process is the question the next subsection takes up, and its answer — a martingale correction that turns the backward ODE into a backward *stochastic* differential equation — is where the costate story crosses into the stochastic setting that chapter 9 will inhabit.

6.4.1 Stochastic costate: a BSDE preview

The previous subsection left the costate story poised at a fracture, and this subsection is about how the fracture is repaired rather than papered over. In the deterministic problem the adjoint equation (6.12) was an ordinary backward ODE, and integrating it caused no anxiety: the agent knew its optimal trajectory X^* exactly, so the terminal value $p_T = \nabla g(X_T^*)$ was a fixed vector available in advance, and one simply ran the ODE from $t = T$ down to the present. The moment the dynamics become the controlled diffusion (6.10), every clause of that sentence fails at once. The trajectory X^* is now a stochastic process adapted to the filtration $\mathbb{F} = (\mathcal{F}_t)$ generated by the driving Brownian motion W; its terminal position X_T^* is not a number but an $\mathcal{F}_T$-measurable random variable, depending on the *entire* future of the noise path; and therefore so is the terminal datum $p_T = \nabla g(X_T^*)$. Yet whatever the costate becomes, it cannot be allowed to lose the one property that made it usable in the first place — it must stay *adapted*, measurable with respect to the information $\mathcal{F}_t$ actually in hand at time t. The costate is, after all, the price the agent reads off to set its feedback control through $\alpha^* = a^*(X^*, p)$, and a control is by definition a process that may consult only the past, never the future. An adapted costate with a terminal value that lives in the future is the exact tension we must resolve.

To see why it really is a tension and not a triviality, imagine ignoring it: keep the backward ODE form pathwise, $\dot{p}_t = -\partial_x \mathfrak{H}(X_t^*, \alpha_t^*, p_t)$, and integrate it sample path by sample path starting from $p_T = \nabla g(X_T^*)$. The resulting p_t would be a deterministic functional of the terminal value and of the path traversed back from T to t; in particular it would encode X_T^*, and so it would "know" at time $t < T$ where the noise is going to have pushed the state by the terminal time. Such a process looks into the future: it is $\mathcal{F}_T$-measurable, not $\mathcal{F}_t$-measurable, and is therefore inadmissible as a costate. Pathwise backward integration, the natural deterministic reflex, is exactly what adaptedness forbids.

The repair is to stop insisting that the equation hold pathwise and instead ask only that an *adapted* process solve it in integrated form — at the price of admitting a second unknown. The cleanest way to see why a second unknown is forced, and what it must be, is the degenerate model case in which the drift is switched off: seek an adapted process p with $\mathrm{d}p_t = Z_t \, \mathrm{d}W_t$ and prescribed terminal value $p_T = \xi$, where ξ is any $\mathcal{F}_T$-measurable random variable. A process with zero drift and an Itô-integral increment is a martingale, so $p_t = \mathbb{E}[\xi \mid \mathcal{F}_t]$ is forced — and this conditional expectation is, by construction, adapted: it is the best estimate of the future datum ξ given only the information available now, with the genuine future dependence averaged out. Adaptedness is thus recovered automatically, but at a cost: the martingale $t \mapsto \mathbb{E}[\xi \mid \mathcal{F}_t]$ is not constant, it has increments, and naming those increments requires a process Z with $\mathbb{E}[\xi \mid \mathcal{F}_t] = \mathbb{E}[\xi] + \int_0^t Z_s \, \mathrm{d}W_s$. That such a Z exists — that *every* square-integrable $\mathcal{F}_T$-measurable random variable is the terminal value of a stochastic integral against W — is precisely the content of the *martingale representation theorem*, the one beyond-prerequisite tool this preview leans on and which chapter 9 develops in full before using it. The structural lesson survives the reinstatement of the drift: a backward equation that fixes an $\mathcal{F}_T$-measurable terminal datum and demands an adapted solution is over-determined for a single unknown — one cannot in general both hit a future target and refuse to look ahead — and the martingale integrand Z is exactly the extra degree of freedom that reconciles the two. Contrast the forward SDE (6.10), where one fixes the *initial* value, lets the increments be driven by the noise, and accepts whatever terminal value emerges: there the lone unknown is the path. Reverse the arrow of time and the bookkeeping changes shape — the terminal value is now the datum, adaptedness is the constraint, and the pair (p, Z), not p alone, is the unknown.

Restoring the drift gives the object this subsection exists to name, a *backward stochastic differential equation* (BSDE). One feature of it has no deterministic shadow and must be put in by hand: when the volatility σ is genuinely state-dependent, the backward drift is governed not by the bare deterministic Pontryagin Hamiltonian $\mathfrak{H}$ but by its *stochastic completion*

$$H^{\mathrm{s}}(x, a, p, Z) \;=\; b(x, a) \cdot p + \operatorname{tr}\big(\sigma(x)^\top Z\big) + L(x, a),$$

which couples the volatility to the new integrand through the extra term $\operatorname{tr}(\sigma^\top Z)$. With that completion the adjoint reads

$$\mathrm{d}p_t = -\partial_x \mathfrak{H}(X_t^*, \alpha_t^*, p_t)\;\mathrm{d}t - \big(\partial_x \sigma(X_t^*)\big)^\top Z_t\;\mathrm{d}t + Z_t\;\mathrm{d}W_t, \qquad p_T = \nabla g(X_T^*), \tag{6.16}$$

whose $\mathrm{d}t$ part is exactly $-\partial_x H^{\mathrm{s}}(X_t^*, \alpha_t^*, p_t, Z_t)$ — the i-th component of the volatility correction being $\operatorname{tr}\big((\partial_{x_i}\sigma)^\top Z_t\big)$. A *solution* is now an adapted *pair* (p, Z): the costate p carries the deterministic adjoint drift $-\partial_x \mathfrak{H}$ *corrected* by the state-dependence of the volatility, while the new integrand Z supplies, instant by instant, the martingale correction $Z_t \,\mathrm{d}W_t$ that keeps p adapted as it is steered toward the random terminal value. Strip the noise ($\sigma \equiv 0$, hence $Z \equiv 0$, the volatility correction gone, and $\mathrm{d}W$ absent) and (6.16) collapses back to the ordinary adjoint ODE (6.12) of the deterministic theory — the BSDE is its honest stochastic completion, not a different animal.

What is the correction Z, concretely? The costate identity of proposition 6.12 answers the question without any new optimization. In the present nondegenerate-diffusion setting the noise smooths the value function, so the regularity hypothesis $u \in C^{1,2}$ that the identity needs is exactly what the diffusion delivers, and we may take $p_t = \nabla u(t, X_t^*)$ as before. Now read ∇u as a (vector-valued) function of (t, x) and apply Itô's formula (theorem 5.9) to the process $t \mapsto \nabla u(t, X_t^*)$ along the optimal diffusion (6.10). The differential splits, as every Itô expansion does, into a finite-variation ("$\mathrm{d}t$") part and a martingale ("$\mathrm{d}W$") part,

$$\mathrm{d}\big[\nabla u(t, X_t^*)\big] = (\text{finite-variation drift})\;\mathrm{d}t \;+\; \underbrace{\mathrm{D}^2\, u(t, X_t^*)\, \sigma(X_t^*)}_{\text{martingale integrand}}\,\mathrm{d}W_t,$$

all coefficients evaluated at (t, X_t^*). The martingale integrand is the only part we need to pin down explicitly, and it follows from the scalar Itô formula applied component by component: for the i-th component $\partial_i u$ of the field, the diffusion part of $\mathrm{d}\big[\partial_i u(t, X_t^*)\big]$ is $\nabla(\partial_i u) \cdot \sigma \, \mathrm{d}W_t$, and the row vector $\nabla(\partial_i u)$ is exactly the i-th row of the Hessian $\mathrm{D}^2 u$. Stacking the d components, the martingale part is governed by the Jacobian of the field ∇u — which is exactly $\mathrm{D}^2 u$ — contracted against the volatility σ through which the Brownian increment enters the state. The finite-variation drift, by contrast, involves third derivatives of u and we do not expand it: its content is fixed for us by HJB, as we note below. Matching the martingale part against the $Z_t \, \mathrm{d}W_t$ term of (6.16) identifies the second unknown outright,

$$Z_t = \mathrm{D}^2 u(t, X_t^*) \, \sigma(X_t^*), \tag{6.17}$$

the Hessian of the value times the volatility; the finite-variation part of the same Itô expansion reproduces the full BSDE drift $-\partial_x \mathfrak{H} - (\partial_x \sigma)^\top Z$ once HJB is used to evaluate $\partial_t \nabla u$. Its first term is exactly the cancellation already performed in proposition 6.12; its second is new — it is precisely the second-order Itô term $\frac{1}{2} \operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 u)$ differentiated through the state-dependence of σ, which equals $(\partial_x \sigma)^\top Z$ and is invisible to the deterministic proposition, where $\sigma \equiv 0$ killed it — so the two pieces of the Itô expansion deliver the two pieces of the BSDE in one stroke. A word of care about (6.17): in dimension $d > 1$ the matrix $Z_t = \mathrm{D}^2 u \, \sigma$ is *not* symmetric, so the ordering of the factors is load-bearing — Z_t is $\mathrm{D}^2 u \, \sigma$ and not $\sigma^\top \mathrm{D}^2 u = (\mathrm{D}^2 u \, \sigma)^\top$, which is a genuinely different matrix even though $\mathrm{D}^2 u$ itself is symmetric. The distinction evaporates only in the scalar Thread A, where $\mathrm{D}^2 u = u_{xx}$ and $\sigma = \sigma$ are numbers, their product $Z_t = \sigma \, u_{xx}$ is a number, and a number equals its own transpose; one should not let the scalar case lull one into dropping the transpose-bookkeeping when the explicit single-agent atom is later widened to vector states.

The identification (6.17) is what entitles us to call (6.16) the *probabilistic face* of the second-order HJB equation (6.11). Recall the linear Feynman–Kac bridge of chapter 5: the solution of a *linear* parabolic PDE is represented as an expectation of a functional of a diffusion. The BSDE is the nonlinear, backward generalization of that same bridge. Its solution $(p, Z) = (\nabla u, \mathrm{D}^2 u \, \sigma)$ encodes the gradient and curvature of the solution u of the *nonlinear* HJB equation (6.11), with the Hamiltonian nonlinearity $\partial_x H^{\mathrm{s}}$ sitting in the BSDE driver where the linear potential sat in Feynman–Kac. Where the PDE (6.11) describes the value as a deterministic field obeying a second-order equation, the BSDE (6.16) describes the very same information probabilistically, as an adapted pair riding the optimal trajectory — two faces, analytic and probabilistic, of one object. This is the dual incarnation promised back in section 6.1 when the conjugate momentum first appeared: the costate that began as a Legendre slot, became a Pontryagin adjoint, and was identified with ∇u now acquires its final form as the leading component of a backward stochastic system.

We deliberately do no more than name the object here, and it is worth being explicit about exactly what has been deferred so the preview stays honest. We have not proved that the BSDE (6.16) has a solution: existence of the adapted pair (p, Z) rests on the martingale representation theorem invoked above, which is itself developed — stated and proved — only in chapter 9. Nor have we coupled the backward costate to the forward state: in (6.16) the trajectory X^* was held fixed and the equation solved for p afterward, but the optimal X^* is itself generated by the feedback $\alpha^* = a^*(X^*, p)$ built from that same p, so state and costate are in truth a single *forward–backward stochastic differential equation* (FBSDE) — forward in X^*, backward in (p, Z), knitted by the minimizer. That FBSDE, and the further McKean–Vlasov coupling that arises when the terminal and running costs are allowed to depend on the law of the population, is the entire subject of chapter 9, the probabilistic counterpart to the analytic mean field game system chapter 8 builds from

HJB. For the main line of this chapter the message to carry forward is simply this: the second-order HJB equation we are about to make permanent in the next section is not the only way to encode the optimizing agent. It has a dual probabilistic incarnation as a backward stochastic equation for the costate, and the two will be welded into the same fabric once the population is released from its frozen state.

6.5 Stochastic control, the control Hamiltonian, and optimal feedback

The previous subsection closed by naming the BSDE as the *probabilistic face* of a second-order HJB equation, and promised that the analytic original would be installed permanently here. We redeem that promise now. Throughout sections 6.1 to 6.4 the diffusion was a guest: it appeared in the verification theorem theorem 6.10 only so that setting $\sigma \equiv 0$ would recover the deterministic theory, and it was switched off again the moment we wanted a Pontryagin trajectory. From here on it is the host. We fix a genuinely nondegenerate volatility and never turn it off, for three reasons the chapter has been accumulating. Noise is the generic situation, not a perturbation of a noiseless ideal; feedback strictly beats open-loop precisely when the realized state can be kicked off its plan, as definition 6.2 argued; and — decisively for the rigour of everything below — a nondegenerate diffusion is exactly what *smooths* the value function, supplying the $C^{1,2}$ regularity that the verification theorem theorem 6.10 demanded as a hypothesis but could not itself produce. The deterministic, first-order theory had to leave that hypothesis dangling, to be rescued later by viscosity solutions; with the diffusion made permanent we can, for the first time, *prove* it.

There is a second, equally deliberate change of furniture, and it is the one that aims the whole section at chapter 8. We now let the running and terminal costs carry a *population law* $m \in \mathcal{P}_2(\mathbb{R}^d)$ as an extra argument: $L(x, a, m)$ and $g(x, m)$. The reader should resist reading anything dynamic into this. At this stage m is an *inert parameter* — a fixed probability measure, chosen once and held frozen, exactly as a coupling constant is held fixed while one solves a single-particle problem. Nothing in this section determines m; no equilibrium condition is imposed on it; the agent optimizes against it as against any other fixed feature of its cost. The only purpose of carrying the slot now is bookkeeping with foresight. When chapter 8 finally releases m from its frozen state — promoting it from a parameter into the unknown of a Nash fixed point, tied back to the agents through their own optimal motion — it will couple to a value function and a feedback that already have the m-slot machined into them. We pay that small notational cost here so that the welding in chapter 8 is a matter of closing a loop, not re-deriving the object. The agent's state accordingly solves the controlled SDE (6.10) with drift $b(x, a)$ and volatility $\sigma(x)$ — a control-independent diffusion, the standard mean field game setting, in which the agent steers the drift but cannot dial the noise.

The instrument is the same Bellman Hamiltonian (6.6) we built in section 6.3, now wearing the measure as a passive third slot — the *control Hamiltonian*

$$H(x, p, m) \;=\; \sup_{a \in A} \Big\{ -b(x, a) \cdot p - L(x, a, m) \Big\}, \tag{6.18}$$

the partial Legendre transform of the running cost in the action, convex in p under (A-Conv) for exactly the reason rehearsed at (6.6): a supremum of affine functions of p is convex with no hypothesis at all, while the genuine content of (A-Conv) — strict convexity and coercivity in the action a — is what keeps the maximizer single-valued. The measure m rides along untouched by the optimization. For each frozen m, (6.18) is *literally* (6.6) with the cost $L(\cdot,\cdot,m)$, so every envelope identity of lemma 6.8 holds verbatim at fixed m — in particular $\partial_p H(x,p,m) = -b\big(x, a^*(x,p,m)\big)$ with a^* the unique maximizing action. The m-slot is inert in precisely the technical sense that it never enters the supremum; it labels the cost, it is not a variable of the control problem.

Switching the noise on changes exactly one line of the dynamic programming derivation, and it is worth seeing which. Introduce the *controlled generator*

$$\mathcal{A}^a\phi(x) \;=\; b(x,a)\cdot\nabla\phi(x) + \tfrac{1}{2}\,\mathrm{tr}\big(\sigma(x)\sigma(x)^\top\,\mathrm{D}^2\,\phi(x)\big),$$

which is nothing but the diffusion generator $\mathcal{A}$ of definition 5.12 with its drift slot pinned to the frozen action value a: one generator for each setting of the knob, the family $\{\mathcal{A}^a\}_{a\in A}$ indexing the infinitesimal motions the agent has available. Now re-run the short-leg expansion of section 6.3 along the controlled diffusion (6.10) in place of the controlled ODE. The only alteration is in how the value at the displaced endpoint accumulates. In the deterministic case the Taylor step gave $u(t+h, X_{t+h}) - u(t,x) \approx h(\partial_t u + b\cdot\nabla u)$, the first-order displacement $X_{t+h} - x \approx h\,b$ dotted into ∇u. With Brownian increments present that displacement also has a *quadratic* part that survives at order h: $\mathbb{E}\Big[(X_{t+h}-x)(X_{t+h}-x)^\top\Big] \approx h\,\sigma\sigma^\top$, the Itô correction of theorem 5.9, contributing $\frac{1}{2}h\ \mathrm{tr}(\sigma\sigma^\top\,\mathrm{D}^2\,u)$ to the expected increment at the same order. Compactly, the expected leg contributes $h\big(\partial_t u + \mathcal{A}^a u\big) + o(h)$, with the entire action-dependence collected into $\mathcal{A}^a u + L(x,a,m)$. Dividing by h, letting $h\downarrow 0$, and infimizing over the constant action exactly as before yields the *second-order Hamilton–Jacobi–Bellman equation*

$$-\partial_t u - \tfrac{1}{2}\,\mathrm{tr}(\sigma\sigma^\top\,\mathrm{D}^2\,u) + H(x,\nabla u, m) = 0, \qquad u(T,x) = g(x,m). \tag{6.19}$$

This is the verification theorem's stochastic HJB (6.11) with the measure argument restored, and it is the same equation read two ways. In *generator form* it is

$$-\partial_t u - \inf_{a\in A}\big\{\mathcal{A}^a u + L(\cdot,a,m)\big\} = 0,$$

which displays the dynamic-programming content directly — the optimal infinitesimal cost rate is the best, over actions, of "the generator acting on the value plus the running cost" — and collapses to (6.19) the instant the infimum is carried out, since the second-order term carries no a and factors out: $\inf_a\{\mathcal{A}^a u + L\} = \frac{1}{2}\,\mathrm{tr}(\sigma\sigma^\top\,\mathrm{D}^2\,u) + \inf_a\{b\cdot\nabla u + L\} = \frac{1}{2}\,\mathrm{tr}(\sigma\sigma^\top\,\mathrm{D}^2\,u) - H(x,\nabla u,m)$, the last step being the definition (6.18) of H as minus that infimum. The two forms are one statement; we keep the generator form in view because it is the form chapter 8 will set opposite a Fokker–Planck operator $\mathcal{A}^*$, the formal adjoint of the generator of the optimally controlled diffusion.

The structural novelty of (6.19) is the second-order term, and under (A-Nondeg) it is exactly what rescues the regularity the first-order theory could not supply. Nondegeneracy is the statement that $\sigma(x)\sigma(x)^\top \succeq \lambda\,\mathrm{Id}$ uniformly in x for some $\lambda > 0$ — the noise genuinely pushes in every direction — which is to say the operator $\frac{1}{2}\,\mathrm{tr}(\sigma\sigma^\top\,\mathrm{D}^2\,\cdot)$ is *uniformly elliptic*. Read backward in time from its terminal datum, (6.19) is then a uniformly parabolic (backward) quasilinear PDE, and parabolic equations *regularize*: an instantaneous diffusion smears any incipient kink in u across space, so that even nonsmooth terminal data $g(\cdot, m)$ are propagated, away from $t = T$, into a value function as smooth as the coefficients permit. This is the analytic content of the slogan that noise smooths the value, and it is the hinge on which the entire section turns: without it u could crease — as it does in the deterministic case — and the verification theorem would have no $C^{1,2}$ object to certify. The precise statement is the following classical existence/regularity result, whose in-book home is the parabolic theory of theorem C.12.

Theorem 6.14 (Classical solvability of the nondegenerate HJB equation)**.** *Assume* (A-Lip)*,* (A-Growth)*,* (A-Nondeg)*,* (A-Conv) *and, in addition, that* $\sigma\sigma^\top$ *and the data* $(x, m) \mapsto H(x, p, m)$*,* $g(\cdot, m)$ *are locally Hölder continuous in* x *(and* H *is* C^1 *in* p*, automatic from lemma 6.8). Then the HJB equation* (6.19) *has a unique solution* $u \in C^{1,2}([0, T) \times \mathbb{R}^d) \cap C([0, T] \times \mathbb{R}^d)$ *with polynomial growth in* x*, uniformly in* t*.*

Two clauses of the hypothesis deserve to be unpacked, because each marks exactly where the proof would fail without it, and together they pin down the precise — and limited — role (A-Nondeg) plays in this book.

Why the Hölder hypotheses cannot be dropped. Uniform parabolicity is necessary but not sufficient for a *classical* solution. Assume only (A-Nondeg) together with merely Lipschitz coefficients — the standing hypotheses of the chapter — and the strongest regularity available is the Krylov–Safonov theory: solutions exist in the parabolic Sobolev class $W_p^{2,1}$ for every $p < \infty$ and are Hölder continuous, but their second spatial derivatives and their time derivative live in L^p, not in C^0. A $W_p^{2,1}$ function need not be twice *continuously* differentiable; its Hessian is defined only almost everywhere and may genuinely fail to be continuous, so it is not a $C^{1,2}$ solution. This is not a cosmetic shortfall. The verification theorem's very first line applies Itô's formula to $u(s, X_s)$, and Itô's formula is *false* for functions whose second derivatives exist only in the L^p sense — it requires a continuous Hessian to control the quadratic variation term pointwise along the path. A merely $W_p^{2,1}$ value cannot be fed to the theorem at all. Closing the gap between $W_p^{2,1}$ and $C^{1,2}$ requires more than ellipticity: it requires the coefficients themselves to carry a modulus of continuity, which is exactly what the local Hölder hypothesis on $\sigma\sigma^\top$, on $H(\cdot, p, m)$, and on $g(\cdot, m)$ supplies. That is why theorem 6.14 cannot be stated under the Lipschitz standing assumptions alone, and why the extra Hölder clause is not decorative.

The standard route, and why it closes. With Hölder data the construction is the textbook freeze-and-iterate argument, and it is worth tracing its logic, because the same scheme recurs wherever a quasilinear parabolic equation is solved. The obstruction in (6.19) is that the principal nonlinearity enters through $H(x, \nabla u, m)$, i.e. through the unknown's own gradient. *Freeze* that gradient: given a fixed continuous vector field $q(t, x)$, replace $H(x, \nabla u, m)$ by $H(x, q, m)$ to obtain a *linear* uniformly parabolic equation for a new unknown w,

$$-\partial_t w - \tfrac{1}{2}\operatorname{tr}\bigl(\sigma\sigma^\top \mathrm{D}^2 w\bigr) + H(x, q, m) = 0, \qquad w(T, \cdot) = g(\cdot, m),$$

in which $H(x, q, m)$ is now a *known* Hölder-continuous source term, not a nonlinearity. To this linear problem the parametrix/Schauder theory of theorem C.12 applies directly: it produces a unique solution $w \in C^{1,2}$ with Gaussian bounds and — crucially — an interior Schauder estimate bounding $\|w\|_{C^{1,2}}$, hence in particular $\|\nabla w\|$, by the Hölder norm of the data. Define the map $\mathcal{T} \colon q \mapsto \nabla w$

that sends a frozen gradient to the gradient of the resulting linear solution. A *fixed point* of $\mathcal{T}$ — a field q with $q = \nabla w$ — is precisely a classical solution of the quasilinear equation (6.19), because then w solves the equation with its own gradient reinserted. That $\mathcal{T}$ has a fixed point is the Schauder fixed-point theorem (equivalently, a method-of-continuity argument): the Schauder estimate shows $\mathcal{T}$ maps a suitable closed bounded convex set of Hölder fields into itself, and that it is *compact* — it gains Hölder regularity, so its image is precompact in the weaker norm — whereupon a continuous compact self-map of such a set has a fixed point by theorem C.12's functional-analytic companion. For the iteration to be well-defined the source $H(x, q, m)$ must depend on q continuously, and for the standard estimates C^1-ly — which is exactly what (A-Conv) guarantees through lemma 6.8, where strict convexity in the action made H a C^1 function of its momentum slot. Drop (A-Conv) and H could carry corners in p, $\mathcal{T}$ would lose the regularity the fixed-point argument consumes, and the scheme would stall. The full construction is Ladyzhenskaya–Solonnikov–Uraltseva [92] and [68, Ch. VI]; we import the quasilinear statement and prove its linear engine, theorem C.12, in-book.

The payoff is precisely the regularity the verification theorem was missing. Granted theorem 6.14, the solution u of (6.19) is $C^{1,2}$, so theorem 6.10 applies on the nose: this u *is* the value function, and the feedback built from it is genuinely optimal — in particular the LQG computation of section 6.7, whose quadratic ansatz is manifestly $C^{1,2}$, inherits this rigour wholesale. This is the precise and limited role (A-Nondeg) plays for us: nondegenerate noise smooths the value function into the classical class, and thereby makes the entire verification programme rigorous *without any recourse to viscosity solutions*. The weak machinery of section 6.6 is, for nondegenerate problems, a luxury one can do without — and it is exactly when (A-Nondeg) fails, or the noise vanishes outright, that the luxury becomes a necessity. Flagging that contrast is how the present section sets up the next.

Remark 6.15 (Optimal feedback)**.** With u now genuinely $C^{1,2}$, the feedback formula of section 6.4 is no longer a formal manipulation but a licensed prescription, and it is the object chapter 8 will consume. In the canonical normalization $b(x, a) = a$ — the normalization remark 6.13 singled out as the only one in which the envelope identity collapses the optimal *drift* onto the optimal *control* — the optimal feedback is read straight off the Hamiltonian's momentum gradient,

$$\alpha^*(t, x) \;=\; -\,\partial_p H\big(x, \nabla u(t, x), m\big),$$

the formula recorded in appendix A. (Outside that normalization one keeps the explicit maximizer $a^*\big(x, \nabla u(t, x), m\big)$ of (6.18) and inverts the drift, exactly as remark 6.13 insisted; the LQG computation of section 6.7, with a gain and an uncontrolled drift both present, is precisely such a case, and reading $\alpha^* = -\partial_p H$ off it blindly would be the sign-and-scaling error that remark exists to forestall.)

This single formula is the seam along which chapter 8 will weld the two halves of a mean field game, and it is worth stating the closed loop in advance so that the present section's frozen-m picture is recognized as one frame of it. The value function solves the *backward* HJB equation (6.19) against a frozen m; its gradient yields the feedback $\alpha^*(t, x) = -\partial_p H(x, \nabla u, m)$; that feedback *is* the drift of the representative agent, so substituting it into the *forward* Fokker–Planck equation of chapter 5 transports an initial population density along the optimally controlled flow. The transported density is a new measure flow $(m_t)_{t\in[0,T]}$ — and the loop *closes* the instant one demands that this transported population coincide with the very m the agent optimized against, feeding back into the costs through the m-slot of (6.18). Freezing m, as we have done throughout this chapter, is exactly the act of cutting that loop open at one point so the single-agent problem can be solved in isolation; chapter 8 reconnects it, and the fixed-point condition that the transported law equal the m in the costs becomes the Nash equilibrium. Everything in this section has been built so that the reconnection requires no re-derivation, only the release of the frozen parameter.

One technical point underwrites the whole construction and is easy to misattribute, so we restate it precisely. What makes $\partial_p H$ single-valued — hence α^* a genuine function rather than a set of competing actions — is the strict convexity and coercivity of the action map $a \mapsto b(x,a)\cdot p + L(x,a,m)$, the operative content of (A-Conv) isolated in lemma 6.8. It is *not* the convexity of H in p that does this work. As section 6.3 showed at length, H is convex in p unconditionally, being a supremum of affine functions, and a merely convex function can still carry corners at which the feedback is ambiguous — the $H = |p|$ example there had a full interval of optimal actions at $p = 0$ despite perfect convexity. Convexity of H in p is the dual *shadow* of strict convexity in a, a consequence and not the cause; the substantive hypothesis lives one level down, in the action map, exactly where section 6.3 located it.

Remark 6.16 (Discounting and infinite horizon)**.** A last variant of the equation deserves to be put on the table now — not for its own sake, but because it will be the cleanest possible arena for the weak-solution theory of the next section. Many problems, especially the stationary mean field games of later chapters, run over an infinite horizon and weight future costs by a *discount rate* $\beta = \beta \geq 0$, replacing the running cost L by $e^{-\beta s}L$ in the objective. Two equivalent bookkeepings turn this into a PDE. One may keep the finite-horizon equation and carry the exponential explicitly; or, more cleanly, one factors the discount out of the value by writing $u(s,x) = e^{-\beta s}\tilde{u}(s,x)$, whereupon differentiating the weight $e^{-\beta s}$ produces a zeroth-order term $\beta\,\tilde{u}$ alongside the usual transport and diffusion terms. In the genuinely stationary regime the horizon is infinite and the coefficients are time-homogeneous, so the agent's situation at every instant is identical: the value cannot depend on the absolute clock, $\partial_t u = 0$, and there is no terminal time at which to impose data. The stationary, infinite-horizon value $u(x) = \inf_\alpha \mathbb{E}\Big[\int_0^\infty e^{-\beta s} L(X_s, \alpha_s, m)\,\mathrm{d}s\Big]$ accordingly solves the *time-independent* HJB equation

$$\beta\, u - \tfrac{1}{2}\operatorname{tr}\!\big(\sigma\sigma^\top \mathrm{D}^2 u\big) + H(x, \nabla u, m) = 0, \tag{6.20}$$

with no time derivative and no terminal condition — the discount term $\beta\, u$ standing in for the vanished $-\partial_t u$ and, when $\beta > 0$, supplying the strict monotonicity in the u-slot that a comparison principle will need in place of a horizon. (Per appendix A, β is always a discount rate here, never an inverse temperature; its resemblance to a mass term in a screened equation is a serviceable mnemonic but carries no thermodynamic content.)

Equation (6.20) is the object we hand forward. Stripped of the time variable and the terminal layer, it isolates the spatial structure of HJB — the competition between the elliptic diffusion term and the convex Hamiltonian — in its barest form, which is exactly why section 6.6 adopts it as the test bed on which to introduce viscosity solutions. And the hand-off is pointed, not incidental. The present section earned a *classical* $C^{1,2}$ solution only because (A-Nondeg) held and the diffusion smoothed the value. The next section confronts the complementary case — degenerate noise, or none at all — where that smoothing is unavailable, u is in general only Lipschitz and creases along the caustics the chapter's physicsnote foreshadowed, and the verification theorem's $C^{1,2}$ hypothesis simply cannot be met. There the classical solvability proved here is a luxury one has lost, and a weaker notion of solution, asking nothing of u beyond continuity, must take its place. That is the notion section 6.6 builds, with (6.20) as its proving ground.

6.6 Viscosity solutions: the correct weak notion

The verification theorem demands a $C^{1,2}$ solution. For first-order Hamilton–Jacobi equations — the degenerate case $\sigma \equiv 0$, and the eikonal equation of the physics note — the value function is in general only Lipschitz: it develops gradient discontinuities at points where two competing optimal trajectories meet, the control analogue of shock formation. At such kinks no classical solution exists, yet the value function is perfectly well-defined and is the object we want. We need a notion of solution that (i) makes sense for merely continuous functions, (ii) selects the value function uniquely among the many a.e.-solutions, and (iii) is stable under limits so that approximations converge to it. *Viscosity solutions*, introduced by Crandall and Lions, are that notion. We give the definition for the stationary equation (6.20) — cleaner because it has no time boundary — and indicate the parabolic modification.

Heuristic (non-rigorous)

The idea is to move all derivatives onto smooth test functions, as with distributions, but respecting the *one-sidedness* that the equation's ellipticity prescribes. At a point where u has an upward kink (a local max of $u - \varphi$ for smooth φ touching from above), the would-be second derivative is $-\infty$ in some direction; the equation, which contains $-\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 \cdot)$ and is therefore *decreasing* in the Hessian, can only be asked to hold as an inequality of the favourable sign there. Demanding the two complementary one-sided inequalities at all such touchings pins the function down exactly.

Write the equation as $F(x, u, \nabla u, \mathrm{D}^2 u) = 0$ with, from (6.20),

$$F(x, r, p, M) = \beta\, r - \tfrac{1}{2} \operatorname{tr}\big(\sigma(x)\sigma(x)^\top M\big) + H(x, p, m).$$

This F is *degenerate elliptic*: $F(x, r, p, M) \le F(x, r, p, M')$ whenever $M \succeq M'$ (the map $M \mapsto -\operatorname{tr}(\sigma\sigma^\top M)$ is nonincreasing in the PSD order). This monotonicity is the structural fact that makes the definition consistent.

Definition 6.17 (Viscosity solution)**.** Let F be degenerate elliptic and $u\colon \mathbb{R}^d \to \mathbb{R}$ continuous.

- u is a *viscosity subsolution* if for every $\varphi \in C^2$ and every local maximum point x_0 of $u - \varphi$,

$$F\big(x_0, u(x_0), \nabla\varphi(x_0), \mathrm{D}^2 \varphi(x_0)\big) \le 0.$$

- u is a *viscosity supersolution* if for every $\varphi \in C^2$ and every local minimum point x_0 of $u - \varphi$,

$$F\big(x_0, u(x_0), \nabla\varphi(x_0), \mathrm{D}^2 \varphi(x_0)\big) \ge 0.$$

- u is a *viscosity solution* if it is both.

For the time-dependent equation (6.19) one uses the same definition with (t, x) in place of x, test functions $\varphi \in C^{1,2}$, the operator $-\partial_t\varphi - \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2\varphi) + H(x, \nabla\varphi, m)$ in place of F, and the terminal condition $u(T, \cdot) = g$ imposed classically.

Two sanity checks anchor the definition. First, *consistency*: if $u \in C^2$ is a classical solution, it is a viscosity solution, and conversely a C^2 viscosity solution solves the equation pointwise (at a touching point of a C^2 function, $\nabla\varphi = \nabla u$ and $\mathrm{D}^2\varphi \succeq \mathrm{D}^2 u$ at a max, $\preceq$ at a min, and degenerate ellipticity converts the two inequalities into the pointwise equation). Second, the inequalities point the "right" way precisely because of the sign in F; reversing the convention on F swaps sub- and supersolutions, a classic source of error.

The reason the definition is the *correct* one is that it restores uniqueness, which a.e.-solutions spectacularly lack. The mechanism is a comparison principle.

Theorem 6.18 (Comparison and uniqueness)**.** *Assume* (A-Lip)*,* (A-Growth) *on the data and* $\beta > 0$ *(or a finite horizon with prescribed terminal data). Let* $\overline{u}$ *be a bounded upper-semicontinuous viscosity subsolution and* $\underline{u}$ *a bounded lower-semicontinuous viscosity supersolution of* $F = 0$*. Then* $\overline{u} \le \underline{u}$ *on* $\mathbb{R}^d$*. Consequently the equation has at most one bounded continuous viscosity solution, and it coincides with the value function.*

The proof is the technical heart of the theory — it runs through the doubling-of-variables device and the Crandall–Ishii lemma on second-order superjets — and rather than relegate it to a citation we give it an in-book home: appendix E develops the comparison principle and the Crandall–Ishii lemma in full, including the precise structural conditions on F that make it work (uniform continuity in x at fixed jet, and the discount or horizon that provides the strict monotonicity in r). The classical references are the "User's Guide" [52], with [12] for the first-order/deterministic theory and [68, Ch. IV–V] for the second-order stochastic case.

Remark 6.19 (Where viscosity solutions are and are not needed)**.** Under (A-Nondeg) the second-order HJB equation (6.19) is uniformly parabolic and has a classical $C^{1,2}$ solution, so for the nondegenerate mean field games that occupy most of this book viscosity theory is a luxury, not a necessity — the verification theorem suffices. Its indispensability appears in three places we will meet: degenerate or first-order models where (A-Nondeg) fails; the rigorous justification that the $C^{1,2}$-classical solution *is* the value when one cannot assume smoothness a priori; and, most importantly later, as the template for the notion of solution of the master equation on $\mathcal{P}_2(\mathbb{R}^d)$ in chapter 12, where no classical calculus is available and the viscosity philosophy — test functions touching from one side — is the only game in town.

6.7 Worked computation: the LQG single agent and its Riccati equation

The viscosity detour behind us, we return to the nondegenerate, classically solvable backbone — where, as remark 6.19 stressed, the verification theorem alone suffices — and solve the first layer of Thread A, the linear–quadratic–Gaussian problem fixed in the project's thread specification, by running the verification programme of theorem 6.10 on an explicit ansatz. This is the atom from which the whole of Part II is built: in chapters 8 and 14 the frozen mean $\bar{m}$ below becomes the unknown of a fixed-point equation, but the single-agent solver — HJB reduces to a scalar Riccati ODE — is exactly the computation performed here.

Worked computation 6.20 (LQG single agent, Thread A layer 1)**.** The representative agent has scalar state $X_t \in \mathbb{R}$ driven by

$$\mathrm{d}X_t = \big(aX_t + b\,\alpha_t\big)\,\mathrm{d}t + \sigma\,\mathrm{d}W_t, \qquad X_0 \sim m_0, \tag{6.21}$$

with real constants a (state feedback), b (control gain), $\sigma > 0$ (noise), and W a scalar Brownian motion. The cost over $[0,T]$ is

$$J(\alpha) = \mathbb{E}\left[\int_0^T \Big(\tfrac{1}{2}\alpha_t^2 + \tfrac{q}{2}\big(X_t - s\,\bar{m}_t\big)^2\Big)\,\mathrm{d}t + \tfrac{q_T}{2}\big(X_T - s_T\,\bar{m}_T\big)^2\right], \tag{6.22}$$

with weights $q, q_T \geq 0$ and coupling constants s, s_T. In this single-agent layer the population mean $\bar{m}_t$ is frozen as a given continuous function of time (in chapter 14 it is determined self-consistently). The control set is $A = \mathbb{R}$.

Hamiltonian and HJB. Here the symbol a is the Thread A *state-feedback constant* of (6.21); we therefore write the action/maximization variable as $\alpha = \alpha$ (the control), reserving a for the constant. The drift is $ax + b\alpha$ and the running cost is $L(x,\alpha) = \frac{1}{2}\alpha^2 + \frac{q}{2}(x - s\bar{m}_t)^2$, so the control Hamiltonian (6.18) is computed by completing the square in α:

$$H_t(x,p) = \sup_{\alpha\in\mathbb{R}}\Big\{ -(ax+b\alpha)p - \tfrac{1}{2}\alpha^2 - \tfrac{q}{2}(x-s\bar{m}_t)^2\Big\} = -axp + \tfrac{1}{2}b^2p^2 - \tfrac{q}{2}\big(x - s\bar{m}_t\big)^2,$$

the supremum attained at $\alpha^* = -bp$. (Note the gain b: the optimal control is $-bp$, not $-p$; this is the general control-affine case of remark 6.13.) The HJB equation (6.19) reads

$$-\partial_t u - \tfrac{\sigma^2}{2}\partial_{xx}u - ax\,\partial_x u + \tfrac{b^2}{2}\big(\partial_x u\big)^2 - \tfrac{q}{2}\big(x - s\bar{m}_t\big)^2 = 0, \qquad u(T,x) = \tfrac{q_T}{2}\big(x - s_T\bar{m}_T\big)^2. \tag{6.23}$$

Quadratic ansatz and the Riccati system. The terminal data are quadratic in x and the equation preserves quadratic profiles, so we posit

$$u(t,x) = \tfrac{1}{2}P(t)\,x^2 + R(t)\,x + S(t),$$

with $\partial_x u = Px + R$, $\partial_{xx}u = P$, and $\partial_t u = \frac{1}{2}\dot{P}x^2 + \dot{R}x + \dot{S}$. Substituting into (6.23) and matching powers of x gives three ordinary differential equations. The x^2 coefficient yields the scalar *Riccati equation*

$$\dot{P}(t) = b^2P(t)^2 - 2a\,P(t) - q, \qquad P(T) = q_T, \tag{6.24}$$

a closed, autonomous, backward ODE for the curvature of the value function. The x^1 coefficient gives a linear equation for R driven by the (frozen) population mean,

$$\dot{R}(t) = (b^2 P(t) - a)R(t) + q\,s\,\bar{m}_t, \qquad R(T) = -q_T\,s_T\,\bar{m}_T, \tag{6.25}$$

and the x^0 coefficient gives the offset, with the noise entering only here,

$$\dot{S}(t) = \tfrac{b^2}{2}R(t)^2 - \tfrac{\sigma^2}{2}P(t) - \tfrac{q}{2}s^2\bar{m}_t^2, \qquad S(T) = \tfrac{q_T}{2}s_T^2\bar{m}_T^2. \tag{6.26}$$

Optimal feedback and certainty equivalence. By remark 6.13 the optimal feedback is $\alpha^* = -b\,\partial_x u$, i.e. the *linear* feedback law

$$\alpha^*(t,x) = -b\big(P(t)\,x + R(t)\big). \tag{6.27}$$

The closed-loop state (6.21) is then a linear SDE with Gaussian solution, the fact that will make the Fokker–Planck step of chapters 8 and 14 explicit. Three structural observations close the computation. First, the feedback gain $bP(t)$ is governed entirely by the Riccati equation (6.24), which does *not* see the noise σ or the coupling $\bar{m}$: this is *certainty equivalence*, the optimal gain is the same as in the deterministic ($\sigma = 0$) problem. Second, the noise enters only the constant offset S through the $-\frac{\sigma^2}{2}P$ term in (6.26); it raises the cost-to-go but leaves the policy unchanged. Third, the coupling to the crowd enters only the linear part R, an inhomogeneous forcing by $\bar{m}_t$ in (6.25) — the seed that, once $\bar{m}$ is no longer frozen but is itself the mean of the closed-loop law, will couple back through (6.25) and close the mean field game.

Solvability of the Riccati equation. Equation (6.24) is a scalar Riccati ODE with constant coefficients; it is solved in closed form by the standard linearization $P = -\dot{\Psi}/(b^2\Psi)$, which turns it into the linear second-order equation $\ddot{\Psi} + 2a\dot{\Psi} - b^2 q\,\Psi = 0$ with constant coefficients, hence elementary exponentials. Because $q, q_T \geq 0$, a comparison argument shows $P(t) \geq 0$ on $[0,T]$ and that no finite-time blow-up occurs when integrating backward from $P(T) = q_T$: the quadratic value function stays convex, consistent with (A-Conv) and with the well-posedness guaranteed by theorem 6.10. The explicit exponential solution, its long-horizon limit $P(t) \to \bar{P}$ as $T - t \to \infty$ (the stable root of $b^2\bar{P}^2 - 2a\bar{P} - q = 0$, i.e. the algebraic Riccati equation), and the matrix generalization are taken up when the thread is completed in chapter 14.

This is the promised atom. Everything explicit in Part II's LQG analysis — Gaussian population flows, closed Riccati–mean systems, the uniqueness/multiplicity phase diagram — is assembled from (6.24)–(6.27) by switching on the coupling that chapters 7 and 8 introduce.

Rigor ledger

Proved.

- Euler–Lagrange equation and transversality for the action functional (theorem 6.1).
- The verification theorem (theorem 6.10): a $C^{1,2}$ solution of the (stochastic) HJB equation with terminal data is the value function and its feedback is optimal — proved in full via Itô's formula.

- The dynamic programming principle (theorem 6.4), including the measurable ε-optimal selection (lemma 6.5) that the deterministic case needs — proved in-book.
- The envelope identity $\partial_p H = -b(\cdot, a^*)$, $\partial_x H = -\partial_x \mathfrak{H}(\cdot, a^*, \cdot)$ for the Bellman Hamiltonian (lemma 6.8), the single-valued feedback and the costate identity both resting on it.
- Identification of the Pontryagin costate with the gradient of the value, $p_t = \nabla u(t, X_t^*)$, and derivation of the adjoint equation from HJB (proposition 6.12).
- Reduction of the LQG single-agent problem to the scalar Riccati system (6.24)–(6.26) with linear optimal feedback (6.27) (worked computation 6.20).

Assumed (referenced by tag).

- (A-Lip), (A-Growth): well-posedness and moment bounds of the controlled state equation (theorem 5.10), used to make the Itô integral a martingale in theorem 6.10.
- (A-Conv): strict convexity/coercivity in the control (equivalently convexity of H in p), hence the single-valued feedback of lemma 6.8 and applicability of verification.
- (A-Nondeg) plus local Hölder continuity of the data: uniform parabolicity giving the classical $C^{1,2}$ value function of theorem 6.14, so that verification applies without viscosity theory.

Deferred (with in-book home).

- Classical solvability of the nondegenerate HJB equation (theorem 6.14): the linear parabolic input is proved in theorem C.12; the quasilinear closure (Schauder fixed point) follows [92], [68, Ch. VI].
- Necessity in the Pontryagin maximum principle theorem 6.11 (spike-variation argument): not used elsewhere in the book — only the in-book costate identity proposition 6.12 and the FBSDE development of chapter 9 are relied upon — so its proof is left to [136, Ch. 2], [97] as further reading.
- The comparison principle for viscosity solutions theorem 6.18 (doubling of variables, Crandall–Ishii lemma): proved in appendix E; classical references [52], [12], [68].
- The adjoint BSDE (6.16), the martingale representation theorem behind its integrand Z, and the FBSDE it generates: developed in chapter 9.

Open / beyond this chapter.

- Existence and uniqueness once $\bar{m}$ (here frozen) is determined by an equilibrium fixed point — the mean field game proper (chapters 8, 10, 11 and 14).
- Optimal control under control-dependent or degenerate diffusion, and the regularity of the value function there, where (A-Nondeg) fails and viscosity theory is essential.

Part I retrospective: the six tools

This chapter closes Part I, and with it the construction of the analytic vocabulary the rest of the book speaks. It is worth pausing to name the six foundational tools we have built and, for each, the single load-bearing result it contributes and the downstream mean-field-game (MFG) or graphon-mean-field-game (GMFG) theorem it powers. Part II begins, in chapter 7, by switching on the first coupling; everything it does is assembled from these six.

- **Chapter 1 — measure and the thermodynamic limit.** The passage from empirical measures of N agents to a deterministic limiting law is what makes "the population" a single mathematical object $m \in \mathcal{P}_2(\mathbb{R}^d)$. This underwrites the very statement of an MFG and reappears as the law-of-large-numbers leg of the propagation-of-chaos and finite-N convergence theorems (chapter 10, chapter 25).
- **Chapter 2 — functional analysis and operators.** Banach–Alaoglu, compact self-adjoint spectral theory, and the fixed-point theorems (Schauder/Kakutani) are the abstract existence engines. They power the existence of MFG equilibria by fixed point (chapter 10) and, through the spectral theory of the graphon operator $\mathbb{W}$, the entire reduction machinery of Part IV (chapter 20, chapter 24).
- **Chapter 3 — probability and weak convergence.** Prokhorov tightness and the topology of weak convergence give the compactness in which equilibria are extracted as limits; this is the analytic heart of the existence proof (chapter 10) and of the stability of equilibria under approximation.
- **Chapter 4 — Wasserstein geometry and derivatives on $\mathcal{P}_2(\mathbb{R}^d)$.** The metric $\mathcal{W}_2$ and the flat/Lions derivatives turn "a function of the population" into a differentiable object. These are exactly the calculus in which the master equation on measure space is written (chapter 12), and the monotonicity (A-Mon) that delivers uniqueness (chapter 11) is a Wasserstein-level statement.
- **Chapter 5 — Itô calculus and Fokker–Planck.** Itô's formula (theorem 5.9), the generator $\mathcal{A}$ and its adjoint $\mathcal{A}^*$, and the forward Fokker–Planck equation supply the *forward* leg of the MFG system: the equation the optimally-controlled population obeys (chapter 8), and the SDE well-posedness (theorem 5.10) on which every probabilistic argument rests.
- **Chapter 6 — optimal control and HJB (this chapter).** The verification theorem (theorem 6.10) and the HJB equation supply the *backward* leg: the equation the representative agent's value function obeys and the optimal feedback $\alpha^* = -\partial_p H$ that closes the loop. Welded to the forward leg of chapter 5 at opposite ends of $[0, T]$, this is the forward–backward MFG system of chapter 8, its probabilistic FBSDE face in chapter 9, and the single-agent atom of the LQG thread carried to its fixed point in chapter 14.

The recurring structural signature — a backward HJB welded to a forward Fokker–Planck, closed by a self-consistency (fixed-point) condition on m — is visible already in this single-agent chapter, where m sits frozen. Part II's task is to release it.

Bibliographic notes

The calculus-of-variations recap of section 6.1 and the deterministic control theory of sections 6.1 and 6.4 follow [97], the concise text the book's plan designates for this chapter; the Pontryagin maximum principle originates with [112]. Dynamic programming and the value function (section 6.2) are due to [17]; the modern treatment of the dynamic programming principle, the verification theorem, and stochastic control we follow is [68] and [136, especially Ch. 2–4], the latter also our reference for the stochastic maximum principle and the adjoint BSDE previewed in section 6.4. The Itô-calculus inputs to the verification proof are from chapter 5 (see [106]). Viscosity solutions (section 6.6) were introduced by Crandall and Lions; the indispensable reference is the "User's Guide" [52], with [12] for the first-order/deterministic theory and [68] for the second-order stochastic theory. The sign and structural conventions for the Hamiltonian, and the forward–backward coupling that this single-agent chapter sets up, are aligned with the mean field game literature we enter next: [93], [36], and [40]. The LQG worked computation continues the linear–quadratic line of [82] and is carried to its mean field fixed point in chapter 14.

Part II

Classical Mean Field Games

Chapter 7

McKean–Vlasov Dynamics and Propagation of Chaos

Picture a single particle adrift in a large swarm. Its own random noise jostles it from instant to instant, but it also feels the others—not any one of them in particular, only their aggregate, the cloud of positions in which it is immersed. Ask the physicist's question: what does that one particle feel as the swarm grows? If each neighbor pushed with a force of fixed size, the total exerted by the other $N-1$ would diverge as $N \to \infty$ and no limit could exist; if the coupling were too weak, the neighbors' influence would fade to nothing and the particle would simply diffuse alone. Exactly one scaling threads between these extremes: let every pair interact at strength $O(1/N)$, so that the force on our particle is an *average* of N contributions rather than a sum. An average of N comparable terms is $O(1)$—neither divergent nor negligible—and, by the law of large numbers, an average of many nearly independent contributions ceases to fluctuate and settles onto its mean. That single observation is the entire physical content of the mean-field limit: the right coupling converts the felt environment into a deterministic, self-generated field, and the swarm's empirical density—not the labels of its members—becomes the only thing to which each particle responds. This chapter makes that reflex precise and quantitative, and then asks what, if anything, it leaves out.

This chapter is the hinge between the toolbox of Part I and the mean field games of Part II. It studies a population of N stochastic particles that interact only through their *collective statistics*, and it makes rigorous the physicist's reflex that, as $N \to \infty$, the fluctuations of those statistics are suppressed and each particle comes to feel a smooth, deterministic, self-generated field. The limiting single-particle law is governed by a *McKean–Vlasov* stochastic differential equation, in which the law of the solution feeds back into its own coefficients, and equivalently by a *nonlinear Fokker–Planck* equation. The precise sense in which finite-N marginals factorize is *propagation of chaos*, which we prove by Sznitman's coupling with a quantitative $O(1/\sqrt{N})$ rate. These are not three separate topics but three faces of a single object—the law of one representative particle in the limit—and the sections are ordered so that meeting one face makes the next inevitable: the finite-N system forces the empirical measure into the foreground (section 7.1); freezing that measure to a deterministic flow yields the McKean–Vlasov equation (section 7.2); its marginals obey the nonlinear Fokker–Planck equation (section 7.4); and propagation of chaos (section 7.3) is the theorem that the finite-N reality and its idealized limit genuinely coincide. The reader should feel the four as one argument unfolding, not as a list of four results.

The descriptive theory of this chapter draws principally on the analytic tools of Part I. From chapter 4 we use the metric space $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ of probability measures with finite second moment, in which the population state lives and in which best responses will later be shown continuous. From chapter 5 we use the theory of Itô stochastic differential equations (existence and uniqueness under Lipschitz and linear-growth coefficients, Itô's formula, the Feynman–Kac/backward-Kolmogorov representation of linear parabolic equations, and the Fokker–Planck/Kolmogorov forward equation as the adjoint evolution of densities), together with the Ornstein–Uhlenbeck worked example. From chapter 3 we use weak convergence of probability measures, tightness, and Prokhorov's theorem; from chapter 2 the Banach contraction principle (theorem 2.36); and from chapter 1 the empirical measure $\mu^N = \frac{1}{N}\sum_i \delta_{X_i}$ and its law of large numbers. One further import is strategic rather than analytic and is confined to the descriptive-versus-strategic pivot of section 7.5: from chapter 6 we borrow the value function, the Hamilton–Jacobi–Bellman equation, and the optimal feedback $\alpha^* = -\partial_p H$ of a single-agent control problem, used there only to contrast the prescribed drift of McKean–Vlasov dynamics with the optimized drift of a game. Throughout, Brownian motion is written W (rendering W); no graphon is present in this chapter, so there is no clash with the graphon kernel, which enters only from chapter 15 onward.

The chapter closes on its single most important conceptual point, the one that motivates all of Part II: McKean–Vlasov dynamics are *descriptive*. Each particle blindly obeys a prescribed law of motion that happens to depend on the population law, and the self-consistency $m_t = \mathcal{L}(X_t)$ is a statistical closure, not a decision. A mean field game replaces the prescribed drift by the *optimal feedback of a control problem*: the population law becomes the output of a Nash equilibrium rather than of an averaging postulate. We isolate exactly what that strategic layer adds, and point to where the next chapters build it (chapter 8, chapter 9, and, for the genuinely harder "propagation of chaos for equilibria," chapter 13).

Notation watch

Two notational collisions are worth naming at the outset, because each arises from a symbol that two well-entrenched literatures both insist on. The first is W: stochastic analysis universally writes Brownian motion W_t (for Wiener), while graphon theory universally writes the kernel $W(x, y)$ (for the limit object of dense graphs). Both are too standard to renounce, so the book keeps each in the part where it reigns and switches letters at the seam. In this chapter $W = W_t$ (and W_t^i for the ith particle) denotes Brownian motion, following the standard usage of the stochastic chapters. The letter W is *not* a graphon here; the graphon kernel and its operator $\mathbb{W}$ do not appear until Part III, where Brownian motion switches to B_t to free the letter W. See the notation watch in appendix A. The second collision is b, again forced by two standard usages: control theory writes the control gain b in the linear dynamics $\mathrm{d}X = (aX + b\alpha)\,\mathrm{d}t + \cdots$, while the diffusion literature writes the drift field $b(\cdot, \cdot)$. The scalar b in the carried linear–quadratic thread (worked computation 7.18) is the *control gain* fixed in the thread specification, whereas elsewhere $b(\cdot, \cdot)$ denotes the drift *field* (rendering the same letter b). To keep the two from colliding, in the linear–quadratic worked computation we never write the drift through the macro $b(\cdot,\cdot)$: there the drift is displayed explicitly as a formula in x and the population mean, precisely so that b appears only as the control gain.

7.1 Weakly interacting particle systems

The picture with which the chapter opened—one particle immersed in a swarm, feeling only the aggregate of its neighbors—must now become an equation, and the slogan "every pair interacts at strength $O(1/N)$" must become a precise Itô system. That is the business of this section. We fix the finite-N object whose limit the rest of the chapter studies, install the empirical-measure language in which the whole development is conducted, and prove the two structural facts on which everything downstream rests: the system is well-posed, and it is *exchangeable*, so that no particle's identity can influence the dynamics—only the collective configuration can. By the end the reader will hold a unique, label-blind N-body process, and the obvious next move—freeze the collective configuration to a deterministic flow and watch a single particle—will set up the McKean–Vlasov equation of section 7.2.

Consider N indistinguishable particles, the ith with state $X_t^{i,N} \in \mathbb{R}^d$, each driven by its own independent noise but coupled to all the others through the population's empirical distribution. (We keep the superscript N on $X_t^{i,N}$ because the law of the ith particle genuinely depends on how many companions it has; the same physical particle sits in a different bath when N changes.) The defining feature of a *weakly interacting* (or *mean-field*) system is the scaling of the coupling: every pair of particles interacts with strength $O(1/N)$, so that the *total* force exerted on any one particle by the other $N-1$ remains $O(1)$ as $N \to \infty$. This is precisely the scaling under which a single particle feels a well-defined average field rather than a sum that diverges or vanishes, exactly as the opening argument demanded. Before writing the dynamics we name the object through which the coupling acts.

Definition 7.1 (Empirical measure)**.** For states $x_1, \dots, x_N \in \mathbb{R}^d$ the *empirical measure* is the random probability measure

$$\mu^N \; := \; \frac{1}{N} \sum_{j=1}^{N} \delta_{x_j} \; \in \; \mathcal{P}(\mathbb{R}^d).$$

For a particle configuration $X_t^{1,N}, \dots, X_t^{N,N}$ we write $\mu_t^N = \frac{1}{N} \sum_{j=1}^N \delta_{X_t^{j,N}}$. If the x_j have a common finite second moment then $\mu^N \in \mathcal{P}_2(\mathbb{R}^d)$ and serves as a point in the Wasserstein space of chapter 4.

This is the same empirical measure introduced in chapter 1, now in its dynamical role. It is the rigorous incarnation of the physicist's "density profile" or "occupation distribution": integrating a test function against it, $\int \phi \, \mathrm{d}\mu^N = \frac{1}{N} \sum_j \phi(x_j)$, returns the population average of ϕ, which is exactly what a measurement of the swarm reports. Two features make it the right state variable. First, it *discards labels*: μ^N records how the population is distributed across state space but forgets which particle sits where, so any quantity expressed through μ^N is automatically symmetric under relabeling—a point that will return as exchangeability. Second, when the x_j are i.i.d. samples from a law m, the empirical measure is the object whose convergence $\mu^N \to m$ *is* the law of large numbers (chapter 1); this is the precise sense in which a fluctuating microscopic configuration sharpens, as N grows, onto a deterministic macroscopic density. The mean field limit of this chapter is that same law of large numbers, made to operate not on a fixed sample but on the interacting dynamics themselves. For now μ_t^N is the channel through which each particle perceives the rest, and we can write the dynamics.

Definition 7.2 (Weakly interacting particle system)**.** Let $b : \mathbb{R}^d \times \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}^d$ and a constant matrix $\sigma \in \mathbb{R}^{d\times d}$ be given, and let $W^1, \dots, W^N$ be independent $\mathbb{R}^d$-valued Brownian motions on a filtered probability space, independent of the i.i.d. initial data $X_0^{1,N}, \dots, X_0^{N,N} \sim m_0 \in \mathcal{P}_2(\mathbb{R}^d)$. The *weakly interacting particle system* is the coupled Itô system, for $i = 1, \dots, N$,

$$\mathrm{d}X_t^{i,N} \;=\; b\big(X_t^{i,N},\; \mu_t^N\big)\,\mathrm{d}t \;+\; \sigma\,\mathrm{d}W_t^i, \qquad \mu_t^N = \frac{1}{N}\sum_{j=1}^N \delta_{X_t^{j,N}}. \tag{7.1}$$

The interaction is called *pairwise* when the drift has the form

$$b(x,\mu) = \int_{\mathbb{R}^d} b_0(x,y)\,\mu(\mathrm{d}y), \qquad \text{so that} \qquad b\big(X_t^{i,N}, \mu_t^N\big) = \frac{1}{N}\sum_{j=1}^N b_0\big(X_t^{i,N}, X_t^{j,N}\big), \tag{7.2}$$

for a fixed kernel $b_0 : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}^d$.

Read (7.1) slowly: each particle has its *own* noise W^i—the W^i are independent, so absent the drift the particles would never meet—and the *only* place the others enter is the second argument μ_t^N of the common drift field b. The coupling is therefore entirely mediated by the empirical measure; this is what “mean-field interaction” means precisely. The pairwise special case (7.2) is the form in which the $O(1/N)$ scaling is laid bare, and it is worth spelling out why. Substituting $\mu_t^N = \frac{1}{N}\sum_j \delta_{X_t^{j,N}}$ into $b(x,\mu) = \int b_0(x,y)\,\mu(\mathrm{d}y)$ turns the integral into the displayed sum: the drift on particle i is

$$b\big(X_t^{i,N}, \mu_t^N\big) = \frac{1}{N}\sum_{j=1}^N b_0\big(X_t^{i,N}, X_t^{j,N}\big) = \underbrace{\frac{1}{N} b_0\big(X_t^{i,N}, X_t^{j,N}\big)}_{\text{one neighbor: } O(1/N)} \times N \text{ terms.}$$

Each individual neighbor j contributes a force $\frac{1}{N} b_0(X^i, X^j)$ of size $O(1/N)$—this is the “$O(1/N)$ pairwise strength” of the slogan—while the *average* of the N such contributions is $O(1)$, because an average of N bounded terms does not grow with N. Had we instead summed undiscounted forces $b_0(X^i, X^j)$ (strength $O(1)$ per pair), the total would be $O(N)$ and would blow up in the limit; had we discounted by $1/N^2$, each particle’s influence and the total alike would vanish. The $1/N$ normalization is the unique choice that keeps the felt field both finite and nontrivial—the discrete shadow of the preamble’s scaling argument. We will use the pairwise form repeatedly, both because it is the cleanest carrier of the scaling and because it is the setting in which the propagation-of-chaos rate of section 7.3 comes out dimension-free.

A word on the constant diffusion. Taking σ a fixed matrix, rather than a field $\sigma(x,\mu)$, is a deliberate simplification made for transparency, not a limitation of the theory, and it is worth being explicit about why we can afford it here. The entire difficulty of the mean-field limit lives in the *drift*: it is the drift that couples the particles, and it is the drift's dependence on μ^N that must be controlled as the empirical measure fluctuates. A measure-dependent volatility adds a second coupled coefficient but no new conceptual obstacle—the Itô isometry converts a diffusion mismatch into exactly the same kind of $\mathcal{W}_2$-Lipschitz estimate the drift already demands. We therefore carry the constant σ through the main arguments to keep the algebra legible, and flag at each stage (see remark 7.10) precisely what a state- and measure-dependent $\sigma(x, \mu)$, obeying the same Lipschitz and nondegeneracy conditions, would change; the only genuinely non-routine point is that the coupling constructions of section 7.3 must then be made on the *driving* Brownian motion rather than pathwise, which remains legitimate. Nothing below relies on σ being constant beyond this convenience.

We now fix the hypotheses under which the system is studied. They are the standing assumptions of the thread specification (appendix A), specialized to what the McKean–Vlasov theory needs—which turns out to be Lipschitz dependence of the drift on *both* of its arguments, the state and the measure, simultaneously.

Assumption 7.3 (Standing hypotheses for this chapter)**.** There is a constant $L > 0$ such that for all $x, x' \in \mathbb{R}^d$ and $\mu, \mu' \in \mathcal{P}_2(\mathbb{R}^d)$,

$$\left|b(x,\mu) - b(x',\mu')\right| \;\le\; L\big(\left|x - x'\right| + \mathcal{W}_2(\mu,\mu')\big), \tag{A-Lip}$$

$$\left|b(x,\mu)\right| \;\le\; L\Big(1 + |x| + \Big(\textstyle\int |y|^2\, \mu(\mathrm{d}y)\Big)^{1/2}\Big), \tag{A-Growth}$$

and the diffusion is uniformly nondegenerate,

$$\sigma\sigma^\top \succeq \lambda I, \qquad \lambda > 0. \tag{A-Nondeg}$$

Each of the three conditions earns its place for a definite reason, and it repays the reader to see the "why" before any of them is used. Take (A-Lip) first. The thread specification states (A-Lip) as "Lipschitz in the state, uniformly in the measure"; here it is strengthened to *joint* Lipschitz continuity in (x, μ) with respect to the combined distance $|\cdot| + \mathcal{W}_2$, and holding the measure fixed recovers the thread's version verbatim. The strengthening is not decorative. Every well-posedness and propagation-of-chaos argument in this chapter is, at bottom, the same contraction: one estimates how much the drift changes when *both* a particle's position and the surrounding measure are perturbed, and one needs that change to be controlled by the perturbations of *both* inputs at once. Were b Lipschitz in x but only, say, continuous in μ, the difference $b(x, \mu) - b(x', \mu')$ could not be bounded by $L\mathcal{W}_2(\mu, \mu')$ in the measure slot, the Grönwall step in theorem 7.9 would have nothing to feed on, and the fixed-point map closing the McKean–Vlasov equation would lose its contraction. Joint Lipschitzness in $|\cdot| + \mathcal{W}_2$ is exactly the hypothesis that makes a perturbation of the law as controllable as a perturbation of the position—the indispensable ingredient of every contraction below.

The growth bound (A-Growth) is the (A-Growth) of the thread specification: the drift grows at most linearly in the state and in the population's root-second-moment. Its job is custodial rather than structural—it prevents the solution from exploding in finite time and guarantees the second moments $\mathbb{E}\Big[|X_t|^2\Big]$ stay finite, which is what lets Itô's formula and the moment estimates run. It buys existence on the whole interval $[0, T]$, not merely up to a blow-up time.

Nondegeneracy (A-Nondeg) is the (A-Nondeg) of the thread specification, and it stands apart from the other two: it is held *in reserve.* We draw attention now to the fact that it plays *no role* in the existence, uniqueness, or chaos results of sections 7.2 to 7.3—those rest on (A-Lip)–(A-Growth) alone. Its sole function is to supply parabolic regularization: a uniformly elliptic diffusion smooths the law, so that under (A-Nondeg) the limiting marginal m_t acquires a strictly positive C^∞ density solving the nonlinear Fokker–Planck equation classically (section 7.4). We keep it visible in the standing list because it is part of the thread's standing hypotheses, but we will be scrupulous about when it is and is not invoked, precisely so the reader can see which conclusions survive its removal (all the probabilistic ones do).

It is reassuring—and important for the worked examples—that the abstract hypothesis (A-Lip) is automatic for the pairwise drifts (7.2) whenever the kernel is Lipschitz, and that this can be checked by hand without any heavy machinery. The point deserves emphasis because the natural tool, Kantorovich–Rubinstein duality, is *not* needed: a direct coupling estimate does the whole job and keeps the chapter self-contained.

Lemma 7.4 (Pairwise Lipschitz kernels satisfy (A-Lip))**.** *If $b_0 : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}^d$ is Lipschitz, with $\ell_x := \mathrm{Lip}(b_0(x,\cdot))$ its Lipschitz constant in the second variable, then for every fixed x the map $\mu \mapsto \int b_0(x,\cdot)\,\mathrm{d}\mu$ is ℓ_x-Lipschitz in $\mathcal{W}_2$:*

$$\Big| \int b_0(x,y)\,\mu(\mathrm{d}y) - \int b_0(x,y')\,\mu'(\mathrm{d}y')\Big| \;\le\; \ell_x\,\mathcal{W}_2(\mu,\mu') \qquad (\mu,\mu' \in \mathcal{P}_2(\mathbb{R}^d)).$$

Consequently a pairwise drift (7.2) with b_0 Lipschitz in both *arguments satisfies (A-Lip), and if in addition b_0 has linear growth it satisfies (A-Growth).*

Proof. Let π be *any* coupling of μ and μ', that is, any probability measure on $\mathbb{R}^d \times \mathbb{R}^d$ with first marginal μ and second marginal μ'. Because the two integrals are the two marginals of $\int b_0(x,\cdot)\,\mathrm{d}\pi$ read in the respective slots,

$$\int b_0(x,y)\,\mu(\mathrm{d}y) - \int b_0(x,y')\,\mu'(\mathrm{d}y') = \int_{\mathbb{R}^d\times\mathbb{R}^d} \big[b_0(x,y) - b_0(x,y')\big]\,\pi(\mathrm{d}y,\mathrm{d}y').$$

Taking norms inside the integral and using the Lipschitz bound $|b_0(x,y) - b_0(x,y')| \le \ell_x\,|y-y'|$,

$$\Big| \int b_0(x,y)\,\mu(\mathrm{d}y) - \int b_0(x,y')\,\mu'(\mathrm{d}y')\Big| \le \ell_x \int |y-y'|\;\pi(\mathrm{d}y,\mathrm{d}y') \le \ell_x \Big(\int |y-y'|^2\;\pi(\mathrm{d}y,\mathrm{d}y')\Big)^{1/2},$$

the last step by the Cauchy–Schwarz (Jensen) inequality $\mathbb{E}[|Z|] \le \mathbb{E}\big[|Z|^2\big]^{1/2}$ applied under π. Now take the infimum over all couplings π: the right-hand square root is, by the very definition of the Wasserstein metric (chapter 4), minimized at the optimal coupling to $\mathcal{W}_2(\mu,\mu')$. This proves the displayed Lipschitz bound. For the consequence: combining it with the Lipschitz bound of b_0 in its first variable gives $|b(x,\mu) - b(x',\mu')| \le \mathrm{Lip}_1(b_0)\,|x-x'| + \ell\,\mathcal{W}_2(\mu,\mu')$ with $\ell := \sup_x \ell_x$, which is (A-Lip) with $L = \max(\mathrm{Lip}_1(b_0),\ell)$; the growth claim is the same estimate applied to $b_0(x,y)$ against $b_0(0,0)$. ☐

No appeal to Kantorovich–Rubinstein duality was made; an admissible coupling and Cauchy–Schwarz sufficed, and the argument is entirely internal to the Wasserstein machinery of chapter 4.

The same idea—bound a difference of measure-integrals by choosing a convenient coupling—is about to do heavier lifting, and in the one special situation we need most it gives a strikingly clean bound that we isolate as a standalone fact, because it will be used four times over in this chapter and the next.

Lemma 7.5 (Index-matching bound for empirical measures)**.** *Let $x_1, \dots, x_N$ and $x'_1, \dots, x'_N$ be two configurations in $\mathbb{R}^d$, with empirical measures $\mu = \frac{1}{N}\sum_j \delta_{x_j}$ and $\mu' = \frac{1}{N}\sum_j \delta_{x'_j}$. Then*

$$\mathcal{W}_2(\mu, \mu')^2 \;\le\; \frac{1}{N}\sum_{j=1}^{N} \left|x_j - x'_j\right|^2. \tag{7.3}$$

Proof. Match the jth atom of μ to the jth atom of μ'. Formally, set

$$\pi := \frac{1}{N}\sum_{j=1}^{N} \delta_{(x_j, x'_j)} \;\in\; \mathcal{P}(\mathbb{R}^d \times \mathbb{R}^d).$$

Its first marginal is $\frac{1}{N}\sum_j \delta_{x_j} = \mu$ and its second marginal is $\frac{1}{N}\sum_j \delta_{x'_j} = \mu'$, so π is an admissible coupling of μ and μ'. By the definition of $\mathcal{W}_2$ as the infimum of $\big(\int |y - y'|^2 \, \mathrm{d}\pi\big)^{1/2}$ over couplings, *any* admissible coupling furnishes an upper bound, and this one gives

$$\mathcal{W}_2(\mu, \mu')^2 \;\le\; \int_{\mathbb{R}^d \times \mathbb{R}^d} |y - y'|^2 \, \pi(\mathrm{d}y, \mathrm{d}y') = \frac{1}{N}\sum_{j=1}^{N} \left|x_j - x'_j\right|^2,$$

which is (7.3). □

The inequality (7.3) says something one should keep in mind: matching atoms by their *index* is rarely the optimal transport plan—a cleverer pairing could move less mass—so $\mathcal{W}_2$ between two empirical measures is generally *strictly* smaller than the index-matched root-mean-square displacement. But for our purposes the inequality is exactly the right tool, because in every estimate below the two configurations will be two evolutions of the *same* labeled particles (the true system and a coupled copy), and we will already control $\frac{1}{N}\sum_j \left|x_j - x'_j\right|^2$ particle by particle. The lemma converts that particle-wise control into control of the Wasserstein distance between the two empirical measures, with no constant lost. It recurs in the proof of proposition 7.6 immediately below, in the contraction estimate of theorem 7.9, and twice inside the Sznitman coupling of theorem 7.15; establishing it once, carefully, is what makes those later appearances one-liners.

We can now dispatch the foundational facts about the N-body system. Two are needed: that (7.1) has a unique solution at all, and that this solution is exchangeable—the rigorous form of "the particles are indistinguishable." The second is the one that earns the empirical-measure language its keep: because the coefficients see the configuration only through the symmetric object μ^N, no particle's label can break into the dynamics, and consequently any statistic we ever compute is a symmetric function of the configuration. This is what licenses passing, in the limit, from N coupled particles to a single representative one.

Proposition 7.6 (Well-posedness of the N-particle system)**.** *Under assumption 7.3, the system (7.1) has a unique strong solution on $[0,T]$, and the solution is exchangeable: for every permutation π of $\{1,\dots,N\}$ the law of $(X^{\pi(1),N},\dots,X^{\pi(N),N})$ equals that of $(X^{1,N},\dots,X^{N,N})$.*

Proof. Well-posedness. The point is to recognize (7.1) as a single $\mathbb{R}^{Nd}$-valued Itô equation with globally Lipschitz, linear-growth coefficients, so that the standard theory of chapter 5 applies verbatim. Stack the states into $\mathbf{X}=(X^{1,N},\dots,X^{N,N})\in\mathbb{R}^{Nd}$ and write the stacked drift block by block,

$$\mathbf{b}(\mathbf{X}):=\big(b(X^i,\mu^N[\mathbf{X}])\big)_{i=1}^N\in\mathbb{R}^{Nd},\qquad \mu^N[\mathbf{X}]:=\frac{1}{N}\sum_{j=1}^N\delta_{X^j},$$

and let the stacked noise be $\mathbf{B}=(W^1,\dots,W^N)$ with the block-diagonal diffusion $\operatorname{diag}(\sigma,\dots,\sigma)$. Then (7.1) reads $\mathrm{d}\mathbf{X}_t=\mathbf{b}(\mathbf{X}_t)\,\mathrm{d}t+\operatorname{diag}(\sigma)\,\mathrm{d}\mathbf{B}_t$, an ordinary Itô SDE on $\mathbb{R}^{Nd}$. It remains to check $\mathbf{b}$ is globally Lipschitz and of linear growth.

Fix two stacked configurations $\mathbf{X},\mathbf{X}'$, with empirical measures μ^N,μ'^N. For the ith block, the joint Lipschitz bound (A-Lip) gives

$$\left|\mathbf{b}(\mathbf{X})_i-\mathbf{b}(\mathbf{X}')_i\right|=\left|b(X^i,\mu^N)-b(X'^i,\mu'^N)\right|\le L\big(\left|X^i-X'^i\right|+\mathcal{W}_2(\mu^N,\mu'^N)\big).$$

The two empirical measures are built from the same number N of atoms, indexed the same way, so lemma 7.5 applies and bounds the measure term *independently of i*:

$$\mathcal{W}_2(\mu^N,\mu'^N)^2\le\frac{1}{N}\sum_{j=1}^N\left|X^j-X'^j\right|^2=\frac{1}{N}\,\left|\mathbf{X}-\mathbf{X}'\right|^2.$$

Substituting and using $(a+b)^2\le 2a^2+2b^2$,

$$\left|\mathbf{b}(\mathbf{X})_i-\mathbf{b}(\mathbf{X}')_i\right|^2\le 2L^2\Big(\left|X^i-X'^i\right|^2+\tfrac{1}{N}\left|\mathbf{X}-\mathbf{X}'\right|^2\Big).$$

Now sum over the N blocks $i=1,\dots,N$. The first term sums to $\sum_i\left|X^i-X'^i\right|^2=\left|\mathbf{X}-\mathbf{X}'\right|^2$, and the second—being *independent of i*—is added N times, contributing $N\cdot\frac{1}{N}\left|\mathbf{X}-\mathbf{X}'\right|^2=\left|\mathbf{X}-\mathbf{X}'\right|^2$. This cancellation of the factor N against the $\frac{1}{N}$ normalization of the empirical measure is the crux: it is exactly why summing the per-block bound over all i leaves a constant that does not grow with N. Hence

$$\left|\mathbf{b}(\mathbf{X})-\mathbf{b}(\mathbf{X}')\right|^2=\sum_{i=1}^N\left|\mathbf{b}(\mathbf{X})_i-\mathbf{b}(\mathbf{X}')_i\right|^2\le 2L^2\big(\left|\mathbf{X}-\mathbf{X}'\right|^2+\left|\mathbf{X}-\mathbf{X}'\right|^2\big)=4L^2\left|\mathbf{X}-\mathbf{X}'\right|^2,$$

so $\mathbf{b}$ is globally Lipschitz on $\mathbb{R}^{Nd}$ with constant $2L$, *uniformly in N*. The identical computation with (A-Growth) in place of (A-Lip) (comparing $\mathbf{b}(\mathbf{X})$ to 0) gives the linear-growth bound $|\mathbf{b}(\mathbf{X})|\le C(1+|\mathbf{X}|)$. The block-diagonal diffusion is constant, hence trivially Lipschitz and bounded. The strong existence-and-uniqueness theorem for Itô SDEs with Lipschitz, linear-growth coefficients (chapter 5) therefore furnishes a unique strong solution $\mathbf{X}$ on $[0,T]$, adapted to the filtration generated by the W^i and the initial data, with $\sup_{t\le T}\mathbb{E}\Big[\left|\mathbf{X}_t\right|^2\Big]<\infty$.

Exchangeability. Fix a permutation σ of $\{1,\dots,N\}$ and consider the relabeled process $Y^i:=X^{\sigma(i),N}$. We claim $\mathbf{Y}=(Y^1,\dots,Y^N)$ solves the *same* system (7.1), but driven by the relabeled inputs $\widetilde{W}^i := W^{\sigma(i)}$ and $Y_0^i = X_0^{\sigma(i),N}$. Indeed, the empirical measure is symmetric in its atoms, $\frac{1}{N}\sum_j \delta_{Y^j} = \frac{1}{N}\sum_j \delta_{X^{\sigma(j)}} = \frac{1}{N}\sum_k \delta_{X^k} = \mu^N$, so permuting the labels leaves μ_t^N unchanged; applying the ith equation of (7.1) at index $\sigma(i)$ gives

$$\mathrm{d}Y_t^i = \mathrm{d}X_t^{\sigma(i),N} = b\big(X_t^{\sigma(i),N}, \mu_t^N\big)\ \mathrm{d}t + \sigma\ \mathrm{d}W_t^{\sigma(i)} = b\big(Y_t^i, \mu_t^N\big)\ \mathrm{d}t + \sigma\ \mathrm{d}\widetilde{W}_t^i,$$

which is precisely the ith equation of the system with the tilde'd inputs. Now use that the inputs are exchangeable in distribution: the initial data $X_0^{i,N}$ are i.i.d. and the noises W^i are i.i.d., so the relabeled inputs $(X_0^{\sigma(i),N}, W^{\sigma(i)})_i$ have the *same joint law* as the original inputs $(X_0^{i,N}, W^i)_i$. Since the solution of the SDE is a measurable functional of its inputs and the system the two solve is identical, the strong uniqueness just established forces $\mathbf{Y}$ to be that same functional of the relabeled inputs; equality of the input laws then gives $\mathcal{L}(\mathbf{Y}) = \mathcal{L}(\mathbf{X})$, i.e. $\mathcal{L}(X^{\sigma(1),N}, \dots, X^{\sigma(N),N}) = \mathcal{L}(X^{1,N}, \dots, X^{N,N})$. This is exchangeability. The mechanism is worth naming once: exchangeability is *forced*, not assumed, and it is forced precisely because the coefficients depend on the configuration only through the label-blind object μ^N while the i.i.d. inputs are themselves exchangeable. □

We now have what the next section needs: a unique, exchangeable N-body process (7.1), governed by a drift that is jointly Lipschitz in state and measure (A-Lip), and the structural principle that *only the empirical measure can enter the dynamics*—no particle's identity ever does. That principle is the hinge. Exchangeability says all N particles are statistically interchangeable, so to understand the swarm it suffices to understand one representative particle; and the only thing that particle reacts to is μ_t^N. The natural move, then, is to ask what happens to a single particle when the empirical measure it feels stops fluctuating—when, by the law of large numbers anticipated in the preamble, μ_t^N settles onto a deterministic flow of measures $t \mapsto m_t$. Freezing μ_t^N to such an m_t decouples the chosen particle from the rest and leaves it obeying a single SDE whose drift depends on m_t; imposing that m_t be the law the particle thereby generates closes the loop. That is the McKean–Vlasov equation, and constructing it is the work of section 7.2.

7.2 The McKean–Vlasov stochastic differential equation

The structural principle that closed section 7.1—that the only thing any particle ever reacts to is the empirical measure μ_t^N, never the identity of its neighbors—is now ready to do its work. A single representative particle's dynamics are pinned down once we know the flow of measures it feels, and exchangeability guarantees that one such representative already describes the whole swarm. So we make precisely the move the previous section set up. We follow one particle, say $i = 1$, and we imagine that the law of large numbers anticipated in the chapter preamble has already done its job: that the fluctuating random measure μ_t^N has settled, as $N \to \infty$, onto a *deterministic* flow of probability measures $t \mapsto m_t$. This is not yet a theorem—that the genuine μ_t^N really does concentrate on such a flow is the content of propagation of chaos in section 7.3—but it is the right heuristic to follow, because it tells us exactly what equation the limiting particle must satisfy, and that equation will turn out to be well-posed in its own right.

Carry the heuristic through. With μ_t^N replaced by a frozen deterministic flow m_t, the first particle's equation in (7.1) loses its coupling to the others entirely: the noises W^j of the other particles no longer enter, and what remains is a *single* Itô SDE,

$$\mathrm{d}X_t^1 = b(X_t^1,\, m_t)\;\mathrm{d}t + \sigma\;\mathrm{d}W_t^1,$$

in which the population appears only through the external field m_t. But m_t cannot be chosen freely. We posited it as the limit of $\mu_t^N = \frac{1}{N}\sum_j \delta_{X_t^{j,N}}$, and in the limit, by exchangeability, every particle has the same law as the first; so the deterministic flow the particle feels must coincide with the law the particle itself generates: $m_t = \mathcal{L}(X_t^1)$. This self-consistency condition is the entire substance of the mean-field limit. Dropping the now-redundant index 1, we arrive at an equation whose drift coefficient depends on the law of its own solution.

Definition 7.7 (McKean–Vlasov SDE)**.** A *McKean–Vlasov* (or *nonlinear*, in McKean's sense) SDE is

$$\mathrm{d}X_t \;=\; b\big(X_t,\; \mathcal{L}(X_t)\big)\;\mathrm{d}t \;+\; \sigma\;\mathrm{d}W_t, \qquad X_0 \sim m_0, \tag{7.4}$$

where $\mathcal{L}(X_t) \in \mathcal{P}_2(\mathbb{R}^d)$ is the law of the solution at time t. A *strong solution* is a process X adapted to the filtration generated by W and X_0, with $\sup_{t\le T}\mathbb{E}\Big[|X_t|^2\Big] < \infty$, satisfying (7.4) together with the self-consistency $m_t = \mathcal{L}(X_t)$ for all t.

It is worth dwelling on the word "nonlinear," because it names something genuinely new and is easy to misread. It does *not* refer to nonlinearity in the state variable x: the drift $b(\cdot, m_t)$ may perfectly well be linear in x, as it is in the carried linear–quadratic thread, and (7.4) is still called nonlinear. The nonlinearity is in the *law*. To see the structure plainly, contrast it with the ordinary SDEs of chapter 5. There the coefficients were prescribed functions of (t, x) fixed in advance: one specified $b(t, x)$ and $\sigma(t, x)$ as data, and the equation $\mathrm{d}X_t = b(t, X_t)\;\mathrm{d}t + \sigma(t, X_t)\;\mathrm{d}W_t$ then *determined* the law $\mathcal{L}(X_t)$ as an output, with no feedback. In (7.4) the law is no longer a passive output: it is plugged back into the very coefficient that drives the equation. The unknown is therefore not just a path $t \mapsto X_t$ but a path *together with* the flow of laws it induces, and the two must be consistent. Said operationally, (7.4) is a *fixed-point equation in path space*: one seeks a process X such that the map $X \mapsto \mathcal{L}(X)$, fed into the drift, reproduces a process with that very law. It is this self-referential map $X \mapsto \mathcal{L}(X)$—an operation on the *distribution* of the unknown, not on its values—that makes the equation nonlinear in McKean's probabilistic sense, and that places it outside the scope of chapter 5. The remainder of this section shows that, despite the self-reference, the equation has one and only one solution, on *any* finite horizon.

Remark 7.8 (The decoupled case as a sanity check)**.** The cleanest way to feel what the law-dependence adds is to switch it off. Suppose the drift does not in fact depend on its measure argument, $b(x, \mu) = b_0(x)$. Then (7.4) degenerates to the ordinary SDE $\mathrm{d}X_t = b_0(X_t)\;\mathrm{d}t + \sigma\;\mathrm{d}W_t$ of chapter 5, the self-consistency condition $m_t = \mathcal{L}(X_t)$ becomes a tautology that imposes nothing, and there is no fixed point to solve—the law is read off at the end and never fed back. Everything genuinely new in this chapter lives in the *coupling* of the drift to m_t, which is exactly the ingredient the fixed-point argument below must control. This is the same lesson the $O(1/N)$ scaling taught at the level of the particle system, now seen at the level of the limit equation.

The strategy for solving (7.4) is dictated by the fixed-point reading we just gave it. If a McKean–Vlasov solution is a flow of measures that reproduces itself, then we should build the map "flow of measures $\mapsto$ the flow it reproduces" explicitly and hunt for its fixed point. That map is the conceptual engine of the entire well-posedness theory, and it is constructed by the one device the heuristic already used: *freeze the measure*. Given any candidate flow μ_t, freezing it turns the daunting law-dependent (7.4) into a tame ordinary SDE—law-dependence gone, coefficients now honest functions of (t, x) to which the full machinery of chapter 5 applies—which we solve, and whose marginal flow we read back off. A flow that comes back to itself under this procedure is a McKean–Vlasov solution; a flow that does not is not. The theorem below makes this precise and, crucially, shows that the procedure contracts.

Theorem 7.9 (Well-posedness of the McKean–Vlasov SDE)**.** *Under assumption 7.3 and* $m_0 \in \mathcal{P}_2(\mathbb{R}^d)$*, the McKean–Vlasov SDE* (7.4) *has a unique strong solution on* $[0, T]$*. Its flow of marginals* $t \mapsto m_t = \mathcal{L}(X_t)$ *lies in* $C([0, T]; \mathcal{P}_2(\mathbb{R}^d))$*, and* $\sup_{t\le T} \mathbb{E}\Big[|X_t|^2\Big] \le C\big(1 + \mathbb{E}\Big[|X_0|^2\Big]\big)e^{CT}$.

Proof. We run a Picard fixed point on the space $\mathcal{C} := C([0, T]; \mathcal{P}_2(\mathbb{R}^d))$ of continuous flows of second-moment measures, metrized by $\mathbf{d}_t(\mu, \nu) := \sup_{s\le t} \mathcal{W}_2(\mu_s, \nu_s)$. The proof has two steps: build the freeze-solve-read-off map Φ and verify it lands inside $\mathcal{C}$ (Step 1); then show that a *power* of Φ contracts, no matter how large T is (Step 2).

Step 1 (the decoupled map Φ). Fix a flow $\mu = (\mu_s)_{s\le T} \in \mathcal{C}$ and freeze the measure argument of the drift at it. This produces the *ordinary* (non-McKean) SDE

$$\mathrm{d}X^\mu_t = b\big(X^\mu_t, \mu_t\big)\ \mathrm{d}t + \sigma\ \mathrm{d}W_t, \qquad X^\mu_0 = X_0 \sim m_0, \tag{7.5}$$

in which μ_t is now a *given* time-dependent input, not an unknown. The coefficient $(t, x) \mapsto b(x, \mu_t)$ inherits from (A-Lip)–(A-Growth) both a Lipschitz bound in x (with constant L, uniformly in t, since freezing the second slot only removes a term from (A-Lip)) and a linear-growth bound in x (the measure-dependent piece $\big(\int |y|^2\, \mu_t(\mathrm{d}y)\big)^{1/2}$ is finite and bounded in t because $\mu \in \mathcal{C}$ has uniformly bounded second moments, so it contributes only a bounded additive constant). The classical existence and uniqueness theory for Itô SDEs with Lipschitz, linear-growth coefficients (chapter 5) therefore furnishes a unique strong solution X^μ on $[0, T]$ with $\sup_{t\le T} \mathbb{E}\Big[|X^\mu_t|^2\Big] < \infty$. Define the map by reading off its marginal flow,

$$\Phi(\mu)_t := \mathcal{L}(X^\mu_t) \in \mathcal{P}_2(\mathbb{R}^d).$$

We must check that $\Phi(\mu)$ is itself a continuous flow, i.e. $\Phi(\mu) \in \mathcal{C}$; the skeleton draft delegated this to chapter 5, but it is short enough to give in full, and seeing it makes the L^2-continuity concrete. Fix $0 \le s < t \le T$. From the integral form of (7.5),

$$X^\mu_t - X^\mu_s = \int_s^t b(X^\mu_r, \mu_r)\ \mathrm{d}r + \sigma\,(W_t - W_s),$$

so by $(a + b)^2 \le 2a^2 + 2b^2$ and the Cauchy–Schwarz inequality applied to the time integral,

$$\mathbb{E}\Big[|X^\mu_t - X^\mu_s|^2\Big] \le 2(t - s)\int_s^t \mathbb{E}\Big[|b(X^\mu_r, \mu_r)|^2\Big]\,\mathrm{d}r + 2\,\mathbb{E}\Big[|\sigma(W_t - W_s)|^2\Big].$$

The drift integrand is bounded uniformly in $r \le T$ by the growth bound (A-Growth) together with $\sup_{r\le T}\mathbb{E}\Big[|X^\mu_r|^2\Big] < \infty$ and $\sup_{r\le T}\int |y|^2\,\mu_r(\mathrm{d}y) < \infty$, say by a constant K; and the Brownian increment contributes $\mathbb{E}\Big[|\sigma(W_t - W_s)|^2\Big] = \operatorname{tr}(\sigma\sigma^\top)(t-s)$. Hence

$$\mathbb{E}\Big[|X^\mu_t - X^\mu_s|^2\Big] \le 2K(t-s)^2 + 2\operatorname{tr}(\sigma\sigma^\top)(t-s) \xrightarrow[t\to s]{} 0.$$

Finally, the *same-path* pair (X^μ_s, X^μ_t) is an admissible coupling of $\Phi(\mu)_s$ and $\Phi(\mu)_t$, so by the very definition of the Wasserstein distance $\mathcal{W}_2(\Phi(\mu)_s,\Phi(\mu)_t)^2 \le \mathbb{E}\Big[|X^\mu_t - X^\mu_s|^2\Big] \to 0$. Thus $t\mapsto \Phi(\mu)_t$ is $\mathcal{W}_2$-continuous, $\Phi(\mu)\in\mathcal{C}$, and we have a genuine self-map $\Phi:\mathcal{C}\to\mathcal{C}$.

The point of the construction is its design feature: a flow μ is a *fixed point* $\Phi(\mu)=\mu$ if and only if the frozen SDE (7.5) is fed the very law it produces, $\mu_t = \mathcal{L}(X^\mu_t)$, which is exactly the self-consistency (7.4) demands; and in that case X^μ solves the McKean–Vlasov equation. Solving (7.4) is therefore *identical* to finding a fixed point of Φ, and nothing has been lost in the translation.

Step 2 (a power of Φ contracts, for any T). We estimate how much Φ separates two inputs. Take two flows $\mu,\nu\in\mathcal{C}$ and—this is the decisive device—drive the two frozen SDEs (7.5) by the *same* Brownian motion W and start them from the *same* initial datum X_0. Then the stochastic integral $\sigma\,\mathrm{d}W_t$ and the initial condition are *identical* in the two equations and cancel exactly in the difference $X^\mu_t - X^\nu_t$; this is what makes the estimate pathwise and removes the Itô integral from view altogether:

$$X^\mu_t - X^\nu_t = \int_0^t \big[b(X^\mu_s,\mu_s) - b(X^\nu_s,\nu_s)\big]\,\mathrm{d}s.$$

Apply the joint Lipschitz bound (A-Lip) inside the integral, then Cauchy–Schwarz in time (which puts a factor t out front), then $(a+b)^2 \le 2a^2+2b^2$ to split the position discrepancy from the measure discrepancy:

$$|X^\mu_t - X^\nu_t|^2 \le t\int_0^t L^2\big(|X^\mu_s - X^\nu_s| + \mathcal{W}_2(\mu_s,\nu_s)\big)^2\,\mathrm{d}s \le 2TL^2\int_0^t\big(|X^\mu_s - X^\nu_s|^2 + \mathcal{W}_2(\mu_s,\nu_s)^2\big)\,\mathrm{d}s.$$

Now take expectations and write $g(t) := \mathbb{E}\Big[|X^\mu_t - X^\nu_t|^2\Big]$. With $B := 2TL^2$ this reads

$$g(t) \;\le\; B\int_0^t g(s)\,\mathrm{d}s \;+\; B\int_0^t \mathcal{W}_2(\mu_s,\nu_s)^2\,\mathrm{d}s.$$

The second integral is a known forcing term, controlled by the separation of the inputs: writing $h(s) := \sup_{r\le s}\mathcal{W}_2(\mu_r,\nu_r)^2 = \mathbf{d}_s(\mu,\nu)^2$, which is nondecreasing, the forcing is at most $a(t) := B\int_0^t h(s)\,\mathrm{d}s$, itself nondecreasing. So $g(t)\le a(t) + B\int_0^t g(s)\,\mathrm{d}s$ with a nondecreasing, and the integral form of Grönwall's inequality (lemma C.1) gives $g(t)\le a(t)\,e^{Bt}$. Spelling out the bookkeeping with $t\le T$ and $B = 2TL^2$,

$$g(t) \;\le\; e^{Bt}\,B\int_0^t h(s)\,\mathrm{d}s \;\le\; \underbrace{2TL^2\,e^{2T^2L^2}}_{=:C}\int_0^t h(s)\,\mathrm{d}s,$$

the exponent being $Bt \le BT = 2T^2L^2$; this is exactly where the displayed constant $C = 2TL^2e^{2T^2L^2}$ comes from. Finally, the common-noise pair (X^μ_s, X^ν_s) is an admissible coupling of $\Phi(\mu)_s$ and $\Phi(\nu)_s$, so $\mathcal{W}_2(\Phi(\mu)_s, \Phi(\nu)_s)^2 \le g(s)$; taking the supremum over $s \le t$ (the right side is already nondecreasing in t) yields the basic one-step estimate

$$\mathbf{d}_t\big(\Phi(\mu), \Phi(\nu)\big)^2 \;=\; \sup_{s\le t} \mathcal{W}_2\big(\Phi(\mu)_s, \Phi(\nu)_s\big)^2 \;\le\; C\int_0^t \mathbf{d}_s(\mu,\nu)^2 \,\mathrm{d}s, \qquad C = 2TL^2 e^{2T^2L^2}. \tag{7.6}$$

A single application of (7.6) is *not* a contraction unless $CT < 1$, that is, unless T is small—the familiar obstruction that a naive Picard iteration overcomes only on a short horizon. The escape is to iterate (7.6) and exploit the time integral, which manufactures a shrinking factorial. Apply it once to $\Phi\mu, \Phi\nu$ and substitute (7.6) again for the integrand:

$$\mathbf{d}_t(\Phi^2\mu, \Phi^2\nu)^2 \le C\int_0^t \mathbf{d}_s(\Phi\mu,\Phi\nu)^2 \,\mathrm{d}s \le C\int_0^t \Big(C\int_0^s \mathbf{d}_r(\mu,\nu)^2 \,\mathrm{d}r\Big)\,\mathrm{d}s \le C^2\,\mathbf{d}_T(\mu,\nu)^2 \int_0^t s\,\mathrm{d}s = C^2\,\mathbf{d}_T(\mu,\nu)^2\,\frac{t^2}{2},$$

where we bounded $\mathbf{d}_r(\mu,\nu)^2 \le \mathbf{d}_T(\mu,\nu)^2$ and did the inner integral. The same step repeated n times produces the nested time integral $\int_0^t\int_0^{s_1}\cdots\int_0^{s_{n-1}} \mathrm{d}s_n\cdots\mathrm{d}s_1 = t^n/n!$, hence by induction

$$\mathbf{d}_t(\Phi^n\mu, \Phi^n\nu)^2 \;\le\; \frac{(Ct)^n}{n!}\,\mathbf{d}_T(\mu,\nu)^2, \qquad \text{and at } t = T, \qquad \mathbf{d}_T(\Phi^n\mu, \Phi^n\nu)^2 \;\le\; \frac{(CT)^n}{n!}\,\mathbf{d}_T(\mu,\nu)^2.$$

The constant C and the horizon T are fixed, but $(CT)^n/n! \to 0$ as $n \to \infty$ *whatever* the value of CT, because the factorial outruns any geometric growth. Choose n large enough that $(CT)^n/n! < 1$; then Φ^n is a strict contraction on the complete metric space $(\mathcal{C}, \mathbf{d}_T)$. By the version of the Banach fixed point theorem for maps a power of which contracts (theorem 2.36), Φ has a unique fixed point $m \in \mathcal{C}$. By Step 1 this fixed point is precisely the marginal flow of the unique strong solution of (7.4), and conversely any solution's flow is such a fixed point, so the solution exists and is unique.

Moment bound. It remains to bound the solution's second moment. Apply Itô's formula to $|X_t|^2$ along (7.4): the martingale part has zero expectation, leaving

$$\mathbb{E}\Big[|X_t|^2\Big] = \mathbb{E}\Big[|X_0|^2\Big] + \mathbb{E}\Big[\int_0^t \big(2X_s\cdot b(X_s,m_s) + \mathrm{tr}(\sigma\sigma^\top)\big)\,\mathrm{d}s\Big].$$

The growth bound (A-Growth) with $m_s = \mathcal{L}(X_s)$, so that $\int |y|^2\, m_s(\mathrm{d}y) = \mathbb{E}\Big[|X_s|^2\Big]$, gives $2X_s\cdot b(X_s, m_s) \le C'(1 + |X_s|^2 + \mathbb{E}\Big[|X_s|^2\Big])$ after Young's inequality; taking expectations and writing $\psi(t) = \mathbb{E}\Big[|X_t|^2\Big]$ yields $\psi(t) \le \mathbb{E}\Big[|X_0|^2\Big] + C''\int_0^t (1+\psi(s))\,\mathrm{d}s$, and Grönwall (lemma C.1) closes it as $\sup_{t\le T}\mathbb{E}\Big[|X_t|^2\Big] \le C(1+\mathbb{E}\Big[|X_0|^2\Big])e^{CT}$. □

Remark 7.10 (Where the hypotheses bite)**.** It repays attention to track exactly which of the standing hypotheses (A-Lip)–(A-Nondeg) the proof consumed, because the answer cleanly separates the probabilistic core of the theory from a regularity refinement that comes later. Three points stand out.

First, *nondegeneracy* (A-Nondeg) *was never used.* The diffusion entered the argument only as the term that *cancels*: the common-noise, common-initial-data coupling of Step 2 was engineered precisely so that $\sigma\,\mathrm{d}W$ drops out of the difference $X^\mu - X^\nu$, leaving the drift estimate, which calls on (A-Lip)–(A-Growth) alone. Existence and uniqueness of the McKean–Vlasov solution—and, in section 7.3, propagation of chaos—therefore hold for *degenerate* σ as well, even $\sigma = 0$. Nondegeneracy is held in reserve for a single purpose: in section 7.4 it makes the generator uniformly elliptic, so that the marginal flow m_t acquires a smooth strictly positive density solving the nonlinear Fokker–Planck equation classically. The probabilistic edifice of this section does not see it.

Second, the *global-in-T* character of the result is not an accident of small data or a short horizon—it is structural, and the mechanism is the nilpotent-kernel iteration $(CT)^n/n! \to 0$. A direct contraction would force $CT < 1$ and confine us to short times, after which one would have to restart and patch intervals together. The factorial removes that restriction outright: *some* power Φ^n contracts no matter how large C and T are, and a map a power of which contracts already has a unique fixed point. This is why theorem 7.9 asserts well-posedness on an arbitrary finite horizon with no smallness assumption whatsoever, and it is the same Volterra-type mechanism that will let the coupled estimates of section 7.3 run all the way to time T.

Third, the constant volatility was, as promised in section 7.1, a convenience and not a crutch. For a measure-dependent volatility $\sigma(x, \mu)$ the argument repeats almost verbatim, with one bookkeeping change and one structural one. The bookkeeping change: the difference $X_t^\mu - X_t^\nu$ now retains a stochastic-integral term $\int_0^t \left[\sigma(X_s^\mu, \mu_s) - \sigma(X_s^\nu, \nu_s)\right] \mathrm{d}W_s$, and taking expectations of its square is handled by the Itô isometry, which converts it into $\int_0^t \mathbb{E}\Big[|\sigma(X_s^\mu, \mu_s) - \sigma(X_s^\nu, \nu_s)|^2\Big]\,\mathrm{d}s$; under a joint Lipschitz bound on σ this is in turn bounded by another const $\cdot \int_0^t \big(\mathbb{E}\Big[|X_s^\mu - X_s^\nu|^2\Big] + \mathcal{W}_2(\mu_s, \nu_s)^2\big)\,\mathrm{d}s$, a term of *exactly the same shape* as the drift contribution—in particular it adds the extra $\int_0^t \mathcal{W}_2(\mu_s, \nu_s)^2\,\mathrm{d}s$ flagged in section 7.1—which the same Grönwall, and the same factorial iteration, absorb with no new idea, merely a larger constant C. The structural change is the one to watch: when the volatility differs between the two equations one can no longer cancel the noise by sharing the path W pointwise, because the two integrands multiply the *same* increment $\mathrm{d}W_s$ by different matrices and the difference no longer vanishes. The coupling that makes the Itô-isometry estimate legitimate must therefore be moved one level down, onto the *driving* Brownian motion: one couples the two solutions by feeding them the same W and measures the residual through the isometry, rather than by demanding the diffusion terms agree pathwise. That is still a valid coupling and still produces an admissible coupling of the two marginal laws, so every estimate above goes through; it is simply the honest place where "share the noise" must be reinterpreted once the noise coefficient itself depends on the unknown law.

The deliverable of this section is now in hand, and it is worth stating plainly what we carry forward, because the next two sections lean on different faces of it. We have a unique strong solution X of the McKean–Vlasov equation (7.4) on the whole interval $[0, T]$, and—above all—its *deterministic* marginal flow $t \mapsto m_t = \mathcal{L}(X_t)$, the fixed point of Φ living in $C\big([0, T]; \mathcal{P}_2(\mathbb{R}^d)\big)$. This single flow is the hinge of the rest of the chapter. Section 7.3 runs the genuine N-body system (7.1) against N independent copies of *this* McKean–Vlasov process, all sharing this same m_t, and asks the converse-facing question the heuristic left open: in what precise sense, and how fast, do the real interacting particles become independent draws from m_t? And section 7.4 takes the very same flow m_t and characterizes it no longer probabilistically but analytically, as the solution of a nonlinear Fokker–Planck PDE. The law of the one representative particle, constructed here by a fixed point in Wasserstein path space, is thus the common object that the chapter's remaining faces—chaos and Fokker–Planck—will each describe in their own language.

7.3 Propagation of chaos

The limit flow $t \mapsto m_t$ that section 7.2 delivered was constructed *forward*: we posited that the empirical measure had already collapsed onto a deterministic flow, followed one particle, and closed the self-consistency loop. But positing the collapse is not proving it. We must now turn around and face the converse-facing question the heuristic quietly deferred: take the genuine, finite, fully coupled N-body system (7.1), the one whose empirical measure really does fluctuate; in what exact sense, and how fast, do its particles become independent copies of *this* limit law m_t? The forward heuristic told us what equation the limit must satisfy; the present section makes the limit itself a theorem, and it must do so by comparing the two systems that the forward argument kept apart—the interacting reality and its idealized, decoupled surrogate.

Before we can prove anything we must say precisely what is to be proved. "The particles become independent draws from m_t" is a slogan, not a statement: at every finite N the particles are emphatically *not* independent—they are coupled through μ_t^N, and particle 1's position carries information about particle 2's through their shared history. Independence can only be an asymptotic property, and the standard way to make it precise is to fix a finite group of particles and ask whether *that* group becomes independent as the population around it grows. This is the notion of *chaoticity*.

Definition 7.11 (m-chaoticity)**.** A sequence of exchangeable $\mathbb{R}^d$-valued random vectors $\left(X^{1,N}, \dots, X^{N,N}\right)_{N\geq 1}$ is *m-chaotic*, for a fixed $m \in \mathcal{P}(\mathbb{R}^d)$, if for every fixed $k \in \mathbb{N}$ the law of the first k coordinates converges weakly to the product measure,

$$\mathcal{L}(X^{1,N}, \dots, X^{k,N}) \xrightarrow[N\to\infty]{} m^{\otimes k}.$$

Read the definition with care, because the order of quantifiers is the entire content. We fix the group size k *first* and let $N \to \infty$ *after*, so k stays bounded while the surrounding population diverges; the appearance of the *product* measure $m^{\otimes k} = m \otimes \cdots \otimes m$ encodes two assertions at once. That the limiting law factorizes across the k coordinates is asymptotic *independence*: any fixed handful of particles decorrelates as the crowd they are embedded in grows. That each factor is the *same* m is asymptotic *identical distribution*: every particle is, in the limit, a copy of the one representative law. Together: any finite group of particles becomes asymptotically i.i.d. with common law m. By exchangeability (proposition 7.6) there is no loss in always taking the *first* k coordinates—any other k have the same joint law—so the single index k controls the whole tower of finite marginals. The case $k = 2$ already carries the essential physics: it says the pair correlation $\mathcal{L}(X^{1,N}, X^{2,N})$ factorizes into $m \otimes m$, i.e. the connected correlation between any two tagged particles vanishes in the limit. Chaoticity is exactly the statement that all such finite-order correlations switch off, leaving a product state.

There is a second, equivalent way to express the same idea, and it is the one a physicist reaches for first, because it is a law of large numbers. Instead of tracking k tagged particles, watch the empirical measure $\mu^N = \frac{1}{N}\sum_j \delta_{X^{j,N}}$—the "density profile" of the swarm—and ask whether this *random* measure concentrates on the *deterministic* m. The next lemma records that these two formulations, factorization of finite marginals and concentration of the empirical measure, are one and the same. We pause to prove it not because the main theorem will lean on it—it will not, as we explain at the close—but because the equivalence is exactly the bridge between the probabilist's language of chaoticity and the physicist's language of a sharpening density, and seeing why they coincide is genuinely clarifying.

Lemma 7.12 (Chaoticity equals the empirical law of large numbers)**.** *For an exchangeable array $(X^{1,N},\dots,X^{N,N})_{N\geq 1}$ and $m\in\mathcal{P}(\mathbb{R}^d)$, the following are equivalent: (i) the array is m-chaotic; (ii) the random empirical measure $\mu^N=\frac{1}{N}\sum_{j=1}^N\delta_{X^{j,N}}$ converges to the deterministic limit m in probability (in the weak topology of $\mathcal{P}(\mathbb{R}^d)$).*

Proof. Weak convergence is tested by bounded continuous functions, and the topology of $\mathcal{P}(\mathbb{R}^d)$ is metrized by countably many such test functions (chapter 3); it therefore suffices to work with a fixed $\phi\in C_b(\mathbb{R}^d)$ and to show that $\langle\mu^N,\phi\rangle\to\langle m,\phi\rangle$ in probability is equivalent to chaoticity, where $\langle\mu,\phi\rangle:=\int\phi\,\mathrm{d}\mu$. Convergence of the random scalar $\langle\mu^N,\phi\rangle=\frac{1}{N}\sum_j\phi(X^{j,N})$—a sample average of ϕ over the population—to the deterministic number $\langle m,\phi\rangle$ is the law of large numbers in its recognizable form, and this is what we relate to factorization of marginals.

(i)⇒(ii). The strategy is the one the physicist expects of a law of large numbers: show the random average has the right mean and a variance that collapses. Both the mean and the variance of $\langle\mu^N,\phi\rangle$ are determined by the one- and two-particle marginals, and chaoticity controls exactly those. For the mean, exchangeability makes every summand identically distributed, so $\mathbb{E}\Big[\langle\mu^N,\phi\rangle\Big]=\frac{1}{N}\sum_j\mathbb{E}\Big[\phi(X^{j,N})\Big]=\mathbb{E}\Big[\phi(X^{1,N})\Big]$, which tends to $\langle m,\phi\rangle$ by the $k=1$ marginal convergence $\mathcal{L}(X^{1,N})\to m$. For the second moment, expand the square of the sum into a double sum and separate the diagonal from the off-diagonal indices:

$$\mathbb{E}\Big[\langle\mu^N,\phi\rangle^2\Big]=\frac{1}{N^2}\sum_{j,\ell}\mathbb{E}\Big[\phi(X^{j,N})\phi(X^{\ell,N})\Big]=\frac{1}{N}\mathbb{E}\Big[\phi(X^{1,N})^2\Big]+\frac{N-1}{N}\mathbb{E}\Big[\phi(X^{1,N})\phi(X^{2,N})\Big].$$

The bookkeeping behind this split is the heart of the computation, so let us spell it out. The double sum has N^2 terms. Of these, the N *diagonal* terms $j=\ell$ each equal $\mathbb{E}\Big[\phi(X^{j,N})^2\Big]=\mathbb{E}\Big[\phi(X^{1,N})^2\Big]$ by exchangeability; divided by N^2 they contribute $N\cdot\frac{1}{N^2}\mathbb{E}\Big[\phi(X^{1,N})^2\Big]=\frac{1}{N}\mathbb{E}\Big[\phi(X^{1,N})^2\Big]$. The remaining $N(N-1)$ *off-diagonal* ordered pairs $j\neq\ell$ each equal $\mathbb{E}\Big[\phi(X^{1,N})\phi(X^{2,N})\Big]$, again by exchangeability (any two distinct indices have the same pair law as $1,2$); divided by N^2 they contribute $\frac{N(N-1)}{N^2}\mathbb{E}\Big[\phi(X^{1,N})\phi(X^{2,N})\Big]=\frac{N-1}{N}\mathbb{E}\Big[\phi(X^{1,N})\phi(X^{2,N})\Big]$. That is the displayed identity. Now pass to the limit term by term. The diagonal piece is $O(1/N)$ because ϕ is bounded, hence $\mathbb{E}\Big[\phi(X^{1,N})^2\Big]\leq\|\phi\|_\infty^2$; it vanishes—this is precisely the $1/N$ suppression of self-interaction, the same factor that made one neighbor's force negligible in section 7.1. The off-diagonal piece has prefactor $\frac{N-1}{N}\to 1$ and, by the $k=2$ marginal convergence $\mathcal{L}(X^{1,N},X^{2,N})\to m\otimes m$ tested against the bounded continuous function $(x,y)\mapsto\phi(x)\phi(y)$, its expectation tends to $\iint\phi(x)\phi(y)\,m(\mathrm{d}x)m(\mathrm{d}y)=\langle m,\phi\rangle^2$. Hence $\mathbb{E}\Big[\langle\mu^N,\phi\rangle^2\Big]\to\langle m,\phi\rangle^2$, while $\mathbb{E}\Big[\langle\mu^N,\phi\rangle\Big]\to\langle m,\phi\rangle$; subtracting the square of the second limit from the first gives $\operatorname{Var}\langle\mu^N,\phi\rangle=\mathbb{E}\Big[\langle\mu^N,\phi\rangle^2\Big]-\mathbb{E}\Big[\langle\mu^N,\phi\rangle\Big]^2\to\langle m,\phi\rangle^2-\langle m,\phi\rangle^2=0$. A random variable whose mean converges to $\langle m,\phi\rangle$ and whose variance vanishes converges to $\langle m,\phi\rangle$ in L^2, hence in probability by Chebyshev. As ϕ was an arbitrary bounded continuous test function, this is (ii). The mechanism is exactly the decorrelation built into chaoticity: the only thing that could keep $\operatorname{Var}\langle\mu^N,\phi\rangle$ from vanishing is a persistent pair correlation, and the $k=2$ factorization is precisely the statement that there is none.

(ii)⇒(i). We must run this in reverse: from concentration of the empirical measure recover factorization of every fixed k-marginal. Fix k and bounded continuous $\phi_1, \ldots, \phi_k \in C_b(\mathbb{R}^d)$; it suffices to show $\mathbb{E}\Big[\prod_{r=1}^k \phi_r(X^{r,N})\Big] \to \prod_{r=1}^k \langle m, \phi_r\rangle$, since products $\prod_r \phi_r$ generate the test functions for weak convergence of the k-marginal to $m^{\otimes k}$. The link to the empirical measure is the product $\prod_{r=1}^k \langle \mu^N, \phi_r\rangle$, which expands into an average over *all* ordered k-tuples of indices,

$$\prod_{r=1}^k \langle \mu^N, \phi_r\rangle = \frac{1}{N^k} \sum_{i_1,\ldots,i_k=1}^N \prod_{r=1}^k \phi_r(X^{i_r,N}),$$

the tagged-particle expectation $\mathbb{E}\Big[\prod_r \phi_r(X^{r,N})\Big]$ being the contribution of one *distinct*, increasingly ordered tuple. Now count: of the N^k ordered k-tuples $(i_1, \ldots, i_k)$, the number with all entries *distinct* is the falling factorial $N(N-1)\cdots(N-k+1) = N^k(1 - O(1/N))$, so for fixed k the distinct tuples make up a fraction $1 - O(1/N)$ of all tuples, and the tuples with at least one repeated index are only an $O(1/N)$ fraction. By exchangeability every distinct tuple contributes the *same* value $\mathbb{E}\Big[\prod_r \phi_r(X^{r,N})\Big]$, while every tuple—distinct or not—is bounded in absolute value by $\prod_r \|\phi_r\|_\infty$. Splitting the average over tuples into the distinct ones and the rest therefore gives

$$\mathbb{E}\left[\prod_{r=1}^k \langle \mu^N, \phi_r\rangle\right] = \frac{N(N-1)\cdots(N-k+1)}{N^k}\, \mathbb{E}\left[\prod_{r=1}^k \phi_r(X^{r,N})\right] \; + \; O(1/N),$$

where the $O(1/N)$ collects the $O(N^{k-1})$ repeated-index tuples, each $O(1/N^k) \cdot \prod_r \|\phi_r\|_\infty$ after normalization. Since the prefactor is $1 - O(1/N)$ and the tagged expectation is bounded, we may absorb its deviation from 1 into the error and solve for the quantity we want:

$$\mathbb{E}\left[\prod_{r=1}^k \phi_r(X^{r,N})\right] = \mathbb{E}\left[\prod_{r=1}^k \langle \mu^N, \phi_r\rangle\right] + O(1/N).$$

It remains to pass to the limit on the right. By (ii) each scalar $\langle \mu^N, \phi_r\rangle \to \langle m, \phi_r\rangle$ in probability, and a finite product of random variables converging in probability converges in probability to the product of the limits; hence $\prod_{r=1}^k \langle \mu^N, \phi_r\rangle \to \prod_{r=1}^k \langle m, \phi_r\rangle$ in probability. This product is, moreover, uniformly bounded by $\prod_r \|\phi_r\|_\infty$, a single deterministic constant, so the *bounded* convergence theorem upgrades convergence in probability of the integrand to convergence of its expectation: $\mathbb{E}\Big[\prod_r \langle \mu^N, \phi_r\rangle\Big] \to \prod_r \langle m, \phi_r\rangle$. Combined with the $O(1/N)$ display, $\mathbb{E}\Big[\prod_r \phi_r(X^{r,N})\Big] \to \prod_r \langle m, \phi_r\rangle$. As k and the ϕ_r were arbitrary, the k-marginal converges to $m^{\otimes k}$, which is (i). □

A remark on the standing of this lemma, so the reader weights it correctly. It is recorded *for orientation*: it certifies that the probabilist's chaoticity and the physicist's law-of-large-numbers concentration are interchangeable, and it shows that the entire tower of finite marginals is governed by the single random object μ^N. But the main result of this chapter will *not* pass through it. The theorem we are about to prove establishes something strictly stronger and more quantitative than either (i) or (ii): rather than weak convergence of marginals or convergence in probability of the empirical measure, it controls the $\mathcal{W}_2$ distance between the genuine k-marginal and the product law $m_t^{\otimes k}$, with an explicit rate. Weak convergence and $\mathcal{W}_2$ convergence of marginals will both fall out of that single estimate as immediate corollaries, so we have no need to route the argument through lemma 7.12; the lemma stands as a conceptual map of the terrain, not as a load-bearing beam.

How, then, will the stronger statement be reached? Not by manipulating laws and marginals abstractly, but by a strikingly concrete device. The target we must hit is $\mathcal{L}(X_t^{1,N},\dots,X_t^{k,N}) \to m_t^{\otimes k}$, ideally in $\mathcal{W}_2$ and with a rate. The idea—Sznitman's—is to build, on the *same* probability space as the real particles, an explicit family of N *independent* McKean–Vlasov copies, each an exact draw from the limit law m_t, and to make each copy shadow its real counterpart as closely as possible by feeding them the *same* Brownian motion and the *same* initial datum. If we can then show that the real particle and its idealized twin stay pathwise close—that their mean-square distance is $O(1/N)$—then the k-marginal of the real system is forced to within $O(1/\sqrt{N})$ of the k-marginal of the i.i.d. copies, which is exactly $m_t^{\otimes k}$. Chaoticity, in this approach, is not proved by checking factorization directly; it is read off from a single pathwise coupling estimate, and that estimate carries its own rate for free. Constructing the coupling and running the estimate is the work of the next subsection.

7.3.1 Sznitman's coupling

We left the previous section having reduced everything to one concrete task. The target is $\mathcal{L}(X_t^{1,N},\dots,X_t^{k,N}) \to m_t^{\otimes k}$, and we resolved to reach it not by checking factorization of marginals abstractly but by the device Sznitman invented for exactly this purpose: build, on the very same probability space as the real particles, a companion system of N *independent* McKean–Vlasov processes—one twin shadowing each real particle—and feed each twin the *same* Brownian motion and the *same* initial datum as the particle it shadows. The twins are exact draws from the limit law m_t; if we can show that a real particle and its twin never drift more than $O(N^{-1/2})$ apart in L^2, then the real k-marginal is squeezed to within $O(N^{-1/2})$ of the k-marginal of the twins, which is $m_t^{\otimes k}$ by independence. The whole of chaoticity, with its rate, then falls out of a single pathwise distance estimate. This subsection constructs that companion system, isolates the one variance estimate that makes the bound dimension-free, and runs the comparison to its conclusion.

Why must we use independent McKean–Vlasov copies, and not, say, N copies of the *interacting* system? Because the goal is to approximate the product law $m_t^{\otimes k}$, and the cleanest object whose marginals are literally $m_t^{\otimes k}$ is a family of genuinely independent processes each distributed as m_t. The single move that makes such a family *useful*—rather than a separate population living on its own probability space—is to refuse it fresh randomness: each copy is driven by the Brownian motion and started from the initial datum of the real particle it is paired with. That sharing is what converts a distributional comparison (hard) into a pathwise comparison (a Grönwall estimate), because when two equations are driven by the same noise their Itô integrals are identical and cancel in the difference, leaving an ordinary integral inequality. We met this exact trick already, twice: in the contraction of theorem 7.9, where common noise removed the stochastic integral from the one-step estimate, and it is about to do the same work here.

Definition 7.13 (The coupled limit system)**.** On the same probability space carrying (7.1), define for $i = 1,\dots,N$ the independent copies

$$\mathrm{d}\bar{X}_t^i = b(\bar{X}_t^i,\ m_t)\ \mathrm{d}t + \sigma\ \mathrm{d}W_t^i, \qquad \bar{X}_0^i = X_0^{i,N}, \quad m_t = \mathcal{L}(\bar{X}_t^i), \tag{7.7}$$

where m_t is the (common, deterministic) flow of the McKean–Vlasov solution from theorem 7.9, the *same* Brownian motion W^i drives the ith copy and the ith particle, and the *same* initial datum is shared. By construction the $\bar{X}^i$ are i.i.d. McKean–Vlasov processes, each with marginal law m_t at time t. We write $\bar{\mu}_t^N := \frac{1}{N}\sum_{j=1}^N \delta_{\bar{X}_t^j}$ for their empirical measure.

It is worth pausing on why the $\bar{X}^i$ are *exactly* independent and *exactly* m_t-distributed, since this is what makes them a legitimate yardstick. Look at (7.7): the flow m_t is frozen—it is the deterministic McKean–Vlasov marginal flow, the *same* for every i, and it does *not* depend on the other copies. So each $\bar{X}^i$ solves an *ordinary* (non-McKean) SDE with a given time-dependent coefficient $(s,x) \mapsto b(x, m_s)$, driven only by its own W^i and its own initial datum $X_0^{i,N}$. The N pairs $(X_0^{i,N}, W^i)$ are independent across i (the initial data are i.i.d. and the Brownian motions are independent, by definition 7.2), and each $\bar{X}^i$ is a fixed measurable functional of its own pair alone; independent inputs through the same functional yield independent outputs, so the $\bar{X}^i$ are i.i.d. Moreover each $\bar{X}^i$ is, individually, a strong solution of the McKean–Vlasov SDE (7.4): its driving law m_s coincides with its own marginal $\mathcal{L}(\bar{X}_s^i)$ precisely because m is the self-consistent fixed point of theorem 7.9 and $\bar{X}_0^i \sim m_0$. Hence $\mathcal{L}(\bar{X}_t^i) = m_t$ for every i and t, and the joint law of any k of them is exactly $m_t^{\otimes k}$. The twins are, in short, an honest i.i.d. realization of the limit, embedded in the same world as the interacting particles so that we may subtract one from the other path by path.

The whole argument turns on a single probabilistic estimate, the *fluctuation variance*, which quantifies how far the empirical measure $\bar{\mu}_t^N$ of N i.i.d. samples sits from its mean m_t *when read through the drift*. It is the place where the law of large numbers enters quantitatively, and—this is the point that propagates into every constant below—for pairwise bounded interactions the estimate is *dimension-free*: the bound depends on the sup-norm of the interaction kernel but not at all on the dimension d of the state space. The reason, which the proof will lay bare, is that the drift reads the empirical measure only through a bounded scalar pairing, so the relevant quantity is an average of bounded $\mathbb{R}^d$-valued summands and its variance is governed by the elementary i.i.d. variance bound, with no geometry of $\mathbb{R}^d$ intervening.

Lemma 7.14 (Fluctuation variance)**.** *Let $b_0 : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}^d$ be bounded measurable with $\|b_0\|_\infty := \operatorname{ess\,sup}|b_0| < \infty$, let $Z_1, \dots, Z_N$ be i.i.d. with law $\rho \in \mathcal{P}(\mathbb{R}^d)$, and set $\varphi(x) := \int_{\mathbb{R}^d} b_0(x,z)\,\rho(\mathrm{d}z)$. Then*

$$\mathbb{E}\Big[\Big|\tfrac{1}{N}\textstyle\sum_{j=1}^N b_0(Z_i, Z_j) - \varphi(Z_i)\Big|^2\Big] \;\le\; \frac{4\,\|b_0\|_\infty^2}{N} \qquad \textit{for each fixed } i.$$

Before the proof, read the statement physically. The quantity $\frac{1}{N}\sum_j b_0(Z_i, Z_j)$ is the empirical average force felt by sample Z_i from the whole population of i.i.d. samples, while $\varphi(Z_i) = \int b_0(Z_i, z)\,\rho(\mathrm{d}z)$ is the *mean-field* force it would feel against the true law ρ. The lemma says the gap between the two—the fluctuation of the realized field about its ideal—has mean square at most $4\|b_0\|_\infty^2/N$. This is a law of large numbers with an explicit $O(1/N)$ variance and a clean constant, and it is the engine of the rate: the $N^{-1/2}$ that appears in the final chaos bound is the square root of this N^{-1}.

Proof. Fix i. The one subtlety is that the index $j = i$ appears in the sum, so the summand $b_0(Z_i, Z_i)$ is *not* independent of the others given Z_i; we therefore peel it off and treat the genuinely off-diagonal part separately. Split

$$\tfrac{1}{N}\sum_{j=1}^{N} b_0(Z_i,Z_j)-\varphi(Z_i)=\underbrace{\tfrac{1}{N}\sum_{j\neq i}\left[b_0(Z_i,Z_j)-\varphi(Z_i)\right]}_{=:S}+\underbrace{\tfrac{1}{N}\left[b_0(Z_i,Z_i)-\varphi(Z_i)\right]}_{=:D}.$$

We now compute the conditional second moment given Z_i, because conditioning on Z_i is exactly what turns the off-diagonal summands into centered, independent contributions. Conditionally on Z_i, each Z_j with $j\neq i$ is still distributed as ρ and is independent of Z_i, so $\mathbb{E}[b_0(Z_i,Z_j)\mid Z_i]=\int b_0(Z_i,z)\,\rho(\mathrm{d}z)=\varphi(Z_i)$. Thus each summand $b_0(Z_i,Z_j)-\varphi(Z_i)$ of S has conditional mean zero—it is *centered* given Z_i—and the summands are conditionally i.i.d. across $j\neq i$. Variances of sums of conditionally independent centered terms add, so

$$\mathbb{E}\Big[|S|^2\mid Z_i\Big]=\frac{1}{N^2}\sum_{j\neq i}\mathbb{E}\Big[|b_0(Z_i,Z_j)-\varphi(Z_i)|^2\mid Z_i\Big]\le\frac{N-1}{N^2}\,\|b_0\|_\infty^2,$$

using for the bound that a conditional variance never exceeds the conditional second moment, $\mathbb{E}\Big[|b_0(Z_i,Z_j)-\varphi(Z_i)|^2\mid Z_i\Big]\le\mathbb{E}\Big[|b_0(Z_i,Z_j)|^2\mid Z_i\Big]\le\|b_0\|_\infty^2$ (centering can only decrease the second moment). The diagonal term D is a function of Z_i alone, hence Z_i-measurable, and $|b_0(Z_i,Z_i)-\varphi(Z_i)|\le 2\,\|b_0\|_\infty$ gives $|D|\le 2\,\|b_0\|_\infty/N$, so $|D|^2\le 4\,\|b_0\|_\infty^2/N^2$.

Here is the step that earns the sharp constant. Given Z_i, the term S is centered (mean zero) while D is deterministic (a constant), so their conditional cross term $2\,\mathbb{E}[\langle S,D\rangle\mid Z_i]=2\,\langle\mathbb{E}[S\mid Z_i]\,,D\rangle=0$ *vanishes*. The conditional second moment of the sum is therefore the bare sum of the two conditional second moments, with no cross contribution:

$$\mathbb{E}\Big[|S+D|^2\mid Z_i\Big]=\mathbb{E}\Big[|S|^2\mid Z_i\Big]+|D|^2\le\frac{N-1}{N^2}\,\|b_0\|_\infty^2+\frac{4}{N^2}\,\|b_0\|_\infty^2=\frac{N+3}{N^2}\,\|b_0\|_\infty^2\le\frac{4\,\|b_0\|_\infty^2}{N}\quad(N\ge 1),$$

the last inequality because $N+3\le 4N$ for $N\ge 1$. Taking expectations over Z_i removes the conditioning and gives the claim. The parenthetical contrast is worth keeping in view: had we bounded crudely by $|S+D|^2\le 2\,|S|^2+2\,|D|^2$, the doubling would have produced a constant near $2+8/N$ rather than 4; it is precisely the *exact* cancellation of the conditional cross term—legitimate because conditioning on Z_i makes S centered and D frozen—that lets us add the two pieces without loss and land on the clean 4. □

The variance scales as $1/N$ *independently of the dimension* d: this is the rigorous version of the central-limit statement "fluctuations of an average of N independent contributions are $O(N^{-1/2})$." Notice exactly where d failed to appear: the only bound used on b_0 was its scalar sup-norm $\|b_0\|_\infty$, and the only probabilistic fact used was that variances of independent centered terms add. Neither sees the dimension. This is the structural reason the coupling delivers a dimension-free rate, and it is the first of the two facts the next subsection will scrutinize: it holds because the drift reads the population through a *bounded pairwise* kernel, and we will see there that relaxing boundedness—passing to the full Wasserstein geometry of the empirical measure—reintroduces a dimension-dependent statistical rate. For now the lemma is exactly the quantitative heart of the mean-field limit, and we are ready to spend it.

Theorem 7.15 (Propagation of chaos, Sznitman)**.** *Assume the pairwise form* (7.2) *with b_0 bounded and Lipschitz (so* (A-Lip)*–*(A-Growth) *hold), $m_0 \in \mathcal{P}_2(\mathbb{R}^d)$, and let $X^{i,N}$ and the coupled copies $\bar{X}^i$ be as in* (7.1) *and* (7.7)*. Then there is a constant $C = C(T, L, \|b_0\|_\infty)$, independent of N and of d, such that*

$$\max_{1\le i\le N} \mathbb{E}\left[\sup_{0\le t\le T} |X_t^{i,N} - \bar{X}_t^i|^2 \right] \le \frac{C}{N}. \tag{7.8}$$

Consequently, for each fixed k and $t \in [0,T]$,

$$\mathcal{W}_2\Big(\mathcal{L}(X_t^{1,N}, \dots, X_t^{k,N}),\, m_t^{\otimes k}\Big) \le \sqrt{\tfrac{Ck}{N}},$$

so the particle system is m_t-chaotic, and each single particle satisfies $\mathcal{W}_2(\mathcal{L}(X_t^{i,N}), m_t) \le \sqrt{C/N} = O(N^{-1/2})$.

Proof. Set $\Delta_t^i := X_t^{i,N} - \bar{X}_t^i$, the gap between the ith real particle and its twin. Because the two systems (7.1) and (7.7) are driven by the *same* Brownian motion W^i and started from the *same* datum $X_0^{i,N}$, the diffusion term $\sigma\, \mathrm{d}W_t^i$ and the initial condition are identical and cancel in the difference; only the drift integral survives:

$$\Delta_t^i = \int_0^t \Big[b(X_s^{i,N}, \mu_s^N) - b(\bar{X}_s^i, m_s) \Big]\, \mathrm{d}s.$$

This is the payoff of sharing the noise: the comparison is now a deterministic-looking integral inequality, and the stochastic integral has disappeared from view. The drift difference confronts two changes at once—the state moved from $\bar{X}_s^i$ to $X_s^{i,N}$, *and* the measure moved from m_s to μ_s^N—so we separate them by inserting two intermediate terms, changing one argument at a time, and along the way replacing the true limit measure m_s first by the twins' empirical measure $\bar{\mu}_s^N$ and then by the real empirical measure μ_s^N:

$$\begin{aligned} b(X_s^{i,N}, \mu_s^N) - b(\bar{X}_s^i, m_s) = &\underbrace{b(X_s^{i,N}, \mu_s^N) - b(\bar{X}_s^i, \mu_s^N)}_{(A)} \\ &+ \underbrace{b(\bar{X}_s^i, \mu_s^N) - b(\bar{X}_s^i, \bar{\mu}_s^N)}_{(B)} + \underbrace{b(\bar{X}_s^i, \bar{\mu}_s^N) - b(\bar{X}_s^i, m_s)}_{(C)}. \end{aligned}$$

Each of the three terms isolates one mechanism, and each is controlled by exactly one of the tools assembled earlier.

Term (A) (state mismatch). Here only the first argument changes, the measure being held at μ_s^N, so the state-Lipschitz part of (A-Lip)—equivalently, the Lipschitzness of b_0 in its first argument under the pairwise form (7.2)—bounds it directly by the gap it is meant to measure,

$$|(A)| \le L\, \left| X_s^{i,N} - \bar{X}_s^i \right| = L\, \left| \Delta_s^i \right|.$$

This is the self-coupling term: it feeds the particle's own discrepancy back into the estimate and will be absorbed by Grönwall.

Term (B) (empirical-measure mismatch, relabel-matched). Here the state is frozen at $\bar{X}_s^i$ and only the measure changes, from the real empirical measure μ_s^N to the twins' empirical measure $\bar{\mu}_s^N$. Both are empirical measures of N atoms indexed the same way—the real atoms $X_s^{j,N}$ versus the twin atoms $\bar{X}_s^j$—so the index-matching bound lemma 7.5 applies, $\mathcal{W}_2(\mu_s^N, \bar{\mu}_s^N)^2 \le \frac{1}{N}\sum_j \left|X_s^{j,N} - \bar{X}_s^j\right|^2 = \frac{1}{N}\sum_j \left|\Delta_s^j\right|^2$. Bounding the drift difference through the pairwise structure gives, in its rawest form, the relabel-matched sum

$$|(B)| \le \frac{L}{N}\sum_{j=1}^N \left|X_s^{j,N} - \bar{X}_s^j\right| = \frac{L}{N}\sum_j \left|\Delta_s^j\right|,$$

the inequality being the pairwise structure used directly: $|(B)| = \left|\frac{1}{N}\sum_j [b_0(\bar{X}_s^i, X_s^{j,N}) - b_0(\bar{X}_s^i, \bar{X}_s^j)]\right| \le \frac{L}{N}\sum_j \left|\Delta_s^j\right|$ by Lipschitzness of b_0 in its second argument. The same control follows from the measure-Lipschitz part of (A-Lip) and the index-matching bound *after squaring*, $|(B)|^2 \le L^2\, \mathcal{W}_2(\mu_s^N, \bar{\mu}_s^N)^2 \le \frac{L^2}{N}\sum_j \left|\Delta_s^j\right|^2$, which is the form we will use in a moment. This term couples particle i to *all* the others through the averaged discrepancy; the crucial point, which exchangeability will exploit, is that it is the *same* average for every i.

Term (C) (the fluctuation). Here both the state $\bar{X}_s^i$ and the kernel are evaluated on the *twins*, and the only change is from their empirical measure $\bar{\mu}_s^N$ to its mean m_s. Written out under (7.2),

$$(C) = b(\bar{X}_s^i, \bar{\mu}_s^N) - b(\bar{X}_s^i, m_s) = \frac{1}{N}\sum_{j=1}^N b_0(\bar{X}_s^i, \bar{X}_s^j) - \int b_0(\bar{X}_s^i, z)\, m_s(\mathrm{d}z),$$

which is *exactly* the object of lemma 7.14 with $Z_j = \bar{X}_s^j$ (i.i.d. with law $\rho = m_s$, by definition 7.13), $\varphi = b(\cdot, m_s)$, and the tagged index i. Abbreviating $G_s^i := (C)$, the fluctuation lemma delivers, with no dependence on d,

$$\mathbb{E}\left[\left|G_s^i\right|^2\right] \le \frac{4\,\|b_0\|_\infty^2}{N}.$$

This is the only term that does not vanish as the gaps Δ^j shrink: it is the irreducible statistical noise of sampling m_s by N points, and it is what ultimately sets the $O(1/N)$ floor of the whole estimate.

Closing the loop by Grönwall. Collect the three bounds. From the integral form, for any $r \le t$, the path increment $\Delta_r^i = \int_0^r [(A) + (B) + (C)]\, \mathrm{d}s$ satisfies, by the Cauchy–Schwarz inequality in time $\left(\int_0^r f\, \mathrm{d}s\right)^2 \le r\int_0^r f^2\, \mathrm{d}s \le T\int_0^t f^2\, \mathrm{d}s$ (using $r \le t \le T$ and extending the nonnegative integrand to $[0, t]$) followed by $(a+b+c)^2 \le 3(a^2+b^2+c^2)$ on the integrand, the uniform bound

$$\sup_{r\le t}\left|\Delta_r^i\right|^2 \le 3T\int_0^t \left[\, |(A)|^2 + |(B)|^2 + |(C)|^2 \,\right] \mathrm{d}s \le 3T\int_0^t \left[L^2\left|\Delta_s^i\right|^2 + \tfrac{L^2}{N}\sum_j \left|\Delta_s^j\right|^2 + \left|G_s^i\right|^2\right] \mathrm{d}s.$$

Two of the three substitutions are immediate; the middle one used the Jensen (power-mean) inequality $\left(\frac{1}{N}\sum_j |\Delta_s^j|\right)^2 \le \frac{1}{N}\sum_j |\Delta_s^j|^2$, which is just convexity of $t \mapsto t^2$ applied to the average, converting the squared *average of magnitudes* from (B) into the *average of squared* magnitudes we can track. Now take expectations. Here exchangeability does the symmetrizing: because the system (7.1) and its coupled copies are exchangeable (proposition 7.6), the gaps Δ^j are identically distributed, so $\mathbb{E}\left[|\Delta_s^i|^2\right]$ is the same for every i and equals the average,

$$\mathbb{E}\left[\left|\Delta_s^i\right|^2\right] = \mathbb{E}\left[\tfrac{1}{N}\sum_j |\Delta_s^j|^2\right] =: \varepsilon_s.$$

This is the decisive simplification: the two different-looking terms $|(A)|^2$ and $|(B)|^2$, one carrying the particle's own gap and one the population average, collapse to the *same* scalar ε_s in expectation. Substituting and using $\mathbb{E}\Big[\big|G_s^i\big|^2\Big] \le 4\,\|b_0\|_\infty^2/N$,

$$\mathbb{E}\left[\sup_{r\le t}\left|\Delta_r^i\right|^2\right] \le 3T\int_0^t\Big(\underbrace{L^2\varepsilon_s}_{(A)}+\underbrace{L^2\varepsilon_s}_{(B)}+\underbrace{\tfrac{4\|b_0\|_\infty^2}{N}}_{(C)}\Big)\,\mathrm{d}s = 3T\int_0^t\Big(2L^2\varepsilon_s+\tfrac{4\|b_0\|_\infty^2}{N}\Big)\,\mathrm{d}s,$$

where the (B) contribution is $\mathbb{E}\Big[\frac{L^2}{N}\sum_j|\Delta_s^j|^2\Big] = L^2\mathbb{E}\Big[\frac{1}{N}\sum_j|\Delta_s^j|^2\Big] = L^2\varepsilon_s$, the same value as (A), so the two add to $2L^2\varepsilon_s$. Now invoke the elementary inequality $\varepsilon_t \le \mathbb{E}\Big[\sup_{r\le t}|\Delta_r^i|^2\Big]$ (the time-t value never exceeds the running supremum) to feed the left side back into the right, obtaining a closed Grönwall inequality for $u(t) := \mathbb{E}\Big[\sup_{r\le t}|\Delta_r^i|^2\Big]$:

$$u(t) \le 6TL^2\int_0^t u(s)\,\mathrm{d}s + \frac{12\,T\,\|b_0\|_\infty^2}{N}\,t.$$

Here the forcing term came from $3T\cdot t\cdot 4\,\|b_0\|_\infty^2/N$, and since $t\le T$ it is bounded by the nondecreasing constant $a := 12\,T^2\,\|b_0\|_\infty^2/N$; the linear coefficient is $B := 6TL^2$. The integral form of Grönwall's lemma (lemma C.1) with nondecreasing forcing gives $u(t)\le a\,e^{Bt}$, and at $t=T$ the exponent is $BT = 6TL^2\cdot T = 6T^2L^2$, so

$$\mathbb{E}\left[\sup_{t\le T}\left|\Delta_t^i\right|^2\right] \;\le\; \frac{12\,T^2\,\|b_0\|_\infty^2}{N}\,e^{6T^2L^2} \;=:\; \frac{C}{N},$$

which is (7.8), with the constant $C = 12\,T^2\,\|b_0\|_\infty^2\,e^{6T^2L^2}$ displayed in full. It depends on T, on the Lipschitz constant L, and on the sup-norm of the kernel—but not on N and, by the dimension-freeness of lemma 7.14, not on d.

Marginal consequences. Fix k and t. The paired array $((X_t^{1,N},\dots,X_t^{k,N}),(\bar X_t^1,\dots,\bar X_t^k))$, viewed as a single random element of $(\mathbb{R}^d)^k\times(\mathbb{R}^d)^k = \mathbb{R}^{dk}\times\mathbb{R}^{dk}$, is an *admissible coupling* of $\mathcal{L}(X_t^{1,N},\dots,X_t^{k,N})$ and $\mathcal{L}(\bar X_t^1,\dots,\bar X_t^k)$, since its two marginals are exactly those two laws. By the defining property of $\mathcal{W}_2$ on $\mathbb{R}^{dk}$—any coupling furnishes an upper bound—and the fact that squared Euclidean distance on $\mathbb{R}^{dk}$ is the sum of the per-particle squared distances,

$$\mathcal{W}_2\Big(\mathcal{L}(X_t^{1:k,N}),\,\mathcal{L}(\bar X_t^{1:k})\Big)^2 \le \sum_{i=1}^k\mathbb{E}\Big[\Big|X_t^{i,N}-\bar X_t^i\Big|^2\Big] = \sum_{i=1}^k\mathbb{E}\Big[\Big|\Delta_t^i\Big|^2\Big] \le \frac{Ck}{N},$$

each summand bounded by C/N from (7.8). But the twins are i.i.d. with law m_t, so $\mathcal{L}(\bar X_t^{1:k}) = m_t^{\otimes k}$ exactly, and the displayed inequality is the asserted $\mathcal{W}_2$ bound. Letting $N\to\infty$ with k fixed sends the right side to zero, so the k-marginal converges to $m_t^{\otimes k}$ in $\mathcal{W}_2$, hence weakly; this is precisely m_t-chaoticity (definition 7.11), now with the explicit rate $\sqrt{Ck/N}$. The case $k=1$ is the single-particle statement $\mathcal{W}_2(\mathcal{L}(X_t^{i,N}),m_t)\le\sqrt{C/N} = O(N^{-1/2})$. □

The estimate (7.8) is the precise, quantitative form of "fluctuations vanish in the thermodynamic limit": two pictures of the same particle—one embedded in the genuine N-body system, one evolving in the idealized mean field m_t—stay within L^2-distance $O(N^{-1/2})$ of each other, uniformly on $[0,T]$, and the constant does not deteriorate with the dimension of the state. Two features of what was just proved deserve to be flagged now, because the next subsection will hold the estimate up to honest scrutiny against exactly them. First, (7.8) bounds the distance between each *particle* and its *copy*—a trajectory-versus-twin bound—and not, at least not yet, the distance $\mathcal{W}_2(\mu_t^N, m_t)$ between the empirical measure and the limit; the two are related but not identical, and conflating them would overstate what we have. Second, the clean dimension-free constant $C = 12\,T^2\,\|b_0\|_\infty^2\,e^{6T^2L^2}$ rode entirely on the *bounded pairwise* structure, which is what let lemma 7.14 avoid the geometry of $\mathbb{R}^d$; and that same constant grows—quadratically in T inside the polynomial, exponentially in T^2 inside the exponential—so the bound is a statement about *bounded horizons*, not all time. Both points are taken up squarely in section 7.3.2. Before that, it is worth seeing the same result through the older eyes of kinetic theory, where it answers a question Boltzmann could only assume away.

Heuristic (non-rigorous): Molecular chaos and the unclosed hierarchy

The probabilist's coupling has a kinetic-theory shadow worth seeing, and reading it makes plain what propagation of chaos accomplishes that a physicist had long wanted. Start from the exact microscopic description. The joint density $f_N(t, x_1, \ldots, x_N)$ of the full N-body configuration of (7.1) obeys a *linear* Fokker–Planck equation in Nd dimensions—linear because, viewed as a single diffusion on $\mathbb{R}^{Nd}$ (the stacked process of proposition 7.6), the system is an ordinary Itô SDE whose forward Kolmogorov equation is the linear continuity-plus-diffusion equation of chapter 5. The catch is its dimension: Nd is astronomical, and one wants instead the evolution of the low-order marginals. So integrate out particles $2, \ldots, N$ to obtain an equation for the one-particle marginal $f_N^{(1)}(t, x_1) = \int f_N \,\mathrm{d}x_2 \cdots \mathrm{d}x_N$. Here the interaction strikes back: the drift on particle 1 is $\frac{1}{N}\sum_j b_0(x_1, x_j)$, and integrating its $j \neq 1$ terms against f_N produces a contribution involving the *two*-particle marginal $f_N^{(2)}(t, x_1, x_2)$—the equation for $f_N^{(1)}$ is not closed, because the force on one particle depends on where a second particle is. Seeking to close it by writing the equation for $f_N^{(2)}$ only defers the problem: that equation calls on $f_N^{(3)}$, which calls on $f_N^{(4)}$, and so on up an infinite tower. This is the BBGKY-type hierarchy: each marginal's evolution is enslaved to the next higher one, and no finite truncation is exact.

The mean-field *Stosszahlansatz*—Boltzmann's "molecular chaos" assumption, *Stosszahlansatz* meaning literally "collision-number hypothesis"—cuts the tower by *fiat*: it postulates that, in the limit, distinct particles are statistically independent, so the two-particle marginal factorizes, $f_N^{(2)}(t, x, y) \approx f^{(1)}(t, x)\, f^{(1)}(t, y)$. Substituting this factorization into the first equation of the hierarchy replaces the unknown $f_N^{(2)}$ by a product of the unknown $f^{(1)}$ with itself, and the result is a single *self-contained nonlinear* equation for $f^{(1)}$ alone—precisely the nonlinear Fokker–Planck equation that section 7.4 will write down and study, in which the drift depends on the very density being evolved. Closure is bought at the price of nonlinearity: the price of forgetting the higher marginals is that the first marginal must now feed back on itself.

The status of that factorization is the whole point. Boltzmann *assumed* it—it was a physical hypothesis about decorrelation, plausible but unproven, and the source of a century of debate about its validity and its compatibility with microscopic reversibility. What theorem 7.15 supplies is a *proof* of a quantitative, propagating version of exactly this hypothesis for the weakly interacting diffusions at hand: the k-marginals do factorize in the limit ($\mathcal{L}(X_t^{1:k,N}) \to m_t^{\otimes k}$), the factorization is not merely asymptotic but comes with the explicit rate $\sqrt{Ck/N}$, and—this is what "propagating" means—it holds *uniformly in time* across the whole horizon $[0,T]$, not just at the initial instant where it was posited. Chaos put in at $t=0$ (the i.i.d. initial data $X_0^{i,N} \sim m_0$) is shown to persist for all $t \le T$ despite the interaction's constant tendency to build up correlations. The one honest caveat is the horizon: the constant C grows with T (section 7.3.2), so what is proved is molecular chaos on bounded time intervals, with no claim, from this argument, about $t \to \infty$. This is the sense in which propagation of chaos is the rigorous incarnation of Boltzmann's *Stosszahlansatz*: the closure the physicist assumed to derive a kinetic equation is, here, a theorem with a rate.

7.3.2 Honest accounting of the rate and its dimension dependence

The proof of theorem 7.15 closed on two notes of caution, deliberately left hanging, and an honest theory must now make good on them. The estimate (7.8) is a beautiful thing—an $O(1/\sqrt{N})$ bound with a constant that does not so much as glance at the dimension d—and precisely because it is so clean it invites overstatement. There are exactly two ways a careless reader could claim more than was proved, and this subsection forecloses both. The first concerns *what* is being measured: the theorem bounds the distance between a particle and its mean-field copy, which is *not* the same as the distance between the empirical measure and its limit, and the difference between the two is exactly where the curse of dimension hides. The second concerns *for how long*: the constant C carries a factor $e^{6T^2L^2}$, so the bound is strong on any fixed horizon but degrades catastrophically as $T \to \infty$, and nothing in the argument survives uniformly in time. We take the two in turn, and in doing so we draw the cleanest possible line between what this book proves from the inside and what it merely quotes from the outside for orientation—a line that matters, because the whole point of the self-containedness discipline is that no conclusion here should secretly lean on an unproved external fact.

First caveat: trajectory rate versus empirical-measure rate. Theorem 7.15 controls $\mathbb{E}\Big[\sup_t \Big|X_t^{i,N} - \bar{X}_t^i\Big|^2\Big]$, the mean-square gap between the ith genuine particle and its mean-field twin $\bar{X}^i$. It is tempting to read off from this a rate for the quantity one most often wants in practice—the speed at which the *empirical measure* $\mu_t^N = \frac{1}{N}\sum_j \delta_{X_t^{j,N}}$ of the real system approaches the limit law m_t in $\mathcal{W}_2$—but the two are genuinely different questions, and the theorem settles only the first. To see exactly how they relate, insert the empirical measure $\bar{\mu}_t^N := \frac{1}{N}\sum_j \delta_{\bar{X}_t^j}$ of the *twins* as an intermediary and apply the triangle inequality for $\mathcal{W}_2$:

$$\mathcal{W}_2(\mu_t^N, m_t) \;\le\; \underbrace{\mathcal{W}_2(\mu_t^N, \bar{\mu}_t^N)}_{\text{(coupling)}} + \underbrace{\mathcal{W}_2(\bar{\mu}_t^N, m_t)}_{\text{(statistics)}}. \tag{7.9}$$

The split is the whole story, because the two terms are answered by two utterly different mechanisms. The first compares the empirical measure of the real particles to the empirical measure of their twins—two clouds of N atoms indexed the same way—so the index-matching bound lemma 7.5 applies atom by atom and the coupling controls it directly:

$$\mathbb{E}\Big[\mathcal{W}_2(\mu_t^N, \bar{\mu}_t^N)^2\Big] \;\le\; \mathbb{E}\Big[\tfrac{1}{N}\textstyle\sum_{j=1}^N \Big|X_t^{j,N} - \bar{X}_t^j\Big|^2\Big] = \mathbb{E}\Big[\tfrac{1}{N}\textstyle\sum_j \Big|\Delta_t^j\Big|^2\Big] \;\le\; \dfrac{C}{N},$$

the last step by exchangeability ($\mathbb{E}\Big[\Big|\Delta_t^j\Big|^2\Big]$ is the same for every j and bounded by C/N from (7.8)). This term is therefore $O(1/N)$ in mean square, *dimension-free*, inherited wholesale from the trajectory bound. The second term carries no particle dynamics at all: $\bar{\mu}_t^N$ is the empirical measure of N *i.i.d.* samples from m_t (the twins are i.i.d. with law m_t by construction), so $\mathcal{W}_2(\bar{\mu}_t^N, m_t)$ is precisely the textbook quantity "how fast does the empirical measure of an i.i.d. sample converge to its parent law in Wasserstein distance?" That is a pure question of statistics, with nothing to do with the interaction, the coupling, or the SDE—and it is the term where the dimension reappears with a vengeance.

Remark 7.16 (The statistical rate and the curse of dimension)**.** The contrast packed into the two terms of (7.9) is the central conceptual lesson of this subsection, and it deserves to be stated as such rather than buried: the *coupling* term is dimension-free, while the *statistical* term is dimension-cursed, and understanding why is understanding what the Sznitman bound really bought us. We begin with the external fact that quantifies the curse. We quote it purely for orientation; *no result of this chapter depends on it*, a point we return to and underline below. For N i.i.d. samples from a measure ρ on $\mathbb{R}^d$ possessing a finite moment of order $q > 4$, the sharp rate of Fournier and Guillin [69] is

$$\mathbb{E}\Big[\mathcal{W}_2(\bar{\mu}^N, \rho)^2\Big] \;\lesssim\; \begin{cases} N^{-1/2}, & d < 4, \\ N^{-1/2}\log N, & d = 4, \\ N^{-2/d}, & d > 4. \end{cases} \tag{7.10}$$

Two features of (7.10) matter for us. The first is the moment caveat, which we state honestly rather than suppress: the displayed clean cases require the parent law to have a finite moment of order $q > 4$; for a thinner tail with only $2 < q \le 4$ finite moments an extra additive term $N^{-(q-2)/q}$, slower than $N^{-1/2}$, appears and degrades the $d < 4$ line. The second is the dimensional phase transition: below $d = 4$ the empirical measure converges at the central-limit rate $N^{-1/2}$, but above it the rate deteriorates to $N^{-2/d}$, which for, say, $d = 10$ is only $N^{-1/5}$—one would need $N \approx 10^{10}$ samples to match what $N \approx 100$ achieves in the plane. This is the celebrated *curse of dimension* for empirical measures: filling out a d-dimensional law to Wasserstein accuracy ε needs on the order of ε^{-d} samples, because $\mathcal{W}_2$ asks the samples to reproduce the parent's *geometry*, and covering a d-dimensional shape with little balls is exponentially expensive in d.

Here is the resolution of the apparent paradox—how can (7.8) be dimension-free when (7.10) is not? The answer is that the two bounds measure the drift's dependence on the population through entirely different lenses. In the Sznitman proof the population entered the estimate *only* through term (C), the fluctuation, and there the drift read the empirical measure not through its full Wasserstein geometry but through the scalar averages $\frac{1}{N}\sum_j b_0(\bar{X}_s^i, \bar{X}_s^j) = \int b_0(\bar{X}_s^i, z)\,\bar{\mu}_s^N(\mathrm{d}z)$. A scalar average of a *bounded* kernel is a one-dimensional random variable no matter how large d is, and its fluctuation about its mean is $O(N^{-1/2})$ by the elementary variance count of lemma 7.14—a count that, as we stressed there, used only the sup-norm $\|b_0\|_\infty$ and the additivity of variances of independent terms, neither of which can see the dimension. The drift, in other words, never asked the empirical measure to be close to m_s in $\mathcal{W}_2$; it asked only that a handful of bounded scalar moments of $\bar{\mu}_s^N$ be close to those of m_s, and *that* weaker demand is met at the dimension-free central-limit rate. The full Wasserstein distance $\mathcal{W}_2(\bar{\mu}_s^N, m_s)$ is a far more stringent thing to control—it demands the whole geometry, not a few bounded test functions—and it is that stringency, not anything about the particle system, that the Fournier–Guillin rate prices in. The lesson is precise and worth carrying forward: *a dimension-free propagation-of-chaos rate is bought by the bounded, averaged way the drift reads the population, and is lost exactly when one insists on the full empirical-measure geometry.*

This also marks the boundary of the dimension-free regime, which honesty requires us to draw. The escape hatch was the bounded pairwise structure (7.2): it is what let term (C) be a bounded scalar average. For a *general* drift $b(x, \mu)$ that is merely Lipschitz in the measure slot—no pairwise kernel, no boundedness—the intermediate-term decomposition of the Sznitman proof still goes through unchanged up to term (C), but $(C) = b(\bar{X}_s^i, \bar{\mu}_s^N) - b(\bar{X}_s^i, m_s)$ can no longer be routed through lemma 7.14; the only tool left is the measure-Lipschitz bound itself,

$$|(C)| \;\le\; L\,\mathcal{W}_2(\bar{\mu}_s^N, m_s),$$

and the Grönwall step then closes on $\max_i \mathbb{E}\Big[\sup_t |\Delta_t^i|^2\Big] \le C \int_0^T \mathbb{E}\Big[\mathcal{W}_2(\bar{\mu}_s^N, m_s)^2\Big]\,\mathrm{d}s$. At this point the forcing is exactly the i.i.d. empirical-measure error of (7.9), and the Fournier–Guillin rate (7.10) becomes the best available input: the propagation-of-chaos rate then inherits the curse, degrading to $N^{-2/d}$ in high dimension. So the dimension-freeness is a property of bounded pairwise interactions, not of propagation of chaos as such.

We close the remark by foregrounding the honesty point, because it is the reason (7.10) appears here at all. *Not one in-book result rests on the Fournier–Guillin estimate.* It is quoted only to explain what would happen outside the bounded-pairwise setting and to put a name to the curse; the actual rate proved in this chapter, the clean $O(1/\sqrt{N})$ of theorem 7.15, rests entirely on the in-book lemma 7.14, whose proof we gave in full and which needs nothing beyond elementary variance bookkeeping. The self-containedness of the chapter is therefore intact: a reader who struck (7.10) and this whole remark from the text would lose a piece of orientation but not a single theorem. We flag the matter explicitly so that the $O(1/\sqrt{N})$ rate is never silently transported to settings (high dimension, general Lipschitz drift, empirical-measure convergence) where it has not been earned.

Second caveat: the horizon constant and the absence of long-time uniformity. The second place the bound could be overstated is in time. The constant in (7.8) was displayed in full as $C = 12\,T^2\,\|b_0\|_\infty^2\,e^{6T^2L^2}$, and the exponential factor $e^{6T^2L^2}$ is not a blemish to be polished away—it is the honest signature of the Grönwall argument that produced it. Recall where it came from: the self-coupling term (A) fed each particle's own gap back into the estimate, and the relabel-matched term (B) fed in the population-averaged gap, so the closed inequality for $u(t) = \mathbb{E}\Big[\sup_{r\le t} |\Delta_r^i|^2\Big]$ carried a linear coefficient $B = 6TL^2$ and Grönwall paid for it with $e^{BT} = e^{6T^2L^2}$. The bound is thus excellent for any *fixed* horizon—on $[0, T]$ it is genuinely $O(1/\sqrt{N})$, dimension-free, with a constant one can write down—but it says nothing whatsoever uniform in T: as $T \to \infty$ the prefactor explodes, and for N fixed the guarantee is vacuous once T is large enough that $e^{6T^2L^2}/N \gtrsim 1$. Reading the estimate as a statement valid for all time would be precisely the overclaim this subsection exists to prevent.

Whether propagation of chaos in fact holds *uniformly* in time is a real and harder question, and the Grönwall route is structurally incapable of answering it, because a worst-case Lipschitz bound only ever lets correlations grow. Obtaining a horizon-free rate requires a genuinely different input: some mechanism that makes the dynamics *contract* rather than merely fail to expand too fast—a convex or strongly monotone drift, a confining potential, a dissipativity condition—so that the correlations built up by the interaction are continually damped instead of accumulating. That is a separate theory with its own hypotheses, and we do not develop it here; we will meet the relevant structural conditions, and the long-time behaviour they buy, when uniform-in-time estimates become indispensable for the equilibrium analysis of chapter 13. For the descriptive theory of the present chapter, bounded horizons are exactly the right setting, and within them the rate is honest and sharp.

With both caveats squarely on the table, the descriptive analytic story of the limit is now complete and honestly told. We have a unique limiting law—the McKean–Vlasov solution of section 7.2—and we know, at the level of *trajectories*, the precise sense and rate in which the finite-N reality converges to it: each particle tracks its mean-field copy to L^2-accuracy $O(N^{-1/2})$ on any fixed horizon, dimension-free, with everything that claim does and does not assert pinned down. The flow of marginals $t \mapsto m_t$ has thereby earned two independent identities. It is the law of the representative particle, constructed by the fixed point of theorem 7.9; and it is the concentration limit of the fluctuating empirical measure, certified by the propagation-of-chaos estimates just audited. There remains one face of this single limiting object still to draw—its evolution as a measure in its own right—and it is where we turn next: section 7.4 takes the very same deterministic flow m_t and asks for its evolution equation, recovering the nonlinear Fokker–Planck equation as the forward (adjoint) law of the McKean–Vlasov diffusion and, under the nondegeneracy (A-Nondeg) held in reserve until now, as a genuine PDE for a smooth density.

7.4 The nonlinear Fokker–Planck equation

By now the deterministic flow of measures $t \mapsto m_t$ has been met from two directions, and they agree. Section 7.2 produced it as the marginal law $m_t = \mathcal{L}(X_t)$ of the unique McKean–Vlasov solution, a continuous curve in $\big(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2\big)$ obtained as the fixed point of the freeze-solve-read-off map Φ; sections 7.3 to 7.3.2 then certified that this same m_t is the genuine $N \to \infty$ limit of the fluctuating empirical measure μ_t^N, with a quantitative $O(1/\sqrt{N})$ rate. What we have so far *not* done is describe how m_t moves in its own right—as a point in measure space tracing out a curve, obeying its own equation, with no particle and no representative path in sight. This is the third and final face of the single limiting object the chapter promised: a partial differential equation for the marginal flow. Supplying it is the business of this section, and it completes the triangle SDE $\leftrightarrow$ law $\leftrightarrow$ PDE whose three vertices are three descriptions of one thing.

The viewpoint that produces such an equation is the *forward*, or adjoint, one, and it is worth recalling why a diffusion law has two complementary evolution equations rather than one. A test function carried by the process, $\phi(X_t)$, evolves under the generator $\mathcal{A}$; this is the *backward* picture, in which one propagates observables. Dually, the distribution of the process—the density that the observables are integrated against—evolves under the formal adjoint $\mathcal{A}^*$; this is the *forward* picture, in which one propagates the state of the population. We follow throughout the global convention fixed in appendix A: *densities evolve forward*, from initial data m_0 specified at $t = 0$, driven by $\mathcal{A}^*$; value functions (which will arrive only with the game of Part II) evolve backward from terminal data at $t = T$, driven by $\mathcal{A}$. The marginal flow m_t is a density in exactly this sense, so it is an object the forward equation governs. The only feature that distinguishes the present situation from the ordinary Fokker–Planck equation of chapter 5 is the one the whole chapter has been organized around: the coefficients of the generator depend on the very law they transport.

To say this precisely we must first name the generator at a *frozen* measure argument, because that is the only honest linear object available—the full generator's measure-dependence is what makes the equation nonlinear, and one cannot adjoin a nonlinear operator term by term until the measure is held fixed. For a fixed $m \in \mathcal{P}_2(\mathbb{R}^d)$ the McKean–Vlasov diffusion $\mathrm{d}X_t = b(X_t, m)\ \mathrm{d}t + \sigma\ \mathrm{d}W_t$ is an ordinary Itô diffusion with constant volatility, and its generator is the second-order elliptic operator

$$(\mathcal{A}_m\phi)(x) = b(x, m) \cdot \nabla\phi(x) + \tfrac{1}{2}\,\mathrm{tr}\big(\sigma\sigma^\top\, \mathrm{D}^2\, \phi(x)\big),$$

the first term a transport (drift) term, the second a diffusion term with the constant matrix $\sigma\sigma^\top$. Its formal adjoint $\mathcal{A}_m^*$, obtained by integrating $\int(\mathcal{A}_m\phi)\,\rho\ \mathrm{d}x = \int \phi\,(\mathcal{A}_m^*\rho)\ \mathrm{d}x$ by parts twice against a smooth density ρ, is

$$(\mathcal{A}_m^*\rho)(x) = -\,\mathrm{div}\big(b(x, m)\,\rho(x)\big) + \tfrac{1}{2}\sum_{i,j}(\sigma\sigma^\top)_{ij}\,\partial^2_{ij}\rho(x),$$

the transport term acquiring a divergence (the sign flip of one integration by parts) and the diffusion term returning to itself (two integrations by parts restoring the sign). The nonlinear Fokker–Planck equation is what results when one evaluates this frozen adjoint at the very measure being transported, $m = m_t$. We can now state the theorem, which packages three claims: that m_t solves this equation weakly, that it is the *unique* such weak solution, and that under nondegeneracy the solution is in fact a classical, smooth, strictly positive density.

Theorem 7.17 (Nonlinear Fokker–Planck equation)**.** *Under assumption 7.3 and $m_0 \in \mathcal{P}_2(\mathbb{R}^d)$, the marginal flow $m_t = \mathcal{L}(X_t)$ of the unique solution of (7.4) is the unique weak solution in $C([0, T]; \mathcal{P}_2(\mathbb{R}^d))$ of the* nonlinear Fokker–Planck *(McKean–Vlasov) equation*

$$\partial_t m_t = \mathcal{A}_{m_t}^* m_t = -\,\mathrm{div}\big(b(\cdot, m_t)\, m_t\big) + \tfrac{1}{2}\sum_{i,j}(\sigma\sigma^\top)_{ij}\,\partial^2_{ij} m_t, \qquad m_t\big|_{t=0} = m_0, \tag{7.11}$$

in the sense that for every $\phi \in C_c^\infty(\mathbb{R}^d)$ and $t \in [0, T]$,

$$\int_{\mathbb{R}^d}\phi\ \mathrm{d}m_t = \int_{\mathbb{R}^d}\phi\ \mathrm{d}m_0 + \int_0^t\!\int_{\mathbb{R}^d}\Big(b(x, m_s)\cdot\nabla\phi(x) + \tfrac{1}{2}\,\mathrm{tr}\left(\sigma\sigma^\top\,\mathrm{D}^2\,\phi(x)\right)\Big)\, m_s(\mathrm{d}x)\ \mathrm{d}s. \tag{7.12}$$

Under (A-Nondeg), for every $t > 0$ the measure m_t has a strictly positive density in $C^\infty(\mathbb{R}^d)$ that solves (7.11) classically.

Proof. From SDE to PDE. The existence half is a direct application of Itô's formula and costs almost nothing, which is the whole point of the forward viewpoint: the SDE already *is* the law's evolution, one need only read it through a test function. Take any $\phi \in C_c^\infty(\mathbb{R}^d)$ and apply Itô's formula (theorem 5.9) to the process $\phi(X_t)$ along the McKean–Vlasov solution. Because the diffusion has the generator $\mathcal{A}_{m_s}$ at time s (its measure slot being the genuine marginal $m_s = \mathcal{L}(X_s)$), this gives

$$\phi(X_t) = \phi(X_0) + \int_0^t \mathcal{A}_{m_s}\phi(X_s)\, \mathrm{d}s + \int_0^t \nabla\phi(X_s)^\top \sigma\, \mathrm{d}W_s,$$

the Itô correction $\frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2\phi)$ already absorbed into $\mathcal{A}_{m_s}\phi$. The last term is a stochastic integral, and the crux is that it is a *true* martingale, not merely a local one—for only then does its expectation vanish. This is where the two standing controls earn their keep: its quadratic variation is $\int_0^t \left|\sigma^\top\nabla\phi(X_s)\right|^2 \mathrm{d}s$, whose expectation is bounded by $\|\sigma\|^2\, \|\nabla\phi\|_\infty^2\, t < \infty$ because $\nabla\phi$ is bounded (here $\phi \in C_c^\infty$ suffices) and, more generally, finite second moments $\sup_{t\le T}\mathbb{E}\Big[|X_t|^2\Big] < \infty$ (theorem 7.9) keep every such integrand integrable. A stochastic integral with square-integrable integrand is a genuine martingale of mean zero, so taking expectations annihilates the last term. Using $\mathbb{E}[\phi(X_s)] = \int \phi\, \mathrm{d}m_s$ on the remaining terms and $m_s = \mathcal{L}(X_s)$ inside the generator yields exactly the weak identity (7.12). The strong form (7.11) is nothing more than its distributional restatement: (7.12) says $\frac{\mathrm{d}}{\mathrm{d}t}\int \phi\, \mathrm{d}m_t = \int \mathcal{A}_{m_t}\phi\, \mathrm{d}m_t = \int \phi\,(\mathcal{A}_{m_t}^* m_t)$ for all test ϕ, which is the definition of $\partial_t m = \mathcal{A}_m^* m$ in the sense of distributions. Existence of a weak solution is thereby settled, and with no use whatsoever of (A-Nondeg): the forward equation holds for the law of *any* Itô diffusion, degenerate or not.

Uniqueness, by duality against the backward equation. Uniqueness is the substantial half, and it is where the chapter's most technical sketch lives. The danger is real: a nonlinear forward PDE can in principle have several weak solutions sharing the same datum, and nothing in the existence argument rules that out. Our strategy converts the question back into one we have already answered. Let $\tilde{m} \in C([0,T];\mathcal{P}_2(\mathbb{R}^d))$ be *any* weak solution of (7.12) with datum m_0. We will show that $\tilde{m}$ is forced to be a fixed point of the very map Φ of theorem 7.9—the freeze-solve-read-off map whose *unique* fixed point is the marginal flow m. Since Φ has exactly one fixed point, $\tilde{m} = m$ follows, and uniqueness for the PDE is inherited from the contraction already proved for the SDE. The device that achieves this is a self-contained *Holmgren duality*: against the forward equation we test not a fixed function but a cleverly chosen *time-dependent* one—the solution of the corresponding backward equation—engineered so that the two evolutions annihilate each other. No external "superposition principle" (the abstract theorem that every weak solution of a Fokker–Planck equation is the law of some diffusion) is invoked; we build the bridge by hand, and (A-Nondeg) is precisely what makes the bridge load-bearing, by guaranteeing the backward solution is smooth enough to test against.

Begin by *freezing the coefficient along the candidate.* Set $\beta_s(x) := b(x,\tilde{m}_s)$; this turns the nonlinear drift into a prescribed, honestly (s,x)-dependent field, because the measure slot has been filled in advance by the *given* curve $\tilde{m}$ we are testing. The freezing inherits good properties from the standing hypotheses: since $s \mapsto \tilde{m}_s$ is $\mathcal{W}_2$-continuous (it lies in $C([0,T];\mathcal{P}_2(\mathbb{R}^d))$) and b is jointly Lipschitz (A-Lip), the field β is continuous in (s,x), globally L-Lipschitz in x uniformly in s, and of linear growth uniformly in s (the growth bound (A-Growth) contributes the moment $\left(\int |y|^2\, \tilde{m}_s(\mathrm{d}y)\right)^{1/2}$, finite and bounded because $\sup_s \int |y|^2\, \tilde{m}_s(\mathrm{d}y) < \infty$ on the compact interval).

These are exactly the regularity properties a linear SDE needs to be well-posed and a linear parabolic equation needs to be solvable.

Now build the test object. Fix a terminal time $\tau \in (0, T]$ and a target observable $\psi \in C_c^\infty(\mathbb{R}^d)$, and let $X^{s,x}$ denote the solution of the *frozen linear* SDE $\mathrm{d}X_r = \beta_r(X_r)\,\mathrm{d}r + \sigma\,\mathrm{d}W_r$ on $[s, \tau]$ started from $X_s = x$. This is an ordinary SDE—no law-dependence remains—so the theory of chapter 5 applies directly. Define the candidate test function as the expected terminal payoff,

$$v(s,x) := \mathbb{E}\big[\psi(X_\tau^{s,x})\big]\,,$$

the value, started at (s, x), of observing ψ at the fixed terminal time τ. This is the Feynman–Kac functional of the frozen problem, and the reason for defining it this way is that it automatically solves the backward equation, which is the equation we need to cancel against the forward one. Indeed, by the backward Kolmogorov / Feynman–Kac representation (theorems 5.15 and 5.16), v solves the *backward* Kolmogorov equation of the frozen diffusion,

$$\partial_s v + \mathcal{A}_{\tilde{m}_s} v = \partial_s v + \beta_s \cdot \nabla v + \tfrac{1}{2}\operatorname{tr}\big(\sigma\sigma^\top \mathrm{D}^2 v\big) = 0 \quad \text{on } [0,\tau), \qquad v(\tau,\cdot) = \psi, \tag{7.13}$$

with the generator at time s being precisely the frozen generator $\mathcal{A}_{\tilde{m}_s}$ that appears in the weak form (7.12). This matching of operators—the backward equation for v carries the *same* $\mathcal{A}_{\tilde{m}_s}$ that the forward weak form pairs against $\tilde{m}_s$—is the entire mechanism of the duality, and it is why v was built from this particular frozen drift and no other.

For the cancellation to be legitimate, v must be smooth enough to serve as a test function in (7.12), and this is the single place where nondegeneracy is indispensable. Under (A-Nondeg) the operator $\mathcal{A}_{\tilde{m}_s}$ is *uniformly parabolic*—its principal part $\frac{1}{2}\sigma\sigma^\top \succeq \frac{\lambda}{2} I$ is strictly positive definite—so the backward equation (7.13) regularizes its terminal datum. Concretely, the interior parabolic regularity theorem theorem C.12(2), applied locally after truncating β outside a large ball (a truncation that changes the equation only far from where we look and so does not affect interior smoothness), upgrades the merely bounded datum ψ to a classical solution $v \in C^{1,2}([0,\tau] \times \mathbb{R}^d)$. Three quantitative bounds come with it, and we will use all three. First, $|v| \le \|\psi\|_\infty$, since v is an average of values of ψ. Second, ∇v and $\mathrm{D}^2 v$ are bounded and continuous, which one can see probabilistically: $v(s,x) = \mathbb{E}[\psi(X_\tau^{s,x})]$ and the flow $x \mapsto X_\tau^{s,x}$ has an L^2-bounded derivative (the Lipschitz dependence of an SDE solution on its initial datum, chapter 5), so differentiating under the expectation against $\psi \in C_c^\infty$ and $\mathrm{D}^2\psi \in C_c^\infty$ produces bounded derivatives of v. Had the diffusion been allowed to degenerate, the regularization would fail, v might be only Lipschitz, $\mathrm{D}^2 v$ would not exist, and there would be no C^2 object to test against the weak form—this is the precise sense in which (A-Nondeg) "makes the duality work." In sum, for each s the function $v(s,\cdot)$ is a bounded C^2 test function with bounded derivatives, exactly the class (7.12) admits once we account for the explicit s-dependence and the non-compact support, which is the next step.

Now test the weak formulation against this time-dependent function and watch the two evolutions cancel. We want to differentiate the scalar map $s \mapsto \int_{\mathbb{R}^d} v(s,\cdot)\,\mathrm{d}\tilde{m}_s$, which couples two motions: the explicit time-dependence of v and the time-dependence of the measure $\tilde{m}_s$. The weak identity (7.12) as stated applies to a *time-independent* test function of *compact support*, whereas $v(s,\cdot)$ has both explicit s-dependence and full (non-compact) support. Two routine approximations remove exactly these two gaps, and because the section's blueprint asks that "routine" be earned, we carry them out.

(i) The compact-support cutoff. Choose cutoffs $\chi_R \in C_c^\infty(\mathbb{R}^d)$ with $\chi_R \equiv 1$ on $\{|x| \le R\}$, $0 \le \chi_R \le 1$, supported in $\{|x| \le 2R\}$, and with $|\nabla \chi_R| \le c/R$ and $\left|\mathrm{D}^2 \chi_R\right| \le c/R^2$ (rescaled copies of one fixed bump). For each fixed s the product $v(s,\cdot)\chi_R \in C_c^\infty(\mathbb{R}^d)$ is an admissible test function, so (7.12) applies to it verbatim. We must check that letting $R \to \infty$ recovers the same identity with $v(s,\cdot)$ itself, i.e. that the cutoff error vanishes. The error is concentrated on the annulus $\{R \le |x| \le 2R\}$, where χ_R is not identically 1, and it enters only through the generator term: writing out $\mathcal{A}_{\tilde m_s}(v\chi_R) - \chi_R \mathcal{A}_{\tilde m_s} v$, the extra contributions are the terms in which at least one derivative falls on χ_R, namely

$$b(x, \tilde m_s) \cdot v\, \nabla \chi_R + \mathrm{tr}(\sigma\sigma^\top \nabla v \otimes \nabla \chi_R) + \tfrac{1}{2}\, v\, \mathrm{tr}(\sigma\sigma^\top \mathrm{D}^2 \chi_R),$$

all supported on $\{R \le |x| \le 2R\}$. On that annulus $|\nabla \chi_R| \le c/R$ and $\left|\mathrm{D}^2 \chi_R\right| \le c/R^2$, while $|v| \le \|\psi\|_\infty$ and $|\nabla v|$ are bounded (from the regularity step) and $|b(x, \tilde m_s)| \le L(1 + |x| + M)$ grows at most linearly by (A-Growth), with $M := \sup_s (\int |y|^2\, \tilde m_s)^{1/2}$ finite. Hence the whole extra integrand is bounded pointwise by $C\, \frac{1}{R}(1 + |x|)$ on the annulus (the dominant term being the drift one, of size $\frac{c}{R} \cdot |x|$; the Hessian term is even smaller, $O(1/R^2)$), and integrating against $\tilde m_s$,

$$\left| \int_{\mathbb{R}^d} [\mathcal{A}_{\tilde m_s}(v\chi_R) - \chi_R \mathcal{A}_{\tilde m_s} v]\, \mathrm{d}\tilde m_s \right| \;\le\; \frac{c}{R} \int_{\{|x| \ge R\}} (1 + |x|)\, \tilde m_s(\mathrm{d}x) \xrightarrow[R\to\infty]{} 0,$$

the limit being zero because $\sup_s \int (1 + |x|^2)\, \tilde m_s(\mathrm{d}x) < \infty$ forces the tail integral $\int_{|x| \ge R} (1 + |x|)\, \mathrm{d}\tilde m_s$ to vanish as $R \to \infty$ (uniformly in s, by dominated convergence against the finite uniform second-moment bound). This is exactly the point at which (A-Growth) pays for itself: it both bounds the drift on the annulus and, through the finite second moments it guarantees, kills the tail. Together with the elementary facts $\int v\chi_R\, \mathrm{d}\tilde m_s \to \int v\, \mathrm{d}\tilde m_s$ and $\int \chi_R \mathcal{A}_{\tilde m_s} v\, \mathrm{d}\tilde m_s \to \int \mathcal{A}_{\tilde m_s} v\, \mathrm{d}\tilde m_s$ (dominated convergence, since the integrands are bounded), the cutoff limit shows that (7.12) holds with the full, non-compactly-supported $v(s,\cdot)$ in place of a compactly supported ϕ.

(ii) The explicit time-dependence. It remains to differentiate $F(s) := \int_{\mathbb{R}^d} v(s,\cdot)\, \mathrm{d}\tilde m_s$ in s. Two effects contribute, and the product rule separates them: the change of v at frozen measure, $\partial_s v$, and the change of the measure at frozen v, governed by the weak form. Rigorously, fix s and write the increment $F(s+h) - F(s)$ as

$$\underbrace{\int [v(s+h,\cdot) - v(s,\cdot)]\, \mathrm{d}\tilde m_{s+h}}_{\to \int \partial_s v\, \mathrm{d}\tilde m_s} + \underbrace{\left(\int v(s,\cdot)\, \mathrm{d}\tilde m_{s+h} - \int v(s,\cdot)\, \mathrm{d}\tilde m_s \right)}_{\to \int \mathcal{A}_{\tilde m_s} v\, \mathrm{d}\tilde m_s \text{ by (7.12)}}.$$

The first bracket, divided by h, converges to $\int \partial_s v\, \mathrm{d}\tilde m_s$ because $\partial_s v$ is continuous and bounded on the relevant compacts (it equals $-\mathcal{A}_{\tilde m_s} v$, bounded by the regularity step) and $\tilde m_{s+h} \to \tilde m_s$ weakly; the second bracket, divided by h, converges to $\int \mathcal{A}_{\tilde m_s} v\, \mathrm{d}\tilde m_s$ by the extended weak identity just established, applied to the fixed test function $v(s,\cdot)$. Both limits are legitimate precisely because v and its first two spatial derivatives, and $\partial_s v$, are bounded and continuous—the dividend of nondegeneracy. Thus $s \mapsto F(s)$ is absolutely continuous with

$$\frac{\mathrm{d}}{\mathrm{d}s} \int_{\mathbb{R}^d} v(s,\cdot)\, \mathrm{d}\tilde m_s = \int_{\mathbb{R}^d} (\partial_s v + \mathcal{A}_{\tilde m_s} v)\, \mathrm{d}\tilde m_s = 0,$$

the integrand vanishing *identically* by the backward equation (7.13). This is the cancellation the construction was designed to produce: v was chosen so that its own backward evolution exactly annuls the forward evolution of $\tilde{m}$.

A constant function—that is what F now is—may be evaluated at the two endpoints, and the two endpoints are exactly the two laws we want to compare. At $s = \tau$, the terminal datum $v(\tau, \cdot) = \psi$ gives $F(\tau) = \int_{\mathbb{R}^d} \psi \, \mathrm{d}\tilde{m}_\tau$. At $s = 0$, we read off the duality identity in full:

$$\int_{\mathbb{R}^d} \psi \, \mathrm{d}\tilde{m}_\tau \;=\; F(\tau) = F(0) = \int_{\mathbb{R}^d} v(0, \cdot) \, \mathrm{d}m_0 \;=\; \int_{\mathbb{R}^d} \mathbb{E}\Big[\psi(X_\tau^{0,x})\Big] \, m_0(\mathrm{d}x) \;=\; \mathbb{E}\Big[\psi(\widehat{X}_\tau)\Big] \;=\; \int_{\mathbb{R}^d} \psi \, \mathrm{d}\,\Phi(\tilde{m})_\tau.$$

Each equality earns its place: the first is $F(\tau) = F(0)$ (F constant); the second is the definition of $F(0)$ with datum m_0; the third unfolds $v(0, x) = \mathbb{E}\big[\psi(X_\tau^{0,x})\big]$; the fourth recognizes that averaging the started-at-x frozen process over $x \sim m_0$ is the same as running the single frozen-drift process $\widehat{X}$ from a random start $X_0 \sim m_0$ (the tower property); and the last is the *definition* of Φ—running the frozen SDE with drift $\beta_s = b(\cdot, \tilde{m}_s)$ from m_0 and reading off its time-τ law is exactly $\Phi(\tilde{m})_\tau$. Since $\psi \in C_c^\infty$ was arbitrary, two measures that integrate every such ψ to the same number are equal, so $\tilde{m}_\tau = \Phi(\tilde{m})_\tau$ for every $\tau \in [0, T]$. That is to say, $\tilde{m}$ is a fixed point of Φ. But Φ has the *unique* fixed point m (theorem 7.9), so $\tilde{m} = m$, and weak solutions are unique. (Note where the two hypotheses split the labor: (A-Nondeg) delivered the smooth v that made the test legitimate, while (A-Growth) guaranteed no blow-up and the finite moments that drove the cutoff limit. Remove the former and the duality has nothing to test against; remove the latter and the tail error need not vanish.)

Regularity. The last claim of the theorem is a bonus that costs nothing once uniqueness has pinned m down, and it is the one place where nondegeneracy buys not just a proof technique but an improved *conclusion*. With $m_s = \mathcal{L}(X_s)$ now established as *the* determined flow, the coefficient $b(\cdot, m_s)$ is no longer an unknown feeding back on itself: it is a fixed, known field. So (7.11) read forward is now an honest *linear* Fokker–Planck equation, with coefficient $b(\cdot, m_s)$—Lipschitz in x and continuous (hence locally Hölder) in (s, x) on bounded sets—and uniformly elliptic principal part $\frac{1}{2}\sigma\sigma^\top \succeq \frac{\lambda}{2} I$ supplied once more by (A-Nondeg). The forward parabolic regularity theorem theorem C.12(3), applied locally to accommodate the linear growth of the drift, then yields that for every $t > 0$ the measure m_t possesses a density in $C^\infty(\mathbb{R}^d)$ solving (7.11) in the classical (pointwise) sense, and that this density is *strictly positive* everywhere, by the parabolic strong maximum principle recorded in the same theorem. The strict positivity has a clean physical reading: a nondegenerate diffusion instantaneously spreads mass to every point of space, so no region can stay empty for any positive time—the hallmark of an irreducible, fully smoothing dynamics. Without (A-Nondeg) none of this survives: a degenerate or vanishing diffusion can leave m_t singular (think of a deterministic flow concentrating mass on a lower-dimensional set), and the equation would hold only in the weak, measure-valued sense established above. □

It is worth pausing on what the theorem says structurally, because it isolates the single source of difficulty and points to the worked computation that exploits its collapse. Equation (7.11) is *nonlinear* for one reason and one reason only: the drift $b(\cdot, m_t)$—and, in the general state- and measure-dependent volatility case flagged in remark 7.10, the diffusion as well—depends on the very solution m_t it transports. Strip that dependence away and the equation is the ordinary linear Fokker–Planck equation of chapter 5. The dependence is, in general, on the *entire* measure m_t, which is what makes the equation a genuinely infinite-dimensional object. But in the cases that admit closed solutions the coupling factors through only *finitely many* functionals of m_t—most often a few moments—and then the nonlinearity collapses dramatically: the law-feedback becomes an ordinary feedback through those finitely many scalars, which themselves close a small system of ODEs. The carried linear–quadratic thread is the paradigm. There the drift couples to m_t only through its first moment $\bar{m}_t = \int x\, m_t(\mathrm{d}x)$, the Gaussian form of the law is preserved, and the infinite-dimensional PDE (7.11) collapses onto a two-scalar (mean and variance) flow solved in closed form. We make this completely explicit in the descriptive baseline of worked computation 7.18 in the next section; for now it is enough to register that "finitely many moments" is exactly the structural escape hatch from infinite dimensions.

Physics note: The self-consistent field

Read (7.11) as a physicist reads any density equation: it is a *continuity equation* for probability mass, $\partial_t m_t + \operatorname{div} J_t = 0$, with current $J_t = b(\cdot, m_t)\, m_t - \frac{1}{2}\sigma\sigma^\top \nabla m_t$ assembled from a convective flux $b(\cdot, m_t)\, m_t$ and a diffusive (Fick) flux $-\frac{1}{2}\sigma\sigma^\top \nabla m_t$. What makes it more than a passive transport equation is that the drift generating the convective current is itself *built from the population it transports*. This is exactly the logical shape of a *self-consistent* (mean) field. The sanctioned analogy is the Curie–Weiss ferromagnet: there each spin feels an effective field proportional to the average magnetization of all the spins, while that average magnetization is in turn fixed by the distribution of spins the field induces—a loop closed by the self-consistency equation $m = \tanh(\beta J m)$ that the reader has surely met. Here the same loop appears, with the average magnetization replaced by the population law m_t and the self-consistency equation replaced by the closure $m_t = \mathcal{L}(X_t)$: the field a particle feels is generated by the law of the ensemble, which is generated by the field. The picture is genuinely illuminating, and it is the only mean-field analogy this chapter sanctions. But it carries one sharp limitation that must be stated now, because the entire next section turns on it. In the Curie–Weiss magnet, and here, the self-consistency is an *averaging postulate*: the response law (the spin's alignment tendency; our drift b) is *given*, fixed by the physics, and the fixed point merely makes the felt field consistent with the induced distribution. In a mean field game, the analogous closure is the output of an *optimization*: each agent's "response law" is not given but chosen to be a best reply, and the population law is selected by a Nash equilibrium rather than by an average. The Curie–Weiss picture is therefore exact for the descriptive theory of this chapter and must be *retired the moment strategy enters*—which is precisely the hinge the next section pries on.

With the third face of the limiting object now in hand, the descriptive theory is complete: a single particle's law $\mathcal{L}(X_t)$, a single representative SDE (7.4), and a single nonlinear PDE (7.11) are three exact descriptions of one object, tied together by the self-consistency closure $m_t = \mathcal{L}(X_t)$, and that closure is—as the physicsnote has just stressed—an *averaging postulate*: the drift is prescribed, and the law feeds back into it mechanically, with nothing optimized and nothing chosen. This is the whole of what the descriptive theory asserts, and also the whole of what it does *not*. The next section takes the physicsnote's parting warning as its organizing question: holding this entire self-consistent edifice fixed, what single ingredient must change to turn it into a *game*? Drawing that dichotomy sharply, against the precisely characterized baseline this chapter has built, is the pivot to Part II.

7.5 The pivot: descriptive dynamics versus strategic equilibrium

The physicsnote that closed section 7.4 left us with a warning, and this section is built to act on it. We have, by now, a complete and self-contained theory of a population evolving under a *prescribed* mean-field law of motion: one representative law $\mathcal{L}(X_t)$, one representative SDE (7.4), one nonlinear Fokker–Planck equation (7.11), all three locked together by the closure $m_t = \mathcal{L}(X_t)$ and made quantitative by the Sznitman coupling of section 7.3. This is the descriptive baseline, and it is finished. But the physicsnote insisted that its central closure is an *averaging postulate*—the drift is fixed by the physics and the fixed point merely makes the felt field consistent with the induced law, with nothing optimized and nothing chosen. The whole of Part II is the single modification that retires that postulate, and the purpose of this section is to isolate exactly what the modification is. We hold the entire self-consistent edifice of this chapter fixed and ask precisely one question: what minimal ingredient must change to turn it into a *game*? The answer is a clean dichotomy—a prescribed, mechanically-obeyed drift with a statistical closure, versus an optimized drift with a Nash closure—and drawing it sharply, against the baseline we have so carefully built, is the reason this chapter exists. The reader who finishes this section will meet the mean field game of the next chapters already knowing the one and only thing it adds.

What McKean–Vlasov is. Look again at the McKean–Vlasov equation (7.4) and ask what kind of object the drift $b(x, m)$ is. It is *given*—exogenous data, fixed before the problem begins, exactly as the response law of a Curie–Weiss spin is fixed by the physics. Each particle obeys it the way a planet obeys gravity: mechanically, with no latitude. No particle chooses anything; there is no cost functional, no objective, no notion of one trajectory being "better" than another and therefore preferred. The sole equation that closes the system is the statistical consistency $m_t = \mathcal{L}(X_t)$, and this consistency carries no optimality content whatsoever—it is the bookkeeping identity that the law a particle feels must equal the law the ensemble of such particles produces, nothing more. We will call a closure of this kind *descriptive* (or, borrowing the language of the modeller, *cooperative*): a field determined by an averaging rule, and a fixed point that is a self-consistency condition with no agent behind it weighing alternatives. Said in a phrase one should carry into Part II: McKean–Vlasov dynamics describe how a crowd *that already knows how to move* spreads out; they are silent on *why* it moves that way, because the "why" was supplied as data. It is exactly that silent "why" that a game will fill in.

What a mean field game adds. The modification is a single substitution, and it is best stated as a slogan before it is written as equations: a mean field game replaces the prescribed drift by the *optimal feedback of a control problem solved against the population.* Where McKean–Vlasov handed the drift to the particle, a game makes the particle *derive* its drift by solving an optimization—and then demands that the population this optimized behaviour generates be the very population it was optimized against. To see how the two halves of that sentence become mathematics, fix a flow

$m = (m_t)$ and endow the representative agent not with a law of motion but with a *controlled* law of motion and a cost to minimize,

$$\mathrm{d}X_t = b(X_t, \alpha_t, m_t)\,\mathrm{d}t + \sigma\,\mathrm{d}W_t, \qquad J(\alpha; m) = \mathbb{E}\left[\int_0^T L(X_t, \alpha_t, m_t)\,\mathrm{d}t + g(X_T, m_T)\right],$$

where α_t is now the agent's *control*—a quantity it is free to choose at each instant—L is a running cost and g a terminal cost. Two features of this setup are worth dwelling on, because they are exactly the seams along which the new structure will appear. First, the agent treats the population flow m as *frozen*: it optimizes against a fixed environment, as though the rest of the crowd were a backdrop it cannot influence. This is not a sleight of hand but the defining approximation of a mean field model, and it is legitimate precisely because a single agent among a continuum carries zero mass and cannot move the aggregate—the same vanishing-of-one-among-many that drove the $O(1/N)$ scaling at the start of the chapter, now read on the strategic side. Second, with m frozen the agent faces an honest single-agent stochastic control problem, exactly the object built in chapter 6; and that theory solves it *backward* in time. One introduces the value function $u(t,x)$, the minimal cost-to-go from state x at time t, which satisfies a Hamilton–Jacobi–Bellman equation carrying a *terminal* datum $u(T,\cdot) = g$; solving that equation backward produces, under the convexity hypothesis (A-Conv), the optimal feedback

$$\alpha^*(t,x) = -\partial_p H(x, \nabla u(t,x), m_t)$$

in the canonical normalization $b(x,a) = a$ in which the control *is* the drift. (For a control-affine drift, such as the carried LQG thread with gain $b \neq 1$, one uses instead the maximizer a^* of the Hamiltonian, and $-\partial_p H$ is then the optimal *drift* rather than the control itself; see remark 6.13. The distinction is notational, not conceptual, and we keep it visible because the LQG worked computation below turns on a gain $b \neq 1$.) To keep the comparison with chapter 8 clean we have let the population enter both the dynamics and the costs; chapter 8 develops the standard case in which m enters through the costs alone, the measure-dependent drift being a routine extension. Now substitute the optimizer back into the dynamics. The agent's drift becomes

$$b^*(x, m_t) := b(x, \alpha^*(t,x), m_t),$$

and this is once again a McKean–Vlasov drift—a function of state and population law—but of a completely different provenance: it is *endogenous*, the output of an optimization rather than an assumption handed down with the model. Up to here we have only solved one agent's problem against a fixed m. The game proper is the closing of the loop: the demand that the population this optimal feedback actually generates coincide with the population m the agents took as given when they optimized,

$$\underbrace{u \text{ solves backward HJB driven by } m,}_{\text{optimization}} \qquad \underbrace{m_t = \mathcal{L}(X_t^*), \quad \partial_t m_t = \mathcal{A}_m^* m_t \text{ with drift } b^*}_{\text{consistency}}. \tag{7.14}$$

The two structural novelties, isolated. Set (7.14) beside the McKean–Vlasov fixed point of theorem 7.9—the demand that the frozen SDE, fed the law it produces, reproduces that law—and the difference resolves into exactly two structural additions. They are independent of each other, and it is worth naming them separately because the chapters of Part II are organized around them.

The first is a *new unknown carrying a new direction of time.* The value function u has no McKean–Vlasov counterpart at all: the descriptive theory never solves an optimization, so it never produces a cost-to-go. And u does not merely add an unknown; it adds an unknown that runs the *wrong way.* It is pinned down not by an initial condition but by the *terminal* datum $u(T, \cdot) = g$—the cost an agent pays for where it ends up—and is therefore solved *backward*, from $t = T$ toward $t = 0$. Meanwhile the population density m still obeys the *forward* Fokker–Planck equation (7.11), propagated from its initial law m_0 at $t = 0$. The two are coupled—u feeds the optimal drift b^* into the equation for m, and m feeds the environment into the HJB equation for u—so the mean field game is not a forward evolution at all but a genuinely *forward–backward* boundary-value problem, with its data prescribed at *opposite ends* of the interval $[0, T]$ and no initial-value formulation. This is a categorical change from everything in this chapter: McKean–Vlasov is a pure forward problem, well-posed by marching from $t = 0$, whereas a game cannot be marched in either direction alone because neither end carries complete data. This forward–backward coupling is the structural signature of the entire subject (appendix A); it is developed analytically, as the coupled HJB/Fokker–Planck system, in chapter 8, and probabilistically, as a McKean–Vlasov forward–backward SDE, in chapter 9.

The second addition is that the closure is now *equilibrium, not consistency.* In the descriptive theory the fixed point asserts a bookkeeping identity: the law generated equals the law fed in. In (7.14) the fixed point asserts something with moral content—it is a *Nash equilibrium*, characterized by the property that *no agent can lower its own cost by a unilateral deviation.* The two coincide as equations only because the agents happen to be playing best responses; conceptually they could not be further apart. A consistency condition is symmetric and cooperative, an averaging postulate with a single natural solution; an equilibrium condition selects the drift b^* as the *argmin* of a functional, and selection by optimization is exactly the operation that can fail to be single-valued. Hence a mean field game equilibrium can be *non-unique*, can *bifurcate* as parameters cross thresholds—the strategic analogue of symmetry breaking—and its uniqueness, when it holds, is bought by structural *monotonicity* conditions (A-Mon) that simply have no place in the descriptive theory, where the closure was unique for free. Uniqueness, its failure, and the monotonicity that restores it are the business of chapter 11.

And one novelty deferred. There is a third change the reader should be warned about now, even though we cannot address it here, because it is easy to assume this chapter has already done more than it has. Propagation of chaos as we proved it is propagation of chaos for a *fixed* dynamics. The particles in (7.1) follow a feedback that was prescribed in advance, and theorem 7.15 shows that their empirical measure concentrates on the McKean–Vlasov law at rate $O(1/\sqrt{N})$. The corresponding statement in a finite N-player *game* is genuinely harder, and the reason is precisely the forward–backward coupling just isolated: in a game each agent best-responds to the *actual* empirical measure of its $N - 1$ opponents, so the optimal feedback is itself a functional of that fluctuating measure—the control and the measure it reacts to fluctuate together, and the convenient separation of "prescribed drift" from "fluctuating population" that made the Sznitman coupling work is gone. Proving that the N-player Nash equilibria nonetheless converge to the mean field game equilibrium is therefore a strictly deeper theorem, "propagation of chaos for equilibria," and the same analysis delivers the ε-Nash property—the statement that the limiting mean field strategy, played in the finite game, is approximately optimal with an error vanishing as $N \to \infty$, which is what licenses using the tractable limit as a surrogate for the intractable finite game. That is the deepest result of Part II and is proved in chapter 13. The Sznitman coupling of this chapter is its *descriptive prototype*: the right tool, applied in the one setting—fixed feedback—where the population can be frozen first and reasoned about afterward.

Worked computation 7.18 (The descriptive baseline of the LQG thread)**.** The cleanest way to feel the dichotomy just drawn is to watch it operate on a model where every object is computable in closed form. We instantiate the whole discussion on Thread A, the linear–quadratic–Gaussian model of the thread specification, but deliberately in its *pre-strategic* form: we put the feedback in by hand rather than deriving it from an optimization, so that the present computation is exactly the descriptive half of the forward–backward loop, and the next chapters can be read as "adding the optimization that selects the feedback constant we here choose arbitrarily." Holding the strategic half in abeyance is the whole point—it lets us see precisely which features of the LQG mean field game are already present at the descriptive level (the Gaussian flow, the moment closure, the $O(1/N)$ chaos) and which are genuinely added by the game (the time-varying optimal gain, the fixed-point closure of the mean).

The scalar state of the representative agent obeys the linear dynamics of the thread, with parameters a, b, σ, s fixed as in the specification,

$$\mathrm{d}X_t = \big(aX_t + b\,\alpha_t\big)\,\mathrm{d}t + \sigma\,\mathrm{d}W_t, \qquad X_0 \sim m_0,$$

where a is the intrinsic state drift, b the control gain, σ the volatility, and $s \in [0,1]$ the strength with which an agent is drawn toward the population. In place of an optimized control we *prescribe* the mean-reverting linear feedback

$$\alpha_t = -\theta(X_t - s\,\bar{m}_t), \qquad \bar{m}_t := \int x\, m_t(\mathrm{d}x) = \mathbb{E}[X_t]\,,$$

with $\bar{m}_t$ the population mean and $\theta \ge 0$ a chosen gain: the agent is pushed back toward the moving target $s\,\bar{m}_t$ at rate θ, a caricature of "follow the crowd" that is linear in the state and couples to the population through its mean alone. Substituting this feedback into the dynamics and collecting the terms linear in X_t gives the linear McKean–Vlasov SDE

$$\mathrm{d}X_t = \Big[(a - b\theta)X_t + b\theta s\,\bar{m}_t\Big]\,\mathrm{d}t + \sigma\,\mathrm{d}W_t, \qquad \bar{m}_t = \mathbb{E}[X_t]\,, \tag{7.15}$$

whose drift, $(a-b\theta)x+b\theta s\int y\,m(\mathrm{d}y)$, couples to the law only through its first moment $\int y\,m(\mathrm{d}y)$—the cleanest possible mean-field interaction, the very "coupling through finitely many moments" that section 7.4 flagged as the structural escape hatch from infinite dimensions. (As promised in the notation watch at the head of the chapter, we display this drift explicitly as a formula in x and the mean, never through the macro $b(\cdot,\cdot)$, precisely so that the symbol b denotes only the control gain and cannot be misread as the drift field.)

The law stays Gaussian and the nonlinear Fokker–Planck closes on two scalars. Because the drift is affine in x and the noise additive and Gaussian, one expects a Gaussian law to stay Gaussian; the work is to show that its two parameters close a self-contained system, and to see the mean-field nonlinearity collapse onto a single scalar. Start with the mean. Taking expectations in (7.15), and using that $\mathbb{E}[\sigma\,\mathrm{d}W_t] = 0$ and $\mathbb{E}[X_t] = \bar{m}_t$, the law-feedback term $b\theta s\,\bar{m}_t$ is already deterministic and passes through the expectation unchanged, so

$$\dot{\bar{m}}_t = (a - b\theta)\bar{m}_t + b\theta s\,\bar{m}_t = \big(a - b\theta(1-s)\big)\bar{m}_t, \qquad \Longrightarrow \qquad \bar{m}_t = \bar{m}_0\,e^{(a-b\theta(1-s))t}.$$

This is the entire nonlinearity of the problem, reduced to one linear scalar ODE: the self-consistent mean evolves at the modified rate $a - b\theta(1-s)$, in which the mean reversion $-b\theta$ is partially undone by the factor s measuring how much the target moves with the crowd. Now subtract this deterministic mean to center the process. The fluctuation $Y_t := X_t - \bar{m}_t$ obeys $\mathrm{d}Y_t = \mathrm{d}X_t - \dot{\bar{m}}_t\,\mathrm{d}t = (a - b\theta)Y_t\,\mathrm{d}t + \sigma\,\mathrm{d}W_t$, where one should notice what has happened: the mean-field term $b\theta s\,\bar{m}_t$, being a function of the mean alone, was exactly absorbed by the centering and has *cancelled*. What remains is an ordinary Ornstein–Uhlenbeck equation (chapter 5) with no population coupling at all. Its variance $v_t := \mathrm{Var}(X_t) = \mathbb{E}\big[Y_t^2\big]$ therefore solves the same linear ODE an uncoupled OU process would—by Itô's formula on Y_t^2, $\mathrm{d}(Y_t^2) = \big(2(a-b\theta)Y_t^2 + \sigma^2\big)\,\mathrm{d}t + 2\sigma Y_t\,\mathrm{d}W_t$, and taking expectations kills the martingale term—

$$\dot{v}_t = 2(a - b\theta)v_t + \sigma^2, \qquad v_0 = \mathrm{Var}(X_0).$$

Hence if $m_0 = \mathcal{N}(\bar{m}_0, v_0)$ then $m_t = \mathcal{N}(\bar{m}_t, v_t)$ for every t, with $(\bar{m}_t, v_t)$ given by the two ODEs above, and the infinite-dimensional nonlinear Fokker–Planck equation (7.11) is solved *in closed form* by this two-parameter Gaussian flow. The point to register is the division of labor: the "nonlinearity" is carried entirely by the scalar mean $\bar{m}_t$ through the convective term, while the variance equation never sees the coupling at all. An infinite-dimensional self-consistency has collapsed onto a single self-referential scalar—exactly the analytic transparency the LQG thread exists to provide, and a concrete instance of the moment-closure mechanism described abstractly at the end of section 7.4.

Propagation of chaos, with an exact constant. The descriptive baseline is also where we can watch the chaos estimate run with every constant known. The N-particle version of the model is (7.1) with drift $(a - b\theta)x + b\theta s\,\frac{1}{N}\sum_j X^{j,N}$, a pairwise interaction whose kernel is $(x, y) \mapsto (a - b\theta)x + b\theta s\,y$ in the sense of (7.2) (again written out so the gain b stands alone). This kernel is *linear in y*, hence *unbounded*, so the bounded-interaction hypothesis under which theorem 7.15 was proved literally fails: the linear LQG model sits outside the hypotheses of our general theorem. This is not a defect to apologize for but an instructive case, because the Gaussian structure supplies the moment control the boundedness hypothesis was only ever a proxy for, and it supplies it *exactly*.

Recall the structure of the Sznitman coupling: one runs each particle $X^{i,N}$ against an independent copy $\bar{X}^i$ of the McKean–Vlasov limit driven by the *same* Brownian motion W^i, and the only obstruction to their agreement is a fluctuation term measuring how far the empirical mean of the coupled copies sits from the true limiting mean. Here that fluctuation term is, exactly,

$$G_s^i = b\theta s\Big(\tfrac{1}{N}\textstyle\sum_{j=1}^N \bar{X}_s^j - \bar{m}_s\Big), \qquad \mathbb{E}\Big[\big|G_s^i\big|^2\Big] = (b\theta s)^2\,\tfrac{v_s}{N},$$

and the second identity is where Gaussianity does its work: the $\bar{X}_s^j$ are i.i.d. $\mathcal{N}(\bar{m}_s, v_s)$, so their sample mean $\frac{1}{N}\sum_j \bar{X}_s^j$ has mean $\bar{m}_s$ and variance v_s/N *exactly*—not up to a constant, but on the nose—whence $\mathbb{E}\big[|G_s^i|^2\big] = (b\theta s)^2 v_s/N$. The unbounded kernel costs us nothing because we never needed a uniform bound on it; we needed control of one centered sample-mean fluctuation, and the Gaussian law hands that over precisely.

The linearity buys a second, sharper, dividend: it lets us bypass the general quadratic-in-T Grönwall estimate of theorem 7.15 entirely. Because the noise is additive, it cancels in the difference $\Delta_t^i := X_t^{i,N} - \bar{X}_t^i$ between the true particle and its coupled limit, leaving a *pathwise linear* ODE,

$$\dot{\Delta}_t^i = (a - b\theta)\Delta_t^i + b\theta s\,\tfrac{1}{N}\textstyle\sum_{j=1}^N \Delta_t^j + G_t^i,$$

in which the term $\frac{1}{N}\sum_j \Delta_t^j$ is the mean coupling and G_t^i the now-quantified forcing. A direct one-dimensional Grönwall applied to this linear system—rather than the Lipschitz-and-square-the-Wasserstein machinery used in general—turns the exact forcing bound into the dimension-free rate with a genuine e^{CT} (not e^{CT^2}) time dependence and an explicit prefactor,

$$\max_{1\le i\le N} \mathbb{E}\Big[\sup_{t\le T}\Big|X_t^{i,N} - \bar{X}_t^i\Big|^2\Big] \;\le\; \frac{(b\theta s)^2\big(\sup_{t\le T} v_t\big)\,T}{N}\, e^{C(a,b,\theta)\,T}.$$

This is the carried-thread incarnation of the $O(1/N)$ bound of theorem 7.15, valid here even though the kernel is unbounded, and with the chapter's promised dimension-freeness made fully explicit (the model is scalar, $d = 1$, and no dimensional constant appears). The improvement from e^{CT^2} to e^{CT} in the exponent is genuinely a feature of the linear drift—a constant-coefficient linear ODE has an exponential, not a Gaussian, comparison function—and not of the general coupling bound, whose exponent must carry the $e^{6T^2L^2}$ of theorem 7.15.

Where the game layer enters. It remains to say exactly which line of the computation above was the arbitrary one, so that the reader can see the seam at which Part II cuts. Everything we did took the gain θ—and indeed the entire mean-reverting form of the feedback—as *given*. That is the descriptive postulate, and it is the one thing a game removes. The optimization that *selects* the feedback was, in fact, already carried out for the single agent in chapter 6: minimizing the representative agent's quadratic cost $J(\alpha) = \mathbb{E}\Big[\int_0^T\big(\frac{1}{2}\alpha_t^2 + \frac{q}{2}(X_t - s\bar{m}_t)^2\big)\,\mathrm{d}t + \cdots\Big]$ over a *frozen* mean trajectory $\bar{m}_t$ yields, by the Riccati theory developed there, not a constant-gain law but the affine optimal feedback

$$\alpha^*(t,x) = -b\big(P(t)\,x + r(t)\big),$$

in which $P(t)$ is the curvature of the value function—the solution of the scalar Riccati ODE—and the offset $r(t)$ solves a separate forced linear ODE that carries the coupling to the frozen mean $\bar{m}_t$ (eqs. (6.24), (6.25) and (6.27)). Compare this optimal law with the prescribed one $\alpha = -\theta(x - s\bar{m}_t)$ and the gap is exactly located: the optimal curvature gain $bP(t)$ is *time-varying*, sweeping toward the terminal data as $t \to T$, whereas our θ was a single constant; and the optimal offset $-br(t)$ is determined by its own ODE rather than being frozen at $b\theta s\,\bar{m}_t$. The constant-θ feedback is thus a deliberately simplified stand-in for the genuinely optimal time-varying law, and the two coincide only in the stationary, long-horizon limit where the Riccati curvature settles to its constant value $P(t) \to \bar{P}$ and the time-dependence washes out. Put the two missing halves together and the reading is complete. The backward, optimization half—the value function, the HJB equation, the feedback $-b(P(t)x + r(t))$—was already supplied for a single agent in chapter 6. The present worked computation is the forward, consistency half: with the feedback frozen, it is exactly the forward leg of (7.14), the Fokker–Planck propagation of the law generated by a fixed drift. What the next chapters (chapters 8 and 14) add is the one ingredient neither half contains on its own—the fixed-point closure $\bar{m}_t = \mathbb{E}[X_t^*]$ that demands the mean trajectory the agents optimize against be self-consistent with the one their optimal feedback generates, welding the backward optimization to the forward consistency into the single forward–backward equilibrium this section has been pointing toward all along. With that hand-off the chapter has done its work: it has delivered a complete descriptive theory and, in the same breath, the precisely drawn baseline against which the strategic layer of Part II is defined.

Rigor ledger

Proved.

- Well-posedness of the weakly interacting N-particle system (7.1) and its exchangeability (proposition 7.6).
- Existence and uniqueness of the McKean–Vlasov SDE (7.4) by a Picard contraction in $C([0,T];\mathcal{P}_2(\mathbb{R}^d))$, global in T (theorem 7.9).
- The fluctuation-variance estimate (lemma 7.14) and, from it, propagation of chaos by Sznitman's coupling with the dimension-free rate $\max_i \mathbb{E}\left[\sup_t \left|X_t^{i,N} - \bar{X}_t^i\right|^2\right] \leq C/N$, hence $O(1/\sqrt{N})$ Wasserstein convergence of finite marginals (theorem 7.15).
- The nonlinear Fokker–Planck equation (7.11) as the forward law of the McKean–Vlasov solution, with uniqueness and (under (A-Nondeg)) smoothness (theorem 7.17), and its closed Gaussian solution for the LQG thread (worked computation 7.18).

Assumed.

- The standing hypotheses assumption 7.3: joint Lipschitz (A-Lip), linear growth (A-Growth), and nondegeneracy (A-Nondeg); plus boundedness of b_0 for the clean $O(1/\sqrt{N})$ rate.
- The Itô-SDE well-posedness and Itô formula of chapter 5, the Wasserstein geometry of chapter 4, and the weak-convergence/tightness apparatus of chapter 3.

Deferred.

- The classical linear parabolic regularity under (A-Nondeg)—the smooth, strictly positive transition density and the $C^{1,2}$ solvability of the backward and forward equations—on which both the uniqueness duality and the smoothness in theorem 7.17 rest: stated and proved (parametrix construction) in theorem C.12. Uniqueness itself is now established in-book by Holmgren duality, with *no* appeal to the Ambrosio–Figalli–Trevisan superposition principle (which would, however, give the analogous statement in the degenerate case; see the bibliographic notes).
- The sharp statistical (Fournier–Guillin) rate of empirical-measure convergence in $\mathcal{W}_2$ (remark 7.16) is quoted for orientation only; *no* in-book result depends on it.
- The strategic layer—HJB/optimal feedback (chapter 6), the forward–backward mean field game system (chapter 8, chapter 9), and propagation of chaos for Nash equilibria with the ε-Nash property (chapter 13).

Open.

- Long-time ($T \to \infty$) uniform-in-time propagation of chaos beyond the e^{CT^2} horizon dependence: requires structural (convexity/contractivity) hypotheses and is genuinely delicate; only special cases are known.
- Quantitative propagation of chaos for *singular* or merely measure-Lipschitz interactions at the optimal dimension-free rate, where the bounded-pairwise mechanism of lemma 7.14 is unavailable.

Bibliographic notes

The McKean–Vlasov equation and the nonlinear-diffusion viewpoint originate with [103], who associated a class of nonlinear parabolic equations with interacting diffusions; the kinetic-theory roots (molecular chaos, the BBGKY hierarchy) trace to Boltzmann and were placed on a probabilistic footing by Kac. The definitive modern treatment of propagation of chaos by coupling, including theorem 7.15 in the bounded-Lipschitz pairwise case, is Sznitman's Saint-Flour course [129]; our well-posedness proof (theorem 7.9) and coupling estimate follow that source and its presentation in [40, Vol. I, Ch. 1], which we recommend as the chapter's companion. The sharp dimension-dependent rate for the convergence of empirical measures in Wasserstein distance (remark 7.16) is due to [69], quoted in remark 7.16 for orientation only. Our uniqueness argument for the nonlinear Fokker–Planck equation is the elementary Holmgren duality against the smooth solution of the backward Kolmogorov equation, self-contained once the parabolic regularity of theorem C.12 is in hand; it uses only nondegeneracy (A-Nondeg). For *degenerate* diffusions, where this duality is unavailable, uniqueness instead rests on the Ambrosio–Figalli–Trevisan superposition principle, treated with full proofs in [40, Vol. I, Ch. 5]; see also [131] for the optimal-transport background of chapter 4. The descriptive-versus-strategic pivot of section 7.5, and the closed-loop McKean–Vlasov structure that the optimization induces, are the founding insight of the mean field game literature [93, 82]; the systematic development we point forward to is [36] (PDE) and [40] (probabilistic), with the convergence problem for N-player Nash equilibria—the strategic analogue of this chapter—in [37].

Chapter 8

The Mean Field Game System: Analytic Formulation

This chapter assembles, for the first time in the book, the full strategic mean field game. Up to now the two halves have been built separately. In chapter 6 we solved the *single* optimally controlled diffusion: dynamic programming produced a value function $u(t,x)$, computed backward from a terminal cost, satisfying a Hamilton–Jacobi–Bellman (HJB) equation whose Hamiltonian $H(x,p,m)$ packages the agent's instantaneous optimization. In chapter 5 and chapter 7 we learned how a *population* of diffusions transports its own law: the density $m(t,x)$ runs forward from an initial profile m_0 and obeys a Fokker–Planck (Kolmogorov forward) equation $\partial_t m = \mathcal{A}^* m$, where $\mathcal{A}^*$ is the formal adjoint of the generator $\mathcal{A}$. In chapter 7 these two ideas were glued in a *descriptive* way: in McKean–Vlasov dynamics the particles follow a *prescribed* dependence of their law, and propagation of chaos guarantees that the empirical measure converges to a deterministic flow.

The mean field game adds the one ingredient McKean–Vlasov lacks, and the addition is a genuine conceptual jump rather than a technical extension — it is the hinge on which all of Part II turns. In a McKean–Vlasov system the dependence of each particle on its own law is *prescribed* from outside: the drift is a given function of (X_t, m_t), and propagation of chaos then *computes* the flow m_t for us, as the deterministic forward evolution that the particles passively realize. The law is an output, but an output of a dynamics we have already fixed, and it can be obtained by integrating forward from a single initial slice. In a mean field game the agents do not follow the law, they *optimize against it*: each treats $t \mapsto m_t$ as the description of a crowd it cannot itself move, computes its own best response to it, and the crowd is in turn the aggregate of exactly those best responses. The law is therefore the *fixed point* of the best-response map, not the endpoint of a prescribed flow — and a fixed point cannot be marched forward from an initial slice, because each agent's optimal response at any instant already depends on the entire future of the crowd. The mean field is no longer postulated; it is the output of a Nash fixed point. A physicist will recognize the closure: this is the self-consistent field of mean field statistical mechanics — the field that moves each particle being the field the particles themselves generate — with one decisive substitution, that the relation closing field to configuration is no longer a thermal average but an *optimization*, each agent's best response taking the place of the Boltzmann weight. The analytic expression of this fixed point is a pair of coupled partial differential equations — a backward HJB driven by the density, and a forward Fokker–Planck driven by the feedback extracted from the value — with data specified at *opposite ends* of the time interval. This forward–backward, two-point boundary structure is the structural signature of the subject and has, as appendix A stresses, no initial-value analogue.

The chapter then follows the logic of that fixed point one consequence at a time. section 8.1 earns the system rather than postulating it: it derives the coupled pair as the $N \to \infty$ limit of an honest N-player Nash equilibrium and then tightens the heuristic into a precise candidate. Once we hold a candidate we must say exactly what it is and why it deserves the name equilibrium, so section 8.2 states the coupled system, gives the two readings — the HJB as a reverse-time value diffusion, the Fokker–Planck as conservation of mass — that organize the rest of Part II, and proves the verification statement that makes solving the two PDEs the very same act as playing a best response. That verification exposes the one feature that makes the object genuinely hard, namely that its data sit at opposite ends of time; section 8.3 therefore dwells on the forward–backward boundary structure and explains why no march from a single time slice can reach the solution. The only way past that obstruction is to solve for the whole flow at once as a fixed point, which is precisely why section 8.4 recasts the system as a fixed point of a best-response map S — the formulation that the existence theory of chapter 10 and the uniqueness theory of chapter 11 actually consume. With the abstract object in hand we ask what governs its behavior, and the answer is the coupling: section 8.5 classifies how the population enters — separable versus non-separable Hamiltonians, local versus nonlocal interactions, and congestion — because each class will demand different hypotheses downstream. For the best-behaved of these classes the strategic problem turns out to hide a single scalar objective: section 8.6 exhibits the variational (potential-game) structure, showing that for monotone separable couplings the whole system is the Euler–Lagrange system of one convex functional, the mean field analogue of an effective action and the conceptual bridge to the Ginzburg–Landau picture of Part IV. Finally section 8.7 advances Thread A to its second layer: the linear–quadratic–Gaussian (LQG) MFG, solved analytically through HJB $\to$ Riccati, Fokker–Planck $\to$ Gaussian flow, and a closed forward–backward fixed-point system for the population mean. The probabilistic counterpart of everything here — the same equilibrium written as a McKean–Vlasov forward–backward stochastic differential equation — is the subject of chapter 9.

Notation watch

Throughout, $u = u(t, x)$ is the value function: it carries *terminal* data $u(T, \cdot) = g$ and is computed *backward* in time. The density $m = m(t, x)$ carries *initial* data $m(0, \cdot) = m_0$ and is transported *forward*. The generator $\mathcal{A}$ acts on test functions (it governs u); its adjoint $\mathcal{A}^*$ acts on densities (it governs m). We fix once the sign of the Hamiltonian: H is a *supremum* (a Legendre transform), so that the *optimal drift* of the controlled diffusion is $b(x, \alpha^*) = -\partial_p H$ (the envelope identity of remark 6.13). In the canonical normalization $b(x, \alpha) = \alpha$, $A = \mathbb{R}^d$ — in which the control *is* the drift — this reads simply $\alpha^* = -\partial_p H$, the form recorded in appendix A; when a control gain is present (as in the LQG thread, whose drift is $ax + b\alpha$) the control is recovered from the maximizer and $-\partial_p H$ remains the optimal *drift* transported by Fokker–Planck. With these conventions the diffusion enters the HJB with a $+\frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 u)$ that has been moved to the left-hand side as $-\frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 u)$; the same operator enters

Fokker–Planck unchanged because $\mathcal{A}^*$ has the *same* second-order part as $\mathcal{A}$. Verify every sign below against conservation of mass $\frac{\mathrm{d}}{\mathrm{d}t}\int m \,\mathrm{d}x = 0$, never against a remembered Hamiltonian sign.

8.1 From N-player Nash to the mean field game

The preamble made a promise: the mean field is not a datum we hand the agents but an object they collectively produce, the law of the population being the fixed point of everyone's best response to it. That promise is at bottom a claim about a limit, and the honest way to earn it is to begin where the game is wholly unambiguous — a finite roster of players, each solving a genuine optimization against the others — and watch what survives as the roster grows. This section carries out that program in two deliberate steps. First we write the finite strategic game and its equilibrium conditions down exactly, with no approximation: N players, each minimizing its own cost, coupled only through the crowd they jointly form, with a Nash equilibrium characterized by a coupled system of N Hamilton–Jacobi–Bellman equations. Then we send $N \to \infty$ heuristically and read off the limiting object, postponing to chapter 13 the proof that the limit really is what we read off. The payoff of the second step is the *form* of the equations that section 8.2 will crystallize as definition 8.1; the discipline of the first is what guarantees that this form is *forced* on us rather than guessed.

What lets the limit close at all is a single structural feature of the finite game, and it is worth naming in advance because both subsections will lean on it: *anonymity*. Each player cares about the others only through their empirical distribution, never through their individual identities, and the players are statistically interchangeable — *exchangeable*. Because the coupling is anonymous and the players exchangeable, the influence of any one rival on any other is only $O(1/N)$, so no single opponent matters in the limit and the law of large numbers can convert the high-dimensional random environment a player faces into a single *deterministic* flow of measures. Anonymity is thus not a modelling convenience but the precise hypothesis under which the N-body coupling decouples: the first subsection uses it to justify writing each cost through the empirical measure, and the second uses it to replace that fluctuating empirical measure by its deterministic mean field limit. We turn first to the finite game, assembling it as an N-fold copy of the single controlled diffusion of chapter 6 coupled through the empirical measure of definition 7.1.

8.1.1 The finite game and its Nash system

We begin, as the section promised, by assembling the finite game out of pieces the reader already owns, adding nothing new except the one channel through which the pieces are allowed to touch. The atom of the construction is the single optimally controlled diffusion of chapter 6: one agent, a state in $\mathbb{R}^d$, a drift it steers through its control, an independent Brownian forcing, and a cost it minimizes. The finite game is nothing more than N synchronous copies of that atom, run on the same clock $[0, T]$, made to interact through the cost in the one way anonymity permits. Building it this way — as an N-fold assembly of an object we have already solved, rather than as a fresh high-dimensional problem — is what will make the eventual collapse to a single representative agent legible: every term we are about to write down is a term from chapter 6 with an index pasted on.

Fix, then, N symmetric players. Player i has state $X_t^i \in \mathbb{R}^d$ governed by the controlled diffusion

$$\mathrm{d}X_t^i \;=\; b\big(X_t^i, \alpha_t^i\big)\ \mathrm{d}t \;+\; \sigma\ \mathrm{d}W_t^i, \qquad X_0^i \sim m_0 \text{ i.i.d.}, \tag{8.1}$$

which is exactly the single state equation of chapter 6 carrying a player label: one independent noise W^i per player, the same drift law b and the same volatility σ for everyone (this is what *symmetric* means), and a common initial law m_0 from which the N starting states are drawn independently. The control $\alpha_t^i \in A$ is chosen in *feedback* form $\alpha_t^i = \alpha^i(t, X_t^1, \ldots, X_t^N)$, a function of the current time and the *entire* configuration of all N states. That the feedback is allowed to read every coordinate, not just the player's own X_t^i, is not a luxury but a necessity: because player i's cost will depend on where the others are, and the others diffuse randomly, an agent who optimizes must in principle condition its instantaneous action on the whole observed state of the game. Were the controls instead chosen in isolation, each looking only at its own state and its own cost, eq. (8.1) would describe N unrelated copies of the chapter 6 problem and there would be nothing to solve jointly. What welds the copies into a game is the structure of the cost.

The coupling between players is *anonymous* in the precise sense flagged above: player i cares about the others only through their *leave-one-out* empirical measure

$$\mu_t^{N,i} \;:=\; \frac{1}{N-1}\sum_{j\neq i}\delta_{X_t^j} \;\in\; \mathcal{P}(\mathbb{R}^d),$$

which is the empirical measure of definition 7.1 — a normalized sum of point masses, one per agent — formed here from the *other* $N-1$ players, with player i's own atom $\delta_{X_t^i}$ deliberately omitted. Two features of this object carry the whole modelling content, and both have a clean physical reading. First, the cost sees the others only through the *distribution* of their states, never through their labels: relabelling the opponents, or swapping which body sits at which point, leaves $\mu_t^{N,i}$ and hence the cost unchanged. The agent perceives a *crowd*, a cloud of mass spread over $\mathbb{R}^d$, not a roster of named rivals — this is precisely the anonymity (exchangeability) that the law of large numbers will later convert into a single deterministic field. Second, the sum runs over $j \neq i$: the agent reacts to the field generated by *everyone else* and not to a field that includes its own contribution. Physically an agent responds to the crowd around it, not to itself; mathematically, leaving the ith atom out is what prevents the self-interaction that would otherwise make "best response to the population" a circular instruction even before the limit. As for the choice of prefactor, $\frac{1}{N-1}$ rather than $\frac{1}{N}$ is the only normalization that makes $\mu_t^{N,i}$ a genuine probability measure once the ith atom has been removed ($N-1$ unit masses divided by $N-1$ integrate to one); had we kept the $\frac{1}{N}$ weight of definition 7.1 the leave-one-out sum would carry total mass $\frac{N-1}{N}$, and the two conventions therefore differ by a relative factor $\frac{N-1}{N} = 1 - \frac{1}{N}$, i.e. by $O(1/N)$. Since every conclusion we draw is a statement about the $N \to \infty$ limit, this $O(1/N)$ discrepancy washes out and the choice is purely one of bookkeeping convenience; we take the normalization that keeps each agent's perceived crowd a bona fide probability law.

With the perceived crowd in hand, player i minimizes the chapter 6-type cost

$$J^i(\alpha^1, \ldots, \alpha^N) \;=\; \mathbb{E}\left[\int_0^T L\big(X_t^i, \alpha_t^i, \mu_t^{N,i}\big)\ \mathrm{d}t \;+\; g\big(X_T^i, \mu_T^{N,i}\big)\right], \tag{8.2}$$

identical in shape to the single-agent cost functional of chapter 6 — a running Lagrangian L integrated to the horizon plus a terminal cost g — except that both L and g now take the perceived crowd $\mu_t^{N,i}$ as a third argument. This is the only place the other players enter J^i, and they enter it anonymously. The notation $J^i(\alpha^1, \dots, \alpha^N)$ makes the strategic structure explicit: player i's realized cost is a functional not only of its own control but of the *whole profile*, because the trajectories X^j that build $\mu_t^{N,i}$ are themselves driven by the other players' controls α^j. Player i can move only α^i; the rest of the profile is its environment.

This is what turns N optimizations into a *game*, and the equilibrium notion is the one that makes each agent's choice consistent with the others'. A *Nash equilibrium* is a profile $(\alpha^{1,*}, \dots, \alpha^{N,*})$ from which no single player can gain by unilaterally deviating: for each i and every admissible alternative control α^i,

$$J^i(\alpha^{1,*}, \dots, \alpha^{i,*}, \dots, \alpha^{N,*}) \;\le\; J^i(\alpha^{1,*}, \dots, \alpha^{i}, \dots, \alpha^{N,*}).$$

Read the inequality literally: hold every other player at its equilibrium strategy $\alpha^{j,*}$, $j \neq i$, let player i alone replace $\alpha^{i,*}$ by any admissible α^i, and the cost cannot go down. Each agent, given what everyone else is doing, is *already* playing a cost-minimizing response; there is no profitable unilateral deviation, hence no regret. Crucially the comparison is one player at a time, with the rest frozen — it is not a statement about jointly optimizing the profile, which is exactly why a Nash equilibrium is in general not the minimizer of any single objective.

It is the "rest frozen" clause that lets us solve for the equilibrium with the tools of chapter 6. Fix i and freeze the others' equilibrium strategies $\alpha^{j,*}$, $j \neq i$. From player i's vantage the states X^j, $j \neq i$, are now *driven processes* with known feedback laws, and player i faces an ordinary stochastic control problem: choose α^i to minimize eq. (8.2) subject to the dynamics eq. (8.1). The only difference from the lone agent of chapter 6 is that the relevant state is no longer X_t^i alone but the full vector $(X_t^1, \dots, X_t^N)$, since the cost depends on the others' positions and those positions evolve. The dynamic programming principle of chapter 6 therefore produces a value function $v^{N,i}(t, x_1, \dots, x_N)$ of *all* N states, satisfying an HJB equation in Nd spatial variables: player i's own coordinate x_i enters through the optimized Hamiltonian, while every other coordinate x_j enters through the *transport* generated by that player's frozen optimal drift. Writing the HJB equation for each i and recording that all N are coupled — each $v^{N,i}$ depends on all states, and the drift carrying coordinate x_j is the maximizer of player j's own problem — yields the *Nash system*: for $i = 1, \dots, N$,

$$-\partial_t v^{N,i} - \sum_{j=1}^{N} \tfrac{1}{2}\operatorname{tr}\big(\sigma\sigma^\top \mathrm{D}^2_{x_j} v^{N,i}\big) - \sum_{j\neq i} b\big(x_j, \alpha^{j,*}\big)\cdot\nabla_{x_j} v^{N,i} + H\big(x_i, \nabla_{x_i} v^{N,i}, \mu^{N,i}\big) \;=\; 0, \tag{8.3}$$

with terminal data $v^{N,i}(T, \cdot) = g(x_i, \mu^{N,i})$. The three blocks of eq. (8.3) are worth reading one at a time. The Hessian sum $\sum_j \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2_{x_j} v^{N,i})$ is the second-order generator of all N independent noises acting on $v^{N,i}$ — one copy of chapter 6's diffusion term per coordinate, present because $v^{N,i}$ must average over every player's Brownian fluctuation. The last term $H(x_i, \nabla_{x_i} v^{N,i}, \mu^{N,i})$ is player i's *own* optimization, collapsed into the Hamiltonian

$$H(x,p,m) \;:=\; \sup_{\alpha\in A}\Big\{ -\, b(x,\alpha)\cdot p - L(x,\alpha,m)\Big\}, \tag{8.4}$$

the Legendre-type transform introduced in chapter 6: maximizing $-b(x,\alpha)\cdot p - L(x,\alpha,m)$ over the admissible controls $\alpha \in A$ is precisely the pointwise best-response computation of dynamic programming, packaging "pick the control that best trades drift against running cost" into a single function of state x, costate $p = \nabla_{x_i} v^{N,i}$, and perceived crowd $m = \mu^{N,i}$. Only the ith coordinate is optimized here, because player i controls only α^i. The middle block is the heart of the matter: the cross terms

$$\sum_{j \neq i} b(x_j, \alpha^{j,*}) \cdot \nabla_{x_j} v^{N,i}$$

transport $v^{N,i}$ along the closed-loop drift of *every other* player. Here $\alpha^{j,*}$ is not a free variable but player j's *own* optimal control — the maximizer of player j's Hamiltonian, i.e. a function of $\nabla_{x_j} v^{N,j}$ — so the equation for $v^{N,i}$ is laced through with the gradients of the *other* players' value functions. This is the exact mechanism by which the N HJB equations cease to be independent: each one's drift terms are built from the others' solutions, and the maximization defining $\alpha^{j,*}$ makes that dependence nonlinear. The cross terms, with $\alpha^{j,*}$ itself a maximizer, are precisely what make eq. (8.3) a genuinely coupled system of N nonlinear PDEs in Nd variables rather than N separate equations.

And that is where the finite game becomes analytically hopeless. A single $v^{N,i}$ is a function on $\mathbb{R}^{Nd}$, a space whose dimension grows *linearly in the number of players*: for N agents in $d = 1$ one must solve N coupled nonlinear PDEs each posed in N spatial dimensions, and for any population worth calling a crowd — thousands, millions — the state space $\mathbb{R}^{Nd}$ defeats every grid, every basis, every direct numerical scheme by sheer dimensional explosion, quite apart from the nonlinear coupling that forbids solving the equations one at a time. There is no realistic N for which one can write the solution down or compute it; one can only set the system up and pray. The escape, and the whole content of the mean field idea, is to stop fighting the dimension and instead let it work *for* us: send $N \to \infty$ and bet that the anonymous, $O(1/N)$ coupling — no single rival mattering — collapses the fluctuating Nd-dimensional environment into one self-consistent field that a single representative agent optimizes against. We turn to that limit next, fixing attention on a single representative player and watching the crowd it faces freeze into a deterministic flow of measures.

8.1.2 The heuristic limit

We left the finite game in an analytic dead end: a system of N coupled nonlinear HJB equations on $\mathbb{R}^{Nd}$, each value function $v^{N,i}$ laced through the gradients of every other player's value, the whole thing growing more intractable with each agent we add. The mean field idea is to turn that growth into an asset. The very feature that made the finite system hopeless — that every player is coupled to a huge crowd of others — is, after the limit, what *simplifies* it, because anonymity makes no single member of that crowd matter and the law of large numbers can then freeze the crowd into a deterministic background. The argument that does this is a chain of approximations rather than a theorem, and the discipline of the present subsection is to keep that distinction honest: we run the chain to read off the *form* of the limiting object, marking each link as heuristic, and we defer to later chapters the three places where a link must be earned. So fix attention, as the section promised, on a single representative player — call it player 1, with no loss of generality since the players are interchangeable — and watch the Nd-dimensional random environment it faces collapse, link by link, into a single deterministic flow of measures that it optimizes against. The collapse runs in five moves — exchangeability, the law of large numbers, the reduction to a single-agent control problem, the envelope read-off of the feedback, and the loop-closing consistency demand — and we take them in turn inside the heuristic box, then immediately audit what the box quietly assumed.

Heuristic (non-rigorous): The mean field collapse

Step 1: exchangeability makes the rivals conditionally i.i.d. Fix attention on player 1 and suppose the equilibrium is *symmetric*, so that all N players use the same feedback law — a natural ansatz, since the players are statistically identical (same dynamics, same cost, same initial law) and there is no label by which the equilibrium could prefer one to another. Now ask what the other players look like from player 1's seat. Each rival X^j obeys the same controlled diffusion eq. (8.1), driven by its own independent noise W^j and reacting to the same anonymous crowd; and crucially, because the coupling is anonymous and the influence of any single agent on any other is only $O(1/N)$ (section 8.1), the rivals are tied to one another only through the faint, shared field they all read, not through any direct pairwise bond. To leading order in $1/N$ that residual dependence is negligible, and conditionally on the common environment the states $X_t^2, \ldots, X_t^N$ are *i.i.d.* samples from one common one-particle law m_t. This is the exchangeable structure of chapter 7 read at the level of the game: identical agents weakly coupled to a common field behave, in the bulk, like independent copies of a single representative diffusion.

Step 2: the law of large numbers freezes the crowd. Player 1 does not see the rivals individually; it sees only their empirical measure $\mu_t^{N,1} = \frac{1}{N-1} \sum_{j \neq 1} \delta_{X_t^j}$, the perceived crowd of section 8.1. But an empirical measure of $N-1$ samples that are i.i.d. to leading order is precisely the object the law of large numbers governs: as $N \to \infty$ its random fluctuations are $O(N^{-1/2})$ and wash out, and $\mu_t^{N,1}$ concentrates on its mean, the common law m_t. Made rigorous, this concentration is exactly the *propagation of chaos* of chapter 7: the random empirical flow converges to the deterministic flow $m_t = \mathcal{L}(X_t^1)$. The decisive consequence is qualitative, not just quantitative. *Before* the limit, player 1 optimizes inside a fluctuating, high-dimensional, stochastic environment — the joint motion of $N-1$ other diffusers. *After* the limit, that environment has frozen into a single *fixed, deterministic* curve in the space of measures, $t \mapsto m_t$. The randomness of the crowd has been integrated away; what remains is a known, non-random schedule of population states.

Step 3: the representative agent solves an ordinary control problem. Once $t \mapsto m_t$ is a fixed, known function of time, player 1 no longer faces a game at all — it faces the *single-agent* stochastic control problem of chapter 6, with the population appearing as nothing more than a prescribed time-dependent parameter inside its cost. Substituting m_t for the perceived crowd in eq. (8.2), player 1 minimizes $\mathbb{E}\Big[\int_0^T L(X_t, \alpha_t, m_t)\, \mathrm{d}t + g(X_T, m_T)\Big]$ over its own control, subject to its own diffusion — a problem in the *one* state X_t, not in the joint configuration of all N players. The Nd-dimensional value function $v^{N,1}(t, x_1, \ldots, x_N)$ of the finite game has collapsed to a value $u(t,x)$ of player 1's own state alone, and dynamic programming (chapter 6) gives it as the solution of a *single* HJB equation in d variables,

$$-\partial_t u - \tfrac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 u) + H(x, \nabla u, m_t) = 0, \qquad u(T, \cdot) = g(\cdot, m_T),$$

with the same Hamiltonian eq. (8.4) as before, now carrying the frozen flow m_t as a parameter in its third slot and in the terminal datum. This is the entire dimensional payoff of the limit:

N coupled equations on $\mathbb{R}^{Nd}$ have become *one* equation on $\mathbb{R}^d$.

Step 4: the envelope identity reads off the optimal drift. The control problem of Step 3 is solved by the pointwise maximizer in the Hamiltonian eq. (8.4), and what the forward dynamics will need is not the control itself but the *closed-loop drift* that control induces. The envelope theorem (remark 6.13) supplies it without re-solving the maximization: differentiating $H(x,p,m) = \sup_\alpha\{-b(x,\alpha)\cdot p - L\}$ in p, only the explicit p-dependence survives at the maximizer, so the optimal feedback $\alpha^*(t,x)$ induces the closed-loop drift

$$b(x,\alpha^*(t,x)) = -\partial_p H(x, \nabla u(t,x), m_t).$$

A caveat on normalization, repeated here because it is the single most common sign trap of the subject: it is the optimal *drift* that equals $-\partial_p H$, not in general the control. The two coincide — $\alpha^* = -\partial_p H$ — only in the canonical normalization $b(x,\alpha)=\alpha$, $A=\mathbb{R}^d$, in which the control *is* the drift; when a control gain is present (the LQG drift $aX + b\alpha$ of the carried thread is the standing example) the control and the transported drift differ by that gain, and it is the drift, not the control, that Fokker–Planck moves.

Step 5: closing the loop — the consistency condition. So far m_t has been an *assumed* input: we froze the crowd, then computed player 1's best response to it. But the crowd is not external. If *every* agent is identical and each plays the same optimal feedback α^* extracted in Step 4, then the common law they collectively generate is not free to be anything — it must be the law of the diffusion actually driven by that feedback. That is, m must solve the Fokker–Planck (Kolmogorov forward) equation for the closed-loop drift $-\partial_p H$,

$$\partial_t m - \tfrac{1}{2}\operatorname{tr}\big(\sigma\sigma^\top \mathrm{D}^2 m\big) - \operatorname{div}\Big(m\,\partial_p H(x,\nabla u, m_t)\Big) = 0, \qquad m(0,\cdot) = m_0,$$

the forward transport of the initial population m_0 along the very feedback that the HJB equation produced. The equilibrium is the demand that these two appearances of m be *the same*: the flow assumed when computing the value must equal the flow produced when the resulting feedback is played out,

$$m \;=\; \mathcal{L}\big(\text{closed-loop diffusion driven by } \alpha^*[m]\big).$$

This is the *consistency* or *Nash certainty equivalence* condition. It is the analytic incarnation of "no agent regrets its choice given what the crowd does, and the crowd is exactly the aggregate of those choices." The HJB equation of Step 3 and the Fokker–Planck equation of Step 5, locked together by this self-consistency, are the mean field game system.

The collapse is seductive, and the prose inside the box moved quickly past three places where a genuine theorem is needed rather than a plausibility argument; honesty about what we have and have not established is the whole point of marking the derivation heuristic. The first gap is the convergence $\mu_t^{N,1} \to m_t$ itself — but *at the equilibrium.* Step 2 invoked propagation of chaos, yet the propagation of chaos of chapter 7 was proved for a *prescribed* McKean–Vlasov dynamics, where the feedback is fixed from outside. Here the feedback is the strategic best response, which itself depends on the very limit law we are trying to establish; the law of large numbers must therefore be made to hold along a Nash profile, with the optimization and the concentration closing on each other simultaneously. That is a strictly deeper statement — the central convergence theorem of Part II — and it is proved only in chapter 13. The second gap is the decoupling of the value functions: Step 3 simply asserted that the Nd-variable $v^{N,1}(t, x_1, \ldots, x_N)$ converges to a function $u(t, x_1)$ of player 1's own coordinate alone, the other coordinates' dependence dissolving into the deterministic parameter m_t. This too requires proof, and it too belongs to the convergence analysis. The third gap is the most basic: Step 5 wrote down a fixed-point demand, but a demand is not a solution. Nothing so far guarantees that any flow m satisfies the consistency condition — that the best-response map has a fixed point at all. Existence is the charge of chapter 10.

It is worth being completely explicit about the resulting division of labor, because it is the pedagogical contract not just of this subsection but of the whole chapter. section 8.1.2 is to be read as the *derivation of an ansatz*, and nothing more: it tells us the *form* the limiting object must take — a backward HJB driven by the population coupled to a forward Fokker–Planck driven by the feedback, pinned by data at opposite ends of $[0, T]$ — but it does *not*, on its own, establish that this object is the genuine $N \to \infty$ limit of the finite Nash equilibria. We deliberately split the burden in two. The claim that the coupled pair is *internally consistent* — that solving the two PDEs really does encode a representative agent best-responding to a population that reproduces itself — is something we can and will verify *directly*, by the verification theorem of section 8.2, with no appeal to any limit and with the finite game nowhere in sight. The separate claim that this internally consistent object is the correct *limit* of the N-player game — that the three gaps above can be closed — is postponed to the convergence theory of chapter 13. The reader should therefore treat everything that follows in this chapter as the study of a self-standing analytic system, justified on its own terms as the equilibrium condition of a representative agent, and should not regard the heuristic's limit-talk as cashed in until chapter 13 does so. What the heuristic has bought us is precise and limited: the *shape* of the equations, forced on us by an argument we trust enough to build on, even though two of its links are still promissory notes.

With that shape in hand, the next section takes over the task of making it exact. It will fix the standing data, state the coupled pair as a precise definition rather than a heuristic readout, read the two equations in the two complementary ways that organize the rest of Part II — the HJB as a reverse-time value diffusion, the Fokker–Planck as conservation of mass — and then discharge the first half of the contract just drawn, proving the verification statement: that this ansatz is internally consistent, a Nash-consistent best response, without yet invoking the limit.

8.2 The coupled system and its two readings

The previous section handed us a shape and a promissory note. The mean field collapse of section 8.1.2 produced, link by heuristic link, a coupled pair — a backward HJB driven by the population, a forward Fokker–Planck driven by the feedback the value generates — but it produced that pair as an *ansatz*, the form an equilibrium must take, not yet a defined object we may reason about on its own terms. The closing discussion there split the work of honoring that ansatz into two clauses: that the coupled pair is *internally consistent* — that solving the two PDEs really does encode a representative agent best-responding to a population that reproduces itself — is provable here and now, directly, with the finite game nowhere in sight; that this consistent object is the genuine $N \to \infty$ *limit* of the Nash equilibria is deferred to the convergence theory of chapter 13. This section discharges the first clause. Our itinerary is four steps and we name them in advance so the reader can hold the whole section in view: first we fix the standing data, pinning down exactly which ingredients are given and under which hypotheses, so that "solve the system" has an unambiguous meaning; then we state the coupled pair as a precise definition rather than a heuristic readout; then we read that one pair of equations in two complementary ways, because — as we are about to argue — the same two equations teach two different lessons depending on which end of time one stands at; and finally we verify the coupling, proving the consistency clause by importing the representative-agent verification theorem of chapter 6.

The two readings deserve a word of motivation before we earn the right to give them, since at first sight reading the same system twice looks like indulgence. It is not. The HJB equation eq. (8.5a) and the Fokker–Planck equation eq. (8.5b) are not two facts about one population; they are two *directions* through the same population, and each direction is natural for exactly one of the fields. Read the HJB equation as a value flow and it runs *against* the clock: data prescribed at the deadline $t = T$, information about the optimal cost-to-go diffusing backward out of the terminal cost as the horizon recedes — a reaction–diffusion equation in reversed time, smoothing the kinks a first-order Hamilton–Jacobi equation would otherwise sharpen. Read the Fokker–Planck equation as a mass flow and it runs *with* the clock: data prescribed at the start $t = 0$, an honest continuity equation transporting a conserved unit of probability forward along the optimal drift while diffusion spreads it. Neither reading is dispensable, because the analytic difficulty of the subject lives precisely in the clash between them — the value wants to be solved from the future, the density from the past — and one cannot feel the force of that clash without first seeing each equation in the time-direction that makes it elementary. Stating both readings is also what exposes how *little* couples the two equations: the HJB needs the population only through m_t, the Fokker–Planck needs the value only through ∇u (via the optimal drift), and nothing else passes between them. That economy — a single measure flowing one way, a single gradient flowing the other — is the whole interface of the mean field game, and it is what makes the fixed-point reformulation of section 8.4 tractable.

Before any of this we must say what is given. The next subsection therefore pauses on the standing data, picking up the general pivot of chapter 7 — where the controlled drift was allowed to depend on the population law along with the state and control — and specializing it to the setting in which the whole rest of the chapter works: a *measure-independent* drift $b(x, \alpha)$, so that the population enters the agent's problem *only through the cost*. This is the standard analytic arena, it already contains the carried LQG thread, and it is the cleanest stage on which to watch the two readings and the verification play out; we record there exactly why the specialization costs us nothing structural and where the more general measure-dependent drift would re-enter.

8.2.1 Standing data and assumptions

The section opened by promising to say what is given before we say what is to be solved, and this is where we pay that debt. A definition that began "a pair (u, m) solving the following two equations" would be hollow until the ingredients of those equations — the state space, the cost, the drift, the noise, and the hypotheses that make the operations in them legitimate — were pinned down. So we pause here to fix the entire stage. Nothing in this subsection is a theorem; its job is to make the next subsection's definition stateable without a single parenthetical caveat, so that when the coupled system appears it appears clean, every object already named and every hypothesis already in force. The reader who wants the equations first may skim to definition 8.1 and refer back; but the price of doing so is that the "why" of each assumption — which is exactly what the narration doctrine of this book asks us to surface — lives here.

We fix the data of the representative-agent problem. The state space is $\mathbb{R}^d$. A *flow of measures* is a map $m\colon [0,T] \to \mathcal{P}_2(\mathbb{R}^d)$, $t \mapsto m_t$, continuous for the metric $\mathcal{W}_2$ (chapter 4); it is the deterministic background the representative agent optimizes against, the frozen crowd that section 8.1.2 manufactured from the law of large numbers. The running cost $L\colon \mathbb{R}^d \times A \times \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}$, the drift $b\colon \mathbb{R}^d \times A \to \mathbb{R}^d$, the (constant, for simplicity of exposition) volatility $\sigma \in \mathbb{R}^{d\times d}$, and the terminal cost $g\colon \mathbb{R}^d \times \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}$ are given. The Hamiltonian $H(x, p, m)$ is defined by eq. (8.4).

One modelling choice has already been made silently in the way these data types are written, and it is worth dragging into the light because the rest of the chapter rides on it. In chapter 7 we worked with the *general* pivot, allowing the controlled drift to read the population law directly, $b = b(X_t, \alpha_t, m_t)$: the crowd could push each agent mechanically, not merely tax it. Here we specialize to a *measure-independent* drift $b(x, \alpha)$, with the population stripped out of the state equation entirely. The consequence is a clean division of labor between the two ways the crowd can act on an agent. In the general model the population enters both the dynamics and the cost; in the present one it enters *only through the cost*, $L(x, \alpha, m)$ and $g(x, m)$, while the law of motion an agent obeys depends on no one but itself. This is not a loss of generality worth worrying about, for three reasons we record now so they need not be relitigated later. First, it is the standard analytic arena for the subject: with the drift inert in m, the Hamiltonian's p-dependence is a fixed Legendre transform and only its m-slot moves with the crowd, which is what makes the two readings of the next subsections — and the variational structure of section 8.6 — come out as cleanly as they do. Second, it already contains the object we have been carrying: the LQG thread's drift $aX + b\alpha$ (worked computation 8.12) is measure-independent, the population there acting purely through a quadratic cost that penalizes deviation from the mean. Third, the genuinely more general case — the *extended* MFG, where the drift does see m — is a routine generalization rather than a new phenomenon: it thickens the coupling between the two equations (the Fokker–Planck drift then depends on m a second time, through b itself) but changes none of the structural features — the forward–backward split, the fixed-point reformulation, the verification logic — that this chapter is built to expose. We carry it out where a result actually needs it and otherwise keep the lighter notation.

With the data fixed we impose the standing hypotheses of the book (appendix A), invoked by their global tags so that the same names mean the same things across all of Part II. The list reads like bookkeeping, but each entry is doing a specific job, and the surest way to understand an assumption is to ask what collapses if it is dropped. We therefore state each tag together with the failure it forestalls.

(A-Lip) b, σ, L, g are Lipschitz in the state, uniformly in time, control, and the measure argument (the latter measured in $\mathcal{W}_2$). Lipschitz control of the coefficients is what keeps the maps in this chapter from being merely formal: it is what makes the closed-loop stochastic differential equation of eq. (8.5b) have a unique strong solution rather than branch or explode, and — in the *joint* (x, m)-Lipschitz form of assumption 7.3, which is how we read the tag wherever the fixed-point and verification arguments below require it — it is what makes the best-response map of section 8.4 continuous in the crowd, so that a small change in the population m produces only a small change in the agent's optimal response. Without a modulus of continuity in m there is no hope of a fixed point, since the very map whose fixed point we seek could jump. The tag (*A-Lip*) thus carries the same meaning throughout Part II.

(A-Growth) b, σ have at most linear growth in the state and L is coercive in the control — it grows fast enough in α (superlinearly, in the canonical normalization where the control *is* the drift) that steering harder is eventually never worth its price. This coercivity is exactly what guarantees that the supremum defining the Hamiltonian in eq. (8.4) is *attained at a finite control and is itself finite*: were L to grow only sublinearly in α, the agent could buy unboundedly favorable drift $-b(x, \alpha) \cdot p$ for asymptotically free, the supremum would run off to $+\infty$, and $H(x, p, m)$ would not even be a well-defined function, let alone one we could differentiate to read off a feedback. The linear growth of b, σ plays the partner role on the forward side: it keeps the closed-loop diffusion from escaping to infinity in finite time, so that mass is conserved and the flow m_t stays a genuine probability measure (the tightness invoked in eq. (8.9)).

(A-Nondeg) $\sigma\sigma^\top \succeq \lambda I$ for some $\lambda > 0$. This is the assumption that buys us *classical* solutions on both ends, and it is the one a physicist should read most physically: a strictly positive amount of noise in every direction means the second-order operator $\frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2\, \cdot)$ is uniformly elliptic, so both equations of eq. (8.5) are uniformly parabolic and their solutions are smoothed by diffusion rather than left to develop the singularities a first-order equation would. Concretely, on the backward side the $\frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2\, u)$ term regularizes the Hamilton–Jacobi nonlinearity into a classical $C^{1,2}$ value function (theorem 6.14); on the forward side the same operator turns the transport of m_0 into a smooth density solving eq. (8.5b) (theorem 5.14). Drop nondegeneracy and both statements weaken at once: the value function survives only in the viscosity sense developed in chapter 6, and the density may concentrate onto lower-dimensional sets where it has no Lebesgue representative. We assume $\lambda > 0$ throughout this chapter precisely so that "the density $m(t, \cdot)$" in definition 8.1 is an honest function we may insert into the cost.

(A-Conv) $L(x, \cdot, m)$ is *strictly* convex in the control. This is the most easily misread of the four, so we separate its two halves carefully. Convexity of the Hamiltonian $H(x, \cdot, m)$ in the costate p is *free*: by its definition eq. (8.4), $H(x, p, m)$ is a pointwise supremum over α of the maps $p \mapsto -b(x, \alpha) \cdot p - L(x, \alpha, m)$, each of which is *affine* in p; and a supremum of affine functions is convex no matter what, with no hypothesis on L at all. So if one wanted only "H convex in p" there would be nothing to assume. The content of the tag lies entirely on the other side: it is the *strict* convexity of L in α that we are buying, and what it buys is a *unique* maximizer in eq. (8.4). Uniqueness is exactly what the rest of the machinery needs — a unique maximizer makes the optimal drift $-\partial_p H$, and hence the feedback α^*, a single-valued function of (t, x), so that eq. (8.5b) transports along a well-defined velocity field and the verification theorem of chapter 6 applies. A merely convex L would leave H convex but possibly non-differentiable in p, the maximizing control set-valued at the kinks, and "the" optimal drift undefined precisely where it matters.

The distinction in (*A-Conv*) between what is free and what is assumed is subtle enough to deserve a concrete instance. Work in the canonical normalization $b(x,\alpha)=\alpha$, where $H(x,p,m) = \sup_\alpha\{-\alpha\cdot p - L(x,\alpha,m)\}$ is literally the Legendre transform of L in its control slot, and take $d=1$ with the bounded control set $A=[-1,1]$. Choose the running cost $L(\alpha)=|\alpha|$, which is convex but *not strictly* convex (it is flat-sided: affine on $[-1,0]$ and on $[0,1]$). The Hamiltonian is then

$$H(p) = \sup_{\alpha\in[-1,1]} \big\{ -\alpha\, p - |\alpha| \big\} = (|p|-1)_+,$$

a perfectly good convex function — convexity came for free, exactly as advertised, even though L was not strictly convex. But look at the maximizer. For $|p|<1$ the unique optimal control is $\alpha^*=0$; for $|p|>1$ it is the saturated value $\alpha^* = -\operatorname{sgn}(p)$. At the borderline costate $p=1$, however, the objective $-\alpha\, p - |\alpha| = -\alpha - (-\alpha) = 0$ is *identically zero for every* $\alpha\in[-1,0]$: the entire segment maximizes, and the optimal control is the whole interval $[-1,0]$ rather than a point. This is precisely the kink of H at $|p|=1$, where H fails to be differentiable and $-\partial_p H$ — the drift Fokker–Planck is supposed to transport along — has no single value. Strict convexity of L is exactly the hypothesis that erases such flat segments: it bends the cost strictly upward in α, so the supremum is attained at one control, H becomes C^1 in p, and the feedback is single-valued everywhere. Replace $|\alpha|$ by $\frac{1}{2}\alpha^2$ and the pathology vanishes: $H(p)=\frac{1}{2}p^2$ is smooth and the maximizer $\alpha^*=-p$ is unique for every p — the familiar LQG arithmetic of the carried thread. The micro-example is thus the whole point of (*A-Conv*) in miniature: convexity of H is automatic; single-valued feedback is not, and it is the strict convexity of L that secures it.

One assumption is conspicuously absent from this list, and its absence is deliberate rather than an oversight. Monotonicity **(A-Mon)** — the Lasry–Lions condition on how the cost responds to the crowd — is *not* needed to *write* the mean field game system, nor to *solve* it for a single equilibrium. Everything in this section and the next, the definition, the two readings, the verification theorem, the fixed-point reformulation, and the existence of a solution, runs on **(A-Lip)**, **(A-Growth)**, **(A-Nondeg)**, **(A-Conv)** alone. What **(A-Mon)** governs is a strictly later and different question: whether the equilibrium so produced is *the only one*, and whether the strategic system secretly minimizes a single convex energy. The first is the uniqueness theory of chapter 11; the second is the variational (potential-game) structure of section 8.6, where monotonicity is exactly the convexity that turns the forward–backward pair into the Euler–Lagrange system of one functional. Keeping monotonicity in reserve is not pedantry: it sharpens the reader's map of the subject by separating the hypotheses that make the equilibrium *exist and make sense* from the single extra hypothesis that makes it *unique and variational*. We therefore omit it here and flag its entry explicitly each time it is switched on downstream.

With the stage fully set — state space, data, Hamiltonian, and the four standing hypotheses all fixed and motivated, and monotonicity consciously held back — we have earned the right to state the system itself. The next subsection does nothing but record, as a precise definition, the coupled pair that section 8.1.2 produced heuristically; because every hypothesis it relies on is now in force by name, that definition can be written cleanly, with no caveat re-litigated, as the object of study for the remainder of the chapter.

8.2.2 The mean field game system

The stage is now fully set. The previous subsection fixed the data (b, σ, L, g), defined the Hamiltonian H by eq. (8.4), and switched on the four standing hypotheses **(A-Lip)**, **(A-Growth)**, **(A-Nondeg)**, **(A-Conv)**, each motivated by the failure it forestalls. Nothing is left undefined and no caveat remains to be relitigated. We have therefore earned the right to do the one thing this subsection exists to do: *record*, as a clean mathematical object, the coupled pair that the mean field collapse of section 8.1.2 produced heuristically. The heuristic already did the creative work — it told us the limiting equilibrium must be a backward HJB driven by the population locked to a forward Fokker–Planck driven by the feedback the value generates, with data at opposite ends of $[0, T]$. What remains is not to discover that form but to pin it down precisely enough to reason about on its own terms, with the finite game and the limit nowhere in sight. That is the content of the following definition; everything after it in this chapter is a study of the object the definition names.

Definition 8.1 (MFG PDE system)**.** A pair (u, m), with $u\colon [0, T] \times \mathbb{R}^d \to \mathbb{R}$ sufficiently smooth and $m\colon [0, T] \to \mathcal{P}_2(\mathbb{R}^d)$ a flow of measures with densities $m(t, \cdot)$, is a *(classical) solution of the mean field game system* with data (m_0, g) if

$$-\partial_t u - \tfrac{1}{2}\operatorname{tr}\big(\sigma\sigma^\top \mathrm{D}^2 u\big) + H(x, \nabla u, m_t) = 0, \qquad u(T, x) = g(x, m_T), \tag{8.5a}$$

$$\partial_t m - \tfrac{1}{2}\operatorname{tr}\big(\sigma\sigma^\top \mathrm{D}^2 m\big) - \operatorname{div}\Big(m\, \partial_p H(x, \nabla u, m_t)\Big) = 0, \qquad m(0, x) = m_0(x), \tag{8.5b}$$

hold on $(0, T) \times \mathbb{R}^d$, where D^2 and div act in the state variable x.

Two equations, two fields, two time directions: the definition is best absorbed not as a black box of symbols but as a sentence one can read aloud. Read as a whole, eq. (8.5) couples a *value* u that is computed backward from the deadline to a *density* m that is transported forward from the start, and the only places the two fields touch are the few we are about to isolate. Before turning each equation over we say what it is in words; after the display we say what its single point of contact with the other field is, because it is exactly the smallness of that contact — the "strikingly economical" coupling that will become a refrain — that the rest of Part II exploits.

Take eq. (8.5a) first. It is the backward Hamilton–Jacobi–Bellman equation of the representative agent, the very equation dynamic programming produced in chapter 6, now carrying a frozen population as a parameter. Its terminal datum $u(T, \cdot) = g(\cdot, m_T)$ sits at the end of the interval and information about the optimal cost-to-go propagates from there backward into $t < T$; the nonlinearity lives entirely in the Hamiltonian $H(x, \nabla u, m_t)$, which eq. (8.4) defined as the agent's pointwise best-response computation. The decisive observation is where the crowd appears in this equation, and where it does *not*. The population m_t enters eq. (8.5a) in exactly two slots — the third argument of H and the measure argument of the terminal cost g — and *nowhere else*. It does not touch the agent's dynamics (the drift b is measure-independent, by the standing specialization of the previous subsection), it does not touch the diffusion operator $\frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 u)$, and it does not touch the costate ∇u directly. From the value's point of view the entire population is a single time-dependent parameter dropped into its running and terminal costs. Hold $t \mapsto m_t$ fixed and eq. (8.5a) is an ordinary single-agent HJB equation of the kind chapter 6 solved; the whole strategic content is smuggled in through that one parametric slot.

Now eq. (8.5b). It is the forward Fokker–Planck (Kolmogorov forward) equation for the density of the closed-loop process: the law of the diffusion the representative agent actually realizes once it plays its optimal feedback. Its datum $m(0,\cdot) = m_0$ sits at the *start* of the interval and the density is pushed forward from there, the mirror image of the HJB's backward sweep. And just as the HJB touched the population in only one place, the Fokker–Planck touches the value in only one place: through the drift that carries the mass, the *optimal drift*

$$b\big(x, \alpha^*(t,x)\big) \;=\; -\,\partial_p H(x, \nabla u(t,x), m_t), \qquad \alpha^*(t,x) \;=\; \operatorname*{arg\,max}_{\alpha\in A} \Big\{ -b(x,\alpha)\cdot\nabla u(t,x) - L(x,\alpha,m_t) \Big\}, \tag{8.6}$$

which depends on the value only through its gradient ∇u. Nothing else of u reaches the forward equation: not its level, not its time derivative, only the spatial gradient, and that only as it is funnelled through $\partial_p H$.

The equality in eq. (8.6) is the *envelope identity* of remark 6.13, and because it is the hinge on which the coupling turns it is worth re-deriving in place rather than merely cited. The Hamiltonian eq. (8.4) is a supremum over controls,

$$H(x,p,m) = \sup_{\alpha\in A} \Big\{ -b(x,\alpha)\cdot p - L(x,\alpha,m) \Big\} = -b(x,\alpha^*)\cdot p - L(x,\alpha^*,m),$$

where $\alpha^* = \alpha^*(x,p,m)$ is the maximizer, single-valued and depending smoothly on (x,p,m) because **(A-Conv)** makes the bracket strictly concave in α with a unique stationary point. Differentiate the right-hand side in p. Naively there are two channels: the explicit p multiplying $-b(x,\alpha^*)$, and the implicit dependence of α^* on p. The second channel vanishes — this is the whole content of the envelope theorem. By the chain rule its contribution is

$$\partial_\alpha \Big[-b(x,\alpha)\cdot p - L(x,\alpha,m) \Big]\Big|_{\alpha=\alpha^*} \cdot\; \partial_p \alpha^*,$$

and the first factor is precisely the first-order optimality condition that *defines* α^*, hence is zero at an interior maximizer. (At a boundary maximizer the same conclusion holds by the standard envelope argument; under **(A-Conv)** together with the coercivity in **(A-Growth)** the maximizer is interior.) Only the explicit channel survives, and it gives at once

$$\partial_p H(x,p,m) \;=\; -\,b\big(x, \alpha^*(x,p,m)\big). \tag{8.7}$$

Evaluating eq. (8.7) at the costate $p = \nabla u(t,x)$ and the frozen crowd $m = m_t$ is exactly eq. (8.6): the gradient of the Hamiltonian *is* the (negative of the) closed-loop drift, recovered without ever re-solving the maximization. This is what makes the forward equation cheap to form from the backward one: one differentiates H, a function already in hand, instead of redoing the agent's optimization at every point.

A warning is built into eq. (8.6), and it is the single most common sign trap of the subject, so we state it sharply and then check it by hand. What m transports is the optimal *drift* $b(x,\alpha^*)$, and that drift equals $-\partial_p H$ — it is *not*, in general, the optimal control α^* itself. The two are distinct objects: α^* is the action the agent chooses, while $b(x, \alpha^*)$ is the velocity that action induces on the state, and only the latter appears in a transport equation, because Fokker–Planck moves mass along velocities, not along control values. The two coincide *exactly* in the canonical normalization $b(x, \alpha) = \alpha,\ A = \mathbb{R}^d$ — the convention of the general theory and of appendix A — in which the control *is* the drift and so $\alpha^* = -\partial_p H$ reads directly off eq. (8.7). The moment a control gain is present they part ways by exactly that gain.

The carried LQG thread is the cleanest place to watch them part, and the computation is short enough to run end to end. There (worked computation 8.12) the drift is $b(x, \alpha) = ax + b\,\alpha$ with control gain b, and the running cost is $L_0(\alpha) = \frac{1}{2}\alpha^2$, so with $p = \partial_x u$ the bracket in eq. (8.6) is

$$-b(x, \alpha)\, p - L_0(\alpha) \;=\; -(ax + b\,\alpha)\, p - \tfrac{1}{2}\alpha^2.$$

Maximizing in α kills the derivative $-b\,p - \alpha = 0$, so the optimal control is

$$\alpha^* = -b\,p = -b\,\partial_x u.$$

The transported drift is a *different* quantity: substitute this α^* back into b,

$$b(x, \alpha^*) = ax + b\,\alpha^* = ax + b\,(-b\,p) = ax - b^2\,\partial_x u \;=\; -\partial_p H,$$

which one may double-check directly from the closed form $H(x, p) = -ax\,p + \frac{1}{2}b^2p^2 + (m\text{-dependent cost})$, whence $\partial_p H = -ax + b^2 p$ and $-\partial_p H = ax - b^2\partial_x u$, the same thing. So the control the agent picks, $\alpha^* = -b\,\partial_x u$, and the drift the crowd transports along, $ax - b^2\partial_x u$, differ both by the gain b (the control is the velocity's controllable part divided through by b) and by the uncontrolled mean-reversion ax that is present in the velocity but absent from the control. Confusing the two would put the wrong velocity into eq. (8.5b) and violate conservation of mass; the envelope identity is precisely the bookkeeping that keeps drift and control straight.

We can now state the structural fact that the two readings of the next two subsections, and the fixed-point reformulation of section 8.4, all lean on. The coupling between eq. (8.5a) and eq. (8.5b) is *strikingly economical*: the backward equation needs the population only through the measure flow m_t, the forward equation needs the value only through the gradient ∇u (funnelled through $\partial_p H$), and *nothing else passes between them.* The entire interface of the mean field game is one measure flowing one way and one gradient flowing the other. This economy is not a cosmetic observation. It is what will let us, in section 8.4, collapse the whole coupled system onto a single best-response map on the space of measure flows — feeding m into the HJB, reading ∇u out of it, pushing the induced drift through Fokker–Planck, and asking for a fixed point — because so little information crosses the seam that the seam can be parametrized by the population flow alone. With the system stated and its interface laid bare, we turn to reading the two equations one at a time, each in the time direction that makes it elementary. We begin with the backward HJB equation, whose parabolic character is easiest to see by running the clock in reverse.

8.2.3 Reading one: HJB as a reverse-time value diffusion

We take the backward equation first, as promised, and the task of this first reading is to dissolve an unease the equation provokes the moment one looks at it as written. In eq. (8.5a) the time derivative carries a minus sign and the diffusion term carries a minus sign too: the agent's value obeys $-\partial_t u - \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 u) + H = 0$. A reader schooled on the heat equation $\partial_t \theta = \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 \theta)$ should flinch here, because moving both minus signs to the other side displays a Laplacian entering with the *wrong* sign relative to a forward-running time derivative — the signature of the *backward* heat equation, the canonical ill-posed problem in which fine features are amplified rather than smoothed and generic data cannot be evolved at all. Were that the correct reading, the HJB equation would be hopeless, and with it the whole left half of the mean field game. It is not the correct reading, and the cleanest way to see why is to stop fighting the clock and run it backward: the equation is not a heat equation evolved into its past but a perfectly ordinary diffusion evolved into its future, provided one agrees to call "the future" the direction in which the deadline recedes.

Make the substitution explicit. The value is anchored by data at the terminal time $t = T$ and computed toward earlier times, so the natural clock for it measures *time remaining until the deadline*. Set

$$\tau \;=\; T - t, \qquad \tilde{u}(\tau, x) \;=\; u(T - \tau, x),$$

so that $\tau = 0$ is the deadline $t = T$ and $\tau = T$ is the present $t = 0$; as the physical clock t runs down from T to 0, the reversed clock τ runs *up* from 0 to T. The only term that feels the reversal is the time derivative, by the chain rule $\partial_\tau \tilde{u} = -\partial_t u$; the spatial operators D^2 and ∇ act in x and are untouched, and the frozen population is simply read at the corresponding instant, $m_t = m_{T-\tau}$. Substituting $-\partial_t u = \partial_\tau \tilde{u}$ into eq. (8.5a) and moving the diffusion and Hamiltonian to the right turns the backward HJB equation into

$$\partial_\tau \tilde{u} = \tfrac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 \tilde{u}) - H(x, \nabla\tilde{u}, m_{T-\tau}), \qquad \tilde{u}(0, x) = g(x, m_T).$$

The single sign flip on the time derivative has done everything. The diffusion term now sits on the right with the *same* sign as the time derivative on the left — exactly the configuration of the ordinary heat equation — and the data, which in the original variables sat awkwardly at the end of the interval, now sit at $\tau = 0$, the natural starting line for a forward problem. In the reversed time τ the equation is therefore a genuine *forward parabolic* (reaction–diffusion) equation: the second-order part is the stabilizing diffusion that smears features out, and **(A-Nondeg)**, which makes $\sigma\sigma^\top \succeq \lambda I$, is precisely the uniform ellipticity that guarantees it smears in every direction at a strictly positive rate. The unease was an artifact of insisting on the physical clock. Read against the deadline, the value diffuses the way temperature does.

This gives the first reading its slogan. The terminal cost $g(\cdot, m_T)$ is the initial datum at $\tau = 0$ — the heat distribution the agent is handed at the deadline — and as τ grows, i.e. as the deadline recedes into the future and the agent has more time to act, the value *diffuses out from the terminal cost*. The cost-to-go at a present state is, in this picture, the terminal penalty seen through a lengthening lens of diffusive smoothing and the deterministic transport we turn to next: the further the deadline, the more the sharp profile of g has spread and been reshaped. The reaction–diffusion analogy is exact down to the two mechanisms a reaction–diffusion equation always combines. The $\frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 \tilde{u})$ term is the *diffusion*: it is the agent's own Brownian noise, integrated into the value because the cost-to-go must average over every future fluctuation of the state, and it acts to spread and smooth. The $-H(x, \nabla\tilde{u}, m_{T-\tau})$ term is the *reaction*: it is nonlinear in the gradient $\nabla\tilde{u}$ and it is the Hamilton–Jacobi transport of cost-to-go, the local bookkeeping by which the agent's optimal trade-off of drift against running cost — packaged once and for all into the Hamiltonian eq. (8.4) — pushes information about future penalties along the characteristics that the optimal feedback carves out. Diffusion blurs; the Hamiltonian transports and reshapes; together they propagate the terminal cost backward into a smooth field of optimal costs-to-go.

It is worth dwelling on why the reaction term, left to itself, would be the source of trouble, because that is where the role of **(A-Nondeg)** becomes physical rather than bookkeeping. Strip the diffusion away — set $\sigma = 0$ — and what remains, $\partial_\tau \tilde{u} = -H(x, \nabla \tilde{u}, \cdot)$, is a pure first-order Hamilton–Jacobi equation. Such equations are the deterministic limit of optimal control, and they are notorious for one behavior: even from perfectly smooth initial data their characteristics cross in finite time, and at the crossing the gradient $\nabla \tilde{u}$ becomes multivalued and the solution develops *kinks* — corners where u is continuous but ∇u jumps, the value analogue of a shock forming in a compressible flow. A classical (twice-differentiable) solution simply ceases to exist past the first crossing, and one is forced into the weaker notion of viscosity solutions to continue at all. Now restore the diffusion. The second-order term acts on any incipient kink exactly as heat conduction acts on a temperature corner: a discontinuity in the gradient is a near-singularity in the Hessian, and $\frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 \tilde{u})$ responds to it with an overwhelming smoothing flux that rounds the corner off before it can sharpen into a genuine singularity. Under **(A-Nondeg)** this happens uniformly and in every direction, and the upshot is that the strictly parabolic HJB equation admits a classical $C^{1,2}$ solution where its first-order shadow would only admit a kinked one — precisely the regularity theorem 6.14 delivers and that definition 8.1 quietly assumed when it spoke of u as "sufficiently smooth" and of ∇u as a genuine velocity to feed the forward equation.

This is the mechanism worth naming, because it recurs throughout the subject: *vanishing viscosity made non-vanishing.* In the classical theory of first-order Hamilton–Jacobi equations one *adds* an artificial viscosity $\varepsilon\Delta$, solves the regularized parabolic problem, and sends $\varepsilon \to 0$; the limit, taken along this vanishing-viscosity sequence, is what *defines* the viscosity solution and selects the physically correct kinked profile. The HJB equation of a genuinely noisy control problem skips the limit entirely. Its viscosity is not an artifice introduced to regularize and then removed; it is the agent's real diffusion $\frac{1}{2}\sigma\sigma^\top$, present in the model from the start and *never* sent to zero. The regularization that the classical theory must engineer by hand, **(A-Nondeg)** hands us for free, with $\lambda > 0$ the guaranteed floor on how much smoothing is always available. That is the precise sense in which the noise of the control problem is "vanishing viscosity made non-vanishing," and it is why, in the nondegenerate setting of this chapter, we may work with honest classical solutions and never mention viscosity solutions again. Should one ever drop **(A-Nondeg)** — allow the diffusion to degenerate in some direction, or pass to a deterministic ($\sigma = 0$) game — the smoothing floor collapses, kinks reappear, and the correct notion of solution reverts to the viscosity solutions developed in chapter 6; everything downstream then carries over in that weaker sense.

The HJB equation is, in short, a value equation that flows *against* the clock: its data live at the deadline and its information propagates from the future into the present, a forward diffusion only once one measures time by how much of it remains. That orientation is not a quirk to be normalized away — it is half of the structural tension this chapter is building toward. For the companion field runs the other way. The density m knows nothing of deadlines; it is handed its initial profile m_0 at $t = 0$ and pushed forward by the very feedback that the value, flowing backward, has just produced.

The next subsection reads eq. (8.5b) in *its* natural direction, recasting it not as a value diffusion but as a continuity equation that conserves mass while transporting it forward along the optimal drift. Holding the two readings side by side will make the asymmetry impossible to miss: one equation is solved from the future, the other from the past, and they are chained to each other at both ends of $[0,T]$. That collision of opposed time directions — the value pulled backward from T, the mass pushed forward from 0, each feeding the other — is the forward–backward tension that section 8.3 will name as the structural signature of the entire subject.

8.2.4 Reading two: Fokker–Planck as conservation of mass

The first reading left the value flowing against the clock, its data pinned at the deadline. Its companion runs the other way. The density m is handed an initial profile m_0 at $t=0$ and pushed forward, and the right way to read eq. (8.5b) is therefore not as a backward value diffusion but in the time-direction natural to a population: as a statement about how a fixed unit of probability is carried around $\mathbb{R}^d$ as time advances. A population density is not an arbitrary field. It must satisfy two non-negotiable constraints to deserve the name at all — it must stay nonnegative (there is no such thing as a negative amount of crowd at a point) and its total mass must stay equal to one (the agents do not multiply or vanish; the same unit of probability is merely rearranged). The task of this second reading is to make both constraints *manifest* rather than hope for them, and the device that does so is the oldest bookkeeping in physics: write the evolution as a conservation law, a continuity equation in which the only thing that ever happens to the density is that it flows. Once eq. (8.5b) is in that form the two constraints fall out almost for free, the first from the divergence theorem and the second from the meaning of the object being transported.

Recast eq. (8.5b), then, as a continuity equation. A continuity equation says that the rate of change of a density at a point is minus the divergence of a *current* — the local flux of stuff through that point — so we must first exhibit the current that eq. (8.5b) is implicitly moving mass along. Define the *probability current*

$$\mathbf{J}(t,x) \;:=\; \underbrace{m(t,x)\,b\big(x,\alpha^*(t,x)\big)}_{\text{advective}} \;-\; \underbrace{\tfrac{1}{2}\,\sigma\sigma^\top\nabla m(t,x)}_{\text{diffusive}}, \tag{8.8}$$

where we used the envelope identity eq. (8.6) to write the optimal drift as $b(x,\alpha^*) = -\partial_p H(x,\nabla u, m_t)$. The two pieces are the two physically distinct ways mass moves, and it is worth naming each. The first, $m\,b(x,\alpha^*)$, is the *advective* (convective) current: a parcel of probability at x is carried bodily along the optimal velocity field $b(x,\alpha^*)$, exactly as a dye is swept along by a fluid, the local flux being density times velocity. The second, $-\frac{1}{2}\sigma\sigma^\top\nabla m$, is the *diffusive* (Fick) current: noise drives mass down its own gradient, from where the crowd is dense toward where it is sparse, at a rate set by the diffusion matrix $\frac{1}{2}\sigma\sigma^\top$. The minus sign is Fick's law made literal — the flux opposes the gradient — and it is this term, present precisely because the agents diffuse, that will later supply the smoothing the existence theory leans on.

Notation watch

The current is set in *boldface* $\mathbf{J}$ deliberately, to keep it apart from the plain letter J, which throughout the book denotes a *cost functional*: the agent's objective $J(\alpha)$ of eq. (8.22) on the LQG thread, and the per-player cost $J^i(\alpha^1, \ldots, \alpha^N)$ of eq. (8.2) carried from chapter 7. The two objects could not be more different in kind — one is a vector field on $\mathbb{R}^d$, the other a real number assigned to a control — but they share a glyph, and the boldface is the only thing that disambiguates them. We never write the current without the boldface, and never the cost functional with it.

With the current named, the claim is that eq. (8.5b) *is* the continuity equation for it,

$$\partial_t m + \operatorname{div} \mathbf{J} = 0, \tag{8.9}$$

and this is a one-line verification worth doing in the open, because it is exactly where a sign error would hide. Take the divergence of eq. (8.8) term by term. The diffusive piece gives, since $\sigma\sigma^\top$ is a constant matrix,

$$\operatorname{div}\Big(\tfrac{1}{2}\sigma\sigma^\top \nabla m\Big) = \sum_{i,j} \tfrac{1}{2}(\sigma\sigma^\top)_{ij}\, \partial_{x_i}\partial_{x_j} m = \tfrac{1}{2}\operatorname{tr}\big(\sigma\sigma^\top\, \mathrm{D}^2\, m\big),$$

the very second-order operator appearing in eq. (8.5b). The advective piece gives $\operatorname{div}(m\, b(x, \alpha^*))$, and using $b(x, \alpha^*) = -\partial_p H$ this is exactly the transport term of eq. (8.5b) with its sign reversed: $\operatorname{div}(m\, b(x, \alpha^*)) = -\operatorname{div}(m\, \partial_p H)$. Assembling,

$$\partial_t m + \operatorname{div} \mathbf{J} = \partial_t m - \tfrac{1}{2}\operatorname{tr}\big(\sigma\sigma^\top\, \mathrm{D}^2\, m\big) - \operatorname{div}\big(m\, \partial_p H(x, \nabla u, m_t)\big),$$

which is precisely the left-hand side of eq. (8.5b). So setting $\partial_t m + \operatorname{div} \mathbf{J} = 0$ *is* the Fokker–Planck equation; the continuity form is not an analogy but a literal rewriting. (This is the place to honor the chapter's standing dictum: every sign in eq. (8.8) should be checked against this identity, never against a remembered formula, because it is the conservation law that the signs must serve.)

Now reap the first constraint. Conservation of total mass is the statement that a continuity equation makes automatic, and the argument is the divergence theorem applied to all of $\mathbb{R}^d$. Integrate eq. (8.9) over the whole space and exchange the time derivative with the spatial integral:

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathbb{R}^d} m(t,x)\, \mathrm{d}x = \int_{\mathbb{R}^d} \partial_t m\, \mathrm{d}x = -\int_{\mathbb{R}^d} \operatorname{div}\mathbf{J}\, \mathrm{d}x = -\lim_{R\to\infty}\int_{\partial B_R} \mathbf{J}\cdot\mathbf{n}\, \mathrm{d}S,$$

the last step being the divergence theorem on the ball B_R of radius R, with $\mathbf{n}$ the outward normal. Everything hinges on that boundary flux vanishing as $R \to \infty$, and this is exactly where a standing hypothesis does load-bearing work rather than decoration. The flux $\int_{\partial B_R} \mathbf{J}\cdot\mathbf{n}\, \mathrm{d}S$ measures the rate at which probability crosses the sphere of radius R outward; it tends to zero only if essentially no mass — and no current — reaches arbitrarily large radii. That is precisely the content of *tightness*: the family $\{m(t,\cdot)\}_{t\in[0,T]}$ keeps all but a vanishing fraction of its mass inside a fixed compact set, with both density and gradient decaying at infinity fast enough to kill the surface integral. Tightness is in turn what **(A-Growth)** buys: the at-most-linear growth of b and σ prevents the closed-loop diffusion from carrying mass off to infinity in finite time, yielding the uniform moment bounds that, by the tightness criterion of chapter 3, confine the flow. With the boundary term gone we are left with

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathbb{R}^d} m(t,x)\ \mathrm{d}x = 0,$$

so the total mass is a constant of the motion; since m_0 is a probability density with $\int m_0 = 1$, every later slice $m(t,\cdot)$ integrates to one as well. Mass does not leak: the unit of probability handed in at $t = 0$ is conserved exactly, only rearranged. This is the first half of "m genuinely transports a probability density."

The second half is nonnegativity, and here the situation is unusually comfortable: there are *two* independent routes to it, and neither requires us to invent any new maximum-principle machinery, because each leans on a fact we have already established for this exact operator. They are worth giving separately, since they illuminate the conclusion from opposite sides — one says nonnegativity is a fact about *probability*, the other that it is a fact about *parabolic PDEs* — and they agree only because theorem 5.14 identifies the two solutions they speak about.

The first route is probabilistic, and it gets nonnegativity for free from the *meaning* of the solution. By the Kolmogorov-forward representation of theorem 5.14, the unique solution of eq. (8.5b) with initial probability density m_0 is nothing other than the family of time-marginal laws of the closed-loop diffusion

$$\mathrm{d}X_t = b\big(X_t, \alpha^*(t,X_t)\big)\ \mathrm{d}t + \sigma\ \mathrm{d}W_t, \qquad X_0 \sim m_0,$$

that is, $m_t = \mathcal{L}(X_t)$ — this stochastic differential equation having a unique strong solution because **(A-Lip)** and **(A-Growth)** make its drift Lipschitz and non-exploding. But a law is, by the very definition of a probability measure, nonnegative: $m_t(E) = \mathbb{P}(X_t \in E) \geq 0$ for every Borel set E, so its density is nonnegative wherever it exists. Nonnegativity here is not something one proves about the PDE at all; it is inherited from the fact that the PDE is solved by a *law*. No comparison argument, no maximum principle, nothing beyond reading off what theorem 5.14 says the solution is.

The second route forgets the probabilistic representation entirely and treats eq. (8.5b) as the linear PDE it manifestly is. Once the value function has been solved and the feedback $\alpha^*(t,x)$ frozen, the velocity field $b(\cdot,\alpha^*(t,\cdot))$ is a *known* coefficient — and a Lipschitz one, because **(A-Nondeg)** makes the value classical (theorem 6.14) and hence its gradient, through which the feedback is read, Lipschitz in space. The equation

$$\partial_t m = \tfrac{1}{2}\,\mathrm{tr}\big(\sigma\sigma^\top\,\mathrm{D}^2\, m\big) - \mathrm{div}\big(m\, b(\cdot,\alpha^*)\big)$$

is then a *linear, uniformly parabolic* equation in the single unknown m, uniform parabolicity being exactly **(A-Nondeg)**'s $\sigma\sigma^\top \succeq \lambda I$. Such operators obey a weak comparison principle: two solutions ordered at the initial time stay ordered for all later times. Apply it with the constant function $m \equiv 0$, which is itself a solution, as the lower barrier. At $t = 0$ we have $m_0 \geq 0$; comparison propagates this ordering forward, giving $m(t,\cdot) \geq 0$ for every t. This needs "no separate maximum-principle apparatus" in the precise sense that the comparison principle for this very operator is already part of the linear parabolic theory packaged in theorem 5.14 — we import it, we do not re-erect it — and uniform parabolicity, the single hypothesis it requires, is one we have assumed from the outset.

Putting the two halves together, eq. (8.5b) does exactly what a population density must: it conserves probability (mass stays one, by the divergence theorem and **(A-Growth)**) and keeps it nonnegative (by either route above), all while transporting the crowd along the optimal feedback and diffusing it at rate $\frac{1}{2}\sigma\sigma^\top$. The forward half of the mean field game is, in this reading, a bona fide conservation law for a genuine probability density — not a formal adjoint written down for symmetry with the HJB, but an honest transport of mass.

Physics note

The Fokker–Planck equation eq. (8.9) is a continuity equation for a conserved density, its current $\mathbf{J}$ split into an advective (drift) part and a Fick (diffusive) part — the same anatomy as the continuity equation of any transported scalar. What is unusual, and is the whole reason a physicist should pause here, is the *origin of the advective velocity.* In ordinary transport theory the drift is an externally prescribed field; here it is generated *self-consistently*: $b(x, \alpha^*) = -\partial_p H(x, \nabla u, m_t)$ is read off from the value u, which was itself computed knowing the very flow m it now transports. The field that moves the crowd is the field the crowd itself generates. This is precisely the self-consistent-field closure of mean field statistical mechanics — the Curie–Weiss magnet feeling the mean magnetization it collectively produces — but with one decisive substitution. In the thermal case the relation that closes field to configuration is an *averaging* postulate (the mean field is a Boltzmann-weighted expectation); here it is an *optimization.* The crowd's drift is the gradient of everyone's best strategy, and everyone's best strategy is computed against the crowd's drift. Replacing the Boltzmann average by a best response is the entire conceptual distance between equilibrium statistical mechanics and a mean field *game.*

The two readings now stand side by side, and the picture they jointly produce is the one the next section must come to terms with: a value flowing backward from the deadline and, locked to it, a conserved probability density flowing forward from the start, the density driven by a drift that the value manufactures and the value shaped by a population that the density *is.* We have called this drift "self-consistent" and the loop "closed," but those are so far slogans — the physicsnote earns them only at the level of a suggestive closure relation. What we have genuinely established is narrower and firmer: that the forward equation, fed a feedback from *any* value function, transports a probability density honestly. Whether the loop actually closes — whether a pair (u, m) solving the two equations together really encodes a representative agent best-responding to a crowd that reproduces itself, rather than two equations that merely happen to share symbols — is a separate claim that a pair of PDEs does not certify on its own. The next subsection takes up exactly that worry, making "self-consistent" precise as a genuine fixed-point property via the verification theorem; and the forward–backward collision we have just laid bare — one equation solved from the future, the other from the past — is what section 8.3 will name as the structural signature of the whole subject.

8.2.5 Why the coupling is legitimate: verification

Reading Two left us with a picture and a debt. The picture is the self-consistent field of the chapter's preamble made nearly tangible: a conserved unit of probability transported forward along a drift that the value function manufactures, while the value in turn is shaped by the very population the density carries. We have been calling that drift "self-consistent" and the loop "closed" since section 8.1.2, but as the close of the previous subsection warned, those are still slogans. A pair of partial differential equations does not become an equilibrium merely because we wrote the two fields with names that share symbols; nothing forces the m that the agent optimizes *against* in eq. (8.5a) to be the same object as the m that the optimal feedback *produces* through eq. (8.5b). We have only *posited* that coincidence, in definition 8.1, by writing the same letter twice. The worry is therefore precise and it must be discharged before the system earns the name we have given it: *is solving the coupled pair really the same act as a representative agent best-responding to a crowd that reproduces itself?* The instrument that settles the question is the verification theorem of stochastic control — imported wholesale from chapter 6 and applied with the population flow held fixed, so that no appeal to any limit and no trace of the finite game enters. The strategy is exactly the one the heuristic anticipated: freeze the crowd, certify that the agent's response to it is genuinely optimal, and then check that the law that response generates is the crowd we froze.

Proposition 8.2 (Representative-agent optimality)**.** *Assume **(A-Lip)**, **(A-Growth)**, **(A-Nondeg)**, **(A-Conv)**. Let $m = (m_t)_{t\in[0,T]}$ be a fixed flow of measures and let u be the classical solution of the backward HJB equation eq. (8.5a) with this m. Then $u(t,x)$ is the value function of the representative agent's control problem against the environment m, namely*

$$u(t,x) = \inf_{\alpha} \ \mathbb{E}\left[\int_t^T L(X_s, \alpha_s, m_s)\ \mathrm{d}s + g(X_T, m_T)\ \Big|\ X_t = x\right],$$

the infimum over admissible feedback controls of the diffusion $\mathrm{d}X_s = b(X_s,\alpha_s)\ \mathrm{d}s + \sigma\ \mathrm{d}W_s$; and the feedback $\alpha^*(t,x)$ of eq. (8.6), whose closed-loop drift is $b(x,\alpha^*(t,x)) = -\partial_p H(x,\nabla u(t,x),m_t)$, is optimal. Consequently the law of the optimally controlled diffusion solves the Fokker–Planck equation eq. (8.5b).

The hypotheses are exactly the four standing ones of the chapter, and it is worth keeping in view — since the proof leans on each in a different place — which clause does which job: nondegeneracy makes the HJB classically solvable so that Itô's formula may be applied to u at all; convexity makes the maximizer in the Hamiltonian unique so that "the" optimal control is a function rather than a set; Lipschitz and growth control keep the closed-loop dynamics from exploding and keep the cost integrals finite. The argument below is a sketch by design — the two engines it runs on, the verification theorem and the forward-equation theorem, are proved in full in chapter 6 and chapter 5 — but it is an honest sketch: we write out the Itô-to-optimality chain explicitly, because it is short and it is exactly where the HJB equation does its work, and we are careful about the one genuinely delicate step, the well-posedness of the closed-loop equation, rather than waving it through.

Proof sketch. Step 0: the value function exists and is regular. Existence of the classical solution u is not at issue here, but it is the platform the rest stands on, so we name it precisely. Hold the flow m fixed. Then the backward HJB equation eq. (8.5a) is a single semilinear parabolic equation in which the population appears nowhere as an unknown: it enters only through the two slots $H(x, \nabla u, m_t)$ and $g(x, m_T)$, i.e. as a *prescribed* time-dependent coefficient and a prescribed terminal datum. Because $t \mapsto m_t$ is $\mathcal{W}_2$-continuous and H, g are Lipschitz in m for $\mathcal{W}_2$ by **(A-Lip)**, that coefficient is merely a Lipschitz-in-time inhomogeneity — it adds no new nonlinearity and no spatial roughness. Under **(A-Nondeg)** the second-order operator is uniformly elliptic, so the equation is uniformly parabolic, and **(A-Conv)** and **(A-Growth)** make H smooth in p with controlled growth; the classical-solvability theorem theorem 6.14 then delivers a unique $C^{1,2}$ solution u of polynomial growth. The proof there is written for a frozen measure m, but it uses of m only that it enters as a coefficient with the stated regularity, so it applies verbatim with $m \mapsto m_t$ a given continuous flow. The point to carry forward is that u is genuinely $C^{1,2}$ — continuously differentiable in time and twice in space — which is exactly the regularity Itô's formula will demand.

Step 1: Itô along an arbitrary control gives $u \le J$. Fix the start (t, x) and let $\alpha = (\alpha_s)_{s\in[t,T]}$ be *any* admissible feedback control, driving the diffusion $\mathrm{d}X_s = b(X_s, \alpha_s)\,\mathrm{d}s + \sigma\,\mathrm{d}W_s$ from $X_t = x$. Write $J(\alpha)$ for the cost in the Proposition. Apply Itô's formula (theorem 5.9) to the $C^{1,2}$ function $s \mapsto u(s, X_s)$:

$$\mathrm{d}\,u(s, X_s) = \Big[\partial_s u + b(X_s, \alpha_s)\cdot\nabla u + \tfrac{1}{2}\operatorname{tr}\big(\sigma\sigma^\top \mathrm{D}^2 u\big)\Big]\,\mathrm{d}s + \nabla u\cdot\sigma\,\mathrm{d}W_s.$$

The stochastic integral is a martingale — ∇u has polynomial growth and the diffusion has finite moments under **(A-Growth)** — so taking expectations and integrating from t to T kills it:

$$\mathbb{E}[u(T, X_T)] - u(t, x) = \mathbb{E}\left[\int_t^T \Big[\partial_s u + b(X_s, \alpha_s)\cdot\nabla u + \tfrac{1}{2}\operatorname{tr}\big(\sigma\sigma^\top \mathrm{D}^2 u\big)\Big]\,\mathrm{d}s\right].$$

Now invoke the HJB equation eq. (8.5a) in the rearranged form $\partial_s u + \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 u) = H(X_s, \nabla u, m_s)$, and the defining inequality of the Hamiltonian eq. (8.4), which says that for *every* control value α_s,

$$H(X_s, \nabla u, m_s) \;\ge\; -b(X_s, \alpha_s)\cdot\nabla u - L(X_s, \alpha_s, m_s),$$

because H is the supremum of exactly that bracket over admissible controls. Substituting, the integrand obeys $\partial_s u + b\cdot\nabla u + \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 u) = H + b\cdot\nabla u \ge -L(X_s, \alpha_s, m_s)$, whence

$$\mathbb{E}[u(T, X_T)] - u(t, x) \;\ge\; -\mathbb{E}\left[\int_t^T L(X_s, \alpha_s, m_s)\,\mathrm{d}s\right].$$

Using the terminal datum $u(T, \cdot) = g(\cdot, m_T)$ and rearranging gives the clean inequality

$$u(t, x) \;\le\; \mathbb{E}\left[\int_t^T L(X_s, \alpha_s, m_s)\,\mathrm{d}s + g(X_T, m_T)\right] = J(\alpha).$$

The value function thus underbounds the cost of every admissible control — which is half of what "value function" means.

*Step 2: equality at the pointwise maximizer, and where **(A-Conv)** enters.* The inequality of Step 1 came from a single inequality, the one between H and the bracket, and it is an equality precisely when the running control achieves the supremum in eq. (8.4) at each instant. That is, choose the feedback $\alpha_s = \alpha^*(s, X_s)$ with α^* the maximizer of eq. (8.6); then the bracket equals H identically along the path, every inequality above becomes an equality, and $u(t,x) = J(\alpha^*)$. Combined with Step 1 this is exactly $u(t,x) = \inf_\alpha J(\alpha) = J(\alpha^*)$: u is the value function and α^* is optimal. Here is where strict convexity earns its keep. For the recipe "play the maximizer" to define an honest feedback we need the maximizer to be a single point, not a flat set; **(A-Conv)** — strict convexity of $L(x,\cdot,m)$ in the control — makes the bracket strictly concave in α, so the argmax in eq. (8.6) is unique, the optimal drift is the single value $-\partial_p H$ by the envelope identity, and $\alpha^*(s,\cdot)$ is a genuine function. Without it the maximizing control could be set-valued at the kinks of H, exactly the pathology the micro-example of section 8.2 exhibited, and "the" optimal feedback would be undefined precisely where the forward equation needs a velocity field.

Step 3: the closed-loop law solves Fokker–Planck. It remains to identify the density the optimal agent produces. Substitute the optimal feedback into the dynamics: the representative agent, playing α^*, realizes the *closed-loop* diffusion

$$\mathrm{d}X_s = b\big(X_s, \alpha^*(s, X_s)\big)\,\mathrm{d}s + \sigma\,\mathrm{d}W_s, \qquad X_0 \sim m_0.$$

By the Kolmogorov-forward (Fokker–Planck) theorem of chapter 5 (theorem 5.14), the law of this diffusion has, under **(A-Nondeg)**, a density $\widetilde{m}(s,\cdot)$ solving $\partial_s \widetilde{m} = \mathcal{A}^*_{\alpha^*}\widetilde{m}$, where $\mathcal{A}^*_{\alpha^*}$ is the formal adjoint of the generator of the closed-loop process — the same second-order part $\frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2\,\cdot)$ as on the backward side, plus the transport $-\operatorname{div}(\,\cdot\, b(x,\alpha^*))$. Now make the one substitution that fuses the two equations: by eq. (8.6) the closed-loop drift *is* the optimal drift, $b(x,\alpha^*) = -\partial_p H(x, \nabla u, m_s)$, so the forward equation for $\widetilde{m}$ reads $\partial_s \widetilde{m} - \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2\,\widetilde{m}) - \operatorname{div}(\widetilde{m}\,\partial_p H(x,\nabla u, m_s)) = 0$ — which is letter for letter the Fokker–Planck equation eq. (8.5b), with the same initial datum m_0. The law the optimal agent generates therefore solves the very equation the density was asked to solve.

Step 4: the delicate point — the closed-loop equation is well-posed. Steps 1–3 quietly assumed that the closed-loop diffusion of Step 3 exists, is unique, and has a single well-defined law to speak of. That is not free, because the drift $x \mapsto b(x, \alpha^*(s,x))$ is itself built by an optimization and could in principle be too rough for the SDE to have a unique strong solution. This is the one step worth pausing on. The optimal drift is the composition $-\partial_p H(x, \nabla u(s,x), m_s)$ of three ingredients: the map $p \mapsto -\partial_p H(x,p,m)$, which is locally Lipschitz because **(A-Conv)** makes H continuously differentiable in p with a Lipschitz gradient; the spatial gradient $\nabla u(s,\cdot)$, which is Lipschitz in x because u is $C^{1,2}$ by Step 0; and the frozen slice m_s, which is a constant in x. A composition of Lipschitz maps is Lipschitz, so $x \mapsto b(x,\alpha^*(s,x))$ is Lipschitz in x, uniformly on $[0,T]$. The standard strong-existence-and-uniqueness theorem for SDEs with Lipschitz drift and (here constant, hence Lipschitz) diffusion then applies: the closed-loop equation has a unique strong solution, its law is well-defined, and Step 3's identification is legitimate. It is precisely the marriage of **(A-Conv)** (smoothness of H in p) with the $C^{1,2}$ regularity of u from **(A-Nondeg)** that supplies this Lipschitz feedback; drop either and the closed-loop drift could lose the regularity that makes "the law of the optimal agent" a single object at all. The full arguments behind the two imported theorems are in chapter 6 (verification) and chapter 5 (forward equation); what we have done here is assemble them against the frozen flow and check the seam where they meet. □

The proposition is exactly the rigorous content of the heuristic's "close the loop," and it is worth saying plainly what has and has not been shown. We did *not* prove that the system has a solution —

m was held fixed throughout, an input we never had to produce. What we proved is the *internal consistency* promised in section 8.2: *if* a pair (u, m) solves eq. (8.5), then the two appearances of m are not an accident of notation but a genuine equilibrium identity — the flow the agent optimizes against is reproduced exactly by the flow its optimal response generates. The double use of the letter m in definition 8.1 is thereby vindicated: a solution of the coupled pair is a flow m such that, when the representative agent best-responds to it, the law it itself generates is m again. The crowd one optimizes against and the crowd one's optimization produces are the same crowd. That is a fixed point, the subject of section 8.4 — and the obstruction standing between this self-map and a march in time, namely that its two equations carry their data at opposite ends of $[0, T]$, is exactly the forward–backward structure that the next section now isolates as the structural signature of the whole subject.

8.3 The forward–backward boundary-value problem

The verification proposition of the last section left us with a sentence to live with: a solution of eq. (8.5) is a flow m such that, when the representative agent best-responds to it, the law its optimization generates is m again — the crowd one optimizes against and the crowd one's optimization produces are the same crowd. That is a self-consistency, and we already saw, in the two readings of section 8.2, that the two equations realizing it run in *opposite* temporal directions. The HJB equation eq. (8.5a) is a value flow read *backward*: its datum sits at the deadline $t = T$, and the optimal cost-to-go diffuses out of the terminal cost g as the horizon recedes toward the present. The Fokker–Planck equation eq. (8.5b) is a mass flow read *forward*: its datum sits at the start $t = 0$, and the initial population m_0 is transported along the optimal drift as the clock advances. The self-consistent flow that verification certified is therefore stitched together from two halves whose data are pinned at *opposite ends* of $[0, T]$.

We pause on this structure — and the whole of the present section does nothing but pause on it — because it is the single feature that sets a mean field game apart from every evolution problem the reader has solved by marching a known state forward, and because it is the seed from which essentially all of the analytic difficulty in Parts II and IV grows. Existence (chapter 10), uniqueness (chapter 11), the master equation that linearizes the fixed point (Part IV), and the convergence of the N-player Nash equilibria (chapter 13) are each hard for the *same* reason, and that reason is the two-point structure we now isolate. It is worth getting it into the bones before any of those chapters lean on it, so we will resist the temptation to state it as a one-line slogan and instead watch, concretely, exactly where an attempt to solve the system the only way one knows how — by integration from a single time slice — breaks down.

So imagine you sit at $t = 0$ holding the one thing the problem actually hands you at that instant: the initial population m_0. You would like to do what every initial-value solver does, namely produce the state an infinitesimal step later and repeat. The Fokker–Planck equation eq. (8.5b) is even willing to oblige in *form* — it is a forward parabolic equation, exactly the kind one integrates from $t = 0$ — but to take the step it demands the velocity field along which to transport the mass, the optimal drift $-\partial_p H(x, \nabla u, m_0)$. That drift is built from $\nabla u(0, \cdot)$, the gradient of the value function *now*. So you turn to the HJB equation to supply $u(0, \cdot)$ — and there the march dies. The HJB equation eq. (8.5a) does not determine u at the present from anything in the present; it determines $u(0,\cdot)$ only as the result of integrating *backward* from the terminal condition $u(T,\cdot) = g(\cdot, m_T)$, and that backward integration reads the population density m_t at *every* intermediate time $t \in [0,T]$ as it goes, because the Hamiltonian's third slot is fed m_t all along the way. To know $u(0,\cdot)$ you must already know the entire future flow $\{m_t\}_{t\in[0,T]}$ — which is the very object you were trying to construct, step by step, starting from the one slice m_0 you possess. You have come full circle without advancing the clock by a single instant: the first forward step needs a value that needs the whole future of the mass that you have not yet built. The symmetric attempt fares no better. Sit instead at $t = T$ holding g, the one datum the value equation offers, and try to integrate the HJB equation backward; at the first step it asks for m_T, the terminal population, which is the *output* of running the forward equation eq. (8.5b) from $t = 0$ all the way to T along a drift that depends on the very u you are trying to compute. Each sweep, in either direction, stalls at its first step on a global-in-time demand for the other field. This is the obstruction in its rawest form, and the following remark records it.

Remark 8.3 (No initial-value reduction)**.** One cannot march eq. (8.5) forward (or backward) in time from a single time slice. To step the density forward via eq. (8.5b) one needs the feedback, hence ∇u at the *current* time; but u at the current time is determined by the HJB equation *integrated backward from* $t = T$, which requires knowing m_t over the *entire* future interval $[t,T]$. Symmetrically, to integrate the HJB equation backward one must already know the future density, which is produced by the forward equation, which in turn needs the value. Neither equation can be advanced one step without the other's *global-in-time* solution already in hand. There is no Cauchy datum at any single time from which both fields evolve: the problem is genuinely a two-point boundary-value problem *in function space*, in which one seeks the pair (u,m) on the whole space–time cylinder $[0,T]\times\mathbb{R}^d$ at once, subject to one constraint (m_0) at the past end and a different constraint (g) at the future end. The forward–backward coupling is not a Cauchy problem with awkward data; it has no initial-value reduction at all.

It is worth being precise about which familiar tool this defeats, because naming the failure points to the cure. The workhorse for ordinary evolution equations is the Picard iteration that underlies the Cauchy–Lipschitz theorem: given the state at one time, one writes the solution as a fixed point of the integral operator "initial datum plus the time-integral of the vector field," and a Lipschitz bound makes that operator a contraction on a short time interval, so the solution exists, is unique, and is obtained by literally iterating short forward steps. Every ingredient of that argument presumes a *Cauchy datum*: a single slice from which the integral operator builds the future. The mean field game system has no such slice to feed the iteration — as the remark shows, no time carries data for *both* fields — so the Picard/Cauchy–Lipschitz machinery does not merely converge slowly or under stronger hypotheses; it does not even get started, because the object it iterates, "the solution as a function of one initial condition," does not exist here. The local-in-time contraction that tames ODEs and parabolic Cauchy problems is simply the wrong shape for a problem whose constraints live at two separated times.

The way past the obstruction is therefore not to repair the march but to abandon it, and to solve for the whole flow at once. The standard device — set up here only far enough to motivate it, made precise in the next section and deployed in chapter 10 — decouples the two ends by turning the self-consistency demand into a search for a fixed point of a map on the space of *density flows* alone. The idea is to break the circle the remark exposed by cutting it at the population: *guess* an entire flow $m = \{m_t\}_{t\in[0,T]}$, treat it as the frozen background of section 8.2, and let each equation run in the one direction that is now unobstructed. With m given over all of $[0,T]$, the HJB equation eq. (8.5a) *can* be integrated backward from g — its third slot is now a known schedule, so the obstruction of the remark is gone — yielding a value u and, by the envelope identity, a feedback drift $-\partial_p H(x, \nabla u, m_t)$. With that feedback in hand the Fokker–Planck equation eq. (8.5b) *can* be integrated forward from m_0, transporting the initial population along the now-known drift to produce a *new* flow, which we will call $\mathsf{S}[m]$. The guess and the output need not agree; a solution of eq. (8.5) is exactly a flow on which they do — a flow left invariant by this guess-solve-read-transport cycle, $m = \mathsf{S}[m]$. One has converted a two-point boundary-value problem with no initial-value reduction into a *fixed-point problem for a single self-map* of the space of flows, at the price of having to find the right flow rather than march to it. That existence of a fixed point is then secured not by contraction but by compactness: the smoothing of **(A-Nondeg)** and the tightness furnished by the mass and moment bounds (chapter 3) make S a continuous self-map of a compact convex set of flows, and a topological fixed-point theorem of the Schauder/Kakutani family (chapter 2) then forces a fixed point to exist. The essential point for the present section is conceptual, and we state it flatly so it is not mistaken: the fixed-point reformulation does *not* remove the forward–backward structure, it *encodes* it. The whole difficulty of the two-point problem has been packed into the single map S, whose evaluation *contains* one backward HJB sweep and one forward Fokker–Planck sweep glued at their data; the fixed points of S are, by construction, precisely the solutions of the two-point problem with its data at both ends. We trade a problem we cannot integrate for a problem we cannot contract, and earn existence from compactness instead of from iteration.

That trade also reveals the true mathematical genus of the object, and it is the one the closing of this section wants to leave the reader holding. A problem whose data sit at two separated ends of an interval, with no evolution from a single slice, is not a Cauchy problem at all; it is a *boundary-value problem*, and boundary-value problems are the native habitat of the calculus of variations, where the stationarity condition of a functional over a time interval generically produces equations constrained at both endpoints rather than initialized at one. The forward–backward mean field game system is the strategic instance of exactly this pattern: data at $t = 0$ and $t = T$, a coupled pair stationary in between. The next two sections cash this observation in along the two routes it opens. section 8.4 takes the fixed-point road just sketched and makes it precise — naming the space of flows and the uniform-Wasserstein metric on it, and defining the best-response map S whose fixed points we have just argued are the equilibria — so that the existence and uniqueness theories of chapter 10 and chapter 11 have a rigorous object to act on. section 8.6 takes the variational road and shows that the analogy with the calculus of variations is, for the special but central class of potential (monotone, separable) couplings, no analogy at all: there the forward–backward pair is *literally* the Euler–Lagrange system of a single convex functional on flows, and solving the mean field game is minimizing one effective action. In the general, non-potential case no such global functional exists and the system remains an irreducibly strategic Nash fixed point — the "action" rendered stationary is each agent's own cost against the crowd, not any quantity the population jointly extremizes — which is precisely why the fixed-point formulation, not a minimization, is the load-bearing one for the rest of Part II.

8.4 The Nash fixed-point reformulation

The previous section ended by abandoning the march and pointing to a different kind of solution. We saw that the forward–backward system eq. (8.5) carries no Cauchy datum at any single time, so the only honest way to reach a solution is to stop integrating from one slice and instead solve for the *entire* flow at once, as the invariant of a single self-map: guess a whole population history m, run the HJB backward and the Fokker–Planck forward against it, and demand that what comes out be what went in. That sketch was deliberately informal — it named no space, no metric, and no map with a domain — and the present section pays the debt. It is also the section in which the verification proposition of section 8.2 finally cashes out structurally. proposition 8.2 taught us to read a solution of the mean field game as a flow that the representative agent *reproduces*: optimize against m, push the initial population forward along the resulting feedback, and recover m itself. That sentence already describes a fixed point in everything but name — "the input flow equals the output flow." What remained was to give the map whose input and output those are a precise home, so that "fixed point" becomes a theorem about an operator on a metric space rather than a turn of phrase. That is exactly what we do now, and the payoff is that the whole of Part II — existence, uniqueness, the master equation, the convergence of the finite game — will from here on speak about *this one operator* rather than about a pair of coupled PDEs.

We begin with the space the flows live in, because the map has nowhere to act until it is named. A *flow of measures*, recall from section 8.2, is a continuous curve $t \mapsto m_t$ in the Wasserstein space $\mathcal{P}_2(\mathbb{R}^d)$; the set of all such curves is

$$\mathfrak{C} \;:=\; C\big([0,T];\mathcal{P}_2(\mathbb{R}^d)\big),$$

the candidate population histories among which an equilibrium is to be found. We metrize it by the *uniform-in-time Wasserstein distance*

$$d_{\mathfrak{C}}(m,m') \;:=\; \sup_{t\in[0,T]} \mathcal{W}_2(m_t,m'_t), \tag{8.10}$$

the sup over the horizon of the slice-by-slice Wasserstein distance built in chapter 4. Two readings of eq. (8.10) are worth keeping in mind, because both will be used downstream. As a *metric*, the uniform distance makes $\mathfrak{C}$ a complete metric space: a Cauchy sequence of flows is uniformly Cauchy in $\mathcal{W}_2$, hence converges at each time to a limit measure, and the uniform control forces the limit curve to be continuous, so it lies back in $\mathfrak{C}$ — completeness being exactly what a contraction argument for uniqueness (chapter 11) will want underfoot. As a *topology*, it is strong enough that the coefficients of our equations, Lipschitz in m by **(A-Lip)**, vary continuously along it, yet weak enough that the bounded sets of flows our estimates produce are precompact — which is exactly what a compactness argument for existence (chapter 10) will want. The same metric thus serves both of the two routes to a fixed point, and choosing it now is what lets the later chapters simply invoke "the space of flows" without re-litigating its structure.

Notation watch

We write the space of flows with the *fraktur* $\mathfrak{C}$, never with the script $\mathcal{C}$. The script letter $\mathcal{C}$ is reserved for the Thread B per-type cost functional of chapter 20, an unrelated object living on the type space $[0,1]$; using distinct alphabets here forestalls a collision at that seam, where flows of measures and per-type costs appear on the same page.

With the stage named we can build the map. The construction is nothing more than one turn of the guess–solve–read–transport cycle of section 8.3, and we lay it out as three steps, citing the well-posedness of each so that the output is a bona fide element of $\mathfrak{C}$ and the map is genuinely a self-map. Define the *best-response map*

$$\mathsf{S}\colon \mathfrak{C} \to \mathfrak{C}$$

as follows. Given a flow $m \in \mathfrak{C}$:

1. *Solve the backward HJB equation against this m.* Freeze the flow in the third slot of the Hamiltonian and in the terminal datum and solve eq. (8.5a) backward from $u(T,\cdot) = g(\cdot, m_T)$, obtaining the representative value $u^{[m]}$. This is exactly the single-agent problem of chapter 6 with a known time-dependent parameter, so under the standing assumptions a unique $C^{1,2}$ classical solution of polynomial growth exists by theorem 6.14 — **(A-Nondeg)** supplying the parabolic smoothing that makes it classical, **(A-Conv)** and **(A-Growth)** making the Hamiltonian well defined and differentiable — and it is the agent's genuine value function by proposition 8.2.

2. *Read off the optimal feedback by the envelope identity.* From $u^{[m]}$ form the optimal control $\alpha^*(t,x) = \arg\max_\alpha\{-b(x,\alpha)\cdot\nabla u^{[m]}(t,x) - L(x,\alpha,m_t)\}$, single-valued by **(A-Conv)**, whose induced closed-loop drift is, by the envelope identity eq. (8.6), $b(x,\alpha^*(t,x)) = -\partial_p H(x, \nabla u^{[m]}(t,x), m_t)$. No optimization is re-solved here: the drift is obtained by differentiating the Hamiltonian already computed in step 1.

3. *Transport the initial population forward along that feedback.* Solve the forward Fokker–Planck equation
$$\partial_t \tilde m - \tfrac{1}{2}\operatorname{tr}\big(\sigma\sigma^\top \mathrm{D}^2\,\tilde m\big) - \operatorname{div}\big(\tilde m\, b(x,\alpha^*)\big) = 0, \qquad \tilde m_0 = m_0,$$
which, with the drift of step 2 now a *known* velocity field, is a *linear* parabolic Cauchy problem; under **(A-Nondeg)** and the Lipschitz, linear-growth control of the drift it has a unique solution that is a continuous flow of probability measures with finite second moment (theorem 5.14), so $\tilde m \in \mathfrak{C}$. Set $\mathsf{S}[m] := \tilde m$.

Each step is well posed precisely because the input m has frozen the one slot that made the coupled system intractable: in step 1 the population is a known schedule, so the HJB obstruction of remark 8.3 is gone and the backward sweep runs; in step 3 the feedback is a known field, so the Fokker–Planck is linear and the forward sweep runs. The map S thus packages exactly one backward sweep and one forward sweep, glued at the seam where step 2 converts value into drift. It is a genuine self-map of $\mathfrak{C}$ — flows in, flows out — and the equilibria are exactly the flows it leaves alone.

Proposition 8.4 (Equivalence of the two formulations). *Under **(A-Lip)**, **(A-Growth)**, **(A-Nondeg)**, **(A-Conv)**, a flow $m \in \mathfrak{C}$ is a fixed point of S if and only if, with $u = u^{[m]}$, the pair (u, m) solves the mean field game system eq. (8.5). The map S encodes one full forward–backward sweep; its fixed points are exactly the mean field equilibria.*

The proposition is the hinge of the whole reformulation: it certifies that nothing is lost in trading the PDE system for the operator, that the two problems have *the same* solution set. The proof is short — it is little more than reading the construction of S in both directions — but each direction says something we want, and naming what each says is the point.

Proof. ($\Rightarrow$, a solution is a fixed point.) Suppose (u, m) solves eq. (8.5). We must show $\mathsf{S}[m] = m$, i.e. that feeding m through the three steps returns m unchanged. Because u already solves the HJB equation eq. (8.5a) driven by this very m, and that equation has a unique solution of the admissible class (theorem 6.14), step 1 recovers precisely $u = u^{[m]}$; step 2 then forms the feedback eq. (8.6) from this u. Now compare the forward problem solved in step 3 with the Fokker–Planck equation eq. (8.5b) that the hypothesis says m already satisfies: they are the *identical* linear Cauchy problem — same initial datum m_0, same second-order operator, same drift $b(x, \alpha^*)$. A linear parabolic Cauchy problem with these coefficients has, under **(A-Nondeg)** and the Lipschitz drift, a *unique* solution (theorem 5.14, chapter 5); since both m and $\tilde{m} = \mathsf{S}[m]$ solve it, they coincide, and $\mathsf{S}[m] = m$. This direction is what makes the reformulation *lossless* in the safe sense: every equilibrium we already believe in is captured as a fixed point, so searching for fixed points can never miss a solution. The uniqueness of the linear forward equation is the load-bearing fact — it is what forbids S from sending an equilibrium flow anywhere other than back to itself.

($\Leftarrow$, a fixed point is a solution.) Suppose conversely $\mathsf{S}[m] = m$. Set $u = u^{[m]}$, the value produced by step 1; by definition of step 1 it solves the backward HJB equation eq. (8.5a) with this m in the coupling slot, which is the first equation of the system. By definition of step 3, the output $\tilde{m} = \mathsf{S}[m]$ solves the forward Fokker–Planck equation eq. (8.5b) with the feedback eq. (8.6) read off u; but the fixed-point hypothesis says $\tilde{m} = m$, so it is m itself that solves eq. (8.5b) with this feedback — the second equation of the system. The pair (u, m) therefore satisfies both equations of eq. (8.5) simultaneously, with the value's coupling slot and the density's transport drift built from the *same* m and the *same* u. This direction is what makes the reformulation *faithful*: it produces no spurious solutions, every fixed point being a genuine equilibrium. The two directions together say the solution sets coincide exactly, which is precisely the licence to study the operator in place of the PDEs. □

The reduction the proposition certifies is, conceptually, the central move of the analytic theory, and it is worth saying plainly why it is the *right* move rather than a mere repackaging. The difficulty of eq. (8.5), isolated in section 8.3, was global-in-time: the value at any instant depends on the whole future of the density, and the density at any instant on the whole past of the feedback, so no local-in-time iteration can even begin. What S does is absorb that entire global coupling *into the definition of one evaluation.* A single application of S already performs a complete backward sweep and a complete forward sweep — it digests the global-in-time entanglement once and for all — so that the only thing left to ask of the flow is a *pointwise* (in $\mathfrak{C}$) condition: that it be a fixed point.

We have not made the coupling disappear; we have repackaged a problem with *no* solvable temporal direction as a problem about a single operator that has no temporal direction at all, only an input and an output. That repackaging is the right move because fixed points of self-maps of nice metric spaces are objects we have powerful, general tools for, whereas forward–backward PDE systems are not. As section 8.3 warned, the trade is from a problem we cannot *integrate* to one we cannot in general *contract*; existence comes not from iterating S to convergence but from the topological fact that **(A-Nondeg)** makes S a *continuous* and in fact *compactifying* self-map — its parabolic smoothing maps bounded sets of flows into precompact ones — so that a Schauder/Kakutani theorem can force a fixed point without any contraction at all. The single hypothesis **(A-Nondeg)** is thus doing double duty: it makes *each* application of S well posed (classical value in step 1, smooth density in step 3) and it makes the *family* of outputs compact, which is what existence will consume.

This is the formulation the rest of Part II actually runs on, and it is worth recording, chapter by chapter, which property of S each downstream result consumes, because that mapping is the reason this section exists. Existence (chapter 10) is a *fixed-point theorem* for S: it uses the compactness just described to produce, with no uniqueness claim, at least one m with $\mathsf{S}[m] = m$. Uniqueness (chapter 11) is a *contraction or monotonicity* statement about S: under the extra Lasry–Lions monotonicity **(A-Mon)** deliberately held in reserve in section 8.2, the map either contracts in the metric eq. (8.10) on short horizons or obeys a global monotonicity estimate, and in either case its fixed point is unique. The master equation (chapter 12) studies how the fixed point *moves* when the data move: it differentiates the dependence of the value $u^{[m]}$ — and hence of S — on the initial measure of the flow, turning the fixed-point relation into a single PDE on the space of measures. And the convergence theory (chapter 13) closes the last promissory note of section 8.1.2 by showing that the finite Nash system eq. (8.3) converges, as $N \to \infty$, to a fixed point of this same S — so that the operator built here is literally the limit object the N-player equilibria approach. In every one of these the coupled PDE system has receded from view and the self-map S stands in its place; proposition 8.4 is the warrant that doing so loses nothing.

We do not prove existence here — that is chapter 10's charge — but proposition 8.4 has already bought the decisive thing: the analytic problem has been reduced from "solve a forward–backward PDE system with data at opposite ends" to "find a fixed point of a self-map of the complete metric space $\mathfrak{C}$," with the regularizing assumption **(A-Nondeg)** making each application of S a well-posed and compactifying operation. That is the object the rest of Part II consumes.

Two roads lead out of this reformulation, and the next sections take them in turn. The only population-dependence left in S sits in a single place — the slot where m enters the Hamiltonian's third argument in step 1's backward HJB, together with the terminal cost — and so the qualitative behavior of the whole operator is governed entirely by *how* the crowd enters there. That observation is the seed of the couplings taxonomy of section 8.5, which classifies the ways m can sit in H (separable versus non-separable, local versus nonlocal, congestion) precisely because each way reshapes step 1, and hence S, differently. The second road is the variational one: for the best-behaved couplings the fixed points of S turn out to be not merely equilibria but *minimizers* of a single convex energy on $\mathfrak{C}$, so that the search for a fixed point becomes a search for the bottom of an effective action — the subject of section 8.6. We hand the operator S and the fixed-point viewpoint to both.

Notation watch

The map S is the best-response operator Φ of appendix A; it acts on *flows* of measures, not on single measures. In stationary (ergodic) MFG and in the static graphon games of chapter 20 the same letter S denotes a self-map of a single measure (or strategy profile); the dynamic best response here is its time-resolved version. We keep the notation S throughout and let the domain disambiguate.

8.5 The structure of the couplings

The fixed-point reformulation of section 8.4 left us with a single self-map S and one sharp observation about it: of all the data feeding the best-response operator, the population m enters in exactly one place. It sits in the third slot of the Hamiltonian inside step 1's backward HJB, together with the terminal cost, and nowhere else — the volatility, the control set, the agent's own p-dependence are all blind to the crowd. The whole strategic content of the mean field game is therefore funneled through a single channel: *how m* occupies that slot. Two equilibria built from the same agent dynamics but a different placement of the crowd in H are, as analytic objects, different animals; two built from the same placement are siblings, whatever the rest of the data. It follows that before we ask any harder question about eq. (8.5) we should classify the channel itself — and that is the business of this section.

The classification is not taxonomy for its own sake. Each distinction it draws is the answer to an *operational* question that the rest of Part II will force us to ask, and the reader should read the three subsections below as the branches of a decision tree to be rerun on every new model, not as a glossary of names to memorize. The first question is structural: does the strategic system secretly minimize a single scalar energy, so that the search for an equilibrium becomes the search for the bottom of an effective action? That hinges on whether the crowd and the control *decouple* inside H — whether the Hamiltonian splits into a p-part and an m-part — and it is the axis of *separable versus non-separable* couplings. The second question is about uniqueness and well-posedness: through what spatial averaging does an agent at x feel the crowd — pointwise through the local density value $m(x)$, or smeared through an integral against the whole measure? That is the axis of *local versus nonlocal* couplings, and it controls both how much regularity the coupling supplies for free and which monotonicity arguments are even available. The third question is dynamical and the most physical: does the crowd merely *tax* an agent's position, or does it change the *price of moving* — making a dense region expensive to traverse? That is *congestion*, the canonical source of non-separability, and it is where the cleanest structural simplifications break down. Variational structure, uniqueness, numerics: the three axes are the three operational questions in the order a practitioner meets them.

These are also exactly the questions the downstream chapters answer, so the taxonomy is the scaffold on which their hypotheses hang. Separability is the precondition the variational section needs and is therefore the first axis we draw, handed straight to section 8.6, which will show that a separable coupling that is in addition *monotone* turns the forward–backward pair into the Euler–Lagrange system of one convex functional — separability supplying the splitting, monotonicity the convexity. The local/nonlocal distinction and the congestion distinction are what the existence and uniqueness theory of chapters 10 and 11 sort their hypotheses by: nonlocal smoothing couplings are the friendly regime where fixed points are easiest to produce and monotonicity is easiest to verify, local and congestive couplings the demanding regime where extra care — and stronger assumptions — is the price of admission. The same two distinctions return, lifted onto a network, when chapter 22 replaces the anonymous crowd by a graphon-kernel coupling $W(x, y)$ and the classification must be redone with the kernel in hand. We take the three axes in turn. The first and most consequential is separability, because it alone decides whether the entire apparatus of section 8.6 is available; we isolate the question of whether H splits in the next subsection.

8.5.1 Separable versus non-separable Hamiltonians

We begin the classification, as the section promised, with the first and most consequential axis, the one that alone decides whether the entire variational apparatus of section 8.6 is even available. The question is the narrowest one can ask about how the crowd sits inside the Hamiltonian, and it is purely structural: in the third slot of $H(x, p, m)$ the crowd m and the costate p are, in principle, entangled — the population could change not only the level of cost an agent pays for sitting at x but the very *rate* at which H responds to its momentum, $\partial_p H$, which is the closed-loop drift the forward equation transports along. Everything in this subsection turns on whether that entanglement is present or absent. So before any finer distinction — before we ask through what spatial averaging the crowd is felt, or whether it taxes position or penalizes motion — we isolate the cleanest possible separation: does H split into a piece that owns all the p-dependence and a piece that owns all the m-dependence, with no term mixing the two? When it does, the agent's optimization and its interaction with the crowd decouple inside H, and a long chain of simplifications follows; when it does not, that chain breaks at its first link. We make the split precise and then trace the chain.

Definition 8.5 (Separable coupling)**.** The Hamiltonian is *separable* if it splits as

$$H(x, p, m) \;=\; H_0(x, p) \;-\; F(x, m), \tag{8.11}$$

with H_0 carrying all the p-dependence and $F\colon \mathbb{R}^d \times \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}$ the *cost coupling*. Otherwise H is *non-separable*.

Read the two summands for what they each mean to the agent. The term $H_0(x, p)$ is the agent's *own* optimization, untouched by the crowd: it is exactly the measure-free Legendre transform $H_0(x, p) = \sup_\alpha\{-b(x, \alpha) \cdot p - L_0(x, \alpha)\}$ of a running cost $L_0(x, \alpha)$ that depends on state and control alone, so the entire p-dependence of H — the part that knows about steering, momentum, and best response — lives here and nowhere else. The term $-F(x, m)$ is the *cost coupling*: an additive levy the agent at x pays for the configuration of the crowd it finds itself in, a levy it has no control authority over. The agent cannot change $F(x, m)$ by steering, because F contains no α and no p; moving its momentum around changes H_0 but leaves the coupling term exactly where it was. Separability is precisely the statement that the population enters as a cost the agent *suffers* but cannot *negotiate* through its control. The minus sign is bookkeeping fixed by our Legendre convention (eq. (8.4) defines H as a supremum, so an additive running cost enters H with a flipped sign); we will see it convert F into an honest, correctly-signed source on the right-hand side of the HJB equation in a moment.

At the level of the data this splitting is nothing but an additive decomposition of the running cost itself,

$$L(x, \alpha, m) \;=\; L_0(x, \alpha) \;+\; F(x, m), \tag{8.12}$$

a control-dependent part L_0 that the agent pays for the effort of steering, and a population-interaction part F that it pays for the company it keeps. Feeding eq. (8.12) through the Legendre transform eq. (8.4) makes the splitting of H automatic: since $F(x, m)$ carries no α, it comes straight out of the supremum,

$$H(x, p, m) = \sup_{\alpha} \{ -b(x, \alpha) \cdot p - L_0(x, \alpha) - F(x, m) \} = \underbrace{\sup_{\alpha} \{ -b(x, \alpha) \cdot p - L_0(x, \alpha) \}}_{H_0(x,p)} - F(x, m),$$

which is exactly eq. (8.11). So "separable Hamiltonian" and "additively separable running cost" are one and the same hypothesis viewed on the two sides of the Legendre transform; one may impose it on L and read it off H, or the reverse.

With the cost coupling pulled out of the supremum, the HJB equation eq. (8.5a) of definition 8.1 acquires a particularly transparent form. Substituting eq. (8.11) and moving the now-p-free coupling term across the equality,

$$-\partial_t u - \tfrac{1}{2} \operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 u) + H_0(x, \nabla u) \;=\; F(x, m_t), \qquad u(T, x) = G(x, m_T), \tag{8.13}$$

where G is the terminal coupling (the separable terminal cost $g(x, m) = G(x, m)$). The structure on display is the cleanest possible: the left-hand side is a *closed*, measure-free Hamilton–Jacobi–Bellman operator in u alone — the operator of a lone agent with no crowd in sight — and the population has been quarantined entirely onto the right-hand side, where the cost coupling $F(x, m_t)$ acts as a prescribed, time-dependent *source* and $G(x, m_T)$ as the terminal datum. The crowd no longer reaches into the nonlinearity; it only forces the equation from outside, the way a known inhomogeneity forces a linear PDE.

This relocation of the crowd to the source is the hinge of the whole subsection, so we state its consequence as sharply as it deserves. The optimal feedback is read off the Hamiltonian by the envelope identity (remark 6.13, recorded in the notation watch at the head of this chapter) as the closed-loop drift $b(x, \alpha^*) = -\partial_p H(x, \nabla u, m_t)$. In the separable case the m-dependence of H sits entirely in the additive term $-F(x, m)$, which carries no p; differentiating in p annihilates it,

$$-\partial_p H(x, p, m) = -\partial_p\big(H_0(x, p) - F(x, m)\big) = -\partial_p H_0(x, p),$$

with the right-hand side a function of (x, p) *with no m left in it.* Hence the optimal drift, and (in the canonical normalization $b(x, \alpha) = \alpha$) the optimal feedback itself,

$$\alpha^*(t, x) \;=\; -\partial_p H_0\big(x, \nabla u(t, x)\big), \tag{8.14}$$

no longer depends on m at all. The population still shapes the value function u — it forces eq. (8.13) through the source F, so ∇u certainly feels the crowd — but it does so only *indirectly*, through the single channel ∇u, and the law mapping ∇u to a drift is fixed once and for all by the agent's own cost L_0. There is no *second*, direct dependence of the drift on m.

It is worth saying in plain words why this single fact is "the decisive simplification" rather than a cosmetic one, because the payoff is collected only two sections later and the reader should carry the reason there. Look at what the forward Fokker–Planck equation eq. (8.5b) now transports along. Its drift is precisely the closed-loop drift $-\partial_p H$, which by eq. (8.14) is a function of $(x, \nabla u)$ and of *no other appearance of* m. Write the momentum field $w = m\,\alpha^* = -m\,\partial_p H_0(x, \nabla u)$ that the density carries; because the velocity $-\partial_p H_0(x, \nabla u)$ does not see m, the field w is *linear* in m at fixed u. This is exactly the property the variational reformulation of section 8.6 will need and exploit: there the forward equation is not solved but imposed as the continuity *constraint* eq. (8.19), $\partial_t m - \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 m) + \operatorname{div} w = 0$, and that constraint is an *affine* (hence convex) condition on the pair (m, w) *only because* w depends linearly on m. The separable feedback's m-independence is what makes "transport the population along the optimal drift" a linear constraint rather than a nonlinear one, and a linear constraint over a convex objective is what lets the entire strategic system collapse into the minimization of one convex energy. Separability is, in this precise sense, the structural precondition that the whole potential-game picture of section 8.6 silently assumes; without it the constraint set is curved and the convex-optimization machinery has nothing to grip.

A one-line instance on the carried thread makes the m-independence concrete. In the LQG arithmetic of Thread A (worked computation 8.12), in canonical normalization the agent's own cost is $L_0(x, \alpha) = \frac{1}{2}|\alpha|^2$, so $H_0(x, p) = \frac{1}{2}|p|^2$ and $-\partial_p H_0 = -p$; the population enters only through the mean-tracking cost $F(x, m) = \frac{q}{2}(x - s\,\bar{m})^2$ with $\bar{m} = \int \xi\, m(\mathrm{d}\xi)$, which carries no control. The optimal feedback is therefore $\alpha^* = -\nabla u$, manifestly free of m: the crowd's mean $\bar{m}$ moves the source term of the HJB equation and hence bends the value function, but the rule "steer opposite to the value gradient" is the same whatever the crowd does. This is exactly why the thread will close in section 8.7 as two backward Riccati equations (the value side, forced by the crowd) plus one forward quadrature for the mean (the density side, transported along an m-free drift), and not as a single tangled nonlinearity.

The contrast with the non-separable case is now sharp, and it is a genuine structural collapse rather than a quantitative complication. If $H(x, p, m)$ does not split, then $\partial_p H$ retains its m-argument, and the feedback

$$\alpha^*(t, x) \;=\; -\partial_p H\big(x, \nabla u(t, x), m_t\big) \tag{8.15}$$

depends on the density *directly* — not only through ∇u but through a second, irreducible appearance of m in the drift law itself. Now follow that m into the forward equation. The Fokker–Planck drift in eq. (8.5b) is this same $-\partial_p H(x, \nabla u, m_t)$, so the transport equation for m carries m in its own velocity field: the unknown appears both as the transported density and inside the law that transports it. The forward equation is no longer a *linear* transport driven by an externally supplied drift but a genuinely *nonlinear* (quasilinear) equation in m, of McKean–Vlasov type, and the momentum field $w = m\,\alpha^* = -m\,\partial_p H(x, \nabla u, m)$ is no longer linear in m. The clean separation of labor that made the separable HJB a forced linear equation and the separable Fokker–Planck a linear constraint is gone: the two equations are coupled through *two* channels in each direction rather than one, and the affine constraint set of the variational problem becomes curved. Non-separable Hamiltonians arise exactly when the crowd changes the *price of moving* rather than merely the cost of being somewhere — when a dense region is expensive to traverse, so the very gain on the control depends on the local density — and the canonical such model is congestion, the subject of the last subsection below. For all such couplings the variational structure of section 8.6 generally fails to exist, and both the uniqueness theory of chapter 11 and the numerical schemes that lean on the potential formulation must be rebuilt on weaker footing.

This first axis thus cleaves the subject in two, and the cleavage organizes everything that follows. On one side sits the separable class, where the feedback is m-independent, the forward equation is a linear constraint, and the door to a convex energy stands open: we hand this class first to the next subsection, which subdivides it by asking *how* the now-quarantined coupling $F(x, m)$ reads the crowd — pointwise through the local density value or smeared through an integral — and then, in its fully developed form, to the variational section that the linearity of the constraint was built to serve. On the other side sits the non-separable class, carrying the warning we have just issued: when the crowd reaches into the drift, the structure that makes the problem tractable dissolves. We pass that warning directly to the congestion subsection, where the leading non-separable model is studied as precisely the place where these simplifications break down.

8.5.2 Local versus nonlocal couplings

Within the separable class, the coupling $F(x, m)$ is *nonlocal* when it depends on m through an integral against a kernel, and *local* when it depends only on the pointwise value of the density at x.

Example 8.6 (Nonlocal coupling)**.** A typical nonlocal cost coupling is a convolution,

$$F(x,m) \;=\; (\phi * m)(x) \;=\; \int_{\mathbb{R}^d} \phi(x-y)\, m(\mathrm{d}y),$$

with an interaction potential ϕ. This F is bounded and Lipschitz in $\mathcal{W}_2$ whenever ϕ is bounded and Lipschitz, so it sits comfortably inside **(A-Lip)**. It is the form most amenable to the existence theory because it is continuous in the *weak* topology, which tightness controls. The mean coupling of Thread A, $F(x, m) = \frac{q}{2}(x - s\,\bar{m})^2$ with $\bar{m} = \int \xi\, m(\mathrm{d}\xi)$, is nonlocal of this kind: it sees m only through its mean.

Example 8.7 (Local coupling)**.** A local coupling has the form $F(x, m) = f(x, m(x))$, depending on the *density value* $m(x)$ at the point x. The archetype is a power law $f(x, \rho) = \rho^\gamma$, modelling an aversion to crowded states that grows with local density. Local couplings are analytically harder: $m \mapsto m(x)$ is not continuous for $\mathcal{W}_2$ (a measure need not even have a density), so existence requires the parabolic smoothing of **(A-Nondeg)** to first guarantee that m_t has a density, and the coupling is then read against that density. They are central to congestion-free crowd-motion models and to the variational theory, where $f(x, \cdot)$ being increasing is exactly the local form of the Lasry–Lions monotonicity **(A-Mon)**.

The distinction matters operationally: nonlocal couplings are weakly continuous and play well with compactness arguments; local couplings demand that one first establish density bounds. We will see both. The graphon coupling of Part IV — the aggregate $(\mathbb{W}\, m)(x) = \int_0^1 W(x, y)\, \langle \cdot, m^y \rangle \;\mathrm{d}y$

of chapter 22 — is a structured nonlocal coupling *in the type variable*, and it is precisely the spatial (type) nonlocality through W that the whole graphon programme is about.

8.5.3 Congestion

The last and most physical of the three axes returns us to the non-separable class that the first subsection set aside with a warning. Congestion is its canonical instance: the crowd raises not the cost of *being* somewhere but the price of *moving* through a dense region, and it is exactly here that the clean separable structure of the preceding subsections breaks down.

Definition 8.8 (Congestion coupling)**.** A *congestion* model is a non-separable Hamiltonian in which the population modulates the cost of control, the canonical form being

$$H(x,p,m) \;=\; \frac{1}{c(x,m)}\,H_0(x,p) \;-\; F(x,m), \qquad c(x,m)>0, \tag{8.16}$$

where $c(x,m)$ is large where m is concentrated, so that moving through a dense region is expensive.

Congestion encodes the realistic feature that, in a crowd, motion itself is costly — one moves slowly through a dense region. Because m multiplies the momentum-dependent part, the optimal feedback $\alpha^* = -\partial_p H = -c(x,m_t)^{-1}\partial_p H_0(x,\nabla u)$ depends on the density, and eq. (8.5b) acquires a drift that is nonlinear in m through c. Congestion problems lie outside the separable/variational framework of section 8.6 in general; their well-posedness theory (existence under structural conditions on c, and the special "congestion-monotone" cases where uniqueness survives) is genuinely harder and is treated in chapters 10 and 11. We flag this as a place where the clean dual structure of the chapter does not extend, rather than papering over the gap.

8.6 Variational and potential-game structure

The taxonomy of section 8.5 closed on a contrast: separability is the structural precondition for a convex energy, and congestion is the model where that precondition dissolves. We now collect the reward separability was held in reserve to buy. For a large and important subclass of couplings — separable, with monotone interaction — the mean field game system eq. (8.5) is not just a coupled pair of equations but the *optimality system of a single minimization.* Such MFGs are called *potential* (or *variational*) games: the strategic forward–backward problem collapses to a convex optimal-control problem on the space of density flows. This is the analytic backbone of the numerical methods of chapter 28 and the conceptual bridge to the Ginzburg–Landau picture that organizes Part IV.

8.6.1 The potential and the energy functional

We work in the separable case eq. (8.11) with dynamics affine in the control through a *constant, invertible* gain: $b(x,\alpha) = B\,\alpha$ with $B \in \mathbb{R}^{d\times d}$ invertible and $A = \mathbb{R}^d$. Relabelling the control

$\alpha \mapsto B\,\alpha$ (a linear change of variables, with L_0 transported accordingly) then normalizes the gain to the identity, so without loss of generality we take $b(x, \alpha) = \alpha$: the agent directly controls its velocity. This is the genuine scope of the variational reduction. A drift with a state-dependent gain $B(x)$, or one not affine in the control, does *not* reduce this way and lies outside the potential framework of this section; we treat it only where it is needed and flag it as such. Take the Lagrangian $L_0(x, \alpha)$ convex in α with Legendre dual $H_0(x, p) = \sup_\alpha\{-\alpha \cdot p - L_0(x, \alpha)\}$. The crucial hypothesis is that the couplings are themselves *gradients*.

Definition 8.9 (Potential coupling)**.** The couplings F, G are of *potential type* if there exist functionals $\mathcal{F}, \mathcal{G} \colon \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}$ whose flat (linear functional) derivatives, in the sense of chapter 4 and appendix A, recover them:

$$F(x, m) = \frac{\delta \mathcal{F}}{\delta m}(m)(x), \qquad G(x, m) = \frac{\delta \mathcal{G}}{\delta m}(m)(x). \tag{8.17}$$

The role of the flat derivative is exactly the one a condensed-matter reader expects of $\delta\mathcal{F}/\delta\rho(x)$ in density-functional theory: it is the "one-body potential" generated by the interaction functional $\mathcal{F}$ at the configuration m. With couplings of potential type, define on flows (m, w) — where $w(t, x) \in \mathbb{R}^d$ is the momentum field (mass times velocity) satisfying the continuity constraint — the *energy functional*

$$\mathcal{J}(m, w) \;=\; \int_0^T\!\!\int_{\mathbb{R}^d} m(t, x)\, L_0\Big(x, \tfrac{w(t,x)}{m(t,x)}\Big)\,\mathrm{d}x\;\mathrm{d}t \;+\; \int_0^T \mathcal{F}(m_t)\;\mathrm{d}t \;+\; \mathcal{G}(m_T), \tag{8.18}$$

to be minimized over pairs (m, w) obeying the (linear) continuity constraint

$$\partial_t m - \tfrac{1}{2}\,\mathrm{tr}(\sigma\sigma^\top\,\mathrm{D}^2\, m) + \mathrm{div}\, w = 0, \qquad m(0, \cdot) = m_0. \tag{8.19}$$

The first term of eq. (8.18) is the total control cost rewritten in terms of the momentum $w = m\,\alpha$; the integrand $(m, w) \mapsto m\,L_0(x, w/m)$ is the *perspective function* of L_0, jointly convex and lower semicontinuous in (m, w) (extended by 0 when $m = w = 0$ and $+\infty$ when $m = 0 \neq w$; we prove these two properties in proposition B.2). The second and third terms are the accumulated and terminal interaction energies.

The reader who has met the phrase "minimize kinetic energy subject to a continuity equation" will recognize eq. (8.18)–eq. (8.19) as a *dynamic optimal-transport* problem of Benamou–Brenier type (appendix D.4), enriched by the interaction terms $\mathcal{F}, \mathcal{G}$. With the quadratic choice $L_0(x, \alpha) = \frac{1}{2}|\alpha|^2$ and no interaction, the kinetic term is exactly the Benamou–Brenier action whose minimum is $\mathcal{W}_2^2$. The one structural difference is the second-order term $-\frac{1}{2}\,\mathrm{tr}(\sigma\sigma^\top\,\mathrm{D}^2\, m)$ inside the constraint eq. (8.19): it is the diffusion, and it is precisely what turns the *deterministic* transport problem into its *viscous* (entropic) version, the dynamic-transport face of the Fokker–Planck equation. The MFG energy is thus a viscous Benamou–Brenier problem with interaction, and this is the precise sense in which $\mathcal{J}$ is an "effective action" for the population.

Lemma 8.10 (Convexity of the energy)**.** *Assume $L_0(x, \cdot)$ is convex and that $\mathcal{F}, \mathcal{G}$ are convex on $\mathcal{P}_2(\mathbb{R}^d)$. Then $\mathcal{J}$ is convex on the (convex) set of (m, w) satisfying eq. (8.19). Convexity of $\mathcal{F}$ is equivalent to the Lasry–Lions monotonicity* ***(A-Mon)*** *of the coupling $F = \frac{\delta\mathcal{F}}{\delta m}(m)(x)$:*

$$\int_{\mathbb{R}^d} (F(x, m_1) - F(x, m_2))\;\mathrm{d}(m_1 - m_2)(x) \;\geq\; 0 \quad \textit{for all } m_1, m_2, \tag{8.20}$$

and likewise for $\mathcal{G}, G$.

Proof sketch. Joint convexity (and lower semicontinuity) of $(m,w) \mapsto m\,L_0(x, w/m)$ is the perspective construction, proved in proposition B.2; integrating in (t,x) preserves convexity, and the constraint set eq. (8.19) is affine, hence convex. For the interaction terms, a functional $\mathcal{F}$ with flat derivative F is convex along the segment $m_\theta = (1-\theta)m_2 + \theta m_1$ iff $\theta \mapsto \frac{\mathrm{d}}{\mathrm{d}\theta}\mathcal{F}(m_\theta) = \int F(x, m_\theta)\,\mathrm{d}(m_1 - m_2)(x)$ is nondecreasing; differentiating once more and the fundamental theorem of calculus turn this into the monotonicity inequality eq. (8.20). The full identification of **(A-Mon)** with convexity is carried out in chapter 11; we use it here only to state the hypothesis in the form the variational structure needs. $\square$

8.6.2 The Euler–Lagrange system is the MFG system

Theorem 8.11 (Potential MFG / variational characterization)**.** *Assume **(A-Lip)**, **(A-Growth)**, **(A-Nondeg)**, **(A-Conv)**, control-affine dynamics, potential couplings (definition 8.9), and $\mathcal{F}, \mathcal{G}$ convex (equivalently, **(A-Mon)**). If (m^*, w^*) minimizes $\mathcal{J}$ of eq. (8.18) subject to eq. (8.19), then there is a function u (the Lagrange multiplier of the constraint eq. (8.19)) such that, writing $m := m^*$,*

1. *the optimal momentum is $w^* = -\,m\,\partial_p H_0(x, \nabla u)$, i.e. the velocity is the optimal feedback $\alpha^* = -\partial_p H_0(x, \nabla u)$;*
2. *u solves the backward HJB equation eq. (8.13) with couplings $F = \frac{\delta \mathcal{F}}{\delta m}(m)(x)$, $G = \frac{\delta \mathcal{G}}{\delta m}(m)(x)$;*
3. *m solves the forward Fokker–Planck equation eq. (8.5b).*

That is, (u, m) solves the mean field game system eq. (8.5). Conversely, under the stated convexity, any classical solution of eq. (8.5) arises this way. The equilibrium density *m^* is unique whenever the interaction is* strictly *monotone — i.e. $\mathcal{F}$ (and $\mathcal{G}$) is strictly convex, so that eq. (8.20) is strict for $m_1 \neq m_2$ — and u is then determined on $\{m^* > 0\}$. We do not claim strict convexity of the energy $\mathcal{J}$ itself: its kinetic integrand $(m,w) \mapsto m\,L_0(x, w/m)$ is positively* 1*-homogeneous and hence never strictly convex, so uniqueness must come from the coupling, not from the kinetic term. The precise statement and proof of uniqueness under strict monotonicity are chapter 11's.*

Proof sketch. Introduce a multiplier $u(t,x)$ for the constraint eq. (8.19) and form the (variational) Lagrangian functional — we write it $\mathfrak{L}$, never $\mathcal{L}$, since the glyph $\mathcal{L} = \mathcal{L}$ is reserved in this book for the law of a random variable (appendix A) and is used in that sense in this very chapter —

$$\mathfrak{L}(m, w, u) = \mathcal{J}(m, w) - \int_0^T \int_{\mathbb{R}^d} u\Big(\partial_t m - \tfrac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 m) + \operatorname{div} w\Big)\,\mathrm{d}x\,\mathrm{d}t.$$

Integrating by parts moves the derivatives onto u; the boundary terms at $t = T$ produce the terminal condition $u(T, \cdot) = G(\cdot, m_T)$, those at $t = 0$ are killed by the fixed initial datum. Stationarity in w gives, pointwise, $\partial_w[mL_0(x, w/m)] = -\nabla u$: the energy contributes $\partial_\alpha L_0(x, w/m)$ (the inner $1/m$ cancels the outer m), while the constraint term $-\iint u \operatorname{div} w$ contributes $+\nabla u$ after integrating $\operatorname{div} w$ by parts, and the two must cancel. Hence $\partial_\alpha L_0(x, \alpha^*) = -\nabla u$ with $\alpha^* = w/m$; by Legendre duality (the maximizer of $H_0(x,p) = \sup_\alpha\{-\alpha \cdot p - L_0(x,\alpha)\}$ satisfies $\partial_\alpha L_0(x,\alpha^*) = -p$) this is exactly $\alpha^* = -\partial_p H_0(x,\nabla u)$, which is claim (1) and shows the velocity is the optimal feedback. Stationarity in m gives, after using the flat-derivative identity $\frac{\delta\mathcal{F}}{\delta m}(m)(x) = F(x,m)$, the HJB equation eq. (8.13), claim (2): the ∂_t, D^2 terms come from the constraint, the $L_0 + \alpha^* \cdot \nabla u = -H_0(x,\nabla u)$ combination is the Legendre identity (evaluating $H_0 = -\alpha^* \cdot \nabla u - L_0$ at the maximizer), and F is the source. Stationarity in u returns the constraint eq. (8.19), which with $w^* = m\,\alpha^*$ is exactly the Fokker–Planck equation eq. (8.5b), claim (3). Convexity (lemma 8.10) makes the stationary point a global minimizer; strict monotonicity of the coupling then pins down the equilibrium density uniquely (chapter 11), the kinetic term being only convex, never strictly so. The rigorous version (existence of a minimizer by the direct method, regularity of the multiplier, and the duality with the *dual* HJB problem) is carried out in chapter 10 and, for the variational numerics, chapter 28. The original references are Lasry–Lions and Cardaliaguet's notes. □

Physics note

theorem 8.11 says that a potential MFG is governed by a single functional $\mathcal{J}$ whose stationary points are the equilibria — exactly the status of an effective action or Ginzburg–Landau free energy, with m the order-parameter field and u the conjugate (multiplier) field. Convexity of $\mathcal{J}$, equivalently Lasry–Lions monotonicity eq. (8.20), is the analogue of thermodynamic stability: a convex free energy has a unique minimizer, so the equilibrium is unique. When the interaction is *attractive* enough to break convexity — the population is rewarded for concentrating — $\mathcal{J}$ acquires multiple stationary points and uniqueness fails, the mean field counterpart of a symmetry-breaking transition. chapter 11 and the LQG phase diagram of chapter 14 make this precise. The reader is cautioned that this variational picture is a *feature of potential couplings*, not of MFG in general: a non-separable Hamiltonian (congestion, definition 8.8) has no such single governing functional, and the equilibrium is then irreducibly a Nash fixed point rather than a minimizer.

8.7 Worked computation: the LQG mean field game, analytic fixed point

With the equilibrium's abstract anatomy now complete — the verification theorem, the Nash fixed point, the coupling taxonomy, and the variational backbone of the potential case — we close the chapter by making all of it explicit on the carried thread. We now advance Thread A to its second layer (appendix A). Layer 1, the single-agent LQG problem with the population mean held fixed, was solved in chapter 6 and produced a scalar Riccati equation for the curvature of the value. Here we *close the loop*: we impose the mean field consistency of proposition 8.4 and exhibit the resulting forward–backward system in fully explicit, closed form. The computation is the analytic skeleton on which the entire LQG capstone chapter 14 is built, and it instantiates every abstract feature of this chapter — backward HJB, forward Fokker–Planck, two-point boundary data, separable nonlocal coupling — on a problem one can solve with pen and paper.

Worked computation 8.12 (LQG MFG fixed point)**.** Recall Thread A (appendix A): the representative agent in $\mathbb{R}$ has scalar state

$$\mathrm{d}X_t = \big(a\,X_t + b\,\alpha_t\big)\,\mathrm{d}t + \sigma\,\mathrm{d}W_t, \qquad X_0 \sim m_0, \tag{8.21}$$

and minimizes, against the population-mean flow $\bar{m}_t := \int \xi\, m_t(\mathrm{d}\xi)$,

$$J(\alpha) = \mathbb{E}\Bigg[\int_0^T \Big(\tfrac{1}{2}\alpha_t^2 + \tfrac{q}{2}\big(X_t - s\,\bar{m}_t\big)^2\Big)\,\mathrm{d}t + \tfrac{q_T}{2}\big(X_T - s_T\,\bar{m}_T\big)^2\Bigg], \tag{8.22}$$

with $q, q_T \geq 0$ and parameters a, b, σ, s, s_T, T as fixed in the thread specification. This is a separable, nonlocal coupling (definition 8.5 and example 8.6): the population enters only through its mean $\bar{m}_t$.

Step 1: HJB → Riccati. The Hamiltonian (the dynamics eq. (8.21) have drift $ax + b\,\alpha$, with b the control gain, and running cost $L_0 = \frac{1}{2}\alpha^2$) gives optimal feedback $\alpha^* = -b\,\partial_x u$ and the HJB equation eq. (8.5a)

$$\partial_t u + a\,x\,\partial_x u + \tfrac{\sigma^2}{2}\,\partial_{xx}u - \tfrac{b^2}{2}\,(\partial_x u)^2 + \tfrac{q}{2}\big(x - s\,\bar{m}_t\big)^2 = 0, \qquad u(T,x) = \tfrac{q_T}{2}\big(x - s_T\,\bar{m}_T\big)^2. \tag{8.23}$$

Because the data are quadratic in x and the equation preserves quadratics, we take the ansatz $u(t,x) = \frac{1}{2}P(t)\,x^2 + r(t)\,x + \chi(t)$. Substituting and matching powers of x yields three ordinary differential equations. The x^2 coefficient gives the scalar *control Riccati equation*

$$\dot{P} = b^2P^2 - 2aP - q, \qquad P(T) = q_T, \tag{8.24}$$

which is decoupled from the population: it is the same curvature equation as in the single-agent problem of chapter 6, and under $q, q_T \geq 0$ it has a unique, nonnegative, bounded solution on $[0,T]$ (no finite-time blow-up backward from q_T, because it is the value of a well-posed convex problem). The x^1 coefficient gives the *offset equation*

$$\dot{r} = (b^2P - a)r + q\,s\,\bar{m}_t, \qquad r(T) = -q_T\,s_T\,\bar{m}_T, \tag{8.25}$$

which carries *all* the population dependence; the x^0 coefficient determines $\chi(t)$ by a quadrature and is irrelevant to the equilibrium mean.

Step 2: Fokker–Planck → Gaussian flow. The optimal feedback is linear, $\alpha^*(t,x) = -b\,\partial_x u = -b\big(P(t)x + r(t)\big)$, so the closed-loop state is the linear (Ornstein–Uhlenbeck-type) diffusion

$$\mathrm{d}X_t = \Big[\big(a - b^2P(t)\big)X_t - b^2r(t)\Big]\,\mathrm{d}t + \sigma\,\mathrm{d}W_t. \tag{8.26}$$

A linear SDE driven by additive Gaussian noise keeps a Gaussian law whenever m_0 is Gaussian (chapter 5); thus $m_t = \mathcal{N}(\bar{m}_t, V_t)$ is fully described by its mean and variance, which solve the closed linear moment equations obtained from eq. (8.26),

$$\dot{\bar{m}}_t = \big(a - b^2P(t)\big)\,\bar{m}_t - b^2r(t), \qquad \bar{m}_0 = \textstyle\int \xi\, m_0(\mathrm{d}\xi), \tag{8.27}$$

$$\dot{V}_t = 2\big(a - b^2P(t)\big)\,V_t + \sigma^2, \qquad V_0 = \mathrm{Var}(m_0). \tag{8.28}$$

The variance equation eq. (8.28) is a *linear* (Lyapunov) ODE that depends only on P and not on the coupling, so the spread of the population is slaved to the Riccati solution and decouples entirely from the fixed point; the Fokker–Planck equation eq. (8.5b) for m_t reduces, on the Gaussian manifold, to exactly eq. (8.27)–eq. (8.28).

Step 3: the closed fixed-point system. The mean field consistency of proposition 8.4 is the demand that the $\bar{m}_t$ appearing as a parameter in the HJB-derived offset eq. (8.25) be the *same* $\bar{m}_t$ produced by the Fokker–Planck mean eq. (8.27). Imposing it couples eq. (8.25) and eq. (8.27) into the linear forward–backward two-point boundary-value problem

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix}\bar{m}_t\\ r_t\end{pmatrix} = \begin{pmatrix}k(t) & -b^2\\ q\,s & -k(t)\end{pmatrix}\begin{pmatrix}\bar{m}_t\\ r_t\end{pmatrix}, \qquad k(t) := a - b^2 P(t), \tag{8.29}$$

with the boundary data split across the two ends,

$$\bar{m}_0 = \textstyle\int \xi\, m_0(\mathrm{d}\xi) \ \ \text{(initial)}, \qquad r_T = -q_T\, s_T\, \bar{m}_T \ \ \text{(terminal)}. \tag{8.30}$$

This is the analytic signature of the mean field game in its barest form: a *forward* unknown $\bar{m}$ pinned at $t = 0$, a *backward* unknown r pinned at $t = T$, coupled at every instant. It is exactly the scalar shadow of the forward–backward structure of section 8.3.

Step 4: solving the fixed point in closed form. The two-point problem eq. (8.29)–eq. (8.30) is solved by a *decoupling field*: seek a scalar function $\pi(t)$ with $r_t = \pi(t)\,\bar{m}_t$ for all t. Differentiating and matching against eq. (8.29) gives a second, lower scalar Riccati equation

$$\dot{\pi} = b^2\pi^2 - 2k(t)\,\pi + q\,s = b^2\pi^2 - 2\big(a - b^2 P(t)\big)\pi + q\,s, \qquad \pi(T) = -q_T\, s_T, \tag{8.31}$$

whose terminal datum is read off from eq. (8.30). Given π, the equilibrium mean is the explicit forward quadrature

$$\bar{m}_t = \bar{m}_0\,\exp\Big(\int_0^t \big(k(\tau) - b^2\pi(\tau)\big)\,\mathrm{d}\tau\Big), \tag{8.32}$$

and then $r_t = \pi(t)\bar{m}_t$, V_t from eq. (8.28), and the full Gaussian flow $m_t = \mathcal{N}(\bar{m}_t, V_t)$ are all explicit. The triple $(P, \pi, \bar{m})$ — two backward Riccati equations and one forward quadrature — *is* the LQG mean field equilibrium in closed form. This is the promised "HJB → Riccati, FP → Gaussian flow, closed fixed-point system."

Existence, uniqueness, and the seam to the phase diagram. The decoupling eq. (8.31) succeeds, and the equilibrium is unique, precisely as long as π does not blow up in finite time on $[0, T]$. Since eq. (8.29) is linear, the two-point problem has a unique solution unless the homogeneous problem has a nontrivial one — a conjugate point — which is exactly a finite-time blow-up of π. For a *repulsive/aligning* coupling in the stabilizing regime ($q\,s \geq 0$ with s not too large) the quadratic term keeps π bounded and the fixed point is unique; for sufficiently strong *attractive* coupling (s large of the destabilizing sign, large horizon T) π can escape to $-\infty$ before $t = 0$, signalling loss of uniqueness — the multiplicity (symmetry-breaking) regime. We do not chart the boundary here: the full phase diagram in (s, q, T), its identification with the failure of **(A-Mon)**/convexity of theorem 8.11, and the matrix-valued generalization are the business of chapter 11 (uniqueness) and chapter 14 (the LQG capstone). The numerical reproduction of eq. (8.31)–eq. (8.32) by a forward–backward solver is carried out, as a validation of both the analytics and the scheme, in chapter 28.

Remark 8.13 (What the worked computation isolates)**.** Three structural facts of this chapter are visible in worked computation 8.12 with no analytic clutter. First, the *decoupling* of the value's curvature (P, the Riccati equation) from the population: P solves the *same* equation as in the single-agent problem, because curvature is a property of the cost geometry, not of the crowd. Second, the population enters only through the *offset* r and the *mean* $\bar{m}$, which form the genuinely game-theoretic forward–backward pair eq. (8.29); this is the LQG incarnation of "HJB needs m, FP needs ∇u, nothing else passes." Third, the variance flow eq. (8.28) is entirely slaved, confirming that in the Gaussian world the only nontrivial fixed point is in the first moment — the order parameter $\bar{m}$. These features survive, suitably generalized, into the graphon LQG of chapter 22, where the scalar mean $\bar{m}_t$ becomes a type-profile $\bar{m}_t(x)$ and the coupling $q\,s$ becomes the graphon operator $q\,s\,\mathbb{W}$.

Rigor ledger

Proved (or proved modulo cited inputs).

- The MFG PDE system eq. (8.5): backward HJB driven by m, forward Fokker–Planck driven by the feedback $-\partial_p H$; its two readings, value-diffusion (section 8.2) and mass-conservation eq. (8.9).
- Representative-agent optimality proposition 8.2 and the equivalence of the PDE system with the Nash fixed point of the best-response map S (proposition 8.4), under **(A-Lip)**, **(A-Growth)**, **(A-Nondeg)**, **(A-Conv)**.
- The coupling taxonomy: separable/non-separable, local/nonlocal, congestion (section 8.5).
- The variational characterization of potential MFG (theorem 8.11): under potential couplings and convexity (equivalently **(A-Mon)**), the system is the Euler–Lagrange system of the convex energy eq. (8.18).
- Thread A, layer 2: the LQG equilibrium in closed form (worked computation 8.12), the triple $(P, \pi, \bar{m})$ with explicit quadrature eq. (8.32).

Assumed.

- The standing assumptions **(A-Lip)**, **(A-Growth)**, **(A-Nondeg)**, **(A-Conv)** for the verification and well-posedness of each half-sweep; **(A-Mon)** only for the convexity in theorem 8.11.
- The single-step well-posedness of the HJB equation (chapter 6) and of the Fokker–Planck equation (chapter 5); propagation of chaos as the justification of section 8.1.2 (chapter 7).

Deferred.

- Existence of a fixed point of S, i.e. of a solution to eq. (8.5): chapter 10 (Schauder/Kakutani, with compactness from chapters 2 and 3).

- Uniqueness and the precise statement of **(A-Mon)**; non-uniqueness/multiplicity: chapter 11; LQG phase diagram in (s, q, T): chapter 14.
- Rigorous direct-method proof of theorem 8.11 and the dual HJB problem; variational numerics: chapter 28.
- The probabilistic (FBSDE) rendering of the same equilibrium: chapter 9; the master-equation linearization: chapter 12; the $N \to \infty$ convergence of eq. (8.3) to the system: chapter 13.
- Degenerate diffusion (dropping **(A-Nondeg)**) and the viscosity-solution formulation: chapter 6 and Appendix E.

Open (at the research frontier).

- Well-posedness of *non-separable* (congestion) MFG beyond structural special cases; sharp conditions on $c(x, m)$ in eq. (8.16).
- Uniqueness outside the monotone regime: the non-convex landscape of theorem 8.11 and the classification of its multiple equilibria.
- Regularity for *local* couplings with strong (super-linear) growth at the boundary of the integrability allowed by **(A-Nondeg)**.

Bibliographic notes

The mean field game system in the form eq. (8.5) originates with Lasry and Lions [93], who introduced the coupled HJB–Fokker–Planck pair, the monotonicity condition for uniqueness, and the variational interpretation of the potential case; and, independently and in the engineering literature, with Huang, Caines, and Malhamé [82] under the name *Nash certainty equivalence*, which is precisely the consistency closure of section 8.1.2. The PDE viewpoint adopted in this chapter — verification against a fixed flow, best-response fixed point, the forward–backward structure, separable/local/nonlocal couplings, and the variational formulation — follows Cardaliaguet's lecture notes [36], the standard analytic reference for Part II; our theorem 8.11 is his treatment of variational MFG, itself going back to [93]. The probabilistic counterpart, to which chapter 9 is devoted, is developed at length in Carmona and Delarue [40], whose Chapters 3–4 give the FBSDE formulation and the two-pictures correspondence we preview here. Congestion models and their well-posedness subtleties, flagged in definition 8.8, trace to the later Lasry–Lions program and are surveyed in [40]; the variational/primal–dual structure underlies the numerical methods of Achdou and Capuzzo-Dolcetta [1], taken up in chapter 28. The forward–backward boundary structure and the convergence of the N-player Nash system eq. (8.3) to the limit eq. (8.5) are the subject of the master-equation monograph of Cardaliaguet, Delarue, Lasry, and Lions [37], the reference for chapters 12 and 13. The LQG worked computation worked computation 8.12 is the mean field specialization of the classical linear–quadratic theory; its mean field form is in [82, 93] and is carried to its phase diagram in chapter 14.

Chapter 9

The Mean Field Game System: Probabilistic Formulation

In chapter 8 we wrote the mean field game equilibrium as a coupled pair of deterministic partial differential equations: a backward Hamilton–Jacobi–Bellman equation for the representative agent's value $u(t,x)$, driven by the population density $m(t,x)$, and a forward Fokker–Planck equation for m, driven by the optimal feedback extracted from u. That is the *analytic* picture of an equilibrium, and it is complete: the pair (u,m) pins the equilibrium down with nothing left over. It is fair to ask why one would want a second description at all.

The reason is that the analytic picture, complete as it is, conceals exactly the objects the rest of the book most needs to handle. It speaks of *fields* on state space, $u(t,x)$ and $m(t,x)$, and says nothing directly about the *trajectories* — the actual paths along which agents move. Yet four of this development's eventual destinations are statements about paths, not fields. The first is the particle limit: a mean field equilibrium is the $N \to \infty$ limit of N-player Nash play, and that convergence is a statement about coupling each player's trajectory to a single limiting one (chapter 13), a statement a pair of densities cannot even phrase. The second is degenerate — or vanishing — diffusion, where the HJB equation may possess no classical solution and the Fokker–Planck no density, while the controlled process and its law remain perfectly well defined. The third is simulation: forward–backward Monte Carlo schemes (chapter 28) integrate paths, not grids, and reach dimensions where finite differences cannot follow. The fourth, furthest off, is the graphon extension of chapter 23, where the state becomes a continuum-indexed family of *processes* coupled through an operator. All four are invisible to two PDEs on $[0,T] \times \mathbb{R}^d$ and native to a description that follows the paths themselves. This chapter builds that description: the very same equilibrium encoded not by two PDEs but by a single coupled *forward–backward stochastic differential equation* (FBSDE) of McKean–Vlasov type, living on path space. The reward, redeemed in section 9.3, is a precise dictionary translating each picture into the other; previewing the motivation now is what makes that dictionary land as a promise kept rather than a surprise sprung.

The two legs of this single equation can be named before they are built. The forward leg is the optimally controlled state process X_t, the trajectory the representative agent actually follows. The backward leg is its *adjoint*, or costate: the stochastic incarnation of the Pontryagin momentum previewed in chapter 6, the variable conjugate to the state that prices, instant by instant, how sensitively the agent's remaining cost responds to being displaced now. In the deterministic control of chapter 6 this costate was a single curve integrated backward from the terminal time. In the presence of noise it cannot stay that simple. A process pinned by data at T and required to remain *adapted* — to depend only on the past of the Brownian motion, never on its future — cannot in general be a deterministic function of the current state. Restoring adaptedness forces a *second* unknown into the backward equation: a process Z_t recording the instantaneous correlation between the costate's fluctuations and the driving noise. The stochastic costate is therefore the *pair* (Y, Z), not Y alone, and the forced appearance of Z — a consequence of the martingale representation theorem (theorem C.17) — is the first genuinely stochastic subtlety of the chapter. We flag it now so that when Z surfaces unbidden in the adjoint equation of section 9.1 it reads as a debt foreseen rather than a rabbit pulled from a hat.

The tools are imported wholesale from earlier chapters. The Itô calculus and stochastic differential equations come from chapter 5; the two backward-in-time results that the adjoint formulation rests on — the martingale representation theorem for the Brownian filtration (theorem C.17) and the Pardoux–Peng existence and uniqueness theorem for backward stochastic differential equations under a Lipschitz driver (theorem C.18) — are proved in full in the stochastic-calculus reference appendix C; the Pontryagin maximum principle and the identification of the costate with the gradient of the value function come from chapter 6; the McKean–Vlasov self-consistency condition — the law of the process feeding back into its own dynamics — comes from chapter 7. The reader should keep chapter 8 open throughout, since the entire payoff of this chapter is the precise dictionary, assembled in section 9.3, between the FBSDE objects here and the PDE objects there. It is worth being equally precise about what this chapter does *not* do. It *sets up* the fixed-point structure of the equilibrium but does not prove that the fixed point exists: the existence and uniqueness questions that structure raises are stated here, with their three governing regimes named, but settled only in chapters 10 and 11. And it *opens* a road it does not yet travel — the measure-dependent decoupling field introduced in section 9.4 is the gateway to the master equation of chapter 12. Knowing in advance what is owed, and to which chapter, lets the reader read the deferrals here as signposts rather than gaps.

We work throughout on a filtered probability space $(\Omega, \mathcal{F}, \mathbb{F} = (\mathcal{F}_t)_{0\le t\le T}, \mathbb{P})$ supporting a k-dimensional Brownian motion $W = (W_t)_{0\le t\le T}$, with $\mathbb{F}$ the (completed, right-continuous) filtration it generates, augmented by the law of the initial condition. As fixed by appendix A and used throughout Parts I–II, Brownian motion carries the letter W (rendered W); no graphon is present in this chapter, so there is no clash. Relative to chapter 8, which works with time-homogeneous coefficients and a constant diffusion matrix, this chapter admits three mild generalizations, each a deliberate choice made for a reason rather than for generality's sake. We allow *time-dependent* coefficients, because the dictionary we are after must cover genuinely time-inhomogeneous models — the LQG thread among them, whose Riccati flow is time-varying — and nothing in the probabilistic argument resists the extra argument. We allow a state- and measure-dependent volatility $\sigma(t, x, m) \in \mathbb{R}^{d\times k}$, so that the noise an agent feels may depend on where it stands and on the crowd around it. But we keep that volatility *uncontrolled*: the control α does not enter σ. This last restriction is the consequential one, and it earns its keep — an uncontrolled diffusion is exactly what keeps the adjoint system first order, a single backward equation for the pair (Y, Z) rather than the additional matrix-valued second-order adjoint that a control-dependent volatility would force. The only change to the Hamiltonian's role is the extra time argument, $H(t,x,p,m)$ in place of $H(x,p,m)$. We retain the global time convention: the value function and its stochastic avatar, the costate, are anchored by *terminal* data at $t=T$ and run *backward*; the state process and the population law are anchored by *initial* data at $t=0$ and run *forward*. The coupling of data at opposite ends of $[0,T]$ is the structural signature of the problem and survives translation into every one of its equivalent forms.

9.1 The representative agent and the stochastic maximum principle

The preamble made two promises this section now redeems: that the costate of the probabilistic picture is the stochastic Pontryagin momentum of chapter 6, and that the equilibrium will be encoded by following individual paths. Both are easiest to secure if we first, deliberately, decline to solve the equilibrium at all. A mean field game asks two things at once — that each agent optimize against the population, and that the population be the aggregate of those very agents — and the two demands are entangled, because the object an agent optimizes against is precisely what its optimization is meant to produce. The standard way to break such a circle is to cut it in two. We *freeze* the population — treat it as a fixed, exogenous environment the agent cannot influence — and solve the resulting pure control problem to completion; only afterward, in section 9.2, do we *close the loop* and demand that the frozen environment coincide with the law the optimization generates. Freezing first is not a stopgap to be apologized for. The frozen problem is a clean, classical stochastic control problem, and its complete solution — an optimal feedback together with an adjoint pair — is exactly the raw material the closure will weld into the McKean–Vlasov FBSDE. Solve the optimization in isolation, and the fixed point of the next section becomes a matter of substitution.

This section carries out the freeze-and-solve step in three movements, mirrored in its three subsections. We first lay down the control problem an agent faces against a fixed population flow: the admissible controls, the cost it pays, the state it steers, and — decisively — the standing assumption that the volatility is uncontrolled, already flagged in the preamble as what keeps the adjoint first order. We then introduce the generalized Pontryagin Hamiltonian, whose pointwise minimizer is the candidate optimal feedback $\hat{\alpha}(t,x,m,y,z)$, and the backward adjoint equation that produces the costate pair (Y,Z) — the equation in which the second unknown Z, foreshadowed above, is forced into being. Finally we prove that the resulting stochastic maximum principle is both necessary and, under convexity, sufficient, so that the search for an optimum collapses into the solution of a coupled system of stochastic equations. The feedback map $\hat{\alpha}$ and the adjoint pair (Y,Z) assembled here are exactly what section 9.2 takes in hand, replacing the frozen flow by the self-consistent law $\mathrm{Law}(X_t)$ to close the loop. To begin we must say precisely what "the frozen population" is; the next subsection makes it concrete as a deterministic curve of probability measures that the agent reads as its environment.

9.1.1 The control problem against a frozen population

We begin exactly where the preceding overview left off: with the resolution to freeze the population before solving anything, and the promise to make the word "frozen" concrete. This subsection carries out that first step — the freeze — probabilistically, and its entire content is to fix, with no ambiguity left over, every object the maximum principle of the next subsection will act on: the environment the agent inhabits, the controls it may choose, the state those controls steer, and the cost it pays. Nothing here is optimized yet; we are laying the table. section 9.2 will later delete the word "frozen" and impose self-consistency, but that step is a substitution, and it can only be a clean substitution if the frozen problem is first pinned down completely.

The frozen population is the least mysterious object in the chapter. It is a deterministic flow of probability measures

$$\mu = (\mu_t)_{0\le t\le T}, \qquad \mu_t \in \mathcal{P}_2(\mathbb{R}^d),$$

which the agent regards as fixed scenery: a movie of how the crowd is distributed across state space, one frame μ_t per instant. Two words in that line carry weight. *Deterministic*, because the representative agent faces no uncertainty about the crowd — the only randomness it contends with is its own Brownian noise; the population curve is a known datum, read off in advance. And valued in $\mathcal{P}_2(\mathbb{R}^d)$, the space of Borel probability measures on $\mathbb{R}^d$ with finite second moment $\int |x|^2\, \mu_t(\mathrm{d}x) < \infty$, because the costs below will measure the agent's state against population statistics — in the LQG thread, literally against the population mean $\int x\, \mu_t(\mathrm{d}x)$ — and those statistics exist precisely when the measures have a finite second moment. Demanding $\mathcal{P}_2(\mathbb{R}^d)$ from the outset is therefore not fastidiousness; it is the minimal regularity that makes the cost functional even well defined, and it is the same space on which the Wasserstein metric $\mathcal{W}_2$ of chapter 4 lives, the metric in which the fixed-point maps of chapter 10 will later be shown continuous.

Against this scenery the agent controls an $\mathbb{R}^d$-valued state process through an $\mathbb{F}$-progressively measurable control $\alpha = (\alpha_t)_{0\le t\le T}$ taking values in a closed convex action set $A \subseteq \mathbb{R}^\ell$. Progressive measurability is the precise rendering of the physical demand that the agent act on information it actually possesses: α_t may depend on the trajectory observed up to time t but not on the future of the noise. Given μ and α, the state solves the Itô SDE

$$\mathrm{d}X_t \;=\; b(t, X_t, \mu_t, \alpha_t)\; \mathrm{d}t \;+\; \sigma(t, X_t, \mu_t)\; \mathrm{d}W_t, \qquad X_0 \sim m_0 \in \mathcal{P}_2(\mathbb{R}^d), \tag{9.1}$$

with drift $b : [0, T] \times \mathbb{R}^d \times \mathcal{P}_2(\mathbb{R}^d) \times A \to \mathbb{R}^d$ and volatility $\sigma : [0, T] \times \mathbb{R}^d \times \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}^{d\times k}$. Read the equation as a balance of two influences on the agent's motion: a steerable drift b, through which the chosen control bends the trajectory and through which the frozen crowd μ_t exerts its pull, and an unsteerable diffusion $\sigma\; \mathrm{d}W_t$, the irreducible noise. The volatility is *uncontrolled*: α does not enter σ. This is the standing assumption of the present chapter, flagged already in the preamble, and is what keeps the adjoint system first order — a single backward equation for the pair (Y, Z) rather than the additional matrix-valued second-order adjoint that a control-dependent volatility would force. The controlled-diffusion case is set aside and revisited only where it matters (remark 9.7).

That eq. (9.1) actually defines a process at all is a debt owed to chapter 5. Under **(A-Lip)** and **(A-Growth)** — Lipschitz and linear-growth coefficients, uniformly in (t, μ) — the SDE well-posedness theorem proved there delivers a unique strong solution adapted to $\mathbb{F}$, for every admissible control, and with it the moment bound

$$\mathbb{E}\Big[\sup_{0\le t\le T}|X_t|^2\Big] < \infty.$$

This bound is not a technical afterthought; it is the load-bearing estimate of everything downstream. It is what guarantees the cost eq. (9.2) is finite rather than $+\infty$, so that comparing two controls is meaningful at all. It is what places the optimal state in the space $\mathcal{S}^2$ of square-integrable, sup-norm-controlled processes (chapter 5), the space in which the backward adjoint of definition 9.3 will be required to live, and the space in which the Itô product-rule manipulations of the maximum-principle proofs have integrable, genuinely-martingale stochastic integrals — without it those integrals need not have zero expectation and the entire duality argument collapses. And it is the seed of the tightness estimates by which chapter 10 extracts limits of best responses. A uniform second moment, in short, is the currency in which the whole probabilistic apparatus is denominated.

With the environment and the state fixed, we can say precisely which controls the agent is allowed to use and what each one costs.

Definition 9.1 (Admissible controls)**.** The set $\mathbb{A}$ of *admissible controls* (the blackboard $\mathbb{A} = \mathbb{A}$, to be kept distinct from the italic action set $A = A$ in which controls take values, and from the calligraphic generator $\mathcal{A} = \mathcal{A}$) consists of all $\mathbb{F}$-progressively measurable processes $\alpha : [0,T]\times\Omega \to A$ with $\mathbb{E}\int_0^T |\alpha_t|^2 \,\mathrm{d}t < \infty$. For $\alpha \in \mathbb{A}$ and the frozen flow μ, the agent's cost is

$$J^\mu(\alpha) \;=\; \mathbb{E}\left[\int_0^T L(t, X_t, \mu_t, \alpha_t)\,\mathrm{d}t \;+\; g(X_T, \mu_T)\right], \tag{9.2}$$

with running cost L and terminal cost g, where X solves eq. (9.1). A control $\hat\alpha \in \mathbb{A}$ is *optimal against* μ if $J^\mu(\hat\alpha) \le J^\mu(\alpha)$ for all $\alpha \in \mathbb{A}$.

The parenthetical in the definition deserves to be read slowly, because three different typefaces of the letter "A" are in play at once and confusing them is the single easiest way to misread the rest of the chapter. The blackboard $\mathbb{A} = \mathbb{A}$ is the *class of admissible control processes* — an infinite-dimensional set of strategies, the search space of the optimization. The italic $A = A$ is the *action set*, a fixed subset of $\mathbb{R}^\ell$ in which a control *value* α_t lives at each instant; it is finite-dimensional and pointwise. And the calligraphic $\mathcal{A} = \mathcal{A}$, which surfaces once we write the generator of X, is a *differential operator*, not a set at all. A process belongs to $\mathbb{A}$, a value to A, and a function to the domain of $\mathcal{A}$; the glyphs are deliberately distinct so the three never collide on the page. The square integrability $\mathbb{E}\int_0^T |\alpha_t|^2 \,\mathrm{d}t < \infty$ is the entrance fee for membership in $\mathbb{A}$: it is exactly what is needed for the controlled drift $b(t, X_t, \mu_t, \alpha_t)$ to be integrable in (t, ω) under the linear growth of **(A-Growth)**, and hence for the state SDE and the cost integral to make sense together.

It remains to say under which hypotheses on the coefficients this problem is not merely posed but solvable cleanly, and to say it concretely rather than by tag, since these are the hypotheses the maximum principle leans on at every step. We impose throughout this section **(A-Lip)**, **(A-Growth)**, and the coercivity/convexity package **(A-Conv)**, and it is worth spelling out what each one buys and what would break in its absence. **(A-Lip)** — the coefficients b, σ, L, g Lipschitz in the state, uniformly in (t, μ) — is what chapter 5 converts into existence and uniqueness of the state process: without a Lipschitz drift the SDE can split into several solutions or explode in finite time, and there would be no single X to attach a cost to. The same Lipschitz bound is what later makes the optimal feedback $\hat{\alpha}$ Lipschitz and the best-response map a contraction in the small-horizon regime, so this hypothesis is felt twice over. **(A-Growth)** — at most linear growth in the state, together with the coercivity of the cost — does two complementary jobs: linear growth forbids the trajectory from escaping to infinity and secures the moment bound $\mathbb{E}[\sup_t |X_t|^2] < \infty$ just discussed, while coercivity of L in the control (the running cost grows without bound as $|\alpha| \to \infty$) forbids the optimizer from buying arbitrarily large control for free, which is what makes a minimizer exist rather than the infimum being approached only in a limit of ever-wilder controls. Strip coercivity away and the cost can be driven down without attaining its bound; strip linear growth away and even the cost of a fixed control can be infinite. **(A-Conv)** is the structural heart of the section and is best stated concretely: we ask that b and σ be affine in (x, α), that $L(t, \cdot, \mu, \cdot)$ be convex in (x, α) with the strong convexity in α that supplies the coercivity above, and that $g(\cdot, \mu)$ be convex and C^1 in x.

The reason this particular package is the right one repays a moment's reflection, because it is exactly what upgrades the maximum principle from a *necessary* condition into a *sufficient* one. The stochastic Pontryagin principle, derived next, will produce a candidate $\hat{\alpha}$ satisfying a first-order stationarity condition; in general such a stationary point is only a *necessary* feature of an optimum, no more than calculus guarantees a vanishing derivative at a minimum. What promotes stationarity to genuine optimality is convexity, and here it must hold jointly in the state and the control, not in the control alone. The affineness of the dynamics is precisely what makes this joint convexity propagate correctly: when b and σ are affine in (x, α), the cost J^μ inherits convexity from the convexity of L and g, because a convex cost composed with an affine state map is again convex — a curved dynamics could bend a convex cost into a non-convex functional and destroy the implication. The strong (uniformly positive-curvature) convexity in α then does the sharper work: it makes the pointwise Hamiltonian minimization of the next subsection have a *unique* minimizer that depends Lipschitz-continuously on its arguments, which is what lets the feedback map $\hat{\alpha}(t, x, m, y, z)$ be substituted back into the dynamics without losing well-posedness. This is the precise probabilistic counterpart of the convexity that makes the HJB Hamiltonian $H(t, x, p, m)$ of chapter 8 convex in p, hence well defined as a Legendre transform: the two statements are the same hypothesis seen in two coordinate systems, and the reconciliation is made explicit in remark 9.11. Drop joint convexity and the maximum principle survives only as a necessary condition, leaving a possible gap between stationary points and minima that a separate verification argument would have to close.

A glance at the LQG thread shows the package is not restrictive in practice but is satisfied on the nose by the canonical example. There the scalar state obeys $\mathrm{d}X_t = (aX_t + b\,\alpha_t)\,\mathrm{d}t + \sigma\,\mathrm{d}W_t$ — drift affine in (x, α), volatility constant and a fortiori uncontrolled — and the cost integrand is $\frac{1}{2}\alpha_t^2 + \frac{q}{2}(X_t - s\,\bar{\mu}_t)^2$ with terminal $\frac{q_T}{2}(X_T - s_T\bar{\mu}_T)^2$, which is strongly convex in α (curvature 1, uniformly positive) and convex in x for $q, q_T \geq 0$. Here $\bar{\mu}_t = \int x\,\mu_t(\mathrm{d}x)$ is the frozen population mean, the only statistic of μ the agent sees. Every clause of **(A-Conv)** holds verbatim, the Hamiltonian minimization of the next subsection will be an unconstrained quadratic with an explicit linear minimizer, and the whole machinery collapses to the Riccati system this thread tracks chapter by chapter. The general theory we are assembling is, in this instance, guaranteed to reproduce that closed form.

Everything the maximum principle needs is now on the table: the environment μ, the admissible class $\mathbb{A}$, the controlled state eq. (9.1), and the cost eq. (9.2) whose minimizer we seek. The optimization itself is the single requirement

$$J^\mu(\hat{\alpha}) \;\le\; J^\mu(\alpha) \qquad \text{for all } \alpha \in \mathbb{A},$$

and as it stands it is a statement about an infinite-dimensional search over strategies — intractable head-on. The next subsection performs the decisive change of viewpoint that the maximum principle prescribes: it reorganizes this global comparison of costs into a *pointwise* condition, instant by instant, by introducing a single function — the Pontryagin Hamiltonian — of the state, the costate, and the control, against which the optimal action can be selected one moment at a time. The costate pair (Y, Z) that prices the state in that function is the object we turn to now.

9.1.2 The Pontryagin Hamiltonian and the adjoint equation

The previous subsection left the optimization in its starkest possible form: find $\hat{\alpha} \in \mathbb{A}$ with $J^\mu(\hat{\alpha}) \le J^\mu(\alpha)$ for *every* competing admissible control. As a literal instruction this is hopeless — it asks us to weigh one strategy against an entire infinite-dimensional space of rivals, each of them a whole stochastic process. The maximum principle's decisive move is to refuse this global comparison and replace it with a *local* one. Rather than compare complete strategies, it prices the consequences of a single instant's decision and asks only that, moment by moment, the agent take the locally cheapest action. The bookkeeping that makes this trade honest is carried by one scalar function of the state, a *costate*, and the control: the generalized Pontryagin Hamiltonian. This subsection builds that function, reads off from it the candidate optimal feedback, and then constructs the backward equation that supplies the costate. The proof that local optimality really is global optimality is deferred to section 9.1; here we are assembling, with care, the objects those theorems will act on.

The word "costate" deserves a pause before any formula, because it is the conceptual hinge of the chapter. Recall from chapter 6 that in deterministic optimal control the adjoint variable — the costate — is the *momentum conjugate to the state*: at each instant it is the marginal cost-to-go, the sensitivity of the remaining optimal cost to an infinitesimal displacement of the current position. It is exactly what lets a purely local calculation feel the entire future, because it has already compressed the future into a single price per unit of displacement. The Hamiltonian is then nothing but the instantaneous rate at which total cost accrues, written so that this price is explicit: the running cost paid right now, plus the future cost the agent's motion is about to incur, the latter obtained by pairing the agent's velocity against the costate. Minimizing this rate over the control at each instant is the local surrogate for minimizing the global cost. In the deterministic theory the costate was a single curve $y(t)$ integrated backward from the terminal time. The genuinely new phenomenon in the stochastic problem, foreshadowed in the chapter preamble, is that the costate can no longer be a single curve: it becomes a *pair* (Y, Z) solving a backward equation, and the second component Z is the price of keeping the costate honest about not being allowed to see the future. We build the Hamiltonian first and earn the pair (Y, Z) immediately afterward.

Definition 9.2 (Generalized Hamiltonian)**.** The *generalized (Pontryagin) Hamiltonian* of the control problem eq. (9.1)–eq. (9.2) is the function

$$\mathcal{H} : [0,T] \times \mathbb{R}^d \times \mathcal{P}_2(\mathbb{R}^d) \times \mathbb{R}^d \times \mathbb{R}^{d\times k} \times A \longrightarrow \mathbb{R},$$

$$\mathcal{H}(t,x,m,y,z,\alpha) \;=\; \langle b(t,x,m,\alpha), y\rangle \;+\; \mathrm{tr}\big(\sigma(t,x,m)^\top z\big) \;+\; L(t,x,m,\alpha). \tag{9.3}$$

Under **(A-Conv)** the map $\alpha \mapsto \mathcal{H}(t,x,m,y,z,\alpha)$ is strictly convex and coercive, so it has a unique minimizer

$$\hat{\alpha}(t,x,m,y,z) \;=\; \operatorname*{arg\,min}_{\alpha\in A}\; \mathcal{H}(t,x,m,y,z,\alpha), \tag{9.4}$$

which is a Lipschitz function of (x,m,y,z) (a consequence of strong convexity and the implicit function theorem; see chapter 6). The associated *reduced Hamiltonian* is $\widehat{\mathcal{H}}(t,x,m,y,z) = \mathcal{H}\big(t,x,m,y,z,\hat{\alpha}(t,x,m,y,z)\big)$.

The formula eq. (9.3) is best read not as a definition to memorize but as three priced ledgers added together, each measuring one channel through which the present instant charges the future. Take them in turn. The first term, $\langle b(t,x,m,\alpha), y\rangle$, is the *cost of motion*. The drift b is the controllable velocity of the state — the rate at which x is about to move — and y is the costate, the marginal cost of displacement; their inner product is therefore the rate at which the agent's chosen motion accrues future cost. This is the single term through which the control reaches into the future: by tilting b the agent buys displacement, and y is the price tag. It is the exact stochastic echo of the $\langle b,p\rangle$ term in the deterministic Pontryagin Hamiltonian of chapter 6. The third term, $L(t,x,m,\alpha)$, is the *cost of the present*: the running cost actually disbursed over the current instant, the only toll the agent pays in cash rather than in future consequences. The middle term, $\mathrm{tr}(\sigma^\top z) = \langle \sigma, z\rangle_F$, is the subtle one and is the term with no deterministic ancestor. It pairs the volatility σ against a second costate z, the component that prices not the displacement of the state but the *fluctuation* of the costate against the driving noise. It is the Hamiltonian's record of how randomness couples to the agent's accounting of the future; concretely it is the avatar, in costate language, of the second-order term $\frac{1}{2}\,\mathrm{tr}(\sigma\sigma^\top D^2 u)$ that the Itô correction contributes to the HJB equation, a correspondence we make exact in section 9.3. Crucially, in the present chapter the volatility is uncontrolled — σ does not depend on α — so this middle term is a *constant* as far as the minimization over α is concerned. The agent's choice sees only the first and third terms; the noise channel contributes to the dynamics of the costate but not to the selection of the action. This is precisely the simplification the standing uncontrolled-diffusion assumption was introduced to buy, and it is why the adjoint system stays first order (remark 9.7).

Because the minimization eq. (9.4) only ever sees the α-dependent part $\langle b(t,x,m,\alpha), y\rangle + L(t,x,m,\alpha)$, the regularity of the feedback $\hat{\alpha}$ is governed entirely by the curvature of this reduced object in α. Here is where the strong convexity packaged into **(A-Conv)** does its sharper work, and it repays spelling out the mechanism rather than leaving it as a parenthetical citation. Strong convexity means the Hessian $\partial^2_{\alpha\alpha}\mathcal{H}$ is bounded below by a fixed $\alpha > 0$ times the identity, uniformly in all arguments; in particular it is everywhere invertible. Suppose first that the minimizer is interior to A, so that it is pinned by the stationarity condition

$$\partial_\alpha \mathcal{H}\big(t,x,m,y,z,\hat{\alpha}(t,x,m,y,z)\big) = 0.$$

This is an implicit equation for $\hat{\alpha}$ in terms of the parameters (x, m, y, z), and its α-Jacobian is exactly the invertible Hessian $\partial^2_{\alpha\alpha}\mathcal{H} \succeq \alpha I$. The implicit function theorem therefore solves it for $\hat{\alpha}$ as a function of the parameters, and differentiating the stationarity relation gives, schematically, $\partial_{(x,m,y,z)}\hat{\alpha} = -\left(\partial^2_{\alpha\alpha}\mathcal{H}\right)^{-1}\partial_{(x,m,y,z)}\partial_\alpha\mathcal{H}$. The inverse Hessian is bounded by $1/\alpha$ and the mixed derivatives are bounded by the Lipschitz constants of the coefficients (**(A-Lip)**), so $\hat{\alpha}$ is Lipschitz in (x, m, y, z) with a constant that scales like (coefficient Lipschitz constant)$/\alpha$. When the minimizer sits on the boundary of the convex set A, the same conclusion holds with the stationarity equality replaced by the variational inequality and the gradient step by the projection onto A, which is itself 1-Lipschitz; strong convexity again furnishes the uniform constant. The upshot is the single fact the rest of the chapter leans on without further comment: the feedback $\hat{\alpha}(t, x, m, y, z)$ is a genuine Lipschitz function of its arguments, so substituting it back into the dynamics produces coefficients that still satisfy **(A-Lip)** and the forward–backward system stays well posed. Take away the uniform lower bound $\alpha > 0$ and the minimizer can jump discontinuously as the parameters cross a flat spot of the Hamiltonian, and the substitution that defines the FBSDE would no longer return a Lipschitz problem.

It is worth seeing the abstraction collapse onto something explicit, so let the LQG thread instantiate every clause. There $b = aX + b\,\alpha$, the volatility σ is a constant scalar σ, and $L = \frac{1}{2}\alpha^2 + \frac{q}{2}(x - s\bar{\mu})^2$, so the Hamiltonian eq. (9.3) reads

$$\mathcal{H}(t, x, \mu, y, z, \alpha) = (ax + b\,\alpha)\,y + \sigma z + \tfrac{1}{2}\alpha^2 + \tfrac{q}{2}(x - s\bar{\mu})^2.$$

The middle term σz carries no α, as advertised; the minimization sees only $b\,\alpha\,y + \frac{1}{2}\alpha^2$, a scalar parabola of curvature 1 (the strong-convexity constant $\alpha = 1$ here), and the stationarity condition $by + \alpha = 0$ gives the closed-form feedback

$$\hat{\alpha}(t, x, \mu, y, z) = -b\,y.$$

The feedback is *linear* in the costate y — manifestly Lipschitz with constant $|b| = |b|/\alpha$, in exact agreement with the bound just derived — and it depends on neither x nor z, a degeneracy special to the quadratic case. Reading it physically: the optimal control is to push against the momentum, with gain set by the coupling b between control and state. This is the seed of the Riccati closed form the thread carries, and it is reassuring to see the general machinery reproduce it without effort.

Notation watch

The symbol $H = H$ is reserved, in chapter 8 and appendix A, for the *HJB* Hamiltonian $H(x, p, m)$ (here carrying the extra time argument, $H(t, x, p, m)$), a function of the state, the costate variable p, and the measure, convex in p, with optimal feedback $\alpha^* = -\partial_p H$. The object in eq. (9.3) is a *different* function — the Pontryagin Hamiltonian, a function of state, costate *and control* — carried by the shared macro $\mathcal{H}$ (a calligraphic $\mathcal{H}$, distinct from the fraktur $\mathfrak{H}$ used for the *deterministic* Pontryagin Hamiltonian of chapter 6). The two are reconciled in the canonical case in remark 9.11; in brief, the reduced Hamiltonian $\widehat{\mathcal{H}}$ equals $-H$ once the z-term is suppressed and y is read as p. Do not confuse $\mathcal{H}$ (this chapter, contains α) with H (chapter 8, control already optimized out). A separate glyph clash to keep in mind: the calligraphic $\mathcal{H}$ of $\mathcal{H}$ is unrelated to the process space $\mathcal{H}^2 = \mathcal{H}^2$

(square-integrable adapted processes, chapter 5) that appears wherever the BSDE solution (Y, Z) is housed; the superscript 2 always distinguishes them.

The notation watch is not a clerical aside but a map of the chapter's central translation, and it is worth restating its content in words. Three Hamiltonians are circulating, and they differ precisely by how much optimization has already been performed. The deterministic Pontryagin Hamiltonian $\mathfrak{H}$ of chapter 6 still carries the control and lives without noise. The generalized Hamiltonian $\mathcal{H}$ of eq. (9.3) is its stochastic upgrade: it still carries the control α as a free argument — that is the whole point, since we are about to *minimize* over it — and it has acquired the extra noise channel $\mathrm{tr}(\sigma^\top z)$. The HJB Hamiltonian H of chapter 8 sits at the far end of the same pipeline, with the control already optimized out: it is a function of state, costate p, and measure only. The reduced Hamiltonian $\widehat{\mathcal{H}}$ of definition 9.2 is the bridge between them — it is $\mathcal{H}$ after the minimization, hence a function of (t, x, m, y, z) with no control left, and the notation watch records the punchline that $\widehat{\mathcal{H}}$ coincides with $-H$ once the noise term is dropped and the probabilistic costate y is identified with the analytic costate p. Holding these three apart now, while they are merely notation, is what lets the dictionary of section 9.3 read as the discovery of a single object in three guises rather than a collision of symbols. The final caution in the box — that the calligraphic $\mathcal{H} = \mathcal{H}$ has nothing to do with the process space $\mathcal{H}^2 = \mathcal{H}^2$ where the costate will be required to live — is exactly the kind of glyph clash that, unflagged, derails a first reading; the superscript carries the whole distinction.

With the Hamiltonian in hand we have the candidate feedback $\hat{\alpha}(t, x, m, y, z)$, but it is useless until we can supply its arguments. The state x and measure m are given along the trajectory; the costate pair (y, z) is not. We now need an equation whose solution *is* the costate — a process (Y_t, Z_t) that, fed into the feedback at each instant, yields the optimal action. The costate must track the marginal cost-to-go along the path, so its terminal value is forced: at the final time there is no future left, and the only sensitivity of remaining cost to the state is the gradient of the terminal cost $\partial_x g$. Its rate of change, run backward from there, must be the rate at which the Hamiltonian varies with the state — the stochastic counterpart of Hamilton's canonical equation $\dot{y} = -\partial_x \mathfrak{H}$ from chapter 6, the equation of motion for momentum. This is the content of the next definition; the only stochastic novelty, the appearance of Z, we explain immediately after.

Definition 9.3 (Adjoint BSDE)**.** Let $\alpha \in \mathbb{A}$ with state X solving eq. (9.1). The *adjoint process* (costate) associated with α is the pair of $\mathbb{F}$-progressively measurable processes (Y, Z), Y valued in $\mathbb{R}^d$ and Z in $\mathbb{R}^{d\times k}$, solving the backward stochastic differential equation

$$\mathrm{d}Y_t \;=\; -\,\partial_x \mathcal{H}(t, X_t, \mu_t, Y_t, Z_t, \alpha_t)\;\mathrm{d}t \;+\; Z_t\;\mathrm{d}W_t, \qquad Y_T \;=\; \partial_x g(X_T, \mu_T), \tag{9.5}$$

where $\partial_x \mathcal{H}$ denotes the gradient in the state argument x alone, holding (m, y, z, α) fixed. Under **(A-Lip)** the driver is Lipschitz in (y, z) and the terminal datum is square-integrable, so by the Pardoux–Peng existence/uniqueness theorem for backward stochastic differential equations (theorem C.18, proved in full in the stochastic-calculus reference) there is a unique solution (Y, Z) in $\mathcal{S}^2 \times \mathcal{H}^2$.

Two features of eq. (9.5) deserve to be drawn out, because together they are what make the adjoint a *backward stochastic* differential equation rather than an ordinary one read in reverse, and the distinction is the first place the stochastic theory genuinely departs from the deterministic skeleton of chapter 6.

The first feature is the *direction of solution*. The equation is anchored at the terminal time: its data is the gradient $\partial_x g(X_T, \mu_T)$ of the terminal cost, and it is solved from $t = T$ back toward $t = 0$. This is not a stylistic choice but a structural necessity, and it is the same necessity that orients the HJB equation it shadows. The costate measures the sensitivity of *remaining* cost to the current state; "remaining" means the cost still to be paid between now and T, so the natural place to know it exactly is at T, where nothing remains and the sensitivity is simply the gradient of the terminal penalty. Information about cost-to-go propagates from the future into the present, which on the page is a flow backward in time. The value function of chapter 8 runs backward for precisely this reason, and the costate, being its gradient (as section 9.3 will prove), inherits the orientation. Forward data would over-determine the problem: one cannot freely prescribe both where the costate starts and the terminal cost it must match.

The second feature is the genuinely stochastic one, and it is the subtlety the chapter preamble promised would surface here. The component Z is *not* prescribed anywhere; it is part of the unknown, solved for alongside Y. To see why it must be there, try to do without it. If we simply integrated the driver backward from the terminal datum, as one would a time-reversed ODE, setting $Y_t = \partial_x g(X_T, \mu_T) + \int_t^T \partial_x \mathcal{H} \, \mathrm{d}s$, then Y_t would depend on the entire trajectory of X — and hence of the Brownian motion — all the way out to the terminal time T. Such a Y_t *anticipates the future*: it is not measurable with respect to $\mathcal{F}_t$, the information available at time t, and so it is not an admissible adapted process. But the costate, as the price the agent attaches to its position *now*, cannot depend on noise that has not yet occurred; adaptedness is non-negotiable. The resolution is to add a corrective martingale term $Z_t \, \mathrm{d}W_t$ whose job is exactly to absorb the part of the terminal datum that looks into the future, redistributing it instant by instant so that what remains, Y_t, depends only on the past. That such a Z exists, and is unique, is the content of the martingale representation theorem (theorem C.17): every square-integrable terminal random variable can be written as its conditional-expectation process plus a single stochastic integral against W, and the integrand of that integral is Z. So Z is not an extra modelling choice we make; it is forced into existence by the collision between terminal pinning and adaptedness, and it is the price of insisting that the costate not cheat by peeking ahead. This is the source of every subtlety that separates a BSDE from a time-reversed ODE, and it is why the stochastic costate is irreducibly a *pair* (Y, Z). The well-posedness of the pair — existence and uniqueness in $\mathcal{S}^2 \times \mathcal{H}^2$ under the Lipschitz driver — is delivered by the Pardoux–Peng theorem (theorem C.18) invoked in the definition; it is the backward analogue of the forward SDE well-posedness imported in section 9.1, and it is what guarantees the adjoint is a bona fide object to compute with rather than a formal expression.

Having built the Hamiltonian, the feedback, and the adjoint, we can now state in one deliberately non-rigorous breath why these are the right objects — why the costate is a momentum and why it runs backward. The argument below is the heuristic engine behind the theorems of section 9.1; reading it first turns those proofs from formal manipulations into a story whose ending is already understood.

Heuristic (non-rigorous)

Why is the costate a momentum, and why does it run backward? Freeze the population and imagine perturbing the optimal control on a vanishingly short interval $[t, t+\epsilon]$ by a "needle" (spike) variation: on that tiny window the agent deviates to some arbitrary action a, and everywhere else it goes back to playing optimally. The first-order change in total cost splits cleanly into two pieces. The first, (i), is the *immediate* change in running cost accumulated over the spike, of order $\big(L(t, X_t, \mu_t, a) - L(t, X_t, \mu_t, \hat{\alpha}_t)\big)\epsilon$ — the price paid on the spot for acting differently. The second, (ii), is subtler and is where the costate is born. By acting differently over $[t, t+\epsilon]$ the agent nudges the state, leaving it at $X_{t+\epsilon}$ displaced by roughly $\big(b(t, X_t, \mu_t, a) - b(t, X_t, \mu_t, \hat{\alpha}_t)\big)\epsilon$ from where it would have been. From $t+\epsilon$ onward the agent resumes optimal play, but it does so from a *shifted* starting point, and that shift propagates through all remaining cost. The total downstream penalty of a unit displacement at time t is, by definition, the sensitivity of the optimal cost-to-go to the current state — the gradient of the value function. Call it Y_t. This is the sense in which the costate is a momentum: it is the exchange rate converting a displacement of the state *now* into units of cost paid *later*, exactly the conjugate-to-position role momentum plays in mechanics. Piece (ii) is then $\langle Y_t, b(t, X_t, \mu_t, a) - b(t, X_t, \mu_t, \hat{\alpha}_t)\rangle\epsilon$, and adding it to piece (i) shows the total first-order cost change is governed by the difference of the generalized Hamiltonian $\mathcal{H}$ evaluated at a versus at $\hat{\alpha}_t$. Optimality forbids this difference from being negative for any a, which is exactly the statement that $\hat{\alpha}_t$ *minimizes* $\mathcal{H}$ pointwise — the minimum principle. Now trace how the sensitivity Y_t itself evolves. Because it measures cost still to come, its natural anchor is the terminal time, where the only cost left is the terminal penalty and the sensitivity is simply $\partial_x g$. Moving the anchor inward, the sensitivity changes at the rate the Hamiltonian changes with the state, $-\partial_x \mathcal{H}$, giving a transport equation that runs *backward* from T — the adjoint equation. The future is what the sensitivity sees, so the future is the direction from which its data must come. Finally, why the second component Z_t? In the stochastic world the sensitivity Y_t is itself a random process, buffeted by the same Brownian motion that drives the state, and adaptedness forbids it from anticipating that noise. The piece of Y's fluctuation that is instantaneously correlated with $\mathrm{d}W_t$ cannot be carried by the drift; it must appear as a separate martingale term, and its integrand is Z_t. So Z is the costate's noise sensitivity, forced into the ledger by the same demand for non-anticipation that orients the equation backward. The next two theorems convert each of these heuristic strokes — the pointwise minimization, the backward adjoint, the forced Z — into honest stochastic analysis.

Everything the maximum principle requires is now assembled. The generalized Hamiltonian eq. (9.3) converts the choice of action into a pointwise minimization; its minimizer eq. (9.4) is the candidate optimal feedback $\hat{\alpha}(t, x, m, y, z)$, Lipschitz by strong convexity; and the adjoint BSDE eq. (9.5) produces the costate pair (Y, Z) that the feedback consumes. The heuristic just given asserts that these fit together in exactly one way: along an optimal trajectory the control minimizes $\mathcal{H}$ instant by instant, with the costate priced by the adjoint run backward from $\partial_x g$. That assertion is, so far, only motivated. What the next subsection owes is its proof, in two directions and with the measure argument held frozen at μ throughout. The *necessary* direction will show that any optimal $\hat{\alpha}$ must satisfy the pointwise minimum condition

$$\mathcal{H}(t, \hat{X}_t, \mu_t, \hat{Y}_t, \hat{Z}_t, \hat{\alpha}_t) = \min_{\alpha \in A} \mathcal{H}(t, \hat{X}_t, \mu_t, \hat{Y}_t, \hat{Z}_t, \alpha),$$

turning the needle-variation heuristic into a rigorous duality computation through the adjoint. The *sufficient* direction will show that, under the convexity of **(A-Conv)**, this same condition is enough to *guarantee* optimality — so that solving the coupled state–adjoint system is not merely a property of the optimum but a complete characterization of it. With necessity and sufficiency both in hand, the search for an optimal control collapses entirely into the solution of a system of stochastic equations, which is exactly the raw material section 9.2 will close into the McKean–Vlasov FBSDE.

9.1.3 Necessity and sufficiency

The previous subsection ended with a promise and a heuristic. The promise was that the three objects we had assembled — the generalized Hamiltonian eq. (9.3), the feedback $\hat{\alpha}(t, x, m, y, z)$ it selects eq. (9.4), and the adjoint pair (Y, Z) the backward equation eq. (9.5) produces — fit together in exactly one way: along an optimal trajectory the control minimizes $\mathcal{H}$ instant by instant against a costate priced by the adjoint. The heuristic, run through a needle variation, made that fit *plausible*. This subsection makes it *true*, and it does so in both directions, with the population argument held frozen at μ from start to finish — we are still inside the frozen problem of section 9.1, optimizing a single agent against fixed scenery, and the word "frozen" will not be deleted until section 9.2.

The two directions answer two different questions and lean on two different hypotheses, and it is worth separating them before either proof begins. *Necessity* asks: if a control is optimal, must it satisfy the minimum principle? This is a first-order question — it differentiates the cost at the optimum and reads off that the derivative cannot point downhill — so it needs the coefficients to be differentiable, but it needs no convexity. *Sufficiency* asks the converse: if a control satisfies the minimum principle, is it optimal? A vanishing first derivative is, in general, only a stationarity certificate, not a proof of minimality; what upgrades it is convexity, exactly as a stationary point of a convex function on the line is automatically its global minimum. So sufficiency is where **(A-Conv)** finally earns the central billing it was given in section 9.1.

Both proofs, for all that they answer opposite questions, are powered by a single mechanical device, and recognizing it once makes both arguments legible. That device is the Itô product rule applied to the pairing $\langle \hat{Y}_t, \cdot \rangle$ of the adjoint against a state-side perturbation — the variational process V in the necessity proof, the genuine displacement $\delta X = X - \hat{X}$ in the sufficiency proof. In each case the adjoint was *built* eq. (9.5) precisely so that, when paired against the state side through Itô, the troublesome $\partial_x \mathcal{H}$ drift it carries cancels the state-sensitivity terms the pairing generates, leaving behind only the control-direction derivative $\partial_\alpha \mathcal{H}$ — the one quantity the agent actually governs. This cancellation is the whole point of the adjoint, and seeing it execute, term by term, is the content of what follows. We carry out the necessity proof first.

Theorem 9.4 (Stochastic maximum principle, necessary condition)**.** *Assume **(A-Lip), (A-Growth), (A-Conv)**, and that the coefficients b, σ, L, g are continuously differentiable in (x, α) with* *derivatives of at most linear growth. Let* $\hat{\alpha} \in \mathbb{A}$ *be optimal against the frozen flow* μ*, with optimal state* $\hat{X}$ *solving eq.* (9.1) *and adjoint* $(\hat{Y}, \hat{Z})$ *solving eq.* (9.5) *along* $(\hat{X}, \hat{\alpha})$*. Then,* $\mathrm{d}t \otimes \mathrm{d}\mathbb{P}$*-almost everywhere,*

$$\mathcal{H}(t, \hat{X}_t, \mu_t, \hat{Y}_t, \hat{Z}_t, \hat{\alpha}_t) \;=\; \min_{\alpha \in A} \mathcal{H}(t, \hat{X}_t, \mu_t, \hat{Y}_t, \hat{Z}_t, \alpha), \tag{9.6}$$

equivalently $\hat{\alpha}_t = \hat{\alpha}(t, \hat{X}_t, \mu_t, \hat{Y}_t, \hat{Z}_t)$ *with the minimizer of eq.* (9.4)*.*

Proof. This is the stochastic Pontryagin principle, the deterministic skeleton of which was given in theorem 6.11 and proposition 6.12; we carry out the stochastic argument in full, with the measure argument frozen at μ throughout. The proof has four movements — a variation, a differentiation, a duality, and a selection — and we take them in that order.

Before the first, a word on *which* variation, because the choice is dictated by the geometry of the action set and it is what makes the present argument shorter than the textbook one. To probe whether $\hat{\alpha}$ is optimal we must perturb it and watch the cost respond. There are two classical ways to perturb a control. A *needle* (or spike) variation replaces $\hat{\alpha}$ by an arbitrary value $a \in A$ on a vanishingly short time window $[t, t+\epsilon]$ and leaves it untouched elsewhere; this is the device one is *forced* to use when A is non-convex, because then the straight-line blend of two admissible controls may leave the action set, and a large deviation on a tiny set is the only admissible perturbation available. A *convex* (Gâteaux) variation instead blends globally, $\alpha^\theta = \hat{\alpha} + \theta(\alpha - \hat{\alpha})$, nudging the control a little at *every* instant toward a rival α. The blend is admissible only if the action set is convex — otherwise $\hat{\alpha}_t + \theta(\alpha_t - \hat{\alpha}_t)$ can fall outside A — and here it is, by hypothesis. Convexity of A is therefore exactly the licence to use the gentler, globally smooth variation, which differentiates cleanly in θ and never requires the delicate $\sqrt{\epsilon}$ bookkeeping of the spike. (The needle variation yields the *same* minimum principle and does not need convexity of A; we simply do not need it, and say so to flag that the convexity of A is a convenience here, not a load-bearing hypothesis of the conclusion.)

Variation and variational equation. Fix any rival $\alpha \in \mathbb{A}$ and, for $\theta \in (0,1]$, set $\alpha^\theta = \hat{\alpha} + \theta(\alpha - \hat{\alpha})$, which lies in $\mathbb{A}$ by convexity of A; write the perturbation direction $\delta\alpha_t = \alpha_t - \hat{\alpha}_t$ and let X^θ be the state driven by α^θ. As $\theta \downarrow 0$ the perturbed state X^θ collapses back onto the optimal state $\hat{X}$, and the question is how fast and in what direction. The answer is the first-order sensitivity of the state to the control perturbation, the *variational process*

$$V_t \;=\; \lim_{\theta \downarrow 0} \frac{X_t^\theta - \hat{X}_t}{\theta},$$

the stochastic analogue of the Jacobi field that propagates an initial nudge through a flow. Differentiating the state SDE eq. (9.1) in θ at $\theta = 0$ — formally, by the chain rule, with the drift and volatility expanded to first order about $(\hat{X}_t, \hat{\alpha}_t)$ — gives the linear SDE this limit must obey,

$$\mathrm{d}V_t = \left[\partial_x b\, V_t + \partial_\alpha b\, \delta\alpha_t\right] \mathrm{d}t + (\mathrm{D}_x\sigma)[V_t]\; \mathrm{d}W_t, \qquad V_0 = 0, \tag{9.7}$$

with initial value $V_0 = 0$ because every X^θ starts from the same $X_0 \sim m_0$, so the perturbation has not yet had time to act. The drift of V has two sources, visible term by term: $\partial_x b\, V_t$ is how the already-accumulated displacement V_t feeds forward through the state-dependence of the drift, and $\partial_\alpha b\, \delta\alpha_t$ is the fresh push injected at time t by the control perturbation itself. The diffusion term $(\mathrm{D}_x\sigma)[V_t]$ is the directional derivative of the volatility in the direction of the displacement, the matrix $\sum_\ell \partial_{x_\ell}\sigma\,(V_t)_\ell \in \mathbb{R}^{d\times k}$; the control perturbation does *not* appear here, because the volatility is uncontrolled — the first place in this proof where the standing assumption pays off, and the reason $\delta\alpha$ enters V only through the drift. All coefficients $\partial_x b, \partial_\alpha b, \mathrm{D}_x\sigma$ are evaluated along the optimal trajectory $(t, \hat{X}_t, \mu_t, \hat{\alpha}_t)$, so they are bounded processes by **(A-Lip)**. That the rescaled differences genuinely converge to V in $\mathcal{S}^2$, and not merely formally, is where the affineness inside **(A-Conv)** is used: when b, σ are affine in (x, α) the first-order expansion is *exact*, with no remainder to control, so the limit is immediate; for merely smooth coefficients one would estimate a second-order remainder, which the affine case spares us. Equation eq. (9.7) then has bounded coefficients and a zero-control diffusion of linear growth, hence a unique solution $V \in \mathcal{S}^2$ with $\mathbb{E}\sup_{t\le T}|V_t|^2 < \infty$ by the linear SDE estimate of chapter 5.

Differentiation of the cost. With the state sensitivity V in hand we can differentiate the cost $J^\mu(\alpha^\theta)$ at $\theta = 0$. Recall from eq. (9.2) that J^μ is the expectation of a running integral of L plus a terminal g; the perturbation θ enters $J^\mu(\alpha^\theta)$ through two channels, directly via the explicit control argument $\alpha_t^\theta = \hat{\alpha}_t + \theta\,\delta\alpha_t$ and indirectly via the perturbed state X_t^θ, whose θ-sensitivity is exactly V. The chain rule therefore produces one term per channel. Since the integrands L, g are C^1 with derivatives of at most linear growth, and $X^\theta \to \hat{X}$ in $\mathcal{S}^2$ with difference quotients dominated by the $\mathcal{S}^2$-bounded V, dominated convergence legitimizes differentiating under the expectation, and we obtain

$$\frac{\mathrm{d}}{\mathrm{d}\theta}\bigg|_{\theta=0^+} J^\mu(\alpha^\theta) = \mathbb{E}\left[\int_0^T \Big(\langle \partial_x L, V_t\rangle + \langle \partial_\alpha L, \delta\alpha_t\rangle\Big)\,\mathrm{d}t + \langle \partial_x g(\hat{X}_T, \mu_T), V_T\rangle\right], \tag{9.8}$$

all cost derivatives evaluated along $(t, \hat{X}_t, \mu_t, \hat{\alpha}_t)$. Read the three terms: $\langle \partial_x L, V_t\rangle$ is the running cost's response to the *displaced state*, $\langle \partial_\alpha L, \delta\alpha_t\rangle$ its response to the *altered control*, and $\langle \partial_x g, V_T\rangle$ the terminal cost's response to the displaced final state. Two of these three — the two carrying the state sensitivity V — are exactly what the adjoint is engineered to absorb. Optimality of $\hat{\alpha}$ forces $J^\mu(\alpha^\theta) \ge J^\mu(\hat{\alpha})$ for every $\theta \in (0, 1]$; dividing by $\theta > 0$ and letting $\theta \downarrow 0$, the one-sided derivative on the right of eq. (9.8) is therefore ≥ 0. This nonnegativity is the entire content of optimality at first order; everything that follows is bookkeeping to extract from it a *pointwise* statement.

Duality through the adjoint. The cost derivative eq. (9.8) still carries the state sensitivity V in two of its three terms, and V is an awkward object — it depends on the perturbation $\delta\alpha$ through the whole history of eq. (9.7). The adjoint exists to launder it away. The instrument is the Itô product rule applied to the scalar process $\langle \hat{Y}_t, V_t\rangle$, the running pairing of the costate against the state sensitivity. Writing the product rule out in full, with $\mathrm{d}\hat{Y}$ from eq. (9.5) and $\mathrm{d}V$ from eq. (9.7),

$$\mathrm{d}\langle \hat{Y}_t, V_t\rangle = \langle \mathrm{d}\hat{Y}_t, V_t\rangle + \langle \hat{Y}_t, \mathrm{d}V_t\rangle + \mathrm{d}\langle \hat{Y}, V,\rangle\, t,$$

three pieces: the costate's increment paired with V, the costate paired with V's increment, and the quadratic covariation of the two. Substitute each. The first piece contributes $-\langle \partial_x \mathcal{H}_t, V_t\rangle\ \mathrm{d}t$ plus a $\mathrm{d}W$ term from $Z_t\ \mathrm{d}W_t$; the second contributes $\langle \hat{Y}_t, \partial_x b\, V_t + \partial_\alpha b\,\delta\alpha_t\rangle\ \mathrm{d}t$ plus a $\mathrm{d}W$ term from $(\mathrm{D}_x\sigma)[V_t]$. The covariation is the term with no deterministic analogue: both $\hat{Y}$ and V are driven by the *same* Brownian motion, $\hat{Y}$ through $Z_t\ \mathrm{d}W_t$ and V through $(\mathrm{D}_x\sigma)[V_t]\ \mathrm{d}W_t$, so their brackets multiply and sum over the k noise components, giving the Frobenius pairing

$$\mathrm{d}\langle \hat{Y}, V,\rangle\, t = \mathrm{tr}\big((\mathrm{D}_x\sigma)[V_t]\,\hat{Z}_t^\top\big)\ \mathrm{d}t = \langle \hat{Z}_t, (\mathrm{D}_x\sigma)[V_t]\rangle_F\ \mathrm{d}t.$$

Now integrate from 0 to T and take expectations. The two $\mathrm{d}W$ contributions are genuine martingale integrals — their integrands $\langle Z_t, V_t\rangle$ and $\langle \hat{Y}_t, (\mathrm{D}_x\sigma)[V_t]\rangle$ are integrable precisely because $V \in \mathcal{S}^2$, $\hat{Y} \in \mathcal{S}^2$ and $\hat{Z} \in \mathcal{H}^2$, which is the moment bound of section 9.1 doing its load-bearing work — so they have zero expectation; and $V_0 = 0$ kills the lower endpoint. What survives is

$$\mathbb{E}\Big[\langle \hat{Y}_T, V_T\rangle\Big] = \mathbb{E}\left[\int_0^T \Big(- \langle \partial_x \mathcal{H}_t, V_t\rangle + \langle \hat{Y}_t, \partial_x b\, V_t + \partial_\alpha b\, \delta\alpha_t\rangle + \langle \hat{Z}_t, (\mathrm{D}_x\sigma)[V_t]\rangle_F \Big)\,\mathrm{d}t\right],$$

where $\partial_x\mathcal{H}_t = \partial_x\mathcal{H}(t, \hat{X}_t, \mu_t, \hat{Y}_t, \hat{Z}_t, \hat{\alpha}_t)$. The cancellation is now visible. Differentiate the definition eq. (9.3) of $\mathcal{H}$ in the state x, holding (y, z, α) fixed:

$$\partial_x\mathcal{H} = \underbrace{(\partial_x b)^\top \hat{Y}}_{\partial_x\langle b, \hat{Y}\rangle} + \underbrace{\langle \hat{Z}, (\mathrm{D}_x\sigma)[\,\cdot\,]\rangle_F}_{\partial_x\,\mathrm{tr}(\sigma^\top \hat{Z})} + \partial_x L,$$

the three pieces being the x-gradients of the three terms of the Hamiltonian in turn. Pair this against V_t: the first piece is $\langle \hat{Y}_t, \partial_x b\, V_t\rangle$ (moving the transpose across the inner product), and it cancels the matching term from the second product piece; the middle piece is $\langle \hat{Z}_t, (\mathrm{D}_x\sigma)[V_t]\rangle_F$, and it cancels the Frobenius covariation term exactly. The only survivor from $-\langle \partial_x\mathcal{H}_t, V_t\rangle$ is $-\langle \partial_x L, V_t\rangle$, and the only survivor from the second product piece is $\langle \hat{Y}_t, \partial_\alpha b\, \delta\alpha_t\rangle = \langle (\partial_\alpha b)^\top \hat{Y}_t, \delta\alpha_t\rangle$. Finally use the terminal condition $\hat{Y}_T = \partial_x g(\hat{X}_T, \mu_T)$ on the left, and the identity reads

$$\mathbb{E}[\langle \partial_x g, V_T\rangle] = \mathbb{E}\left[\int_0^T \Big(- \langle \partial_x L, V_t\rangle + \langle (\partial_\alpha b)^\top \hat{Y}_t, \delta\alpha_t\rangle \Big)\,\mathrm{d}t\right]. \tag{9.9}$$

This is the payoff of having built the adjoint exactly as we did: the troublesome terminal term $\langle \partial_x g, V_T\rangle$ on the left, and the troublesome running state-sensitivity $\langle \partial_x L, V_t\rangle$ on the right, are now expressed through the adjoint, with the control perturbation $\delta\alpha$ entering only through the single clean term $\langle (\partial_\alpha b)^\top \hat{Y}_t, \delta\alpha_t\rangle$.

Collapse. Now feed the duality eq. (9.9) back into the cost derivative eq. (9.8). The terminal term $\langle \partial_x g, V_T\rangle$ in eq. (9.8) is, by eq. (9.9), equal to the right-hand integral, so substituting gives

$$0 \le \frac{\mathrm{d}}{\mathrm{d}\theta}\Big|_{0+} J^\mu(\alpha^\theta) = \mathbb{E}\left[\int_0^T \Big(\underbrace{\langle \partial_x L, V_t\rangle}_{\text{from } eq.\ (9.8)} + \langle \partial_\alpha L, \delta\alpha_t\rangle \underbrace{- \langle \partial_x L, V_t\rangle}_{\text{from } eq.\ (9.9)} + \langle (\partial_\alpha b)^\top \hat{Y}_t, \delta\alpha_t\rangle \Big)\,\mathrm{d}t\right].$$

The whole purpose of the adjoint is now consummated: the two $\langle \partial_x L, V_t\rangle$ terms — the running cost's response to the state displacement, entering once from the cost derivative and once, with opposite sign, from the duality — cancel identically, and with them goes every appearance of the state sensitivity V. What is left contains only the control direction $\delta\alpha_t = \alpha_t - \hat{\alpha}_t$:

$$0 \le \frac{\mathrm{d}}{\mathrm{d}\theta}\Big|_{0+} J^\mu(\alpha^\theta) = \mathbb{E}\left[\int_0^T \langle \partial_\alpha L + (\partial_\alpha b)^\top \hat{Y}_t, \delta\alpha_t\rangle\,\mathrm{d}t\right] = \mathbb{E}\left[\int_0^T \langle \partial_\alpha \mathcal{H}(t, \hat{X}_t, \mu_t, \hat{Y}_t, \hat{Z}_t, \hat{\alpha}_t), \alpha_t - \hat{\alpha}_t\rangle\,\mathrm{d}t\right].$$

The last equality is again just the definition eq. (9.3) read in the control argument: differentiating $\mathcal{H} = \langle b, y\rangle + \mathrm{tr}(\sigma^\top z) + L$ in α gives $\partial_\alpha\mathcal{H} = (\partial_\alpha b)^\top y + \partial_\alpha L$, with *no* contribution from the middle term $\mathrm{tr}(\sigma^\top z)$ because σ does not depend on the control. This is the second dividend of the uncontrolled-diffusion assumption: the very quantity the agent is steering, $\partial_\alpha\mathcal{H}$, sees the noise channel not at all. We have arrived at the clean variational inequality $\mathbb{E}\int_0^T \langle \partial_\alpha \mathcal{H}_t, \alpha_t - \hat{\alpha}_t \rangle \, \mathrm{d}t \geq 0$, valid for every admissible α — a single scalar inequality that still, however, averages over space and time. The last movement turns it pointwise.

Pointwise minimization. The inequality $\mathbb{E}\int_0^T \langle \partial_\alpha \mathcal{H}_t, \alpha_t - \hat{\alpha}_t \rangle \, \mathrm{d}t \geq 0$ holds for *every* admissible $\alpha \in \mathbb{A}$, and we now squeeze a pointwise statement out of this freedom in the choice of α. The argument is by contradiction. Suppose the desired pointwise inequality failed — suppose that on some set $G \subseteq [0,T] \times \Omega$ of positive $\mathrm{d}t \otimes \mathrm{d}\mathbb{P}$ measure there existed, at each $(t, \omega) \in G$, an action $a = a(t, \omega) \in A$ with

$$\langle \partial_\alpha \mathcal{H}(t, \hat{X}_t, \mu_t, \hat{Y}_t, \hat{Z}_t, \hat{\alpha}_t), a - \hat{\alpha}_t \rangle < 0.$$

Because $\partial_\alpha \mathcal{H}$ is continuous in its arguments and $(\hat{X}, \hat{Y}, \hat{Z})$ are progressively measurable, a measurable-selection theorem furnishes such an $a(t, \omega)$ as a progressively measurable function on G — this is the technical role of measurability, to guarantee the pointwise improving direction can be assembled into a bona fide *process*. Define the rival control $\alpha_t = a(t, \omega)$ on G and $\alpha_t = \hat{\alpha}_t$ off G; it is admissible (it takes values in A and inherits square-integrability from $\hat{\alpha}$ and the boundedness of the selection). For this particular rival the integrand $\langle \partial_\alpha \mathcal{H}_t, \alpha_t - \hat{\alpha}_t \rangle$ is strictly negative on G and zero off it, so the expectation $\mathbb{E}\int_0^T \langle \partial_\alpha \mathcal{H}_t, \alpha_t - \hat{\alpha}_t \rangle \, \mathrm{d}t < 0$, contradicting the variational inequality we just proved. Hence no such G exists, and

$$\langle \partial_\alpha \mathcal{H}(t, \hat{X}_t, \mu_t, \hat{Y}_t, \hat{Z}_t, \hat{\alpha}_t), a - \hat{\alpha}_t \rangle \geq 0 \qquad \text{for all } a \in A, \quad dt \otimes \mathrm{d}\mathbb{P}\text{-a.e.} \tag{9.10}$$

It remains only to recognize eq. (9.10) for what it is. It says that at $\hat{\alpha}_t$ no admissible direction $a - \hat{\alpha}_t$ is a descent direction for $\alpha \mapsto \mathcal{H}(t, \hat{X}_t, \mu_t, \hat{Y}_t, \hat{Z}_t, \alpha)$. For a convex function on a convex set — and under **(A-Conv)** this map is convex on A — "no admissible descent direction" is not merely necessary for a minimum but *equivalent* to it: a convex function lies above its supporting hyperplane at $\hat{\alpha}_t$, so a nonnegative directional derivative toward every other point forces $\mathcal{H}(\cdots, a) \geq \mathcal{H}(\cdots, \hat{\alpha}_t)$ for all a. That is exactly the minimum principle eq. (9.6), and equivalently $\hat{\alpha}_t = \hat{\alpha}(t, \hat{X}_t, \mu_t, \hat{Y}_t, \hat{Z}_t)$ with the unique minimizer of eq. (9.4). The optimal control is thus pinned, pathwise and instant by instant, by the costate the adjoint supplies. □

So much for necessity. We have shown that *if* a control is optimal it must solve the minimum principle — but a skeptic is entitled to ask whether this is worth anything operationally. Necessity alone licenses no algorithm: it tells us what an optimum looks like, not that anything looking like that is an optimum. There could in principle be controls satisfying eq. (9.6) that are saddle points or worse, and a separate *verification* argument — typically a comparison against a candidate value function solving HJB — would be needed to certify any of them. The next theorem removes that need entirely. Under the convexity already assumed in **(A-Conv)**, the minimum principle is not only necessary but *sufficient*: any control solving it *is* optimal, full stop. This is the precise sense in which the probabilistic formulation earns its keep. It converts the optimization — an infinite-dimensional search over strategies — into the solution of a system of coupled stochastic equations, the forward state and the backward adjoint, with the minimum principle as the algebraic tie between them, and no auxiliary value function to be guessed or verified. The engine of the proof is the same Itô pairing as before, run this time on the genuine displacement $\delta X = X - \hat{X}$ rather than the infinitesimal V, and the role played at first order by differentiation is played here, globally, by convexity's defining inequality — that a convex function lies above each of its tangents.

Theorem 9.5 (Stochastic maximum principle, sufficient condition)**.** *Assume* ***(A-Lip)***, ***(A-Growth)*** *and the following convexity (a precise form of* ***(A-Conv)****): for each (t,μ) the map $(x,\alpha)\mapsto \mathcal{H}(t,x,\mu_t,y,z,\alpha)$ is convex for every (y,z), and $x\mapsto g(x,\mu_T)$ is convex. Let $\hat\alpha\in\mathbb{A}$, with state $\hat X$ and adjoint $(\hat Y,\hat Z)$, satisfy the minimum condition eq. (9.6) $\mathrm{d}t\otimes\mathrm{d}\mathbb{P}$-a.e. Then $\hat\alpha$ is optimal against μ: $J^\mu(\hat\alpha)\le J^\mu(\alpha)$ for all $\alpha\in\mathbb{A}$.*

Proof. The strategy is to bound the cost gap $J^\mu(\alpha)-J^\mu(\hat\alpha)$ from below by zero for an *arbitrary* competitor α, using two convexity inequalities glued together by an Itô pairing. Fix $\alpha\in\mathbb{A}$ with state X, and write the genuine displacement $\delta X_t = X_t-\hat X_t$ — not infinitesimal now, but the full difference between the rival trajectory and the candidate. Suppress the frozen argument μ_t for readability and abbreviate the Hamiltonian along the two trajectories, $\mathcal{H}_t[\alpha]=\mathcal{H}(t,X_t,\mu_t,\hat Y_t,\hat Z_t,\alpha_t)$ (rival state and control, but *candidate* costate) and $\hat{\mathcal{H}}_t=\mathcal{H}(t,\hat X_t,\mu_t,\hat Y_t,\hat Z_t,\hat\alpha_t)$ (everything at the candidate). From the definition eq. (9.2) of the cost,

$$J^\mu(\alpha)-J^\mu(\hat\alpha)=\mathbb{E}\left[\int_0^T\big(L(t,X_t,\alpha_t)-L(t,\hat X_t,\hat\alpha_t)\big)\,\mathrm{d}t+g(X_T)-g(\hat X_T)\right].$$

We bound the terminal and running pieces separately, and the adjoint is what stitches them.

The terminal piece, by convexity of g. A convex differentiable function lies above its tangent plane: $g(X_T)\ge g(\hat X_T)+\langle\partial_x g(\hat X_T),X_T-\hat X_T\rangle$. Since $\hat Y_T=\partial_x g(\hat X_T)$ is exactly the adjoint's terminal datum, this reads

$$g(X_T)-g(\hat X_T)\ \ge\ \langle\hat Y_T,\delta X_T\rangle. \tag{9.11}$$

Convexity of the terminal cost has thus traded an unknown terminal difference for a linear functional of δX_T paired against the costate — precisely the form the Itô pairing can process.

The pairing, by Itô. Apply the product rule to $\langle\hat Y_t,\delta X_t\rangle$, with $\mathrm{d}(\delta X_t)=\mathrm{d}X_t-\mathrm{d}\hat X_t$ supplied by eq. (9.1) at (X,α) and at $(\hat X,\hat\alpha)$, and $\mathrm{d}\hat Y_t$ by eq. (9.5). As in the necessity proof the expansion has three pieces. The drift of $\hat Y$ contributes $-\langle\partial_x\hat{\mathcal{H}}_t,\delta X_t\rangle\,\mathrm{d}t$; the drift of δX contributes $\langle\hat Y_t,b(t,X_t,\alpha_t)-b(t,\hat X_t,\hat\alpha_t)\rangle\,\mathrm{d}t$; and the covariation of the two martingale parts — $\hat Z_t\,\mathrm{d}W_t$ against $(\sigma(t,X_t)-\sigma(t,\hat X_t))\,\mathrm{d}W_t$ — contributes the Frobenius term $\mathrm{tr}[(\sigma(t,X_t)-\sigma(t,\hat X_t))^\top\hat Z_t]\,\mathrm{d}t$. The two genuine stochastic integrals are martingales by the $\mathcal{S}^2\times\mathcal{H}^2$ integrability and so drop out under expectation; $\delta X_0=0$ kills the lower endpoint. Hence

$$\mathbb{E}\Big[\langle\hat Y_T,\delta X_T\rangle\Big]=\mathbb{E}\left[\int_0^T\Big(\langle\hat Y_t,b(t,X_t,\alpha_t)-b(t,\hat X_t,\hat\alpha_t)\rangle+\mathrm{tr}\big[(\sigma(t,X_t)-\sigma(t,\hat X_t))^\top\hat Z_t\big]-\langle\partial_x\hat{\mathcal{H}}_t,\delta X_t\rangle\Big)\,\mathrm{d}t\right]. \tag{9.12}$$

The first two terms inside the integral are not arbitrary: they are exactly the drift and volatility channels of the Hamiltonian *difference*. Writing out $\mathcal{H}_t[\alpha]=\langle b(t,X_t,\alpha_t),\hat Y_t\rangle+\mathrm{tr}(\sigma(t,X_t)^\top\hat Z_t)+L(t,X_t,\alpha_t)$ and subtracting the same with hats, the inner-product and trace terms reproduce precisely the first two integrands of eq. (9.12), and the leftover is the running-cost difference:

$$\langle\hat Y_t,b(t,X_t,\alpha_t)-b(t,\hat X_t,\hat\alpha_t)\rangle+\mathrm{tr}\big[(\sigma(t,X_t)-\sigma(t,\hat X_t))^\top\hat Z_t\big]=\mathcal{H}_t[\alpha]-\hat{\mathcal{H}}_t-\big(L(t,X_t,\alpha_t)-L(t,\hat X_t,\hat\alpha_t)\big).$$

(The volatility carries no control, so $\sigma(t,X_t)$ versus $\sigma(t,\hat X_t)$ differ only through the state; this is why the trace difference is a pure δX effect.)

Assembling the bound. Now combine. Substitute eq. (9.12) for $\mathbb{E}\langle \hat{Y}_T, \delta X_T\rangle$ into the terminal inequality eq. (9.11), then insert the result into the cost gap. The running-cost difference $L(t, X_t, \alpha_t) - L(t, \hat{X}_t, \hat{\alpha}_t)$ appears once in the cost gap with a plus sign and once inside eq. (9.12) with a minus sign, so the two cancel exactly — the mirror image of the $\partial_x L$ cancellation in the necessity proof — and what remains is

$$J^\mu(\alpha) - J^\mu(\hat{\alpha}) \;\geq\; \mathbb{E}\left[\int_0^T \Big(\mathcal{H}_t[\alpha] - \hat{\mathcal{H}}_t - \langle \partial_x \hat{\mathcal{H}}_t, \delta X_t\rangle\Big)\, \mathrm{d}t\right].$$

The cost gap is now controlled entirely by the Hamiltonian, with no trace of the running cost or the terminal cost left over: the adjoint has folded both into $\mathcal{H}$.

Closing with the second convexity inequality and the minimum principle. It remains to show the integrand is nonnegative. Here the *joint* convexity of $(x, \alpha) \mapsto \mathcal{H}(t, x, \mu_t, \hat{Y}_t, \hat{Z}_t, \alpha)$ enters — and note it must be joint, in the state and control together, for what follows; convexity in the control alone would not suffice, since the bound carries a genuine state displacement δX_t as well as a control displacement, and it is exactly the affineness of b, σ inside **(A-Conv)** that makes $\mathcal{H}$ jointly convex in (x, α) and so licenses the joint inequality. The tangent-plane inequality for this convex function, expanded about the candidate point $(\hat{X}_t, \hat{\alpha}_t)$ and evaluated at (X_t, α_t), gives

$$\mathcal{H}_t[\alpha] - \hat{\mathcal{H}}_t \;\geq\; \langle \partial_x \hat{\mathcal{H}}_t, \delta X_t\rangle + \langle \partial_\alpha \hat{\mathcal{H}}_t, \alpha_t - \hat{\alpha}_t\rangle.$$

The first term on the right is exactly the $-\langle \partial_x \hat{\mathcal{H}}_t, \delta X_t\rangle$ sitting (with opposite sign) in the bound above, so it cancels, and the integrand is bounded below by $\langle \partial_\alpha \hat{\mathcal{H}}_t, \alpha_t - \hat{\alpha}_t\rangle$. But this last quantity is nonnegative for *every* competitor, and that is precisely the hypothesis we are handed: the minimum condition eq. (9.6) says $\hat{\alpha}_t$ minimizes $\alpha \mapsto \mathcal{H}(t, \hat{X}_t, \mu_t, \hat{Y}_t, \hat{Z}_t, \alpha)$ over the convex set A, so its directional derivative toward any admissible α_t is ≥ 0, i.e. $\langle \partial_\alpha \hat{\mathcal{H}}_t, \alpha_t - \hat{\alpha}_t\rangle \geq 0$. The integrand is therefore ≥ 0 pointwise, its expectation is ≥ 0, and $J^\mu(\alpha) \geq J^\mu(\hat{\alpha})$. Since α was arbitrary, $\hat{\alpha}$ is optimal. □

The two theorems together close the circle the section opened. theorem 9.4 shows that optimality *implies* the coupled system — the forward state eq. (9.1), the backward adjoint eq. (9.5), and the feedback tie $\hat{\alpha}_t = \hat{\alpha}(t, \hat{X}_t, \mu_t, \hat{Y}_t, \hat{Z}_t)$ — and theorem 9.5 shows the system *implies* optimality. Solving the system and optimizing are, under **(A-Conv)**, the same act. What we have manufactured, then, is a *solution operator*: a map that takes a frozen population flow μ and returns the unique optimal response of the representative agent, packaged as the triple $(\hat{X}, \hat{Y}, \hat{Z})$ together with the feedback it induces. This operator is the entire deliverable of section 9.1. It is also, exactly, the raw material the next section welds shut: section 9.2 will demand that the law $\mathrm{Law}(\hat{X}_t)$ of the optimal state *coincide* with the very flow μ_t the agent optimized against, turning the solution operator into a fixed-point problem and the frozen parameter into a self-consistent unknown. Before we strike the freeze, two remarks fix the precise seam at which that closure happens — what changes, and what must not.

Remark 9.6 (MFG versus mean field control: a decisive seam)**.** There is a single line in the adjoint equation eq. (9.5) that silently encodes the difference between the two great cousins of this theory, and it deserves to be made loud, because the FBSDE the next section builds inherits the choice. The adjoint differentiates $\mathcal{H}$ in the state x *only*, with the measure μ_t held frozen — there is no ∂_μ term.

That is exactly right for the mean field *game*. In a game the representative agent is a *price-taker*: it is one negligible atom in a continuum, its own deviation moves the population law not at all, and so when it computes how a displacement of its state changes its future cost it is entitled to treat μ as inert scenery. The population's response is not denied — it is simply deferred, imposed afterward and from the outside as the self-consistency condition $\mu_t = \mathrm{Law}(X_t)$ of section 9.2, never felt by the optimizer during its optimization.

Mean field *control* — the cooperative problem, in which a single central planner chooses one feedback rule and applies it to the *whole* population, optimizing the population's average cost — is a different beast precisely here. The planner is not a price-taker: when it perturbs the common control it moves every agent at once, hence moves the law μ_t itself, hence changes the cost that the law-dependence of L, b, σ feeds back to everyone. Differentiating the cost now picks up that channel, and the adjoint equation acquires an extra drift term,

$$\widetilde{\mathbb{E}}[\partial_\mu \mathcal{H}(t, \widetilde{X}_t, m_t, \widetilde{Y}_t, \widetilde{Z}_t, \widetilde{\alpha}_t)(X_t)],$$

where $\partial_\mu = \partial_\mu$ is the Lions derivative of chapter 4 — the derivative of a function of a *measure*, which is itself a function of a probe point in state space — and $\widetilde{\mathbb{E}}$ is expectation over an *independent copy* $(\widetilde{X}, \widetilde{Y}, \widetilde{Z}, \widetilde{\alpha})$ of the solution, drawn from the same law m_t but independent of the trajectory being written.

The argument bookkeeping in that term is the subtle part, and it is worth slowing down to read it, because the tilde and the evaluation point play opposite roles and confusing them inverts the meaning. The object $\partial_\mu \mathcal{H}(t, \cdot, m_t, \cdot)(\cdot)$ is a function of *two* kinds of state argument: the ordinary arguments inside $\mathcal{H}$, and the Lions "probe" argument that comes after the parenthesis. The inner arguments $(\widetilde{X}_t, \widetilde{Y}_t, \widetilde{Z}_t, \widetilde{\alpha}_t)$ all wear tildes: they belong to the independent copy, the *representative other agent* whose cost is being differentiated, and $\widetilde{\mathbb{E}}$ averages them out over the population — this is the planner summing the marginal harm its perturbation does to a typical member of the crowd. The Lions evaluation point, by contrast, is X_t *without* a tilde: it is the state of the very equation being written, the agent whose adjoint this is. In words: "average, over a random other agent $\widetilde{X}$, the sensitivity of that agent's Hamiltonian to the population mass located at my own current position X_t." Swap the tilde onto X_t and you would instead be asking how a random agent's cost responds to mass at a random other location — a different, and wrong, quantity. The asymmetry — integrate the copy, evaluate at the self — is the signature of the Lions derivative and the whole content of the extra term.

The LQG thread makes the gap concrete and quantitative. Take the running cost $\frac{q}{2}(x - s\bar{\mu}_t)^2$ with $\bar{\mu}_t = \int \xi \, \mu_t(\mathrm{d}\xi)$ the population mean. In the game, the adjoint sees only ∂_x of this, namely $q(x - s\bar{\mu}_t)$, with $\bar{\mu}_t$ frozen. In the control problem the planner additionally registers that nudging the common control shifts $\bar{\mu}_t$, and the Lions derivative of $\frac{q}{2}(x - s\bar{\mu})^2$ in the mean direction contributes an extra term proportional to qs, evaluated by averaging the other agents' costates. The upshot is that the effective mean-reversion coefficient in the control adjoint is shifted relative to the game adjoint — in the symmetric quadratic case the game coupling s is effectively replaced by something like $s(2 - s)$ or, in the standard normalization, the coupling is *doubled* — and the two equilibria genuinely differ. This is the probabilistic root of the "price of anarchy" between competitive and cooperative mean field solutions: same Hamiltonian, different adjoint, different fixed point. For the development that follows the moral is a single sentence: the system eq. (9.13) we are about to close is the *game* FBSDE, built on the ∂_μ-free adjoint, and every well-posedness and master-equation statement downstream is a statement about the game; the control problem is its near twin, separated from it by exactly the term displayed above.

Remark 9.7 (Controlled diffusion: why the first-order adjoint suffices only when σ is uncontrolled)**.** The standing assumption that the volatility σ does not depend on the control was invoked three times in the proofs above — it deleted $\delta\alpha$ from the diffusion of the variational process eq. (9.7), it killed the control-dependence of $\partial_\alpha \mathcal{H}$, and it made the trace term in eq. (9.12) a pure state effect. It is worth being explicit about what would go wrong without it, because the breakdown is structural, not a mere loss of convenience. Suppose $\sigma = \sigma(t, x, m, \alpha)$. Then perturbing the control perturbs the *noise* the agent feels, and a perturbation of the noise is a far more violent thing than a perturbation of the drift: in the Itô calculus the diffusion contributes at order $\sqrt{\mathrm{d}t}$, so its square contributes at order $\mathrm{d}t$, the same order as the drift. Concretely, a needle variation of size $a - \hat{\alpha}$ on a window of length ϵ now changes the state at second order through the quadratic variation, by an amount that does *not* vanish faster than the first-order terms. The clean first-order expansion that produced the variational process and the single duality eq. (9.9) is no longer the whole story; a second-order term survives, and the minimum principle eq. (9.6) acquires an extra piece quadratic in $\sigma(t, x, m, a) - \sigma(t, x, m, \hat{\alpha})$.

That quadratic piece must be *priced*, and a price is a costate. The new term measures the cost of injected randomness, and the cost of randomness is set by the *curvature* of the cost-to-go — exactly the second derivative D^2u of the value function, since a convex cost-to-go penalizes spread. So a *second* adjoint appears, a matrix-valued pair (P, Q) solving a second-order BSDE whose terminal datum is the Hessian $\partial^2_{xx} g$ and whose role is to carry D^2u along the trajectory, just as the first adjoint (Y, Z) carries the gradient ∇u. The Hamiltonian to be minimized then gains a Frobenius term $\frac{1}{2}\operatorname{tr}[(\sigma(t, x, m, \alpha) - \hat{\sigma})^\top P\,(\sigma(t, x, m, \alpha) - \hat{\sigma})]$ coupling the control to this curvature, and the pointwise minimization eq. (9.4) couples to P. This is the general Peng stochastic maximum principle, genuinely heavier machinery: two coupled adjoint systems, one first order and one second order, rather than the single (Y, Z) we have worked with. We exclude it deliberately. The uncontrolled-diffusion assumption is what keeps the entire chapter's adjoint apparatus first order — one BSDE, one costate pair — and it is no real loss of generality for our purposes: the LQG thread has constant volatility, and the overwhelming majority of mean field models of interest, where noise is an exogenous environmental input rather than a decision variable, satisfy it on the nose. The reader who needs the controlled-volatility theory will find the second-order maximum principle and its matrix BSDE developed in full in [40] (Vol. I, Ch. 4); for this book it is a road deliberately not taken, flagged here so that the first-order adjoint of eq. (9.13) reads as a considered restriction rather than an oversight.

9.2 The McKean–Vlasov FBSDE and the fixed point in path space

The previous section discharged, in full, the half of the mean field problem that can be solved in isolation. With the population held frozen at an arbitrary flow μ, the stochastic maximum principle

— necessity and sufficiency both established — collapsed the agent's infinite-dimensional optimization into the solution of a coupled state–adjoint system, and it did more than characterize a candidate: under **(A-Conv)** it certified that the minimizer of the pointwise Hamiltonian *is* the optimum. What we hold in hand, therefore, is not a heuristic but a verified solution operator. To any frozen scenery μ it assigns the optimally controlled state, its law, and the costate that prices it; feeding a flow in at one end, it returns the best response to that flow at the other. Everything in the present section is the consequence of a single act performed on this operator: we delete the word "frozen."

Deleting it is the whole of the mean field game. A frozen μ was always a fiction — a placeholder standing in for the crowd while we pretended the agent could not influence it — and the equilibrium demand is precisely that the fiction become true of itself. The agent optimizes against μ and, in doing so, generates a state process X with its own law $\mathrm{Law}(X_t)$; self-consistency is the requirement that this generated law be the very scenery optimized against, $\mu_t = \mathrm{Law}(X_t)$ at every instant. This is the McKean–Vlasov closure of chapter 7, but imposed now on a process of a new kind. In chapter 7 self-consistency was asked of a *prescribed* dynamics: the drift was given, and the fixed point only had to make the law feeding that drift agree with the law the drift produced. Here the dynamics being made self-consistent is itself the output of an optimization — the drift carries the optimal feedback $\hat{\alpha}$, which depends on the costate, which depends through its terminal gradient on the very law we are closing. The closure therefore wraps a fixed point in the measure around a problem that is already a fixed point in time, and it is worth being precise, before any formulas, about how many distinct knots this ties. We are closing the *game* FBSDE — the system built on the ∂_μ-free adjoint isolated in the mean-field-game-versus-control remark just above — not its cooperative twin; every well-posedness and master-equation statement that follows is a statement about the game.

The object the closure produces, assembled in definition 9.8 below, stacks three difficulties in one equation, and naming them in advance is what keeps the rest of the section from reading as a list of unrelated technical hurdles. The first is *forward–backward coupling*: the state runs forward from its initial law m_0 while the adjoint runs backward from its terminal gradient, and the two are chained through the feedback, so that data pinned at opposite ends of $[0, T]$ must be reconciled along a single trajectory — the two-point boundary tension that is the governing signature of the whole chapter. The second is *distributional coupling*: the coefficients see not just the trajectory but its law $\mathrm{Law}(X_t)$, so the unknown is not one path but a path together with the measure it induces, and that measure feeds back into the very equations that generate it. The third is the *implicit feedback*: the drift and the adjoint driver both contain $\hat{\alpha}$, which is defined only as the argmin of a minimization, so even pointwise the system is specified implicitly rather than in closed form. Each difficulty would be serious alone; what makes the mean field game FBSDE its own subject is that the three are nested — the distributional coupling sits outside the forward–backward coupling, which sits outside the implicit feedback — so that resolving one does not unwrap the others. The strong convexity of **(A-Conv)** already tamed the innermost knot in section 9.1, rendering $\hat{\alpha}$ a genuine Lipschitz function of its arguments; the outer two are the business of the existence theory, and the honest accounting of when they can be undone is the well-posedness trichotomy this section closes on.

The section develops these in order. Definition 9.8 substitutes the optimal feedback and imposes $\mu_t = \mathrm{Law}(X_t)$ to write the McKean–Vlasov FBSDE itself, the central equation eq. (9.13) of the chapter; a notation watch there records a seam we must not let pass silently, that the probabilistic law $m_t = \mathrm{Law}(X_t)$ appearing in those coefficients is the *same* object as the population density $m(t,\cdot)$ of chapter 8, the two coinciding wherever the diffusion is nondegenerate and the probabilistic law being the more primitive when it is not. We then give the equilibrium its two complementary fixed-point readings — one a fixed point of the best-response map on flows of measures, the geometry closest to the PDE picture of chapter 8 and to the Schauder/Kakutani arguments of chapter 10; the other a fixed point directly on path space, the natural home of the contraction and continuation methods and of the propagation of chaos of chapter 13. Finally we state, honestly and without reproving them, the three regimes under which the fixed point is known to exist: small horizon (or equivalently small coupling) by contraction, arbitrary horizon under Lasry–Lions monotonicity by continuation, and arbitrary horizon without monotonicity by compactness at the cost of possible multiplicity. This chapter sets the fixed-point structure up; chapters 10 and 11 settle whether it has a solution. The equilibrium object the closure delivers is exactly what section 9.3 will read in its second coordinate system, identifying the costate with the value gradient and proving the probabilistic and analytic pictures to be one equilibrium twice described; and the two-point boundary tension named above, which no translation removes, is precisely what the decoupling field of section 9.4 is built to resolve. We begin by performing the substitution and imposing the consistency that turn the verified solution operator into a closed fixed point.

9.2.1 Closing the loop

We rejoin the development exactly where the maximum principle left it. With the population flow μ frozen at an arbitrary curve of measures, the agent has solved its problem in full: the optimally controlled state obeys eq. (9.1), the costate is the adjoint pair (Y,Z) from eq. (9.5), and the two are tied together by the feedback $\hat{\alpha}_t = \hat{\alpha}(t, X_t, \mu_t, Y_t, Z_t)$, the unique pointwise minimizer of the generalized Hamiltonian. This is a complete, verified solution operator: hand it a frozen scenery μ and it returns the best response to that scenery. Turning it into a mean field game is the work of two operations performed in a fixed order, and pulling them apart is what makes the closure a clean substitution rather than a leap.

The first operation is *substitution*, and it is pure bookkeeping. In the frozen problem the action α_t was an independent unknown, ranging over the admissible class $\mathbb{A}$ while we searched for its optimal value. Once the maximum principle has identified that value as $\hat{\alpha}_t = \hat{\alpha}(t, X_t, \mu_t, Y_t, Z_t)$, we may simply write the feedback in wherever a control appears — in the state drift $b(t, X_t, \mu_t, \alpha_t)$ and in the adjoint driver $\partial_x \mathcal{H}(t, X_t, \mu_t, Y_t, Z_t, \alpha_t)$. The control ceases to be a free variable; the only unknowns surviving the substitution are the triple (X,Y,Z) and the flow they evolve against. This step changes nothing about the problem's content. It merely records, in the equations themselves, the optimality already proved.

The second operation is the entire physical content of the mean field game, and it is the one the frozen problem was built to suspend. The flow μ was always a fiction: a placeholder for the crowd, held fixed so that a single agent could optimize as though it could not move the crowd at all. Equilibrium is the demand that the fiction come true of itself — that the scenery the agent optimized against be reproduced, exactly, by the agents optimizing. The optimally controlled state

X has a law $\mathrm{Law}(X_t)$ at each instant, and self-consistency is the requirement

$$\mu_t \;=\; \mathrm{Law}(X_t), \qquad 0 \le t \le T,$$

imposed at every time simultaneously. This is the McKean–Vlasov closure of chapter 7, but the process it now closes is of a new kind. In chapter 7 the dynamics being made self-consistent was *prescribed*: the drift was given, and the only fixed point was to make the law feeding the drift agree with the law the drift produces. Here the dynamics is itself the output of an optimization. Its drift carries $\hat{\alpha}$, which depends on the costate Y, whose terminal value $\partial_x g(X_T, m_T)$ depends in turn on the very law m_T we are closing. Substitute, then impose consistency, and the verified solution operator becomes a closed system that determines its own input.

Definition 9.8 (The MFG FBSDE)**.** Substituting the optimal feedback eq. (9.4) and imposing the consistency $\mu_t = \mathrm{Law}(X_t)$, a *mean field game equilibrium in probabilistic form* is a tuple (X, Y, Z) of $\mathbb{F}$-progressively measurable processes, together with the flow $m_t = \mathrm{Law}(X_t)$, solving the McKean–Vlasov forward–backward system

$$\begin{cases} \mathrm{d}X_t = b\big(t, X_t, m_t, \hat{\alpha}_t\big)\ \mathrm{d}t + \sigma\big(t, X_t, m_t\big)\ \mathrm{d}W_t, & X_0 \sim m_0, \\ \mathrm{d}Y_t = -\,\partial_x \mathcal{H}\big(t, X_t, m_t, Y_t, Z_t, \hat{\alpha}_t\big)\ \mathrm{d}t + Z_t\ \mathrm{d}W_t, & Y_T = \partial_x g\big(X_T, m_T\big), \\ \ \hat{\alpha}_t = \hat{\alpha}\big(t, X_t, m_t, Y_t, Z_t\big), & m_t = \mathrm{Law}(X_t). \end{cases} \tag{9.13}$$

The qualifier "McKean–Vlasov" refers to the dependence of the coefficients on the *law* $m_t = \mathrm{Law}(X_t)$ of the solution itself; this is what makes eq. (9.13) a distributed fixed point rather than a system for a single trajectory.

The system eq. (9.13) is the probabilistic mean field game, the central object of the chapter. Before turning it over to the existence theory, it is worth dwelling on the single adjective that distinguishes it from every forward–backward system we have written so far — "McKean–Vlasov" — because it is precisely this feature that lifts the equation out of the realm of one trajectory and makes it a problem about a whole ensemble at once.

In an ordinary (forward–backward) stochastic differential equation, the coefficients at time t depend on the solution only through its current *value* $X_t(\omega)$ along the single sample path ω. Such an equation can be solved one realization at a time: fix the Brownian path, and the coefficients become known functions of the unknown trajectory, with no reference to any other realization. The frozen-flow system of section 9.1 was of exactly this kind, which is why the maximum principle could solve it pathwise against a μ supplied from outside. The closure destroys that independence. After we impose $m_t = \mathrm{Law}(X_t)$, the coefficients depend not on the value $X_t(\omega)$ but on the *law* of X_t — a single deterministic measure obtained by averaging over *all* realizations ω at once. No trajectory can now be solved in isolation, because the equation that governs it refers to the distribution of the entire ensemble it belongs to. The unknown is therefore not a path but a path-together-with-its-own-law, and the solution must satisfy the self-referential demand that the law it induces be the law its coefficients already presumed. This is what is meant by calling eq. (9.13) a *distributed* fixed point: the fixed-point condition is not on a number or a function but on a probability measure spread across the whole population, and it is reflexive — the measure must reproduce itself. The LQG thread makes the abstraction tangible. There the only statistic of m_t the coefficients see is the population mean $\bar{m}_t = \int x \, m_t(\mathrm{d}x) = \mathbb{E}[X_t]$, so the state drift of a single agent reads $aX_t - b^2 Y_t$ with no overt mean, but the running and terminal costs pull the agent toward $s\bar{m}_t$ and $s_T \bar{m}_T$, and through the adjoint this places $\mathbb{E}[X_t]$ — an average over the ensemble — inside the equation each member of the ensemble obeys. Every path is coupled to the mean of all paths; solving for one requires knowing the law of all.

With the closure understood, we can name the obstructions it erects. The system stacks three distinct difficulties, and they are not independent hurdles to be cleared in any order but *nested* shells, each enclosing the next, so that resolving one does not by itself unwrap the others. Reading them off the three lines of eq. (9.13) is the cleanest way to see both what each one is and how it sits relative to the rest.

The innermost is the *implicit feedback*, visible in the third line of eq. (9.13). The control $\hat{\alpha}_t = \hat{\alpha}(t, X_t, m_t, Y_t, Z_t)$ that drives the state and enters the adjoint driver is not given by a closed formula; it is defined only as the argmin eq. (9.4) of the Hamiltonian minimization. Even pointwise, then — even with the trajectory, the law, and the costate all in hand at a single instant — the system specifies its own coefficients only implicitly, through an optimization that must be solved before the dynamics can be evaluated. This is the knot that **(A-Conv)** already untied in section 9.1: strong convexity made the minimizer unique and Lipschitz in (x, m, y, z), so that substituting it back returns coefficients still satisfying **(A-Lip)**. The innermost shell is, by the time we reach this section, already open. What remains is to undo the two that enclose it.

The middle shell is the *forward–backward coupling*, the structural signature the whole chapter is organized around. The first line of eq. (9.13) runs the state forward from its initial law m_0; the second runs the adjoint backward from its terminal gradient $\partial_x g(X_T, m_T)$; and the feedback chains them, since the forward drift needs Y_t to know which way to push while the backward terminal datum needs X_T to know where to start. Data are thus pinned at *opposite ends* of $[0, T]$ and must be reconciled along a single trajectory — a two-point boundary-value problem in time, not an initial-value one that can be integrated in a single sweep. This is the tension flagged in the chapter preamble as surviving every translation of the equilibrium, and it is exactly what the decoupling field of section 9.4 will be built to resolve, by expressing the backward unknown as a function of the forward state and collapsing the two-point structure into a single forward equation.

The outermost shell is the *distributional coupling* introduced by the closure itself. Through $m_t = \mathrm{Law}(X_t)$ the law appears as an argument of the drift, the diffusion, the Hamiltonian, and the terminal gradient, so the forward–backward system of the inner two shells is not solved once but must be solved *consistently with the measure it generates*. Even if one could, for a given candidate flow, resolve the implicit feedback and the forward–backward coupling and produce a solution (X, Y, Z), that solution would induce a law $\mathrm{Law}(X_t)$ which need not equal the flow one started from; equilibrium demands they agree. This is the shell that sits strictly outside the other two — it wraps an entire forward–backward solve inside a further fixed point on the space of measure flows — and it is the one neither convexity nor a decoupling field removes. Settling it is the business of the existence theory, and the honest accounting of when it can be undone is the well-posedness trichotomy this section closes on.

Notation watch

The law $m_t = \mathrm{Law}(X_t)$ in eq. (9.13) is the *same* object as the population density $m(t,\cdot) = m(t,\cdot)$ of chapter 8: where the PDE chapter writes a density on $\mathbb{R}^d$, here we write the law of a random variable. Under **(A-Nondeg)** this law has a density and the two coincide; without nondegeneracy the probabilistic object is the more primitive one, since $\mathrm{Law}(X_t)$ is defined whether or not a density exists. We use m_t for the law and $m(t,\cdot)$ for its density interchangeably, flagging only where the distinction bites.

This is not a pedantic distinction but one that decides which of the two pictures is the more fundamental, and the answer matters for the whole programme of the chapter. When the diffusion is uniformly nondegenerate — **(A-Nondeg)**, $\sigma\sigma^\top \succeq \lambda I$ for some $\lambda > 0$ — the noise smooths the law instantly: for every $t > 0$ the measure $\mathrm{Law}(X_t)$ is absolutely continuous with respect to Lebesgue measure and possesses a density, so that $m_t(\mathrm{d}x) = m(t,x)\,\mathrm{d}x$ and the probabilistic law of the present chapter coincides with the Fokker–Planck density $m(t,\cdot)$ of chapter 8 as the same object written in two notations. In that regime nothing is lost by sliding between "law" and "density." But the coincidence is a privilege of nondegeneracy, not a structural truth. Strip the smoothing away — let the diffusion degenerate, or vanish outright — and $\mathrm{Law}(X_t)$ can be singular: in the noiseless limit it is a Dirac mass transported along a deterministic flow, a measure with no density at all, on which the Fokker–Planck equation has no classical meaning. The probabilistic object survives this collapse untouched, because $\mathrm{Law}(X_t)$ is defined for any random variable whether or not a density exists; it is the more primitive of the two. This is one of the four motivations the chapter preamble offered for building the probabilistic picture in the first place — the case where the analytic picture has no density to speak of while the controlled process and its law remain perfectly well defined — and the notationwatch is where that promised payoff first shows its hand. Throughout this chapter the diffusion is nondegenerate and we treat m_t and $m(t,\cdot)$ as one; the reader should simply remember which one is load-bearing should the floor of nondegeneracy ever be removed.

The system eq. (9.13) is now assembled in full: a single McKean–Vlasov forward–backward equation, its feedback substituted in and its population law closed back on itself, carrying in one object the three nested couplings just anatomized. What it does not yet carry is an answer to the question the existence theory must ask of it. We have written the equilibrium as a fixed point, but "fixed point" is so far only a word; to feed the equation to the contraction, continuation, and compactness arguments that establish solvability, we must say in precisely *what sense* it is a fixed point — on what space, of what map — and there turns out to be more than one honest answer, each suited to a different downstream proof. The next subsection takes eq. (9.13) in hand and reads it as a fixed-point problem in two complementary ways: as a fixed point of the best-response map on flows of measures, the geometry nearest the PDE picture of chapter 8, and as a fixed point directly on path space, the natural home of the contraction and propagation-of-chaos methods to come.

9.2.2 The fixed point in path space

The previous subsection finished assembling eq. (9.13) and handed it on with a single unanswered question. We have called the equilibrium a fixed point, but that word has so far done no work: a fixed point is a point left invariant by a map, and we have named neither the map nor the space it acts on. Until we do, the system is an equation with a self-referential clause $m_t = \mathrm{Law}(X_t)$ and no apparatus to test it against. The business of this subsection is to convert that self-reference into an honest fixed-point problem — to exhibit a map whose invariant points are exactly the equilibria of eq. (9.13) — so that the existence theory of the next subsection has something concrete to act on. The reason we must work a little here, rather than write down "the" fixed-point map and move on, is that the distributional coupling can be cut in more than one place, and the cut one chooses decides which downstream proof becomes natural and which becomes awkward. There turn out to be two honest cuts, giving two fixed-point formulations of the same equilibrium, and the practical content of this subsection is not only to state both but to say precisely *which later chapter uses which, and why.* Both are used in the existence theory of chapter 10 and the propagation-of-chaos analysis of chapter 13; neither is more correct than the other, but each is adapted to a different machine.

The flow-of-measures fixed point. The first cut severs the loop at the marginal flow, and it reproduces, in probabilistic clothing, the best-response operator the analytic chapter already built. Recall from section 8.4 and proposition 8.4 that the mean field game equilibrium was characterized there as a fixed point of a map S that took a candidate population flow, solved the representative agent's optimization against it, and returned the population the optimizers generate. That map was realized in chapter 8 by the HJB/Fokker–Planck sweep — solve HJB against the frozen flow for the value, extract the feedback, push the density forward by Fokker–Planck. We now realize *the very same operator* through the FBSDE instead of the PDE pair, and the equivalence of the two realizations is one instance of the dictionary section 9.3 will prove in full. The construction is exactly the freeze-and-solve of section 9.1 read as a map. Given an input flow

$$\mu = (\mu_t)_{0 \le t \le T} \in C\big([0,T]; \mathcal{P}_2(\mathbb{R}^d)\big),$$

a continuous curve of second-moment measures, one freezes it as exogenous scenery and solves the *decoupled* forward–backward system obtained from eq. (9.13) by replacing every McKean–Vlasov occurrence of $m_t = \mathrm{Law}(X_t)$ with the frozen μ_t. The point of the substitution is that it severs precisely the outermost shell anatomized in the previous subsection: with μ frozen, the law no longer feeds back on itself, and what remains is the *standard* (not McKean–Vlasov) FBSDE of the single-agent problem of section 9.1, whose forward and backward legs are now coupled only to each other and not to their own distribution. That decoupled system is solvable by the single-agent theory already in hand; let X^μ denote its optimal state, and output the flow of its time-marginals,

$$\mathsf{S}(\mu) \;=\; \big(\mathrm{Law}(X_t^\mu)\big)_{0 \le t \le T}. \tag{9.14}$$

The operator S is the best response made literal: hand it a guess for the crowd, and it returns the crowd that the optimal responders to that guess actually form. A flow m is a mean field game equilibrium precisely when the guess is self-reproducing, that is when it is a fixed point,

$$\mathsf{S}(m) = m,$$

for then the population the agents form against m is m itself — which is the closure condition $m_t = \mathrm{Law}(X_t)$ of eq. (9.13) stated as the invariance of a map.

This is the formulation that sits nearest chapter 8, and that is exactly why it is the one the Schauder/Kakutani existence arguments of chapter 10 are built on. A topological fixed-point theorem of that kind asks for two things and nothing more: a convex compact set carried into itself, and a continuous map carrying it. The flow-of-measures picture supplies both in the most transparent way, because its unknown is a low-dimensional, geometrically tame object — a curve in the Wasserstein space $\mathcal{P}_2(\mathbb{R}^d)$ — on which compactness and continuity have concrete, checkable meanings, rather than a measure on the infinite-dimensional path space whose compactness is harder to certify. This is the WHY behind preferring it downstream, and it splits into the two analytic inputs that chapter 10 owns. The first is *continuity of* S *in the Wasserstein metric*: if two frozen flows μ and μ' are close in $\sup_t \mathcal{W}_2(\mu_t, \mu'_t)$, the decoupled FBSDEs they drive have nearby coefficients, so by the stability of SDEs and BSDEs in their data (chapter 5) their optimal states are close in $\mathcal{S}^2$, hence their marginal laws are close in $\mathcal{W}_2$ — this is what makes S continuous, and it is the estimate chapter 10 makes quantitative. The second is the *compactness* that lets a fixed-point theorem bite at all: the candidate flows must be confined to a set that is compact in the topology of uniform Wasserstein convergence, which by Prokhorov's theorem means the marginals $\mathsf{S}(\mu)_t$ must be *tight* — their mass cannot leak to infinity — uniformly in t, together with an equicontinuity in t that prevents the curve from jittering. Tightness is bought from the uniform second-moment bound $\mathbb{E}[\sup_t |X_t|^2] < \infty$ established in section 9.1; equicontinuity from the Hölder-in-time estimate the SDE supplies. Both inputs, finally, lean on the regularizing effect of **(A-Nondeg)**: it is the nondegenerate noise that smooths the marginals enough to keep the best-response map continuous rather than merely measurable across the kinks where the feedback's optimization changes regime, and that prevents the output laws from concentrating into singular limits that would escape the compact set. We only flag these here and name their owner; chapter 10 develops each into a theorem.

The path-space fixed point. The second cut severs the loop one level higher, at the law of the *whole trajectory* rather than at its time-marginals, and although it encodes the same equilibrium it is the formulation the harder existence machinery prefers. Read eq. (9.13) now as a single McKean–Vlasov FBSDE and seek a fixed point directly on path space. One fixes a candidate law of the entire forward path,

$$\mathbf{m} = \mathrm{Law}(X) \in \mathcal{P}_2(C([0,T];\mathbb{R}^d)),$$

a single probability measure on the space of continuous trajectories — not a curve of marginals but one object living over the whole horizon at once — solves the standard FBSDE that results when this $\mathbf{m}$ is frozen into the coefficients, reads off the law of the forward component of the solution, and demands that it agree with $\mathbf{m}$. The two cuts are related by marginalization: projecting a path-space law $\mathbf{m}$ onto its value at time t recovers the flow μ_t, so a path-space fixed point projects to a flow-of-measures fixed point, while the converse requires the extra information of how the marginals are tied together along trajectories. Why climb to the heavier object? Because two of the chapter's eventual destinations are statements about trajectories that the marginal flow cannot even phrase, and on path space they become natural. The contraction and continuation methods of the next subsection are estimates on the solution *process* — they bound $\mathcal{S}^2$-distances between whole paths produced by competing input laws, and the cleanest such bound lives in the metric $\mathcal{W}_2$ on $\mathcal{P}_2(C([0,T];\mathbb{R}^d))$, which compares trajectories end to end rather than slice by slice; the forward–backward stability that drives the contraction is genuinely a path-space estimate and only descends to marginals as a corollary. And the propagation of chaos of chapter 13 is, by its very statement, a path-space convergence: the empirical measure of the N players' *trajectories* converges to $\mathbf{m}$, and each player's path couples to an independent copy of the McKean–Vlasov solution path. The limit object that N-particle Nash play converges to is precisely this path-space law, so the formulation in which the limit theorem is stated, and proved, must be the one whose unknown is $\mathbf{m}$. The marginal flow is the right stage for compactness and the PDE comparison; the path-space law is the right stage for contraction, continuation, and the particle limit — and pinning this division of labor down is exactly what lets the next subsection name, for each of its three regimes, the object the regime acts on without re-deriving it.

With both cuts on the table we can record, once and for all, what a solution *is*, in the function spaces the rest of the chapter will demand of it. The definition fixes the regularity of all three unknowns of eq. (9.13) simultaneously, so that every estimate downstream has a normed home to live in.

Definition 9.9 (Solution of the MFG FBSDE)**.** A *solution* of eq. (9.13) on $[0, T]$ is a triple (X, Y, Z) with $X \in \mathcal{S}^2(\mathbb{R}^d)$, $Y \in \mathcal{S}^2(\mathbb{R}^d)$, $Z \in \mathcal{H}^2(\mathbb{R}^{d\times k})$, adapted to $\mathbb{F}$, such that the integral forms of the forward and backward equations hold $\mathbb{P}$-a.s. with $\hat{\alpha}$ given by eq. (9.4) and $m_t = \mathrm{Law}(X_t)$ for all $t \in [0, T]$. The spaces $\mathcal{S}^2$ (square-integrable, with sup-norm) and $\mathcal{H}^2$ (square-integrable in $\mathrm{d}t \otimes \mathrm{d}\mathbb{P}$) are those of chapter 5.

The choice of spaces in definition 9.9 is not bookkeeping; each is forced by what its unknown must do. The forward state and the backward Y are asked to live in $\mathcal{S}^2$ — processes with $\mathbb{E}[\sup_t |\cdot|^2] < \infty$, finite second moment in the *sup* norm — because both are compared pathwise: the state's sup-moment is what we just saw delivers tightness of the marginals $\mathrm{Law}(X_t)$ for the flow-of-measures fixed point, and Y's membership in $\mathcal{S}^2$ is the backward analogue established for the adjoint in section 9.1, the regularity in which the dictionary $Y_t = \nabla u(t, X_t)$ of section 9.3 will be read. The martingale integrand Z asks only for the weaker $\mathcal{H}^2$ — square-integrability in $\mathrm{d}t \otimes \mathrm{d}\mathbb{P}$, with no sup — because Z is never evaluated at a single instant but only ever integrated against $\mathrm{d}W$, and the Itô isometry weighs it precisely in that $\mathrm{d}t \otimes \mathrm{d}\mathbb{P}$ norm; demanding a sup-bound on Z would be both unnecessary and, in general, false. That the closure $m_t = \mathrm{Law}(X_t)$ is imposed *for every* $t \in [0, T]$, and not merely almost everywhere, is what ties the triple back to a genuine flow $m \in C([0, T]; \mathcal{P}_2(\mathbb{R}^d))$ — continuity in t coming for free from $X \in \mathcal{S}^2$ — so that the solution of definition 9.9 and the fixed point $\mathsf{S}(m) = m$ of eq. (9.14) are two names for one equilibrium, the path-space triple on one side and its projected marginal flow on the other.

These are the objects the existence theory must now act on: the best-response map S of eq. (9.14) on the flow space $C([0, T]; \mathcal{P}_2(\mathbb{R}^d))$, its path-space refinement on $\mathcal{P}_2(C([0, T]; \mathbb{R}^d))$, and the solution triple $(X, Y, Z) \in \mathcal{S}^2 \times \mathcal{S}^2 \times \mathcal{H}^2$ of definition 9.9 they are required to produce. We have written the equilibrium as a fixed point in two precise senses and matched each to its downstream proof, but we have not asked the one question that decides whether any of this machinery turns over: does a fixed point exist at all? The closure that made the system self-consistent is also what makes its solvability genuinely in doubt — the decoupled FBSDE can already blow up before the McKean–Vlasov layer is even imposed — so the answer cannot be free. The next subsection asks it honestly and finds not one answer but three, each buying existence through a different mechanism acting on one of the two fixed-point objects just defined, and each at a different cost.

9.2.3 Well-posedness: three regimes

The previous subsection handed us the equilibrium written as a fixed point in two precise senses — the best-response map S on the flow space $C([0,T];\mathcal{P}_2(\mathbb{R}^d))$ of eq. (9.14), and its path-space refinement on $\mathcal{P}_2(C([0,T];\mathbb{R}^d))$ — together with the solution triple $(X,Y,Z) \in \mathcal{S}^2 \times \mathcal{S}^2 \times \mathcal{H}^2$ of definition 9.9 they must produce. Writing the equilibrium as a fixed point is a genuine achievement, but it is not yet a proof that anything sits at the fixed point. The honest question, postponed until now precisely so that we could pose it against concrete objects, is whether eq. (9.13) has a solution at all. It does not come for free, and it is worth being exact about why, because the reason is the same forward–backward tension that has run through the whole chapter.

The obstruction is not the McKean–Vlasov closure — it is already present once μ is frozen. Strip the self-consistency away and look at the *decoupled* FBSDE, an ordinary (non-McKean–Vlasov) forward–backward system with μ held fixed. One might expect this to be harmless: a forward SDE with Lipschitz coefficients has a unique global solution by chapter 5, and a backward SDE with a Lipschitz driver has a unique global solution by Pardoux–Peng (theorem C.18). Each leg, in isolation, is globally well posed on any horizon. What can fail is their *coupling*. The forward drift depends on the costate Y through the feedback $\hat{\alpha}$, and the costate is pinned at the terminal time; the backward equation depends in turn on the forward state. The cleanest way to see the damage this two-way dependence can do is to anticipate the decoupling field $U(t,x)$ of section 9.4, the function for which $Y_t = U(t,X_t)$: substituting this ansatz into eq. (9.13) and applying Itô turns the coupled system into a single quasilinear parabolic PDE for U, a Riccati-type equation. And Riccati equations blow up. The scalar caricature $\dot{u} = u^2$, with smooth bounded data, escapes to $+\infty$ in finite time; the genuine decoupling-field equation inherits exactly this nonlinearity from the feedback's dependence on Y, so that for a long enough horizon T, or a strong enough coupling between the legs, U — and with it ∇u — can cease to exist while each leg taken alone remains perfectly tame. Finite-time blow-up of the decoupling field is the precise mechanism by which a globally Lipschitz forward–backward system can have *no* global solution, and it is the obstruction every regime below must defeat. The McKean–Vlasov layer, far from healing this, can only compound it: the closure feeds the law of the forward state back into the very coefficients whose blow-up we are trying to avert.

Against this obstruction we have three honest answers, not one. Each secures a solution through a different mechanism, acting on a different one of the fixed-point objects just recalled, and each pays a different price — in the size of the horizon, in a structural hypothesis on the couplings, or in the loss of uniqueness. We state all three together and then read off, regime by regime, what mechanism is at work and what it costs.

Theorem 9.10 (Well-posedness of the MFG FBSDE)**.** *Grant **(A-Lip)**, **(A-Growth)**, **(A-Nondeg)**, and **(A-Conv)**, so that the feedback $\hat{\alpha}$ of eq.* (9.4) *is well defined and Lipschitz. Then the McKean–Vlasov FBSDE eq.* (9.13) *admits a solution (X,Y,Z) in the sense of definition 9.9 in each of the following regimes:*

(i) (Small horizon / small coupling.) *There is $T_0 > 0$, depending only on the Lipschitz constants,* *such that for $T \leq T_0$ the solution exists and is unique. The mechanism is a contraction of the best-response map* S *on* $C([0,T];\mathcal{P}_2(\mathbb{R}^d))$*.*

(ii) (Monotonicity.) *If in addition the Lasry–Lions monotonicity **(A-Mon)** holds for the cost couplings (chapter 11), then a solution exists and is unique for* every *horizon T, by the continuation-in-parameter method along the monotone structure.*

(iii) (Compactness, no monotonicity.) *Without monotonicity but with bounded, continuous couplings, a solution exists for every T (uniqueness may fail) via a Schauder fixed point for* S*; this is the existence theorem of chapter 10.*

Proof sketch and pointers. The three regimes are proved in full in chapters 10 and 11; the purpose here is not to reprove them but to expose the mechanism each one runs on, and to mark precisely where the self-contained argument of this chapter ends and the imported argument of the neighbouring chapters begins. Read this sketch as a map of three roads, with the destinations owned elsewhere.

Regime (i): contraction. This is the cheapest mechanism and the one that lives closest to objects already in hand. The best-response map eq. (9.14) takes a candidate flow μ, solves the *decoupled* control problem against it — which is well posed by the single-agent theory of section 9.1 and the Pardoux–Peng theorem, exactly the "each leg alone is fine" fact from the discussion above — and returns the law of the resulting optimal state. A solution of the MFG is a fixed point $\mathsf{S}(\mu) = \mu$. The claim is that on a short horizon S is a strict contraction in a suitably weighted Wasserstein-sup metric on $C([0,T];\mathcal{P}_2(\mathbb{R}^d))$, so that Banach's theorem supplies a unique fixed point. The mechanism is propagation control: perturb the input flow by a small Wasserstein amount δ, and ask how far the output flow moves. The perturbation reaches the output only through the measure-arguments of the coefficients, is transported along the state and adjoint by their standard stability estimates in the coefficients (chapter 5) amplified by the Lipschitz feedback $\hat{\alpha}$, and accumulates over the interval $[0,T]$. Each of these steps contributes a bounded factor, and the accumulation contributes the length of the interval, so the output moves by at most $C\,T\,\delta$ for an explicit constant C built from the Lipschitz data. When $C\,T < 1$ the map contracts; setting $T_0 := 1/C$ gives the threshold of the theorem, and Banach delivers existence *and* uniqueness in one stroke — the only regime that gets both from a single argument. This is also the precise sense in which "small coupling" and "small horizon" are interchangeable. The constant C *absorbs the Lipschitz constants of the couplings* $\partial_m b, \partial_m L, \partial_m g$ — the derivatives of the coefficients in their measure argument, which are exactly the channels through which a perturbation of the input flow becomes a perturbation of the output — so the contraction constant is the product (coupling Lipschitz constant)$\times T$ up to fixed structural factors. Shrinking the coupling shrinks C and restores $C\,T < 1$ at a *fixed*, possibly large, horizon T, exactly as shrinking T restores it at fixed coupling: the same product is being driven below 1, and it is indifferent to which factor one shrinks. The full contraction estimate, with the weight and the constant made explicit, is carried out in chapter 10; primary source [40] (Vol. I, Ch. 4, the small-time theorem).

Regime (ii): continuation under monotonicity. The contraction of (i) is local in the horizon by its very nature — the factor T cannot be argued away — so reaching arbitrary T demands a different idea. One embeds eq. (9.13) in a one-parameter family $(\mathcal{F}_\lambda)_{\lambda\in[0,1]}$ that interpolates between a trivially solvable system at $\lambda = 0$ (the couplings switched off, so the legs decouple and each is globally well posed) and the target system at $\lambda = 1$. Let $S \subseteq [0, 1]$ be the set of parameters for which $\mathcal{F}_\lambda$ is solvable. The continuation method shows S is both open and closed in $[0, 1]$ and nonempty (it contains 0); since $[0, 1]$ is connected, $S = [0, 1]$ and in particular $1 \in S$. Openness is the easy half: near a solvable parameter the small-horizon contraction of (i), applied to the *increment* in λ rather than to the whole problem, lets one step a short distance in λ by the same Banach argument, so S contains a neighbourhood of each of its points. Closedness is the half that needs structure, and it is exactly where **(A-Mon)** enters. To pass to a limit of solvable parameters one needs the solutions not to run off to infinity as λ approaches the boundary of S — precisely the finite-time blow-up the opening warned of, now threatening in the parameter direction rather than the time direction. The Lasry–Lions monotonicity supplies the *a priori bound* that forecloses it: pairing the difference of two solutions against the difference of their adjoints and integrating by parts — the same computation that drives the Lasry–Lions uniqueness proof of chapter 11 — produces a sign-definite quantity, and monotonicity forces that sign to bound the solution uniformly in λ. With the a priori bound in hand the blow-up cannot occur, S is closed, and the system is solvable, and in fact uniquely solvable, for *every* horizon. The price is structural: **(A-Mon)** is a genuine hypothesis on the couplings — crowd-aversion rather than crowd-seeking — and models that violate it (imitation, congestion with the wrong sign) fall outside this regime and into the next. This is the Carmona–Delarue continuation method [40] (Vol. I, Ch. 4); the monotonicity hypothesis and the pairing identity that powers the a priori bound are stated and proved in full in chapter 11.

Regime (iii): compactness without monotonicity. When neither the horizon is small nor the couplings monotone, contraction and continuation both fail, and one falls back on the weakest tool that still produces a fixed point: Schauder. One restricts S to a convex compact set $\mathcal{K}$ of flows and shows it maps $\mathcal{K}$ continuously into itself, whereupon the Schauder–Kakutani theorem of chapter 2 furnishes a fixed point inside $\mathcal{K}$. The compactness is not free; it is bought from the diffusion. Under **(A-Nondeg)** the noise is uniformly nondegenerate, which regularizes the marginal laws $\mathrm{Law}(X_t)$ and, together with the tightness estimates of chapter 3, makes the relevant set of flows precompact in the Wasserstein-sup topology — this is the same parabolic-smoothing role the nondegeneracy plays for the decoupling field in theorem 9.14. Continuity of S follows from the stability of the single-agent problem in its data. What Schauder gives, however, is strictly less than what Banach gave in (i): it produces *a* fixed point but no contraction, and therefore *no* claim of uniqueness. This is exactly where uniqueness is lost. Two distinct flows can both be fixed points of S, and without monotonicity to enforce the sign that would collapse them, nothing rules this out — the multiplicity is real, and it is the symmetry-breaking phenomenon previewed in chapter 11 and made explicit for the LQG thread in chapter 14. The argument and the precise function-space setting are the content of chapter 10; we state the result here only to place the FBSDE on the same well-posedness footing as the PDE system, and defer the construction to avoid duplicating that chapter. □

It is worth stating cleanly what this subsection has and has not done, because the division of labor is itself part of the architecture. We have deliberately *not* reproved existence: chapter 10 owns the small-horizon and Schauder constructions, chapter 11 owns the monotone continuation, and our job here was to set up the FBSDE — its fixed-point objects, its hypotheses, its blow-up obstruction — so that the proofs there have something precise to act on. What *has* been established intrinsically, and owes nothing to the later chapters, is the equivalence of the three readings of the equilibrium assembled across this chapter (the single-agent stochastic maximum principle of section 9.1, the flow-of-measures fixed point, and the path-space fixed point of section 9.2), together with the exact hypotheses under which each well-posedness mechanism turns over: small horizon or small coupling for contraction, **(A-Mon)** for monotone continuation, and **(A-Nondeg)** with bounded continuous couplings for compactness. Uniqueness, where it holds, is revisited under **(A-Mon)** in chapter 11; multiplicity, where monotonicity fails, is the symmetry-breaking phenomenon previewed there and made explicit for the LQG thread in chapter 14.

The payoff of having paid this price is that the FBSDE now stands on exactly the same well-posedness footing as the PDE pair of chapter 8: three regimes — short horizon, monotone coupling, nondegenerate compactness — guarantee a solution in each picture, and they are not merely analogous regimes but, as the next section will show, the *same* regimes read in two coordinate systems. That is the claim we are now in a position to make good. With both descriptions known to possess solutions under the same conditions, the question is no longer whether each exists but whether the two are one, and that is precisely section 9.3, where the dictionary $Y_t = \nabla u(t, X_t)$ identifies the probabilistic equilibrium with the analytic one. The blow-up obstruction we met at the head of this subsection — the forward–backward coupling that can destroy a global solution — is not forgotten in that translation either: it is exactly what the *decoupling field* of section 9.4 is built to resolve, and the small-horizon and monotone mechanisms named here reappear there as the two regimes in which that field exists, the device standing behind both existence arguments and, once the population is promoted from frozen parameter to genuine argument, at the doorstep of the master equation of chapter 12.

9.3 Two pictures of one equilibrium

The chapter opened by setting the probabilistic picture deliberately against the analytic one of chapter 8 and promising, as the reward for the detour through path space, a precise dictionary between them. We are now in a position to redeem that promise. The previous subsection did the last piece of preparatory work: it placed the FBSDE eq. (9.13) on exactly the same well-posedness footing as the PDE pair of chapter 8, with the very same three regimes — short horizon, monotone coupling, nondegenerate compactness — delivering a solution in each picture. That coincidence is suggestive, but on its own it proves nothing about identity. Two genuinely different objects can happen to exist under the same hypotheses; that both the field system and the process system are solvable precisely when the horizon is short, or the coupling monotone, or the diffusion nondegenerate, does not yet show that a solution of one *is* a solution of the other. The decisive question, the one this section settles, is sharper than coexistence: are the two descriptions the same equilibrium written twice, related by an explicit and invertible change of coordinates? The answer is yes, and the change of coordinates is the dictionary $Y_t = \nabla u(t, X_t)$ this section now assembles.

It is worth stating the thesis of the section in its strongest form, because the two subsections that follow exist precisely to substantiate it. The naive expectation is hierarchical: one of the two descriptions is the “real” one and the other a derived convenience, a shadow cast by the fundamental object onto a more tractable surface. The claim here is the opposite, and it is more symmetric.

Neither the fields (u, m) on state space nor the processes (X, Y, Z) on path space is the underlying reality of which the other is an image. They are two coordinate systems on the one set of equilibria, related by an invertible dictionary, and choosing between them is choosing a chart, not choosing what is true. What separates them is not fundamentality but *transparency*: each chart renders one structural feature of the equilibrium manifest while leaving another implicit. The value gradient is the cleanest illustration, and it is no accident that it is also the hinge of the whole dictionary. In the PDE picture ∇u is a *derived* quantity — one must first solve the Hamilton–Jacobi–Bellman equation for the field u and only then differentiate it — whereas in the FBSDE picture the same object appears as a *primitive* unknown, the backward process Y solved for directly alongside the state. Conversely, the smoothness of u, which the parabolic theory of chapter 8 reads off almost for free, is buried in the path picture, recoverable only through the decoupling field. The same equilibrium content sits in plain sight in one chart and in the shadows in the other, and which is which flips from object to object. That is the precise sense in which neither picture is more fundamental and each makes a different aspect transparent.

The section makes this thesis good in two movements, one per subsection. The first, *The dictionary*, exhibits the literal translation. Its entire weight rests on a single identity — the costate is the gradient of the value function evaluated along the optimal trajectory, $Y_t = \nabla u(t, X_t)$, with its curvature companion $Z_t = \mathrm{D}^2\, u\, \sigma$ — from which the reconciliation of the two Hamiltonians, the agreement of the two optimal feedbacks, and the literal equality of the two population laws all follow. This identity is the dictionary the chapter preamble promised, and proving it is what turns the structural analogy of the previous paragraph into a theorem. The second movement, *What each picture sees better*, substantiates the other half of the thesis: it lays out the division of labor between the charts — which structural questions the field picture answers with the least friction, which the path picture answers with the least friction — and in doing so it motivates the FBSDE machinery that the later chapters lean on, from the propagation of chaos of chapter 13 to the Monte Carlo solvers of chapter 28.

The hinge identity does more than close the present chapter; it is the seed of everything that comes after it. Once $Y_t = \nabla u(t, X_t)$ is established with the population flow frozen, section 9.4 promotes it into the *decoupling field* $U(t, x) = \nabla u(t, x)$, the function that collapses the two-point boundary structure of the FBSDE — forward initial law at $t = 0$, backward terminal gradient at $t = T$, the single tension that has shadowed every form of the equilibrium in this chapter — into one Markovian forward equation. Promote the population in turn from frozen parameter to genuine argument, and that same decoupling field becomes the master field standing at the doorstep of chapter 12. The boxed equation of the next subsection is thus not only the chapter's payoff but the first stone of the road to the master equation. To lay it we must first put the analytic picture back on the table — the HJB and Fokker–Planck equations of chapter 8, rewritten in the sign convention native to the adjoint of this chapter — and then ask, field by field, where each of its objects goes under the translation. That is the task the next subsection takes up.

9.3.1 The dictionary

The previous section put the thesis on the table and named the task that will prove it: take the analytic picture of chapter 8, set it beside the path picture assembled in section 9.2, and ask — field by field, process by process — where each object of the one goes under translation into the other. This subsection performs that translation, and the discovery it reports is that the entire correspondence is governed by a *single* identity, the costate read as a value gradient, from which every other matching follows as a corollary. We begin by laying the two pictures side by side in one notation, so that the question "what maps to what" can even be posed sharply; only then do we apply Itô's formula to the candidate translation and watch it solve the adjoint equation of its own accord.

To pose the question sharply we must first be in a regime where both pictures are literally available as classical objects, because the dictionary we are about to write evaluates *derivatives* of the value function along trajectories, and those derivatives must exist to be evaluated. We therefore assume for this subsection the regularity under which the analytic picture is classical: the HJB value function $u(t,x) = u(t,x)$ of chapter 8 is $C^{1,2}$ on $[0,T) \times \mathbb{R}^d$ — once continuously differentiable in time and twice in space — and $\sigma = \sigma(t,x)$ is uncontrolled, the standing restriction of the whole chapter. Each half of this hypothesis earns its place. The $C^{1,2}$ smoothness is exactly what makes $\nabla u(t,x)$ and $\mathrm{D}^2 u(t,x)$ well-defined functions, so that the candidate processes $Y_t = \nabla u(t,X_t)$ and $Z_t = \mathrm{D}^2 u(t,X_t)\,\sigma(t,X_t)$ are objects one can form at all; the uncontrolled volatility is what keeps the adjoint first order, so that the costate is the pair (Y,Z) rather than the larger second-order adjoint a control-dependent σ would force (remark 9.7). Under the nondegeneracy hypothesis **(A-Nondeg)** the $C^{1,2}$ regularity is not an extra assumption but a consequence: the interior parabolic regularity of theorem C.12 extracts it from the equation itself, the noise smoothing the value into a classical solution. In the degenerate case no such bootstrap is available and the smoothness must be posited outright, which is what we do here, in full awareness that section 9.4 will later have to recover it by other means.

With the regularity fixed, we put the analytic equilibrium back on the table. Recall from chapter 8 that the equilibrium value solves the backward HJB equation. We write it here in the sign convention *opposite* to eq. (8.5a) — one obtains the present form by multiplying that equation through by -1, so the two are line-for-line identical and nothing mathematical has changed — because this is the convention in which the HJB drift will line up term for term with the adjoint driver of eq. (9.5), sparing us a sign chase in the middle of the Itô computation. In this convention,

$$\partial_t u + \tfrac{1}{2}\,\mathrm{tr}(\sigma\sigma^\top \mathrm{D}^2 u) - H(t,x,\nabla u, m_t) = 0, \qquad u(T,x) = g(x,m_T), \tag{9.15}$$

with the HJB Hamiltonian $H = H$ of appendix A (here carrying the extra time argument, as flagged in the chapter preamble). The population density, in turn, evolves by the forward Fokker–Planck equation $\partial_t m_t = \mathcal{A}_t^* m_t$, with m_0 given, where the generator $\mathcal{A}_t$ carries the optimal feedback drift $b(t,x,m_t,\alpha^*(t,x))$ and $\alpha^* = -\partial_p H(t,x,\nabla u, m_t)$.

These two equations carry the same two-end tension that has shadowed every form of the equilibrium in this chapter: the value u is pinned at the *terminal* time $t = T$ by $g(x,m_T)$ and runs backward, while the density m is pinned at the *initial* time $t = 0$ by m_0 and runs forward, the two coupled through the feedback α^* that u generates and the law m that u reads. The FBSDE eq. (9.13) carries the identical tension — backward Y pinned at T, forward X pinned at 0 — which is the first sign that the translation we are about to make is not a coincidence but a change of coordinates that preserves structure. The question this subsection answers is now concrete enough to state as a table: the analytic chart holds two *fields* on state space, the value $u(t,x)$ and the density $m(t,x)$, while the path chart holds three *processes* along the trajectory, the state X_t, the costate Y_t, and its noise sensitivity Z_t. The density m_t is the same object in both — it is literally $\mathrm{Law}(X_t)$ either way, as the closure of section 9.2 already arranged — so the only genuine unknowns in the dictionary are how the value field u and its derivatives produce the backward processes Y and Z. We claim, and now prove, that the answer is the most economical one imaginable: Y is the gradient of u read along X, and Z is its Hessian, contracted with the volatility. Everything else — the agreement of the two Hamiltonians, the agreement of the two feedbacks — is bookkeeping once this is secured.

Before we can match the HJB equation eq. (9.15) to the adjoint eq. (9.5) we must settle one piece of translation that is logically prior to the Itô computation, because the two equations are written in terms of two *different* Hamiltonians. The HJB equation carries $H(t,x,p,m)$, the analytic Hamiltonian of chapter 8 with the control already optimized out and a free costate slot p; the adjoint carries $\mathcal{H}(t,x,m,y,z,\alpha)$, the Pontryagin Hamiltonian of definition 9.2 with the control still present. The notation watch following definition 9.2 already warned that these are distinct functions related by a Legendre transform; we now make that relation quantitative in the canonical case, since it is exactly the substitution the proof will invoke when it differentiates the HJB drift.

Remark 9.11 (Reconciling the two Hamiltonians)**.** In the canonical case $b(t,x,m,\alpha)=\alpha$ (the control is the drift) and σ constant, the reduced Pontryagin Hamiltonian of definition 9.2 is $\widehat{\mathcal{H}}(t,x,m,y)=\min_\alpha\{\langle\alpha,y\rangle+L(t,x,m,\alpha)\}=-H(t,x,y,m)$, where $H(t,x,p,m)=\sup_\alpha\{-\langle\alpha,p\rangle-L(t,x,m,\alpha)\}$ is exactly the convex-conjugate HJB Hamiltonian of chapter 8. The optimal feedbacks agree: $\hat\alpha(t,x,m,y)=-\partial_p H(t,x,y,m)=\alpha^*$ once $y=p$. The sign flip is the Legendre-duality bookkeeping and nothing more; both conventions encode the same optimization.

The single line worth dwelling on is the sign flip $\widehat{\mathcal{H}}=-H$, because it is not an accident of one convention but the visible fingerprint of Legendre duality, and seeing why it is there dissolves any worry that the two pictures might disagree. The Pontryagin Hamiltonian is built by *minimizing* the running cost plus the priced motion, $\widehat{\mathcal{H}}(t,x,m,y)=\min_\alpha\{\langle\alpha,y\rangle+L\}$; the HJB Hamiltonian is, by the convention of chapter 8, the *maximum* of the negated quantity, $H(t,x,p,m)=\sup_\alpha\{-\langle\alpha,p\rangle-L\}$. A minimum of f is minus the maximum of $-f$, so the two are negatives of each other the instant one sets $p=y$ — the two costate variables, the probabilistic y and the analytic p, are the same momentum wearing different letters. The flip is therefore forced by the choice to define the analytic Hamiltonian as a *convex* function of p (a supremum of affine functions is convex), the choice that made the Legendre transform of chapter 8 well posed in the first place. That the optimal feedbacks nonetheless agree, $\hat\alpha=-\partial_p H=\alpha^*$, is the reassurance that the sign flip is bookkeeping and not substance: differentiating a Legendre pair returns the same argmin from either side. We will use this remark in the proof in exactly the form $H=-\widehat{\mathcal{H}}$, to turn a gradient of the HJB Hamiltonian into a gradient of the Pontryagin driver.

We can now state the dictionary as a proposition and prove it. The statement has two halves that face in opposite directions, and it is worth flagging the asymmetry before reading it. The forward half — from the analytic solution to the probabilistic one — is elementary: it is a single application of Itô's formula, and we prove it here in full. The converse half — from the probabilistic solution back to the analytic one — is genuinely harder, because it must reconstruct a *field* on all of state space out of processes that only ever visit the trajectory, and that reconstruction is exactly the work of the decoupling field of section 9.4; we state it here and point to where it is discharged. The honest content provable on the spot is the forward half, and it is where the boxed identity is born.

Proposition 9.12 (FBSDE–PDE dictionary)**.** *Under the regularity above, let $m = (m_t)$ be an equilibrium flow and u the corresponding HJB solution eq.* (9.15)*. Let X solve the forward equation of eq.* (9.13) *with this m, and set*

$$Y_t \;=\; \nabla u(t, X_t), \qquad Z_t \;=\; \mathrm{D}^2\, u(t, X_t)\, \sigma(t, X_t). \tag{9.16}$$

Then (X, Y, Z) solves the FBSDE eq. (9.13) *with the same $m_t = \mathrm{Law}(X_t)$. Conversely, if (X, Y, Z, m) solves eq.* (9.13) *and the FBSDE admits a sufficiently regular decoupling field (section 9.4), then that field's x-gradient reconstructs ∇u and u solves eq.* (9.15)*. The two formulations are equivalent representations of the same equilibrium.*

Proof. The whole forward half is one application of Itô's formula, organized so that the HJB equation supplies exactly the cancellation the adjoint needs. We carry it out in four steps: differentiate the candidate Y_t by Itô to read off both its martingale part and its drift; differentiate the HJB equation in x to get a second expression for that drift; match the two; and check the terminal datum.

Step 1: Itô on $Y_t = \nabla u(t, X_t)$, and the birth of Z. Treat Y componentwise: its i-th component is the scalar $Y_t^i = \partial_{x_i} u(t, X_t)$, to which the scalar Itô formula of chapter 5 applies along the forward dynamics $\mathrm{d}X_t = b\ \mathrm{d}t + \sigma\ \mathrm{d}W_t$ of eq. (9.13),

$$\mathrm{d}Y_t^i = (\partial_t + \mathcal{A}_t)(\partial_{x_i} u)(t, X_t)\ \mathrm{d}t + (\nabla\, \partial_{x_i} u)(t, X_t)^\top \sigma(t, X_t)\ \mathrm{d}W_t,$$

where $\mathcal{A}_t f \;=\; \langle b, \nabla f\rangle + \frac{1}{2}\, \mathrm{tr}(\sigma\sigma^\top\, \mathrm{D}^2 f)$ is the generator of X from chapter 5. Stacking the d components, the drift is the vector $(\partial_t \nabla u + \mathcal{A}_t \nabla u)(t, X_t)$ — the generator acting entrywise on the gradient — and the martingale integrand is the $d \times k$ matrix whose i-th row is $(\nabla\, \partial_{x_i} u)^\top \sigma$, namely the Jacobian of ∇u (which is the Hessian $\mathrm{D}^2\, u$) times the volatility:

$$\mathrm{d}Y_t = (\partial_t \nabla u + \mathcal{A}_t \nabla u)(t, X_t)\ \mathrm{d}t + (\,\mathrm{D}^2\, u\, \sigma)(t, X_t)\ \mathrm{d}W_t.$$

Comparing the martingale term against the $Z_t\ \mathrm{d}W_t$ of the adjoint eq. (9.5) forces $Z_t = \mathrm{D}^2\, u(t, X_t)\, \sigma(t, X_t)$ — the second line of eq. (9.16). This is not an extra postulate: once $Y = \nabla u$, the martingale representation theorem (theorem C.17) leaves the integrand Z with no freedom, and Itô computes it for us as the curvature $\mathrm{D}^2\, u$ read along the path and contracted against the noise. The shape is worth pausing on, because it is the single most common transcription error in this calculation. Since $\mathrm{D}^2\, u \in \mathbb{R}^{d\times d}$ and $\sigma \in \mathbb{R}^{d\times k}$, the product $\mathrm{D}^2\, u\, \sigma$ lies in $\mathbb{R}^{d\times k}$, which is exactly the shape required for $Z_t\ \mathrm{d}W_t$ to be an $\mathbb{R}^d$ vector when $\mathrm{d}W_t \in \mathbb{R}^k$ — a $(d \times k)$ matrix against a k-vector gives a d-vector, matching $\mathrm{d}Y_t \in \mathbb{R}^d$. The transposed object $\sigma^\top\, \mathrm{D}^2\, u$ is $k \times d$ and would make the dimensions inconsistent; it is the scalar-state identity written down without minding the order of the factors, and it coincides with the correct expression only in the degenerate case $d = k = 1$, where every matrix is a scalar and order does not matter. We flag the trap precisely because the $d = k = 1$ LQG thread, the example one instinctively checks against, is exactly the case that cannot detect it.

Step 2: differentiate the HJB equation in x. We now need a second formula for the drift $\partial_t \nabla u + \mathcal{A}_t \nabla u$, and the HJB equation eq. (9.15) supplies it once we differentiate it in the state. That this is permitted is the one analytic debt of the proof: differentiating eq. (9.15) a further time in x requires $u \in C^{1,3}$ in the relevant sense, one derivative beyond the $C^{1,2}$ already assumed. Under **(A-Nondeg)** this is free — the interior parabolic regularity of theorem C.12 bootstraps the HJB solution to as many spatial derivatives as the coefficients allow, the nondegenerate noise smoothing u at every interior point — while in the degenerate case it is part of the standing classical-regularity hypothesis of this subsection. Granting it, apply ∇ to eq. (9.15). The time and second-order terms differentiate directly; the Hamiltonian term $H(t, x, \nabla u, m_t)$ must be differentiated through *both* of its x-dependences — the explicit one and the one routed through the slot ∇u — by the chain rule:

$$\nabla_x \big[H(t, x, \nabla u, m_t)\big] = \underbrace{(\partial_x H)(t, x, \nabla u, m_t)}_{\text{explicit } x} + \underbrace{\mathrm{D}^2 u\, (\partial_p H)(t, x, \nabla u, m_t)}_{\text{through } \nabla u},$$

the second term being the Hessian (the Jacobian of ∇u) contracted with the costate-gradient $\partial_p H$. Differentiating the whole equation therefore gives

$$\partial_t \nabla u + \tfrac{1}{2} \nabla\, \operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 u) - \partial_x H - \mathrm{D}^2 u\, \partial_p H = 0.$$

Step 3: match the two drifts, and watch the cancellation. Write the Step-1 drift as $\partial_t \nabla u + \mathrm{D}^2 u\, b + \frac{1}{2} \operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2(\nabla u))$, where the middle term is the first-order part of $\mathcal{A}_t \nabla u$ — the generator's drift acting entrywise on the gradient, which stacks the components $\langle b, \nabla \partial_{x_i} u\rangle$ into the vector $\mathrm{D}^2 u\, b$ — and the last is its second-order part acting entrywise. Substitute the Step-2 expression for $\partial_t \nabla u$. Along the optimal path the forward drift is the optimal feedback $b = \alpha^*(t, X_t) = -\partial_p H$ (the canonical feedback of remark 9.11). Hence $\mathrm{D}^2 u\, b = -\mathrm{D}^2 u\, \partial_p H$, which *exactly cancels* the $+\mathrm{D}^2 u\, \partial_p H$ carried in from Step 2. This cancellation is the whole mechanism: the second-order sensitivity of the value, $\mathrm{D}^2 u\, \partial_p H$, is precisely what the agent's optimal motion is steering against, and the two annihilate. What survives is

$$\text{drift of } \mathrm{d}Y_t = \partial_x H + \Big[\tfrac{1}{2} \operatorname{tr}\big(\sigma\sigma^\top \mathrm{D}^2(\nabla u)\big) - \tfrac{1}{2} \nabla\, \operatorname{tr}\big(\sigma\sigma^\top \mathrm{D}^2 u\big)\Big].$$

The bracket is the difference between differentiating the second-order term *after* the generator has acted entrywise and *before*; the two disagree only where ∇ falls on the x-dependent volatility σ, and that residue is exactly minus the x-derivative of the Frobenius pairing $\operatorname{tr}(\sigma^\top Z)$ with $Z = \mathrm{D}^2 u\, \sigma$ held fixed — the noise channel of the Pontryagin Hamiltonian. (When σ is constant in x, as in the LQG thread, the bracket vanishes identically and this subtlety disappears.) Finally, by remark 9.11 the analytic Hamiltonian is the negated reduced Pontryagin one, $H = -\widehat{\mathcal{H}}$, and the envelope theorem gives $\partial_x H = -\partial_x L$ evaluated at the optimizer; assembling the surviving terms,

$$\text{drift of } \mathrm{d}Y_t = -\partial_x L - \partial_x \operatorname{tr}(\sigma^\top Z) = -\partial_x \mathcal{H}(t, X_t, m_t, Y_t, Z_t, \hat{\alpha}_t), \qquad \hat{\alpha}_t = \alpha^*(t, X_t),$$

since in the canonical case $b = \alpha$ is x-independent so $\partial_x \langle b, y\rangle = 0$ and $\partial_x \mathcal{H} = \partial_x L + \partial_x \operatorname{tr}(\sigma^\top z)$. This is precisely the driver of the adjoint eq. (9.5).

Step 4: the terminal datum. At $t = T$ the dictionary gives $Y_T = \nabla u(T, X_T) = \nabla_x g(X_T, m_T)$, using the terminal condition $u(T, x) = g(x, m_T)$ of eq. (9.15); this is exactly the terminal datum $Y_T = \partial_x g(X_T, m_T)$ of eq. (9.5). With the driver matched in Step 3 and the terminal value matched here, the pair (Y, Z) of eq. (9.16) solves the same backward equation as the adjoint, and by the uniqueness half of Pardoux–Peng (theorem C.18) it *is* that adjoint. Together with the forward leg, which X solves by hypothesis with $m_t = \mathrm{Law}(X_t)$, the triple (X, Y, Z) solves the FBSDE eq. (9.13). This proves the forward direction.

The converse. The reverse implication — that any sufficiently regular FBSDE solution arises from an HJB solution this way — cannot be a single Itô stroke, because it must manufacture a field u on *all* of $\mathbb{R}^d$ out of a process Y that lives only on the random trajectory. The bridge is the decoupling field of section 9.4: a deterministic function $U(t, x)$ representing the backward process as $Y_t = U(t, X_t)$, whose existence and regularity are the content of theorem 9.14 and whose in-book proof is the small-horizon contraction of chapter 10 together with its monotone extension in chapter 11. Given such a U, its x-antiderivative reconstructs u with $\nabla u = U$, and running the four steps above backward shows that this u solves eq. (9.15); uniqueness of the BSDE solution (theorem C.18) then makes the two constructions genuinely inverse to each other, so the correspondence is a bijection of equilibria and not merely a one-way map. The general form of the dictionary — controlled diffusion, common noise, the second-order adjoint these force — is carried out in [40] (Vol. I, Ch. 3–4); our standing uncontrolled-diffusion assumption is exactly what spares us that apparatus here. □

The proof produced two identities, but only the first is worth committing to memory, because the second is its derivative and the rest of the dictionary is its corollary. The entry to keep is

$\boxed{Y_t = \nabla u(t, X_t)}$ the costate is the gradient of the value function, evaluated along the optimal trajectory.

Read it as the resolution of the very puzzle the chapter opened with. The value gradient ∇u is, in the analytic picture, the marginal cost-to-go — how much the agent's remaining cost rises if its position is nudged — and the Pontryagin costate Y was *defined* in chapter 6 to be exactly that marginal cost-to-go, the momentum conjugate to the state. The box says these two readings of "marginal cost of displacement" are literally the same number, one computed as a field and then sampled at X_t, the other carried as a process. The momentum the agent prices its position with *is* the slope of the value landscape it stands on. This is why Y appears in the FBSDE as a primitive unknown while in the PDE it is a derived quantity: the path picture solves for the slope directly and never forms the field u at all.

The second component $Z_t = \mathrm{D}^2 u(t, X_t)\, \sigma(t, X_t)$ is then forced, and it has an equally clean reading: it is the *curvature* of the value function, the Hessian $\mathrm{D}^2 u$, sampled along the path and projected onto the noise directions by σ. Where Y measures the slope of the cost landscape, Z measures how that slope bends as the noise jostles the state — the rate at which the marginal cost-to-go itself fluctuates. The LQG thread makes this concrete and is the cleanest possible check. There $u(t, x) = \frac{1}{2} P_t x^2 + \dots$ is quadratic in the state, so its Hessian $\mathrm{D}^2 u = P_t$ is the scalar Riccati coefficient — *deterministic*, independent of x — and the dictionary gives $Z_t = P_t\, \sigma$, a deterministic process equal to the volatility times the Riccati gain. That Z is deterministic in the LQG case is not a coincidence but the signature of quadratic value: a parabola has constant curvature, so its second derivative carries no randomness, and the noise sensitivity of the costate collapses to a time-function. We verify this Riccati-for-Riccati in the worked computation worked computation 9.16, where the FBSDE's backward coefficient is matched against the HJB's Riccati flow and the two are seen to be the same equation.

With the box and its curvature companion in hand, the remaining matchings are immediate. The optimal feedback in the two pictures, $\hat{\alpha}(t, X_t, m_t, Y_t, Z_t)$ from the Pontryagin minimization and $\alpha^*(t, X_t) = -\partial_p H(t, X_t, \nabla u, m_t)$ from the HJB Legendre transform, coincide the moment $Y = \nabla u$ is substituted, by the feedback agreement of remark 9.11. The population law is not merely matched but *identical* in both pictures — it is $\mathrm{Law}(X_t)$ either way, the same measure under one name — as the notation watch of definition 9.2 already recorded. So the entire equilibrium content lines up: the PDE picture stores it as two *fields* on state space, (u, m); the FBSDE picture stores it as two coupled *processes* on path space, (X, Y) with the forced companion Z; and the single bridge between the two storehouses is "evaluate the field along the random trajectory." The two-end tension — terminal data on the backward object, initial data on the forward one — is preserved verbatim by the translation, which is the structural reason the dictionary could be an exact change of coordinates rather than an approximation.

Physics note

The relationship between the two formulations is, structurally, the relationship between the Schrödinger and Heisenberg pictures of a dynamical theory. In the analytic (PDE) picture the unknowns are *fields* on configuration space — the value $u(t, x)$ and the density $m(t, x)$ — evolving by deterministic equations, like a wavefunction obeying a PDE while the configuration label x stays put. In the probabilistic (FBSDE) picture the state x itself becomes a *process* X_t that moves, and the dynamical content is carried by operator-valued (here, process-valued) objects X_t, Y_t, Z_t evaluated along that motion; the field u has been "pushed onto the trajectory" via $Y_t = \nabla u(t, X_t)$, just as a Heisenberg operator is a Schrödinger operator conjugated by the flow. The two pictures compute identical observables — here, the equilibrium cost and the law m_t — and the choice between them is a choice of convenience: fields when one wants regularity and PDE technology, processes when one wants probabilistic representations, Monte Carlo, or the N-player coupling of chapter 13. As always, the analogy is organizational only; it proves nothing, and the equivalence is the rigorous content of proposition 9.12.

The boxed identity $Y_t = \nabla u(t, X_t)$ is the chapter's payoff, but it is also a handoff in two directions, and naming both now is what lets the rest of the development read as consequences rather than fresh starts. Forward in this chapter, it is the seed of section 9.4: there we hold t and x fixed rather than riding the trajectory, turning the pathwise identity into the deterministic *decoupling field* $U(t, x) = \nabla u(t, x)$ of eq. (9.18), the function that collapses the FBSDE's two-point boundary structure into a single Markovian forward equation and, once the population is promoted from frozen parameter to genuine argument, becomes the master field at the doorstep of chapter 12. Sideways into the threads, it is what the worked computation worked computation 9.16 will check explicitly, matching the FBSDE's backward coefficient to the HJB's Riccati flow and confirming the dictionary Riccati-for-Riccati in the one case where every object is closed-form. But before either of those, the equivalence we have just proved raises a practical question it does not answer: if the two pictures are genuinely the same equilibrium, which one should a working analyst reach for, and why? Having shown the charts interchangeable, we now ask what each makes easy — the subject of the next subsection.

9.3.2 What each picture sees better

The dictionary just proved settles a question of principle: the field picture (u, m) of chapter 8 and the path picture (X, Y, Z) of this chapter are not two theories of the equilibrium but two coordinate systems on one. Yet an equivalence of content is not an equivalence of convenience, and the moment the two charts are known to describe the same object a practical question presses forward that the equivalence theorem itself does not answer: faced with a concrete task — proving a regularity estimate, establishing the particle limit, writing a solver — which chart should the working analyst open, and why? The honest answer is that it depends entirely on the task, because the very feature that makes the translation exact also guarantees that each object of the equilibrium sits in plain view in one chart and in the shadows in the other. This subsection makes the division of labor explicit, not as a matter of taste but as a structural fact about which questions become *easy* in which chart, so that the chapters ahead can reach for the right one deliberately rather than by habit. The single tension that has organized the whole chapter — forward data pinned at $t = 0$, backward data pinned at $t = T$ — is what the choice ultimately turns on: each picture makes one end of that tension transparent and pays for it by obscuring the other.

Begin with the field picture, because its strengths are the ones the reader has already met. The unknowns there are honest functions on $[0, T] \times \mathbb{R}^d$, and functions on a fixed domain are exactly what the machinery of partial differential equations was built to control. This is not a vague slogan; it is the reason three specific and otherwise hard-won kinds of information are nearly free in the analytic chart. The first is *regularity.* Parabolic Schauder and energy estimates — the statements that a solution of the HJB or Fokker–Planck equation is as smooth as its data and its coefficients permit, with quantitative Hölder or Sobolev bounds — are theorems about fields, proved by differentiating the equation and testing it against itself on the state domain. They have no direct pathwise meaning: a single trajectory X_t is nowhere differentiable in t, so "the solution is $C^{2,\alpha}$ in x" is a sentence the path picture cannot even pronounce without first reconstructing the field $u(t, x) = u(t, \cdot)$ off the trajectory. When one needs to know that the value function is twice differentiable — which is, not incidentally, exactly the hypothesis under which the dictionary $Y_t = \nabla u(t, X_t)$ of section 9.3 was established — one proves it on the field and then transports the conclusion to the path, never the reverse. The second is the *maximum principle*: the assertion that a sub/supersolution of a parabolic equation attains its extremes on the parabolic boundary, from which comparison, uniqueness, and a priori sup-norm bounds all flow. It is a pointwise statement about a field touching a barrier from one side, geometrically vivid on the function $u(t, x)$ and with no clean counterpart in a description that has dissolved the field into a bundle of paths. The third is the *variational and potential structure* that appears when the Hamiltonian is separable: in that case the MFG system is the optimality condition of a single convex functional on the space of flows, and the whole equilibrium can be read as a minimizer. That reading lives entirely on the fields — it is a statement about a functional of (u, m) — and it is the seam through which numerical optimization and Γ-convergence arguments enter.

These three are not an arbitrary catalogue; they converge on the one place the book most needs the field picture, which is *monotonicity*. The Lasry–Lions monotonicity condition that drives the uniqueness theory of chapter 11 is the statement that the coupling $\int (f(t,x,m) - f(t,x,m'))\,(m - m')(\mathrm{d}x) \geq 0$ has a definite sign — a pairing of two *measures* tested against the difference of two *fields*. Its entire force is extracted by integrating the difference of two copies of the HJB/Fokker–Planck system against each other over state space and watching the cross terms cancel by the divergence theorem, leaving a signed quantity. Every ingredient of that computation — the integration by parts, the cancellation, the resulting energy identity — is a manipulation of fields on $\mathbb{R}^d$, and attempting it on trajectories would mean reconstructing precisely the densities and gradients the field picture hands over for free. This is why chapter 11 is written almost entirely in the analytic chart: monotonicity is a field phenomenon, and the path picture would only get in its way. The same loyalty governs computation. Finite-difference and semi-Lagrangian schemes (chapter 28) discretize the HJB and Fokker–Planck equations directly, placing the unknowns (u,m) on a grid over state space and stepping the coupled system in time; they inherit, grid-cell by grid-cell, exactly the monotonicity and comparison structure just described, which is what makes them provably convergent. For low-dimensional state spaces these grid methods are the gold standard, and they are native to the fields. The price of all this, and it is the price the rest of the subsection is about, is that the field chart makes the *forward* end of the equilibrium — the actual law of the actual paths — into a derived quantity, recovered only by solving a second PDE, and says nothing at all about individual trajectories.

Turn now to the path picture, whose strengths are the exact complement: it makes the *trajectories* primitive and pays by relegating the fields to derived objects. The reason this matters is that several of the book's most important destinations are, at bottom, statements about paths that the field chart cannot phrase. The cleanest is the *particle limit* of chapter 13. A mean field equilibrium is the $N \to \infty$ limit of N-player Nash play, and the precise form of that convergence — propagation of chaos — is the assertion that each player's optimal trajectory $X_t^{i,N}$ can be coupled, on the *same* probability space, to an independent copy of the limiting McKean–Vlasov process X_t built in section 9.2, so that $\mathbb{E}\sup_t |X_t^{i,N} - X_t|^2 \to 0$. This is a statement about two processes being close *pathwise*; it lives or dies on a coupling of trajectories, and a pair of densities on $\mathbb{R}^d$ cannot so much as state it, because two laws being close says nothing about whether the underlying paths can be realized near one another. The FBSDE, carrying the trajectory as its forward unknown, is the only chart in which the coupling estimate can even be written, and the moment bound $\mathbb{E}[\sup_t |X_t|^2] < \infty$ that has underwritten every estimate of this chapter is precisely the currency in which that limit is controlled. The path picture is not a convenience here; it is a precondition.

The second destination is *degenerate or vanishing diffusion.* The dictionary $Y_t = \nabla u(t, X_t)$ was proved under enough regularity for u to be twice differentiable, but that regularity is a luxury the field chart cannot always afford. When the volatility σ degenerates — loses rank in some directions, or shrinks toward zero in a vanishing-viscosity limit — the HJB equation loses its parabolicity and may possess no classical solution, and the Fokker–Planck equation may propagate a singular measure with no density at all. At that point the field picture has no objects to manipulate: $u(t,x)$ exists only as a viscosity solution, m_t only as a measure, and the smooth manipulations of the analytic chart stall. The path picture, by contrast, never required a density or a smooth field. The controlled process X_t and its law $\mathrm{Law}(X_t)$ remain perfectly well defined as soon as the coefficients are Lipschitz, entirely independent of whether σ is nondegenerate, and the FBSDE continues to encode the equilibrium when the PDE system has ceased to make classical sense. This robustness is structural, not incidental: the probabilistic objects are built from the trajectory outward and never pass through the field, so they survive exactly the degeneracies that destroy the field.

The third destination is *simulation in high dimension*, and it is the computational mirror image of the field chart's grid methods. The finite-difference schemes praised above discretize state space, and their cost grows like the number of grid points, which is exponential in the state dimension d — the curse of dimensionality, fatal beyond a handful of dimensions. Forward–backward Monte Carlo solvers (chapter 28) escape it by discretizing *paths* instead of grids: they simulate the forward state X_t by an Euler scheme and solve the backward (Y, Z) by regression or a deep-network parametrization along the simulated trajectories, with a cost that scales with the number of sample paths rather than the volume of a grid. These schemes are statements about the FBSDE in its own native terms — they integrate the very forward–backward system this chapter constructed — and they reach dimensions where no finite-difference grid can follow. Here the two-end tension of the equilibrium reappears as the central numerical difficulty: the forward simulation needs an initial condition the backward equation has not yet supplied, and it is exactly the decoupling field of the next section that the better schemes approximate to break the deadlock.

The fourth and furthest destination is the *graphon generalization* of chapter 23, and it is the one that most decisively favors the path picture. There the single representative agent is replaced by a continuum of types $x \in [0, 1]$, each carrying its own state process X_t^x, and the mean field coupling is replaced by an operator coupling through the graphon: agent x feels not the global law but the kernel-weighted aggregate $(\mathbb{W}\, m)(x) = \int_0^1 W(x, x')\, m^{x'}\, \mathrm{d}x'$ of its neighbors' laws. In the field chart this would demand a *family* of HJB/Fokker–Planck pairs indexed by a continuum, coupled through $\mathbb{W}$ — an object that is awkward even to write down and worse to estimate. In the path chart the generalization is almost transparent: one simply lets the state become the type-indexed family of processes $(X_t^x)_{x\in[0,1]}$ and replaces the self-consistent law $\mathrm{Law}(X_t)$ feeding back into the dynamics by its graphon average $\mathbb{W}\ \mathrm{Law}(X_t^{\cdot})$, leaving the entire forward–backward architecture of this chapter structurally intact. The McKean–Vlasov closure becomes a graphon closure; the adjoint, the Hamiltonian, and the fixed-point reading all survive the substitution with only the coupling relabelled. That the probabilistic formulation absorbs the graphon with so little friction, while the analytic one strains, is the clearest single piece of evidence that the path picture is the right vehicle for Part III, and it is the reason this chapter was placed where it is in the arc of the book.

The balance sheet is therefore clean and worth stating in one breath. The field picture owns regularity, comparison, monotonicity, and low-dimensional grids — everything that flows from having honest functions on a fixed state space, and everything chapter 11 and the finite-difference half of chapter 28 will lean on. The path picture owns the particle limit, robustness under degeneracy, high-dimensional Monte Carlo, and the graphon extension — everything that flows from carrying the trajectory itself, and everything chapter 13, chapter 23, and the simulation half of chapter 28 will lean on. Neither is more fundamental; the dictionary guarantees that anything provable in one is true in the other, but not that it is equally *visible*. The rest of Part II, and the graphon chapters beyond it, are built on the probabilistic machinery assembled here precisely because their questions are path questions, and it is worth the reader's carrying forward the habit of asking, before opening either chart, which end of the equilibrium the task lives on.

That question — which end — returns us to the structural tension the chapter opened with and has never resolved: the forward state X is pinned by its initial law at $t = 0$, the backward adjoint (Y, Z) by its terminal gradient at $t = T$, and every translation between the charts has carried this two-point coupling along untouched rather than dissolved it. The field picture hides the tension by never forming the trajectory; the path picture wears it on its sleeve, as the boundary-value structure of the FBSDE itself. Confronting it head-on is the business of the next section. The device that resolves it lives on the FBSDE side — it is the path picture's own answer to its own difficulty — and it is nothing other than the boxed identity $Y_t = \nabla u(t, X_t)$ read in a new way: hold t and x fixed instead of riding the trajectory, and the pathwise relation becomes a deterministic function expressing the backward unknown as a function of the forward one. That function is the *decoupling field*, and it collapses the two-point boundary problem into a single Markovian forward equation. We take it up now.

9.4 Decoupling fields and the road to the master equation

That function — the device the previous section named to resolve the FBSDE's two-point tension, the forward unknown X pinned at $t = 0$ against the backward unknown (Y, Z) pinned at $t = T$, and the object that turns out to be the seed of the master equation of chapter 12 — is the *decoupling field*: a deterministic map expressing the backward unknown through the forward one. We define it, exhibit the collapse it induces, and identify it with the value gradient.

Definition 9.13 (Decoupling field)**.** Consider the FBSDE eq. (9.13) with the population flow $m = (m_t)$ held fixed at an equilibrium (so the system is now a standard, non-McKean–Vlasov FBSDE). A measurable function $U : [0, T] \times \mathbb{R}^d \to \mathbb{R}^d$ is a *decoupling field* for this FBSDE if the unique solution satisfies

$$Y_t \;=\; U(t, X_t) \qquad \text{for all } t \in [0, T],\ \mathbb{P}\text{-a.s.} \tag{9.17}$$

When U is differentiable in x, the second adjoint component is $Z_t = \partial_x U(t, X_t)\, \sigma(t, X_t)$, with $\partial_x U \in \mathbb{R}^{d\times d}$ the Jacobian of U (so $Z_t \in \mathbb{R}^{d\times k}$, consistent with definition 9.3).

The decoupling field, when it exists, collapses the two-point boundary structure into a single forward equation: substituting eq. (9.17) into the forward dynamics of eq. (9.13) makes X a self-contained (Markov) diffusion with drift $b(t, x, m_t, \hat{\alpha}(t, x, m_t, U(t, x), \partial_x U\, \sigma))$, and the backward equation is then solved *automatically* by $Y_t = U(t, X_t)$. Comparing with the dictionary eq. (9.16), the decoupling field of the MFG FBSDE is exactly the gradient of the HJB value function,

$$U(t, x) \;=\; \nabla u(t, x). \tag{9.18}$$

This is the precise sense in which "solving the FBSDE" and "solving the HJB equation" are the same act: the decoupling field is the value gradient, and the Markovian forward equation it produces is the optimally controlled state SDE whose law solves Fokker–Planck.

Theorem 9.14 (Existence of the decoupling field)**.** *Grant **(A-Lip)**, **(A-Growth)**, **(A-Nondeg)**, **(A-Conv)**, with the equilibrium flow m fixed. Then there is a horizon $T_0 > 0$ such that for $T \le T_0$ the decoupled FBSDE eq.* (9.13) *has a unique Lipschitz decoupling field U, given by eq.* (9.18)*; under **(A-Mon)** the field exists and is Lipschitz for every T. The map $(t, x) \mapsto U(t, x)$ is the classical or viscosity gradient of the HJB solution, and eq.* (9.17) *holds.*

Proof sketch. For small T this is the four-step scheme / contraction argument of Ma–Protter–Yong and Delarue: one posits the relation $Y_t = U(t, X_t)$, derives by Itô a quasilinear parabolic PDE for U (a system, with the HJB equation eq. (9.15) as the potential whose gradient is U), and solves it by contraction in a space of Lipschitz fields, the horizon bound controlling the contraction constant. The nondegeneracy **(A-Nondeg)** supplies the parabolic smoothing that makes U Lipschitz; under **(A-Mon)** an a priori gradient bound replaces the small-horizon restriction and the field extends to all T, exactly as in theorem 9.10(ii). The identification $U = \nabla u$ is proposition 9.12. The in-book home of the full argument is the existence theory of the neighbouring chapters: the small-horizon contraction is carried out in chapter 10, the monotone a priori gradient bound that extends the field to every horizon in chapter 11, and the measure-dependent (master-field) version in chapter 12; this theorem records the result and the mechanism, and the construction itself is owned there. The Ma–Protter–Yong four-step scheme and the Delarue contraction are the original sources [40] (Vol. I, Ch. 4), with the master-equation construction in [37]; the global-in-T degenerate case is delicate and we do not claim it here. □

9.4.1 From decoupling field to master field

So far the decoupling field $U(t, x)$ was built with the equilibrium flow m *frozen.* The deeper object — and the subject of chapter 12 — is obtained by letting the field depend on the population state itself. Suppose that for every initial population $m \in \mathcal{P}_2(\mathbb{R}^d)$ (started at the current time t) the MFG has a unique equilibrium, and define the *master field*

$$\mathcal{V}(t, x, m) \;=\; u^{(t,m)}(t, x), \tag{9.19}$$

the equilibrium value at state x when the population, currently distributed as m, evolves forward in its own equilibrium from time t. Its x-gradient $\mathcal{U}(t, x, m) = \nabla_x \mathcal{V}(t, x, m)$ is the *measure-dependent decoupling field*: along the equilibrium it satisfies

$$Y_t \;=\; \mathcal{U}(t, X_t, m_t) \;=\; \nabla_x \mathcal{V}(t, X_t, m_t), \tag{9.20}$$

which upgrades the frozen-flow relation eq. (9.17) by making the dependence on the population explicit. The function $\mathcal{V}$ is no longer a function on $[0, T] \times \mathbb{R}^d$ but on $[0, T] \times \mathbb{R}^d \times \mathcal{P}_2(\mathbb{R}^d)$; differentiating the consistency relation eq. (9.20) along the equilibrium dynamics, using the Lions derivative ∂_μ of chapter 4 for the measure argument, produces a single equation for $\mathcal{V}$ — the *master equation* — that subsumes the entire forward–backward system into one Hamilton–Jacobi equation on the space of measures. That derivation, its well-posedness in the monotone regime, and its role as the generating object from which both the FBSDE and the PDE system descend by the method of characteristics, are the content of chapter 12. We have arrived exactly at its doorstep: the master field is the decoupling field with the population promoted from a frozen parameter to a genuine argument.

Remark 9.15. The promotion in eq. (9.19)–eq. (9.20) is the structural reason the master equation restores the Markov property at the level of the population. The frozen-flow decoupling field $U(t,x)$ knows only the current agent state; the master field $\mathcal{U}(t,x,m)$ knows the current agent state *and* the current population, which is the full state of the mean field system. This is the minimal enrichment that turns the forward–backward, non-Markov-in-m MFG into a forward, Markov-in-(x,m) flow — and it is indispensable once a common noise shocks the population (chapter 26), since then m_t is itself random and only the master field tracks it.

9.5 Worked computation: the LQG thread as an FBSDE

We now carry Thread A (the linear–quadratic–Gaussian mean field game, fixed in the project thread specification) through the probabilistic formulation, and check that it reproduces the analytic closed form of chapters 8 and 14. This is the FBSDE incarnation of the same equilibrium; every Riccati coefficient that appears matches the one obtained from the HJB equation, as the dictionary eq. (9.16) demands.

Worked computation 9.16 (Thread A: the scalar LQG MFG in FBSDE form)**.** Recall the scalar Thread A model: state, for the representative agent,

$$\mathrm{d}X_t = \big(aX_t + b\,\alpha_t\big)\,\mathrm{d}t + \sigma\,\mathrm{d}W_t, \qquad X_0 \sim m_0,$$

and cost over $[0,T]$, against the population mean $\bar{m}_t = \int \xi\, m_t(\mathrm{d}\xi) = \mathbb{E}[X_t]$,

$$J(\alpha) = \mathbb{E}\left[\int_0^T \Big(\tfrac{1}{2}\alpha_t^2 + \tfrac{q}{2}\big(X_t - s\,\bar{m}_t\big)^2\Big)\,\mathrm{d}t + \tfrac{q_T}{2}\big(X_T - s_T\,\bar{m}_T\big)^2\right],$$

with $a, b, \sigma \in \mathbb{R}$, $q, q_T \geq 0$, and coupling strengths s, s_T. The diffusion is constant (hence **(A-Nondeg)** for $\sigma \neq 0$) and the data are convex, so the sufficient maximum principle theorem 9.5 applies.

Hamiltonian and feedback. With costate y the generalized Hamiltonian eq. (9.3) is

$$\mathcal{H}(t,x,y,z,\alpha) = (ax + b\alpha)\,y + \sigma\,z + \tfrac{1}{2}\alpha^2 + \tfrac{q}{2}(x - s\bar{m}_t)^2,$$

minimized over α at $\partial_\alpha \mathcal{H} = by + \alpha = 0$, i.e.

$$\hat{\alpha}(t,x,y) = -b\,y. \tag{9.21}$$

The optimal feedback is *linear in the costate* — the probabilistic signature of a quadratic value function.

The MFG FBSDE. Substituting eq. (9.21) and the state derivative $\partial_x \mathcal{H} = ay + q(x - s\bar{m}_t)$ into eq. (9.13) gives the scalar McKean–Vlasov FBSDE

$$\begin{cases} \mathrm{d}X_t = \big(aX_t - b^2 Y_t\big)\,\mathrm{d}t + \sigma\,\mathrm{d}W_t, & X_0 \sim m_0, \\ \mathrm{d}Y_t = -\big(aY_t + q(X_t - s\bar{m}_t)\big)\,\mathrm{d}t + Z_t\,\mathrm{d}W_t, & Y_T = q_T\big(X_T - s_T\bar{m}_T\big), \\ \bar{m}_t = \mathbb{E}[X_t]. \end{cases} \tag{9.22}$$

Affine decoupling ansatz. Because the system is linear and the coupling enters only through the deterministic mean $\bar{m}_t$, we posit the affine decoupling field

$$Y_t = P_t\,X_t + r_t, \tag{9.23}$$

with deterministic P_t, r_t. Applying Itô to eq. (9.23) along the forward dynamics and matching with the backward dynamics of eq. (9.22) term by term: the martingale parts give $Z_t = P_t\sigma$, the coefficient of X_t gives the scalar Riccati equation

$$\dot{P}_t = b^2 P_t^2 - 2aP_t - q, \qquad P_T = q_T, \tag{9.24}$$

and the constant term gives the linear offset equation

$$\dot{r}_t = (b^2 P_t - a)r_t + q\,s\,\bar{m}_t, \qquad r_T = -q_T\,s_T\,\bar{m}_T. \tag{9.25}$$

Equation eq. (9.24) is *identical* to the Riccati equation for the curvature of the HJB value function in chapters 6 and 14: indeed, by the dictionary eq. (9.16), $Y_t = \partial_x u(t, X_t)$ with $u(t,x) = \frac{1}{2}P_t x^2 + r_t x + (\text{const})$, so P_t is exactly the value's second derivative and $Z_t = \sigma\,\partial_{xx}u = \sigma\,P_t$ matches the second line of eq. (9.16). The probabilistic and analytic pictures share one Riccati equation.

Closing the fixed point. Taking expectations of the forward equation in eq. (9.22) and using eq. (9.23) with $\mathbb{E}[Y_t] = P_t\bar{m}_t + r_t$ yields the mean evolution

$$\dot{\bar{m}}_t = (a - b^2 P_t)\bar{m}_t - b^2 r_t, \qquad \bar{m}_0 = \int \xi\, m_0(\mathrm{d}\xi). \tag{9.26}$$

Equations eq. (9.25) and eq. (9.26) form a *linear forward–backward two-point boundary value problem* in $(\bar{m}_t, r_t)$ — the deterministic shadow of the FBSDE, with $\bar{m}$ pinned at $t = 0$ and r at $t = T$. This is exactly the deterministic forward–backward system whose existence and uniqueness the LQG companion of chapter 10 analyzes; the curvature Riccati P_t, the offset r_t, and the mean $\bar{m}_t$ here are the same objects, in the same canonical symbols, that the explicit LQG fixed point of chapters 10 and 14 produces from the HJB/Fokker–Planck side. It is itself solved by a second decoupling: since the system is homogeneous and the terminal datum $r_T = -q_T s_T \bar{m}_T$ is proportional to $\bar{m}_T$, the ansatz $r_t = \pi_t\bar{m}_t$ reduces it to a second scalar Riccati,

$$\dot{\pi}_t = b^2\pi_t^2 - 2(a - b^2 P_t)\pi_t + q\,s, \qquad \pi_T = -q_T\,s_T, \tag{9.27}$$

after which the mean closes into a single linear ODE

$$\dot{\bar{m}}_t = (a - b^2 P_t - b^2\pi_t)\bar{m}_t, \qquad \bar{m}_0 \text{ given}, \tag{9.28}$$

solved in closed form by an exponential of the time integral of its coefficient. The full equilibrium is thus $(P_t, \pi_t, \bar{m}_t)$ from eq. (9.24), eq. (9.27), eq. (9.28), with $r_t = \pi_t \bar{m}_t$ and the feedback $\hat{\alpha}_t = -b(P_t X_t + \pi_t \bar{m}_t)$.

Consistency and the Gaussian law. With this linear feedback the forward equation is an Ornstein–Uhlenbeck process with Gaussian initial law, so X_t is Gaussian for all t and $m_t = \mathrm{Law}(X_t)$ is the Gaussian $\mathcal{N}(\bar{m}_t, v_t)$ whose variance v_t solves the linear (Lyapunov) ODE $\dot{v}_t = 2(a - b^2 P_t)v_t + \sigma^2$, $v_0 = \mathrm{Var}(m_0)$ — decoupled from the mean, as it must be, since the cost couples only to $\bar{m}_t$. This reproduces, from the probabilistic side, exactly the closed-form LQG equilibrium that chapter 14 obtains analytically; the carried thread is consistent across the two pictures, Riccati for Riccati. The sign regime in which eq. (9.27) admits a global solution (no finite-time blow-up of π_t) is the uniqueness regime; its boundary, where multiplicity sets in, is the phase diagram analyzed in chapters 11 and 14.

Rigor ledger

Proved (in this chapter).

- The stochastic maximum principle for the representative agent against a frozen population: a full proof of necessity by the convex-variation/adjoint-duality argument (theorem 9.4) and a full proof of sufficiency under convexity (theorem 9.5), with the adjoint BSDE eq. (9.5) and the generalized Hamiltonian eq. (9.3).
- The FBSDE–PDE dictionary proposition 9.12: $Y_t = \nabla u(t, X_t)$, $Z_t = \mathrm{D}^2\, u(t, X_t)\, \sigma(t, X_t)$ (valued in $\mathbb{R}^{d\times k}$), with the reconciliation of the Pontryagin and HJB Hamiltonians (remark 9.11).
- The identification of the frozen-flow decoupling field with the value gradient, $U = \nabla u$ (eq. (9.18)), and the promotion to the measure-dependent master field (eq. (9.19)–eq. (9.20)).
- The complete LQG thread in FBSDE form (worked computation 9.16), with its two Riccati equations and closed-form mean, shown to share the Riccati curvature P_t with the analytic solution of chapters 8 and 14.

Assumed (named standing hypotheses).

- **(A-Lip)**, **(A-Growth)** for SDE/BSDE well-posedness and Lipschitz feedback; **(A-Conv)** for the existence and Lipschitz regularity of the Hamiltonian minimizer and for sufficiency of the maximum principle; **(A-Nondeg)** for parabolic smoothing of the decoupling field; **(A-Mon)** for global-in-T well-posedness and uniqueness.
- Uncontrolled diffusion $\sigma = \sigma(t, x, m)$ throughout (controlled diffusion deferred, remark 9.7).

Deferred (with pointers).

- Existence/uniqueness of the MFG FBSDE: stated as theorem 9.10 in three regimes; the Schauder/compactness proof is chapter 10, the monotone continuation proof and the pairing identity are chapter 11; primary source [40].
- Existence and Lipschitz regularity of the decoupling field (theorem 9.14): the small-horizon contraction is owned by chapter 10, the monotone a priori gradient bound extending it to every horizon by chapter 11, and the measure-dependent (master-field) version by chapter 12; the global-in-T degenerate case is not claimed here. Primary sources [40, 37].
- The master equation derived from the master field eq. (9.20): chapter 12.
- BSDE theory — the Pardoux–Peng existence/uniqueness theorem (theorem C.18) and the martingale representation theorem (theorem C.17) — is proved in full in the stochastic-calculus reference appendix C.

Open / honestly flagged.

- Controlled-diffusion MFG requires the second-order adjoint and is not treated here; general well-posedness there remains partial.
- Uniqueness outside the monotone or small-horizon regimes is genuinely open in general; theorem 9.10(iii) gives existence only, and the LQG thread (worked computation 9.16) shows multiplicity is a real possibility once eq. (9.27) loses its global solution.

Bibliographic notes

The probabilistic approach to mean field games via forward–backward stochastic differential equations is due to Carmona and Delarue, and the canonical reference for every result of this chapter is their two-volume monograph [40, 41]; Volume I, Chapters 1–4, contains the stochastic maximum principle for mean field control and games, the McKean–Vlasov FBSDE, the small-time and monotone well-posedness theorems, and the decoupling-field analysis, all in greater generality (controlled diffusions, common noise) than we have presented. The stochastic Pontryagin principle and the adjoint BSDE rest on the backward SDE theory of Pardoux and Peng, proved in full in appendix C; the decoupling-field (four-step / continuation) method for FBSDEs originates with Ma, Protter and Yong and with Delarue, and is exposited in [40]. The equivalence of the probabilistic and analytic formulations, and the identification of the costate with the gradient of the value function, is the FBSDE counterpart of the Lasry–Lions PDE system [93] treated analytically in chapter 8 following [36]; the Nash-certainty-equivalence origin of the same fixed point is [82]. The master field and the passage from the decoupling field to the master equation, sketched at the end of this chapter, are developed rigorously in [37] and in chapter 12. The LQG worked computation follows the explicit linear–quadratic theory that chapter 14 treats as the capstone of Part II; its probabilistic form, with the two Riccati equations, is standard and appears in [40] (Vol. I, Ch. 3) and the references therein. The graphon generalization of the FBSDE formulation, in which the representative agent becomes a continuum-indexed family coupled through the operator $\mathbb{W}$, is the subject of chapter 23.

Chapter 10

Existence of Mean Field Game Equilibria

The two preceding chapters built the mean field game (MFG) system in its two complementary pictures: the analytic, partial-differential picture of a backward Hamilton–Jacobi–Bellman (HJB) equation coupled to a forward Fokker–Planck (FP) equation (chapter 8), and the probabilistic, path-space picture of a forward–backward stochastic differential equation of McKean–Vlasov type (chapter 9). Each of those chapters wrote down, with care, what an equilibrium *is*: a population profile together with the optimal response to it that reproduces that very profile. What neither chapter did — and neither could, with the tools it carried — is take the next step and assert that such a profile can in fact be found. That step is the entire business of the present chapter, and it is worth pausing to see that it is a genuinely different kind of statement. To write the equations an object must satisfy is to *describe* the object; to assert that those equations have a solution is to claim the object *exists*, and the second claim does not follow from the first. One can write perfectly sensible equations that nothing satisfies — a polynomial with no real root, an ordinary differential equation whose solution escapes to infinity before the horizon is reached, a self-consistency relation with no self-consistent value. The coupled HJB–FP system of chapter 8 and the McKean–Vlasov FBSDE of chapter 9 are descriptions of exactly this kind: exact, but silent on whether anything answers to them. Supplying the missing existential quantifier — *there exists* a flow of measures that is its own best response — is the one task of this chapter.

We supply it the way one always must when no formula for the solution is on offer: not by constructing the equilibrium, but by recasting the equilibrium condition as a fixed point of a single map — the *best-response map* — and proving abstractly that the map has a fixed point. The instruments are the ones Part I assembled for exactly this purpose: the topological fixed-point theorems of chapter 2 (Schauder for single-valued maps, Kakutani–Fan–Glicksberg for set-valued ones), the compactness machinery of weak convergence and tightness from chapter 3, and the Wasserstein geometry of chapter 4, which turns the space of population profiles into a metric space on which those theorems can act. A topological fixed-point theorem is a deliberately modest instrument: it never tells us *which* profile is the equilibrium, never produces a formula, and says nothing about uniqueness. It certifies only that the set of equilibria is nonempty. That certificate is precisely, and only, what we are after; uniqueness is a separate question, deferred in full to chapter 11.

The architecture of the argument is one every physicist already owns under another name: it is the self-consistent field. Posit a field — here a candidate population profile m. Solve the one-body problem in that field: compute how a single representative agent, facing the frozen population m, optimally responds. Now let the entire ensemble respond in the identical way, since the agents are interchangeable, and read off the new profile that this collective response generates. Equilibrium is the demand that the profile read off at the end equal the profile posited at the start. This is the Curie–Weiss loop — guess a magnetisation, compute the molecular field it produces, solve the single-spin problem in that field, read off the average magnetisation, and require it to match the guess — transplanted from a static thermal average to a dynamic optimisation over an entire trajectory. The spine of the whole chapter is this loop, made into a map $m \mapsto \mathsf{S}(m)$ whose fixed points are the equilibria.

Everything subtle is concentrated in the single word *equals*. Asking two numbers to be equal is trivial; asking two elements of an infinite-dimensional space of measure-valued trajectories to be equal, when the map relating them is nonlinear and — this is the crux — in general *not* a contraction, is not. Were S a contraction, the self-consistent-field iteration $m^{(0)}$, $m^{(1)} = \mathsf{S}(m^{(0)}), \ldots$ would converge to a unique field and there would be nothing to prove beyond Banach's theorem; but generic MFGs admit no such contraction, the iteration may wander, and the field may have several self-consistent values. When contraction fails, the only remaining lever is *compactness*: one shows that the iteration cannot escape some compact set of profiles, so that the orbit must accumulate somewhere, and one arranges that an accumulation point is forced to be fixed. Compactness in a space of measures is never free — it must be manufactured — and the single structural hypothesis that manufactures it is the nondegeneracy of the diffusion, (A-Nondeg). *This is the hero of the chapter, and the reader should watch for it.* Here is its first entrance: the parabolic smoothing that a nondegenerate diffusion provides is exactly what converts a merely bounded, merely measurable optimal response into a *precompact* family of responses — one that Arzelà–Ascoli and Prokhorov can trap in a compact set (section 10.2).

That same hypothesis is then asked to do a second, independent job, and the reader should watch for it a second time. Trapping the orbit in a compact set delivers an accumulation point; but to conclude that the accumulation point is a *fixed* point one needs the map S to be *continuous*, so that the limit may be passed through it. Continuity of the best-response map is again a parabolic-regularity statement — it rests on the continuous dependence of the HJB solution on its frozen data, which is false without ellipticity — and so (A-Nondeg) returns, in section 10.3, to supply it. The hypothesis thus earns its billing twice over: once to make the arena compact, once to make the map continuous on it. Strip it away and both halves of the Schauder argument collapse at a single stroke; this is also why the LQG thread, whose diffusion is nondegenerate but whose *data* are unbounded, will need separate handling rather than falling out as a corollary.

With the strategy fixed, the chapter proceeds in four movements, each buying a piece of the argument at a stated price. Section 10.1 (this section) fixes the state space of candidate equilibria — flows of probability measures — and defines the best-response map precisely; its cost is a deliberate choice of topology, the order-one Wasserstein distance in place of the order-two distance natural in chapter 9, and its purchase is a sharply posed fixed-point question together with the single/set-valued dichotomy that organises everything after. Section 10.2 produces the convex compact set on which the map will be shown to act, from the moment and equicontinuity estimates that a bounded optimal feedback buys, with tightness (chapter 3) as the engine; its cost is an a priori bound on the feedback — exactly what fails for unbounded LQG data — and its purchase is the arena Schauder requires. Section 10.3 proves the map continuous, the one place where parabolic regularity (A-Nondeg) is genuinely indispensable, and assembles the Schauder existence theorem; its cost is the restriction to bounded, regularising couplings, and its purchase is existence *with no monotonicity assumed* and hence — honestly — no uniqueness claimed. Section 10.4 treats the harder case in which the optimal feedback is not unique: we relax controls to randomised ones, pass to a set-valued best response, invoke the Kakutani–Fan–Glicksberg theorem, and recover a genuine feedback by measurable selection; its cost is passage to weak equilibria carried on laws rather than flows, and its purchase is existence under dramatically weaker hypotheses. Throughout, uniqueness is *not* our concern — it is the subject of chapter 11 and rests on the Lasry–Lions monotonicity condition (A-Mon); here a game may well have many equilibria, and our theorems guarantee only that their set is nonempty. Section 10.5 closes the chapter by returning to the linear–quadratic–Gaussian (LQG) thread (Thread A): it shows that the thread *violates* the abstract theorem's hypotheses — its data are unbounded, so the compactness construction does not apply — yet collapses to a finite-dimensional linear two-point problem with a sharper existence-and-uniqueness statement, confirming that the explicit Gaussian flow built earlier is indeed *an* equilibrium and, at short horizon, the unique one. This is a deliberate counterpoint: the abstract theorem is not the last word, and the place it fails to reach is the very place where the multiplicity and symmetry-breaking story of chapter 11 and chapter 14 will begin.

Throughout this chapter no graphon is present, so we follow the Part I–II convention of appendix A and write Brownian motion as W_t.

10.1 Equilibrium as a fixed point

Turning the self-consistency loop into a fixed-point question takes four steps, and the four subsections below are precisely those steps, in the order any fixed-point argument needs them: the objects, the space they inhabit, the map, and the structure of the map. We first recall — not redefine — the data of the game and the coupled backward-HJB / forward-FP system that the analytic picture of chapter 8 hands us, since that system is the substrate on which the map is built and the place where the two pictures of chapters 8 and 9 are seen to describe one and the same equilibrium. We then choose the space in which candidate equilibria are sought — a space of measure-valued trajectories — and explain why its topology is the one metrised by the order-one Wasserstein distance rather than the order-two distance natural to the L^2 estimates of chapter 9. With the data and the arena fixed we define the best-response map S itself, as the two-stage operation *solve the frozen-flow HJB equation, then run the closed-loop dynamics it dictates*, and record that a fixed point of S is exactly an equilibrium. Finally we observe that S is a genuine single-valued map or only a set-valued correspondence according to whether the optimal feedback is unique — a dichotomy that cleaves the rest of the chapter into the Schauder route (sections 10.2 and 10.3) and the Kakutani route (section 10.4). What this section hands forward is therefore a precisely defined map S on the ambient space $\mathcal{M}$, together with the demand — discharged in the next section — for a nonempty convex compact set on which to run it, and, until section 10.4, the standing restriction to the single-valued, strictly convex regime.

10.1.1 The data of the game and the MFG system

The chapter preamble committed to a claim, and this subsection's task is to make it concrete enough to build on. The claim is that the analytic backward-HJB / forward-FP system of chapter 8 and the probabilistic McKean–Vlasov FBSDE of chapter 9 are not two equilibria but two descriptions of one: a single self-consistency condition, viewed in two coordinate systems. To turn that condition into a fixed point we need one concrete substrate on which to erect the best-response map, and of the two pictures the analytic one is the more convenient launching pad — it presents the equilibrium as a pair of coupled equations whose coupling we can literally *freeze*, solve, and re-read. So we begin by recalling, deliberately rather than redefining, the objects that chapters 8 and 9 already own; the reader who has those chapters in hand should find nothing new here except the framing.

The representative agent has state $X_t \in \mathbb{R}^d$ on the horizon $[0, T]$, with controlled dynamics

$$\mathrm{d}X_t \;=\; -\,\partial_p H\big(X_t, \nabla u(t, X_t)\big)\;\mathrm{d}t \;+\; \sigma(X_t)\;\mathrm{d}W_t, \qquad X_0 \sim m_0, \tag{10.1}$$

where $\sigma : \mathbb{R}^d \to \mathbb{R}^{d\times d}$ is the volatility and $H = H(x, p)$ is the Hamiltonian of the control problem. It is worth pausing on why the drift is the particular expression $-\partial_p H$ rather than some free control still to be chosen: the drift in eq. (10.1) is *already optimised*. In the canonical MFG the agent steers its own drift directly, $\mathrm{d}X_t = \alpha_t\;\mathrm{d}t + \sigma(X_t)\;\mathrm{d}W_t$, paying a running cost $L(x, \alpha)$ for the effort, and the Hamiltonian is the Legendre transform of that cost in the control,

$$H(x, p) \;=\; \sup_{\alpha}\big\{-\alpha\cdot p - L(x, \alpha)\big\}.$$

Differentiating under the envelope theorem — only the explicit p-dependence survives, because the α-derivative vanishes at the maximiser — gives $\partial_p H(x, p) = -\alpha^*(x, p)$, so the maximising control is $\alpha^*(x, p) = -\partial_p H(x, p)$. The verification theorem of chapter 6, valid under convexity (A-Conv), certifies that substituting this feedback (evaluated along the value function's gradient $p = \nabla u(t, X_t)$) into the dynamics is genuinely optimal. That substitution is exactly what eq. (10.1) records: the open-loop control has been replaced by the closed-loop optimal-feedback drift $-\partial_p H(\cdot, \nabla u)$, the optimal-feedback map of appendix A. The state equation thus already encodes the agent's best response to whatever value function u it is handed.

What makes this a *game* rather than a lone control problem is that the value function u is not given from outside; it is shaped by the population. The population is described by a *flow of measures* $t \mapsto m_t$ — the time-indexed distribution of agents over state space — and the representative agent's costs are coupled to it in two places. The *running coupling* $F[m]$ records how the instantaneous cost an agent pays at time t depends on where everyone else is then; the *terminal coupling* $G[m]$ records how the cost charged at the horizon depends on the final configuration m_T. We write both with the measure inside square brackets and the spatial argument outside, $F[m](x)$ and $G[m](x)$, a deliberate piece of notation: the brackets signal a *functional*, generally nonlocal, dependence on the entire measure m, while x is the ordinary pointwise evaluation of the resulting function of state. This is the same bracket-outside convention under which the Lasry–Lions pairing is written in the thread specification and in chapter 11, and F, G are precisely the objects whose monotonicity is named (A-Mon) and exploited there for uniqueness — a property we neither assume nor use in the present chapter.

Assembling the optimised dynamics and the population coupling, the MFG system recalled from chapter 8 is the coupled pair

$$-\partial_t u - \tfrac{1}{2}\operatorname{tr}\big(\sigma\sigma^\top \mathrm{D}^2 u\big) + H(x, \nabla u) = F[m_t](x), \qquad u(T, \cdot) = G[m_T](\cdot), \tag{10.2}$$

$$\partial_t m - \tfrac{1}{2}\sum_{i,j} \partial^2_{ij}\big((\sigma\sigma^\top)_{ij}\, m\big) - \operatorname{div}\big(m\, \partial_p H(x, \nabla u)\big) = 0, \qquad m_0 \text{ given.} \tag{10.3}$$

The two equations are mirror images that move in opposite directions in time. As stressed in appendix A and chapter 8, the HJB equation eq. (10.2) is solved *backward*: its data live at the terminal time $t = T$, where $u(T, \cdot) = G[m_T]$, and the value propagates information about the future cost landscape back toward the present, telling each agent how to steer now in anticipation of where the crowd will be later. The Fokker–Planck (continuity) equation eq. (10.3) is solved *forward*: its datum is the initial distribution m_0 at $t = 0$, and it transports the population's density ahead in time under the very drift $-\partial_p H(x, \nabla u)$ that the value function dictates. The data therefore sit at *opposite ends* of the interval $[0, T]$, and the equations are bolted together — m feeds the HJB source and terminal data, u feeds the FP drift — across that whole span. It is this two-point, backward-forward coupling, and not either parabolic equation taken alone, that is the defining structural feature of the game: each equation in isolation is a textbook problem, but the demand that they hold *simultaneously*, with the forward density generating the backward cost that in turn generates the forward density, is precisely the self-consistency that the chapter throughline identifies with a fixed point. The feedback closing the loop is

$$\alpha^*(t, x) \;=\; -\,\partial_p H\big(x, \nabla u(t, x)\big), \tag{10.4}$$

the optimal-feedback map $\alpha^* = -\partial_p H$ of appendix A: a single well-defined function — the unique maximiser — when (A-Conv) holds with *strict* convexity, and a possibly set-valued object when convexity is merely weak. That dichotomy, latent here in the $\arg\max$ behind eq. (10.4), is the fork that organises the whole chapter, sending the strictly convex case down the Schauder route and the degenerate case down the Kakutani route of section 10.4.

Notation watch: Where the measure sits, and the structural restriction it carries

The master convention of appendix A and the systems of chapters 8 and 9 carry the measure *inside* the Hamiltonian, $H = H(x, p, m)$ with a single terminal cost $g(x, m)$. Throughout this chapter we use the equivalent *separable* decomposition that pulls the measure-dependence out into the additive couplings,

$$H(x, p, m) \;=\; H(x, p) \;+\; F[m](x), \qquad g(x, m) \;=\; G[m](x),$$

so that the frozen-flow Hamiltonian $H(x, p)$ is genuinely measure-free and the entire coupling is transparent in F, G. This is not a cosmetic rewriting, and it is worth spelling out so that a reader crossing chapter 9→chapter 10 is not ambushed. In chapter 9 the central object was a Hamiltonian of *three* arguments, $H(x,p,m)$, the population entering on the same footing as state and momentum; here, abruptly, the Hamiltonian appearing in eqs. (10.1) to (10.4) has only *two*, $H(x,p)$. Taken at face value the central object would seem to have silently shed an argument — to have changed arity between two chapters that are supposed to describe the same game — and a careful reader would be right to be alarmed. The reconciliation is mechanical but must be stated. Separability means the measure enters *additively* and through the *state slot only*: the three-argument Hamiltonian of chapters 8 and 9 is recovered as $H_{chapter\ 8}(x,p,m) = H(x,p)+F[m](x)$, with $G[m] := g(\cdot,m)$, the second "missing" argument having been relocated into the explicit source term $F[m]$ of the HJB equation rather than deleted. Because the added piece $F[m](x)$ does not depend on p, the momentum derivative is untouched, $\partial_p H_{chapter\ 8}(x,p,m) = \partial_p H(x,p)$: the optimal-feedback drift eq. (10.4) is exactly the measure-free one, and the population's only influence on an agent's motion is through the additive cost landscape $F[m]$, never through the agent's responsiveness to its own momentum. This is the standard *separable* (non-congestion) setting of analytic MFG and is exactly the class isolated in definition 8.5. What it *excludes* is precisely the case where the crowd modulates the momentum dependence itself — an m-dependent control cost $L(x,\alpha,m)$ that makes manoeuvring more expensive in a dense region, i.e. true congestion — for there $H(x,p,m)$ is genuinely non-additive in m, the drift $\partial_p H(x,p,m)$ feels the population directly, and the clean freeze-and-solve structure below breaks down. Such couplings demand the displacement-monotonicity refinements developed in chapter 11, and we defer them there; all existence statements in the present chapter are for the separable class unless stated otherwise.

The separable structure is not merely a bookkeeping convenience: it is what makes the best-response map definable in the first place. Read eq. (10.2) once more with the population trajectory m held *fixed* inside the couplings. Then the right-hand source $(t,x) \mapsto F[m_t](x)$ and the terminal data $x \mapsto G[m_T](x)$ are simply *given* functions, carrying no live dependence on the unknown u, and the HJB equation *decouples* from the Fokker–Planck equation: it becomes a single backward parabolic problem with prescribed data, of exactly the kind chapters 6 and 8 know how to solve. This frozen-flow viewpoint — freeze m inside F and G, watch the HJB equation detach — is the hinge on which the entire construction turns, and the next two subsections build directly on it: solving the frozen problem and then transporting the resulting law forward is what the best-response map *does*. But before we can speak of freezing a flow and varying it, we must say precisely what kind of object a candidate flow m is, and in what space it lives — with what notion of distance two candidate populations are deemed close. That is the question the next subsection takes up.

10.1.2 The space of candidate equilibria

The previous subsection left us with a recipe we are not yet equipped to execute: freeze the population trajectory m inside the couplings F and G, watch the HJB equation detach into a decoupled backward parabolic problem, solve it, and transport the resulting law forward. To make that recipe into a *map* — something we can iterate, bound, and hand to a fixed-point theorem — we must first pin down what kind of object is being frozen and varied. What, precisely, is a "candidate population trajectory"? In what set does it range? And, the question that turns out to govern everything downstream, with what notion of nearness are two such candidates judged close? This last choice is not a technicality to be settled in passing. The instruments we intend to deploy — Schauder, Kakutani–Fan–Glicksberg — speak entirely in the vocabulary of a topology: compactness, continuity, and convexity are all properties of a set or a map *relative to* a notion of convergence, and a topology chosen too strong will leave our candidate set non-compact, while one chosen too weak will leave the map discontinuous. The present subsection fixes the arena and its metric, and — because the natural-looking choice is the wrong one here — explains at length why we depart from the distance that served chapter 9 so well.

A candidate equilibrium is, before anything else, a population trajectory. We make this the primary unknown.

Definition 10.1 (Flows of measures)**.** For $p \geq 1$, let $\mathcal{P}_p(\mathbb{R}^d)$ carry the Wasserstein distance $\mathcal{W}_p$ of chapter 4. A *flow of measures* is a continuous map $m = (m_t)_{t\in[0,T]} \in C\big([0,T];\mathcal{P}_p(\mathbb{R}^d)\big)$, the latter equipped with the uniform metric

$$\mathsf{d}_p(m, m') \;=\; \sup_{t\in[0,T]} \mathcal{W}_p(m_t, m'_t).$$

We write $\mathcal{M} := C\big([0,T];\mathcal{P}_1(\mathbb{R}^d)\big)$ for the ambient space of the existence argument and reserve the second moment as an a priori bound rather than as part of the topology.

Three features of definition 10.1 deserve to be read slowly, because each is a decision rather than a reflex. First, the unknown is a *trajectory of measures*, not a single measure: an equilibrium of a dynamic game is a whole history $t \mapsto m_t$ of how the crowd is distributed at each instant, and the self-consistency we are chasing must hold at every time simultaneously. Second, we demand the trajectory be *continuous* in time — no instantaneous jumps in the population — and we measure two trajectories by the *uniform* (sup-over-time) distance d_p, the supremum of the instantaneous Wasserstein gaps. The uniform metric is the right one because it makes $C([0,T];\mathcal{P}_p)$ *complete* whenever $\mathcal{P}_p$ is: a d_p-Cauchy sequence of flows is, instant by instant, a $\mathcal{W}_p$-Cauchy sequence of measures with a uniform-in-time modulus, so the pointwise limits exist and inherit continuity, and the limit is again a flow. Completeness is not optional decoration; it is what lets us pass to limits inside the space rather than falling out of it, and every compactness statement below is ultimately a statement about which subsets of this complete space are precompact. Third — and this is the decision the rest of the subsection defends — the ambient space is built on $\mathcal{P}_1$, with $\mathcal{W}_1$ supplying the topology, while the second moment is held back as a separate, quantitative bound that never enters the metric.

That third decision is worth stating as a slogan before we justify it: $\mathcal{W}_1$ *is the topology; the second moment is a leash.* The topology is the weak notion of nearness in which we will demand compactness and continuity; the leash is a strong quantitative estimate — a uniform ceiling on $\int |x|^2\, m_t(\mathrm{d}x)$ — that we carry along to prevent mass from escaping to infinity, but which we deliberately refuse to fold into the definition of "close." The reason for the split is structural and will recur at every step. Compactness in a space of measures is manufactured from a moment bound through tightness and Prokhorov's theorem (chapter 3); a uniform second moment is exactly the lever that buys it. But a moment bound buys *tightness*, which is relative compactness for *weak* convergence, and weak convergence is a weak topology. If we were to insist on a strong metric — one demanding that the leash itself converge — we would be asking for precisely the kind of convergence that tightness does not deliver, and the compactness we worked to obtain would evaporate at the last step. Keeping the moment out of the metric is what lets the leash do its one job (trapping mass) without contaminating the topology in which limits are taken.

The choice of $\mathcal{W}_1$ for that topology is not merely the path of least resistance; it pays off twice, and both payoffs are cashed in the sections that follow. The first payoff is that, on exactly the sets we will work over, $\mathcal{W}_1$-convergence and weak convergence are *the same thing.* On any family of measures with uniformly integrable first moments — in particular any family carrying a uniform bound on a moment of order strictly greater than one, and our second-moment leash is such a bound — $\mathcal{W}_1$ metrises weak convergence (theorem D.11). The practical consequence is decisive: when tightness and Prokhorov hand us a weakly convergent subsequence, that subsequence is *automatically* $\mathcal{W}_1$-convergent, with no further work. Compactness in the metric we actually care about thus comes free the instant we have a moment bound, which is precisely why the moment bound is the only nontrivial input to the compact-set construction of section 10.2. The second payoff is dual in character. By the Kantorovich–Rubinstein representation (theorem D.10), $\mathcal{W}_1(\mu,\nu)$ equals the supremum of $\int f \, \mathrm{d}(\mu-\nu)$ over all 1-Lipschitz test functions f. This is exactly the language the stability estimates of section 10.3 speak. Those estimates control $\mathsf{S}(m)$ by coupling two controlled processes and bounding $\mathbb{E}|X_t^m - X_t^{m'}|$ — a first-moment, 1-Lipschitz-tested quantity — so the metric and the estimate are matched at the source: $\mathcal{W}_1$ is, by duality, the smallest distance the coupling estimate can possibly produce, and no order is wasted converting between them.

Remark 10.2 (Why not $\mathcal{W}_2$, the distance of chapter 9?)**.** A reader fresh from chapter 9 has every right to expect the order-two distance here too. There the FBSDE well-posedness of theorem 9.10 ran a *small-time contraction* of the best-response map in the $\mathcal{W}_2$-sup metric on $C([0,T];\mathcal{P}_2(\mathbb{R}^d))$, and that was the natural choice: the probabilistic estimates were L^2 estimates — Itô isometries, second-moment Grönwall bounds — and $\mathcal{W}_2$, being the L^2 transport cost, is the metric in which an L^2 contraction reads off cleanly. When the engine is contraction, one wants the *strongest* metric in which the map still contracts, because a contraction in a stronger metric is a stronger statement and the completeness needed for Banach's theorem comes for free. The compactness route inverts this preference exactly. Here there is no contraction to exploit; the engine is Prokhorov, and what we need is for our bounded candidate set to be *precompact.* Precompactness is easiest in the *weakest* reasonable metric, and so we want the weaker distance, not the stronger one.

The reason the strong distance actively fails is worth stating in full, since it is the crux of the whole topological choice. On a set of measures bounded only in the second moment, $\mathcal{W}_2$-convergence is strictly stronger than weak convergence: $\mathcal{W}_2(\mu_n,\mu)\to 0$ holds if and only if $\mu_n\to\mu$ weakly *and* the second moments converge, $\int |x|^2 \, \mathrm{d}\mu_n \to \int |x|^2 \, \mathrm{d}\mu$, the latter amounting to the demand that no second-moment mass leak out along the tails — and a uniform *ceiling* on the second moment does nothing to force the second moments to *converge*, since mass can slosh out to large radii while staying under the ceiling. Consequently the weakly convergent subsequences that Prokhorov manufactures from our moment bound need not be $\mathcal{W}_2$-convergent at all: the compactness we can honestly produce is $\mathcal{W}_1$-compactness, never $\mathcal{W}_2$-compactness, on a merely second-moment-bounded set. (To metrise weak convergence by $\mathcal{W}_2$ one would need a uniform bound on a moment of order strictly greater than *two*, a leash we have no a priori means to tighten.) There is a second, independent reason to avoid $\mathcal{W}_2$ even setting compactness aside: $\mathcal{W}_2$-continuity of the best-response map is more than we can cheaply guarantee, since it would require controlling the convergence of second moments of the output law under perturbations of the frozen flow, whereas the 1-Lipschitz coupling estimate delivers $\mathcal{W}_1$-continuity directly and for free. Both halves of the Schauder argument — compactness of the arena and continuity of the map — therefore point the same way, toward the order-one distance.

With definition 10.1 we have fixed the arena. The ambient space is $\mathcal{M} = C([0,T];\mathcal{P}_1(\mathbb{R}^d))$, complete under the uniform order-one metric d_1; the second moment rides along as an a priori leash that will, in section 10.2, be spent on tightness and on equicontinuity in time to carve a convex compact subset out of $\mathcal{M}$. This is exactly the concrete domain and codomain the next subsection needs: it takes the freeze-and-solve recipe of the frozen-flow viewpoint and reads it as an honest self-map of $\mathcal{M}$ — freeze a flow $m \in \mathcal{M}$, solve the decoupled HJB equation it sources, close the loop by transporting m_0 forward under the optimal feedback, and land on a new flow $\mathsf{S}(m) \in \mathcal{M}$ — in the very metric d_1 in which its continuity (section 10.3) and the invariant set's compactness (section 10.2) will be proved.

10.1.3 The best-response map

The previous subsection fixed the arena: the ambient space $\mathcal{M} = C([0,T];\mathcal{P}_1(\mathbb{R}^d))$, complete under the uniform order-one metric d_1, with the second moment carried along as an a priori leash. We now have a domain and a codomain, and a precise notion of when two candidate populations are close. What we do *not* yet have is the object whose fixed points we are after: the map that turns one candidate flow into another. Building that map is the business of this subsection, and it amounts to nothing more than executing, as an honest self-map of $\mathcal{M}$, the freeze-and-solve recipe that the frozen-flow viewpoint of section 10.1 has been promising. The recipe has three movements — freeze, solve, close the loop — and we walk through each in turn, recording at every step why the operation is licensed by results already in hand, so that the map we end with is not a formal stipulation but a genuinely constructed object.

Freeze. Fix a candidate flow $m \in \mathcal{M}$ and substitute it into the coupling terms of eq. (10.2) wherever the population appears. The running source collapses to the *given* function $(t,x) \mapsto F[m_t](x)$ — a prescribed inhomogeneity, no longer carrying any live dependence on the unknown value u — and the terminal data collapses to the given function $x \mapsto G[m_T](x)$. This is exactly the decoupling that separability bought us in section 10.1: because the measure entered F and G additively and through the state slot only, freezing m removes the population from the equation entirely except as known data, and the two-point backward–forward coupling that made the system a *game* is, for the moment, broken.

Solve. What remains is a single equation. The HJB equation eq. (10.2), with its couplings frozen, is now a *decoupled*, semilinear, backward parabolic problem with prescribed source and terminal data — precisely the class chapters 6 and 8 are equipped to handle. Here (A-Nondeg) makes its first working appearance in the construction: nondegeneracy of $\sigma\sigma^\top$ renders the equation *uniformly parabolic*, which is what guarantees a classical $C^{1,2}$ solution rather than a mere viscosity solution, and a classical solution is what we need for the gradient ∇u in the feedback to exist pointwise. The control-theoretic existence and verification theory of chapter 6, valid under the convexity (A-Conv), then returns two things: a value function u^m solving the frozen HJB equation, and — through the optimal-feedback formula eq. (10.4) read off from u^m — an optimal feedback $\alpha^{*,m}(t,x) = -\partial_p H(x, \nabla u^m(t,x))$. The verification theorem is what certifies that this feedback is not merely a formal critical point but genuinely the optimal response of a representative agent who believes the population will follow m.

Close the loop. The agent now *acts* on this optimal feedback, and so does every other agent, since they are interchangeable. Feeding $\alpha^{*,m}$ into the closed-loop dynamics eq. (10.1) gives a well-posed stochastic differential equation with drift $-\partial_p H(x, \nabla u^m)$ — bounded and (under the standing Lipschitz hypotheses) Lipschitz in x, hence admitting a unique strong solution X^m started from $X_0^m \sim m_0$. Equivalently, and this is the analytic face of the same operation, one solves the Fokker–Planck equation eq. (10.3) with that *given* drift and initial datum m_0; with the drift now prescribed, eq. (10.3) is a *linear* continuity equation, no longer coupled to anything. Either way the output is a new flow of measures, the law of the optimally controlled state at each instant. Call it $\mathsf{S}(m)$. The loop has closed: we posited m, the population responded optimally to it, and $\mathsf{S}(m)$ is the profile that response generates.

That this output is again a legitimate element of $\mathcal{M}$ — a continuous flow in $\mathcal{P}_1$ — is not automatic, and it is precisely what the compactness section will verify: the moment bound of lemma 10.6 keeps $\mathsf{S}(m)_t$ in $\mathcal{P}_1$ at every instant, and the time equicontinuity of lemma 10.7 makes $t \mapsto \mathsf{S}(m)_t$ continuous in $\mathcal{W}_1$. For now we take those for granted and record the map.

We have, in effect, re-derived on the analytic side the best-response map already introduced in the path-space picture of eq. (9.14). We re-present it here for the ambient space $\mathcal{M}$ of definition 10.1.

Definition 10.3 (Best-response map and equilibrium)**.** The *best-response map* (or *Nash map*) is the assignment

$$\mathsf{S} : \mathcal{M} \longrightarrow \mathcal{M}, \qquad \mathsf{S}(m) \; = \; \Big(\mathrm{Law}\,(X_t^m) \Big)_{t \in [0,T]},$$

where X^m solves the closed-loop SDE eq. (10.1) with $u = u^m$ the solution of the decoupled HJB equation eq. (10.2) for the frozen flow m, and $X_0^m \sim m_0$. A *mean field game equilibrium* is a flow $m^\star \in \mathcal{M}$ with

$$\mathsf{S}(m^\star) \; = \; m^\star.$$

This is the same object as eq. (9.14); only the topology in which we shall run the fixed point differs. Theorem 9.10(i) ran the *small-time* contraction in the $\mathcal{W}_2$-sup metric on $C([0,T]; \mathcal{P}_2(\mathbb{R}^d))$, the natural home for the L^2 probabilistic estimates there; here, where the engine is compactness rather than contraction, we deliberately work in the weaker $\mathcal{W}_1$-sup metric of definition 10.1 (one always has $\mathcal{W}_1 \le \mathcal{W}_2$, and on sets carrying a uniform bound on a moment of order strictly greater than one — in particular the uniform second-moment bounds in force here — $\mathcal{W}_1$ metrises weak convergence, chapter 4; note that $\mathcal{W}_2$ itself does *not* metrise weak convergence on merely second-moment-bounded sets, which is precisely why the compactness argument needs the weaker distance), and this is what the Kantorovich–Rubinstein duality below will exploit.

A fixed point of S is exactly a solution of the coupled system eq. (10.2)–eq. (10.3): the flow used to compute the value equals the flow that the resulting optimal behaviour generates, which is the self-consistency condition. The whole of the existence question is therefore:

does the map S of definition 10.3 have a fixed point?

Heuristic (non-rigorous)

The map S *is* the self-consistent-field (SCF) iteration of mean field theory, transplanted from a static average to a dynamic optimisation. Run it as an actual loop. Start from any guessed population trajectory $m^{(0)} \in \mathcal{M}$ — the constant flow $m_t^{(0)} \equiv m_0$ will do. Solve the one-body problem in that frozen field, i.e. the decoupled HJB equation eq. (10.2) with couplings $F[m_t^{(0)}]$, $G[m_T^{(0)}]$, to obtain the value $u^{(0)} = u^{m^{(0)}}$ and the feedback it dictates; let the whole interchangeable ensemble respond by that feedback and read off the law it generates,

$$m^{(1)} = \mathsf{S}(m^{(0)}), \qquad m^{(2)} = \mathsf{S}(m^{(1)}), \qquad \dots, \qquad m^{(k+1)} = \mathsf{S}(m^{(k)}).$$

This is the SCF orbit. Two regimes are possible, and the whole strategic choice of the chapter is which one we are in. *(i) Contraction.* If S is a contraction in d_1, that is $\mathsf{d}_1(\mathsf{S}(m), \mathsf{S}(m')) \le \kappa\, \mathsf{d}_1(m, m')$ with some $\kappa < 1$, then the orbit is Cauchy — $\mathsf{d}_1(m^{(k+1)}, m^{(k)}) \le \kappa^k \mathsf{d}_1(m^{(1)}, m^{(0)})$ — so by completeness of $\mathcal{M}$ it *converges*, and its limit is the *unique* fixed point: existence and uniqueness at one stroke, by Banach rather than Schauder, with the iteration itself a convergent algorithm for the equilibrium. This is the favourable regime — monotone or weakly coupled data, or a short horizon T that starves the feedback–density feedback loop of time to amplify — and we will watch it operate concretely for the LQG thread at short horizon in section 10.5, where S collapses to a genuine contraction on a finite-dimensional parameter and the fixed point can be solved for in closed form. *(ii) No contraction.* Generic MFGs supply no such $\kappa < 1$. Then the orbit $(m^{(k)})$ carries *no* convergence guarantee: it may oscillate, cycle, or drift, and the field may possess several distinct self-consistent values among which the iteration never settles. All one can still salvage is the weaker fact that the orbit cannot *escape* — the moment and equicontinuity bounds of section 10.2 confine every $m^{(k)}$ to one compact set $\mathcal{K}$ — so the sequence must at least *accumulate* somewhere in $\mathcal{K}$, even if it never converges as a whole. Compactness buys an accumulation point; continuity of S (section 10.3) then forces that accumulation point to be *fixed*. This is the Schauder/Kakutani route, and the gap between "converges" and "merely stays in a compact set" is exactly the gap between Banach's theorem and the topological fixed-point theorems that the rest of the chapter is built to cross.

Physics note

The SCF loop $m \mapsto \mathsf{S}(m)$ is the exact dynamic analogue of the Curie–Weiss self-consistency loop, but the one-body problem sitting inside each iteration is of a fundamentally different character, and it is worth being precise about the difference. In Curie–Weiss mean field theory the self-consistent magnetisation $m = \tanh(\beta_{\mathrm{T}} J m)$ is fixed by a *static* averaging postulate: posit a molecular field Jm, solve the single-spin problem in it — a one-line thermal average, $\langle \sigma \rangle = \tanh(\beta_{\mathrm{T}} J m)$ — and demand consistency. The one-body solve is an *instantaneous* computation; there is no time in it, and the only equation is the scalar transcendental fixed point.

Here the one-body solve is not instantaneous. To compute a single representative agent's optimal response to a frozen flow m one must solve the HJB equation eq. (10.2) on the entire interval $[0, T]$ — a *boundary-value problem in time*, not a static minimisation. The value $u^m(t, x)$ obeys a backward parabolic equation whose only data sit at the terminal time, $u^m(T, \cdot) = G[m_T]$, and the solution propagates that terminal information backward to determine how the agent should steer *now* in anticipation of the cost it will face *later*: the optimal action at time t is fixed by events at all times $s > t$. The density, meanwhile, is transported *forward* by eq. (10.3) from its datum m_0 at $t = 0$. So even at the level of a single SCF iteration — before any self-consistency is imposed — the computation already threads information in both directions of time: backward through the value, forward through the law, with the data pinned at *opposite ends* of $[0, T]$. The static thermal average has been replaced by a two-point problem in time, and the fixed-point demand $\mathsf{S}(m) = m$ then couples this backward object to this forward one. This is why no equilibrium thermodynamics furnishes the relevant intuition: a thermal average is memoryless and instantaneous, whereas an optimal control is anticipatory and spread over the horizon. The SCF *outer* loop is faithfully Curie–Weiss; the *inner* solve is a boundary-value problem with no thermal-equilibrium counterpart. Multiplicity of self-consistent fields, when it occurs, is nonetheless the genuine dynamic counterpart of symmetry breaking, and we return to it in chapter 11.

The existence question is now sharply posed, and we have a constructed map to ask it of. But before we can deploy any fixed-point theorem against S, one structural feature of the construction must be confronted, because it determines *which* theorem we may use. The whole of S pivots on the feedback eq. (10.4), $\alpha^{*,m}(t, x) = -\partial_p H(x, \nabla u^m(t, x))$, and we quietly assumed in the *solve* step that this expression names a single well-defined function — that $\partial_p H(x, \cdot)$ returns one value, not a set. When it does, S is a genuine single-valued map and Schauder's theorem is the right instrument; the compact invariant set of section 10.2 and the continuity estimate of section 10.3 then complete the argument. When it does not — when the $\arg\max$ hidden inside $\partial_p H$ can return several optimal actions — S ceases to be a map at all and becomes a set-valued correspondence, and a different, set-valued fixed-point theorem must take over. The next subsection examines the feedback formula precisely where this fork lies, asking exactly when its $\arg\max$ is a singleton and when it is not, and so cleaves the remainder of the chapter into the Schauder route and the Kakutani route.

10.1.4 Two regimes: single-valued versus set-valued response

The previous subsection ended by isolating the one feature of the construction that decides *which* fixed-point theorem we are entitled to deploy. Everything in S funnels through the feedback eq. (10.4), $\alpha^{*,m}(t, x) = -\partial_p H(x, \nabla u^m(t, x))$, and that expression is innocent only if it names *one* number for each (t, x). But $-\partial_p H(x, p)$ is not a primitive datum of the game; it is shorthand for an optimisation.

Recall from the derivation of eq. (10.1) that the Hamiltonian is the Legendre–Fenchel transform of the running cost in the control, $H(x,p) = \sup_{a\in A}\{-a\cdot p - L(x,a)\}$, so that the maximising action is the *argmax*

$$\alpha^*(x,p) \;\in\; \arg\max_{a\in A} \{ -\; a\cdot p - L(x,a)\}, \qquad p = \nabla u^m(t,x), \tag{10.5}$$

and the clean differential identity $\alpha^* = -\partial_p H$ is licensed *only* when this arg max is a singleton and $H(x,\cdot)$ is consequently differentiable. The question this subsection settles is exactly: when is the set in eq. (10.5) a single point, and when can it contain several? The answer is the fork in the road for the entire chapter, because a single point makes S a bona fide *map* and hands the argument to Schauder, whereas a genuine set makes S a *correspondence* and forces the heavier set-valued machinery.

When the argmax is a singleton. The decisive sufficient condition is *strict* convexity of the running cost $L(x,\cdot)$ — equivalently, strict convexity of the Hamiltonian $H(x,\cdot)$ in the momentum, the strong form of (A-Conv). The picture is the elementary one behind the Legendre transform: maximising the concave function $a \mapsto -a\cdot p - L(x,a)$ over the action set is locating the tangency where a hyperplane of slope $-p$ first touches the strictly concave graph, and a *strictly* concave graph admits exactly one such tangency. Strict convexity therefore makes $H(x,\cdot)$ not merely differentiable but C^1 with a single-valued gradient, so eq. (10.5) collapses to the lone maximiser $\alpha^*(x,p) = -\partial_p H(x,p)$, a genuine function of (x,p). The carried LQG thread is the cleanest instance: there $L(x,a) = \frac{1}{2}|a|^2$ (up to the linear state coupling), the Hamiltonian is the quadratic $H(x,p) = \frac{1}{2}|p|^2 + \cdots$, strictly convex in p with the explicit unique maximiser $\alpha^* = -p$, and no ambiguity can arise anywhere. Whenever the cost is uniformly convex the feedback $\alpha^{*,m}$ is thus a single well-defined function, X^m is the unique strong solution of one closed-loop SDE, and $\mathsf{S}(m)$ is a single flow — the regime in which S is honestly a self-map of $\mathcal{M}$.

Three ways single-valuedness can fail. Drop strict convexity and three distinct mechanisms can each return more than one optimal action on a set of (t,x) of positive measure; it is worth seeing each as a separate picture, because they are repaired by different devices in section 10.4, and the reader who can name the failure can anticipate the cure.

(i) *Merely convex H (a flat maximiser set).* If $L(x,\cdot)$ is convex but not *strictly* so, its graph carries an affine stretch; dually, $H(x,\cdot)$ has a corner, or equivalently $-\partial_p H$ is replaced by a set-valued subdifferential. The tangent hyperplane of slope $-p$ can then kiss the graph along a whole flat segment, and eq. (10.5) is that entire segment — a convex set of equally-optimal actions rather than a point. The agent is genuinely indifferent among a range of drifts. *Picture: a Hamiltonian with a kink, its argmax an interval.* Here the maximiser set is already convex and nonempty, so nothing needs convexifying; what is needed is only to *pick* one optimiser per (t,x) in a measurable way, and that is the job of the measurable-selection step.

(ii) *Non-convex action set (the optimiser sits between two actions).* If A itself is not convex — two isolated allowed drifts, say, with nothing in between — the set of *attainable* averaged dynamics need not be convex, and the maximisation can prefer a value strictly between two pure actions that the agent is not permitted to play. This is precisely the obstruction by which a finite game can lack a pure-strategy Nash equilibrium: the best response "wants to mix." *Picture: a double-well payoff with the optimum stranded on the forbidden ridge between the wells.* Selection alone cannot help, because no single admissible action is optimal; the repair must first *convexify* the problem by allowing the agent to randomise — the relaxed (Young-measure) controls of definition 10.17 — restoring an optimiser in the convex hull before any selection is attempted.

(iii) *Degenerate diffusion (no classical gradient to feed the formula).* If (A-Nondeg) fails and $\sigma\sigma^\top$ is allowed to degenerate, the HJB equation eq. (10.2) loses its uniform parabolicity and u^m is in general only a *viscosity* solution, possessing no classical gradient ∇u^m at every point. The feedback eq. (10.4) then has no pointwise meaning on the (possibly large) set where u^m is merely Lipschitz with a kink, and $\arg\max$ in eq. (10.5) is read against a momentum p that is itself set-valued. *Picture: a value landscape with creases, the gradient — and hence the prescribed drift — undefined along each crease.* This is the failure that cannot be wished away by any convexity of H; it is repaired by abandoning the deterministic-flow formulation altogether and seeking a *weak* equilibrium carried on laws, where the control enters only through the martingale problem of definition 10.18 and need never be read off a gradient.

In all three cases the conclusion is the same in form: "the" optimal feedback is no longer a function, the assignment $m \mapsto \mathsf{S}(m)$ returns a *set* of admissible response flows rather than a single one, and S has degenerated from a map into an upper-hemicontinuous correspondence. Schauder's theorem, which speaks only of single-valued maps, then has nothing to act on, and a fixed point must instead be extracted by a set-valued theorem — the Kakutani–Fan–Glicksberg theorem of chapter 2 — after which an honest, executable feedback is recovered by measurable selection. That is the entire programme of section 10.4, and the two devices it deploys map onto the three failures exactly as flagged above: relaxation cures the non-convexity of (ii) and the gradient-lessness of (iii) by enlarging the strategy space, while selection cures the residual indeterminacy of (i) — and the leftover ambiguity in (ii)–(iii) — by choosing one optimiser measurably.

This dichotomy is the organising decision of the chapter, and we make it explicit so the later turn to set-valued analysis arrives as a planned manoeuvre rather than a surprise. The two routes diverge here and do not meet again until the closing synthesis: under *strict* convexity (A-Conv) together with nondegeneracy (A-Nondeg) — the regime in which all three failure modes are simultaneously excluded — the feedback is a single function, S is a continuous self-map, and the Schauder route applies; dropping either hypothesis admits one or more of the failures and routes the argument through Kakutani. *For the next two sections we therefore adopt the single-valued regime as a standing assumption*: we assume throughout sections 10.2 and 10.3 that (A-Nondeg) and the strict form of (A-Conv) hold, so that $\alpha^{*,m}$ is a genuine function and S a genuine map, and we build the Schauder argument for that map without further comment on set-valuedness. The set-valued machinery is deferred in its entirety to section 10.4, which drops both crutches and shows that an equilibrium survives all three failures above. With the regime now fixed, the immediate task is the one posed at the close of section 10.1: Schauder needs a nonempty convex compact set carried into itself, and producing that invariant set — in the single-valued regime just adopted — is the business of section 10.2, to which we now turn.

10.2 Compactness: the invariant set for the best-response map

The previous section closed by adopting the single-valued, strictly convex regime as a standing assumption and naming the debt it left outstanding. Schauder's theorem (chapter 2) certifies a fixed point only for a *continuous* self-map of a *nonempty convex compact* set, and so far we possess neither half of that hypothesis: S acts on the whole ambient space $\mathcal{M} = C([0,T];\mathcal{P}_1(\mathbb{R}^d))$, which is complete but hopelessly too large to be compact. In $\mathcal{M}$ mass can run off to infinity and a flow can wiggle in time arbitrarily fast, so there is nothing for Schauder to grip. The two missing pieces split into two cleanly separated tasks, and the chapter splits with them: the present section manufactures the set $\mathcal{K}$ — nonempty, convex, compact, and carried into itself by S — and section 10.3 supplies the continuity of S on it. This answers, in the affirmative, exactly the question left hanging at the end of section 10.1: yes, S does possess an invariant compact set, and here is how to build one. We work throughout in the single-valued regime just fixed, so that S is a genuine map and the containment $\mathsf{S}(\mathcal{K}) \subseteq \mathcal{K}$ is an honest statement about where points go, not where sets go.

The strategy for building $\mathcal{K}$ is the one the throughline has been signalling all along. No contraction is available, so compactness cannot be inherited from the dynamics — it must be *manufactured*, and the raw material is a pair of *a priori bounds* on the output flows: a ceiling on how far their mass can stray from the origin (a moment bound), and a ceiling on how fast they can move in time (an equicontinuity bound). A flow that is at once spatially confined and temporally slow simply cannot escape a compact set; that is the entire mechanism, and the remainder of the section is the labour of producing the two bounds and reading off the compactness they force. Both bounds, remarkably, descend from a single quantitative fact about the closed-loop dynamics — that the optimal drift is uniformly bounded — so we isolate that fact first and give it a name. We do so deliberately, because it is the one ingredient of the whole construction that can fail, and *does* fail for the LQG thread, forcing the separate treatment of section 10.5.

Assumption 10.4 (Bounded optimal feedback)**.** There is a constant $M < \infty$ such that, for every flow $m \in \mathcal{M}$, the optimal feedback drift is bounded:

$$\left\|\partial_p H(\cdot, \nabla u^m(t,\cdot))\right\|_\infty \;\leq\; M, \qquad t \in [0,T].$$

Assumption 10.4 reads, on its face, like an extra demand bolted onto the game — a fresh restriction on the data, asserted precisely where it happens to be convenient. If it genuinely were that, it would be a weakness in the argument, a fact assumed at the point of use rather than earned. It is not. Assumption 10.4 is a *consequence* of the primitive hypotheses already in force, and following the deduction is worth the few lines it takes, for two reasons: it shows the boundedness is bought rather than postulated, and it is the first place in the construction where the chapter's hero, nondegeneracy (A-Nondeg), does load-bearing work. The drift to be bounded is $-\partial_p H(x, \nabla u^m)$ from eq. (10.4), a composition of two pieces: the fixed map $\partial_p H$, which the standing growth hypotheses keep under control on any bounded set of momenta, and the gradient ∇u^m of the frozen-flow value, which is the only piece that carries any dependence on the population trajectory m. Bounding the drift uniformly in m therefore reduces cleanly to bounding ∇u^m uniformly in m — a Lipschitz bound on the value function that must hold no matter which population trajectory was frozen to source it. That uniform Lipschitz bound is the content of the next lemma; we state it, read assumption 10.4 off it, and record the mechanism of its proof while deferring the full parabolic estimate to appendix E.

Lemma 10.5 (Uniform gradient bound for the value)**.** *Assume (A-Lip), (A-Growth), (A-Nondeg), (A-Conv), that the couplings F, G are bounded with $F[\mu](\cdot), G[\mu](\cdot)$ uniformly Lipschitz in x uniformly in μ, and that $p \mapsto \partial_p H(x,p)$ is continuous with at most linear growth. Then there is a constant $L_u < \infty$, depending only on the data and on T but* not *on the frozen flow m, such that the HJB solution u^m of eq. (10.2) satisfies $\|\nabla u^m(t,\cdot)\|_\infty \le L_u$ for all $t \in [0,T]$. Consequently assumption 10.4 holds with $M = \sup_{|p|\le L_u,\, x} |\partial_p H(x,p)|$.*

Proof. The estimate is the uniform-in-m Lipschitz bound for the value function, proved in full as theorem E.17 of appendix E; here we give the mechanism, because seeing where the constant L_u comes from is exactly seeing where the boundedness of the couplings and nondegeneracy (A-Nondeg) enter. The cleanest route is through the stochastic-control representation of the value (theorem 6.10),

$$u^m(t,x) \;=\; \inf_\alpha \; \mathbb{E}_{t,x}\Big[\int_t^T \big(L(X_r,\alpha_r) + F[m_r](X_r)\big)\, \mathrm{d}r \;+\; G[m_T](X_T) \Big],$$

the infimum over admissible controls of the running-plus-terminal cost of the controlled process started at $X_t = x$. To bound the Lipschitz constant of $x \mapsto u^m(t,x)$ we compare the values at two starting points x and x' by a *synchronous coupling*: run both trajectories with the *same* control and driven by the *same* Brownian path, so that they differ *only* through their initial condition. The separation $\Delta_r := X_r - X'_r$ then carries no independent noise increment — the $\sigma\, \mathrm{d}W$ terms enter only through the state-Lipschitz discrepancy of σ — and (A-Lip), the uniform state-Lipschitz property of the drift and diffusion with constant Λ, gives by Grönwall's inequality (lemma C.1) the pathwise bound

$$|\Delta_r| \;\le\; e^{\Lambda(r-t)}\, |x - x'|, \qquad r \in [t,T].$$

This is where the exponential is born: two synchronously-coupled trajectories spread apart at most exponentially in elapsed time, at the rate Λ that measures how strongly the dynamics can amplify a state discrepancy, so a gap present at time t is magnified by the factor $e^{\Lambda(r-t)}$ by time r. Feeding this into the value representation, and using that the *same* control makes the $L(X_r,\alpha_r)$ contributions cancel between the two trajectories so that only the couplings remain,

$$|u^m(t,x) - u^m(t,x')| \;\le\; \mathbb{E}_{t,x}\Big[\int_t^T \|\nabla_x F[m_r]\|_\infty\, |\Delta_r|\, \mathrm{d}r + \|\nabla G[m_T]\|_\infty\, |\Delta_T| \Big] \;\le\; \Big(\int_t^T e^{\Lambda(r-t)} \|\nabla_x F[m_r]\|_\infty\, \mathrm{d}r + e^{\Lambda(T-t}$$

The terminal datum sits furthest in the future, at distance $T - t$, and therefore suffers the *full* amplification $e^{\Lambda(T-t)}$; the running source at an intermediate time r suffers only $e^{\Lambda(r-t)} \le e^{\Lambda(T-t)}$, and replacing it by the worst-case terminal factor pulls the exponential out of the integral. Dividing by $|x - x'|$ and letting $x' \to x$ identifies the left side with $\|\nabla u^m(t,\cdot)\|_\infty$ and yields exactly the displayed bound

$$\|\nabla u^m(t,\cdot)\|_\infty \;\le\; e^{\Lambda(T-t)} \Big(\|\nabla G[m_T]\|_\infty + \int_t^T \|\nabla_x F[m_r]\|_\infty\, \mathrm{d}r \Big) \;\le\; L_u.$$

Two features make this the lemma we want, and each corresponds to one hypothesis. First, the bound is *uniform in m*: the frozen flow enters only through $\nabla_x F[m_r]$ and $\nabla G[m_T]$, and these are controlled by the Lipschitz constants of F and G in the state *uniformly in the measure argument* — exactly the boundedness/Lipschitz hypothesis on the couplings — so that $L_u = e^{\Lambda T}(\mathrm{Lip}_x G + T\,\mathrm{Lip}_x F)$ depends on the data and on T but on no property whatsoever of the particular trajectory m that was frozen. This uniformity is the whole point: it is what will make the moment and equicontinuity bounds below hold with one set of constants across the entire candidate set. Second, the representation itself is licensed by (A-Nondeg): nondegeneracy of $\sigma\sigma^\top$ renders the frozen HJB equation uniformly parabolic, hence its solution u^m a genuine classical $C^{1,2}$ solution (theorem C.12), so that ∇u^m exists pointwise and the feedback eq. (10.4) — and with it the synchronous-coupling control used above — actually denotes something. Strip away (A-Nondeg) and u^m degenerates to a mere viscosity solution with a kinked, possibly set-valued gradient, and the very first line of the argument loses its meaning. The PDE-side counterpart of the same estimate is the classical Bernstein gradient bound, obtained by differentiating the equation and applying the maximum principle to $|\nabla u^m|^2$; both routes are carried out in theorem E.17, and either delivers the same constant L_u. Finally, setting $M = \sup_{|p|\le L_u,\,x} |\partial_p H(x,p)|$ — finite because $\partial_p H(x,\cdot)$ has at most linear growth and is evaluated only on the bounded momentum range $|p| \le L_u$ — yields assumption 10.4. Cf. [36, 93, Ch. 3] for exactly this use inside an MFG existence proof. □

Notation watch

It is essential to be honest about the scope of assumption 10.4 and lemma 10.5, because the price they exact is exactly the price the carried thread cannot pay. The deduction above needed two things: couplings F, G that are *bounded* and Lipschitz in the state (uniformly in the measure), and a $\partial_p H$ that stays bounded on the range of ∇u. The LQG thread of appendix A (Thread A) violates *both*. Its running coupling $F[m](x) = \frac{q}{2}(x - s\bar{m})^2$ is *quadratic* in x, hence neither bounded nor globally Lipschitz; and its optimal feedback works out to the affine law $-bPx - b\,r$, which is *linear*, hence unbounded, in x. Neither the uniform gradient bound L_u nor the drift ceiling M survives: a linear feedback transports mass at a rate that grows with $|x|$, with no a priori ceiling. The abstract existence theorem assembled in this section therefore simply does *not* reach Thread A. This is not an oversight to be patched but a structural fact to be respected: LQG existence is recovered separately, by the explicit linear-Gaussian construction of section 10.5, where the very unboundedness that defeats the compactness argument is turned to advantage through the closed-form Riccati/mean reduction. The reader should carry this flag forward; it is the seam along which the abstract and the explicit halves of the chapter are stitched.

With assumption 10.4 now established as a consequence of the data, the uniform drift ceiling M is in hand, and the two a priori bounds that will define $\mathcal{K}$ follow from it by short and entirely classical stochastic-calculus estimates. The first controls *space* — it caps the second moment of every output flow, keeping mass from escaping to infinity — and the second controls *time* — it caps how fast an output flow can move, making each a uniformly continuous curve in $\mathcal{W}_1$. We prove them in turn; neither uses anything beyond the drift bound $|b^m| \le M$, the diffusion bound $\|\sigma\|_\infty \le \Sigma$, and the Itô isometry.

Lemma 10.6 (Uniform moment bound). *Assume (A-Nondeg) with $\|\sigma\|_\infty \le \Sigma$ and assumption 10.4.*

Let $m_0 \in \mathcal{P}_2(\mathbb{R}^d)$. Then for every $m \in \mathcal{M}$ the output flow $\mathsf{S}(m)$ satisfies

$$\sup_{t\in[0,T]} \int_{\mathbb{R}^d} |x|^2\, \mathsf{S}(m)_t(\mathrm{d}x) \;\le\; R^2 := C\Big(1 + \textstyle\int |x|^2 m_0(\mathrm{d}x) + M^2T^2 + \Sigma^2 T\Big),$$

with C a universal constant.

Proof. Let X^m be the closed-loop process of definition 10.3, with drift $b^m(t,x) = -\partial_p H(x, \nabla u^m(t,x))$, so that $|b^m| \le M$ pointwise by assumption 10.4. Written in integral form the process is

$$X_t^m \;=\; X_0 \;+\; \underbrace{\int_0^t b^m(s, X_s^m)\,\mathrm{d}s}_{\text{drift}} \;+\; \underbrace{\int_0^t \sigma(X_s^m)\,\mathrm{d}W_s}_{\text{martingale}},$$

a sum of three terms, and we bound the size of each. The elementary inequality $|a+b+c|^2 \le 3(|a|^2+|b|^2+|c|^2)$ — a one-line consequence of Cauchy–Schwarz, or of the convexity of $r \mapsto r^2$ applied to the average $\frac{1}{3}(a+b+c)$ — separates the three contributions:

$$|X_t^m|^2 \;\le\; 3|X_0|^2 \;+\; 3\Big|\int_0^t b^m(s, X_s^m)\,\mathrm{d}s\Big|^2 \;+\; 3\Big|\int_0^t \sigma(X_s^m)\,\mathrm{d}W_s\Big|^2.$$

The drift integral is controlled deterministically: since $|b^m| \le M$, Jensen's inequality (equivalently Cauchy–Schwarz in time) gives $\big|\int_0^t b^m\,\mathrm{d}s\big|^2 \le t\int_0^t |b^m|^2\,\mathrm{d}s \le t\cdot tM^2 = M^2t^2$, with no expectation needed. The martingale integral is controlled in mean square by the *Itô isometry*, which converts the square of a stochastic integral into the time-integral of the squared integrand,

$$\mathbb{E}\Big|\int_0^t \sigma(X_s^m)\,\mathrm{d}W_s\Big|^2 \;=\; \mathbb{E}\int_0^t \operatorname{tr}\big(\sigma\sigma^\top(X_s^m)\big)\,\mathrm{d}s \;\le\; \Sigma^2 t,$$

the last step using the diffusion bound $\|\sigma\|_\infty \le \Sigma$ so that $\operatorname{tr}(\sigma\sigma^\top) \le \Sigma^2$ pointwise. Taking expectations in the separated inequality and inserting these two estimates,

$$\mathbb{E}\Big[|X_t^m|^2\Big] \;\le\; 3\,\mathbb{E}\Big[|X_0|^2\Big] + 3\,M^2t^2 + 3\,\Sigma^2 t.$$

Taking the supremum over $t \in [0,T]$ and recalling $\operatorname{Law}(X_0) = m_0$ gives the claim with $C = 3$ (any larger constant absorbing the 1+ also works). Notice how each of the three data quantities surfaces in R^2 for a transparent reason: the initial spread $\int |x|^2 m_0$ through X_0, the transport budget M^2T^2 through a drift that can push for time T at speed M, and the diffusive spread $\Sigma^2 T$ through the noise accumulated over $[0,T]$. □

The moment bound is the spatial half of the construction: it confines the output flows to a $\mathcal{W}_1$-bounded region of $\mathcal{P}_1$ at every instant. The temporal half is next — a bound on how far an output flow can travel in $\mathcal{W}_1$ over a short time interval. The same drift ceiling M and diffusion ceiling Σ that controlled the moment now control the increment, and the only new idea is to read $\mathcal{W}_1$ as a coupling distance so that the displacement of the *law* is bounded by the expected displacement of the *process*.

Lemma 10.7 (Equicontinuity in time)**.** *Under the hypotheses of lemma 10.6, every output flow $\mathsf{S}(m)$ satisfies*

$$\mathcal{W}_1\big(\mathsf{S}(m)_s, \mathsf{S}(m)_t\big) \;\le\; \omega(|t-s|) := M\,|t-s| + \Sigma\sqrt{|t-s|}, \qquad s,t \in [0,T].$$

Proof. The first step turns a question about measures into a question about the process. The pair (X^m_s, X^m_t) is, by construction, a coupling of the two marginals $\mathrm{Law}(X^m_s) = \mathsf{S}(m)_s$ and $\mathrm{Law}(X^m_t) = \mathsf{S}(m)_t$, and since $\mathcal{W}_1$ is the *infimum* of $\mathbb{E}|U - V|$ over all couplings (U, V) of its two arguments (chapter 4), this particular coupling furnishes an upper bound:

$$\mathcal{W}_1(\mathsf{S}(m)_s, \mathsf{S}(m)_t) \;\le\; \mathbb{E}[|X^m_t - X^m_s|]\,.$$

It remains to bound the expected increment of the process. For $s < t$, subtracting the integral forms at the two times leaves $X^m_t - X^m_s = \int_s^t b^m(r, X^m_r)\,\mathrm{d}r + \int_s^t \sigma(X^m_r)\,\mathrm{d}W_r$, so by the triangle inequality

$$\mathbb{E}[|X^m_t - X^m_s|] \;\le\; \mathbb{E}[*]\int_s^t |b^m(r, X^m_r)|\,\mathrm{d}r + \mathbb{E}[*]\left|\int_s^t \sigma(X^m_r)\,\mathrm{d}W_r\right|.$$

The drift term is immediate from $|b^m| \le M$: it is at most $M(t-s)$. The martingale term needs the one genuine estimate. We cannot apply the Itô isometry directly, because that governs the *second* moment of a stochastic integral, not the first; so we first raise to the square root by Jensen's inequality (the concavity of $r \mapsto \sqrt{r}$, equivalently Cauchy–Schwarz on $\mathbb{E}|\cdot| = \mathbb{E}|\cdot|\cdot 1$) and *then* apply the isometry:

$$\mathbb{E}[*]\left|\int_s^t \sigma(X^m_r)\,\mathrm{d}W_r\right| \;\le\; \left(\mathbb{E}\left|\int_s^t \sigma(X^m_r)\,\mathrm{d}W_r\right|^2\right)^{1/2} \;=\; \left(\mathbb{E}\int_s^t \mathrm{tr}(\sigma\sigma^\top(X^m_r))\,\mathrm{d}r\right)^{1/2} \;\le\; \Sigma\sqrt{t-s}.$$

(The Burkholder–Davis–Gundy inequality of appendix A would give the same $\sqrt{t-s}$ scaling more robustly, controlling $\mathbb{E}\sup$ of the increment rather than the increment at the endpoint; the elementary Jensen-plus-isometry route suffices here.) Combining the two terms gives $\mathbb{E}[|X^m_t - X^m_s|] \le M(t-s) + \Sigma\sqrt{t-s}$, which is $\omega(|t-s|)$. □

The shape of the modulus repays a second look. The two terms scale differently in the time gap: the drift contributes a Lipschitz piece $M|t-s|$, but the diffusion contributes a *half-Hölder* piece $\Sigma\sqrt{|t-s|}$, and for small $|t-s|$ the square root dominates. This $\sqrt{\cdot}$ is the unmistakable fingerprint of Brownian motion — mass spreads like $\sqrt{\text{time}}$, not like time — and it is the reason the output flows are $\frac{1}{2}$-Hölder rather than Lipschitz in time. Decisively, the modulus ω is *independent of* m: every output flow obeys the same modulus, set once and for all by the two constants M and Σ. That uniformity is precisely what an equicontinuity hypothesis demands, and it is the second of the two a priori bounds we set out to collect. With space controlled by lemma 10.6 and time controlled by lemma 10.7, both uniformly in m, we can now assemble the compact set.

Lemma 10.8 (A convex compact invariant set)**.** *With R from lemma 10.6 and ω from lemma 10.7, define*

$$\mathcal{K} \;=\; \Big\{ m \in \mathcal{M} :\; m_0 \textit{ fixed},\; \sup_t \int |x|^2 m_t(\mathrm{d}x) \le R^2,\; \mathcal{W}_1(m_s, m_t) \le \omega(|t-s|)\ \forall s,t \Big\}.$$

Then $\mathcal{K}$ is nonempty, convex, and compact in $(\mathcal{M}, \mathsf{d}_1)$, and $\mathsf{S}(\mathcal{K}) \subseteq \mathcal{K}$.

Proof. There are four things to check — nonempty, self-map, convex, compact — and the first three are quick; the weight is in compactness, which is where the moment bound is finally spent.

Nonempty. The constant flow $m_t \equiv m_0$ lies in $\mathcal{K}$: it has the prescribed initial value, its second moment $\int |x|^2 m_0(\mathrm{d}x)$ is $\le R^2$ by the definition of R, and its $\mathcal{W}_1$ increments vanish, so the equicontinuity bound $0 \le \omega(|t-s|)$ holds trivially. So $\mathcal{K} \neq \varnothing$, and Schauder will not be applied to the empty set — a precaution that is not idle, since an invariant set carved out by inequalities can perfectly well turn out to be empty.

Self-map. This is exactly what the two preceding lemmas were for. Lemma 10.6 says every output flow $\mathsf{S}(m)$ obeys the second-moment ceiling R^2, and lemma 10.7 says it obeys the modulus ω; both hold for every $m \in \mathcal{M}$, in particular for every $m \in \mathcal{K}$. Together with $\mathsf{S}(m)_0 = \mathrm{Law}(X_0) = m_0$ this is precisely the statement that $\mathsf{S}(m) \in \mathcal{K}$. Hence $\mathsf{S}(\mathcal{K}) \subseteq \mathcal{K}$. (Note the asymmetry that makes the construction work: the two lemmas bound the *output* regardless of the input, so the image of the *whole* ambient space already lands in $\mathcal{K}$; the restriction to $\mathcal{K}$ is needed only to have a compact convex domain for Schauder, not to make the containment hold.)

Convex. Take two members m, m' and a weight $\theta \in [0,1]$, and form the pointwise mixture $m_t^\theta = \theta m_t + (1-\theta) m'_t$. Each defining constraint survives the mixture, for an elementary reason in each case. The initial value is right because $m_0^\theta = \theta m_0 + (1-\theta) m_0 = m_0$. The second-moment ceiling survives because $\mu \mapsto \int |x|^2 \,\mathrm{d}\mu$ is *linear* in μ, so the second moment of the mixture is the mixture of the second moments, each $\le R^2$, hence $\le R^2$. The equicontinuity ceiling survives because $\mathcal{W}_1$ is *jointly convex*,

$$\mathcal{W}_1(\theta\mu_1 + (1-\theta)\nu_1,\ \theta\mu_2 + (1-\theta)\nu_2) \ \le\ \theta\, \mathcal{W}_1(\mu_1, \mu_2) + (1-\theta)\, \mathcal{W}_1(\nu_1, \nu_2),$$

which one sees by *superposing* the two optimal transport plans (a convex combination of couplings is again a coupling of the corresponding mixed marginals, and its cost is the mixture of the two costs). Applying this with $\mu_i = m$-values and $\nu_i = m'$-values at times s, t bounds $\mathcal{W}_1(m_s^\theta, m_t^\theta)$ by $\theta\,\omega + (1-\theta)\,\omega = \omega$. So $m^\theta \in \mathcal{K}$, and $\mathcal{K}$ is convex — the property Schauder needs in order to have a target for the would-be fixed point.

Compact. This is the heart of the matter. Compactness in $(\mathcal{M}, \mathsf{d}_1)$ is compactness of a family of *curves* $t \mapsto m_t$ from the compact interval $[0,T]$ into the metric space $(\mathcal{P}_1, \mathcal{W}_1)$, and the right tool is the generalized Arzelà–Ascoli theorem (theorem B.24): a family of maps from a compact interval into a complete metric space is relatively compact in the uniform metric provided it is (i) uniformly equicontinuous and (ii) pointwise relatively compact, the target space being (iii) complete. We verify the three inputs.

(i) Uniform equicontinuity is built into $\mathcal{K}$ by fiat: every member obeys the single modulus ω of lemma 10.7, which is what "uniform" means here.

(ii) Pointwise relative compactness is where the second moment is cashed, and it is worth doing in two stages because the moment buys two distinct things. Fix a time t and consider the slice $\mathcal{K}_t := \{m_t : m \in \mathcal{K}\} \subseteq \mathcal{P}_1(\mathbb{R}^d)$; we must show it is relatively compact *in* $\mathcal{W}_1$. *Stage one (weak relative compactness).* The uniform bound $\int |x|^2\, m_t(\mathrm{d}x) \le R^2$ forces *tightness* by Markov's inequality: the mass that any member places beyond radius ρ is

$$m_t(\{|x| > \rho\}) \ \le\ \frac{1}{\rho^2} \int_{|x|>\rho} |x|^2\, m_t(\mathrm{d}x) \ \le\ \frac{R^2}{\rho^2} \ \xrightarrow[\rho\to\infty]{}\ 0,$$

uniformly over $\mathcal{K}_t$, so the slice is uniformly tight, and Prokhorov's theorem (chapter 3) converts uniform tightness into relative compactness *for weak convergence*. *Stage two (the $\mathcal{W}_1$ upgrade).* Weak relative compactness is not yet what we need, because on $\mathcal{P}_1(\mathbb{R}^d)$ the metric $\mathcal{W}_1$ is *strictly stronger* than weak convergence in general: a weakly convergent sequence can fail to converge in $\mathcal{W}_1$ if first-moment mass leaks out along the tails. The exact characterization (theorem D.12) is that $\mathcal{W}_1(\mu_n, \mu) \to 0$ holds iff $\mu_n \to \mu$ weakly *and* $\int |x| \, \mathrm{d}\mu_n \to \int |x| \, \mathrm{d}\mu$, i.e. weak convergence plus convergence of the first moments; and the second condition follows automatically from the first precisely when the first moments are *uniformly integrable* (Vitali's theorem, the integrable upgrade of dominated convergence). Uniform integrability is exactly the extra mileage the second moment buys for free: for any member,

$$\int_{|x|>\rho} |x| \, m_t(\mathrm{d}x) \;\le\; \frac{1}{\rho} \int_{|x|>\rho} |x|^2 \, m_t(\mathrm{d}x) \;\le\; \frac{R^2}{\rho} \;\xrightarrow[\rho\to\infty]{}\; 0,$$

uniformly over $\mathcal{K}_t$ — the tails of the first moment are uniformly small because a second moment is uniformly bounded. Hence any weakly convergent sequence extracted in stage one is, by Vitali, also first-moment convergent, and therefore $\mathcal{W}_1$-convergent. Weak relative compactness has been upgraded to $\mathcal{W}_1$ relative compactness, and this upgrade is the entire reason the construction is carried out in $\mathcal{P}_1$ with $\mathcal{W}_1$ rather than in $\mathcal{P}_2(\mathbb{R}^d)$ with $\mathcal{W}_2$: a second-moment *ceiling* controls the first-moment tails but not the second-moment tails, so it upgrades weak compactness to $\mathcal{W}_1$ but *not* to $\mathcal{W}_2$.

(iii) Completeness of the target: $(\mathcal{P}_1, \mathcal{W}_1)$ is a complete metric space (theorem D.11), as recorded when we fixed the arena in definition 10.1.

By theorem B.24, inputs (i)–(iii) make $\mathcal{K}$ *relatively* compact in $(\mathcal{M}, \mathsf{d}_1)$: every sequence in $\mathcal{K}$ has a subsequence converging in d_1 to *some* flow in $\mathcal{M}$. To finish we must promote relative compactness to compactness, i.e. show $\mathcal{K}$ is *closed*, so that the limit flow lies back in $\mathcal{K}$ rather than escaping it. Let $m^{(n)} \in \mathcal{K}$ with $\mathsf{d}_1(m^{(n)}, m) \to 0$; we check each defining constraint passes to the limit m. The initial value is fixed because evaluation at $t = 0$ is d_1-continuous, so $m_0 = \lim m_0^{(n)} = m_0$. The equicontinuity bound passes by the triangle inequality: $\mathcal{W}_1(m_s, m_t) \le \mathcal{W}_1(m_s, m_s^{(n)}) + \mathcal{W}_1(m_s^{(n)}, m_t^{(n)}) + \mathcal{W}_1(m_t^{(n)}, m_t) \;\le\; 2\,\mathsf{d}_1(m^{(n)}, m) + \omega(|t-s|) \to \omega(|t-s|)$. The delicate constraint is the second-moment ceiling, and here is the one place the choice to use an *upper bound* rather than an equality pays off decisively. Convergence in $\mathcal{W}_1$ does *not* imply convergence of second moments — mass can slide outward in the limit — so we cannot expect $\int |x|^2 m_t^{(n)} \to \int |x|^2 m_t$. What we *do* have is one-sided: the second moment is *lower-semicontinuous* under $\mathcal{W}_1$ (indeed under weak) convergence, by Fatou's lemma applied to the nonnegative lower-semicontinuous integrand $|x|^2$ (theorem D.11), whence

$$\int |x|^2 \, m_t(\mathrm{d}x) \;\le\; \liminf_n \int |x|^2 \, m_t^{(n)}(\mathrm{d}x) \;\le\; R^2.$$

Lower semicontinuity points in exactly the helpful direction: in the limit the second moment can only *drop*, never jump above the ceiling, so a ceiling constraint is automatically preserved. (Had we instead pinned the second moment to a fixed *value*, the limit could have fallen short and left $\mathcal{K}$; the inequality is what makes $\mathcal{K}$ closed.) All three constraints survive, so $m \in \mathcal{K}$, $\mathcal{K}$ is closed, and a closed relatively compact subset of the complete space $(\mathcal{M}, \mathsf{d}_1)$ is compact. □

Remark 10.9 (Where tightness does the work)**.** It is worth standing back to see which single ingredient did the real work, because once it is isolated the whole compactness edifice can be held in one thought. Strip away the bookkeeping and the only non-elementary input above is Prokhorov's theorem — the equivalence "uniform tightness $\Leftrightarrow$ relative weak compactness" of chapter 3 — applied to the time-slices, with everything else (Markov, Vitali, Fatou, Arzelà–Ascoli) elementary glue. The lesson to carry forward is a slogan: *compactness in the space of population profiles is not a gift of the dynamics; it is bought, and the currency is a second moment.* The two a priori bounds spend that currency on two complementary confinements. The drift ceiling M controls how far mass can be transported per unit time, which is equicontinuity — confinement in *time*. The initial second moment together with the diffusion ceiling Σ control how far mass can be from the origin at all, which is tightness — confinement in *space*. Confine a family of curves in both space and time, uniformly, and Arzelà–Ascoli traps it in a compact set. Remove the moment bound and the purchase fails at the source: this is exactly what happens for the LQG thread, where the linear feedback drives the support outward at a rate proportional to its own extent, with no a priori ceiling, so that no fixed R confines the iterates and tightness is unavailable. The compactness construction of this section therefore genuinely does not apply there, and section 10.5 must — and does — exploit the explicit linear structure in its place, recovering existence by closed-form algebra rather than by trapping.

We have now manufactured the compact arena that Schauder's first demand requires. The set

$$\mathcal{K} \;=\; \Big\{\, m\in\mathcal{M}:\; m_0 \text{ fixed},\; \sup_t \int |x|^2 m_t(\mathrm{d}x)\le R^2,\; \mathcal{W}_1(m_s,m_t)\le\omega(|t-s|)\ \forall s,t \,\Big\}$$

of lemma 10.8 is a nonempty, convex, compact subset of $(\mathcal{M},\mathsf{d}_1)$ that S maps into itself: a concrete arena on which the fixed-point theorem can act. Everything Schauder asks of the *domain* is in hand. What remains is everything it asks of the *map*: that S, restricted to $\mathcal{K}$, be *continuous* in the metric d_1. That single missing ingredient — no formality, but the second and most demanding place the chapter's hero (A-Nondeg) does its work — is the business of the next section. We take $\mathcal{K}$ as fixed from here on and turn to proving S continuous on it.

10.3 Continuity of the best response and the Schauder theorem

Section 10.2 discharged the first of Schauder's two demands: it produced a nonempty convex compact set $\mathcal{K}\subset(\mathcal{M},\mathsf{d}_1)$ that S carries into itself, the arena on which a fixed point can be sought. But Schauder's theorem asks for *two* things, and a compact convex invariant domain is only the first; the second is that the map acting on that domain be *continuous*. The two demands are not interchangeable, and continuity is no afterthought: a discontinuous self-map of a compact convex set can wander forever without ever sitting still — continuity is precisely what forbids the orbit from accumulating at a point that the map then hurls elsewhere, and it is what lets one pass a limit *through* the map to certify that an accumulation point is fixed. Without it the compactness we laboured for in section 10.2 buys nothing at all. Supplying that one missing ingredient, and then assembling it with the compact set into the existence theorem, is the entire business of this section. It is the analytic heart of the chapter, and the second place the diffusion's nondegeneracy (A-Nondeg) is genuinely indispensable.

Why (A-Nondeg) must return *here* is the single sentence the reader should carry through everything below: *continuity of* S *factors through the stability of the frozen HJB solve, and that stability is a parabolic-regularity statement that is false without ellipticity.* Unpacked: to know that two nearby population profiles m and m' produce nearby responses $\mathsf{S}(m)$ and $\mathsf{S}(m')$, we must know that the value functions u^m and $u^{m'}$ they source are close — and, more delicately, that their *gradients* are close, since it is ∇u^m, not u^m itself, that drives the closed-loop dynamics. That the gradient of the HJB solution depends continuously on the equation's frozen data is exactly a parabolic estimate: it is the interior Schauder bound that uniform parabolicity supplies and that a degenerate diffusion destroys. Strip the ellipticity and u^m collapses to a mere viscosity solution whose gradient can jump across creases under arbitrarily small perturbations of the data; the response then need not depend continuously on the profile at all, and the fixed-point argument loses its second leg. So the hero of the chapter earns its billing a second time over: once, in section 10.2, to make the arena compact; here, to make the map continuous on it. Strip (A-Nondeg) away and *both* legs of Schauder fail at a single stroke — which is also the structural reason the LQG thread, nondegenerate but unbounded in its data, will not fall out as a corollary of the theorem assembled here.

The section proceeds in two movements, matching its two subsections. The first proves continuity by *factoring* the best-response map into the three elementary operations it is literally built from and showing each continuous in turn (the stability lemmas), then packaging the three back into continuity of S itself (proposition 10.13). The second feeds that proposition, together with the compact invariant set already in hand, into Schauder's theorem and reads off existence (theorem 10.14) — pausing to state honestly what the theorem costs, and to record that the probabilistic FBSDE route of chapter 9 delivers the identical conclusion through the two-pictures dictionary.

10.3.1 Stability of the decoupled problems

Continuity of S would be a formidable thing to attack head-on — the map sends a measure-valued trajectory to a measure-valued trajectory through a nonlinear, nonlocal, infinite-dimensional pipeline — were it not for one structural fact that makes the attack routine: S is not a monolith but a *composition* of three far simpler operations, and a composition of continuous maps is continuous. The strategy is therefore the oldest one in analysis, divide and conquer: write S as the chain of arrows it is literally assembled from in definition 10.3, prove each link continuous in isolation, and concatenate. The chain is

$$m \xmapsto{\text{(HJB)}} u^m \xmapsto{\textit{eq. } (10.4)} b^m = -\partial_p H(\cdot, \nabla u^m) \xmapsto{\text{(FP / SDE)}} \mathsf{S}(m) :$$

solve the frozen-flow HJB equation to obtain the value u^m; *differentiate and substitute* into the optimal-feedback formula eq. (10.4) to obtain the closed-loop drift b^m; *transport* the initial law m_0 forward under that drift (equivalently, solve the now-linear Fokker–Planck equation) to obtain the output flow. The three arrows are of three quite different characters — a parabolic PDE solve, a pointwise algebraic substitution, and a stochastic transport — and we treat their continuity separately, in that order. The first is the hard one and the only place ellipticity is consumed; the middle is an exercise in the continuity of an explicit function; the third is a synchronous-coupling argument. We establish each on $\mathcal{K}$, where the uniform a priori bounds of section 10.2 are in force.

It is worth flagging at the outset that each of the three links, examined closely, leans on exactly one of the three structural luxuries that the previous section's hand-off named as *crutches* — the conveniences the single-valued Schauder argument is permitted, and which section 10.4 must then do without. The first arrow leans on (A-Nondeg) to make the HJB solve regular and stable; the second leans on *strict* convexity of $H(x, \cdot)$ to keep the feedback a single-valued continuous function of the gradient; the third leans on the *Lipschitz* character of the resulting drift to run a pathwise coupling. As we walk the chain we will pause at each link to mark precisely which crutch it uses and what fails if it is removed, so that the reader reaches section 10.4 already knowing the three weaknesses that section is built to repair.

The first arrow: stability of the HJB solve. The whole difficulty is concentrated here. We must show that perturbing the frozen population m slightly perturbs the value u^m slightly — and, crucially, perturbs its *gradient* slightly, since it is ∇u^m, not u^m, that closes the loop. This is a *stability* statement for a backward parabolic equation under perturbation of its data, and it is exactly here that uniform parabolicity does its work: it is what upgrades a bare C^1-in-x ceiling on the value into a compactness statement in $C^{1,2}$ strong enough to pass to the limit in the equation *and* in its gradient. Absent (A-Nondeg) the lemma below has no estimate to invoke.

Lemma 10.10 (Stability of HJB in the frozen flow)**.** *Under the hypotheses of lemma 10.5, suppose the couplings are continuous for weak convergence: $\mu_n \to \mu$ weakly with $\sup_n \int |x|^2 \,\mathrm{d}\mu_n < \infty$ implies $F[\mu_n](\cdot) \to F[\mu](\cdot)$ and $G[\mu_n](\cdot) \to G[\mu](\cdot)$ locally uniformly. If $m^{(n)} \to m$ in $(\mathcal{K}, \mathsf{d}_1)$, then $u^{m^{(n)}} \to u^m$ and $\nabla u^{m^{(n)}} \to \nabla u^m$ locally uniformly on $[0,T] \times \mathbb{R}^d$.*

Proof. The argument has three movements: manufacture a uniform regularity bound (here ellipticity is spent), feed in the convergence of the data (here d_1-convergence is spent), and close by compactness and uniqueness.

Step 1: a uniform interior Hölder bound on the family. By lemma 10.5 every member of the family obeys the *same* gradient ceiling, $\|\nabla u^{m^{(n)}}(t,\cdot)\|_\infty \le L_u$, with L_u independent of n, of t, and of the frozen flow — this uniformity is exactly what lets one estimate the whole sequence with a single constant. On any parabolic cylinder $Q = (t_0, t_1) \times B_\rho$ compactly contained in $[0,T) \times \mathbb{R}^d$, the frozen HJB equation eq. (10.2) is, for each n, the linear uniformly parabolic equation

$$-\partial_t u^{(n)} - \tfrac{1}{2}\,\mathrm{tr}\big(\sigma\sigma^\top \mathrm{D}^2\, u^{(n)}\big) \;=\; g^{(n)}(t,x), \qquad g^{(n)}(t,x) \;:=\; F[m_t^{(n)}](x) - H\big(x, \nabla u^{(n)}(t,x)\big),$$

where we have moved the semilinear term to the right and written $u^{(n)} = u^{m^{(n)}}$. The gradient ceiling is what makes this right-hand side *bounded uniformly in n*: the coupling F is bounded by hypothesis, and $H(x,\cdot)$ is evaluated only on the ball $|p| \le L_u$, where it too is bounded. (A-Nondeg) supplies a uniform ellipticity sandwich $\lambda I \preceq \sigma\sigma^\top \preceq \Lambda I$ with $\lambda > 0$ independent of x. A bounded right-hand side, uniform parabolicity, and bounded terminal/lateral data give first a uniform interior Hölder bound on $u^{(n)}$ and $\nabla u^{(n)}$; with $\nabla u^{(n)}$ now Hölder, $g^{(n)}$ is itself Hölder (uniformly in n, since H is locally Lipschitz on the fixed ball $|p| \le L_u$), and a single application of the interior parabolic Schauder estimate theorem E.19 promotes the family to a uniform bound in the Hölder space $C^{1+\theta/2,\,2+\theta}_{\mathrm{loc}}(Q)$ — a bound on the value, its time derivative, and its spatial derivatives up to second order, uniform in n. This is the one step that consumes ellipticity: strip away the uniform lower bound $\lambda > 0$ and there is no interior Schauder estimate, hence nothing to keep the second derivatives bounded as the data are perturbed.

Step 2: the frozen data converge locally uniformly. Step 1 is blind to the limit; to identify it we must use the convergence of the inputs, and this is where d_1-convergence of the flows is cashed. By hypothesis $m^{(n)} \to m$ in $(\mathcal{K}, \mathsf{d}_1)$, that is $\sup_t \mathcal{W}_1(m_t^{(n)}, m_t) \to 0$; in particular, at each fixed time t, $m_t^{(n)} \to m_t$ in $\mathcal{W}_1$ and hence weakly, while the uniform second-moment ceiling R^2 in force on $\mathcal{K}$ (lemma 10.6) keeps the masses tight and their first moments uniformly integrable. The assumed coupling continuity for weak convergence then converts this weak convergence of the populations into locally uniform convergence of the *data* they source: $F[m_t^{(n)}](\cdot) \to F[m_t](\cdot)$ and $G[m_T^{(n)}](\cdot) \to G[m_T](\cdot)$, locally uniformly in x. So both the right-hand source and the terminal datum of the frozen HJB equation converge, locally uniformly, to those of the limiting frozen equation.

Step 3: extract a limit, identify it, and conclude for the whole sequence. By Step 1 the family is bounded in $C^{1+\theta/2,\,2+\theta}_{\mathrm{loc}}$, so by the Arzelà–Ascoli theorem (theorem B.24, in its real-valued form) it is precompact in $C^{1,2}_{\mathrm{loc}}$: some subsequence $u^{(n_k)}$ converges in $C^{1,2}_{\mathrm{loc}}$ to a limit $\bar{u}$, together with its first spatial derivative and the derivatives appearing in the equation. Passing to the limit in eq. (10.2) along this subsequence — the second-order terms converge because the convergence is in $C^{1,2}_{\mathrm{loc}}$, and the data converge by Step 2 — shows that $\bar{u}$ solves the HJB equation with the limiting frozen flow m. But that decoupled equation has *at most one* solution: by the classical comparison principle for the uniformly parabolic semilinear HJB (a fortiori the viscosity comparison principle theorem E.14), $\bar{u} = u^m$. Every subsequential limit is therefore the *same* function u^m, and the whole sequence converges to it; the elementary reason is spelled out in the paragraph below. In particular $\nabla u^{(n)} \to \nabla u^m$ locally uniformly, which is the gradient convergence the next arrow needs. The interior Schauder estimate and the comparison principle are proved in appendix E; in the viscosity formulation, should one ever drop to that level, the identical conclusion follows from the stability of viscosity solutions under local uniform convergence of the data — if $u^{(n_k)}$ converges locally uniformly and the data converge locally uniformly, the limit is again a viscosity solution, and comparison again pins it to u^m (appendix E; [36, §2–3]). □

The shape of that argument is worth naming, because it recurs throughout the chapter: it is a *compactness–uniqueness* argument, and it is the standard way to prove a continuous dependence one cannot estimate directly. One never bounds $u^{m^{(n)}} - u^m$ by hand. Instead the uniform parabolic estimate makes the sequence $\{u^{m^{(n)}}\}$ precompact in $C^{1,2}_{\mathrm{loc}}$; every limit point is pinned to the *same* flow u^m by uniqueness for the decoupled equation; and the elementary topological fact that "a sequence all of whose subsequential limits coincide, in a space where the sequence is precompact, converges to that common value" forces the whole sequence to converge.

That last fact is the one piece of the argument that is purely topological, and since it is used silently again and again it is worth spelling out once, because it is the precise mechanism by which subsequential information becomes whole-sequence information. Suppose, for contradiction, that $u^{(n)} \not\to u^m$ in $C^{1,2}_{\mathrm{loc}}$. Then convergence fails on some compact cylinder Q: there is an $\varepsilon > 0$ and an infinite set of indices $n_1 < n_2 < \cdots$ along which $\|u^{(n_k)} - u^m\|_{C^{1,2}(Q)} \geq \varepsilon$ for every k. But the *sub*sequence $\{u^{(n_k)}\}$ satisfies the hypotheses of Step 1 verbatim — the uniform Hölder bound knows nothing of which indices we kept — so it is itself precompact in $C^{1,2}_{\mathrm{loc}}$ and admits a further subsequence converging to some limit; by Steps 2–3 that limit can only be u^m. Along that further subsequence, then, $\|u^{(n_{k_j})} - u^m\|_{C^{1,2}(Q)} \to 0$, contradicting the standing lower bound $\geq \varepsilon$. No such bad cylinder can exist, so the whole sequence converges. The device works for exactly two reasons, and both are supplied by (A-Nondeg): *(i)* precompactness, so that *every* subsequence has a convergent sub-subsequence (Step 1), and *(ii)* uniqueness of the limit, so that all those sub-subsequential limits coincide (Step 3). Either one alone is useless; together they upgrade "some subsequence converges to u^m" into "the whole sequence converges to u^m," which is the genuinely continuous-dependence statement the lemma claims.

The single load-bearing hypothesis at both junctures is, again, uniform parabolicity: it produces the $C^{1,2}$ bound through the interior Schauder estimate, and it underwrites the comparison principle that delivers uniqueness. Delete (A-Nondeg) and both supports collapse at once — there is no uniform $C^{1,2}$ bound from which to extract a limit, and no classical comparison to identify it — which is the precise sense in which this arrow, and with it the continuity of S, is simply false in the degenerate case. This is the second appearance of the chapter's hero promised in the section opening, and it is the load-bearing one.

The middle arrow: continuity of the feedback substitution. This link is almost free, and it is the one place strict convexity — rather than nondegeneracy — is spent. The arrow $\nabla u^m \mapsto b^m = -\partial_p H(\cdot, \nabla u^m)$ is nothing but pointwise composition with the fixed function $p \mapsto -\partial_p H(x,p)$. Under the strict form of (A-Conv) that function is single-valued and continuous — it is the unique Legendre maximiser of eq. (10.5), and the argmax of a strictly concave family depends continuously on its slope. The elementary reason behind that last clause is the maximum theorem specialised to a unique maximiser: the maximiser correspondence of a continuous, jointly concave objective is always upper hemicontinuous, and an upper hemicontinuous correspondence whose values are *singletons* is exactly a continuous function. Strict concavity is what collapses the values to singletons; without it the correspondence could jump, and continuity would fail. So the locally uniform convergence $\nabla u^{m^{(n)}} \to \nabla u^m$ delivered by the first arrow passes straight through to locally uniform convergence $b^{(n)} \to b$ of the drifts: composing a locally uniformly convergent sequence of gradients with the fixed continuous map $-\partial_p H$ preserves local uniform convergence, since on each compact set $-\partial_p H$ is uniformly continuous. Were H only weakly convex this very arrow would already be set-valued, and we would be travelling the Kakutani road of section 10.4 rather than the Schauder one — single-valuedness here is precisely one of the crutches the present argument leans on and the next section knocks away. With the drifts now known to converge, only the third arrow remains: that convergent drifts transport the common initial law m_0 to convergent output flows.

Lemma 10.11 (Stability of the Fokker–Planck / closed-loop SDE)**.** *Let $b^{(n)} \to b$ locally uniformly with $\sup_n \|b^{(n)}\|_\infty \leq M$, let each $b^{(n)}$ and the limit b be Lipschitz in x uniformly in t (as the interior Schauder estimate theorem E.19 provides for the smoothing-coupling class, where $b^{(n)} = -\partial_p H(\cdot, \nabla u^{m^{(n)}})$ with $\nabla u^{m^{(n)}}$ uniformly C^1 in x), and let σ satisfy (A-Nondeg) and (A-Lip). Let $X^{(n)}$, X solve the SDEs with drifts $b^{(n)}$, b, diffusion σ, and common initial law m_0. Then* $\mathrm{Law}(X^{(n)}) \to \mathrm{Law}(X)$ *in $C([0,T];\mathcal{P}_1)$, i.e.* $\mathsf{d}_1\big(\mathrm{Law}(X^{(n)}_\cdot), \mathrm{Law}(X_\cdot)\big) \to 0$.

Proof. We use the *direct* (synchronous) *coupling*: drive $X^{(n)}$ and X by the *same* Brownian motion W, started from the *same* draw $X_0 \sim m_0$, so that the two processes differ only through their drifts. Both SDEs are well-posed: their drifts are bounded (by M) and Lipschitz in x, and σ is Lipschitz and nondegenerate, so theorem 5.10 gives unique strong solutions — boundedness of the drift removes any growth obstruction. Writing $D_t^{(n)} = X_t^{(n)} - X_t$ and subtracting the two integral equations,

$$D_t^{(n)} = \underbrace{\int_0^t \Big(b^{(n)}(s, X_s^{(n)}) - b(s, X_s)\Big)\,\mathrm{d}s}_{\text{drift gap}} \;+\; \underbrace{\int_0^t \Big(\sigma(X_s^{(n)}) - \sigma(X_s)\Big)\,\mathrm{d}W_s}_{\text{martingale}}. \tag{10.6}$$

The very form of the martingale term is the dividend of synchronous coupling, and it is worth dwelling on. Because both processes carry the *common* diffusion σ against the *common* Brownian motion, subtracting them leaves the single difference $\sigma(X_s^{(n)}) - \sigma(X_s)$, whose integrand is *small in the gap* — of order $\Lambda_\sigma |D_s^{(n)}|$ by the Lipschitz property of σ — and which therefore vanishes as the processes come together. Had we instead driven $X^{(n)}$ and X by *independent* Brownian motions, subtraction would have left two stochastic integrals against different noises that do *not* combine; their quadratic variation would be of order $\sigma\sigma^\top$, an $O(1)$ floor that no amount of drift closeness could erase, and the estimate below would be impossible. The synchronous coupling is precisely the device that makes the noise cancel down to a gap-controlled remainder; this is also exactly the device that *fails* in the relaxed setting of remark 10.12, where there is no common pathwise driver to couple against.

Now estimate. The drift gap is split by the standard *add-and-subtract* trick: insert and remove $b^{(n)}(s, X_s)$,

$$b^{(n)}(s, X_s^{(n)}) - b(s, X_s) = \underbrace{\big[b^{(n)}(s, X_s^{(n)}) - b^{(n)}(s, X_s)\big]}_{\text{self-improving: Lipschitz in the gap}} + \underbrace{\big[b^{(n)}(s, X_s) - b(s, X_s)\big]}_{\text{data: } b^{(n)}\to b \text{ along the fixed process } X},$$

which separates the part that can be folded back into $|D^{(n)}|$ from the part that measures how far the input drifts are from their limit. The first bracket is bounded by $\Lambda_b |D_s^{(n)}|$ using $\mathrm{Lip}_x b^{(n)} \le \Lambda_b$ (uniform in n); the second is the genuine forcing, evaluated along the *fixed* limit process X, and carries no $D^{(n)}$. Square the identity eq. (10.6), take the running supremum, and use $|a+b+c|^2 \le 3(|a|^2+|b|^2+|c|^2)$ to treat the three contributions separately. On the self-improving drift term, Cauchy–Schwarz in time gives $\big(\int_0^t \Lambda_b |D_s^{(n)}|\,\mathrm{d}s\big)^2 \le \Lambda_b^2\, t \int_0^t |D_s^{(n)}|^2\,\mathrm{d}s \le \Lambda_b^2\, T \int_0^t |D_s^{(n)}|^2\,\mathrm{d}s$; on the data term, the same Cauchy–Schwarz gives a factor T in front of $\int_0^T |b^{(n)}(s, X_s) - b(s, X_s)|^2\,\mathrm{d}s$; on the martingale term, the Burkholder–Davis–Gundy inequality (theorem C.3) replaces the supremum of the stochastic integral by its quadratic variation, $\mathbb{E}\sup_{r\le t} |\int_0^r (\sigma(X^{(n)}) - \sigma(X))\,\mathrm{d}W|^2 \le c_{\mathrm{BDG}}\, \mathbb{E}\int_0^t |\sigma(X_s^{(n)}) - \sigma(X_s)|^2\,\mathrm{d}s \le c_{\mathrm{BDG}}\,\Lambda_\sigma^2\, \mathbb{E}\int_0^t |D_s^{(n)}|^2\,\mathrm{d}s$ by the Lipschitz bound on σ. Collecting the three,

$$\mathbb{E}\sup_{r\le t} |D_r^{(n)}|^2 \;\le\; C\,\mathbb{E}\int_0^t |D_s^{(n)}|^2\,\mathrm{d}s \;+\; C\,\mathbb{E}\int_0^T \big|b^{(n)}(s, X_s) - b(s, X_s)\big|^2\,\mathrm{d}s,$$

where the single constant $C = C(\Lambda_b, \Lambda_\sigma, T) = 3\max\{\Lambda_b^2\, T + c_{\mathrm{BDG}}\Lambda_\sigma^2,\ T\}$ collects, transparently, the three sources: the factor 3 from the triple square, the term $\Lambda_b^2 T$ from the drift-Lipschitz constant and the Cauchy–Schwarz time factor, the term $c_{\mathrm{BDG}}\Lambda_\sigma^2$ from the universal BDG constant times the diffusion-Lipschitz constant, and the lone T from the data term. Crucially C depends only on the structural constants $\Lambda_b, \Lambda_\sigma$ and the horizon T — never on n — so the same constant governs every member of the sequence. Grönwall's inequality (lemma C.1) applied to $\phi(t) = \mathbb{E}\sup_{r\le t}|D_r^{(n)}|^2$, whose self-referential term is $C\int_0^t \phi$, then gives

$$\mathbb{E}\sup_{r\le T}|D_r^{(n)}|^2 \;\le\; C\,e^{CT}\,\varepsilon_n, \qquad \varepsilon_n \;:=\; \mathbb{E}\int_0^T \left|b^{(n)}(s,X_s) - b(s,X_s)\right|^2 \,\mathrm{d}s.$$

It remains to see that the forcing $\varepsilon_n \to 0$, and this is the one place the hypothesis $b^{(n)} \to b$ *locally uniformly* is used. Fix ω. The path $s \mapsto X_s(\omega)$ is continuous on $[0,T]$, so its image is a *compact* subset of $[0,T]\times\mathbb{R}^d$; local uniform convergence of $b^{(n)}$ to b is uniform on that compact image, whence $\sup_{s\le T}|b^{(n)}(s,X_s(\omega)) - b(s,X_s(\omega))| \to 0$, and in particular the integrand tends to 0 for every s and $\mathcal{P}()$-a.e. ω. The integrand is dominated, uniformly in n, by $(2M)^2$ — both drifts are bounded by M — which is an integrable majorant on the finite-measure space $[0,T]\times\Omega$. The dominated convergence theorem therefore yields $\varepsilon_n \to 0$. Finally, since the synchronous coupling realises both marginals on one probability space, it is an admissible coupling of $\mathrm{Law}(X_t^{(n)})$ and $\mathrm{Law}(X_t)$, so by the very definition of $\mathcal{W}_1$ together with Jensen,

$$\mathcal{W}_1\big(\mathrm{Law}(X_t^{(n)}), \mathrm{Law}(X_t)\big) \;\le\; \mathbb{E}\,|D_t^{(n)}| \;\le\; \Big(\mathbb{E}\sup_{r\le T}|D_r^{(n)}|^2\Big)^{1/2} \;\le\; \big(C\,e^{CT}\,\varepsilon_n\big)^{1/2}$$

uniformly in t. Taking the supremum over $t\in[0,T]$ shows $\mathsf{d}_1\big(\mathrm{Law}(X_\cdot^{(n)}), \mathrm{Law}(X_\cdot)\big) \le (C\,e^{CT}\varepsilon_n)^{1/2} \to 0$, which is the claimed d_1-convergence. □

The coupling argument just run leaned, decisively, on the drift being *Lipschitz* in x: that Lipschitz constant Λ_b is what made the add-and-subtract trick produce the self-improving term $C\,\mathbb{E}\int_0^t |D_s^{(n)}|^2\,\mathrm{d}s$ that Grönwall absorbs into exponential growth. Without it the first bracket of the drift gap could not be folded back into $|D^{(n)}|$, there would be no differential inequality to close, and the whole pathwise estimate would evaporate. This is the third and last of the three crutches the single-valued argument rests on — nondegeneracy for the HJB solve, strict convexity for the feedback, and now Lipschitz drift for the transport — and, like the other two, it is a luxury the rough case of section 10.4 cannot afford. There the optimal feedback is read off a value function that need not be differentiable, so the drift is at best bounded and measurable, never Lipschitz, and the synchronous coupling has nothing to contract. The device that replaces it is different in kind — it abandons the pathwise coupling altogether and argues stability at the level of *laws* — and we record it now, in its own right, because naming it here is what makes the structure of section 10.4 inevitable rather than ad hoc: that section is not a fresh start but precisely the substitution of this one tool for the one the present lemma used.

Remark 10.12 (The martingale-problem route, for the relaxed setting)**.** Suppose the limiting drift is only *bounded* and locally-uniformly approximated — not Lipschitz, so that eq. (10.6) no longer closes. The repair keeps the same goal, $\mathrm{Law}(X^{(n)}) \to \mathrm{Law}(X)$, but proves it without ever forming the pathwise difference $D^{(n)}$, through *martingale-problem stability*, in three moves that exactly mirror the compactness–uniqueness skeleton of lemma 10.10. *First* (compactness), the laws $\{\mathrm{Law}(X^{(n)})\}$ on path space $C([0,T];\mathbb{R}^d)$ are tight: the uniform drift and diffusion bounds give the Kolmogorov–Chentsov moment estimate theorem C.9 on increments, which is the path-space analogue of the equicontinuity that bought tightness in section 10.2, so Prokhorov supplies weakly convergent subsequences. *Second* (identification), every weak limit solves the martingale problem for the limiting generator — the defining martingales of the approximants pass to the limit because the test functions are smooth and the coefficients converge — so each subsequential limit is a solution of the limiting dynamics. *Third* (uniqueness), that martingale problem is *well-posed* (unique in law) under (A-Nondeg) by theorem C.21: nondegeneracy, the very hypothesis that bought regularity on the analytic side, here buys uniqueness in law on the probabilistic side. With all subsequential limits forced to coincide, the same "every subsequence has a further subsequence to the same limit" device used above promotes weak convergence of subsequences to convergence of the full sequence, and the time-marginals then converge in $\mathcal{W}_1$ via the uniform moment bound of lemma 10.6. This is not an optional alternative proof of the present lemma; it is the *only* route available once the feedback ceases to be Lipschitz, and it is the engine that section 10.4 will run — in its controlled, set-valued form, where the drift is replaced by a relaxed control and the martingale problem becomes a controlled martingale problem — which is exactly why we develop the controlled version in appendix C.13. The reader should therefore read this remark not as a digression but as the advertisement for section 10.4: it isolates the single mechanism that must change, and shows that everything else — compactness, identify the limit, uniqueness upgrades subsequences to the whole sequence — is structurally identical to the argument just completed.

All three arrows are now established: the HJB solve is stable (lemma 10.10), the feedback substitution is continuous under strict convexity, and the closed-loop transport is stable (lemma 10.11). Concatenating them costs nothing further — the work was in the links. The proposition below simply chases a convergent sequence of profiles through the chain, arrow by arrow, and reads off that the outputs converge in d_1; it is the bookkeeping that joins the three stability statements into the one continuity statement Schauder demands.

Proposition 10.13 (Continuity of the best-response map)**.** *Under the standing hypotheses (A-Lip), (A-Growth), (A-Nondeg), (A-Conv), the boundedness and continuity of the couplings F, G assumed in lemmas 10.5 and 10.10, and strict convexity of $H(x,\cdot)$ (so that the feedback eq.* (10.4) *is single-valued and continuous in ∇u), the map $\mathsf{S} : \mathcal{K} \to \mathcal{K}$ is continuous.*

Proof. Continuity is sequential continuity on the metric space $(\mathcal{K}, \mathsf{d}_1)$, so let $m^{(n)} \to m$ in $\mathcal{K}$ and chase the convergence along the three arrows of the chain.

First arrow. By lemma 10.10 — whose hypotheses are exactly items (A-Lip)–(A-Conv) together with the boundedness and weak-continuity of F, G assumed here — $u^{m^{(n)}} \to u^m$ and, what we actually use, $\nabla u^{m^{(n)}} \to \nabla u^m$ locally uniformly on $[0,T] \times \mathbb{R}^d$.

Middle arrow. Strict convexity of $H(x,\cdot)$ makes $p \mapsto \partial_p H(x,p)$ a single-valued continuous function (the unique maximiser of eq. (10.5)), so composing the locally uniformly convergent gradients with it preserves local uniform convergence: the drifts $b^{(n)} = -\partial_p H(\cdot, \nabla u^{m^{(n)}})$ converge locally uniformly to $b = -\partial_p H(\cdot, \nabla u^m)$. Two uniform bounds ride along, and the third arrow needs both: first, $\|b^{(n)}\|_\infty \le M$ for every n by assumption 10.4 (the gradients sit inside the ball $|p| \le L_u$ on which $\partial_p H$ is bounded by M); second, the interior Schauder estimate theorem E.19 bounds $\{u^{m^{(n)}}\}$ in

$C^{1,2}$ uniformly in n, so each $\nabla u^{m^{(n)}}$, and hence each $b^{(n)}$, is Lipschitz in x with one constant Λ_b uniform in n and t.

Third arrow. The drifts $b^{(n)}, b$ are thus bounded by M, Lipschitz in x with the common constant Λ_b, locally uniformly convergent, and paired with the nondegenerate Lipschitz diffusion σ and the common initial law m_0 — precisely the hypotheses of lemma 10.11. That lemma delivers $\mathsf{S}(m^{(n)}) = \mathrm{Law}(X^{(n)}_\cdot) \to \mathrm{Law}(X_\cdot) = \mathsf{S}(m)$ in d_1. Since $\mathsf{S}(m^{(n)}) \to \mathsf{S}(m)$ for every d_1-convergent input sequence, S is continuous on $\mathcal{K}$. $\square$

This is the deliverable of the section. The best-response map S, restricted to the compact convex set $\mathcal{K}$ that section 10.2 carved out, is a continuous self-map in the order-one metric d_1 — proved by factoring it into the three arrows of definition 10.3 and showing each stable, with (A-Nondeg) consumed once at the HJB solve and once more in the comparison principle, strict convexity consumed once at the feedback, and the Lipschitz drift consumed once at the transport. The compactness of the arena was the first of Schauder's two demands and was settled in section 10.2; the continuity just proved is the second. With both now in hand, nothing stands between us and a fixed point but the act of quoting Schauder's theorem — which is exactly what the next subsection does.

10.3.2 The existence theorem

The previous subsection handed us the last missing ingredient. Factoring S into its three constituent arrows and proving each link stable, proposition 10.13 established that S, restricted to the compact convex set $\mathcal{K}$, is *continuous* in the order-one metric d_1. That was the second of Schauder's two demands; the first — a nonempty convex compact invariant arena $\mathcal{K}$ with $\mathsf{S}(\mathcal{K}) \subseteq \mathcal{K}$ — was carved out of $\mathcal{M}$ back in section 10.2. The two demands now hold *simultaneously, on the very same set*, and each was paid for at one of the two places (A-Nondeg) was spent: the moment-and-equicontinuity construction that made $\mathcal{K}$ compact, and the parabolic stability of the HJB solve that made S continuous. The fixed-point theorem of chapter 2 exists precisely to convert "compact convex domain" plus "continuous self-map" into "has a fixed point," so the mathematical work is behind us; what remains is to quote the theorem correctly and then read off what its fixed point *means.*

"Quote it correctly" hides one genuine wrinkle, and it is the only new labour in this subsection. Schauder's theorem as stated and proved in chapter 2 lives on a *Banach space*: its proof runs by finite-dimensional projection followed by Brouwer's theorem, and both of those steps need the linear and the normed structure of a vector space. But $\mathcal{M} = C([0,T]; \mathcal{P}_1(\mathbb{R}^d))$ is a space of *measure-valued curves*, and a probability measure is not, on its face, an element of any vector space — one cannot add two probability measures and stay a probability measure. Before Schauder can act we must therefore exhibit $\mathcal{M}$ as a compact convex subset *of an honest Banach space*, in a way that does not disturb the d_1-topology in which compactness and continuity were proved. That realisation, through the Kantorovich–Rubinstein normed space of signed measures, is the one technical move in the proof below; once it is in place the theorem drops out. We state the existence theorem, prove it by this route, and then spend the rest of the subsection being honest about what it delivers — in particular that it asserts existence with *no* uniqueness, and that through the two-pictures dictionary it is verbatim the existence statement promised on the probabilistic side in chapter 9.

Theorem 10.14 (Existence of MFG equilibria, regularising couplings)**.** *Assume:*

(i) *(A-Lip), (A-Growth), (A-Nondeg), (A-Conv), with $H(x,\cdot)$ strictly convex and C^1, and $\partial_p H$ of at most linear growth in p;*

(ii) *the couplings F, G are bounded, uniformly Lipschitz in x uniformly in the measure argument, and continuous for weak convergence of second-moment-bounded measures (as in lemma 10.10);*

(iii) $m_0 \in \mathcal{P}_2(\mathbb{R}^d)$.

Then the best-response map S has a fixed point $m^\star \in \mathcal{K}$. Equivalently, the MFG system eq. (10.2)–eq. (10.3) admits a solution $(u^\star, m^\star)$ with $m^\star \in C([0,T]; \mathcal{P}_2(\mathbb{R}^d))$, $u^\star$ Lipschitz in x uniformly in t, and $m^\star$ uniformly $\frac{1}{2}$-Hölder in time for $\mathcal{W}_1$.

Proof. The two hypotheses Schauder consumes are already proved. By lemma 10.8, $\mathcal{K}$ is a nonempty convex compact subset of the metric space $(\mathcal{M}, \mathsf{d}_1)$, and $\mathsf{S}(\mathcal{K}) \subseteq \mathcal{K}$; by proposition 10.13, $\mathsf{S}\big|_{\mathcal{K}}$ is continuous in d_1. Everything below is the single act of placing these facts in a form Schauder accepts.

Realising $\mathcal{K}$ inside a Banach space. As flagged above, $\mathcal{P}_1(\mathbb{R}^d)$ is not a vector space, so we must first locate it inside one. Enlarge it to the real vector space of finite signed Borel measures of finite first moment; this is a genuine linear space — signed measures add and scale freely — and $\mathcal{P}_1(\mathbb{R}^d)$ sits inside it as a *convex* subset, since a convex combination $\theta\mu + (1-\theta)\nu$ of probability measures is again a probability measure, and a difference $\mu - \nu$ of two of them is a signed measure of total mass zero. Norm this vector space by the dual-bounded-Lipschitz (Kantorovich–Rubinstein) norm

$$\|\nu\|_{\mathrm{KR}} = \sup\Big\{ \textstyle\int \phi \, \mathrm{d}\nu : \ \mathrm{Lip}(\phi) \le 1, \ \|\phi\|_\infty \le 1 \Big\},$$

and write $(\mathcal{M}_{\mathrm{KR}}, \|\cdot\|_{\mathrm{KR}})$ for the resulting normed (Banach, after completion) space (theorem D.10). The point of this particular norm is that it reproduces the transport geometry we have been working in. By Kantorovich–Rubinstein duality, $\mathcal{W}_1(\mu,\nu) = \sup\{\int \phi \, \mathrm{d}(\mu-\nu) : \mathrm{Lip}(\phi) \le 1\}$, the same supremum but without the sup-norm cap on the test function. Because the both-caps test class is the smaller of the two, one has the one-sided bound $\|\mu - \nu\|_{\mathrm{KR}} \le \mathcal{W}_1(\mu,\nu)$ for all μ, ν, so $\|\cdot\|_{\mathrm{KR}}$ is in general *not* equal to $\mathcal{W}_1$ but the (weaker) dual-bounded-Lipschitz distance, which metrises weak convergence. On the second-moment-bounded, tight set $\mathcal{K}$, however, $\mathcal{W}_1$ *also* metrises weak convergence (theorem D.11), so the additional cap is immaterial for the *topology* it induces: the two distances are equivalent there, and $\mathcal{P}_1(\mathbb{R}^d)$ embeds into $\mathcal{M}_{\mathrm{KR}}$ as a homeomorphism onto its image, with $\mathcal{W}_1$-convergence on a second-moment-bounded set coinciding with $\|\cdot\|_{\mathrm{KR}}$-convergence. Lifting from measures to curves, $\mathcal{M} = C([0,T]; \mathcal{P}_1)$ embeds in the Banach space $C([0,T]; \mathcal{M}_{\mathrm{KR}})$ under the uniform-in-time norm, whose induced topology agrees on $\mathcal{K}$ with that of the order-one metric d_1 of definition 10.1. Under this embedding the set $\mathcal{K}$ keeps both properties verbatim: it is *convex* because convexity is an affine notion preserved by the linear embedding (a convex combination of flows is computed time-slice by time-slice and stays in $\mathcal{K}$ by lemma 10.8), and it is *compact* because

d_1-compactness is a topological notion and the embedding is a homeomorphism onto its image. The gain from doing the bookkeeping this way is concrete: because $\mathcal{K}$ now lives in a *normed* space, we may invoke the clean compact-convex Schauder theorem theorem 2.38 *as stated*, without reaching for its locally convex (Tychonoff–Schauder) generalisation — the version one is forced into when the only available ambient structure is the weak topology on measures, which is locally convex but not normable. Here the Kantorovich–Rubinstein norm hands us normability for free, so the lighter theorem suffices.

Applying Schauder. The ambient space $C([0,T];\mathcal{M}_{\mathrm{KR}})$ is Banach, $\mathcal{K}$ is a compact convex subset of it, and $\mathsf{S}:\mathcal{K}\to\mathcal{K}$ is a continuous self-map. These are exactly the hypotheses of theorem 2.38, which therefore applies directly and produces a point $m^\star\in\mathcal{K}$ with $\mathsf{S}(m^\star)=m^\star$.

Unwinding the fixed point into a solution of the MFG system. A fixed point of S is more than an abstract certificate; spelled out through definition 10.3 it *is* a solution of the coupled HJB–FP system, and it is worth tracing the implication slot by slot. Recall that $\mathsf{S}(m)$ was built by freezing the population inside the couplings, solving the resulting decoupled HJB equation for a value u^m, reading off the optimal feedback, and transporting m_0 forward under it. Set $u^\star := u^{m^\star}$. By construction $u^\star$ solves the HJB equation eq. (10.2) whose source and terminal data are $F[m_t^\star]$ and $G[m_T^\star]$ — but because $m^\star$ is the *fixed* flow, those frozen couplings are no longer a provisional guess: they are the genuine equilibrium couplings, so $u^\star$ solves the full, self-referential HJB equation of the MFG system, not merely a decoupled surrogate. The optimal feedback $\alpha^{*,\star}=-\partial_p H(\cdot,\nabla u^\star)$ it generates drives the closed-loop SDE eq. (10.1), whose time-marginals are by definition $\mathsf{S}(m^\star)$. The fixed-point equation $\mathsf{S}(m^\star)=m^\star$ says precisely that those time-marginals *are* $m^\star$ itself, so $m^\star$ is the law of the optimally controlled state and hence solves the Fokker–Planck equation eq. (10.3) with the drift generated by $u^\star$ and initial datum m_0. The two equations, deliberately decoupled throughout the construction by the freezing device, are thus *re-coupled exactly at the fixed point*: the flow used to compute the value equals the flow the value's optimal response generates. That re-coupling is the self-consistency condition the chapter set out to solve, and $(u^\star,m^\star)$ is an MFG equilibrium in the sense of definition 10.3.

Regularity of the solution. The asserted regularity is inherited from the two constructions the fixed point was extracted from. That $m^\star\in C([0,T];\mathcal{P}_2(\mathbb{R}^d))$ with a uniform $\frac{1}{2}$-Hölder modulus in time for $\mathcal{W}_1$ is the membership in $\mathcal{K}$, whose defining moment and equicontinuity bounds are lemmas 10.6 and 10.7; that $u^\star$ is Lipschitz in x uniformly in t is the gradient ceiling $\|\nabla u^{m^\star}\|_\infty\le L_u$ of lemma 10.5, which held uniformly over *every* frozen flow and so in particular at $m^\star$. ☐

Remark 10.15 (What the theorem buys, and what it costs)**.** Every fixed-point existence theorem is a bargain, and it pays to read the price tag. The cost of theorem 10.14 is concentrated in hypothesis (ii): the couplings F,G must be *bounded and smoothing*. This is no idle technical convenience — it is exactly the property that made the gradient ceiling lemma 10.5 uniform over all frozen flows m, and that uniform ceiling was the seed of everything downstream (the moment and equicontinuity bounds defining $\mathcal{K}$, and the uniform $C^{1,2}$ estimate underwriting continuity). A coupling whose value or gradient could blow up as the population concentrates would break that ceiling at the source and the whole construction with it. The class that qualifies is the *nonlocal/regularising* one, and it is worth keeping three concrete admissible templates in view. *(a) Convolution couplings,* $F[m](x)=(\phi*m)(x)=\int\phi(x-y)\,m(\mathrm{d}y)$ with a bounded, Lipschitz kernel ϕ: the convolution smooths the measure into a function whose sup norm and Lipschitz constant are controlled by ϕ alone, uniformly in m, no matter how singular m becomes. *(b) Scalar-moment couplings,* $F[m](x) = f(x, \int \eta \, \mathrm{d}m)$ with η bounded and f bounded and Lipschitz: here the population enters only through a finite-dimensional bounded statistic $\int \eta \, \mathrm{d}m$, so F inherits f's boundedness and regularity directly. *(c) Mollified local couplings,* $F[m](x) = f(x, (\rho_\varepsilon * m)(x))$ with f bounded Lipschitz and ρ_ε a fixed mollifier — a regularised stand-in for the genuinely local cost $f(x, m(x))$ that depends on the pointwise density, which is itself *not* admissible because $m \mapsto m(x)$ is neither bounded nor weakly continuous. What the theorem *buys* in exchange is substantial: a classical-in-x, Lipschitz value function $u^\star$ and a time-continuous equilibrium flow $m^\star$, obtained with *no monotonicity hypothesis whatsoever* on the couplings. The silence on monotonicity is the honest cost on the other side of the ledger: with no (A-Mon) in force the theorem claims existence and *only* existence, and the equilibrium it produces may be one of several. This is the standard division of labour in the analytic MFG literature [93, 36]: nondegeneracy plus bounded smoothing couplings $\Rightarrow$ existence by Schauder, here; monotonicity (A-Mon) $\Rightarrow$ uniqueness, separately, in chapter 11. The two relaxations the theorem still owes both trace to a hypothesis it could not drop — (ii)'s boundedness and (i)'s strict convexity — and each is bought back elsewhere: *unbounded data* costs the compactness construction and is recovered by linear structure for the LQG thread in section 10.5, while *non-unique feedback* costs single-valuedness and is recovered by set-valued fixed-point theory in section 10.4.

Remark 10.16 (The probabilistic route gives the same conclusion)**.** The fixed point can equally be sought on flows directly in the FBSDE picture of chapter 9: freeze m, solve the McKean–Vlasov-decoupled forward–backward system for (X^m, Y^m, Z^m), and set $\mathsf{S}(m) = \mathrm{Law}(X^m_\cdot)$. Schauder applies verbatim once the same compactness (tightness of $\{\mathrm{Law}(X^m_\cdot)\}$) and continuity (stability of FBSDE solutions in the frozen flow) are in hand; this is the route of [40, Ch. 3–4, Vol. I]. We do not need to re-run the fixed point in the probabilistic picture, however: the FBSDE–PDE dictionary proposition 9.12 identifies the law of the closed-loop state computed from (X^m, Y^m, Z^m) with the law computed from the HJB value u^m, so the equilibrium flow $m^\star$ produced above *is* a solution of the McKean–Vlasov FBSDE of chapter 9, and conversely. This is exactly what theorem 9.10(iii) promises when it calls the Schauder fixed point "the existence theorem of chapter 10": the PDE and probabilistic existence proofs are two coordinatisations of the one Schauder argument, transported across the dictionary, mirroring the "two pictures" theme of chapter 9.

This completes the single-valued existence story, and before moving on it is worth tallying exactly what it leaned on — because the two sections that follow are each defined precisely by one support this argument could not do without. The Schauder argument just assembled rested on three crutches, each entering at an identifiable point above. *Single-valued feedback*: the optimal-feedback formula eq. (10.4) had to name one drift, not a set, for S to be a genuine map rather than a correspondence and for Schauder even to have an object to act on. *Strict convexity* of $H(x, \cdot)$: this is what made the middle arrow of the factorization continuous, rendering the Legendre maximiser a single continuous function of momentum. *Lipschitz drift*: this is what powered the synchronous-coupling proof of lemma 10.11, supplying the self-improving Grönwall estimate that delivered transport stability. Above these three sat a fourth hypothesis, hidden in plain sight in (ii) and flagged in remark 10.15: the *boundedness* of the data, without which the gradient ceiling — and hence the entire compactness arena $\mathcal{K}$ — never gets off the ground.

Two of the chapter's promised relaxations are therefore now precisely owed, and we name both so that each later section arrives pre-motivated rather than as a fresh start. The first is *unbounded data*. The LQG thread carried throughout the book has linear-quadratic costs whose data grow without bound in the state, so it violates hypothesis (ii) outright and falls outside theorem 10.14 entirely — the compactness construction simply does not apply to it. Section 10.5 shows that this is no obstruction in disguise: the very linearity that breaks boundedness collapses the fixed-point problem to a finite-dimensional two-point linear system with a sharper existence-and-uniqueness statement, recovering existence by structure where the abstract theorem could not reach. The second is *non-unique feedback*. When the first three crutches fail together — a merely convex Hamiltonian with a flat maximiser set, a non-convex action set whose optimiser wants to mix, or a degenerate diffusion whose value is only a viscosity solution with no pointwise gradient — the formula eq. (10.4) returns a *set* of optimal drifts and S ceases to be a map at all. Section 10.4 confronts exactly this case and shows that an equilibrium survives nonetheless, at the price of relaxing controls, replacing the single-valued S by a set-valued best response settled by the Kakutani–Fan–Glicksberg theorem in place of Schauder, and recovering an honest, executable feedback after the fact by measurable selection. The next section takes up the second of these; the LQG counterpoint waits for section 10.5.

10.4 Relaxed equilibria and measurable selection

The previous section closed by tallying the three crutches the Schauder argument leaned on and naming the two relaxations it still owed; this section discharges the second of them. The route of sections 10.2 and 10.3 delivered an equilibrium only in the favourable regime where the best-response map S is a genuine single-valued, continuous self-map of $\mathcal{M}$ — the regime in which a nondegenerate diffusion (A-Nondeg) and a *strictly* convex Hamiltonian (the strong form of (A-Conv)) cooperate to make the optimal-feedback formula eq. (10.4) name exactly one drift for each (t, x). That is the smooth side of the single-valued/set-valued dichotomy posed in section 10.1. We now cross to the rough side. We drop the two supports that the existence theorem flagged as removable — *single-valuedness* of the feedback and the *strict convexity* of H that guaranteed it — and ask what survives when S is no longer a map at all but a *correspondence*, returning a whole set of optimal drifts for each (t, x) in place of a single one.

It helps first to see that the three distinct ways single-valuedness failed, catalogued in the "two regimes" analysis of section 10.1, are at bottom one obstruction. The three mechanisms there were a merely convex Hamiltonian whose argmax in eq. (10.5) is a flat segment rather than a point; a non-convex action set A on which the optimiser is stranded strictly between two admissible drifts; and a degenerate diffusion that, with (A-Nondeg) abandoned, leaves u a viscosity solution with no classical gradient to feed eq. (10.4). Different as the three pictures look, they share a single geometric root: the set of *attainable* instantaneous dynamics — the drifts an agent can actually produce, weighed against their cost — need not be convex, and over a non-convex attainable set the cost-optimal velocity can be one that no single admissible action realises. When that happens no deterministic feedback is optimal, and the Schauder construction, which presupposed exactly one closed-loop SDE to transport the population forward, has nothing to transport. The maximiser set in eq. (10.4) fails to be a singleton not by accident but because the underlying optimisation has genuinely no pure solution.

This is not a new pathology peculiar to mean field games; it is the oldest difficulty in game theory, and it has a classical cure, which we carry as the motivation for everything below. A finite game can fail to possess a *pure*-strategy Nash equilibrium for exactly this reason — matching pennies is the textbook witness: against any deterministic choice the opponent has a strict deterministic counter, so the pure best-response correspondence jumps from one extreme to the other and closes on nothing, and no pure profile is left fixed. Von Neumann's resolution, the founding move of the subject, was to *enlarge the strategy space*: permit each player a *mixed* strategy, a probability distribution over actions rather than one action. Mixing convexifies. Recomputed over distributions of actions, the attainable payoffs fill out the convex hull of the pure ones; the best-response correspondence acquires nonempty convex closed values and an upper-semicontinuous graph; and a fixed point reappears — which is precisely the structure Nash fed to Kakutani's theorem to prove that every finite game has an equilibrium in mixed strategies. The relaxation we are about to perform is this very move, transplanted to a continuous-time control problem. The mean field analogue of a mixed strategy is a *relaxed control*: at each instant the agent plays not a single action but a probability measure over actions, and the state is driven by the resulting *averaged* drift. Averaging *is* convexification; it returns to the attainable dynamics exactly the convexity that the non-convex modes destroyed, and with it an optimiser and the upper-semicontinuity that a fixed-point theorem demands. The slogan to carry through the section is that *relaxed controls are to a mean field game what von Neumann's mixed strategies are to a finite one.*

With that motivation fixed, the section proceeds in three movements, and it is worth saying in advance which failure mode each repairs, since the two devices are not interchangeable. The first subsection performs the von Neumann move itself: it defines relaxed (Young-measure) controls and the associated notion of a *weak*, or relaxed, equilibrium, carried — in the path-space style of chapter 9 — as a single law on trajectory-and-control space rather than as a deterministic flow paired with a feedback. The convexity that randomisation buys is, crucially, visible only one level up: it is manifest on the *joint* law of state and control, where mixing two candidate equilibria is literally averaging two measures, and *not* on the state-marginal flow alone, on which the law of the controlled path is not an affine image of the control. That is why the fixed point must migrate off the flow m and onto the joint law Q — the business of the second subsection, which erects the set-valued best response on joint laws and settles its fixed point with the Kakutani–Fan–Glicksberg theorem (theorem 2.40) in place of Schauder, through its three checks: nonempty convex values, closed graph, and a convex compact domain. Relaxation is what cures the genuinely non-convex modes, where it manufactures an optimiser that did not exist before. It does *not*, by itself, return the deterministic feedback an agent must ultimately execute, nor does it resolve the residual indifference of the flat-maximiser mode, where the optimiser set was already convex and nonempty and the only difficulty was *choosing* one element of it. Both of those are the task of the third subsection: a *measurable selection* plucks a single optimiser from the maximiser set at each (t, x), coherently enough across (t, x) to define a genuine feedback, by the classical selection theorems (theorem B.29). Selection without relaxation disposes of a flat maximiser set; relaxation without selection convexifies but does not yet execute; only together do they close the dichotomy that has organised the whole chapter.

At the end of these three movements the abstract existence theory is complete along both of the branches it was ever going to need for *bounded* data: Schauder for the smooth, single-valued regime of theorem 10.14, and Kakutani for the rough, set-valued regime of theorem 10.19, with an honest feedback recovered in either case. The one kind of game that escapes both branches is one whose data are *unbounded*, for then the compactness arena itself never gets built — and that is exactly the carried LQG thread, which section 10.5 will show slips out of the entire compactness apparatus only to be caught, far more tightly, by its own linear structure. We begin with the cure itself.

10.4.1 Relaxed controls and weak equilibria

Before the formalism, the picture — recalled in one line from the section opening: over a non-convex attainable set the optimiser "wants to sit between two actions," and von Neumann's cure is to let the agent *randomise*, playing a probability distribution over actions rather than a single action. The averaged dynamics then range over the *convex hull* of the pure drifts, the value function becomes upper-semicontinuous, and an optimiser exists. A randomisation rule, time-indexed, is exactly a measure on $[0,T] \times A$ projecting to Lebesgue measure in time — a *relaxed control.* With this motivation we state the definition.

Definition 10.17 (Relaxed control and relaxed feedback)**.** A *relaxed (open-loop) control* on the action set $A \subseteq \mathbb{R}^k$ is a measure ρ on $[0,T] \times A$ whose time-marginal is Lebesgue measure, i.e. $\rho(\mathrm{d}t, \mathrm{d}a) = \rho_t(\mathrm{d}a)\ \mathrm{d}t$ with each $\rho_t \in \mathcal{P}(A)$. A *relaxed feedback* is a measurable map $(t,x) \mapsto \rho_{t,x} \in \mathcal{P}(A)$. The relaxed state dynamics replace the drift $b(x,a)$ by its average $\bar{b}(t,x) = \int_A b(x,a)\, \rho_{t,x}(\mathrm{d}a)$ and the running cost likewise.

One subtlety deserves emphasis, lest relaxation seem to change the problem: under (A-Nondeg) and convexity (A-Conv) the relaxed and strict problems have the *same* value and the same optimal feedback (no genuine randomisation is needed — a Dirac relaxed control $\rho_{t,x} = \delta_{\alpha^*(t,x)}$ is optimal), so relaxation changes nothing in the regime of theorem 10.14 and only buys generality where that theorem does not apply — precisely the merely-convex or degenerate case at hand.

Definition 10.18 (Weak / relaxed MFG equilibrium)**.** A *weak MFG equilibrium* is a probability measure P on the canonical path-and-control space $\Omega = C([0,T];\mathbb{R}^d) \times \{\text{relaxed controls}\}$ such that, writing $m_t = P \circ (X_t)^{-1}$ for its state time-marginals:

(a) *Consistency:* under P the canonical process solves the controlled martingale problem associated with eq. (10.1) driven by the relaxed control, with $X_0 \sim m_0$;

(b) *Optimality:* P-almost every realisation of the control is optimal for the cost functional in which the population is frozen to the flow $(m_t)_t$ that P itself generates.

Definition 10.18 is the path-space formulation of equilibrium owned conceptually by chapter 9: instead of a deterministic flow m and a feedback, one carries a single law P on trajectories, and the self-consistency is that the population flow read off P is the very flow against which P is optimal. It subsumes definition 10.3: a strong equilibrium $(u^\star, m^\star)$ induces a weak equilibrium

$P^\star = \mathrm{Law}(X^\star_\cdot, \delta_{\alpha^*})$. The advantage is that weak equilibria exist under dramatically weaker hypotheses, because the fixed point is now sought for a set-valued map on a space of *laws*, where Kakutani's machinery is available.

10.4.2 The set-valued best response and Kakutani–Fan–Glicksberg

The correct ambient object for the set-valued fixed point is *not* the flow m but the *joint law* of state and relaxed control, because it is on joint laws — not on their state-marginals — that convexity is manifest (one literally mixes the measures). Let $\mathcal{Q}$ be the set of probability measures Q on the path-and-control space $\Omega = C([0,T];\mathbb{R}^d) \times \mathcal{R}$, where $\mathcal{R}$ is the (compact, metrisable) space of relaxed controls of definition 10.17, such that: Q has time-marginal flow $m^Q_t = Q \circ X_t^{-1}$ lying in the convex compact set $\mathcal{P}_{\mathrm{e}}$ of flows built as in lemma 10.8 (or, on a compact state space such as the torus $\mathbb{T}^d$, automatically), $Q \circ X_0^{-1} = m_0$, and under Q the canonical process solves the controlled martingale problem of definition 10.18(a). The set $\mathcal{Q}$ is convex and compact for the topology of weak convergence (the constraints — moment bounds, fixed initial law, the martingale-problem identity — are all convex and closed). Define the *set-valued best response* on $\mathcal{Q}$,

$$R(Q) \;=\; \Big\{ P \in \mathcal{Q} \;:\; P \text{ is relaxed-optimal against the frozen flow } m^Q \Big\} \subseteq \mathcal{Q}, \tag{10.7}$$

i.e. $P \in R(Q)$ iff the control marginal of P is, P-a.s., optimal for the cost in which the population is frozen to m^Q (and P solves the same martingale problem). A fixed point $Q^\star \in R(Q^\star)$ is a Q that is optimal against its own flow $m^{Q^\star}$ — exactly a weak MFG equilibrium (definition 10.18), whose equilibrium flow is the state-marginal $m^\star = m^{Q^\star}$.

The fixed-point theorem for correspondences is the Kakutani–Fan–Glicksberg theorem, which the book proves in theorem 2.40: *a correspondence $\Psi : \mathcal{C} \rightrightarrows \mathcal{C}$ on a nonempty convex compact subset $\mathcal{C}$ of a locally convex Hausdorff space, with nonempty convex closed values and closed graph, has a fixed point.* (The weak topology on $\mathcal{Q}$ is not normable, so the genuinely locally convex version proved there — not merely the Banach Schauder of theorem 2.38 — is what is needed here.)

Theorem 10.19 (Existence of weak MFG equilibria)**.** *Assume (A-Lip), (A-Growth) and (A-Nondeg), that the action set A is compact (or that coercivity (A-Growth) confines optimal relaxed controls to a compact set), that the drift, volatility and running/terminal costs are continuous in (x, a, m) with the cost convex in the relaxed sense, and that the couplings are continuous for weak convergence. Then the correspondence R of eq.* (10.7) *satisfies the hypotheses of theorem 2.40, and hence the game admits a weak MFG equilibrium in the sense of definition 10.18.*

Proof. Three claims must be checked for R on the convex compact set $\mathcal{Q}$; each is a named in-book result, applied to the controlled martingale problem. *(1) Nonempty values.* For each frozen Q (hence frozen flow m^Q) the relaxed control problem attains its optimum: by theorem C.22 the relaxed admissible set is compact in the Young-measure topology and the relaxed cost is lower semicontinuous, so a minimiser exists, and lifting it to a joint law gives a nonempty $R(Q) \subseteq \mathcal{Q}$. *(2) Convex values.* If $P_0, P_1 \in R(Q)$ and $\theta \in [0,1]$, the mixture $P_\theta = \theta P_0 + (1-\theta)P_1$ is again a probability measure on Ω; it solves the same (linear-in-P) martingale-problem identity, lies in $\mathcal{Q}$, and has cost

$\theta\,\mathrm{cost}(P_0) + (1-\theta)\,\mathrm{cost}(P_1)$, which equals the common optimal value, so $P_\theta \in R(Q)$. Convexity holds *because we mix the joint laws*: it is precisely to make this step legitimate that the fixed point is run on $\mathcal{Q}$ rather than on the state-marginal flows, on which $\mathrm{Law}(X_\cdot)$ is not an affine image of the control. *(3) Closed graph.* If $Q^{(n)} \to Q$ and $P^{(n)} \in R(Q^{(n)})$ with $P^{(n)} \to P$, then by stability of the controlled martingale problem (theorem C.23; the limit solves the martingale problem for the limiting frozen flow, using (A-Nondeg) for well-posedness and the assumed continuity of coefficients and couplings) the limit P is admissible, and by Berge's maximum theorem (theorem B.27; upper semicontinuity of the value and closedness of the arg min correspondence under the continuous data) P is optimal against m^Q, so $P \in R(Q)$. Compactness of $\mathcal{Q}$ was noted above (or follows from compactness of the state space). Theorem 2.40 then provides $Q^\star \in R(Q^\star)$, a weak equilibrium with flow $m^\star = m^{Q^\star}$. The controlled-martingale-problem framework and its Young-measure inputs are developed in appendix C.13; this is the route of Lacker [88] and [40, Ch. 3, Vol. I]. □

10.4.3 From a weak equilibrium back to a feedback: measurable selection

Theorem 10.19 produces a law $P^\star$, possibly carrying a genuinely randomised control. For applications one wants a *feedback* — a function $(t,x) \mapsto \alpha^*(t,x)$ that an agent can actually execute. When is the relaxed equilibrium realisable as a (Markov, deterministic) feedback? The obstruction is exactly the non-uniqueness of the maximiser in eq. (10.4): the optimiser correspondence

$$(t,x) \;\longmapsto\; A^\star(t,x) \;=\; \operatorname*{arg\,max}_{a\in A} \big\{ -\langle b(x,a), p^\star(t,x)\rangle - L(x,a,m_t^\star)\big\}, \qquad p^\star = \nabla u^\star,$$

may be a set, not a point. The maximand here is exactly the integrand whose supremum *defines* the Hamiltonian: with $H(x,p,m) = \sup_{a\in A}\{-\langle b(x,a),p\rangle - L(x,a,m)\}$ the Legendre–Fenchel transform introduced in section 10.1, $A^\star(t,x)$ is the set of maximisers attaining $H(x,p^\star,m_t^\star)$, and when $H(x,\cdot)$ is strictly convex this set collapses to the singleton $\{-\partial_p H\}$, recovering the single-valued feedback α^* of eq. (10.4). In the rough case one must choose one element of $A^\star(t,x)$ for each (t,x), *measurably*. This is a selection problem, and it is solved by the classical selection theorems.

Lemma 10.20 (Measurable selection of the optimal feedback)**.** *Suppose A is a Polish space, the map $(t,x) \mapsto A^\star(t,x)$ has nonempty closed values, and it is measurable in the sense that $\{(t,x) : A^\star(t,x) \cap U \neq \emptyset\}$ is measurable for every open $U \subseteq A$ (a consequence of continuity of $(t,x,a) \mapsto$ the maximand and measurability of $p^\star = \nabla u^\star$). Then $A^\star$ admits a measurable selection: there is a measurable $\alpha^* : [0,T]\times\mathbb{R}^d \to A$ with $\alpha^*(t,x) \in A^\star(t,x)$ for all (t,x).*

Proof. This is an instance of the Kuratowski–Ryll-Nardzewski selection theorem (theorem B.29): a measurable correspondence with nonempty closed values into a Polish space admits a measurable selection. Its hypotheses are met here because the maximand is jointly continuous in a and Carathéodory-measurable in (t,x) through $p^\star(t,x) = \nabla u^\star(t,x)$, so $A^\star$ is a closed-valued measurable multifunction. (When $A \subseteq \mathbb{R}^k$ and the maximand is continuous, one does not even need the general theorem: the explicit *lexicographic* selection "take the optimiser of smallest first coordinate, then smallest second, . . . " is itself measurable — the elementary Filippov selection of control theory — and we give that self-contained argument in theorem B.29's proof as the Euclidean special case.) □

Remark 10.21 (The role of nondegeneracy, restated)**.** Under (A-Nondeg) *and* strict convexity (A-Conv), $A^\star(t,x)$ is a singleton for a.e. (t,x): the value function is once differentiable in x (parabolic regularity) and the strictly convex Hamiltonian has a unique maximiser, so the selection problem is vacuous and the feedback eq. (10.4) is already a function. Selection theory is needed exactly when one of these two is dropped — degenerate diffusion (only viscosity u, gradient may not exist classically) or non-strictly-convex H (flat maximiser set). The chapter's two halves are thus the two sides of a single dichotomy: *nondegenerate + strictly convex* gives a continuous single-valued S and Schauder (theorem 10.14); *neither* gives an upper-hemicontinuous set-valued S, Kakutani, and a measurably selected feedback (theorem 10.19 and lemma 10.20).

10.5 Thread A: the LQG equilibrium is the equilibrium

The abstract existence theory is now complete on both of the branches it was built for — Schauder for the smooth, single-valued regime (theorem 10.14) and Kakutani for the rough, set-valued one (theorem 10.19) — but, as the previous section warned, both branches presuppose data bounded enough to build the compactness arena, and exactly one carried example slips out of both. We close the chapter by honouring the carried-thread duty for it: we apply the existence viewpoint to the LQG mean field game (Thread A) and confirm that the explicit Gaussian flow — constructed at the level of Riccati equations in chapter 6 (single agent) and assembled into a fixed point in chapter 14 — is genuinely *an* MFG equilibrium, and that at short horizon it is the *unique* one. As flagged in the notation watch of section 10.2, the LQG data are unbounded, so theorem 10.14 does not apply directly; the linear structure supplies its own, sharper, existence proof.

Worked computation 10.22 (The LQG best response collapses to a scalar fixed point)**.** Recall the scalar Thread A model: the representative agent has

$$\mathrm{d}X_t = (aX_t + b\,\alpha_t)\;\mathrm{d}t + \sigma\;\mathrm{d}W_t, \qquad X_0 \sim m_0,$$

and cost

$$J(\alpha) = \mathbb{E}[*] \int_0^T \left(\tfrac{1}{2}\alpha_t^2 + \tfrac{q}{2}\,(X_t - s\,\bar m_t)^2\right) \mathrm{d}t + \tfrac{q_T}{2}\,(X_T - s_T \bar m_T)^2,$$

with $\bar m_t = \int x\, m_t(\mathrm{d}x)$ the population mean and parameters $a, b, \sigma, q, q_T \geq 0, s, s_T, T$ as fixed in the thread specification. The coupling enters *only* through the scalar function $t \mapsto \bar m_t$; this is the structural windfall of the linear model.

Step 1 — the single-agent best response (frozen $\bar m$). For a frozen continuous mean $\bar m : [0,T] \to \mathbb{R}$, the verification theorem of chapter 6 gives a value function quadratic in the state,

$$u(t,x) = \tfrac{1}{2} P(t)\,x^2 + r(t)\,x + \chi(t),$$

whose coefficients solve, backward from $t = T$,

$$-\dot P = 2aP - b^2 P^2 + q, \qquad\qquad P(T) = q_T, \tag{10.8}$$

$$-\dot r = (a - b^2 P)\,r - q\,s\,\bar m_t, \qquad\qquad r(T) = -q_T\, s_T\, \bar m_T, \tag{10.9}$$

and χ a quadrature that does not affect the feedback. Here $P(t)$ is the Riccati curvature and $r(t)$ the linear (decoupling) offset of the value, in the canonical thread-A symbols fixed in the thread specification; this is the deterministic shadow of the forward–backward stochastic system eq. (9.22) of worked computation 9.16, with the costate curvature there named P and the costate offset named r identically. The Riccati equation eq. (10.8) is decoupled from the population (it is the single-agent curvature of chapter 6); under $q, q_T \geq 0$ it has a unique bounded nonnegative solution P on $[0, T]$. The optimal feedback is linear,

$$\alpha^*(t, x) = -b\,\partial_x u(t, x) = -b\big(P(t)x + r(t)\big),$$

so the closed-loop dynamics are the linear SDE

$$\mathrm{d}X_t = \big[(a - b^2P(t))X_t - b^2 r(t)\big]\,\mathrm{d}t + \sigma\,\mathrm{d}W_t.$$

Step 2 — the output flow is Gaussian, and its mean closes. Because the closed loop is linear with additive Gaussian noise and m_0 is (taken) Gaussian, $m_t = \mathsf{S}(m)_t$ is Gaussian for all t: $m_t = \mathcal{N}(\hat{m}(t), V(t))$. The mean and variance solve

$$\begin{aligned} \dot{\hat{m}}(t) &= (a - b^2P(t))\,\hat{m}(t) - b^2 r(t), & \hat{m}(0) &= \bar{m}_0 := \textstyle\int x\, m_0(\mathrm{d}x), \\ \dot{V}(t) &= 2(a - b^2P(t))\,V(t) + \sigma^2, & V(0) &= \mathrm{Var}(m_0). \end{aligned} \tag{10.10}$$

The variance equation is *autonomous* — it does not see the coupling — so V is determined once and for all by P; the entire population interaction lives in the mean.

Step 3 — the fixed point is a scalar linear two-point problem. Equilibrium demands $\mathsf{S}(m) = m$, i.e. $\hat{m} \equiv \bar{m}$. Imposing this in eq. (10.10) and coupling it to eq. (10.9) gives the closed linear forward–backward system for the pair $(\bar{m}, r)$,

$$\begin{cases} \dot{\bar{m}}(t) = (a - b^2P(t))\,\bar{m}(t) - b^2 r(t), & \bar{m}(0) = \bar{m}_0, \\ -\dot{r}(t) = (a - b^2P(t))\,r(t) - q\,s\,\bar{m}(t), & r(T) = -q_T\,s_T\,\bar{m}(T), \end{cases} \tag{10.11}$$

a two-point boundary-value problem with data split between $t = 0$ and $t = T$ — the finite-dimensional shadow of the forward–backward MFG structure, identical term for term to the deterministic reduction eq. (9.22) of the FBSDE in worked computation 9.16. Any solution $(\bar{m}^\star, r^\star)$ of eq. (10.11) yields the equilibrium flow $m^\star_t = \mathcal{N}(\bar{m}^\star(t), V(t))$; this is precisely the explicit closed form assembled in chapter 14.

It remains to show that eq. (10.11) has a solution — existence of the LQG equilibrium — and to confirm that the closed-form flow is *the* equilibrium in the natural class.

Proposition 10.23 (Existence and small-horizon uniqueness for LQG). *Fix Gaussian $m_0 \in \mathcal{P}_2(\mathbb{R})$ and parameters with $q, q_T \geq 0$. Let P be the unique nonnegative bounded solution of eq. (10.8) on $[0, T]$.*

(i) *The map $\bar{m} \mapsto \hat{m} =: \Psi(\bar{m})$ defined by solving eq. (10.9) then eq. (10.10) is affine and continuous on $C([0, T]; \mathbb{R})$; it can be written $\Psi(\bar{m}) = c + \mathsf{L}\bar{m}$ with c the response to the initial datum $\bar{m}_0$ and L a bounded linear operator whose norm satisfies*

$$\|\mathsf{L}\| \;\leq\; \Gamma\, e^{2\gamma T}\big(|s_T| q_T\, T + |s| q\, T^2\big) \;\leq\; \Gamma\, e^{2\gamma T}\big(|s| q + |s_T| q_T\big) \max(T, T^2)$$

for constants Γ, γ *depending only on* a, b *and* $\sup_{[0,T]} P$ *(in particular independent of* T*, since* $\sup_{[0,T]} P$ *stays bounded as* T *grows). In particular* $\|\mathsf{L}\| \to 0$ *as* $T \to 0$.

(ii) *If* T *is small enough that* $\|\mathsf{L}\| < 1$*, then* Ψ *is a contraction, the fixed-point equation* $\bar{m} = \Psi(\bar{m})$ *— equivalently the boundary-value problem eq.* (10.11) *— has a* unique *solution* $\bar{m}^\star = (I - \mathsf{L})^{-1} c$*, and hence the LQG game has the unique equilibrium flow* $m_t^\star = \mathcal{N}(\bar{m}^\star(t), V(t))$.

(iii) *For arbitrary* T*, eq.* (10.11) *is a linear two-point boundary-value problem; it has a unique solution whenever the operator* $I - \mathsf{L}$ *is invertible, i.e. unless the associated homogeneous problem (*$\bar{m}_0 = 0$*,* $\bar{m} \equiv \mathsf{L}\bar{m}$*) has a nontrivial solution — a non-generic "conjugate-point" degeneracy. The set of horizons* T *at which* $I - \mathsf{L}$ *is singular is discrete (eq.* (10.12) *below), so for all but at most a discrete set of* T *the equilibrium exists and is unique. At an exceptional* T *the linear problem is* singular *and behaves dichotomously: writing* $\Psi(\bar{m}) = c + \mathsf{L}\bar{m}$*, the equilibrium equation* $(I - \mathsf{L})\bar{m} = c$ *has* no *solution when* $c \notin \mathrm{Range}(I - \mathsf{L})$ *(non-existence of an LQG equilibrium at that horizon) and a whole affine family of solutions when* $c \in \mathrm{Range}(I - \mathsf{L})$ *(genuine multiplicity). Only the latter is the multiplicity / symmetry-breaking case taken up for the explicit threshold in proposition 11.8 of chapter 11 and, in time-dependent closed form, in chapter 14; non-uniqueness or non-existence is in either case a measure-zero, discrete-in-*T *phenomenon, not an open region.*

Proof. (i) Solve eq. (10.9) by the backward variation-of-constants formula. Writing $\Theta(t) = \exp\big(\int_0^t (a - b^2 P(\tau))\,\mathrm{d}\tau\big)$ for the closed-loop fundamental solution, the linear ODE eq. (10.9) for the offset r integrates to

$$r(t) = \frac{\Theta(t)}{\Theta(T)}\big(-q_T s_T\,\bar{m}(T)\big) + \Theta(t)\int_t^T \frac{q\,s\,\bar{m}(\tau)}{\Theta(\tau)}\,\mathrm{d}\tau,$$

which is linear in $\bar{m}$ with no constant term; hence $r = \mathsf{L}_r\bar{m}$ for a bounded linear L_r. The two summands are bounded separately: the boundary term by $e^{\gamma T} q_T |s_T|$ and the integral term by $e^{\gamma T} q|s|\,T$ (the exponential ratios $\Theta(t)/\Theta(\tau)$ are bounded by $e^{\gamma T}$ with $\gamma = \sup_{[0,T]} |a - b^2 P|$, and the τ-integral over $[t, T]$ contributes the extra factor T), so $\|\mathsf{L}_r\| \le e^{\gamma T}(q_T|s_T| + q|s|\,T)$. Then $\hat{m}$ solves eq. (10.10), a forward linear ODE with source $-b^2 r = -b^2\mathsf{L}_r\bar{m}$ and initial datum $\bar{m}_0$; variation-of-constants again gives $\hat{m} = c + \mathsf{L}\bar{m}$ with $c(t) = \Theta(t)\bar{m}_0$ (independent of the input $\bar{m}$) and $\mathsf{L} = -b^2\,\mathcal{I} \circ \mathsf{L}_r$, where the bounded forward solution operator $\mathcal{I}$ contributes a further factor $b^2 e^{\gamma T} T$. Composing,

$$\|\mathsf{L}\| \;\le\; b^2 e^{2\gamma T}\big(q_T|s_T|\,T + q|s|\,T^2\big),$$

which is the bound of part (i) with $\Gamma = b^2$. The running-coupling term carries *two* powers of T (one from each of the backward and forward integrations) and the terminal term only one; both vanish as $T \to 0$. *(ii)* For T small the right side is < 1; the contraction mapping theorem (theorem 2.36) gives the unique fixed point $\bar{m}^\star = (I - \mathsf{L})^{-1} c = \sum_{k\ge 0} \mathsf{L}^k c$. *(iii)* The system eq. (10.11) is linear with split boundary data; by the standard theory of linear two-point boundary-value problems it is solvable, and uniquely, iff $I - \mathsf{L}$ is invertible. Concretely, let $\Phi(t) \in \mathbb{R}^{2\times 2}$ be the fundamental matrix of the homogeneous first-order system obtained by stacking $(\bar{m}, r)$ in eq. (10.11) (forget the inhomogeneous data $\bar{m}_0$ and the terminal source). The split boundary conditions $\bar{m}(0) = 0$ and

$r(T) + q_T s_T \bar{m}(T) = 0$ have a nontrivial common solution iff

$$\Delta(T) \;:=\; \det \begin{pmatrix} e_{\bar{m}}^{\top}\,\Phi(0) \\ (e_r + q_T s_T e_{\bar{m}})^{\top}\,\Phi(T) \end{pmatrix} \;=\; 0, \tag{10.12}$$

where $e_{\bar{m}}, e_r$ are the coordinate vectors. The entries of Φ are solutions of a linear ODE with real-analytic (indeed smooth) coefficients in t, hence $T \mapsto \Delta(T)$ is real-analytic and not identically zero (for small T it is nonzero by part (ii)), so its zeros are isolated. Away from them $I - \mathsf{L}$ is invertible and the equilibrium exists and is unique; at a zero, the dichotomy of the proposition statement holds by the Fredholm alternative for the finite-rank perturbation $I - \mathsf{L}$ of the identity. $\square$

Heuristic (non-rigorous): Conjugate points: the geometric content of eq. (10.12)

The two-point problem eq. (10.11) asks the forward mean-flow (started at $\bar{m}_0$, $t = 0$) and the backward adjoint-flow (started from the terminal coupling, $t = T$) to match in the middle. For most horizons they match in exactly one way. The vanishing of $\Delta(T)$ is precisely the event that the forward and backward linear flows become *compatible along a one-parameter family* — a zero mode of the linearised boundary-value operator. This is the same phenomenon as a *conjugate point* in the classical calculus of variations, where the second-variation operator on $[0, T]$ acquires a kernel and the minimiser ceases to be unique. Here it is the finite-dimensional precursor of the genuine symmetry-breaking threshold of the full MFG, developed for the explicit phase boundary in proposition 11.8 (chapter 11) and chapter 14. Note that $\Delta(T) = 0$ is a codimension-one (discrete-in-T) event: multiplicity is a knife-edge, never an interval.

Remark 10.24 (Reconciling with the abstract theory)**.** Proposition 10.23 is the honest LQG existence statement, and it differs in spirit from theorem 10.14 in exactly the way the notation watch promised. The LQG coupling is unbounded, so the uniform moment/gradient bounds underpinning lemma 10.8 are unavailable — yet the *linear–Gaussian* structure collapses the infinite-dimensional fixed point on $\mathcal{M}$ to a *finite* (indeed scalar-flow) linear problem eq. (10.11), where existence is read off the theory of linear boundary-value problems and short-horizon uniqueness off a contraction. Two lessons survive to the general theory. First, the relevant "mean field" here is not the whole measure flow but its mean $\bar{m}_t$: the best response factors through a finite-dimensional sufficient statistic, the Gaussian structure being preserved by S. Second, uniqueness is *not* automatic — it holds for small T (or, as chapter 11 will show, whenever the coupling sign makes the problem Lasry–Lions monotone, e.g. $s \le 0$, "aversion to the crowd"), and can fail at large T with attractive coupling, exactly the regime in which the homogeneous problem of part (iii) acquires a nontrivial solution. The explicit uniqueness/multiplicity threshold for the stationary-tuned reduction — the condition $b^2 qs = A_\infty^2$ and the critical horizons of eq. (11.14) — is derived in proposition 11.8 of chapter 11; the full time-dependent phase diagram in (s, q, T) for general $q_T \neq P_\infty$ is the capstone of chapter 14.

Rigor ledger

Proved.

- Equilibria of the MFG system eq. (10.2)–eq. (10.3) are exactly the fixed points of the best-response map S (definition 10.3).
- Under (A-Lip), (A-Growth), (A-Nondeg), (A-Conv) with strictly convex H and *bounded, smoothing* couplings, S maps a convex compact set of flows $\mathcal{K}$ continuously into itself, so a fixed point exists by Schauder (theorem 10.14). Compactness of $\mathcal{K}$ rests on a uniform second moment (tightness, Prokhorov, chapter 3) plus uniform $\frac{1}{2}$-Hölder time-regularity (lemmas 10.6 to 10.8); continuity rests on parabolic stability of HJB (A-Nondeg) and SDE/martingale-problem stability (lemmas 10.10 and 10.11 and proposition 10.13).
- When the feedback is non-unique (degenerate diffusion or non-strict convexity), relaxed/weak equilibria (definition 10.18) exist via the Kakutani–Fan–Glicksberg theorem (theorem 2.40) applied to a set-valued best response on *joint* path-and-control laws (theorem 10.19), whose nonempty/convex/closed-graph inputs are the in-book relaxed-control existence and stability results theorems C.22 and C.23 and Berge's theorem theorem B.27; a measurable feedback is recovered by the Kuratowski–Ryll-Nardzewski selection (lemma 10.20, proved at theorem B.29).
- The LQG thread: the explicit Gaussian flow is an equilibrium; the fixed point is the scalar linear two-point problem eq. (10.11); it has a unique solution at short horizon (contraction) and for all but a discrete set of T (worked computation 10.22 and proposition 10.23).

Assumed.

- The named standing assumptions (A-Lip), (A-Growth), (A-Nondeg), (A-Conv) as stated in appendix A; bounded, uniformly-Lipschitz, weakly-continuous couplings for the Schauder theorem; compact action set (or coercive confinement) for the relaxed theorem.
- Assumption 10.4 (bounded optimal feedback), derived from (A-Nondeg) plus bounded smoothing couplings in lemma 10.5 but *not* valid for the unbounded LQG data.

Deferred (each to a named in-book proof; external citations are for attribution only).

- The uniform parabolic gradient (Bernstein) estimate underlying lemma 10.5, the interior Schauder estimate and the classical comparison principle underlying lemma 10.10: proved in appendix E (theorems E.14, E.17 and E.19), on the classical solvability/transition-density theory of theorem C.12; cf. [36, 93].
- The generalized Arzelà–Ascoli theorem (theorem B.24) and the $\mathcal{W}_1$ Wasserstein facts — Kantorovich–Rubinstein duality, metrisation of weak convergence, completeness, and tightness/uniform-integrability compactness — (theorems D.10 to D.12) used in lemma 10.8.

- For the smoothing-coupling (Schauder) route the closed-loop SDE stability (lemma 10.11) is proved in-book by direct coupling (theorems 5.10 and C.3 and lemma C.1); the martingale-problem well-posedness and relaxed-control compactness/stability needed for the weak route are theorems C.21 to C.23 of appendix C.13, with Berge's theorem theorem B.27 and the Kuratowski–Ryll-Nardzewski selection theorem B.29; cf. [88, 40].
- *Uniqueness* of equilibria in general: to chapter 11 (Lasry–Lions monotonicity (A-Mon)); the explicit LQG uniqueness/multiplicity threshold to proposition 11.8, the full phase diagram to chapter 14.
- Convergence of N-player Nash equilibria to these MFG equilibria: to chapter 13.

Open.

- Existence with *degenerate* diffusion and *unbounded, non-smoothing* couplings simultaneously, without passing to relaxed/weak equilibria, is delicate and only partially understood; the strong-equilibrium (genuine feedback) theory there is incomplete.
- Sharp characterisation of the exceptional horizons T in proposition 10.23(iii) across the full parameter range, and the precise boundary between the existence-only and existence-and-uniqueness regimes, is the subject of chapters 11 and 14; for general (non-LQG) attractive couplings it is open.

Bibliographic notes

The fixed-point strategy for MFG existence originates with Lasry and Lions [93], who established existence for the analytic system under nondegenerate diffusion and regularising couplings; the Schauder argument as organised here — best response on flows of measures, compactness from parabolic gradient bounds and tightness, continuity from HJB stability — follows Cardaliaguet's lecture notes [36], which remain the cleanest analytic reference and to which the deferred parabolic estimates of lemmas 10.5 and 10.10 should be traced. The probabilistic counterpart (remark 10.16), in which the same Schauder fixed point is run on path-space laws via FBSDE stability, is developed in Carmona–Delarue, Volume I [40, Ch. 3–4], which also contains the Kakutani-based existence of equilibria with non-unique controls. The weak/relaxed equilibrium formulation of section 10.4, the controlled-martingale-problem set-up, and the Kakutani–Fan–Glicksberg existence theorem in that setting are due to Lacker [88]; we prove the relaxed-control compactness and stability and the controlled-martingale-problem well-posedness in appendix C.13. The fixed-point, maximum, and measurable-selection theorems themselves (theorems 2.40, B.27 and B.29) are classical and may be found in Aliprantis–Border [6, Ch. 17–18] and Granas–Dugundji [79]. The Wasserstein compactness inputs (tightness $\Rightarrow$ $\mathcal{W}_1$-relative compactness) are theorem D.12, proved from chapters 3 and 4; cf. [131]. The LQG worked computation continues the Nash-certainty-equivalence line of Huang, Caines and Malhamé [82]; its boundary-value/Riccati form eq. (10.11) and the multiplicity threshold are taken up again in chapters 11 and 14.

Chapter 11

Uniqueness and the Lasry–Lions Monotonicity Condition

The previous chapter (chapter 10) earned us *at least one* mean field game equilibrium: under boundedness, Lipschitz, and nondegeneracy hypotheses a fixed point of the best-response map S exists for regularising couplings (theorem 10.14), and for the carried linear–quadratic thread the equilibrium is constructed explicitly (proposition 10.23). Existence, however, is only half of what a useful theory owes us, and on its own it is close to epistemically empty. A mean field game is supposed to be a predictive object: feed it the data of a population – the dynamics, the costs, the initial distribution – and it returns the self-consistent future, the trajectory along which every agent's anticipation of the crowd is borne out by the crowd that those anticipations produce. If that return value is a *set* rather than a point, the model has told us only that the future will be one of several mutually incompatible things, and it has given us no rule for saying which. Two equilibria are two contradictory forecasts from one and the same dataset; absent a further selection principle, a model with several equilibria predicts nothing at all. A theory that aspires to forecast must therefore deliver not merely *an* equilibrium but *the* equilibrium. This chapter asks when it can, and isolates the single structural hypothesis under which uniqueness holds for *arbitrary* time horizon: the *Lasry–Lions monotonicity condition*, the precise form of the standing assumption tagged **(A-Mon)** in appendix A.6. That one hypothesis has a dual face we will meet from both sides. Read physically, it is the statement that the interaction is *repulsive* – agents are crowd-averse, each paying to sit where others already sit – and such an interaction convexifies the equilibrium energy landscape, leaving a single basin and nothing to choose between. Read analytically, it is the exact sign that an old and beautiful duality computation needs in order to turn the forward–backward coupling into a sum of manifestly nonnegative terms; the proof it buys is three lines of integration by parts and is one of the most illuminating arguments in the subject.

We import the mean field game system in its analytic form from chapter 8 – the backward Hamilton–Jacobi–Bellman (HJB) equation for the value $u = u(t, x)$, solved *backward* from terminal data at $t = T$, coupled to the forward Fokker–Planck (FP) equation for the population density $m = m(t, x)$, solved *forward* from initial data at $t = 0$. As fixed once and for all in appendix A.1, value runs backward and mass runs forward: the optimizer reasons from the terminal payoff back to now, while the crowd is carried by its history from the initial distribution onward. This opposition of arrows is not a notational accident but the structural signature of the problem, and it is precisely the reason uniqueness is delicate – there is no single time direction along which to march the coupled pair and watch errors decay, as the rest of this chapter makes explicit. From chapter 6 we import the control Hamiltonian $H(x,p)$, convex in the adjoint variable p; that convexity (assumption **(A-Conv)**) is what makes the optimal feedback single-valued and, as we will see, contributes one of the favorable signs in the uniqueness identity for free. From chapter 4 we import the flat (linear functional) derivative $\frac{\delta \cdot}{\delta m}(m,x)$ and the geometry of $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$, the language in which "the coupling is the derivative of an energy" and "monotone means convex" are made precise. And we carry forward the Linear–Quadratic–Gaussian (LQG) thread (Thread A), whose parameters $a, b, \sigma, q, q_T, s, s_T, T$ are fixed in the thread specification and whose mean-coupling strength s will turn out to be the exact knob that tunes the system across the uniqueness boundary.

The chapter has a single arc, and it is worth seeing the whole of it before the first symbol. We begin (section 11.1) by establishing the *problem*: why uniqueness is not automatic, why the forward–backward structure defeats the contraction arguments that settle ordinary initial-value problems, and – through an attractive-coupling thought experiment – why a *sign* condition is the natural cure. That section ends by demanding exactly the object the next one supplies: section 11.2 pins the vague "repulsive enough" down to the checkable, horizon-free inequality eq. (11.3), the Lasry–Lions monotonicity condition, and interprets it as a crowd-averse coupling that convexifies the equilibrium landscape. Section 11.3 then spends that hypothesis: it proves the uniqueness theorem by the Lasry–Lions duality computation, given in full because it is the prototype every later uniqueness theorem in the book imitates. Having seen *why* monotonicity works, we ask what happens without it: section 11.4 reads the loss of uniqueness as a genuine symmetry-breaking / phase-coexistence phenomenon, sudden rather than gradual, with a Curie–Weiss self-consistency lurking underneath. Section 11.5 makes all of this computable on Thread A: we reduce the LQG mean field game to a deterministic two-point boundary-value problem for the population mean and read off its exact uniqueness/multiplicity phase diagram in (s, q, T), including the soft band where monotonicity fails yet uniqueness survives. Finally section 11.6 surveys the modern refinements – displacement monotonicity and weak monotonicity – that reach beyond the Lasry–Lions regime, and section 11.7 assembles the full menu of uniqueness hypotheses and locates the boundary of the uniqueness region. The destination is not local: the monotone regime is exactly the regime in which the master equation of chapter 12 is well posed, and the graphon uniqueness theory of chapter 24 is built on the operator generalization of the very computation given here. The short duality identity of this chapter is therefore load-bearing for much of the book that follows.

11.1 Why uniqueness is not automatic

The preamble flagged the value-backward/mass-forward structure as the reason uniqueness is delicate. It is time to turn that asserted signature into an argument, because seeing exactly *how* the opposed arrows defeat the usual uniqueness machinery is what tells us what a cure must look like.

Begin with the machinery that does work, so the contrast is sharp. In a standard *initial-value* problem – a forward stochastic differential equation, a forward parabolic PDE – Lipschitz data buy uniqueness for free by a Grönwall estimate. The mechanism is worth recalling in one line, because everything below is about why it is unavailable here. Suppose two solutions y_1, y_2 of $\dot{y} = b(t, y)$ share the same initial datum, with b Lipschitz in y with constant C. Then their difference $\delta := y_1 - y_2$ satisfies $\frac{\mathrm{d}}{\mathrm{d}t}\frac{1}{2}|\delta|^2 = \delta \cdot (b(t, y_1) - b(t, y_2)) \le C|\delta|^2$, and since $|\delta(0)|^2 = 0$, Grönwall's inequality forces $|\delta(t)|^2 \le |\delta(0)|^2 e^{2Ct} = 0$ for all t. The argument has exactly one moving part: a single time direction, with the data nailed down at one end, along which any discrepancy is propagated and shown to stay zero. Uniqueness is automatic precisely because the problem has a direction to march.

The mean field game system has no such direction, and this is the whole difficulty. It is a *forward–backward* system: the value u is pinned at the *final* time T, the density m is pinned at the *initial* time 0, and the two are coupled through the entire interval $[0, T]$. Neither field can be marched alone. If we try to integrate the pair forward from $t = 0$ we know $m(0) = m_0$ but not $u(0)$, because u is determined by data at the far end; if we try to integrate backward from $t = T$ we know $u(T)$ but not $m(T)$, because m is determined by data at the near end. The honest way to phrase the problem is as a *shooting* problem – guess the missing datum at one end, integrate to the other, and adjust the guess until the boundary condition there is met – and the map from guess to mismatch can perfectly well vanish at more than one guess. That is multiplicity. The Grönwall trick collapses because the difference $\bar{u} = u_1 - u_2$ of two value functions starts at zero at the *terminal* time while the difference $\bar{m} = m_1 - m_2$ of two densities starts at zero at the *initial* time; there is no single instant at which *both* discrepancies are known to vanish, so no Grönwall loop closes. Concretely, the feedback is genuinely two-sided: agents best-respond to the population they *anticipate* over the whole horizon, and the population is the aggregate of exactly those best responses, so a long horizon gives the loop time to support several mutually consistent configurations – several anticipations, each self-fulfilling. (The one regime that survives is a short horizon, where the round trip is too brief for the loop to wind up; we return to it below and make the threshold $C\,T < 1$ explicit.) The technical reading of this chapter is: find the one structural condition under which, even though no Grönwall direction exists, a *different* bookkeeping device – a time-integrated pairing of the two discrepancies against each other – still forces them to vanish.

To set up that bookkeeping we first fix notation, recalling from chapter 8 the mean field game system in the analytic form we will use throughout. Write $\nu := \frac{1}{2}\sigma^2 > 0$ for the diffusion coefficient; the strict positivity here is exactly **(A-Nondeg)**, and although the uniqueness argument will use almost nothing about ν, nondegeneracy reappears at the very last step to guarantee that the linear equations with frozen coefficients are themselves uniquely solvable, so we keep it in view from the start. Let the coupling enter through two functionals

$$F\colon \mathcal{P}_2(\mathbb{R}^d) \to C(\mathbb{R}^d) \cap L^1(\mathbb{R}^d), \qquad G\colon \mathcal{P}_2(\mathbb{R}^d) \to C(\mathbb{R}^d) \cap L^1(\mathbb{R}^d),$$

the running coupling and the terminal coupling. Each takes a population measure m and returns a function of the state x: the number $F(x, m)$ is the extra running cost an agent sitting at x pays because the rest of the population is distributed as m, and $G(x, m)$ is the analogous terminal cost. This is how the crowd is felt in the single agent's problem – not as a force, but as a state-dependent surcharge that the population's own shape dictates. Two structural facts about the codomain are doing quiet work and are recorded here once. Continuity, $F(\cdot, m) \in C(\mathbb{R}^d)$, is what lets the cost be evaluated pointwise along trajectories. Integrability, $F(\cdot, m) \in L^1(\mathbb{R}^d)$, is what we will need in section 11.2: the monotonicity condition eq. (11.3) is built from the pairing

$\int_{\mathbb{R}^d} (F(x,m) - F(x,m'))\,(m-m')(\mathrm{d}x)$, an integral of a cost *difference* against the finite signed measure $m - m'$, and it is the L^1 membership of $F(\cdot, m)$ that makes this integral absolutely convergent rather than a formal symbol. The same membership is what makes the time-integrated pairing in the uniqueness proof of section 11.3 a genuine number; we will not flag it again, but it is the reason every integral in the chapter is allowed to be written down. A classical solution of the mean field game system is a pair $(u, m) = (u, m)$ solving

$$-\partial_t u - \nu\,\Delta u + H(x, \nabla u) = F(x, m_t), \qquad u(T, \cdot) = G(x, m_T), \tag{11.1}$$

$$\partial_t m - \nu\,\Delta m - \operatorname{div}(m\,\partial_p H(x, \nabla u)) = 0, \qquad m(0, \cdot) = m_0, \tag{11.2}$$

on $[0, T] \times \mathbb{R}^d$. It pays to read the two equations slowly, because every sign in them is about to matter. The first, eq. (11.1), is the HJB equation of the representative agent who treats the population path $m_\cdot$ as given exogenous data: $u(t, x)$ is the optimal cost-to-go from state x at time t, the term $H(x, \nabla u)$ is the minimized Hamiltonian encoding the agent's best instantaneous trade-off, $F(x, m_t)$ is the crowd surcharge entering as a source, and the terminal datum $u(T, \cdot) = G(\cdot, m_T)$ records the final payoff. The signs $-\partial_t u$ and $-\nu\Delta u$ are the fingerprints of a *backward* equation: data are given at $t = T$ and the equation is integrated toward smaller t, so that the heat operator regularizes in the correct (backward) time direction. The second, eq. (11.2), is the Fokker–Planck (forward Kolmogorov) equation for the density of the closed-loop state, integrated *forward* from $m(0, \cdot) = m_0$; here $+\partial_t m$ and the same $-\nu\Delta m$ make the diffusion regularize forward in time. The two operators differ only by the orientation of time – this is the value-backward, mass-forward opposition of arrows in its sharpest form.

The link that closes the loop is the drift. The agent's optimal feedback control is $\alpha^* = -\partial_p H(x, \nabla u)$ – the minus sign is the convention of appendix A.4, where the Hamiltonian is the Legendre transform of the running cost and its p-gradient returns the optimizing velocity with a sign set so that the agent descends the cost. An agent following this feedback moves with velocity α^*, so the *population* of such agents is transported by exactly the vector field $\alpha^* = -\partial_p H(x, \nabla u)$. That is why the drift appearing in eq. (11.2) is not some independent datum but is forced to equal $\partial_p H(x, \nabla u)$: writing the transport term as $-\operatorname{div}(m\,\partial_p H(x, \nabla u))$ is the same as writing $+\operatorname{div}(m\,\alpha^*)$ on the other side, i.e. eq. (11.2) is the continuity equation $\partial_t m + \operatorname{div}(m\,\alpha^*) = \nu\Delta m$ with the agents' own optimal velocity. The forward equation is slaved to the backward one through this drift, and the backward equation is slaved to the forward one through the coupling F; that mutual slaving, with the two boundary data at opposite ends, *is* the forward–backward coupling. We collect eqs. (11.1) and (11.2) and refer to them jointly as the *MFG system*.

Notation watch: Constant scalar diffusion, and why the argument does not need it

For transparency we have written the second-order terms with a *constant scalar* diffusion, $\nu\Delta u$ and $\nu\Delta m$ with $\nu = \frac{1}{2}\sigma^2$. It is worth being explicit that this is a convenience of display and not a hypothesis the theorem leans on, because a reader could reasonably worry that constancy is smuggling something in. Chapter 10 carries the existence theory for a genuinely state-dependent, matrix volatility $\sigma(x)$, with generator $\mathcal{A}u = \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top\,\mathrm{D}^2\,u)$ and Fokker–Planck operator $\mathcal{A}^* m = \frac{1}{2}\sum_{ij}\partial^2_{ij}((\sigma\sigma^\top)_{ij} m)$. The two operators are formal adjoints by construction: $\mathcal{A}^*$ is built so that $\int(\mathcal{A}\varphi)\,\psi = \int\varphi\,(\mathcal{A}^*\psi)$ for test functions φ, ψ, which is just integration by parts twice, moving both derivatives off φ and onto ψ. Now look ahead to where the diffusion enters the uniqueness proof. It enters in exactly one place: the diffusion contributions to $\frac{\mathrm{d}}{\mathrm{d}t}\int \bar{u}\,\bar{m}$ must cancel, i.e. we need

$$\int(-\mathcal{A}\bar{u})\,\bar{m} + \int\bar{u}\,(\mathcal{A}^*\bar{m}) = -\int(\mathcal{A}\bar{u})\,\bar{m} + \int(\mathcal{A}\bar{u})\,\bar{m} = 0,$$

where the first equality is the adjoint relation applied to $\varphi = \bar{u}$, $\psi = \bar{m}$, and the sign flip comes from the backward orientation of the HJB diffusion against the forward orientation of the FP diffusion. (For the scalar Laplacian this is the Green's identity $\int(-\nu\Delta\bar{u})\bar{m} + \int\bar{u}(\nu\Delta\bar{m}) = 0$ used in section 11.3.) Nothing in this cancellation looks at *whether* σ is scalar, constant, or even continuous in x – it uses only that the operator driving the value and the operator driving the mass are formal adjoints of each other, paired against sufficiently decaying fields. That self-adjoint pairing is the entire footprint of the diffusion on the argument; constancy and scalarity are never invoked. We keep the scalar ν only to declutter the displays, and every statement extends verbatim to the matrix-volatility existence class of chapter 10 – under **(A-Nondeg)** for the final solvability step and sufficient decay for the integrations by parts – by replacing $\nu\Delta$ with $\mathcal{A}$ and $\mathcal{A}^*$ throughout.

With the system fixed, we can say concretely how multiplicity is born, and the cleanest way is to watch the feedback loop run in the one regime where it misbehaves: an *attractive* coupling, where an agent prefers to sit where the crowd already is.

Heuristic (non-rigorous)

The whole difficulty sits in the two boundary conditions pointing in opposite directions, and an attractive coupling lets us see it turn into multiplicity in a small number of steps. Suppose the couplings are attractive: $F(x, m)$ is *lower* where m has more mass, so an agent's cost is reduced by being near the crowd. Trace the loop one revolution. *(1)* Posit an anticipation: every agent believes the population will concentrate near a point x_0. *(2)* Best response to it: since sitting near x_0 is now cheap, the optimal feedback $\alpha^* = -\partial_p H(x, \nabla u)$ steers each agent toward x_0. *(3)* Aggregate the responses: the Fokker–Planck equation eq. (11.2) transports the realized population toward x_0, so it does concentrate there. *(4)* Compare with the anticipation: the realized concentration near x_0 matches – indeed reinforces – the one we posited, so the anticipation is self-consistent and we have an equilibrium. The crucial point is step (3) feeding step (1): concentration begets cheapness begets concentration. This is a positive feedback, and a positive feedback has no reason to have a unique fixed point. Run the identical argument with a *different* anchor $x_1 \neq x_0$ and it closes just as well: believe in x_1, drift to x_1, realize x_1. Two anticipations, two self-fulfilling populations, two equilibria – the best-response map S has more than one fixed point. This is precisely the Curie–Weiss self-reinforcement of a mean-field ferromagnet, where the belief "the magnetization is m" produces, through each spin aligning with the mean field it generates, a realized magnetization that can sit at more than one self-consistent value once the coupling is strong enough; section 11.4 makes that analogy exact. What forbids the runaway is the opposite sign: a *repulsive* coupling, for which $F(x,m)$ is *higher* where m concentrates, so that step (3) feeds back into step (1) with a minus – every attempt to concentrate raises the local cost and pushes mass back out, damping the loop instead of amplifying it. Monotonicity, defined in the next section, is the rigorous form of "the coupling is repulsive enough that this damping wins at every horizon."

The phrase "the damping wins" can be made quantitative, and it is worth previewing how, because it tells us which quantity the eventual proof will track. One cannot hope to control $\bar{u} = u_1 - u_2$ and $\bar{m} = m_1 - m_2$ separately – each is pinned at the wrong end for a Grönwall march, as we saw. The object that *is* controllable is their pairing $\int_{\mathbb{R}^d} \bar{u}\,\bar{m}\,\mathrm{d}x$, the natural duality between a difference of value functions (a function of the state) and a difference of populations (a signed measure on the state). This scalar knows about both discrepancies at once and, crucially, vanishes automatically at $t = 0$ (where $\bar{m} = 0$) so that its behavior is governed by the terminal end alone. The content of the uniqueness theorem in section 11.3 is that, under a repulsive sign condition on the coupling, the time evolution of $\int \bar{u}\,\bar{m}$ has a definite sign that traps it between zero and zero, forcing $\bar{u}$ and $\bar{m}$ to coincide – a contraction not in any fixed norm but in this particular bilinear pairing, and one that holds *uniformly in* T because the favorable signs accumulate monotonically over $[0,T]$ rather than competing against a growing exponential. The reader can hold onto $\int \bar{u}\,\bar{m}$ as the single quantity the whole chapter is built to control; the monotonicity condition is engineered to be exactly what gives it the right sign.

Before formalizing that condition, two clarifications guard against false hope. First, uniqueness can hold without monotonicity if the horizon is short: on $[0,T]$ with T small the forward–backward coupling is a genuine contraction *regardless* of the coupling's sign, because the round trip described above is too brief for the feedback loop to wind up. This is not new to this chapter – it is precisely the small-horizon regime of the McKean–Vlasov FBSDE proved in theorem 9.10(i). There the best-response map S is shown to be Lipschitz with constant $C\,T$, where C aggregates the Lipschitz constants of the data, so that S is a genuine contraction the moment $C\,T < 1$, and the Banach fixed-point theorem then forces a unique equilibrium; this is the honest reappearance, in the present language, of the Grönwall mechanism we said was unavailable – it is available, but only on a horizon short enough that the contraction factor stays below one, and the admissible window $T < 1/C$ shrinks as the coupling (and hence C) strengthens. We revisit this estimate in section 11.7, and Thread A will display the window explicitly as the band $T < T_c$. Monotonicity is exactly what removes the horizon restriction and upgrades uniqueness to *all* T.

Second, monotonicity is *sufficient but not necessary*: there are couplings that violate it outright yet still yield a unique equilibrium at every horizon. This is not a minor caveat but a quantitative fact we will be able to measure. The LQG thread of section 11.5 exhibits a whole *soft band* of parameters – attractive couplings that are anti-monotone by the sign computation eq. (11.10), yet too weak relative to the individual cost curvature to support multiplicity – in which uniqueness holds for every T despite the failure of **(A-Mon)**. The gap between the monotonicity threshold and the true multiplicity threshold is the precise width of this band, and it is the precise measure of how conservative the Lasry–Lions condition is. None of this diminishes the condition's value: its worth is that it is *checkable* (a single inequality, verifiable directly on the data), *horizon-free* (it asks nothing about T), and exactly the structure under which the deeper objects of the theory – the potential/variational formulation of chapter 8 and the master equation of chapter 12 – become well behaved.

We have thus generated a precise demand. The heuristic told us we need a coupling that is "repulsive enough"; the preview of $\int \bar{u}\,\bar{m}$ told us this must mean "repulsive enough that a certain pairing of cost differences against population differences has a definite sign"; and the clarifications told us the condition must be horizon-free and checkable, strong enough to defeat the feedback loop at every T but understood to be merely sufficient. What is missing is the inequality itself: a clean, checkable, T-independent sign condition on F and G that says "pushing mass into a region raises the cost there." Supplying that inequality – pinning the word repulsive to the pairing $\int (F(x,m) - F(x,m'))(m-m')(\mathrm{d}x)$ whose absolute convergence we have just secured through the L^1 membership of the couplings – is the business of the next section, and it is the definition of Lasry–Lions monotonicity to which we now turn.

11.2 The Lasry–Lions monotonicity condition

The previous section closed by manufacturing a precise want: a coupling "repulsive enough" that the pairing of cost differences against population differences carries a definite sign, written as an inequality that is *checkable* (verifiable on the data alone) and *horizon-free* (silent about T) – strong enough to defeat the feedback loop at every T yet understood from the outset to be only sufficient. It also secured the lone piece of regularity that lets such a pairing be a genuine number rather than a formal symbol: the L^1 membership of the couplings, which makes $\int (F(x,m)-F(x,m'))(m-m')(\mathrm{d}x)$ an absolutely convergent integral. This section supplies the inequality those demands were converging on, names it, and – because the sign in it is the single thing a physicist is most likely to read backward – spends the rest of its length pinning down what the inequality *means*, along two independent axes: an operator-theoretic reading (a cost paired against the shift that produced it) and a geometric reading (convexity of an energy along straight-line interpolations of populations). Each axis is realized by a concrete model class, and the geometric one is the bridge to the variational picture of chapter 8 that the proof in the next section will lean on.

Definition 11.1 (Lasry–Lions monotonicity)**.** A coupling functional $F\colon \mathcal{P}_2(\mathbb{R}^d) \to C(\mathbb{R}^d) \cap L^1$ is *(Lasry–Lions) monotone* if for all $m, m' \in \mathcal{P}_2(\mathbb{R}^d)$,

$$\int_{\mathbb{R}^d} (F(x,m) - F(x,m'))\,(m-m')(\mathrm{d}x) \;\geq\; 0. \tag{11.3}$$

It is *strictly* monotone if equality in eq. (11.3) holds only when $m = m'$. The standing assumption **(A-Mon)** is that the running coupling F and the terminal coupling G are both monotone in this sense.

This is the rigorous form of "repulsive enough," and it is worth dwelling on why it has exactly the shape it does. Read the integrand factor by factor. The signed measure $\Delta := m - m'$ records *how the population was shifted*: it is positive where the new configuration m has piled up extra mass relative to the old m', and negative where mass was vacated. It has zero total mass, $\int \mathrm{d}\Delta = 0$, because both m and m' are probability measures – a shift moves mass around without creating or destroying it. The function $F(x, m) - F(x, m')$ records *the change in cost* that this very shift induced at each location x. The pairing in eq. (11.3) is then the natural duality between a cost (a function of the state) and a population shift (a finite signed measure on the state), and the inequality demands that the change in cost, *weighted by the shift that produced it*, be nonnegative on average. The crowd-averse content is now exact: where the shift deposited extra mass ($\mathrm{d}\Delta > 0$), the induced cost should have gone *up* ($F(x, m) - F(x, m') > 0$), so that the product is positive; where mass was vacated, the cost should have gone down, and the product is again positive. A coupling for which crowding a region makes that region more expensive will have the two factors aligned in sign at every x, and the integral cannot be negative. This is the sign the feedback-loop heuristic asked for, now written as a single scalar inequality on the data.

There is a second, equivalent reading that explains why the analytic machinery of the next section works at all. Regard $m \mapsto F(\cdot, m)$ as a map sending a point of $\mathcal{P}_2(\mathbb{R}^d)$ to an element of the dual space of (signed measures tested against) functions of the state. Inequality eq. (11.3) is precisely the statement that this map is a *monotone operator* in the sense of nonlinear functional analysis: pairing the increment of the operator, $F(\cdot, m) - F(\cdot, m')$, against the increment of its argument, $m - m'$, yields a nonnegative number. Monotone operators are exactly the class for which the "energy decreases along the flow" bookkeeping of the previous section – a contraction not in a norm but in a bilinear pairing – has teeth, and this is the structural reason the same three-line computation will close in section 11.3 even though no Grönwall direction exists. The reader does not need the general theory of monotone operators; what matters is that eq. (11.3) is its defining inequality specialized to our F, and that this is the abstract slot the uniqueness proof plugs into.

Notation watch

The single most common slip a physicist makes here is a sign, and it is worth stating the convention four ways so that none of them surprises later. Monotonicity is a statement about *costs*, with the sign fixed by eq. (11.3), and throughout this chapter F and G are costs: the agent *minimizes*, so larger F is worse. With that fixed:

- A *monotone* coupling is one for which crowding a region *raises* the cost there. It is the *stabilizing*, *crowd-averse*, *repulsive* case – congestion, aversion to company – and it is the regime in which uniqueness holds at every horizon. Monotone = repulsive = stabilizing.

- An *anti-monotone* (or non-monotone) coupling is one for which crowding a region *lowers* the cost there. It is the *attractive*, *aggregating*, *imitative* case – the agent is rewarded for company – and it is precisely the regime where uniqueness can fail.

The trap is this: a physicist trained to think of an *attractive potential* as the "nice," energy-minimizing, ground-state-having case, or to think in terms of a *payoff to be maximized* rather than a cost to be minimized, will instinctively call attraction stabilizing. In the MFG cost convention it is the reverse. Attraction is *anti*-monotone and is where the landscape becomes nonconvex and equilibria proliferate; repulsion is monotone and is where the landscape stays convex and the equilibrium is unique. If at any later point a payoff $-F$ or a free energy $-\mathcal{F}$ is written, the inequality eq. (11.3) flips, and the maximization convention would call the *concave* case the good one; we never switch conventions inside this chapter, but the reader translating to a Hamiltonian-energy language elsewhere should carry the minus sign explicitly.

Two model classes turn the abstract inequality into something one can recognize on sight. The first is the most elementary and exhibits the pointwise mechanism in its purest form; the second exposes the geometric content – that monotonicity is convexity of an energy – and is the bridge to the variational reading.

Proposition 11.2 (Local couplings)**.** *Let F be local, $F(x,m) = f(x, m(x))$, defined for m with a density and with $f(x,\cdot)$ nondecreasing in its second argument for every x. Then F is monotone, and strictly monotone if each $f(x,\cdot)$ is strictly increasing.*

Proof. Because the coupling is local, the cost at x sees the population only through its density $m(x)$ at that same point, and the entire integrand factorizes location by location. Fix two densities m, m' and look at a single point x. The two factors of the integrand are $f(x, m(x)) - f(x, m'(x))$ and $m(x) - m'(x)$. If $m(x) \geq m'(x)$ then, since $f(x,\cdot)$ is nondecreasing, $f(x, m(x)) \geq f(x, m'(x))$, so both factors are ≥ 0 and their product is ≥ 0; if instead $m(x) \leq m'(x)$ then $f(x, m(x)) \leq f(x, m'(x))$, both factors are ≤ 0, and their product is again ≥ 0. Either way the integrand $\big(f(x, m(x)) - f(x, m'(x))\big)\big(m(x) - m'(x)\big)$ is nonnegative *pointwise* – a product of two factors that a monotone $f(x,\cdot)$ forces to share a sign. Integrating a pointwise-nonnegative function over x keeps the sign, so $\int \big(f(x,m) - f(x,m')\big)(m - m')\,\mathrm{d}x \geq 0$, which is eq. (11.3). If each $f(x,\cdot)$ is *strictly* increasing the product is strictly positive wherever $m(x) \neq m'(x)$ and zero only where $m(x) = m'(x)$; the integral therefore vanishes only when $m = m'$ a.e., i.e. $m = m'$, which is strict monotonicity. ☐

This is the congestion or crowd-aversion model, and a concrete instance fixes it in mind. Take $f(x,\rho) = \rho$, so that $F(x,m) = m(x)$: the running cost an agent pays for sitting at x is exactly the local density of the crowd there, a flat per-capita congestion charge. Then $f(x,\cdot)$ is strictly increasing, the proposition gives strict monotonicity, and the pairing is the manifestly nonnegative $\int \big(m(x) - m'(x)\big)^2\,\mathrm{d}x = \|m - m'\|_{L^2}^2$ – the squared L^2 distance between the two populations, which is zero only when they coincide. The physical reading is immediate: doubling the crowd at a point doubles the toll there, so any attempt to over-concentrate is self-penalizing, and there is no way for two distinct populations to both be self-consistent. The opposite sign, $f(x,\cdot)$ *decreasing* – for instance $f(x,\rho) = -\rho$, a per-capita reward for company – is aggregation or imitation; the same pairing comes out as $-\|m - m'\|_{L^2}^2 \leq 0$, the integrand is nonpositive pointwise, and the coupling is anti-monotone. The single scalar $\int (F(x,m) - F(x,m'))(m - m')$ has flipped sign with the monotonicity of f, exactly as the notationwatch warned.

The second model class exposes the geometric content of monotonicity: it is exactly convexity of an energy. This is the reading that makes "unique equilibrium" intelligible as "unique minimizer of a convex functional," and it is the one the next section ultimately formalizes.

Proposition 11.3 (Potential couplings and convex energy)**.** *Suppose F is the flat derivative of a functional $\mathcal{F}\colon \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}$,*

$$F(x, m) = \frac{\delta \mathcal{F}}{\delta m}(m, x),$$

in the sense of appendix A.3. Then F is monotone if and only if $\mathcal{F}$ is convex along linear interpolations of measures, i.e. $\epsilon \mapsto \mathcal{F}\big((1-\epsilon)m' + \epsilon m\big)$ is convex on $[0, 1]$ for all m, m'.

Proof. The idea is to reduce a statement about a functional on the infinite-dimensional space $\mathcal{P}_2(\mathbb{R}^d)$ to a statement about an ordinary scalar function of one real variable, by restricting $\mathcal{F}$ to a straight segment of measures and reading convexity off the sign of the second derivative. Write

$$m_\epsilon := (1-\epsilon)m' + \epsilon m = m' + \epsilon(m - m'), \qquad \varphi(\epsilon) := \mathcal{F}(m_\epsilon),$$

so that $\epsilon \mapsto m_\epsilon$ is the affine path from m' (at $\epsilon = 0$) to m (at $\epsilon = 1$). Its velocity is the constant signed measure $m - m'$, a finite measure of zero total mass: as ϵ advances, the population is interpolated linearly, neither gaining nor losing total mass. The function φ is a real function on $[0, 1]$, and the proposition is the assertion that φ is convex for every choice of endpoints m, m' exactly when F is monotone.

First derivative. By the defining property of the flat derivative (appendix A.3), which is precisely the chain rule for an affine perturbation of the argument, differentiating $\mathcal{F}$ along the constant-velocity path produces the flat derivative integrated against that velocity:

$$\varphi'(\epsilon) = \int \frac{\delta \mathcal{F}}{\delta m}(m_\epsilon, x)\,(m - m')(\mathrm{d}x) = \int F(x, m_\epsilon)\,(m - m')(\mathrm{d}x). \tag{11.4}$$

Already eq. (11.4) contains the monotonicity pairing in disguise: it is the cost $F(\cdot, m_\epsilon)$ paired against the population shift $m - m'$, evaluated at the intermediate configuration m_ϵ.

Second derivative. To differentiate eq. (11.4) a second time we need the rate of change of the integrand $x \mapsto F(x, m_\epsilon)$ as ϵ advances. The argument m_ϵ again moves with constant velocity $m - m'$, so this is once more a flat derivative – but now of the map $m \mapsto F(x, m)$, which is itself the first flat derivative of $\mathcal{F}$. Differentiating a flat derivative again is what *defines* the second flat derivative, and we make the iteration explicit. Hold the first slot x fixed and regard $m \mapsto F(x, m) = \frac{\delta \mathcal{F}}{\delta m}(m, x)$ as a scalar functional of m; its flat derivative, taken in m at a probe point y, is by definition the kernel $\dfrac{\delta^2 \mathcal{F}}{\delta m^2}(m)(x, y)$, characterized by the requirement that for every affine direction $m - m'$,

$$\frac{\mathrm{d}}{\mathrm{d}\epsilon} F(x, m_\epsilon) = \int \frac{\delta^2 \mathcal{F}}{\delta m^2}(m_\epsilon)(x, y)\,(m - m')(\mathrm{d}y). \tag{11.5}$$

In words: eq. (11.5) is just eq. (11.4) applied one level down, to the functional $F(x, \cdot)$ in place of $\mathcal{F}$, with the probe variable renamed y to keep it distinct from the fixed first slot x. The kernel is *symmetric*, $\dfrac{\delta^2 \mathcal{F}}{\delta m^2}(m)(x, y) = \dfrac{\delta^2 \mathcal{F}}{\delta m^2}(m)(y, x)$, and the symmetry is Clairaut's theorem – the equality of mixed second partials – transported to this setting. To see it, perturb $\mathcal{F}$ in two independent directions at once, $m \mapsto m + \epsilon\,\delta_x + \eta\,\delta_y$ (formally; rigorously one uses smooth bump approximations of the Dirac masses), and form $\Psi(\epsilon, \eta) := \mathcal{F}(m + \epsilon\,\delta_x + \eta\,\delta_y)$. Differentiating in ϵ first then in η recovers the second flat derivative with the slots in one order, $\partial_\eta \partial_\epsilon \Psi(0, 0) = \frac{\delta^2 \mathcal{F}}{\delta m^2}(m)(x, y)$; doing it in the other order gives $\partial_\epsilon\partial_\eta\Psi(0,0) = \frac{\delta^2\mathcal{F}}{\delta m^2}(m)(y,x)$. Since Ψ is a smooth function of the two real variables (ϵ,η), Clairaut's theorem equates the two mixed partials, and the two slot orders therefore agree. This symmetric kernel is part of the second-order differential calculus on $\mathcal{P}_2(\mathbb{R}^d)$ assembled in chapter 4 and appendix D; here we need only the elementary iterate eq. (11.5) and the right to differentiate eq. (11.4) under the integral sign. That last right is genuine and must be licensed, not assumed: differentiation under the integral is the statement that the difference quotients of $F(x,m_\epsilon)$ in ϵ converge to eq. (11.5) *and* are dominated, uniformly in ϵ, by a fixed integrable function so that the limit may be taken inside the integral. Both hold because the second flat derivative $\delta^2\mathcal{F}/\delta m^2$ is assumed bounded and continuous on the line segment $\{m_\epsilon : \epsilon\in[0,1]\}$, which is a compact subset of $\mathcal{P}_2(\mathbb{R}^d)$: boundedness furnishes the integrable dominating function (a constant times the total variation of $m-m'$, which is finite), continuity furnishes the pointwise convergence of the difference quotients, and dominated convergence then justifies passing $\mathrm{d}/\mathrm{d}\epsilon$ through the x-integral in eq. (11.4). Carrying this out and inserting eq. (11.5),

$$\varphi''(\epsilon) = \frac{\mathrm{d}}{\mathrm{d}\epsilon}\int F(x,m_\epsilon)\,(m-m')(\mathrm{d}x) = \iint \frac{\delta^2\mathcal{F}}{\delta m^2}(m_\epsilon)(x,y)\,(m-m')(\mathrm{d}x)\,(m-m')(\mathrm{d}y).$$

This is the symmetric bilinear form $\delta^2\mathcal{F}/\delta m^2$ evaluated on the *same* signed measure $m-m'$ in both arguments – a quadratic form in the population shift.

Both directions. Convexity of φ for every pair m,m' is, for a twice-differentiable function of one real variable, exactly $\varphi''\geq 0$ on $[0,1]$; by the display this is the nonnegativity of the quadratic form $\delta^2\mathcal{F}/\delta m^2$ on all signed measures of zero total mass (every such measure arises as $m-m'$ for suitable populations, up to scaling). Monotonicity eq. (11.3) is the difference-quotient form of the very same statement, and the fundamental theorem of calculus interpolates between them. Indeed, with $\Delta := m-m'$, the monotonicity pairing is the increment of φ' across the segment:

$$\int \big(F(x,m)-F(x,m')\big)\,\mathrm{d}\Delta = \varphi'(1)-\varphi'(0) = \int_0^1 \varphi''(\epsilon)\,\mathrm{d}\epsilon,$$

where the first equality is eq. (11.4) read at the two endpoints $\epsilon=1$ (giving $\int F(\cdot,m)\,\mathrm{d}\Delta$) and $\epsilon=0$ (giving $\int F(\cdot,m')\,\mathrm{d}\Delta$), and the second is the fundamental theorem applied to φ'. If $\varphi''\geq 0$ the right-hand integral is ≥ 0, so the pairing is ≥ 0 and F is monotone – convexity implies monotonicity. Conversely, suppose F is monotone. Apply eq. (11.3) not to the full segment but to a short sub-segment from m_ϵ to $m_{\epsilon+h}$, whose population shift is $h(m-m')$; the pairing is then $h^2(\varphi''(\epsilon)+o(1))\geq 0$, and dividing by h^2 and letting $h\to 0$ gives $\varphi''(\epsilon)\geq 0$ at almost every ϵ. Hence monotonicity of F for all pairs forces $\varphi''\geq 0$, i.e. convexity of $\mathcal{F}$ along every segment. The two properties are equivalent. □

Proposition 11.3 is the bridge to the variational picture of chapter 8, and it is worth spelling out the bridge, because the closing intuition of this chapter – that monotone coupling means a convex equilibrium landscape with a single basin – rests on it. In the separable, control-affine setting of section 8.6, where the running cost splits into a control part and a population part and the couplings are of potential type ($F=\frac{\delta\mathcal{F}}{\delta m}(m,x)$, $G=\frac{\delta\mathcal{G}}{\delta m}(m,x)$ for energies $\mathcal{F},\mathcal{G}$, as in definition 8.9), the entire forward–backward MFG system eqs. (11.1) and (11.2) is not merely a coupled pair of equations but the *Euler–Lagrange optimality system of one scalar functional.* That functional is the energy $\mathcal{J}(m,w)$ of eq. (8.18): a kinetic (control) cost accumulated along a density flow, plus the running and terminal interaction energies $\int_0^T \mathcal{F}(m_t)\,\mathrm{d}t + \mathcal{G}(m_T)$, minimized over density flows (m, w) that obey the continuity constraint. The precise content of "Euler–Lagrange" is that stationarity of $\mathcal{J}$ – setting its first variation to zero, with the value function u appearing as the Lagrange multiplier enforcing the continuity constraint – reproduces the HJB equation eq. (11.1) for u and the Fokker–Planck equation eq. (11.2) for m exactly (theorem 8.11). A solution of the MFG system is therefore a critical point of a single energy, and the strategic forward–backward problem collapses to one minimization.

Now feed proposition 11.3 into this. The interaction energies $\mathcal{F}, \mathcal{G}$ are convex along linear interpolations of measures precisely when their flat derivatives F, G are monotone; the kinetic term of $\mathcal{J}$ is convex on its own (it is the perspective function of a convex Lagrangian, jointly convex in the density–momentum pair, lemma 8.10), and the continuity constraint cuts out a convex set of flows. So under **(A-Mon)** the energy $\mathcal{J}$ is a convex functional on a convex domain, and a convex functional on a convex domain has its minimizers forming a convex set – and a *single* minimizing density once the convexity is strict, which strict monotonicity of the coupling supplies (theorem 8.11). Uniqueness of the equilibrium is then nothing more exotic than uniqueness of the minimizer of a convex energy: a single basin, with nothing to choose between because there is nowhere else for the landscape to dip. This is the geometric reading promised at the section's outset, and it is the picture to carry into the proof. The general uniqueness theorem of section 11.3 does *not* require a potential structure – it works for any monotone couplings, separable Hamiltonian or not – but it is exactly this convex-landscape intuition that the duality computation there will make rigorous without ever naming the energy: *monotone coupling = convex equilibrium landscape = unique equilibrium.*

We hand the next section two things it will spend. First, the monotonicity inequality eq. (11.3) as a usable tool with its sign nailed down: paired against a population difference, a difference of monotone costs is ≥ 0, and in the time-integrated identity of the proof this is exactly the term that enters with a favorable (uniqueness-forcing) contribution. Second, the convex-energy reading just developed, which tells us *in advance* what the proof must find – that two candidate equilibria cannot both sit at the bottom of a single convex bowl – so that the duality computation of section 11.3 reads not as a trick but as the concrete realization of "a convex landscape has one minimum."

11.3 The uniqueness theorem

The previous section handed us two things to spend, and this section spends them. The first was the monotonicity inequality eq. (11.3) with its sign nailed down: a difference of monotone costs, paired against the population difference that produced it, is ≥ 0. The second was the picture that inequality encodes – *monotone coupling = convex equilibrium landscape* – which told us in advance what any honest proof must discover, that two candidate equilibria cannot both sit at the bottom of a single convex bowl. We now make that picture rigorous. The remarkable feature of the argument is that it never names the energy whose convexity proposition 11.3 exhibited; it does not even require the couplings to be of potential type. It works directly on the forward–backward system eqs. (11.1) and (11.2), extracting convexity wherever it is hidden – in the Hamiltonian through **(A-Conv)**, in the couplings through **(A-Mon)** – and assembling those hidden convexities into a single identity that pins the two solutions together. The argument is short, exact, and worth presenting in full because it is the prototype for every uniqueness theorem in the book: the graphon version of chapter 24 is this same computation with the scalar pairing replaced by an operator pairing, and the master-equation monotonicity of chapter 12 is its differential shadow. Its engine is a single time-integrated pairing – the quantity $\int \bar{u}\,\bar{m}$ flagged in section 11.1 as the one scalar that knows about both discrepancies at once – whose time derivative, after one Green's identity and one integration by parts, turns out to be a sum of manifestly signed terms.

Before the theorem we isolate the one elementary fact about convex functions that the proof consumes. Convexity **(A-Conv)** of the Hamiltonian was imported in the preamble as a hypothesis on $H(x,\cdot)$; the proof needs it in a specific, quantitative form – not as "the graph curves upward" but as a nonnegative *gap* between the Hamiltonian and its own linearization. That gap is the Bregman divergence, and the lemma below is nothing more than the statement that convexity makes it nonnegative. It is the analytic operationalization of the p-convexity imported in **(A-Conv)**: every later appearance of convexity in the proof enters through this one quantity.

Lemma 11.4 (Bregman nonnegativity)**.** *Under **(A-Conv)**, for every x the Bregman divergence of $H(x,\cdot)$,*

$$D_H(x;p,q) := H(x,p) - H(x,q) - \partial_p H(x,q)\cdot(p-q),$$

satisfies $D_H(x;p,q) \geq 0$ for all $p,q \in \mathbb{R}^d$. If $H(x,\cdot)$ is strictly convex, then $D_H(x;p,q) = 0$ if and only if $p = q$.

Proof. The three terms of $D_H(x;p,q)$ are, in order, the value of the function at p, the value of its tangent (first-order Taylor) approximation built at q, and – assembled with the indicated signs – the gap between them. To see this, fix x and abbreviate $h(p) := H(x,p)$. The tangent plane to the graph of h at the base point q is the affine function

$$\ell_q(p) := h(q) + \partial_p h(q)\cdot(p-q),$$

the unique affine function agreeing with h in value and gradient at q. With this notation $D_H(x;p,q) = h(p) - \ell_q(p)$ is exactly the vertical gap at the point p between the graph of h and the tangent plane drawn at q. Convexity of h is, by the first-order characterization of convexity, precisely the statement that the graph never dips below any of its tangent planes: $h(p) \geq \ell_q(p)$ for every pair p,q. Hence the gap is nonnegative, $D_H(x;p,q) \geq 0$, which is the claim. If h is *strictly* convex the graph meets each tangent plane only at the single point of tangency, so the gap is strictly positive whenever $p \neq q$ and vanishes if and only if $p = q$. (For twice-differentiable h the same fact reads off Taylor's theorem with integral remainder,

$$D_H(x;p,q) = \int_0^1 (1-\theta)\,(p-q)^\top\,\partial_{pp}^2 h(q+\theta(p-q))\,(p-q)\;\mathrm{d}\theta,$$

a manifestly nonnegative integral of the convex – hence positive-semidefinite – Hessian against the squared increment, strictly positive once that Hessian is positive definite.) One feature will matter in the proof: the divergence is in general *not* symmetric in its two arguments, since it measures the gap from a designated base point q. The uniqueness computation will use both orderings, $D_H(x;\nabla u_1,\nabla u_2)$ and $D_H(x;\nabla u_2,\nabla u_1)$, one weighted by each of the two densities. □

Theorem 11.5 (Lasry–Lions uniqueness)**.** *Assume* ***(A-Lip)****,* ***(A-Nondeg)****, and* ***(A-Conv)*** *with $H(x,\cdot)$ strictly convex, and assume* ***(A-Mon)****: the couplings F and G are monotone in the sense of definition 11.1. Then the MFG system eqs.* (11.1) *and* (11.2) *has at most one classical solution (u,m) for which the formal integrations by parts below are justified — concretely, u of at most quadratic growth with ∇u of at most linear growth in x, and m with finite second moment and enough spatial decay (e.g. Gaussian-type tails) that the products $\bar u\,\bar m$, $\nabla\bar u\cdot m_i\partial_p H_i$ and the boundary terms at spatial infinity vanish. This regularity is the one delivered by chapter 10: for bounded regularising couplings the Lipschitz-in-x value of theorem 10.14 (with the gradient bound of lemma 10.5), and for the Gaussian LQG thread of worked computation 11.7 the explicit quadratic value and Gaussian density of proposition 10.23, for which the polynomial growth of ∇u is dominated by the Gaussian decay of m.*

The list of growth and decay conditions in the statement looks fussy, but each clause pays for one specific manipulation in the proof, and it is worth reading the hypothesis as a checklist of exactly the integrations by parts to come. There are three. First, the pairing $\int \bar u\,\bar m$ must itself be a finite number that can be differentiated in time: this asks that the product $\bar u\,\bar m$ be integrable and that the boundary term at spatial infinity in $\frac{\mathrm{d}}{\mathrm{d}t}\int \bar u\,\bar m$ vanish, which holds once $\bar u$ grows no faster than polynomially while $\bar m$ – a difference of two densities of finite second moment with fast tails – decays fast enough to overwhelm that polynomial. Second, the Green's identity that cancels the diffusion integrates by parts *twice*, transferring two derivatives from $\bar u$ across to $\bar m$ and back; each transfer drops a surface term of the form $\oint_{|x|=R}(\nabla\bar u\,\bar m - \bar u\,\nabla\bar m)$, and these vanish as $R\to\infty$ only because $\nabla\bar u$ is at most linearly growing while m_i and ∇m_i carry Gaussian-type decay. Third, the single integration by parts of the divergence (transport) term moves one derivative from $\bar u$ onto the flux $m_i\,\partial_p H_i$, dropping the surface term $\oint_{|x|=R}\bar u\,m_i\,\partial_p H_i$, which again dies because the at-most-quadratic $\bar u$ and the at-most-linearly-growing $\partial_p H_i$ are crushed by the decay of m_i. None of these clauses is idle: a value function growing like $e^{|x|}$, or a density with merely algebraic tails, could leave a nonzero flux at infinity and break the very cancellations the proof is built on. The reason we may *assert* the conditions rather than hope for them is that chapter 10 already delivered them on exactly the solution classes we care about. For bounded regularising couplings, theorem 10.14 produces a value u globally Lipschitz in x – so ∇u is bounded, a fortiori of linear growth – with the explicit gradient bound of lemma 10.5, while the Fokker–Planck density it transports has finite second moment with tail decay inherited from the nondegenerate diffusion. For the LQG thread of worked computation 11.7 the situation is cleaner still and entirely explicit: the value is the exact quadratic $u(t,x)=\frac{1}{2}P(t)x^2+r(t)x+c(t)$, so ∇u is exactly affine in x, and the density m_t is exactly Gaussian, so its Gaussian decay dominates that affine growth at every order and every boundary term is not merely small but identically convergent. The hypotheses of the theorem are thus not an extra burden placed on the reader; they are a property the previous chapter's solutions *have*, recorded here so that the integrations by parts below are licensed rather than formal.

Proof. Suppose, against the conclusion, that the system admits *two* classical solutions (u_1,m_1) and (u_2,m_2) – both with the regularity just discussed – and form their differences

$$\bar u := u_1 - u_2, \qquad \bar m := m_1 - m_2.$$

Everything hinges on the single scalar $t \mapsto \int_{\mathbb{R}^d} \bar{u}(t,x)\,\bar{m}(t,x)\;\mathrm{d}x$, the pairing of the two discrepancies announced in section 11.1. The plan is to compute its time derivative honestly from the differential equations (Steps 1–3), then integrate that derivative over $[0,T]$ and evaluate the two endpoint contributions from the boundary data (Step 4). The endpoint sum will turn out to be nonnegative, while the integrated derivative is a sum of terms each of which the hypotheses force to be nonpositive; the only way a nonnegative number can equal a sum of nonpositive numbers is for every one of them to vanish, and that collapse is what forces the two solutions to coincide (Step 5).

Step 1: the equations for the differences. Because both pairs solve the *same* system, the difference of two copies of an equation kills every term common to them and leaves only the nonlinear discrepancies. Subtract the two copies of the HJB equation eq. (11.1): the linear operator $-\partial_t - \nu\Delta$ and the terminal rule subtract cleanly, while the Hamiltonian and the coupling, being nonlinear, leave *differences* rather than zero,

$$\partial_t \bar{u} = -\nu\Delta\bar{u} + \big(H(x,\nabla u_1) - H(x,\nabla u_2)\big) - \big(F(x,m_1) - F(x,m_2)\big),$$

where $\partial_t \bar{u}$ has been moved to the left in forward-time form. Likewise subtract the two copies of the Fokker–Planck equation eq. (11.2); here the diffusion is linear and subtracts, while the transport term leaves the difference of the two probability fluxes,

$$\partial_t \bar{m} = \nu\Delta\bar{m} + \operatorname{div}\big(m_1\,\partial_p H(x,\nabla u_1) - m_2\,\partial_p H(x,\nabla u_2)\big).$$

We will not solve either equation; the point is only to pair them against each other.

Step 2: differentiate the pairing and watch the diffusion cancel. Differentiate the pairing under the integral sign – licensed by the decay hypotheses, which make the integrand and its t-derivative dominated – using the product rule,

$$\frac{\mathrm{d}}{\mathrm{d}t}\int \bar{u}\,\bar{m} = \int \partial_t\bar{u}\;\bar{m} + \int \bar{u}\;\partial_t\bar{m},$$

and substitute the two difference equations of Step 1. This produces four kinds of term: the two diffusion terms, the Hamiltonian-difference term, the transport (divergence) term, and the coupling-difference term. Take them in turn. The two diffusion contributions are $\int(-\nu\Delta\bar{u})\bar{m}$ from $\partial_t\bar{u}$ and $\int \bar{u}(\nu\Delta\bar{m})$ from $\partial_t\bar{m}$, and they cancel *against each other* – this is the one place the opposed time-orientations of the two equations pay a dividend. Integrating by parts twice (once to move a gradient off $\bar{u}$ onto $\bar{m}$, a second time to move it back, with the surface terms at infinity vanishing by the assumed decay) is Green's second identity,

$$\int(-\nu\Delta\bar{u})\,\bar{m} + \int \bar{u}\,(\nu\Delta\bar{m}) = -\nu\int \Delta\bar{u}\,\bar{m} + \nu\int \bar{u}\,\Delta\bar{m} = 0,$$

since $\int \Delta\bar{u}\,\bar{m} = \int \bar{u}\,\Delta\bar{m}$ for sufficiently decaying fields. The diffusion has removed itself from the computation entirely, at no sign cost – the "diffusion cancels for free" phenomenon we return to after the proof. The transport term $\int \bar{u}\,\operatorname{div}(\cdot)$ is handled by a *single* integration by parts, moving the divergence off the flux and onto $\bar{u}$ as a gradient (again the surface term at infinity vanishes by decay),

$$\int \bar{u}\;\operatorname{div}(m_1\partial_p H_1 - m_2\partial_p H_2) = -\int \nabla\bar{u}\cdot(m_1\partial_p H_1 - m_2\partial_p H_2),$$

where from here on we abbreviate $H_i := H(x, \nabla u_i)$ and $\partial_p H_i := \partial_p H(x, \nabla u_i)$. Collecting the surviving terms – the Hamiltonian difference paired with $\bar{m}$, the transported flux paired with $\nabla \bar{u}$, and the coupling difference paired with $\bar{m}$ – gives

$$\frac{\mathrm{d}}{\mathrm{d}t} \int \bar{u}\,\bar{m} = \underbrace{\int (H_1 - H_2)\,\bar{m} - \int \nabla \bar{u} \cdot (m_1 \partial_p H_1 - m_2 \partial_p H_2)}_{=:\ \mathcal{B}(t)} - \int (F(x, m_1) - F(x, m_2))\,\bar{m}. \tag{11.6}$$

Step 3: the Hamiltonian term is a sum of Bregman divergences. The bracket $\mathcal{B}(t)$ in eq. (11.6) is where convexity **(A-Conv)** earns its keep. Write out its two pieces with $\bar{m} = m_1 - m_2$ in the first and $\nabla \bar{u} = \nabla u_1 - \nabla u_2$ in the second, and sort the resulting terms by which density, m_1 or m_2, they multiply. The Hamiltonian-difference term contributes $(H_1 - H_2)$ against m_1 and against $-m_2$; the flux term contributes $-(\nabla u_1 - \nabla u_2) \cdot \partial_p H_1$ against m_1 (from the $m_1 \partial_p H_1$ piece) and $+(\nabla u_1 - \nabla u_2) \cdot \partial_p H_2$ against m_2 (from the $-m_2 \partial_p H_2$ piece). Grouping by density,

$$\mathcal{B}(t) = \int m_1 \Big[(H_1 - H_2) - (\nabla u_1 - \nabla u_2) \cdot \partial_p H_1\Big] - \int m_2 \Big[(H_1 - H_2) - (\nabla u_1 - \nabla u_2) \cdot \partial_p H_2\Big].$$

Now read each bracket against the definition $D_H(x; p, q) = H(x, p) - H(x, q) - \partial_p H(x, q) \cdot (p - q)$ of lemma 11.4, and the two orderings the lemma warned about appear. For the first bracket take base point $q = \nabla u_1$ and evaluation point $p = \nabla u_2$: then $H(x, p) - H(x, q) = H_2 - H_1$ and $\partial_p H(x, q) \cdot (p - q) = \partial_p H_1 \cdot (\nabla u_2 - \nabla u_1)$, so $D_H(x; \nabla u_2, \nabla u_1) = (H_2 - H_1) - \partial_p H_1 \cdot (\nabla u_2 - \nabla u_1)$, which is exactly the *negative* of the first bracket; the first bracket is therefore $-D_H(x; \nabla u_2, \nabla u_1)$. For the second bracket take $q = \nabla u_2$, $p = \nabla u_1$: then $D_H(x; \nabla u_1, \nabla u_2) = (H_1 - H_2) - \partial_p H_2 \cdot (\nabla u_1 - \nabla u_2)$, which is exactly the second bracket, so the second bracket is $+D_H(x; \nabla u_1, \nabla u_2)$. This is precisely why the Bregman divergence had to be kept asymmetric: the two halves of $\mathcal{B}$ use the two opposite base points. Substituting both,

$$\mathcal{B}(t) = -\int m_1\, D_H(x; \nabla u_2, \nabla u_1)\ \mathrm{d}x\ -\ \int m_2\, D_H(x; \nabla u_1, \nabla u_2)\ \mathrm{d}x\ \le\ 0, \tag{11.7}$$

The sign is now forced, and it is worth stating slowly. Each density is nonnegative, $m_1, m_2 \ge 0$ (they are population densities), and each Bregman divergence is nonnegative, $D_H \ge 0$, by lemma 11.4 – which is just **(A-Conv)** in operational form. A sum of two nonnegative integrands enters $\mathcal{B}(t)$ with two minus signs, so $\mathcal{B}(t) \le 0$ for every t, *independently of anything about the couplings.* This is the favorable sign that the agents' own strictly convex optimization supplies for free.

Step 4: integrate in time and account for the boundary data. We have $\frac{\mathrm{d}}{\mathrm{d}t} \int \bar{u}\,\bar{m}$; recover the pairing itself by integrating eq. (11.6) over the whole horizon $[0, T]$, so the left-hand side telescopes to the difference of the pairing at the two endpoints, $\left[\int \bar{u}\,\bar{m}\right]_{t=T} - \left[\int \bar{u}\,\bar{m}\right]_{t=0}$. This is where the two boundary data, pinned at opposite ends – the structural obstruction of section 11.1 – finally enter, and they enter with the right signs. At the initial time the two populations share the prescribed datum, $m_1(0) = m_2(0) = m_0$, so $\bar{m}(0) = 0$ and the entire pairing vanishes at $t = 0$ regardless of $\bar{u}(0)$: the near-end boundary term costs us nothing, and the value's unknown initial behaviour never has to be controlled. At the terminal time the two value functions share the terminal *rule* $u_i(T, \cdot) = G(\cdot, m_i(T))$ but not its value, because the terminal populations $m_i(T)$ may differ; thus

$\bar{u}(T) = G(x, m_1(T)) - G(x, m_2(T))$, and the far-end boundary term is the pairing of this terminal cost difference against the terminal population difference,

$$\Big[\int \bar{u}\,\bar{m}\Big]_{t=T} = \int \left(G(x, m_1(T)) - G(x, m_2(T))\right)\left(m_1(T) - m_2(T)\right)\,\mathrm{d}x \;\geq\; 0.$$

That this is ≥ 0 is exactly monotonicity of the terminal coupling G (**(A-Mon)**): it is the inequality eq. (11.3) applied to G at the two terminal populations $m_1(T), m_2(T)$. So the left-hand side of the time-integrated identity equals the nonnegative terminal term minus zero. Therefore

$$0 \;\leq\; \int \left(G(x, m_1(T)) - G(x, m_2(T))\right)(m_1 - m_2)(T) = \int_0^T \mathcal{B}(t)\,\mathrm{d}t - \int_0^T\!\!\int \left(F(x, m_1) - F(x, m_2)\right)(m_1 - m_2)\,\mathrm{d}x\,\mathrm{d}t. \tag{11.8}$$

Read eq. (11.8) as the balance it is. The left-hand side is ≥ 0 by the terminal monotonicity just used. The right-hand side is a sum of two contributions, and *both* are ≤ 0: the first, $\int_0^T \mathcal{B}(t)\,\mathrm{d}t$, is nonpositive because $\mathcal{B}(t) \leq 0$ pointwise in t by eq. (11.7) (the Bregman/convexity sign); the second, $-\int_0^T \int (F(x, m_1) - F(x, m_2))(m_1 - m_2)$, is nonpositive because the integral it negates is ≥ 0 by monotonicity of the running coupling F (eq. (11.3), now carrying an overall minus). We have thus trapped a nonnegative quantity between zero and a sum of two nonpositive quantities. The squeeze is decisive: a number that is simultaneously ≥ 0 and equal to a sum of terms each ≤ 0 can only be zero, and each nonpositive term must *itself* be zero (a sum of nonpositive numbers vanishes only if every summand does). Hence all three pieces vanish separately:

$$\int_0^T \mathcal{B}(t)\,\mathrm{d}t = 0, \qquad \int_0^T\!\!\int \left(F(x, m_1) - F(x, m_2)\right)(m_1 - m_2)\,\mathrm{d}x\,\mathrm{d}t = 0, \qquad \int \left(G(x, m_{1,T}) - G(x, m_{2,T})\right)(m_1 - m_2)(T) \tag{11.9}$$

Step 5: from the vanishing identity back to $m_1 = m_2$ and $u_1 = u_2$. The three equalities of eq. (11.9) are scalar statements – three integrals are zero – and the work of this step is to upgrade them to the pointwise conclusion that the two solutions coincide. Begin with the Bregman one. Since $\int_0^T \mathcal{B}(t)\,\mathrm{d}t = 0$ while $-\mathcal{B}(t)$ is, by eq. (11.7), the x-integral of the two manifestly nonnegative densities $m_1\,D_H(x; \nabla u_2, \nabla u_1)$ and $m_2\,D_H(x; \nabla u_1, \nabla u_2)$, the time integral of a nonnegative integrand can vanish only if that integrand vanishes almost everywhere. Hence

$$m_1(t,x)\,D_H(x; \nabla u_2, \nabla u_1) = 0 \quad \text{and} \quad m_2(t,x)\,D_H(x; \nabla u_1, \nabla u_2) = 0 \qquad \text{for a.e. } (t,x).$$

Now invoke *strict* convexity, the hypothesis not yet spent. By the strict clause of lemma 11.4, $D_H(x; p, q) = 0$ forces $p = q$; so at any point where $m_1 > 0$ the first equality forces $\nabla u_2 = \nabla u_1$, and at any point where $m_2 > 0$ the second forces the same equality $\nabla u_1 = \nabla u_2$. The two value gradients therefore agree *wherever either population carries mass* – precisely on the set that transport can see. Pushed through the optimal-feedback map this says the two closed-loop drifts coincide there, $\partial_p H(x, \nabla u_1) = \partial_p H(x, \nabla u_2)$ on $\{m_1 > 0\} \cup \{m_2 > 0\}$. (Off that set the drift is irrelevant, since the Fokker–Planck flux $m_i\,\partial_p H_i$ is multiplied by a density that is zero there.)

This is exactly the input needed to collapse the two forward equations into one. Each m_i solves eq. (11.2) with its own drift $\partial_p H_i$; but on the union of supports – the only place either flux is nonzero – those drifts are equal, and both equations carry the same diffusion ν and the same initial datum m_0. So m_1 and m_2 are two solutions of *one and the same* linear Fokker–Planck equation: a forward Kolmogorov equation whose drift and diffusion are now *frozen*, i.e. state-dependent but no longer solution-dependent. The logical chain that closes the argument is the imported well-posedness of that linear equation, and it is worth naming link by link, because this is the only place the existence-theory of the earlier chapters is consumed. The frozen Fokker–Planck equation is the forward (Kolmogorov) equation of the single, decoupled SDE

$$\mathrm{d}X_t = -\,\partial_p H\big(X_t, \nabla u(t, X_t)\big)\ \mathrm{d}t + \sigma\ \mathrm{d}W_t, \qquad X_0 \sim m_0,$$

with the now-common drift $-\partial_p H$ and diffusion σ. Under **(A-Lip)** that drift is Lipschitz and under **(A-Nondeg)** the diffusion is nondegenerate, so this SDE is well posed and possesses a *unique solution in law* by theorem 5.10. The time-marginals $t \mapsto \mathrm{Law}(X_t)$ of that law are a solution of the Fokker–Planck equation, and by theorem 5.14 the Fokker–Planck equation has a *unique* measure-valued solution issuing from m_0 – so any density that solves it must be those marginals. Both m_1 and m_2 solve it from the same m_0; each therefore equals the common marginal law, and $m_1 \equiv m_2$. This is the precise sense in which "the Fokker–Planck marginal inherits the SDE's uniqueness": well-posedness in law upstream (theorem 5.10) is transported to uniqueness of the density downstream (theorem 5.14), with nondegeneracy guaranteeing a genuine density to compare in the first place.

With the densities now equal, the couplings they generate are equal too: $F(x, m_1) = F(x, m_2)$ for every t, and $G(x, m_1(T)) = G(x, m_2(T))$. Feed this back into the backward equation. Both u_1 and u_2 now solve the *same* HJB equation eq. (11.1) – identical source $F(\cdot, m)$, identical Hamiltonian, identical terminal datum $G(\cdot, m(T))$ – so their difference $\bar{u}$ solves a homogeneous backward parabolic equation with zero terminal datum. The comparison principle for that equation (theorem 6.18), applied once to $\bar{u}$ and once to $-\bar{u}$, forces $\bar{u} \le 0$ and $\bar{u} \ge 0$, hence $\bar{u} \equiv 0$ and $u_1 \equiv u_2$. (This is the one place the HJB well-posedness theory of chapter 6 is invoked – not to construct the value, which we already hold, but to certify that the value is *determined* by its data, so that equal data give equal values.) The two solutions we started from agree in both components; the system has at most one classical solution. $\square$

The argument is three lines of integration by parts, but it rewards a second, slower look, because it is unusually transparent about which hypothesis does which job – and that transparency is exactly what the rest of the chapter exploits. Four ingredients went in, and they played strictly separated roles.

First, the diffusion cancelled for free. The two second-order terms met as a Green's-identity pair and annihilated each other before any sign question could arise; nondegeneracy **(A-Nondeg)** was never used to control them, and the entire computation is silent about the size, shape, or even constancy of ν until the final step. Nondegeneracy re-enters only in Step 5, and only to certify that the *linear*, frozen-coefficient Fokker–Planck and HJB equations are uniquely solvable – a well-posedness role, not a sign role. For the purposes of uniqueness the diffusion is a spectator.

Second, convexity of the Hamiltonian was *always* favorable and *always* present. The Bregman term eq. (11.7) is the analytic price of the agents' optimization being genuinely strict, and **(A-Conv)** guarantees it carries the uniqueness-forcing sign $\mathcal{B} \le 0$ *no matter what the couplings are*. It is a structural surplus the single-agent problem contributes to the population problem unconditionally; it never fights us.

Third – and this is the crux – the *only* coupling-dependent signs in the whole computation live in the boundary identity eq. (11.8), and they are supplied by monotonicity alone. The running term $-\int_0^T\int(F_1-F_2)(m_1-m_2)$ and the terminal term $\int(G_1-G_2)(m_1-m_2)$ are the two places where the data about *how the crowd is felt* enters, and **(A-Mon)** is precisely the hypothesis that fixes their signs the favorable way. Everything else in the proof would run verbatim for an attractive coupling; these two terms are the entire footprint of the interaction's sign on uniqueness.

Fourth, and consequently, removing monotonicity does not break a step of the proof – it removes a sign. Reread eq. (11.8) with F and G *anti*-monotone: the running and terminal pairings now point the wrong way, the right-hand side is no longer a sum of nonpositive terms, and the squeeze that trapped everything at zero simply unclamps. A negative coupling term can be balanced against the still-favorable Bregman term, the net can stay finite, and two genuinely distinct solutions (u,m) can satisfy the identity at once. This is not a weakness of the argument to be patched; the proof has correctly located the exact membrane across which uniqueness must fail. The identity eq. (11.8) is a sign ledger, and monotonicity is the single entry that keeps it balanced.

That last observation is the hinge into the next section. We have learned not merely that monotonicity *suffices* for uniqueness, but *where* – in one identity – its work is concentrated: the boundary identity eq. (11.8) is the one place the coupling's sign is read, and it is exactly that identity which loses its definite sign the moment the coupling turns anti-monotone. The natural question is then no longer analytic but structural: if the sign can fail, *what kind of object is the multiple equilibrium that the failure permits?* Answering that is the business of section 11.4, which reads the sign failure physically, as a symmetry-breaking threshold rather than a mere loss of a constant.

Remark 11.6 (Why the clean statement is the undiscounted finite-horizon one)**.** It is worth seeing precisely where discounting disturbs this bookkeeping, because the answer explains why theorem 11.5 is stated without a discount and why that is the version chapter 12 consumes. A discounted running cost replaces the HJB equation eq. (11.1) by $-\partial_t u+\beta\,u-\nu\Delta u+H(x,\nabla u)=F(x,m_t)$, i.e. it adds the linear zeroth-order term $\beta\,u$ with the discount rate $\beta=\beta>0$ of appendix A.1. Run the proof again. The difference equation for $\bar u$ now carries an extra $+\beta\,\bar u$, so differentiating the pairing produces one new contribution,

$$\frac{\mathrm{d}}{\mathrm{d}t}\int\bar u\,\bar m\ \supset\ \beta\int\bar u\,\bar m,$$

and after the time integration of Step 4 the identity eq. (11.8) acquires the extra term $\beta\int_0^T\int\bar u\,\bar m\ \mathrm{d}x\ \mathrm{d}t$. Here is the difficulty in one sentence: this new term is the time integral of the very pairing $\int\bar u\,\bar m$ whose sign the proof was built to *deduce*, not a quantity known to be signed along the way. The other three terms of eq. (11.8) were each pinned – the boundary term nonnegative by **(A-Mon)**, the running and Bregman terms nonpositive by **(A-Mon)** and **(A-Conv)** – but $\bar u\,\bar m$ inherits no sign from either hypothesis, because the pairing can be positive at some times and negative at others. So the squeeze no longer closes: a genuinely indefinite term has entered the ledger, and the clean "nonnegative = sum of nonpositives ⇒ all vanish" collapse is lost. One can still recover uniqueness under extra smallness of β or of the horizon, but the finite-horizon, undiscounted statement is the one that needs *no* such qualification, and that unconditional cleanliness is exactly why we made it the theorem.

Two honest escapes deserve mention. For the discounted *ergodic* (stationary) problem the difficulty evaporates rather than worsens: there is no time integration at all, the forward–backward pair collapses to a single coupled elliptic system, and the monotonicity computation runs on that stationary pair directly and is in fact cleaner – the offending $\int \bar{u}\,\bar{m}$ term has nowhere to accumulate (see [93, 36]). And in the explicitly solvable LQG thread of section 11.5 the indefinite term is computable in closed form, so discounting can be carried there by hand. But for the general finite-horizon theory we keep to the undiscounted statement, which is precisely the regime in which the master equation of chapter 12 is shown well posed: the monotonicity that buys uniqueness here is the same hypothesis under which that equation's characteristics do not cross, and chapter 12 imports theorem 11.5 in exactly this undiscounted finite-horizon form.

11.4 Failure of uniqueness as symmetry breaking

The proof ended on a structural observation rather than an analytic one. We learned not just that monotonicity suffices for uniqueness but *where*, in the whole forward–backward apparatus, its entire work is concentrated: in the single boundary entry of the sign ledger eq. (11.8). When the coupling is anti-monotone – attractive, imitative, aggregating – that one entry flips, the right-hand side stops being a sum of nonpositive terms, the squeeze that trapped $\int \bar{u}\,\bar{m}$ between zero and zero unclamps, and two genuinely distinct solutions can satisfy the identity at once. The proof has thus located, to the nearest sign, the membrane across which uniqueness must fail. But locating the membrane is not the same as understanding what lies on the far side, and that is the question this section takes up. The analytic statement "the boundary term changes sign" needs to be turned into a structural one: *what kind of object is the multiple equilibrium that the sign failure permits?* Is it a pathology – two solutions that happen, accidentally, to coincide in the pairing – or is it something with a shape, a phenomenon a physicist would recognize on sight?

It is the latter, and naming it correctly is what explains the most striking feature of the transition. A multiple equilibrium is a set of mutually incompatible self-consistent populations, each one an anticipation that the crowd it generates exactly fulfils; the heuristic of section 11.1 already glimpsed two of them, the belief in a concentration at x_0 and the belief in a concentration at $x_1 \neq x_0$, each closing the loop "concentration begets cheapness begets concentration" on its own anchor. What that heuristic did not yet say is that these coexisting solutions do not switch on gradually as the attraction is dialed up. They appear all at once, at a sharp value of the coupling, and below that value there is genuinely only one. Loss of uniqueness is a *threshold* phenomenon, not a continuous softening, and the reason is the same reason a ferromagnet magnetizes at a critical temperature and not before: the multiple equilibrium is *spontaneous symmetry breaking*. This is the chapter's one sanctioned physical picture, and it earns its place precisely because it predicts the suddenness that the analytic sign-flip, read literally, would leave unexplained.

To set up the picture, reduce the feedback loop to the one scalar it turns on. Take the attraction to act through the population mean – each agent is rewarded for sitting near $\bar{m}_t = \int \xi\, m_t(\mathrm{d}\xi)$, the LQG coupling of section 11.5. Then the entire self-consistent problem projects onto a single condition on that mean: given an anticipated mean $\bar{m}$, every agent best-responds to a crowd anchored there, the aggregate of those responses has its own mean, and equilibrium is the demand that the produced mean equal the anticipated one. This is a scalar fixed-point equation $\bar{m} = \mathcal{R}(\bar{m})$, and the number of equilibria is just the number of its fixed points. Whether that number is one or several is decided by a single derivative, and that is exactly the Curie–Weiss situation.

Physics note: Multiplicity as broken symmetry

Consider the attractive mean-coupling just described: each agent prefers to be near the population mean. The self-consistent condition on the mean is a fixed-point equation of the schematic form $\bar{m} = \mathcal{R}(\bar{m})$, where $\mathcal{R}$ is the population mean produced when every agent best-responds to a crowd anchored at $\bar{m}$. This is structurally the Curie–Weiss self-consistency $m = \tanh(\beta_{\mathrm{T}}(h + Jm))$ for the magnetization of a mean-field ferromagnet, the response curve $\mathcal{R}$ playing the role of $m \mapsto \tanh(\beta_{\mathrm{T}}(h + Jm))$ and the attraction strength playing the role of the coupling $\beta_{\mathrm{T}} J$. Take the symmetric case ($h = 0$, no external bias), so that $\bar{m} = 0$ – the unmagnetized, "everyone sits at the origin" configuration – always solves $\mathcal{R}(0) = 0$. The fate of that symmetric solution is governed by the slope $\mathcal{R}'(0)$. *Below threshold*, $\mathcal{R}'(0) < 1$: the response curve crosses the diagonal only once, $\mathcal{R}$ is a contraction near the symmetric point, and $\bar{m} = 0$ is the unique fixed point – weak attraction cannot overcome each agent's private incentives and the only consistent crowd is the symmetric one. *Above threshold*, $\mathcal{R}'(0) > 1$: the response curve now leaves the diagonal steeper than 45° at the origin, so the symmetric solution is no longer a contraction but a repeller, and the curve must recross the diagonal on either side. A *pair* of new fixed points $\pm\bar{m}_*$ appears, born together out of the destabilized symmetric one – the analog of spontaneous magnetization, where below the Curie temperature a nonzero $\pm M$ appears in place of the demagnetized state. The agents have collectively committed to clustering left or clustering right; the equilibrium has *broken the symmetry* of the symmetric anticipation that the model itself respects. The transition is sharp – it is the crossing $\mathcal{R}'(0) = 1$, an instability of a single mode, not a gradual blurring – which is exactly why uniqueness fails suddenly.

Crucially, the static fixed-point equation $\bar{m} = \mathcal{R}(\bar{m})$ does *not*, by itself, say which branch is realized: $+\bar{m}_*$ and $-\bar{m}_*$ enter on a perfectly equal footing, just as tanh gives no reason to prefer up-magnetization to down. Selecting one requires extra input beyond the equilibrium condition – a *selection principle* – and the candidates are exactly the ones that will recur in this book: dynamic stability (keep only equilibria that are attracting under a learning or best-response dynamics), a vanishing-viscosity or entropic refinement (add a small regularizer, solve, and take the regularizer to zero, the limit picking a distinguished branch), or the boundary-layer analysis of the master equation in chapter 12 (which resolves the choice on a fast time scale the finite-dimensional system hides). Each is the game-theoretic counterpart of how a physical ferromagnet picks a magnetization sign: by its history, or by an infinitesimal external field that tilts the otherwise balanced double well. The monotone (repulsive) regime is the one with no such ambiguity because it has *positive susceptibility everywhere*: there crowding a region always raises its cost, every perturbation is restored rather than amplified, $\mathcal{R}'$ never reaches 1, and there is simply no symmetric solution to destabilize and no symmetry to break. That is the same statement, in magnetic language, as the convex-energy reading of section 11.2: by proposition 11.3 a monotone coupling makes the equilibrium energy convex along interpolations of populations, so its landscape is a single convex basin with one minimizer. "Positive susceptibility," "convex landscape," and "single basin" are three names for one fact – a stable, restoring response – and the double well with its two minima is the picture of what monotonicity forbids.

It bears repeating, because the style of this book insists on it, that the magnetic picture is here to *motivate* and nothing more: not one step of the uniqueness theorem leaned on it, and the threshold it predicts will in the next section be derived from the equations alone. The analogy's job is to make the right expectation – a sharp transition, a born-in-pairs branch structure, an unselected sign – feel inevitable before we compute it. With that expectation in hand, strip the analogy away and ask what survives as mathematics.

The mathematical residue is sharper, and more favorable, than the general picture might suggest, and it is the content of the next section. In the explicitly solvable LQG model the response map $\mathcal{R}$ is not a transcendental curve like tanh but *linear*: the self-consistency condition on the mean reduces to a linear two-point boundary-value problem in time – a forward equation for the mean trajectory slaved to a backward equation for the optimal feedback, closed by data at opposite ends. Linearity is a windfall, because a linear self-consistency problem has either exactly one solution or a whole subspace of them, with no middle ground: multiplicity appears *precisely* when that boundary-value problem becomes singular, i.e. when its homogeneous version acquires a nonzero solution. The condition for singularity is therefore an exact equation on the parameters, not an inequality to be estimated. And it is more selective than mere anti-monotonicity. A singular boundary-value problem requires the coupled forward–backward dynamics to be *oscillatory* rather than exponential – the homogeneous solution must be able to start and end at zero without being identically zero, which a monotone, sign-definite system can never do – and oscillation sets in only when the attraction is not merely present but *strong relative to the curvature of the individual cost*, strong enough to overpower each agent's private pull toward its own optimum. This is the quantitative content of the soft band promised in section 11.1: between the failure of monotonicity (the sign computation eq. (11.10) turning the wrong way) and the true onset of multiplicity (the boundary-value problem actually going singular) lies a measurable gap of attractive-but-weak couplings where the equilibrium is still unique at every horizon. The threshold separating the two is sharp and computable.

That sets the mandate for section 11.5 exactly. The symmetry-breaking story has promised a threshold that is at once sharp – a clean equality on the parameters (s, q, T), not a conservative bound – and computable in closed form. Delivering it is now a matter of doing the linear algebra the analogy stood in for: reduce the LQG mean field game to its linear two-point boundary-value problem for the population mean, and read off, from the determinant that governs that problem's solvability, the exact locus where it goes singular. The next section carries out precisely that reduction and produces the uniqueness/multiplicity phase diagram in (s, q, T), soft band and all.

11.5 Worked computation: the LQG uniqueness phase diagram

The previous section ended by issuing a mandate and standing aside. Its symmetry-breaking picture predicted – on the strength of an analogy, not yet a computation – that the loss of uniqueness in an attractive mean field game is a *threshold* phenomenon: sharp rather than gradual, with equilibria born in pairs out of a destabilized symmetric solution, the way a ferromagnet magnetizes at its Curie point. And it promised that the carried LQG thread, being exactly solvable, would deliver that threshold as a clean equation on the parameters rather than an estimate. This section makes good on that promise. We advance Thread A by carrying the LQG mean field game to the point where its uniqueness/multiplicity boundary can be read off in closed form, and we discover that the boundary is sharper and more structured than the abstract monotonicity criterion would lead one to expect: not one threshold but two, separated by a measurable gap, and beyond the second a discrete ladder of resonant horizons rather than a solid region of failure.

This is the "sign/uniqueness" layer of the thread promised in the thread specification; the full closed-form solution – value, density, and Riccati system together – is assembled in the capstone chapter 14, and here we extract only what bears on uniqueness. The payoff is a concrete witness, computable to the last constant, for the chapter's central qualitative claim: that Lasry–Lions monotonicity is *sufficient but not necessary.* We will see the monotone region, the region where monotonicity fails yet uniqueness survives, and the region where it genuinely fails, all three drawn on one diagram in the parameters (s, q, T), with σ – the noise – nowhere to be found.

Worked computation 11.7 (LQG mean field game: reduction to a mean boundary-value problem)**.** Recall the scalar LQG model of Thread A. The representative agent has state

$$\mathrm{d}X_t = (aX_t + b\,\alpha_t)\ \mathrm{d}t + \sigma\ \mathrm{d}W_t, \qquad X_0 \sim m_0,$$

and minimizes, against a population mean path $\bar m_t := \int \xi\, m_t(\mathrm{d}\xi)$,

$$J(\alpha) = \mathbb{E}\left[\int_0^T \left(\tfrac{1}{2}\alpha_t^2 + \tfrac{q}{2}\,(X_t - s\,\bar m_t)^2\right) \mathrm{d}t + \tfrac{q_T}{2}\,(X_T - s_T\,\bar m_T)^2\right],$$

with $q, q_T \geq 0$, and $s, s_T \in \mathbb{R}$ the mean-coupling strengths. The running coupling, read as a functional of the population, is $F(x,m) = \frac{q}{2}(x - s\,\bar m)^2$ with $\bar m = \int \xi\, m(\mathrm{d}\xi)$.

Monotonicity of the LQG coupling. Before touching the dynamics it pays to locate the model on the map drawn in section 11.2: is this coupling monotone, and for which parameters? The answer will tell us in advance which slice of parameter space the general theorem theorem 11.5 already covers, so that the work of this section is confined to the complement. The test is definition 11.1: pair the cost difference against the population difference and read off the sign. Take two populations m, m' with means $\bar m, \bar m'$, and abbreviate the *shift in the mean* by $\Delta := \bar m - \bar m' = \int \xi\,(m - m')(\mathrm{d}\xi)$. The coupling $F(x,m) = \frac{q}{2}(x - s\bar m)^2$ depends on the population only through its mean, so its difference is a quadratic in x whose coefficients see m, m' only through $\bar m, \bar m'$. Expanding the two squares and cancelling the common $\frac{q}{2}x^2$,

$$F(x,m) - F(x,m') = \tfrac{q}{2}\Big[(x - s\bar m)^2 - (x - s\bar m')^2\Big] = \tfrac{q}{2}\Big(-2s\,x\,\Delta + s^2(\bar m - \bar m')(\bar m + \bar m')\Big),$$

where the cross term $-2sx(\bar m - \bar m') = -2sx\Delta$ is linear in x and the remaining term $s^2(\bar m^2 - \bar m'^2)$ is a constant in x. Now integrate against the signed measure $m - m'$. Two elementary facts about that measure do all the work: it has zero total mass, $\int(m - m') = 0$, because both are probability measures, which kills the constant term outright; and its first moment is exactly the mean shift,

$\int x\,(m-m')(\mathrm{d}x) = \Delta$, which converts the linear term into $-2s\Delta \cdot \Delta$. Hence only the cross term survives,

$$\int \big(F(x,m) - F(x,m')\big)\,(m-m')(\mathrm{d}x) = \tfrac{q}{2}\big(-2s\,\Delta^2\big) = -\,q\,s\,(\bar m - \bar m')^2. \tag{11.10}$$

The entire monotonicity content of the LQG model is compressed into this one line, and its sign is transparent: the right-hand side is a fixed negative multiple, $-qs$, of the perfect square $(\bar m - \bar m')^2$. The pairing is therefore ≥ 0 for *all* pairs of populations precisely when $qs \leq 0$, i.e., with $q > 0$ fixed, precisely when $s \leq 0$. This is the crowd-averse regime: with $s < 0$ the agent's target $s\bar m$ sits on the *opposite* side of the origin from the crowd, so the cost pushes each agent away from where the others are, and the coupling is monotone (repulsive) in the exact sense of definition 11.1. The imitative regime $s > 0$, where the agent is drawn *toward* $s\bar m$ and hence toward the crowd, makes eq. (11.10) negative and is anti-monotone – the attractive, multiplicity-prone case the symmetry-breaking section warned about. (The terminal coupling $G(x,m) = \frac{q_T}{2}(x - s_T\bar m)^2$ obeys the identical computation with s_T in place of s.) The verdict from the general theory is immediate and one-directional: by theorem 11.5, $s \leq 0$ together with $s_T \leq 0$ already guarantees a unique equilibrium at *every* horizon T, with no further computation. What that theorem says nothing about is the half-line $s > 0$, and it is precisely there – in the anti-monotone imitative regime – that the interesting question lives: exactly how far into $s > 0$ does uniqueness survive before the feedback loop finally winds up? Answering that is what the rest of the reduction is for.

The HJB and the reduction. We now run the representative agent's optimization with the mean path $\bar m_\cdot$ treated as given exogenous data, exactly as the MFG system eq. (11.1) prescribes, and then close the loop by demanding that the realized mean equal the anticipated one. Substituting the LQG Hamiltonian – minimizing $\frac{1}{2}\alpha^2 + (ax + b\alpha)\partial_x u$ over α gives $\alpha^* = -b\,\partial_x u$ and minimized value $ax\,\partial_x u - \frac{b^2}{2}(\partial_x u)^2$ – the HJB eq. (11.1) for this model reads

$$-\partial_t u = \tfrac{q}{2}(x - s\bar m_t)^2 + a\,x\,\partial_x u - \tfrac{b^2}{2}(\partial_x u)^2 + \tfrac{\sigma^2}{2}\partial_{xx} u, \qquad u(T,x) = \tfrac{q_T}{2}(x - s_T\bar m_T)^2,$$

with optimal feedback $\alpha^* = -b\,\partial_x u$. Every term on the right is at most quadratic in x (the source $\frac{q}{2}(x - s\bar m_t)^2$ is quadratic, the drift term $ax\,\partial_x u$ multiplies x by a derivative, the quadratic term $(\partial_x u)^2$ squares a derivative), and the terminal datum is quadratic; so the value cannot generate higher powers, and the quadratic structure is preserved by the ansatz

$$u(t,x) = \tfrac{1}{2}P(t)\,x^2 + r(t)\,x + c(t).$$

Here, in the carried-thread notation fixed for the LQG solution quantities, $P(t)$ is the value's Riccati curvature – the quadratic coefficient, the same object written P in chapter 10 for the single-agent problem and in chapter 12 for the master equation – and $r(t)$ is its linear coefficient, the only coefficient through which the population mean will turn out to act. With $\partial_x u = Px + r$ and $\partial_{xx} u = P$, substitute and collect by powers of x. The coefficient of x^2 gives, after dividing the matched relation $-\frac{1}{2}\dot P = -\frac{b^2}{2}P^2 + aP + \frac{q}{2}$ by $-\frac{1}{2}$, the scalar Riccati equation

$$\dot P = b^2 P^2 - 2a\,P - q, \qquad P(T) = q_T, \tag{11.11}$$

whose terminal datum $P(T) = q_T$ is read off the x^2 coefficient of $u(T,\cdot)$. The decisive feature of eq. (11.11) is that its right-hand side contains *no* $\bar m$: the curvature equation is *autonomous and* *decoupled* from the mean, a Riccati ODE the agent could solve before knowing anything about the crowd. Matching the coefficient of x^1 – which collects $-\dot{r}$ on the left and $-qs\bar{m}_t + ar - b^2Pr$ on the right – gives the *linear* equation for the linear coefficient,

$$\dot{r} = q\, s\, \bar{m}_t - \big(a - b^2 P(t)\big)\, r, \qquad r(T) = -q_T s_T\, \bar{m}_T; \tag{11.12}$$

the source $qs\bar{m}_t$ is where the crowd finally enters, and the terminal datum $r(T) = -q_T s_T \bar{m}_T$ is the linear coefficient of $\frac{q_T}{2}(x - s_T\bar{m}_T)^2$. The constant term gives an equation for $c(t)$ that feeds back nowhere – c shifts the value by an x-independent amount and changes neither the feedback $\alpha^* = -b(Px + r)$ nor the dynamics – so we discard it. To close the loop we compute the realized mean. Inserting the feedback into the state equation, the closed-loop dynamics are $\mathrm{d}X_t = \big((a - b^2P)X_t - b^2 r\big)\,\mathrm{d}t + \sigma\,\mathrm{d}W_t$, an Ornstein–Uhlenbeck-type linear SDE; taking expectations annihilates the martingale $\sigma\,\mathrm{d}W_t$ and leaves the forward linear ODE for the mean,

$$\dot{\bar{m}}_t = \big(a - b^2 P(t)\big)\, \bar{m}_t - b^2\, r(t), \qquad \bar{m}_0 = \int x\, m_0(\mathrm{d}x). \tag{11.13}$$

Read eqs. (11.12) and (11.13) together and the structure of the whole problem is laid bare. The curvature P is determined once and for all by eq. (11.11), independent of everything else; with P in hand, the remaining unknowns are the pair $(r, \bar{m})$, governed by two coupled *linear* ODEs – a backward one for r (terminal datum) slaved to $\bar{m}$, a forward one for $\bar{m}$ (initial datum) slaved to r. The most consequential observation is what is *absent*: the noise level σ enters only the variance of X_t – it appears nowhere in eqs. (11.11) to (11.13), which see only the *expectation* of the state. The diffusion stirs each agent's position but leaves the mean trajectory, and hence the self-consistency condition, untouched. We have therefore reduced the question of how many equilibria the stochastic mean field game admits to a question about a *deterministic* two-variable linear system: **the uniqueness question is entirely governed by the deterministic forward–backward pair $(r, \bar{m})$.** This is the precise vindication, in the solvable thread, of the general remark from section 11.1 that the uniqueness proof barely used the diffusion; here it does not use it at all.

Uniqueness as a two-point boundary-value problem. The pair $(r, \bar{m})$ is exactly the kind of object the chapter has been circling: two linear ODEs with their data pinned at *opposite* ends – $\bar{m}$ at $t = 0$, r at $t = T$ – and coupled through the interior, the same value-backward/mass-forward opposition that defeated the Grönwall march in section 11.1, now stripped down to two scalars. This is a linear two-point boundary-value problem (BVP), and writing it in matrix form makes its solvability a question of linear algebra. Stacking $(\bar{m}, r)$ and writing the closed-loop rate inline as $a - b^2P(t)$,

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix}\bar{m}\\ r\end{pmatrix} = M(t)\begin{pmatrix}\bar{m}\\ r\end{pmatrix}, \qquad M(t) = \begin{pmatrix} a - b^2P(t) & -b^2 \\ qs & -(a - b^2P(t)) \end{pmatrix}, \qquad \bar{m}_0 \text{ given}, \quad r(T) + q_T s_T\, \bar{m}(T) = 0,$$

where the off-diagonal entries are read directly off eq. (11.13) (the $-b^2 r$ source for $\bar{m}$) and eq. (11.12) (the $qs\,\bar{m}$ source for r), and the two diagonal entries are equal and opposite because r runs with rate $-(a - b^2P)$ where $\bar{m}$ runs with $+(a - b^2P)$. Note in passing that $M(t)$ is *traceless*, $\operatorname{tr} M(t) = 0$; this is not an accident but the forward–backward antisymmetry of the system, and it will be the single algebraic fact that drives the threshold analysis below. The boundary conditions are an initial datum on $\bar{m}$ and a terminal linear relation tying $r(T)$ to $\bar{m}(T)$. Now comes the structural point that makes the LQG case so clean. The map from the initial datum $\bar{m}_0$ to the solution is *affine*: solve the homogeneous flow, then add the particular response to $\bar{m}_0$. Consequently the equilibrium is unique if and only if the associated *homogeneous* BVP – same equations and same terminal relation but with $\bar{m}_0 = 0$ – has only the trivial solution $(r, \bar{m}) \equiv 0$. An affine system whose homogeneous part has only the zero solution is invertible and returns exactly one answer for each datum; an affine system whose homogeneous part has a nonzero solution returns either no answer or an entire one-parameter family. This is the linear-algebra dichotomy with no middle ground that section 11.4 promised: *multiplicity is exactly singularity of the homogeneous BVP*. It admits a nonzero $(r, \bar{m})$ that starts at $\bar{m}_0 = 0$ yet is not identically zero – a self-consistent oscillation of the mean that needs no external push to sustain it – and at such a parameter value the inhomogeneous problem degenerates, the LQG signature of equilibrium multiplicity. The phase boundary we are after is therefore the locus in parameter space where this homogeneous problem first goes singular.

To turn this into an explicit phase boundary we must contend with the fact that $M(t)$ has time-dependent entries through $P(t)$, which would force us to track the full Riccati flow. The autonomy of the Riccati equation eq. (11.11) lets us sidestep this cleanly. Its right-hand side is a fixed quadratic in P, so it has *equilibria* – the roots of the algebraic Riccati equation $b^2P^2 - 2aP - q = 0$ – and the curvature relaxes onto one of them. The relevant root is the *stabilizing* one,

$$P_\infty = \frac{a + \sqrt{a^2 + b^2 q}}{b^2}, \qquad A_\infty := a - b^2 P_\infty = -\sqrt{a^2 + b^2 q} < 0,$$

chosen by the $+$ sign of the discriminant so that the resulting closed-loop rate $A_\infty = a - b^2 P_\infty$ is *negative*: this is the root that makes the controlled state mean-revert rather than blow up, and the strict negativity $A_\infty < 0$ (which holds for every $q > 0$, since then $\sqrt{a^2 + b^2 q} > |a|$) is the single sign that the whole threshold proof will lean on. The number A_∞ is the constant closed-loop rate at the stationary curvature. If we now tune the terminal weight to $q_T = P_\infty$, the terminal datum of eq. (11.11) already sits at the equilibrium, so the solution is *exactly* constant, $P(t) \equiv P_\infty$ for all t, and therefore $a - b^2 P(t) \equiv A_\infty$: the matrix $M(t)$ loses its time dependence and the BVP acquires constant coefficients, which is what makes a closed-form threshold possible. This tuning costs us no generality of substance: for a generic terminal weight $q_T \neq P_\infty$ the curvature $P(t)$ is a nonconstant Riccati trajectory that relaxes toward P_∞ as one integrates away from $t = T$, the matrix $M(t)$ is correspondingly time-dependent, and the same analysis goes through with the propagator of the variable-coefficient system in place of e^{Mt} – qualitatively identical, threshold included, but no longer expressible in elementary functions, and so deferred to the numerical treatment of chapter 14. Tuning $q_T = P_\infty$ buys the closed form and nothing else. We also set $s_T = 0$, removing the terminal coupling so that the terminal relation collapses to the clean homogeneous condition $r(T) = 0$; this isolates the running coupling s as the sole knob and is again a convenience, not a restriction, since a nonzero s_T only shifts the terminal line $r(T) = -q_T s_T \bar{m}(T)$ without changing the oscillatory/non-oscillatory dichotomy that decides multiplicity.

Proposition 11.8 (LQG uniqueness/multiplicity threshold)**.** *In the LQG mean field game of worked computation 11.7 with $q > 0$, terminal weight $q_T = P_\infty$, and $s_T = 0$, define*

$$\Omega^2 := b^2 q\, s - A_\infty^2 = b^2 q\,(s - 1) - a^2.$$

1. *If* $\Omega^2 \le 0$ *– in particular whenever* $s \le 1+\dfrac{a^2}{b^2 q}$*, and a fortiori for every* $s \le 0$ *– the homogeneous BVP has only the trivial solution and the equilibrium is* unique for all horizons T*.*

2. *If* $\Omega^2 > 0$ *– equivalently* $s > 1 + \dfrac{a^2}{b^2 q}$ *– the homogeneous BVP has a nontrivial solution* exactly *at the discrete sequence of horizons* T_n *(*$n = 1, 2, \dots$*) solving*

$$\tan(\Omega T) = \frac{\Omega}{A_\infty}, \tag{11.14}$$

and only there. At each T_n *the equilibrium is non-unique (or fails to exist); for every other* $T > 0$*, including every* T *strictly between consecutive resonances, the equilibrium is* unique*. The smallest resonance* $T_c := T_1$ *marks the first loss of horizon-free uniqueness; for* $a = 0$ *it is* $T_c = \left(\pi - \arctan\sqrt{s-1}\,\right)/\left(b\sqrt{q(s-1)}\right)$*.*

Proof. The whole proof is the solution of one linear constant-coefficient system, read off through its propagator, with the sign of Ω^2 deciding among four qualitatively different behaviors. We begin by finding the propagator. The matrix M is traceless, $\operatorname{tr} M = 0$, so its two eigenvalues are $\pm\lambda$ with $\lambda^2 = -\det M$; and

$$\det M = -(a - b^2 P_\infty)^2 - (-b^2)(qs) = -A_\infty^2 + b^2 qs,$$

so that $\lambda^2 = -\det M = A_\infty^2 - b^2 qs = -\Omega^2$, with $\Omega^2 := b^2 qs - A_\infty^2$ as in the statement (using $A_\infty^2 = a^2 + b^2 q$ gives the stated form $\Omega^2 = b^2 q(s-1) - a^2$). Because M is traceless it satisfies its own characteristic equation $M^2 = -\det M\, I = -\Omega^2 I$ by the Cayley–Hamilton theorem – the 2×2 statement that $M^2 - (\operatorname{tr} M)M + (\det M)I = 0$. This single relation is what makes the matrix exponential elementary: powers of M collapse onto $\{I, M\}$. Summing the exponential series in even and odd powers,

$$e^{Mt} = \sum_{k\ge 0} \frac{(Mt)^k}{k!} = \Big(\sum_{j\ge 0} \frac{(-\Omega^2)^j t^{2j}}{(2j)!}\Big) I + \Big(\sum_{j\ge 0} \frac{(-\Omega^2)^j t^{2j+1}}{(2j+1)!}\Big) M,$$

where we used $M^{2j} = (-\Omega^2)^j I$ and $M^{2j+1} = (-\Omega^2)^j M$. When $\Omega^2 > 0$ the two bracketed series are exactly $\cos(\Omega t)$ and $\Omega^{-1}\sin(\Omega t)$, so

$$e^{Mt} = \cos(\Omega t)\, I + \Omega^{-1} \sin(\Omega t)\, M;$$

when $\Omega^2 < 0$ the alternating signs become non-alternating and the same series are $\cosh(\omega t)$ and $\omega^{-1}\sinh(\omega t)$ with $\omega^2 := -\Omega^2 > 0$; and the borderline $\Omega^2 = 0$ is the limit $e^{Mt} = I + Mt$. The sign of Ω^2 thus controls whether the deterministic mean–feedback loop oscillates or relaxes, and that is the entire physics of the threshold.

Now impose the boundary conditions on the *homogeneous* BVP. We must produce a nonzero solution with $\bar m_0 = 0$, so start at $(\bar m_0, r_0) = (0, r_0)$ with $r_0 \ne 0$ and propagate to $t = T$ by e^{MT}. The first column of e^{MT} multiplies the (vanishing) initial mean, so the $qs\,\bar m_0$ pathway contributes nothing and only the r_0-column survives. Reading the second (r) component of $e^{MT}(0, r_0)^\top$ off the propagator – the I term contributes $\cos(\Omega T)\, r_0$ and the M term contributes $\Omega^{-1}\sin(\Omega T)$ times the lower-right entry $-A_\infty$ of M acting on r_0 – gives, in the oscillatory case,

$$r(T) = r_0\Big[\cos(\Omega T) - \tfrac{A_\infty}{\Omega}\sin(\Omega T)\Big].$$

With $s_T = 0$ the terminal relation is simply $r(T) = 0$, and since $r_0 \neq 0$ this is solvable exactly when the bracket vanishes, $\cos(\Omega T) = \frac{A_\infty}{\Omega}\sin(\Omega T)$, i.e. $\tan(\Omega T) = \Omega/A_\infty$, which is eq. (11.14). A nontrivial homogeneous solution exists if and only if the horizon T solves that transcendental equation; everything below is the case analysis of when it has roots and how they are distributed.

Hyperbolic case $\Omega^2 < 0$. The loop relaxes rather than oscillates. With $\omega = \sqrt{-\Omega^2} > 0$ real, the same propagator computation with $\cosh, \sinh$ in place of $\cos, \sin$ yields

$$r(T) = r_0\Big[\cosh(\omega T) - \tfrac{A_\infty}{\omega}\sinh(\omega T)\Big].$$

Now the two negatives conspire in our favor: $A_\infty < 0$ makes $-\frac{A_\infty}{\omega} > 0$, while $\cosh(\omega T) \geq 1 > 0$ and $\sinh(\omega T) > 0$ for $T > 0$, so the bracket is a sum of two strictly positive terms and is > 0 for *every* $T > 0$. (Equivalently, $\tanh(\omega T) \in (0, 1)$ never reaches the negative value Ω/A_∞ that eq. (11.14) would demand.) The bracket never vanishes, the only homogeneous solution is the trivial one, and the equilibrium is unique at every horizon. This is part (i): the condition $\Omega^2 < 0$ is $b^2 q(s-1) < a^2$, i.e. $s < 1 + a^2/(b^2 q)$, and in particular every $s \leq 0$ gives $\Omega^2 = b^2 q(s-1) - a^2 < -a^2 \leq 0$ with room to spare, recovering the monotone region from the other direction.

Marginal case $\Omega^2 = 0$. Exactly on the borderline $b^2 qs = A_\infty^2$ the two eigenvalues $\pm\lambda$ have collided at the origin, $\det M = 0$, and M is *nilpotent*: Cayley–Hamilton gives $M^2 = -\Omega^2 I = 0$ because M is traceless and now singular. The exponential series truncates after two terms, $e^{Mt} = I + Mt$, and the second component is the *linear* (non-oscillatory) function

$$r(T) = r_0\,(1 - A_\infty T).$$

Since $A_\infty < 0$, the factor $1 - A_\infty T = 1 + |A_\infty| T > 0$ for every $T > 0$; the bracket again never vanishes, the homogeneous BVP is trivial, and uniqueness holds on the borderline too. With the hyperbolic and marginal cases together we have established uniqueness for all of $\Omega^2 \leq 0$, completing part (i).

Oscillatory case $\Omega^2 > 0$. Now the eigenvalues have re-emerged on the imaginary axis as $\pm i\Omega$, the loop genuinely oscillates, and the bracket can vanish. Write

$$h(T) := \cos(\Omega T) - \tfrac{A_\infty}{\Omega}\sin(\Omega T),$$

the function whose zeros are the resonant horizons. It is a single sinusoid: combining the cosine and sine into one phase-shifted cosine, $h(T) = \mathcal{A}\cos(\Omega T + \varphi)$ with amplitude

$$\mathcal{A} = \sqrt{1 + \tfrac{A_\infty^2}{\Omega^2}} \;>\; 1,$$

the inequality being strict because $A_\infty \neq 0$ contributes a strictly positive second term under the root. The amplitude exceeding 1 is the decisive quantitative fact, and it is worth seeing why it forces zeros to exist: $h(0) = \cos 0 - \frac{A_\infty}{\Omega}\sin 0 = 1$, so the sinusoid *starts* at the value 1, which lies strictly inside its range $[-\mathcal{A}, \mathcal{A}]$ since $\mathcal{A} > 1$; a sinusoid that starts strictly between its extremes must subsequently reach 0, and being periodic it returns to 0 once per half-period thereafter. Concretely the zeros of $\mathcal{A}\cos(\Omega T + \varphi)$ occur where $\Omega T + \varphi = \frac{\pi}{2} + k\pi$, i.e. at $T = (\frac{\pi}{2} - \varphi + k\pi)/\Omega$, a *discrete arithmetic progression* $T_1 < T_2 < \cdots$ with common spacing π/Ω (one zero per half-period, as a non-degenerate sinusoid has). These T_n are precisely the positive solutions of $\tan(\Omega T) = \Omega/A_\infty$, eq. (11.14). The homogeneous BVP is singular exactly at the T_n – where $h(T_n) = 0$ – and at no other horizon: for any $T \notin \{T_n\}$, and in particular for every T in an open interval (T_n, T_{n+1}) strictly between consecutive resonances, $h(T) \neq 0$, the relevant propagator entry is nonzero, the affine BVP is invertible, and the equilibrium is unique. Hence even in the strongly imitative regime multiplicity does not fill an interval of horizons; it is confined to a *countable, evenly spaced, measure-zero* set of resonant horizons, with uniqueness restored on every gap between them. This is the LQG realization of the general principle that multiple equilibria are non-generic, and it dovetails exactly with proposition 10.23(iii), where these same T_n appear from the existence side as the *conjugate points* of the linear two-point problem – the horizons at which the forward–backward shooting map drops rank. Existence (Ch. 10) sees them as the horizons where the explicit equilibrium formula develops a $0/0$; uniqueness (here) sees them as the horizons where the homogeneous problem acquires a nonzero solution; they are one and the same discrete ladder.

It remains to evaluate the smallest resonance $T_c = T_1$ in closed form in the cleanest subcase $a = 0$ (no intrinsic drift), where the algebra is fully transparent. Then $A_\infty = -\sqrt{b^2 q} = -b\sqrt{q}$ and $\Omega = \sqrt{b^2 q(s-1)} = b\sqrt{q(s-1)}$, so the gain b and the weight $\sqrt{q}$ cancel in the ratio, $\Omega/A_\infty = -\sqrt{s-1}$, and eq. (11.14) becomes $\tan(\Omega T) = -\sqrt{s-1}$. Since the right-hand side is negative, the smallest positive root has ΩT in the second quadrant: $\Omega T_c = \pi - \arctan\sqrt{s-1}$. Dividing by $\Omega = b\sqrt{q(s-1)}$ gives the closed form $T_c = \big(\pi - \arctan\sqrt{s-1}\big)/\big(b\sqrt{q(s-1)}\big)$ recorded in the statement. As a sanity check on the geometry: at the onset $s \to 1^+$ we have $\Omega \to 0^+$, the second-quadrant angle $\pi - \arctan\sqrt{s-1} \to \pi$, and $T_c \to \infty$ – the first resonance recedes to infinite horizon exactly as the oscillatory regime is entered, so the transition into multiplicity is continuous in the horizon even though it is sharp in s. $\square$

Proposition 11.8 has done more than locate a single threshold; it has partitioned the parameter half-plane into three qualitatively distinct regions, and it is worth stating them as a clean trichotomy because each carries a different lesson for the chapter's thesis. As s increases from $-\infty$ at fixed q, a, b, the coupling passes from monotone, through an anti-monotone-but-still-unique band, into the genuinely multiplicity-prone regime; the schematic in fig. 11.1 draws the result in the (s, T) plane.

- **Monotone region, $s \le 0$.** Crowd aversion: the agent is pushed away from the mean. The coupling satisfies **(A-Mon)** by eq. (11.10) (which is ≥ 0 exactly when $s \le 0$), and uniqueness holds for all (q, T). Here the two halves of the chapter meet: the general duality theorem theorem 11.5 and the explicit BVP computation proposition 11.8(i) both certify uniqueness, by completely different routes – one an integration-by-parts identity, the other a non-oscillatory propagator – and they agree, as they must, since they are reading the same fact off the same model.

- **Soft anti-monotone region, $0 < s \le 1 + a^2/(b^2 q)$.** Imitation, but weak relative to the individual cost curvature. Now the agent is drawn *toward* the mean, so the coupling is anti-monotone and eq. (11.10) is strictly negative: the Lasry–Lions condition **(A-Mon)** *fails*, and theorem 11.5 has nothing to say. Yet the equilibrium remains unique at every horizon T, because $\Omega^2 = b^2 q(s-1) - a^2 \le 0$ keeps the homogeneous BVP non-oscillatory (the hyperbolic/marginal cases of the proof), so the loop relaxes instead of resonating. This band is the concrete, computable witness the chapter has been promising that *monotonicity is sufficient but not necessary*: an explicit open set of attractive couplings, of width $s_\star = 1 + a^2/(b^2 q)$ in s, on which monotonicity is violated and uniqueness nonetheless holds for all T. It also quantifies *how badly* the abstract criterion overshoots, which the third structural fact below makes precise.

- **Resonant horizons,** $s > 1 + a^2/(b^2 q)$**.** Strong imitation. The agent now overshoots the crowd hard enough that the closed loop turns oscillatory (Ω real), and the homogeneous BVP becomes singular – but only at the *discrete* horizons $T_n(s, q)$ of eq. (11.14), spaced π/Ω apart. At each T_n the equilibrium is non-unique (or fails to exist); at every other horizon, including each open interval (T_n, T_{n+1}) between resonances, it remains unique. The careful reading is therefore that what is lost beyond $s_\star = 1 + a^2/(b^2 q)$ is not uniqueness on a range of horizons but *unconditional*, horizon-free uniqueness: a discrete ladder of resonant horizons $T_n(s)$ switches on, the first rung being $T_c = T_1$, and T_c decreases as s increases – stronger attraction brings the first resonance sooner, the first rung sliding down toward $t = 0$ as the imitation stiffens. These are exactly the conjugate points of proposition 10.23(iii) seen from the uniqueness side.

Three structural facts deserve emphasis, because each is a transferable lesson rather than an LQG accident. First, the boundary is governed entirely by the *deterministic* pair $(r, \bar{m})$: the noise level σ dropped out of eqs. (11.12) and (11.13) and never reappeared, so the phase diagram lives in (s, q, T) alone, exactly as the thread specification anticipated, with σ an inert spectator that broadens each agent's marginal without moving the mean or shifting a single threshold. Uniqueness of a *stochastic* game is decided by a *deterministic* two-point problem. Second, the transition is genuinely a threshold and not a gradual erosion, and the proof exhibits the mechanism: horizon-free uniqueness persists intact as s grows, untouched, right up to $b^2 q s = A_\infty^2$, where the real eigenvalue pair $\pm\omega$ of M *coalesces* at the origin (the marginal nilpotent case) and then re-emerges on the imaginary axis as $\pm i\Omega$, converting relaxation into oscillation. It is this eigenvalue collision – a spectral event at a precise parameter value – that makes the loss of uniqueness abrupt, and it is the exact mathematical content of the "spontaneous symmetry breaking" language of section 11.4: the symmetric solution loses stability not by softening but by a pair of modes crossing into oscillation. Third, the monotonicity threshold ($s = 0$) and the true multiplicity threshold ($s_\star = 1 + a^2/(b^2 q)$) are *different* numbers, separated by a band of width at least 1 in s – exactly 1 when $a = 0$, wider when the intrinsic drift a is present. That gap is not a defect of our analysis but the precise, model-by-model measure of how *conservative* the Lasry–Lions condition is: it forbids the entire half-line $s > 0$, whereas the truth forbids only $s > s_\star$, so the condition discards a whole band of well-behaved attractive couplings to buy the convenience of a single checkable inequality. A sharper, less conservative structural hypothesis would shave into that band – which is precisely the question the next section takes up.

Remark 11.9 (Interpreting the critical attraction $s = 1$)**.** The threshold $s_\star = 1 + a^2/(b^2 q)$ has a clean reading, cleanest in the driftless case $a = 0$ where it sits exactly at $s = 1$. Recall that the agent's running cost is $\frac{q}{2}(x - s\bar{m})^2$, so the agent is penalized for deviating from the moving target $s\,\bar{m}$. The value $s = 1$ is the precise point at which that target *tracks the population mean* *one-for-one*: each agent wants to sit exactly where the average agent sits. Below it, $s < 1$, the target is a fractional copy of the mean – the agent chases a damped image of the crowd, $s\bar{m}$ moves less than $\bar{m}$, and any collective drift is partially resisted, so the feedback is self-correcting and a unique consistent mean survives at every horizon. At $s > 1$ the agent *overshoots*: the target $s\bar{m}$ moves *further* than the crowd it imitates, so a small collective lean to the right makes everyone want to be even further right than the crowd already is, and the response amplifies the displacement instead of damping it. That is the self-amplifying feedback the symmetry-breaking section described, and it becomes fatal to horizon-free uniqueness once the horizon is long enough for the overshoot to compound – which is exactly why the first resonance T_c is finite for $s > 1$ and recedes to $+\infty$ as $s \downarrow 1$. The correction term $a^2/(b^2 q)$ raises the bar above 1 by exactly the amount the agent's private incentives stiffen it against the crowd: a large individual penalty q for straying from one's own target, or a strong intrinsic mean-reversion encoded in a, both anchor the agent to its private optimum and demand a more aggressive overshoot before the collective mode can run away. The ratio $a^2/(b^2 q)$ is the dimensionless measure of private stiffness relative to control authority b, and it is precisely the width of the soft band.

The figure makes the trichotomy legible at a glance, and it is worth reading deliberately because the geometry of the third region is easy to misdraw. Figure 11.1 plots the (s, T) plane at fixed q, a, b. To the left of $s = 0$ is the monotone half-plane, unique for every T; the vertical strip $0 < s \leq s_\star$ is the soft band, still unique for every T despite violating monotonicity, so the entire region $s \leq s_\star$ is a solid block of uniqueness with no internal structure. The essential point is what happens for $s > s_\star$: the failure of uniqueness there is *not* a shaded region but a family of *curves*. Each resonant horizon $T_n(s)$ traces one curve $T = T_n(s)$ sweeping upward as $s \downarrow s_\star$ (where every T_n escapes to $+\infty$) and descending as s grows; the curves do not fill area, and the open gaps between consecutive curves $T_n(s) < T < T_{n+1}(s)$ are themselves regions of uniqueness. Uniqueness is thus the generic (open, full-measure) condition everywhere on the diagram, and multiplicity lives only on the measure-zero curves – the lowest of which, $T_c(s) = T_1(s)$, is the boundary of horizon-free uniqueness and the one a modeller working at a fixed long horizon meets first as the imitation strength is dialed up.

We have, in this one solvable model, the entire phase structure the chapter set out to expose: the monotone region where the general theorem applies, the soft band that proves the theorem's hypothesis is merely sufficient, and the resonant ladder that shows how – and how suddenly – uniqueness finally fails. But the soft band leaves a pointed question hanging. The Lasry–Lions condition discarded the whole half-line $s > 0$ because it tests convexity of the equilibrium energy along *linear* interpolations of populations, the flat mixing $m_\epsilon = (1-\epsilon)m' + \epsilon m$ of proposition 11.3; and the LQG computation has just shown that this flat notion of "straight line" is conservative – it condemns couplings that are in fact perfectly well behaved. That should provoke the suspicion that linear interpolation is not the only, or even the most natural, notion of a straight path between two populations. On $\mathcal{P}_2(\mathbb{R}^d)$ there is a second one: the Wasserstein geodesic, which slides mass along optimal transport routes rather than fading one density into another. Convexity along *that* family of straight lines is a different, incomparable condition – displacement monotonicity – and it buys uniqueness in regimes the flat condition cannot reach, just as the flat condition reaches regimes it cannot. The LQG soft band is the concrete evidence that there is room, and demand, for such alternative structural hypotheses. The next section takes up exactly this: what other, genuinely

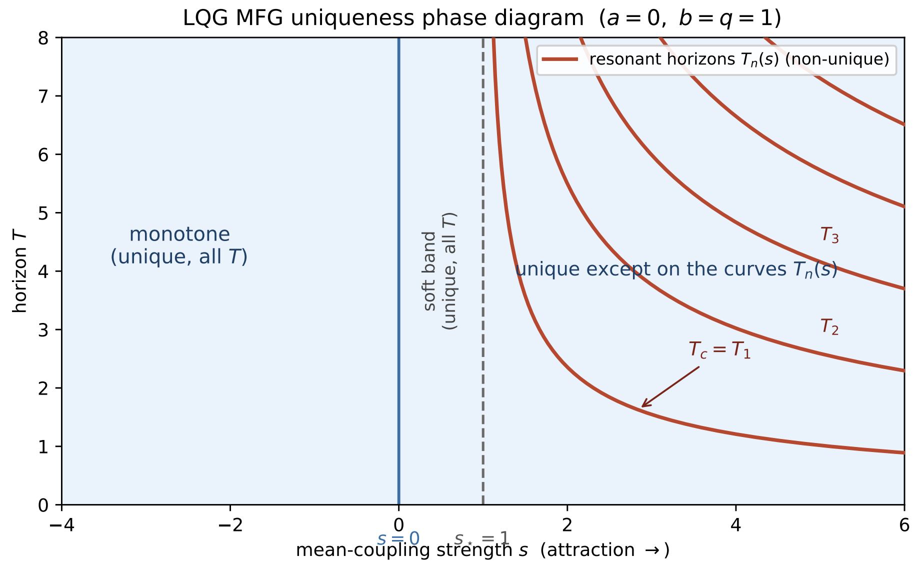

Figure 11.1: Schematic uniqueness phase diagram of the LQG mean field game in the (s, T) plane at fixed q, a, b (proposition 11.8). For $s \leq 0$ the coupling is Lasry–Lions monotone and the equilibrium is unique for all T. A soft band $0 < s \leq 1 + a^2/(b^2 q)$ remains unique for all T despite violating monotonicity. Beyond $s_\star = 1 + a^2/(b^2 q)$ the equilibrium is unique except on a *discrete* family of resonant horizon curves $T_n(s)$ (the solutions of eq. (11.14), drawn as curves, not a filled region), where uniqueness fails; the lowest curve $T_c(s) = T_1(s)$ marks the first loss of horizon-free uniqueness and decreases in s. Between consecutive curves the equilibrium is again unique, in agreement with proposition 10.23(iii).

different, convexities on the space of populations purchase uniqueness, and how flat (linear-mixing) monotonicity sits beside displacement (mass-transport) monotonicity as one of several incomparable sufficient conditions.

11.6 Displacement monotonicity and modern refinements

The LQG soft band left us with a sharpened complaint rather than a loose end. The Lasry–Lions condition condemned the entire imitation half-line $s > 0$, yet the explicit computation showed that a whole sub-band of those couplings produces a unique equilibrium at every horizon. The condition is, demonstrably, conservative – and the diagnosis offered at the close of the previous section located the conservatism precisely: **(A-Mon)** tests convexity of the equilibrium energy only along *linear* interpolations of populations, the flat mixing $m_\epsilon = (1 - \epsilon)m' + \epsilon m$ of proposition 11.3. That is one notion of a straight line between two populations, but it is not the only one, and on the space of probability measures it is arguably not even the most natural one. Linear mixing fades one density into another without moving a single particle: to interpolate "half-way" from m' to m it simply averages the two densities pointwise, leaving mass exactly where it already sat in either configuration and merely re-weighting it. The geometry of $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ – the geometry the whole transport picture of chapter 4 was built to respect – prefers a different straight line, one in which mass is physically *carried* from where m' puts it to where m wants it, each parcel travelling the shortest route. This section takes up the structural conditions that ride on that second straight line, contrasts them honestly with the flat condition the chapter's theorem actually consumes, and – because the full theory is a recent and technical development – is explicit about where the boundary of what this book proves lies.

Recall from chapter 4 that $\mathcal{W}_2$ is not an arbitrary metric on $\mathcal{P}_2(\mathbb{R}^d)$ but a *geodesic* distance: between any two measures there is a constant-speed shortest path, and that path is got by optimal transport, not by mixing. Concretely, if T is the optimal map pushing m' forward to m (the Monge map, when it exists), the constant-speed geodesic is the *McCann displacement interpolation*

$$\mu_\theta \;=\; \big((1-\theta)\,\mathrm{Id} + \theta\, T\big)_\sharp\, m', \qquad \theta \in [0,1],$$

constructed in full in appendix D (appendix D.3): each particle starting at x under m' slides along the straight segment from x to its destination $T(x)$, and μ_θ is the snapshot of the whole cloud at fraction θ of the journey. This is a genuinely different curve in $\mathcal{P}_2(\mathbb{R}^d)$ from the linear segment m_ϵ. The cleanest way to see the difference is two equal point masses: with $m' = \delta_a$ and $m = \delta_b$, linear mixing gives $m_\epsilon = (1-\epsilon)\delta_a + \epsilon\delta_b$, a pair of spikes whose *weights* shift from a to b while the spikes themselves never move; displacement interpolation gives $\mu_\theta = \delta_{(1-\theta)a+\theta b}$, a single spike that *travels* from a to b. Mixing reweights in place; transport moves. Convexity of an energy along these two families of straight lines is therefore convexity in two different senses, and there is no reason to expect them to agree.

McCann's insight was that many energies that are emphatically *not* convex along linear mixing are convex along displacement – the internal (entropy-type) energies, the potential energies $\int V\,\mathrm{d}m$ with V convex, and the interaction energies $\iint K\,\mathrm{d}m\,\mathrm{d}m$ with K convex all become convex once one interpolates by transport rather than by mixing. This is the convexity that the geometry of $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ sees, and it is the natural input to any argument that itself lives on that geometry – in particular to the master equation, whose unknown is a function *on* $\mathcal{P}_2(\mathbb{R}^d)$ and whose well-posedness is controlled by how energies bend along the metric's own geodesics. We can now state the condition for orientation.

Definition 11.10 (Displacement convexity and displacement monotonicity)**.** A functional $\mathcal{F}\colon \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}$ is *displacement convex* if for every constant-speed Wasserstein geodesic $(\mu_\theta)_{\theta\in[0,1]}$ in $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ — the McCann displacement interpolation constructed in appendix D (appendix D.3) — the map $\theta \mapsto \mathcal{F}(\mu_\theta)$ is convex. A coupling $F = \delta\mathcal{F}/\delta m$ is then called *displacement monotone*; equivalently (for F regular enough that the L-derivative $\partial_\mu F$ of appendix A.3 exists), displacement monotonicity is the positivity of the second variation of $\mathcal{F}$ along geodesics, a condition on $\partial_\mu F$ and its spatial gradient rather than on F paired with $m - m'$.

The last clause is the one a physicist should pause on, because it is exactly where the two monotonicities part company, and it is worth saying *why* the displacement condition falls on the spatial gradient of the L-derivative rather than on the bare cost difference $F(\cdot, m) - F(\cdot, m')$ that eq. (11.3) pairs against $m - m'$. The reason is the one the point-mass picture already made visible: along a geodesic, mass moves. Differentiate $\theta \mapsto \mathcal{F}(\mu_\theta)$ once and one gets, by the chain rule on $\mathcal{P}_2(\mathbb{R}^d)$ (appendix A.3), the flat derivative $F(\cdot, \mu_\theta)$ paired against the velocity of the curve; but the velocity of a displacement geodesic is not a re-weighting, it is a transport field $\nabla\phi$ (the gradient of a Kantorovich potential), so the pairing is against the *motion* of mass. Differentiating a second time then asks how the cost itself changes as each particle is carried along its segment, and a transported particle samples the cost at shifting *locations*: what enters is therefore the rate of change of F in the state variable, i.e. the spatial gradient ∂_x of the L-derivative $\partial_\mu F$, contracted twice against the transport field. The schematic shape of the second variation is

$$\frac{\mathrm{d}^2}{\mathrm{d}\theta^2}\,\mathcal{F}(\mu_\theta) \;=\; \int \Big\langle \partial_x\partial_\mu F(x,\mu_\theta)\,\nabla\phi(x),\,\nabla\phi(x)\Big\rangle\,\mu_\theta(\mathrm{d}x) \;+\; (\text{lower-order transport terms}),$$

and displacement monotonicity is the demand that this quadratic form in the displacement field $\nabla\phi$ be nonnegative. Contrast the flat second variation $\varphi''(\epsilon) = \iint \frac{\delta^2\mathcal{F}}{\delta m^2}(m_\epsilon)(x,y)\,(m-m')(\mathrm{d}x)(m-m')(\mathrm{d}y)$ of proposition 11.3, which never differentiates F in space at all, because under linear mixing nothing moves in space – only the weights change, so only the bare values of the cost (through the kernel $\delta^2\mathcal{F}/\delta m^2$) are sampled. *Mixing sees cost values; transport sees cost gradients.* That single sentence is the whole reason the two conditions are different objects rather than two encodings of one object, and it is why one is a condition on F paired with $m-m'$ while the other is a condition on $\partial_x\partial_\mu F$.

Notation watch

Lasry–Lions ("flat") monotonicity and displacement monotonicity are *not* nested: neither implies the other. A coupling can be flat-monotone but not displacement-monotone and vice versa. The two conditions coincide for the trivial (decoupled) case and overlap for specific structured couplings, but in general they cut out different – both non-empty – regions of model space. It is a genuine error to treat "monotone" as unambiguous; one must say *which* monotonicity.

The non-nesting is not an abstract caution; one model class exhibits it on a single line of algebra, and it is worth doing because it makes the two conditions concretely incomparable rather than merely "not known to be comparable." Take a pure interaction energy $\mathcal{F}(m) = \frac{1}{2}\iint K(x-y)\,m(\mathrm{d}x)\,m(\mathrm{d}y)$ with K even, whose flat derivative is the convolution $F(x,m) = (K*m)(x)$. Its flat monotonicity pairing collapses to a single quadratic form in the population shift $\Delta = m - m'$,

$$\int \big(F(x,m) - F(x,m')\big)\,\Delta(\mathrm{d}x) = \iint K(x-y)\,\Delta(\mathrm{d}x)\,\Delta(\mathrm{d}y),$$

which is nonnegative for *every* zero-mass Δ precisely when K is of positive type – by Bochner's theorem, when its Fourier transform $\widehat{K} \geq 0$. Displacement convexity of the very same $\mathcal{F}$, on the other hand, is McCann's criterion that the interaction kernel K be *convex* as a function on $\mathbb{R}^d$. These two requirements – positive-definite versus convex – are logically independent, and one can fail while the other holds. A smooth bump such as a centered Gaussian $K(z) = e^{-|z|^2/2}$ has $\widehat{K} \geq 0$, so it is flat-monotone, yet it is concave in a neighborhood of the origin and hence *not* convex, so it is not displacement-monotone. Conversely the quadratic kernel $K(z) = |z|^2$ is convex, hence displacement-monotone, but its flat pairing evaluates (using $\int \Delta = 0$, so the $|x|^2$ and $|y|^2$ pieces drop) to $\iint |x-y|^2 \Delta(\mathrm{d}x)\Delta(\mathrm{d}y) = -2\big|\int x\,\Delta(\mathrm{d}x)\big|^2 \leq 0$, which is strictly negative as soon as m, m' differ in mean – it is flat *anti*-monotone. So here are two couplings, each satisfying exactly one of the two conditions and violating the other. The conditions are genuinely incomparable, and "F

is monotone" is, without a qualifier, an ambiguous sentence. (Note this is the cleanest separating example, not a claim that the two notions never meet: an entropy or a strictly increasing local congestion cost can be both at once. The point is only that membership in one class is no evidence of membership in the other.)

With the geometry and the separation in hand, the operational dichotomy is clean, and it is the one piece of this section the rest of the chapter actually uses. Lasry–Lions monotonicity is what theorem 11.5 consumes: it is the sign that makes the boundary pairing $\int \bar{u}\,\bar{m}$ accumulate favorably and delivers uniqueness of the MFG *system* eqs. (11.1) and (11.2) itself, working directly on the coupled PDEs in physical state space. Displacement monotonicity is the analogue one level up, on the space of measures: it is the sign that makes the relevant second-order differential operator on $\mathcal{P}_2(\mathbb{R}^d)$ – the one whose vanishing is the *master equation* of chapter 12 – monotone, and thereby delivers well-posedness of that equation, and through it uniqueness, in regimes the flat condition cannot certify. The headline such regime is the *non-separable* Hamiltonian, where the running cost couples the control and the measure together (the agent's optimal velocity itself depends on the crowd, not merely its cost), so that the clean splitting into a control part and a population part that underwrites the flat-monotone variational picture of chapter 8 is simply unavailable; certain congestion models and the master equation under common noise sit in the same camp. There the duality identity of section 11.3 has no monotone term to extract, and one must instead ask the energy to bend the right way along the metric's own geodesics – which is displacement convexity.

Here the chapter reaches the boundary of what it proves, and the style of the book obliges us to mark that boundary rather than paper over it. The master equation is built and shown well posed *under Lasry–Lions monotonicity* in chapter 12, in-book and in full; that is the route this text certifies. The *displacement*-monotone theory – the proof that the condition just stated yields a monotone master operator and hence well-posedness for non-separable couplings – is a more recent and considerably more technical development, and we do not reproduce it. The precise functional inequality is a positivity condition on $\partial_x \partial_\mu F$ and its symmetrization, paired against arbitrary square-integrable displacement fields (the $\nabla\phi$ of the second-variation formula above); the argument that it propagates to monotonicity of the master operator, and from there to a unique classical solution, is due to Gangbo–Mészáros and collaborators and to Mou–Zhang [75, 76, 104], and it rests on the displacement-convexity calculus on $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ assembled in appendix D. We state the condition for orientation and attribute the theory to those sources deliberately: this is a survey-and-attribute passage, not a bare "see [reference]" standing in for an argument the chapter pretends to make. The honest reason it is out of scope is concrete rather than rhetorical – the proof needs the full second-order differential calculus on Wasserstein space (Lions derivatives, the chain rule along geodesics, and the master operator's coercivity estimates) at a level of technical machinery this chapter has not built and chapter 12 builds only for the separable, flat-monotone case. A reader who wants the theorem in force should read it as the displacement analogue of theorem 11.5, with the same architecture (a monotone pairing forces two solutions to coincide) transplanted from the system in state space to the master equation on measure space.

A fourth route rounds out the picture, and unlike displacement monotonicity it is not a different structure but a quantitative softening of the one we already proved. *Lasry–Lions monotonicity up to a small constant* – equivalently *weak monotonicity* – asks only that the coupling be monotone *after* subtracting a controlled non-monotone perturbation: eq. (11.3) is allowed to fail, but by no more than a fixed deficit. Uniqueness then survives provided that deficit is dominated, either by the diffusion's regularizing strength (a nondegenerate ν smooths the feedback loop and can absorb a small wrong-sign coupling) or by a short enough horizon (too little time for the residual instability to wind up). This is exactly the quantitative bridge between the chapter's two extremes. At one end sits the unconditional, horizon-free uniqueness of theorem 11.5, which demands the full sign condition and asks nothing of T; at the other sits the short-horizon contraction of theorem 9.10(i), which demands no sign condition but caps T. Weak monotonicity interpolates: the more nearly monotone the coupling, the longer the horizon that can be tolerated, recovering the unconditional theorem as the deficit shrinks to zero and the short-horizon theorem as it grows. This is the weak-monotonicity programme of Ahuja and others [4], and it is precisely the soft-band phenomenon the LQG thread exhibited, now named as a general mechanism: the band of attractive-but-too-weak couplings that the explicit computation found uniquely solvable at every horizon is exactly the regime where the non-monotone defect is small enough for the diffusion to swallow it.

We have thus put on the table two further routes to uniqueness beyond the short-horizon contraction and the Lasry–Lions condition the chapter has spent: displacement monotonicity, a genuinely different and incomparable structural hypothesis that reaches the non-separable models the flat condition cannot, and weak monotonicity, a quantitative relaxation that trades a small non-monotone defect against diffusion or horizon. Four conditions now stand assembled – short-horizon, Lasry–Lions, displacement, weak – each buying uniqueness at a different price in structure and a different reach in T. The next section lays them side by side and reads off the boundary of the uniqueness region they jointly map out, ordered from the cheapest and most local to the structural and horizon-free.

11.7 The boundary of the uniqueness regime

The previous section finished assembling the cast: four routes to a unique equilibrium — short-horizon contraction, Lasry–Lions monotonicity, displacement monotonicity, and weak monotonicity — each buying the same conclusion at a different price. It is time to make good on the promise to lay them side by side and read off, from the comparison, where the uniqueness region ends and what lies past its edge. The right way to see the four conditions is not as a list of unrelated sufficient hypotheses but as points along a single axis of trade: at one end, conditions that ask almost nothing of the *structure* of the coupling but demand a short *horizon*; at the other, conditions that ask a definite structural sign but then give uniqueness for *every* horizon. Each route pays for what it spares. Reading them in that order — cheapest and most local first, structural and horizon-free last — is reading down the chapter's own argument, from the elementary contraction of section 11.1 to the duality identity of section 11.3 and the refinements of section 11.6.

The first route asks for no structure at all and pays in horizon. **Short horizon (any coupling).** If T is small, the forward–backward best-response map S is a contraction on $C([0,T];\mathcal{P}_2(\mathbb{R}^d))$: its Lipschitz constant is $C\,T$, where C aggregates the Lipschitz constants of the data (the couplings F, G and the Hamiltonian's velocity field), so the moment $C\,T < 1$ the Banach fixed-point theorem forces a unique fixed point. This is the small-horizon well-posedness already proved in theorem 9.10(i), and it needs *no sign condition* whatever — attractive or repulsive, the round trip from initial mass to terminal value and back is simply too brief for the feedback loop to wind up. It is the honest reappearance of the Grönwall mechanism that section 11.1 declared unavailable: available after all, but only on a horizon clamped below $1/C$. That clamp is exactly the defect. The admissible window $T < 1/C$ *shrinks as the coupling strengthens*, because a stronger interaction raises C, and it collapses to nothing in the strongly attractive limit where $C \to \infty$. The LQG thread displays the window concretely: the band $T < T_c$ certified by proposition 11.8 holds for every imitation strength s, but the upper edge $T_c = (\pi - \arctan\sqrt{s-1})/(b\sqrt{q(s-1)})$ descends as s climbs past its critical value, so the short-horizon guarantee buys less and less time precisely where one would most want it. Short-horizon uniqueness is therefore the universal but local route: good for any model, good only briefly.

The second route reverses the trade. **Lasry–Lions monotonicity (any horizon).** Under **(A-Mon)** — the single inequality eq. (11.3), that crowding a region raises its cost — uniqueness holds for *all* T, by theorem 11.5. There is no horizon restriction to shrink, because the favorable signs in the duality identity accumulate monotonically over $[0, T]$ rather than racing a growing exponential; lengthening the horizon only adds more nonnegative terms to a quantity already trapped between zero and zero. This is the chapter's workhorse, and its value is threefold and worth restating in one breath: it is *checkable* (a single pairing, verifiable on the data without solving anything), *horizon-free* (it never mentions T), and exactly the structural hypothesis under which the deeper machinery of the book runs. The variational picture of chapter 8 is well behaved precisely here — monotone coupling is convexity of the equilibrium energy, so the Euler–Lagrange system has one critical point because a convex bowl has one bottom — and the master equation of chapter 12 is well posed precisely here, for the same reason read one level up. The price is honest and was paid in full in section 11.5: monotonicity is sufficient, not necessary, and it is conservative by exactly the width of the LQG soft band.

The third route is not a relaxation of the second but a genuine alternative, reaching models the second cannot certify. **Displacement monotonicity (any horizon).** As section 11.6 established, this is an *incomparable* structural hypothesis — convexity of the energy along Wasserstein geodesics rather than along linear mixtures, a condition on the spatial gradient $\partial_x \partial_\mu F$ rather than on F paired with $m - m'$ — neither implying nor implied by **(A-Mon)** (definition 11.10). It too gives uniqueness at every horizon, and its reach is the *non-separable* Hamiltonians where the agent's optimal velocity itself depends on the crowd, so that the clean control/population splitting underwriting the flat-monotone variational picture is unavailable and the duality identity of section 11.3 has no monotone term to extract. Uniqueness there comes instead through a displacement-monotone master-equation argument, attributed in section 11.6 to [75, 104] and *not reproduced in-book*: the proof needs the full second-order differential calculus on $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ at a level of machinery this chapter has not built. It enters the menu as the structural route to non-separable models, with the explicit caveat that the book certifies the flat-monotone case and surveys, rather than proves, this one.

The fourth route is the quantitative bridge between the first two, and it is what the LQG computation was secretly an instance of. **Weak / approximate monotonicity.** Here eq. (11.3) is allowed to fail, but by no more than a controlled deficit; uniqueness survives provided that deficit is dominated — by the diffusion's regularizing strength (a nondegenerate ν smooths the feedback loop and absorbs a small wrong-sign coupling) or by a short enough horizon (too little time for the residual instability to compound) [4]. This is a continuous interpolation along the very axis the menu is ordered by: as the non-monotone defect shrinks to zero it recovers the unconditional horizon-free theorem of route (2), and as the defect grows it degrades to the horizon-capped contraction of route (1). The soft band of section 11.5 — the attractive-but-too-weak couplings $0 < s \leq s_\star$ that the explicit computation found uniquely solvable at every horizon — is exactly this mechanism made visible: a small anti-monotone defect, swallowed by the private cost curvature q and the diffusion, leaving uniqueness intact where **(A-Mon)** had already given up.

This is the whole interior of the uniqueness region, and the four routes between them map it out. What the menu also makes visible is its *boundary* — and here the LQG phase diagram is the indispensable witness, because it shows the boundary is not approached asymptotically but reached at a sharp, computable threshold. Past $s = s_\star$, at the resonant horizon $T_c(s) = T_1(s)$ of proposition 11.8, uniqueness fails abruptly: the loss is an eigenvalue collision, a spectral event at a precise parameter value, not a gradual erosion. Outside the menu, then, lies genuine multiplicity, and the natural next question is the one this chapter cannot fully answer. *At* and *beyond* the boundary, where several mutually incompatible equilibria coexist, which one does the world play? This is the subject of *selection theory*, and the candidate principles are several: one may keep only the dynamically stable equilibria (those robust to small perturbations of belief), or take the vanishing-viscosity limit (the configuration selected as the noise that smooths the landscape is sent to zero), or single out the equilibrium consistent with the classical solution of the master equation where one exists. Each is reasonable, none is universal, and they need not agree. It must be stated plainly, in keeping with the book's refusal to paper over its edges: *a complete and general selection principle for non-monotone mean field games is not known.* It is one of the genuine open problems of the subject, revisited in chapter 31; the honest summary is that uniqueness, where this chapter secures it, is a structural gift, and where the structure fails the theory presently offers a forecast only up to a finite menu of self-consistent futures it cannot yet rank.

There is, however, one direction in which the boundary becomes *sharper* rather than more mysterious, and it is the direction the rest of the book travels: replacing the global mean coupling by a network. This chapter's entire phase structure was organized around a single scalar knob, the imitation strength s, with the critical attraction sitting at $s = 1$ in the driftless case — the point, recorded in remark 11.9, at which each agent's target $s\bar{m}$ tracks the population mean one-for-one, so that a small collective lean reproduces itself instead of damping out. The graphon generalization of chapter 24 keeps exactly this physics but indexes it by the coupling *kernel*. There the agent is drawn not toward the global mean $\bar{m}$ but toward the graphon-aggregated neighbor mean $(\mathbb{W}\,\bar{m})(x) = \int_0^1 W(x,y)\,\bar{m}(y)\,\mathrm{d}y$, weighting the crowd by network proximity, and the self-consistent collective lean is no longer a single number but a *mode* on the type space $[0,1]$. The runaway that destroys uniqueness happens when the strategic gain s amplifies some such mode faster than the private cost curvature can restore it; and which mode runs away first is settled by the operator $\mathbb{W}$. The fastest-growing mode is the leading eigenvector of $\mathbb{W}$ — the network-centrality (Perron) profile that weights each type by how strongly the kernel funnels the crowd toward it — and the threshold is governed by the corresponding eigenvalue, hence by the operator norm $\|\mathbb{W}\|$ (the spectral radius for the self-adjoint kernels of **(A-Reg-W)**). Heuristically, the scalar resonance $s = 1$ becomes the operator competition $s\,\|\mathbb{W}\| \asymp 1$: uniqueness is the regime where strategic monotonicity wins against the kernel's amplification, exactly the operator-norm smallness recorded as **(A-Coupling)**, and the critical coupling at which it fails is a symmetry-breaking threshold tied to the spectral radius of $\mathbb{W}$ — the same physics as this chapter's $s = 1$ line, now reading off network centrality rather than a single mean. The constant graphon $W \equiv c$ collapses the operator back to multiplication by c and recovers Thread A's scalar threshold with s rescaled by c, which is the consistency check that the two pictures are one. We state this only as the teaser it is: chapter 24 carries the actual theorem, the precise constant in **(A-Coupling)**, and the proof, which is this chapter's duality computation with the scalar pairing $\int \bar{u}\,\bar{m}$ promoted to a pairing in $L^2[0,1]$ against the operator $\mathbb{W}$.

That promotion is the chapter's exit, and it is worth naming what travels. The single duality identity proved in section 11.3 — one Green's identity, one integration by parts, a sum of manifestly signed terms — is not a self-contained curiosity but the seed of the book's later well-posedness theory. It hands forward to chapter 12 the fact that the master equation is well posed *exactly* in the monotone regime mapped here, with the chapter's convex-landscape reading becoming the monotonicity of the master operator; and it hands forward to chapter 24 the operator generalization just previewed, where the same computation, run in L^2 against $\mathbb{W}$, yields graphon uniqueness up to the spectral threshold. The throughline that opened the chapter — existence gives *an* equilibrium, a predictive theory needs *the* equilibrium — thus closes not at this chapter's edge but at the entrance to the two that build on it: the geometry of where uniqueness lives, why it can fail suddenly, and how to compute the boundary, is the geometry those later chapters inherit.

Rigor ledger

Proved.

- theorem 11.5: under **(A-Lip)**, **(A-Nondeg)**, **(A-Conv)** with strict convexity, and **(A-Mon)**, the MFG system eqs. (11.1) and (11.2) has at most one classical solution, via the Lasry–Lions duality identity eq. (11.8).
- propositions 11.2 and 11.3: local crowd-averse couplings are monotone; potential couplings are monotone iff their energy is flat-convex.
- worked computation 11.7 and proposition 11.8: the LQG mean field game reduces to a deterministic two-point BVP for $(r, \bar{m})$; its coupling is monotone iff $s \le 0$ (eq. (11.10)); the exact loss of horizon-free uniqueness occurs at $b^2 qs = A_\infty^2$, beyond which non-uniqueness sits only on the discrete resonant horizons eq. (11.14), giving the three-regime phase diagram in (s, q, T), independent of σ.

Assumed.

- Existence of a classical solution with the decay/regularity making the integrations by parts valid – imported from theorem 10.14 (bounded regularising couplings, with the value's x-Lipschitz bound lemma 10.5) and proposition 10.23 (the Gaussian LQG thread); the small-horizon contraction is theorem 9.10(i).
- Uniqueness in law for the linear SDE / Fokker–Planck equation with fixed coefficients (theorems 5.10 and 5.14) and the comparison/uniqueness principle for the backward HJB equation (theorem 6.18), used to close Step 5 of theorem 11.5.

- The second-order flat-derivative calculus on $\mathcal{P}_2(\mathbb{R}^d)$ underlying proposition 11.3 (chapter 4 and appendix D); the displacement-interpolation geometry of definition 11.10 (appendix D.3).

Deferred.

- Displacement monotonicity: precise functional inequality and its use for master-equation well-posedness with non-separable Hamiltonians – surveyed in section 11.6 and attributed to [75, 76, 104]; the displacement-convexity calculus it rests on is in appendix D. Not reproduced in-book.
- Discounted/ergodic monotonicity argument (remark 11.6) → [93].
- The graphon uniqueness theorem and the $\|\mathbb{W}\|$ threshold → chapter 24.
- The full time-dependent ($q_T \neq P_\infty$) LQG threshold, solved numerically → chapters 14 and 28.

Open.

- A general selection principle among multiple equilibria in the non-monotone regime (chapter 31).
- Sharp characterization of the full uniqueness region for non-separable Hamiltonians beyond the displacement-monotone class.

Bibliographic notes

The monotonicity condition and the duality proof of uniqueness originate with Lasry and Lions [93]; the lecture-note treatment we have followed most closely, including the finite-horizon computation of theorem 11.5 and the integration-by-parts structure, is Cardaliaguet [36]. The probabilistic counterpart and the role of monotonicity in the well-posedness of mean field FBSDEs and the master equation are developed in Carmona–Delarue [40, 41], and the master-equation well-posedness under monotonicity is the central theme of Cardaliaguet–Delarue–Lasry–Lions [37], to which chapter 12 is the introduction.

Displacement convexity is McCann's notion from optimal transport [131]; its deployment as a monotonicity condition for mean field games – displacement monotonicity – and the resulting global well-posedness of master equations for non-separable Hamiltonians are due to Gangbo and Mészáros and collaborators [75, 76] and, in the non-separable setting, to Mou and Zhang [104]. The weak/approximate monotonicity condition under common noise is Ahuja [4].

The LQG phase analysis of section 11.5 is the uniqueness layer of the linear–quadratic thread completed in chapter 14; the reduction of LQG mean field games to coupled Riccati/mean systems is classical, going back to the Nash-certainty-equivalence framework of Huang, Caines, and Malhamé [82]. The reading of equilibrium multiplicity as spontaneous symmetry breaking, and of the monotone regime as the convex, positive-susceptibility regime, is folklore in the mathematical-physics literature on mean field games; we have kept it to a single physics note, and the graphon refinement – multiplicity at a spectral/centrality threshold – is taken up in chapters 20 and 24.

Chapter 12

The Master Equation

Up to this point the mean field game has presented itself as a *system*, and in two equivalent guises. The first is analytic: a backward Hamilton–Jacobi–Bellman equation for the representative agent's value $u = u(t, x)$, coupled to a forward Fokker–Planck equation for the population density $m = m(t, x)$, with data fixed at *opposite* ends of the interval $[0, T]$ — the value pinned by a terminal condition at $t = T$, the density by an initial condition at $t = 0$ (chapter 8). The second is probabilistic: a McKean–Vlasov forward–backward stochastic differential equation in path space, in which a forward state process and a backward adjoint are locked together by the self-consistency demand that the law of the state coincide with the measure the cost reacts to (chapter 9). We solved this system for existence (chapter 10) and, under Lasry–Lions monotonicity (A-Mon), for uniqueness (chapter 11: the precise monotonicity inequality is definition 11.1 and the uniqueness theorem is theorem 11.5, both imported by label below). Both guises share one defining feature. The unknown is a *pair* of objects glued along a forward–backward seam, with split boundary data, and to know the answer at any interior time one must solve the two halves *together*, propagating in opposite directions until they are made consistent. The population enters the agent's problem only as a curve that has already been computed.

This chapter performs a genuine change of viewpoint. It compresses the entire apparatus into a *single* scalar equation for one unknown function

$$U : [0, T] \times \mathbb{R}^d \times \mathcal{P}_2(\mathbb{R}^d) \longrightarrow \mathbb{R},$$

the *master equation.* Its value $U(t, x, m)$ is the equilibrium cost-to-go of an agent who finds herself at state x at time t when the *entire population distribution* is m — a third, free argument that the bare value function $u(t, x)$ never carried. What is *gained* is precisely that argument: one object that answers the cost-to-go question for *every* conceivable population, not merely the one realized along a particular equilibrium, and that is therefore Markovian in the true state of the game and differentiable in the population. The forward–backward seam dissolves, because the population is no longer something solved for in advance but an explicit input slot. What is *paid* is the arena. The new unknown is no longer a function of a finite-dimensional state but a function on the infinite-dimensional Wasserstein space $\mathcal{P}_2(\mathbb{R}^d)$, and to even write its equation we must learn to differentiate in the measure argument. The tools for that are the flat and Lions derivatives built in chapter 4 and recorded in appendix A.3; they are the literal price of admission, and we assemble them in section 12.2.

This is not mere economy of bookkeeping; it buys three things the system cannot, and the chapter is organized to deliver each as a promise kept. *First*, a Markovian, single-equation picture. Because U carries the population as an argument, it is a value function in the genuine game state (x, m), and its equation turns out to be a Hamilton–Jacobi equation posed on the space of measures whose method of characteristics is *exactly* the MFG system of chapter 8 — the two coupled PDEs are recovered as the ODEs one integrates along the characteristic flows of the single equation (sections 12.4 and 12.5). *Second*, the engine of finite-player convergence. The very differentiability that the system lacks — the derivative of the value in the population direction — is what supplies the smooth "mean field expansion" of the N-player Nash value, and through it the convergence of the N-player game to the mean field limit with quantitative, optimal-order rates (chapter 13). *Third*, and decisively, the only formulation that survives *common noise* — a shock felt simultaneously by every agent. Under common noise the population measure stops being a deterministic curve and becomes a genuine stochastic process; the forward–backward system, which presumed a predetermined population trajectory, loses its meaning, whereas the master equation merely acquires second-order derivatives in m and keeps its form (section 12.7). The first section makes the case for the first of these by exhibiting, sharply, what goes wrong without U; the rest of the chapter delivers the other two.

Two standing conventions govern everything below, and it is worth foregrounding them because the master equation lives at the meeting point of both directions of time. Value functions are solved *backward*, carrying terminal data at $t = T$; population densities evolve *forward*, carrying initial data at $t = 0$ (appendix A.1). The master function U is a value, so it inherits a *terminal* condition at $t = T$, namely the terminal coupling G; but its measure argument is a density, so along any equilibrium that argument is transported forward from $t = 0$. This double bookkeeping — backward in the value, forward in the population it is evaluated against — is the entire content of the chapter in miniature, and the reader should keep it in view.

We also fix, once, the dynamics. We work in the canonical setting of chapter 8, in which the controlled drift is the control itself and the diffusion is an additive constant,

$$\mathrm{d}X_t \;=\; \alpha_t \,\mathrm{d}t \;+\; \sigma \,\mathrm{d}W_t, \qquad X_0 \sim m_0, \tag{12.1}$$

with σ constant and nondegenerate (A-Nondeg). This is chosen deliberately as the clean vehicle: with the drift equal to the control and σ a constant, every term in the master equation has an unobstructed interpretation, and the new measure-derivative content is not hidden behind state-dependent coefficients. Nothing structural is lost by it — the general Lipschitz drift of the standing assumptions, a state- and measure-dependent diffusion, and a non-separable Hamiltonian all produce the *same* equation with the coefficients evaluated in the obvious places — and that general case is carried in full in the worked remark (remark 12.4), which is also the form chapter 13 imports. Treat the canonical setting as the lit stage and the worked remark as the proof that the lighting changes nothing.

The chapter is a map in three movements. We first *derive* the master equation without common noise and prove its exact equivalence with the system (section 12.2–section 12.6): the differentiation machinery, the derivation, the reading of the result as a Hamilton–Jacobi equation on $\mathcal{P}_2(\mathbb{R}^d)$ whose characteristics are the MFG system, and the existence/uniqueness question that its first-order-in-m structure forces. We then *turn on common noise* and record the modifications it forces (section 12.7), deferring the full graphon-and-common-noise theory to chapter 26. Finally we make everything *explicit* on the carried LQG thread (section 12.8): we compute its decoupling field, exhibit the master equation as a finite system of Riccati equations, and verify that it reproduces the fixed point of chapter 8 exactly. We begin, in the next section, with the question that justifies the whole undertaking: why one equation, and what precisely is wrong with the value function we already have.

12.1 Why a single equation? The non-Markovian obstruction

Recall the equilibrium value function of the classical MFG. Fix an initial population $m_0 \in \mathcal{P}_2(\mathbb{R}^d)$. Solving the MFG system produces a forward flow of measures $(m_t)_{t\in[0,T]}$ and a value $u(t,x)$ satisfying

$$-\partial_t u - \tfrac{1}{2}\operatorname{tr}\big(\sigma\sigma^\top \mathrm{D}^2 u\big) + H(x,\nabla u) = F(x,m_t), \qquad u(T,x) = G(x,m_T), \tag{12.2a}$$
$$\partial_t m - \tfrac{1}{2}\operatorname{tr}\big(\sigma\sigma^\top \mathrm{D}^2 m\big) - \operatorname{div}\big(m\,\partial_p H(x,\nabla u)\big) = 0, \qquad m_0 \text{ given}, \tag{12.2b}$$

the system of chapter 8. Here $H(x,p)$ is the Hamiltonian, convex in p under (A-Conv), and the optimal feedback is $\alpha^*(x,p) = -\partial_p H(x,p)$ (appendix A.4); F and G are the running and terminal couplings to the population, monotone under (A-Mon).

The function $u(t,x)$ answers the question "what is my optimal cost-to-go from (t,x)?" — but read the small print. It answers it *only for the one population flow generated by the particular initial condition* m_0. Built into the very numbers $u(t,x)$ is the assumption that the crowd around the agent is, and always will be, the equilibrium slice m_t obtained by solving eq. (12.2b) forward from that fixed m_0. Change m_0 and the whole function u changes; u is indexed, silently, by an initial population it never displays.

This is a real defect, not a cosmetic one, and it is worth making concrete. Imagine the equilibrium crowd at time t is the configuration m_t, and ask the agent a counterfactual: "suppose that, when you arrive at x at time t, you instead find the population already massed elsewhere, in some $m \neq m_t$ — a denser cluster to your left, say, raising the congestion cost of moving there. What is your optimal cost-to-go now?" The bare value function $u(t,x)$ has *no answer*. It was computed against m_t and only m_t; it has no value attached to the contingency $m \neq m_t$, because that population never appears anywhere in its construction. The agent who genuinely faced such a crowd would re-optimize — her continuation cost, her optimal feedback, everything downstream depends on the population she actually sees — but u cannot express the dependence, having frozen it. In dynamic-programming language, $u(t,x)$ is therefore *not a value function in a Markov state.* The true state of the game is the pair (x,m) — one's own position *and* the population that prices one's choices — and a value function deserving the name must be a function of both. The bare u knows only the realized slice $m = m_t$; it is a value function on a one-dimensional curve drawn through an infinite-dimensional state space, not a value function on that state space. Restoring the missing argument is the entire task of the chapter, and the object that restores it is $U(t,x,m)$.

Heuristic (non-rigorous)

The right way to feel the gap is the difference between a *trajectory* and a *flow*. Take an ordinary differential equation $\dot{y} = v(y)$. Solving it from one fixed initial point y_0 produces a single curve $t \mapsto y(t)$ — one trajectory, valid for that one start. The *flow map* $(t, y_0) \mapsto y(t; y_0)$ is a different and larger object: it returns the solution started from *every* initial point at once. It is the flow map, not any single trajectory, that is the genuinely Markovian object, because it can answer the question "where will I be in time s?" from *wherever* I happen to find myself now — it composes with itself, $y(t+s; y_0) = y(t;\, y(s; y_0))$, which is exactly the semigroup property a Markov state must have. A single trajectory cannot compose with itself; it only knows the one orbit it traces.

The two formulations of the mean field game stand in exactly this relation. The MFG system eq. (12.2), solved from a fixed m_0, is the single *trajectory*: the one equilibrium flow through that one initial population, with $u(t,x)$ its value read off along the way. The master equation is the *flow map*. What we want is a function $U(t,x,m)$ that, *whatever* population m is presented at time t — realized or counterfactual — returns

$$U(t,x,m) \;=\; \text{the equilibrium cost-to-go of an agent at } x \text{ when the crowd is } m.$$

Here m is a free input slot, ranging over all of $\mathcal{P}_2(\mathbb{R}^d)$, precisely the slot the bare u lacked. The connection between the two is then a single, sharp identity: along the actual equilibrium flow (m_t) generated by the given m_0, the master function evaluated at the running population must reproduce the bare value,

$$u(t,x) \;=\; U(t,x,m_t), \qquad t \in [0,T]. \tag{12.3}$$

This is the flow-map-restricted-to-a-trajectory statement made literal: u is the slice of U taken along the one characteristic curve $m_\cdot$, just as a single ODE solution is the flow map evaluated along one orbit. The bare value function is recovered from the master function by evaluation; the master function is the strictly richer object that also values every off-equilibrium crowd. And here is the lever that turns this picture into an equation: because eq. (12.3) holds for *all* t, *differentiating this identity in* t must be consistent with the HJB equation that u already satisfies, and forcing that consistency — once we know how U responds to the motion of its measure argument — will produce a closed equation for U itself. That differentiation is the derivation of the master equation, carried out in section 12.3.

So far one might object that the flow map is a luxury: if only m_0 is ever realized, why value crowds that never occur? The objection collapses the moment one introduces *common noise*, and it is worth seeing why, because common noise turns the flow map from a convenience into a logical necessity. In the games of chapter 8 each agent carries her own independent Brownian motion, the idiosyncratic shocks average out across the continuum, and the population m_t evolves *deterministically* — it is a single curve one can compute in advance and then hold fixed while each agent optimizes against it. That is exactly what makes the bare $u(t,x)$ tenable: there is only ever one slice to value.

Common noise destroys that. Suppose, on top of her private shocks, every agent is buffeted by one *shared* Brownian motion W^0 — a market-wide shock, a common weather, an aggregate sentiment. This shock does not average out: it pushes the entire population the same way at the same instant, so the aggregate m_t is itself jostled randomly. The population ceases to be a deterministic curve and becomes a *random measure*, a stochastic process $t \mapsto m_t$ adapted to the common-noise filtration, taking a genuinely different value on each realization of W^0. Now "the realized slice" is not a single object that can be solved for ahead of time; *which* population the agent will face at time t is not known until the shared shock has played out, and the same agent at the same (t, x) may confront a whole distribution of possible crowds. A value function that hard-codes one trajectory m_t literally cannot be written down, because there is no one trajectory. What *can* be written down is a function $U(t, x, m)$ that has already valued *every* contingency m in advance; one then simply evaluates it at the population the shared shock actually produces. The per-crowd object is no longer an upgrade — it is the only thing that survives. We make this precise, and see common noise add the promised second-order m-derivatives to the master equation, in section 12.7.

Physics note

The master equation is the mean field game's *effective action* viewed as a generating functional. In a many-body field theory one integrates out microscopic degrees of freedom to obtain a functional $\Gamma[m]$ of the order-parameter configuration m, whose functional derivatives reproduce the physical correlation and response functions. Here $U(t, x, m)$ plays the role of Γ: its x-gradient $\nabla_x U$ is the equilibrium "momentum" (the decoupling field of section 12.5), and its measure-derivative $\frac{\delta U}{\delta m}(t, x, m, y)$ (with (t, x) frozen) is the linear response of one agent's value to an infinitesimal reweighting of the crowd. The analogy is structural and motivational only; unlike a thermal effective action, U encodes a *strategic* (Nash) fixed point with no variational principle behind it in the non-potential case, and nothing below relies on the picture.

We now have the program in hand: the object we want is the flow map $U(t, x, m)$, valuing every crowd; its tie to the equilibrium we already understand is the restriction identity eq. (12.3), $u(t, x) = U(t, x, m_t)$; and the route to a closed equation for U is, as flagged twice above, to *differentiate this identity in* t and demand consistency with the HJB equation. The one ingredient still missing is the meaning of that differentiation, for the right-hand side $U(t, x, m_t)$ depends on t not only explicitly, in its first slot, but *implicitly*, through the population m_t that the Fokker–Planck equation eq. (12.2b) transports in time. Differentiating it therefore demands a chain rule on the space of measures — a rule for how a smooth functional of the population changes as the population is carried along a Fokker–Planck flow. Building that chain rule, from the flat and Lions derivatives, is exactly the business of the next section.

12.2 Differentiation along a flow of measures

The previous section left us with one concrete obligation. The restriction identity $u(t, x) = U(t, x, m_t)$ ties the bare value to the master function along the equilibrium flow, and the plan announced there — twice — is to extract a closed equation for U by *differentiating this identity in* t and demanding consistency with the HJB equation that u already obeys. The left-hand side is a function of t through (t, x) alone, and we know how to differentiate it. The right-hand side is where the work is: t enters $U(t, x, m_t)$ *twice*, once explicitly in the first slot and once *implicitly* through the population m_t, which is being carried along in time by the Fokker–Planck equation. So before we can differentiate the identity we must answer a single self-contained question: how does a smooth functional of the population change as the population is transported by a Fokker–Planck flow? That question is a chain rule on the space of measures, and assembling it is the entire business of this section. Everything downstream in the chapter is this one lemma applied — with a particular choice of functional and a particular drift.

A chain rule needs a notion of derivative, and on $\mathcal{P}_2(\mathbb{R}^d)$ there are two of them, because a functional of a measure can be perturbed in two genuinely different ways. We recall both from chapter 4 and appendix A.3, but it pays to recover the intuition first, since the two derivatives play visibly different roles in the formula we are after.
