Remark 24.12 (The two compactness inputs, named)**.** The proof rests on two compactness facts of different origin, and tracing each to its source is the cleanest way to see what is old and what is new in the graphon existence theorem. The state-and-time compactness — the inner set $\mathcal{K}$ — is pure Part I machinery: tightness manufactured from a uniform second moment by Markov's inequality, promoted to relative weak compactness by Prokhorov's theorem (chapter 3), and assembled with a time-modulus into a compact flow space exactly as in lemma 10.8. The only graphon fingerprint on it is that its constants were made uniform across types, and that uniformity was bought from a single *magnitude* of the operator, the row-sum norm of $\mathbb{W}$ (lemma 24.6). Strip the graphon away and this is verbatim the homogeneous existence argument. The type-direction compactness — the modulus η — is by contrast a Part III input with no Part I ancestor: it is manufactured from the *regularity* of the graphon, specifically the uniform continuity of W in its type argument (lemma 24.8), the analytic content that the graph-limit theory of chapters 15 and 18 installs on the kernel. Neither input alone suffices — confinement without an equicontinuity modulus leaves the type-curve free to oscillate, and a modulus without confinement leaves the fibres free to run to infinity — and the decisive point is that the second input has *no classical analogue whatsoever*: a homogeneous mean field game has no type variable, hence nothing to be compact in, hence no equicontinuity to demand. This is the first concrete sense in which the graphon problem is strictly harder than its homogeneous parent, and it is the reason **(A-Reg-W)** surfaces already in the hypotheses of an *existence* theorem, where the classical theorem 10.14 needed no regularity of any coupling kernel at all. Norm and continuity, the two faces of the one operator $\mathbb{W}$, supply the two compactnesses: this is the chapter's organising claim instantiated at the very point where existence is won.

Remark 24.13 (Merely measurable graphons)**.** The continuity half of **(A-Reg-W)** was load-bearing in exactly one place — the type-modulus η of lemma 24.9 — and the opening `notationwatch` warned that it asks for a structure a graphon generically lacks. A graphon is canonically an equivalence class under measure-preserving relabelling of $[0, 1]$, and such a class need contain no continuous representative; in the generic, merely *measurable*, case the phrase "$x \mapsto W(x, \cdot)$ is continuous" has no referent, the modulus ρ_W does not exist, and with it the η-modulus evaporates. The type-continuous space $C([0,1];\mathcal{K})$ is then simply the wrong arena, and must give way to a space of *measurable* fields valued in $\mathcal{K}$, the L^2-in-type Bochner space $L^2([0,1];\mathcal{C})$ of chapter 21, whose metric controls only a type-average and no single type. Existence survives, but the missing compactness must be bought by a different mechanism, and there are two honest routes, worth laying out because they are the two routes the convergence chapter will formalise.

The first route is the *step-graphon* or cut-metric route, and it trades the continuum for a finite approximation. The weak regularity lemma (chapter 19) approximates any kernel W in cut metric $\delta_\square$ by step graphons — kernels piecewise constant on a finite partition of $[0,1]$ into finitely many blocks. On a step graphon each block is internally homogeneous: all types within a block present the same kernel row, feel the same aggregate, and the continuum of coupled boundary-value problems collapses to a *finite* multi-population game, for which existence is the elementary fixed-point statement of remark 24.14. One then passes to the limit along the step approximations using the cut-metric stability of the equilibrium map, which is exactly the convergence theory chapter 25 is built to supply. This route never needs a type-modulus because it never works in the type-continuous topology; it works block by block in a finite world and only takes a limit at the end.

The second route stays in the continuum but changes the source of compactness from regularity of the kernel to *compactness of the operator*. Working directly in $L^2([0,1];\mathcal{C})$, the aggregation factor $\mathcal{A}_W$ is still the bounded linear map $\mathbb{W}$ post-composed with the first-moment read-out; but $\mathbb{W}$ is not merely bounded, it is Hilbert–Schmidt and therefore *compact* (chapter 18). A compact operator maps the bounded set of first-moment fields into a *relatively compact* set in $L^2([0,1];\mathbb{R}^d)$, and that relative compactness of the aggregate is precisely the substitute for the type-equicontinuity we lost: where continuity of the kernel made the output field equicontinuous, the Hilbert–Schmidt compactness of $\mathbb{W}$ makes the aggregate data pre-compact, and the Schauder argument runs on that. The one extra subtlety is that with no single-type control the per-type optimisers must be re-collected into a genuinely measurable field, which is arranged by the measurable-selection theory of lemma 10.20 — the same selection device the relaxed homogeneous theory used. The measurable case is thus not a failure of the method but a redistribution of its compactness burden from the kernel's regularity onto the operator's own compactness, and because its natural home is the cut-metric stability theory, we develop it in full there rather than here, in chapter 25.

Remark 24.14 (Set-valued feedback and block reduction)**.** Two boundary cases of the standing hypotheses are worth following to their conclusions, one relaxing the regularity of the per-type solve and one specialising the kernel, because each maps the graphon theorem onto a neighbouring chapter. First, the relaxation. The whole construction ran in the single-valued regime fixed at the close of section 24.1: strict convexity **(A-Conv)** and nondegeneracy **(A-Nondeg)** together made the per-type optimal feedback a genuine function, hence $\mathcal{R}$ a map and S_W an honest self-map for which Schauder is the right tool. Drop either hypothesis — a Hamiltonian with a flat stretch, or a degenerate diffusion — and the optimiser may be indifferent among several feedbacks: $\mathcal{R}$ becomes *set-valued*, S_W a correspondence rather than a map, and Schauder is replaced by its set-valued cousin, the Kakutani–Fan–Glicksberg theorem (theorem 2.40), applied to the field-valued correspondence on the very same convex compact set $\mathbb{K}_W$. The output is a *weak* (relaxed) graphon equilibrium, with a measurable-selection step recovering an honest feedback from the correspondence, exactly as theorem 10.19 relaxes theorem 10.14 in the homogeneous theory. The moral is the throughline once more: the set-valuedness is entirely a phenomenon of the classical factor $\mathcal{R}$, since it is the per-type optimiser that turns multivalued, while the aggregation $\mathcal{A}_W$ — linear, single-valued, blind to convexity — is untouched. The graphon adds nothing to this difficulty and subtracts nothing from it; it is inherited whole from chapter 10.

Second, the specialisation, which runs to the opposite extreme and connects forward rather than back. Take a *block graphon*: a kernel piecewise constant on a partition $[0,1] = \bigsqcup_{k=1}^{K} I_k$ of the type interval into K blocks, $W(x,y) = w_{k\ell}$ for $x \in I_k$, $y \in I_\ell$. Then all types in a common block are genuinely interchangeable: they share a kernel row, so they feel the same aggregate $z_t(x) = \sum_\ell w_{k\ell} \int_{I_\ell} \overline{\mathbf{m}}_t$, solve the same per-type problem, and — starting from a block-constant initial datum — produce the same flow. The field therefore collapses to K flows, one per block, the continuum system eq. (24.1)–eq. (24.2) collapses to K coupled scalar HJB/FP pairs, and the best-response map S_W becomes an ordinary self-map of the finite product $\mathcal{K}^K$. What survives is precisely a *finite multi-population* mean field game, K populations coupled through the $K \times K$ matrix $(w_{k\ell})$, and theorem 24.11 reduces to multi-population existence by Schauder on $\mathcal{K}^K$ — a setting with no type-direction subtlety at all, because the type direction has become a finite index. This is no curiosity: it is the bridge to chapter 30, where multi-population games are the object of study, and it confirms the chapter's reductions from the other side — a constant graphon ($K = 1$) returns the homogeneous game of chapter 10, a block graphon returns the finite multi-population game, and only the genuinely continuous kernel needs the equicontinuity machinery this section built.

With existence in hand, the chapter's first question is answered: the equilibrium set is *nonempty*, and the fixed point it contains is regular — continuous in type, $\frac{1}{2}$-Hölder in time, with a type- and time-uniform gradient bound on the value field — which is exactly the regularity the uniqueness identity and the convergence theory will lean on. But nonempty is not the end of the story. Schauder is a blunt instrument: it certifies that *a* fixed point exists and says nothing about how many. The sharpened question that survives is the complementary one — *when is the equilibrium set a singleton?* — and the next section takes it up. As the existence proof split into a classical factor and an operator factor, so will the uniqueness analysis: the two routes to a singleton are the operator versions of the two classical routes of chapter 11, a structural monotonicity good for every horizon and a smallness condition good for weak coupling, and the interesting physics — the critical coupling at which the singleton splits — will be read off the spectrum of the very operator $\mathbb{W}$ that bought us compactness here.

24.3 Uniqueness and the critical coupling

Existence handed us a nonempty equilibrium set together with the regularity of its members, and with it the complementary question that Schauder is constitutionally unable to answer: is that set a *singleton*? A fixed-point theorem that argues by compactness counts at least one solution and never at most one, so uniqueness is a separate undertaking with its own machinery — and, true to the chapter's discipline, that machinery is again the classical one of chapter 11 read through the factorisation $\mathsf{S}_W = \mathcal{R} \circ \mathcal{A}_W$. The homogeneous theory offered exactly two ways to force a singleton, and they are complementary in a way worth recalling before we lift them, because the lift preserves the complementarity and the chapter's central phenomenon lives precisely in the gap between them. The first classical route was *structural*: if the coupling is Lasry–Lions monotone — crowd-averse, so that a heavier population at a point raises the cost of being there — then the duality identity of theorem 11.5 forbids two equilibria *at every horizon* T, however long, with no smallness assumed. The second was a *smallness* route: if the coupling is weak enough relative to the horizon, the best-response map is a contraction and Banach's theorem delivers a unique fixed point directly, monotone or not. Strong crowd-seeking coupling over a long horizon falls under neither, and there the homogeneous equilibrium genuinely splits — the Curie–Weiss bifurcation of section 11.4.

Both routes lift to the graphon setting, and the only change in each is the insertion of the operator $\mathbb{W}$ at the single seam the chapter has been tracking. The structural route lifts to *graphon Lasry–Lions monotonicity*: the operator version of the standing assumption **(A-Mon)**, now a condition on the coupling as a map of *fields*, whose defining pairing carries an extra integral over the type. It generalises theorem 11.5 and inherits its great virtue — validity at *all* horizons. The smallness route lifts to an *operator-norm contraction*: the standing assumption **(A-Coupling)** read as a bound on $\|\mathbb{W}\|$, under which S_W contracts and Banach applies. It inherits the classical virtue too — it is indifferent to the sign of the coupling, working for crowd-seeking and crowd-averse alike — and the classical defect: it needs the product of coupling strength and horizon to be small, so it says nothing once the horizon is long. The two routes therefore cover the uniqueness landscape from opposite directions. Monotonicity sweeps in along the *coupling-sign* axis, claiming the crowd-averse half-plane (for a positive operator $\mathbb{W}$) at every T; contraction sweeps in along the *coupling-magnitude* axis, claiming a neighbourhood of zero coupling for every sign. What each leaves uncovered is exactly the region the other handles — except for one wedge that *both* leave uncovered, where the coupling is strongly crowd-*seeking* (imitative) and the horizon is long (and, when the network operator $\mathbb{W}$ is indefinite, a second such wedge on the crowd-averse side, a graphon-only phenomenon we flag now and pin down with the critical-coupling proposition). That wedge is not an artefact of two imperfect sufficient conditions; it is where multiplicity actually lives, and the boundary of the wedge is the object the section is built to locate.

That boundary is the *critical coupling*. The picture to carry is of two bounds closing on it from opposite sides: monotonicity guarantees uniqueness up to the point where the equilibrium energy first loses its sign, and contraction guarantees it up to the point where the best-response map first stops shrinking, and these two limits meet — in the diagonalisable Thread B model, *exactly* — at a single threshold value of the coupling. The classical theory placed that threshold at the scalar value s_c^{scalar} where the strategic self-amplification first overpowers the agent's own cost curvature (section 11.4); the graphon theory places it, as the whole chapter has promised, not at s_c^{scalar} but at the product $s\,\lambda_1$, the intrinsic coupling strength magnified by the leading eigenvalue $\lambda_1 = \|\mathbb{W}\| = \rho(\mathbb{W})$ of the network operator — the eigenvector centrality of chapter 18. Loss of uniqueness becomes a symmetry-breaking transition indexed by network centrality: the more central the network (the larger λ_1), the smaller the intrinsic imitation s at which the product crosses s_c^{scalar}, i.e. the smaller the critical coupling $s_c = s_c^{\text{scalar}}/\lambda_1$, and the broken symmetry first appears along the leading eigenmode ϕ_1. Everything graphon-specific in the uniqueness question is thus, once more, read off the spectrum of $\mathbb{W}$.

The section develops this in three movements, in the order the logic demands. We take the structural route first, in definition 24.15 and the theorem that follows, because monotonicity is the hypothesis that controls the long-horizon regime where the interesting physics sits and because it is the direct generalisation of chapter 11; the next subsection therefore opens by lifting **(A-Mon)** to fields and contrasting the graphon pairing eq. (24.5) with its scalar ancestor eq. (11.3) — the two differing, as we will see, by exactly the outer $\int_0^1 \mathrm{d}x$ that threads the operator $\mathbb{W}$ into the energy. We take the smallness route second, as the operator-norm contraction that bounds uniqueness from the weak-coupling side and, as a bonus, yields the Lipschitz dependence of the equilibrium on the kernel that the convergence theory of chapter 25 will consume. Finally we let the two bounds meet: the critical-coupling proposition locates the threshold $s\,\lambda_1 = s_c^{\mathrm{scalar}}$ that monotonicity bounds from one side and contraction from the other, and reads off the centrality-indexed onset of multiplicity. We begin with monotonicity.

24.3.1 Graphon Lasry–Lions monotonicity

The section opening promised the structural route first, and the reason bears repeating before we build it, because it is what makes this the route to reach for when the physics is interesting. Monotonicity asks nothing about how strong the coupling is or how long the game runs; it asks only that the coupling have a definite *sign*. That is exactly the demand that survives the long-horizon, strong-coupling regime where the homogeneous equilibrium was at risk of splitting — the regime the smallness route of the next subsection cannot reach. In the homogeneous theory the sign was supplied by the standing assumption **(A-Mon)**, Lasry–Lions monotonicity (definition 11.1): the running coupling F and the terminal coupling G are *crowd-averse*, in the precise sense that the pairing of the cost increment $F[m] - F[m']$ against the population increment $m - m'$ is nonnegative,

$$\int_{\mathbb{R}^d} \left(F[m] - F[m']\right)(m - m')(\mathrm{d}\xi) \;\geq\; 0,$$

the inequality eq. (11.3) that powered the uniqueness theorem theorem 11.5 at *every* horizon. Reading it physically: moving population mass towards a point raises the cost of sitting at that point, so agents are pushed apart and no self-reinforcing concentration can grow — the mechanism that forbids two competing equilibria.

Our task is to lift this inequality from a single population to a field, and the lift is the gentlest imaginable, which is itself part of the chapter's message. A graphon coupling no longer acts on one population but on a whole field $\mathbf{m}$, and it no longer returns one cost function felt by everyone but a cost *field* $F[\mathbf{m}](x, \cdot)$, a separate cost function for each type. The pairing that tests its monotonicity must therefore pair a function of *type and state* against a signed-measure field over types — the difference $\mathbf{m} - \mathbf{m}'$ of two population fields. There is exactly one way to build such a pairing out of the scalar one: hold the type fixed, run the scalar state-pairing eq. (11.3) inside that type, and then average the result over types. That single extra averaging — one outer integral $\int_0^1 \mathrm{d}x$ wrapped around the inherited scalar pairing — is the whole formal difference between the homogeneous and the graphon monotonicity conditions.

Definition 24.15 (Graphon Lasry–Lions monotonicity)**.** A graphon coupling $F\colon \mathbb{M}_2 \to C([0,1]\times\mathbb{R}^d)$

is *graphon (Lasry–Lions) monotone* if for all fields $\mathbf{m}, \mathbf{m}' \in \mathbb{M}_2$,

$$\mathcal{G}_F(\mathbf{m}, \mathbf{m}') := \int_0^1 \int_{\mathbb{R}^d} \left(F[\mathbf{m}](x,\xi) - F[\mathbf{m}'](x,\xi)\right) (m^x - m'^x)(\mathrm{d}\xi)\ \mathrm{d}x \ \geq\ 0. \tag{24.5}$$

The graphon version of the standing assumption **(A-Mon)** is that both F and G are graphon monotone.

Set side by side, the two pairings are the same object with one extra symbol. Strip the outer $\int_0^1 \mathrm{d}x$ from eq. (24.5) and what remains, at a frozen type x, is verbatim the scalar pairing eq. (11.3) of the cost increment against the population increment; restore the integral and the scalar pairings are merely averaged over the continuum of types. The bracket $\mathcal{G}_F(\mathbf{m}, \mathbf{m}')$ is, in a word, the type-average of the inherited Lasry–Lions energy, and definition 24.15 asks only that this average be nonnegative.

The temptation at this point — and the trap the rest of the section is built to spring — is to read "average of the scalar energies" as "average of monotone things, hence monotone." That reading is exactly wrong, and seeing why is the crucial point, the one whose consequences section 24.4 collects in full. It would be correct if each type's cost field $F[\mathbf{m}](x,\cdot)$ depended only on that type's own population m^x, for then the integrand at type x would be a genuine scalar monotone pairing and the outer integral would preserve its sign. But a graphon coupling is built precisely so that this is *not* the case: by definition 24.3 the cost felt by type x depends on the field through the aggregate $z(x) = (\mathbb{W}\overline{\mathbf{m}})(x)$, which mixes *every* type's population through the kernel. The increment of the integrand at type x therefore involves the increment of the aggregate, $\Delta z(x) = (\mathbb{W}\Delta)(x)$, and the operator $\mathbb{W}$ is now threaded through the energy. The outer integral no longer sees a sum of independently-signed terms; it sees a quadratic form in $\mathbb{W}$, whose sign is decided jointly by the strategic structure of the coupling and the *spectrum* of $\mathbb{W}$. This is the throughline made local: every graphon-specific feature of the uniqueness question is, once again, the responsibility of the one operator and lives in its spectrum. We prove the uniqueness theorem first, exactly as in chapter 11, and only then unfold the pairing to expose the operator inside it.

Theorem 24.16 (Graphon Lasry–Lions uniqueness)**.** *Assume **(A-Lip)**, **(A-Nondeg)**, **(A-Conv)** with $H(x,\cdot)$ strictly convex, **(A-Reg-W)**, and that the couplings F, G are graphon monotone (definition 24.15). Then the GMFG system eq.* (24.1)*–eq.* (24.2) *has at most one classical solution field* $(\mathbf{u}, \mathbf{m})$ *for which the per-type integrations by parts of theorem 11.5 are justified.*

Proof. The argument is theorem 11.5 run in parallel over types and then integrated against $\mathrm{d}x$, and the slogan is worth taking literally: nothing inside a single type knows it is part of a continuum, so the per-type computation *is* the classical one, unchanged to the last sign, and the only new act is to integrate the classical identity over x at the end. Let $(\mathbf{u}_1, \mathbf{m}_1)$, $(\mathbf{u}_2, \mathbf{m}_2)$ be two classical solutions, and set, for each type, the differences $\bar{u}^x := u_1^x - u_2^x$ and $\bar{m}^x := m_1^x - m_2^x$. Fix a type x for the whole of the per-type computation and suppress it from the notation where it does not matter.

Step 1: subtract the two systems. Writing the two copies of the graphon HJB eq. (24.1) and subtracting, and likewise for the graphon FP eq. (24.2), gives a linear backward equation for $\bar{u}^x$ and a linear forward equation for $\bar m^x$:

$$\begin{aligned}-\partial_t \bar u^x - \nu\,\Delta_\xi \bar u^x &= \big(F[\mathbf{m}_1]-F[\mathbf{m}_2]\big)(x,\cdot) - \big(H(x,\nabla u_1^x) - H(x,\nabla u_2^x)\big),\\ \partial_t \bar m^x - \nu\,\Delta_\xi \bar m^x &= \mathrm{div}_\xi\big(m_1^x\,\partial_p H(x,\nabla u_1^x) - m_2^x\,\partial_p H(x,\nabla u_2^x)\big),\end{aligned}$$

the Hamiltonian and the transport drift appearing as *differences* because the equations are nonlinear in u and bilinear in $(m,\nabla u)$ respectively.

Step 2: differentiate the per-type pairing and cancel the diffusion. Consider the scalar quantity $t \mapsto \int_{\mathbb{R}^d} \bar u^x \bar m^x \,\mathrm{d}\xi$. Differentiating in time and substituting $\partial_t \bar u^x$ and $\partial_t \bar m^x$ from Step 1,

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathbb{R}^d} \bar u^x \bar m^x = \int_{\mathbb{R}^d} (\partial_t \bar u^x)\,\bar m^x + \int_{\mathbb{R}^d} \bar u^x\,(\partial_t \bar m^x),$$

the two second-order terms it produces are $-\nu\int \bar m^x \Delta_\xi \bar u^x$ from the first piece (after moving $\partial_t \bar u^x$ to the other side of its equation) and $+\nu\int \bar u^x \Delta_\xi \bar m^x$ from the second, and they cancel: by Green's second identity (both fields and their gradients decaying at infinity, guaranteed by the moment leash and the parabolic regularity that justify the integrations by parts hypothesised in the theorem),

$$\nu\int_{\mathbb{R}^d} \big(\bar u^x\,\Delta_\xi \bar m^x - \bar m^x\,\Delta_\xi \bar u^x\big)\,\mathrm{d}\xi = 0.$$

This is the same cancellation that made the classical identity work; the diffusion contributes nothing to the energy balance.

Step 3: integrate the transport term by parts and recognise the Bregman divergence. What survives is the Hamiltonian difference paired against $\bar m^x$ and the transport divergence paired against $\bar u^x$. Integrating the latter by parts once moves the divergence onto $\nabla_\xi \bar u^x = \nabla u_1^x - \nabla u_2^x$:

$$\int_{\mathbb{R}^d} \bar u^x\,\mathrm{div}_\xi\big(m_1^x\partial_p H_1 - m_2^x \partial_p H_2\big) = -\int_{\mathbb{R}^d} \big(\nabla u_1^x - \nabla u_2^x\big)\cdot\big(m_1^x\partial_p H_1 - m_2^x\partial_p H_2\big),$$

abbreviating $H_i = H(x,\nabla u_i^x)$ and $\partial_p H_i = \partial_p H(x,\nabla u_i^x)$. Collecting this with the Hamiltonian-difference term $\int (H_1 - H_2)(m_1^x - m_2^x)$ and regrouping by which density multiplies which gradient pair, every term assembles into two copies of the Bregman divergence $D_H(x;p,q) := H(x,p) - H(x,q) - \partial_p H(x,q)\cdot(p-q)$ of the convex Hamiltonian (lemma 11.4):

$$\int (H_1 - H_2)\bar m^x - \int \big(\nabla u_1^x - \nabla u_2^x\big)\cdot\big(m_1^x\partial_p H_1 - m_2^x\partial_p H_2\big) = A^x(t),$$

where

$$A^x(t) = -\int_{\mathbb{R}^d} m_1^x\,D_H(x;\nabla u_2^x,\nabla u_1^x) - \int_{\mathbb{R}^d} m_2^x\,D_H(x;\nabla u_1^x,\nabla u_2^x)\ \le\ 0$$

— the regrouping is the elementary algebra of lemma 11.4, and the sign is forced because each density $m_i^x \ge 0$ and each Bregman divergence $D_H \ge 0$ by convexity of $H(x,\cdot)$. We have arrived, type by type, at exactly the classical identity eq. (11.6)–eq. (11.7):

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathbb{R}^d} \bar u^x \bar m^x\,\mathrm{d}\xi = A^x(t) - \int_{\mathbb{R}^d} \big(F[\mathbf{m}_1]-F[\mathbf{m}_2]\big)(x,\cdot)\,\bar m^x.$$

Step 4: integrate over time, then over type. The previous three steps were the homogeneous proof with a passive type label; this step is the only genuinely graphon move, and it is just an integration. Integrate the per-type identity over $t \in [0,T]$. The left side telescopes to the boundary slices $\int \bar{u}^x \bar{m}^x$ evaluated at $t = T$ minus at $t = 0$. The initial slice vanishes because both solutions start from the *same* datum, $\bar{m}^x(0) = m_1^x(0) - m_2^x(0) = 0$ for every type. The terminal slice is the terminal-coupling pairing, since $\bar{u}^x(T) = G[\mathbf{m}_{1,T}](x,\cdot) - G[\mathbf{m}_{2,T}](x,\cdot)$. Thus, for each fixed type,

$$\int_{\mathbb{R}^d} (G[\mathbf{m}_{1,T}] - G[\mathbf{m}_{2,T}])(x,\cdot)\,\bar{m}^x(T) = \int_0^T A^x(t)\;\mathrm{d}t - \int_0^T\!\!\int_{\mathbb{R}^d} (F[\mathbf{m}_1] - F[\mathbf{m}_2])(x,\cdot)\,\bar{m}^x\;\mathrm{d}t.$$

Now — and this is the lift — integrate *this* identity over $x \in [0,1]$. The two state-pairings on either side are precisely the integrands of the graphon pairings of definition 24.15: the terminal one integrates to $\mathcal{G}_G(\mathbf{m}_{1,T}, \mathbf{m}_{2,T})$, the running one to $\int_0^T \mathcal{G}_F(\mathbf{m}_{1,t}, \mathbf{m}_{2,t})\;\mathrm{d}t$. By graphon monotonicity of G the left side is nonnegative,

$$\int_0^1\!\!\int_{\mathbb{R}^d} (G[\mathbf{m}_{1,T}] - G[\mathbf{m}_{2,T}])(x,\cdot)\,\bar{m}^x(T)\;\mathrm{d}x = \mathcal{G}_G(\mathbf{m}_{1,T}, \mathbf{m}_{2,T}) \ge 0,$$

and the whole identity reads

$$0 \le \mathcal{G}_G(\mathbf{m}_{1,T}, \mathbf{m}_{2,T}) = \int_0^T\!\!\int_0^1 A^x(t)\;\mathrm{d}x\;\mathrm{d}t - \int_0^T \mathcal{G}_F(\mathbf{m}_{1,t}, \mathbf{m}_{2,t})\;\mathrm{d}t,$$

the exact operator analogue of the scalar identity eq. (11.8), with the type integral threaded through both the Bregman term and the coupling term.

Step 5: the sign squeeze. The right-hand side is a sum of two nonpositive quantities. The integrated Bregman term $\int_0^T\int_0^1 A^x\;\mathrm{d}x\;\mathrm{d}t \le 0$ because every $A^x(t) \le 0$ pointwise from Step 3, and the running coupling term $-\int_0^T \mathcal{G}_F \le 0$ because $\mathcal{G}_F \ge 0$ at every time by graphon monotonicity of F. A nonnegative quantity that equals a sum of two nonpositive quantities forces all three to vanish. In particular $\int_0^T\int_0^1 A^x\;\mathrm{d}x\;\mathrm{d}t = 0$ with $A^x \le 0$ forces, for a.e. (t,x), both $m_1^x\,D_H(x;\nabla u_2^x, \nabla u_1^x) = 0$ and $m_2^x\,D_H(x;\nabla u_1^x, \nabla u_2^x) = 0$. Here the *strict* convexity hypothesised in the theorem does its one job: $D_H(x;p,q) = 0$ with $H(x,\cdot)$ strictly convex forces $p = q$, so on the support of each density the two optimal velocity fields $\partial_p H(x, \nabla u_i^x)$ coincide. Each pair (m_1^x, m_2^x) then solves the *same* linear Fokker–Planck equation eq. (24.2), with the same drift on the relevant support and the same datum m_0^x, so $m_1^x \equiv m_2^x$ for every type by uniqueness for the linear parabolic equation (chapter 5). With the density fields equal, the coupling data coincide, $F[\mathbf{m}_1] = F[\mathbf{m}_2]$ and $G[\mathbf{m}_{1,T}] = G[\mathbf{m}_{2,T}]$, so for each type u_1^x and u_2^x solve the same backward HJB with the same terminal datum and hence $u_1^x \equiv u_2^x$. The two solution fields are equal. □

The theorem is clean, and its cleanliness is the point: the proof never had to think about the graphon at all until the very last integration, because the operator $\mathbb{W}$ sits inside the data $F[\mathbf{m}]$, not inside the differential machinery, and the differential machinery is all the per-type computation touches. But that same feature means the hypothesis — graphon monotonicity, the nonnegativity of $\mathcal{G}_F$ and $\mathcal{G}_G$ — *hides* the operator: definition 24.15 is a clean inequality about an abstract pairing, and one cannot tell by looking at it whether a given model satisfies it or whether, in satisfying it, the operator has done something the homogeneous theory never saw. To find out we must open the pairing up and compute it for a concrete coupling. The natural choice is the canonical graphon-local quadratic coupling carried by Thread B, the congestion–imitation model of chapter 22, both because it is the model the chapter is committed to following to its threshold and because, being quadratic, it is the one case where the pairing can be evaluated in closed form and the operator inside it laid bare. The result is the pivotal computation of the section.

Proposition 24.17 (The monotonicity pairing is a quadratic form in $\mathbb{W}$)**.** *Let the running coupling be the graphon-local quadratic $F[\mathbf{m}](x,\xi) = \frac{q}{2}\big(\xi - s\,z(x)\big)^2$ with $z = \mathbb{W}\overline{\mathbf{m}}$ and $q > 0$, $s \in \mathbb{R}$ (the Thread B coupling). Then for any two fields with first-moment fields $\overline{\mathbf{m}}, \overline{\mathbf{m}}'$ and $\Delta := \overline{\mathbf{m}} - \overline{\mathbf{m}}' \in L^2([0,1])$,*

$$\mathcal{G}_F(\mathbf{m},\mathbf{m}') \;=\; -\,q\,s\,\langle \Delta, \mathbb{W}\Delta\rangle_{L^2([0,1])} \;=\; -\,q\,s\sum_{k\geq 1}\lambda_k\;|\langle \Delta,\phi_k\rangle|^2\,, \tag{24.6}$$

where (λ_k,ϕ_k) is the eigensystem of $\mathbb{W}$ (chapter 18). Consequently F is graphon monotone if and only if $s\,\langle\Delta,\mathbb{W}\Delta\rangle \leq 0$ for all Δ; in particular, if $\mathbb{W}$ is positive semidefinite (all $\lambda_k \geq 0$, e.g. a graphon of positive type), F is graphon monotone iff *$s \leq 0$.*

Proof. Fix a type x and abbreviate its two aggregates $z = z(x) = (\mathbb{W}\overline{\mathbf{m}})(x)$ and $z' = z'(x) = (\mathbb{W}\overline{\mathbf{m}}')(x)$, with increment $\Delta z(x) = z - z'$. The quadratic running cost is a perfect square, so its increment factors as a difference of squares,

$$F[\mathbf{m}](x,\xi) - F[\mathbf{m}'](x,\xi) = \tfrac{q}{2}\big[(\xi - sz)^2 - (\xi - sz')^2\big] = \tfrac{q}{2}\big[(\xi - sz) + (\xi - sz')\big]\big[(\xi - sz) - (\xi - sz')\big].$$

The second bracket is $-s\,\Delta z(x)$ and the first is $2\xi - s(z+z')$, so multiplying out,

$$F[\mathbf{m}](x,\xi) - F[\mathbf{m}'](x,\xi) = \tfrac{q}{2}\big[-2s\,\xi\,\Delta z(x) + s^2(z+z')\,\Delta z(x)\big].$$

The first term is linear in the state ξ; the second — the one carrying the awkward s^2 — is *independent* of ξ, a constant in the state variable for each fixed type. That is exactly what makes it disappear under the pairing. Pair the increment against the signed measure $(m^x - m'^x)(\mathrm{d}\xi)$ and use the two elementary moment identities that the pairing structure hands us for free. The zeroth moment of the increment vanishes, because both m^x and m'^x are probability measures of total mass one:

$$\int_{\mathbb{R}^d}(m^x - m'^x)(\mathrm{d}\xi) = 1 - 1 = 0,$$

which annihilates the ξ-independent s^2 term wholesale — a constant integrated against a measure of zero total mass contributes nothing, and the entire quadratic-in-s piece is gone. The first moment of the increment is, by the very definition of the first-moment field, the increment of the means:

$$\int_{\mathbb{R}^d}\xi\,(m^x - m'^x)(\mathrm{d}\xi) = \overline{\mathbf{m}}(x) - \overline{\mathbf{m}}'(x) = \Delta(x).$$

Only the linear term survives, and it survives as

$$\int_{\mathbb{R}^d}\big(F[\mathbf{m}] - F[\mathbf{m}']\big)(x,\cdot)\,(m^x - m'^x)(\mathrm{d}\xi) = \tfrac{q}{2}\big(-2s\,\Delta z(x)\big)\,\Delta(x) = -qs\,\Delta z(x)\,\Delta(x).$$

This is the per-type integrand of $\mathcal{G}_F$. It remains only to integrate it over the type, which is where the operator finally appears in the open: $\Delta z = z - z' = \mathbb{W}\overline{\mathbf{m}} - \mathbb{W}\overline{\mathbf{m}}' = \mathbb{W}\Delta$ by linearity of $\mathbb{W}$, so

$$\mathcal{G}_F(\mathbf{m},\mathbf{m}') = \int_0^1\big(-qs\,\Delta z(x)\,\Delta(x)\big)\;\mathrm{d}x = -qs\int_0^1(\mathbb{W}\Delta)(x)\,\Delta(x)\;\mathrm{d}x = -qs\,\langle\Delta,\mathbb{W}\Delta\rangle_{L^2([0,1])}.$$

The spectral form is then the eigendecomposition of the integral operator: since $\mathbb{W}$ is self-adjoint Hilbert–Schmidt (chapter 18) it diagonalises as $\mathbb{W} = \sum_k \lambda_k \, \phi_k \otimes \phi_k$ in the orthonormal eigenbasis (ϕ_k), so expanding $\Delta = \sum_k \langle \Delta, \phi_k \rangle \phi_k$ gives $\langle \Delta, \mathbb{W}\Delta \rangle = \sum_k \lambda_k \, |\langle \Delta, \phi_k \rangle|^2$, which is eq. (24.6). The monotonicity criterion is immediate: $\mathcal{G}_F \geq 0$ for all fields exactly when $s \, \langle \Delta, \mathbb{W}\Delta \rangle \leq 0$ for all $\Delta \in L^2([0,1])$. And if $\mathbb{W} \succeq 0$ — every $\lambda_k \geq 0$, as for a graphon of positive type — then $\langle \Delta, \mathbb{W}\Delta \rangle \geq 0$ always, so the criterion reduces to the single scalar inequality $s \leq 0$. □

Proposition 24.17 is the heart of the matter, and it is worth saying exactly what it changed. The classical computation eq. (11.10) gave $\mathcal{G}_F = -qs \, \Delta^2$, with Δ the single scalar difference of global means, and the verdict was a clean scalar dichotomy: monotonicity holds iff $s \leq 0$. There was one knob, the strategic sign s, and one thing it controlled, the sign of a square. The graphon computation keeps the prefactor $-qs$ but replaces the scalar square Δ^2 by the quadratic form $\langle \Delta, \mathbb{W}\Delta \rangle$ in the field of mean-differences — and a quadratic form in an operator is a far richer object than a square. Now *two* independent things can spoil monotonicity. The first is the classical one: imitation, $s > 0$, which flips the sign of the whole pairing just as before. The second is new and graphon-only: an *indefinite* operator $\mathbb{W}$, one with some negative eigenvalue $\lambda_k < 0$, for which $\langle \Delta, \mathbb{W}\Delta \rangle$ takes both signs as Δ ranges over $L^2([0,1])$ — positive when Δ aligns with a positive eigenmode, negative when it aligns with a negative one. With an indefinite $\mathbb{W}$ the pairing cannot be signed by choosing s at all: even the crowd-averse $s < 0$, which is monotone in every homogeneous model, fails graphon monotonicity along the negative eigenmodes. And indefiniteness is the generic situation, not a pathology: a graphon of positive type (every $\lambda_k \geq 0$) is special, while a generic symmetric kernel — any bipartite-like or disassortative structure, where unlike types attract — has eigenvalues of both signs. Graphon monotonicity is therefore a *joint* condition on the strategic sign and the spectrum, and per-type monotonicity — the scalar $s \leq 0$ of chapter 11, asserted independently at each type — is by itself neither necessary (a crowd-seeking $s > 0$ can still be graphon-monotone if it acts only through negative eigenmodes) nor sufficient (a crowd-averse $s < 0$ fails along negative eigenmodes of an indefinite $\mathbb{W}$).

Two threads leave this subsection with that observation, pointing in opposite directions, and naming them is how the section is stitched to what follows. The first is a limitation handed to the next subsection. The structural route just built is horizon-free — it bought uniqueness at *every* T, which is exactly the regime the smallness route will be unable to reach — but proposition 24.17 shows the price of that strength: it demands a definite *sign* of the joint strategy–spectrum quantity $s \, \langle \Delta, \mathbb{W}\Delta \rangle$, and there are whole models (imitative couplings, indefinite networks) where no such sign is available. A route that asks for no sign at all would cover precisely those models. That is the motivation for the operator-norm contraction of the next subsection: it abandons the sign and asks instead for *smallness*, the standing assumption **(A-Coupling)** on $\|\mathbb{W}\|$, and because the aggregation $\mathcal{A}_W$ is linear, that smallness is read off a single operator norm — the only graphon-specific factor in the whole estimate. The second thread is the central phenomenon handed forward to the synthesis. The indefinite-operator mechanism just uncovered — monotonicity lost not to imitation but to the network's own geometry, along the negative eigenmodes of $\mathbb{W}$ — has no homogeneous analogue whatever, and it is the cleanest instance of the chapter's claim that every graphon-specific surprise lives in the spectrum of $\mathbb{W}$. We resist drawing its consequences here, because they belong with the others: the full catalogue of what is genuinely harder than in the classical theory, the second crowd-averse multiplicity wedge it opens, and its place beside the centrality-indexed threshold $s\,\lambda_1$, is collected once in the synthesis of section 24.4.

24.3.2 Small coupling: the operator-norm contraction

The monotonicity route just finished is strong where it applies — it buys uniqueness at *every* horizon — but the previous subsection closed by naming exactly the price of that strength: it demands a definite *sign* of the joint strategy–spectrum quantity $s\,\langle \Delta, \mathbb{W}\Delta\rangle$, and there are whole families of models, the imitative couplings and the indefinite networks, where no such sign is to be had. A route that asked for no sign at all would cover precisely those models, and the obvious thing to trade the sign for is *smallness*: if the coupling is weak, the best-response map cannot do much harm regardless of which way it pushes, and a single contraction estimate should pin the fixed point. This second route asks nothing of the sign; it asks the coupling to be weak. It is the operator form of the short-horizon contraction of chapter 11, with the operator norm $\|\mathbb{W}\|$ as the smallness parameter — the standing assumption **(A-Coupling)**, $\|\mathbb{W}\| < \kappa$.

The reason this works, and works cleanly, is the factorisation $\mathsf{S}_W = \mathcal{R} \circ \mathcal{A}_W$ of eq. (24.4). The per-type solve $\mathcal{R}$ is the classical machine of chapters 10 and 11, and *classically* the best-response map is already a contraction once the horizon is short or the coupling weak — that is the homogeneous short-horizon route, nothing new. Everything graphon-specific has been quarantined in the aggregation $\mathcal{A}_W$, and $\mathcal{A}_W$ is *linear*. A linear map has exactly one Lipschitz constant, its operator norm, and there is nothing else to estimate: the entire graphon contribution to how much the map can stretch a perturbation is the single number $\|\mathcal{A}_W\|$, which (the first moment being a contraction) is the operator norm of $\mathbb{W}$. The smallness we must demand is therefore not a smallness of the data, nor of the Hamiltonian, nor of anything per-type — all of that lives in $\mathcal{R}$ and is classical — but precisely a smallness of $\mathbb{W}$. This is the content of **(A-Coupling)**, and it is why the standing assumption is phrased as a bound on $\|\mathbb{W}\|$ alone: the factorisation makes the operator norm the *only* graphon-specific factor in the whole estimate, so it is the only thing the smallness threshold can possibly constrain.

Proposition 24.18 (Contraction of the graphon best response)**.** *Assume* ***(A-Lip)****,* ***(A-Nondeg)****,* ***(A-Conv)****,* ***(A-Reg-W)****, and assumption 24.5. There is a constant $C_T < \infty$, depending only on T, the Lipschitz constants of F_0, G_0 in their aggregate argument, and the data of chapter 10, such that the graphon best response is Lipschitz on $(\mathbb{K}_W, \mathsf{D})$ with*

$$\mathsf{D}(\mathsf{S}_W(\mathbf{m}), \mathsf{S}_W(\mathbf{m}')) \;\le\; C_T\;\|W\|_{L^\infty_x L^1_y}\;\mathsf{D}(\mathbf{m}, \mathbf{m}'), \tag{24.7}$$

where $\|W\|_{L^\infty_x L^1_y} = \operatorname{ess\,sup}_x \int_0^1 |W(x,y)|\,\mathrm{d}y$ is the row-sum ($L^\infty \to L^\infty$) operator norm of $\mathbb{W}$. Hence if $C_T\;\|W\|_{L^\infty_x L^1_y} < 1$ — the sup-in-type form of the standing smallness assumption ***(A-Coupling)*** *with $\kappa := 1/C_T$ — the map S_W is a contraction, and the GMFG has a* unique *equilibrium, for* any *sign of the coupling. Since $\|\mathbb{W}\| = \rho(\mathbb{W}) = \lambda_1 \le \|W\|_{L^\infty_x L^1_y}$ (remark 24.19), this sufficient condition is more conservative than the exact spectral threshold λ_1 of proposition 24.23, with which it coincides for the constant kernel.*

Proof sketch and pointer. The argument is a single composition: send a field perturbation through the linear aggregation, then through the classical per-type solve, and read off the product of the two Lipschitz constants. The whole point of the factorisation $\mathsf{S}_W = \mathcal{R} \circ \mathcal{A}_W$ (eq. (24.4)) is that these two factors can be estimated in complete isolation, the first carrying all of the graphon and none of the analysis, the second all of the analysis and none of the graphon. We take them in turn and multiply.

Step 1: the aggregation $\mathcal{A}_W$ is linear, so its Lipschitz constant is an operator norm. Fix two candidate fields $\mathbf{m}, \mathbf{m}' \in \mathbb{K}_W$. Because $\mathcal{A}_W$ is the composition of the first-moment read-out $\mathbf{m} \mapsto \overline{\mathbf{m}}$ with the integral operator $\mathbb{W}$, both linear, the difference of the aggregates it produces is the operator applied to the difference of the moment fields,

$$\mathcal{A}_W(\mathbf{m}) - \mathcal{A}_W(\mathbf{m}') = \mathbb{W}(\overline{\mathbf{m}} - \overline{\mathbf{m}}'), \qquad \text{i.e.} \qquad z_t - z_t' = \mathbb{W}(\overline{\mathbf{m}}_t - \overline{\mathbf{m}}_t') \text{ for each } t.$$

There is no cross term and no remainder: linearity is exactly the statement that a perturbation passes through $\mathcal{A}_W$ unaltered in form, only rescaled. To bound the rescaling we need two facts, one about the moment read-out and one about $\mathbb{W}$, joined at the choice of metric. First, the moment read-out does not amplify: by lemma 24.2 the first moment is 1-Lipschitz from $\mathcal{W}_1$ into $\mathbb{R}$ (equivalently, Kantorovich–Rubinstein with the admissible test function $\xi \mapsto \xi$), so at every type y and time t, $|\overline{\mathbf{m}}_t(y) - \overline{\mathbf{m}}_t'(y)| \le \mathcal{W}_1(m_t^y, m_t'^y) \le \mathsf{D}(\mathbf{m}, \mathbf{m}')$, the last step by the definition of the uniform-in-type metric as a supremum over types and times. Taking the supremum over y and t,

$$\sup_t \|\overline{\mathbf{m}}_t - \overline{\mathbf{m}}_t'\|_{L^\infty([0,1])} \le \mathsf{D}(\mathbf{m}, \mathbf{m}').$$

The moment difference is thus controlled in $L^\infty([0,1])$, the natural target of the uniform-in-type metric D — and this is the hinge that fixes which norm of $\mathbb{W}$ governs the estimate. Second, $\mathbb{W}$ maps $L^\infty([0,1])$ to $L^\infty([0,1])$ with operator norm exactly the row sum,

$$\|\mathbb{W}\|_{L^\infty \to L^\infty} = \operatorname*{ess\,sup}_x \int_0^1 |W(x,y)| \, \mathrm{d}y = \|W\|_{L_x^\infty L_y^1},$$

because $|(\mathbb{W}g)(x)| \le \int |W(x,y)| \, |g(y)| \, \mathrm{d}y \le \|g\|_\infty \int |W(x,y)| \, \mathrm{d}y$ and the bound is attained, type by type, by the sign-matching $g = \operatorname{sgn} W(x, \cdot)$. Composing the two facts,

$$\sup_t \|z_t - z_t'\|_{L^\infty} \le \|\mathbb{W}\|_{L^\infty \to L^\infty} \sup_t \|\overline{\mathbf{m}}_t - \overline{\mathbf{m}}_t'\|_{L^\infty} \le \|W\|_{L_x^\infty L_y^1} \, \mathsf{D}(\mathbf{m}, \mathbf{m}').$$

So in the uniform-in-type metric the aggregation is a Lipschitz map of fields with constant exactly the row-sum norm. It bears repeating, because it is the one subtlety the whole subsection turns on, that this is *not* the L^2 spectral radius: the metric D measures fields uniformly in type, which is an L^∞ measurement, and the operator norm an L^∞ input forces out of $\mathbb{W}$ is the row sum, not λ_1 (remark 24.19). The row-sum norm, not the spectral radius, is the contraction's genuine smallness parameter.

Step 2: the per-type solve $\mathcal{R}$ is Lipschitz in its frozen data, classically. This factor carries no graphon at all. For each fixed type x the map $\mathcal{R}$ is the homogeneous best response $\mathsf{S}^x_{z(x)}$ of definition 10.3, driven by the frozen scalar-in-type data curve $t \mapsto z_t(x)$, and its Lipschitz dependence on that data is precisely the stability content of chapters 10 and 11. Concretely, suppose two data curves z, z' differ by $\sup_t |z_t(x) - z'_t(x)| \le \epsilon$. Through the Lipschitz dependence of F_0, G_0 on their aggregate slot (assumption 24.5) this perturbs the source and terminal data of the type-x HJB eq. (24.1) by $O(\mathrm{Lip}(F_0, G_0)\,\epsilon)$ in the relevant norm; the HJB stability estimate lemma 10.10, an interior Schauder/maximum-principle bound made quantitative by the uniform ellipticity λ from **(A-Nondeg)**, then perturbs the value gradient $\nabla_\xi u^x$ — and hence the optimal feedback $-\partial_p H(x, \nabla_\xi u^x)$ — by $O(\mathrm{Lip}(F_0, G_0)\,\epsilon)$ as well. A perturbed feedback drives a perturbed forward flow: the FP stability estimate lemma 10.11, run as a Grönwall comparison of the two closed-loop SDEs sharing the noise B^x and started from the common datum m_0^x, integrates that drift perturbation along the horizon and bounds the resulting law gap by $O(L_{\mathcal{R}}(T)\,\mathrm{Lip}(F_0, G_0)\,\epsilon)$ in $\sup_t \mathcal{W}_1$. The Grönwall constant $L_{\mathcal{R}}(T)$ is exactly where the horizon enters, a point we return to immediately below. None of this knows there is a type variable; it is the chapter 10 machine run verbatim inside a single type, which is why we import it rather than reprove it.

Step 3: compose and apply Banach. Feeding the Step-1 bound on the data gap, with $\epsilon = \|W\|_{L^\infty_x L^1_y}\ \mathsf{D}(\mathbf{m}, \mathbf{m}')$, into the Step-2 per-type Lipschitz estimate, uniformly over types, gives

$$\mathsf{D}(\mathsf{S}_W(\mathbf{m}), \mathsf{S}_W(\mathbf{m}')) \le L_{\mathcal{R}}(T)\,\mathrm{Lip}(F_0, G_0)\ \|W\|_{L^\infty_x L^1_y}\ \mathsf{D}(\mathbf{m}, \mathbf{m}'),$$

which is eq. (24.7) with $C_T = L_{\mathcal{R}}(T)\,\mathrm{Lip}(F_0, G_0)$ — a constant built entirely from per-type, graphon-free data, multiplying the single graphon factor $\|W\|_{L^\infty_x L^1_y}$. When $C_T\ \|W\|_{L^\infty_x L^1_y} < 1$ the map S_W is a strict contraction of the complete metric space $(\mathbb{K}_W, \mathsf{D})$ into itself (the invariant set $\mathbb{K}_W$ of lemma 24.10 is closed, hence complete), and the Banach fixed-point theorem supplies a unique fixed point, reached by iteration from any starting field — a *unique* equilibrium, with no demand whatever on the sign of the coupling. The per-type Lipschitz estimate is the content of chapter 6 and [40, Ch. 3–4, Vol. I]; all we have added is to isolate the dependence on $\|\mathbb{W}\|$, which the factorisation shows is the only graphon-specific factor in the whole chain. $\square$

Two features of proposition 24.18 deserve emphasis, because each fixes the contraction route's place relative to its two neighbours — the horizon-free monotonicity route on one side, the exact spectral threshold on the other.

First, the route is intrinsically *finite-horizon.* The constant $C_T = L_{\mathcal{R}}(T)\,\mathrm{Lip}(F_0, G_0)$ inherits the growth of the per-type Grönwall stability constant $L_{\mathcal{R}}(T)$, which generally *increases* with T: a perturbation of the feedback is integrated along the whole horizon, and the longer the horizon the more it can accumulate, exactly as a Grönwall factor e^{cT} grows. Consequently the smallness threshold $\kappa = 1/C_T$ *shrinks* as T increases — a coupling weak enough to be contracted over a short horizon may be too strong over a long one — so weak-coupling uniqueness is a finite-horizon statement, and it says nothing in the long-horizon regime unless it is reinforced by the monotonicity structure of the previous subsection. This is precisely the operator counterpart of the classical short-horizon route (chapter 11, item 1 of its boundary menu) and of the soft band of proposition 11.8: there too smallness bought uniqueness only below a horizon-dependent ceiling, and there too the only way to uniqueness at *every* horizon ran through monotonicity. The graphon adds nothing qualitatively new here; it merely reads the same ceiling off $\|\mathbb{W}\|$ instead of off the scalar coupling. The division of labour between the two routes — monotonicity for long horizons, smallness for weak coupling — is identical to the homogeneous one, with $\mathbb{W}$ inserted at the single place the coupling enters.

Second, the chapter's smallness and threshold quantities all sit at the *top of the spectrum* of $\mathbb{W}$, but they are not literally one number, and the difference between them is conceptually load-bearing rather than a technicality. The sup-in-type contraction proved here is governed by the row-sum norm $\|W\|_{L_x^\infty L_y^1}$, the $L^\infty \to L^\infty$ operator norm forced out of $\mathbb{W}$ by the uniform-in-type metric D. The *exact* multiplicity threshold, by contrast, is set by the $L^2 \to L^2$ operator norm $\|\mathbb{W}\| = \rho(\mathbb{W}) = \lambda_1$ — the leading eigenvalue, the eigenvector-centrality scale of chapter 18 — which is what the L^2 spectral diagonalisation of proposition 24.23 delivers. These two are not equal: the row sum *dominates* λ_1, with equality only for special kernels. The contraction route is therefore a strictly *conservative* sufficient condition — it can fail to certify uniqueness in a regime where the exact threshold still grants it — and that conservatism is the price of working in the comfortable L^∞/uniform metric rather than the heavier L^2 Bochner setting. The next remark makes the gap between the two norms precise, with the elementary inequality that orders them and a worked rank-one kernel that exhibits the strict inequality; the upshot to carry forward is that the monotonicity route and the exact LQG threshold both meet at λ_1, and that common boundary — not the row sum — is the true critical coupling.

Remark 24.19 (Which operator norm: row-sum versus spectral radius)**.** Two operator norms of $\mathbb{W}$ appear above and must not be conflated. The *row-sum norm* $\|W\|_{L_x^\infty L_y^1} = \operatorname{ess\,sup}_x \int_0^1 |W(x,y)|\,\mathrm{d}y$ is the $L^\infty \to L^\infty$ operator norm; it is what the aggregation step produces in the uniform-in-type metric D (lemma 24.6, proposition 24.18). The $L^2 \to L^2$ operator norm equals the spectral radius, $\|\mathbb{W}\| = \rho(\mathbb{W}) = \lambda_1$, because $\mathbb{W}$ is self-adjoint Hilbert–Schmidt (chapter 18); this is the *canonical* norm of **(A-Coupling)** and the one in the exact LQG threshold proposition 24.23. They satisfy

$$\|\mathbb{W}\| = \lambda_1 \ \le\ \|W\|_{L_x^\infty L_y^1},$$

with equality for the constant kernel and *strict* inequality in general — e.g. for the non-constant rank-one kernel $W(x,y) = f(x)f(y)$, $f(x) = \frac{1}{5} + \frac{4}{5}x$, one has $\lambda_1 = \|f\|_{L^2}^2 \approx 0.41$ but $\|W\|_{L_x^\infty L_y^1} = \|f\|_\infty \|f\|_{L^1} = 0.6$. The inequality itself is elementary: by Perron–Frobenius (theorem 18.7) the leading eigenvalue $\lambda_1 = \rho(\mathbb{W})$ has a nonnegative eigenfunction $\phi_1 \ge 0$, and evaluating $\lambda_1\phi_1(x) = \int_0^1 W(x,y)\phi_1(y)\,\mathrm{d}y \le \|\phi_1\|_\infty \int_0^1 W(x,y)\,\mathrm{d}y$ at a type where ϕ_1 approaches its essential supremum gives $\lambda_1 \le \|W\|_{L_x^\infty L_y^1}$ (the symmetric Schur-test bound). Consequently the sup-in-type contraction route constrains the *larger* quantity and is genuinely more conservative than the exact spectral threshold λ_1; the two coincide only when the kernel is constant (or, more generally, has constant row sums, where the Perron eigenfunction is itself constant). Running the contraction instead in the L^2-in-type metric d_2 of chapter 23 replaces the row-sum norm by $\|\mathbb{W}\| = \lambda_1$ exactly, at the cost of the heavier Bochner setting; we keep D and accept the conservative constant.

The same contraction estimate, applied to two *different* kernels at the same per-type data, shows that in the weak-coupling regime the equilibrium depends Lipschitz-continuously on the kernel. This is the precise stability statement on which the finite-network convergence theory of chapter 25 rests, so we record it as a labelled export.

Proposition 24.20 (Lipschitz dependence of the equilibrium on the kernel)**.** *Let W, W' be graphons satisfying **(A-Reg-W)** and assumption 24.5 with the* same *per-type data F_0, G_0 and initial field $\mathbf{m}_0$, both in the contraction regime of proposition 24.18 ($C_T \|W\|_{L_x^\infty L_y^1} < 1$ and likewise for W'), with* *unique equilibria* $\mathbf{m}^\star_W, \mathbf{m}^\star_{W'}$. *Then, with* R *the uniform second-moment radius of the equilibrium fields,*

$$\mathsf{D}(\mathbf{m}^\star_W, \mathbf{m}^\star_{W'}) \;\le\; \frac{C_T\, R\, \|W - W'\|_{L^\infty_x L^1_y}}{1 - C_T\, \|W\|_{L^\infty_x L^1_y}}. \tag{24.8}$$

The identical estimate holds with the $L^2 \to L^2$ *operator norm* $\|\mathbb{W} - \mathbb{W}'\|$ *replacing the row-sum norm when the contraction is run in the* L^2*-in-type metric* d_2 *of chapter 23.*

Proof. Write $\mathsf{S}_W, \mathsf{S}_{W'}$ for the two best-response maps; they share the per-type factor $\mathcal{R}$ and differ only in the aggregation $\mathcal{A}_W$ versus $\mathcal{A}_{W'}$. For a fixed field $\mathbf{m}$ the two aggregates differ through the kernel alone, $z_t - z'_t = (\mathbb{W} - \mathbb{W}')\overline{\mathbf{m}}_t$, so by the L^∞ aggregation bound of lemma 24.6 and the per-type Lipschitz constant $C_T = L_{\mathcal{R}}(T)\,\mathrm{Lip}(F_0, G_0)$ of proposition 24.18,

$$\mathsf{D}(\mathsf{S}_W(\mathbf{m}), \mathsf{S}_{W'}(\mathbf{m})) \;\le\; C_T \sup_t \left\|(\mathbb{W} - \mathbb{W}')\overline{\mathbf{m}}_t\right\|_\infty \;\le\; C_T\, R\, \|W - W'\|_{L^\infty_x L^1_y}\,.$$

Now compare the two fixed points, inserting $\mathsf{S}_W(\mathbf{m}^\star_{W'})$ and using the contraction eq. (24.7) for S_W:

$$\mathsf{D}(\mathbf{m}^\star_W, \mathbf{m}^\star_{W'}) = \mathsf{D}(\mathsf{S}_W(\mathbf{m}^\star_W), \mathsf{S}_{W'}(\mathbf{m}^\star_{W'})) \le C_T\, \|W\|_{L^\infty_x L^1_y}\; \mathsf{D}(\mathbf{m}^\star_W, \mathbf{m}^\star_{W'}) + C_T\, R\, \|W - W'\|_{L^\infty_x L^1_y}\,.$$

Solving for $\mathsf{D}(\mathbf{m}^\star_W, \mathbf{m}^\star_{W'})$ gives eq. (24.8); the L^2-in-type version is identical with d_2 and $\|\mathbb{W} - \mathbb{W}'\|$ throughout. ☐

Because the cut metric controls the operator norm of the difference $\mathbb{W} - \mathbb{W}'$ (chapters 17 and 18), eq. (24.8) is exactly the $\delta_\square$-stability of the equilibrium that the sampled-network convergence theorem of chapter 25 consumes.

24.3.3 The critical coupling

We can now say where, and why, uniqueness fails. Combine the two routes. Graphon monotonicity (theorem 24.16) gives uniqueness for all T whenever $s\,\langle \Delta, \mathbb{W}\Delta\rangle \le 0$ for all Δ, i.e. (for $\mathbb{W} \succeq 0$) whenever $s \le 0$. Small coupling (proposition 24.18) gives uniqueness for any s when $|s|\;\|\mathbb{W}\|$ is small enough relative to $1/T$. Between these lies a regime — strong, imitative coupling $s > 0$ over a long horizon — where neither applies, and there the equilibrium can split. The threshold is set by the largest eigenvalue.

Proposition 24.21 (Critical coupling, graphon-local quadratic model)**.** *Consider the GMFG with the graphon-local quadratic coupling of proposition 24.17, dynamics and parameters as in Thread B (section 24.5). Let* $\lambda_1 = \|\mathbb{W}\| = \rho(\mathbb{W}) > 0$ *be the leading eigenvalue of* $\mathbb{W}$ *(the eigenvector-centrality scale, chapter 18, equal to the spectral radius by Perron–Frobenius, theorem 18.7), with eigenfunction* ϕ_1*. Then the equilibrium is unique for all horizons whenever*

$$\max_k s\,\lambda_k \;\le\; 1 + \frac{a^2}{b^2 q} \;=:\; s_c^{\mathrm{scalar}}, \tag{24.9}$$

a condition guaranteed by the sign-robust bound $|s|\;\lambda_1 \le s_c^{\mathrm{scalar}}$ *(since* $\lambda_1 = \rho(\mathbb{W}) \ge |\lambda_k|$ *for every* k*). In the* imitation regime $s > 0$ *the binding mode is the leading one and eq. (24.9) reads* $s\,\lambda_1 \le s_c^{\mathrm{scalar}}$*;*

for $s\,\lambda_1 > s_c^{\text{scalar}}$ *uniqueness then fails at and beyond a finite critical horizon* T_c*, with the instability carried first by the leading eigenmode* ϕ_1*, and the critical coupling is* $s_c = s_c^{\text{scalar}}/\lambda_1$ *(equal to* $1/\lambda_1 = 1/\|\mathbb{W}\|$ *when* $a = 0$*). In the* crowd-averse regime $s < 0$ *the binding mode is instead the most negative eigenvalue* $\lambda_{\min} < 0$*: if* $\mathbb{W} \succeq 0$ *then eq.* (24.9) *holds automatically and uniqueness is horizon-free, but for an* indefinite $\mathbb{W}$ *uniqueness can still fail — at* $|s|\,|\lambda_{\min}| > s_c^{\text{scalar}}$*, along the mode* $\phi_{\min}$ *— the crowd-aversion-on-an-indefinite-network phenomenon stressed in section 24.4. There is, in particular, no unconditional crowd-averse uniqueness on an indefinite kernel.*

The proof is the spectral reduction of Thread B, carried out in full in section 24.5 (proposition 24.23). We state the proposition here because it is the conceptual centre of the chapter, and pause on its meaning.

Physics note: Loss of uniqueness as centrality-indexed symmetry breaking

The classical multiplicity threshold of chapter 11 was the line $s = 1$ (for $a = 0$): an agent whose target overshoots the crowd ($s > 1$) destabilises the symmetric equilibrium once the horizon is long enough to let the overshoot accumulate, and a pair of asymmetric equilibria appears — the mean field game's spontaneous magnetisation, the Curie–Weiss bifurcation of section 11.4. The graphon refinement is that the relevant coupling is no longer the scalar s but the *product* $s\,\lambda_1$, where λ_1 is the leading eigenvalue of the network operator $\mathbb{W}$. The same self-amplification now operates along the leading eigenfunction ϕ_1 — the eigenvector centrality profile of chapter 18 — because that is the direction in type space the operator $\mathbb{W}$ stretches most. A network with a large λ_1 (a strongly connected or highly central structure) reaches the symmetry-breaking threshold at a *smaller* intrinsic imitation strength s: connectivity amplifies imitation. The broken-symmetry order parameter is the projection $\langle \overline{\mathbf{m}}, \phi_1 \rangle$ of the population mean onto the central mode. This is the precise sense, promised in chapter 11 and chapter 20, in which the uniqueness threshold of a graphon mean field game is a competition between strategic monotonicity and the spectrum of $\mathbb{W}$, with the critical coupling tied to network centrality. The static graphon game of chapter 20 sees the same threshold as an operator-norm condition $s\,\|\mathbb{W}\| < 1$ for the contraction of its equilibrium map; the dynamic theory here recovers it as the onset of multiplicity, and refines it with the horizon dependence $T_c(s, \lambda_1)$.

24.4 What is genuinely harder than classical mean field games

It is worth collecting, plainly, the ways in which the graphon problem demands more than the homogeneous one, since each is a place where a classical instinct misleads. There are three, and all three are visible in the two theorems above.

1. Compactness acquires a type direction. A classical mean field game equilibrium is a single flow, and existence needs compactness in state and time only — tightness plus equicontinuity, the Part I toolkit. A graphon equilibrium is a field over the continuum of types, and existence needs, in addition, compactness in the type direction. That compactness is *not* a consequence of the dynamics; it is bought from the regularity of the graphon, **(A-Reg-W)**: continuity of W in type yields the equicontinuity modulus η of lemma 24.9, and Hilbert–Schmidt compactness of $\mathbb{W}$ is its substitute when continuity fails (remark 24.13). A measurable-only graphon is genuinely harder; there is no classical analogue of the difficulty because there is no classical type variable.

2. Monotonicity must survive composition with $\mathbb{W}$. The Lasry–Lions uniqueness mechanism is a sign — the equilibrium energy is convex, the boundary pairing is favourable. Classically this sign is a property of the coupling alone (definition 11.1). In the graphon problem the pairing eq. (24.5) factors through the operator: proposition 24.17 shows it equals $-qs\langle\Delta, \mathbb{W}\Delta\rangle$, a quadratic form in the *operator* $\mathbb{W}$. A perfectly crowd-averse per-type coupling (the most monotone case classically, $s < 0$) composed with an *indefinite* $\mathbb{W}$ — the generic case, since symmetric kernels have spectra of both signs — yields a pairing of indefinite sign, hence *no* global monotonicity, hence no horizon-free uniqueness from theorem 24.16. The two signs that must align — the strategic sign (state space, the convexity of the cost in the aggregate) and the spectral sign (type space, the definiteness of $\mathbb{W}$) — are independent, and their interplay has no homogeneous counterpart, where $\mathbb{W}$ is the scalar multiplication by $\int W$ and is automatically of one sign. This is the precise content of the chapter's coverage mandate: *the interplay of strategic monotonicity with the spectral properties of* $\mathbb{W}$.

3. The threshold is spectral, not scalar. Where the classical multiplicity boundary was a number ($s = s_c^{\text{scalar}}$, remark 11.9), the graphon boundary is a number times the leading eigenvalue ($s\lambda_1 = s_c^{\text{scalar}}$, eq. (24.9)), and the unstable direction is a specific eigenfunction (eigenvector centrality, chapter 18) rather than the uniform mode. Two graphons with the same $\int W$ but different spectral radii have different uniqueness thresholds; centrality, invisible to the classical theory, sets the bifurcation. A practical corollary, exploited in chapter 25, is that the uniqueness regime is *not* stable under arbitrary graph perturbation, only under perturbations small in a norm controlling the top of the spectrum — the cut metric controls $\|\mathbb{W}\|$ (chapters 17 and 18), so $\delta_\square$-close graphons have close thresholds, which is exactly the stability the convergence theory needs.

None of this makes the graphon problem qualitatively intractable; the proofs above are the classical proofs plus an operator. But it relocates the difficulty into the spectrum of $\mathbb{W}$, and a reader who carries over the classical reflex — "crowd aversion gives uniqueness" — without checking the sign of $\mathbb{W}$ will be wrong precisely when the network is interesting.

24.5 Worked computation: the graphon LQG threshold

We now discharge the carried-thread duty by carrying Thread B (the graphon LQG model) to its exact uniqueness/multiplicity threshold, proving proposition 24.21, and verifying the reductions promised in the thread specification. The computation is the operator lift of the LQG analysis of section 11.5, and it is fully explicit: the continuum of coupled boundary-value problems diagonalises over the eigenmodes of $\mathbb{W}$, and each mode is a copy of the scalar problem of worked computation 11.7 with s replaced by $s\lambda_k$.

Worked computation 24.22 (Graphon LQG: spectral reduction of the equilibrium)**.** Recall Thread B. Each type-x agent has scalar state

$$\mathrm{d}X_t^x = (aX_t^x + b\,\alpha_t^x)\,\mathrm{d}t + \sigma\,\mathrm{d}B_t^x, \qquad X_0^x \sim m_0^x,$$

and minimises, against the graphon aggregate $z_t(x) = (\mathbb{W}\overline{\mathbf{m}}_t)(x)$ of eq. (24.3),

$$J^x(\alpha^x) = \mathbb{E}\left[\int_0^T \left(\tfrac{1}{2}(\alpha_t^x)^2 + \tfrac{q}{2}\big(X_t^x - s\,z_t(x)\big)^2\right)\mathrm{d}t + \tfrac{q_T}{2}\big(X_T^x - s_T\,z_T(x)\big)^2\right],$$

with $q, q_T \geq 0$, $s, s_T \in \mathbb{R}$, and parameters a, b, σ, T as fixed in the thread specification.

Step 1 — per-type reduction. For a frozen aggregate path $z_\cdot(x)$ the per-type problem is exactly the scalar LQG problem of worked computation 11.7 with $s\,\bar{m}_t$ replaced by $s\,z_t(x)$. The value is quadratic, $u^x(t,\xi) = \frac{1}{2}P(t)\xi^2 + r^x(t)\xi + c^x(t)$, with the curvature $P(t)$ solving the *type-independent* Riccati equation eq. (11.11), $\dot{P} = b^2P^2 - 2aP - q$, $P(T) = q_T$ (type-independent because the quadratic-in-ξ part of the cost, $\frac{q}{2}\xi^2$, is the same for every type — only the linear coupling carries x); we use the carried-thread solution symbols of chapter 11 (Riccati curvature P, linear offset r, constant c). The linear coefficient solves, mirroring eq. (11.12),

$$\dot{r}_t^x = q\,s\,z_t(x) - \big(a - b^2P(t)\big)r_t^x, \qquad r^x(T) = -q_Ts_T\,z_T(x),$$

and the closed-loop mean $\overline{\mathbf{m}}_t(x) = \mathbb{E}[X_t^x]$ solves, mirroring eq. (11.13),

$$\dot{\overline{\mathbf{m}}}_t(x) = \big(a - b^2P(t)\big)\overline{\mathbf{m}}_t(x) - b^2r_t^x, \qquad \overline{\mathbf{m}}_0(x) = \textstyle\int \xi\,m_0^x(\mathrm{d}\xi).$$

As classically, the noise σ enters only the type-wise variance (an autonomous equation decoupled from the coupling), so the uniqueness question is governed entirely by the deterministic field pair $(r_t, \overline{\mathbf{m}}_t) \in L^2([0,1]) \times L^2([0,1])$.

Step 2 — diagonalise over the spectrum of $\mathbb{W}$. The two field equations couple only through $z_t = \mathbb{W}\overline{\mathbf{m}}_t$. Expand in the eigenbasis (λ_k, ϕ_k) of $\mathbb{W}$ (chapter 18): write $\overline{m}_t^{(k)} = \langle \overline{\mathbf{m}}_t, \phi_k\rangle$ and $r_t^{(k)} = \langle r_t, \phi_k\rangle$. Since $\langle z_t, \phi_k\rangle = \langle \mathbb{W}\overline{\mathbf{m}}_t, \phi_k\rangle = \lambda_k\overline{m}_t^{(k)}$, projecting the two field equations onto ϕ_k *decouples* the modes:

$$\dot{\overline{m}}^{(k)} = A(t)\,\overline{m}^{(k)} - b^2r^{(k)}, \qquad \dot{r}^{(k)} = q\,s\,\lambda_k\,\overline{m}^{(k)} - A(t)\,r^{(k)}, \qquad r^{(k)}(T) = -q_Ts_T\lambda_k\,\overline{m}^{(k)}(T), \tag{24.10}$$

with $A(t) := a - b^2P(t)$. This is *exactly* the scalar two-point boundary-value problem of worked computation 11.7 — compare its matrix $M(t) = \left(\begin{smallmatrix} A & -b^2 \\ qs & -A\end{smallmatrix}\right)$ — with the single replacement $s \mapsto s\,\lambda_k$. The continuum GMFG has split into a family of independent copies of the classical LQG game, one per eigenmode, with mode-k coupling $s\lambda_k$.

The spectral reduction makes the threshold immediate: the GMFG equilibrium is unique iff *every* mode-k boundary-value problem eq. (24.10) is nonsingular, and a mode is the classical problem at coupling $s\lambda_k$, whose exact threshold we already computed in proposition 11.8.

Proposition 24.23 (Graphon LQG uniqueness/multiplicity threshold)**.** *In the graphon LQG game of worked computation 24.22 with $q > 0$, terminal weight $q_T = P_\infty$ (so $P(t) \equiv P_\infty$, $A(t) \equiv A_\infty = -\sqrt{a^2 + b^2q}$, as in proposition 11.8) and $s_T = 0$, define for each eigenvalue λ_k of $\mathbb{W}$*

$$\Omega_k^2 := b^2q\,s\,\lambda_k - A_\infty^2.$$

1. *If $\Omega_k^2 \le 0$ for every k — equivalently $s\,\lambda_k \le 1 + a^2/(b^2q)$ for all k, which for $s > 0$ reduces to the single condition on the leading eigenvalue $s\,\lambda_1 \le 1 + a^2/(b^2q)$ — the equilibrium is unique for all horizons T.*

2. *If $\Omega_k^2 > 0$ for some k, the equilibrium is non-unique at the discrete horizons solving $\tan(\Omega_k T) = \Omega_k/A_\infty$ (eq. (11.14) with $\Omega \to \Omega_k$). The smallest critical horizon T_c is attained by the mode maximising $s\lambda_k$ — for $s > 0$, the leading mode $\lambda_1 = \|\mathbb{W}\|$ with eigenfunction ϕ_1 — and at T_c the emergent non-trivial homogeneous solution is supported on that eigenmode.*

In particular the critical coupling is $s_c = \big(1 + a^2/(b^2q)\big)/\lambda_1$, and for $a = 0$, $s_c = 1/\lambda_1 = 1/\|\mathbb{W}\|$, proving proposition 24.21.

Proof. Each mode eq. (24.10) is the constant-coefficient scalar BVP of proposition 11.8 with s replaced by $s\lambda_k$; that proposition's analysis applies verbatim. The homogeneous BVP (initial datum $\overline{m}_0^{(k)} = 0$) has only the trivial solution iff $\Omega_k^2 \le 0$ (hyperbolic/non-oscillatory case), giving part (i); and is singular at the horizons solving eq. (11.14) with Ω_k iff $\Omega_k^2 > 0$, giving part (ii). The GMFG equilibrium is unique iff all modes are nonsingular (the modes are independent and the inhomogeneous data $\overline{\mathbf{m}}_0$ distribute across them), so uniqueness for all T requires $\Omega_k^2 \le 0$ for every k, i.e. $s\lambda_k \le 1 + a^2/(b^2q)$ for all k. For $s > 0$ the binding mode is the largest $\lambda_k = \lambda_1 = \|\mathbb{W}\|$ (the leading eigenvalue equals the spectral radius for *any* graphon, the kernel being nonnegative, by Perron–Frobenius theorem 18.7 — not merely for a graphon of positive type); for $s < 0$ the binding mode is the most negative λ_k, and the condition is automatically satisfied when $\mathbb{W} \succeq 0$ (recovering the monotone regime $s \le 0$ of proposition 24.17), but *not* for an indefinite $\mathbb{W}$, where a sufficiently negative $\lambda_{\min}$ makes $\Omega_{\min}^2 = b^2q\,|s|\,|\lambda_{\min}| - A_\infty^2 > 0$. The smallest T_c is set by the largest Ω_k^2, hence by the maximal $s\lambda_k$, with the bifurcating solution supported on the corresponding eigenfunction. Setting $s\lambda_1 = 1 + a^2/(b^2q)$ gives s_c; $a = 0$ gives $s_c = 1/\lambda_1$. □

Remark 24.24 (Consistency of the two uniqueness routes)**.** The monotonicity route (theorem 24.16, proposition 24.17) and the spectral threshold (proposition 24.23) agree, as they must. Monotonicity demanded $s\langle\Delta, \mathbb{W}\Delta\rangle \le 0$ for all Δ; for $\mathbb{W} \succeq 0$ this is $s \le 0$, and indeed $s \le 0$ gives $\Omega_k^2 = b^2qs\lambda_k - A_\infty^2 \le -A_\infty^2 < 0$ for every k (since $s\lambda_k \le 0$), so part (i) holds and the equilibrium is unique for all T. The threshold computation extends this into the band $0 < s\lambda_1 \le 1 + a^2/(b^2q)$ where monotonicity has already failed but uniqueness survives — the operator version of the soft band of proposition 11.8, the explicit witness that graphon monotonicity is sufficient but not necessary, with the gap measured by the leading eigenvalue.

We close by verifying the reductions the thread specification requires.

Proposition 24.25 (Reductions of the graphon LQG threshold)**.**

1. Constant graphon. *If $W(x, y) \equiv c > 0$, then $\mathbb{W}$ has the single nonzero eigenvalue $\lambda_1 = c$ with constant eigenfunction $\phi_1 \equiv 1$, and proposition 24.23 reduces to the classical proposition 11.8 with effective coupling $s_{\text{eff}} = s\,c$: uniqueness for all T iff $s\,c \le 1 + a^2/(b^2q)$, recovering Thread A with rescaled coupling as the thread specification demands.*

2. Rank-one graphon. *If $W(x,y) = f(x)f(y)$ with $f \in L^2([0,1])$, $f \not\equiv 0$, then $\mathbb{W}$ has the single nonzero eigenvalue $\lambda_1 = \|f\|_{L^2}^2 = \int_0^1 f^2$, with eigenfunction $\phi_1 = f/\|f\|_{L^2}$; all other modes have $\lambda_k = 0$ and are unconditionally unique. The whole field collapses to the scalar order parameter $\varrho_t := \langle \overline{\mathbf{m}}_t, f\rangle$ (the carried-thread symbol of chapter 20, chapter 21), the aggregate is $z_t(x) = f(x)\,\varrho_t$, and the GMFG reduces to a single self-consistent scalar BVP with coupling $s\,\|f\|_{L^2}^2$. The critical coupling is $s_c = (1 + a^2/(b^2 q))/\|f\|_{L^2}^2$, and for $a = 0$, $s_c = 1/\|f\|_{L^2}^2$.*

3. Block graphon. *If W is piecewise constant on a partition $[0,1] = \bigsqcup_{k=1}^K I_k$, the field collapses to K population means and the GMFG to a finite K-population LQG game; the eigenvalues of $\mathbb{W}$ are those of the $K \times K$ block-weight matrix $\widehat{W}_{k\ell} = W_{k\ell}\,|I_\ell|$, and proposition 24.23 reduces to its multi-population thresholds, the bridge to chapter 30.*

Proof. (i) The constant kernel $W \equiv c$ has $\mathbb{W}f = c\,(\int_0^1 f)\mathbf{1}$, a rank-one operator with range the constants; its only nonzero eigenvalue is $\lambda_1 = c$ (eigenfunction $\mathbf{1}$, since $\mathbb{W}\mathbf{1} = c\mathbf{1}$), all other eigenvalues vanish. Only the uniform mode $\overline{m}^{(1)} = \langle \overline{\mathbf{m}}, \mathbf{1}\rangle = \int_0^1 \overline{\mathbf{m}}$, the global mean, carries coupling, and eq. (24.10) for $k = 1$ is the classical BVP at coupling sc; the zero modes are trivially unique. (ii) The rank-one kernel gives $\mathbb{W}g = f\langle g, f\rangle$, eigenvalue $\lambda_1 = \langle f, f\rangle = \|f\|_{L^2}^2$ on $\phi_1 = f/\|f\|_{L^2}$, zero on $f^\perp$. The only coupled mode is $\overline{m}^{(1)} = \langle \overline{\mathbf{m}}, \phi_1\rangle = \varrho_t/\|f\|_{L^2}$, and $z_t(x) = (\mathbb{W}\overline{\mathbf{m}}_t)(x) = f(x)\langle \overline{\mathbf{m}}_t, f\rangle = f(x)\varrho_t$, so the dynamics of ϱ_t close on themselves — the cleanest GMFG worked example, a single scalar self-consistency. The threshold follows from $\lambda_1 = \|f\|_{L^2}^2$. (iii) A block graphon is constant on each $I_k \times I_\ell$, so m^x depends on x only through its block; the field reduces to K flows and $\mathbb{W}$ to the matrix $\widehat{W}_{k\ell} = W_{k\ell}\,|I_\ell|$ acting on the block-constant functions $\mathbb{R}^K$, whose eigenvalues drive eq. (24.10). The weight $|I_\ell|$ sits on the *column* because it is produced by the dy-integration in $(\mathbb{W}f)(x) = \int_0^1 W(x,y)f(y)\,\mathrm{d}y$; although $\widehat{W}$ is thereby asymmetric, it is conjugate to the symmetric matrix $S_{k\ell} = |I_k|^{1/2}\,W_{k\ell}\,|I_\ell|^{1/2}$ through $\widehat{W} = \mathrm{diag}(|I_k|)^{-1/2}\,S\,\mathrm{diag}(|I_k|)^{1/2}$, so its eigenvalues are real and coincide with the nonzero eigenvalues of the self-adjoint $\mathbb{W}$ — it is simply $\mathbb{W}$ expressed in the block basis, under which $L^2([0,1])$ carries the inner-product weights $|I_\ell|$. The finite system is the multi-population LQG game of chapter 30. ☐

The rank-one case (ii) is the promised Curie–Weiss-type closure: a single scalar order parameter ϱ_t, a self-consistency equation $\varrho = \mathcal{R}(\varrho)$ analogous to the magnetisation fixed point of section 11.4, and a bifurcation at $s\,\|f\|_{L^2}^2 = 1$ ($a = 0$) which is the spontaneous breaking of the symmetry $\varrho \mapsto -\varrho$ in the homogeneous limit. The graphon has done nothing but rescale the classical coupling $s \mapsto s\lambda_1$ — but $\lambda_1 = \|f\|_{L^2}^2$ is a property of the *network*, the squared L^2-mass of the centrality profile f, and this is the entire conceptual payoff of the chapter in a single formula.

Rigor ledger

Proved.

- theorem 24.11: under **(A-Lip)**, **(A-Growth)**, **(A-Nondeg)**, **(A-Conv)**, **(A-Reg-W)** with W continuous in type, and bounded smoothing graphon-local couplings (assumption 24.5), the GMFG system eq. (24.1)–eq. (24.2) has an equilibrium field, by Schauder on the field space; compactness from per-type tightness (chapter 3, made uniform in type by $\|\mathbb{W}\|$) and type-equicontinuity from graphon continuity (lemma 24.9).

- theorem 24.16: graphon Lasry–Lions monotonicity eq. (24.5) of F, G yields uniqueness for all T, via the operator lift of the theorem 11.5 duality identity.
- proposition 24.17: for the quadratic graphon-local coupling the monotonicity pairing equals $-qs\langle\Delta, \mathbb{W}\Delta\rangle$; monotonicity is the joint condition $s\langle\Delta, \mathbb{W}\Delta\rangle \leq 0$, reducing to $s \leq 0$ only when $\mathbb{W} \succeq 0$.
- proposition 24.18: in the uniform-in-type metric D, S_W is $C_T \|W\|_{L^\infty_x L^1_y}$-Lipschitz, hence a contraction (unique equilibrium, any sign) when $C_T \|W\|_{L^\infty_x L^1_y} < 1$ (**(A-Coupling)**); C_T grows with T. The row-sum norm dominates the spectral radius $\|\mathbb{W}\| = \lambda_1$ (remark 24.19), so the route is conservative relative to the exact threshold.
- proposition 24.20: in the contraction regime the equilibrium is Lipschitz in the kernel, $\mathsf{D}(\mathbf{m}^\star_W, \mathbf{m}^\star_{W'}) \leq C_T R \|W - W'\|_{L^\infty_x L^1_y} / (1 - C_T \|W\|_{L^\infty_x L^1_y})$ — the $\delta_\square$-stability exported to chapter 25.
- worked computation 24.22 and proposition 24.23: the graphon LQG equilibrium diagonalises over the spectrum of $\mathbb{W}$ into per-mode copies of the chapter 11 scalar BVP with $s \to s\lambda_k$; the exact threshold is $s\lambda_1 = 1 + a^2/(b^2 q)$ (critical coupling $s_c = (1 + a^2/(b^2 q))/\lambda_1$, and $1/\|\mathbb{W}\|$ for $a = 0$), with the bifurcation carried by eigenvector centrality ϕ_1.
- proposition 24.25: constant, rank-one, and block graphons recover Thread A (rescaled coupling), the Curie–Weiss scalar closure, and finite multi-population MFG, respectively.

Assumed.

- The classical per-type machinery imported from chapter 10: the uniform gradient bound lemma 10.5, the moment/equicontinuity estimates lemmas 10.6 and 10.7, the stability estimates lemmas 10.10 and 10.11, and Schauder/Kakutani (chapter 2).
- The spectral theorem for self-adjoint Hilbert–Schmidt operators and the identification of λ_1 with eigenvector centrality (chapter 18); existence of a classical solution with the per-type decay making the integrations by parts of theorem 24.16 valid (chapters 10 and 11).
- Bounded smoothing couplings for the abstract existence theorem; the LQG thread (unbounded data) is handled by the explicit construction of section 24.5, exactly as in section 10.5.

Deferred.

- Merely measurable graphons and the L^2-in-type / cut-metric route to existence (remark 24.13) $\to$ chapter 25.
- Set-valued feedback (weak graphon equilibria via Kakutani–Fan–Glicksberg, remark 24.14) and measurable selection $\to$ the graphon analogue of section 10.4.

- The time-dependent ($q_T \neq P_\infty$) graphon LQG threshold, solved numerically with type-grid quadrature for $\mathbb{W}$ → chapter 28.
- Displacement-monotone graphon couplings and the graphon master equation's well-posedness → chapter 26.

Open.

- A sharp characterisation of uniqueness for indefinite $\mathbb{W}$ with non-quadratic graphon couplings, where the strategic and spectral signs genuinely compete and neither theorem 24.16 nor proposition 24.18 is tight.
- A selection principle among the multiple equilibria emerging beyond the critical coupling, refining the homogeneous open problem of chapter 11 to the eigenmode-indexed graphon setting (chapter 31).
- Existence and uniqueness for unbounded (L^p) graphons, where $\|\mathbb{W}\|$ may be infinite and the contraction threshold degenerates → chapter 27.

Bibliographic notes

The graphon mean field game and its system of equations are due to Caines and Huang [33, 34], whose existence theory for the GMFG equations proceeds, as here, by a fixed point on a space of measure-valued maps indexed by the type, combining the classical MFG fixed-point argument of Lasry–Lions [93] and Cardaliaguet [36] with the graphon operator of Lovász [99]. The factorisation of the best response into graphon aggregation followed by a type-wise classical solve, and the resulting reduction of all graphon-specific behaviour to the operator $\mathbb{W}$, is the organising device of the probabilistic treatment of stochastic graphon games by Carmona, Cooney, Graves and Laurière [39]; our existence proof follows the analytic route with the Schauder machine of chapter 10, and the compactness inputs — per-type tightness via Prokhorov (chapter 3) and type-equicontinuity from graphon continuity — are the two halves emphasised in remark 24.12.

The uniqueness theory is the operator lift of the Lasry–Lions monotonicity argument [93, 36] of chapter 11; the observation that monotonicity of the graphon coupling is a joint condition on the strategic structure and the spectrum of $\mathbb{W}$ — so that an indefinite kernel can destroy uniqueness even for crowd-averse costs — is the graphon-specific phenomenon, and the operator-norm smallness condition **(A-Coupling)** is the dynamic counterpart of the contraction condition $s\,\|\mathbb{W}\| < 1$ for the static graphon game of Parise and Ozdaglar [108] in chapter 20. The reading of the critical coupling $s\lambda_1 = s_c^{\text{scalar}}$ as a centrality-indexed symmetry-breaking threshold continues the Curie–Weiss analogy of chapter 11; the LQG spectral reduction of section 24.5, in which the continuum equilibrium diagonalises over the eigenmodes of $\mathbb{W}$ into copies of the scalar Nash-certainty-equivalence system of Huang, Caines and Malhamé [82], is the graphon layer of the linear–quadratic thread completed numerically in chapter 28. The connection to finite-network games and the cut-metric stability of the uniqueness regime are the subject of chapter 25; the modern landscape of graphon and other heterogeneous extensions is surveyed in [11] and revisited in chapters 30 and 31.

Chapter 25

Convergence from Finite Networks to the Graphon Limit

The graphon mean field game (GMFG) of chapters 21 to 23 and its solution theory (chapter 24) were built, as the classical mean field game (MFG) before them, by writing down the limit object and studying it on its own terms: a continuum of types $x \in [0,1]$, a field of value functions u^x and population measures m^x, and a single coupling operator $\mathbb{W}$ tying them together across types. This chapter closes the loop for networks, exactly as chapter 13 closed it for the homogeneous mean field. We begin from a genuine finite, non-cooperative game — N agents sitting on the vertices of an actual graph, each minimizing its own cost, each best-responding to its neighbors — and ask in what precise sense, and at what rate, this game is approximated by the GMFG as the network grows and converges to the graphon.

The new difficulty, and the reason this chapter is not merely chapter 13 with decorations, is that *two* limits are now in play and they are not the same limit. The first is the familiar mean field limit $N \to \infty$: even on a fixed network, the number of agents per "type" must grow before fluctuations of the local population are suppressed. The second is *graph convergence*: the finite network G_N must itself converge to the graphon W, and the natural topology for this — the cut metric $\delta_\square$ of chapter 17 — is weaker and slower than Wasserstein sampling. For a graph $G(N, W)$ sampled from W (the W-random graph of chapter 19) both limits are taken *simultaneously* and the same parameter N controls both, so the joint rate is governed by whichever mechanism is slower. Separating the two error sources, identifying when the limits commute, and finding what controls the joint rate is the analytic content of sections 25.3 to 25.5.

It helps to read these three sections as one argument carried to three destinations rather than as three separate topics. Section 25.3 does the analytic labour: it splits the total error into a mean-field part and a graph part, bounds each, and in doing so uncovers the cut-versus-operator dichotomy that decides the joint rate. The two sections after it are what that labour buys. The practically decisive result is the network ε-Nash theorem (theorem 25.13): the decentralized GMFG strategy, computed once on the continuum and handed to each of the N vertices according to its type, is an ε_N-Nash equilibrium of the finite game on $G(N, W)$, with $\varepsilon_N \to 0$ explicitly. This is what licenses the use of the GMFG to *design interventions on real networks* — the comparative-statics and centrality program of chapter 20 — because it certifies that no agent on the true finite graph can gain more than ε_N by deviating from the prescription read off the limit. We carry Thread B through this theorem on a sampled graph in worked computation 25.15, which is this chapter's discharge of the carried-thread duty. We close with the stability statement that makes the cut metric earn its keep (section 25.5): macroscopically equivalent networks — those close in $\delta_\square$ — produce close equilibrium aggregates, so the equilibrium one designs is robust to the part of the wiring the cut metric cannot see.

We import from chapters 21 to 23 the GMFG state space (a field of measures $x \mapsto m^x \in \mathcal{P}(\mathbb{R}^d)$), the coupled HJB–Fokker–Planck system across the kernel, and the graphon McKean–Vlasov dynamics; from chapter 24 the existence and uniqueness of the GMFG solution (theorem 24.11) and the contraction estimate proposition 24.18 for the best-response map in the field argument $\mathbf{m}$ at fixed kernel (from which we *derive* here, in section 25.5, the Lipschitz dependence of the solution on the *kernel*); from chapter 17 the cut norm $\|\cdot\|_\square$, the cut metric $\delta_\square$, and the equivalence of the cut norm with the $\infty \to 1$ operator norm; from chapter 19 the W-random graph $G(N, W)$ and the concentration of its empirical graphon; and from chapter 13 the entire architecture of the homogeneous convergence problem — the Nash system, the ε-Nash mechanism (theorem 13.6), the propagation-of-chaos lemma (lemma 13.5), and the value-versus-trajectory rate dichotomy (remark 13.14) — which we generalize rather than repeat. The standing assumptions are referenced by tag: (A-Lip), (A-Growth), (A-Nondeg), (A-Conv) on the dynamics and costs, (A-Mon) for uniqueness in the monotone regime, and the graphon assumptions (A-Reg-W) and (A-Coupling) of appendix A.

We keep the conventions of appendix A: value functions u^x carry terminal data and are solved backward, population fields m^x carry initial data and flow forward.

Notation watch

We are in Part IV, where a graphon W is in scope, so the letter W denotes the *kernel* throughout and Brownian motions are written B: agent i's independent noise is B^i, and the representative type-x noise is B^x. The macro W (which renders W) is not used in this chapter. The type $x \in [0, 1]$ is an exchangeable label, never a spatial coordinate; in particular $|x - y|$ has no meaning and the only geometry on $[0, 1]$ is the one W assigns through $\mathbb{W}$. Following the W-random graph of chapter 19, the *doubly-indexed* symbol ξ_{ij} denotes the edge weight between vertices i and j; an agent's *private state* is written $X_t^i \in \mathbb{R}^d$ here (and the generic real argument of the interaction observable is the dummy ζ). These never collide, since the edge symbol always carries two vertex subscripts. We flag that the master-equation chapter chapter 26, where no edge array appears, reverts to the book-wide convention in which the *bare* symbol ξ denotes the private state; the clash is confined to the glyph and does not affect any displayed expression here.

25.1 The finite game on a network

The preamble promised to begin not from the limit object but from a genuine finite, non-cooperative game, and this section makes that object completely explicit, fixing every datum the rest of the chapter consumes. Nothing here is asymptotic: there are finitely many agents, a fixed graph wiring them together, and each agent solves an honest stochastic control problem against the others. In the language of the commuting square that organizes section 25.3, this is the bottom-left corner — the concrete game the GMFG is later certified to approximate — and it must be pinned down before any limit can be named.

The game refines the anonymous game of chapter 13 in exactly one place, and it is worth isolating that single change before any symbol is committed, because the whole chapter is the bookkeeping of its consequences. In chapter 13 every agent felt the same object, the global empirical measure $\mu^N = \frac{1}{N}\sum_j \delta_{X^j}$, and the game was symmetric under permuting the agents wholesale: each was an anonymous member of one undifferentiated crowd. A network breaks that democracy. Agent i is wired to some vertices and not to others, and it responds not to the population at large but to the states of the vertices it can see, each weighted by the strength of the edge to it. Replace "global crowd" by "weighted neighbourhood" and chapter 13 becomes the present chapter; the single-agent dynamics, the cost structure, and the equilibrium concept all carry over unchanged. The entire analytic burden ahead is that this one replacement turns a single empirical measure into a vertex-dependent, edge-weighted aggregate whose limit is no longer a number-of-agents limit alone but is entangled with the convergence of the wiring itself — the two-limit tension flagged in the preamble.

Three pieces of data specify an agent's situation, and it pays to feel the distinct role of each, since the convergence theory treats them by completely different mechanisms. The first is the agent's *type* $x_i \in [0,1]$. It is neither a state nor a strategy but the agent's fixed latent position in the graphon: the coordinate that decides, through W, how likely it is to be wired to any other vertex and how strongly. The natural physical reading is a *lattice site carrying quenched disorder*. In a disordered spin system each site is assigned, once and for all, a coupling or field drawn from some distribution and then frozen, and the dynamics run inside that fixed environment; here the type is drawn once (or placed deterministically), frozen for the whole horizon $[0,T]$, and the strategic dynamics unfold in the wiring it induces. The types are *quenched*, not *annealed* — fixed before play, never averaged over while the game runs — and the distinction is not cosmetic: the GMFG will turn out to be the annealed (disorder-averaged) law, while the finite game is a single quenched realization, a contrast developed in the physics note that closes section 25.3. We must resist reading x_i as a spatial coordinate: as the chapter's opening notationwatch insists, the only geometry on $[0,1]$ is the one W assigns, and $|x_i - x_j|$ by itself means nothing.

The second datum is the agent's *private state* $X_t^i \in \mathbb{R}^d$, the one genuinely dynamical, controlled quantity. It evolves over $[0,T]$ driven by the agent's own admissible control and its own independent Brownian motion B^i, and it is what each agent steers to minimize its cost. The third datum is the *edge array* ξ_{ij}, the realized wiring: a symmetric, doubly-indexed family recording the weight of the link between vertices i and j. It is sharply distinct from the type. The type is *where* a vertex sits in the latent space; the edge is the realized *connection* between two vertices, which — in the sampled model below — is itself random given the positions. Keeping these two separate is what later lets us isolate a "type-sampling" error from an "edge-sampling" error and discover that they converge at different rates.

Two questions stand between this data and the dynamics, and they organize the two subsections that follow. First, where does the network come from? An analyst designing an intervention works with one observed graph, given and non-random; the convergence theory, by contrast, gets its sharpest statements from a graph *sampled* from the kernel W, where the types and edges are random in a controlled way. These two provenances are not interchangeable — the sampled case carries an extra layer of randomness the deterministic case lacks, and the rates differ accordingly — so section 25.1.1 sets them side by side and says precisely how each network arises. Second, how does an agent compress its neighbours into the finite vector of observables that drives its state and cost, and how does that vector slot into the single-agent control problem of chapter 6? That is the business of section 25.1.2, which builds the neighbour aggregate and writes down the dynamics, cost, and equilibrium concept that the Nash system of section 25.2 and the convergence theory will consume.

25.1.1 Types, edges, and the sampled graph

The previous section isolated the three data of an agent's situation — type, private state, edge array — and flagged that the very first of the two questions standing between that data and the dynamics, namely *where the network comes from*, splits into two provenances the convergence theory cannot treat alike. We now make that split precise, because every rate quoted later in the chapter is attached to one provenance or the other. An analyst designing an intervention holds one graph in hand: it was measured once and is thereafter fixed, nothing about it is random, and the only limit one can even imagine is the same wiring rule applied to more and more vertices. The convergence theory, by contrast, gets its cleanest and sharpest statements by positing that the network was itself *generated* by the kernel — the latent positions scattered into $[0,1]$ and the edges switched on at random with the probabilities W prescribes. Both provenances are legitimate, both feed the identical dynamics–cost machinery of section 25.1.2 downstream, but the sampled model carries an extra layer of randomness the observed graph lacks, and it is exactly that extra layer the rates of section 25.3.2 will have to pay for. The definition records the two side by side so that this difference is visible in one place.

Definition 25.1 (The finite network)**.** A *finite weighted network* is a pair $(\boldsymbol{x}^N, \xi^N)$ where $\boldsymbol{x}^N = (x_1, \dots, x_N) \in [0,1]^N$ is the vector of types and $\xi^N = (\xi_{ij})_{i,j\in[N]}$ is a symmetric array of edge weights $\xi_{ij} = \xi_{ji} \in [0,1]$ with $\xi_{ii} = 0$. Two instances recur:

1. *(Deterministic network.)* A given real network: the types x_i and the weights $\xi_{ij} \in [0,1]$ are prescribed, non-random data. This is the case relevant to designing interventions on an observed graph.

2. *(Sampled graph $G(N,W)$.)* Given a graphon W satisfying (A-Reg-W), draw the types either on the *regular grid* $x_i = \frac{i-1/2}{N}$ or i.i.d. $x_i \sim \mathrm{Unif}\,[0,1]$, and then, conditionally on $\boldsymbol{x}^N$, draw the edges independently,

$$\xi_{ij} \sim \mathrm{Bernoulli}\big(W(x_i,x_j)\big), \qquad i<j, \qquad \xi_{ji} = \xi_{ij}, \tag{25.1}$$

   with $\xi_{ii} = 0$. The resulting random simple graph is the *W-random graph* $G(N,W)$ of chapter 19.

We write $\bar{\xi}_{ij} := \mathbb{E}[\xi_{ij} \mid \boldsymbol{x}^N] = W(x_i, x_j)$ for the conditional edge probability in the sampled case, and $\bar{\xi}_{ij} = \xi_{ij}$ in the deterministic case.

Two clauses of this definition deserve to be read slowly, because the entire two-error decomposition that drives the chapter is already latent in them. The Bernoulli prescription eq. (25.1) says that, *given the types*, the link between i and j is the outcome of a single biased coin whose bias is the kernel value $W(x_i, x_j)$: the better aligned two latent positions are in the geometry W assigns, the more likely the edge fires. The realized edge $\xi_{ij} \in \{0, 1\}$ is therefore a noisy one-bit readout of the smooth quantity $W(x_i, x_j) \in [0, 1]$, and the conditional expectation in the last line strips that noise away. Reading $\bar{\xi}_{ij} = \mathbb{E}[\xi_{ij} \mid \boldsymbol{x}^N] = W(x_i, x_j)$ from the inside out: the bar denotes an average over the edge coins *only*, with the latent positions $\boldsymbol{x}^N$ held fixed — it is the annealed value of the wiring at quenched types — and that average returns precisely the probability the edge is present, which the model set equal to $W(x_i, x_j)$. The residual $\xi_{ij} - \bar{\xi}_{ij}$ is then a mean-zero fluctuation of order one per edge, and it is the raw material of the *edge-sampling* error; the separate discrepancy between the quenched positions $\boldsymbol{x}^N$ and the continuum label they are meant to sample is the raw material of the *quadrature* error. In the deterministic case there are no coins to average over, so we set $\bar{\xi}_{ij} = \xi_{ij}$ by convention: the prescribed weights *are* their own conditional expectation, the edge-sampling fluctuation vanishes identically, and only whatever discrepancy the fixed positions carry survives. Keeping $\bar{\xi}_{ij}$ on the page, even when it equals ξ_{ij}, is what lets a single later estimate cover both provenances.

This is the precise sense in which the sampled graph $G(N, W)$ is the canonical bridge between the finite and the continuum worlds: it is the one model that carries *both* sources of finiteness at once and, crucially, carries them transparently rather than fused together. The types $\boldsymbol{x}^N$ are N samples of the continuum label x — a Monte-Carlo or quadrature discretization of the integral over $[0, 1]$ out of which every continuum aggregate is built — while the edges ξ_{ij} are Bernoulli discretizations of the kernel *values* themselves. A deterministic real network blends these two errors inseparably: its single realized wiring is whatever it is, with no reference kernel against which to ask "how far off is the position" versus "how far off is the edge". The sampled model, by contrast, holds the two apart by construction — one error lives in the positions, the other in the coins — and that separation is exactly what permits section 25.3.2 to attach a *distinct rate* to each mechanism, and to discover that those rates differ. That two-source decomposition, edge sampling against quadrature, is the first thing this subsection hands forward.

The two ways of placing the types trade analytic convenience against modelling realism, and the choice shows up directly in the quadrature rate. The regular grid $x_i = (i - \frac{1}{2})/N$ lays the N types down at the midpoints of an even partition of $[0, 1]$; it is a deterministic midpoint quadrature rule, and like any midpoint rule on a sufficiently regular integrand it converges fast — the quadrature error will turn out to be $O(N^{-1})$ under (A-Reg-W). The i.i.d. uniform choice $x_i \sim \mathrm{Unif}\,[0, 1]$ instead scatters the types at random; it is the honest model of a network whose vertices arrived from an unknown population and were never arranged on any grid, but random sampling fluctuates, so its quadrature error is the slower Monte-Carlo $O(N^{-1/2})$. As a one-line micro-example, estimating $\int_0^1 g$ for a Lipschitz g by $\frac{1}{N}\sum_i g(x_i)$ incurs error $O(1/N)$ from grid midpoints but only $O(N^{-1/2})$ from i.i.d. draws, by the elementary central limit theorem; the rows $W(x_i, \cdot)$ inherit exactly this contrast. The grid is thus the cleaner object for *stating* rates, while the i.i.d. model is the one that connects to the exchangeability and de-Finetti picture of chapter 19. Both, once the next definition packages them as a kernel, produce a step graphon converging to W; they differ only in how fast, and through which quadrature mechanism.

To *quantify* the phrase "the finite network converges to W" we must first make the network and the kernel live in the same space, and as written they do not: one is an $N \times N$ array of numbers, the other a function on the unit square. The device that reconciles them is the pixel picture of chapter 15. Partition $[0, 1]$ into N equal type cells, one per vertex, and inflate each matrix entry ξ_{kl} into a constant block over the pixel $I_k \times I_l$. The result is an honest graphon — a symmetric measurable function on $[0, 1]^2$ — that looks like a coarse, blocky image of W: the (k, l) pixel is shaded by the realized edge ξ_{kl}, and as N grows the pixels shrink and the image sharpens toward the continuous kernel, exactly as a photograph resolves when its resolution is raised. This blocky kernel is what we call the *empirical step graphon*; "step" because it is piecewise constant on the grid of pixels, and "operationally" it is nothing more than the adjacency array reread as a function, so that the cut metric $\delta_\square$ and the integral operator $\mathbb{W}$ apply to it verbatim.

Definition 25.2 (Empirical step graphon)**.** Given a finite weighted network $(\boldsymbol{x}^N, \xi^N)$ with types on the regular grid, let $I_k = [\frac{k-1}{N}, \frac{k}{N})$ be the k-th type cell. The *empirical step graphon* is the symmetric kernel

$$W_N(x, y) := \xi_{kl} \qquad \text{for } x \in I_k,\ y \in I_l, \tag{25.2}$$

the function on $[0, 1]^2$ that is constant ξ_{kl} on the pixel $I_k \times I_l$. Its integral operator is $\mathbb{W}_N$, $(\mathbb{W}_N f)(x) = \int_0^1 W_N(x, y) f(y)\, \mathrm{d}y$. For i.i.d. types one orders them increasingly before forming the cells, or works with the labelled empirical kernel directly; the distinction does not affect $\delta_\square$, which quotients by relabelling (chapter 17).

The final clause of the definition disposes of a bookkeeping subtlety peculiar to the i.i.d. case, and it is worth spelling out because it is the chapter's first encounter with the defining feature of the cut metric. With random types there is no reason the labels $1, \ldots, N$ should emerge in increasing order of x_i, so the pixels $I_k \times I_l$ would be shaded by edges between vertices whose positions are scrambled relative to the grid that the cells impose. One can repair this by sorting the types increasingly before cutting the cells — relabelling the vertices so that vertex k owns cell I_k — or one can skip the sort and work with the labelled empirical kernel as it stands. It makes no difference to anything we ever measure, and the reason is structural rather than incidental: the cut metric $\delta_\square$ is defined as an *infimum over relabellings* (chapter 17), so by construction it is blind to the order in which the vertices happened to be enumerated. Two step graphons differing only by a permutation of their cells sit at cut distance zero from one another; sorting the types merely selects a convenient representative inside a single $\delta_\square$-equivalence class, and never alters the object the convergence theory sees. This is the first appearance of a theme that will organize the entire chapter: the cut metric resolves a network only up to the relabellings that scramble individual vertex identities, which is precisely why it can certify *macroscopic* equivalence while remaining silent about *per-vertex* data — the very tension that section 25.5 sharpens into the cut-versus-operator dichotomy.

With both avatars of the finite network now in hand and each packaged as a kernel, two threads run forward out of this subsection. The first is the operator pair $(\mathbb{W}_N, \mathbb{W})$, the empirical operator set against its continuum limit: the distance between them is the object the stability theorems of section 25.5 will control — in cut norm when only the unlabelled network is available, in the stronger operator norm when the labels are known — and the decomposition of $W_N - W$ into its edge-sampling and quadrature parts, made explicit above, is exactly the input section 25.3.2 consumes to assign a separate rate to each. The second thread is the type-and-state data $(\boldsymbol{x}^N, X_0^i)$: the latent positions just fixed and the private states they seed. These are what the next subsection sets into motion. The agents now move, compress their neighbours through the wiring just defined into the finite vector of aggregated observables, and pay costs — recovering, vertex by vertex, the GMFG coupling form of chapters 21 and 22.

25.1.2 Dynamics, the neighbour aggregate, and costs

The previous subsection fixed the static scaffolding — the latent types $\boldsymbol{x}^N$, the realized wiring ξ^N, and the seed states X_0^i — and packaged the wiring as a kernel so that the continuum operator $\mathbb{W}$ could later be brought to bear. Nothing has moved yet. We now set the game in motion: each agent acquires a controlled state that evolves over $[0, T]$, pays a cost along the way, and — this is the only channel through which the network enters the dynamics — feels the other agents *solely* through what its own neighbourhood is doing. The task of this subsection is to write down that coupling in a way that slots, vertex by vertex, into the single-agent control problem of chapter 6, and to do so in exactly the form the GMFG coupling already took in chapters 21 and 22, so that the limit we eventually take has somewhere to land.

The guiding principle is that the interaction is *local and anonymous within a neighbourhood*. "Local" because agent i sees only the vertices it is wired to, not the population at large; "anonymous" because, within that neighbourhood, it does not track *which* neighbour sits in which state but only the aggregate they collectively present. This is the network refinement of the anonymity that made the homogeneous game of chapter 13 tractable: there the agent felt the whole crowd through a single empirical measure, here it feels a weighted slice of the crowd through a single aggregated vector. To make "the aggregate they present" precise we must first say *what* about a neighbour's state is felt, and that is the role of the interaction observable.

Fix once and for all a bounded, Lipschitz *interaction observable* $h : \mathbb{R}^d \to \mathbb{R}^\ell$. Its job is to extract from a neighbour's full state $X_t^j \in \mathbb{R}^d$ the finite list of scalar features — ℓ of them — through which that neighbour is allowed to influence agent i. The reader should think of h as the modeller's declaration of *what is socially visible*: not the entire microscopic state, but a chosen handful of summary statistics of it. Three instances cover essentially all the models in this book and are worth keeping in view, because each turns the abstract h into something concrete. In Thread B (the graphon LQG set up in chapter 22) the state is scalar, $\ell = 1$, and $h(\zeta) = \zeta$ is the identity: a neighbour is visible only through its position, and the aggregate built below will reproduce exactly the graphon-aggregated neighbour mean $z_t(x) = (\mathbb{W}\bar{m}_t)(x)$ that the thread couples to. In a *congestion* model h is a mollified (smoothed) indicator of a region of state space, so that the aggregate measures a smeared local density — how crowded agent i's neighbourhood is near a given location — and the cost can then penalize moving into congested territory. And in the master-equation development of chapter 26 the very same object reappears under the name ϕ; we flag the synonymy now so that the reader meeting ϕ there does not take it for a new ingredient.

The two hypotheses on h earn their place by exactly what they prevent. Boundedness is what lets the cut-norm aggregation lemma of section 25.3.1 apply: that lemma controls the aggregate only for observables bounded by some M, because a cut-norm estimate tests the kernel against functions valued in $[-1, 1]$, and an unbounded h would carry no such normalization. Lipschitz continuity is what couples the *convergence of states* to the *convergence of aggregates*: in the propagation-of-chaos estimate of section 25.3.3 we bound $|h(X_t^j) - h(\bar{X}_t^{x_j})|$ by $[h]_{\mathrm{Lip}}\, |X_t^j - \bar{X}_t^{x_j}|$, so without it a small error in the states could produce an uncontrolled error in the aggregate they feed. Boundedness can be relaxed to linear growth — which is what one needs to take $h(\zeta) = \zeta$ literally in Thread B, where the states are unbounded Gaussians — provided the relevant moments of the equilibrium law are controlled; (A-Lip) and (A-Growth) together are stated so as to permit exactly this extension, and the Gaussian states of Thread B supply the requisite moment bounds automatically, so no separate hypothesis is incurred there.

With the observable chosen, the aggregate writes itself: sum each visible neighbour's feature vector $h(X_t^j)$ against the strength ξ_{ij} of the edge to it, and normalize. The only genuine decision is the normalization, and it is not cosmetic — it decides which continuum object the finite aggregate is an approximation *of*, and hence which limit theorem this whole chapter is proving. We make the decision deliberately and record it in the definition.

Definition 25.3 (Neighbour aggregate)**.** The *normalized neighbour aggregate* felt by agent i at time t is

$$z_t^i \;:=\; \frac{1}{N} \sum_{j=1}^{N} \xi_{ij}\, h(X_t^j) \;\in\; \mathbb{R}^{\ell}. \tag{25.3}$$

The normalization is by N, not by the degree, so that z_t^i approximates the *operator* aggregate $\int_0^1 W(x_i, y)\langle h, m_t^y\rangle\, \mathrm{d}y$ rather than a degree-normalized average; this is the *dense* convention of chapters 15 and 19, under which the typical degree is $\Theta(N)$ and the graphon controls the edge density.

It is worth tracing, in one line of heuristic bookkeeping, why dividing by N is exactly what makes z_t^i converge to the operator integral, since this is the hinge on which the dense convention turns. Suppose the network is sampled from W, so $\mathbb{E}[\xi_{ij} \mid \boldsymbol{x}^N] = W(x_i, x_j)$, and suppose the neighbours have roughly settled into the type-x_j equilibrium law, so $h(X_t^j) \approx \langle h, m_t^{x_j}\rangle$ on average. Then

$$z_t^i = \frac{1}{N} \sum_{j=1}^{N} \xi_{ij}\, h(X_t^j) \;\approx\; \frac{1}{N} \sum_{j=1}^{N} W(x_i, x_j)\, \langle h, m_t^{x_j}\rangle,$$

and the right-hand side is precisely a Monte-Carlo / Riemann sum, over the N type samples x_j, of the integral $\int_0^1 W(x_i, y)\langle h, m_t^y\rangle\, \mathrm{d}y$. The factor $1/N$ is the quadrature weight that turns the sum into the integral; the $\Theta(N)$ neighbours each contribute an $O(1/N)$ term, and their number and their weight cancel to leave an $O(1)$ limit. This is the dense scaling at work, and it is why the typical degree must grow like N: if it did not, the sum would have too few terms to converge to a continuum average. The two error mechanisms of section 25.3.2 are already visible in this one display — replacing ξ_{ij} by $W(x_i, x_j)$ is the *edge-sampling* step, and replacing the sum by the integral is the *quadrature* step — and the chapter's later labour is to make each step quantitative.

With the aggregate in hand, the rest is the single-agent template of chapter 6 read off verbatim, with one substitution: wherever that chapter's controlled diffusion and cost referred to the population — through the mean field in the homogeneous case — they now refer to agent i's private aggregate z_t^i. The aggregate plays exactly the role the mean field played, and the reader who has internalized chapter 6 can read the following two displays as "a controlled SDE whose coefficients depend on the state, an external signal, and the control, with a running-plus-terminal cost of the same three arguments," the external signal being z_t^i:

$$\mathrm{d}X_t^i = b(X_t^i,\, z_t^i,\, \alpha_t^i)\ \mathrm{d}t \;+\; \sigma(X_t^i,\, z_t^i)\ \mathrm{d}B_t^i, \qquad X_0^i \sim m_0^{x_i}, \tag{25.4}$$

$$J^{N,i}(\alpha^1,\dots,\alpha^N) = \mathbb{E}\left[\int_0^T L(X_t^i,\, z_t^i,\, \alpha_t^i)\ \mathrm{d}t \;+\; g(X_T^i,\, z_T^i)\right]. \tag{25.5}$$

The coefficients b, σ, L, g are the *same* functions of $(\text{state}, \text{aggregate}, \text{control})$ for every agent, and this shared functional form is the structural fact that makes the agents interchangeable. But the interchangeability is conditional, and the precise sense in which it holds is worth dwelling on, because the entire propagation-of-chaos machinery rests on it. The agents are *not* exchangeable as raw random variables: agent i and agent j differ in their types $x_i \neq x_j$, hence in their wiring, their initial laws $m_0^{x_i}$ versus $m_0^{x_j}$, and the aggregates they feel. What is true is that, *once the type vector $\boldsymbol{x}^N$ is fixed*, the construction treats every agent by the identical rule — same coefficients, independent noises, independent initial draws — so that the joint law of the states is exchangeable under any permutation that simultaneously permutes the types. In probabilistic terms, exchangeability holds *conditionally on $\boldsymbol{x}^N$*, not marginally. This is exactly the quenched-disorder reading of the types from section 25.1.1: freeze the disorder (the types), and the agents become a symmetric ensemble; average over the disorder, and the symmetry is between *type-labelled* agents, not bare ones. Every law-of-large-numbers and chaos estimate in this chapter is therefore taken in the conditional measure $\mathbb{P}(\cdot \mid \boldsymbol{x}^N)$, and only afterwards, if one wishes the annealed statement, averaged over the types. Keeping this order straight — condition first, average second — is what prevents the two error sources from being silently fused.

The coefficients satisfy (A-Lip), (A-Growth), (A-Nondeg), (A-Conv) in the pair (x, z), the state and the aggregate, so that the single-agent control problem each frozen aggregate induces is well-posed by the verification theory of chapter 6; nondegeneracy in particular is what will later license the parabolic regularity of the network Nash system. The initial law $m_0^{x_i}$ may depend on the type — different kinds of agent may start from different distributions — and the noises and seeds B^i, X_0^i are mutually independent and independent of the network $(\boldsymbol{x}^N, \xi^N)$, so that all of the dependence between agents is routed through the aggregate and none leaks in through correlated inputs. We write $a := \sigma\sigma^\top$ for the diffusion matrix and $\mathcal{A}^\alpha$ for the controlled single-state generator as in chapter 13.

Notation watch

Two normalizations of the aggregate appear in the literature and must not be confused. The *operator* aggregate eq. (25.3), normalized by N, converges to $\int W(x_i, y)\langle h, m^y\rangle\, \mathrm{d}y$ and is the correct object for *dense* graphons. The *degree*-normalized average $\frac{1}{d_i}\sum_j \xi_{ij} h(X_t^j)$, where $d_i = \sum_j \xi_{ij}$, converges instead to the *conditional* mean given that a neighbour exists; the two agree only when the degree profile is constant. Throughout this chapter, and consistently with chapters 21 and 22, the aggregate is operator-normalized. The degree normalization becomes the natural one only in the sparse regime of chapter 27, where the dense scaling fails.

The clause that the two normalizations "agree only when the degree profile is constant" is worth unpacking, since it is the cleanest way to see what each one measures. The degree of vertex i is $d_i = \sum_j \xi_{ij}$, which in the dense sampled model concentrates around $N\int_0^1 W(x_i, y)\,\mathrm{d}y$, the *degree function* $d(x_i)$ of the graphon evaluated at the vertex's type. The operator aggregate divides the weighted sum by N; the degree aggregate divides it by $d_i \approx N\,d(x_i)$. The two therefore differ exactly by the factor $d(x_i)$: the operator aggregate is $d(x_i)$ times a probability average of h over the neighbour distribution, while the degree aggregate strips that factor off and reports the bare conditional mean "what does a typical neighbour look like, given that it is a neighbour." If every type has the same degree — a *regular* graphon, $d(x) \equiv d$, the constant-degree profile, of which the constant graphon $W \equiv c$ is the basic example — then $d(x_i)$ is the same constant for all i and the two normalizations coincide up to that overall rescaling, which can be absorbed into the coupling. The moment the degree varies with type — a hub feels many neighbours, a leaf few — they part company: operator-normalization preserves the fact that a hub aggregates *more* influence than a leaf, which is precisely the network heterogeneity the GMFG is built to track, whereas degree-normalization quotients that heterogeneity away. For the dense graphon games of this book we want to keep it, so we normalize by N.

It remains to say what an agent is allowed to know when it chooses its control, and what it means for a profile of such choices to be in equilibrium. Both the admissibility classes and the equilibrium concept are imported verbatim from chapter 13; the only change is to the informational primitive, which the network refines from "own state" to "own state and own type." Because the import is literal, a one-sentence reminder of the three classes is owed to the reader rather than a bare cross-reference. An *open-loop* strategy is a control process adapted to the full information filtration — the agent may, in principle, react to everything that has happened, including the whole configuration of the network — and serves mainly as the largest class against which deviations are tested. A *Markovian closed-loop* strategy collapses that dependence to feedback on the current configuration of states, $\alpha_t^i = \mathsf{a}(t, \boldsymbol{X}_t)$, the natural class for a dynamic-programming characterization. A *decentralized* strategy is the most restrictive and the one the GMFG actually delivers: the agent's control depends only on its *own* current state, with no access to the states of others. The single network novelty is that "own" now includes the agent's type, which is private, observable data it carries from birth.

Definition 25.4 (Admissible strategies and equilibria)**.** Let $\mathbb{F}^N$ be the filtration generated by the network $(\boldsymbol{x}^N, \xi^N)$, the initial states, and the Brownian motions. *Open-loop*, *Markovian closed-loop*, and *decentralized* strategies are defined as in definition 13.1, with a decentralized strategy now of the form $\alpha_t^i = \mathsf{a}(t, X_t^i, x_i)$ — feedback on agent i's own state *and its type* (we write the feedback map in sans-serif a to keep it distinct from the diffusion matrix $a = \sigma\sigma^\top$ and the Thread B/A scalar state-feedback parameter a). A profile $\boldsymbol{\alpha}^\star$ is a *Nash equilibrium* if no unilateral deviation strictly lowers any agent's cost, and an ε-*Nash equilibrium* (definition 13.2, eq. eq. (13.4)) if no unilateral deviation lowers any agent's cost by more than ε.

The reason to insist on the decentralized class, beyond its realism, is that it is the class the limit object naturally produces and the class the ε-Nash theorem of section 25.4 will certify. The GMFG of chapters 22 and 24 is solved once on the continuum and returns, for each type, a feedback $\widehat{\mathsf{a}}(t,\cdot,x)$ that depends on the agent's state and type alone; handing the type-x_i feedback to vertex i produces a decentralized profile on the finite graph automatically. The whole convergence program is the assertion that this profile, read off the limit, is nearly optimal on the genuine finite game just defined — and it is decentralized strategies, not the larger open-loop or Markovian classes, that the agents can actually implement without observing the network.

The finite game is now completely specified, and two objects pass forward from it. The first is the per-agent aggregate z_t^i of eq. (25.3), the quenched, edge-weighted coupling that the next section installs in place of the empirical measure to write down the network's exact Nash system: it is the finite-N object whose limit, the operator aggregate $z_t(x) = \int_0^1 W(x,y)\langle h, m_t^y\rangle\,\mathrm{d}y = (\mathbb{W}\bar{h}_t)(x)$ with $\bar{h}_t(y) = \langle h, m_t^y\rangle$, the GMFG couples to, and the gap between the two is the graph error the chapter must pay. The second is the cost functional eq. (25.5) in its frozen-aggregate form: because $J^{N,i}$ depends on the other agents *only* through z_t^i, an agent contemplating a deviation while every neighbour holds its strategy fixed faces an honest single-agent control problem against a given signal, and it is precisely this envelope — optimize against the frozen aggregate, then control how far the aggregate itself moved — that the ε-Nash proof of section 25.4 will run. With the game, its coupling, and its equilibrium concept fixed, we turn to what its *exact* equilibrium looks like.

25.2 The Nash system on the network

The finite game of section 25.1 is now specified down to its last datum: the quenched aggregate z_t^i through which each agent feels its neighbours, and the decentralized class in which we eventually want to play. Before we can say in what sense, and at what rate, the GMFG approximates this game, we owe ourselves a sharp look at the thing being approximated — the *exact* equilibrium of the finite game, written as precisely as the equilibrium of any finite-player stochastic differential game can be written, namely as the solution of a coupled system of partial differential equations. This is the network analogue of the Nash system that organized the homogeneous convergence problem in chapter 13, and recording it here is not a detour but the diagnostic step of the whole chapter. Every feature that makes this system useless as a computational object is a feature the GMFG limit exists to cure, and only by seeing the exact system on the page can we name — with no hand-waving — exactly what the limit must buy us. We therefore transcribe the chapter 13 architecture with one and only one structural change, the empirical measure giving way to the quenched, edge-weighted aggregate $z^i_{\boldsymbol{X}}$, and then read off from the transcription the obstructions that send us to the continuum.

It pays to recall, in one breath, the logic by which such a system is derived, because the network case reuses it verbatim and the only novelty is where the new aggregate slots in. The recipe is the dynamic-programming recipe of single-agent control (chapter 6), run N times under a self-consistency constraint. Freeze every agent but one to its equilibrium feedback, so that the remaining agent faces an honest single-controller problem; solve that problem by dynamic programming to get an HJB equation; then impose that the optimizer this produces for each agent coincides with the feedback the *other* agents had frozen, which closes the N best responses into one simultaneous fixed point. The unknown the machinery produces is, for each agent i, a value function of the *entire* configuration $\boldsymbol{X} = (X^1, \dots, X^N)$ — not of agent i's state alone — because in a feedback equilibrium agent i's continuation cost depends on where everyone is: everyone's future motion feeds back, through the wiring, into the aggregate agent i will feel. With that picture in place the statement reads as the expected N-fold HJB system, decorated by the network through the aggregate.

Proposition 25.5 (The network Nash system)**.** *Fix the network* $(\boldsymbol{x}^N, \xi^N)$*. Suppose the game eq.* (25.4)*–eq.* (25.5) *admits a Markovian Nash equilibrium whose value functions* $v^{N,i}(t, \boldsymbol{X})$*,* $\boldsymbol{X} = (X^1, \dots, X^N) \in (\mathbb{R}^d)^N$*, are of class* $C^{1,2}$*. With the Hamiltonian and optimal feedback of eq.* (13.5) *written here in the aggregate variable,* $H(x, z, p) = \sup_\alpha\{-p \cdot b(x, z, \alpha) - L(x, z, \alpha)\}$ *and* $\alpha^\star(x, z, p) = \arg\max$*, the family* $(v^{N,i})$ *solves on* $[0, T) \times (\mathbb{R}^d)^N$

$$-\partial_t v^{N,i} - \sum_{j=1}^{N} \tfrac{1}{2}\operatorname{tr}\Big(a(x_j, z^j_{\boldsymbol{X}})\, \mathrm{D}^2_{X_j} v^{N,i}\Big) - \sum_{j\neq i} b\Big(X_j, z^j_{\boldsymbol{X}}, \widehat{\alpha}^{\,j}\Big) \cdot \nabla_{X_j} v^{N,i} + H\Big(X_i, z^i_{\boldsymbol{X}}, \nabla_{X_i} v^{N,i}\Big) = 0, \quad (25.6)$$

with terminal data $v^{N,i}(T, \boldsymbol{X}) = g(X_i, z^i_{\boldsymbol{X}})$*, where* $z^i_{\boldsymbol{X}} = \frac{1}{N}\sum_k \xi_{ik} h(X_k)$ *is the aggregate evaluated at the configuration and* $\widehat{\alpha}^{\,j} = \alpha^\star(X_j, z^j_{\boldsymbol{X}}, \nabla_{X_j} v^{N,j})$*. Conversely a classical solution with these feedbacks verifies a Markovian Nash equilibrium.*

The display eq. (25.6) packs a great deal into little space, and it repays being read term by term, in words, before we argue that it is correct. The two auxiliary objects come first. The *Hamiltonian* $H(x, z, p) = \sup_\alpha\{-p \cdot b(x, z, \alpha) - L(x, z, \alpha)\}$ is, exactly as in chapter 6, the result of a pointwise optimization over the control: it asks, for an agent of type x feeling aggregate z and carrying the costate (the value gradient) p, what is the best instantaneous trade-off between steering — the term $-p \cdot b$, the rate at which moving lowers the cost-to-go — and paying the running cost L. The maximizer of that bracket is the *optimal feedback* $\alpha^\star(x, z, p) = \arg\max$, the control an agent in that situation would actually choose. The only departure from chapter 13 is that both now carry the aggregate z as a frozen second argument in place of the empirical measure: structurally nothing has changed, the population label has just been swapped for the network's local readout of the population.

The coupling itself lives entirely in one symbol. The expression $z^i_{\boldsymbol{X}} = \frac{1}{N}\sum_k \xi_{ik} h(X_k)$ is the neighbour aggregate of definition 25.3, but *evaluated at a frozen configuration* $\boldsymbol{X}$ rather than along the random trajectory: it is the deterministic function of the N positions $\boldsymbol{X}$ obtained by summing each vertex k's feature vector $h(X_k)$ against the edge weight ξ_{ik} joining it to i and dividing by N. Reading it as a function of $\boldsymbol{X}$, not of time, is what makes eq. (25.6) an autonomous PDE on configuration space: agent i's coupling at the point $\boldsymbol{X}$ is whatever $z^i_{\boldsymbol{X}}$ says it is there. This is the single place the graph enters — through the weights ξ_{ik} in that sum — and it is why the system is *quenched*: the array ξ and the types $\boldsymbol{x}^N$ are fixed data baked into the coefficients, not variables of the problem.

The differential operator on the left then reads as the generator of the whole configuration acting on agent i's value, exactly as a single-agent HJB but enlarged from $\mathbb{R}^d$ to $(\mathbb{R}^d)^N$. The second-order sum $\sum_{j=1}^N \frac{1}{2}\operatorname{tr}(a(x_j, z^j_{\boldsymbol{X}})\, \mathrm{D}^2_{X_j} v^{N,i})$ runs over *all* N blocks because every state diffuses, controlled or not, each with its own diffusion matrix $a = \sigma\sigma^\top$ evaluated at that vertex's type and aggregate. The first-order sum $\sum_{j\neq i} b(X_j, z^j_{\boldsymbol{X}}, \widehat{\alpha}^j) \cdot \nabla_{X_j} v^{N,i}$ runs only over $j \neq i$ and transports $v^{N,i}$ along the *frozen* equilibrium drifts of the other agents, each agent j moving under its own optimal feedback $\widehat{\alpha}^j = \alpha^\star(X_j, z^j_{\boldsymbol{X}}, \nabla_{X_j} v^{N,j})$. The block $j = i$ is excluded from this sum precisely because agent i's own drift is not frozen but optimized, and that optimization is the last term $H(X_i, z^i_{\boldsymbol{X}}, \nabla_{X_i} v^{N,i})$: agent i's contribution enters not as a fixed transport but inside the Hamiltonian, the signature of the one block that is being controlled rather than watched. The terminal data $v^{N,i}(T, \boldsymbol{X}) = g(X_i, z^i_{\boldsymbol{X}})$ is the agent's own terminal cost, again coupled to the others only through its aggregate.

Proof sketch. The argument is the freeze-and-close argument of proposition 13.3 run on the network, and it is worth tracing the three movements explicitly so that the phrase "verbatim network transcription" is earned rather than asserted; what is genuinely unchanged and what is genuinely new will then stand out cleanly.

Freeze, and a control problem appears. Fix one agent i and commit every other agent $j \neq i$ to its equilibrium feedback $\widehat{\alpha}^j$. By the definition of Nash equilibrium (definition 25.4), agent i's equilibrium control is, against this frozen environment, its *optimal* control: it has no profitable deviation. Hence $v^{N,i}$ is the value function of a single ordinary stochastic control problem, posed on the full configuration space $(\mathbb{R}^d)^N$ — agent i steers only its own block X^i, while each X^j with $j \neq i$ is an uncontrolled diffusion carrying the now-fixed drift $b(X_j, z^j_{\boldsymbol{X}}, \widehat{\alpha}^j)$ and diffusion $\sigma(X_j, z^j_{\boldsymbol{X}})$. Agent i must nonetheless track the entire configuration, because the aggregate $z^i_{\boldsymbol{X}}$ it pays through depends on where its neighbours are. This is identical to the homogeneous reduction; the only thing that has changed is that the frozen coefficients are evaluated at $z^j_{\boldsymbol{X}}$ rather than at the empirical measure μ^N.

Dynamic programming gives an HJB on $(\mathbb{R}^d)^N$. Apply the dynamic programming principle of chapter 6 to this single problem with the enlarged state space. The generator of the configuration splits into the diffusion of all N blocks (the second-order sum), the frozen transport of the $j \neq i$ blocks (the first-order sum), and agent i's own drift, which sits inside the instantaneous minimization $\min_\alpha\{b(X_i, z^i_{\boldsymbol{X}}, \alpha) \cdot \nabla_{X_i} v^{N,i} + L(X_i, z^i_{\boldsymbol{X}}, \alpha)\}$. By the defining relation of the Hamiltonian as a maximized negated bracket, this inner minimum is exactly $-H(X_i, z^i_{\boldsymbol{X}}, \nabla_{X_i} v^{N,i})$ and its minimizer is $\alpha^\star(X_i, z^i_{\boldsymbol{X}}, \nabla_{X_i} v^{N,i})$. Substituting and moving signs reproduces the i-th equation of eq. (25.6). Nondegeneracy (A-Nondeg) is what licenses this step: it supplies the parabolic regularity (appendix C.9) that makes the candidate value $C^{1,2}$ and legitimizes the Itô expansion behind the verification half.

Self-consistency upgrades best response to equilibrium. So far we have only used that agent i optimizes against *some* frozen feedbacks; the equation would hold against any fixed environment. What makes the family $(v^{N,i})_i$ an equilibrium is the closure condition that the minimizer just computed for agent i, namely $\alpha^\star(X_i, z^i_{\boldsymbol{X}}, \nabla_{X_i} v^{N,i})$, coincides with the feedback $\widehat{\alpha}^i$ the other agents froze when they solved their own problems. Each agent's optimal response reproduces the feedback the others assumed; the freezing is a fixed point, not an arbitrary choice. This is why the system is simultaneous: agent i's equation contains $\nabla_{X_j} v^{N,j}$ through $\widehat{\alpha}^j$, so no value can be solved without all the others at once. The converse — that a classical $C^{1,2}$ solution with these feedbacks verifies a Markovian Nash equilibrium — is the verification theorem of chapter 6 applied agent by agent, the Itô expansion of $v^{N,i}$ along any admissible deviation showing optimality via the Hamiltonian's one-sided inequality.

It is now possible to say precisely what is unchanged and what is new, which is the whole point of recording the system. *Unchanged* is the entire architecture: the freeze-one-agent reduction, the dynamic-programming step, the appearance of the same Hamiltonian and the same optimal feedback, the self-consistent closure, and the verification converse — every one of these is the homogeneous argument with the symbol μ^N mechanically replaced by $z^i_{\boldsymbol{X}}$. *New* is only the nature of that replacing symbol. The empirical measure μ^N coupled agent i to the entire population symmetrically; the aggregate $z^i_{\boldsymbol{X}} = \frac{1}{N}\sum_k \xi_{ik} h(X_k)$ couples it only to its graph neighbours, with weights ξ_{ik}, and these weights are *quenched random data* fixed by the realized network. That single change in the coupling object — from a symmetric population functional to a vertex-dependent, edge-weighted, randomly-frozen sum — is the entire content of the network refinement; [34] records the same system for the network case. The next remark unfolds why that change, small as it looks on the page, is what forces two limits rather than one. □

Remark 25.6 (Why the network Nash system is worse than chapter 13)**.** The system eq. (25.6) is, exactly as in remark 13.4, the *complete* answer to the finite game: it contains every Markovian equilibrium, for every N and every realized network. And exactly as there, it is useless as something one could actually solve. Diagnosing why is the specification of the cure, and the network inherits all three homogeneous pathologies and then adds a fourth of its own, which is the one that reshapes the limit object.

The three inherited pathologies are precisely those of remark 13.4. First, *dimension*: each $v^{N,i}$ is a function on $[0,T]\times(\mathbb{R}^d)^N$, so resolving it on a grid costs a number of nodes exponential in Nd, the curse of dimensionality in its purest form, fatal already at moderate N and d. Second, the *N-fold simultaneous coupling*: through the feedbacks $\widehat{\alpha}^j = \alpha^\star(X_j, z^j_{\boldsymbol{X}}, \nabla_{X_j} v^{N,j})$, the equation for $v^{N,i}$ depends on the gradients $\nabla_{X_j} v^{N,j}$ of every other value function, so the N equations cannot be solved one at a time but only all at once — the analytic fingerprint of the self-consistency in the proof. Third, the *intrinsic forward–backward structure*: once a limit is taken the terminal data on the value and the initial data on the population do not disappear but become the two-point boundary coupling of the MFG system, and that is structural, not a defect — it expresses that rational agents anticipate the future while the crowd is pushed by the past, and any honest limit must keep it. None of these three is new; each is repaired (the first two) or respected (the third) by the limit in exactly the manner of chapter 13.

The fourth pathology is the genuinely new one, and it is what makes this chapter more than chapter 13 with subscripts. The coefficients of eq. (25.6) are *quenched random data*: the realized types $\boldsymbol{x}^N$ and the realized edges ξ^N are frozen into every coefficient through the aggregates $z^j_{\boldsymbol{X}}$. In the homogeneous game the coefficients were deterministic and identical for all agents, so a single representative agent could stand for the crowd; here two agents of different types see different wirings, different aggregates, and hence genuinely different equations, and the network itself is, in the sampled model, a random object. This has a consequence even at the level of *stating* the limit. One cannot pass to "the" limiting equation, because there is no single agent and no single coefficient field to converge to; the limit must average over the disorder in the right way and resolve the result by type. The object that results is therefore not one PDE pair but an entire *field* of

HJB–Fokker–Planck systems, one (u^x, m^x) for each continuum type $x \in [0,1]$, coupled across types only through the operator $\mathbb{W}$ — the GMFG of chapter 22. The quenched fourth pathology is exactly why the limit object acquired a continuum of equations rather than collapsing, as in chapter 13, to a single one: heterogeneity that the mean field could average away is here *indexed*, not erased.

This is also why the curing substitution is now *double* rather than single. In chapter 13 the cure was one replacement, the empirical measure μ^N by the deterministic mean field m_t. Here the coupling that must go to the continuum is the quenched neighbour sum $z^i_{\boldsymbol{X}} = \frac{1}{N}\sum_k \xi_{ik} h(X_k)$, and it must be replaced by the GMFG aggregate

$$z^i_{\boldsymbol{X}} \;=\; \frac{1}{N}\sum_k \xi_{ik}\, h(X_k) \quad\rightsquigarrow\quad z_t(x_i) \;=\; \int_0^1 W(x_i,y)\,\langle h, m^y_t\rangle\; \mathrm{d}y \;=\; (\mathbb{W}\bar{h}_t)(x_i),$$

the GMFG aggregation of definition 24.3 (eq. eq. (24.3)) with the first moment there replaced by the observable mean $\bar{h}_t(y) = \langle h, m^y_t\rangle$. The substitution is best read as two replacements performed in sequence — precisely the condition-then-average order fixed in section 25.1.2 — and seeing them as separate is the entire reason the chapter must run two limits. The first replacement is over the *disorder*: swap each random edge ξ_{ik} for its annealed value $\bar{\xi}_{ik} = W(x_i, x_k)$, averaging out the coin flips while holding the types fixed. The second is over the *configuration*: swap the empirical sum $\frac{1}{N}\sum_k W(x_i,x_k)h(X_k)$, a Riemann/Monte-Carlo sum over the sampled types x_k with the neighbours settled into their type-equilibrium laws, for the continuum integral $\int_0^1 W(x_i,y)\langle h, m^y_t\rangle\,\mathrm{d}y$ against the equilibrium field. The first replacement is the *edge-sampling* step, the second the *quadrature*-plus-*chaos* step; together they carry the quenched, fluctuating, per-realization neighbour sum to its annealed, deterministic, continuum value. That neither replacement is free — each costs an error, and the two errors have different sizes and need not be taken in the same way — is the single analytic fact that organizes everything downstream.

Justifying this double substitution *with a rate*, and discovering that its two halves are two genuinely different limits, is the program of sections 25.3 to 25.4. The very fact that the limit object is a field of systems rather than one PDE is what guarantees the two limits cannot be collapsed into one: the configuration limit $N \to \infty$ resolves the field's individual entries (one type's HJB–FP pair at a time, the graph held fixed), while the disorder/graph limit ties those entries together through the convergence of the wiring $W_N \to W$. The next section takes exactly this hand-off, organizing the two replacements into two limits with separate difficulties, rates, and commutation behaviour.

25.3 The two limits and their order

The previous section ended by handing us a precise debt: the curing substitution that carries the finite game to the GMFG is now *double*, the quenched neighbour sum $z^i_{\boldsymbol{X}} = \frac{1}{N}\sum_k \xi_{ik} h(X_k)$ going over to the operator aggregate $\int_0^1 W(x_i,y)\langle h, m^y_t\rangle\,\mathrm{d}y$ in two steps — first average out the edge coins at frozen types, then pass the resulting Riemann sum over the sampled types to its continuum integral — and we owe a *rate* for it. This section is where that debt is reorganized before it is paid. The reorganization is the single conceptual move on which the rest of the chapter rests: the two replacements are not two stages of one limit but two *genuinely different* limits, with different difficulty, different rates, and — near the critical coupling — different verdicts on whether the answer depends on the order in which they are taken. Naming them, drawing the diagram that holds them apart, and stating the quantitative claim that closes the chapter is the whole business here; the three subsections that follow then supply, in turn, the engine, the per-limit rates, and the assembled bound.

It is worth saying at once which two limits these are, because the names will recur on every page. The first is the one already familiar from chapter 13: the *mean field, or sampling, limit* $N \to \infty$. Even with the wiring held absolutely fixed, the finite game is not the GMFG, because each "type" is represented by only finitely many agents and the local population it presents still fluctuates; only as the number of agents per type grows do those fluctuations wash out and propagation of chaos take hold. This limit is about the *count* of agents, and it is graph-agnostic — it would run unchanged on any fixed network. The second limit is new to the network setting: *graph convergence*, the statement that the finite wiring W_N itself approaches the continuum kernel W. This limit is about the *wiring*, not the head-count, and its natural topology is the weak cut metric $\delta_\square$ of chapter 17 rather than any sampling distance on measures. The reason these cannot be folded into one is structural and was already exposed in remark 25.6: the limit object is not a single PDE but a *field* of HJB–Fokker–Planck systems indexed by the continuum type, and the sampling limit resolves the field's individual entries (one type's pair at a time, the graph frozen) while the graph limit is what ties those entries together through the operator $\mathbb{W}$. Two jobs, two limits.

Before drawing the diagram that separates them we fix the standing notation the whole section, and indeed the rest of the chapter, will use without further comment. Throughout, $z_t(x) = (\mathbb{W}\bar{h}_t)(x)$ denotes the GMFG aggregate of definition 24.3, where $\bar{h}_t(y) = \langle h, m_t^y \rangle$ is the equilibrium mean of the interaction observable at type y and $(u^x, m^x)_{x\in[0,1]}$ is the GMFG solution of chapters 22 and 24 for the limiting graphon W. This $z_t(x)$ is the continuum target of the finite per-agent aggregate z_t^i: the object the double substitution is trying to reach, written compactly as the action of the coupling operator $\mathbb{W}$ on the field of observable means. Reading $z_t(x_i)$ in place of z_t^i in the dynamics eq. (25.4)–eq. (25.5) is precisely what turns the finite game into the GMFG, so the entire error of the limit is the discrepancy $z_t^i - z_t(x_i)$, and the two limits are nothing but the two halves of that discrepancy.

The cleanest way to see that there really are two halves, and that they can in principle be taken in either order, is to lay the four objects they connect at the corners of a square. Each side of the square performs *one* of the two operations in isolation; the two routes from the starting corner to the GMFG differ only in the order. The point of drawing it is to make the question "does the order matter?" into a geometric one — whether the square commutes — and to make visible, in the labels on the arrows, that the two operations are bookkept by two different errors.

Heuristic (non-rigorous)

Picture the double limit as a commuting square:

$$\begin{array}{ccc}
\text{finite game on } G(N,W) & \xrightarrow{N\to\infty \text{ (POC, graph frozen)}} & \text{GMFG on the step graphon } W_N \\
\downarrow{\scriptstyle \delta_\square(W_N,W)\to 0} & & \downarrow{\scriptstyle \text{stability}} \\
\text{finite game with } \mathbb{W}\text{-coupling} & \xrightarrow{N\to\infty} & \text{GMFG on } W.
\end{array}$$

The right column is *stability of the GMFG solution under perturbation of the kernel* (chapter 24, and section 25.5); the top arrow is *propagation of chaos with the network held fixed* (the mean field limit of chapters 13 and 23). The diagonal — sampling $G(N, W)$ and letting $N \to \infty$ once — is what actually happens, and the square commuting says the diagonal reaches the same corner. The total error therefore splits into a *mean-field/sampling* part, of size r_N (the Fournier–Guillin rate of lemma 13.5), and a *graph* part, of size $\delta_\square(W_N, W)$ or the operator error $\|\mathbb{W}_N - \mathbb{W}\|_{L^2 \to L^2}$. The chapter's quantitative claim is that these two add, and the slower one wins.

The diagram is worth walking around arrow by arrow, because each side is a theorem this chapter either imports or proves, and naming what each one does is half the work of the convergence proof. Start at the top-left corner, the only fully concrete object on the page: the genuine finite game of section 25.1, played on one realized sample $G(N, W)$ with its quenched types and edges. There are exactly two things one can do to it.

The *top arrow* freezes the realized wiring and lets the agent count grow. "Frozen" is the operative word: we do not let the graph converge to anything: we keep the realized step graphon W_N exactly as sampled, and ask only that $N \to \infty$ so that the population at each type fills in. This is propagation of chaos in the precise sense of chapters 13 and 23 — synchronous coupling, Grönwall, the suppression of empirical fluctuations — carried out verbatim on the fixed network. Its destination is therefore not the GMFG on W but the GMFG *on the step graphon* W_N: the limit honours whatever wiring it was handed. The error this arrow costs is the mean-field/sampling error, the same r_N that governed the homogeneous theory, and it is graph-blind — it does not see how close W_N is to W, only how many agents there are.

The *right column* is the operation that the top arrow refused to perform: it holds the GMFG structure fixed and *moves the kernel*, from the step graphon W_N to the limit W. Both endpoints are continuum objects — fields of HJB–Fokker–Planck systems — so nothing here is a sampling statement at all; this arrow is purely about how the GMFG *solution* responds when its coupling operator is perturbed. That it responds continuously, with a modulus, is exactly the stability of the GMFG under kernel perturbation: the contraction estimate proposition 24.18 of chapter 24, sharpened in section 25.5 into Lipschitz dependence of the equilibrium on the kernel. The error this arrow costs is therefore a *graph* error, measured by how far W_N sits from W in the topology in which the GMFG solution is continuous — the cut distance $\delta_\square(W_N, W)$ when only the unlabelled network is available, or the stronger operator distance $\|\mathbb{W}_N - \mathbb{W}\|$ when the labels are known.

The *left arrow* and *bottom arrow* together form the alternative route, and they are the same two operations performed in the opposite order. The left arrow replaces each realized random edge ξ_{ij} by its annealed value $\bar{\xi}_{ij} = W(x_i, x_j)$ — it averages out the Bernoulli coins of eq. (25.1) while leaving the head-count and the quenched types alone, producing a finite game whose coupling is already the operator $\mathbb{W}$ rather than a realized adjacency array. This is the disorder average, and its cost is again a graph error, $\delta_\square(W_N, W) \to 0$. The bottom arrow then runs propagation of chaos on that $\mathbb{W}$-coupled finite game, $N \to \infty$, landing on the GMFG for W. Reading down-then-across rather than across-then-down has swapped the order: graph first, sampling second.

Now the geometric question has content. Both routes start at the same finite game and both *can* end at "GMFG on W", so one may legitimately ask whether they agree — whether across-then-down equals down-then-across. That is what it *means* for the square to commute. The diagonal is the third path and the only one that is physically real: when one actually samples $G(N, W)$ and lets N grow, one is not free to send the agent count to infinity with the wiring pinned, nor to perfect the wiring with the count pinned, because — and this is the hinge of the entire chapter — *the same parameter N controls both.* On a sampled graph there are not two independent knobs but one: incrementing N simultaneously adds agents (advancing the sampling limit) *and* refines the realized wiring toward W (advancing the graph limit). The two clocks are geared to a single shaft. One therefore never walks the sides of the square in sequence; one travels the diagonal, taking both limits at once. The assertion that the diagonal reaches the same corner as the two side-routes is precisely the assertion that the joint limit agrees with either iterated limit — that the order does not matter and the two limits commute — which is why "the square commutes" and "the joint limit is well posed" are one and the same statement.

This single-parameter coupling is also what fixes how the two errors combine, and the conclusion is the one piece of arithmetic the reader should carry out of this section. Because N drives both mechanisms, the total discrepancy $z_t^i - z_t(x_i)$ inherits *both* a sampling contribution and a graph contribution, each a function of the one N, and — as the joint estimate of section 25.3.3 will make precise — they enter *additively*: the total error is bounded by $C\,(r_N + \gamma_N)$, with r_N the mean-field/sampling rate and γ_N the graph rate. A sum of two decaying terms decays no faster than its slower summand; so the joint rate is governed by whichever of the two mechanisms is the bottleneck. This is the memorable form of the chapter's quantitative claim: *the two errors add, and the slower one wins.* It also tells us in advance where the drama will be. If γ_N is a healthy polynomial $N^{-1/2}$ — which, we will find, requires *knowing the latent labels* — the graph contributes on the same footing as the sampling term and may even be negligible beside it. But if the network is known only up to relabelling, so that the only available graph topology is the cut metric, then γ_N degrades to a glacial $1/\sqrt{\log N}$, slower than every polynomial, and the graph limit alone sets the pace of the whole convergence. The gap between these two regimes — polynomial versus logarithmic — is exactly the value of knowing the types, and it is a recurring refrain from here to the end of the chapter.

Three jobs remain, and they are exactly the three subsections ahead. First, both the right column (stability) and the graph half of the diagonal were just asserted to be "measured by $\delta_\square$", but nothing yet explains *why* the cut distance is the right yardstick for a game whose data are value functionals and costs. The answer is a single estimate — the cut norm controls the action of the coupling operator on bounded observables — and section 25.3.1 proves it, showing that $\delta_\square$ is the right norm precisely because it is the norm in which the aggregate z_t enters the value functionals eq. (25.5). Second, with that engine in hand, section 25.3.2 quantifies the graph error γ_N itself, and in doing so uncovers the cut-versus-operator dichotomy: the two error mechanisms latent in the double substitution — edge sampling and quadrature — converge at genuinely different rates, and the cut metric controls only type-*averaged* quantities while per-agent control demands either known labels or the stronger operator norm. Third, section 25.3.3 assembles the sampling rate r_N and the graph rate γ_N into the additive bound eq. (25.11) promised above, working in the contraction regime where the square is exact. That last qualification is not a throwaway: the commuting square, and with it the very right to speak of "the" joint limit and its rate, is a luxury of the contraction/monotone regime. Outside it — near the critical coupling where the GMFG equilibrium can fail to be unique — the order of limits can change the answer, and self-averaging over the quenched wiring can break down exactly as it does at a glass transition. Remark 25.12 states precisely when the order matters, and the physics note closing this section reads the whole construction as the strategic counterpart of quenched-versus-annealed averaging over disorder — the reading already promised in section 25.1.1, now earned by the machinery in between.

25.3.1 The cut-norm aggregation lemma

The previous section drew the commuting square and, in doing so, made a promise it did not keep: it asserted again and again — on the right column for stability, and on the graph half of the diagonal for joint convergence — that the graph error is "measured by $\delta_\square$," without ever explaining why the cut distance, and not some other distance between kernels, is the right yardstick. That promissory note comes due here. The reason is not aesthetic and not a matter of convenience; it is forced by the way the network actually enters the game. The only channel through which the wiring touches an agent's dynamics and cost is the aggregate $z_t(x) = (\mathbb{W}\bar{h}_t)(x)$ of eq. (25.3), and the cost functional eq. (25.5) does not consume that aggregate raw: it consumes it *integrated against the population*, smeared over types and tested against bounded data. The natural distance on kernels is therefore whichever one measures how much $\mathbb{W}$ can move such a tested, type-averaged readout — and that distance, it turns out, is exactly the cut distance. The single estimate that makes this identification precise, lemma 25.7 below, is the technical engine of the entire chapter: every later rate, every stability statement, every ε-Nash guarantee passes through it. This is the moment the cut metric of chapter 17 stops being imported machinery and earns its place in the GMFG story.

Because that whole story now rests on one norm, we recall it from first principles, in enough words that a reader who skipped chapter 17 can follow without turning back. The *cut norm* of a kernel $U : [0,1]^2 \to \mathbb{R}$ is

$$\|U\|_\square \;=\; \sup_{S,T\subseteq[0,1]} \Big| \int_{S\times T} U(x,y)\;\mathrm{d}x\;\mathrm{d}y \Big|,$$

the largest total mass U can pile up over any rectangle $S \times T$ of types. It is a deliberately *weak* norm: it never looks at U at a point, only at its integral over blocks, so two kernels that disagree violently on a thin sliver but agree on every fat rectangle are close in it. This blockwise, averaging character is precisely why it is the right topology for graph convergence — it is blind to the microscopic relabelling of vertices and sees only macroscopic edge densities, the very quantities the GMFG limit is built to track. For the proof we need it in an equivalent, more flexible guise. Testing U against *indicators* $\mathbf{1}_S, \mathbf{1}_T$ is the same, up to a universal constant, as testing it against arbitrary functions valued in $[-1,1]$; this is the cut-norm/$\infty\to 1$ comparison,

$$\|U\|_\square \;\le\; \|U\|_{\infty\to 1} \;:=\; \sup_{f,g:[0,1]\to[-1,1]} \Big| \int_{[0,1]^2} U(x,y)f(x)g(y)\,\mathrm{d}x\;\mathrm{d}y \Big| \;\le\; 4\;\|U\|_\square\,, \tag{25.7}$$

proved in chapter 17 (it is the standard comparison of [99, §8], [72]). The lower bound is immediate — indicators are themselves admissible f, g, with $[0,1]$ rescaled into $[-1,1]$ — and the upper bound, the only nontrivial direction, comes from writing a general $[-1,1]$-valued f as an average of $\pm$ indicators and the same for g, so the bilinear form is a convex combination of rectangle masses and cannot exceed the largest of them by more than the factor 4. The single fact to carry forward is that bounding $\|U\|_\square$ bounds the bilinear pairing $\int Ufg$ for *every* pair of bounded test functions, with only a harmless factor of 4 lost. That pairing is exactly the shape in which the aggregate enters the cost, so the bridge from "the kernels are cut-close" to "the games are close" is built into the norm itself.

Lemma 25.7 (Cut norm controls the aggregate)**.** *Let W, W' be graphons and let $g, g' : [0,1] \to \mathbb{R}$ be measurable with $\|g\|_\infty, \|g'\|_\infty \le M$. For $f : [0,1] \to [-1,1]$,*

$$\Big| \int_0^1 f(x)\,[(\mathbb{W}g)(x) - (\mathbb{W}'g')(x)]\,\mathrm{d}x \Big| \;\le\; 4M\,\|W - W'\|_\square \;+\; \|W'\|_1\,\|g - g'\|_\infty\,, \tag{25.8}$$

where $\|W'\|_1 = \int_{[0,1]^2} |W'| \le 1$. In particular, for $g = g'$ bounded by M, $\left|\int f\,[(\mathbb{W} - \mathbb{W}')g]\right| \le 4M\,\|W - W'\|_\square$ for every $f : [0,1] \to [-1,1]$.

Before the proof, it is worth reading the inequality eq. (25.8) for what it says, because its two-term shape is not incidental: it is the lemma's whole message. The quantity on the left is a single tested, type-averaged readout of the difference between two aggregates — the aggregate built from kernel W and observable g, against the one built from W' and g' — and these are exactly the two ingredients that can drift apart when we replace the true continuum coupling by a finite-network proxy: the *kernel* can be wrong (we used the sampled $\mathbb{W}_N$ instead of $\mathbb{W}$) and the *observable* can be wrong (the neighbours' empirical feature law has not yet relaxed to the equilibrium $\bar{h}_t$). The right-hand side charges separately for each: a cut-distance term for the kernel error, scaled by the observable's amplitude M, and a sup-distance term for the observable error, scaled by the kernel's L^1 mass. This is precisely the clean separation the joint estimate of section 25.3.3 needs — one term it will feed the graph rate γ_N, the other the mean-field/sampling rate r_N — and it is why the lemma is stated for two kernels and two observables at once rather than only for the difference $\mathbb{W} - \mathbb{W}'$.

Proof. The argument is short, and its only idea is to separate the two ways the aggregates can differ so that each meets the tool built for it. Add and subtract the mixed term $\mathbb{W}'g$ to split the difference of aggregates into a *kernel part*, where the observable is held fixed and the kernel changes, and an *observable part*, where the kernel is held fixed and the observable changes:

$$(\mathbb{W}g) - (\mathbb{W}'g') = \underbrace{(\mathbb{W} - \mathbb{W}')\,g}_{\text{kernel}} + \underbrace{\mathbb{W}'(g - g')}_{\text{observable}}.$$

Integrating against f and using the triangle inequality, it suffices to bound the two pieces separately.

For the kernel part, unfold the operator into its integral kernel and read the result as a bilinear form in the kernel difference:

$$\int_0^1 f\,[(\mathbb{W} - \mathbb{W}')g] = \int_{[0,1]^2} (W - W')(x,y)\,f(x)\,g(y)\,\mathrm{d}x\,\mathrm{d}y.$$

This is the pairing eq. (25.7) controls, but only for test functions valued in $[-1,1]$; f already qualifies, while g is bounded by M, not 1. We therefore normalize, applying eq. (25.7) to $U = W - W'$ with the admissible pair $(f,\, g/M)$ — both now valued in $[-1,1]$ — and pulling the scalar M back out:

$$\Big| \int_{[0,1]^2} (W - W')\,f\,g \Big| = M \Big| \int_{[0,1]^2} (W - W')\,f\,(g/M) \Big| \le M\,\|W - W'\|_{\infty\to 1} \le 4M\,\|W - W'\|_\square\,.$$

The factor 4 is the price of eq. (25.7); the factor M is the amplitude of the observable, and it is the reason boundedness of h was demanded back in section 25.1.2, for an unbounded observable would carry no such normalization and the cut norm would say nothing about its aggregate.

For the observable part the kernel does not move, so no cut-norm subtlety arises and a crude pointwise bound is enough. Since $|f| \le 1$ and $|(g-g')(y)| \le \|g-g'\|_\infty$ uniformly,

$$\Big|\int_0^1 f\,\mathbb{W}'(g-g')\Big| \le \int_{[0,1]^2} |W'(x,y)|\,|g-g'|(y)\;\mathrm{d}x\;\mathrm{d}y \le \|W'\|_1\;\|g-g'\|_\infty\,.$$

Here the whole observable error is taken in sup norm and the kernel contributes only its total L^1 mass $\|W'\|_1 = \int_{[0,1]^2} |W'| \le 1$ — the dense-graphon bound, since W' takes values in $[0,1]$. Adding the two displays gives eq. (25.8). The final clause is the special case $g = g'$, for which the observable part vanishes identically and only the cut term survives. □

The lemma earns its title: any tested, type-averaged, bounded functional of the aggregate — and the value functionals eq. (25.5), read at equilibrium, are exactly of this kind — is moved by no more than the cut distance of the kernels (times the observable's amplitude) plus the sup-distance of the observables (times the kernel's mass). When two networks are cut-close and their equilibrium observables agree, every welfare-type readout the game produces is close. That is the positive content, and it is everything the cut-rate branch downstream will need.

But the lemma also tells us, with equal force, what it cannot do, and this negative half is just as important to internalize because it is invoked repeatedly later as though already understood. The estimate controls $\int_0^1 f(x)\,[\cdots]\;\mathrm{d}x$, an *integral over types*, and nothing more. It says nothing about the value $[\cdots](x)$ at a single fixed type x. One is tempted to read this as a weakness of the proof — surely a sharper argument would deliver the pointwise statement — but it is not. It is a true feature of the cut metric, forced by the very averaging that makes the cut norm the right topology for graph convergence, and the cleanest way to see that it is unavoidable is to exhibit two kernels that are cut-close yet have a wildly different aggregate at one type.

Take the constant graphon $W \equiv \frac{1}{2}$ — every pair of types equally and moderately linked — and build W' from it by severing a single vertex. Concretely, fix one type cell $I_k = [\frac{k-1}{N}, \frac{k}{N})$ and set $W' = \frac{1}{2}$ everywhere except on the cross-shaped strip $\{x \in I_k\} \cup \{y \in I_k\}$, where $W' = 0$: the vertex sitting at I_k has been disconnected from the network, while every other edge is left untouched. The two kernels differ only on that strip, a set of measure $\frac{2}{N} - \frac{1}{N^2}$, and there by at most $\frac{1}{2}$, so $\|W - W'\|_\square \le \|W - W'\|_1 \le \frac{1}{N}$: in cut distance the two networks are indistinguishable as $N \to \infty$, and lemma 25.7 duly certifies that their aggregates agree on every type-average. Indeed, take the simplest observable $g \equiv 1$ ($M = 1$). The type-averaged readout is

$$\int_0^1 |(\mathbb{W}-\mathbb{W}')g|(x)\;\mathrm{d}x \;=\; \underbrace{\Big(1-\tfrac{1}{N}\Big)\cdot\tfrac{1}{2N}}_{x\notin I_k} \;+\; \underbrace{\tfrac{1}{N}\cdot\tfrac{1}{2}}_{x\in I_k} \;=\; O\Big(\tfrac{1}{N}\Big),$$

comfortably inside the lemma's bound $4M\,\|W - W'\|_\square \le 4/N$. Yet at the severed type itself the two aggregates could not be further apart: for $x \in I_k$, $(\mathbb{W}g)(x) = \int_0^1 \frac{1}{2}\;\mathrm{d}y = \frac{1}{2}$ while $(\mathbb{W}'g)(x) = 0$, a pointwise gap of $\frac{1}{2} = O(1)$ that does not shrink with N at all. The type-average is tiny because the one deviant type carries weight only $\frac{1}{N}$ in the integral and is drowned out; the pointwise value at that type is order one because nothing is averaging it against its well-behaved neighbours. Two cut-close kernels can thus agree on every type-integral and still disagree completely in a single row — and no estimate built on the cut norm can ever rule this out, because the cut norm cannot see a single row in the first place.

This micro-instance is the seed of a tension that organizes the rest of the chapter, so it is worth naming what it forces. The cut-norm engine delivers control of *type-averaged* equilibrium quantities only — aggregate welfare, mean effort, the population-integrated cost — and this is exactly the control that flows forward: to the cut-rate item of section 25.3.2, to the unlabelled branch of the joint-convergence theorem in section 25.3.3, to the type-averaged ε-Nash guarantee, and to the cut-stability theorem of section 25.5, the statement that macroscopically equivalent networks produce close equilibrium aggregates. What it cannot deliver — pointwise-in-type, per-agent control — is not a gap the cut metric will ever close, and the single-severed-row example shows why in one picture. Closing that gap requires strictly more information about the network than its cut-equivalence class contains: either the latent labels themselves, which buy a per-vertex bound at the polynomial rate $N^{-1/2}$, or the stronger operator-norm control of chapter 18, which dominates the cut norm and does see individual rows. The dichotomy is therefore not a temporary inconvenience but the permanent shape of the theory, and section 25.5 resolves it explicitly. For now we have the engine; the immediately next task is to point it at the one kernel difference the chapter most cares about. Section 25.3.2 applies lemma 25.7 to the sampled operator $\mathbb{W}_N$, separating the edge-sampling and quadrature mechanisms hidden in $W_N - W$ and contrasting the pointwise control the known labels afford against the weaker cut control that is all an unlabelled network allows.

25.3.2 The graph error of the sampled network

The cut-norm aggregation lemma of section 25.3.1 is a general instrument: it bounds any tested, type-averaged readout of a difference of aggregates by the cut distance of the kernels (times the observable's amplitude) plus the sup-distance of the observables (times the kernel's mass). The previous subsection built that instrument and then, in the single-severed-row example, drew its boundary — it controls type-integrals and is constitutionally blind to any single row, a limitation that no sharper argument on the cut norm can repair and that, as flagged there, will eventually have to be paid for either with the labels or with the stronger operator norm. We now point the instrument at the one kernel difference the chapter actually cares about, $W_N - W$: the gap between the sampled empirical step graphon of definition 25.2 and the kernel it was drawn from. This is the right column of the commuting square of section 25.3 in concrete form — the graph held against its own limit, the mean-field limit set aside — and the question it poses is exactly: how far is $\mathbb{W}_N$ from $\mathbb{W}$, and in *what sense*?

That last qualifier is the whole point, because the answer is not one number but two, attached to two different notions of "how far," and it is the single most important quantitative fact of the chapter. Recall from section 25.1.1 that the discrepancy $W_N - W$ is assembled from two independent mechanisms living in two different places. The *edge-sampling* part is the mean-zero fluctuation $\xi_{ij} - W(x_i, x_j)$ of the Bernoulli coins, present only because the realized wiring is a noisy one-bit readout of the smooth kernel value. The *quadrature* part is the discrepancy between the N frozen type positions $\boldsymbol{x}^N$ and the continuum label they are meant to sample, present even if the coins were exact. Pointing the cut-norm engine at $W_N - W$ forces us to track both — but, more consequentially, it forces us to decide *what we are allowed to know about the wiring*, and that single modelling choice splits the answer in two. If the analyst holds the latent types $\boldsymbol{x}^N$ in hand — the latent-position model, where the positions were measured or estimated — the natural object is the error at one *named* vertex, the pointwise aggregate error e_N^i, and we shall see it is controlled at the polynomial rate $N^{-1/2}$. If instead the network is delivered only up to relabelling — an unlabelled graph, with no access to the positions — then the only object the cut metric can even speak about is the type-average, and it is controlled at the far slower rate $1/\sqrt{\log N}$. Two genuinely different error notions, controlled at two genuinely different rates: this is the cut-versus-operator dichotomy of section 25.5 in its sharpest, most quantitative form, and the proposition records both halves side by side.

Proposition 25.8 (Graph error of $G(N,W)$)**.** *Let W satisfy* (A-Reg-W) *and let $G(N,W)$ be sampled as in definition 25.1, with empirical step graphon W_N (definition 25.2). Fix bounded $g : [0,1] \to \mathbb{R}$, $\|g\|_\infty \le M$. There are two distinct error quantities, controlled at two genuinely different rates — this distinction, between a single vertex's aggregate and a type-average, is the quantitative heart of the chapter and the source of the cut-versus-operator dichotomy of section 25.5.*

1. (Known labels: per-agent pointwise error.) *If the types $\boldsymbol{x}^N$ are known (the latent-position model), the* pointwise *aggregate error at vertex i, $e_N^i := [(\mathbb{W}_N - \mathbb{W})g](x_i) = \frac{1}{N}\sum_j(\xi_{ij} - W(x_i,x_j))g_j + q_N^i$, satisfies, uniformly in i,*

$$\max_{i\le N} \mathbb{E}\big[(e_N^i)^2 \,|\, \boldsymbol{x}^N\big]^{1/2} \;\le\; \underbrace{C\,M\,N^{-1/2}}_{\textit{edge sampling}} + \underbrace{q_N}_{\textit{quadrature}}\;, \tag{25.9}$$

where $q_N^i = \frac{1}{N}\sum_j W(x_i,x_j)g_j - \int_0^1 W(x_i,y)g(y)\,\mathrm{d}y$ is the one-dimensional quadrature error of the row $W(x_i,\cdot)g$ and $q_N = \sup_i |q_N^i|$; under (A-Reg-W) *with W, g Lipschitz-continuous in type, $q_N = O(N^{-1/2})$ for i.i.d. labels and $q_N = O(N^{-1})$ for the regular grid.*

2. (Unknown labels: type-averaged tested error.) *If the network is known only up to relabelling — so that W_N and W must be compared in $\delta_\square$ — then for the* type-averaged *tested error $E_N := \int_0^1 f(x)[(\mathbb{W}_N - \mathbb{W})g](x)\,\mathrm{d}x$ with $f : [0,1] \to [-1,1]$, the second sampling lemma of chapter 19 (remark 19.5, eq. eq.* (19.2)*; proved in full in theorem F.9) gives*

$$\delta_\square(W_N, W) \;\le\; \frac{C}{\sqrt{\log N}} \quad \textit{with high probability,} \tag{25.10}$$

improving to a polynomial rate $\delta_\square(W_N,W) = O(N^{-c})$ when W is of bounded "complexity" (a step graphon, or Hölder with a weak-regularity modulus, corollary 19.9). Combined with lemma 25.7, $|E_N| \le 4M\,\delta_\square(W_N,W)$ for every $f : [0,1] \to [-1,1]$.

The constants depend on M, the Lipschitz data of W, and the moments of h under the equilibrium law, not on N. Note the gap: the per-agent error (1) *is $O(N^{-1/2})$ but is available* only with known labels*, while the unlabelled comparison* (2) *controls only the type-average and at the far slower $1/\sqrt{\log N}$ rate.*

The two items are the two halves of the same modelling decision, and it helps to read them as a single sentence before proving either. With the labels known we may ask the strong, local question — what is the error in the aggregate felt by *this* vertex i? — and item (1) answers it at the healthy polynomial rate $N^{-1/2}$, the price being that we must actually possess $\boldsymbol{x}^N$. Without the labels we may ask only the weak, global question — what is the error in a population-integrated readout? — and item (2) answers *that* through the cut metric, at the logarithmic rate $1/\sqrt{\log N}$. The proof of the first item is a clean decomposition into the two mechanisms named above and a one-line second-moment estimate of each; the proof of the second is a citation to the sampling theory of chapter 19 composed with the aggregation lemma. What deserves the most care is neither computation but the *asymmetry* between them: why the strong question has no unlabelled answer at all, no matter how slow a rate we would settle for.

Proof sketch. (1). Start from the empirical step graphon. On the regular grid the row of $\mathbb{W}_N$ at vertex i is the cell average $(\mathbb{W}_N g)(x_i) = \frac{1}{N}\sum_j \xi_{ij} g_j$, with g_j the average of g over cell I_j, because W_N is piecewise constant ξ_{ij} on the pixel $I_i \times I_j$ by eq. (25.2). Subtracting the continuum aggregate $(\mathbb{W}g)(x_i) = \int_0^1 W(x_i, y)g(y)\,\mathrm{d}y$ and inserting the intermediate sum $\frac{1}{N}\sum_j W(x_i, x_j)g_j$ splits the error into exactly the two mechanisms anticipated above,

$$e_N^i = \underbrace{\frac{1}{N}\sum_j (\xi_{ij} - W(x_i, x_j))g_j}_{\text{edge part: random coins}} + \underbrace{q_N^i}_{\text{quadrature: discrete vs. continuum}}, \qquad q_N^i = \frac{1}{N}\sum_j W(x_i, x_j)g_j - \int_0^1 W(x_i, y)g(y)\,\mathrm{d}y.$$

The first piece moves the realized edges to their conditional means and is pure edge-sampling noise; the second piece, q_N^i, holds the kernel exact and charges only for replacing an integral by a finite sum over the type positions. We bound each in turn, conditionally on $\boldsymbol{x}^N$ throughout — this is the condition-first-average-second discipline of section 25.1.2, and it is what keeps the two mechanisms from being silently fused, since the edge part is random given $\boldsymbol{x}^N$ while the quadrature part is deterministic given $\boldsymbol{x}^N$.

For the *edge part*, write $Y_j := \xi_{ij} - W(x_i, x_j)$. Conditionally on $\boldsymbol{x}^N$, the sampling model eq. (25.1) makes the coins $\{\xi_{ij}\}_{j\neq i}$ independent Bernoullis with means $W(x_i, x_j)$, so the $\{Y_j\}_{j\neq i}$ are independent, mean zero, and bounded in $[-1, 1]$. The edge part $S := \frac{1}{N}\sum_{j\neq i} Y_j g_j$ is thus a sum of $N-1$ independent mean-zero terms, each of conditional weight $|g_j|/N \leq M/N$. Its conditional mean is zero, and — this is the only step that uses independence — the variance of a sum of independent variables is the sum of their variances, with no cross terms, so

$$\mathbb{E}[S^2 \mid \boldsymbol{x}^N] = \mathrm{Var}\left(S \mid \boldsymbol{x}^N\right) = \frac{1}{N^2}\sum_{j\neq i} g_j^2 \;\mathrm{Var}\left(Y_j \mid \boldsymbol{x}^N\right) = \frac{1}{N^2}\sum_{j\neq i} g_j^2\, W(x_i, x_j)(1 - W(x_i, x_j)).$$

Each Bernoulli variance is at most $\frac{1}{4}$ and each $g_j^2 \leq M^2$, so the sum of $N-1$ terms is at most $(N-1)\,M^2/4$, whence $\mathbb{E}[S^2 \mid \boldsymbol{x}^N] \leq M^2/(4N)$ and the conditional root-mean-square edge error is at most $\frac{1}{2}M\,N^{-1/2}$. This is the edge term $CMN^{-1/2}$ of eq. (25.9) with $C = \frac{1}{2}$ (the crude bound $\mathrm{Var}(Y_j) \leq 1$ would give $C = 1$; either suffices). The estimate is the elementary $\sqrt{N}$ law of large numbers made quantitative: each of the $\Theta(N)$ neighbours contributes an $O(1/N)$ term, the N variances add to $O(1/N)$, and the standard deviation is its square root, $O(N^{-1/2})$. Crucially, every constant used — the count $N-1$, the amplitude M, the Bernoulli variance $\frac{1}{4}$ — is the same for every vertex and does not depend on *which* i we chose, so the bound holds uniformly and the maximum over $i \le N$ inherits it verbatim. Nothing here depends on the state dimension d: the summands are scalar features bounded by M/N, which is why the edge rate is $N^{-1/2}$ regardless of d, a fact we will lean on heavily in remark 25.9.

For the *quadrature part* q_N^i there are no coins to average — it is fixed once $\boldsymbol{x}^N$ is fixed — and it is precisely the one-dimensional error of approximating $\int_0^1 \Phi$ by $\frac{1}{N}\sum_j \Phi(x_j)$ for the row integrand $\Phi(y) := W(x_i, y)g(y)$, which under (A-Reg-W) with g Lipschitz is Lipschitz-continuous in y, uniformly in the row index x_i. Its size depends entirely on *how the types were placed*, the very trade-off flagged in section 25.1.1. For i.i.d. labels $x_j \sim \mathrm{Unif}\,[0,1]$, the sum $\frac{1}{N}\sum_j \Phi(x_j)$ is an average of N i.i.d. bounded random variables with mean $\int_0^1 \Phi$; its variance is $\frac{1}{N}\operatorname{Var}(\Phi(x_1)) = O(1/N)$, so by the elementary central limit theorem its fluctuation about the integral is $O(N^{-1/2})$ — the Monte-Carlo rate. For the regular grid $x_j = (j - \frac{1}{2})/N$ the same sum is the *midpoint quadrature rule*: it samples Φ at the centre of each cell I_j of width $1/N$, and on each such cell the centred evaluation cancels the first-order term, so a single cell's error is $O(N^{-2})$ for a Lipschitz integrand (as the Lipschitz hypothesis supplies). Summing N cells gives the deterministic $O(N^{-1})$, twice as fast as the random placement. This is the same grid-versus-i.i.d. contrast already met for $\int_0^1 g$ in section 25.1.1, now applied row by row, and it is uniform in i because the Lipschitz modulus of Φ is uniform in the row. Taking $q_N = \sup_i |q_N^i|$ and adding the two contributions gives eq. (25.9). We have used only the conditional second moment; if one wants the bound to hold not merely in L^2 but with high probability, the bounded-differences inequality lemma 19.3 of chapter 19 applies — changing one edge coin moves e_N^i by at most M/N, so McDiarmid gives Gaussian tails of width $N^{-1/2}$ — but the joint-convergence and ε-Nash theorems downstream consume only the L^2 statement, so we keep it.

(2). The cut rate eq. (25.10) is not proved afresh here; it *is* the second sampling lemma of chapter 19 (remark 19.5, eq. eq. (19.2)), proved in full at theorem F.9, which states exactly that the empirical step graphon of a W-random graph converges to W in cut distance. The $1/\sqrt{\log N}$ appearing there is the worst-case weak-regularity rate: it traces to the weak regularity lemma of chapter 17, which approximates an *arbitrary* graphon by a step graphon on k parts with cut error $O(1/\sqrt{\log k})$ and no better in general, and a sample of N vertices can resolve only of order $\log N$ such parts, leaving the $1/\sqrt{\log N}$ residue. This is genuinely slow — slower than any power of N — and it is why an *unlabelled* graph limit is the chapter's bottleneck. When W is of bounded complexity, however, the worst case does not bind: a step graphon, or a Hölder kernel whose weak-regularity modulus is polynomial (corollary 19.9), is already well approximated by a fixed or slowly growing number of parts, and the rate improves to a polynomial $O(N^{-c})$. Either way, composing the cut bound with the final clause of lemma 25.7 taken at $g = g'$ turns it into a bound on the type-averaged tested error, $|E_N| \le 4M\,\delta_\square(W_N, W)$, valid for every $f : [0,1] \to [-1,1]$ at once.

It remains to make vivid the asymmetry promised above: *why no analogue of eq.* (25.10) *can ever control the per-agent row error* e_N^i, so that the labels in item (1) are not a convenience but a strict necessity. The reason is the very fact that made the cut norm the right topology in section 25.3.1, read in reverse. The cut rate bounds $\delta_\square(W_N, W)$, which by the aggregation lemma bounds every type-*averaged* readout; but the single-severed-row construction of section 25.3.1 exhibited two graphons W, W' at cut distance $O(1/N)$ — as close as one likes — whose aggregates nevertheless differ by $O(1)$ at one named type, the disconnected vertex. Transport that construction here: a hypothetical theorem bounding $\max_i |e_N^i|$ by some function of $\delta_\square(W_N, W)$ would have to certify $|e_N^i|$ small whenever the cut distance is small, yet the severed-row example produces cut-distance $O(1/N)$ with a row error pinned at $O(1)$. Any such "cut rate for a row" would therefore have to be $O(1)$ — no decay at all, hence no theorem. The obstruction is not that our argument is too weak; it is that the cut metric, being an infimum over relabellings, has *erased* the identity of vertex i and so cannot make any claim attached to it. Recovering a per-vertex statement demands strictly more information than the cut-equivalence class contains: either the labels $\boldsymbol{x}^N$ themselves, which (1) converts into the $N^{-1/2}$ rate, or the operator-norm control of chapter 18, which dominates the cut norm and does see individual rows. This is exactly the unresolved tension section 25.5 will discharge. □

Remark 25.9 (The graph limit is the bottleneck)**.** This remark is the chapter's quantitative thesis, so it is worth stating with care. proposition 25.8 is the precise form of the heuristic that "the slower limit wins," but to know *which* limit is slower one must hold the magnitude of the mean-field rate r_N up against the graph rate, and the comparison has a twist that the homogeneous theory never sees: r_N is dimension-dependent while the graph edge error is not. By the propagation-of-chaos estimate lemma 13.5 (eq. eq. (13.12)) the Fournier–Guillin sampling rate degrades with the state dimension d — $r_N \le CN^{-1/4}$ for $d \le 3$, worsening to $r_N \le CN^{-1/d}$ in high dimension $d > 4$ — because empirically approximating a measure on $\mathbb{R}^d$ in Wasserstein distance becomes harder as d grows. The graph edge error of proposition 25.8(1), by contrast, is $O(N^{-1/2})$ *regardless of* d: as the variance computation above made explicit, it aggregates scalar features bounded by M/N, an object the curse of dimensionality never touches. The two rates therefore cross as d varies, and three regimes result, which it is the business of this remark to separate.

Known labels, low dimension ($d \le 3$). Here the analyst possesses the latent positions, so the per-agent rate (1) is in force, and both graph mechanisms are polynomial: edge sampling at $N^{-1/2}$ and quadrature at $N^{-1/2}$ (i.i.d. placement) or N^{-1} (grid). The mean-field rate $r_N \le CN^{-1/4}$ is polynomial too, but it is already a full power of N slower than the graph error — $N^{-1/4}$ against $N^{-1/2}$ — so even in low dimension the mean field, not the graph, is the slower limit, and it alone sets the joint rate at $O(N^{-1/4})$, paced by propagation of chaos. The regime is nonetheless benign: every mechanism converges polynomially, and the joint rate is simply whichever exponent is smallest, here the mean field's $N^{-1/4}$.

Known labels, higher dimension ($d \ge 3$). The graph edge error stays pinned at $N^{-1/2}$ while r_N continues to slow with d (toward $N^{-1/d}$), so the gap only widens: the *mean field*, already the slower limit in low dimension, falls ever further behind the graph error as d grows. The lesson is that knowing the positions buys a fast graph rate but does nothing for the sampling of the high-dimensional state space; in every dimension it is the propagation of chaos, the same mechanism that governed the graphless theory of chapter 13, that paces the convergence, and increasingly so past $d \approx 4$, where r_N leaves the $N^{-1/4}$ plateau.

Unknown labels (any dimension). Now only (2) is available, and the cut-distance rate $1/\sqrt{\log N}$ is slower than *every* polynomial, hence slower than both r_N and the known-label graph error, for every d. The graph convergence becomes the sole, dominant bottleneck, and the logarithm swamps all the polynomial machinery upstream of it. This is the structural novelty absent from chapter 13:

with no graph there, the only rate was r_N and it was always polynomial; the network can introduce a genuinely *slower* limit, one whose slowness is not a matter of a worse exponent but of leaving the polynomial scale entirely.

The three regimes localize the chapter's headline number. The *value of knowing the types* is precisely the gap between the polynomial graph rate $N^{-1/2}$ of (1) and the logarithmic unlabelled rate $1/\sqrt{\log N}$ of (2) — and it is essential to read this as a *pure graph-error gap*, taken with the mean-field part r_N held *fixed and identical* on both sides. The labels do not improve, and could not improve, the propagation of chaos: r_N is the same whether or not one knows $\boldsymbol{x}^N$. What the labels change is only the graph column of the error, and there they convert a logarithmic rate into a polynomial one. The difference between a network one can resolve down to individual vertices and a network one knows only macroscopically is thus, quantitatively, exactly the difference between $N^{-1/2}$ and $1/\sqrt{\log N}$: a polynomial against a logarithm, the single most consequential gap the chapter measures.

The two error rates this subsection has isolated are exactly the two raw materials the rest of the chapter assembles. We bundle the graph column into a single symbol γ_N — the graph rate — equal to $O(N^{-1/2})$ when the labels are known (the edge-and-quadrature sum of (1)) and to $O(1/\sqrt{\log N})$ when the network is unlabelled (the cut rate of (2)), and hand it forward. Section 25.3.3 adds γ_N to the mean-field/sampling rate r_N under the chapter 24 contraction hypothesis that makes the GMFG best-response map a contraction and the commuting square exact, producing the joint bound $C(r_N + \gamma_N)$; the same γ_N then propagates into the network ε-Nash rate of section 25.4. The dichotomy itself — the gap between the polynomial labelled rate and the logarithmic unlabelled one — passes to remark 25.14, where it is read as the irreducible price of the network's extra structure, and to section 25.5, which banks the unlabelled, cut-controlled half as robustness to the part of the wiring no relabelling can recover. With both errors named and rated, we are ready to combine them.

25.3.3 Joint convergence in the contraction regime

The previous two subsections delivered the two raw materials this one assembles. Section 25.3.1 built the engine — the cut-norm aggregation lemma lemma 25.7, which converts closeness of kernels into closeness of the tested aggregates that drive the costs — and section 25.3.2 spent that engine on the one kernel difference the chapter actually cares about, $W_N - W$, extracting from it the graph rate γ_N: a healthy $\gamma_N = O(N^{-1/2})$ when the latent labels are known, and the glacial $\gamma_N = O(1/\sqrt{\log N})$ when the network is delivered only up to relabelling. The mean-field/sampling rate r_N of lemma 13.5 has been on hand since chapter 13. The commuting-square heuristic of section 25.3 promised that these two errors simply *add*, with the slower one setting the pace; the business of this subsection is to honour that promise as a theorem about the actual finite trajectories, with the synchronous-coupling propagation-of-chaos argument of lemma 13.5 doing the combining.

That promise is not free: it holds only where the commuting square is genuinely exact, and that is the *contraction regime* of chapter 24. It is worth recalling exactly what that regime is and why it is precisely the hypothesis the square needs, because the whole right column of the diagram rests on it. Under (A-Coupling), the operator-norm smallness $\|\mathbb{W}\| < \kappa$ makes the GMFG best-response map — the map that sends a guessed field of aggregates to the field the agents' optimal responses actually generate — a contraction in the field argument $\mathbf{m}$ at fixed kernel (proposition 24.18). A contraction has a *unique* fixed point, and that fixed point moves Lipschitz-continuously with the data of the problem. The datum we are about to perturb is the *kernel* itself: the right column of the square is nothing but the statement that the GMFG solution depends Lipschitz-continuously on the coupling operator $\mathbb{W}$, with a finite modulus that section 25.5 will pin down. Outside the contraction regime that modulus can blow up, the fixed point can split into several branches, and the right column loses its very meaning — there is no longer a single solution to track as the kernel moves. This is why the square is exact *here* and only here, and why every rate in this subsection is, as the chapter's refrain has it, a luxury of the contraction regime. Remark 25.12 returns to precisely what fails as $\|\mathbb{W}\| \uparrow \kappa$; for now we stand inside the regime where the GMFG solution is single-valued and Lipschitz in the kernel, and harvest the clean additive bound it makes available.

Theorem 25.10 (Joint convergence with rate)**.** *Assume* (A-Lip), (A-Growth), (A-Nondeg)*,* (A-Conv)*,* (A-Reg-W)*, and* (A-Coupling) *in the contraction regime of chapter 24, so that the GMFG system for W has a unique solution $(u^x, m^x)_x$ with feedback $\widehat{\alpha}(t,x,X) = \alpha^\star(X, z_t(x), \nabla u^x(t,X))$ bounded and Lipschitz in X, uniformly in (t,x). Let $(X^{i,N})_{i\le N}$ be the closed-loop states of the finite game on $G(N,W)$* under the GMFG decentralized profile *$\alpha_t^i = \widehat{\alpha}(t, x_i, X_t^i)$, and let $(\bar{X}^{x_i})_{i\le N}$ be independent copies of the graphon McKean–Vlasov solution of chapter 23 for the limiting W, driven by the same (B^i, X_0^i). Then there is C, independent of N, such that*

$$\max_{i\le N} \mathbb{E}\Big[\sup_{t\le T} \big|X_t^{i,N} - \bar{X}_t^{x_i}\big|^2\Big]^{1/2} \;\le\; C\big(r_N + \gamma_N\big), \tag{25.11}$$

where r_N is the Fournier–Guillin sampling rate of lemma 13.5 and γ_N is the graph error of proposition 25.8: $\gamma_N = O(N^{-1/2})$ for known labels under (A-Reg-W)*, and $\gamma_N = O(1/\sqrt{\log N})$ for unlabelled networks. Consequently the type-resolved empirical field converges in the precise sense of corollary 25.11 below.*

The theorem is the network upgrade of the homogeneous propagation-of-chaos bound lemma 13.5, and the proof reuses that argument's spine wholesale, so the honest thing is to flag the single new joint where the graph enters and lavish the attention there. The spine is *synchronous coupling*: we run the true finite state $X^{i,N}$ and its GMFG-limit surrogate $\bar{X}^{x_i}$ on the *same* Brownian motion B^i and the *same* initial draw X_0^i, so that the two trajectories differ *only* through the one channel we care about — the aggregate each feels — and not through any spurious mismatch of noise or starting point. The squared difference then obeys a differential inequality whose forcing term is exactly the aggregate discrepancy $z_t^i - z_t(x_i)$, and the entire content of the proof is to decompose that discrepancy, recognise that one of its pieces is itself the average of the squared state errors (which closes a Grönwall loop), and bound the two remaining pieces by the two rates already in hand. We carry this out now.

Proof sketch. The synchronous-coupling Itô estimate. Couple $X^{i,N}$ to $\bar{X}^{x_i}$ through the same noise B^i and the same initial state $X_0^i \sim m_0^{x_i}$, and write $\Delta_t^i := X_t^{i,N} - \bar{X}_t^{x_i}$ for their difference, so that $\Delta_0^i = 0$. Both processes solve the same SDE under the same GMFG decentralized feedback $\widehat{\alpha}(t, x_i, \cdot)$

and the same driving B^i; they differ only in the aggregate fed to the coefficients — the realized z_t^i for $X^{i,N}$, the GMFG value $z_t(x_i)$ for $\bar{X}^{x_i}$. Itô's formula (theorem 5.9) applied to $|\Delta_t^i|^2$ gives

$$\mathrm{d}|\Delta_t^i|^2 = 2\,\Delta_t^i\cdot\big(b(X_t^{i,N}, z_t^i, \widehat{\alpha}_t^{i,N}) - b(\bar{X}_t^{x_i}, z_t(x_i), \widehat{\alpha}_t^i)\big)\,\mathrm{d}t + \big\|\sigma(X_t^{i,N}, z_t^i) - \sigma(\bar{X}_t^{x_i}, z_t(x_i))\big\|^2\,\mathrm{d}t + \mathrm{d}M_t^i,$$

where $\widehat{\alpha}_t^{i,N} = \widehat{\alpha}(t, x_i, X_t^{i,N})$ and $\widehat{\alpha}_t^i = \widehat{\alpha}(t, x_i, \bar{X}_t^{x_i})$, and the martingale increment $\mathrm{d}M_t^i = 2\,\Delta_t^i\cdot(\sigma(X_t^{i,N}, z_t^i) - \sigma(\bar{X}_t^{x_i}, z_t(x_i)))\,\mathrm{d}B_t^i$ collects the stochastic-integral part. Here is where synchronous coupling earns its keep, and the point is worth making explicit rather than asserting it as in the homogeneous proof. Because both states are driven by the *same* B^i, the two diffusion contributions enter the Itô correction as a single *difference* $\sigma(X^{i,N}) - \sigma(\bar{X}^{x_i})$ — which is itself $O(|\Delta_t^i|)$ by the Lipschitzness of σ — rather than as two independent noises whose cross-variation would not cancel and would inject an $O(1)$ diffusive spreading no Grönwall argument could absorb. The surviving stochastic integral $\int_0^t \mathrm{d}M_s^i$ is a genuine martingale: its integrand is adapted and square-integrable under (A-Lip) and the moment bounds of (A-Growth), so $\mathbb{E}[M_t^i] = 0$ and the noise drops out of the expectation *entirely.* Taking expectations and using the Lipschitz bounds on $b, \sigma, \widehat{\alpha}$ in the pair (X, z) — the optimal feedback $\widehat{\alpha}$ is Lipschitz in X uniformly in (t, x) by the contraction-regime regularity assumed in the theorem, and (A-Lip) covers b, σ — both deterministic terms are dominated by $C(|\Delta_t^i|^2 + |z_t^i - z_t(x_i)|^2)$, whence

$$\frac{\mathrm{d}}{\mathrm{d}t}\mathbb{E}\big|X_t^{i,N} - \bar{X}_t^{x_i}\big|^2 \;\le\; C\,\mathbb{E}\big|X_t^{i,N} - \bar{X}_t^{x_i}\big|^2 \;+\; C\,\mathbb{E}\big|z_t^i - z_t(x_i)\big|^2,$$

where $z_t^i = \frac{1}{N}\sum_j \xi_{ij} h(X_t^{j,N})$ is the realized aggregate and $z_t(x_i) = \int W(x_i, y)\bar{h}_t(y)\,\mathrm{d}y$ its GMFG value. The decisive step is the decomposition of the aggregate discrepancy into the same three pieces as in proposition 25.8, now with the *interacting* states:

$$z_t^i - z_t(x_i) = \underbrace{\frac{1}{N}\sum_j \xi_{ij}\big(h(X_t^{j,N}) - h(\bar{X}_t^{x_j})\big)}_{\text{(I) coupling}} + \underbrace{\frac{1}{N}\sum_j (\xi_{ij} - W(x_i, x_j))h(\bar{X}_t^{x_j})}_{\text{(II) edge sampling}} + \underbrace{\Big[\frac{1}{N}\sum_j W(x_i, x_j)h(\bar{X}_t^{x_j}) - z_t(x_i)\Big]}_{\text{(III) quadrature+state sampling}}.$$

Term (I)*, the coupling term, closes the loop.* Bound it using the Lipschitzness of h and $|\xi_{ij}| \le 1$,

$$\Big|\frac{1}{N}\sum_j \xi_{ij}\big(h(X_t^{j,N}) - h(\bar{X}_t^{x_j})\big)\Big| \;\le\; \frac{1}{N}\sum_j |\xi_{ij}|\,[h]_{\mathrm{Lip}}\,|X_t^{j,N} - \bar{X}_t^{x_j}| \;\le\; [h]_{\mathrm{Lip}}\,\frac{1}{N}\sum_j |X_t^{j,N} - \bar{X}_t^{x_j}|.$$

This is the self-referential piece: it bounds the aggregate error feeding agent i's equation by the *average* of the very state errors the system is trying to control. It is the genuine propagation-of-chaos feedback — every agent's trajectory error is forced, through the wiring, by the mean of all the others' — and when it is squared, inserted back into the differential inequality, and the maximum over i is taken, it produces a term $C\,\max_j \mathbb{E}|\Delta_t^j|^2$ on the *same side* as the unknown, exactly the shape Grönwall's inequality lemma C.1 absorbs. It contributes nothing to the rate; it is what makes the loop closeable, precisely as in the homogeneous estimate lemma 13.5.

Term (II)*, edge sampling, is tractable because we condition on the reference paths.* This is the one place the graph's own randomness enters the trajectory estimate, and the entire art is the choice of conditioning. Work conditionally on the labels $\boldsymbol{x}^N$ *and* on the whole family of reference paths $(\bar{X}_t^{x_j})_j$. The reason it must be the *reference* system rather than the interacting one is a genuine independence that the reference system enjoys and the interacting system does not: the limit surrogate $\bar{X}^{x_j}$ is driven by B^j, X_0^j and the kernel W alone and *never consults the realized edges* ξ, so given $\boldsymbol{x}^N$ the edge coins $\{\xi_{ij}\}_j$ are independent of the frozen features $\{h(\bar{X}_t^{x_j})\}_j$. Term (II) is therefore, conditionally, a sum of independent mean-zero summands $\frac{1}{N}(\xi_{ij} - W(x_i, x_j))\, h(\bar{X}_t^{x_j})$: mean zero because $\mathbb{E}[\xi_{ij} - W(x_i, x_j) \mid \boldsymbol{x}^N] = 0$ by the sampling model eq. (25.1), and independent across j because the coins are. The conditional variance is then the *sum* of the per-edge variances, with no cross terms, each of size $O(1/N^2)$ since the summand carries the weight $1/N$ and a bounded feature; the N of them add to $O(1/N)$, so $\mathbb{E}[|(\mathrm{II})|^2 \mid \boldsymbol{x}^N, \bar{X}] = O(1/N)$ and the root-mean-square is $O(N^{-1/2})$. This is *exactly* the edge-sampling estimate of proposition 25.8(1), now with the bounded reference features $h(\bar{X}_t^{x_j})$ playing the role of the deterministic test weights g_j there. Had we instead conditioned on the interacting states $X_t^{j,N}$, those *do* depend on the edges — they are coupled to them through the very aggregates we are estimating — the independence would have failed, and the variance computation would have collapsed into uncontrolled cross terms. Conditioning on the graph-independent reference system is precisely what severs that entanglement, and it is why term (II) is the per-agent pointwise aggregate error of proposition 25.8(1), available because the labels are known.

Term (III)*, quadrature and state sampling, is the Fournier–Guillin rate.* With the edges averaged out and the kernel held exact, what remains is the discrepancy between the empirical average $\frac{1}{N}\sum_j W(x_i, x_j)\, h(\bar{X}_t^{x_j})$ over the N i.i.d. type–state pairs $(x_j, \bar{X}_t^{x_j})$ and its expectation $z_t(x_i) = \int W(x_i, y)\bar{h}_t(y)\,\mathrm{d}y$. This is pure sampling error, and it splits into two sub-mechanisms. The *quadrature* part q_N is the error of approximating the type-integral by the sum over the sampled positions — the deterministic row-quadrature error already weighed in proposition 25.8, $O(N^{-1})$ on the grid and $O(N^{-1/2})$ for i.i.d. types. The *state-sampling* part is the error of replacing each equilibrium feature mean $\bar{h}_t(x_j) = \langle h, m_t^{x_j}\rangle$ by the single random draw $h(\bar{X}_t^{x_j})$; this is the empirical-measure fluctuation the Fournier–Guillin estimate of lemma 13.5 controls at the rate r_N in $\mathcal{W}_2$, and because h is Lipschitz, $\mathcal{W}_2$-control of the empirical measure transfers to control of the averaged feature. Term (III) is thus of size $r_N + q_N$, both pieces *graph-blind*: they would survive even if the wiring were exact, and they are exactly the errors the homogeneous theory of chapter 13 already paid.

Assembling. Inserting the three bounds into the differential inequality gives

$$\frac{\mathrm{d}}{\mathrm{d}t}\mathbb{E}|\Delta_t^i|^2 \;\le\; C\,\mathbb{E}|\Delta_t^i|^2 + C\Big(\underbrace{\frac{1}{N}\sum_j \mathbb{E}|\Delta_t^j|^2}_{\text{(I), the loop}} + \underbrace{N^{-1}}_{\text{(II), edges}} + \underbrace{(r_N + q_N)^2}_{\text{(III), sampling}}\Big).$$

Take the maximum over $i \le N$, so that the (I)-term becomes $C\max_j \mathbb{E}|\Delta_t^j|^2$ on the right-hand side, and apply Grönwall's inequality lemma C.1 on $[0,T]$ with the vanishing initial datum $\Delta_0^i = 0$; promoting $\sup_t \mathbb{E}$ to $\mathbb{E}\sup_t$ costs only a Burkholder–Davis–Gundy estimate on the martingale M^i, exactly as in lemma 13.5. The result is $\max_i \mathbb{E}\sup_{t\le T}|\Delta_t^i|^2 \le C(r_N + \gamma_N)^2$. The state-sampling part of (III) supplies the r_N in $C(r_N + \gamma_N)$; the graph rate collects the rest, $\gamma_N = (\mathrm{II}) + (\mathrm{III}) = O(N^{-1/2}) + O(q_N) = O(N^{-1/2})$ for *known* labels, since the quadrature q_N is itself at worst $O(N^{-1/2})$. This is eq. (25.11).

For *unlabelled* networks the per-agent argument of term (II) is no longer available, and the reason is structural rather than a deficiency of technique. Tracing the labelled proof, the decisive move was to control the *pointwise* row error $[(\mathbb{W}_N - \mathbb{W})\bar{h}_t](x_i)$ at the single *named* vertex i — that pointwise quantity is what the Grönwall loop for a fixed i consumes, and it is what proposition 25.8(1) controlled by exploiting the labels. Strip the labels away and we can no longer name a vertex at all: the only object the cut metric can even speak about is the *type-averaged* tested aggregate $\int f(x)[(\mathbb{W}_N - \mathbb{W})\bar{h}_t](x)\,\mathrm{d}x$, which lemma 25.7 bounds by $4\left\|\bar{h}_t\right\|_\infty \delta_\square(W_N, W)$. The single-severed-row example of section 25.3.1 showed once and for all that no bound on a type-average can ever control an individual row: it exhibited two $\delta_\square$-close graphons differing by $O(1)$ in one row sum while agreeing on every integral. The cut lemma therefore delivers *only* the weaker, type-averaged trajectory bound, got by testing the aggregate-error term against the slowly varying weights and invoking lemma 25.7:

$$\Big(\frac{1}{N}\sum_{i\le N}\mathbb{E}\big[\sup_{t\le T}|X_t^{i,N} - \bar{X}_t^{x_i}|^2\big]\Big)^{1/2} \;\le\; C\big(r_N + \delta_\square(W_N, W)\big), \tag{25.12}$$

The uniform-in-i bound eq. (25.11) survives in the unlabelled case *only* under the stronger operator-norm control $\|\mathbb{W}_N - \mathbb{W}\|_{L^2\to L^2}$ of theorem 25.17 — which dominates the cut norm and *does* see individual rows — with γ_N there replaced by that operator distance; but a single sampled graph does not deliver operator-norm closeness at the cut rate, so the honest unlabelled conclusion is the average eq. (25.12). This is nothing but the cut-versus-operator dichotomy of section 25.3.2 resurfacing one level up, now at the level of *trajectories* rather than aggregates: cut distance controls only type-averaged motion of the population, whereas per-agent motion of a named vertex demands either the labels or the operator norm.

It is worth pausing to confirm that nothing in this proof was imported on faith; the self-containedness owed by the book is met. The graphon propagation-of-chaos estimate underlying terms (I)–(III) is *not* an external input: terms (I) and (III) are the synchronous-coupling and $\mathcal{W}_2$-sampling estimates of lemma 13.5 (the Fournier–Guillin rate r_N, proved in-book at lemma 13.5), and term (II) is the edge-sampling estimate of proposition 25.8(1) proved above; the kernel-perturbation dependence used here is the contraction-regime stability proved in this chapter as theorems 25.16 and 25.17 (built on the contraction estimate proposition 24.18). The graphon-system law of large numbers of [15, 16] is the corresponding general (non-contraction) statement, recorded for attribution. □

The headline consequence advertised before the proof — that the finite system reproduces, type by type, the GMFG field m_t^x — needs a careful statement of *which* empirical measure could possibly converge to m_t^x, and the difficulty is one the homogeneous theory never faced. In chapter 13 the target was a single measure and the global empirical measure $\frac{1}{N}\sum_j \delta_{X_t^j}$ was the obvious approximant. Here the target is a *continuum* of measures, one per type, and at a single exact type x the regular grid places exactly *one* agent — the vertex whose position is x. A single Dirac mass cannot approximate a whole distribution m_t^x; one sample is not an empirical law. The fix is to widen the aperture: gather all the agents whose types lie within a small window δ_N of x, treat them as approximate samples of the type-x law, and let the window shrink slowly enough that it always contains many agents ($N\delta_N \to \infty$) yet fast enough that the types it pools are all genuinely near x ($\delta_N \to 0$). This is exactly a histogram or kernel-smoothing bandwidth, and the corollary's content is the balance between its two competing demands. The honest statement therefore localizes over a shrinking window.

Corollary 25.11 (Convergence of the type-resolved empirical field)**.** *Adopt the hypotheses of theorem 25.10 with* known *labels (regular grid or i.i.d.), and let the type field $x \mapsto m_t^x$ be type-Hölder with modulus ω_W (finite under* (A-Reg-W)*, by lemma 24.9). Fix a bandwidth $\delta_N \downarrow 0$ with $N\delta_N \to \infty$, and for $x \in [0,1]$ define the* windowed empirical field

$$\widehat{m^{x,N}}_t \;:=\; \frac{1}{|\mathcal{N}_N(x)|}\sum_{j\in\mathcal{N}_N(x)} \delta_{X_t^{j,N}}, \qquad \mathcal{N}_N(x) := \{\, j \le N : |x_j - x| \le \delta_N \,\}, \tag{25.13}$$

the empirical law of the states whose types lie within δ_N of x. Then

$$\sup_{x\in[0,1]} \mathbb{E}\,\mathcal{W}_2\big(\widehat{m^{x,N}}_t, m_t^x\big) \;\le\; \underbrace{C(r_N+\gamma_N)}_{coupling} + \underbrace{r_{\lfloor N\delta_N\rfloor}}_{within\text{-}window\ sampling} + \underbrace{\omega_W(\delta_N)}_{localization\ bias} \xrightarrow[N\to\infty]{} 0. \tag{25.14}$$

Since $r_{\lfloor N\delta_N\rfloor} \to 0$ (as $N\delta_N \to \infty$) and $\omega_W(\delta_N) \to 0$ (as $\delta_N \to 0$), the right side vanishes; if $\omega_W(\delta) \le C\delta^\beta$, balancing the last two terms yields a polynomial rate added to the coupling error.

Proof. Fix x and abbreviate $\mathcal{N} = \mathcal{N}_N(x)$, $n = |\mathcal{N}|$, the number of agents whose types fall in the window. We first record that n is large, since the whole construction depends on it. For the regular grid the window $[x-\delta_N, x+\delta_N]$ deterministically contains $n \asymp 2N\delta_N$ cell-centres, so $n \asymp N\delta_N \to \infty$ by the standing hypothesis $N\delta_N \to \infty$. For i.i.d. labels n is a binomial count, $n \sim \mathrm{Bin}(N,p)$ with success probability $p = \mathbb{P}(|x_1 - x| \le \delta_N) \asymp 2\delta_N$, so $\mathbb{E}n \asymp 2N\delta_N$; the multiplicative Chernoff bound for binomials gives $\mathbb{P}\big(n < \tfrac12\mathbb{E}n\big) \le e^{-\Omega(\mathbb{E}n)} = e^{-\Omega(N\delta_N)}$, so with probability $1 - e^{-\Omega(N\delta_N)}$ the window holds at least $\tfrac12 N\delta_N$ agents. This is exactly what the bandwidth condition $N\delta_N \to \infty$ buys: it drives the failure probability to zero and makes n deterministically large, so that the within-window law of large numbers below has enough samples to act on. On this high-probability event we treat $n \asymp N\delta_N$ throughout. Insert two intermediate measures and use the triangle inequality for $\mathcal{W}_2$:

$$\mathcal{W}_2\big(\widehat{m^{x,N}}_t, m_t^x\big) \le \underbrace{\mathcal{W}_2\big(\widehat{m^{x,N}}_t,\, \tfrac1n\sum_{j\in\mathcal{N}}\delta_{\bar X_t^{x_j}}\big)}_{(a)} + \underbrace{\mathcal{W}_2\big(\tfrac1n\sum_{j\in\mathcal{N}}\delta_{\bar X_t^{x_j}},\, \tfrac1n\sum_{j\in\mathcal{N}} m_t^{x_j}\big)}_{(b)} + \underbrace{\mathcal{W}_2\big(\tfrac1n\sum_{j\in\mathcal{N}} m_t^{x_j},\, m_t^x\big)}_{(c)}.$$

For (a), coupling the two empirical measures atom by atom through the synchronous coupling of theorem 25.10, $(a) \le \big(\tfrac1n\sum_{j\in\mathcal{N}}|X_t^{j,N} - \bar X_t^{x_j}|^2\big)^{1/2}$, whose expectation is at most $\max_{i\le N}\mathbb{E}[\,|X_t^{i,N} - \bar X_t^{x_i}|^2]^{1/2} \le C(r_N+\gamma_N)$ by eq. (25.11). For (b): conditionally on the labels the $\bar X_t^{x_j}$, $j\in\mathcal{N}$, are independent with laws $m_t^{x_j}$, so (b) is the empirical-measure sampling error of n independent draws from a mixture, of size $r_n = r_{\lfloor N\delta_N\rfloor}$ (the Fournier–Guillin rate of lemma 13.5, in expectation). For (c): convexity of $\mathcal{W}_2$ and the type-modulus give $(c) \le \tfrac1n\sum_{j\in\mathcal{N}}\mathcal{W}_2(m_t^{x_j}, m_t^x) \le \omega_W(\delta_N)$, since $|x_j - x| \le \delta_N$ for $j \in \mathcal{N}$. Taking expectations, summing, and the supremum over x (the three bounds are uniform in x) gives eq. (25.14). □

The three terms of eq. (25.14) make the bandwidth trade-off explicit, and it is worth carrying out the optimisation, because it tells us the windowing never becomes the bottleneck. The two window-dependent terms pull in opposite directions: the within-window sampling error $r_{\lfloor N\delta_N\rfloor}$ *improves* as the window widens (more agents $n \asymp N\delta_N$ to average over), while the localization bias $\omega_W(\delta_N)$ *worsens* (the pooled types stray farther from x). The coupling error $C(r_N+\gamma_N)$ is independent of the bandwidth and is simply inherited from the joint-convergence theorem. Choosing

δ_N is thus the classical bias–variance balance of nonparametric smoothing. Concretely, if the type field is Hölder, $\omega_W(\delta) \le C\delta^\beta$, and the sampling rate behaves as $r_n \asymp n^{-a}$ for the relevant exponent a (for instance $a = \frac{1}{4}$ in low state dimension, by lemma 13.5), then $r_{\lfloor N\delta_N \rfloor} \asymp (N\delta_N)^{-a}$, and the two bandwidth-dependent terms balance when $(N\delta_N)^{-a} \asymp \delta_N^\beta$, i.e. at $\delta_N \asymp N^{-a/(a+\beta)}$, leaving a polynomial windowing overhead of order $N^{-a\beta/(a+\beta)}$ added to the irreducible coupling error $C(r_N + \gamma_N)$. Since this overhead is polynomial, the field-resolution step adds nothing of a worse order than the trajectory rate the theorem already certified — the windowing is a clean polynomial refinement, never the dominant cost (which remains the graph limit whenever the labels are unknown).

Remark 25.12 (Where the order of limits matters)**.** Everything above was harvested inside the contraction regime, where the commuting square is exact and "the" joint limit and its rate are well posed. It is worth spelling out what goes wrong as one leaves that regime, because the failures are not abstract pathologies but precisely the places the chapter's central refrain — *rates and commutation are contraction-regime luxuries* — earns its keep. Two distinct failure modes are worth naming.

First, the right column loses its modulus at the critical coupling. The whole force of theorem 25.10 flowed through the Lipschitz dependence of the GMFG solution on the kernel, which was a gift of the contraction $\|\mathbb{W}\| < \kappa$. As $\|\mathbb{W}\| \uparrow \kappa$ that contraction degrades — the best-response map's Lipschitz constant approaches 1 — and the modulus of the solution-in-kernel map blows up like $(1 - \|\mathbb{W}\|/\kappa)^{-1}$, governed by the spectral gap of $\mathbb{W}$ at threshold. The right arrow of the commuting square then no longer carries a finite constant, the joint rate eq. (25.11) degrades accordingly, and — worse — at the threshold the GMFG equilibrium can cease to be unique (the symmetry-breaking bifurcation of chapter 24). Once there are several limit equilibria, the order in which one takes $N \to \infty$ and $\delta_\square(W_N, W) \to 0$ can select *different* branches: the iterated limits need not agree, and the square genuinely fails to commute. There is then no single object "the GMFG limit" for the finite game to approximate, and the very question the chapter answers becomes ill-posed.

Second, closed-loop finite equilibria can carry extra randomness. Theorem 25.10 certified the *decentralized* GMFG profile, in which each vertex plays feedback on its own state and type alone. Had we instead tried to take the limit of the finite game's genuine *closed-loop* Nash equilibria — the solutions of the network Nash system eq. (25.6), where each value function depends on the entire configuration — the subtlety of remark 13.10 reappears, and on a network it is compounded. Closed-loop limits can carry extra randomness from *two* sources at once: the configuration coupling, exactly as in the homogeneous case, and now the quenched graph as well. Such limits need not be the Markovian GMFG solution at all; the cheap top-down direction of section 25.4, which only ever asks whether the decentralized profile is approximately optimal, sidesteps this difficulty entirely, which is one reason it is the direction the chapter actually leans on.

Under the monotone regime (A-Mon) both pathologies vanish: monotonicity restores uniqueness of the GMFG equilibrium without any smallness on $\|\mathbb{W}\|$, all routes around the square agree, and the closed-loop and decentralized limits coincide, exactly as in chapter 13. The honest summary is the doubled version of remark 13.15: a clean joint rate and order-independence are not generic features of the convergence problem but luxuries of the contraction or monotone regime — and outside it, the best one can say is that some limit exists, with no promise of a rate or of commutation.

Physics note

The two limits are the strategic counterpart of *quenched* versus *annealed* averaging over disorder, and the analogy is tight enough to name each arrow of the commuting square. The network $(\boldsymbol{x}^N, \xi^N)$ is quenched randomness, fixed once before the dynamics run, like the bond disorder of a spin glass or the conductances of a random-resistor network: the agents play *in* a frozen environment, never averaging over it. Propagation of chaos with the graph held fixed — the top arrow — is then exactly the statement that the system *self-averages* over its own quenched wiring: a single typical realization of the random graph produces the same macroscopic equilibrium as the disorder average would, the per-realization fluctuations washing out as $N \to \infty$. This is the strategic analogue of a self-averaging free energy, whose value at a single typical disorder sample equals its disorder-averaged value in the thermodynamic limit. Graph convergence — the left arrow — is the complementary statement that the disorder average itself relaxes to the graphon's *annealed* law, the GMFG on W. The two limits commute precisely when the system self-averages *uniformly* in the disorder, and this is exactly what the contraction condition (A-Coupling) guarantees: a contraction has one equilibrium that depends smoothly on the wiring, so no realization can drift onto a different branch. Uniform self-averaging is precisely what breaks down near a critical coupling, where the equilibrium bifurcates and different disorder realizations can fall into different basins — the strategic image of a glass transition, at which self-averaging famously fails and sample-to-sample fluctuations of the order parameter no longer vanish. Finally, the cut metric is the natural "macroscopic" topology here for the same reason a coarse-grained free energy is the natural thermodynamic observable: it sees only those features of the wiring that survive averaging over large patches, and is blind to the microscopic relabelling of individual sites. Lemma 25.7 is the precise statement that the equilibrium costs depend on the network only through such coarse, patch-averaged features — which is exactly why the cut-controlled, unlabelled conclusions are the ones that bank as robustness in section 25.5.

With the trajectory-level convergence now certified — the finite closed-loop states on $G(N, W)$ tracking the GMFG limit at the additive rate $C(r_N + \gamma_N)$, uniformly in i when the labels are known and in type-average otherwise — two debts pass forward, in two directions. The first runs into section 25.4. The ε-Nash theorem there must turn this statement *about trajectories* into a statement *about incentives*, and it does so cheaply, reusing the Step-1 aggregate control of this proof — the per-agent bound on $z_t^i - z_t(x_i)$ assembled from terms (I)–(III) — without ever solving the intractable network Nash system of section 25.2. That is the decisive economy of the top-down direction: certifying that the decentralized profile is nearly optimal needs only propagation of chaos for one *fixed* feedback, the very object we have just controlled, and never the finite game's own equilibrium. The known/unlabelled split and the $r_N + \gamma_N$ rate pass through to that theorem unchanged. The second debt runs into section 25.5, but in the reverse direction, for the proof above has *borrowed* from it: the Lipschitz-in-kernel dependence that made the right column of the square exact was invoked here on credit, and section 25.5 is where that credit is paid — the cut-metric and operator-norm kernel-perturbation estimates theorems 25.16 and 25.17, built on the contraction estimate proposition 24.18, are exactly the inputs this proof cited. We turn first to the incentive statement, the practically decisive payoff, and return to settle the stability debt afterward.

25.4 The ε-Nash property on large finite networks

The previous subsection handed us a statement about *trajectories*: under the decentralized GMFG profile the finite states on $G(N, W)$ track the graphon McKean–Vlasov limit at the additive rate $C(r_N + \gamma_N)$, uniformly in the vertex when the labels are known and only in type-average otherwise. That is a fact about where the agents *go*. The result an intervention designer actually needs is a fact about what the agents *want* — a statement about *incentives*: that no vertex, contemplating any unilateral deviation, can lower its own cost by more than a vanishing amount. This section performs that conversion, turning the trajectory bound into an ε-Nash certificate, and it is the result that justifies using the GMFG to design behaviour on real graphs.

The conversion is the cheap one, and it is worth being explicit at the outset about *why* it is cheap, because the economy is the whole point. We are running the top-down direction of chapter 13, transported to the network: solve the GMFG once on the continuum, read off the decentralized feedback as a function of an agent's own state *and its type*, hand it to each vertex of $G(N, W)$, and certify that the resulting profile is an approximate Nash equilibrium of the finite game. The decisive observation — exactly as in theorem 13.6 — is that certifying approximate optimality of *one fixed* profile never requires solving the finite game's own equilibrium. The intractable object of section 25.2, the coupled N-body Nash system eq. (25.6) on configuration space, simply does not appear. All we ever ask is: when every neighbour holds the GMFG feedback fixed and a single tagged agent is free to do anything, how much can that one agent gain? And answering it needs only one analytic input — propagation of chaos for the *fixed* dynamics the common feedback induces — which is precisely the Step-1 aggregate control section 25.3.3 already proved. The bottom-up direction, which would track the genuine closed-loop equilibria of the finite game and watch them converge, is the expensive one we deliberately avoid (and, as remark 25.12 warned, the one that can fail to converge to the Markovian limit at all). The top-down statement we prove here is both cheaper and the one that licenses intervention design.

Before the theorem we must pin down precisely *what strategy* is being handed to the vertices, because the entire force of the result lives in how little that strategy needs to know. The GMFG of chapters 22 and 24 was solved once, on the continuum, and returned a field of value functions $(u^x)_x$ together with the self-consistent field of aggregates $z_t(x) = (\mathbb{W}\bar{h}_t)(x)$, $\bar{h}_t(y) = \langle h, m_t^y \rangle$. Feeding these into the pointwise maximizer $\alpha^\star$ of the Hamiltonian — the same $\alpha^\star$ that appeared in the single-agent verification theorem of chapter 6 and in the network Nash system eq. (25.6) — produces the *decentralized GMFG feedback*

$$\widehat{\alpha}(t, x, X) \;:=\; \alpha^\star(X,\, z_t(x),\, \nabla u^x(t, X)), \qquad z_t(x) = (\mathbb{W}\bar{h}_t)(x). \tag{25.15}$$

The structure of eq. (25.15) is the crux, and it pays to read off each of its three arguments. The control depends on the agent's own current state X; on the agent's type x, which enters in two places — as the label selecting the value function u^x and as the point at which the continuum aggregate field $z_t(\cdot)$ is sampled; and on time t. It depends on *nothing else*: not on the states of any other vertex, not on the realized wiring ξ, not even on the private states of the agent's own neighbours. The frozen aggregate $z_t(x)$ has already been computed on the continuum and is a fixed deterministic function once the GMFG is solved; the agent does not re-read its neighbourhood to evaluate its control. This is exactly the decentralized class of definition 25.4, and the single network novelty over the homogeneous case is the explicit appearance of the type x as a private datum the agent carries from birth. The *GMFG profile* on the finite network is then the strategy in which vertex i plays its own type's feedback,

$$\alpha_t^i = \widehat{\alpha}(t, x_i, X_t^i),$$

read off the limit and implemented with no observation of the graph. It is an implementable, fully decentralized recipe; the theorem says it is also nearly optimal.

One point of emphasis fixes the strength of the guarantee. "Nearly optimal" must be read against a *class* of permitted deviations, and we test against the largest one: the *open-loop* class of definition 25.4. A tagged agent contemplating a deviation is allowed any control process adapted to the full information filtration $\mathbb{F}^N$ — it may, in principle, react to the entire history of every vertex's state and to the realized network itself, far more than the decentralized profile it is deviating from could ever see. Certifying that even such an omniscient, history- and graph-dependent deviation cannot gain more than ε_N is the strongest form the ε-Nash statement can take; a guarantee against the smaller Markovian or decentralized deviation classes would be weaker and easier. That we get the open-loop guarantee for free is a structural gift of the cost: because each $J^{N,i}$ depends on the other agents *only* through the scalar aggregate z_t^i, a deviating agent faced with its neighbours' frozen GMFG feedback confronts an honest *single-agent* control problem against an exogenous signal, and against a single-agent control problem the optimum over open-loop controls and the optimum over feedback controls coincide. This is the envelope structure the proof exploits.

Theorem 25.13 (Network ε-Nash property)**.** *Assume* (A-Lip), (A-Growth), (A-Nondeg), (A-Conv), (A-Reg-W)*, that the GMFG solution* (u^x, m^x) *has a feedback* $\widehat{\alpha}$ *bounded and Lipschitz in* X *uniformly in* (t, x)*, and that* b, σ, L, g *are Lipschitz in the aggregate* z *uniformly in* (X, α) *on the relevant range. Let the network be* $G(N, W)$ *with known types. Then the GMFG profile* $\alpha_t^i = \widehat{\alpha}(t, x_i, X_t^i)$ *is an* ε_N*-Nash equilibrium of the finite game eq.* (25.4)*–eq.* (25.5) *in the open-loop class, with*

$$\varepsilon_N \;\le\; C\big(r_N + \gamma_N\big) \;\xrightarrow[N\to\infty]{}\; 0, \tag{25.16}$$

r_N *and* γ_N *as in theorem 25.10,* C *independent of* N*. For* unlabelled *networks — where only* $\delta_\square(W_N, W)$ *is available — the per-agent* ε*-Nash guarantee is* not *certified by the cut distance (lemma 25.7 controls only type-averages, and two* $\delta_\square$*-close graphons can differ arbitrarily in a single vertex's aggregate); what holds instead is the weaker* type-averaged *guarantee*

$$\frac{1}{N}\sum_{i\le N}\Big[J^{N,i}(\widehat{\alpha}, \widehat{\alpha}^{-i}) - \inf_{\eta} J^{N,i}(\eta, \widehat{\alpha}^{-i})\Big] \;\le\; C\big(r_N + \delta_\square(W_N, W)\big), \tag{25.17}$$

that the average *regret across agents is small. The uniform-in-*i ε*-Nash bound eq.* (25.16) *persists for unlabelled networks only under the stronger operator-norm control* $\|\mathbb{W}_N - \mathbb{W}\|_{L^2\to L^2}$ *(theorem 25.17), with* γ_N *replaced by that operator distance.*

Proof. The architecture is the three-problem triangle inequality of theorem 13.6, transported to the network with the graphon aggregate $z_t(x_i)$ playing the role the mean field played there. Fix the tagged agent i and a candidate open-loop deviation $\alpha^i = \eta$, every other vertex keeping the GMFG profile $\widehat{\alpha}^{-i}$. We will compare three costs for this agent: its *true* finite-game cost $J^{N,i}(\eta, \widehat{\alpha}^{-i})$ under the realized aggregate; an idealized *frozen-aggregate* cost $J^{\mathrm{G}}_{x_i}(\eta)$ in which the realized aggregate is replaced by the deterministic continuum value $z_\cdot(x_i)$; and the same frozen-aggregate cost evaluated at the prescribed feedback $\widehat{\alpha}$ itself. The strategy is to show that the first two costs are close (Step 2, the analytic input), that the GMFG feedback is exactly optimal for the third (Step 3, the strategic input), and to chain the three into the ε-Nash inequality. Everything rests on one estimate, so we establish it first.

Step 1: the deviator's environment stays close to its type's frozen aggregate, uniformly over deviations. When agent i switches to η, the other $N-1$ vertices do not react: they are running the prescribed decentralized feedback $\widehat{\alpha}(\cdot, x_j, \cdot)$, which depends on vertex j's own state and type alone and is blind to what i does. Their joint motion is therefore (almost) exactly the closed-loop graphon system already analysed in theorem 25.10, and the realized aggregate felt by i, $z^i_t = \frac{1}{N}\sum_j \xi_{ij} h(X^j_t)$, is precisely the object the Step-1 aggregate decomposition of that theorem controlled. The conclusion we import is

$$\mathbb{E}\sup_{t\le T}\left|z^i_t - z_t(x_i)\right|^2 \;\le\; C\,(r_N + \gamma_N)^2, \tag{25.18}$$

the per-agent bound assembled there from the coupling term, the edge-sampling term, and the quadrature/state-sampling term, with $z_t(x_i) = (\mathbb{W}\bar{h}_t)(x_i)$ the frozen continuum aggregate at the known type x_i. The one new point, on which the entire ε-Nash argument turns, is that eq. (25.18) holds *uniformly over the deviation* η — the constant C does not depend on which control the tagged agent chose. This is not automatic and deserves to be seen clearly. The aggregate z^i_t is built from the *neighbours'* states $\{X^j_t\}_{j\neq i}$, weighted by the edges ξ_{ij}; the agent's own deviation η enters that sum only through the single self-term $\xi_{ii}h(X^i_t)$, and $\xi_{ii} = 0$ by definition 25.1. The deviator therefore contributes *nothing* to its own aggregate directly. Its only channel of influence is indirect: a deviation moves X^i, which through the edges ξ_{ji} could in principle perturb the neighbours X^j that feed back into z^i. But here the single-atom scaling intervenes. In the aggregate $z^j_t = \frac{1}{N}\sum_k \xi_{jk} h(X^k_t)$ that drives neighbour j, agent i appears as exactly *one* summand, $\frac{1}{N}\xi_{ji}h(X^i_t)$, of weight $1/N$; with $|\xi_{ji}| \le 1$ and h bounded by some M, that summand is at most M/N in absolute value, however wildly η swings X^i. The deviator is a single atom of mass $1/N$ in a sea of N agents, and a single atom can shift any neighbour's aggregate by at most $O(1/N)$. Propagating this $O(1/N)$ perturbation through the neighbours' Lipschitz dynamics and back into z^i adds only a further $O(1/N)$ to the right-hand side of eq. (25.18) — an amount already absorbed into γ_N, which is itself no smaller than $O(N^{-1/2})$. Hence the bound holds with a single constant valid for *every* admissible open-loop η. This uniformity is exactly what lets the same Step-1 estimate serve simultaneously the deviation we are testing and the prescribed profile, so that both ends of the chain below are controlled by one inequality.

Step 2: the true cost and the frozen-aggregate cost are close. Introduce the *representative type-x_i control problem*: an agent of type x_i steering X^i under eq. (25.4) but with the realized aggregate z^i_t everywhere replaced by the deterministic frozen continuum value $z_t(x_i)$, and paying the cost eq. (25.5) with the same replacement. Write $J^{\mathrm{G}}_{x_i}(\eta)$ for its value under control η. This is an honest single-agent control problem against an exogenous, deterministic signal — precisely the problem the GMFG was built to solve — and it is the bridge between the finite game and the continuum. The claim is that the true finite cost and this idealized cost differ by no more than the rate:

$$\left|J^{N,i}(\eta, \widehat{\alpha}^{-i}) - J^{\mathrm{G}}_{x_i}(\eta)\right| \;\le\; C\,(r_N + \gamma_N) \qquad \text{uniformly over admissible } \eta.$$

The two cost functionals are evaluated along the *same* control η and the *same* driving noise; they differ only because one feeds the realized aggregate z^i_t into the coefficients b, σ, L, g while the other feeds the frozen $z_t(x_i)$. Subtracting the two state equations and using the Lipschitz dependence of b, σ on the aggregate (a standing hypothesis of the theorem), the difference of the two state trajectories is forced by $|z^i_t - z_t(x_i)|$ and controlled, via Grönwall's inequality lemma C.1, by $\mathbb{E}\sup_t |z^i_t - z_t(x_i)|^2$; the Lipschitz dependence of L, g on the aggregate then converts that state discrepancy, together with the direct aggregate discrepancy inside the running and terminal costs, into the cost gap. Inserting the Step-1 bound eq. (25.18) gives the displayed inequality, and because Step 1 was uniform in η so is this. In particular the same estimate holds at the prescribed control $\eta = \widehat{\alpha}$.

Step 3: the GMFG feedback is optimal against the frozen aggregate. This is the only genuinely strategic step, and it is where the continuum solution earns its keep. By the very construction of the GMFG (chapters 6 and 22), the type-x_i feedback $\widehat{\alpha}(\cdot, x_i, \cdot) = \alpha^\star(\cdot, z_\cdot(x_i), \nabla u^{x_i})$ is, by the verification theorem of chapter 6, the *optimal* control of the representative type-x_i agent against its own frozen aggregate $z_\cdot(x_i)$. That is precisely the optimality statement that closes the GMFG fixed point, here read at the single type x_i. Hence

$$J^{\mathrm{G}}_{x_i}(\widehat{\alpha}) \;\le\; J^{\mathrm{G}}_{x_i}(\eta) \qquad \text{for every admissible } \eta.$$

Note that this optimality is exact and carries no error term: it is a property of the continuum problem, decided before any finite network is sampled. The finite-N error lives entirely in Steps 1–2; Step 3 contributes only the clean inequality that lets us pivot from the prescribed control to an arbitrary deviation.

Chaining. Now assemble the three inequalities for the tagged agent. Reading left to right, we bound the prescribed profile's true cost by its frozen cost (Step 2 at $\eta = \widehat{\alpha}$), replace the prescribed control by the deviation η in the frozen problem (Step 3), and convert back to the deviation's true cost (Step 2 at η):

$$J^{N,i}(\widehat{\alpha}, \widehat{\alpha}^{-i}) \overset{\text{St.2}}{\le} J^{\mathrm{G}}_{x_i}(\widehat{\alpha}) + C(r_N + \gamma_N) \overset{\text{St.3}}{\le} J^{\mathrm{G}}_{x_i}(\eta) + C(r_N + \gamma_N) \overset{\text{St.2}}{\le} J^{N,i}(\eta, \widehat{\alpha}^{-i}) + 2C(r_N + \gamma_N).$$

The two applications of Step 2 each cost one factor of $C(r_N + \gamma_N)$ and they add; Step 3 is free. The endpoints read $J^{N,i}(\widehat{\alpha}, \widehat{\alpha}^{-i}) \le J^{N,i}(\eta, \widehat{\alpha}^{-i}) + 2C(r_N + \gamma_N)$, which is exactly the defining inequality eq. (13.4) of an ε-Nash equilibrium with $\varepsilon_N = 2C(r_N + \gamma_N)$. The bound holds for *every* open-loop deviation η, because the only η-dependent ingredient, Step 1, was uniform in η; and it holds for *each* agent i separately, because Step 1 controlled the *pointwise* aggregate error at the *named* vertex x_i, which is available precisely when the labels are known (proposition 25.8(1)). This is the genuine per-agent certificate of eq. (25.16): no individual vertex, however it deviates, gains more than ε_N.

The unlabelled case. Strip the labels away and the per-agent argument of Step 1 fails at its root. The chain above consumed the pointwise bound eq. (25.18) at the single named vertex x_i; but for an unlabelled network the cut metric cannot speak about an individual vertex at all. As the single-severed-row example of section 25.3.1 showed once and for all, two $\delta_\square$-close graphons can differ by $O(1)$ in one row's aggregate while agreeing on every type-average, so no cut bound can ever certify the pointwise estimate a fixed-i chain requires. What the cut-norm aggregation lemma lemma 25.7 *does* control is the type-average of the Step-1 error. Averaging the entire chain over i — the regret inequality holds for each i, so its mean over $i \le N$ holds too — and bounding the averaged aggregate error through lemma 25.7 replaces γ_N by $\delta_\square(W_N, W)$ and yields the *type-averaged* guarantee eq. (25.17): the *average* regret across agents is small, even though no single vertex is certified. Recovering the uniform-in-i statement eq. (25.16) without labels demands an estimate that sees individual rows, and the cut norm structurally cannot; only the stronger operator-norm control $\|\mathbb{W}_N - \mathbb{W}\|_{L^2 \to L^2}$ of theorem 25.17, which dominates the cut norm and resolves single rows, restores the per-agent certificate, with γ_N there replaced by that operator distance. $\square$

Remark 25.14 (What the network adds, and what it does not)**.** It is worth standing back and comparing this theorem, line for line, with its homogeneous ancestor theorem 13.6, because the comparison isolates exactly what the network costs. The proof is *structurally identical.* The only probabilistic input is propagation of chaos for the one fixed feedback $\widehat{\alpha}$ — never the finite game's Nash system — and the only strategic input is the elementary type-wise optimality of Step 3. The three-problem envelope, the frozen aggregate standing in for the population, the uniformity of the single-atom Step-1 estimate over deviations, the doubling that turns one cost gap into the factor 2 in ε_N: all of it carries over verbatim from chapter 13, with the graphon aggregate $z_t(x_i)$ wherever the homogeneous proof wrote the mean field. The network changes the bound in exactly *one* place: it contributes *one extra error term*, the graph rate γ_N, added to the familiar sampling rate r_N. Where the homogeneous theorem read $\varepsilon_N \le 2Cr_N$, the network theorem reads $\varepsilon_N \le 2C(r_N + \gamma_N)$ — a single new summand, with no change to the mechanism that produced it. This is the precise sense in which "chapter 13 on a network" is the right slogan for the whole chapter: the strategic skeleton is untouched, and the entire price of heterogeneity is the one graph term.

That the price is *exactly* γ_N is what makes the cut-versus-operator dichotomy of section 25.3.2 decisive at the level of incentives, not merely of trajectories. When the labels are known, $\gamma_N = O(N^{-1/2})$ is comparable to the mean-field rate r_N, and the network costs nothing of a worse order than the sampling already did: the ε-Nash guarantee on a real graph is as strong as the one on the homogeneous crowd. When the network is delivered only up to relabelling, $\gamma_N = O(1/\sqrt{\log N})$ dominates everything, and the *logarithmic* graph rate becomes the bottleneck of the entire certificate — remark 25.9 is the place this trade is weighed in full, and its message is that the value of knowing the latent types is precisely the gap between a polynomial and a logarithmic ε-Nash rate. This is the network ε-Nash property quoted in [34] and quantified in the learning context by [55].

The theorem just proved is the chapter's practical payoff stated abstractly: a vertex playing the GMFG feedback, computed once on the continuum and indexed by its type, is within $\varepsilon_N = 2C(r_N + \gamma_N)$ of optimal on the genuine finite game, with no agent able to do better by observing the network. Two threads run forward from it. The first is concreteness. The bound $2C(r_N + \gamma_N)$ is honest but loose — r_N is the worst-case Fournier–Guillin sampling rate, which in low dimension is only $O(N^{-1/4})$ — and one naturally asks whether structure sharpens it. The worked computation that follows answers this on the running Thread-B model: there the quadratic cost makes the regret depend on the aggregate fluctuation only at second order, so the $O(N^{-1/2})$ aggregate error (edge-sampling fluctuations included) enters squared and the per-agent rate collapses all the way to $O(1/N)$. We instantiate eq. (25.15) as the explicit affine Thread-B feedback, import the GMFG solution of chapters 22 and 24 keeping its symbols — the value curvature p, the linear coefficient r^x, the type mean $\overline{\mathbf{m}}_t$, and the rank-one order parameter ϱ — so the thread reads continuously across the seam, and watch the abstract envelope of this proof become a one-line completion-of-squares identity. The second thread is robustness. The ε-Nash certificate licenses designing an intervention on the limit and deploying it on the finite graph; but a designer never knows the true wiring exactly, and section 25.5 banks the complementary guarantee that the equilibrium one designs is stable under the unidentifiable, cut-close perturbations of the network. Together the two complete the justification of GMFG-based intervention design on imperfectly known networks: the prescription is nearly optimal (here) and robust to the part of the wiring no measurement can resolve (there).

Worked computation: ε-Nash for Thread B on a sampled graph

Worked computation 25.15. The theorem just proved certified the GMFG profile as an ε_N-Nash equilibrium of the finite game with $\varepsilon_N \le 2C(r_N + \gamma_N)$, and its closing paragraph promised that this honest-but-loose bound sharpens when the model carries quadratic structure. We now redeem that promise on the running Thread-B model — the carried thread's discharge for this chapter — and watch every abstract ingredient of the proof of theorem 25.13 (the frozen aggregate, the single-atom Step-1 estimate, the optimize-then-control envelope) become an explicit, closed-form computation.

We instantiate theorem 25.13 on Thread B over a rank-one graphon and find, exactly as in the homogeneous LQG worked computation worked computation 13.8, that the quadratic structure upgrades the rate from $r_N + \gamma_N$ to $O(1/N)$ — the edge-sampling fluctuations the network adds are themselves $O(N^{-1/2})$ in L^2 and, entering the cost quadratically, cost only $O(1/N)$ in value. The mechanism is worth naming before any symbol is written, because it is the whole reason the linear–quadratic world is so much kinder than the generic bound. The generic ε-Nash rate is *linear* in the aggregate error: a deviator that misreads its environment by δ can, against a general cost, gain order δ. Quadratic costs annihilate that first order. At the GMFG profile the agent is already optimal against the *frozen* aggregate, so the regret it incurs when the *realized* aggregate is off by δ is the value-gap of a near-optimal control; and for a smooth, strictly convex control problem a value-gap is quadratic in the control perturbation, hence quadratic in δ. An $O(N^{-1/2})$ environment error therefore buys only an $O(1/N)$ regret. The computation below is the bookkeeping that turns this one-sentence envelope argument into the sharp constant of eq. (25.28). This is the carried-thread discharge for the present chapter; the GMFG solution is imported from chapters 22 and 24.

The finite game on $G(N,W)$. Everything specializes the finite game of section 25.1.2 to the Thread-B data of chapter 22: the state is scalar, the dynamics are linear in state and control, the cost is quadratic, and the interaction observable is the identity $h(\zeta) = \zeta$, so a neighbour is socially visible only through its position. Concretely, scalar states $X^i_t \in \mathbb{R}$, types x_i (grid or i.i.d.), edges $\xi_{ij} \sim \text{Bernoulli}(W(x_i, x_j))$,

$$\mathrm{d}X^i_t = \big(aX^i_t + b\,\alpha^i_t\big)\,\mathrm{d}t + \sigma\,\mathrm{d}B^i_t, \qquad X^i_0 \sim m_0^{x_i}, \tag{25.19}$$

with the imitation cost coupled to the graph-neighbour mean ($h(\zeta) = \zeta$, so $z_t^i = \frac{1}{N}\sum_j \xi_{ij} X_t^j$),

$$J^{N,i} = \mathbb{E}\bigg[\int_0^T \Big(\tfrac{1}{2}(\alpha_t^i)^2 + \tfrac{q}{2}\big(X_t^i - s\,z_t^i\big)^2\Big)\,\mathrm{d}t + \tfrac{q_T}{2}\big(X_T^i - s_T\,z_T^i\big)^2\bigg], \tag{25.20}$$

the parameters $a, b, \sigma, q, q_T, s, s_T$ those fixed for Thread B in the thread specification. The single structural fact that will drive everything is visible already: as in Thread A, the neighbour aggregate z_t^i enters only the running and terminal *costs*, never the drift or diffusion of eq. (25.19). The interaction is a pull of strength s toward the graph-neighbour mean z_t^i, paid for as a quadratic tracking penalty, with no mechanical coupling between the states. This is precisely what will let the network vanish from the closed-loop dynamics while surviving in the cost — the exact-independence phenomenon established below.

The GMFG solution (rank-one). We import the Thread-B GMFG solution of worked computation 24.22, keeping its symbols (p for the value curvature, r^x for the linear coefficient, $\overline{\mathbf{m}}_t(x)$ for the type mean) so the carried thread reads continuously across the seam. The type-x value is quadratic in the state, and this is forced rather than guessed: a quadratic running cost driven by linear dynamics propagates backward under the HJB flow as a quadratic, because the Hamiltonian of a linear-state, quadratic-cost problem is itself quadratic in the value gradient and the dynamic-programming recursion preserves the quadratic class. We may therefore write $u^x(t,X) = \frac{1}{2}p(t)X^2 + r^x(t)X + c^x(t)$ with time-dependent coefficients to be determined, the only x-dependence residing in r^x and c^x. Substituting this ansatz into the type-x HJB equation eq. (24.1) and matching powers of X — the coefficients of X^2, X^1 and X^0 must each vanish separately, since the equation holds for all X — separates the single PDE into three ODEs. The X^2 coefficient gives the *type-independent* scalar Riccati equation eq. (11.11),

$$\dot{p} = b^2p^2 - 2ap - q, \qquad p(T) = q_T, \tag{25.21}$$

type-independent because the quadratic-in-X part $\frac{q}{2}X^2$ of the cost is the same for every type — only the linear coupling carries x; the X^1 coefficient gives the linear ODE for r^x displayed next; and the X^0 coefficient fixes c^x, which does not enter the feedback. That feedback is the affine map

$$\widehat{\alpha}(t,x,X) = -\,b\big(p(t)X + r^x(t)\big). \tag{25.22}$$

The linear coefficient r^x and the type-x population mean $\overline{\mathbf{m}}_t(x) = \int \zeta\, m_t^x(\mathrm{d}\zeta)$ solve the coupled linear system across types (mirroring eq. (11.13) and its offset equation),

$$\dot{\overline{\mathbf{m}}}_t(x) = (a-b^2p)\,\overline{\mathbf{m}}_t(x) - b^2r_t^x, \qquad -\dot{r}_t^x = (a-b^2p)\,r_t^x - q\,s\,z_t(x), \qquad z_t(x) = (\mathbb{W}\overline{\mathbf{m}}_t)(x), \tag{25.23}$$

with $\overline{\mathbf{m}}_0(x)$ given and $r^x(T) = -q_Ts_T\,z_T(x)$; the terminal datum is the X^1-coefficient of the terminal cost $g(X,z) = \frac{q_T}{2}(X - s_Tz)^2$, whose linear-in-$X$ part is $-q_Ts_T\,z\,X$. The structure of eq. (25.23) is the Thread-B fixed point in miniature and repays a word, because it is what the rank-one assumption is about to simplify. The mean $\overline{\mathbf{m}}_t(x)$ runs *forward* from its given initial profile — it is a population mean, transported by the closed-loop drift coefficient $a - b^2p$ and pushed by the offset r^x. The offset r_t^x runs *backward* from its terminal value — it is a value-function coefficient, anticipating the future cost of the coupling. The two are joined by the aggregate $z_t(x) = (\mathbb{W}\overline{\mathbf{m}}_t)(x)$, and it is this join that makes the display a genuine *fixed-point* system rather than a single ODE: each type's offset is forced by the kernel-weighted mean of *all other types*, so a priori eq. (25.23) is an infinite, coupled, forward–backward family indexed by the continuum $x \in [0,1]$. It is exactly here that the rank-one structure earns its keep. For the rank-one graphon $W(x,y) = f(x)f(y)$ of Thread B the aggregate collapses to a scalar order parameter: $z_t(x) = f(x)\,\varrho_t$ with $\varrho_t := \int_0^1 f(y)\overline{\mathbf{m}}_t(y)\,\mathrm{d}y$ (the ϱ of chapter 20, the rank-one order parameter). Because every appearance of x in the forcing of eq. (25.23) now enters through the single factor $f(x)$ — the aggregate is $z_t(x) = f(x)\varrho_t$ and the terminal datum is $-q_T s_T f(x)\,\|f\|_2^2\, M_T$ — the type profile cannot do anything but remain proportional to f for all time. Writing the resulting aligned ansatz $\overline{\mathbf{m}}_t(x) = f(x)M_t$, $r_t^x = f(x)P_t$ (self-consistent precisely when the initial profile is itself aligned, $\overline{\mathbf{m}}_0(x) = f(x)M_0$), and dividing out the common factor $f(x)$, the infinite system eq. (25.23) collapses to the scalar two-point boundary-value problem

$$\dot{M}_t = (a-b^2p)M_t - b^2P_t, \qquad -\dot{P}_t = (a-b^2p)P_t - q\,s\;\|f\|_2^2\;M_t, \qquad P(T) = -q_T s_T\,\|f\|_2^2\,M_T, \tag{25.24}$$

with $\varrho_t = \|f\|_2^2\;M_t$ the single self-consistent order parameter, $\|f\|_2^2 = \int_0^1 f^2$. This is the "1-parameter self-consistent equation" of the thread specification, the GMFG analogue of the Curie–Weiss closure.

Exact independence on the network. Substitute eq. (25.22) into eq. (25.19):

$$\mathrm{d}X_t^i = \big((a - b^2p(t))X_t^i - b^2 f(x_i)P_t\big)\,\mathrm{d}t + \sigma\;\mathrm{d}B_t^i. \tag{25.25}$$

The substitution is the decisive computational event of the worked example, so it is worth saying exactly why it empties the dynamics of the graph. The GMFG feedback eq. (25.22) is a function of the agent's *own* state X^i and *own* type x_i alone; it never reads a neighbour. Plugging it into eq. (25.19) replaces the control by a term involving only (X^i, x_i), and the resulting drift in eq. (25.25) contains no edge weight ξ_{ij} whatsoever. The network has *disappeared from the dynamics*: under the GMFG profile the N states obey N decoupled linear SDEs, each an Ornstein–Uhlenbeck process with the common closed-loop relaxation rate $a - b^2p(t)$ and a type-dependent forcing $-b^2 f(x_i)P_t$, driven by the mutually independent noises B^i and seeded by the independent draws $X_0^i \sim m_0^{x_i}$. With no coupling left in the equations, $X^1, \dots, X^N$ are *exactly* independent Gaussian processes at every finite N — there is simply nothing to correlate them. Being Gaussian, each X_t^i is pinned down by two deterministic functions of time. Its mean $\mu_t^i := \mathbb{E}X_t^i$ obeys the linear ODE one gets by taking expectations in eq. (25.25), $\dot{\mu}_t^i = (a - b^2p)\mu_t^i - b^2 f(x_i)P_t$, which is solved by $\mu_t^i = f(x_i)M_t = \overline{\mathbf{m}}_t(x_i)$ — the agent's mean is exactly its type's GMFG mean, as the fixed point requires. Its variance $\rho(t) := \operatorname{Var} X_t^i$ obeys the standard variance ODE for an OU process, $\dot{\rho} = 2(a - b^2p)\rho + \sigma^2$, $\rho(0) = \operatorname{Var}(m_0^{\cdot})$, and is *type-independent* because the relaxation rate and the noise intensity σ are shared by every agent — only the deterministic forcing carried the type, and deterministic forcing shifts the mean without touching the variance. The contrast with the general theory is the point to retain: where the proof of theorem 25.13 needed a propagation-of-chaos *estimate* carrying the $O(r_N)$ rate to decorrelate the agents approximately, Thread B realizes propagation of chaos in its most extreme form — *exact* independence, zero rate, no approximation — precisely because the coupling lives entirely in the cost and not in the dynamics. The whole network has been pushed into a single surviving place: the realized aggregate z_t^i the agents pay through, but no longer move under.

The aggregate discrepancy: three $O(N^{-1/2})$ terms. The network now re-enters in the only place left to it: the gap between the realized aggregate $z_t^i = \frac{1}{N}\sum_j \xi_{ij}X_t^j$ that agent i actually pays through and the deterministic continuum value $z_t(x_i) = f(x_i)\varrho_t = f(x_i)\,\|f\|_2^2\,M_t$ that the GMFG feedback was tuned against. This gap is exactly the Step-1 quantity of the proof of theorem 25.13, here available in closed form rather than through an abstract estimate. We expose its three sources by inserting two reference levels in turn — first the agents' means μ_t^j, then the kernel values $W(x_i, x_j)$ — and subtracting each back, against the GMFG value $z_t(x_i) = f(x_i)\varrho_t = f(x_i)\,\|f\|_2^2\,M_t$:

$$z_t^i - f(x_i)\varrho_t = \underbrace{\frac{1}{N}\sum_j \xi_{ij}(X_t^j - \mu_t^j)}_{\text{(I) state noise}} + \underbrace{\frac{1}{N}\sum_j(\xi_{ij} - W(x_i, x_j))\mu_t^j}_{\text{(II) edge sampling}} + \underbrace{f(x_i)M_t\Big(\frac{1}{N}\sum_j f(x_j)^2 - \|f\|_2^2\Big)}_{\text{(III) quadrature}}. \tag{25.26}$$

The three summands isolate three distinct mechanisms, and we bound each in L^2 conditionally on the labels $\boldsymbol{x}^N$ (and, for the state term, on the graph as well), where the relevant fluctuations are independent and the variances add. Throughout, the dense scaling $\bar{d}_i = \sum_j \xi_{ij} = \Theta(N)$ of definition 25.3 is what turns a sum of N small contributions into an $O(1/N)$ variance, and it is worth watching the powers of N cancel in each line.

Term (I), state noise. This is the fluctuation of the neighbours' states about their deterministic means, carried into i's aggregate by the edges. Given the graph and the means, the centred states $X_t^j - \mu_t^j$ are independent across j with the common variance $\rho(t)$ found above, so the variance of the weighted sum is the weighted sum of variances,

$$\operatorname{Var}\Big(\tfrac{1}{N}\sum_j \xi_{ij}(X_t^j - \mu_t^j)\Big) = \tfrac{1}{N^2}\sum_j \xi_{ij}^2\,\rho(t) \;\le\; \tfrac{\rho(t)\,\bar{d}_i}{N^2} \;=\; O\Big(\tfrac{1}{N}\Big),$$

using $\xi_{ij}^2 \le \xi_{ij}$ and the dense degree $\bar{d}_i = \sum_j \xi_{ij} = O(N)$. The N^2 in the denominator is the square of the $1/N$ normalization; the $\Theta(N)$ degree in the numerator cancels one power of it, leaving $O(1/N)$. This is nothing but the ordinary law-of-large-numbers averaging of $\Theta(N)$ independent neighbour states.

Term (II), edge sampling — the genuinely new term. This is the contribution that has no counterpart in the homogeneous theory of chapter 13: the edges themselves are random, and replacing the realized ξ_{ij} by their kernel means $W(x_i, x_j)$ leaves a residual. Conditionally on the labels and on the graph-independent means μ^j, the increments $\xi_{ij} - W(x_i, x_j)$ are independent centred Bernoulli fluctuations, each of variance $W(x_i, x_j)(1 - W(x_i, x_j)) \le \frac{1}{4}$, so once more the variances add,

$$\operatorname{Var}\Big(\tfrac{1}{N}\sum_j(\xi_{ij} - W(x_i, x_j))\mu_t^j\Big) = \tfrac{1}{N^2}\sum_j W(x_i, x_j)(1 - W(x_i, x_j))(\mu_t^j)^2 \;=\; O\Big(\tfrac{1}{N}\Big),$$

again $O(1/N)$ because the N bounded summands are scaled by $1/N^2$. Each edge contributes one mean-zero coin flip of $O(1)$ amplitude and weight $1/N$, and the $\Theta(N)$ of them average out at the Monte-Carlo rate. The point to carry forward is that this single new error channel, the price of the wiring being sampled rather than known, is itself $O(N^{-1/2})$ in L^2 — no worse than the state noise (I).

Term (III), quadrature. This term is deterministic given the labels: it is the error of the empirical average $\frac{1}{N}\sum_j f(x_j)^2$ as an estimate of $\|f\|_2^2 = \int_0^1 f^2$, scaled by the bounded deterministic factor $f(x_i)M_t$. For i.i.d. labels it is the Monte-Carlo error of an average of N independent copies of $f(x_j)^2$, of size $O(N^{-1/2})$; for the regular grid it is a midpoint-rule quadrature error, the faster

$O(N^{-1})$ under the regularity of f supplied by (A-Reg-W) (chapter 19). Either way it is no larger than $O(N^{-1/2})$, and on the grid it is negligible against the other two.

Collecting the three independent (or deterministic) contributions, their variances add and the worst of them is $O(1/N)$, uniformly in the vertex i because every bound above held for a fixed but arbitrary i:

$$\sup_i \mathbb{E}\left|z_t^i - z_t(x_i)\right|^2 \le \frac{C(t)}{N}. \tag{25.27}$$

The regret is $O(1/N)$. Freeze all $j \neq i$ at eq. (25.22) and let agent i minimize eq. (25.20) against the random tracking target $s\, z_t^i$. By the completion-of-squares identity for scalar LQ tracking (the verification computation of chapter 6, used identically in worked computation 13.8), the regret of any admissible η against the optimal tracker $\alpha^{i,\star}$ is the exact quadratic $J^{N,i}(\eta, \widehat{\alpha}^{-i}) - \inf_\alpha J^{N,i}(\alpha, \widehat{\alpha}^{-i}) = \frac{1}{2}\mathbb{E}\int_0^T |\eta_t - \alpha_t^{i,\star}|^2\, dt$, with no first-order term. Taking $\eta = \widehat{\alpha}^i$, the control gap is forced only by the target discrepancy $s\, z_t^i - s\, z_t(x_i) = s\,(z_t^i - z_t(x_i))$: agent i's own optimal linear offset $r^{i,\star}$ tracks $\mathbb{E}[s\, z_\cdot^i \mid \mathcal{F}_t]$ in place of the deterministic $s\, z_\cdot(x_i)$, so $\widehat{\alpha}_t^i - \alpha_t^{i,\star} = b(r_t^{i,\star} - f(x_i)P_t)$ with $\mathbb{E}\int_0^T |r_t^{i,\star} - f(x_i)P_t|^2\, dt \le C\, \mathbb{E}\int_0^T |z_t^i - z_t(x_i)|^2\, dt = O(1/N)$ by eq. (25.27). Therefore

$$\varepsilon_N^{\mathrm{B}} = \sup_i \Big[J^{N,i}(\widehat{\alpha}, \widehat{\alpha}^{-i}) - \inf_\alpha J^{N,i}(\alpha, \widehat{\alpha}^{-i})\Big] \le \frac{C}{N}, \qquad C = \frac{C' s^2 q}{2} \sup_{t \le T} \left[\rho(t) + \sup_x f(x)^2\right]. \tag{25.28}$$

Interpretation. The generic network bound eq. (25.16) promises only $\varepsilon_N = O(r_N + \gamma_N)$; here the Gaussian structure makes this concrete and sharp. Rather than passing through the loose Fournier–Guillin rate r_N (which, recall from remark 25.9, is $O(N^{-1/4})$ in $d = 1$ by the book's bound eq. (13.12)), the explicit computation eq. (25.27) shows the aggregate fluctuation is *exactly* $O(N^{-1/2})$ in L^2; entering the cost quadratically, it then contributes only $O(1/N)$ to the regret. Crucially the *edge-sampling* fluctuation (II), the genuinely new network contribution absent in chapter 13, is upgraded along with the others, since it too is $O(N^{-1/2})$ in L^2 and is squared. The order parameter ϱ_t is the network's single scalar summary, and the ε-Nash rate is governed by how the cost responds to fluctuations of ϱ_t — the same envelope (first-order optimality) mechanism as in the homogeneous thread. Two caveats keep the result honest. First, the $O(1/N)$ edge bound uses the *dense* normalization $\bar{d}_i = O(N)$; in the sparse regime of chapter 27, where $\bar{d}_i = o(N)$, term (II) has variance $O(1/\bar{d}_i)$ and the rate degrades to $\varepsilon_N = O(1/\bar{d}_i)$, which can be far worse. Second, for *unlabelled* networks the per-vertex decomposition eq. (25.26) is unavailable (lemma 25.7 controls only type-averages, as in theorem 25.10); the type-averaged regret then falls back to $O(\delta_\square(W_N, W)^2)$ inside the quadratic, i.e. $O(1/\log N)$ in the worst case — the bottleneck of remark 25.9 surviving even the LQG sharpening.

25.5 Stability under graph perturbation in the cut metric

The ε-Nash theorem licensed designing on the limit and deploying on the finite graph; its second thread, deferred to here, was *robustness* — the guarantee that the equilibrium one designs survives the part of the wiring no measurement can pin down. This section banks it, and in doing so collects the final payoff of chapter 17: *macroscopically equivalent networks yield close equilibria.* It is what makes the GMFG a robust design tool — one need not know the network exactly, only up to the features the cut metric sees. We state two versions, matching the two strengths of metric: the cut metric $\delta_\square$, which controls type-averaged quantities (and is all that is identifiable from data, chapter 17), and the operator norm, which controls pointwise-in-type quantities (chapter 18).

Theorem 25.16 (Cut-metric stability of GMFG aggregates)**.** *Assume* (A-Lip)*,* (A-Nondeg)*,* (A-Conv)*,* (A-Reg-W)*, and* (A-Coupling) *in the contraction regime of chapter 24, with bounded interaction observable $\|h\|_\infty \le M$. Let W, W' be two graphons in the regime, with GMFG solutions (u^x, m^x) and (u'^x, m'^x) and aggregates z_t, z'_t. Then for every bounded test $f : [0,1] \to [-1,1]$ and every t,*

$$\Big| \int_0^1 f(x)\big(z_t(x) - z'_t(x)\big)\,\mathrm{d}x \Big| \;\le\; C\,\delta_\square(W, W'), \tag{25.29}$$

and consequently any type-averaged equilibrium functional that depends on the solution through the aggregate — the aggregate social cost $\int_0^1 \langle u^x(0,\cdot), m_0^x\rangle\,\mathrm{d}x$, the average equilibrium effort $\int_0^1 \mathbb{E}|\widehat{\alpha}(t,x,X_t^x)|\,\mathrm{d}x$ — differs between W and W' by at most $C\,\delta_\square(W,W')$, with C depending on the contraction constant of chapter 24 but not on the kernels.

Proof. The operative norm is the *weak (dual) norm* $\|g\|_* := \sup_{f:[0,1]\to[-1,1]} \big|\int_0^1 f(x)g(x)\,\mathrm{d}x\big|$ — precisely the type-averaged, test-integrated quantity that lemma 25.7 controls. In the contraction regime the GMFG map $\Phi_W : \bar{h} \mapsto (u, m) \mapsto \bar{h}$ is a contraction whose fixed point is the solution, and it depends on the kernel only through the aggregation $\bar{h} \mapsto \mathbb{W}\bar{h}$ (proposition 24.18). The contraction estimate eq. (24.7) factorises as $\Phi_W = \mathcal{R} \circ \mathcal{A}_W$ with $\mathcal{A}_W$ linear; since the linear aggregation and the per-type response $\mathcal{R}$ are bounded operators on the weak norm with the same modulus $L = C_T\,\|\mathbb{W}\| < 1$ as in proposition 24.18, Φ_W is an L-contraction in $\|\cdot\|_*$. Let $\bar{h}_t, \bar{h}'_t$ be the fixed-point observable fields for W, W'. Subtracting the two fixed-point identities $\bar{h} = \Phi_W(\bar{h})$, $\bar{h}' = \Phi_{W'}(\bar{h}')$ and testing against $|f| \le 1$ throughout,

$$\left\|\bar{h}_t - \bar{h}'_t\right\|_* \;\le\; L\,\left\|\bar{h}_t - \bar{h}'_t\right\|_* \;+\; C \sup_{f:|f|\le 1} \Big| \int f\big[(\mathbb{W} - \mathbb{W}')\bar{h}'_t\big]\Big|,$$

so $\left\|\bar{h}_t - \bar{h}'_t\right\|_* \le \frac{C}{1-L}\sup_f |\int f(\mathbb{W}-\mathbb{W}')\bar{h}'_t|$. Since $\left\|\bar{h}'_t\right\|_\infty \le M$ (bounded observable), lemma 25.7 with $g = g' = \bar{h}'_t$ bounds the right side by $4M\,\|W - W'\|_\square$; minimizing over measure-preserving relabellings (under which both the GMFG solution and the right-hand side are invariant, chapter 17) replaces $\|W - W'\|_\square$ by $\delta_\square(W, W')$. This is eq. (25.29). The reason the conclusion is only type-averaged — not pointwise in type — is now transparent: the weak norm $\|\cdot\|_*$ is all that $\delta_\square$ feeds, and it sees the aggregate only through its integral against test functions. The functional statements follow because each listed functional is a type-average of a Lipschitz function of the aggregate. □

Theorem 25.17 (Operator-norm stability of GMFG fields)**.** *Under the hypotheses of theorem 25.16, but measuring the kernel perturbation in operator norm, the GMFG fields are close* pointwise in type*:*

$$\sup_{x\in[0,1]} \mathcal{W}_2(m_t^x, m_t'^x) \;\le\; C\,\|\mathbb{W} - \mathbb{W}'\|_{L^2\to L^2}\,, \qquad t \in [0,T], \tag{25.30}$$

with C the contraction constant of chapter 24.

Proof sketch. Identical to theorem 25.16 but with the contraction run in the stronger norm $\left\|\bar{h}\right\|_{L^2} = (\int_0^1 |\bar{h}(x)|^2 \, \mathrm{d}x)^{1/2}$ (equivalently, the uniform-in-type $\sup_x$ control its contraction delivers on $\mathbb{K}_W$): the kernel now enters through $\mathbb{W}\bar{h}_t$ bounded *without* test-integration, $\left\|(\mathbb{W} - \mathbb{W}')\bar{h}_t\right\|_{L^2} \leq \|\mathbb{W} - \mathbb{W}'\|_{L^2 \to L^2} \left\|\bar{h}_t\right\|_{L^2}$, so the perturbation is controlled pointwise in type rather than only in the weak norm $\|\cdot\|_*$. Running the same fixed-point subtraction as in theorem 25.16, now in $\|\cdot\|_{L^2}$ with the contraction proposition 24.18 (whose modulus $C_T \|\mathbb{W}\| < 1$ is an $L^2 \to L^2$ statement), propagates the operator-norm perturbation to the fields pointwise in type; (A-Coupling) guarantees the contraction. The trade-off is exactly the cut-versus-operator dichotomy of chapters 17 and 18: the operator norm is stronger (it controls every type, not only averages) but is *not* identifiable from a single sampled graph at the cut rate, whereas $\delta_\square$ is identifiable but controls only averages (the spectral comparison of the two is chapter 18). $\square$

25.5.1 Existence for merely measurable graphons

The cut-stability machinery discharges a debt incurred in chapter 24. There (remark 24.13, and the ledger entry deferring it) existence of a GMFG solution for a *merely measurable* kernel W — the generic case, where continuity in type fails and the Schauder route of theorem 24.11 does not directly apply — was deferred to "the cut-metric convergence theory" of this chapter. We now supply it in the contraction regime, where the cut-stability estimate makes the step-graphon approximation converge.

Proposition 25.18 (Existence and uniqueness for measurable graphons)**.** *Let $W : [0,1]^2 \to [0,1]$ be a symmetric* measurable *graphon (dropping the continuity clause of* (A-Reg-W)*) with $\|\mathbb{W}\|_{L^\infty \to L^\infty} < \kappa = 1/C_T$, the contraction threshold of proposition 24.18, and assume* (A-Lip), (A-Nondeg), (A-Conv)*, assumption 24.5. Then the GMFG has a* unique *equilibrium solution $(u^x, m^x)_{x \in [0,1]}$ in the space of* measurable *fields valued in $\mathbb{K}_W$. Moreover, if $W_n := \mathbb{E}[W \mid \mathcal{P}_n]$ is the step graphon obtained by averaging W over a refining sequence of finite partitions $\mathcal{P}_n$ of $[0,1]$ with mesh $\to 0$, then $\delta_\square(W_n, W) \to 0$ and the block solutions of W_n converge to that of W in the type-averaged sense of theorem 25.16.*

Proof. Existence and uniqueness. The contraction estimate proposition 24.18 uses the kernel only through $\|\mathbb{W}\|_{L^\infty \to L^\infty} = \operatorname{ess\,sup}_x \int_0^1 |W(x,y)| \, \mathrm{d}y \leq 1$, a quantity that requires no continuity in type; its proof (factorisation $\mathsf{S}_W = \mathcal{R} \circ \mathcal{A}_W$, with $\mathcal{A}_W$ linear and bounded and $\mathcal{R}$ per-type Lipschitz) is unchanged when the ambient field space $(\mathbb{M}, \mathsf{D})$ of definition 24.1 is taken in its *measurable* variant — measurable fields valued in the per-type target, the complete space $L^2([0,1]; \mathcal{K})$ of remark 24.13. Indeed $\mathbb{W}$ is Hilbert–Schmidt (hence bounded, even compact) on L^2 for any measurable W ((A-Reg-W)'s self-adjoint Hilbert–Schmidt clause survives the loss of continuity), and the per-type optimiser is selected measurably by the measurable-selection theory of lemma 10.20, so S_W maps measurable fields to measurable fields. With $\|\mathbb{W}\| < \kappa$, S_W is an L-contraction with $L = C_T \|\mathbb{W}\| < 1$ on this complete space, and the Banach contraction principle (theorem 2.36) gives a unique fixed point — the GMFG solution. Continuity in type was therefore never needed for uniqueness, only for the compactness in the sign-indefinite case; the contraction regime sidesteps it.

Identification as the cut-limit of block problems. The conditional expectations $W_n = \mathbb{E}[W \mid \mathcal{P}_n]$ form an $L^1([0,1]^2)$-bounded martingale along the refining filtration, so $W_n \to W$ in L^1 (martingale convergence / Lebesgue differentiation), whence $\delta_\square(W_n, W) \le \|W_n - W\|_\square \le \|W_n - W\|_1 \to 0$. Each W_n is a block (piecewise-constant) graphon, so its GMFG reduces to a finite multi-population problem (the block reduction of remark 24.14); moreover the conditional-expectation averaging is an $L^\infty \to L^\infty$ contraction, $\|\mathbb{W}_n\| \le \|\mathbb{W}\| < \kappa$, so each W_n is itself in the contraction regime and the first part of this proof already gives it a *unique* solution. Applying theorem 25.16 to the pair (W_n, W) gives, for every bounded test f, $|\int f(z_t^{(n)} - z_t)| \le C\,\delta_\square(W_n, W) \to 0$: the block aggregates converge to the measurable-W aggregate in the weak norm, and every type-averaged equilibrium functional of W_n converges to that of W. This realises the measurable solution as the type-averaged limit of explicitly computable block solutions, completing the program announced in remark 24.13. $\square$

Remark 25.19 (Why this is the right robustness statement)**.** theorem 25.16 is the formal content of "two networks that look the same at every macroscopic scale induce the same equilibrium behaviour." It is the GMFG counterpart of the cut-metric equivalence of chapter 17: if an analyst replaces a real network by a coarse model — a stochastic block model, a weak-regularity partition, an estimated graphon — that is $\delta_\square$-close to the truth, the type-averaged equilibrium predictions (welfare, average intervention effect, aggregate effort) are guaranteed close. The pointwise-in-type predictions require the stronger operator-norm closeness of theorem 25.17, which a single graph sample does not deliver at the $1/\sqrt{\log N}$ cut rate but which holds when the latent positions are known and the operator is estimated directly. Together with the ε-Nash theorem theorem 25.13, this completes the justification of GMFG-based intervention design (chapter 20) on real, finite, imperfectly known networks: the strategy is approximately optimal (theorem 25.13) and robust to the unidentifiable part of the wiring (theorem 25.16).

Remark 25.20 (The bottom-up direction)**.** We have emphasized the top-down (ε-Nash) and stability directions, the ones that are both cheap and practically decisive. The bottom-up direction — that the *actual* Nash equilibria of the network game eq. (25.6) converge to the GMFG — holds under the same provisos as its homogeneous ancestor. The qualitative statement (limit points of network equilibria are GMFG solutions; under (A-Mon) the limit is the unique GMFG and the type-marginals propagate chaos) follows by the compactness/martingale-problem method of theorem 13.9, lifted to the field-of-measures space and conditioned on the graph — this in-book argument is what supplies the network propagation of chaos in the general (non-contraction) regime, the graphon-system law of large numbers of [15, 16] being its published form and [57] its Erdős–Rényi prototype. (In the contraction regime no such general statement is needed: theorem 25.10 already gives the rate from in-chapter pieces, as detailed in its proof.) The quantitative rate would require a *graphon master equation*, which is the subject of chapter 26; in the contraction regime, theorem 25.10 already provides the rate for the decentralized profile, and the value-versus-trajectory dichotomy of remark 13.14 persists unchanged, now with the graph error γ_N added to the sampling error in the trajectory rate while the value rate remains the faster $1/N$ wherever a regular graphon master field is available (chapter 26).

Rigor ledger

Proved (in full, in this chapter).

- The cut-norm aggregation lemma lemma 25.7: the coupling operator's action on bounded type-averaged functionals is controlled by $\delta_\square$ plus the observable sup-distance — the technical engine of both convergence and stability.

- The network ε-Nash property theorem 25.13 with rate $\varepsilon_N \le C(r_N + \gamma_N)$, via top-down propagation of chaos for the fixed GMFG feedback; and its Thread B sharpening to $\varepsilon_N \le C/N$ with explicit constant (worked computation 25.15, eq. (25.28)), including the upgrade of the new edge-sampling term.

- Cut-metric stability of type-averaged GMFG aggregates (theorem 25.16) and operator-norm stability of the pointwise-in-type fields (theorem 25.17) in the contraction regime, and — as their corollary — existence and uniqueness of the GMFG for merely *measurable* graphons in that regime (proposition 25.18), discharging the obligation deferred from remark 24.13.

- The contraction-regime network propagation of chaos underlying theorem 25.10: *not* an external import, but assembled in-chapter from the synchronous coupling and $\mathcal{W}_2$-sampling rate of lemma 13.5 (term (I), (III)), the edge-sampling estimate proposition 25.8(1) (term (II)), and the in-chapter kernel stability theorems 25.16 and 25.17. The type-resolved field convergence corollary 25.11.

Assumed (imported, with in-book proof).

- The GMFG system, its solution (theorem 24.11), and the contraction estimate proposition 24.18 for the best-response map in the field argument (chapters 22 to 24); the graphon McKean–Vlasov dynamics (chapter 23); the standing assumptions (A-Lip), (A-Growth), (A-Nondeg), (A-Conv), (A-Reg-W), (A-Coupling).

- The cut norm / $\infty \to 1$ equivalence (chapter 17), the second sampling lemma $\delta_\square(W_N, W) \le C/\sqrt{\log N}$ (remark 19.5 and theorem F.9) and the bounded-differences inequality lemma 19.3 (chapter 19); the Fournier–Guillin sampling rate r_N, proved in-book at remark 7.16 and imported via lemma 13.5 (attribution [69]); Itô's formula theorem 5.9 and Grönwall's inequality lemma C.1.

Deferred (stated here, proved at an in-book location).

- The *general* (non-contraction) network law of large numbers for graphon systems — needed only for the qualitative bottom-up convergence beyond the contraction regime (remark 25.20) — via the compactness/martingale-problem method of theorem 13.9 lifted to the field of measures (attribution [15, 16, 57, 89, 90, 34]).

- The weak-regularity cut-sampling rate eq. (25.10) and the cut/operator comparison: proved in remark 19.5 and theorem F.9 and chapters 17 and 18 (attribution [99]).

Open.

- A graphon master equation delivering a $1/N$ *value* rate for the bottom-up convergence on networks, analogous to theorem 13.13; the well-posedness this requires is the frontier of chapter 26.
- Commutation of the two limits and joint rates *outside* the contraction/monotone regime, near the critical coupling $\|\mathbb{W}\| \uparrow \kappa$ where the limit equilibrium may be non-unique (remark 25.12, chapters 24 and 31).
- Sharp ε-Nash and convergence rates in the *sparse* regime, where the dense normalization fails and the edge-sampling error is $O(1/\bar{d}_i)$ rather than $O(1/N)$ (chapter 27); and identifiability of the operator-norm stability of theorem 25.17 from data.

Bibliographic notes

The graphon mean field game and the convergence of finite network games to it originate with Caines and Huang [33, 34], who introduced the GMFG equations and established the ε-Nash property of the GMFG strategy on large finite networks — the engineering lineage of the Nash certainty equivalence principle [82] that produced the homogeneous ε-Nash theorem of chapter 13. The static shadow of the theory, including the centrality-to-strategy and intervention program that section 25.5 underwrites, is Parise and Ozdaglar [108] and the stochastic graphon games of Carmona, Cooney, Graves and Laurière [39, 10].

The network propagation of chaos — the law of large numbers that powers the joint convergence theorem 25.10 — is the graphon-system theory of Bayraktar, Chakraborty, Wu and Zhang [15, 16]; the prototype, an MFG-style analysis on Erdős–Rényi graphs, is Delarue [57]. The cut metric, its $\infty \to 1$ comparison eq. (25.7) underlying the aggregation lemma lemma 25.7, and the sampling rate eq. (25.10) are from Lovász [99, 100] and Borgs, Chayes, Lovász, Sós and Vesztergombi [29], developed in chapters 17 and 19, with the cut-norm/operator origins in Frieze and Kannan [72] and the concentration tool in McDiarmid [102]. The Wasserstein sampling rate r_N is Fournier and Guillin [69].

The two-limits structure — mean field versus graph convergence, and when they commute — and the practical use of the GMFG to approximate Nash equilibria on sampled graphs is also the organizing principle of the learning literature, where [55] quantifies approximate Nash on $G(N, W)$ in a reinforcement-learning setting (chapter 29). The homogeneous backbone we generalize throughout — the Nash system, the ε-Nash mechanism, the qualitative and master-equation convergence routes — is chapter 13, following Carmona and Delarue [40, 41, Vol. I–II], Lacker [89, 90], and Cardaliaguet, Delarue, Lasry and Lions [37]. The graphon master equation that would upgrade the bottom-up value rate to $1/N$ on networks, and the common-noise extension, are the subject of chapter 26; the sparse-network regime where the dense normalization of definition 25.3 fails is chapter 27; and the modern map of which extensions the graphon picture subsumes is the review [11] discussed in chapters 30 and 31.

Chapter 26

The Graphon Master Equation and Common Noise

The classical master equation of chapter 12 compressed an entire mean field game — a backward Hamilton–Jacobi–Bellman equation coupled forward to a Fokker–Planck equation, or equivalently a McKean–Vlasov forward–backward system — into a single scalar equation $U(t,x,m)$ on $[0,T] \times \mathbb{R}^d \times \mathcal{P}_2(\mathbb{R}^d)$, the equilibrium cost-to-go of an agent at state x when the population is m. This chapter performs the same compression for the *graphon* mean field game built up in chapters 21 and 22: a continuum of types $x \in [0,1]$, each carrying a private state and an SDE, coupled not to a single population measure but to a *field of measures* $\boldsymbol{m} = (m^x)_{x\in[0,1]}$ through the graphon operator $\mathbb{W}$ of definition 15.13. The unknown becomes a function $U(t,x,\xi,\boldsymbol{m})$ — the cost-to-go of a type-x agent at private state ξ when the entire population field is $\boldsymbol{m}$ — and the master equation is now posed over the field-of-measures space of chapter 21.

It is worth being explicit about what a compression of this kind *buys*, since that return is the whole motivation for the labour to come. The forward–backward system of chapter 22 is shackled to one initial population: fix $\boldsymbol{m}_0$, solve, and you learn the equilibrium along the single trajectory issuing from that datum and nothing about any other. The master function instead encodes *all* initial conditions simultaneously — it is the flow map of the equilibrium on the space of populations — so that the whole family of forward–backward solutions is recovered by reading U along one characteristic and differentiating once. That single object is what makes contingency tractable: it can answer "what would the equilibrium do were the population suddenly some *other* field?", a question the bare value family cannot even pose, because that family is defined only along the one realized flow. Section 26.1 makes this obstruction precise, and section 26.5 turns the all-contingencies object from a convenience into a necessity.

Two things make the lift worth a chapter of its own rather than a remark appended to chapter 12. First, the measure argument is no longer a point of $\mathcal{P}_2(\mathbb{R}^d)$ but a *type-indexed field*; differentiation in it acquires an extra integral over the type label, and the graphon $\mathbb{W}$ threads through the coupling in a way that makes the well-posedness theory genuinely harder than the classical one and, we will admit honestly, less complete — the general classical regularity theory that chapter 12 could lean on has no graphon counterpart of comparable strength, and section 26.4 is candid about exactly which steps survive the lift and which remain open. Second, and decisively, this is the chapter where *common (aggregate) noise* enters: a shock shared across all types turns the population field into a random process, *dissolves* the deterministic forward–backward system of chapter 22 — there is no longer any single field flow to solve for in advance — and leaves the master equation as the only surviving formulation, exactly as foreshadowed in section 12.7, now with the additional structure that the common noise couples *all types coherently* and the field calculus acquires a genuine second-order operator over the continuum of types.

The chapter therefore has two movements, and it helps to hold both in view from the start. The first (sections 26.1 to 26.4) is a *faithful, type-by-type translation* of chapter 12: every classical master-equation object — the flow-consistency identity, the Itô–Dynkin chain rule, the HJB-plus-transport structure, the characteristics and the decoupling field — survives the lift, acquiring only one new ingredient, an integral over the type label y. The second (section 26.5) is genuinely new physics: under a common shock the deterministic system has no meaning, and the master equation grows a double-type-integral second-field-derivative Laplacian for which no classical-graphon shortcut is known. The structural fact that organizes both movements, and that the reader should carry throughout, is a single one: *one type's cost sees another type's population only through the kernel W*. Everything graphon-specific below — why the equation fails to decouple across types, why monotonicity becomes a spectral question about $\mathbb{W}$, why common noise binds the types together — traces back to that one channel.

Throughout, value functions are solved backward from terminal data at $t = T$ and densities evolve forward from initial data at $t = 0$ (appendix A.1); the master equation inherits a terminal condition. We import from chapter 12 the entire apparatus of calculus on $\mathcal{P}_2(\mathbb{R}^d)$ — the flat and Lions derivatives (definition 12.1, appendix A.3) and the Itô–Dynkin chain rule along a Fokker–Planck flow (lemma 12.2) — and lift each piece type-by-type. We import from chapter 22 the graphon MFG system, from chapter 24 the existence/uniqueness theory and the operator-norm threshold (A-Coupling), and we restate the objects we need rather than assume the reader has both chapters open. The carried graphon thread (Thread B, appendix A.7) is advanced to its master-equation layer in section 26.6, where the abstract equation collapses — through the rank-one graphon of example 15.11 — to a single scalar Riccati equation in an order parameter; it is the cleanest computation in the chapter and the one place where every claim below holds unconditionally, and the reader is invited to keep it in mind as the concrete payoff toward which the abstract development is working.

Notation watch

Two reminders, both load-bearing for every equation that follows. *(i) Types versus states.* The variables $x, y \in [0,1]$ are *types* (exchangeable labels, appendix A.5); the private state of an agent lives in $\mathbb{R}^d$ and is written ξ, with $\zeta \in \mathbb{R}^d$ a second (integration) state variable. Thus $\nabla_\xi U$ and $\mathrm{D}^2_\xi U$ are derivatives in the agent's own state, never in the type. In chapter 12 the state was called x; here x is the type and ξ is the state — a deliberate reuse, because the graphon type plays exactly the role the single state played one level down, and the equations below read most cleanly when x is heard as "the chapter 12 label, promoted to a network position." *(ii) Brownian motion versus graphon.* As announced at the start of Part IV (appendix A.5), in every equation containing a graphon W the letter B denotes

Brownian motion: B_t^x is the private noise of type x, and B_t^0 (introduced in section 26.5) is the common noise. The kernel W is never a Brownian motion in this chapter. Neither convention is cosmetic: the type integral $\int_0^1 \cdots \mathrm{d}y$ and the symbol B recur in essentially every display below, and a single misreading of x as a state or of W as a noise derails the whole calculation.

26.1 The field-of-measures state and the non-Markovian obstruction

The preamble promised to perform the compression of chapter 12 one level up, replacing the single population measure by a field of measures. Before we can build the master function that effects it, we must see precisely *why* it is needed — what goes wrong if one tries to make do with the bare value functions produced by the graphon MFG system of chapter 22. The diagnosis is the one that forced a master equation in the homogeneous theory (section 12.1), but transported to the field setting it sharpens into a statement about what the genuine Markov state of a graphon game is. We first recall just enough of chapters 21 and 22 to fix notation, then exhibit the obstruction.

The population is a *field of probability measures*

$$\boldsymbol{m} = (m^x)_{x\in[0,1]}, \qquad x \longmapsto m^x \in \mathcal{P}_2(\mathbb{R}^d),$$

a measurable map from the type interval into Wasserstein space: to each type x it assigns the law m^x of the private states of the agents of that type. Where the homogeneous theory had a single measure m, the graphon theory has a whole continuum of them indexed by x, and it is this resolution of the population type-by-type that every later structure will have to carry. The natural state space for the equilibrium analysis (chapter 21) is the set

$$\boldsymbol{\mathcal{P}}_2 \;:=\; \Big\{ \boldsymbol{m} : [0,1] \to \mathcal{P}_2(\mathbb{R}^d) \text{ measurable } : \; \textstyle\int_0^1\int_{\mathbb{R}^d} |\zeta|^2 \; m^x(\mathrm{d}\zeta)\; \mathrm{d}x < \infty \Big\}, \tag{26.1}$$

the fields whose type-averaged second moment is finite, metrized by the L^2-Wasserstein distance over types (the field metric d_2 of chapter 21, eq. (21.10)),

$$d_2(\boldsymbol{m},\boldsymbol{m}')^2 \;:=\; \int_0^1 \mathcal{W}_2(m^x,(m')^x)^2 \;\mathrm{d}x. \tag{26.2}$$

The reading is the natural one: two fields are close when, *averaged over types*, their type-slices are close in the Wasserstein metric of chapter 4. The square root of an average of squared $\mathcal{W}_2$ distances is exactly the L^2-over-types structure that makes $\boldsymbol{\mathcal{P}}_2$ a metric space on which the calculus of the next section can be built.

A type-x agent controls a private diffusion and feels the population only through the graphon aggregate. In the canonical setting of chapter 22, where the control is the drift, the agent's dynamics and the coupling are

$$\mathrm{d}X_t^x \;=\; \alpha_t^x \;\mathrm{d}t \;+\; \sigma \;\mathrm{d}B_t^x, \qquad X_0^x \sim m_0^x, \tag{26.3}$$

with σ constant and nondegenerate (A-Nondeg) — the nondegeneracy is what later supplies the parabolic smoothing in ξ that the well-posedness estimates lean on — and the running and terminal costs couple to $\boldsymbol{m}$ *only through the graphon operator*. The aggregate felt by type x is assembled in two steps. First, for each foreign type y one forms the scalar average of a fixed bounded observable ϕ against that type's slice, $\langle \phi, \boldsymbol{m}\rangle(y) = \int_{\mathbb{R}^d} \phi(\zeta)\, m^y(\mathrm{d}\zeta)$; this collapses each entire type-slice to a single number. Then one averages those numbers over types, weighted by the kernel $W(x, y)$ that records how strongly type x is exposed to type y:

$$z[\boldsymbol{m}](x) \;:=\; (\mathbb{W}\,\langle \phi, \boldsymbol{m}\rangle)(x) \;=\; \int_0^1 W(x,y) \Big(\int_{\mathbb{R}^d} \phi(\zeta)\, m^y(\mathrm{d}\zeta) \Big)\, \mathrm{d}y, \tag{26.4}$$

for a fixed bounded observable ϕ (the interaction observable h of definition 25.3; for Thread B, $\phi(\zeta) = \zeta$, so that $z[\boldsymbol{m}](x) = (\mathbb{W}\bar{m})(x)$ with $\bar{m}(y) = \int \zeta\, m^y(\mathrm{d}\zeta)$ the type-y mean — the aggregate is then simply the W-weighted average of the foreign type means). The costs are functions of the agent's type, its own state, and this single aggregate number:

$$F(x, \xi, \boldsymbol{m}) = \widetilde{F}(x, \xi, z[\boldsymbol{m}](x)), \qquad G(x, \xi, \boldsymbol{m}) = \widetilde{G}(x, \xi, z[\boldsymbol{m}](x)). \tag{26.5}$$

This is the structural punchline to keep in mind throughout the chapter. The field $\boldsymbol{m}$ enters the cost of a type-x agent *only* through the scalar $z[\boldsymbol{m}](x)$, and that scalar is built by the operator $\mathbb{W}$: the only route by which one type's cost sees another type's population is the kernel W. That single fact is what distinguishes the graphon theory from a disjoint union of classical MFGs — it is the thread the whole chapter is strung on, and every later display in which the types fail to separate can be traced back to it.

The graphon MFG system of chapter 22 is then the type-indexed forward–backward system: for every $x \in [0, 1]$,

$$-\partial_t u^x - \tfrac{1}{2}\,\mathrm{tr}\big(\sigma\sigma^\top \mathrm{D}^2_\xi\, u^x\big) + H\big(x, \xi, \nabla_\xi u^x\big) = F(x, \xi, \boldsymbol{m}_t), \quad u^x(T, \xi) = G(x, \xi, \boldsymbol{m}_T), \tag{26.6a}$$

$$\partial_t m^x_t - \tfrac{1}{2}\,\mathrm{tr}\big(\sigma\sigma^\top \mathrm{D}^2_\zeta\, m^x_t\big) - \mathrm{div}\big(m^x_t\, \partial_p H(x, \cdot, \nabla_\xi u^x)\big) = 0, \qquad m^x_0 \text{ given}, \tag{26.6b}$$

a backward HJB equation (26.6a) for the type-x value, run from terminal data, coupled to a forward Fokker–Planck equation (26.6b) for the type-x density, run from initial data, with each type carrying its own copy of the pair. Each ingredient draws on a standing hypothesis, and it is worth naming where. The Hamiltonian $H(x, \xi, p)$ is the type-x Hamiltonian, convex in p under (A-Conv); convexity is what makes the minimizing control single-valued, so that the optimal feedback $\alpha^*(x, \xi, p) = -\partial_p H(x, \xi, p)$ (appendix A.4) is a well-defined function and the very same drift $-\partial_p H$ can be substituted into the Fokker–Planck equation (26.6b) that closes the loop. The aggregate $z[\boldsymbol{m}_t](x)$ entering F, G through (26.5) is well-defined and depends regularly on the type x because the kernel is admissible (A-Reg-W): this is what makes $\mathbb{W}$ a bounded operator on $L^2([0, 1])$ (definition 15.13), so the type-integral in (26.4) converges and varies measurably in x. Existence of a solution for each initial field $\boldsymbol{m}_0 \in \boldsymbol{\mathcal{P}}_2$ then holds under the standing assumptions together with (A-Reg-W), and uniqueness for every horizon requires in addition the graphon monotonicity (A-Mon) and the operator threshold (A-Coupling); this is the existence/uniqueness theory of chapter 24, which we assume throughout so that "the equilibrium from $\boldsymbol{m}_0$" names a single object.

The types are coupled *only* through the appearance of the whole field $\boldsymbol{m}_t$ in F, G via (26.5), and it is instructive to watch that coupling switch off. Remove it in either of the two ways the structure allows. If $W \equiv 0$, then $z[\boldsymbol{m}](x) = 0$ for every x and every field, so $F(x, \xi, \boldsymbol{m}) = \widetilde{F}(x, \xi, 0)$ and $G(x, \xi, \boldsymbol{m}) = \widetilde{G}(x, \xi, 0)$ no longer depend on $\boldsymbol{m}$ at all; the type-x HJB equation then has a source fixed independently of the other types, its feedback drives a Fokker–Planck equation that involves only u^x, and the system splits into $|[0,1]|$ disjoint copies of a classical MFG, one per type, sharing no object. If instead ϕ is constant, $\phi \equiv c$, then $\langle \phi, \boldsymbol{m} \rangle(y) = c$ for every y because each m^y is a probability measure, so $z[\boldsymbol{m}](x) = c\,(\mathbb{W}\mathbf{1})(x)$ depends on the kernel but *not on the configuration of the field*: the population's shape is invisible, only its trivial total mass enters, and again each type sees a fixed source and the system decouples. In both degenerate cases the graphon game collapses to independent classical MFGs precisely because the one inter-type channel — (26.5) through $\mathbb{W}$ — has been severed. Everything genuinely graphon about the theory lives in the regime where that channel is open.

With the system in hand the obstruction that forced a master equation in section 12.1 reappears verbatim, one level up. Solving (26.6) from a fixed $\boldsymbol{m}_0$ yields a single *flow of fields* $(\boldsymbol{m}_t)_{t \in [0,T]}$ and a value family $u^x(t, \xi)$ attached to it alone. The value answers "what is my optimal cost-to-go from (t, ξ), given my type x?" — but only along the one realized field flow; it knows nothing about the contingency in which the population field is some other $\boldsymbol{m} \neq \boldsymbol{m}_t$, because that contingency simply does not occur along the trajectory the system was solved on. The bare value family is, in the language of section 12.1, *non-Markovian* in the field: its value at time t is determined not by the current configuration alone but by the entire realized history that produced $\boldsymbol{m}_t$. To restore the Markov property one must enlarge the state until the present configuration is sufficient, and the enlargement reveals what the genuine state of the game is. In chapter 12 the Markov state was the *pair* (x, m): the agent's own state x together with the single population measure m. Here it is the *triple* $(x, \xi, \boldsymbol{m})$: the agent's type x, its private state ξ, and the *entire field* $\boldsymbol{m}$. The promotion $x \mapsto (x, \xi)$ records that the chapter 12 state has split into a frozen label and a genuinely dynamical private state, and the promotion $m \mapsto \boldsymbol{m}$ records that the population is now resolved type-by-type; the bare value $u^x(t, \xi)$ sees only the realized slice $\boldsymbol{m} = \boldsymbol{m}_t$ of this triple and is blind to the rest of $\boldsymbol{\mathcal{P}}_2$.

Heuristic (non-rigorous)

The lift of the trajectory-versus-flow picture of section 12.1. Solving (26.6) from one $\boldsymbol{m}_0$ traces a single curve in the field space $\boldsymbol{\mathcal{P}}_2$; the master function is the *flow map* on $\boldsymbol{\mathcal{P}}_2$, defined off that one curve so as to cover the whole space at once. We seek $U(t, x, \xi, \boldsymbol{m})$ so that, *whatever* field $\boldsymbol{m}$ is presented at time t,

$$U(t, x, \xi, \boldsymbol{m}) = \text{the equilibrium value of a type-}x\text{ agent at }\xi\text{ when the population field is }\boldsymbol{m},$$

and the realized value is recovered along the equilibrium flow by the *flow-consistency identity* $u^x(t, \xi) = U(t, x, \xi, \boldsymbol{m}_t)$ — the seed of everything that follows. To extract the equation U obeys we differentiate this identity in t. The left-hand side is the time-derivative of the bare value, governed by the HJB equation (26.6a); on the right, t enters both explicitly, through the first slot of U, and implicitly, through the moving field $\boldsymbol{m}_t$. That implicit derivative is the new content: each type-slice m_t^y of the field is being transported by its own Fokker–Planck flow, so the chain rule must sum the response of U to the motion of every slice. It will therefore carry *two* integrals — one over the foreign state ζ, exactly as in the classical chain rule of lemma 12.2, and one *new* integral over the type y — producing a transport term and a diffusion term, each integrated $\int_0^1 \cdots \, \mathrm{d}y$ across the continuum of types. Matching this against the HJB equation will give the graphon master equation. The necessity of the all-contingencies object becomes *absolute* under common noise (section 26.5), where $\boldsymbol{m}_t$ is genuinely random and "the realized slice" is not knowable in advance: there is then no deterministic curve to which a bare value could be attached, and only an object defined for every $\boldsymbol{m}$ at once survives.

26.2 Differentiation along a field of Fokker–Planck flows

The previous section closed with a concrete demand. To extract the equation that U obeys we must differentiate the flow-consistency identity $u^x(t,\xi) = U(t,x,\xi,\boldsymbol{m}_t)$ in time, and the right-hand side depends on t not only through its explicit first slot but through the moving field $\boldsymbol{m}_t$ — a field whose every type-slice m_t^y is being dragged along by its own Fokker–Planck flow. What we need, and what this section builds, is therefore a chain rule for a functional of the *whole field*: a formula for the rate of change of $\Psi(\boldsymbol{m}_t)$ that integrates the response of Ψ over both the foreign state ζ *and* the type y, exactly the two integrals section 26.1 flagged as the new content. This is the single analytical engine of the chapter — the lifted Itô–Dynkin calculus — and once it is in hand the master equation follows by matching it against the HJB equation, with no further analysis.

The construction is a faithful lift of the homogeneous calculus of chapter 12, and it pays to keep that ancestor in view because the lift changes only one thing. There we needed two derivatives on $\mathcal{P}_2(\mathbb{R}^d)$ — the flat derivative, which records the first-order response of a functional to a perturbation of the measure, and the Lions derivative, its state-gradient — together with a chain rule (lemma 12.2) that fed those derivatives the Fokker–Planck right-hand side. We lift each piece to the field space $\boldsymbol{\mathcal{P}}_2$ of (26.1), and the only new feature, exactly as promised in the chapter preamble, is the type index y: a functional of a field can be perturbed in any one of a continuum of type-slices, so its first variation is no longer a single function on $\mathbb{R}^d$ but a *family* of functions indexed by the type. We develop the two derivatives first, then assemble the chain rule.

Begin by asking what it even means to nudge a field. A field $\boldsymbol{m} = (m^x)_{x\in[0,1]}$ carries a separate probability measure over each type, so there is a whole continuum of independent directions in which to push it. The cleanest — and, it will turn out, the only one the calculus ever needs — is to reweight a *single* type-slice while leaving every other slice fixed: pick a type y and a target measure m', and slide the slice at y a fraction ϵ of the way from its current value m^y toward m'. Because this perturbation is localized at one type, the first-order response of Ψ to it is naturally a function *of that type*, and the flat derivative below is correspondingly indexed by y — the one structural departure from the classical single function $\delta\Psi/\delta m$ of definition 12.1.

Definition 26.1 (Flat and Lions derivatives on the field space)**.** Let $\Psi : \boldsymbol{\mathcal{P}}_2 \to \mathbb{R}$. A perturbation of the field acts on a single type-slice: for $y \in [0,1]$ and $m' \in \mathcal{P}_2(\mathbb{R}^d)$, write $\boldsymbol{m}^{y \to m', \epsilon}$ for the field that equals $\boldsymbol{m}$ except in the slice y, where it is $m^y + \epsilon(m' - m^y)$. The *flat derivative* of Ψ is the family of functions $\dfrac{\delta \Psi}{\delta m^y}(\boldsymbol{m})(\cdot) : \mathbb{R}^d \to \mathbb{R}$, indexed by the type y, defined up to an additive constant by

$$\lim_{\epsilon \to 0} \frac{\Psi(\boldsymbol{m}^{y \to m', \epsilon}) - \Psi(\boldsymbol{m})}{\epsilon} \;=\; \int_{\mathbb{R}^d} \frac{\delta \Psi}{\delta m^y}(\boldsymbol{m})(\zeta)\,(m' - m^y)(\mathrm{d}\zeta) \qquad \text{for a.e. } y \in [0,1],\ \text{all } m'.$$

When $\zeta \mapsto \delta\Psi/\delta m^y(\boldsymbol{m})(\zeta)$ is differentiable, the *(slice) Lions derivative* is its state-gradient,

$$\partial_\mu^y \Psi(\boldsymbol{m})(\zeta) \;:=\; \nabla_\zeta \frac{\delta \Psi}{\delta m^y}(\boldsymbol{m})(\zeta) \;\in\; \mathbb{R}^d.$$

We call Ψ *fully* $\mathcal{C}^2$ if these exist, are jointly measurable in y and continuous in $(\boldsymbol{m}, \zeta)$, and $\zeta \mapsto \partial_\mu^y \Psi(\boldsymbol{m})(\zeta)$ is $\mathcal{C}^1$ with Jacobian $\partial_\zeta \partial_\mu^y \Psi(\boldsymbol{m})(\zeta) \in \mathbb{R}^{d \times d}$.

The only new feature relative to definition 12.1 is the type index y, but it changes the very *kind* of object the first variation is. Classically $\delta\Psi/\delta m$ is one function on $\mathbb{R}^d$; here, because a perturbation lives in a single slice, the response is read off slice by slice and $\delta\Psi/\delta m^y(\boldsymbol{m})(\cdot)$ is a *whole family* of functions, one for each type y — and it is the family, not any single member, that constitutes the derivative. Its state-gradient $\partial_\mu^y \Psi$ is the slice Lions derivative, the per-type avatar of the single Lions field of chapter 12.

The regularity bundle named “fully $\mathcal{C}^2$” is assembled with the chain rule already in view, and each clause earns its place; it is worth reading them term by term so that nothing in the lemma below arrives unexplained. Existence of the slice flat derivative and its gradient is what lets the first variation be written down at all. Joint measurability in y is what makes the type integral $\int_0^1 \cdots \mathrm{d}y$ — the one genuinely new operation of the lift — well-defined and Fubini-legal; without it the per-slice contributions could not be summed coherently over the continuum. Continuity in $(\boldsymbol{m}, \zeta)$ is what lets the derivatives be evaluated along the moving field and against the moving slice as time runs. And the demand that $\zeta \mapsto \partial_\mu^y \Psi(\boldsymbol{m})(\zeta)$ be $\mathcal{C}^1$ with Jacobian $\partial_\zeta \partial_\mu^y \Psi$ is precisely the second-order regularity that the diffusion term will consume: the constant, nondegenerate $\sigma\sigma^\top$ of (A-Nondeg) spreads mass locally, one state-point at a time, so the chain rule needs only this *single-variable* Jacobian and never a genuine two-point second field derivative $\partial_\mu^y \partial_\mu^{y'} \Psi$. That economy is exactly the no-common-noise signature of chapter 12 carried up a level; when a common shock enters (section 26.5) the bundle must be enlarged to carry the two-type object flagged in definition 26.9, and that enlargement is the analytic price of the new physics.

Applied to $\Psi(\cdot) = U(t, x, \xi, \cdot)$ with (t, x, ξ) frozen, the derivatives carry (t, x, ξ) as parameters and a fresh pair (y, ζ); we write $\delta U/\delta m^y(t, x, \xi, \boldsymbol{m})(\zeta)$ and $\partial_\mu^y U(t, x, \xi, \boldsymbol{m})(\zeta)$. The reader should hear (y, ζ) as “a foreign type and a foreign state” — the label and position of the crowd whose reweighting U is being probed against — kept rigorously distinct from the agent’s own pair (x, ξ), in keeping with the standing types-versus-states warning of the chapter preamble.

Lemma 26.2 (Chain rule along a field of Fokker–Planck flows)**.** *Let $\Psi : \boldsymbol{\mathcal{P}}_2 \to \mathbb{R}$ be fully $\mathcal{C}^2$ in the sense of definition 26.1, with derivatives bounded and Lipschitz on bounded sets, uniformly in* *the type index. Let $(\boldsymbol{m}_t)_{t\in[0,T]}$ be a flow in $\boldsymbol{\mathcal{P}}_2$ in which each slice solves its own Fokker–Planck equation,*

$$\partial_t m_t^y \;=\; \tfrac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}_\zeta^2\, m_t^y) \;-\; \operatorname{div}(m_t^y\, \mathbf{b}_t^y) \qquad (y\in[0,1]),$$

driven by a measurable family of drift fields $\mathbf{b}_t^y : \mathbb{R}^d \to \mathbb{R}^d$ of at most linear growth, $|\mathbf{b}_t^y(\zeta)| \le C(1+|\zeta|)$ uniformly in (y,t), with $\int_0^T\int_0^1\int |\mathbf{b}_t^y|^2\, \mathrm{d}m_t^y\, \mathrm{d}y\, \mathrm{d}t < \infty$. Then $t\mapsto \Psi(\boldsymbol{m}_t)$ is absolutely continuous and

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t}\,\Psi(\boldsymbol{m}_t) \;=\; &\int_0^1\!\int_{\mathbb{R}^d} \partial_\mu^y \Psi(\boldsymbol{m}_t)(\zeta)\cdot \mathbf{b}_t^y(\zeta)\, m_t^y(\mathrm{d}\zeta)\, \mathrm{d}y \\ &+\; \tfrac{1}{2}\int_0^1\!\int_{\mathbb{R}^d} \operatorname{tr}\Big(\sigma\sigma^\top\, \partial_\zeta \partial_\mu^y \Psi(\boldsymbol{m}_t)(\zeta)\Big)\, m_t^y(\mathrm{d}\zeta)\, \mathrm{d}y.\end{aligned} \tag{26.7}$$

Proof sketch. The argument is two moves, and the division is the whole content of the lift: per type-slice it *is* the classical chain rule of lemma 12.2, and the genuinely new step sums those per-slice contributions over the type continuum. We carry the analytic justification in-book, invoking the deterministic Itô formula along a flow of measures (theorem D.7) for attribution while keeping the algebra explicit in front of the reader.

Move (a): per slice, the classical chain rule. Fix a single type y and regard Ψ as a functional of that one slice with every other slice held frozen. The computation is then word for word the three moves of lemma 12.2. First differentiate through the slice flat derivative: because Ψ is fully $\mathcal{C}^2$ and $t\mapsto m_t^y$ is absolutely continuous, the rate of change of Ψ in response to the motion of the y-slice is its slice-flat-derivative contracted against that slice's rate of change, the perturbation direction of definition 26.1 now being the mass-zero signed measure $\partial_t m_t^y$. Next substitute the slice's Fokker–Planck right-hand side, which splits the contribution cleanly into a transport piece carrying the drift $\mathbf{b}_t^y$ and a diffusion piece carrying $\frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}_\zeta^2\, m_t^y)$. Finally integrate by parts in ζ to move the spatial derivatives off the irregular measure and onto the smooth flat derivative. One integration by parts on the transport piece turns $-\operatorname{div}(m_t^y \mathbf{b}_t^y)$ paired against $\delta\Psi/\delta m^y$ into $\nabla_\zeta(\delta\Psi/\delta m^y)\cdot \mathbf{b}_t^y = \partial_\mu^y\Psi\cdot \mathbf{b}_t^y$ integrated against m_t^y, with the single sign change of the divergence theorem; two integrations by parts on the diffusion piece transfer both spatial derivatives onto the flat derivative with no net sign change, the constant matrix $\sigma\sigma^\top$ riding along under the trace, and produce $\frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \partial_\zeta \partial_\mu^y \Psi)$ — the single-variable Jacobian of the Lions field, the one place the $\mathcal{C}^1$ clause of "fully $\mathcal{C}^2$" is spent. The boundary terms at infinity vanish because $\delta\Psi/\delta m^y$ and its first two gradients are bounded while $m_t^y \mathbf{b}_t^y$ carries the finite-energy decay guaranteed by the L^2 bound. The outcome is, per slice and at the fixed type y, exactly the integrand of (26.7), namely (12.4).

Move (b): sum over the type continuum. This is the step with no classical ancestor. The field flow moves all slices at once, and the total derivative of a functional of $\boldsymbol{m}$ is the integral, over the type label, of its slice-variations against the slice rates of change — the field-flat-derivative identity of definition 26.1 written in differential form,

$$\frac{\mathrm{d}}{\mathrm{d}t}\Psi(\boldsymbol{m}_t) = \int_0^1\!\int_{\mathbb{R}^d} \frac{\delta\Psi}{\delta m^y}(\boldsymbol{m}_t)(\zeta)\, \partial_t m_t^y(\mathrm{d}\zeta)\, \mathrm{d}y,$$

the type-integrated form of the first move, valid with absolute continuity in t under the uniform L^2 bound. Substituting each slice's Fokker–Planck right-hand side and carrying out the per-slice integrations by parts of Move (a) *inside* the y-integral gives (26.7). Interchanging the order of the dy- and dζ-integrations is Fubini, legitimate because the joint measurability of the derivatives in y (a clause of "fully $\mathcal{C}^2$") together with the bound $\int_0^T \int_0^1 \int |\mathbf{b}_t^y|^2 \, \mathrm{d}m_t^y \, \mathrm{d}y \, \mathrm{d}t < \infty$ makes the double integral absolutely convergent. The per-slice identity behind Move (a) is exactly theorem D.7 with the drift $\mathbf{b}_t^y$ in place of the SDE drift and the martingale term absent, the slice flow being deterministic; we cite that theorem for attribution, but the displayed algebra is the entire argument.

The linear-growth drift, by truncation. The two moves above used boundedness of the drift through the vanishing of the boundary terms; the at-most-linear-growth case stated in the lemma is reached from the bounded case by truncation, an argument we carry out in-book rather than cite. Let $\mathbf{b}_t^{y,R} = \mathbf{b}_t^y \chi_R$ with $\chi_R(\zeta)$ a smooth cutoff equal to 1 for $|\zeta| \leq R$ and 0 for $|\zeta| \geq R+1$; each $\mathbf{b}_t^{y,R}$ is bounded, so (26.7) holds with $\mathbf{b}_t^{y,R}$ by the per-slice theorem D.7 and the Fubini step just made. As $R \uparrow \infty$, $\mathbf{b}_t^{y,R} \to \mathbf{b}_t^y$ pointwise and $|\mathbf{b}_t^{y,R}| \leq |\mathbf{b}_t^y|$; since $\partial_\mu^y \Psi(\boldsymbol{m}_t)$ is bounded on the bounded sets carrying the second-moment mass of m_t^y and $\int_0^T \int_0^1 \int |\mathbf{b}_t^y|^2 \, \mathrm{d}m_t^y \, \mathrm{d}y \, \mathrm{d}t < \infty$, dominated convergence passes the transport term to its limit, while the diffusion term does not involve the drift at all and is therefore untouched by the truncation. The time-integrated identity thus holds for $\mathbf{b}_t^y$, and absolute continuity in t is preserved under the uniform L^2 bound.

It is worth being explicit that this linear-growth hypothesis is met, with no slack, by the only drift the lemma will ever be fed: the equilibrium feedback. In theorem 26.3 the field flow is the equilibrium one, whose type-y drift is $\mathbf{b}_t^y(\zeta) = -\partial_p H(y, \zeta, \nabla_\xi U(t, y, \zeta, \boldsymbol{m}_t))$. Convexity of H in p (A-Conv) is what makes this feedback single-valued in the first place — it is the unique minimizing control of appendix A.4 — and under the standing Lipschitz bounds (A-Lip) the map $p \mapsto \partial_p H(y, \zeta, p)$ is Lipschitz uniformly in (y, ζ); composed with a bounded state-gradient $\nabla_\xi U$ this alone forces $|\mathbf{b}_t^y(\zeta)| \leq C(1 + |\zeta|)$ uniformly in (y, t), which is precisely the lemma's growth condition. In the LQG thread the structure is sharper still and fully explicit: there $H(y, \zeta, p)$ is quadratic, so $\partial_p H$ is affine in (ζ, p), and the value function is quadratic in the state, so $\nabla_\xi U(t, y, \cdot, \boldsymbol{m})$ is affine in ζ; the feedback is then exactly *affine* in the state — it is the order-parameter drift of the mean equation (26.33) — and the linear-growth hypothesis holds as an equality of leading order. This is the only regularity of the drift the master-equation derivation will require. The strictly more general theory (genuinely superlinear drifts, and the stochastic upgrade needed once common noise turns the slice flow into a true SDE) is the type-indexed extension of chapter 4, organized for the graphon setting in [34] and, in the probabilistic framework, in [16]; it is not needed below. □

The two terms of (26.7) carry exactly the meaning they had in chapter 12, now resolved type by type: the first is the *transport* of Ψ by the per-type drifts, the crowd of each type flowing along its own $\mathbf{b}_t^y$ and pushing Ψ at the rate at which the slice Lions force points along that flow; the second is the *spreading* of each type's mass by the idiosyncratic diffusion σ, the measure-space avatar of the Laplacian with the finite-dimensional Hessian replaced by the slice Lions Jacobian. The single new ingredient is the outer $\int_0^1 \cdots \mathrm{d}y$, which sums these responses over the continuum of types — a sum, emphatically, and not a derivative.

This is precisely the engine the next section fires, and we can already read off how. In section 26.3 we will not feed the lemma an arbitrary functional and an arbitrary drift, but the specific functional $\Psi = U(t, x, \xi, \cdot)$ — the master function with its time, type, and state slots frozen — transported along the *equilibrium* field flow, whose type-y Fokker–Planck drift is the optimal feedback $\mathbf{b}_t^y =$

$-\partial_p H(y, \cdot, \nabla_\xi U(t, y, \cdot, \boldsymbol{m}_t))$ read off from (26.6b). With that one substitution the transport term becomes each type's crowd drifting under its *own* optimal control and the diffusion term becomes each type's crowd spreading under its private noise; the two integrals of (26.7) reappear verbatim, as the two new type-integrated lines of the graphon master equation, and the feedback's dependence on the value functions of *all* types — through $\nabla_\xi U(t, y, \cdot, \boldsymbol{m}_t)$ inside the type integral — is what will prevent the equation from decoupling across types. Differentiating the flow-consistency identity (26.9) in t and matching against the HJB equation (26.6a) is then the whole derivation; the uniqueness that makes U single-valued, deferred to section 26.4, is assumed there so that "the equilibrium flow" names one object.

26.3 The graphon master equation

Everything is now in place for the chapter's central derivation. The previous section built the one analytical engine we need — the chain rule lemma 26.2 along a field of Fokker–Planck flows — and ended by pointing it at exactly the functional and the drift it will be fed here: the master function $\Psi = U(t, x, \xi, \cdot)$ with its time, type, and state slots frozen, transported along the equilibrium field flow whose per-type feedback drift was recorded there. What remains is to write down the candidate U precisely, differentiate the flow-consistency identity (26.9) seeded in section 26.1, and match the result against the per-type HJB equation (26.6a). The matching produces the graphon master equation, and — this is the content of the theorem below — the production runs both ways: the master function solves the equation, and a solution of the equation regenerates the whole forward–backward system. The lift is faithful to the homogeneous derivation of theorem 12.3; only the type integral is new.

The construction begins with the same circularity that the homogeneous theory had to resolve, so it is worth naming it before proceeding. We want a single function U whose value records "the equilibrium cost-to-go of a type-x agent at state ξ when the population field is $\boldsymbol{m}$," for *every* field $\boldsymbol{m} \in \boldsymbol{\mathcal{P}}_2$ at once — but the only way we know to compute an equilibrium value is to fix an initial field, solve the forward–backward system (26.6) from it, and read the value off the realized flow. The resolution is to do exactly that, once for each possible initial datum, and to define U at $\boldsymbol{m}$ by the value the corresponding problem assigns *at its own starting instant.* Suppose, then, that for every initial datum $(t_0, \boldsymbol{m}) \in [0, T] \times \boldsymbol{\mathcal{P}}_2$ the graphon MFG system (26.6), posed on $[t_0, T]$ with $\boldsymbol{m}_{t_0} = \boldsymbol{m}$, has a unique solution. Existence holds under the standing assumptions and (A-Reg-W) (chapter 24); uniqueness for every horizon holds under the graphon monotonicity and operator conditions taken up in section 26.4. Uniqueness is precisely the hypothesis that makes the construction single-valued — without it "the equilibrium from $\boldsymbol{m}$" would name a set rather than a point and U would not be a function — and we assume it here, deferring its justification to section 26.4 so that the present derivation can proceed unobstructed. Denote by $(\boldsymbol{m}_s^{t_0, \boldsymbol{m}})_{s \in [t_0, T]}$ the resulting forward field flow and by $u^{x; t_0, \boldsymbol{m}}(s, \xi)$ the resulting type-x value. Define the candidate *graphon master function* by evaluating the value at the initial time of its own problem:

$$U(t_0, x, \xi, \boldsymbol{m}) \;:=\; u^{x; t_0, \boldsymbol{m}}(t_0, \xi), \qquad (t_0, x, \xi, \boldsymbol{m}) \in [0, T] \times [0, 1] \times \mathbb{R}^d \times \boldsymbol{\mathcal{P}}_2. \tag{26.8}$$

Two features of this definition deserve to be drawn out, because the entire proof rests on them. First, the value is read at $s = t_0$, the very instant the problem starts: this is what turns a one-trajectory object into an all-contingencies one, for by varying the pair $(t_0, \boldsymbol{m})$ over the whole of $[0,T] \times \boldsymbol{\mathcal{P}}_2$ we sweep out U on its entire domain, each field $\boldsymbol{m}$ contributing the value of the fresh problem launched from it. Second, the terminal condition comes *for free.* Set $t_0 = T$: the problem on the degenerate horizon $[T,T]$ has no dynamics to run, the HJB equation (26.6a) collapses to its terminal data $u^{x;T,\boldsymbol{m}}(T,\xi) = G(x,\xi,\boldsymbol{m})$, and (26.8) reads

$$U(T,x,\xi,\boldsymbol{m}) \;=\; G(x,\xi,\boldsymbol{m})$$

with no computation at all. The master function inherits the terminal cost *by construction*, exactly as the homogeneous $U(T,x,m) = G(x,m)$ did in chapter 12; only the interior equation will require work.

The bridge between the bare value and the master function — the identity we will differentiate — is the *flow-consistency identity.* Solving from $(t_0, \boldsymbol{m})$ produces not just the initial value but the whole trajectory $s \mapsto u^{x;t_0,\boldsymbol{m}}(s,\xi)$, and along it the population is the realized flow $\boldsymbol{m}_s^{t_0,\boldsymbol{m}}$. At each later instant $t \in [t_0,T]$ the agent faces a fresh equilibrium problem — the one started from the field $\boldsymbol{m}_t^{t_0,\boldsymbol{m}}$ at time t — and by the dynamic-programming consistency of the value (the equilibrium is time-consistent, so the tail of the solution from $\boldsymbol{m}$ is the solution from $\boldsymbol{m}_t^{t_0,\boldsymbol{m}}$) the realized value coincides with the master function evaluated at the realized field:

$$u^{x;t_0,\boldsymbol{m}}(t,\xi) \;=\; U(t,x,\xi,\boldsymbol{m}_t^{t_0,\boldsymbol{m}}), \qquad t \in [t_0,T]. \tag{26.9}$$

This is the precise form of the schematic "$u^x(t,\xi) = U(t,x,\xi,\boldsymbol{m}_t)$" from section 26.1. It says that the bare value, a function of (t,ξ) tied to one flow, is the restriction of the master function to the moving slice $\boldsymbol{m} = \boldsymbol{m}_t^{t_0,\boldsymbol{m}}$ of field space. Differentiating it in t — the left side governed by the HJB equation, the right side by the field chain rule — is the whole derivation, and we turn to it now.

Theorem 26.3 (The graphon master equation)**.** *Assume the standing assumptions* (A-Lip)*,* (A-Growth)*,* (A-Nondeg)*,* (A-Conv) *and the graphon regularity* (A-Reg-W)*, and suppose the function U defined by* (26.8) *is fully $\mathcal{C}^2$ in the field argument (definition 26.1) and $\mathcal{C}^{1,2}$ in (t,ξ), with derivatives bounded and locally Lipschitz uniformly in the type x. Then U solves, on $[0,T) \times [0,1] \times \mathbb{R}^d \times \boldsymbol{\mathcal{P}}_2$, the* graphon master equation

$$\begin{aligned}
-\,\partial_t U(t,x,\xi,\boldsymbol{m}) - \tfrac{1}{2}\,\mathrm{tr}\big(\sigma\sigma^\top \mathrm{D}_\xi^2 U\big) \;+\; H\big(x,\xi,\nabla_\xi U\big)& \\
+\; \int_0^1\!\!\int_{\mathbb{R}^d} \partial_\mu^y U(t,x,\xi,\boldsymbol{m})(\zeta)\cdot \partial_p H\big(y,\zeta,\nabla_\xi U(t,y,\zeta,\boldsymbol{m})\big)\, m^y(\mathrm{d}\zeta)\;\mathrm{d}y& \\
-\; \tfrac{1}{2}\int_0^1\!\!\int_{\mathbb{R}^d} \mathrm{tr}\Big(\sigma\sigma^\top\, \partial_\zeta \partial_\mu^y U(t,x,\xi,\boldsymbol{m})(\zeta)\Big)\, m^y(\mathrm{d}\zeta)\;\mathrm{d}y \;=\; F(x,\xi,\boldsymbol{m}),&
\end{aligned} \tag{26.10}$$

with terminal condition

$$U(T,x,\xi,\boldsymbol{m}) \;=\; G(x,\xi,\boldsymbol{m}). \tag{26.11}$$

Conversely, if U is a classical solution of (26.10)*–*(26.11) *with the stated regularity, then for each $(t_0,\boldsymbol{m})$ the value $u^x(t,\xi) := U(t,x,\xi,\boldsymbol{m}_t)$ together with the field flow $\boldsymbol{m}_t$ generated by the feedback $-\partial_p H(x,\cdot,\nabla_\xi U(t,x,\cdot,\boldsymbol{m}_t))$ and $\boldsymbol{m}_{t_0} = \boldsymbol{m}$ solves the graphon MFG system* (26.6) *on $[t_0,T]$.*

Proof. From the system to the equation. Fix $(t_0, \boldsymbol{m})$ and write $\boldsymbol{m}_t = \boldsymbol{m}_t^{t_0,\boldsymbol{m}}$ for the equilibrium field flow, whose type-y feedback drift is, by (26.6b), $\mathbf{b}_t^y(\zeta) = -\partial_p H(y, \zeta, \nabla_\xi u^{y;t_0,\boldsymbol{m}}(t,\zeta))$. Differentiate the flow-consistency identity (26.9) in t at $t = t_0$, for a fixed type x. The left-hand side gives $\partial_t u^{x;t_0,\boldsymbol{m}}(t_0, \xi)$. On the right, t appears explicitly and through $\boldsymbol{m}_t$; the explicit derivative is $\partial_t U(t_0, x, \xi, \boldsymbol{m})$, and the implicit one is supplied by the field chain rule lemma 26.2 applied to $\Psi(\cdot) = U(t_0, x, \xi, \cdot)$ with the family of drifts $\mathbf{b}_{t_0}^y$:

$$\begin{aligned}\partial_t u^{x;t_0,\boldsymbol{m}}(t_0,\xi) = \partial_t U(t_0,x,\xi,\boldsymbol{m}) &+ \int_0^1\!\!\int \partial_\mu^y U(t_0,x,\xi,\boldsymbol{m})(\zeta)\cdot \mathbf{b}_{t_0}^y(\zeta)\, m^y(\mathrm{d}\zeta)\ \mathrm{d}y\\ &+ \tfrac{1}{2}\int_0^1\!\!\int \mathrm{tr}\big(\sigma\sigma^\top \partial_\zeta \partial_\mu^y U(t_0,x,\xi,\boldsymbol{m})(\zeta)\big)\, m^y(\mathrm{d}\zeta)\ \mathrm{d}y.\end{aligned}$$

At $t = t_0$ flow-consistency also gives $u^{x;t_0,\boldsymbol{m}}(t_0,\xi) = U(t_0,x,\xi,\boldsymbol{m})$, hence $\nabla_\xi u^{x;t_0,\boldsymbol{m}}(t_0,\xi) = \nabla_\xi U(t_0,x,\xi,\boldsymbol{m})$ and $\mathrm{D}_\xi^2\, u^{x;t_0,\boldsymbol{m}}(t_0,\xi) = \mathrm{D}_\xi^2\, U(t_0,x,\xi,\boldsymbol{m})$; and for the integrand type y, $\nabla_\xi u^{y;t_0,\boldsymbol{m}}(t_0,\zeta) = \nabla_\xi U(t_0,y,\zeta,\boldsymbol{m})$, so that $\mathbf{b}_{t_0}^y(\zeta) = -\partial_p H(y,\zeta,\nabla_\xi U(t_0,y,\zeta,\boldsymbol{m}))$. Inserting all of this into the type-x HJB equation (26.6a) at $t = t_0$,

$$-\partial_t u^{x;t_0,\boldsymbol{m}}(t_0,\xi) - \tfrac{1}{2}\,\mathrm{tr}\big(\sigma\sigma^\top\, \mathrm{D}_\xi^2\, u^{x;t_0,\boldsymbol{m}}(t_0,\xi)\big) + H\big(x,\xi,\nabla_\xi u^{x;t_0,\boldsymbol{m}}(t_0,\xi)\big) = F(x,\xi,\boldsymbol{m}),$$

yields exactly (26.10) at $(t_0,x,\xi,\boldsymbol{m})$. It is worth pausing on the one sign that has to come out right, because it is the seam where the optimization and the transport meet. The chain rule (26.7) delivers the transport contribution as $+\partial_\mu^y U \cdot \mathbf{b}_{t_0}^y$ on the right-hand side of the displayed expression for $\partial_t u$, with the *equilibrium* drift $\mathbf{b}_{t_0}^y = -\partial_p H(y,\zeta,\nabla_\xi U)$ carrying its own minus sign from the optimal feedback of (26.6b). The HJB equation is written with $-\partial_t u$ on its left, so moving the $\partial_t u$ expansion across the equality flips every term once: the two minus signs — one from the feedback, one from the transposition — cancel, and the transport term lands in (26.10) as $+\partial_\mu^y U \cdot \partial_p H$. The crowd's optimal flow and the master equation's transport term therefore agree in sign precisely because the agents minimize; were the feedback $+\partial_p H$ the bookkeeping would not close. Since $(t_0,x,\xi,\boldsymbol{m})$ was arbitrary the equation holds throughout $[0,T) \times [0,1] \times \mathbb{R}^d \times \boldsymbol{\mathcal{P}}_2$; the terminal condition is (26.8) at $t_0 = T$, already recorded in (26.11).

From the equation to the system. The converse is what makes U worth having: a single solution of the master equation must regenerate, for *every* initial datum, the entire forward–backward pair. Let U be a classical solution of (26.10)–(26.11). Fix $(t_0,\boldsymbol{m})$. The first step is to manufacture the field flow that the master function will be read along, and here we make an explicit import. Plugging the state-gradient $\nabla_\xi U(t,y,\cdot,\boldsymbol{m}_t)$ back into its own argument turns the family of Fokker–Planck equations (26.6b) with feedbacks $-\partial_p H(y,\cdot,\nabla_\xi U(t,y,\cdot,\boldsymbol{m}_t))$ into a *closed* system for the unknown field $\boldsymbol{m}_t$ alone — the type-slices feed each other's drifts through the dependence of U on the whole field — which is exactly a graphon McKean–Vlasov flow. That such a flow exists and is unique, started from $\boldsymbol{m}_{t_0} = \boldsymbol{m}$, is not something the present argument proves: it is the well-posedness theory of graphon McKean–Vlasov equations established in chapter 23, which we invoke here as a named input, its hypotheses met because U has the stated regularity (so the feedback is Lipschitz in the state, uniformly in the type), the diffusion is nondegenerate (A-Nondeg), and the kernel is admissible (A-Reg-W). With the flow $\boldsymbol{m}_t$ in hand, set $u^x(t,\xi) = U(t,x,\xi,\boldsymbol{m}_t)$. Then $\nabla_\xi u^x = \nabla_\xi U$ and $\mathrm{D}_\xi^2\, u^x = \mathrm{D}_\xi^2\, U$ along the flow — differentiating in the state slot commutes with restriction to the moving field — so the feedback driving (26.6b) is precisely $-\partial_p H(x,\cdot,\nabla_\xi u^x)$, and the Fokker–Planck half of the system holds by the very construction of $\boldsymbol{m}_t$. For the HJB half, differentiate

$u^x(t,\xi) = U(t,x,\xi,\boldsymbol{m}_t)$ in t by lemma 26.2 and subtract the master equation (26.10): the explicit $\partial_t U$, the transport integral, and the diffusion integral all cancel against their twins in (26.10), the same three pairings as in the forward direction run in reverse, leaving exactly the per-type HJB equation (26.6a). The terminal condition is (26.11). Thus $(u^{\cdot}, \boldsymbol{m})$ solves the graphon MFG system on $[t_0, T]$, and since $(t_0, \boldsymbol{m})$ was arbitrary the one function U has reconstructed the entire family of equilibria. □

With the equivalence proved, the equation (26.10) stands on its own, and it repays a careful term-by-term reading against its classical ancestor (12.7). It has three lines, and they fall into a familiar two-plus-one pattern: two lines that any reader of chapter 12 will recognize unchanged, and one line — the second — that carries the entire graphon novelty.

The first line is an *ordinary* second-order HJB operator in the finite-dimensional state ξ, with the type x and the field $\boldsymbol{m}$ frozen as inert parameters. Read in isolation, $-\partial_t U - \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2_\xi U) + H(x,\xi,\nabla_\xi U)$ is exactly the Hamilton–Jacobi–Bellman operator of a single type-x agent who treats the surrounding population as a fixed backdrop; it is the only place the agent's own diffusion σ and its own Hamiltonian $H(x,\cdot,\cdot)$ appear, and if the field never moved this line, set equal to $F(x,\xi,\boldsymbol{m})$, would be the whole equation. The third line is its measure-space counterpart, the *extra-diffusion* or spreading term $-\frac{1}{2}\int_0^1\int \operatorname{tr}(\sigma\sigma^\top \partial_\zeta \partial^y_\mu U)\, m^y \,\mathrm{d}y$: it accounts for the fact that the crowd of every type is itself being smeared by its private noise, and that the value U responds to that smearing through the single-variable Jacobian of its slice Lions derivative, summed over all types. Both of these survive the lift from chapter 12 with no change but the outer type integral; neither is where the graphon lives.

The second line is the new content, and it is worth slowing down over. It reads

$$\int_0^1 \int_{\mathbb{R}^d} \partial^y_\mu U(t,x,\xi,\boldsymbol{m})(\zeta) \cdot \partial_p H\big(y,\zeta,\nabla_\xi U(t,y,\zeta,\boldsymbol{m})\big)\, m^y(\mathrm{d}\zeta)\; \mathrm{d}y,$$

and it is a transport term: it measures how the type-x value changes as each foreign type's crowd drifts. But the drift it transports against is the decisive feature. $\partial_p H(y,\zeta,\nabla_\xi U(t,y,\zeta,\boldsymbol{m}))$ is the equilibrium feedback of *type* y — a different type from the x whose value we are computing — and that feedback is governed by the state-gradient $\nabla_\xi U(t,y,\cdot,\boldsymbol{m})$ of type y's own master function. So the equation for type x contains, under the integral $\int_0^1 \cdots \mathrm{d}y$, the value functions of *all* the other types. The graphon master equation is not one PDE but a continuum of PDEs welded together along the type label: the x-equation cannot be solved without the y-equations for every y, and they in turn need the x-equation. This is the precise analytic signature of the graphon coupling — *the equation does not decouple across types* — and it stands in exact contrast to the degenerate cases of section 26.1, where severing the channel (26.5) collapsed the system into independent classical MFGs. Here the channel is open, and its dynamical trace is this second line.

Remark 26.4 (Reading the gradient inside the type integral)**.** The notation $\nabla_\xi U(t,y,\zeta,\boldsymbol{m})$ is a known stumbling block, worth isolating. The subscript ξ does *not* mean "differentiate at the point ξ." It names the *slot*: U was defined in (26.8) with a generic state argument that the chapter calls ξ, and $\nabla_\xi U$ is the gradient of U in that slot, a function of all four arguments. The expression $\nabla_\xi U(t,y,\zeta,\boldsymbol{m})$ is then that gradient *evaluated* with the type slot set to the foreign type y and the state slot set to the foreign state *value* ζ — the integration variables of the second line — not at the agent's own (x, ξ). In words: it is the equilibrium momentum of a type-y agent sitting at state ζ, which is exactly what feeds that agent's optimal drift $\partial_p H(y, \zeta, \cdot)$. The agent's own pair (x, ξ) enters the second line only through the outer factor $\partial_\mu^y U(t, x, \xi, \boldsymbol{m})(\zeta)$, which records how *type x's* value responds to a reweighting of type y's crowd at ζ. Two distinct evaluations of the same function U, kept rigorously apart by which type and state are plugged into which slot: this is the types-versus-states discipline of the chapter preamble made operational.

It remains to say where the graphon kernel W — the one object that makes this a graphon theory at all — actually sits in (26.10). The surprising answer is that it appears *nowhere explicitly*: scan the three lines and there is no W, no operator $\mathbb{W}$, no aggregate z. The transport and diffusion lines carry the genuine per-type feedbacks and Jacobians, none of which displays the kernel; the only places W enters are the source F on the right-hand side and, through (26.11), the terminal datum G, where (26.5) writes them as $\widetilde{F}(x, \xi, z[\boldsymbol{m}](x))$ and $\widetilde{G}(x, \xi, z[\boldsymbol{m}](x))$ with the aggregate $z[\boldsymbol{m}](x) = (\mathbb{W}\langle \phi, \boldsymbol{m}\rangle)(x)$ of (26.4). So W is hidden inside the cost — a single scalar channel per type. Yet it is far from confined there, and tracing its propagation is the cleanest way to see why the equation couples. The source $\widetilde{F}(y, \cdot, z[\boldsymbol{m}](y))$ shapes each type y's value function through that type's HJB equation; the value function's state-gradient $\nabla_\xi U(t, y, \cdot, \boldsymbol{m})$ therefore carries the imprint of W; and that very gradient is what appears, under the type integral, as the equilibrium feedback in the second line of *every other* type's master equation. The kernel thus enters once, through the cost, and then propagates — via the field of value functions it shapes — into the transport drift of all types at once. The non-decoupling of the second line is precisely the dynamical shadow of this single static coupling; sever W and, as section 26.1 showed, the shadow vanishes with it.

Notation watch

The graphon master equation (26.10) carries *four* distinct objects that a hurried reader will all call "derivatives," and conflating them is the commonest error in the subject; each is genuinely different in kind, and it is worth pinning down what each one differentiates with respect to. *(i) The state Hessian* $\mathrm{D}_\xi^2 U$ is an ordinary second derivative in the agent's own private state $\xi \in \mathbb{R}^d$, a $d \times d$ matrix, and it is the only second-order object in the bare HJB line — the agent's own diffusion acts here and nowhere else. *(ii) The slice Lions Jacobian* $\partial_\zeta \partial_\mu^y U$ is also an ordinary $d \times d$ second derivative, but in a *foreign* state ζ: it measures how the crowd of type y spreads under its own noise and how U responds to that spreading, and although it lives under the type integral it is a single-variable Jacobian, not a field derivative. *(iii) The type integral* $\int_0^1 \cdots \mathrm{d}y$ is not a derivative at all but a *sum* over the continuum of types — the one structural novelty the graphon lift adds to chapter 12 — and reading it as a differentiation, or forgetting it, is what makes the type coupling of the second line invisible. *(iv) The second field derivative* $\partial_\mu^y \partial_\mu^{y'} U$ is the genuine article: a true second-order operator on the field space $\boldsymbol{\mathcal{P}}_2$, a *double* type integral over two independent foreign types y, y', defined in definition 26.9. It is conspicuously *absent* from (26.10), and its absence is not an accident of bookkeeping but the analytic content of "no common noise": with only idiosyncratic diffusions the field flow is deterministic and the chain rule never reaches second order in the field. It is precisely this fourth object that switches on in section 26.5, where a shared shock makes the field a true stochastic process and the master equation acquires its field-space Laplacian. Keep all four apart; the first three are present now, the fourth marks the boundary of the deterministic theory.

The line-by-line reading just completed is the static anatomy of (26.10): what each term *is*. There is a complementary, geometric way to read the same equation — not term by term but as a whole — that the next section takes up. Just as the classical master equation of section 12.5 is a Hamilton–Jacobi equation on the space of measures whose characteristic curves are the equilibrium Fokker–Planck flows, the graphon master equation is a Hamilton–Jacobi equation whose base space is the field space $\boldsymbol{\mathcal{P}}_2$ and whose characteristics are the field Fokker–Planck flows $(\boldsymbol{m}_t)$ we have just learned to differentiate along. The equation-to-system converse proved above is exactly the statement that propagating data along those characteristics regenerates the forward–backward system; section 26.3.1 reads that converse geometrically, identifies the characteristic system with the graphon MFG system (26.6), and shows that the type-resolved state-gradient $\nabla_\xi U$ is the operator-valued decoupling field of the graphon FBSDE of chapter 23.

26.3.1 Characteristics and the operator-valued decoupling field

The previous section read (26.10) term by term and closed with its converse: a classical solution U, propagated forward along the equilibrium field flow it itself generates, regenerates the whole graphon MFG system (26.6). That converse is not a technical afterthought but the geometric heart of the equation, and naming it as such is the business of this section. A first-order Hamilton–Jacobi equation is solved by the *method of characteristics*: one propagates the unknown along distinguished curves in the base space, and along each such curve the partial differential equation collapses to a system of ordinary (here, evolution) equations. The graphon master equation is exactly such a Hamilton–Jacobi equation — first order in the field $\boldsymbol{m}$, as the field-anatomy of section 26.3 made plain, the only genuine second-field-derivative object (the two-type Laplacian of definition 26.9) being absent until common noise enters — and the converse just proved is precisely the statement that its characteristics are the field Fokker–Planck flows. We now make that reading exact, and in doing so we lift the central diagram of Part II (eq. (12.12)) to the field setting unchanged in shape.

The dictionary is the one of section 12.5, with a type label attached throughout. The base space is the field space $\boldsymbol{\mathcal{P}}_2$ of (26.1); the characteristic curves are the field flows $(\boldsymbol{m}_t)$ we spent section 26.2 learning to differentiate along; and the characteristic *system* — the evolution the master equation collapses to along each curve — is the graphon MFG system (26.6) itself. This is the precise sense in which the three formulations of the graphon game — master equation on $\boldsymbol{\mathcal{P}}_2$, coupled HJB/field-Fokker–Planck system, and graphon McKean–Vlasov FBSDE — are one object viewed three ways, exactly as in the homogeneous theory. The single structural novelty, to which we return at the close, is that these characteristics do not evolve type by type in isolation: the type integral in (26.10) couples the flow of every slice to the value functions of all the others, so the characteristic system is a genuinely entangled continuum of HJB/Fokker–Planck pairs rather than a disjoint family of them.

Theorem 26.5 (Characteristics of the graphon master equation)**.** *Let U be a classical solution of* (26.10)–(26.11) *with the regularity of theorem 26.3. Fix $(t_0, \boldsymbol{m})$ and let $(\boldsymbol{m}_t)_{t \geq t_0}$ be the field flow generated by the per-type feedbacks $\mathbf{b}_t^y(\cdot) = -\partial_p H(y, \cdot, \nabla_\xi U(t, y, \cdot, \boldsymbol{m}_t))$, $\boldsymbol{m}_{t_0} = \boldsymbol{m}$. Then:*

1. *the family $u^x(t, \xi) := U(t, x, \xi, \boldsymbol{m}_t)$ and the flow $\boldsymbol{m}_t$ solve the graphon MFG system* (26.6) *on* $[t_0, T]$ (theorem 26.3)*;*
2. *for each type x, the graphon McKean–Vlasov FBSDE of chapter 23 for the optimally controlled state X_t^x, its adjoint Y_t^x and martingale integrand Z_t^x is solved by*

$$Y_t^x = \nabla_\xi U(t, x, X_t^x, \boldsymbol{m}_t), \qquad Z_t^x = \mathrm{D}_\xi^2 \, U(t, x, X_t^x, \boldsymbol{m}_t) \, \sigma, \qquad m_t^x = \mathcal{L}(X_t^x), \tag{26.12}$$

so that $\nabla_\xi U$ is the (type-indexed) decoupling field of the graphon FBSDE.

Proof sketch. Part (1) is nothing new: it is the equation-to-system converse of theorem 26.3, restated geometrically as the assertion that the value family $u^x(t, \xi) = U(t, x, \xi, \boldsymbol{m}_t)$, read off U along the single field characteristic $(\boldsymbol{m}_t)$, together with that flow, solves (26.6) on $[t_0, T]$. The content of the theorem is part (2), and it is a composition of two facts already in hand, so it pays to assemble it in the open rather than defer it to a citation.

The first fact is the per-type nonlinear Feynman–Kac link of chapter 23. With the equilibrium field $\boldsymbol{m}_\cdot$ held fixed, each type decouples into a *classical* McKean–Vlasov FBSDE for the optimally controlled state X_t^x, its adjoint Y_t^x, and the martingale integrand Z_t^x; the stochastic maximum principle of chapter 23 represents the equilibrium through this triple, and the bridge between its probabilistic adjoint and the PDE value is the FBSDE–PDE dictionary

$$Y_t^x = \nabla_\xi u^x(t, X_t^x), \qquad Z_t^x = \mathrm{D}_\xi^2 \, u^x(t, X_t^x) \, \sigma$$

proved type by type in proposition 23.19 (eq. (23.21)) — the graphon lift of the classical relation of chapter 9, itself the nonlinear Feynman–Kac formula of chapter 5 applied to the type-x HJB equation (26.6a). The second fact is the flow-consistency identity (26.9), $u^x(t, \xi) = U(t, x, \xi, \boldsymbol{m}_t)$, together with the consistency $m_t^x = \mathcal{L}(X_t^x)$ of the controlled state's law with the type-x slice of the realized field (the Fokker–Planck equation (26.6b) is exactly the forward equation for $\mathcal{L}(X_t^x)$). The composition is now a single substitution. Differentiating $u^x(t, \xi) = U(t, x, \xi, \boldsymbol{m}_t)$ once and twice in the state ξ and evaluating at $\xi = X_t^x$ turns $\nabla_\xi u^x(t, X_t^x)$ into $\nabla_\xi U(t, x, X_t^x, \boldsymbol{m}_t)$ and $\mathrm{D}_\xi^2 \, u^x(t, X_t^x)$ into $\mathrm{D}_\xi^2 \, U(t, x, X_t^x, \boldsymbol{m}_t)$; inserting these into the dictionary and writing $m_t^x = \mathcal{L}(X_t^x)$ yields precisely (26.12). (As in theorem 12.6, the form $Z_t^x = \mathrm{D}_\xi^2 \, U \, \sigma$ is the one Itô's formula produces directly from $Y_t^x = \nabla_\xi U(t, x, X_t^x, \boldsymbol{m}_t)$; with the constant symmetric σ of (A-Nondeg) it coincides with the transpose convention $\sigma^\top \, \mathrm{D}_\xi^2 \, U$ of chapter 23.)

It remains to say in what sense $\nabla_\xi U$ is a *decoupling field*, since that term carries the whole structural payload of part (2) and earns both adjectives in the section title. A forward–backward system is, on its face, anticipative: the backward components (Y_t^x, Z_t^x) are pinned by terminal data at T and so appear to depend on the entire future of the forward state. A decoupling field is a *deterministic* function that severs this entanglement — it expresses the backward component at time t through the present forward state and present field alone, $Y_t^x = \nabla_\xi U(t, x, X_t^x, \boldsymbol{m}_t)$, with no reference to the future. Equation (26.12) both names that function — it is the state-gradient of the master function — and exhibits why it well-poses the FBSDE: once the decoupling field is known, the coupled forward–backward problem reduces to a single forward SDE,

$$\mathrm{d}X_t^x = -\partial_p H\big(x, X_t^x, \nabla_\xi U(t, x, X_t^x, \boldsymbol{m}_t)\big)\ \mathrm{d}t + \sigma\ \mathrm{d}B_t^x,$$

whose adjoint Y_t^x is then *read off* the field rather than solved for. That such a deterministic representation exists, is Lipschitz, and is measurable in the type is exactly the graphon decoupling-field theorem theorem 23.21, proved in chapter 23 for the fixed-field per-type FBSDEs. The present theorem only *composes* that family with the master function through (26.9), promoting the fixed-field decoupling fields $U^x(t,\xi)$ of eq. (23.21) to the single measure-dependent object $\nabla_\xi U(t,x,\xi,\boldsymbol{m})$ — precisely the promotion theorem 23.21 announced and deferred to this chapter. The in-book argument therefore runs entirely through chapter 23 for the per-type fields and through theorem 26.3 for their assembly into U; the graphon decoupling-field-to-master promotion is treated in [34, 16], to which we defer only for attribution and further reading.

Finally, the two adjectives. The field $\nabla_\xi U$ is *type-indexed* because the FBSDE was: there is one backward triple (X^x, Y^x, Z^x) for every type x, and the map $x \mapsto \nabla_\xi U(t,x,\cdot,\boldsymbol{m})$ ranges over the whole continuum of types, a per-type gradient rather than a single one. And it is *operator-valued* in the field argument: the sensitivity of the entire family of decoupling fields to a perturbation of the population is governed by the slice field-derivative $\partial_\mu^y \nabla_\xi U(t,x,\xi,\boldsymbol{m})(\zeta)$, an object carrying *two* type labels (x,y) rather than a scalar — nudging the slice at the foreign type y moves the decoupling field of type x through the kernel this double-indexed derivative defines. That kernel is, once more, the $\mathbb{W}$-threaded coupling that runs through every display of the chapter ((26.5)): the only route by which one type's decoupling field feels another type's population is the same operator $\mathbb{W}$, and it is this operator-valued dependence that theorem 26.7 will have to control across the spectrum of $\mathbb{W}$. $\square$

The three faces and the two maps between them are summarized by the lift of the central diagram of Part II, eq. (12.12), to the field setting. Read horizontally, the top row says: restricting the master function to a single field characteristic $\boldsymbol{m}_\cdot$ produces the graphon MFG system's value family $u^x = U(\cdot, x, \cdot, \boldsymbol{m}_\cdot)$; the bottom row says: restricting the decoupling field $\nabla_\xi U$ to the same flow, with $X_t^x \sim m_t^x$, furnishes the FBSDE adjoint Y_t^x through (26.12). Read vertically, the left map is differentiation in the state ξ, which turns the master equation into the decoupling field; the right map is the per-type Feynman–Kac dictionary, which turns the MFG value into the probabilistic FBSDE picture. The figure is identical in shape to its homogeneous ancestor; only the labels carry the lift — the single measure m becomes a field $\boldsymbol{m}$, the state x splits into the type x and the private state ξ, and every arrow now runs uniformly across the continuum of types.

$$\boxed{\begin{array}{ccc} \textbf{Graphon master equation} & \xrightarrow{\text{restrict to } \boldsymbol{m}_t} & \textbf{Graphon MFG system} \\ U(t,x,\xi,\boldsymbol{m}) & & (u^x,\boldsymbol{m}) = (U(\cdot,x,\cdot,\boldsymbol{m}_\cdot),\, \boldsymbol{m}_\cdot) \\ \big\downarrow \nabla_\xi & & \big\downarrow \text{Feynman–Kac} \\ \textbf{Decoupling field} & \xrightarrow{\text{evaluate along } \boldsymbol{m}_t,\ X_t^x\sim m_t^x} & \textbf{Graphon McKean–Vlasov FBSDE} \\ \nabla_\xi U(t,x,\xi,\boldsymbol{m}) & & (X_t^x, Y_t^x, Z_t^x) \end{array}} \tag{26.13}$$

Stand back, and the lift is revealed to be faithful to the last detail: every arrow of the diagram and every identification in the theorem is the homogeneous statement of section 12.5 with a type label attached and the measure m promoted to a field $\boldsymbol{m}$. The genuine graphon novelty is confined to exactly two places, and it is worth saying precisely which, because the remainder of the chapter turns on them. First, the *base space*: the characteristics no longer live in $\mathcal{P}_2(\mathbb{R}^d)$ but in the larger field space $\boldsymbol{\mathcal{P}}_2$, a continuum of measures rather than one, so a single point of the base space is now an entire type-resolved population. Second, the *type integral*: where the homogeneous characteristic system was one HJB/Fokker–Planck pair, the graphon characteristic system (26.6) is a continuum of such pairs, bound together by the $\int_0^1 \cdots \,\mathrm{d}y$ in (26.10) through which one type's value enters every other type's transport. The binding is, as always in this chapter, the single channel (26.5): were $\mathbb{W}$ to vanish the characteristics would separate into $|[0,1]|$ independent classical flows, one per type, and the diagram (26.13) would split into a disjoint union of copies of eq. (12.12). It is precisely the open coupling that fuses the continuum of characteristics into one entangled object, and that is the throughline the chapter has been tracing since (26.4).

This geometric reading does more than organize the equivalence; it hands the next section the lever it needs to force uniqueness. Any classical solution of (26.10)–(26.11) must, by part (1), agree with the value the graphon MFG system assigns along every field characteristic it generates. But the characteristics issuing from a fixed time t_0, as the initial field $\boldsymbol{m}$ ranges over $\boldsymbol{\mathcal{P}}_2$, *fill the whole base space* — through each point of $\{t_0\} \times \boldsymbol{\mathcal{P}}_2$ there passes exactly one such curve, namely the equilibrium flow launched from that field. A classical solution is therefore pinned, at the instant t_0, to the system's value at *every* field at once: if the graphon MFG system is uniquely solvable from each datum, the master function is unique, $U(t_0, x, \xi, \boldsymbol{m}) = u^{x;t_0,\boldsymbol{m}}(t_0, \xi)$ with no freedom left. This is Step 4 of the well-posedness argument of section 26.4, and it explains why uniqueness of U can be settled by the characteristics *before* the harder regularity question — whether a U smooth enough to count as a classical solution exists at all — is touched. The next section takes up exactly that conditional structure, weighing the two competing hypotheses that make the construction good: graphon monotonicity, which keeps the characteristics from crossing at every horizon, versus operator-norm smallness of $\mathbb{W}$ together with a short horizon, which buys the same conclusion by contraction.

One feature of the whole picture deserves to be flagged now, because its eventual loss is the pivot on which the chapter turns. Everything in this section rests on the characteristics being *deterministic* curves: the field flow $(\boldsymbol{m}_t)$ is a definite trajectory in $\boldsymbol{\mathcal{P}}_2$, fixed the moment its initial field is named, so that "the value along the characteristic" is a well-defined function and propagating data along it is meaningful. This is exactly the structure that common noise will dissolve (section 26.5). A shock shared across all types turns $(\boldsymbol{m}_t)$ into a genuine stochastic process — the characteristics become random, there is no longer a single curve through each initial field along which to read U, and the method of characteristics, the organizing principle of this entire section, simply ceases to apply. When that happens the master equation stops being a convenient repackaging of a system one could in principle have solved flow by flow and becomes the *only* surviving formulation; the price it pays for that survival is the double-type-integral second-field-derivative Laplacian that the deterministic theory, with its first-order Hamilton–Jacobi structure, was spared.

26.4 Well-posedness in the monotone regime

The derivation of the previous sections came with a debt, and this section pays as much of it as the current theory can. Theorem 26.3 produced the graphon master equation (26.10) *conditionally* — exactly as theorem 12.3 did one level down — under the standing assumption that the candidate U of (26.8) is already smooth enough for the field derivatives in (26.10) to make sense. Section 26.3.1 then showed that, granting such a U exists, the method of characteristics nails it down uniquely: a classical solution is pinned at each instant t_0 to the system's value at *every* field at once, because the equilibrium characteristics through $\{t_0\} \times \boldsymbol{\mathcal{P}}_2$ fill the whole base space. What neither result settles is the prior question on which both rest — whether a U of the required regularity exists at all. That question is, for graphons, genuinely less settled than in the classical case, and the purpose of this section is to be candid about precisely which parts of the answer are theorems and which are conjectures verified only in special structures. Honesty here requires a three-way split: what is *proved* outright (the equivalence of formulations, and a Lipschitz estimate on U), what is *reduced* to the classical template (the construction, given the graphon existence theory of chapter 24), and what remains genuinely *open* (the differentiability that turns the Lipschitz U into a classical solution).

We organize the discussion around the two competing structural conditions that have run through Parts II and IV, the same pair section 26.3.1 handed us as the alternative hypotheses that keep the characteristics from crossing. The first is *monotonicity*: a sign condition on the coupling that, as in the Lasry–Lions theory of chapter 12, buys uniqueness and a priori control at *every* horizon, however long. The second is *operator-norm smallness* of $\mathbb{W}$ together with a *short horizon*: a quantitative smallness that buys the same conclusion cheaply, by making a best-response map a contraction, but only locally. Classically these two routes are independent — monotonicity is a property of the coupling F alone, with no operator in sight. The graphon novelty, and the crux of this whole section, is that the two become entangled: because the field reaches the cost only through $\mathbb{W}$, the monotonicity condition itself turns into a spectral statement about the network operator, so that "the sign of the interaction" and "the spectrum of $\mathbb{W}$" can no longer be discussed apart. We make that entanglement precise first, then walk the well-posedness argument step by step, flagging the one step where the graphon theory genuinely falls short of its classical model.

Graphon monotonicity and its spectral reading

We begin by lifting the Lasry–Lions condition to the field. Recall (chapter 11, eq. (12.13)) that classically a coupling is monotone when, for any two populations, the difference of the costs they assign, paired against the difference of the populations, is nonnegative — a statement that the interaction *discourages* concentration, pushing the crowd to spread rather than to clump, and the analytic engine behind uniqueness for all horizons. The field version replaces the single measure by the field and adds the one new operation of the lift, an integral over the type label.

Definition 26.6 (Graphon Lasry–Lions monotonicity)**.** The coupling F (and likewise G) is *graphon-monotone* if, for all $\boldsymbol{m}, \boldsymbol{m}' \in \boldsymbol{\mathcal{P}}_2$,

$$\int_0^1 \int_{\mathbb{R}^d} \left(F(x,\xi,\boldsymbol{m}) - F(x,\xi,\boldsymbol{m}')\right) \left(m^x - (m')^x\right)(\mathrm{d}\xi)\ \mathrm{d}x \ \geq\ 0. \tag{26.14}$$

This is the field-integrated lift of the Lasry–Lions inequality (12.13); it is the condition referred to by the tag (A-Mon) in the graphon part.

Read (26.14) slice by slice and the lift is transparent. For each fixed type x the inner integral $\int_{\mathbb{R}^d}(F(x,\xi,\boldsymbol{m})-F(x,\xi,\boldsymbol{m}'))(m^x-(m')^x)(\mathrm{d}\xi)$ is *exactly* the classical Lasry–Lions pairing (12.13) for the type-x cost and the type-x slices; the outer $\int_0^1\cdots\mathrm{d}x$ then averages those per-type pairings over the continuum. So the definition asks not that each type be monotone on its own, but that the *type-average* of the per-type pairings be nonnegative — a weaker, genuinely field-level demand, and the natural one given that the field metric (26.2) itself measures distance as an L^2-over-types average. This is the only sense in which (26.14) departs from a verbatim copy of the homogeneous condition, and it is the same departure — one integral over x — that distinguishes every field object in the chapter from its chapter 12 ancestor.

The reason this definition cannot be left at the slice-by-slice reading, and the reason the graphon theory is harder than a disjoint union of classical ones, is that the cost $F(x,\xi,\boldsymbol{m})$ does not in fact depend on the slice m^x alone: through the coupling form (26.5) it sees the *whole* field, and only through the operator $\mathbb{W}$. That single channel turns the pairing (26.14) into a quadratic form built from $\mathbb{W}$, and it is worth carrying out the substitution in full, because the compression of several steps into one line is exactly the kind of move the reader should see worked. Take the linearized, mean-coupled case of Thread B, where the cost is affine in the aggregate,

$$\widetilde{F}(x,\xi,z) \;=\; -\,c(x)\,\xi\,z \;+\; (\text{terms independent of } z), \tag{26.15}$$

with $c(x)$ the type-x coupling strength and, as fixed in eq. (26.4) for Thread B, the interaction observable $\phi(\zeta)=\zeta$, so that the aggregate felt by type x is the W-weighted average of the foreign type means, $z[\boldsymbol{m}](x)=(\mathbb{W}\bar{m})(x)$ with $\bar{m}(y)=\int\zeta\,m^y(\mathrm{d}\zeta)$. Introduce the shorthand

$$\Delta(y) \;:=\; \int_{\mathbb{R}^d}\phi\;\mathrm{d}\big(m^y-(m')^y\big) \;=\; \int_{\mathbb{R}^d}\zeta\,\big(m^y-(m')^y\big)(\mathrm{d}\zeta) \tag{26.16}$$

for the change, type by type, in the aggregated observable — here simply the change in the type-y mean. Now substitute. Because (26.15) is affine in z, the cost difference at fixed (x,ξ) collapses to a single product,

$$F(x,\xi,\boldsymbol{m})-F(x,\xi,\boldsymbol{m}') \;=\; -\,c(x)\,\xi\,\big(z[\boldsymbol{m}](x)-z[\boldsymbol{m}'](x)\big) \;=\; -\,c(x)\,\xi\,(\mathbb{W}\Delta)(x),$$

the last equality because $z[\boldsymbol{m}](x)-z[\boldsymbol{m}'](x)=(\mathbb{W}(\bar{m}-\bar{m}'))(x)=(\mathbb{W}\Delta)(x)$ by linearity of $\mathbb{W}$ and the definition (26.16) of Δ. Insert this into the monotonicity pairing (26.14) and pull the factor $-c(x)(\mathbb{W}\Delta)(x)$, which is constant in ξ, out of the inner integral:

$$\int_0^1\int_{\mathbb{R}^d}\big(F(x,\xi,\boldsymbol{m})-F(x,\xi,\boldsymbol{m}')\big)\big(m^x-(m')^x\big)(\mathrm{d}\xi)\;\mathrm{d}x=-\int_0^1 c(x)\,(\mathbb{W}\Delta)(x)\Big(\int_{\mathbb{R}^d}\xi\,\big(m^x-(m')^x\big)(\mathrm{d}\xi)\Big)\,\mathrm{d}x.$$

The inner integral that survives is $\int_{\mathbb{R}^d}\xi\,(m^x-(m')^x)(\mathrm{d}\xi)$, which by the very definition (26.16) — with the aggregation observable $\phi(\zeta)=\zeta$ appearing again, now as the test function of the pairing — is exactly $\Delta(x)$. This coincidence is not an accident of bookkeeping but the structural reason a clean quadratic form appears at all: the observable the cost integrates the population against is the *same* observable that builds the aggregate, so the pairing closes on Δ against itself. The result is

$$-\int_0^1 c(x)\,\Delta(x)\,(\mathbb{W}\Delta)(x)\;\mathrm{d}x \;=\; -\,\big\langle\, c\,\Delta,\ \mathbb{W}\Delta\,\big\rangle_{L^2([0,1])}, \tag{26.17}$$

a quadratic form in Δ built from $\mathbb{W}$ and weighted by the coupling profile c.

Equation (26.17) is the crux of the entire section, so it is worth dwelling on what it says. Graphon monotonicity (26.14) holds (to leading order, in this linearized case) precisely when the form $-\langle c\,\Delta, \mathbb{W}\Delta\rangle_{L^2}$ is nonnegative for every admissible Δ — that is, when $\langle c\,\Delta, \mathbb{W}\Delta\rangle \leq 0$. This is a *spectral* condition on the self-adjoint operator $\mathbb{W}$ of definition 15.13 (self-adjoint because W is symmetric under (A-Reg-W)), read against the sign and magnitude of c. Take the cleanest instance, a constant coupling $c(x) \equiv c$: the condition becomes $c\,\langle \Delta, \mathbb{W}\Delta\rangle \leq 0$ for all Δ, which when $c > 0$ demands that $\mathbb{W}$ be negative semidefinite on the reachable directions, and when $c < 0$ demands the opposite. The *sign* of c — whether the interaction is of congestion/competitive type, penalizing alignment with the aggregate, or of imitation/aligning type, rewarding it — selects which half of the spectrum of $\mathbb{W}$ must be empty, and the *size* of the relevant eigenvalues fixes how much monotonicity there is to spend. This is the precise sense, already flagged at chapter 24, in which graphon monotonicity entangles the strategic sign of the interaction with the spectrum of the network operator.

The entanglement has a consequence that the homogeneous theory never forces, and it must be stated plainly because it is what makes (A-Mon) and (A-Coupling) inseparable here. Classically, monotonicity (A-Mon) is a property of the coupling F in isolation: no operator enters its statement, and one verifies it once and for all by inspecting F. In the graphon setting the field touches the cost *only* through $\mathbb{W}$ — this is the one inter-type channel that section 26.1 identified as carrying everything graphon-specific — so the very inequality that defines monotonicity is a joint condition on the coupling sign c *and* the operator $\mathbb{W}$. One cannot certify monotonicity by looking at F alone and then separately impose a smallness threshold on $\mathbb{W}$; the two are bound into the single quadratic form (26.17). Concretely, an interaction that is monotone for one kernel can fail to be for another with the same coupling profile but a differently signed spectrum, and a kernel near the operator threshold of (A-Coupling) is exactly one whose extreme eigenvalue brings the form (26.17) to the edge of degeneracy. This is why, throughout what follows, the operator-norm threshold (A-Coupling) cannot be divorced from the monotonicity question the way it can in chapter 12, and it is the structural fact the LQG computation of section 26.6 will realize concretely, where the spectral condition becomes the requirement that an operator Riccati equation not blow up.

The well-posedness theorem and its honest accounting

With the monotonicity condition understood as a spectral statement, we can state what is proved and stage the proof so that the one open step stands out from the complete ones.

Theorem 26.7 (Well-posedness of the graphon master equation, monotone regime)**.** *Assume* (A-Lip), (A-Growth), (A-Nondeg), (A-Conv), (A-Reg-W), *that H and the couplings F, G are sufficiently smooth with derivatives bounded uniformly in $(x, \boldsymbol{m})$, and that F, G are graphon-monotone* (26.14)*. Suppose moreover that for every $(t_0, \boldsymbol{m})$ the graphon MFG system* (26.6) *has a unique classical solution on $[t_0, T]$, with a priori bounds independent of T and a d_2-Lipschitz dependence on $\boldsymbol{m}_{t_0}$ (the existence/uniqueness theory of chapter 24). Then the function U of* (26.8) *is the unique candidate master function; it is d_2-Lipschitz in $\boldsymbol{m}$ uniformly in (t, x, ξ), and wherever it possesses the field-$\mathcal{C}^2$*

and state-$\mathcal{C}^{1,2}$ regularity of theorem 26.3 it is the unique classical solution of the graphon master equation (26.10)–(26.11)*.*

The qualifier "wherever it possesses the regularity" in the conclusion is not a hedge to be glossed over; it is the precise location of the gap, and the proof is organized to make that location unmistakable. The architecture is that of theorem 12.8, lifted type by type, in four steps: construct U, show it is Lipschitz, show it is differentiable, and verify it solves the equation uniquely. Three of the four lift cleanly. The third does not, and we mark it as a hypothesis rather than dress it as a theorem.

Proof sketch, and an honest accounting of the gap. The architecture is that of theorem 12.8, lifted, and we are explicit about which steps are complete and which are reduced.

Step 1 (construction and single-valuedness). Under the hypotheses, chapter 24 provides a unique solution of (26.6) for each $(t_0, \boldsymbol{m})$ with bounds uniform in T, and (26.8) then defines U pointwise by reading that solution's value at the initial instant of its own problem. The single-valuedness of U *is* uniqueness of the system: without it "the equilibrium from $\boldsymbol{m}$" would name a set and (26.8) would not define a function. Two facts make this step work for all horizons, and both trace to monotonicity. First, the graphon-monotone coupling (26.14) is what prevents the equilibrium characteristics — the field flows of section 26.3.1 — from crossing as the horizon T grows, exactly as the classical inequality (12.13) did in chapter 12; were two distinct flows to cross, two values would be assigned to one field and U would fail to exist as a function. Second, monotonicity supplies the a priori bound uniform in T, so that the construction does not deteriorate as the horizon lengthens. Given the existence theory of chapter 24, this step is complete.

Step 2 (Lipschitz estimate in the field). We claim $|U(t, x, \xi, \boldsymbol{m}) - U(t, x, \xi, \boldsymbol{m}')| \le C\, d_2(\boldsymbol{m}, \boldsymbol{m}')$, uniformly in (t, x, ξ). The mechanism is the field lift of the classical Step 2 pairing, and it is worth seeing where each hypothesis enters. One compares the two equilibria launched from the nearby fields $\boldsymbol{m}, \boldsymbol{m}'$, pairs the difference of their HJB systems against the difference of their field-Fokker–Planck systems, and — the one new operation — *integrates the resulting identity over the type label.* Three forces then meet. The graphon-monotone coupling (26.14) enters this energy identity with a favorable sign, exactly as the quadratic form (26.17) predicts, and supplies the dissipation that closes the estimate. The cross terms that monotonicity does not directly kill are of two kinds: those local to a type-slice are absorbed by (A-Nondeg), whose uniformly nondegenerate $\sigma\sigma^\top$ gives the parabolic smoothing in the state ξ that controls the difference of the value gradients; and those that couple distinct slices — the genuinely graphon terms, in which one type's discrepancy feeds another's through the kernel — are bounded by the operator norm $\|\mathbb{W}\|$, which quantifies exactly how strongly the type integral $\int_0^1 \cdots \mathrm{d}y$ mixes the slices. The role of $\|\mathbb{W}\|$ here is the analytic shadow of its appearance in the spectral form (26.17): the same operator that decides whether monotonicity holds also sets the size of the inter-slice coupling the estimate must dominate. In practice one need not redo this pairing from scratch, because chapter 24 already delivers its conclusion at the level of the *system*: by hypothesis the field-MFG pair $(u^{\cdot}, \boldsymbol{m})$ depends d_2-Lipschitz on its initial field $\boldsymbol{m}_{t_0}$, with a constant independent of the horizon. Since $U(t, x, \xi, \boldsymbol{m}) = u^{x;t,\boldsymbol{m}}(t, \xi)$ is precisely that system's value read at the initial time of its own problem (26.8), the system Lipschitz bound transfers *directly* to U, giving the claimed estimate with the same constant. This is the graphon lift of Step 2 of theorem 12.8, where the identical pairing is carried out for a single measure; integrating the monotonicity identity over types and absorbing the $\|\mathbb{W}\|$-weighted cross terms by (A-Nondeg) is the only change. As a by-product the estimate bounds the slice flat derivative, hence the Lions field $\partial^y_\mu U$, uniformly in the type — the first-order field regularity that Step 3 must upgrade to genuine differentiability.

Step 3 (differentiability in the field). This is where the classical and graphon theories part, and the honesty of the whole section lives in being exact about why. A Lipschitz function need not be differentiable, so Step 2 alone does not entitle us to the derivatives $\partial^y_\mu U$ and $\partial_\zeta\partial^y_\mu U$ that the master equation (26.10) contains as *genuine* objects rather than mere difference quotients. To produce them one differentiates the forward–backward system (26.6) itself in the direction of a single slice perturbation $m^y \to m^y + \epsilon(m' - m^y)$. The result is a *linearized graphon MFG system*: a forward–backward pair, posed simultaneously over the whole continuum of types, for the first-order response $(\partial u, \partial m)$ of the equilibrium to the perturbation. Its source is concentrated at the perturbed type y, but its solution is felt at every type, because the linearized coupling propagates the disturbance through $\mathbb{W}$ just as the nonlinear one does. If this linearized system is uniquely solvable with estimates uniform in the perturbed type y, its solution *is* the flat derivative $\delta U/\delta m^y$, its state-gradient the Lions derivative $\partial^y_\mu U$, and their continuity in $(\boldsymbol{m}, \zeta, y)$ follows from continuity of the linearized data; a second linearization, in a second slice y', would deliver the second-order field regularity. The obstacle is not the existence of *a* solution but the demand for estimates that are uniform in two directions at once: *across the continuum of types*, so that no slice's response blows up relative to its neighbours as the type label varies, and *against the spectrum of* $\mathbb{W}$, so that the inter-slice feedback the operator induces does not amplify without control as one approaches the threshold of (A-Coupling). It is the combination — a uniform-in-type estimate that also survives the full strength of the operator — that has no general proof. In the classical case (12.8) the corresponding linearized-system estimates and the genuine twice-differentiability in m are carried out in full; the standard reference for that program is [37], and we cite it here *for attribution* — to name the classical template the graphon case aims at — and emphatically *not* as a stand-in for a graphon argument, which would violate the self-containedness the book holds itself to. No theorem at the strength of [37] is presently available over a continuum of types coupled by a general admissible kernel. What *does* rescue Step 3 is additional structure that collapses the type continuum or the spectrum to something finite-dimensional and explicitly controllable: a separable or finite-rank kernel, for which $\mathbb{W}$ has finitely many nonzero eigenvalues and the linearized system reduces to a finite coupled set; a block (piecewise-constant) graphon, for which the continuum of types degenerates to finitely many populations and the problem becomes a classical multi-population MFG to which the homogeneous theory applies verbatim; and, sharpest of all, the linear–quadratic case of section 26.6, where the value is quadratic in the state, the field derivatives are computed in closed form, and the entire differentiability question reduces to the solvability of an operator Riccati equation. In each of these the uniform-in-type, uniform-in-spectrum estimate can be exhibited by hand. We therefore state Step 3 honestly as a hypothesis — verified in the special structures just named, open in general — and defer the formal tier-by-tier accounting to section 26.7. This is the one place where the graphon master equation is not yet on the footing its classical ancestor enjoys.

Step 4 (verification and uniqueness). Wherever Steps 1–3 hold, the loop closes exactly as in section 26.3.1. Theorem 26.3 shows the constructed U, now known to carry the required derivatives, solves the master equation (26.10); and theorem 26.5 forces uniqueness without any further regularity input, by the characteristic argument of the previous section: any classical solution must agree with the system's (unique) value along every field characteristic, and the characteristics through $\{t_0\} \times \boldsymbol{\mathcal{P}}_2$ fill the base space, leaving no field at which a competing solution could differ. Uniqueness is thus settled by the deterministic characteristics — a point worth remembering, because it is precisely this mechanism that common noise will dismantle in section 26.5.

In summary, the accounting is three-way. We prove outright the *equivalence* of the formulations (theorems 26.3 and 26.5) and the *Lipschitz estimate* on U (Steps 1–2). We *reduce* the construction to the graphon existence theory of chapter 24. And we leave *open* the genuine classical *regularity* (Step 3), reducing it to a linearized-system analysis that is complete only in the special structures named above. We do not claim a general graphon well-posedness theorem of the strength of [37]; none is known, and the closing section keeps the book honest by laying out exactly that boundary. □

There is, alongside this conditional all-horizons result, an *unconditional* statement that costs nothing beyond smallness, and naming it sharpens what monotonicity is actually for.

Remark 26.8 (Short horizon and the operator threshold)**.** The honest *unconditional* statement, valid without any monotonicity assumption at all, is the contraction one. If either the horizon T is small or the operator norm $\|\mathbb{W}\|$ is below the threshold (A-Coupling), the best-response map on the field flow is a contraction (chapter 24): iterating "given a field flow, compute each type's optimal response, recompute the field it induces" converges to a unique fixed point. The construction (26.8) is then well defined, inherits the smoothness of the data directly — no linearized-system analysis is needed, because the contraction supplies differentiable dependence on the datum for free — and the graphon master function exists, is unique, and is classical, *with no gap of the Step 3 kind*. This is the graphon face of remark 12.11. What is instructive is how the roles split. Classically the cheap route to local well-posedness is smallness of T alone; in the graphon setting that role is *shared* between two knobs, the horizon T and the operator norm $\|\mathbb{W}\|$, and either one being small suffices. The horizon controls how long errors have to compound; the operator norm controls how strongly a discrepancy at one type feeds back, through the kernel, to the others — the very mixing measured in Step 2. A long horizon can be tolerated if the network coupling is weak, and a strong network if the horizon is short; only when both are large does the contraction fail and one must fall back on monotonicity. The substantive open problem is exactly to remove the smallness on *both* knobs and replace it by monotonicity *for all horizons and all admissible kernels* — which, as Step 3 made plain, theorem 26.7 achieves only partially.

The boundary this section has drawn — proved equivalence and Lipschitz estimate on one side, open differentiability on the other — is handed forward in two directions. To section 26.7 it goes for the formal tier-by-tier accounting that closes the chapter, where the Step 3 obstruction is set beside the other conditional pieces of the theory and the proved core is separated cleanly from the conjectural shell. And to section 26.6 it goes as a challenge met: the linear–quadratic thread is the special structure in which everything *does* close, where the abstract "spectral condition on $\mathbb{W}$" of (26.17) stops being a conjecture and becomes the concrete, checkable requirement that an operator Riccati equation admit a global solution on $[0, T]$. The reader should carry into that computation the expectation set here: the place where Step 3 is rescued is the place where the field derivatives are available in closed form, and the spectral threshold that this section could only state is one the LQG model will let us see directly, as the leading eigenvalue of $\mathbb{W}$ driving — or failing to drive — a scalar Riccati equation to blow-up.

26.5 Common (aggregate) noise

Two threads laid down earlier in the chapter now converge, and their meeting is the chapter's decisive payoff. Section 26.1 promised that the all-contingencies object U — a mere convenience in the deterministic theory, where one could always fall back on solving the forward–backward system from a fixed datum — would become an outright *necessity* the moment the population field turned genuinely random. And section 26.3.1 rested the entire deterministic theory on one geometric picture: the graphon master equation is a *first-order* Hamilton–Jacobi equation on the field space $\boldsymbol{\mathcal{P}}_2$, its characteristics are the equilibrium field Fokker–Planck flows, and solving it amounts to running a single such curve and reading U off along it. Section 26.4 then mapped the boundary of that deterministic theory. This section crosses the boundary. We add a shock shared across all types, and the effect is total: the field flow ceases to be a curve and becomes a stochastic process; there is no longer any single characteristic to run; the deterministic forward–backward system (26.6) and the characteristic dictionary of section 26.3.1 both dissolve; and the master equation, the one object defined for *every* field at once, is left standing as the only surviving formulation. The promise of section 26.1 is thereby made good in its strongest form. And the equation pays for its new indispensability by growing a genuine second-order operator over the type continuum — the field-space Laplacian whose conspicuous *absence* the notation-watch of section 26.3 singled out as the very signature of "no common noise." That term now switches on, and accounting for it is the technical heart of the section.

We add the shock concretely. Let $B^0 = (B^0_t)$ be a single Brownian motion, independent of the private noises $(B^x)_{x\in[0,1]}$, common to the entire population, and let each type-x agent be driven by it:

$$\mathrm{d}X^x_t \;=\; \alpha^x_t\,\mathrm{d}t \;+\; \sigma\,\mathrm{d}B^x_t \;+\; \sigma_0\,\mathrm{d}B^0_t, \qquad X^x_0 \sim m^x_0, \tag{26.18}$$

with σ_0 a constant common-noise volatility (the type-independent case; we comment on type-dependent common noise at the end of the section). The single increment $\sigma_0\,\mathrm{d}B^0_t$ is added to the dynamics of *every* agent of *every* type at once: it is one and the same random push, felt coherently across the whole population. It is exactly this coherence — not the mere presence of extra noise — that reorganizes the theory; were each type handed its own independent aggregate shock the slices would still fluctuate separately and nothing structural would change. Write $\mathbb{F}^0 = (\mathcal{F}^0_t)$ for the filtration generated by B^0. The right population object is then no longer the unconditional law of a type's state, because averaging over the common shock *as well as* the private noise would wash out precisely the coherent response we have just built in, returning us to a deterministic background. What survives the shock is the law *conditioned* on the realized common path — the *conditional field*

$$m^x_t \;=\; \mathcal{L}(X^x_t \,|\, \mathcal{F}^0_t), \qquad x \in [0,1], \tag{26.19}$$

the configuration of type x's crowd *given* everything the global shock has done up to time t. With the common path frozen by the conditioning, the only randomness left inside each slice is the independent private noise, over which a law of large numbers still averages; but the slice that results is now carried along *with* the shock rather than sitting still. The whole field $\boldsymbol{m}_t = (m_t^x)_x$ is therefore itself a *stochastic process* valued in $\boldsymbol{\mathcal{P}}_2$ and adapted to $\mathbb{F}^0$: a random point of field space, re-randomized at every instant by an increment $\mathrm{d}B_t^0$ that no conditioning on the past can anticipate.

Heuristic (non-rigorous)

The conditional McKean–Vlasov picture. Fix, in imagination, one realized path of the common noise B^0 and condition on it. Two sources of randomness drove each agent: the private noise B^x, idiosyncratic to the agent, and the common noise B^0, shared by all. The conditioning removes the second, and what is left inside each type is a continuum of agents driven by *independent* private noises — exactly the configuration in which the law of large numbers operated in the deterministic theory of chapter 22. So the empirical distribution of type x still concentrates on a deterministic conditional law; the law of large numbers has *not* failed. What has changed is what it concentrates *around*: the averaging now happens around the common-noise path, and the limiting slice is dragged along by the realized B^0 rather than standing still.

Made concrete, the conditional field $\boldsymbol{m}_t$ obeys a *stochastic* Fokker–Planck equation, one slice at a time. Each m_t^x still satisfies the deterministic transport-and-spreading of (26.6b), but the common increment $\sigma_0 \, \mathrm{d}B_t^0$ contributes two further effects, worth separating because they are genuinely different in kind. First, because every agent of type x receives the *same* push $\sigma_0 \, \mathrm{d}B_t^0$, the whole slice is *rigidly translated* by that increment — a transport of the entire conditional law, not a smearing of it; this is a first-order martingale term carrying $\mathrm{d}B_t^0$. Second, the part of the common fluctuation that the conditioning at time t has not yet resolved contributes, through Itô's correction, an extra $\frac{1}{2}\sigma_0\sigma_0^\top$ *spreading* of the slice, identical in form to the private-noise spreading $\frac{1}{2}\sigma\sigma^\top$ already present and merely upgrading the diffusion coefficient. The rigid translation is the genuinely new feature; the extra spreading is only a coefficient bump. Crucially, both are driven by the *same* B^0 in every slice at once — the single fact that will, two displays from now, knit all types' fluctuations together into one coherent second-order object.

The consequence for the equilibrium is decisive. It is no longer a deterministic forward–backward field flow but a *random* one: the population reacts coherently to each realization of the global shock, the realized field at time t depends on the entire history of B^0 up to t, and the value functions must be adapted to information disclosed only as time runs forward. There is no single curve $\boldsymbol{m}_t$ to solve for in advance — one cannot know "the realized slice" before the shock that produces it has happened — and so the deterministic system (26.6), which presupposed exactly such a curve, loses its meaning, just as the characteristic picture of section 26.3.1 that was built on it.

This is precisely the situation the master equation was built for, and the reason section 26.1 could promise its necessity would become absolute. The bare value family of (26.6) was a function of (t, ξ) pinned to one deterministic field flow; with that flow gone there is nothing left to pin it to, and it cannot even be written down. The master function suffers no such collapse. $U(t, x, \xi, \boldsymbol{m})$

was constructed in (26.8) to assign a value to *every* field $\boldsymbol{m} \in \boldsymbol{\mathcal{P}}_2$, in advance and independently of which one is realized — it is the equilibrium cost-to-go of a type-x agent at ξ *whatever* the population field happens to be. Precisely because it is defined for every contingency at once, it can be *composed* with the random field: the realized value of a type-x agent is the stochastic process

$$u_t^x(\xi) \;=\; U\big(t, x, \xi, \boldsymbol{m}_t\big),$$

the master function evaluated along the conditional flow, and the optimal feedback is read off exactly as in the deterministic case, $\nabla_\xi U(t, x, X_t^x, \boldsymbol{m}_t)$, now itself a process adapted to $\mathbb{F}^0$ through its third and fourth arguments — the lift to the random flow of the decoupling-field reading (26.12). The flow-consistency identity (26.9) thus survives the shock verbatim, with its deterministic flow replaced by the conditional one; everything downstream of it can be recomputed by differentiating it along the new, random characteristic. This is the exact graphon lift of section 12.7: there, common noise turned the homogeneous master equation from a convenience into the only available description; here the same reversal occurs one level up, over the entire field of types. The master equation is no longer a luxury but the sole surviving formulation.

To find the equation U satisfies along the random flow we need two ingredients, and the section assembles them in turn: the object that gets differentiated *twice* in the field — absent from the entire deterministic development, switched on now for the first time — and the Itô formula that does the differentiating along the random flow. We begin with the new derivative.

Why a *second* field derivative should surface now, when the deterministic chain rule of lemma 26.2 never reached past the first, is worth seeing before the definition is written down. In the deterministic theory each slice was transported by its own drift and spread by its own *independent* private noise; distinct slices fluctuated independently, their cross-correlations vanished, and the chain rule closed at first order in the field with only the single-variable Jacobian $\partial_\zeta \partial_\mu^y \Psi$ of the slice Lions derivative. Under common noise every slice is driven by the *same* B^0, so distinct slices are now perfectly correlated, and Itô's correction will pair the response of a functional to a perturbation of slice y with its response to a perturbation of slice y'. That pairing is a genuine second-order object on the field space, indexed by *two* types at once. It is the second field derivative, and we define it first.

Definition 26.9 (Second field derivative)**.** Let $\Psi : \boldsymbol{\mathcal{P}}_2 \to \mathbb{R}$ be fully $\mathcal{C}^2$ (definition 26.1) and suppose, for each fixed slice y and foreign state ζ, the $\mathbb{R}^d$-valued map $\boldsymbol{m} \mapsto \partial_\mu^y \Psi(\boldsymbol{m})(\zeta)$ is itself slice-differentiable. The *second field derivative* of Ψ is the family

$$\partial_\mu^y \partial_\mu^{y'} \Psi(\boldsymbol{m})(\zeta, \zeta') \;:=\; \partial_\mu^{y'}\big[\, \boldsymbol{m} \mapsto \partial_\mu^y \Psi(\boldsymbol{m})(\zeta) \,\big](\zeta') \;\in\; \mathbb{R}^{d \times d},$$

indexed by the *pair* of types (y, y') and evaluated at the pair of foreign states (ζ, ζ'): the slice-y' Lions derivative of the slice-y Lions derivative. Equivalently $\partial_\mu^y \partial_\mu^{y'} \Psi = \nabla_\zeta \nabla_{\zeta'} \frac{\delta^2 \Psi}{\delta m^y \delta m^{y'}}$, where the second flat derivative $\frac{\delta^2 \Psi}{\delta m^y \delta m^{y'}}(\boldsymbol{m})(\zeta, \zeta')$ is the slice-y' flat derivative of $\boldsymbol{m} \mapsto \frac{\delta \Psi}{\delta m^y}(\boldsymbol{m})(\zeta)$. This is the slice-wise lift of the classical second Lions derivative ∂_μ^2 of definition D.6: restricted to a single slice it *is* ∂_μ^2, and the type pair (y, y') is the only new index. Under joint measurability in (y, y') and continuity in $(\boldsymbol{m}, \zeta, \zeta')$ it is symmetric, $\partial_\mu^y \partial_\mu^{y'} \Psi(\boldsymbol{m})(\zeta, \zeta') = \big(\partial_\mu^{y'} \partial_\mu^y \Psi(\boldsymbol{m})(\zeta', \zeta)\big)^\top$. We say Ψ is *fully $\mathcal{C}^2$ with second field derivative* when this object exists, is jointly measurable, and is continuous and bounded on bounded sets.

Two readings of $\partial_\mu^y \partial_\mu^{y'} \Psi$ will recur and it pays to fix them now. When $y = y'$ it is the ordinary classical second Lions derivative definition D.6 of Ψ restricted to that single slice — the object that already governed common noise in the homogeneous theory of chapter 12. When $y \neq y'$ it is the genuinely new content: it measures how the response of Ψ to a reweighting of slice y is itself altered by a reweighting of a *different* slice y', a cross-type curvature that has no homogeneous ancestor at all and that, in the deterministic theory, never had occasion to appear because distinct slices were uncorrelated. It is precisely this off-diagonal, two-type piece that the common noise will activate.

With the new derivative in hand, the second ingredient is the Itô formula that carries a functional of the field along the random flow — the stochastic upgrade of the deterministic chain rule lemma 26.2, with the conditional slices of (26.19) now solving *stochastic* Fokker–Planck equations rather than deterministic ones.

Lemma 26.10 (Stochastic field chain rule under common noise)**.** *Let $\Psi : \boldsymbol{\mathcal{P}}_2 \to \mathbb{R}$ be fully $\mathcal{C}^2$ with second field derivative (definition 26.9), derivatives bounded and Lipschitz on bounded sets uniformly in the type indices. Let $(\boldsymbol{m}_t)$ be the conditional field flow (26.19) whose slices solve the* stochastic *Fokker–Planck equations*

$$\mathrm{d}m_t^y = \Big[\tfrac{1}{2}\operatorname{tr}\big((\sigma\sigma^\top + \sigma_0\sigma_0^\top)\,\mathrm{D}_\zeta^2\, m_t^y\big) - \operatorname{div}\big(m_t^y\,\mathbf{b}_t^y\big)\Big]\,\mathrm{d}t - \sigma_0^\top \nabla_\zeta m_t^y\ \mathrm{d}B_t^0 \qquad (y \in [0,1]), \tag{26.20}$$

driven by the common Brownian motion B^0 and a measurable family of drift fields $\mathbf{b}_t^y$ of at most linear growth with $\int_0^T\int_0^1\int |\mathbf{b}_t^y|^2\ \mathrm{d}m_t^y\ \mathrm{d}y\ \mathrm{d}t < \infty$. Then $t \mapsto \Psi(\boldsymbol{m}_t)$ is an Itô process and

$$\begin{aligned}\mathrm{d}\Psi(\boldsymbol{m}_t) = \Big[\int_0^1\!\!\int \partial_\mu^y \Psi \cdot \mathbf{b}_t^y\ \mathrm{d}m_t^y\ \mathrm{d}y + \tfrac{1}{2}\int_0^1\!\!\int \operatorname{tr}\big((\sigma\sigma^\top + \sigma_0\sigma_0^\top)\,\partial_\zeta\partial_\mu^y\Psi\big)\,\mathrm{d}m_t^y\ \mathrm{d}y \\ + \tfrac{1}{2}\int_0^1\!\!\int_0^1\!\!\iint \operatorname{tr}\big(\sigma_0\sigma_0^\top\,\partial_\mu^y\partial_\mu^{y'}\Psi(\boldsymbol{m}_t)(\zeta,\zeta')\big)\,\mathrm{d}m_t^y(\zeta)\ \mathrm{d}m_t^{y'}(\zeta')\ \mathrm{d}y\ \mathrm{d}y'\Big]\,\mathrm{d}t \\ + \int_0^1\!\!\int \partial_\mu^y\Psi \cdot \sigma_0\ \mathrm{d}m_t^y\ \mathrm{d}y\ \ \mathrm{d}B_t^0.\end{aligned} \tag{26.21}$$

Proof sketch. The argument is, as for the deterministic chain rule, two moves: a per-slice conditional Itô formula, and the sum over the type continuum — but the second move now carries the whole new content, because the common noise correlates the slices and the sum acquires an off-diagonal part. We carry the algebra in-book, citing the conditional Itô formula theorem D.8 only for attribution.

Move (a): per slice, the conditional Itô formula. Fix one type y, freeze every other slice, and apply theorem D.8 — the Itô formula along the conditional law $m_t^y = \mathcal{L}(X_t^y \mid \mathcal{F}_t^0)$ of the diffusion (26.18). It produces four contributions, and each is the conditional counterpart of a term already understood. The transport drift $\partial_\mu^y\Psi \cdot \mathbf{b}_t^y$ is the slice's optimal-feedback transport, exactly as in lemma 26.2. The spreading carries the *upgraded* diffusion $\sigma\sigma^\top + \sigma_0\sigma_0^\top$: the common noise smears the conditional slice just as the private noise does — the second of the two effects isolated in the heuristic above — which is the slice-wise origin of the second integrand in (26.21). The second-Lions term $\frac{1}{2}\operatorname{tr}(\sigma_0\sigma_0^\top\partial_\mu^2\Psi)$ is the curvature contribution of the slice's own martingale fluctuation, the conditional analogue of the common-noise term in chapter 12. And the martingale $\partial_\mu^y\Psi \cdot \sigma_0\ \mathrm{d}B_t^0$ records the rigid translation of the slice by the unresolved increment $\mathrm{d}B_t^0$ — the first effect of the heuristic. So far this is the homogeneous common-noise calculation of section 12.7, run inside one type with every other type held fixed.

Move (b): sum over types, and the cross-slice correlation. Now release the freezing and sum the per-slice contributions over the continuum, as in Move (b) of lemma 26.2. The transport, spreading, and martingale terms each acquire merely the outer $\int_0^1 \cdots \mathrm{d}y$, reproducing the first, second, and last lines of (26.21). The second-order term is where the lift is genuinely new, and the reason is the single fact that every slice is driven by the *same* B^0. The conditional slice m_t^y has, by (26.20), the martingale part $-\sigma_0^\top \nabla_\zeta m_t^y \, \mathrm{d}B_t^0$; hence for two distinct types the cross quadratic variation

$$\mathrm{d}\langle m^y, m^{y'} \rangle_t \;=\; (\sigma_0^\top \nabla_\zeta m_t^y) \otimes (\sigma_0^\top \nabla_\zeta m_t^{y'}) \; \mathrm{d}t \;\neq\; 0 \qquad (y \neq y'),$$

because both martingale parts are proportional to the *one* increment $\mathrm{d}B_t^0$ and so are perfectly correlated — the very feature that vanished in the deterministic theory, where each slice carried its own independent noise and these covariations were zero. Itô's second-order correction for a functional of all the slices therefore picks up not only the diagonal $y = y'$ contributions (the per-slice second-Lions terms of Move (a)) but also the entire off-diagonal $y \neq y'$ family. Both are governed by the second field derivative of definition 26.9 — the diagonal by its restriction to one slice, the off-diagonal by its genuine two-type part — and summing them is summing over *both* type labels independently. The per-slice second-Lions term is thus promoted to the *double* type integral $\int_0^1 \int_0^1 \cdots \mathrm{d}y \; \mathrm{d}y'$ of the third line of (26.21), contracted through $\sigma_0 \sigma_0^\top$ against $\partial_\mu^y \partial_\mu^{y'} \Psi$. This single promotion — diagonal sum $\to$ double integral — is the entire structural difference between the deterministic and the common-noise field calculus.

The linear-growth and integrability hypotheses license the integrations by parts and the Fubini interchanges exactly as in lemma 26.2; the truncation argument of that proof carries over slice by slice with the conditional Itô formula in place of the deterministic one, and the martingale term is square-integrable under the same uniform L^2 bound. The rigorous Itô–Wentzell statement on $\boldsymbol{\mathcal{P}}_2$ that underlies the displayed bookkeeping is the field lift of theorem D.8, organized for the graphon setting in [16]; we cite it for the analytic justification but the displayed algebra is the whole argument. $\square$

With both ingredients in hand we can differentiate the value process $u_t^x(\xi) = U(t, x, \xi, \boldsymbol{m}_t)$ along the conditional flow and read off the equation. The derivation is the stochastic twin of theorem 26.3: there the deterministic chain rule expanded $\mathrm{d}U/\,\mathrm{d}t$ and we matched against the type-x HJB; here Itô's formula expands $\mathrm{d}U$ and we match the resulting *drift* against the same HJB, the martingale part integrating to zero. The new subtlety is that U now depends on t through *two* channels that both carry the common increment $\sigma_0 \; \mathrm{d}B_t^0$ — the agent's own state $\xi = X_t^x$ and the field $\boldsymbol{m}_t$ — so Itô couples them. It is worth writing the expansion out, because the coupling is exactly where the two new terms come from. Apply Itô–Wentzell to $U(t, x, X_t^x, \boldsymbol{m}_t)$:

$$\begin{aligned}\mathrm{d}U = \partial_t U \; \mathrm{d}t \;+\; \nabla_\xi U \cdot \mathrm{d}X_t^x \;+\; \tfrac{1}{2}\,\mathrm{tr}\big(\mathrm{D}_\xi^2 U \; \mathrm{d}\langle X^x \rangle_t\big) \;+\; \big[\text{field drift of lemma 26.10}\big] \; \mathrm{d}t \\ +\; \Big(\int_0^1 \!\! \int \partial_\mu^y U \cdot \sigma_0 \; \mathrm{d}m_t^y \; \mathrm{d}y\Big) \, \mathrm{d}B_t^0 \;+\; \mathrm{d}\big\langle\, \nabla_\xi U \cdot X^x, \text{ field martingale} \,\big\rangle_t.\end{aligned} \tag{26.22}$$

The first line collects the ordinary Itô expansion in the agent's own state together with the field drift already computed in lemma 26.10; the second line collects the field martingale of that lemma and the cross-variation between the two B^0-driven channels. Two of these pieces are new relative to the deterministic derivation, and they are precisely the two places the common increment enters twice.

First, the quadratic variation of the agent's own state is now $\mathrm{d}\langle X^x\rangle_t = (\sigma\sigma^\top + \sigma_0\sigma_0^\top)\,\mathrm{d}t$, since X^x carries both the private and the common Brownian increments; so the term $\frac{1}{2}\operatorname{tr}(\mathrm{D}^2_\xi U\;\mathrm{d}\langle X^x\rangle_t)$ contributes, on top of the $\frac{1}{2}\operatorname{tr}(\sigma\sigma^\top\,\mathrm{D}^2_\xi U)$ already in (26.10), the extra agent diffusion $\frac{1}{2}\operatorname{tr}(\sigma_0\sigma_0^\top\,\mathrm{D}^2_\xi U)$. Second, the cross-variation in the last term of (26.22) is nonzero precisely because both channels are driven by the *same* B^0: the agent's state contributes the increment $\nabla_\xi U\cdot\sigma_0\,\mathrm{d}B^0_t$ and the field contributes the martingale $\big(\int_0^1\!\int \partial^y_\mu U\cdot\sigma_0\,\mathrm{d}m^y_t\,\mathrm{d}y\big)\,\mathrm{d}B^0_t$, and their joint quadratic variation pairs the agent-state gradient ∇_ξ with the slice Lions derivative ∂^y_μ, both contracted through $\sigma_0\sigma_0^\top$. Because mixed derivatives commute, the resulting integrand is the single mixed object $\nabla_\xi\partial^y_\mu U$ — the agent–field cross term — integrated against m^y over the foreign state and over the type. (Had the agent's own noise and the common noise been independent, this cross-variation would vanish and the term would be absent; it is a pure consequence of the shared shock.)

Collecting the drift of (26.22) — which includes the field drift of lemma 26.10, itself carrying the population-spreading upgrade $\sigma\sigma^\top\to\sigma\sigma^\top+\sigma_0\sigma_0^\top$ and the double-type-integral second-field-derivative term — and matching it against the type-x HJB exactly as in theorem 26.3, the master equation acquires, added to the left-hand side of (26.10), *four* families of σ_0-terms. Two are *coefficient upgrades* of second-order lines already present in (26.10) — the agent's own diffusion and the population spreading, each promoting $\sigma\sigma^\top\to\sigma\sigma^\top+\sigma_0\sigma_0^\top$ — and two are *genuinely new*, the agent–field cross term just isolated and the double-type-integral field Laplacian inherited from lemma 26.10:

$$
\begin{aligned}
&-\tfrac{1}{2}\operatorname{tr}\big(\sigma_0\sigma_0^\top\,\mathrm{D}^2_\xi U\big)\;-\;\tfrac{1}{2}\int_0^1\!\!\int_{\mathbb{R}^d}\operatorname{tr}\big(\sigma_0\sigma_0^\top\,\partial_\zeta\partial^y_\mu U(t,x,\xi,\boldsymbol{m})(\zeta)\big)\,m^y(\mathrm{d}\zeta)\;\mathrm{d}y\\
&-\;\int_0^1\!\!\int_{\mathbb{R}^d}\operatorname{tr}\big(\sigma_0\sigma_0^\top\,\nabla_\xi\partial^y_\mu U(t,x,\xi,\boldsymbol{m})(\zeta)\big)\,m^y(\mathrm{d}\zeta)\;\mathrm{d}y\\
&-\;\tfrac{1}{2}\int_0^1\!\!\int_0^1\!\!\int_{\mathbb{R}^d}\!\int_{\mathbb{R}^d}\operatorname{tr}\big(\sigma_0\sigma_0^\top\,\partial^y_\mu\partial^{y'}_\mu U(t,x,\xi,\boldsymbol{m})(\zeta,\zeta')\big)\,m^y(\mathrm{d}\zeta)\,m^{y'}(\mathrm{d}\zeta')\;\mathrm{d}y\;\mathrm{d}y',
\end{aligned}
\tag{26.23}
$$

where $\partial^y_\mu\partial^{y'}_\mu U$ is the second field derivative (definition 26.9). It pays to read the four families one at a time, since each has a distinct mechanical origin in the Itô expansion (26.22) and a distinct role in the equation. *(i) The agent's own extra diffusion* $-\frac{1}{2}\operatorname{tr}(\sigma_0\sigma_0^\top\,\mathrm{D}^2_\xi U)$ is the simplest: the common noise enlarges the quadratic variation of the agent's private state from $\sigma\sigma^\top$ to $\sigma\sigma^\top+\sigma_0\sigma_0^\top$, so the ordinary second-order Itô term in ξ gains the $\sigma_0\sigma_0^\top$ piece. It is local in ξ and involves no type integral at all; it would be present even for an isolated agent. *(ii) The population self-spreading* $-\frac{1}{2}\int_0^1\!\int\operatorname{tr}(\sigma_0\sigma_0^\top\partial_\zeta\partial^y_\mu U)\,m^y\;\mathrm{d}y$ is the matching upgrade of the third line of (26.10): it arises because each conditional slice now spreads by the full $\sigma\sigma^\top+\sigma_0\sigma_0^\top$ of (26.20), and U responds through the same single-variable Lions Jacobian that carried the private spreading, summed over types. *(iii) The agent–field cross term* $-\int_0^1\!\int\operatorname{tr}(\sigma_0\sigma_0^\top\nabla_\xi\partial^y_\mu U)\,m^y\;\mathrm{d}y$ is the joint quadratic variation isolated in (26.22): the agent's own state and the field both translate under the *same* $\sigma_0\;\mathrm{d}B^0$, and Itô's correction pairs the agent-state gradient with the slice Lions derivative, the mixed object $\nabla_\xi\partial^y_\mu U$ under a single type integral. *(iv) The double-type-integral field Laplacian* $-\frac{1}{2}\int_0^1\!\int_0^1\!\iint\operatorname{tr}(\sigma_0\sigma_0^\top\,\partial^y_\mu\partial^{y'}_\mu U)\,m^y\,m^{y'}\;\mathrm{d}y\;\mathrm{d}y'$ is the genuinely new object, the one the entire deterministic development was missing. Its decisive feature — the only way in which it exceeds the classical common-noise formula (12.17) — is its *type structure*: the *double* type integral $\int_0^1\!\int_0^1\cdots\mathrm{d}y\;\mathrm{d}y'$. A single common noise correlates *all pairs of types* coherently, exactly the nonvanishing cross-slice quadratic variations of lemma 26.10, so the second-order field operator pairs slice y with slice y' across the entire continuum, weighting the pairing by $\sigma_0\sigma_0^\top$.

The collapse to the classical theory is the cleanest sanity check on all four. Set the type space $[0,1]$ to a single point: every type integral $\int_0^1 \cdots \mathrm{d}y$ becomes a bare evaluation, the double integral $\int_0^1\int_0^1 \cdots$ becomes a single second-Lions term, the two-type derivative $\partial_\mu^y \partial_\mu^{y'} U$ reduces to the classical $\partial_\mu^2 U$, and (26.23) reduces *term for term* to the four common-noise corrections of the homogeneous master equation (12.17) — agent diffusion, measure spreading, agent–measure cross term, and measure Laplacian. The graphon formula adds nothing over chapter 12 except the resolution of each correction over the type continuum and the binding of distinct types through the off-diagonal of (iv); nothing graphon-specific would be lost or gained were there only one type.

The last term in (26.23) is a Laplacian on the field space, and its appearance changes the analytic character of the whole equation: it supplies the second-order regularization in the field direction that was *wholly absent* in the deterministic theory (section 26.3, where the notation-watch flagged exactly this object as missing), and with it the graphon master equation becomes *parabolic on* $\boldsymbol{\mathcal{P}}_2$ rather than first-order. This is, exactly as in chapter 12, at once a blessing and a burden, and the two readings are worth holding together. It is a *blessing* because the field-space smoothing can compensate for the loss of the deterministic-characteristics method that common noise destroyed: the parabolicity is, in the classical case, precisely what makes well-posedness possible under *weak* (rather than strict) monotonicity [4], the noise regularizing where the monotonicity alone would not suffice. It is a *burden* because a second field derivative integrated across *two* independent type labels is an analytically heavy object — it lives on pairs of types and carries a full matrix kernel — and controlling it is the principal obstacle to a complete graphon well-posedness theory, the graphon-specific reason the program of section 26.4 could not be closed in general. The very term that rescues the equation from the collapse of its characteristics is the term that no classical-graphon shortcut is known to tame.

Physics note

Common noise is the closest the graphon mean field story comes to a genuine fluctuating order-parameter field. A single global mode B_t^0 shakes *every* type coherently, so the macroscopic state — here an entire *field* $\boldsymbol{m}_t$ over the type continuum — becomes a stochastic process rather than a deterministic background. The double-type-integral term in (26.23) is the propagator of that global mode: it pairs the linear response at type y with the linear response at type y' and diffuses them together, the order-parameter "two-point function" the deterministic mean-field description could not see. The graphon adds genuinely new structure over the homogeneous case of chapter 12: the global shock is felt by different types with strengths that the kernel W and the type profile redistribute, so the fluctuation of the order parameter is itself *type-resolved*. As always this is orientation only — nothing below the line of a theorem rests on it — and the quantitative content is the (incomplete) well-posedness theory of section 26.7.

Remark 26.11 (Type-dependent common noise and a common-noise graphon)**.** The single global B^0 of (26.18) is the simplest aggregate shock. A natural and strictly more general structure replaces the scalar σ_0 by a *type-dependent* loading $\sigma_0(x)$, or even couples the types to a *family* of common noises through a second kernel — a "common-noise graphon" $W_0(x,y)$ — so that the coherent shock felt by type x is $\int_0^1 W_0(x,y)\,\mathrm{d}B_t^y$ for a continuum of independent global modes. The structure of the extra terms (26.23) is unchanged in form, but $\sigma_0\sigma_0^\top$ is replaced inside the double integral by the covariance kernel $W_0 \star W_0(y,y') = \int_0^1 W_0(y,r)W_0(y',r)\,\mathrm{d}r$, which modulates how strongly the global fluctuation correlates types y and y'. This is the natural arena for the physicist's intuition — a spatially structured noise correlated through the network — and it is essentially uncharted; we flag it for the research map of chapter 31.

Four families of σ_0-terms have been written down and named, but for the general equation that is all we can do: (26.23) is the structural form of the common-noise master equation, and section 26.4 has already conceded that its well-posedness in the field direction is open. The honest tier-by-tier accounting of what is proved and what is conjectural — including the status of the double-type-integral term and of the common-noise-graphon extension of remark 26.11 — is gathered in section 26.7, to which the order-parameter-fluctuation reading of the physics box and the research questions of chapter 31 are handed forward. But before that reckoning the chapter owes the reader the one place where the abstract is made wholly concrete. The natural next question is operational: in a model where every field derivative is available in closed form, how do these four families actually *act* — which survive, which vanish, and what does the surviving structure say? The linear–quadratic thread answers it completely. Section 26.4 identified LQG as the special structure in which the field regularity does close; we now use that closure to evaluate (26.10) and its common-noise correction (26.23) explicitly, continuing Thread B rather than re-deriving it. There the quadratic value function makes $\partial_\mu^y U$ affine and $\partial_\mu^y \partial_\mu^{y'} U$ *constant* in the field, the abstract equation collapses to an operator Riccati equation, and the common-noise families sort themselves cleanly — a certainty-equivalence computation in which the population-spreading term integrates away while the agent's own diffusion, the cross term, and the field Laplacian survive in a fully explicit form. That is the business of the next section.

26.6 Worked computation: the graphon LQG master equation

The chapter has built an abstract object and then mapped the limits of what can be said about it. Section 26.3 derived the graphon master equation (26.10); section 26.4 conceded that its general well-posedness in the field direction is open, while singling out the linear–quadratic structure as the one special case in which the field regularity provably *does* close; and section 26.5 grew the equation a double-type-integral Laplacian (26.23) and left standing the operational question it could not answer in general — in a model where every field derivative is available in closed form, how do the four families of common-noise terms actually act, which survive, and what does the surviving structure say? This section answers all of it at once, by the only route the chapter has that is unconditional: we advance Thread B (appendix A.7) to its master-equation layer, the graphon lift of the LQG computation of section 12.8, and there every abstract object of sections 26.3 and 26.5 acquires an explicit closed form. This is the one section in which every claim is unconditional. The linear–quadratic structure makes the master function explicit, reduces the abstract equation (26.10) to a single *operator* Riccati equation on $L^2([0,1])$, and — through the rank-one graphon of example 15.11 — collapses that to a *scalar* Riccati equation in an order parameter; the common-noise correction (26.23) then sorts itself by a certainty-equivalence computation that leaves the feedback untouched. We continue the thread rather than re-derive its setup: the model, the parameter names, and the coupling are exactly those fixed in appendix A.7, carried forward without restatement.

The model is Thread B with its fixed parameter names. Each type-x agent carries a scalar state governed by the linear dynamics

$$\mathrm{d}X_t^x = (aX_t^x + b\,\alpha_t^x)\,\mathrm{d}t + \sigma\,\mathrm{d}B_t^x, \qquad X_0^x \sim m_0^x, \tag{26.24}$$

with a the state feedback, b the control gain, σ the private-noise intensity, and B^x the type-x idiosyncratic Brownian motion of the chapter's notation watch — the kernel W below is never a noise. The agent pays the linear–quadratic cost

$$J^x(\alpha^x) = \mathbb{E}\left[\int_0^T \left(\tfrac{1}{2}(\alpha_t^x)^2 + \tfrac{q}{2}\big(X_t^x - s\,z_t(x)\big)^2\right)\mathrm{d}t + \tfrac{q_T}{2}\big(X_T^x - s_T\,z_T(x)\big)^2\right], \tag{26.25}$$

with $q, q_T \geq 0$ the running and terminal state-cost weights and s, s_T the mean-coupling strengths that pull the agent toward (or, in the repulsive sign, away from) the aggregate it feels. That aggregate is the only place the population enters, and it is the graphon average of the neighbour mean,

$$z_t(x) = (\mathbb{W}\bar{m}_t)(x) = \int_0^1 W(x,y)\,\bar{m}_t(y)\,\mathrm{d}y, \qquad \bar{m}_t(y) = \int \zeta\, m_t^y(\mathrm{d}\zeta). \tag{26.26}$$

This is the general coupling form (26.5) specialized to the interaction observable $\phi(\zeta) = \zeta$: the foreign type-slice m_t^y is collapsed to its scalar mean $\bar{m}_t(y)$, and the kernel $W(x,y)$ then averages those means over types to form the single number $z_t(x)$ that type x responds to. The whole channel by which one type's cost sees another type's population — the thread the chapter is strung on — runs through this one scalar, built by $\mathbb{W}$.

It is worth isolating the structural feature that makes the entire reduction below possible, because everything that follows is an exploitation of it. *The field $\boldsymbol{m}$ enters the cost only through its type-mean field $\bar{m}_t(\cdot) = \int \zeta\, m_t^{\cdot}(\mathrm{d}\zeta)$*, which is a single element of $L^2([0,1])$ — one real-valued function over types, not the full field of measures. The higher moments of each slice, its shape, its tails, all are invisible to (26.25); only the first moment survives, and it survives type by type as the profile $\bar{m}_t$. Consequently every field functional we shall meet below — the value U, its slice-Lions derivative, the population-sensitivity operator — depends on $\boldsymbol{m}$ *solely through* $\bar{m} \in L^2([0,1])$. This is the linchpin. It demotes the infinite-dimensional differentiation in $\boldsymbol{m}$ to ordinary calculus on the Hilbert space $L^2([0,1])$: a field derivative becomes a directional derivative in the mean profile, the slice-Lions derivative becomes constant in the foreign state (as we verify in (26.29)), and the abstract graphon master equation (26.10) becomes an equation for operators on $L^2([0,1])$. Without this collapse there would be no closed form; with it, the whole apparatus of chapter 12's LQG computation lifts verbatim, the single scalar coupling constant replaced by the operator $\mathbb{W}$.

Two reduction checks, demanded by the thread specification, anchor the general computation to ground already covered and pin down the cleanest case. Setting $W \equiv c$ (the constant graphon) makes every type feel the same aggregate up to the scale c, and the system must collapse to Thread A of appendix A.7 with the coupling rescaled — the homogeneous LQG MFG, recovered as the no-network limit. The rank-one kernel $W(x,y) = f(x)f(y)$ of example 15.11 is the opposite extreme and the clean case: there $\mathbb{W}$ is a single projector, the operator Riccati lives in a one-dimensional family, and the entire continuum of types is governed by a single scalar *order parameter*. We verify the constant-graphon reduction as the special case of the rank-one collapse and exhibit the rank-one reduction as the section's payoff.

The computation proceeds in three steps, each making one abstract object of the chapter explicit, and a fourth that returns to common noise. First we write the per-type HJB equation and posit the linear–quadratic ansatz for U, mirroring the classical LQG ansatz of section 12.8 but with the population-sensitivity coefficient promoted from a scalar to a time-dependent operator on $L^2([0,1])$; this is where the "depends on $\boldsymbol{m}$ only through $\bar{m}$" observation is cashed in and where the field-Laplacian (third) line of (26.10) is shown to vanish. Second we insert the ansatz, match powers of the state, and reduce the abstract master equation to a scalar curvature Riccati and an *operator* Riccati equation for the population-sensitivity. Third we specialize to the rank-one kernel and watch the operator Riccati collapse to a scalar Riccati in the order parameter, recovering Thread A along the way. The closing step adds the common shock and carries out the certainty-equivalence computation that section 26.5 promised. We begin with the first.

The per-type HJB and the operator ansatz

We begin exactly where the setup left us. The field $\boldsymbol{m}$ entered the cost (26.25) through one scalar per type, the graphon aggregate $z_t(x) = (\mathbb{W}\bar{m}_t)(x)$, and so — the linchpin observation of the previous pages — every field functional we shall produce depends on $\boldsymbol{m}$ *only through the mean profile* $\bar{m} \in L^2([0,1])$. The first step of the computation is to turn that dependence into an explicit guess for the master function U, and to verify on the spot that the guess kills one of the three lines of the abstract equation (26.10). We do this by following the classical LQG calculation of section 12.8 clause for clause, with the single difference that what was a scalar coefficient there is here an operator on $L^2([0,1])$ — the place where the network, and only the network, enters.

The natural object to write first is the per-type Hamilton–Jacobi–Bellman equation, because the master function is built to reproduce it slice by slice. Hold the equilibrium field flow $\boldsymbol{m}_\cdot$ fixed, so that type x sees a prescribed aggregate trajectory $z_t(x) = (\mathbb{W}\bar{m}_t)(x)$ and decouples into a *classical* stochastic control problem: minimize (26.25) over α^x subject to the linear dynamics (26.24). This is the type-x instance of the graphon MFG system's HJB equation (26.6a), and writing $u^x(t,\xi)$ for its value function, the dynamic programming principle gives the usual minimized Bellman operator. The control enters the Hamiltonian only through the two terms it touches — the running quadratic penalty $\frac{1}{2}(\alpha^x)^2$ and the drift contribution $b\,\alpha^x\,\partial_\xi u^x$ — and minimizing $\alpha \mapsto \frac{1}{2}\alpha^2 + b\,\alpha\,\partial_\xi u^x$ over the scalar α (a strictly convex parabola, so the minimizer is the unique stationary point) returns the optimal feedback

$$\alpha^* = -b\,\partial_\xi u^x,$$

at which the bracket takes the value $-\frac{b^2}{2}(\partial_\xi u^x)^2$. Substituting this feedback back into the Bellman equation and adding the uncontrolled drift $a\xi$, the idiosyncratic diffusion $\frac{1}{2}\sigma^2\partial_{\xi\xi}$, and the state penalty $\frac{q}{2}(\xi - s\,z_t(x))^2$ from (26.25) produces the type-x HJB equation

$$\partial_t u^x + a\xi\,\partial_\xi u^x - \tfrac{b^2}{2}(\partial_\xi u^x)^2 + \tfrac{1}{2}\sigma^2\,\partial_{\xi\xi}u^x + \tfrac{q}{2}\big(\xi - s\,z_t(x)\big)^2 = 0, \tag{26.27}$$

with terminal condition $u^x(T,\xi) = \frac{q_T}{2}(\xi - s_T z_T(x))^2$ read off the terminal cost of (26.25). This is exactly the homogeneous LQG HJB equation (12.20) of section 12.8 with the scalar mean $\bar{m}_t$ replaced by the type-resolved aggregate $z_t(x)$; the type label is carried inertly through the equation, and all the network's content sits inside that one driving term.

It is worth saying precisely how (26.27) is the linear–quadratic instance of the general per-type HJB (26.6a) that the whole chapter has been written around, because the bundling is the same one used at every abstract step. The general equation reads $-\partial_t u^x - \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2_\xi u^x) + H(x,\xi,\nabla_\xi u^x) = F(x,\xi,\boldsymbol{m}_t)$. Collecting the two terms of (26.27) that depend on u^x through its state-gradient $p = \partial_\xi u^x$ — the uncontrolled drift term $a\xi\, p$ and the post-minimization control term $-\frac{b^2}{2}p^2$ — and matching signs with the general form identifies the type-x Hamiltonian of the thread as

$$H_{\mathrm{LQG}}(\xi,p) = -a\xi\, p + \tfrac{b^2}{2}p^2.$$

This is the scalar, type-independent specialization of the general $H(x,\xi,p)$ of section 26.3: it is convex in p (the coefficient $\frac{b^2}{2} > 0$ is exactly hypothesis (A-Conv) made concrete), so its p-gradient $\partial_p H_{\mathrm{LQG}}(\xi,p) = -a\xi + b^2 p$ is the single-valued affine map that recovers the optimal drift $-\partial_p H_{\mathrm{LQG}} = a\xi - b^2 p$, matching the closed loop $aX^x + b\alpha^* = aX^x - b^2\partial_\xi u^x$ of (26.24). The driving term F is the pure state penalty $F(x,\xi,\boldsymbol{m}) = -\frac{q}{2}(\xi - s\, z[\boldsymbol{m}](x))^2$ of (26.5) with interaction observable $\phi(\zeta) = \zeta$. The notation watch of section 12.8 flagged this bundling of the uncontrolled drift into H; we keep general (a,b) rather than normalizing so that the constant-graphon reduction lands on Thread A without a change of variables.

Quadratic data propagate quadratically. The terminal value is quadratic in ξ and the only $\boldsymbol{m}$-dependence in (26.27) is the term $\frac{q}{2}(\xi - s\, z_t(x))^2$, which is *linear* in the aggregate $z_t(x)$ and hence, since $z_t = \mathbb{W}\bar{m}_t$ is itself linear in the mean profile, linear in $\bar{m}_t$. A value function whose data are quadratic in the state and affine in a linear functional of the field stays quadratic in the state and affine in that functional for all time; this is the structural inheritance that the LQG ansatz codifies. We therefore posit a master function quadratic in the state ξ whose state-gradient is affine in the mean field through a *time-dependent linear operator* $\mathcal{R}_t$ on $L^2([0,1])$:

$$\nabla_\xi U(t,x,\xi,\boldsymbol{m}) = P(t)\,\xi + (\mathcal{R}_t\bar{m})(x), \qquad \bar{m}(y) = \int \zeta\, m^y(\mathrm{d}\zeta). \tag{26.28}$$

The two coefficients carry different ranks for a structural reason, and unpacking it is the whole point of the ansatz. The first, $P(t)$, is a *scalar*: it is the curvature of the value in the agent's own state, $P(t) = \partial_{\xi\xi}u^x$, and it cannot carry a type label because nothing in the problem that sets it does. The state dynamics (26.24) have type-independent coefficients (a,b,σ), and the quadratic state weight q in (26.25) is likewise the same for every type; the curvature of an agent's value in its own state is fixed by its own dynamics and its own penalty alone, never by who its neighbours are, so $P(t)$ is one number shared across the continuum of types. This is the exact graphon counterpart of the scalar $P(t)$ of the classical ansatz (12.21): the self-curvature is colour-blind to the network. The second coefficient, $(\mathcal{R}_t\bar{m})(x)$, is where the network is the entire story. It is the type-x *population-sensitivity* — how much agent x's marginal value $\nabla_\xi U$ shifts when the population's mean profile shifts — and it is a *linear functional of the whole mean field* $\bar{m} \in L^2([0,1])$, evaluated at the type x. The operator $\mathcal{R}_t$ is the object that does the routing: it takes the entire crowd mean $\bar{m}$, a function over all foreign types, and returns the function over types $x \mapsto (\mathcal{R}_t\bar{m})(x)$ whose value at x is the sensitivity felt by an agent of type x. Where the homogeneous theory of section 12.8 had a single scalar sensitivity $\pi(t)$ collapsing the one population mean $\bar{m}$ into one number, the graphon theory must keep an operator, because there is no longer one mean and one sensitivity but a continuum of each, woven together by the network: $\mathcal{R}_t$ is the matrix-valued (here operator-valued) promotion of $\pi(t)$, and the next subsection will show it inherits the kernel $\mathbb{W}$ that built the coupling in the first place.

A small concrete check fixes the picture. If the kernel were the constant graphon $W \equiv c$, every agent would feel the same scalar aggregate $z_t(x) = c\,\langle \bar{m}_t \rangle$, the population-sensitivity would have to be a single number times that one aggregate, and $\mathcal{R}_t$ would degenerate to multiplication by a scalar — precisely the homogeneous $\pi(t)$ (up to the factor c) of (12.21). The operator $\mathcal{R}_t$ is exactly what is needed when different types feel different aggregates, and it reduces to the classical scalar in the no-network limit, as the thread's reduction check demands.

The ansatz has an immediate and decisive consequence for the abstract equation: it switches off the extra-diffusion line of (26.10). To see this we compute the field derivatives of U and watch them collapse. Because U depends on the field $\boldsymbol{m}$ only through the single linear functional $\bar{m}(y) = \int \zeta\, m^y(\mathrm{d}\zeta)$ — nudging the slice m^y by a test perturbation δm^y moves $\bar{m}(y)$ by $\int \zeta\, \delta m^y(\mathrm{d}\zeta)$ and moves nothing else — the flat (linear-functional) derivative is itself linear in the foreign state ζ, and the slice-Lions derivative, its ζ-gradient, is therefore *constant in* ζ:

$$\frac{\delta U}{\delta m^y}(t,x,\xi,\boldsymbol{m})(\zeta) = \partial_{\bar{m}(y)}U\cdot\zeta, \qquad \partial_\mu^y U(t,x,\xi,\boldsymbol{m})(\zeta) = \partial_{\bar{m}(y)}U \text{ (independent of } \zeta\text{)}, \qquad \partial_\zeta \partial_\mu^y U \equiv 0. \tag{26.29}$$

The middle equality is the chain rule for the slice-Lions derivative $\partial_\mu^y U = \nabla_\zeta(\delta U/\delta m^y)$ of section 26.2: since $\delta U/\delta m^y(\zeta) = \partial_{\bar{m}(y)}U \cdot \zeta$ is exactly linear in ζ, its ζ-gradient is the constant coefficient $\partial_{\bar{m}(y)}U$, with the foreign state ζ gone. The right-hand identity is then immediate and is the whole content: a function that does not depend on ζ has vanishing ζ-Jacobian, so $\partial_\zeta \partial_\mu^y U \equiv 0$ pointwise in every argument.

That one line is what kills the spreading term. The extra-diffusion (third) line of the master equation (26.10) is, in full, $-\frac{1}{2}\int_0^1\int \operatorname{tr}(\sigma\sigma^\top\, \partial_\zeta\partial_\mu^y U)\, m^y(\mathrm{d}\zeta)\, \mathrm{d}y$, and its integrand is built from precisely the Jacobian $\partial_\zeta\partial_\mu^y U$ that (26.29) has just shown is identically zero. With a vanishing integrand the integral vanishes, type by type and state by state, so the entire third line of (26.10) drops out of the thread's master equation. The reason is exactly the one anticipated below theorem 12.3 for the homogeneous LQG case, lifted unchanged but for the outer type integral: the cost couples the field through a *first* moment only, and a first-moment coupling is blind to how each type's crowd spreads under its private noise. The spreading term measures the value's response to that smearing through the ζ-Jacobian of the Lions derivative, and a linear-in-ζ Lions derivative has no curvature for the diffusion to act on. Were the cost to couple through a second moment — as it would if (26.25) penalized the variance of the neighbour field rather than its mean — the Lions derivative would acquire a genuine ζ-dependence, its Jacobian would be nonzero, and the spreading term would survive; it is the mean-field nature of Thread B's coupling, nothing softer, that makes the line disappear.

With the extra-diffusion line gone, the abstract equation (26.10) for the thread has been pared to its first two lines: the per-type HJB operator and the type-integrated transport term. The ansatz (26.28) now stands ready to be fed into them. The next subsection does exactly that — it inserts the quadratic-in-ξ, operator-affine guess into the per-type HJB (26.27), uses the just-established vanishing of the spreading term to drop the second-field-derivative bookkeeping, and matches powers of the state ξ. The ξ^2 coefficient will pin the scalar curvature $P(t)$ to a scalar Riccati equation, and the ξ^1 coefficient will pin the population-sensitivity operator $\mathcal{R}_t$ to an *operator* Riccati equation on $L^2([0,1])$ in which the kernel $\mathbb{W}$ finally appears.

Reduction to an operator Riccati equation

The previous subsection delivered two things we now spend. It posited the operator ansatz (26.28) — a master function quadratic in the state ξ whose state-gradient is affine in the mean profile through the population-sensitivity operator $\mathcal{R}_t$ on $L^2([0,1])$ — and it proved, from the linearity of the slice-Lions derivative in ζ (26.29), that the extra-diffusion (third) line of the abstract master equation (26.10) is identically zero on the thread. With that line gone the equation has been pared to its first two, and the work that remains is purely algebraic: insert the ansatz into the per-type HJB (26.27), sort the result by powers of the state ξ, and let each power pin down one coefficient of the guess. Because the data are quadratic in ξ and the ansatz keeps them so, only three powers occur — ξ^2, ξ^1, ξ^0 — and the first two carry all the dynamical content. We write the value in the form the ansatz forces,

$$u^x(t,\xi) = \tfrac{1}{2}P(t)\,\xi^2 + \psi_t(x)\,\xi + \chi_t(x), \qquad \psi_t(x) = (\mathcal{R}_t\bar{m}_t)(x), \tag{26.30}$$

the linear coefficient $\psi_t(x)$ being precisely the type-x population-sensitivity $(\mathcal{R}_t\bar{m})(x)$ of (26.28) evaluated along the equilibrium mean profile $\bar{m}_t$. Its three derivatives are $\partial_t u^x = \frac{1}{2}\dot{P}\,\xi^2 + \dot{\psi}_t\,\xi + \dot{\chi}_t$, $\partial_\xi u^x = P\,\xi + \psi_t(x)$, and $\partial_{\xi\xi}u^x = P$, and the only nonlinearity, the squared gradient, expands as $(\partial_\xi u^x)^2 = P^2\xi^2 + 2P\,\psi_t(x)\,\xi + \psi_t(x)^2$. Substituting all of this into (26.27) and grouping by powers of ξ is the entire computation; we take the powers in turn.

At order ξ^2 the surviving terms are the curvature derivative $\frac{1}{2}\dot{P}$ from $\partial_t u^x$, the drift contribution aP from $a\xi\,\partial_\xi u^x$, the post-minimization term $-\frac{b^2}{2}P^2$ from $-\frac{b^2}{2}(\partial_\xi u^x)^2$, and the penalty $\frac{q}{2}$ from $\frac{q}{2}(\xi - sz_t(x))^2$. Their sum must vanish, $\frac{1}{2}\dot{P} + aP - \frac{b^2}{2}P^2 + \frac{q}{2} = 0$, which is the scalar curvature Riccati of Thread A,

$$\dot{P} = b^2P^2 - 2aP - q, \qquad P(T) = q_T, \tag{26.31}$$

with the terminal value $P(T) = q_T$ read off the ξ^2 coefficient of the terminal cost $\frac{q_T}{2}(\xi - s_Tz_T(x))^2$. Two features deserve emphasis. First, (26.31) is *identical* to the homogeneous LQG curvature Riccati (12.25a): the self-curvature of an agent's value in its own state is governed by its own dynamics (a, b, σ) and its own penalty q, q_T alone. Second, and as a corollary, it is *independent of the kernel*: neither W nor the aggregate $z_t(x)$ appears anywhere in it, because the ξ^2 balance never sees the driving term — the coupling $z_t(x)$ enters the penalty only at orders ξ^1 and ξ^0, multiplying ξ and 1, never ξ^2. The network is invisible to the curvature; this is the analytic face of the colour-blindness of $P(t)$ argued for the ansatz.

At order ξ^1 the terms are $\dot{\psi}_t$ from $\partial_t u^x$, the drift contribution $a\psi_t$ from $a\xi\,\partial_\xi u^x$, the cross term $-\frac{b^2}{2}\cdot 2P\psi_t = -b^2P\psi_t$ from the squared gradient, and the cross term $-q\,s\,z_t(x)$ from expanding $\frac{q}{2}(\xi - sz_t(x))^2$. (The diffusion term $\frac{1}{2}\sigma^2\partial_{\xi\xi}u^x = \frac{1}{2}\sigma^2 P$ is a pure constant and contributes only at order ξ^0, feeding χ_t; it never touches ψ_t.) Setting the ξ^1 sum to zero, $\dot\psi_t + a\psi_t - b^2 P\psi_t - qsz_t = 0$, gives the backward equation for the population-sensitivity coefficient,

$$\dot\psi_t(x) = -(a - b^2 P)\,\psi_t(x) + q\,s\,z_t(x), \qquad \psi_T(x) = -q_T s_T\, z_T(x), \tag{26.32}$$

with $z_t = \mathbb{W}\bar m_t$, and the terminal value $\psi_T(x) = -q_T s_T z_T(x)$ read off the ξ^1 coefficient $-q_T s_T z_T(x)$ of the terminal penalty. This is a backward linear ODE for the profile $\psi_t \in L^2([0,1])$, run from $t = T$, whose only inhomogeneity is the graphon-averaged neighbour mean $z_t = \mathbb{W}\bar m_t$ — the lone place the kernel reaches into the linear order.

Equation (26.32) is backward and driven by the population, so to close it we need how the population moves. The closed-loop type-mean field evolves *forward*: the optimal feedback is $\alpha^* = -b\,\partial_\xi u^x = -b(PX_t^x + \psi_t(x))$, so the controlled drift in (26.24) is $aX_t^x + b\alpha^* = (a - b^2P)X_t^x - b^2\psi_t(x)$, and taking expectations — the idiosyncratic noise $\sigma\,\mathrm{d}B_t^x$ is mean-zero and the drift is affine, so $\mathbb{E}[X_t^x] = \bar m_t(x)$ obeys the drift with X_t^x replaced by its mean — gives

$$\dot{\bar m}_t(x) = (a - b^2 P)\,\bar m_t(x) - b^2\,\psi_t(x), \qquad \bar m_0 \text{ given.} \tag{26.33}$$

Equations (26.32)–(26.33) together are a *linear forward–backward system in* $L^2([0,1])$: a backward profile ψ_t run from terminal data and a forward profile $\bar m_t$ run from initial data, the two locked together. It is worth saying exactly where the types touch. Strip out the kernel for a moment by setting $W = \mathrm{id}$ (so $z_t = \bar m_t$): the pair (26.32)–(26.33) would then be a *pointwise* family of scalar ODEs, one per type x, sharing no information — a disjoint union of classical LQG mean-field problems. The genuine kernel reinserts itself in a single spot, the term $q\,s\,z_t(x) = q\,s\,(\mathbb{W}\bar m_t)(x)$ of (26.32), which mixes the mean of *every* type into the sensitivity of type x. The forward–backward system is therefore coupled across types *only through the operator* $\mathbb{W}$ — the one inter-type channel the chapter is strung on, now made completely concrete as the off-diagonal of a linear system on $L^2([0,1])$.

To read off the master function we must turn this forward–backward pair into a single backward equation for the operator $\mathcal{R}_t$ that encodes the equilibrium relation between sensitivity and population. The device is the one used for every Riccati closure: posit that the backward coefficient is, at each time, a fixed *linear* function of the current forward mean,

$$\psi_t = \mathcal{R}_t\,\bar m_t, \qquad \mathcal{R}_t : L^2([0,1]) \to L^2([0,1]) \text{ linear,} \tag{26.34}$$

which is exactly the equilibrium content of the ansatz (26.28): the population-sensitivity profile is the operator $\mathcal{R}_t$ applied to the current mean profile. Differentiating (26.34) in time — $\mathcal{R}_t$ and $\bar m_t$ both move, so the product rule on $L^2([0,1])$ contributes two terms — and substituting the forward law (26.33) for $\dot{\bar m}_t$ and then (26.34) itself for the ψ_t that appears inside it,

$$\dot\psi_t = \dot{\mathcal{R}}_t\bar m_t + \mathcal{R}_t\dot{\bar m}_t = \dot{\mathcal{R}}_t\bar m_t + \mathcal{R}_t\big[(a - b^2P)\bar m_t - b^2\psi_t\big] = \dot{\mathcal{R}}_t\bar m_t + \mathcal{R}_t\big[(a - b^2P)\bar m_t - b^2\mathcal{R}_t\bar m_t\big].$$

On the other side, the backward law (26.32) reads, after the same substitution $\psi_t = \mathcal{R}_t\bar m_t$ and $z_t = \mathbb{W}\bar m_t$,

$$\dot\psi_t = -(a - b^2P)\,\mathcal{R}_t\bar m_t + q\,s\,\mathbb{W}\bar m_t.$$

Equating the two expressions for $\dot\psi_t$ and gathering every term onto one side gives

$$\Big[\dot{\mathcal{R}}_t - b^2\mathcal{R}_t^2 + 2(a - b^2P)\mathcal{R}_t - q\,s\,\mathbb{W}\Big]\bar m_t = 0,$$

an identity asserting that a single time-dependent operator annihilates the mean profile $\bar{m}_t$. Here is the step that converts the identity into an operator equation, and it deserves to be said out loud rather than waved through. The relation must hold not for one $\bar{m}_t$ but for *every* mean profile reachable at time t, because the master function is required to be correct off the single equilibrium trajectory — as $\boldsymbol{m}$, and hence $\bar{m}_0$, ranges over the whole field space, $\bar{m}_t$ ranges over the image of $L^2([0,1])$ under the forward flow (26.33). That flow is a linear, invertible ODE on $L^2([0,1])$ (its solution operator is the time-ordered exponential of a bounded generator, hence boundedly invertible), so the reachable set $\{\bar{m}_t : \bar{m}_0 \in L^2([0,1])\}$ is *all* of $L^2([0,1])$. An operator that kills every vector of $L^2([0,1])$ is the zero operator; the bracket must therefore vanish identically, and we have landed the *operator Riccati equation*

$$\dot{\mathcal{R}}_t = b^2\,\mathcal{R}_t^2 - 2(a - b^2P)\,\mathcal{R}_t + q\,s\,\mathbb{W}, \qquad \mathcal{R}_T = -q_Ts_T\,\mathbb{W}, \tag{26.35}$$

with the terminal datum $\mathcal{R}_T = -q_Ts_T\mathbb{W}$ forced by matching the closure (26.34) against the terminal $\psi_T = -q_Ts_Tz_T = -q_Ts_T\mathbb{W}\bar{m}_T$ of (26.32).

This is the exact graphon lift of the scalar population-sensitivity Riccati (12.25b): term by term it is the homogeneous equation $\dot{\pi} = b^2\pi^2 - 2(a - b^2P)\pi + q\,s$ with the scalar π promoted to the operator $\mathcal{R}_t$ and the bare coupling constant 1 in the source promoted to the graphon operator $\mathbb{W}$. And it is worth tracing each term back to its parent in the abstract master equation (26.10), to make plain that (26.35) *is* that equation in the linear–quadratic case and not a separate computation. The third line of (26.10) was killed in the previous subsection; the first line (the per-type HJB operator $-\partial_tU - \frac{1}{2}\sigma^2\,\mathrm{D}_\xi^2\,U + H$) and the second line (the type-integrated transport $\int_0^1\int \partial_\mu^y U \cdot \partial_pH \;\mathrm{d}m^y\;\mathrm{d}y$) are what we matched. The quadratic term $b^2\mathcal{R}_t^2$ descends from the post-minimization Hamiltonian $H = -a\xi p + \frac{b^2}{2}p^2$, whose $\frac{b^2}{2}p^2$ piece produced the cross term $-b^2P\psi_t$ and, after the closure substitution turned ψ_t into $\mathcal{R}_t\bar{m}_t$ inside the product rule, the genuinely quadratic $b^2\mathcal{R}_t^2$. The linear term $-2(a - b^2P)\mathcal{R}_t$ collects the uncontrolled drift a and the P-coupling from both the backward law and the forward transport — it is the type-integrated transport line evaluated on the affine LQG feedback. The source term $q\,s\,\mathbb{W}$ is the sole survivor that carries the network: it descends directly from $F(x,\xi,\boldsymbol{m}) = -\frac{q}{2}(\xi - s(\mathbb{W}\bar{m})(x))^2$, the right-hand side of (26.10), which is the one and only place the graphon entered the abstract equation at all. The operator Riccati thus exhibits, in miniature and in closed form, the chapter's organizing claim: every classical master-equation object survives the lift, and $\mathbb{W}$ enters only through the cost coupling, here as the inhomogeneity $q\,s\,\mathbb{W}$.

Two structural facts about the solution $\mathcal{R}_t$ make the next subsection possible, and both follow from the operator Riccati itself once one watches what the flow preserves. The first is that $\mathcal{R}_t$ *is self-adjoint for every* t. The terminal datum $\mathcal{R}_T = -q_Ts_T\mathbb{W}$ is self-adjoint because $\mathbb{W}$ is: the kernel is symmetric, $W(x,y) = W(y,x)$, under the graphon regularity (A-Reg-W), so $\mathbb{W} = \mathbb{W}^*$ on $L^2([0,1])$. And the right-hand side of (26.35) maps self-adjoint operators to self-adjoint operators: if $\mathcal{R}$ is self-adjoint then so is $\mathcal{R}^2$, the scalar coefficients b^2, $a - b^2P$, $q\,s$ are real, and $\mathbb{W}$ is self-adjoint, so the whole right side is self-adjoint. The self-adjoint operators form a closed real-linear subspace of the bounded operators, the Riccati vector field is tangent to it, and the ODE has a unique solution; hence the trajectory launched from the self-adjoint terminal datum stays self-adjoint for all t. The second fact is sharper and is what collapses the problem: $\mathcal{R}_t$ *is a function of* $\mathbb{W}$ *alone*. Concretely, $\mathcal{R}_t$ commutes with every bounded operator that commutes with $\mathbb{W}$. To see it, fix any S with $[S,\mathbb{W}] = 0$ and track the commutator $C_t := [S,\mathcal{R}_t] = S\mathcal{R}_t - \mathcal{R}_tS$. Differentiating (26.35) and using that $[S,\,\cdot\,]$ is a derivation,

$$\dot{C}_t = [S, \dot{\mathcal{R}}_t] = b^2(\mathcal{R}_t C_t + C_t \mathcal{R}_t) - 2(a - b^2 P)\, C_t + q\, s\, [S, \mathbb{W}] = b^2(\mathcal{R}_t C_t + C_t \mathcal{R}_t) - 2(a - b^2 P)\, C_t,$$

because the source commutator $[S, \mathbb{W}]$ vanishes by assumption; the term $[S, \mathcal{R}_t^2] = \mathcal{R}_t[S, \mathcal{R}_t] + [S, \mathcal{R}_t]\mathcal{R}_t = \mathcal{R}_t C_t + C_t \mathcal{R}_t$ is the only nontrivial bookkeeping. This is a *linear, homogeneous* ODE for C_t, and its terminal value is $C_T = [S, \mathcal{R}_T] = -q_T s_T\, [S, \mathbb{W}] = 0$. A linear homogeneous ODE with zero terminal data has only the zero solution, so $C_t \equiv 0$: $\mathcal{R}_t$ commutes with S. Since S was an arbitrary operator commuting with $\mathbb{W}$, the operator $\mathcal{R}_t$ lies in the bicommutant of $\mathbb{W}$ — it is, in the precise sense, a function of $\mathbb{W}$. The payoff is spectral. The graphon operator is compact and self-adjoint (Hilbert–Schmidt, since $W \in L^2([0,1]^2)$ under (A-Reg-W); definition 15.13), so by the spectral theorem for compact self-adjoint operators (theorem 2.26) it has an orthonormal eigenbasis $(\varphi_k)_{k\geq 1}$ of $L^2([0,1])$ with real eigenvalues $\lambda_k \to 0$, $\mathbb{W}\varphi_k = \lambda_k \varphi_k$. A function of $\mathbb{W}$ is diagonal in that basis: $\mathcal{R}_t \varphi_k = r_k(t)\varphi_k$, and projecting the operator Riccati (26.35) onto the mode φ_k turns it into a single *scalar* Riccati equation per eigenvalue,

$$\dot{r}_k = b^2\, r_k^2 - 2(a - b^2 P)\, r_k + q\, s\, \lambda_k, \qquad r_k(T) = -q_T s_T\, \lambda_k,$$

the eigenvalue λ_k entering only as a rescaling of the source. The infinite-dimensional operator equation has thereby decoupled into a countable family of one-dimensional Riccati equations, one for each graphon mode, with the network entering each through its eigenvalue alone.

With the operator pinned down, the master function is fully explicit. Reassembling the expansion (26.30) with $\psi_t(x) = (\mathcal{R}_t \bar{m})(x)$ from the closure (26.34),

$$U(t, x, \xi, \boldsymbol{m}) = \tfrac{1}{2} P(t)\, \xi^2 + (\mathcal{R}_t \bar{m})(x)\, \xi + \chi_t(x, \bar{m}), \tag{26.36}$$

with χ_t the (quadratic-in-$\bar{m}$) constant term determined by the leftover order-ξ^0 matching, which contributes nothing to the feedback and which we do not need to track. The state-gradient of (26.36) is the affine map $\nabla_\xi U = P(t)\xi + (\mathcal{R}_t \bar{m})(x)$ of the ansatz (26.28); restricted to the equilibrium flow with $X_t^x \sim m_t^x$ it furnishes the *operator-valued decoupling field* of theorem 26.5,

$$Y_t^x = P(t) X_t^x + (\mathcal{R}_t \bar{m}_t)(x),$$

the type-indexed adjoint of the graphon FBSDE, now read as a scalar self-curvature $P(t)$ times the agent's own state plus the operator-routed population sensitivity $(\mathcal{R}_t \bar{m}_t)(x)$ — the abstract decoupling field of (26.12) made completely concrete by the linear–quadratic structure.

The operator Riccati (26.35) is as far as the general kernel can be pushed in closed form, but its diagonalization in the $\mathbb{W}$-eigenbasis has already done the decisive work: the continuum of types is governed, mode by mode, by scalar Riccati equations indexed by the graphon spectrum. The next subsection cashes this in on the cleanest possible spectrum. Taking the rank-one kernel of example 15.11, where $\mathbb{W}$ has a *single* nonzero eigenvalue, the diagonal family above retains exactly one active mode: the operator Riccati collapses to a single scalar Riccati and the whole infinite-dimensional field is carried by one scalar order parameter.

Rank-one collapse to a scalar order parameter

The previous subsection left the graphon LQG equilibrium encoded in the operator Riccati (26.35), and then proved the one structural fact that makes it tractable: $\mathcal{R}_t$ is a function of $\mathbb{W}$ alone, hence diagonal in the graphon eigenbasis (φ_k), so the single operator equation splits into the countable family of scalar Riccati equations $\dot r_k = b^2 r_k^2 - 2(a - b^2 P) r_k + q\, s\, \lambda_k$, one per eigenvalue λ_k, with the network reaching each mode only through its eigenvalue. That family is as far as a general kernel can be pushed, because in general infinitely many eigenvalues are nonzero and the modes, though uncoupled from one another, must all be carried at once. The rank-one (Curie–Weiss) graphon is the spectrum on which this family degenerates to a single member: $\mathbb{W}$ has exactly *one* nonzero eigenvalue, so all but one of the r_k are slaved to a kernel-free source and only one mode is dynamically alive. This is the case the thread has been pointing at since example 15.11, and on it the entire infinite-dimensional field condenses to one scalar. We work it in full.

Take the rank-one graphon $W(x, y) = f(x)f(y)$ of example 15.11. Its operator acts by projecting onto the single direction f and rescaling: $\mathbb{W}g = f\, \langle f, g\rangle_{L^2([0,1])}$, that is $\mathbb{W} = (f \otimes f)$, the rank-one operator with range the line $\mathbb{R}f$. It has a *single* nonzero eigenvalue, found by feeding it its own range vector: $\mathbb{W}f = f\, \langle f, f\rangle = \|f\|^2_{L^2([0,1])}\, f$, so f is an eigenfunction with eigenvalue

$$\lambda = \lambda_1 = \|\mathbb{W}\| = \|f\|^2_{L^2([0,1])}\,,$$

the leading eigenvalue in the spectral ordering of chapter 18; every direction orthogonal to f is annihilated, $\mathbb{W}g = 0$ for $g \perp f$, so $\lambda_2 = \lambda_3 = \cdots = 0$. In the diagonal family of the previous subsection only the mode $\varphi_1 = f/\|f\|$ carries a nonzero source $q\, s\, \lambda_1 = q\, s\, \lambda$; every other mode solves $\dot r_k = b^2 r_k^2 - 2(a - b^2 P) r_k$ with $r_k(T) = 0$, whose unique solution is $r_k \equiv 0$. The operator is therefore confined for all time to the one-dimensional family of multiples of the projector,

$$\mathcal{R}_t = r(t)\, (f \otimes f),$$

and the entire content of (26.35) is the scalar function $r(t)$.

Substituting this ansatz collapses the operator equation by inspection, and the one algebraic fact it needs is how the projector squares. Since $(f \otimes f)^2 g = (f \otimes f)(f\langle f, g\rangle) = f\, \langle f, f\rangle\, \langle f, g\rangle = \lambda\, f\langle f, g\rangle = \lambda\, (f \otimes f)g$, the projector obeys $(f \otimes f)^2 = \lambda\, (f \otimes f)$ — it is idempotent up to the eigenvalue — so

$$\mathcal{R}_t^2 = r(t)^2\, (f \otimes f)^2 = r(t)^2 \lambda\, (f \otimes f).$$

Putting $\dot{\mathcal{R}}_t = \dot r\, (f \otimes f)$, $\mathcal{R}_t^2 = r^2 \lambda\, (f \otimes f)$, and $\mathbb{W} = (f \otimes f)$ into (26.35) makes every term a multiple of the single operator $(f \otimes f)$; equating the scalar coefficients gives the *scalar* Riccati equation

$$\dot r = b^2 \lambda\, r^2 - 2(a - b^2 P)\, r + q\, s, \qquad r(T) = -q_T s_T, \tag{26.37}$$

the terminal value $r(T) = -q_T s_T$ read off the rank-one terminal datum $\mathcal{R}_T = -q_T s_T \mathbb{W} = -q_T s_T (f \otimes f)$. Stare at this equation against its homogeneous ancestor: it is *identical* to the classical LQG population-sensitivity Riccati (12.25b), $\dot r = b^2 r^2 - 2(a - b^2 P) r + q\, s$, save for the single replacement $b^2 \mapsto b^2 \lambda$ in the quadratic term. The leading graphon eigenvalue λ rescales the effective control gain, and nothing else of the network survives: the whole apparatus of types, the kernel, the operator $\mathbb{W}$, has been compressed into one number multiplying the quadratic Riccati term. This is the precise sense in which a rank-one network behaves as a single LQG agent with a renormalized gain.

What plays the role of the population in this collapsed picture is a single scalar, the *order parameter*

$$\varrho_t \;:=\; \langle f, \bar m_t\rangle_{L^2([0,1])} = \int_0^1 f(y)\,\bar m_t(y)\,\mathrm{d}y, \tag{26.38}$$

the projection of the type-mean profile onto the active direction f — exactly the static and dynamic order parameter ϱ fixed for Thread B in the thread specification. Once the field is rank-one, ϱ_t is all of it the equilibrium ever feels, and every population-dependent object reduces to f times this scalar. The aggregate felt by type x is, directly from the projector form of $\mathbb{W}$,

$$z_t(x) = (\mathbb{W}\bar m_t)(x) = f(x)\,\langle f, \bar m_t\rangle = f(x)\,\varrho_t,$$

so the neighbour mean every type reacts to is its own coupling weight $f(x)$ times the one global number ϱ_t. The population-sensitivity coefficient inherits the same shape: $\psi_t(x) = (\mathcal{R}_t\bar m_t)(x) = r(t)\,(f\otimes f)\bar m_t(x) = r(t)\,f(x)\,\langle f,\bar m_t\rangle = r(t)\,f(x)\,\varrho_t$. Both the sensitivity profile and the aggregate are rigidly proportional to f, with ϱ_t the lone free amplitude.

The order parameter then obeys a *closed* scalar ODE, obtained by projecting the forward mean evolution onto f. Pair (26.33), $\dot{\bar m}_t(x) = (a - b^2P)\bar m_t(x) - b^2\psi_t(x)$, against f in $L^2([0,1])$, using that the pairing commutes with the time derivative:

$$\dot\varrho_t = \langle f, \dot{\bar m}_t\rangle = (a - b^2P)\,\langle f,\bar m_t\rangle - b^2\,\langle f,\psi_t\rangle.$$

The first pairing is $\langle f,\bar m_t\rangle = \varrho_t$ by definition. The second is the place the projector simplification does its work: since $\psi_t = r\,(f\otimes f)\bar m_t = r\,\mathbb{W}\bar m_t$,

$$\langle f,\psi_t\rangle = r\,\langle f,\mathbb{W}\bar m_t\rangle = r\,\lambda\,\langle f,\bar m_t\rangle = r\,\lambda\,\varrho_t,$$

where the middle step is the self-adjoint eigenvalue identity $\langle f,\mathbb{W}\bar m_t\rangle = \langle \mathbb{W}f,\bar m_t\rangle = \lambda\langle f,\bar m_t\rangle = \lambda\varrho_t$ — the one explicit simplification that closes the equation, the operator $\mathbb{W}$ pulled off the mean and replaced by its eigenvalue λ. Collecting the two pairings gives the closed scalar ODE

$$\dot\varrho_t = (a - b^2P)\,\varrho_t - b^2\lambda\,r(t)\,\varrho_t = \big(a - b^2P - b^2\lambda r(t)\big)\,\varrho_t, \qquad \varrho_0 = \langle f,\bar m_0\rangle. \tag{26.39}$$

It is a linear scalar ODE for ϱ_t run *forward* from ϱ_0, its rate $a - b^2P - b^2\lambda r(t)$ assembled from the agent's own dynamics, the curvature P, and the sensitivity r rescaled by the same effective coupling $b^2\lambda$ that appeared in the quadratic Riccati term — the kernel entering, here too, only through λ.

This is the cleanest realization of the thread's promise. The graphon master equation for a *continuum* of types has reduced, on the rank-one kernel, to three coupled scalar equations run on $[0,T]$: the curvature Riccati P (26.31), the population-sensitivity Riccati r (26.37), both backward from terminal data, and the order-parameter ODE ϱ_t (26.39), forward from initial data. That is *exactly the size of the classical LQG master system of worked computation 12.15* — the same triple (P, r, ϱ) of two backward Riccati scalars and one forward mean — with the single, decisive modification that the coupling is rescaled by the leading eigenvalue, $b^2 \mapsto b^2\lambda$ wherever the network acts. An entire field theory has been packed, with no loss, into the homogeneous master system run with a renormalized gain. The full master function is then (26.36) with $\mathcal{R}_t = r(t)(f \otimes f)$,

$$U(t, x, \xi, \boldsymbol{m}) = \tfrac{1}{2}P(t)\,\xi^2 + r(t)\,f(x)\,\varrho\,\xi + \chi_t(x, \varrho),$$

its state-gradient $\nabla_\xi U = P(t)\xi + r(t)f(x)\varrho$ a function of the one scalar ϱ through the population, and its decoupling field $Y_t^x = P(t)X_t^x + r(t)f(x)\varrho_t$ likewise.

The reduction check the thread specification demands is the constant graphon, and it falls out as the boundary case $f \equiv$ const. Set $W(x, y) \equiv c$; this is rank-one with $f \equiv \sqrt{c}$, since $f(x)f(y) = \sqrt{c}\cdot\sqrt{c} = c$. The leading eigenvalue is then $\lambda = \|f\|^2 = \int_0^1 c\,\mathrm{d}y = c$, and the order parameter $\varrho_t = \langle f, \bar{m}_t\rangle = \sqrt{c}\int_0^1 \bar{m}_t(y)\,\mathrm{d}y = \sqrt{c}\,\bar{\bar{m}}_t$ is, up to the constant $\sqrt{c}$, the *global* mean $\bar{\bar{m}}_t = \int_0^1 \bar{m}_t$ — every type weighted equally, as a constant kernel demands. The scalar Riccati (26.37) becomes $\dot{r} = b^2 c\,r^2 - 2(a - b^2P)r + q\,s$, which is precisely the homogeneous Thread A population-sensitivity Riccati with *effective coupling* b^2c: the constant graphon recovers the classical LQG MFG, its single coupling constant c multiplying the control gain exactly as Thread A's coupling does. This is the reduction the thread specification requires, and it confirms that the rank-one collapse degenerates, at $f \equiv \sqrt{c}$, to the homogeneous theory with no residue.

We now hand the common-noise subsection a completely explicit, finite scalar machinery: the curvature P, the sensitivity r, and the order parameter ϱ_t, the last carrying the whole population. There the same three scalars are stress-tested against a genuine aggregate shock — the four common-noise families of section 26.5 made concrete on this kernel — to see which gains feel the noise and which only the level does. The same reduction also sets up the threshold of remark 26.13: because the network has been compressed into the single effective coupling $b^2\lambda$, the question of whether the equilibrium exists for every horizon becomes the question of whether the scalar Riccati (26.37) keeps r finite, and that is governed entirely by the leading eigenvalue $\lambda = \|\mathbb{W}\|$ — a kernel whose spectral radius is too large can drive r to blow up in finite time, the spectral blow-up threshold the next subsections make precise.

The effect of common noise

Add the common shock $\sigma_0\,\mathrm{d}B_t^0$ of (26.18) to the dynamics (26.24). The conditional type-mean $\bar{m}_t(x) = \mathbb{E}[X_t^x \mid \mathcal{F}_t^0]$ now solves the *stochastic* forward equation

$$\mathrm{d}\bar{m}_t(x) = \big[(a - b^2P)\bar{m}_t(x) - b^2\psi_t(x)\big]\,\mathrm{d}t + \sigma_0\,\mathrm{d}B_t^0, \tag{26.40}$$

the common noise translating every type-slice coherently. The decisive — and at first surprising — fact is that the feedback Riccati system is *unchanged*: the curvature P (26.31) and the population-sensitivity operator $\mathcal{R}_t$ (26.35), equivalently $r(t)$ in the rank-one case (26.37), do not feel σ_0 at all. This is the linear–quadratic certainty-equivalence principle, lifted to the graphon: additive common noise shifts the *level* of the value but not its *gains*. We make this precise in the rank-one case.

Write the constant part of the master function (26.36) as a quadratic in the order parameter $\varrho = \langle f, \bar{m}\rangle$,

$$\chi_t(x, \bar{m}) = \tfrac{1}{2}\,g_t(x)\,\varrho^2 + h_t(x), \tag{26.41}$$

and insert the full master function $U = \frac{1}{2}P\xi^2 + r\,f(x)\varrho\,\xi + \chi_t$ into the graphon master equation *including* the common-noise terms (26.23). Matching powers of ξ and ϱ slot by slot, the orders ξ^2 and $\xi\varrho$ reproduce exactly the σ_0-free Riccati equations (26.31) and (26.37) (since $\partial_\zeta\partial^y_\mu U \equiv 0$ kills the population-self-spreading term (ii) of (26.23), and terms (i),(iii),(iv) are all of order $\xi^0\varrho^0$). The order ϱ^2 matches the ϱ^2*-coefficient* (a gain) g_t, and the constant order $\xi^0\varrho^0$ matches the *level* h_t:

$$\dot g_t(x) = -2\big(a - b^2P - b^2\lambda r\big)\,g_t(x) + \big(b^2r^2 - qs^2\big)f(x)^2, \qquad g_T(x) = q_Ts_T^2\,f(x)^2, \tag{26.42a}$$

$$\dot h_t(x) = -\tfrac{1}{2}\sigma^2 P\;\underbrace{-\,\tfrac{1}{2}\sigma_0^2\,P - \sigma_0^2\,r\,f(x)\,\beta - \tfrac{1}{2}\sigma_0^2\,g_t(x)\,\beta^2}_{\text{common-noise cost, }\beta=\langle f,\mathbf{1}\rangle}, \qquad h_T(x) = 0. \tag{26.42b}$$

The point is now an equation, not an adjective: the ϱ^2-coefficient g_t in (26.42a) — the curvature of the value in the order parameter, a *gain* — carries *no* σ_0, exactly the certainty-equivalence statement; the entire common-noise cost $\propto \sigma_0^2$ enters only the *level* h_t in (26.42b), as three terms tracing to the three nonvanishing families of (26.23): the agent's own extra diffusion (i) $\frac{1}{2}\sigma_0^2P$, the agent–field cross term (iii) $\sigma_0^2 rf\beta$ from $\nabla_\xi\partial^y_\mu U = rf(x)f(y)$, and the second-field-derivative double integral (iv) $\frac{1}{2}\sigma_0^2 g_t\beta^2$ from $\partial^y_\mu\partial^{y'}_\mu U = g_t(x)f(y)f(y')$. The order parameter itself becomes the *random* process (26.40)-paired-with-f,

$$\mathrm{d}\varrho_t = \big(a - b^2P - b^2\lambda r\big)\,\varrho_t\;\mathrm{d}t + \sigma_0\,\beta\;\mathrm{d}B^0_t, \qquad \beta = \langle f,\mathbf{1}\rangle = \textstyle\int_0^1 f, \tag{26.43}$$

and the master function, evaluated along this random ϱ_t, delivers the equilibrium value; the deterministic system of chapter 22 could not, which is the worked-computation face of why the master equation is indispensable under common noise.

Worked computation 26.12 (Graphon LQG master equation, operator Riccati, and rank-one collapse)**.** For the graphon LQG game (26.24)–(26.25), the master function is the quadratic (26.36); its state-curvature P solves the kernel-independent scalar Riccati (26.31), and its population-sensitivity $\mathcal{R}_t$ solves the self-adjoint *operator* Riccati (26.35), the exact lift of the classical (12.25b) with the scalar coupling replaced by $\mathbb{W}$; the extra-diffusion term vanishes identically. On the rank-one kernel $W = f\otimes f$ the operator Riccati collapses to the scalar Riccati (26.37) with $b^2 \mapsto b^2\lambda$ ($\lambda = \|f\|^2$ the leading eigenvalue), the entire field reduces to the scalar order parameter (26.38), and the constant graphon recovers Thread A. Additive common noise leaves P, $\mathcal{R}_t$ and the order-parameter *gain* g_t untouched (certainty equivalence) and feeds the common-noise cost $\propto\sigma_0^2$ into the *level* h_t alone (26.42b), through the three nonvanishing families of (26.23); the equilibrium order parameter becomes the random process (26.43). Every statement here is unconditional — no regularity hypothesis of theorem 26.7 is needed — because the linear–quadratic structure makes the master function explicit.

Remark 26.13 (Where uniqueness enters, and the spectral threshold)**.** Global existence of the operator Riccati solution $\mathcal{R}_t$ on all of $[0,T]$ corresponds to existence of a global classical graphon master solution: a finite-time blow-up of $\mathcal{R}_t$ marks the failure of the global decoupling field — the loss of a unique classical master solution — and hence governs uniqueness of the graphon LQG equilibrium for every initial field. In the rank-one case (26.37) shows this turns on the scalar r not blowing up, which — through the effective coupling $b^2\lambda$ — is governed by the leading eigenvalue $\lambda = \|\mathbb{W}\|$ of the network operator. This is the LQG face of the spectral entanglement of section 26.4:

the operator-norm threshold (A-Coupling) is precisely the condition that keeps r finite for all horizons, and a kernel with too large a leading eigenvalue can drive the population-sensitivity Riccati to blow up in finite time, the master solution to cease to exist, and graphon equilibria to multiply — the network-resolved version of the LQG phase boundary of worked computation 14.10.

26.7 The state of the theory: proved versus conjectural

This chapter sits at the live boundary of the subject, and the book's standard requires us to be exact about what is established. We separate four tiers.

What is proved here, in full. The equivalence of the three graphon formulations — master equation, field MFG system, graphon FBSDE — is complete: the field chain rule lemma 26.2, the derivation theorem 26.3, and the characteristics theorem 26.5 are honest theorems, each a clean type-by-type lift of its classical ancestor whose only new ingredient is the integral over the type continuum. The graphon LQG master equation of worked computation 26.12 — the operator Riccati (26.35), the rank-one collapse (26.37), the common-noise certainty equivalence — is unconditional and explicit.

What is reduced to the classical template. Well-posedness in the monotone regime (theorem 26.7) is established along the same architecture as [37], and Steps 1–2 (construction, single-valuedness, and the d_2-Lipschitz estimate) are complete *given* the graphon existence/uniqueness theory of chapter 24. In the special structures — separable and finite-rank kernels, the linear–quadratic case, block graphons (which reduce the field problem to a finite multi-population MFG, the bridge to chapter 30) — the full classical-strength regularity follows, and the master equation is classically well posed. The short-horizon / small-coupling contraction regime (remark 26.8) is unconditional for all admissible kernels.

What is conjectural. A general classical well-posedness theorem for the graphon master equation, of the strength available classically, is *not* known. The obstruction is Step 3 of theorem 26.7: controlling the linearized graphon MFG system uniformly across the continuum of types and against the full spectrum of $\mathbb{W}$. We expect — and the LQG operator Riccati (26.35) strongly suggests, since it is well posed for all horizons exactly when the spectrum of $\mathbb{W}$ keeps the Riccati flow finite — that monotonicity together with a spectral condition on $\mathbb{W}$ suffices, but a complete proof for general nonlinear couplings and general (A-Reg-W) kernels is open. The common-noise theory is less complete still: even the classical common-noise master equation is delicate ([37, 41, 4]), and its graphon lift, with the double-type-integral second-field-derivative term (26.23), has been carried through only in the linear–quadratic and finite-rank cases. The type-dependent common-noise / common-noise-graphon structure of remark 26.11 is essentially unstudied.

What lies beyond the dense theory. Everything in this chapter assumes a bounded, dense graphon (A-Reg-W) and the field space $\boldsymbol{\mathcal{P}}_2$ of (26.1). For sparse and L^p kernels the operator

$\mathbb{W}$ need not be bounded on $L^2([0,1])$, the spectral arguments behind (26.17) and (26.35) require revision, and the very existence of the field-of-measures master function is open; this is the subject of chapter 27, and the master equation under common noise on sparse limits is among the sharpest open problems flagged in the research map of chapter 31.

Rigor ledger

Proved.

- The field chain rule for fully $\mathcal{C}^2$ functionals along a field of Fokker–Planck flows (lemma 26.2), the type-integrated lift of lemma 12.2, with the linear-growth drift reached by an in-book truncation argument; and its stochastic upgrade under common noise (lemma 26.10), lifting the conditional Itô formula theorem D.8 slice-wise.
- The second field derivative $\partial_\mu^y \partial_\mu^{y'} U$ (definition 26.9), the slice-wise lift of the classical second Lions derivative definition D.6.
- The graphon master equation and its equivalence with the graphon MFG system: the equation (26.10)–(26.11) holds for the constructed U, and conversely its classical solutions generate solutions of the field system (theorem 26.3); the type integral, not a measure derivative, is the structural novelty.
- Characteristics: field Fokker–Planck flows are the characteristic curves, $\nabla_\xi U$ is the (type-indexed, operator-valued in LQG) graphon-FBSDE decoupling field, and the three pictures coincide (theorem 26.5).
- The graphon LQG master equation in closed form: vanishing extra-diffusion, the operator Riccati (26.35), the rank-one scalar collapse (26.37) to an order parameter, the constant-graphon recovery of Thread A, and additive-common-noise certainty equivalence (worked computation 26.12).
- The structural form of the common-noise terms (26.23) (two coefficient upgrades and two genuinely new terms), in particular the double-type-integral second-field-derivative Laplacian on $\boldsymbol{\mathcal{P}}_2$, derived from lemma 26.10.

Assumed (imported).

- The field-of-measures space $\boldsymbol{\mathcal{P}}_2$ and its metric (chapter 21); the graphon MFG system (26.6) and the optimal-feedback relation (chapter 22, appendix A.4); the graphon McKean–Vlasov flow and FBSDE with its Feynman–Kac/decoupling link (chapter 23).
- Graphon existence/uniqueness, the graphon monotonicity (A-Mon, definition 26.6), and the operator-norm threshold (A-Coupling) (chapter 24); standing assumptions (A-Lip),(A-Growth),(A-Nondeg),(A-Conv),(A-Reg-W) of appendix A.6.
- The flat and Lions derivatives, the second Lions derivative (definition D.6), and the Itô calculus on $\mathcal{P}_2(\mathbb{R}^d)$ — both the deterministic flow formula (theorem D.7) and the conditional/common-noise Itô–Wentzell formula (theorem D.8) — of chapter 4 and chapter 12 (definition 12.1, appendix A.3), here lifted slice-wise.

- The graphon operator and its spectral/positivity properties (definition 15.13, lemma 15.15) and the rank-one graphon (example 15.11).

Deferred.

- The full classical regularity of the graphon master function (Step 3 of theorem 26.7): reduced to the graphon existence theory of chapter 24 and the linearized-system analysis, complete only in the special structures named in section 26.7; the classical template is [37] and [41], Ch. 4–5.
- The full common-noise well-posedness theory, including the role of nondegeneracy of σ_0 and weak-monotonicity arguments ([4]); structure only here.
- The block-graphon reduction to multi-population MFG (chapter 30) and the finite-network ε-Nash transfer (chapter 25).

Open.

- A general classical well-posedness theorem for the graphon master equation, monotone + spectral, for nonlinear couplings and general (A-Reg-W) kernels (section 26.7).
- The graphon master equation under common noise beyond the linear–quadratic/finite-rank cases; the type-dependent / common-noise-graphon structure of remark 26.11.
- The entire theory on sparse / L^p / graphex limits, where $\mathbb{W}$ is unbounded and even existence of the field master function is unsettled (chapters 27 and 31).

Part IV retrospective

The graphon synthesis is now complete as a parallel of Part II. We set up a continuum of type-indexed agents and the field-of-measures state (chapter 21); wrote the coupled HJB–Fokker–Planck system across the kernel (chapter 22) and its probabilistic twin (chapter 23); proved existence and uniqueness with the operator-norm threshold (chapter 24); transferred the limit to and from finite networks (chapter 25); and, in this chapter, compressed the whole apparatus into the graphon master equation and used it to admit common noise. The single structural lesson of Part IV is that *every classical object survives the lift type-by-type, and the only genuinely new ingredient is the graphon operator* $\mathbb{W}$ — it enters the cost coupling, threads through the type integral that prevents the master equation from decoupling, sets the spectral threshold for uniqueness, and modulates how a common shock correlates the types. Where $\mathbb{W}$ is benign (small norm, rank-one, block) the theory is as complete and explicit as the homogeneous one; where its spectrum is large or its structure sparse, the frontier opens. Part V turns to that frontier: sparsity and L^p kernels (chapter 27), numerics for the field system (chapter 28), learning (chapter 29), the heterogeneity zoo (chapter 30), and the open-problem map (chapter 31).

Bibliographic notes

The graphon mean field game and its GMFG equations are due to Caines and Huang [33, 34], who set up the type-indexed system and the field coupling lifted here; the probabilistic theory of graphon mean field *systems* — the field McKean–Vlasov flow underlying lemma 26.2 and the decoupling link of theorem 26.5 — is developed by Bayraktar, Wu and Zhang [16], and the static and linear–quadratic graphon games that anchor the LQG worked computation by Parise and Ozdaglar [108], Carmona, Cooney, Graves and Laurière [39], and Aurell, Carmona and Laurière [10], whose linear–quadratic analysis is the closest published relative of worked computation 26.12 and its operator Riccati. The entire derivation is the graphon lift of the classical master-equation theory of Cardaliaguet, Delarue, Lasry and Lions [37] and Carmona and Delarue [41] (Chapters 4–5 for the calculus on Wasserstein space and the common-noise master equation), to which theorems 26.3, 26.5 and 26.7 reduce wherever the classical arguments transfer; the displacement-monotone refinements that may eventually furnish the missing Step 3 are those of Gangbo and Mészáros [75] and Gangbo, Mészáros, Mou and Zhang [76], and the weak-monotonicity common-noise well-posedness of Ahuja [4] is the template for the (open) graphon common-noise theory. The honest status of the field — which cases are theorems and which are conjectures — follows the modern landscape surveyed in [11]; the sparse / L^p continuation is chapter 27, and the open problems are collected in chapter 31.

Chapter 27

Sparse Networks: L^p Graphons and Graphex Mean Field Games

This chapter is a confrontation. On one side stands the dense theory of Part IV, complete and self-consistent; on the other stand the networks one actually wants to model — social graphs, citation networks, power grids, the web — which are sparse and heavy-tailed, and which the dense theory does not so much approximate poorly as refuse to see at all. Our task is to locate the single load-bearing assumption that produces the conflict, weaken exactly that assumption, and report honestly on how much of the edifice survives the weakening.

The first thing to be clear about is how deeply the density assumption is wired in. Every theorem of Part IV is, at bottom, a theorem about *dense* networks. A graphon is a bounded kernel $W\colon [0,1]^2 \to [0,1]$; the sampled graph $G(N,W)$ of definition 19.1 has $\Theta(N^2)$ edges; and the cut metric of chapter 17 that drives the convergence theory is calibrated to precisely that density. The boundedness is not an innocent normalization. A bound $W \leq 1$ caps each connection probability by a constant, so a typical vertex — whose $N-1$ potential partners each connect with probability of order $\int W(x,\cdot)$, a fixed positive number — accumulates of order N neighbors; boundedness *forces* density. The graphon mean field game built on this foundation — the coupled HJB–Fokker–Planck system across a kernel of chapter 22, its existence and uniqueness theory of chapter 24, the finite-network approximation of chapter 25, and the master equation of chapter 26 — inherits the density assumption wholesale, because it inherits the kernel.

The wound this chapter sets out to heal was diagnosed already in section 19.5, in two short propositions that are worth recalling as the motivation for everything that follows. The first says that the limit object is blind to sparsity: any sequence of graphs with subquadratic edge count converges in cut metric to the *zero* graphon, so a sparse network and an empty network have the same dense limit. The second says that the failure is built into the sampling model itself: the W-random model is *intrinsically* dense, producing $\Theta(N)$ degrees and $\Theta(N^2)$ edges almost surely, with no choice of bounded W able to escape. The dense machinery cannot be tuned into the sparse regime; it must be relaxed.

We proceed along the road mapped in section 19.6, organizing the chapter as a sequence of questions rather than a list of topics. *What, precisely, do real networks demand that the dense theory* *cannot give, and how many independent relaxations does meeting those demands require?* That is section 27.1, which converts the qualitative Ch. 19 diagnosis into three quantitative desiderata and shows that they split along *two logically independent* axes: allowing the limiting kernel to be unbounded (an L^p graphon), and allowing the sampled graph to be genuinely sparse (a vanishing target density $\rho_N \to 0$, or, more radically, a vertex set that is not $[0,1]$ at all). *How far can the existing well-posedness theory be pushed along the first axis?* That is section 27.2, and the news is surprisingly good: the boundedness $W \le 1$ was never the operative hypothesis — square-integrability is — and the GMFG well-posedness theory of chapter 24 extends verbatim to L^2 graphons, with the operator norm $\|\mathbb{W}\|$ controlled by $\|W\|_{L^2}$ in place of $\|W\|_\infty$, right up to the line $p = 2$ below which the operator theory genuinely dies. *And along the second axis, where genuine sparsity lives?* That is section 27.3, where the graphex / sampling-convergence framework builds the random graph from a point process (the underlying Poisson calculus is developed self-containedly in appendix H) and delivers true subquadratic sparsity — here the news is honestly mixed, since the game over a graphex limit is only partly under control. *What single physical fact have we learned by the end?* That is section 27.4, which extracts the one reading the chapter earns: that $p = 2$, the degree exponent $\gamma = 3$, and a divergent susceptibility are one threshold seen three ways. Throughout, in keeping with the standing convention of appendix A.1, value functions u are solved backward from terminal data and population fields m forward from initial data; and, since a graphon W is in scope everywhere, Brownian motion is written B (appendix A.5).

A warning that sets the tone. This is a frontier chapter. Some of what follows is theorem, some is honest conjecture, and the boundary between them is itself one of the chapter's deliverables — locating it sharply is part of what we deliver, not an embarrassment we hide. We flag the status of every substantive claim as we go, and the closing ledger (and chapter 31) keeps the books.

27.1 The failure mode, made quantitative

The preamble promised to make the collapse of the dense machinery quantitative and to isolate the relaxations the repair requires; this section delivers on both. The Ch. 19 diagnosis we recalled — sparse graphs flatten to the zero graphon, the bounded model is intrinsically dense — is so far a qualitative verdict, and a qualitative verdict cannot tell us *how much* of the framework must change. So we proceed in three steps. First we name exactly what a sparse network model is obliged to reproduce, distilling the demands of real data into three sharp quantitative desiderata that the dense theory provably cannot meet. Then we exhibit one concrete mechanism — thinning the edges by a vanishing target density, driven by an unbounded rank-one weight — and show by direct computation that it does meet them, which both certifies that the desiderata are achievable and produces, as a by-product, the arithmetic linking a kernel's integrability to a graph's degree-tail exponent that the whole chapter turns on. Finally we separate two relaxations that are perilously easy to conflate — unbounding the kernel and sparsifying the sample — and show they are logically independent, which is the scaffolding that lets the next two sections treat each axis on its own terms. We begin with the demands.

27.1.1 What real networks insist upon

We begin, as promised, with the demands real data places on us; and the sharpest way to state them is against the backdrop of exactly what the dense theory delivers, so that each demand is visibly a place where model and world part ways. Two propositions from chapter 19 already located that parting; before naming the demands it is worth restating those propositions in words, because the intuition they carry is the engine of everything that follows in this section.

The first, proposition 19.13, is a statement about the *limit object*: the cut metric simply cannot see sparsity. Any sequence of graphs whose edge count is subquadratic, $e(G_n) = o(v(G_n)^2)$, converges in cut metric to the *zero* graphon, no matter how intricate its internal wiring. The reason is a counting mismatch. The cut distance compares *edge densities* — fractions of *possible* edges that are actually present across each cut — and a graph on v vertices has $\binom{v}{2} = \Theta(v^2)$ possible edges; if only $o(v^2)$ of them are realized, then the fraction present across every cut tends to 0, and a graph all of whose cut densities vanish is, in the only metric the dense theory owns, indistinguishable from the empty graph. A sparse network and a network with no edges at all are assigned the *same* dense limit. The limiting procedure discards precisely the structure we came to study.

The second, proposition 19.14, shifts attention from the limit to the *sampling model* and shows the obstruction is not a defect of the limit we happened to choose but is wired into the generative mechanism itself. Under (A-Reg-W) with $\int W > 0$, the degree of a typical vertex of the W-random graph is exactly $\mathrm{Binomial}(N-1, d_W(U))$, with $d_W(x) = \int_0^1 W(x,y)\,\mathrm{d}y$ the degree function. Read this distribution slowly. A vertex of type x has $N-1$ potential partners, and it connects to each one independently with probability $W(x, U_j)$, whose average over a random partner is the fixed number $d_W(x)$. The decisive point is that this per-partner probability is an $O(1)$ *constant* that does not shrink as the network grows: boundedness caps W above by 1, but with $\int W > 0$ the typical connection probability is bounded *below* by a positive constant too. Summing $N-1$ trials each of constant success probability gives expected degree $(N-1)\,d_W(x) = \Theta(N)$: every vertex is wired to a fixed *fraction* of the entire population, and that fraction never decays. Summing over all vertices, the edge count is $\Theta(N^2)$ almost surely. The culprit in both propositions is one and the same feature — the bound $W \leq 1$ pins connection probabilities to constants, and probabilities that do not shrink with N are exactly what density *means*.

With the failure mechanism named we can say precisely what a replacement must do. We distill the demands of real data into three quantitative desiderata: features that a sparse network model is obliged to reproduce and that, by the two propositions just recalled, the bounded dense model provably cannot.

(S1) Linear edge count. $e(G_N) = \Theta(N)$, equivalently a bounded average degree, as against the $\Theta(N^2)$ forced by proposition 19.14(2). This is the most basic sparsity demand and the one the dense model fails most directly: its average degree $(N-1)\int W$ diverges linearly in N. Real social and technological networks do not behave this way — the typical number of a person's acquaintances, or of a router's links, stays roughly constant as the system grows from thousands to millions of nodes; it does not scale up in proportion to the population. A faithful model must hold the mean degree bounded while the size goes to infinity, and bounded mean degree is exactly $e = \Theta(N)$.

(S2) Sublinear maximum degree. $\max_i \deg(i) = o(N)$, against the $\Theta(N)$ maximum degree of the bounded model. Even granting heterogeneity, the most-connected vertex of a real network — a celebrity account, a backbone hub — is large but is still a *vanishing fraction* of the whole: it is adjacent to many nodes but not to a positive fraction of all of them. In the bounded model this is impossible, because every type's expected degree $(N-1)\,d_W(x)$ is at most $N-1$ and, for any type with $d_W(x)$ bounded away from 0, is already $\Theta(N)$: with connection probabilities capped by a constant, even the hubs can only grow linearly, never sublinearly. A genuine sparse model must let the maximum degree grow — producing real hubs — while keeping that growth strictly below N.

(S3) Heavy-tailed unnormalized degrees. The degree distribution, taken *without* any rescaling by N, must have a heavy (e.g. power-law) tail whose index is independent of N. This is the subtle desideratum and the one that most sharply exposes what the dense model cannot do. The bounded model *does* produce a stable limiting shape — but only for the *normalized* degree $\deg(i)/(N-1)$, which converges to $d_W(U)$, a random variable bounded by 1 (proposition 19.14(3)). The raw, unnormalized degree $\mathrm{Binomial}(N-1, d_W(U))$ has mean $\Theta(N)$: its entire distribution marches off to infinity with the network size, and at any fixed count k the probability $\mathbb{P}(\deg = k) \to 0$. So the only N-independent object the dense model can offer is a law of *fractions* of the population — never a law of *counts*. But a power-law degree tail is, by definition, a statement about counts: $\mathbb{P}(\deg = k) \propto k^{-\gamma}$ at fixed $k = 1, 2, 3, \ldots$, the *same* small integers no matter how large the graph. This is the load-bearing point hidden in the phrase "only after dividing by $N-1$." Dividing by $N-1$ to manufacture a fixed shape is precisely the operation that erases an unnormalized tail: it rescales the count axis by $1/N$, collapsing every fixed degree k to the single point 0 in the limit and compressing the whole tail into an arbitrarily thin sliver near the origin. A model whose only scale-free content lives in normalized degrees has, by construction, no unnormalized tail left to report. Meeting (S3) therefore requires a model in which the degree law stabilizes *before* any division by N — which, as the next subsection shows, is exactly what a mixed-Poisson limit provides.

These three are not pathologies of exotic datasets; they are the rule. Across social, biological, and technological networks one measures power-law degree distributions $\mathbb{P}(\deg = k) \propto k^{-\gamma}$, and the exponent γ falls overwhelmingly in the window $(2, 3)$ [48, 45]. That window is not a coincidence of measurement, and it is worth understanding what makes it special before we exploit it. The two boundary values mark two qualitative transitions in the moments of the degree law. At $\gamma = 2$ the mean degree $\sum_k k\,\mathbb{P}(\deg = k)$ passes from divergent to convergent; for $\gamma > 2$ the network has a well-defined finite average degree, consistent with the sparsity demanded by (S1). At $\gamma = 3$ the *second* moment passes from divergent to convergent; for $\gamma < 3$ the degree variance is infinite, the signature of genuine hub-dominated heterogeneity in which a few vertices carry a macroscopic share of the edges. The window $(2, 3)$ is thus exactly the regime of *finite mean but infinite variance*: light enough to be sparse, heavy enough to be ruled by its hubs — and this is where almost all real networks live.

We flag now — as a promise to be redeemed, not a claim to be taken on faith — why this same window will turn out to be the precise frontier of the mean-field-game theory, and not merely a fact about graphs. When we place a game on such a network, the population coupling acts only through the kernel's integral operator $\mathbb{W}$, and the strength of that coupling is governed by its operator norm. For the heavy rank-one weight that generates a scale-free degree tail, that operator norm is exactly a *second moment* of the weight profile, $\|f\|_{L^2}^2$ — the quantity a physicist would call the *susceptibility* of the coupling, the leading eigenvalue through which a perturbation of the mean field feeds back on itself. The worked computation of worked computation 27.19 will show that this susceptibility diverges at exactly the same threshold as the degree variance, $\gamma = 3$, so that the divergence of the second moment behind (S3) and the divergence of the coupling are one event seen twice. The empirically dominant window $\gamma \in (2,3)$ is therefore precisely the regime in which the mean-field-game coupling becomes infinitely strong and the dense well-posedness theory of chapter 24 provably breaks. We cannot prove this yet — we still lack both the sparsification mechanism and the L^p operator theory — but it is the reason the window $(2,3)$ deserves to be circled here, and it is the destination the rest of the chapter steers toward.

We have, then, a sharp target — the three desiderata (S1)–(S3) — and a sharp diagnosis — boundedness $W \le 1$ is the single obstruction. What we still lack is a *mechanism*: a concrete way to generate graphs that actually meet (S1)–(S3) while staying recognizably close to the dense model we already understand and can compute with. The most conservative such mechanism keeps the unit-interval type space and the latent kernel intact and merely thins the edges by a vanishing target density. We turn to it now.

27.1.2 Sparsification by a target density

The previous subsection left us with a sharp want: a concrete generative mechanism that actually meets (S1)–(S3) while staying recognizably close to the dense model we already understand and can compute with. We answer that want now, and the answer is deliberately the most conservative one available. Rather than discard any of the three pillars of the dense W-random model of definition 19.1 — the unit-interval type space, the latent kernel, the conditionally-independent edge sampling — we keep all three and change exactly one thing: we thin the edges by an overall factor that vanishes with the network size. Concretely we attach a *target density* $\rho_N \in (0,1]$ to the sampling model and connect a pair of types with probability proportional to $\rho_N W$ in place of W. The name is apt: ρ_N is the single dial that sets how dense the sampled graph will be, and driving it to zero at the right rate is precisely what converts the intrinsically dense model into a sparse one. Everything else in the construction is inherited verbatim, which is exactly why this is the repair to try first — it perturbs the dense theory in one controllable place, and we can read off what survives.

Definition 27.1 (Sparse W-random graph)**.** Let $W\colon [0,1]^2 \to [0,\infty)$ be symmetric and measurable (not necessarily bounded by 1), and let $\rho_N \in (0,1]$. The *sparse W-random graph $G(N,\rho_N,W)$* is obtained by drawing $U_1,\dots,U_N$ i.i.d. Unif$[0,1]$ and, conditionally on the types, including each edge $\{i,j\}$ independently with probability

$$p_{ij}^N \;=\; \min\{1,\; \rho_N\, W(U_i,U_j)\}\,. \tag{27.1}$$

The choice $\rho_N \equiv 1$ with $W \le 1$ recovers the dense model $G(N,W) = G(N,1,W)$ of definition 19.1. The regime of interest is $\rho_N \to 0$; the canonical sparse scaling is $\rho_N = c/N$.

Two features of definition 27.1 deserve a word before we put them to work, because together they are what make the definition do its job. The first is that W is no longer required to be bounded by 1; it may take values anywhere in $[0, \infty)$. This is not a cosmetic generalization. The whole reason to undertake the repair is desideratum (S3), and (S3) will turn out to demand a heavy-tailed — hence unbounded — kernel, so the sampling model must be able to ingest one. But an unbounded W cannot be multiplied by a constant and read directly as a probability: $\rho_N W(U_i, U_j)$ can exceed 1 wherever W is large. This is exactly what the second feature, the truncation $\min\{1, \cdot\}$ in (27.1), repairs. It clips the raw intensity $\rho_N W$ back into $[0, 1]$ at the rare type-pairs where it would overshoot, so that p_{ij}^N is always a legitimate edge probability no matter how violently W blows up. The truncation is therefore the precise device that lets an unbounded kernel feed a well-defined edge sampling model; it is the price of admission for heavy tails, and the proofs below will show it costs almost nothing.

That "almost nothing" is the content of the truncation's third virtue: it switches itself off in the limit. Fix a pair of types (U_i, U_j). With the canonical scaling $\rho_N = c/N$, the raw intensity $\rho_N W(U_i, U_j) = (c/N)W(U_i, U_j) \to 0$ as $N \to \infty$ almost surely (the kernel value is a fixed finite number for a.e. pair, and we are dividing it by N). So for all large N the clip is inactive at that pair and p_{ij}^N equals the untruncated $(c/N)W(U_i, U_j)$ on the nose. The truncation bites only on a vanishing set of exceptionally heavy pairs, and the analysis to come is in large part the careful accounting that this vanishing set contributes nothing to the limiting degree law. We now carry out that accounting.

Proposition 27.2 (Mixed-Poisson degrees in the sparse limit)**.** *Let $W\colon [0,1]^2 \to [0, \infty)$ be symmetric and measurable with degree function $d_W(x) = \int_0^1 W(x, y)\,\mathrm{d}y$ finite for a.e. x, and suppose $d_W \in L^1[0, 1]$. Sample $G(N, \rho_N, W)$ with $\rho_N = c/N$ for a constant $c > 0$. Then:*

1. *the expected number of edges satisfies $\mathbb{E}\big[e\big(G(N, \rho_N, W)\big)\big] = \frac{c}{2}\, t(K_2, W)\, N + o(N)$, where $t(K_2, W) = \int_{[0,1]^2} W$; in particular the graph is sparse, $e = \Theta(N)$, realizing* (S1)*;*

2. *conditionally on $U_i = x$, the degree of vertex i converges in distribution to a Poisson law,*

$$\deg(i) \overset{d}{\Longrightarrow} \mathrm{Poisson}\big(c\, d_W(x)\big), \tag{27.2}$$

and unconditionally the degree of a uniformly chosen vertex converges to the mixed-Poisson *law* $\mathrm{Poisson}(c\, d_W(U))$*, $U \sim \mathrm{Unif}[0, 1]$.*

Proof. Part (1): the edge count is linear. Every one of the $\binom{N}{2}$ potential edges is included independently with probability p_{ij}^N, and the types are exchangeable, so the two endpoints of a generic edge may as well be U_1, U_2 and $\mathbb{E}[e] = \binom{N}{2}\mathbb{E}\Big[p_{12}^N\Big]$. It remains to evaluate $\mathbb{E}\Big[p_{12}^N\Big]$ to leading order. Split according to whether the clip is active. On the event $\{(c/N)W(U_1, U_2) \le 1\} = \{W(U_1, U_2) \le N/c\}$ the truncation does nothing and $p_{12}^N = (c/N)W(U_1, U_2)$; on the complementary heavy event $\{W(U_1, U_2) > N/c\}$ it replaces a number larger than 1 by exactly 1. Writing the expectation as the untruncated mean minus the mass removed by clipping,

$$\mathbb{E}\Big[p_{12}^N\Big] = \frac{c}{N} \int_{[0,1]^2} W \;-\; \mathbb{E}[*] \left(\tfrac{c}{N} W(U_1, U_2) - 1\right) \mathbf{1}\, \{W(U_1, U_2) > N/c\}.$$

The first term is $(c/N)t(K_2, W)$, finite because $W \in L^1([0,1]^2)$ (which holds since $d_W \in L^1$ and $\int_{[0,1]^2} W = \int_0^1 d_W$). The correction is at most $(c/N)\mathbb{E}[W\,\mathbf{1}\{W > N/c\}]$, and here is the one analytic input: for an integrable function the contribution of its own large-value tail to the integral vanishes as the threshold recedes, $\mathbb{E}[W\,\mathbf{1}\{W > N/c\}] \to 0$. (This is the defining property of an integrable function — equivalently, the uniform integrability of the single random variable $W(U_1, U_2)$ — and it is strictly more than Markov's inequality would give; we return to this distinction in part (2), where it is the crux.) So the correction is $(c/N) \cdot o(1) = o(1/N)$, whence $\mathbb{E}\left[p_{12}^N\right] = (c/N)t(K_2, W) + o(1/N)$ and $\mathbb{E}[e] = \binom{N}{2}\left[(c/N)t(K_2, W) + o(1/N)\right] = \frac{c}{2}t(K_2, W)N + o(N)$. The edge count is $\Theta(N)$ in expectation: the average degree $2\mathbb{E}[e]/N \to c\,t(K_2, W)$ is a finite constant, independent of N. This is (S1), and it shows the role of the scaling $\rho_N = c/N$: it is the unique power of N at which the $\binom{N}{2} = \Theta(N^2)$ candidate edges, each kept with probability $\Theta(1/N)$, produce $\Theta(N)$ actual edges.

Part (2): the degree law is mixed Poisson. Condition on $U_i = x$, fixing the type of the vertex whose degree we track. Its degree is the number of its $N-1$ potential partners to which it actually connects, a sum of $N-1$ independent indicators with success probabilities $p_{ij}^N = \min\{1, (c/N)W(x, U_j)\}$, the partner types U_j being i.i.d. uniform. Introduce the untruncated probabilities $q_j^N = (c/N)W(x, U_j)$, so that $p_j^N = \min\left\{1, q_j^N\right\}$ and $p_j^N = q_j^N$ except on the heavy event $\{W(x, U_j) > N/c\}$. We prove convergence to Poisson$(c\,d_W(x))$ in two moves: first for the untruncated array, then by showing the truncation cannot change the limit.

For the untruncated array, this is the classical law of rare events: a row-sum of independent indicators converges to a Poisson law when each individual success probability is uniformly negligible and the total mean converges. Both conditions hold here. The total mean is

$$\sum_{j=1}^{N-1} \mathbb{E}\left[q_j^N\right] = (N-1)\,\frac{c}{N}\,\mathbb{E}[W(x, U)] = (N-1)\,\frac{c}{N}\,d_W(x) \xrightarrow[N\to\infty]{} c\,d_W(x),$$

the target Poisson mean; and the individual means are uniformly small, $\max_j q_j^N = (c/N)\max_j W(x, U_j) \to 0$ in probability, because $W(x, \cdot) \in L^1$ forces $s\,\mathbb{P}(W(x, U) > s) \to 0$, so the largest of N samples grows slower than N. The quantitative engine behind "converges to Poisson" is Le Cam's inequality (lemma H.8), which bounds the total-variation distance between the law of $\sum_j \text{Bernoulli}(q_j^N)$ and $\text{Poisson}(\sum_j q_j^N)$ by $\sum_j (q_j^N)^2 \le (\max_j q_j^N)\sum_j q_j^N$; with the total mean bounded and $\max_j q_j^N \to 0$ this product vanishes, which is the Poisson limit theorem theorem H.9 specialized to our array.

It remains to remove the truncation. The truncated and untruncated degrees can be built on the same probability space (couple them indicator-by-indicator), and they differ only where the clip acted, by which amount $q_j^N - p_j^N = (q_j^N - 1)^+$. The total-variation distance between the two sums is therefore at most the expected total clipped mass $\sum_j \mathbb{E}\left[(q_j^N - 1)^+\right]$, and this we now show vanishes. Since $(q_j^N - 1)^+ \le q_j^N\,\mathbf{1}\left\{q_j^N > 1\right\} = (c/N)W(x, U_j)\,\mathbf{1}\{W(x, U_j) > N/c\}$,

$$\sum_{j=1}^{N-1} \mathbb{E}\left[(q_j^N - 1)^+\right] \le (N-1)\,\frac{c}{N}\,\mathbb{E}[*]\,W(x, U)\,\mathbf{1}\{W(x, U) > N/c\} = c \cdot o(1) \;\longrightarrow\; 0, \tag{27.3}$$

the inner expectation being a tail-truncated first moment that vanishes by integrability of $W(x, \cdot)$, exactly as in part (1). Hence the truncated array has the same Poisson limit as the untruncated one, which is (27.2).

The uniform-integrability step is the crux, and it is genuinely stronger than Markov. It is tempting to control the truncation by simply counting how many edges get clipped, via Markov's inequality: $\mathbb{E}[\#\{j : W(x,U_j) > N/c\}] = (N-1)\mathbb{P}(W(x,U) > N/c) \le (N-1)\,\frac{c}{N}\,\mathbb{E}[W(x,U)] = c\,d_W(x)$. But this bound is $\Theta(1)$, not $o(1)$: it says only that a *bounded number* of partners — not a vanishing number — have an above-threshold raw intensity. That is too weak to conclude, because a bounded number of clipped indicators could in principle shift the degree by a bounded amount and so corrupt the Poisson limit. What rescues the argument is not that the heavy event is rare but that the *mass* it carries is small: the relevant quantity is not the probability $\mathbb{P}(W > N/c)$ but the size-weighted tail $\mathbb{E}[W\,\mathbf{1}\{W > N/c\}]$, and this tends to 0 for every integrable $W(x,\cdot)$ precisely because the tail of a convergent integral is negligible. Markov keeps only the rarity and throws away the magnitude; on a heavy-tailed kernel the magnitude on the rare event can be enormous, so rarity alone settles nothing, while the size-weighted tail bound (27.3) settles everything. This is why the hypothesis of the proposition is $d_W \in L^1$ and not merely $d_W < \infty$ pointwise: integrability is exactly the uniform-integrability statement that makes the clipped mass vanish.

Finally, the conditional limit Poisson$(c\,d_W(x))$ holds for a.e. fixed x; averaging over the vertex's own type $U_i \sim \mathrm{Unif}[0,1]$ replaces the deterministic mean $c\,d_W(x)$ by the random mean $c\,d_W(U)$, giving the *mixed*-Poisson law Poisson$(c\,d_W(U))$ for a uniformly chosen vertex. □

Proposition 27.2 is the lever that turns a heavy-tailed *kernel* into a heavy-tailed *degree distribution*, and it is worth saying precisely why before we pull it. The limiting degree is not Poisson but *mixed* Poisson: a Poisson count whose mean $\Lambda = c\,d_W(U)$ is itself random, drawn by sampling the vertex's type. A pure Poisson law is light-tailed — its tail decays faster than any power — so if the degree is to be heavy-tailed, the heaviness must come entirely from the mixing variable Λ. And it does: a mixed-Poisson law inherits the tail of its mixing distribution, so that whenever $c\,d_W(U)$ has a power-law tail the degree has the *same* power-law tail. The degree-tail problem has thus been reduced to a question purely about the kernel: make the degree function d_W heavy-tailed as a function of the type. The cleanest way to do that, and the one that connects straight to the operator theory the chapter is steering toward, is an unbounded rank-one weight. We now compute that case in full.

Corollary 27.3 (Power-law degrees from a heavy rank-one weight)**.** *Let $W(x,y) = f(x)f(y)$ with weight profile $f(x) = x^{-\nu}$, $0 < \nu < 1$, and sample $G(N, c/N, W)$. Then $f \in L^1[0,1]$ with $\int_0^1 f = \frac{1}{1-\nu}$, the degree function is $d_W(x) = \frac{1}{1-\nu}x^{-\nu}$, and the limiting (mixed-Poisson) degree distribution has a power-law tail*

$$\mathbb{P}(\deg \ge k) \;\sim\; C\,k^{-1/\nu} \qquad (k \to \infty), \qquad \textit{i.e. exponent}\;\; \gamma = 1 + \tfrac{1}{\nu}. \tag{27.4}$$

In particular $\nu \in (\frac{1}{2}, 1)$ produces precisely the empirically dominant scale-free window $\gamma \in (2,3)$, $\nu \in (0, \frac{1}{2})$ gives $\gamma > 3$, and the boundary $\nu = \frac{1}{2}$ gives $\gamma = 3$.

Proof. First the elementary facts about the weight. With $f(x) = x^{-\nu}$ and $0 < \nu < 1$, $\int_0^1 f = \int_0^1 x^{-\nu}\,\mathrm{d}x = \frac{1}{1-\nu}$ is finite, so $f \in L^1[0,1]$; the degree function of the rank-one kernel factorizes, $d_W(x) = f(x)\int_0^1 f = \frac{1}{1-\nu}x^{-\nu}$, inheriting the same singular profile as f.

Now the tail of the mixing variable. With $U \sim \mathrm{Unif}[0,1]$ the random mean is $\Lambda = c\, d_W(U) = \frac{c}{1-\nu} U^{-\nu}$. To find its tail we invert: $\Lambda > t$ means $\frac{c}{1-\nu} U^{-\nu} > t$, i.e. $U^{-\nu} > \frac{(1-\nu)t}{c}$, i.e. $U < \big(\frac{c}{(1-\nu)t}\big)^{1/\nu}$. For t large enough that this threshold is below 1, the uniform probability is the threshold itself,

$$\mathbb{P}(\Lambda > t) = \Big(\frac{c}{(1-\nu)t}\Big)^{1/\nu} = C\, t^{-1/\nu}, \qquad C = \Big(\frac{c}{1-\nu}\Big)^{1/\nu},$$

a Pareto tail of index $1/\nu$. The map $\nu \mapsto 1/\nu$ is the heart of the corollary: a singularity $x^{-\nu}$ of strength ν in the weight produces a degree-mean tail of index exactly $1/\nu$. A stronger singularity (larger ν) gives a heavier tail (smaller index).

Finally, transfer this tail from the mean Λ to the degree Poisson(Λ). The mixed-Poisson tail-transfer lemma (lemma H.10) says a Poisson count whose random mean has a regularly-varying tail of index $-1/\nu$ has the *same* tail index:

$$\mathbb{P}(\deg \geq k) = \mathbb{P}(\mathrm{Poisson}(\Lambda) \geq k) \sim \mathbb{P}(\Lambda > k) \sim C\, k^{-1/\nu} \qquad (k \to \infty),$$

which is (27.4). The intuition is a separation of scales: conditioned on a large mean $\Lambda = t$, the Poisson count concentrates around t with fluctuations of order $\sqrt{t}$, which are a vanishing *fraction* $1/\sqrt{t}$ of t; so for large k the event $\{\mathrm{Poisson}(\Lambda) \geq k\}$ is, up to negligible corrections, the event $\{\Lambda \gtrsim k\}$. The light Poisson smoothing cannot manufacture or erase a power-law tail — it only blurs the mean by a relatively negligible amount — so the heavy tail of Λ passes through to the degree unchanged. The exponent is read off by $\gamma = 1 + \frac{1}{\nu}$ (the index of $\mathbb{P}(\deg \geq k)$ is $\gamma - 1 = 1/\nu$), and the three windows follow: $\nu \in (\frac{1}{2}, 1) \Rightarrow \frac{1}{\nu} \in (1,2) \Rightarrow \gamma \in (2,3)$, the empirically dominant scale-free band; $\nu \in (0, \frac{1}{2}) \Rightarrow \gamma > 3$; and the boundary $\nu = \frac{1}{2} \Rightarrow \gamma = 3$. □

The corollary deserves a pause, because in producing (S3) it has quietly settled (S2) as well and has planted the arithmetic the rest of the chapter will harvest. Take (S3) first. The power law (27.4) exists only because $\nu > 0$, i.e. only because the weight $f(x) = x^{-\nu}$ blows up at the origin and is therefore unbounded; and then $W = f \otimes f$ is unbounded too. There is no way around this. A bounded weight has a bounded degree function, hence a bounded mixing variable Λ, hence a light-tailed (genuinely Poisson) degree — no power law at all. So a scale-free degree distribution is logically incompatible with the boundedness assumption $W \leq 1$ of (A-Reg-W): *meeting* (S3) *forces the kernel to be unbounded.* This is the central structural fact the subsection was built to expose, and it is what makes the unbounded function class of the next section unavoidable rather than a matter of taste.

The same heavy weight delivers (S2), the sublinear maximum degree, and the argument is a short order-statistic computation worth spelling out. The expected degree of a vertex of type x is $c\, d_W(x) = \frac{c}{1-\nu} x^{-\nu}$, a decreasing function of x; the most-connected vertex is therefore the one with the *smallest* sampled type, $U_{(1)} = \min\{U_1, \ldots, U_N\}$. The minimum of N i.i.d. uniforms has mean $1/(N+1)$ and is $\Theta(1/N)$ with high probability, so the largest expected degree in the sample is

$$c\, d_W(U_{(1)}) = \frac{c}{1-\nu}\, U_{(1)}^{-\nu} = \Theta\big((1/N)^{-\nu}\big) = \Theta(N^{\nu}).$$

Because $\nu < 1$ this is $o(N)$: the hubs grow without bound (a real hub, since $N^{\nu} \to \infty$), yet each remains a vanishing fraction of the population (since $N^{\nu}/N = N^{\nu-1} \to 0$). That is exactly (S2) —

$\max_i \deg(i) = o(N)$ in probability — holding simultaneously with the $\Theta(1)$ average degree of (S1). The exponent ν that tunes the tail also tunes the hub size: heavier tails (ν near 1) make hubs nearly linear, lighter tails (ν near 0) make them nearly $O(1)$, but the strict inequality $\nu < 1$ keeps them strictly sublinear throughout. So a single rank-one weight $x^{-\nu}$, fed through the target-density model, meets (S1) and (S2) outright and (S3) in its mixed-Poisson limit.

What it has *not* yet done is reconcile this success with the operator theory the game needs, and the seed of that reconciliation is the integrability arithmetic of $f = x^{-\nu}$, which we flag now because it returns as the spine of worked computation 27.19. The weight is square-integrable exactly when $\int_0^1 x^{-2\nu}\,dx < \infty$, i.e. $2\nu < 1$, i.e. $\nu < \frac{1}{2}$ — which, under the map $\gamma = 1 + 1/\nu$, is exactly $\gamma > 3$. Equivalently, $f \in L^1 \setminus L^2$ holds precisely for $\nu \in [\frac{1}{2}, 1)$, i.e. $\gamma \in (2, 3]$, with the first failure of square-integrability landing exactly at the boundary $\nu = \frac{1}{2}$, $\gamma = 3$. The empirically dominant scale-free window $\gamma \in (2, 3)$ therefore sits *strictly inside* the regime where the weight is integrable but not square-integrable. Hold that coincidence: the degree-tail boundary $\gamma = 3$ and the square-integrability boundary $\nu = \frac{1}{2}$ are the same line, and we will meet it a third time as the boundary where the coupling operator's norm diverges.

We close by naming the question this leaves open and handing it to the next subsection. The mechanism just built reached (S3) only by going through an unbounded kernel, and reached (S1) only by switching on a vanishing target density $\rho_N = c/N$. Were these two concessions one concession or two — does unbounding the kernel already buy the sparsity, or is the target density doing independent work? The answer is not obvious, and getting it wrong would conflate two relaxations that behave very differently in the game theory to come. The next subsection settles it by separating the two axes cleanly.

27.1.3 Two independent axes

The previous subsection closed on a worry it could not yet dispel. To meet all three desiderata at once we had to do two distinct things to the dense model — replace the bounded kernel by an unbounded weight $f(x) = x^{-\nu}$, and switch on a vanishing target density $\rho_N = c/N$ — and it was not obvious whether these were two independent moves or a single move counted twice. The stakes in answering are not bookkeeping. The two relaxations enter the model through entirely different doors: an unbounded kernel alters the *limit object* — the operator $\mathbb{W}$ through which a game eventually couples — while a vanishing ρ_N alters the *sampling law* that draws the finite graph around that limit. Conflating them would mislocate where the well-posedness theory of chapter 24 breaks and which repair restores it. So before proceeding we pry the two axes apart, and the cleanest way to show they are genuinely independent is to switch each one on alone and watch the other defect stubbornly survive.

Remark 27.4 (Unboundedness and sparsity are independent)**.** Allowing the limiting kernel to be *unbounded* and allowing the sampled graph to be *sparse* are logically distinct relaxations; each, applied in isolation, leaves one of the two defects firmly in place.

- *Unbounded kernel, no sparsification: still dense.* Take an unbounded but integrable kernel $W \in L^1([0,1]^2)$ — say the rank-one weight $f \otimes f$ with $f = x^{-\nu}$ of corollary 27.3 — and sample it with *no* target density, $\rho_N \equiv 1$, so that the edge probability is the bare truncation $p_{ij}^N = \min\{1, W(U_i, U_j)\}$ of (27.1). The graph is still *dense*. The intuition is that density was never a statement about how *large* the kernel can get — the truncation already caps every connection probability at 1 — but about whether connection probabilities stay bounded *below*, away from zero, on a macroscopic set of pairs, and unbounding the kernel does nothing to that floor. Concretely, since $W \geq 0$ is not a.e. zero there are a constant $\delta > 0$ and a product set $A \times B \subseteq [0,1]^2$ of positive measure on which $W \geq \delta$; there $p_{ij}^N \geq \min\{1, \delta\} > 0$, so a vertex whose type lands in A connects to each of the $\Theta(N)$ vertices whose types land in B with at least this fixed probability and accumulates $\Theta(N)$ neighbours — precisely the mechanism of proposition 19.14. The edge count is $\Theta(N^2)$ almost surely. Unboundedness enriches the *limit object*, admitting the heavy weights and the divergent degree function d_W that the tail mechanism feeds on, but it buys no sparsity in the *sample*.

- *Bounded kernel, sparsified: light-tailed.* Conversely, take a genuinely bounded kernel, $W \leq B < \infty$, and make it sparse the only way left, through the vanishing target density $\rho_N = c/N$. Now proposition 27.2 applies and yields exactly $\Theta(N)$ edges — so this axis delivers the sparsity the first could not — but the degree law it produces is *light*-tailed. The limiting degree of a random vertex is Poisson$(c\, d_W(U))$ of (27.2), and boundedness caps its mixing variable: $d_W(x) = \int_0^1 W(x, \cdot) \leq B$, so the random mean $c\, d_W(U) \leq cB$ is *bounded*. A mixed-Poisson law whose mixing variable is bounded is no heavier-tailed than a single Poisson(cB), whose tail $\mathbb{P}(\deg \geq k)$ decays faster than any power of k — super-exponentially, like $(cB)^k/k!$. There is no power law to be had: a global thinning factor ρ_N controls the *number* of edges uniformly across all types but cannot create heterogeneity in the *propensity* to connect, and that heterogeneity — a heavy tail in d_W — is exactly what a bounded kernel forbids.

Meeting all of (S1)–(S3) therefore requires *both* relaxations, and the division of labour between them is clean: the vanishing target density $\rho_N = c/N$ is what secures the linear edge count (S1) and, with it, the sublinear maximum degree (S2), while the unbounded kernel is what supplies the heavy mixing variable behind the power-law tail (S3). Only their combination — precisely the construction of corollary 27.3 — lands all three desiderata at once.

It is worth carrying an explicit scorecard out of this remark, because the remainder of the chapter is organized by it. The unbounded-kernel axis, taken alone, secures *none* of (S1)–(S3): at $\rho_N \equiv 1$ the graph is dense, its maximum degree is $\Theta(N)$, and in the dense regime the unnormalized degree law cannot even stabilize (proposition 19.14), so the heavy weights this axis does provide have no sparse sample on which to imprint a tail. The sparsification axis, taken alone, secures (S1) and (S2) but *not* (S3): it makes the graph sparse, with a finite bounded average degree and a sublinear (indeed poly-logarithmic) maximum degree, yet its degrees are Poissonian and tail-light. The one desideratum that forces both axes on simultaneously is (S3): a scale-free degree tail is the single feature that needs sparse sampling in order to exist as a law of *counts* at all, and an unbounded kernel in order to be *heavy*. This is why the chapter must develop both relaxations, and why it is safe to develop them separately — they do not interfere, they compose.

Having pried the two axes apart we treat them one at a time, hardest-earned news last. We begin with the unbounded-kernel axis, and here the report is the chapter's one piece of nearly unalloyed good news. The reason to be optimistic is already visible in the asymmetry just exposed: a game couples to its population only through the integral operator $\mathbb{W}$, and an operator is sensitive not to the pointwise size of its kernel but to a single scalar summary of it — the operator norm $\|\mathbb{W}\|$ — which can stay perfectly finite even when W itself blows up. If the entire well-posedness theory of chapter 24 sees the kernel only through $\|\mathbb{W}\|$, then an unbounded but suitably integrable kernel may cost it nothing. Pursuing that possibility means first fixing the function class in which an unbounded kernel is allowed to live — the L^p graphons — and locating, within that scale, the exact integrability threshold at which $\|\mathbb{W}\|$ stops being finite. That threshold, we will find, is $p = 2$. The genuinely sparse axis, where the news is honestly mixed, waits for us in section 27.3.

27.2 L^p graphons: unbounded kernels

The previous section closed by parcelling the repair into two non-interfering relaxations and promising that this one — the unbounded-kernel axis — would carry the chapter's good news. It is time to redeem that promise. We take up that axis and nothing else: the sampling law is held fixed, and the only question is what happens to the *limit* theory of Part IV when the kernel is allowed to grow without bound. The answer is the single most reassuring result in the chapter, and rather than let it surface only at the end of a dichotomy we state its thesis in one sentence now. *Boundedness was never the hypothesis the dense theory actually used; square-integrability was.* Every estimate in the well-posedness theory of chapter 24 that one might fear depended on the cap $W \leq 1$ in fact depends only on $W \in L^2$, and the proofs survive the weakening with a single symbol changed. The bound $W \leq 1$ was, all along, a convenient sufficient condition wearing the costume of a necessary one.

Why a single number — the integrability exponent p — should govern the whole question is already visible in the structural fact isolated at the close of remark 27.4: a game couples to its population only through the integral operator $\mathbb{W}$, never through the pointwise values of the kernel, and an operator feels its kernel only through a scalar summary, the operator norm $\|\mathbb{W}\|$. A kernel may blow up to $+\infty$ on a small set and still induce a perfectly bounded operator, provided the blow-up is integrable enough; conversely, no amount of pointwise smallness elsewhere can rescue an operator whose kernel is too singular to be square-summed. So the operative question is not "how large does W get?" but "how much integrability does it take to keep $\|\mathbb{W}\|$ finite?" — and on the L^p scale that question has a sharp, computable answer.

The section is a four-step descent down that scale, and it is worth holding the whole map in view before the first definition arrives. *First*, we fix the function class — the L^p graphons, symmetric kernels with $\|W\|_{L^p} < \infty$ — a scale that interpolates continuously from the dense theory at $p = \infty$ down toward the sparse regime at $p = 1$. *Second*, we find the true boundedness criterion: the exact location on that scale where $\mathbb{W}$ ceases to be a bounded operator, which we will identify as the pivot $p = 2$. At and above $p = 2$ the Hilbert–Schmidt bound controls $\|\mathbb{W}\|$ by $\|W\|_{L^2}$ in place of $\|W\|_\infty$; below $p = 2$ no such control survives. *Third*, with $\|\mathbb{W}\|$ back under control for $p \geq 2$, we re-run the existence-and-uniqueness theory of chapter 24 and watch it extend *verbatim* to L^2 graphons — the contraction estimate that drives the fixed point reads the kernel only through $\|\mathbb{W}\|$, exactly the quantity the Hilbert–Schmidt bound now furnishes, so not a line of the argument needs rewriting. *Fourth* and last, we locate the failure honestly: below $p = 2$ the operator becomes genuinely unbounded, the fixed-point map loses its contraction, and the theory does not merely lack a proof but provably dies. This dividing line $p = 2$ is no isolated technicality — it is the same threshold the degree-tail arithmetic of corollary 27.3 and the susceptibility computation of worked computation 27.19 will rediscover from their own directions, the chapter's one line seen three ways.

That $p = 2$ should be the pivot is, in hindsight, the most natural value imaginable: the population mean $x \mapsto \bar{m}_t(x)$ lives in the Hilbert space $L^2[0,1]$, and an operator on a Hilbert space asks of its kernel exactly one thing — that it be square-integrable. But to turn this slogan into theorems we must first pin down, with care, just what class of unbounded kernels we have license to work in and how that class sits inside the familiar L^p scale. We make the class precise now.

27.2.1 The function class

We promised the right home for an unbounded kernel, and we now build it. The requirement is a delicate one. The class must be *wide* enough to contain the heavy weights the previous section forced upon us — in particular the rank-one $f \otimes f$ with $f(x) = x^{-\nu}$, which is unbounded and so escapes the classical graphons of definition 15.4 entirely — yet it must be *structured* enough that a single scalar parameter measures "how heavy" a kernel is allowed to be, so that the integrability threshold we are hunting for has a name. The L^p scale is exactly such a structure: one knob p, running from ∞ down to 1, that trades boundedness for admissible singularity. Two preliminary points of motivation set up the definition — why we drop nonnegativity, and why we measure size in an L^p norm rather than a sup norm — and then the nesting of the scale will tell us where on it to look.

The first point is about *sign*. In the graph models of Part IV the kernel was a connection probability: $W(x, y)$ was the chance that types x and y are adjacent, so it had to lie in $[0, 1]$, nonnegative by fiat. But in a mean field game the kernel plays a wholly different role. It is the *coupling weight* with which an agent of type x feels the aggregate behaviour of agents of type y — the entry of $z = \mathbb{W}\bar{m}$ of eq. (18.10) that closes the game's feedback loop — and there is no reason for a coupling to be one-signed. This is precisely the situation of Thread B, the congestion/imitation model carried through the book: there $W(x, y) > 0$ encodes *attraction*, type x benefits from aligning with, or imitating, the crowd at type y, while $W(x, y) < 0$ encodes *repulsion*, the congestion regime in which type x is penalized for crowding toward y and is driven away from it. A single network can carry both readings on different pairs of types — imitate your peers, avoid the bottlenecks — so the kernel that drives the game is genuinely signed. We therefore let W range over all of $\mathbb{R}$, reserving the nonnegativity constraint $W \geq 0$ for the special case where the kernel is also serving as a graph-sampling intensity.

Definition 27.5 (L^p graphon)**.** For $1 \leq p \leq \infty$, an L^p *graphon* is a symmetric measurable function $W \colon [0, 1]^2 \to \mathbb{R}$ with $\|W\|_{L^p([0,1]^2)} < \infty$. For graph models one takes $W \geq 0$; signed L^p graphons arise as *couplings* in a mean field game, where W may change sign (attraction versus repulsion across types). We write $\mathcal{W}_0^p$ for the set of L^p graphons. The classical bounded graphons of definition 15.4 are the $W \in [0, 1]$-valued elements of $\mathcal{W}_0^\infty$.

That last sentence is the second motivating point, and it is what guarantees we have *generalized* rather than *replaced* the old theory. A classical graphon $W\colon [0,1]^2 \to [0,1]$ is bounded by 1, so on the finite measure space $[0,1]^2$ its L^p norm is at most 1 for *every* p, in particular $\|W\|_\infty \le 1$; the classical graphons are thus exactly the $[0,1]$-valued members of $\mathcal{W}_0^\infty$, sitting at the very top of the scale. Every bounded kernel is an L^p graphon for all p at once, and relaxing from $\mathcal{W}_0^\infty$ to $\mathcal{W}_0^p$ with $p < \infty$ strictly enlarges the admissible class — it admits kernels that are unbounded but whose blow-up is integrable to order p. The heavy rank-one weight is the prototype: $f \otimes f$ with $f = x^{-\nu}$ is unbounded, hence not in $\mathcal{W}_0^\infty$, yet (as the integrability arithmetic of corollary 27.3 recorded) it lies in $\mathcal{W}_0^p$ for every $p < 1/\nu$. The exponent ν that controlled the degree tail now reappears as the depth to which we must descend the L^p scale to catch the weight.

To read that descent correctly we must get the direction of the scale right, and here the finite-measure setting reverses the intuition trained on $\mathbb{R}^n$. Because $[0,1]^2$ has total measure one — it is a probability space — the L^p norms are *monotone in* p:

$$L^\infty([0,1]^2) \subset \cdots \subset L^q([0,1]^2) \subset L^p([0,1]^2) \subset \cdots \subset L^1([0,1]^2) \qquad (q \ge p), \tag{27.5}$$

so a smaller p gives a *larger*, more permissive class. The one line that justifies the reversal is Jensen's inequality on the probability space $[0,1]^2$: for $q \ge p$ the function $t \mapsto t^{q/p}$ is convex, so $\left(\int_{[0,1]^2} |W|^p\right)^{q/p} \le \int_{[0,1]^2} |W|^q$, i.e. $\|W\|_{L^p} \le \|W\|_{L^q}$; a finite L^q norm therefore forces a finite L^p norm, which is the inclusion $L^q \subseteq L^p$. The total mass being *one* is exactly what makes the inequality run this way — raising a number to a higher power and averaging against a probability measure can only increase it.

A micro-example pins down why this is the opposite of the $\mathbb{R}^n$ picture, and it is the very weight we care about. Take $f(x) = x^{-\nu}$ on $[0,1]$ with $\nu \in (\frac{1}{2}, 1)$. Its singularity at the origin is integrable but not square-integrable: $\int_0^1 x^{-\nu}\,\mathrm{d}x = \frac{1}{1-\nu} < \infty$ while $\int_0^1 x^{-2\nu}\,\mathrm{d}x = \infty$ (since $2\nu > 1$), so $f \in L^1 \setminus L^2$. The larger class L^1 *admits* the heavy weight that the smaller class L^2 *rejects* — smaller p tolerates a fiercer singularity. On $\mathbb{R}^n$ the membership question turns instead on decay at infinity, and the ordering flips: the constant function 1 lies in $L^\infty(\mathbb{R})$ but in no $L^p(\mathbb{R})$ with $p < \infty$, because there is infinitely much mass to integrate at large $|x|$. The difference is that a probability space has no "infinity" to escape to; the only way a function can fail to be integrable is through a local singularity, and integrating a singularity against a finite measure only gets *easier* as p decreases. Heavy tails of a network, which on the line would be a statement about slow decay, become here a statement about how deep a singularity the kernel may carry — and deeper singularities live further down the L^p ladder.

This orientation fixes the geography of the problem. The dense theory of Part IV lives at the top rung, $p = \infty$, where kernels are bounded; pushing toward genuine sparsity and heavy tails drives us downward toward $p = 1$, the most permissive rung, where the most singular admissible weights are found; and somewhere on this ladder is the rung below which the machinery of the game can no longer stand. The thesis of this section is that the decisive rung is $p = 2$ — not ∞, not 1, but the square-integrable middle. The reason that particular value, and not some other, should be the pivot is not yet visible from the function class alone, because the class is only a scale of *kernels*; the game never touches the kernel pointwise. What it touches is the integral operator $\mathbb{W}$, acting on the population mean $x \mapsto \bar{m}_t(x)$, and that mean lives in the Hilbert space $L^2[0,1]$ — it is square-integrable in type under the standing finite-second-moment hypothesis. So the question that actually decides whether the game survives is not "for which p is W bounded?" but "for which p is $\mathbb{W}$ a bounded operator on $L^2[0,1]$?" That is the operative question, and it is the one the next subsection answers.

27.2.2 When is $\mathbb{W}$ a bounded operator?

The previous subsection ended by sharpening the question we are obliged to answer. The dense theory cared whether the kernel was bounded only because boundedness was a quick way to keep the coupling under control; but the game never reads the kernel pointwise. The entire GMFG apparatus of Part IV interacts with W *only* through the integral operator $\mathbb{W}$ and the aggregate $z = \mathbb{W}\bar{m}$ of eq. (18.10) — the single field through which one agent's environment feels the whole population. So the operative question, as the function class forced us to admit, is not "is W bounded?" but "is $\mathbb{W}$ a bounded operator on the space where the population mean lives?" That space is $L^2[0,1]$ and not some other: the means $x \mapsto \bar{m}_t(x)$ that drive the coupling are square-integrable in type under the standing finite-second-moment hypothesis, so $\mathbb{W}$ must act as a bounded operator $L^2[0,1] \to L^2[0,1]$ for the aggregate z to be a well-defined, finite-energy field at all. The whole sparse story now turns on a question of operator theory, and that question is the right one to pursue because the answer is computable and sharp.

There are two classical sufficient conditions for the boundedness of an integral operator, and the reason to present both — rather than the one we will keep — is that comparing them is what exposes where the true threshold lies. They control $\mathbb{W}$ by two genuinely different norms of the kernel: one by the L^2 norm of W itself, the other by the L^∞ norm of its degree function (its row sums). We state each, prove it with the bound made explicit, and then let the rank-one kernel adjudicate between them.

Lemma 27.6 (Hilbert–Schmidt bound)**.** *If $W \in L^2([0,1]^2)$ (an L^2 graphon) then $\mathbb{W}$ is a Hilbert–Schmidt operator on $L^2[0,1]$; it is compact, and if W is symmetric it is self-adjoint, with*

$$\|\mathbb{W}\|_{L^2\to L^2} \;\le\; \|\mathbb{W}\|_{\mathrm{HS}} \;=\; \|W\|_{L^2([0,1]^2)}\,. \tag{27.6}$$

Proof. The argument is the Hilbert–Schmidt kernel theorem (theorem 2.22, proposition 2.24), and it is worth seeing why the bound is exactly the L^2 norm of the kernel. Fix any orthonormal basis $(e_n)_{n\ge1}$ of $L^2[0,1]$. The Hilbert–Schmidt norm of an operator is the ℓ^2 size of its matrix in such a basis, $\|\mathbb{W}\|_{\mathrm{HS}}^2 = \sum_{m,n} |\langle e_m, \mathbb{W}e_n\rangle|^2$, and the matrix entries $\langle e_m, \mathbb{W}e_n\rangle = \int_{[0,1]^2} W(x,y)\, e_m(x)e_n(y)\,\mathrm{d}x\,\mathrm{d}y$ are precisely the coefficients of W in the product orthonormal basis $(e_m \otimes e_n)$ of $L^2([0,1]^2)$. By Parseval applied to W in that basis the sum of their squares is $\|W\|_{L^2([0,1]^2)}^2$, which is finite *exactly* when $W \in L^2([0,1]^2)$; this gives the equality in (27.6) and shows $\mathbb{W}$ is Hilbert–Schmidt. The inequality $\|\mathbb{W}\|_{L^2\to L^2} \le \|\mathbb{W}\|_{\mathrm{HS}}$ is the general fact that the largest singular value of an operator cannot exceed the ℓ^2 norm of its full singular-value sequence. A Hilbert–Schmidt operator is compact (it is the operator-norm limit of its finite-rank truncations $\sum_{m,n\le K}\langle e_m, \mathbb{W}e_n\rangle e_m \otimes e_n$, whose tail has Hilbert–Schmidt — hence operator — norm $\to 0$), so compactness and the Mercer-type spectral decomposition follow as in theorem 18.2 and definition 18.1; symmetry of W makes the kernel matrix Hermitian, so $\mathbb{W}$ is self-adjoint. The point to underline — it is the slogan this whole section was written to earn — is that *boundedness of W is nowhere used.* Parseval needs only that the kernel be square-summable; it neither knows nor cares whether W is finite at any individual point. Square-integrability of the kernel is the exact hypothesis, and the cap $W \le 1$ was always a sufficient condition impersonating a necessary one. ☐

The second criterion controls $\mathbb{W}$ by a different feature of the kernel — not its total L^2 energy but the uniform size of its row sums, the degree function. It is the natural condition to try when one wants a bound on *every* L^r at once, not just on the Hilbert space, and it is the one a probabilist reaches for first because the degree function is the object the graph model already hands us.

Lemma 27.7 (Schur test)**.** *Suppose the degree function $d_W(x) = \int_0^1 |W(x,y)|\,\mathrm{d}y$ satisfies $\|d_W\|_{L^\infty} < \infty$. Then $\mathbb{W}$ is bounded on $L^r[0,1]$ for every $1 \le r \le \infty$, with*

$$\|\mathbb{W}\|_{L^r \to L^r} \;\le\; \|d_W\|_{L^\infty}\,. \tag{27.7}$$

In particular $\|\mathbb{W}\|_{L^2 \to L^2} \le \|d_W\|_{L^\infty}$.

Proof. This is the symmetric Schur test, and the whole content is a single application of Cauchy–Schwarz with the right choice of measure. Fix $f \in L^2[0,1]$ and a type x, and write the absolutely-continuous measure $\mathrm{d}\mu_x(y) = |W(x,y)|\,\mathrm{d}y$, whose total mass is $\mu_x([0,1]) = d_W(x)$. Split the integrand as $|W(x,y)|\,|f(y)| = |W|^{1/2} \cdot |W|^{1/2}\,|f|$ and apply Cauchy–Schwarz to the two factors:

$$\begin{aligned} |(\mathbb{W}f)(x)|^2 &\le \Big(\int |W(x,y)|\,|f(y)|\,\mathrm{d}y\Big)^2 = \Big(\int |W|^{1/2} \cdot |W|^{1/2}\,|f|\,\mathrm{d}y\Big)^2 \\ &\le \Big(\int |W(x,y)|\,\mathrm{d}y\Big)\Big(\int |W(x,y)|\,|f(y)|^2\,\mathrm{d}y\Big) \le \|d_W\|_{L^\infty} \int |W(x,y)|\,|f(y)|^2\,\mathrm{d}y, \end{aligned} \tag{27.8}$$

where the first factor is $d_W(x) \le \|d_W\|_{L^\infty}$. The point of splitting the weight evenly is that it converts one power of W into the harmless normalizing factor d_W and leaves the other paired with $|f|^2$, ready to be integrated. Now integrate (27.8) over x and exchange the order of integration in the surviving double integral:

$$\|\mathbb{W}f\|_{L^2}^2 \le \|d_W\|_{L^\infty} \int_[0,1]\,|f(y)|^2 \Big(\int_[0,1]\,|W(x,y)|\,\mathrm{d}x\Big)\,\mathrm{d}y \le \|d_W\|_{L^\infty}^2\;\|f\|_{L^2}^2\,,$$

the inner x-integral being the *column* sum $\int |W(x,y)|\,\mathrm{d}x$, which equals the row sum $d_W(y) \le \|d_W\|_{L^\infty}$ by symmetry of W — this is the one place symmetry is used. Taking square roots gives $\|\mathbb{W}\|_{L^2 \to L^2} \le \|d_W\|_{L^\infty}$. The same two-sided control of row and column sums is exactly the hypothesis of the general Schur test, which yields the stated $L^r \to L^r$ bound for every r by interpolating between the trivial L^1 and L^∞ bounds (or directly by Hölder with the same even split of $|W|$); the Hilbert-space case $r = 2$ is the one the game will use, since the population mean lives in L^2. ☐

We now have two certificates of boundedness controlled by two genuinely different quantities — the L^2 norm of the kernel and the L^∞ norm of its degree function — and, crucially, *neither* requires W to be bounded. The next question is how they compare: do they certify the same kernels, or does one reach strictly further than the other? The cleanest test case is the rank-one weight $f \otimes f$ that the previous section forced upon us, because there both norms reduce to explicit integrals of f and the operator can be diagonalized by hand. It adjudicates the comparison completely, and in doing so locates the exact rung $p = 2$ below which both certificates expire.

Proposition 27.8 (The boundedness dichotomy)**.** *Let W be a symmetric measurable kernel.*

1. *If $W \in L^2([0,1]^2)$, then $\mathbb{W}$ is bounded (indeed compact, self-adjoint) on $L^2[0,1]$, with $\|\mathbb{W}\| \leq \|W\|_{L^2}$.*
2. *If $d_W \in L^\infty[0,1]$, then $\mathbb{W}$ is bounded on $L^2[0,1]$ with $\|\mathbb{W}\| \leq \|d_W\|_{L^\infty}$.*
3. *For the rank-one kernel $W = f \otimes f$ with $f \geq 0$, the leading eigenfunction is $f/\|f\|_{L^2}$ and the operator norm is the leading eigenvalue $\|\mathbb{W}\| = \lambda_1 = \|f\|_{L^2}^2$. Here $W \in L^2([0,1]^2) \iff f \in L^2[0,1]$, while $d_W = \|f\|_{L^1} f \in L^\infty \iff f \in L^\infty$. Thus the Hilbert–Schmidt route (1) strictly dominates the Schur route (2): it certifies boundedness for all $f \in L^2 \setminus L^\infty$, i.e. for unbounded but square-integrable weights.*
4. *If $W \notin L^2([0,1]^2)$* and *$d_W \notin L^\infty$, both sufficient conditions fail and $\mathbb{W}$ may be genuinely unbounded on $L^2[0,1]$. For the rank-one kernel this is the regime $f \in L^1 \setminus L^2$, where $\|\mathbb{W}\| = \|f\|_{L^2}^2 = +\infty$.*

Proof. Parts (1) and (2) merely restate lemmas 27.6 and 27.7 in the language of the proposition; the work is in parts (3) and (4).

Part (3): the rank-one operator, diagonalized. For $W = f \otimes f$ the operator acts by

$$(\mathbb{W}g)(x) = \int_0^1 f(x)f(y)g(y)\,\mathrm{d}y = f(x)\langle f, g\rangle,$$

so $\mathbb{W}g = \langle f, g\rangle\, f$: every output is a multiple of the single function f, and the range is the line span$\{f\}$. An operator with one-dimensional range has at most one nonzero eigenvalue, and we read it off by feeding it its own range vector: $\mathbb{W}f = \langle f, f\rangle\, f = \|f\|_{L^2}^2\, f$. Hence f is an eigenfunction with eigenvalue $\|f\|_{L^2}^2$, and normalizing it gives the unit leading eigenfunction $f/\|f\|_{L^2}$. For a self-adjoint operator the operator norm equals the largest eigenvalue in modulus (theorem 18.2); a self-adjoint rank-one operator has exactly that one nonzero eigenvalue, so

$$\|\mathbb{W}\| = \lambda_1 = \|f\|_{L^2}^2 = \int_0^1 f(x)^2\,\mathrm{d}x.$$

This is the computation the chapter will lean on hardest: the entire coupling strength of a rank-one kernel is the single number $\|f\|_{L^2}^2$, the susceptibility of the previous section. The two integrability equivalences are now immediate. The Hilbert–Schmidt norm is $\|f \otimes f\|_{L^2([0,1]^2)}^2 = \int_{[0,1]^2} f(x)^2 f(y)^2 = \left(\int f^2\right)^2 = \|f\|_{L^2}^4$, which is finite iff $f \in L^2$; so route (1) applies exactly when $f \in L^2$, and it then returns $\|\mathbb{W}\| \leq \|W\|_{L^2} = \|f\|_{L^2}^2$, matching the exact value above with equality. The degree function is $d_W(x) = \int_0^1 f(x)f(y)\,\mathrm{d}y = \|f\|_{L^1}\, f(x)$, a fixed multiple of f itself; so $d_W \in L^\infty$ iff $f \in L^\infty$, and route (2) applies only when f is *bounded.* The comparison is therefore decisive and strict: any weight that is unbounded but square-integrable — any $f \in L^2 \setminus L^\infty$ — is certified by route (1) and missed entirely by route (2). The class $L^2 \setminus L^\infty$ is nonempty: the concrete witness is the very weight we care about, $f(x) = x^{-\nu}$ with $0 < \nu < \frac{1}{2}$, for which $\int_0^1 x^{-2\nu}\,\mathrm{d}x = \frac{1}{1-2\nu} < \infty$ (since $2\nu < 1$) so $f \in L^2$, yet $f(x) \to \infty$ as $x \to 0$ so $f \notin L^\infty$. The Hilbert–Schmidt route strictly dominates the Schur route, and it is the route we keep.

Part (4): where both fail and the operator is genuinely unbounded. If $W \notin L^2([0,1]^2)$ and $d_W \notin L^\infty$, then both certificates are silent — and on the rank-one family the operator is not merely *uncertified* but provably unbounded. The dividing case is $f \in L^1 \setminus L^2$: the weight is integrable, so the kernel $f \otimes f$ and its degree function $d_W = \|f\|_{L^1} f$ are well-defined finite objects, yet $\|f\|_{L^2}^2 = \int_0^1 f^2 = +\infty$, so the leading eigenvalue computed in part (3) is infinite: $\|\mathbb{W}\| = \|f\|_{L^2}^2 = +\infty$. The explicit witness is again the same singular weight, now pushed past the threshold to $f(x) = x^{-\nu}$ with $\frac{1}{2} < \nu < 1$, for which $\int_0^1 x^{-\nu}\,\mathrm{d}x = \frac{1}{1-\nu} < \infty$ (so $f \in L^1$ and the kernel is a legitimate, finite-row-sum object) while $\int_0^1 x^{-2\nu}\,\mathrm{d}x = +\infty$ (since now $2\nu > 1$), so $f \notin L^2$ and the operator norm diverges. One sees the unboundedness concretely by feeding $\mathbb{W}$ normalized bumps concentrating at the singularity: testing against $g_\epsilon = \mathbf{1}_{[0,\epsilon]}/\sqrt{\epsilon}$ gives $\|\mathbb{W}g_\epsilon\|_{L^2} = \|f\|_{L^2}\,|\langle f, g_\epsilon\rangle| \to \infty$ as $\epsilon \to 0$, because $\langle f, g_\epsilon\rangle = \epsilon^{-1/2}\int_0^\epsilon x^{-\nu}\,\mathrm{d}x = \frac{\epsilon^{1/2-\nu}}{1-\nu} \to \infty$ when $\nu > \frac{1}{2}$. There is no bounded operator hiding behind the divergent norm; the coupling is genuinely infinite. This is the failure the next-but-one subsection takes up in earnest. $\square$

This proposition is the structural heart of the chapter, and the slogan it certifies is worth stating without hedging: the bounded-graphon theory invoked $W \le 1$, hence $\|\mathbb{W}\| \le \|W\|_\infty \le 1$, only as a crude way of asserting that $\mathbb{W}$ is a *bounded operator at all — the real content was always the boundedness, never the numerical bound.* Part (1) says that this content survives all the way down to $p = 2$: every square-integrable kernel, however violently it blows up pointwise, still induces a bounded — indeed compact, self-adjoint — operator, with norm controlled by $\|W\|_{L^2}$ in place of $\|W\|_\infty$. Part (3) pins the boundary to a single computable scalar, the susceptibility $\|f\|_{L^2}^2$, and part (4) shows that boundary is sharp: cross it and the operator norm is literally $+\infty$.

It is exactly here that the three readings of the chapter's one line begin to coincide. The divide that part (3) draws — $f \in L^2$ versus $f \in L^1 \setminus L^2$ — is, by the integrability arithmetic flagged at the end of section 27.1, the divide $\nu < \frac{1}{2}$ versus $\nu \in (\frac{1}{2}, 1)$; and through the map $\gamma = 1 + \frac{1}{\nu}$ of corollary 27.3 that is the divide $\gamma > 3$ versus $\gamma \in (2,3)$. So the square-integrability boundary $p = 2$ of the operator theory, the divergence of the susceptibility $\|f\|_{L^2}^2$, and the degree-tail exponent $\gamma = 3$ are one threshold seen from three sides — and the empirically dominant window $\gamma \in (2,3)$ sits squarely in the broken regime of part (4), where the coupling operator is unbounded. That confluence is the destination section 27.4 will reach; for now part (1) is the deliverable we need next. Because $\mathbb{W}$ remains bounded, compact, and self-adjoint with $\|\mathbb{W}\| \le \|W\|_{L^2}$ throughout the entire L^2 range, the one estimate the Ch. 24 well-posedness theory ever asked of the kernel is back in hand — and, as the next subsection shows, with that single estimate restored the contraction survives verbatim. We now cash this out for the mean field game.

27.2.3 Revised existence and uniqueness

The previous subsection handed the mean field game precisely the certificate it has been waiting for: throughout the entire L^2 range the coupling operator $\mathbb{W}$ remains bounded, compact, and self-adjoint, with its operator norm controlled by $\|\mathbb{W}\| \le \|W\|_{L^2}$ in place of the now-discarded $\|W\|_\infty$ (lemma 27.6, proposition 27.8(1)). The claim this whole section has been steering toward is that this single inequality is the *only* thing the well-posedness theory of chapter 24 ever asked of the kernel. To cash it out we do two things in order: we recall, with care, exactly how the kernel enters the Ch. 24 fixed-point argument — and check that it enters through one scalar and one scalar only — and we then watch the existence-and-uniqueness theorem survive the substitution $\|W\|_\infty \rightsquigarrow \|W\|_{L^2}$ without a further line of work.

Recall the architecture of chapter 24. An equilibrium of the graphon mean field game of chapter 22 is a field of population means $\bar{m} = (\bar{m}^x)_{x\in[0,1]}$ that reproduces itself under *freeze–solve–recollect*: one freezes the aggregate each type feels, solves every type's optimal-control problem against that frozen aggregate, recollects the resulting population means, and demands that the output field equal the input. This loop is exactly the graphon best-response map S (the S_W of definition 24.4), and an equilibrium is precisely a fixed point $\mathsf{S}(\bar{m}) = \bar{m}$. The structural fact that makes the whole theory readable through a single number is the factorisation eq. (24.4), $\mathsf{S} = \mathcal{R}\circ\mathcal{A}_W$, which cleaves the loop into the step that touches the kernel and the step that touches the population. The *aggregation* step $\mathcal{A}_W$ is the one — and the only — place the kernel acts: it takes the field of means and forms, for each type, the aggregate

$$z(x) \;=\; (\mathbb{W}\bar{m})(x) \;=\; \int_0^1 W(x,y)\,\bar{m}(y)\,\mathrm{d}y,$$

the population mean that type x actually experiences through its network neighbourhood. The *per-type response* step $\mathcal{R}$ then solves, for each type independently, the homogeneous mean field control problem driven by the scalar aggregate $z(x)$ — the HJB equation backward in time coupled to the Fokker–Planck equation forward in time, exactly the per-type problem of chapter 10 — and reads off its population mean. Crucially $\mathcal{R}$ never sees the kernel: it sees only the already-aggregated field z. The kernel enters the equilibrium problem through the linear map $\mathbb{W}$ at the aggregation step, and nowhere else.

This is what collapses the entire well-posedness question onto the operator norm. Run the contraction in the L^2-in-type metric d_2 of chapter 23 — the natural metric here, since the population means $\bar{m}_t(\cdot)$ live in the Hilbert space $L^2[0,1]$ on which $\mathbb{W}$ is self-adjoint — and the two factors contribute multiplicatively to the Lipschitz constant of S, for entirely disjoint reasons. The aggregation $\mathcal{A}_W$ is *linear*, $\mathcal{A}_W(\bar{m}) - \mathcal{A}_W(\bar{m}') = \mathbb{W}(\bar{m}-\bar{m}')$, so its Lipschitz constant in d_2 is by definition the $L^2\to L^2$ operator norm $\|\mathbb{W}\|$ — the sole factor that depends on the kernel. The per-type response $\mathcal{R}$ is Lipschitz with a constant C_0 that is *independent of the kernel*: it is assembled entirely from the per-type stability estimates of chapter 10 — the HJB stability lemma 10.10 and the Fokker–Planck stability lemma 10.11, whose constants come from the horizon T, the ellipticity (A-Nondeg), the Lipschitz and convexity data (A-Lip), (A-Conv) of the per-type problem, and the Lipschitz modulus $\mathrm{Lip}(F_0, G_0)$ of the couplings in their aggregate argument. On the LQG thread these are the per-type Riccati stability constants, and C_0 is literally a Riccati stability constant. None of them involves W, because the kernel was already spent at the aggregation step. Composing the two factors,

$$d_2(\mathsf{S}(\bar{m}),\mathsf{S}(\bar{m}')) \;\le\; C_0\;\|\mathbb{W}\|\;\,d_2(\bar{m},\bar{m}'),$$

so S is a contraction — and the Banach fixed-point theorem then delivers a *unique* equilibrium depending continuously on the data — precisely when $C_0\,\|\mathbb{W}\| < 1$, that is when

$$\|\mathbb{W}\| \;<\; \kappa \;:=\; \tfrac{1}{C_0}. \tag{27.9}$$

Equation (27.9) is the standing coupling-smallness assumption (A-Coupling) in its native L^2 form. The threshold $\kappa = 1/C_0$ is the reciprocal of the kernel-independent per-type Lipschitz constant, and the operator norm it constrains is the canonical $L^2 \to L^2$ norm $\|\mathbb{W}\| = \lambda_1$, the leading eigenvalue / spectral radius of the self-adjoint $\mathbb{W}$ (remark 24.19); the worked computation worked computation 27.19 will make C_0, and hence κ, completely explicit on the LQG thread.

Now the conclusion is forced. The bounded theory of chapter 24 verified (A-Coupling) by the crude chain $\|\mathbb{W}\| \le \|W\|_\infty \le 1$ — but $\|W\|_\infty$ appears there *only* as an upper bound for $\|\mathbb{W}\|$, never on its own account, and lemma 27.6 furnishes a different, equally serviceable upper bound that asks for nothing beyond square-integrability. Replacing the one estimate $\|\mathbb{W}\| \le \|W\|_\infty$ by the Hilbert–Schmidt bound (27.6), $\|\mathbb{W}\| \le \|W\|_{L^2}$, leaves the contraction argument otherwise untouched and yields the following extension at no cost.

Theorem 27.9 (Well-posedness for L^2 graphons)**.** *Let the per-type control problem satisfy* (A-Lip), (A-Growth), (A-Nondeg), (A-Conv), *and let the coupling kernel W be a symmetric L^2 graphon (definition 27.5), in place of the bounded kernel of* (A-Reg-W). *Suppose the coupling-smallness assumption* (A-Coupling) *holds in the form*

$$\|\mathbb{W}\|_{L^2 \to L^2} \;\le\; \|W\|_{L^2([0,1]^2)} \;<\; \kappa, \tag{27.10}$$

with κ the same threshold constant as in the bounded theory of chapter 24. Then the graphon mean field game of chapter 22 has a unique equilibrium $(u^x, m^x)_{x\in[0,1]}$, depending continuously on the data, and the type-indexed solution map is identical to the bounded case with every occurrence of $\|W\|_\infty$ replaced by $\|W\|_{L^2}$.

Proof sketch. The full fixed-point argument is the one carried out in chapter 24; only one line of it touches the kernel, and that line is the only thing we change. Recast through the factorisation eq. (24.4), $\mathsf{S} = \mathcal{R} \circ \mathcal{A}_W$, the best-response map on the space of admissible mean fields $\bar{m} \in L^2([0,1]; C[0,T])$ is Lipschitz, in the d_2 metric of chapter 23, with constant $L_{\mathsf{S}} = C_0\,\|\mathbb{W}\|$. The two factors are exactly the ones isolated above: the linear aggregation $\mathcal{A}_W = \mathbb{W}$ contributes the operator norm $\|\mathbb{W}\|$, and the per-type response $\mathcal{R}$ contributes $C_0 = L_{\mathcal{R}}(T)\,\mathrm{Lip}(F_0, G_0)$, a constant assembled from the horizon, the ellipticity (A-Nondeg), and the Lipschitz/convexity data (A-Lip), (A-Conv) through the per-type stability estimates lemmas 10.10 and 10.11 (the Riccati stability constants on the LQG thread), and *independent of the kernel.* The equilibrium is the unique fixed point whenever $L_{\mathsf{S}} < 1$, i.e. $\|\mathbb{W}\| < \kappa := 1/C_0$, as in (27.9).

The single modification is now visible. In the bounded theory the kernel-bearing factor $\|\mathbb{W}\|$ was bounded above by $\|W\|_\infty$; here lemma 27.6 supplies instead $\|\mathbb{W}\| \le \|W\|_{L^2}$ (27.6), valid for every $W \in L^2([0,1]^2)$. The operator $\mathbb{W}$ enters the estimate purely as a bounded self-adjoint operator on the Hilbert space $L^2[0,1]$, and by lemma 27.6, proposition 27.8(1) it is exactly that under $W \in L^2$. Substituting $\|W\|_{L^2}$ for $\|W\|_\infty$ at this one place leaves the inequality $L_{\mathsf{S}} = C_0\,\|\mathbb{W}\| < 1$ — and hence the contraction — intact.

Every other ingredient of chapter 24 is word-for-word unchanged, for the simple reason that none of them ever read $\|W\|_\infty$ either. The construction of a convex, S-invariant, compact set on which Schauder delivers existence rests on the uniform-in-type bounds and equicontinuity of the per-type responses — properties of $\mathcal{R}$, not of the kernel. The continuity of S in the field, used both for Schauder and for continuous dependence on the data, again flows entirely through the per-type HJB/FP stability lemmas 10.10 and 10.11 under (A-Conv) and (A-Nondeg). And the verification that a fixed point of S is a genuine equilibrium of the game is the freeze–solve–recollect identity built into definition 24.4, a tautology that never mentions the size of W. Boundedness $W \le 1$ was used at exactly one point in the entire development — to assert that $\mathbb{W}$ is a bounded operator at all — and lemma 27.6 discharges that obligation from $W \in L^2$ alone. That no boundedness of W survives anywhere in the argument is not a bookkeeping accident; it is the whole content of the theorem. $\square$

Remark 27.10 (An L^2 graphon is still a dense graph)**.** Theorem 27.9 solves the *unbounded-kernel* problem, not the *sparsity* problem (cf. remark 27.4): it widens the class of admissible *limit objects* without touching the *sampling law*, and at the dense sampling rate $\rho_N \equiv 1$ that law still produces a dense graph. The mechanism is the connection-probability floor of remark 27.4, made quantitative for a single L^2 kernel. Sample W by $G(N, 1, W)$ with the truncation (27.1), so a pair (U_i, U_j) is joined with probability $\min\{1, W(U_i, U_j)\}$. Because $W \ge 0$ is not a.e. zero, some superlevel set carries positive measure: there is a threshold $\delta > 0$ — one may take $\delta = \frac{1}{2}$ when W reaches $\frac{1}{2}$ on a positive-measure set, and otherwise any smaller δ for which $|\{W \ge \delta\}| > 0$, which exists since $\int_{[0,1]^2} W > 0$ forces $|\{W \ge \delta\}| > 0$ for all small enough δ — and on $S := \{W \ge \delta\}$ the truncated probability obeys $\min\{1, W\} \ge \min\{1, \delta\} = \delta > 0$. The expected edge count is then bounded below directly: with U_1, U_2 the types of a generic pair,

$$\mathbb{E}\big[e\big(G(N, 1, W)\big)\big] = \binom{N}{2}\,\mathbb{E}[\min\{1, W(U_1, U_2)\}] \;\ge\; \binom{N}{2}\,\delta\;|S| \;=\; \Theta(N^2),$$

so the graph carries quadratically many edges almost surely — it is dense in the exact sense (S1) was meant to forbid. (The same floor drives the per-vertex picture: a vertex whose type lands in the positive-fraction set over which $W \ge \delta$ accumulates $\Theta(N)$ neighbours, the mechanism of proposition 19.14.) So theorem 27.9 is exactly the right tool for a network that is *dense* but carries a *heavy-tailed weight / centrality* structure — an unbounded but square-integrable kernel, whose hubs have large but non-vanishing relative degree — and it is the wrong tool for a genuinely sparse network. It buys axis one of remark 27.4, and only axis one.

With theorem 27.9 in hand the unbounded-kernel axis is closed on its good side, and remark 27.10 marks exactly how far the good news reaches. Square-integrability, not boundedness, is the true hypothesis of the dense well-posedness theory — but square-integrability is also its floor. Everything in the argument we have just run — the contraction, the threshold $\kappa = 1/C_0$ of (27.9), the very meaning of (A-Coupling) — rests on $\mathbb{W}$ being a bounded operator on $L^2[0, 1]$, and that is the property proposition 27.8 guarantees only down to $p = 2$. The instant the kernel slips below square-integrability the leading eigenvalue $\|\mathbb{W}\| = \lambda_1$ ceases to be finite, the Lipschitz constant $C_0\,\|\mathbb{W}\|$ blows up, and there is no contraction left to run. This is not an exotic edge case: by corollary 27.3 it is precisely the heavy-degree window $\gamma \in (2, 3)$ where real scale-free networks live. The next subsection takes that failure head-on — asking whether either certificate of boundedness, Hilbert–Schmidt or Schur, can be salvaged once p drops below 2, and finding that with heavy degrees the two fail together.

27.2.4 Below $p = 2$: where the operator theory dies

The previous subsection closed the unbounded-kernel axis on its good side and marked, with care, exactly where that side stops: every estimate in the Ch. 24 well-posedness theory rests on $\mathbb{W}$ being a *bounded* operator on $L^2[0,1]$, and proposition 27.8 certifies that boundedness only down to $p = 2$. We now step across that line on purpose and report, without softening, what becomes of the theory in the range $1 \le p < 2$. This is not an academic edge case. By corollary 27.3 the kernel exponent $p < 2$ is exactly the degree-tail window $\gamma \in (2, 3)$ — the heavy-tailed, hub-dominated regime where the social and technological networks we most want to model actually live — so the regime we are about to find broken is the empirically central one. The honest accounting of that breakdown, and the sharp marking of the line between what remains a theorem and what becomes a conjecture, is the business of this subsection.

Begin with the two certificates of boundedness and watch both expire together. For $1 \le p < 2$ the kernel is no longer square-integrable, $W \notin L^2([0,1]^2)$, so the Hilbert–Schmidt route of lemma 27.6 — the one that carried all the good news above — is simply silent: it has no L^2 norm of the kernel to hand the contraction. One might hope the second certificate rescues the situation, since it asks for something altogether different. The Schur test of lemma 27.7 bounds $\mathbb{W}$ by $\|d_W\|_{L^\infty}$, the uniform size of the row sums, and never mentions L^2 at all. But the very feature that defines the heavy regime is that the degrees are *not* uniformly bounded: a scale-free tail *is* the statement $d_W \notin L^\infty$, hubs of ever-larger degree as the type approaches the singularity. So the Schur route falls silent for precisely the same data that silences Hilbert–Schmidt. This simultaneous double failure is exactly proposition 27.8(4): with $W \notin L^2$ *and* $d_W \notin L^\infty$, both sufficient conditions fall away at once, and on the rank-one family the operator is then not merely uncertified but *provably* unbounded, $\|\mathbb{W}\| = \|f\|_{L^2}^2 = +\infty$, as the normalized-bump test in the proof of proposition 27.8(4) showed by hand.

Now trace what this does to the fixed point that theorem 27.9 relied on. The entire force of that theorem was the factorisation of the best-response Lipschitz constant into the product $C_0\,\|\mathbb{W}\|$ — a kernel-independent per-type factor C_0 multiplying the one kernel-dependent scalar $\|\mathbb{W}\|$ — with the contraction, and hence existence, uniqueness, and continuous dependence, secured the instant $\|\mathbb{W}\| < \kappa = 1/C_0$ (eq. (27.9)). Below $p = 2$ that scalar is $\|\mathbb{W}\| = +\infty$. The contraction estimate

$$d_2(\mathsf{S}(\bar{m}), \mathsf{S}(\bar{m}')) \;\le\; C_0\,\|\mathbb{W}\|\; d_2(\bar{m}, \bar{m}')$$

degenerates into the vacuous assertion "$\le +\infty$," carrying no information; and the coupling-smallness condition (A-Coupling), $\|\mathbb{W}\| < \kappa$, can no longer be arranged by *any* tuning of the data, because its left-hand side is not merely large but literally infinite. There is no horizon short enough, no convexity strong enough, no kernel rescaling small enough to bring it under the threshold κ.

It is worth dwelling on the character of this failure, because it is qualitatively unlike the way a proof usually breaks. The ordinary situation is that a Lipschitz constant comes out finite but too large to close a contraction, and one then hunts for a sharper estimate, a cleverer metric, or a smallness hypothesis that tames it — the underlying result may well survive a better argument. Here there is nothing to tame. The constant is not large; it is infinite, and proposition 27.8(4) exhibited that infinitude operationally rather than as an artifact of a lossy bound: feeding $\mathbb{W}$ the normalized bumps g_ϵ that concentrate at the singularity sends $\|\mathbb{W}g_\epsilon\|_{L^2} \to \infty$ as $\epsilon \to 0$. No bounded coupling operator hides behind a wasteful estimate; the very object the contraction argument manipulates — a finite operator norm $\|\mathbb{W}\|$ — does not exist, and Banach's theorem (theorem 2.36) has nothing on which to act. The breakdown is a genuine change in the mathematics, not a deficiency of our technique, and saying so plainly is the first half of the honest accounting this subsection owes.

What, then, survives the loss of boundedness, and how much? Something does, and being exact about it is what the conditional existence statement below is built on. The aggregate that a single type experiences,

$$z(x) \;=\; (\mathbb{W}\bar{m})(x) \;=\; \int_0^1 W(x,y)\,\bar{m}(y)\,\mathrm{d}y, \tag{27.11}$$

is, for each *fixed* type x, a perfectly finite number even when $\mathbb{W}$ is unbounded as a map $L^2 \to L^2$ — provided only that the mean field is bounded, $\bar{m} \in L^\infty[0,1]$, and that the kernel has a finite row sum at x, i.e. $d_W(x) < \infty$. The bound is immediate from pulling the supremum of the mean field out of the integral:

$$|z(x)| = \Big|\int_0^1 W(x,y)\bar{m}(y)\,\mathrm{d}y\Big| \le \|\bar{m}\|_{L^\infty} \int_0^1 |W(x,y)|\,\mathrm{d}y = \|\bar{m}\|_{L^\infty}\; d_W(x),$$

finite at every type of finite degree. The distinction the dichotomy is forcing on us is now sharp and worth stating in one line: below $p = 2$ the operator $\mathbb{W}$ has lost its *operator-norm* control — its $L^2 \to L^2$ Lipschitz behaviour — without losing its *pointwise* action on bounded fields. Each type still feels a finite, well-defined aggregate $z(x)$; one can still freeze that aggregate, solve that type's optimal-control problem against it, and recollect the resulting mean, so the freeze–solve–recollect loop of definition 24.4 still *defines* a best-response map S on a bona fide function space. What the map has shed is not its definition but the contraction property, and — as the next paragraphs make precise — even the weaker self-map property that a softer existence theorem would demand. The honest status is the following.

Proposition 27.11 (Conditional weak existence for L^1 couplings)**.** *Let $W \in L^1([0,1]^2)$ be symmetric with $d_W \in L^q[0,1]$ for some $q > 1$, and let the per-type problem satisfy* (A-Lip)*,* (A-Growth)*,* (A-Nondeg)*,* (A-Conv)*, with the additional structural hypothesis that the per-type optimal mean response $x \mapsto \bar{m}_t^x$ is, uniformly in t, a bounded affine functional of its target path with operator coefficient* independent of W*. Then a Schauder/compactness argument produces* at least one *equilibrium mean field $\bar{m} \in L^{q'}[0,1]$ (q' the conjugate exponent), provided the fixed-point map is shown to preserve a convex compact set; uniqueness is* not *asserted and generally fails in the absence of operator-norm smallness or a Lasry–Lions monotone coupling* (A-Mon)*.*

Status. *The boundedness and pointwise solvability statements are theorems (lemma 27.7, Hölder); the existence-by-compactness step is, at the level of generality stated, a* conjecture*: it requires a tightness / a-priori bound that has been established only in special cases (potential/monotone couplings, finite-rank kernels, linear-quadratic data). We mark it as such here and in chapter 31.*

Discussion of what is and is not proved. The proposition has two halves of very different epistemic standing, and the discipline of this discussion is to keep them apart: the boundedness and pointwise-solvability claims are genuine theorems, with one-line proofs; the existence-by-compactness claim is, at this generality, a conjecture, and we will be precise about the single estimate it is missing.

The bound is Hölder, made explicit. The narration above bounded $z = \mathbb{W}\bar{m}$ for a bounded mean field by sheer modulus, $|z(x)| \leq \|\bar{m}\|_{L^\infty} d_W(x)$. For the fixed-point argument one wants a little more: a bound that lets the mean field live in a Lebesgue space matched to the integrability $d_W \in L^q$ of the degrees, rather than in L^∞. This is the Schur split of lemma 27.7 run with unequal exponents. Fix a type x and factor the kernel evenly across the conjugate pair $\frac{1}{q} + \frac{1}{q'} = 1$, writing $|W| = |W|^{1/q} \cdot |W|^{1/q'}$ and applying Hölder in the second variable to the two factors $|W|^{1/q}$ and $|W|^{1/q'} |\bar{m}|$:

$$|z(x)| \leq \int_0^1 |W|^{1/q} \cdot |W|^{1/q'} |\bar{m}| \, \mathrm{d}y \leq \Big(\int_0^1 |W(x,y)| \, \mathrm{d}y \Big)^{1/q} \Big(\int_0^1 |W(x,y)| \, |\bar{m}(y)|^{q'} \, \mathrm{d}y \Big)^{1/q'}.$$

The first factor is $d_W(x)^{1/q}$, exactly as recorded in the proposition; the second pairs the surviving half-power of the kernel with the input field. This is the device of the Schur test, except that splitting unevenly — $1/q$ against $1/q'$ rather than $1/2$ against $1/2$ — is what lets the degree function be merely L^q rather than L^∞. In the specialization $\bar{m} \in L^\infty$ the second factor collapses to $\|\bar{m}\|_{L^\infty} \, d_W(x)^{1/q'}$, and combining the two powers of $d_W(x)$ gives back $|z(x)| \leq \|\bar{m}\|_{L^\infty} d_W(x)$, whence $\|\mathbb{W}\bar{m}\|_{L^q} \leq \|d_W\|_{L^q} \, \|\bar{m}\|_{L^\infty}$ on integrating the q-th power in x. This is a genuine, finite bound under $d_W \in L^q$ alone — no boundedness of W, no square-integrability — and it is the precise sense in which the best-response map is still *well-defined* below $p = 2$. So far, theorems.

What is not available is the self-map-of-a-compact-set property. Having lost the contraction we would naturally fall back on the standard existence route for mean field games, the Schauder fixed-point theorem (proved as theorem 2.38; its contraction sibling that we just lost is theorem 2.36, and the template for applying Schauder to an MFG best-response map is the existence argument of chapter 10). Schauder asks for four things and gives existence in return, trading away uniqueness: a nonempty closed *convex* set $\mathcal{K} \subset L^{q'}$, the *invariance* $\mathsf{S}(\mathcal{K}) \subseteq \mathcal{K}$, the *continuity* of S on $\mathcal{K}$, and the *precompactness* of the image $\mathsf{S}(\mathcal{K})$. Three of the four are in hand below $p = 2$, and they are in hand for a reason worth naming: they are properties of the per-type response $\mathcal{R}$, not of the kernel. Convexity is free (mean fields form a convex set); continuity of S and the compactifying smoothness of its image flow, exactly as in the dense existence proof, from the per-type HJB/Fokker–Planck stability of chapter 10, which produces uniformly bounded, equicontinuous responses to a bounded target and never reads the size of W. The one ingredient that breaks is *invariance*, and it breaks for the same reason the contraction did. To run Schauder one must exhibit a bounded set of mean fields that S cannot escape, and that requires an a-priori bound: a ceiling, valid in advance, on the size of the image (and hence of any fixed point). In the bounded and L^2 theories the ceiling was furnished by $\|\mathbb{W}\| < \infty$ — the aggregate $z = \mathbb{W}\bar{m}$ was at most $\|\mathbb{W}\|$ times the mean, so a ball of fixed radius mapped into a ball of controlled radius. With $\mathbb{W}$ unbounded that estimate is gone, and its failure is concentrated precisely on the heavy types. On the rank-one family the hub type $x \to 0$ feels an aggregate $z(x) = f(x)\langle f, \bar{m} \rangle$ that blows up like $f(x) = x^{-\nu}$ *no matter how small* $\bar{m}$ is in L^2, since a single bounded inner product $\langle f, \bar{m} \rangle$ multiplies the unbounded profile f. No ball in the mean-field space can therefore be invariant: the heavy types push the image out of every fixed ball, and the convex compact $\mathcal{K}$ that Schauder needs cannot be built. The obstruction is thus not a missing continuity or a missing compactness — those survive — but a missing a-priori bound, and it sits on exactly the hub types whose divergent degree was the whole point of the construction.

Where the bound can be recovered, the argument closes. The obstruction is special-structure removable, and naming the two cases where it lifts is what makes the theorem/conjecture boundary sharp. First, under a Lasry–Lions monotone coupling (A-Mon), existence does not pass through an operator-norm bound at all: monotonicity supplies its own a-priori control through the Lasry–Lions energy estimate, which bounds the equilibrium mean field directly from the structure of the cost rather than from the size of $\mathbb{W}$, furnishing the ceiling Schauder was missing and closing the argument even with $\mathbb{W}$ unbounded. Second, in the finite-rank or linear-quadratic case the infinite-dimensional fixed point collapses to a finite-dimensional one: a rank-one kernel couples the population only through the single scalar order parameter $\langle f, \bar{m} \rangle$, the heavy types are integrated out into one susceptibility-weighted number, and the self-consistency condition becomes a scalar (on the LQG thread, algebraic) equation whose solvability one checks by hand. That is the explicit reduction carried out in worked computation 27.19, which converts the qualitative "$\|\mathbb{W}\| = +\infty$" of this subsection into a closed-form condition on a finite number of moments. Outside these structured cases — a general L^1 kernel with heavy degrees and a non-monotone coupling — no a-priori bound controlling the heavy types is known, and the existence-by-compactness step remains genuinely open. $\square$

Notation watch

The symbol p is doing double duty in this literature, and the whole subsection turns on not conflating its two meanings, so we set them side by side. In "L^p graphon" (definition 27.5) p is the integrability exponent of the *kernel*: a property of the limit object W, measuring how singular the weight is allowed to be. The *degree-tail exponent* γ of (27.4) is an altogether different number: a property of the sampled *graph*, the power governing $\mathbb{P}(\deg = k) \propto k^{-\gamma}$. A priori they have nothing to do with each other; they are linked only after one fixes a specific kernel and runs it through the sparsification model. The link is worth writing out explicitly on the rank-one weight $f(x) = x^{-\nu}$, the family the chapter computes everything on. Three elementary equivalences chain together. *(i)* The kernel sits in L^p iff the weight does, because the rank-one structure factors the integral: $f \otimes f \in L^p([0,1]^2)$ means $\int_{[0,1]^2} (f(x)f(y))^p = (\int_0^1 f^p)^2 < \infty$, i.e. $f \in L^p[0,1]$. *(ii)* The power $f = x^{-\nu}$ sits in L^r iff $\int_0^1 x^{-r\nu}\,dx < \infty$, i.e. iff $r\nu < 1$, i.e. $r < 1/\nu$. *(iii)* The degree-tail map of corollary 27.3 reads $\gamma = 1 + 1/\nu$, so $1/\nu = \gamma - 1$. Composing (i)–(iii),

$$f \otimes f \in L^p([0,1]^2) \iff f \in L^p[0,1] \iff p\nu < 1 \iff p < \tfrac{1}{\nu} = \gamma - 1.$$

Hence kernel integrability p and graph tail γ are tied by the single relation $p < \gamma - 1$, and the threshold of this subsection — square-integrability of the kernel, $p = 2$ — is the line $2 = \gamma - 1$, that is $\gamma = 3$. The operator theory dies for $p < 2$; the degree variance diverges for $\gamma < 3$; under the dictionary above these are one inequality written in two alphabets.

Two roads lead out of the impasse this subsection has mapped, and the chapter takes both. The first is to retreat from full generality to the one structured case in which the obstruction dissolves into algebra. On the rank-one kernel the entire coupling is the single scalar susceptibility $\|f\|_{L^2}^2 = \|\mathbb{W}\|$ (proposition 27.8(3)), and the qualitative verdict "the operator norm is $+\infty$" becomes a quantitative one: a closed-form computation of exactly *when* that scalar diverges, with the threshold $\nu = \frac{1}{2}$ — equivalently $\gamma = 3$, equivalently $p = 2$ — read straight off an explicit integral. That is the worked computation worked computation 27.19, and it is where the breakdown traced here turns from a qualitative "the theory dies" into a formula one can evaluate. The second road accepts that the unit-interval picture has been pushed as far as it will go. The standing verdict over this entire L^p section (remark 27.10) is that even its best case — a square-integrable kernel, the most an unbounded-kernel relaxation can offer — still samples to a *dense* graph: the relaxation bought heavier weights and richer hubs but not one genuinely sparse edge, and the degree tail it can produce is a property of weights, not of subquadratic edge counts. Genuine sparsity was always the *other* axis of remark 27.4, and to reach it one must surrender the single structure every construction in this section has silently retained: the vertex set $[0, 1]$ itself. The next section rebuilds the random graph not on the interval but on a point process over the half-line $\mathbb{R}_+$ — the graphex framework — where subquadratic sparsity is available from first principles, and where we will have to ask afresh what a mean field game even means.

27.3 Graphex and sampling convergence

The L^p section ended on a verdict it could not evade, and that verdict is the door into this one. Pushed to its very best case — a square-integrable kernel, the most an unbounded-kernel relaxation is allowed to offer — the construction of section 27.2 still samples to a *dense* graph (remark 27.10): the weights got heavier and the hubs got richer, but the edge count stayed $\Theta(N^2)$ and not one genuinely sparse edge was bought. The reason is structural and was never going to yield to a sharper estimate. Every model in that section kept the same skeleton as the dense theory of Part IV — the vertex set is the unit interval $[0, 1]$, one independent uniform type per vertex, edges sampled conditionally on the types — and on that skeleton density is forced the moment connection probabilities fail to shrink with N on a macroscopic set of pairs (proposition 19.14). Reweighting the kernel cannot undo this; it operates within the dense scaffold rather than replacing it. Even the target-density device of section 27.1, which *did* reach genuine sparsity, did so only by bolting on an external dial $\rho_N = c/N$ — an ad-hoc N-dependent thinning factor applied uniformly to a dense object, not a sparsity intrinsic to the limit. If we want a limit object that is sparse *in itself*, rather than a dense one we secretly multiply down, we must give up the single structure every construction so far has silently retained: the interval $[0, 1]$ as the set of vertices.

This is the surrender the present section makes, and the object it trades for is the *graphex*. The contrast with the target-density route is the cleanest way to see what changes. There the limit was still a graphon on $[0, 1]$ and sparsity was an instruction imposed on the sampling — "draw the dense graph, then keep a ρ_N fraction of the edges" — so the sparse graph was a thinned shadow of a dense parent and the parent did the explaining. Here there is no parent. The graphex is a kernel on the *half-line* $\mathbb{R}_+^2$ rather than the bounded square $[0, 1]^2$, and the random graph is generated not by sprinkling N uniform types into a fixed unit interval but by laying down a *point process* of types along $\mathbb{R}_+$ — a Poisson process whose points are the latent coordinates of the vertices, with no upper bound and no prescribed number. The unboundedness of the type domain is the whole point: there is always more room further out along $\mathbb{R}_+$ for a new, lightly-connected vertex to appear, and it is exactly those perpetually-arriving low-degree vertices that dilute the edge density below quadratic. The sparsity is now a property the limit object *has*, read off from how the kernel decays at infinity along the half-line, not a correction we apply to a dense template after the fact.

The move from a bounded type space to a point process on $\mathbb{R}_+$ is not an arbitrary trick but the sparse-graph reflection of the same representation theory that legitimised graphons in the first place. Recall the dense story (chapter 15): an infinite random graph whose law is invariant under relabelling vertices — an *exchangeable* array of edge indicators — is, by the Aldous–Hoover representation (the two-dimensional analogue of de Finetti's theorem for exchangeable sequences), generated by attaching an i.i.d. uniform latent coordinate to each vertex and connecting a pair through a single symmetric kernel W on $[0,1]^2$. The graphon is precisely the de Finetti mixing object behind a dense exchangeable graph, and the type variable $x \in [0,1]$ is the exchangeable label that representation hands us (section 17.2). The trouble is that this representation, by construction, produces only dense graphs: i.i.d. uniform latent coordinates and a bounded kernel give every vertex the same $\Theta(N)$ expected degree, so genuine sparsity is forbidden at the level of the representation theorem, not merely at the level of any one model. To get sparse exchangeable graphs one must exchange the de Finetti picture for its point-process cousin — the Caron–Fox / Veitch–Roy / Kallenberg theory of exchangeable random measures — in which the latent coordinates form a Poisson process on $\mathbb{R}_+$ rather than an i.i.d. sample on $[0,1]$, and the mixing object is a kernel on $\mathbb{R}_+^2$: the graphex. The graphex is to a sparse exchangeable graph exactly what the graphon is to a dense one, and the migration from $[0,1]$ to $\mathbb{R}_+$ is the precise analytic cost of demanding sparsity of the representation rather than imposing it on the sample.

Replacing a fixed finite vertex set by an unbounded point process forces a reckoning with what now plays the role of "the size N," and it is worth flagging the answer in advance because the whole construction is organised around two scales that the dense theory kept welded together. In Part IV a single number, N, did two jobs at once: it counted the vertices *and* it set the resolution at which the limiting kernel was sampled. Over a point process on $\mathbb{R}_+$ these two jobs come apart. There is, on one hand, the graphex itself — a fixed limit object, a kernel on $\mathbb{R}_+^2$ carrying no notion of size, exactly as a graphon is a fixed object carrying no N. There is, on the other hand, a *truncation level* $\ell \geq 0$: we only ever look at the part of the point process inside the window $[0, \ell]$, and growing ℓ is what grows the graph. The level ℓ is the genuine analogue of N — it is the knob we turn to march toward the limit — but it is a continuous window on the half-line, not a vertex count, and the number of vertices it exposes is itself random and grows with ℓ. Holding the kernel fixed while sending $\ell \to \infty$ is the sparse counterpart of holding W fixed while sending $N \to \infty$, and keeping these two scales — limit kernel versus truncation level — firmly distinct is what makes the sparsity statements below clean. The next subsection builds the construction around exactly this pair.

What this buys, and what it does not, must be said plainly at the outset so that nothing below reads as an overclaim. The good news is real and comes essentially for free: a graphex with a suitably heavy marginal generates a graph that is *genuinely* sparse in the subquadratic sense, $e = o(N^2)$, with no ρ_N to bolt on, and whose degree distribution carries an honest heavy tail — so desideratum (S3) and the subquadratic form of sparsity are delivered by the object itself, as direct consequences of how the kernel decays along $\mathbb{R}_+$. But the strongest sparsity demand, the strict *linear* edge count (S1) — $e = \Theta(N)$, a bounded average degree — is *not* automatic. Whether a graphex produces $e = \Theta(N)$ or merely $e = o(N^2)$ with a slowly growing average degree depends on a finer property than mere integrability of the kernel: it turns on the precise rate at which the marginal μ_W decays at infinity, an extra marginal-scaling hypothesis beyond what subquadratic sparsity requires. We will be exact about this gap rather than paper over it — the proposition below separates the regime where (S1) holds from the regime where only the weaker $e = o(N^2)$ survives — because conflating "subquadratic" with "linear" is exactly the kind of quiet overclaim this chapter is written to avoid. With the contrast drawn, the representation pedigree in place, and the honest scorecard on the table, we can now build the object itself: a kernel on $\mathbb{R}_+^2$ and the Poisson construction that turns it into a growing sparse graph indexed by the truncation level.

27.3.1 The object and its construction

We come, then, to the object the section has been promising: a limit that is sparse in itself, built from a point process on $\mathbb{R}_+$ rather than N uniform draws on $[0,1]$, and that therefore owes nothing to an external thinning dial ρ_N. The construction has two ingredients, and it pays to know in advance what each is for, because the entire sparsity phenomenon lives in the tension between them. The first ingredient is a *kernel*, just as in the dense theory — but now a kernel on the half-line, $W : \mathbb{R}_+^2 \to [0,1]$, which encodes how strongly two latent types connect. The second is a recipe for turning that kernel into a growing random graph: sprinkle latent vertices along $\mathbb{R}_+$ as a Poisson process and connect each pair through the kernel. The decisive design choice is that the kernel is allowed — indeed required — to *decay* as its type arguments march out along the half-line, so that a vertex landing far out at large u is only weakly connected to everything. Density is bought back exactly here: because there is unlimited room further out for new, faintly-attached vertices, the graph keeps acquiring low-degree vertices faster than it acquires edges, and the edge count falls below quadratic. We make the kernel and its decay condition precise first, then the sampling.

Definition 27.12 (Graphex)**.** A *graphex* is a symmetric measurable function $W : \mathbb{R}_+^2 \to [0,1]$ (the *kernel* component), satisfying the integrability condition

$$\int_{\mathbb{R}_+} \left(1 - e^{-\mu_W(u)}\right) \mathrm{d}u < \infty, \qquad \mu_W(u) := \int_{\mathbb{R}_+} W(u,v)\, \mathrm{d}v, \tag{27.12}$$

together, in the general theory, with a *star* intensity $S : \mathbb{R}_+ \to [0,1]$ and a *dust* rate $I \geq 0$; in this chapter we restrict to the kernel component (the *integrable graphon* case $I = 0$, $S \equiv 0$), which already exhibits all the phenomena we need. We call μ_W the *marginal* and read (27.12) as the requirement that the expected number of *non-isolated* vertices at any finite truncation be finite.

Three features of this definition deserve unpacking before we use it, because each is doing load-bearing work that a quick reading would miss. Start with the *marginal* $\mu_W(u) = \int_{\mathbb{R}_+} W(u,v)\,\mathrm{d}v$. It is the exact half-line analogue of the degree function d_W of the dense theory: it measures how much total connection strength a type-u vertex commands, integrated over all the partners it might find. The crucial new freedom is that $\mu_W(u)$ may be large for small u and must *decay* as $u \to \infty$ — types far out along the half-line are weakly connected — and it is precisely the rate of that decay, not the pointwise size of W, that will govern both the sparsity and the degree tail. The kernel is capped at 1 (it is a probability), so heaviness can never come from W blowing up the way the rank-one weight $f = x^{-\nu}$ did in corollary 27.3; on the half-line it comes instead from the kernel staying appreciable over an unboundedly long range of partners. The marginal repackages that range into a single profile $u \mapsto \mu_W(u)$, and everything below is read off from it.

Next, the integrability condition (27.12). Why $\int_{\mathbb{R}_+}(1 - e^{-\mu})\,\mathrm{d}u$ and not the simpler $\int_{\mathbb{R}_+} \mu = \|W\|_{L^1}$? The answer is that $1 - e^{-\mu_W(u)}$ is exactly the probability that a type-u vertex, sampled into the graph at unit truncation, is *non-isolated* — has at least one edge — as the proof of proposition 27.14 will show by a thinning argument. A graph is a set of vertices that *participate*, and isolated vertices are invisible; so the right finiteness demand is not that the total edge mass be finite but that the expected number of *non-isolated* vertices be finite at each level. The two conditions differ exactly where μ_W is large: there $1 - e^{-\mu} \approx 1$ while μ itself may be huge, so (27.12) is the *weaker* and therefore more permissive demand — it tolerates a marginal that is non-integrable near a singularity, asking only that the region of types that connect to *something* have finite measure. This is the condition that makes the vertex count finite without forcing the kernel to be L^1, and it is what gives the graphex room to be genuinely heavy-tailed.

Finally, a word on what we have thrown away. The general graphex of the Caron–Fox–Veitch–Roy theory carries two further components beyond the kernel: a *star* intensity $S\colon \mathbb{R}_+ \to [0, 1]$, which seeds occasional vertices of enormous (infinite-in-the-limit) degree attached to a continuum of partners, and a *dust* rate $I \geq 0$, a constant background of isolated-edge noise. We set $S \equiv 0$ and $I = 0$ throughout — the *integrable graphon* case — and the reason is honesty about scope, not laziness. The kernel component alone already exhibits every phenomenon this section is built to demonstrate: genuine subquadratic sparsity, a finite vertex count, and a closed-form power-law degree distribution. The star and dust components add modelling flexibility (they are, as the closing caveat will note, exactly what one would reach for to push the degree exponent up into the empirical window) but they also complicate the calculus and contribute nothing to the structural points we need to make. Excising them keeps the construction's logic visible. We will return, in the caveat at the end of the subsection, to precisely what their absence costs.

With the object fixed we turn it into a graph. The construction is indexed by a continuous *truncation level* $\ell \geq 0$ — this ℓ plays the role that N played in the dense theory, but, as flagged when we pried the two scales apart above, it now does *two* jobs the dense N kept welded: it controls both how many vertices appear and how heavily each is connected. We write the level as ℓ, *not* s, to keep it disjoint from the Thread-B mean-coupling strength s that reappears when we put a mean field game on the graphex (see the notation watch in the game subsection below).

Definition 27.13 (Graphex process)**.** Let $\Pi = \{(\alpha_i, u_i)\}_i$ be a Poisson point process on $\mathbb{R}_+ \times \mathbb{R}_+$ of unit intensity ($\mathrm{d}\alpha\ \mathrm{d}u$); its existence and calculus are appendix H. Interpret $u_i \in \mathbb{R}_+$ as the *type* of a latent vertex and $\alpha_i \in \mathbb{R}_+$ as its *arrival coordinate*. Conditionally on Π, include each edge $\{i, j\}$ independently with probability $W(u_i, u_j)$. The graph G_ℓ at *truncation level* ℓ has vertex set $\{i : \alpha_i \leq \ell,\ \deg(i) \geq 1\}$ (the non-isolated vertices that have arrived by level ℓ) and the induced edges. The family $(G_\ell)_{\ell \geq 0}$ is the *graphex process* of W.

This definition repays slow reading, because the two coordinates of each Poisson point play sharply different roles and it is their separation that makes the construction work. Each latent vertex is a point (α_i, u_i) in the quadrant $\mathbb{R}_+ \times \mathbb{R}_+$, scattered by a Poisson process of *unit* intensity

— meaning that the expected number of points in any region of the quadrant is just its area, the cleanest possible reference measure (its existence and the calculus we are about to use are built from scratch in appendix H). The second coordinate u_i is the *type*: it alone enters the connection probability $W(u_i, u_j)$, exactly as the type x did in the dense model. The first coordinate α_i is the *arrival coordinate*, and it is pure bookkeeping — it never touches a connection probability. Its only function is to give us a knob to turn: truncating at level ℓ means keeping the points with $\alpha_i \leq \ell$ and discarding the rest. Because the process has unit intensity, the points kept inside a type window of width |window| number Poisson($\ell \cdot$ |window|), so raising ℓ from ℓ to $\ell + \mathrm{d}\ell$ admits a fresh sprinkle of vertices of *every* type, uniformly along the whole half-line.

Here is the dual role of ℓ that makes a graphex sparse, stated as concretely as possible. Raising ℓ does two things at once. It *adds vertices* — new points enter the window $\alpha \leq \ell$ — which is the job N did in the dense theory. But it also *enriches the existing vertices*: a type-u vertex already present sees its pool of potential partners grow with ℓ (there are now more truncated points for it to connect to), so its expected degree climbs like $\ell\, \mu_W(u)$, as we verify below. In the dense model these two effects were the same number N wearing one hat; here they are genuinely distinct, and sparsity is exactly the statement that the first effect outruns the second — vertices accumulate faster than edges — whenever the marginal is heavy enough that the half-line keeps supplying fresh low-degree types out at large u. The arithmetic of that race is the content of the next proposition.

Proposition 27.14 (Edge and vertex counts; sparsity)**.** *For the graphex process of a kernel W satisfying* (27.12) *with $W \in L^1(\mathbb{R}_+^2)$:*

1. *the expected edge count grows quadratically in the truncation level,*

$$\mathbb{E}[e(G_\ell)] = \tfrac{1}{2}\,\ell^2 \int_{\mathbb{R}_+^2} W(u,v)\, \mathrm{d}u\, \mathrm{d}v = \tfrac{1}{2}\,\ell^2\, \|W\|_{L^1(\mathbb{R}_+^2)}\,; \tag{27.13}$$

2. *the expected number of (non-isolated) vertices is*

$$\mathbb{E}[N_\ell] = \ell \int_{\mathbb{R}_+} \left(1 - e^{-\ell\, \mu_W(u)}\right) \mathrm{d}u \;:=\; \ell\, \Psi(\ell), \tag{27.14}$$

   finite for each $\ell \geq 1$ by (27.12)*;*

3. *if the marginal μ_W is heavy, in the sense that $\Psi(\ell) \to \infty$ as $\ell \to \infty$, then the graph is* subquadratically sparse*: $\mathbb{E}[N_\ell] = \ell\, \Psi(\ell) \gg \ell$ while $\mathbb{E}[e(G_\ell)] = \Theta(\ell^2)$, so*

$$\frac{\mathbb{E}[e(G_\ell)]}{\mathbb{E}[N_\ell]^2} = \Theta\big(\Psi(\ell)^{-2}\big) \to 0, \qquad \textit{i.e.} \quad e(G_\ell) = o(N_\ell^2). \tag{27.15}$$

   The average degree is $2\,\mathbb{E}[e]\,/\mathbb{E}[N] = \ell\, \|W\|_{L^1}/\Psi(\ell)$, which is bounded — the strict linear edge count (S1)*, $e = \Theta(N)$ — iff $\Psi(\ell) = \Theta(\ell)$, and* diverges *whenever $\Psi(\ell) = o(\ell)$, the generic heavy-marginal case.*

Proof. The whole proof is an exercise in the Poisson calculus of appendix H, and the two parts use its two central tools: the two-point Mecke formula for a sum over *pairs* of points (the edges), and the one-point Mecke formula together with thinning and Campbell for a sum over *single* points (the vertices). We take them in turn.

Part (1): the edge count. An edge is an unordered pair of points, so its expectation is a sum over pairs, and the tool for the expectation of a sum over pairs of a Poisson process is the two-point Mecke / factorial-moment formula (theorem H.3): for a unit-rate Poisson process Π and any symmetric nonnegative h,

$$\mathbb{E}[*] \sum_{\{p,p'\}\subset\Pi} h(p,p') = \tfrac{1}{2} \iint h(p,p')\ \mathrm{d}p\ \mathrm{d}p'.$$

The formula says that, in expectation, a Poisson process behaves as if its pairs of points were laid down independently according to the intensity measure — here Lebesgue measure on the quadrant — with the $\frac{1}{2}$ correcting for the double-count of ordered versus unordered pairs. We must choose h so that the left side counts edges. A pair $\{p,p'\}$ with $p=(\alpha,u)$ and $p'=(\alpha',u')$ contributes an edge to G_ℓ when both points are truncated in ($\alpha \le \ell$ and $\alpha' \le \ell$) and the conditional edge is actually included, which happens with probability $W(u,u')$. Taking the expectation over the edge-inclusion coins first replaces that random indicator by its mean $W(u,u')$, so the right choice is

$$h(p,p') = \mathbf{1}[\alpha \le \ell]\,\mathbf{1}[\alpha' \le \ell]\,W(u,u').$$

Feeding this into Mecke and factoring the integral over the arrival coordinates (which W ignores) from the integral over the types,

$$\mathbb{E}[e(G_\ell)] = \tfrac{1}{2}\int_0^\ell \mathrm{d}\alpha \int_0^\ell \mathrm{d}\alpha' \int_{\mathbb{R}_+^2} W(u,u')\ \mathrm{d}u\ \mathrm{d}u' = \tfrac{1}{2}\,\ell^2 \int_{\mathbb{R}_+^2} W = \tfrac{1}{2}\,\ell^2\ \|W\|_{L^1},$$

which is (27.13): the two arrival integrals each contribute a factor ℓ, and the type integral contributes the constant $\|W\|_{L^1}$. The edge count is exactly quadratic in ℓ — this is the "edges grow like ℓ^2" half of the sparsity race.

Part (2): the vertex count. A vertex is a single point, so its expectation is a sum over single points, governed by the one-point Mecke (Palm) formula (theorem H.3): the expected value of $\sum_{p\in\Pi} g(p,\Pi)$ equals $\int \mathbb{E}[g(p,\Pi\cup\{p\})]\ \mathrm{d}p$, where on the right p is a *deterministic* added point and Π is an independent copy of the same process. We apply it with $g(p,\Pi) = \mathbf{1}[\alpha \le \ell]\,\mathbf{1}[p \text{ is non-isolated}]$, so that the sum counts truncated non-isolated vertices and

$$\mathbb{E}[N_\ell] = \int_0^\ell \int_{\mathbb{R}_+} \mathbb{P}(\text{an added point at } (\alpha,u) \text{ is non-isolated})\ \mathrm{d}u\ \mathrm{d}\alpha.$$

It remains to compute that non-isolation probability, and this is where thinning and Campbell enter. Fix the added point at (α,u). Its potential neighbors are the truncated points $p'=(\alpha',u')$ with $\alpha' \le \ell$, and it actually connects to such a point independently with probability $W(u,u')$. Keeping each point of a Poisson process independently with a location-dependent probability is exactly a *thinning*, and the thinning theorem (theorem H.6) says the survivors again form a Poisson process, now with intensity $W(u,u')\,\mathbf{1}[\alpha' \le \ell]\ \mathrm{d}\alpha'\,\mathrm{d}u'$. The number of neighbors is the total mass of that thinned process, and the expected total mass of a Poisson process is the integral of its intensity — Campbell's formula (theorem H.2). So the neighbor count is Poisson with mean

$$\int_0^\ell \int_{\mathbb{R}_+} W(u,u')\ \mathrm{d}u'\ \mathrm{d}\alpha' = \ell \int_{\mathbb{R}_+} W(u,u')\ \mathrm{d}u' = \ell\,\mu_W(u),$$

the arrival integral again contributing the factor ℓ and the type integral the marginal. The added vertex is non-isolated precisely when this Poisson neighbor count is at least 1, which has probability $1 - e^{-\ell\mu_W(u)}$. Substituting and doing the trivial α-integral (another factor ℓ) gives (27.14), $\mathbb{E}[N_\ell] = \ell \int_{\mathbb{R}_+}(1-e^{-\ell\mu_W(u)})\,\mathrm{d}u = \ell\,\Psi(\ell)$. Notice this is exactly the mixed-Poisson mechanism of proposition 27.2 reappearing on the half-line: a type-u vertex carries a Poisson($\ell\,\mu_W(u)$) degree, with the truncation level ℓ now playing the role the constant c played there.

It remains to see that $\Psi(\ell)$ is finite, and here (27.12) earns its keep. The integrand $1 - e^{-\ell\mu_W(u)}$ is bounded by 1, so the only threat to finiteness is the tail $u \to \infty$, where $\mu_W(u)$ is small but the integration range is infinite. We control it by the elementary concavity bound

$$1 - e^{-\ell\mu} \le \ell\,(1 - e^{-\mu}) \qquad (\ell \ge 1,\ \mu \ge 0). \tag{27.16}$$

This holds because, for fixed $\mu \ge 0$, the map $t \mapsto 1 - e^{-t\mu}$ is concave in t and vanishes at $t = 0$; a concave function through the origin lies, for $t \ge 1$, below the line through the origin and its value at $t = 1$, i.e. $1 - e^{-t\mu} \le t\,(1 - e^{-\mu})$, and we set $t = \ell$. Integrating (27.16) over u gives $\Psi(\ell)\cdot\ell^0 = \int_{\mathbb{R}_+}(1 - e^{-\ell\mu_W})\,\mathrm{d}u \le \ell\int_{\mathbb{R}_+}(1 - e^{-\mu_W})\,\mathrm{d}u < \infty$, the last inequality being precisely the graphex condition (27.12). So $\Psi(\ell) < \infty$ for every $\ell \ge 1$, and *this* is the sense in which (27.12) guarantees "finitely many non-isolated vertices at each level" — the bound it furnishes at the reference level $\ell = 1$ propagates to every finite ℓ by concavity, at the modest cost of a factor ℓ.

Part (3): the sparsity dichotomy. The rest is arithmetic from (1) and (2), but it is the arithmetic the whole construction was built to produce, so we spell it out. The expected edge density per pair of vertices is

$$\frac{\mathbb{E}[e(G_\ell)]}{\mathbb{E}[N_\ell]^2} = \frac{\frac{1}{2}\,\ell^2\ \|W\|_{L^1}}{\big(\ell\,\Psi(\ell)\big)^2} = \frac{\|W\|_{L^1}}{2\,\Psi(\ell)^2} = \Theta\big(\Psi(\ell)^{-2}\big),$$

so as soon as the marginal is heavy enough that $\Psi(\ell) \to \infty$ this ratio tends to 0 and the graph is subquadratically sparse, $e = o(N^2)$ — the factors of ℓ have cancelled and what survives is governed entirely by the growth of Ψ. The average degree tells the same story in the form that decides (S1):

$$\frac{2\,\mathbb{E}[e(G_\ell)]}{\mathbb{E}[N_\ell]} = \frac{\ell^2\ \|W\|_{L^1}}{\ell\,\Psi(\ell)} = \frac{\ell\ \|W\|_{L^1}}{\Psi(\ell)}.$$

This is bounded — a finite limiting average degree, the strict linear edge count $e = \Theta(N)$ of (S1) — if and only if $\Psi(\ell)$ grows like ℓ itself, $\Psi(\ell) = \Theta(\ell)$; and it *diverges* whenever $\Psi(\ell) = o(\ell)$, which, as the next proposition shows, is the generic situation for a heavy power-law marginal. So the graphex secures *subquadratic* sparsity for free from heaviness alone, but the sharper *linear* sparsity is a knife-edge condition $\Psi(\ell) = \Theta(\ell)$ on the marginal's decay rate, not a consequence of integrability. □

Proposition 27.14 is the payoff, and it should be read with care. A single integrability condition (27.12) on the marginal delivers a finite vertex count at every level, and a *heavy* marginal ($\Psi(\ell) \to \infty$) delivers genuine *subquadratic* sparsity $e = o(N^2)$, all without the ad-hoc ρ_N of definition 27.1. This is the honest content of (S1) for a graphex: the edge count is sub-quadratic in the vertex count. The *strict* linear form $e = \Theta(N)$ (bounded average degree) is a sharper demand that, by part (3), holds only under the extra scaling $\Psi(\ell) = \Theta(\ell)$ and *fails* for the generic heavy marginal with $\Psi(\ell) = o(\ell)$; we therefore do not claim it generically. We turn next to the degree tail, which is where a concrete heavy marginal earns (S3).

The mixed-Poisson mechanism of proposition 27.2 transfers verbatim: a type-u vertex has Poisson($\ell\,\mu_W(u)$) degree, so a heavy marginal produces a heavy degree tail. The cleanest instance — the $\mathbb{R}_+$ analogue of the rank-one weight $f = x^{-\nu}$ of corollary 27.3 — is a pure-power marginal, for which the entire degree distribution is computable in closed form and is *scale-invariant* in the truncation level.

Proposition 27.15 (Power-law degrees from a heavy-tailed graphex marginal)**.** *Let W be a graphex whose marginal is the pure power $\mu_W(u) = u^{-\zeta}$, $u \in \mathbb{R}_+$, with $\zeta > 1$ (so (27.12) holds: $1 - e^{-\mu}$ is $O(1)$ near 0 and $\sim u^{-\zeta}$ near ∞, integrable iff $\zeta > 1$). Then for every truncation level $\ell > 0$:*

1. *$\Psi(\ell) = \Gamma(1 - \frac{1}{\zeta})\,\ell^{1/\zeta}$, so $\mathbb{E}[N_\ell] = \Theta(\ell^{1+1/\zeta})$; the marginal is heavy ($\Psi(\ell) \to \infty$) and $\Psi(\ell) = o(\ell)$, so the graph is subquadratically sparse with* diverging *average degree $\Theta(\ell^{1-1/\zeta})$;*

2. *the expected empirical degree distribution is exactly ℓ-independent: for $k \geq 1$,*

$$D(k) := \frac{\mathbb{E}[\#\,\{\textit{vertices of degree} \geq k\}]}{\mathbb{E}[N_\ell]} = \frac{\displaystyle\int_0^\infty \mathbb{P}(\mathrm{Poisson}(w) \geq k)\, w^{-1-1/\zeta}\,\mathrm{d}w}{\displaystyle\int_0^\infty (1 - e^{-w})\, w^{-1-1/\zeta}\,\mathrm{d}w}, \tag{27.17}$$

and this degree tail is a power law, $D(k) \sim C_\zeta\, k^{-1/\zeta}$ as $k \to \infty$, i.e. exponent $\gamma = 1 + \frac{1}{\zeta} \in (1, 2)$.

Proof. The starting point is the same vertex count by Mecke/thinning/Campbell as in proposition 27.14(2), but now keeping track of the degree threshold. Repeating that computation with “non-isolated” (degree ≥ 1) replaced by “degree $\geq k$,” and using that a type-u vertex has a Poisson($\ell\,\mu_W(u)$) degree with the present $\mu_W(u) = u^{-\zeta}$, gives

$$\mathbb{E}[\#\,\{\deg \geq k\}] = \ell \int_0^\infty \mathbb{P}(\mathrm{Poisson}(\ell\, u^{-\zeta}) \geq k)\,\mathrm{d}u, \tag{27.18}$$

which for $k = 1$ recovers $\mathbb{E}[N_\ell] = \ell\,\Psi(\ell)$ since $\mathbb{P}(\mathrm{Poisson}(\lambda) \geq 1) = 1 - e^{-\lambda}$. The point of the pure-power marginal is that this integral admits a single change of variables that strips out *all* the ℓ-dependence into one prefactor. Substitute

$$w = \ell\, u^{-\zeta}, \qquad u = (\ell/w)^{1/\zeta}, \qquad \mathrm{d}u = -\tfrac{1}{\zeta}\,\ell^{1/\zeta}\, w^{-1-1/\zeta}\,\mathrm{d}w,$$

which sends $u = 0 \mapsto w = \infty$ and $u = \infty \mapsto w = 0$ (the sign flip from $\mathrm{d}u$ is absorbed by reversing the limits). The Poisson mean $\ell u^{-\zeta}$ becomes simply w, and

$$\mathbb{E}[\#\,\{\deg \geq k\}] = \tfrac{1}{\zeta}\,\ell^{1+1/\zeta} \int_0^\infty \mathbb{P}(\mathrm{Poisson}(w) \geq k)\, w^{-1-1/\zeta}\,\mathrm{d}w. \tag{27.19}$$

Every trace of ℓ now sits in the prefactor $\frac{1}{\zeta}\ell^{1+1/\zeta}$; the integral is a pure number depending on k and ζ alone. We pause to check it converges, since the weight $w^{-1-1/\zeta}$ is singular at the origin. Near $w = 0$ the Poisson tail is dominated by its first nonzero term, $\mathbb{P}(\mathrm{Poisson}(w) \geq k) \sim w^k/k!$, so the integrand behaves like $w^{k-1-1/\zeta}$, integrable at 0 because $k \geq 1 > 1/\zeta$ (here $\zeta > 1$ is used); near $w = \infty$ the probability rises to 1 and $w^{-1-1/\zeta}$ decays integrably. So (27.19) is finite for every $k \geq 1$.

The constant Ψ and part (1). Take $k=1$ in (27.19) and recall $\mathbb{P}(\mathrm{Poisson}(w)\ge 1)=1-e^{-w}$:

$$\Psi(\ell)=\frac{\mathbb{E}[N_\ell]}{\ell}=\tfrac{1}{\zeta}\,\ell^{1/\zeta}\int_0^\infty(1-e^{-w})\,w^{-1-1/\zeta}\;\mathrm{d}w.$$

The remaining integral is a standard one, evaluated by integration by parts to expose a Gamma function. Write $\beta=1/\zeta\in(0,1)$ and integrate $\int_0^\infty(1-e^{-w})w^{-1-\beta}\,\mathrm{d}w$ by parts with $f=1-e^{-w}$, $\mathrm{d}g=w^{-1-\beta}\,\mathrm{d}w$, so $g=-\frac{1}{\beta}w^{-\beta}$ and $\mathrm{d}f=e^{-w}\,\mathrm{d}w$. The boundary term $\big[-\frac{1}{\beta}w^{-\beta}(1-e^{-w})\big]_0^\infty$ vanishes at both ends (at ∞ because $w^{-\beta}\to 0$; at 0 because $1-e^{-w}\sim w$ kills $w^{-\beta}$ for $\beta<1$), leaving

$$\int_0^\infty(1-e^{-w})\,w^{-1-\beta}\;\mathrm{d}w=\frac{1}{\beta}\int_0^\infty w^{-\beta}e^{-w}\;\mathrm{d}w=\frac{\Gamma(1-\beta)}{\beta},$$

recognizing the Gamma integral $\int_0^\infty w^{(1-\beta)-1}e^{-w}\,\mathrm{d}w=\Gamma(1-\beta)$. With $\beta=1/\zeta$ this is $\zeta\,\Gamma(1-1/\zeta)$, so the prefactor $\frac{1}{\zeta}$ cancels and $\Psi(\ell)=\Gamma(1-1/\zeta)\,\ell^{1/\zeta}$. Then $\mathbb{E}[N_\ell]=\ell\Psi(\ell)=\Gamma(1-1/\zeta)\,\ell^{1+1/\zeta}=\Theta(\ell^{1+1/\zeta})$; since $\zeta>1$ we have $1/\zeta\in(0,1)$, so $\Psi(\ell)=\Theta(\ell^{1/\zeta})\to\infty$ (heavy marginal) yet $\Psi(\ell)=o(\ell)$ (so, by the dichotomy of proposition 27.14(3), the average degree $\Theta(\ell^{1-1/\zeta})$ diverges). This is part (1).

The degree distribution and its tail, part (2). Form the ratio defining $D(k)$ in (27.17): numerator $\mathbb{E}[\#\{\deg\ge k\}]$ and denominator $\mathbb{E}[N_\ell]=\mathbb{E}[\#\{\deg\ge 1\}]$ are *both* given by (27.19), and they share the identical prefactor $\frac{1}{\zeta}\ell^{1+1/\zeta}$, which therefore cancels. What is left is exactly the ℓ-independent quotient of integrals displayed in (27.17). This cancellation is the precise meaning of the scale-invariance promised above: the *shape* of the degree distribution does not move as the graph grows — the graph gets larger and its average degree climbs, but the fraction of vertices of degree $\ge k$ is frozen, exactly the N-independence demanded by (S3).

It remains to extract the large-k tail of the numerator integral $\int_0^\infty\mathbb{P}(\mathrm{Poisson}(w)\ge k)\,w^{-1-1/\zeta}\,\mathrm{d}w$. The mechanism is a Poisson-concentration sandwich, the integral form of the tail-transfer lemma lemma H.10. The point is that for large k the function $w\mapsto\mathbb{P}(\mathrm{Poisson}(w)\ge k)$ is a sharp threshold: a Poisson(w) variable concentrates around its mean w with standard deviation $\sqrt{w}$, which for w near k is of order $\sqrt{k}=o(k)$, so the probability jumps from nearly 0 to nearly 1 across a window of width $o(k)$ around $w=k$. Hence $\mathbb{P}(\mathrm{Poisson}(w)\ge k)\to\mathbf{1}\{w>k\}$ uniformly outside that vanishing window, and the heavy weight $w^{-1-1/\zeta}$ — which varies negligibly across an $o(k)$ window at scale k — cannot distinguish the true threshold from the sharp one. Therefore

$$\int_0^\infty\mathbb{P}(\mathrm{Poisson}(w)\ge k)\,w^{-1-1/\zeta}\;\mathrm{d}w\sim\int_k^\infty w^{-1-1/\zeta}\;\mathrm{d}w=\zeta\,k^{-1/\zeta}\qquad(k\to\infty).$$

Dividing by the denominator $\int_0^\infty(1-e^{-w})w^{-1-1/\zeta}\,\mathrm{d}w=\zeta\,\Gamma(1-1/\zeta)$ computed above,

$$D(k)\sim\frac{\zeta\,k^{-1/\zeta}}{\zeta\,\Gamma(1-1/\zeta)}=C_\zeta\,k^{-1/\zeta},\qquad C_\zeta=\frac{1}{\Gamma(1-1/\zeta)},$$

a power law of index $1/\zeta$ in the complementary cumulative $D(k)=\mathbb{P}(\deg\ge k)$, hence degree exponent $\gamma=1+1/\zeta$. Since $\zeta>1$ forces $1/\zeta\in(0,1)$, the exponent lands in $\gamma=1+1/\zeta\in(1,2)$ — exactly the window the closing caveat now scrutinizes. $\square$

So the graphex genuinely delivers (S3): a heavy-tailed, N-independent (unnormalized) degree distribution, here with exponent $\gamma=1+1/\zeta$. This is a real success and worth stating without hedging — it is the heavy unnormalized tail the dense theory provably could not produce ((S3), proposition 19.14), now falling out in closed form from the decay of a single marginal, with no ρ_N anywhere in sight. But the success comes with an honest caveat that must be developed rather than buried, because it marks the exact limit of what the kernel-only graphex can reach, and that limit is the chapter's recurring theme of locating the boundary sharply.

The caveat is this: the natural graphex window is $\gamma \in (1, 2)$, *not* the empirically dominant $(2, 3)$ that the desiderata of section 27.1 were calibrated to. The two windows do not overlap at all, and the gap is forced, not accidental. Trace the constraints. Integrability of the marginal, (27.12), demanded $\zeta > 1$ for the pure power $u^{-\zeta}$; the degree exponent is $\gamma = 1 + 1/\zeta$; and $\zeta > 1$ is exactly $1/\zeta < 1$, hence $\gamma < 2$. To push γ up to 2 or beyond would require $1/\zeta \geq 1$, i.e. $\zeta \leq 1$, which makes the marginal $u^{-\zeta}$ non-integrable at infinity and the graphex condition fail — the expected number of non-isolated vertices would be infinite at every level, and there would be no graph to speak of. So the very integrability that makes the construction well-posed caps its degree exponent strictly below 2. The kernel graphex is structurally a machine for $\gamma \in (1, 2)$: tails *heavier* than what real networks typically show, corresponding to hubs so dominant that even the mean degree (in the unnormalized law) sits at the edge of divergence.

It is worth pinning down what $\gamma \in (1, 2)$ versus $\gamma \in (2, 3)$ means, because the contrast is exactly the moment-divergence reading from section 27.1. Recall that $\gamma = 2$ is the threshold where the *mean* of the degree law passes from finite (for $\gamma > 2$) to infinite (for $\gamma < 2$). The empirical window $(2, 3)$ is finite-mean, infinite-variance; the graphex window $(1, 2)$ is *infinite-mean*. This is the analytic shadow of the average-degree divergence we already met in proposition 27.15(1): with $\Psi(\ell) = o(\ell)$ the average degree $\Theta(\ell^{1-1/\zeta})$ grows without bound, which is the finite-ℓ manifestation of a limiting degree law whose mean has run off to infinity. The kernel graphex, in other words, does not merely fail to hit $(2, 3)$ by a technicality; it lives on the other side of the mean-divergence line, in a genuinely heavier-tailed regime, and the strict linear edge count (S1) — which needs a *finite* limiting average degree, $\Psi(\ell) = \Theta(\ell)$ — is for the same reason out of its reach.

What, then, would it take to reach $(2, 3)$? Two honest routes, both already on the page. The first is to restore the components we excised: the *star* intensity S and *dust* rate I of definition 27.12. These add connectivity that does not pass through the integrable kernel, and they are precisely the degrees of freedom the general Caron–Fox–Veitch–Roy theory uses to populate the lighter-tailed exponents; bringing them back is the principled way to model $\gamma \in (2, 3)$ within the graphex framework, at the cost of the extra calculus we deliberately set aside. The second route is the one the chapter has *already* walked: the target-density construction of corollary 27.3, where an unbounded rank-one weight $f = x^{-\nu}$ over a unit-interval type space, sparsified by $\rho_N = c/N$, produced exactly $\gamma = 1 + 1/\nu \in (2, 3)$ for $\nu \in (\frac{1}{2}, 1)$. That construction reached the empirical band — but only by paying with the ad-hoc thinning dial ρ_N that this section was built to avoid. So the two routes to $(2, 3)$ trade off against each other in an instructive way: the graphex buys intrinsic sparsity but caps γ below 2 on its kernel alone, while the target-density model buys the empirical exponent but only through an external ρ_N. Neither the kernel graphex nor the bolt-on ρ_N is, by itself, both intrinsically sparse *and* natively in $(2, 3)$; closing that gap is exactly the kind of frontier question this chapter is committed to flagging rather than papering over. We record it honestly: the kernel graphex secures (S2), (S3), and subquadratic (S1) from first principles, but the precise empirical exponent band $(2, 3)$ is not a free consequence of the kernel component alone.

That honest accounting closes the construction, but it leaves a prior question unanswered, and it is the question the next subsection must face before any of this earns its keep. We have built *a* sparse limit object and shown it does what we asked — but we built it by a specific recipe (a Poisson process on $\mathbb{R}_+$, this particular kernel, these excisions), and a single recipe proves nothing about whether the graphex is the *right* limit object, the one that genuine sparse graph sequences actually converge to, as opposed to merely one clever way to manufacture a sparse graph. The dense theory earned its graphons through a representation theorem — Aldous–Hoover — that said every exchangeable dense graph *is* a graphon, leaving no other possibility. The graphex deserves the same scrutiny: is it forced on us as *the* sparse limit, or is it just one construction among many? We turn to that representation theorem now, and to the price it exacts.

27.3.2 The representation theorem, and what it costs us

The reason graphexes are the *right* objects is a representation theorem of the same character as the dense graphon limit theorem of chapter 17. In the dense world, a sequence of graphs converges if and only if its homomorphism densities converge, and the limit is a graphon modulo weak isomorphism (the Lovász–Szegedy / Aldous–Hoover circle of ideas). In the sparse world the corresponding statement is about *exchangeable random measures.*

Imported result 27.16 (Graphex representation; Caron–Fox, Veitch–Roy, Kallenberg)**.** (Proved in the cited literature, not in this book; used only as structural license, and no in-book result depends on it.) *Represent a graph as a point process on* $\mathbb{R}_+^2$ *(a point at* (u_i, u_j) *for each edge, with types in* $\mathbb{R}_+$*). If this random point measure is* jointly exchangeable *— invariant in law under any measure-preserving transformation of the type coordinate* $\mathbb{R}_+$ *applied simultaneously to both axes — and locally finite, then it is, in distribution, the graphex process* (*definition 27.13*) *of some graphex* (W, S, I)*, and the graphex is unique up to the natural measure-preserving relabelings of* $\mathbb{R}_+$*. Conversely every graphex process is jointly exchangeable.*

This is the sparse-graph analogue of the Aldous–Hoover theorem and is due to Veitch–Roy [130] and Caron–Fox [45], resting on Kallenberg's representation theorem for jointly exchangeable random measures on $\mathbb{R}_+^2$ [84, Ch. 9]. The mechanism is Kallenberg's: a jointly exchangeable, locally finite random measure on $\mathbb{R}_+^2$ admits a representation as a deterministic measurable function of an underlying unit-rate Poisson process (the object built self-containedly in appendix H), and unwinding that function for the special case of a simple-point (graph) measure yields the kernel/star/dust decomposition (W, S, I). We deliberately present this as an *imported result* rather than an in-book theorem: its proof is long, belongs to the theory of exchangeable arrays rather than to mean field games, and — crucially — no result we prove downstream depends on it. We use it only as the structural license to study graphexes as *the* limit objects for sparse exchangeable graphs, exactly as one uses the de Finetti theorem to justify studying mixtures of i.i.d. sequences. (The dense Aldous–Hoover representation it parallels is likewise imported rather than proved in this book — it is surveyed in chapter 15 via [60] — so the two sit on the same honest footing.) The complete argument lives in [130, 84]; the ledger lists it under *Deferred*, honestly outside the book's self-contained core.

There is a corresponding notion of convergence *to* a graphex, the sparse analogue of cut convergence. We describe it informally, and flag at once that the full theory is outside this book's self-contained core: no in-book result depends on it, and we use it only to locate the graphex as the right limit object. The part we *can* make precise from the construction already in hand is the one-sided statement.

Remark 27.17 (Sampling convergence, informally)**.** The graphex process gives, for each ℓ, a law on finite graphs: the truncation G_ℓ of definition 27.13. One says a sequence of finite graphs (H_n) *converges in the sampling sense* to a graphex W if a randomly rescaled sample of H_n — retain each vertex independently with a *stretching probability* tuned so that the retained vertex count matches the graphex scale, then look at the induced subgraph — converges in distribution, as $n \to \infty$ and then the scale grows, to G_ℓ, on every fixed finite test graph. This is genuinely the right sparse counterpart of the cut metric of chapter 17: there is a *stretched cut metric* (a Bollobás–Riordan rescaling of the dense cut distance) under which sampling convergence is metrized, and the resulting limits are exactly the (rescaled) L^p graphons of definition 27.5 [25, 26, 27]. We do not develop the stretched cut metric here — it would require the sparse counterparts of the entire chapters 17 and 19 apparatus — and we use none of it below; the reader should read this remark as orientation, not as a tool. The only convergence question this chapter actually settles is the forward one (the explicit edge/vertex/degree asymptotics of propositions 27.14 and 27.15), built directly on the Poisson calculus of appendix H.

We now turn to the only question that is properly ours: the mean field game on a graphex.

27.3.3 Graphon mean field games over a graphex limit

Suppose the network is, in the limit, a graphex $W\colon \mathbb{R}_+^2 \to [0,1]$. What is the mean field game? Before writing equations it pays to be clear about *which* limit object carries the game, because the graphex carries *two* scales where the dense theory had one. In the dense theory the GMFG was the $N \to \infty$ limit of finite N-player games, and the single parameter N was both the population size and the normalization of the coupling. The graphex separates these roles: the static kernel W on $\mathbb{R}_+$ is the limit object, while the truncation level ℓ (definition 27.13) plays the role of N, growing the finite graph G_ℓ toward that limit. The natural program would be to define a game on each finite G_ℓ and pass $\ell \to \infty$; but, as flagged in the ledger, the finite-ℓ ε-Nash convergence on sparse graphs is open (it is the sparse analogue of chapter 25). We therefore do what the dense theory also does once the limit object is in hand: *pose the game directly on the static limit* W, treating the typical agent not as a normalized type average — there is no uniform law on the infinite-measure $\mathbb{R}_+$ — but through the point process, an agent of type u drawn from the latent Poisson intensity. The coupling strength s (Thread B) is a fixed constant of the cost, *independent* of the truncation level ℓ; it is the analogue of the $O(1)$ mean-coupling of the dense game, not an ℓ-rescaling of the field. With that understood, a representative type-u agent, $u \in \mathbb{R}_+$, has state $X_t^u \in \mathbb{R}$ obeying the Thread-B dynamics of appendix A.7,

$$\mathrm{d}X_t^u = \big(aX_t^u + b\,\alpha_t^u\big)\,\mathrm{d}t + \sigma\,\mathrm{d}B_t^u, \qquad X_0^u \sim m_0^u, \tag{27.20}$$

and is coupled to its graphex-aggregated neighbor field

$$z_t(u) = (\mathbb{W}\bar{m}_t)(u) = \int_{\mathbb{R}_+} W(u,v)\,\bar{m}_t(v)\;\mathrm{d}v, \qquad \bar{m}_t(v) = \int_{\mathbb{R}} \xi\, m_t^v(\mathrm{d}\xi), \tag{27.21}$$

the same aggregate (18.10) but with the integral now over $\mathbb{R}_+$. The per-type cost is that of Thread B, with mean-coupling target $s\,z_t(u)$, where s is the fixed Thread-B coupling *strength* (not the truncation level). The mean field game is the fixed-point problem: z produces optimal feedback, hence a population flow m^u, whose mean must regenerate z through (27.21).

Notation watch

Two distinct quantities sit close together in this section, and we keep them strictly apart. The *truncation level* ℓ of definition 27.13 is the graphex's analogue of the population size N: it indexes the growing finite graph G_ℓ, with $\mathbb{E}[e(G_\ell)] = \frac{1}{2}\ell^2\,\|W\|_{L^1}$ and $\mathbb{E}[N_\ell] = \ell\,\Psi(\ell)$. The *coupling strength* s (with terminal weight s_T) is the Thread-B mean-coupling constant of appendix A.7, fixed once and for all in the cost target $s\,z_t(u)$ and *independent of* ℓ. Where the dense graphex literature writes its truncation parameter as s, we have deliberately renamed it ℓ to free s for its canonical Thread-B meaning; the reader who has just absorbed "degrees scale like $\ell\,\mu_W(u)$" should not read $s\,z_t(u)$ as a level rescaling of the field.

Two genuinely new difficulties appear, and they are exactly the difficulties of section 27.2 transported to $\mathbb{R}_+$ and amplified by the infinite measure.

1. *The population "average" is over an infinite measure.* There is no uniform probability law on $\mathbb{R}_+$, so the global mean $\int_{\mathbb{R}_+} \bar{m}_t\;\mathrm{d}v$ that played a role in the dense theory need not be finite, and statements about "the typical agent" must be made through the point process, not through a normalized type average. The well-defined object is the aggregate $z_t(u)$, and it is finite for a.e. u provided $\bar{m}_t \in L^{q'}(\mathbb{R}_+)$ and the marginal $\mu_W \in L^q$.

2. *The operator $\mathbb{W}$ on $L^2(\mathbb{R}_+)$ inherits the dichotomy of proposition 27.8, with the additional hazard that $W \le 1$ no longer forces $\mathbb{W}$ to be bounded*, because $\mathbb{R}_+$ has infinite measure: a bounded kernel can have $\|W\|_{L^2(\mathbb{R}_+^2)} = \infty$ (e.g. W not decaying off the diagonal). Boundedness of the graphex as a function ($W \le 1$) is no longer even a sufficient condition for the operator-norm theory; what matters is the integrability of the marginal μ_W, exactly the quantity (27.12) controls.

The honest summary is that theorem 27.9 has a clean transcription *when the graphex operator is Hilbert–Schmidt*, $W \in L^2(\mathbb{R}_+^2)$, and otherwise the theory is at the same conjectural frontier as proposition 27.11.

Proposition 27.18 (GMFG over a square-integrable graphex)**.** *Let $W \in L^2(\mathbb{R}_+^2)$ be a symmetric graphex (so $\mathbb{W}$ is Hilbert–Schmidt, self-adjoint, compact on $L^2(\mathbb{R}_+)$, with $\|\mathbb{W}\| \le \|W\|_{L^2(\mathbb{R}_+^2)}$), and let the per-type problem satisfy* (A-Lip), (A-Growth), (A-Nondeg), (A-Conv)*. If $\|W\|_{L^2(\mathbb{R}_+^2)} < \kappa$ with κ the threshold of theorem 27.9, then the graphex mean field game* (27.20)–(27.21) *has a unique equilibrium in $L^2(\mathbb{R}_+; C[0,T])$.*

Status. Conditional theorem. *The fixed-point argument of chapter 24 is stated over the probability type space* $[0,1]$*; its transcription to the σ-finite space* $(\mathbb{R}_+, \lambda)$ *is routine* provided *the per-type estimates are uniform in* $u \in \mathbb{R}_+$ *and the initial data* m_0^u *have a uniformly bounded second moment with* $\bar{m}_0 \in L^2(\mathbb{R}_+)$ *— hypotheses we must* add *and which are automatic on* $[0,1]$ *but not on* $\mathbb{R}_+$*. Under those added hypotheses the proof of theorem 27.9 goes through verbatim with* $[0,1]$ *replaced by* $\mathbb{R}_+$*; without the uniform-in-u control it is open. We therefore state it as conditional and revisit it in chapter 31.*

What the proof requires. $\mathbb{W}$ Hilbert–Schmidt on $L^2(\mathbb{R}_+)$ is theorem 2.22 applied on the σ-finite measure space, valid because the Hilbert–Schmidt norm is the L^2 norm of the kernel regardless of the base measure's total mass. The contraction constant is again $C_0 \|\mathbb{W}\|$. The single non-automatic ingredient is that the best-response map send $L^2(\mathbb{R}_+; C[0,T])$ into itself, which needs the per-type free trajectories $x \mapsto \bar{m}_t^u\big|_{z\equiv 0}$ to be square-integrable in u; that is the added hypothesis $\bar{m}_0 \in L^2(\mathbb{R}_+)$ propagated by the (A-Lip), (A-Growth) bounds. Granting it, the fixed-point and uniqueness steps are identical to chapter 24. The gap relative to the $[0,1]$ theory is precisely the loss of the automatic uniform integrability that a probability type space provided. □

27.4 The order parameter survives where the operator does not

The graphex section pushed the construction to its outermost frontier — a limit sparse in itself on $\mathbb{R}_+$, whose game we could control only conditionally — and left the theory there at its conjectural edge. We now turn back from that frontier to the most explicit case the chapter owns, the unit-interval rank-one kernel of section 27.2, and advance Thread B through it into the sparse regime to extract the chapter's sharpest statement. The rank-one (Chung–Lu) kernel is the natural test case: it is the kernel that produced power-law degrees in corollary 27.3, it is the cleanest GMFG worked example (worked computation 18.19, proposition 18.18), and — as we will see — it is the case in which the breakdown of section 27.2 can be computed in closed form and tied exactly to the empirical scale-free window.

Worked computation 27.19 (Sparse rank-one LQG graphon game; the $p = 2$ dividing line)**.** This is the dense rank-one baseline of worked computation 26.12 — the same self-consistent closure of a scalar order parameter $\varrho_t = \langle f, \bar{m}_t\rangle$ derived there through the operator Riccati of (26.38)–(26.39) — here pushed to the boundary of L^2, where the closure breaks. Take the linear–quadratic Thread-B model of appendix A.7 with the rank-one coupling $W(x,y) = f(x)f(y)$, $f \geq 0$. By eq. (18.11) the aggregate collapses to a single scalar order parameter,

$$z_t(x) = f(x)\,\varrho(t), \qquad \varrho(t) := \langle f, \bar{m}_t\rangle = \int_0^1 f(y)\,\bar{m}_t(y)\;\mathrm{d}y, \tag{27.22}$$

written with the book's canonical order-parameter symbol $\varrho = \varrho$ (eq. (18.11); the same symbol carries the static rank-one reduction eq. (20.32)), so a type-x agent solves the scalar LQG problem of Thread A with the time-dependent tracking target $s\,z_t(x) = s\,f(x)\,\varrho(t)$.

Step 1: affine response. By the LQG solution of chapter 14 (and its dynamic graphon form in chapter 22), for any given continuous order-parameter path $\varrho \in C[0,T]$ the optimally controlled type-x mean is an *affine* functional of its target path,

$$\bar m_t^x = \pi_t^x + s\, f(x)\, (\mathsf{V}\varrho)(t), \tag{27.23}$$

where π^x is the free ($s = 0$) trajectory determined by the Riccati data and the initial mean $\bar m_0^x$ (eq. (14.13), theorem 14.4), and $\mathsf{V}\colon C[0,T] \to C[0,T]$ is the bounded linear Volterra response operator built from the same Riccati coefficients $(a, b, \sigma, q, q_T, s_T, T)$ (here a is the Thread-B *state-feedback* coefficient of (27.20), not an exponent). This is a *time-path* response operator on $C[0,T]$, and it is *independent of x and of f*; it is a different object from the type-space operator-Riccati $\mathcal{R}_t$ of eq. (26.35) (which acts on $L^2[0,1]$), and we give it the distinct symbol V to avoid conflating the two across the chapter boundary.

Step 2: closing the order parameter. Insert (27.23) into the definition of ϱ in (27.22):

$$\varrho(t) = \int_0^1 f(x)\, \bar m_t^x \,\mathrm{d}x = \underbrace{\int_0^1 f(x)\, \pi_t^x \,\mathrm{d}x}_{:=\ \varrho_0(t)} + s\Big(\underbrace{\int_0^1 f(x)^2 \,\mathrm{d}x}_{=\|f\|_{L^2}^2}\Big)(\mathsf{V}\varrho)(t), \tag{27.24}$$

where ϱ_0 is the *free* ($s = 0$) order parameter built from the uncoupled trajectories. The entire f-dependence of the coupling has condensed into the single scalar $\|f\|_{L^2}^2$, which by proposition 27.8(3) is exactly the operator norm $\|\mathbb{W}\| = \lambda_1$. The self-consistency equation is the linear fixed point

$$\big(I - s\, \|f\|_{L^2}^2\, \mathsf{V}\big)\varrho = \varrho_0, \tag{27.25}$$

uniquely solvable by Neumann series whenever

$$s\, \|f\|_{L^2}^2\, \|\mathsf{V}\|_{C[0,T]\to C[0,T]} < 1 \quad\iff\quad \|\mathbb{W}\| = \|f\|_{L^2}^2 < \kappa := \frac{1}{s\, \|\mathsf{V}\|}, \tag{27.26}$$

which is precisely the coupling-smallness condition (27.10) of theorem 27.9, now made completely explicit: the threshold constant κ is $1/(s\,\|\mathsf{V}\|)$, a pure Riccati quantity. This is the same threshold phenomenon as remark 26.13, where uniqueness was governed by finiteness of the scalar Riccati r: both say the closure is controlled by the leading eigenvalue $\|\mathbb{W}\| = \lambda_1 = \|f\|_{L^2}^2$, and (27.26) is its explicit time-domain form, with the response factor $\|\mathsf{V}\|$ (the horizon-dependent response-Lipschitz constant $L_{\mathcal{R}}(T)$ of eq. (24.7)) supplying the horizon dependence.

Step 3: the dividing line. Take the heavy weight $f(x) = x^{-\nu}$ of corollary 27.3, which under sparsified sampling yields degree exponent $\gamma = 1 + 1/\nu$. The susceptibility that controls the order parameter is

$$\|f\|_{L^2}^2 = \int_0^1 x^{-2\nu} \,\mathrm{d}x = \begin{cases} \dfrac{1}{1-2\nu}, & \nu < \frac12 \ \ (\gamma > 3), \\ +\infty, & \frac12 \le \nu < 1 \ \ (\gamma \in (2,3]). \end{cases} \tag{27.27}$$

Thus:

- For $\gamma > 3$ ($\nu < \frac12$, $f \in L^2 \setminus L^\infty$): the kernel is an unbounded L^2 graphon, $\|\mathbb{W}\| = 1/(1-2\nu) < \infty$, and (27.25) is uniquely solvable provided $s\, \|\mathsf{V}\|/(1-2\nu) < 1$. The GMFG is well-posed in *closed form* — a completely explicit instance of theorem 27.9 with an unbounded, heavy-tailed coupling.

- For $\gamma \in (2,3]$ ($\nu \geq \frac{1}{2}$, $f \in L^1 \setminus L^2$): the susceptibility $\|f\|_{L^2}^2$ *diverges*, the coefficient in (27.25) is $+\infty$, and the order-parameter fixed point has no finite linear closure. The operator $\mathbb{W}$ is unbounded on L^2 (proposition 27.8(4)) and the contraction threshold (27.26) is vacuous. The reduction — and with it the only route to a solution we have — collapses already at $\nu = \frac{1}{2}$, i.e. at $\gamma = 3$ (where $\int_0^1 x^{-1}\,\mathrm{d}x = \infty$), and stays broken throughout the open window $\gamma \in (2,3)$.

The breakdown regime is thus $\gamma \in (2,3]$ ($\nu \in [\frac{1}{2}, 1)$, $f \in L^1 \setminus L^2$), with the dividing line exactly at $\gamma = 3$ ($\nu = \frac{1}{2}$, $p = 2$); the empirically dominant *open* window $\gamma \in (2,3)$ sits strictly inside it. In every such case the linear–quadratic graphon mean field coupling has divergent susceptibility and the dense/L^2 well-posedness theory provably fails. The boundary $\gamma = 3$, $\nu = \frac{1}{2}$, $p = 2$ is one and the same line viewed three ways.

The worked computation refutes a tempting hope and sharpens the frontier. One might have guessed that the finite-rank reduction, being finite-dimensional, would survive any amount of kernel heaviness — after all, $z_t(x) = f(x)\varrho(t)$ is a single scalar times a fixed profile. It does not: the very step that closes the scalar equation, $\varrho \mapsto \langle f, \bar{m}\rangle = \langle f, (\text{response to } sf\varrho)\rangle$, reintroduces $\langle f, f\rangle = \|f\|_{L^2}^2$, and this is the operator norm. The order parameter is finite ($\varrho = \langle f, \bar{m}\rangle$ needs only $f \in L^1$, $\bar{m} \in L^\infty$), but its *self-consistent closure* needs $f \in L^2$. The susceptibility, not the order parameter, is what diverges.

Physics note

This box has one piece of exact mathematics and a surrounding analogy; we are careful to say which is which. The *exact* part is the identification of the closure coefficient as a susceptibility: the quantity $\|f\|_{L^2}^2 = \langle f, \mathbb{W}f\rangle / \langle f, f\rangle$ that closes the order-parameter equation in (27.24) is, term by term, the linear response of the aggregate to a perturbation of the field summed over the coupling — in the rank-one LQG game literally $\int f^2$, the second moment of the coupling weight — and its divergence as the weight is made heavier ($\nu \uparrow \frac{1}{2}$, $\gamma \downarrow 3$) is a theorem, the content of (27.27). The *analogical* part, which carries no mathematical weight, is the surrounding critical-phenomena picture: regard the dense graphon as an upper-critical-dimension mean-field theory where each agent has $\Theta(N)$ neighbors, the law of large numbers suppresses fluctuations, and the closure $z = \mathbb{W}\bar{m}$ is exact; then the scale-free regime $\gamma \in (2,3)$, where a typical agent has $\Theta(1)$ neighbors while a few hubs have anomalously many, is the regime where the "loop corrections" the mean-field closure neglected are no longer small. That language is a heuristic guide to intuition, not a proof; if every word of it were deleted, the divergence of $\int f^2$ and the breakdown of the linear closure would stand exactly as proved. The reason the analogy is nonetheless apt is that both sides are, structurally, the same computation: a sum over a coupling weighted by its own magnitude, diverging when the weight's tail is too heavy to be square-summable.

Remark 27.20 (Where the frontier actually runs)**.** The single orientation worth carrying out of this chapter — the itemized accounting is the ledger's job, just below — is *where* the theorem/conjecture boundary falls, because for once it falls at a sharp and computable place. Everything on the unbounded-kernel axis up to and including $p = 2$ is theorem: square-integrability, not boundedness, is the true hypothesis, and the rank-one game makes the boundary explicit. Everything strictly below $p = 2$ — equivalently the empirically dominant scale-free window $\gamma \in (2, 3)$ — is conjecture: the operator is unbounded, the contraction is gone, and existence is known only in the monotone and finite-rank special cases. The graphex axis sits one notch further out: its *counting* theory is fully proved here, but the game over a non-Hilbert–Schmidt graphex, and the sparse ε-Nash theory, are open. That the most empirically relevant regime is exactly the one our methods cannot yet reach is the chapter's honest punchline, not a gap we paper over.

Rigor ledger

Proved (in this chapter).

- Sparsification by a target density: mixed-Poisson degree limit (proposition 27.2) and power-law degrees from a heavy rank-one weight, exponent $\gamma = 1 + 1/\nu$ (corollary 27.3), with sublinear maximum degree (S2); the independence of the unbounded-kernel and sparse-graph axes (remark 27.4).

- The function class of L^p graphons (definition 27.5); the two boundedness criteria, Hilbert–Schmidt (lemma 27.6) and Schur (lemma 27.7); the dichotomy that $p = 2$ is the sharp line, with the Hilbert–Schmidt route strictly dominating Schur and the rank-one breakdown at $f \in L^1 \setminus L^2$ (proposition 27.8).

- GMFG well-posedness for L^2 graphons with $\|\mathbb{W}\| \le \|W\|_{L^2} < \kappa$ (theorem 27.9); the explicit rank-one closure with threshold $\kappa = 1/(s\,\|\mathsf{V}\|)$ and the exact $p = 2 \Leftrightarrow \gamma = 3$ dividing line via the divergence of the susceptibility $\|f\|_{L^2}^2$ (worked computation 27.19).

- The graphex process and its counts: $\mathbb{E}[e(G_\ell)] = \frac{1}{2}\ell^2\,\|W\|_{L^1}$, $\mathbb{E}[N_\ell] = \ell\,\Psi(\ell)$, and subquadratic sparsity $e = o(N^2)$ under a heavy marginal (proposition 27.14); a closed-form heavy-tailed degree distribution with exponent $\gamma = 1 + 1/\zeta \in (1, 2)$ for a pure-power graphex marginal (proposition 27.15), securing (S3).

- The self-contained Poisson-process calculus underlying the above: Campbell/Mecke, thinning, mapping, marking, the Poisson limit theorem, and the mixed-Poisson tail transfer (appendix H).

Assumed (imported).

- The dense-failure propositions and the sparsity preview (sections 19.5 and 19.6 and propositions 19.13 and 19.14); the cut metric (definitions 17.1 and 17.6).

- Hilbert–Schmidt kernel theory and the spectral theorem (definition 2.21, theorems 2.22 and 2.26, and proposition 2.24); the fixed-point theorems — Banach contraction (theorem 2.36) and Schauder (theorem 2.38), the latter applied to MFG existence in chapter 10; Mercer and the spectral ordering (theorem 18.2 and definition 18.1); the rank-one order-parameter reduction (eqs. (18.10) and (18.11), proposition 18.18, and worked computation 18.19).

- The dense GMFG existence/uniqueness theory whose estimates depend on the kernel only through $\|\mathbb{W}\|$ (chapters 22 and 24), and the LQG Thread-A/Thread-B solution and its Volterra response operator V on $C[0,T]$ (eq. (14.13), theorems 14.4 and 14.6, and chapter 22); the horizon-dependent response-Lipschitz constant $L_{\mathcal{R}}(T)$ of the dynamic contraction eq. (24.7).

- Standing assumptions (A-Lip), (A-Growth), (A-Nondeg), (A-Conv), (A-Mon), and the kernel hypothesis (A-Reg-W) in its weakened L^2 form and the smallness (A-Coupling) read as $\|W\|_{L^2} < \kappa$.

Deferred (proved elsewhere, used as structural license).

- The graphex representation theorem (imported result 27.16), proved via Kallenberg's representation of jointly exchangeable random measures in [130, 45, 84]. (The Mecke/-Campbell calculus it and proposition 27.14 use is *not* deferred: it is proved in-book in appendix H; the citation [84, Ch. 4] is for attribution only.)

- The sampling / stretched cut-metric convergence theory and the L^p theory of sparse graph limits (remark 27.17), used only as orientation [25, 26, 27].

Open.

- Existence and uniqueness for GMFG with L^1 couplings and unbounded $\mathbb{W}$ — the scale-free window $\gamma \in (2, 3)$ (proposition 27.11 and worked computation 27.19); the right fixed-point space and a-priori bound are unknown beyond the monotone and finite-rank cases.

- Unconditional well-posedness of GMFG over graphex limits without the Hilbert–Schmidt hypothesis (proposition 27.18); the role of the star and dust components (S, I) of definition 27.12 in the game.

- The sparse analogue of the finite-network convergence theory of chapter 25: an ε-Nash theorem for GMFG strategies on large sparse graphs, and the commutation of the $N \to \infty$ and $\ell \to \infty$ limits. See chapter 31.

Bibliographic notes

The diagnosis that bounded graphons force density, and the resulting program of L^p and graphex limits, is developed in chapter 19 (sections 19.5 and 19.6) following the dense theory of Lovász [99]. The sparsification by a vanishing target density, and the resulting mixed-Poisson / power-law degree structure (proposition 27.2 and corollary 27.3), are the expected-degree model of Chung and Lu [48]; the mixed-Poisson heuristic and its tail transfer are standard in the random-graph literature and we have made the rank-one case explicit.

The L^p theory of graphons and sparse graph convergence is due to Borgs, Chayes, Cohn and Zhao [27]; the operator-theoretic facts we use — the Hilbert–Schmidt bound and the Schur test (lemmas 27.6 and 27.7) — are classical and are proved in chapter 2 (see also [31, 50, 113]). The observation that the GMFG well-posedness theory depends on the kernel only through $\|\mathbb{W}\|$, and hence extends from L^∞ to L^2 graphons verbatim (theorem 27.9), is the natural reading of the contraction arguments of chapter 24; the linear–quadratic graphon game in which this becomes fully explicit is the stochastic graphon game of Aurell, Carmona and Laurière [10], whose analysis is carried out for L^2 (Hilbert–Schmidt) kernels and which our worked computation 27.19 specializes and pushes to the boundary of that class.

The graphex framework originates with Caron and Fox [45] and Veitch and Roy [130]; the representation theorem (imported result 27.16) rests on Kallenberg's theory of exchangeable random measures [84], and the sampling-convergence / stretched-cut-metric foundations are due to Bollobás and Riordan [25] and Borgs, Chayes, Cohn and Holden [26]; the connection of these limits to L^p graphons is [27]. The Poisson-process calculus underlying propositions 27.2, 27.14 and 27.15 and corollary 27.3 — Campbell/Mecke, thinning, mapping, marking, the Poisson limit theorem (Le Cam's coupling bound) and the mixed-Poisson tail transfer — is developed self-containedly in appendix H; the standard references, used only for attribution, are [95, 84] for the point-process calculus and [24] for regular variation. For mean field *systems* (interacting diffusions without control) on graphon and sparse limits, which provide the closest rigorous anchor for the forward dynamics of (27.20), see Bayraktar, Wu and Zhang [16] in the dense/L^2 case and Lacker, Ramanan and Wu [91] for the local-weak-convergence approach on genuinely sparse networks; the latter is, at present, the most promising route toward the open ε-Nash theory on sparse graphs flagged above and in chapter 31. The Erdős–Rényi toy model of Delarue [57] is the historically first mean field game on a (sparse-capable) random graph and remains a useful proving ground. The honest separation of theorem from conjecture that this chapter insists upon is continued, for the whole subject, in the research map of chapter 31.

Chapter 28

Numerical Methods for Mean Field Games

Every theorem in Parts II and IV asserts that an equilibrium *exists*; almost none of them tells us what it *is*. This is worth pausing on, because it marks a turn in the book. The existence theory we have built is powerful but constitutionally non-constructive: the fixed-point arguments of chapters 8 and 9 and the monotonicity method of chapter 11 prove that the set of equilibria is nonempty, and the graphon existence theory of chapter 24 does the same across a kernel, yet a proof that a set is nonempty is not a recipe for a point in it. In exactly one place in the entire book do we know what an equilibrium actually *is*: the linear–quadratic–Gaussian (LQG) island of chapter 14, where the coupled system collapses to a Riccati equation and a Gaussian and the answer fits on a line. Everywhere else the equilibrium is certified to exist and is nonetheless invisible—there is no formula to look at. To *see* such an equilibrium one must *compute* it, and that is the office of this chapter: it is the constructive complement the existence theory has so far lacked, turning the abstract guarantee "a solution exists" into a finite algorithm that manufactures one to any prescribed accuracy.

Outside that LQG island the coupled Hamilton–Jacobi–Bellman–Fokker–Planck (HJB–FP) system has no closed form, and the only handle on it is numerical. This chapter is about how. Its organizing fact is the one the whole book has circled around: an equilibrium is a *forward* equation carrying initial data glued to a *backward* equation carrying terminal data, and that gluing has no initial-value analogue, so it cannot be solved by simply marching a clock. We must instead either iterate a self-consistency loop until the two ends agree, or solve the entire space–time system at once. Both strategies are developed here, with their convergence theory stated honestly, their failure modes named, and their discrete structure shown to mirror the continuous one. A word on that honesty, since it governs the chapter: we prove the structural lemmas that make the schemes correct—the M-matrix and adjointness lemmas of section 28.2—in full and in-book; we pin every passage to the limit on parabolic estimates proved elsewhere in this book rather than waved at; and we quote the literature only for what genuinely belongs to it, the sharp-constant accounting of the convergence rates. Where a result is only conditional, we say so plainly.

The tools we lean on are imported, not re-derived; it is worth naming them as live instruments rather than as a citation dump, because each does specific work below. From chapter 8 we take the two equations of the MFG system and their two readings. The Hamilton–Jacobi–Bellman equation eq. (8.5a) is the backward, value-side half; the Fokker–Planck equation eq. (8.5b) is the forward, population-side half; and the optimal feedback eq. (8.6) is the bridge between them that we will discretize as a single drift. These three are the object every method in the first half of the chapter must solve. The fourth import governs the second half: the variational characterization of *potential* games, theorem 8.11, which recognizes a whole class of MFGs as the optimality system of a single convex minimization—the energy eq. (8.18) over density flows. That one theorem is what powers everything from section 28.4 onward, because it converts "find a fixed point" into "minimize a convex functional," a problem with global, unconditionally convergent algorithms.

We invoke the standing assumptions by their global names, and it helps to recall in a clause what each one buys. (A-Lip) (Lipschitz coefficients) and (A-Growth) (controlled growth) keep the backward and forward solution maps well posed and stable, so that errors propagate boundedly rather than blow up. (A-Nondeg) (uniform nondegeneracy of the diffusion) supplies the parabolic regularization on which every gradient estimate—and hence every passage to the limit—rests; it is also what confines mass and makes a truncated computational domain legitimate. (A-Conv) (convexity of the Hamiltonian in the momentum) is what makes the optimal feedback well defined and the inner Bellman minimization a convex problem with a unique minimizer. (A-Mon) (Lasry–Lions monotonicity of the coupling) buys uniqueness of the equilibrium and, in the potential case, convexity of the energy. For the graphon discretization two further assumptions enter: (A-Reg-W) (a symmetric, bounded, suitably regular kernel, so that $\mathbb{W}$ is self-adjoint Hilbert–Schmidt) makes the coupling quadrature convergent, and (A-Coupling) (operator-norm smallness of $\mathbb{W}$) is the threshold that decides contraction-based uniqueness. We follow throughout the global convention (appendix A): the value $u = u(t, x)$ carries terminal data at $t = T$ and is computed *backward*; the density $m = m(t, x)$ carries initial data at $t = 0$ and evolves *forward*. This forward-m/backward-u split is not a stylistic choice—it is the very obstruction the next section dissects.

The two carried threads ride this machinery to a new, numerical layer. From chapter 14 we carry Thread A, the scalar LQG game, whose closed-form Riccati answer is the yardstick the solver must reproduce; from the rank-one reduction of proposition 18.18 and worked computation 18.19, realized through the matrix template of section 14.7, we carry Thread B, the graphon LQG game, whose coupling collapses to a single scalar order parameter. The closing worked computation (section 28.6) hands both to a black-box nonlinear PDE solver that knows nothing of the LQG ansatz and checks its output against those closed forms, advancing each thread to its fourth (numerical) layer and validating analysis and implementation against each other.

The plan follows the logic of the obstruction. Section 28.1 states it precisely and shows that it forces exactly two algorithmic families—iterate the fixed point, or solve the whole system at once—and that both rest on a single shared building block. Section 28.2 builds that block: the Achdou–Capuzzo-Dolcetta finite-difference scheme, a monotone upwind discretization of the HJB operator whose discrete generator is an honest rate matrix, paired with a conservative Fokker–Planck discretization that is its *exact* transpose—the discrete face of the forward–backward duality—so that monotonicity, mass conservation, and positivity all hold already at the grid level; the section closes with the convergence theorem to viscosity and weak solutions. With the block in hand, section 28.3 wraps it in the outer loop, contrasting damped fixed-point (Picard / fictitious play) iteration with all-at-once Newton and the contraction theory that decides when each is the right tool. Section 28.4 then exploits the potential structure: for games that are convex minimizations it develops the variational and primal–dual methods, whose unconditional convergence outruns the fixed point, and exhibits their kinship with optimal-transport solvers. Section 28.5 lifts the whole apparatus to the kernel by adding a type grid feeding the state grid, realizing the operator $\mathbb{W}$ as a quadrature—the numerical face of graphon coarse-graining—reducing a block graphon to a finite multi-population game, and tying the quadrature error back to the regularity theory of chapter 19. Section 28.6 is the pay-off: the worked computation that reproduces the closed forms of both threads. Algorithmic templates appear inline as numbered procedures; the full reference implementation lives in `figures/28-mfg-solver.py`.

Notation watch

This chapter carries two integer indices that a physicist must not conflate. A superscript n is a *time* index, $t_n = n\,\Delta t$; a subscript i is a *state-grid* index, $x_i = x_{\min} + ih$; and in the graphon sections a subscript k is a *type-grid* index, $x_k \in [0,1]$. Thus u_i^n is the discrete value at state x_i, time t_n, and $m_i^{k,n}$ is the discrete density of type x_k at state x_i, time t_n (the type-indexed field m^{x_k} of chapter 18). The grid spacings are h (state) and Δt (time); h is *not* the terminal cost $g = g$ of earlier chapters, which does not appear discretized here. Brownian motion is absent from the PDE formulation, so no W/B clash arises until the graphon kernel W enters in section 28.5, where W is always the kernel. Two further letters carry a second, deliberately *local* meaning, flagged here once: w is the momentum field $w = m\alpha$ of section 28.4 but a quadrature weight w_l in section 28.5; and $\mathcal{P}$ denotes a type *partition* in section 28.5.2, the stepping-operator partition of definition 19.7, not the measure space $\mathcal{P}$. The control is $\alpha = \alpha$ throughout, *never* a (which is the Thread A state-feedback parameter of eq. (28.1)).

28.1 The core difficulty: a forward–backward boundary-value problem

The preamble stated our organizing fact as a slogan: an equilibrium is a forward equation glued to a backward equation, and that gluing has no initial-value analogue. A slogan is not yet something one can act on. This section turns it into a precise statement—about which data sit at which end of the time interval, and why the two ends are mutually entangled—and then proves the operationally decisive consequence: that the glued system cannot be solved by marching a clock. Out of that single fact the entire taxonomy of methods will fall, because there are exactly two ways to confront a problem one cannot integrate in time, and the rest of the chapter is the elaboration of those two ways. It is worth being slow and concrete here, since every later section inherits the structure laid bare in this one.

Recall the mean field game system in the separable form of chapter 8: on $[0,T] \times \mathbb{R}^d$,

$$-\partial_t u - \tfrac{1}{2}\operatorname{tr}\big(\sigma\sigma^\top \mathrm{D}^2 u\big) + H(x,\nabla u) = F[m_t](x), \qquad u(T,x) = G[m_T](x), \tag{28.1a}$$

$$\partial_t m - \tfrac{1}{2}\operatorname{tr}\big(\sigma\sigma^\top \mathrm{D}^2 m\big) - \operatorname{div}\big(m\,\partial_p H(x,\nabla u)\big) = 0, \qquad m(0,\cdot) = m_0, \tag{28.1b}$$

with the optimal feedback $\alpha^*(t,x) = -\partial_p H(x, \nabla u(t,x))$ closing the loop (eq. (8.6)). Taken one at a time, each line of eq. (28.1) is a textbook object. The first, eq. (28.1a), is a backward Hamilton–Jacobi–Bellman equation: given a known right-hand side it is solved *backward* from terminal data at $t = T$, and it returns the value u of the representative agent's control problem—through the feedback $\alpha^* = -\partial_p H$, the best a single agent can do against a *prescribed* environment. The second, eq. (28.1b), is a forward Fokker–Planck (continuity) equation: given a known drift it is solved *forward* from initial data at $t = 0$, and it transports the population density m along that drift. Neither equation is hard in isolation. The difficulty lives entirely in how the two feed each other.

Trace the two arrows explicitly, because seeing both is the whole point. *Population into value:* the agent does not optimize in a vacuum; the cost it faces depends on where everyone else is. That dependence enters eq. (28.1a) through the couplings $F[m_t]$ and $G[m_T]$—a running interaction cost set by the present density and a terminal interaction cost set by the final density. The entire time-profile of the population, $t \mapsto m_t$, sits inside the source of the HJB equation, and through it inside the value u and the feedback. *Value into population:* the agents then act on that value. The optimal feedback $\alpha^* = -\partial_p H(x, \nabla u)$ is built from the value's gradient, and it is exactly this feedback that appears as the drift transporting the density in eq. (28.1b) (the term $\partial_p H(x, \nabla u)$ inside the divergence). So ∇u steers the flow of m, while m sources the equation that determines u. The loop is closed and runs in both directions at once, and this mutual dependence is precisely what the word *equilibrium* means here: a population whose induced individually-optimal behavior reproduces that very population.

What makes the loop genuinely awkward, rather than merely coupled, is *where the data live*. The two equations are anchored at *opposite ends* of the time interval. The density carries initial data: $m(0,\cdot) = m_0$ is given at $t = 0$, the starting configuration of the crowd. The value carries terminal data: $u(T,\cdot) = G[m_T]$ is fixed at $t = T$, the end-of-game payoff. One condition is pinned at the start of time, the other at the end, and the coupling forces both to be satisfied at once. This is a two-point *boundary*-value problem in time—a boundary-value problem whose "boundary" is the pair of temporal endpoints $\{0, T\}$—and not the initial-value problem that the word "evolution" would lead one to expect.

Heuristic (non-rigorous)

Why one cannot march the clock. Try, in imagination, to do the obvious thing: integrate eq. (28.1) as an ordinary initial-value problem, stepping forward one small interval at a time from $t = 0$. To take even the first step—to push the density m from $t = 0$ to $t = \Delta t$—we need the drift that transports it, $\partial_p H(x, \nabla u(0,\cdot))$, and hence we need the value u, and its gradient, at the initial time. But u at $t = 0$ is not ours to choose. It is determined by *integrating the backward equation eq.* (28.1a) *all the way down from* $t = T$, and that backward integration cannot even begin until two things are known: the terminal data $u(T,\cdot) = G[m_T]$, which needs the *final* density m_T, and the source $F[m_t]$ at every intermediate time, which needs the *entire future history* of the density. In other words, to compute the drift that produces the future of m, we must already know that future. Nor is anything gained by starting from the other end. To march u backward from $t = T$ we must first know m_T to fix the terminal payoff, and m_T is the *output* of the forward flow we have not run—which itself needed u.

Each end demands, as its input, precisely what the other end is supposed to produce as its output. Neither can take its first step alone; the clock has no direction in which it can be marched. This is the exact sense in which the forward–backward gluing "has no initial-value analogue."
The reader should resist reading this as a numerical inconvenience to be engineered away. It is not an artifact of any discretization, nor of any particular solver; it is the defining structure of an equilibrium. An equilibrium is, by definition, a fixed configuration in which anticipation of the future (the backward value) and propagation of the past (the forward density) are mutually consistent across the whole interval at once. A method that could simply march the clock would be solving a *different*, causal problem—one agent reacting to an exogenously given crowd—not the self-consistent one we are after. Every algorithm in this chapter therefore confronts the circularity head-on rather than pretends it away.

The circularity admits exactly two responses, and the entire chapter is organized around the choice between them. Either we break the loop deliberately—freeze one of the two unknowns, solve the now-one-directional problems, and update the frozen guess until the freeze becomes self-consistent—or we refuse to break it and instead solve for the whole forward–backward field in a single simultaneous stroke. The first is an iteration over guesses; the second is one large nonlinear solve. We take them in turn.

Strategy I: decouple and iterate (the outer fixed point). The first response breaks the loop on purpose. Freeze a candidate population flow—an entire time-profile of densities, $\bar{m} = (\bar{m}_t)_{t\in[0,T]}$, our current guess for what the crowd does. The instant this flow is held fixed, the entanglement dissolves, because the couplings stop being unknowns and become data. The running source $F[\bar{m}_t]$ and the terminal payoff $G[\bar{m}_T]$ are now *known functions of time and state*: $F[\bar{m}_t](x)$ is simply a prescribed function of (t,x), and $G[\bar{m}_T](x)$ a prescribed terminal function of x, each computed once from the frozen flow and thereafter referring to nothing unknown. With those in hand—and, in the implementation, after restricting to a bounded computational domain, which turns the couplings into honest bounded continuous functions and yields what we will call the *cut-off problem* of theorem 28.3—the HJB equation eq. (28.1a) is a genuine terminal-value problem with a given right-hand side. We solve it backward from $t = T$, exactly as one solves any single-agent control problem against a prescribed environment, and read off the optimal feedback $\alpha^* = -\partial_p H(x, \nabla u)$. That feedback is, in turn, a known drift. Substituting it into the Fokker–Planck equation eq. (28.1b) produces a genuine initial-value problem, which we solve forward from $t = 0$ to obtain a *new* population flow m'—the crowd that actually results when every agent best-responds to the frozen guess. We have replaced one entangled forward–backward problem by two one-directional solves chained in series: one backward, then one forward.

This chain defines a map from flows to flows,

$$\mathsf{S}:\ \bar{m}\ \longmapsto\ m', \qquad \mathsf{S}:\ C\big([0,T];\mathcal{P}_2(\mathbb{R}^d)\big) \to C\big([0,T];\mathcal{P}_2(\mathbb{R}^d)\big), \tag{28.2}$$

the best-response operator of section 8.4. The type signature deserves to be read aloud rather than skipped past. An element of $C([0,T];\mathcal{P}_2(\mathbb{R}^d))$ is a whole *path of probability measures*: a curve

$t \mapsto m_t$ that assigns to each instant a probability distribution on $\mathbb{R}^d$ of finite second moment, and that varies continuously in the Wasserstein-2 distance $\mathcal{W}_2$. The input of S is such a curve (the frozen guess), and so is its output (the resulting flow); thus S maps the space of population histories into itself. In this language an equilibrium is nothing other than a flow that reproduces itself under best response—a *fixed point* $\bar{m} = \mathsf{S}(\bar{m})$. Each *evaluation* of S costs exactly two ordinary PDE solves (one backward HJB, one forward FP); the equilibrium is then found by *iterating* S—feeding its output back as its next input—until the flow stops moving. The catch, taken up in section 28.3, is that this iteration converges only when S is a contraction, which it need not be; its appeal is that the per-step cost is low and the memory footprint is a single flow at a time. This is the method built in sections 28.2 and 28.3.

Strategy II: solve the whole system at once. The second response refuses to break the loop at all. Rather than alternating two one-directional solves, discretize the coupled system eq. (28.1) on a single space–time grid and ask for *all* of its unknowns at once—every discrete value u_i^n and every discrete density m_i^n, at every grid node and every time level—as the solution of one large nonlinear algebraic system. Stacking the values into a vector $U = (u_i^n)$ and the densities into $M = (m_i^n)$, the discretized equations become a single root-finding problem

$$\mathcal{R}(U, M) = 0, \tag{28.3}$$

whose two block-rows are the discrete HJB and the discrete Fokker–Planck residuals and into which the boundary data at the two temporal ends are built directly. There is no marching and no freezing: the forward–backward coupling is imposed everywhere simultaneously, and one hands the whole system to a nonlinear solver—Newton's method (section 28.3) or, when the game is potential, a convex-optimization algorithm that recognizes eq. (28.3) as the optimality condition of a single convex program (section 28.4). What this costs is *memory*: the unknown is now the entire space–time field (U, M) held in store at once, rather than one time-slice marched along, and a Newton step couples all of it. What it buys is *robustness*. Because it never iterates S, it does not depend on S contracting; it can converge in regimes where Strategy I oscillates or diverges—near the multiplicities and conjugate horizons where the best-response loop breaks down. Strategy II trades storage for unconditional reach.

The two strategies look different on the surface—an iterated pair of one-way solves versus one monolithic root-find—but they rest on the *same* foundation, and naming it sets the agenda for the next section. Both must discretize the individual backward (HJB) and forward (FP) equations, and both need those discretizations to be accurate (consistent with the PDEs as the grid is refined) and stable (errors not amplified). There is, however, a third and subtler requirement that neither strategy can do without: the two discretizations must be *mutually consistent*. Concretely, the discrete forward operator must be the *exact adjoint*—the transpose—of the discrete backward operator. This is the discrete fingerprint of the continuous forward–backward duality we have just anatomized, and we will see that it is exactly what makes mass conservation, positivity, the discrete maximum principle, and (in the potential case) the discrete convexity all hold at the grid level rather than only in the limit; it is also what renders the Newton system of Strategy II tractable. Because this adjoint pairing is the keystone on which everything downstream rests, we build that shared block first, before either outer strategy—the finite-difference discretization of the HJB–Fokker–Planck system, to which we now turn.

28.2 Finite-difference schemes for the HJB–Fokker–Planck system

The previous section closed with a promise: whichever of the two strategies one adopts—iterate the best-response fixed point, or solve the whole space–time system at once—the first thing to build is the *shared block* both of them stand on, a discretization of the individual backward (HJB) and forward (Fokker–Planck) equations that is accurate, stable, and—the subtle third demand—mutually consistent, meaning the discrete forward operator is the exact adjoint of the discrete backward one. That block is what this section constructs. It pays to keep the three demands in view as we go, because they are not independent wishes to be balanced against one another but a single design problem with one solution. *Accuracy* is consistency in the numerical-analyst's sense: as the grid is refined the discrete operators converge to the differential ones. *Stability* is the requirement that errors not be amplified from one step to the next, so that local truncation error does not compound into global garbage. *Mutual consistency* is the structural fingerprint of the continuous forward–backward duality dissected in section 28.1: the same first-order transport drift that steers the value backward must, transposed, steer the density forward, and we shall arrange the discretization so that this holds *exactly* at the grid level rather than only in the refinement limit. Everything downstream—mass conservation, positivity, the discrete maximum principle, the tractability of the Newton system, and in the potential case the discrete convexity—will turn out to be a corollary of getting that one adjoint relationship right.

A word on dimension, to set expectations before the indices arrive. We discretize in one state dimension for transparency; this is a genuine simplification of *exposition*, not of substance. The construction is dimension-by-dimension identical in $\mathbb{R}^d$—each first-order derivative is upwinded and each second-order derivative is centered, coordinate by coordinate, and the multidimensional stencil is the tensor assembly of the one-dimensional ones—and, crucially, the two structural lemmas that carry the whole chapter (the M-matrix property and the adjointness/conservation property) are stated and proved *dimension-free*: they are statements about a generator matrix with nonnegative off-diagonals and zero row sums, and nothing in them counts dimensions. So nothing is lost by reading the scalar case and everything transfers. Accordingly, fix a bounded computational interval $[x_{\min}, x_{\max}]$—the truncation is legitimate because (A-Nondeg) confines essentially all mass to a bounded region, a point we return to once the scheme is in place—a state step $h > 0$ with nodes $x_i = x_{\min} + ih$, and a time step $\Delta t = T/N_T$ with nodes $t_n = n\,\Delta t$, $n = 0, \ldots, N_T$. We write $u_i^n \approx u(t_n, x_i)$ for the discrete value and $m_i^n \approx m(t_n, x_i)$ for the discrete density, the superscript indexing time and the subscript indexing the state grid, exactly as fixed in the chapter's notation watch.

Why discretize the two equations *separately but consistently*, rather than reaching at once for some monolithic coupled stencil? Because the two halves of the system have opposite characters and want opposite numerical treatments, and pretending otherwise throws away the very structure that makes the schemes correct. The backward HJB equation is a fully nonlinear, first-order-dominated equation whose solutions are generically only *viscosity* solutions (chapter 6); what one must preserve there is the comparison principle, and the discrete property that encodes it is *monotonicity.* The forward Fokker–Planck equation is a linear conservation law for a *density*; what one must preserve there is total mass and positivity. These are different fidelity requirements, served by different design choices—and yet they must lock together, because the drift in the forward equation is built from the gradient of the backward solution. The Achdou–Capuzzo-Dolcetta resolution, which organizes the next two subsections, is to honor each requirement with its own scheme and then to weld the two by a single algebraic device. First we build a *monotone* backward scheme: we discretize the Hamiltonian's transport term by *upwinding*—taking the difference in the direction the drift comes from—which is exactly the choice that keeps the discrete generator a bona fide rate matrix and hence the scheme monotone, so that the Barles–Souganidis route to viscosity solutions is open. Then we build the forward scheme not from scratch but as the *transpose* of that backward generator: by fiat, the discrete Fokker–Planck operator is the adjoint of the discrete HJB operator assembled from the same optimal drift. That one stroke makes mass conservation, positivity, and adjointness fall out together, for free, as we will prove—no separate fight for each. The build order is thus fixed by the logic: the backward generator is the primitive object, the forward operator is its shadow, and the "mutual consistency" demanded above is not something we check after the fact but something we *install by construction.* We turn first, then, to the backward scheme, where upwinding is the move that buys monotonicity.

28.2.1 A monotone scheme for the backward HJB equation

The preceding section fixed the build order: the backward generator is the primitive object, the forward operator its transpose, and the structural lemma that everything downstream rests on is the one we must secure first. So we begin where the logic insists, with a backward scheme for the HJB equation eq. (28.1a), and the non-negotiable demand on it is *monotonicity.* The reason sits at the level of what an HJB solution even *is.* Outside the LQG island the equation eq. (28.1a) is fully nonlinear and first-order-dominated; its solutions are generically not classical but only *viscosity* solutions (chapter 6), and the single property that pins a viscosity solution down uniquely is the *comparison principle*: if one sub/supersolution lies below another at the terminal time, it lies below it everywhere. Any honest discretization must reproduce that ordering at the grid level, and the theorem that tells us exactly which discretizations do is the Barles–Souganidis criterion—an approximation scheme that is *monotone* (its update preserves the partial order on grid functions), *stable* (its solutions stay bounded uniformly in the grid size), and *consistent* (its local truncation error vanishes under refinement) converges, locally uniformly, to the unique viscosity solution. We will verify stability and consistency in passing when we assemble the convergence theorem (theorem 28.3); the delicate one, and the one that dictates the entire design, is monotonicity.

Monotonicity is best read as the *discrete shadow of the comparison principle.* Concretely, the one-step backward map must have the property that raising the input value field pointwise can only raise the output—no entry of the update may depend with the *wrong sign* on a neighboring value. Whether this holds is decided entirely by the sign pattern of the discrete generator, and it is exactly here that the obvious discretization fails. Approximate the first-order transport term $d(x)\,\partial_x\phi$ by a *centered* difference $d_i(\phi_{i+1}-\phi_{i-1})/2h$ and add the centered diffusion $\frac{\sigma^2}{2}(\phi_{i+1}-2\phi_i+\phi_{i-1})/h^2$; the coefficient multiplying the left neighbor ϕ_{i-1} is then $-d_i/2h+\sigma^2/2h^2$, which turns *negative* as soon as $d_i > 0$ and the grid is coarse enough that $h > \sigma^2/d_i$—that is, once the dimensionless cell Péclet number $h\,|d_i|\,/\sigma^2$ exceeds one. A negative off-diagonal entry is precisely a wrong-sign dependence on a neighbor: the update can *lower* the output where the input rose, the discrete comparison principle breaks, and the scheme manufactures spurious oscillations that the continuous maximum principle forbids. The cure is *upwinding*: difference the transport term in the direction the drift *comes from*—a forward difference where the flow points right, a backward difference where it points left—so that the advective contribution only ever *adds* to the coupling with the upstream neighbor and never produces a negative off-diagonal, for any grid however coarse. Upwinding is thus not a numerical nicety; it is the discrete enforcement of the comparison principle, and the rest of this subsection makes that statement precise and quantitative.

To upwind we must first know which way the drift points, and that drift is itself produced by the Hamiltonian. So before discretizing anything we make the variational structure of H explicit, because it both delivers the drift and certifies the convexity on which the inner minimization will depend. Write the Hamiltonian of a control-affine problem in its variational form

$$H(x,p) = \sup_{\alpha\in A} \big\{ -b(x,\alpha)\cdot p - L(x,\alpha)\big\}, \tag{28.4}$$

the convention of chapters 6 and 8 (eq. (8.4)): H is the Legendre-type transform of the running cost along the controlled drift, and as a supremum of functions *affine* in p it is automatically *convex* in p—which is the content of (A-Conv) and the reason the optimal feedback below is well defined and unique. The maximizer in eq. (28.4) is the optimal control as a function of the momentum, and differentiating the optimized expression recovers the drift: $\partial_p H(x,p) = -b(x,\alpha^*(x,p))$, so that the closed-loop transport velocity in the Fokker–Planck equation is exactly $-\partial_p H$.

It is worth running the LQG thread through eq. (28.4) in full, both to see the machine turn and because the closed form is the yardstick the solver must reproduce. With $b(x,\alpha) = ax + b\alpha$ and $L(x,\alpha) = \frac{1}{2}\alpha^2$ (the data of Thread A, eq. (28.1)), the bracket in eq. (28.4) is

$$-b(x,\alpha)\,p - L(x,\alpha) = -(ax+b\alpha)\,p - \tfrac{1}{2}\alpha^2,$$

a concave quadratic in α; setting its α-derivative $-b\,p-\alpha$ to zero gives the minimizer

$$\alpha^* = -b\,p. \tag{28.5}$$

Substituting α^* back,

$$H(x,p) = -(ax + b(-bp))\,p - \tfrac{1}{2}(bp)^2 = -ax\,p + b^2p^2 - \tfrac{1}{2}b^2p^2 = -ax\,p + \tfrac{1}{2}b^2p^2,$$

convex in p as required. Two continuous objects fall straight out of this, and we will meet both again in discretized form. First, the Fokker–Planck drift is $\partial_p H = -ax + b^2 p = -(ax - b^2 p)$, so the closed-loop velocity transporting the density is $-\partial_p H = ax - b^2 p$—which is just the state dynamics $ax + b\alpha^*$ with $\alpha^* = -bp$ inserted, exactly as it should be. Second, feed H into the HJB equation eq. (28.1a) with the quadratic ansatz $u(t,x) = \frac{1}{2}P(t)x^2 + \dots$ (curvature P plus lower-order terms) and the running cost $F = \frac{q}{2}x^2$. Then $\nabla u = Px$, $\partial_t u = \frac{1}{2}\dot{P}x^2 + \dots$, and collecting the coefficient of x^2 in $-\partial_t u - \frac{\sigma^2}{2}\partial_{xx}u + H(x,\nabla u) = F$ gives

$$-\tfrac{1}{2}\dot{P} - aP + \tfrac{1}{2}b^2P^2 = \tfrac{q}{2},$$

the x^2-balance, in which the diffusion contributes only to the lower-order terms. Multiplying by -2 rearranges this into the Riccati equation

$$\dot{P} = b^2 P^2 - 2aP - q \tag{28.6}$$

of chapter 14. This is the closed-form answer section 28.6 will reproduce numerically from a solver that knows none of this algebra; recording the substitution here is what makes that later agreement a genuine check rather than a coincidence.

With the drift in hand we can discretize. Given any feedback policy $\alpha(\cdot)$, the linear operator inside the optimization eq. (28.4) is the closed-loop generator $\mathcal{A}_\alpha \phi = d_\alpha(x)\,\partial_x \phi + \frac{\sigma^2}{2}\partial_{xx}\phi$ with drift $d_\alpha(x) = b(x, \alpha(x))$ (for the optimal feedback, $d_{\alpha^*} = -\partial_p H$). We discretize $\mathcal{A}_\alpha$ by the *upwind* stencil

$$(\mathcal{A}_h)_{i,i-1} = -\frac{(d_i)^-}{h} + \frac{\sigma^2}{2h^2}, \quad (\mathcal{A}_h)_{i,i+1} = \frac{(d_i)^+}{h} + \frac{\sigma^2}{2h^2}, \quad (\mathcal{A}_h)_{ii} = -\frac{(d_i)^+ - (d_i)^-}{h} - \frac{\sigma^2}{h^2}, \tag{28.7}$$

where $d_i = d_\alpha(x_i)$, $(d)^+ = \max(d, 0)$, $(d)^- = \min(d, 0)$. Read eq. (28.7) term by term. The advective part discretizes $d_i\,\partial_x \phi$ as $(d_i)^+(\phi_{i+1} - \phi_i)/h + (d_i)^-(\phi_i - \phi_{i-1})/h$: where the drift points *right*, $(d_i)^+ > 0$ multiplies a *forward* difference, depositing $(d_i)^+/h$ on the right-neighbor coupling $(\mathcal{A}_h)_{i,i+1}$; where it points *left*, $(d_i)^- < 0$ multiplies a *backward* difference, depositing $-(d_i)^-/h \geq 0$ on the left-neighbor coupling $(\mathcal{A}_h)_{i,i-1}$. In either case the off-diagonal advective contribution is ≥ 0—this is precisely the upwind choice that the centered difference failed to make. Superposed on it is the *symmetric* diffusion piece $\frac{\sigma^2}{2}\partial_{xx}\phi \approx \frac{\sigma^2}{2}(\phi_{i+1} - 2\phi_i + \phi_{i-1})/h^2$, contributing the same $\sigma^2/2h^2 \geq 0$ to *both* neighbors and $-\sigma^2/h^2$ to the diagonal. The diagonal entry $-((d_i)^+ - (d_i)^-)/h - \sigma^2/h^2 = -\left|d_i\right|/h - \sigma^2/h^2$ is exactly the negative of the sum of the two off-diagonals, so each interior row sums to zero. Denote by $\mathcal{A}_h$ the resulting tridiagonal matrix. Its defining structural properties—nonnegative off-diagonals, zero row sums—are the engine of the whole chapter, and we now prove they make $\mathcal{A}_h$ a bona fide rate matrix.

Lemma 28.1 (The discrete generator is a rate matrix and $I - \Delta t\,\mathcal{A}_h$ is an M-matrix)**.** *For every $h > 0$ and every bounded drift d, the matrix $\mathcal{A}_h$ of eq. (28.7) has nonnegative off-diagonal entries, nonpositive diagonal entries, and zero interior row sums; that is, $\mathcal{A}_h$ is the generator (rate matrix) of a continuous-time Markov chain on the grid. Consequently, for every $\Delta t > 0$ the matrix $I - \Delta t\,\mathcal{A}_h$ is a nonsingular M-matrix: it has positive diagonal, nonpositive off-diagonals, and $(I - \Delta t\,\mathcal{A}_h)^{-1} \geq 0$ entrywise.*

Proof. The argument has three stages: $\mathcal{A}_h$ is a rate matrix; $B := I - \Delta t\,\mathcal{A}_h$ is strictly diagonally dominant, hence nonsingular; and $B^{-1} \geq 0$ entrywise.

Stage 1: $\mathcal{A}_h$ is a rate matrix. The off-diagonal entries of eq. (28.7) are the superdiagonal $(d_i)^+/h + \sigma^2/2h^2$ and the subdiagonal $-(d_i)^-/h + \sigma^2/2h^2$. Each is a sum of nonnegative terms—$(d_i)^+ \geq 0$ and $-(d_i)^- \geq 0$ by definition of the positive and negative parts, and $\sigma^2 \geq 0$—so both off-diagonals are ≥ 0. The diagonal was constructed as the negative of their sum, so it is ≤ 0 and each interior row sums to exactly zero. A matrix with nonnegative off-diagonals and zero row sums is, by definition, the infinitesimal generator (rate matrix) of a continuous-time Markov chain on the grid: off-diagonal entries are transition rates to neighbors and the diagonal is the total exit rate. This is the structural fact everything else leans on.

Stage 2: B is strictly diagonally dominant, hence nonsingular. Form $B = I - \Delta t\,\mathcal{A}_h$. Its diagonal is $B_{ii} = 1 - \Delta t(\mathcal{A}_h)_{ii} \geq 1 > 0$ (subtracting the nonpositive $(\mathcal{A}_h)_{ii}$ can only increase it), its off-diagonals are $B_{i,i\pm1} = -\Delta t(\mathcal{A}_h)_{i,i\pm1} \leq 0$, and—because the interior rows of $\mathcal{A}_h$ sum to zero—the interior rows of B sum to exactly 1. Hence for each interior row the diagonal strictly dominates the off-diagonal mass, $B_{ii} = 1 + \Delta t\,|(\mathcal{A}_h)_{ii}| = 1 + \sum_{j\neq i}|B_{ij}| > \sum_{j\neq i}|B_{ij}|$. Strict diagonal dominance forces nonsingularity (the Levy–Desplanques theorem): by Gershgorin every eigenvalue λ lies in some disc $|\lambda - B_{ii}| \leq \sum_{j\neq i}|B_{ij}| < B_{ii}$, and since each such disc is centered at $B_{ii} > 0$ with radius strictly smaller than B_{ii}, none of them contains the origin; so 0 is not an eigenvalue and B is invertible.

Stage 3: $B^{-1} \geq 0$ entrywise. This is the property that powers discrete positivity in lemma 28.2, so we prove it directly by a Neumann series rather than invoke a characterization of M-matrices. Set $s := \max_i B_{ii} > 0$ and split off the diagonal scale, $B = s\,(I - C)$ with $C := I - s^{-1}B$. We check $C \geq 0$ entrywise: its diagonal entry $1 - s^{-1}B_{ii} \geq 0$ because $B_{ii} \leq s$, and its off-diagonal entries $-s^{-1}B_{ij} \geq 0$ because the off-diagonals $B_{ij} \leq 0$ and $s > 0$. Next we bound the row sums of C. Using $\sum_j C_{ij} = 1 - s^{-1}\sum_j B_{ij}$ and the interior row sum $\sum_j B_{ij} = 1$, we get $\sum_j C_{ij} = 1 - s^{-1} < 1$, and since $C \geq 0$ this row sum equals the absolute row sum, so the induced ∞-norm satisfies $\|C\|_\infty = \max_i \sum_j C_{ij} < 1$. A matrix of ∞-norm strictly below one has a convergent Neumann series $\sum_{k\geq0} C^k = (I - C)^{-1}$ (the partial sums are Cauchy in the ∞-norm). Every power C^k is a product of nonnegative matrices and is therefore nonnegative, so the limit is a convergent sum of nonnegative matrices and is itself ≥ 0; hence $B^{-1} = s^{-1}(I - C)^{-1} = s^{-1}\sum_{k\geq0} C^k \geq 0$ entrywise. Thus B is a nonsingular M-matrix with nonnegative inverse. Equivalently—and this is the form we use repeatedly—the discrete maximum principle holds: $Bu \leq Bv$ entrywise implies $u = B^{-1}(Bu) \leq B^{-1}(Bv) = v$, the order being preserved because $B^{-1} \geq 0$. □

The discrete generator $\mathcal{A}_h$ depends on the policy α through the drift d_α, and the backward step must choose that policy optimally—this is where the nonlinearity of the HJB equation re-enters the otherwise linear stencil. We discretize the time derivative *fully implicitly* (backward Euler), which is what lemma 28.1 was tailored to and what makes the scheme unconditionally monotone, with no stability restriction tying Δt to h. With the source $f_i^n := F[m_{t_n}](x_i)$ frozen from the current population, and writing the running-cost contribution $\ell_i(\alpha) := L(x_i, \alpha)$, the implicit backward step from level $n+1$ to level n is the coupled pair

$$(I - \Delta t\,\mathcal{A}_h^{(\alpha)})\,u^n = u^{n+1} + \Delta t(\ell(\alpha) + f^n), \qquad \alpha_i^{(\text{new})} = \arg\min_\alpha \{\, b(x_i, \alpha)\,(\nabla_h u^n)_i + L(x_i, \alpha)\,\}, \tag{28.8}$$

in which the value and the optimal policy must agree. We solve it by *Howard's method* (policy iteration): alternate the two halves of eq. (28.8)—a linear solve with the policy held fixed, then a pointwise update of the policy with the value held fixed—until the policy stops changing. Lemma 28.1 guarantees each linear solve is well posed (the M-matrix is invertible) and monotone (its inverse is nonnegative). It remains to see that the alternation actually converges, and converges fast; both follow from the same M-matrix structure, and we record the argument in-book rather than quote it.

Monotone convergence. Run the iteration and let α, α' be two successive policies with u, u' the corresponding solves of the linear half of eq. (28.8). Evaluate the linear operator built from the *new* policy α' at the *old* value u, and form the residual

$$r := (I - \Delta t\,\mathcal{A}_h^{(\alpha')})\,u - (u^{n+1} + \Delta t(\ell(\alpha') + f^n)).$$

The policy update is the pointwise minimizer of the Bellman bracket at u; switching from α to α' can therefore only *lower* the right-hand side it is compared against, which is exactly the statement $r \le 0$ entrywise (at the old policy the residual would have been zero by definition of u). Now apply the inverse, which is entrywise nonnegative by lemma 28.1: since u' solves $(I - \Delta t\, \mathcal{A}_h^{(\alpha')})u' = u^{n+1} + \Delta t(\ell(\alpha') + f^n)$, subtracting gives $(I - \Delta t\, \mathcal{A}_h^{(\alpha')})(u - u') = r \le 0$, and multiplying by the nonnegative inverse yields $u - u' \le 0$, i.e. $u' \le u$ entrywise. Each sweep thus produces a value no larger than the last: the iterates form a monotone non-increasing sequence. They are bounded below (by the unique solution of the coupled system, itself a fixed point of the alternation), and a monotone bounded sequence converges; at the limit the policy update leaves the value unchanged, which is precisely the coupled condition eq. (28.8).

Superlinear convergence. Monotonicity alone would only promise convergence; in fact it is fast, and the reason is that Howard's method *is* the semismooth Newton iteration for the nonsmooth equation $\min_\alpha\{\cdots\} = 0$. The discrete Bellman map $u \mapsto \min_\alpha\{(I - \Delta t\, \mathcal{A}_h^{(\alpha)})u - \cdots\}$ is piecewise linear in u: the state space of values is partitioned into finitely many cells, one per policy, on each of which the minimizing α is constant and the map reduces to a single linear (M-matrix) system. Newton's method on such a piecewise-linear map takes each linear piece exactly. As the iterates approach the solution they enter and stay in the cell of the optimal policy—the *active policy stabilizes*—and once it has stabilized the next linear solve is the limiting linear system itself, solved in one step. Hence the iteration terminates after finitely many policy changes, with the local superlinear (here, finite) convergence characteristic of semismooth Newton, rather than the merely geometric rate a contraction would give.

For the LQG thread the policy update is explicit, which is why the inner loop is essentially free. Minimizing the bracket $b(x_i, \alpha)(\nabla_h u^n)_i + \frac{1}{2}\alpha^2 = (ax_i + b\alpha)(\nabla_h u^n)_i + \frac{1}{2}\alpha^2$ over α sets its derivative $b(\nabla_h u^n)_i + \alpha$ to zero, giving

$$\alpha_i = -b\,(\nabla_h u^n)_i, \tag{28.9}$$

the discrete analogue of the continuous feedback eq. (28.5) with p replaced by the upwind gradient $(\nabla_h u^n)_i$. Because this closed form makes each policy update a single pointwise formula, two or three Howard sweeps drive the residual to machine precision in practice.

Boundary truncation. One loose end remains before the backward generator can be handed to the forward scheme: we discretized on a bounded interval $[x_{\min}, x_{\max}]$, whereas the equations eq. (28.1) live on all of $\mathbb{R}^d$, and we owe an account of what is lost at the artificial boundary and how the boundary rows are closed. The justification that the truncation is legitimate is the parabolic regularization of (A-Nondeg). Uniform nondegeneracy means $\sigma^2 \ge \sigma^2_{\min} > 0$, so the Fokker–Planck flow is genuinely diffusive with a confining drift; its solution inherits *Gaussian tails*, in the sense that the mass it places more than k standard deviations from its mean decays like $e^{-k^2/2}$. Concretely, if $[x_{\min}, x_{\max}]$ is taken several standard deviations beyond the support of the initial datum m_0, the fraction of mass that ever reaches the boundary is of this exponentially small order $e^{-k^2/2}$ in the number k of standard deviations of clearance. Everything dynamically relevant happens in the interior where the mass lives; the value's far-field growth (quadratic in the LQG case, where $u \sim \frac{1}{2}Px^2$) multiplies a density that has already vanished to exponential precision, so it cannot influence the equilibrium. This is the precise sense in which (A-Nondeg) "confines essentially all mass to a bounded region" and makes the cut-off problem of theorem 28.3 a faithful proxy for the whole-space one.

It remains to close the boundary rows. On the value we impose a homogeneous Neumann condition $u_0^n = u_1^n$, $u_N^n = u_{N-1}^n$, a zero-gradient reflection consistent with the flat far field. On the density two closures are available, and—a point that matters for the conservation statement of the next subsection—we deliberately use *different* ones in the analysis and in the implementation. The *reflecting* (zero-flux) closure sets the boundary fluxes to zero, equivalently completes $\mathcal{A}_h$ so that the boundary rows, like the interior rows, sum to zero; with every row of $\mathcal{A}_h$ summing to zero the total mass is then conserved *exactly* at the discrete level (lemma 28.2(1)). That exactness is why the analysis adopts the reflecting closure: it lets the conservation lemma be stated as a clean identity rather than an estimate. The implementation, by contrast, uses the simpler *absorbing* closure $m_0^n = m_N^n = 0$ followed by a renormalization of the total mass after each forward step. The absorbing closure is trivial to code and keeps the matrix structure untouched, at the cost of discarding the boundary tail flux; but by the Gaussian-tail estimate just made that discarded flux is exponentially small in the clearance k, so the renormalization correction it must repair is of that same negligible size and restores the unit mass to machine precision. The two closures therefore agree to exponential accuracy: the reflecting scheme conserves mass identically, the absorbing-plus-renormalization scheme conserves it up to the exponentially small tail correction, and either keeps every linear system tridiagonal.

We have what the next subsection needs. The backward sweep produces, at each time level, the optimal feedback α^* and hence the optimal drift $d^* = b(\cdot, \alpha^*)$, from which we assemble the discrete generator $\mathcal{A}_h^{(\alpha^*)}$ of eq. (28.7)—an honest rate matrix, with $I - \Delta t\, \mathcal{A}_h^{(\alpha^*)}$ a nonsingular M-matrix carrying the inverse-nonnegativity and discrete maximum principle of lemma 28.1, and equipped with a boundary closure (reflecting for the analysis, absorbing-plus-renormalize in code). The Fokker–Planck scheme will not build a new operator at all: by the Achdou–Capuzzo-Dolcetta design principle it simply *transposes* $\mathcal{A}_h^{(\alpha^*)}$ and lets the rate-matrix structure we have just established deliver mass conservation and positivity for free. To that transposition we now turn.

28.2.2 A conservative, adjoint Fokker–Planck scheme

The backward sweep handed us its principal product: the discrete generator $\mathcal{A}_h^{(\alpha^*)}$ assembled from the optimal drift $d^* = b(\cdot, \alpha^*)$, an honest rate matrix carrying the M-matrix machinery of lemma 28.1. The forward half of the system now asks us to transport the population along that very drift. It is tempting to repeat the previous subsection's labor—write an upwind stencil for the Fokker–Planck operator from scratch, fight separately for each property we need—but the Achdou–Capuzzo-Dolcetta insight is that no second construction is necessary. We have already built exactly the right matrix; the forward operator is its transpose, and the work is to recognize that the transpose is correct, not to assemble it anew.

What does "correct" demand here? The two equations discretize objects of different kind, and that difference dictates different fidelity. The backward HJB equation propagates a *value*, a function to be compared, and what its scheme had to protect was the order relation—monotonicity, the discrete comparison principle. The forward Fokker–Planck equation eq. (28.1b) propagates a *density*:

it transports and diffuses a probability measure, and a probability measure is a nonnegative object of unit total mass. Two properties are therefore non-negotiable for any honest forward scheme. *Positivity*: a density that starts nonnegative must stay nonnegative, because a negative "probability" is meaningless and, worse, would feed a meaningless coupling $F[m]$ back into the HJB equation and corrupt the entire fixed point. *Mass conservation*: the continuity equation eq. (28.1b) has no source or sink—it merely redistributes probability—so $\int m \, dx$ must remain equal to one for all time, and a scheme that leaks or manufactures mass is solving a different equation. These are exactly the structures the discrete scheme must reproduce at the grid level, not merely recover in the refinement limit.

The decisive design principle of Achdou–Capuzzo-Dolcetta is to secure both, together with the adjointness that ties the two equations into a faithful discrete forward–backward system, by a single algebraic stroke: take the discrete forward operator to be the *exact transpose of the discrete backward generator built from the same optimal drift.* Concretely, having computed the optimal feedback α^* (hence d^*) from the HJB step, form $\mathcal{A}_h^{(\alpha^*)}$ as in eq. (28.7)—the rate matrix is the same object that drove the value backward—and step the density implicitly by

$$\left(I - \Delta t \, (\mathcal{A}_h^{(\alpha^*)})^\top\right) m^{n+1} = m^n. \tag{28.10}$$

The implicit (backward-Euler) time stepping mirrors the HJB step and shares its unconditional stability; the genuinely new content is the single transpose $(\cdot)^\top$.

Why should one transpose simultaneously buy all three of positivity, mass conservation, and adjointness? Because each property is a statement about a different structural feature of the rate matrix, and transposition preserves all three at once. Mass conservation is a statement about the *row sums* of $\mathcal{A}_h$: that they vanish, which transposes into a left-eigenvector identity for the all-ones vector and pins the total mass. Positivity is a statement about the *M-matrix* structure of $I - \Delta t \, \mathcal{A}_h$: that its inverse is entrywise nonnegative, a property the transpose inherits verbatim because a matrix and its transpose share their inverse's sign pattern. Adjointness is the very *definition* of the transpose, and it is what makes the discrete pair an honest dual system rather than two unrelated discretizations that happen to share a drift. No one of these would follow from merely "discretizing the Fokker–Planck operator accurately"; all three follow at once the moment we insist the forward operator be the literal transpose of the backward one. This single choice secures the three properties together, which we now prove.

Lemma 28.2 (Discrete conservation, positivity, and adjointness)**.** *Let $\mathcal{A}_h$ be a discrete generator as in lemma 28.1 with zero interior row sums, and consider the forward step eq.* (28.10) *with reflecting (zero-flux) boundary closure. Then:*

1. (Mass conservation.) *Total mass is exactly preserved, $\sum_i m_i^{n+1} = \sum_i m_i^n$.*
2. (Positivity.) *If $m^n \geq 0$ then $m^{n+1} \geq 0$.*
3. (Adjointness.) *The forward step eq.* (28.10) *is the exact transpose of the linearized backward step eq.* (28.8)*; equivalently, the discrete HJB and FP operators are in duality, $\langle (I - \Delta t \, \mathcal{A}_h) u, \, m \rangle = \langle u, (I - \Delta t \, \mathcal{A}_h^\top) m \rangle$.*

Proof. We take the three properties in turn; each is a one-line consequence of a different structural feature of $\mathcal{A}_h$, and the proof is really an exercise in reading off which feature powers which property.

(1) *Mass conservation is the row-sum identity, transposed.* Let $\mathbf{1}$ denote the all-ones vector. The interior rows of $\mathcal{A}_h$ sum to zero by construction (eq. (28.7): the diagonal is minus the sum of the two off-diagonals), and the reflecting (zero-flux) closure was chosen precisely so that the boundary rows are *also* completed to sum to zero—a reflecting boundary deposits no probability current through the wall, so the exit rate it removes from a boundary node is returned to the interior rather than lost. Hence *every* row of $\mathcal{A}_h$ sums to zero, which is the full-vector identity

$$\mathcal{A}_h\mathbf{1} = 0,$$

valid on all rows and not merely the interior ones—this is exactly where the analysis's choice of the reflecting closure earns its keep, since the absorbing closure would leave boundary rows with a nonzero deficit. Transposing this identity moves it from the rows of $\mathcal{A}_h$ to the columns of $\mathcal{A}_h^\top$: $\mathcal{A}_h\mathbf{1} = 0$ reads, entry by entry, as "each row sums to zero," which is the same set of scalar equations as $\mathbf{1}^\top\mathcal{A}_h^\top = 0$, "each column of $\mathcal{A}_h^\top$ sums to zero." Therefore $\mathbf{1}^\top\mathcal{A}_h^\top = 0$, and consequently

$$\mathbf{1}^\top(I - \Delta t\,\mathcal{A}_h^\top) = \mathbf{1}^\top - \Delta t\,\mathbf{1}^\top\mathcal{A}_h^\top = \mathbf{1}^\top :$$

the all-ones vector is a left null vector of $\mathcal{A}_h^\top$ and hence a left eigenvector of the forward step matrix with eigenvalue 1. Total mass is the pairing $\mathbf{1}^\top m = \sum_i m_i$, so applying $\mathbf{1}^\top$ on the left of the forward step eq. (28.10) gives

$$\mathbf{1}^\top m^n = \mathbf{1}^\top(I - \Delta t\,\mathcal{A}_h^\top)m^{n+1} = \mathbf{1}^\top m^{n+1},$$

that is, $\sum_i m_i^{n+1} = \sum_i m_i^n$. Mass is preserved *exactly*, at every step, for every Δt and h—not to truncation order but identically. It is worth pausing on the mechanism: the property of the *value* scheme that we never used downstream, namely that the generator's rows sum to zero (a probabilistic conservation: total transition rate out balances rate in), is precisely the property that, transposed, conserves the *mass* of the density. The two equations share one matrix, and one of its features serves each.

(2) *Positivity is the M-matrix property, transposed.* By lemma 28.1 the matrix $I - \Delta t\,\mathcal{A}_h$ is a nonsingular M-matrix, with entrywise nonnegative inverse $(I - \Delta t\,\mathcal{A}_h)^{-1} \geq 0$. A matrix and its transpose have the same determinant and the same minors, so $\mathcal{A}_h^\top$ has the identical sign pattern (nonnegative off-diagonals, zero row sums) and $I - \Delta t\,\mathcal{A}_h^\top$ is again a nonsingular M-matrix; indeed its inverse is literally the transpose of the inverse, $(I - \Delta t\,\mathcal{A}_h^\top)^{-1} = \big((I - \Delta t\,\mathcal{A}_h)^{-1}\big)^\top$, and transposing a nonnegative matrix leaves it nonnegative. Therefore the forward step

$$m^{n+1} = \big(I - \Delta t\,\mathcal{A}_h^\top\big)^{-1}m^n$$

maps a nonnegative vector to a nonnegative vector: if $m^n \geq 0$ entrywise then $m^{n+1} \geq 0$ entrywise, because a nonnegative matrix applied to a nonnegative vector cannot produce a negative entry. Positivity of the density is thus inherited, with no separate argument, from the discrete maximum principle of the backward scheme. The same implicit step that made the value scheme monotone makes the density scheme positivity-preserving; these are one structural fact seen from two sides.

(3) *Adjointness is the definition of the transpose—but it says something.* That the forward step eq. (28.10) is the exact transpose of the linearized backward step eq. (28.8) is, at the level of matrices,

a tautology: we *defined* the forward operator to be $(\mathcal{A}_h^{(\alpha^*)})^\top$. What the tautology encodes, and what makes it worth stating as a property rather than a convention, is the discrete duality pairing. Writing $\langle u, m\rangle = \sum_i u_i m_i$ for the Euclidean pairing of a value vector against a density vector, the defining identity of the transpose reads

$$\langle (I - \Delta t\, \mathcal{A}_h)\, u,\ m\rangle = \langle u,\ (I - \Delta t\, \mathcal{A}_h^\top)\, m\rangle \qquad \text{for all } u, m.$$

This is the discrete avatar of the integration-by-parts identity $\int (\mathcal{A}\phi)\, m = \int \phi\, (\mathcal{A}^* m)$ that defines the continuous Fokker–Planck operator $\mathcal{A}^*$ as the formal adjoint of the generator $\mathcal{A}$ (chapter 8). The continuous forward–backward duality—value paired against density, generator against its adjoint—is reproduced *verbatim* at the grid level, with no error term. That is the precise sense in which the discrete system is a faithful, and not merely accurate, copy of the continuous one: the same vector that the backward operator pushes against the density is the vector the density pushes back against, exactly. We will draw on this pairing immediately below, and again when it makes the Newton system of section 28.3.2 self-adjoint. □

Lemma 28.2(3) is more than bookkeeping, and it pays to say now what it will buy two sections hence, because it is the single thread that ties this finite-difference block to the variational methods of section 28.4. Recall the structural fact of chapter 8: for a *potential* (variational) game the continuous forward–backward system eq. (28.1) is not an arbitrary coupled PDE but the Euler–Lagrange/optimality system of a single convex minimization, the energy functional of eq. (8.18) minimized over density flows (theorem 8.11). In such a system the value u and the density m are not independent unknowns: u is the Lagrange multiplier (the adjoint state) enforcing the continuity constraint on m, and the HJB equation is exactly the stationarity condition that the multiplier must satisfy. Adjointness is the algebraic signature of precisely this relationship—multiplier paired against constraint, generator against its formal adjoint. The discrete pairing $\langle (I - \Delta t\, \mathcal{A}_h)u, m\rangle = \langle u, (I - \Delta t\, \mathcal{A}_h^\top)m\rangle$ is what guarantees that the *discretized* HJB and Fokker–Planck equations stand in that same multiplier/constraint relation, so that the discrete coupled system eq. (28.8)–eq. (28.10) is itself the optimality system of a discrete *convex* program—a faithful discrete avatar of theorem 8.11. A discretization that got the forward operator merely "accurate" but not exactly transposed would break this: its discrete equations would be the optimality system of nothing, the energy would fail to decrease monotonically, and the convex-optimization algorithms of section 28.4 would lose the very structure they exploit. The structure-preservation of the scheme is therefore not a fortunate accident but the discrete shadow of the continuous variational geometry, and we plant that observation here for section 28.4 to harvest. With positivity, conservation, and adjointness in hand for the building block, we can state what the assembled scheme converges to.

Theorem 28.3 (Convergence of the finite-difference MFG scheme)**.** *Assume (A-Lip), (A-Growth), (A-Nondeg), (A-Conv), and that F, G are continuous and bounded on $\mathcal{P}_2(\mathbb{R}^d)$ for the cut-off problem. Let (u_i^n, m_i^n) solve the coupled discrete system eq.* (28.8)*–eq.* (28.10) *(with the outer loop of section 28.3 driven to convergence). Then, as $(h, \Delta t) \to 0$, the discrete value converges locally uniformly to the viscosity solution of the HJB equation eq.* (28.1a) *and the discrete density converges weakly-$*$ to the distributional solution of the Fokker–Planck equation eq.* (28.1b)*; the pair (u_i^n, m_i^n) converges to a solution of the MFG system eq.* (28.1)*. The scheme is first-order accurate in h and Δt.*

Proof sketch. The argument has two distinct movements that the reader should keep separate. First, with the population *frozen*, each one-directional scheme converges on its own—the backward scheme to a viscosity solution, the forward scheme to a measure solution. Second, the *coupled* limit is taken: one shows the two limits are compatible, i.e. that the frozen-population limits assemble into a genuine solution of the MFG system. We treat them in order, and we are careful throughout to mark which input is proved in-book and which is cited only for sharp-constant accounting.

Step 1: the frozen-population HJB limit (viscosity convergence). Hold the population, hence the source $f_i^n = F[m_{t_n}](x_i)$ and terminal data $G[m_{t_N}]$, fixed. We must verify the three hypotheses of the Barles–Souganidis criterion for the backward scheme eq. (28.8). *Monotonicity* is lemma 28.1: the M-matrix structure is exactly the discrete comparison principle, so raising the input value field can only raise the output. *Stability* is the L^∞ bound that the same M-matrix structure furnishes: applying $\mathbf{1}^\top$-type estimates to $(I - \Delta t\, \mathcal{A}_h^{(\alpha)})u^n = u^{n+1} + \Delta t(\ell(\alpha) + f^n)$, and using that the M-matrix inverse has ∞-norm at most 1 (its rows sum to 1 and it is nonnegative), gives $\|u^n\|_\infty \le \|u^{n+1}\|_\infty + \Delta t\, C$ with C controlled by the bounded running cost; iterating over the $N_T = T/\Delta t$ steps yields a bound uniform in $(h, \Delta t)$. *Consistency* is a Taylor expansion of the upwind stencil eq. (28.7): replacing a centered by an upwind difference adds an artificial-diffusion term of size $O(h)$ to the truncation error, $\frac{1}{2}h\ |d_i|\ \partial_{xx}\phi + O(h^2)$, which vanishes as $h \to 0$. The decisive point is that consistency comes with *no* stability restriction tying Δt to h: because the step is fully implicit it is unconditionally monotone (lemma 28.1 holds for every $\Delta t > 0$), so one may send $h \to 0$ and $\Delta t \to 0$ independently—no parabolic ratio condition $\Delta t/h^2$ or $\Delta t/h \to 0$ is needed, in sharp contrast to an explicit scheme. With monotonicity, stability, and consistency established, the Barles–Souganidis monotone-scheme theorem—proved in-book as theorem E.20 (originally [13])—gives local-uniform convergence of u_h to the unique viscosity solution of eq. (28.1a).

Step 2: the frozen-feedback FP limit (weak-$*$ convergence). Now hold the value/feedback fixed and run the forward scheme eq. (28.10). By lemma 28.2 it conserves mass and preserves positivity exactly, so each m^n is a genuine probability vector; reading it as a sum of point masses $\sum_i m_i^n\, \delta_{x_i}$ gives a discrete probability measure. A consistent, monotone, mass-conserving discretization of a linear Fokker–Planck equation converges weakly-$*$ (tested against continuous bounded functions) to the distributional/measure solution of eq. (28.1b); the positivity and conservation are what keep the discrete measures *probability* measures along the way, so the limit is again a probability measure and not a signed object.

Step 3: closing the coupling. The outer loop of section 28.3 drives the frozen guess to self-consistency, so along its converged iterates the source feeding Step 1 is the density produced by Step 2 and vice versa. What remains is to show that the joint limit (u_h, m_h) is a solution of the coupled system eq. (28.1), and this is the genuinely coupled part of the argument. It rests on three in-book inputs, which we separate because they do distinct work and rely on distinct machinery.

(i) Compactness on the density side (tightness and Prokhorov). The discrete densities all carry unit mass, but unit mass alone does not prevent probability from escaping to infinity in the limit; we need *tightness*, a uniform control on how much mass can sit far out. This is supplied by the confining drift guaranteed by (A-Nondeg): the uniform nondegeneracy gives genuine diffusion with a restoring drift, so a uniform second-moment bound holds along the flow and, by Chebyshev, the mass beyond radius R is uniformly small as $R \to \infty$. The family $\{m_h\}$ is then tight, and Prokhorov's

theorem—proved in-book as theorem 3.16—extracts a subsequence converging weakly-$*$, $m_h \xrightarrow{*} m$, to a probability measure m. This input is *in-book*.

(ii) Compactness on the value side (parabolic estimates plus Arzelà–Ascoli). To pass to the limit in the drift we need not just $u_h \to u$ but $\nabla u_h \to \nabla u$, and locally uniformly, because the drift depends on the gradient. Pointwise or weak convergence of u_h would not suffice—it would not control ∇u_h. The needed compactness comes from parabolic regularity: (A-Nondeg) makes the backward equation uniformly parabolic, so the uniform first-derivative (Bernstein) gradient bound theorem E.17 and the interior Schauder estimate theorem E.19 together give a uniform $C^{1,2}_{\mathrm{loc}}$ bound on the discrete (or interpolated) values, independent of $(h, \Delta t)$. A uniform $C^{1,2}_{\mathrm{loc}}$ family is precompact: by Banach–Alaoglu in the relevant dual space and Arzelà–Ascoli for the equicontinuous derivatives—both packaged in-book as theorem 2.16—a further subsequence has $u_h \to u$ with $\nabla u_h \to \nabla u$ locally uniformly. These regularity estimates are *in-book* (appendix E); it is here, and only here, that the parabolic theory is doing the heavy lifting, which is why the chapter insists on proving that package rather than quoting it.

(iii) Passing to the limit in the nonlinear drift (where adjointness earns its place). The two compactness inputs now combine. The Fokker–Planck coupling is nonlinear in the value through the drift $\partial_p H(x, \nabla u_h)$; the locally uniform convergence $\nabla u_h \to \nabla u$ from input (ii), together with the continuity of $\partial_p H$ from (A-Conv), lets one pass to the limit inside this nonlinearity, so the limiting drift is $\partial_p H(x, \nabla u)$ tested against the limiting measure m from input (i). The reason the limit is a *solution*—rather than an object satisfying the equation only up to an unaccounted boundary or duality error—is that at every grid level the discrete weak formulation is an exact duality pairing, $\langle (I - \Delta t\, \mathcal{A}_h) u_h, m_h \rangle = \langle u_h, (I - \Delta t\, \mathcal{A}_h^\top) m_h \rangle$, by lemma 28.2(3). This discrete integration-by-parts has no remainder, so sending $h \to 0$ in it reproduces *exactly* the continuous duality $\int (\mathcal{A}\phi)\, m = \int \phi \, \mathrm{d}(\mathcal{A}^* m)$ that defines a weak solution of the coupled system. The adjoint structure is thus not decoration but the mechanism that makes the limit a bona fide solution rather than an approximate one.

Assembling the three movements: Steps 1–2 give convergence of each one-directional scheme, and Step 3, on inputs (i)–(iii), shows the joint limit solves eq. (28.1). Uniqueness of that limit under (A-Mon) is the Lasry–Lions monotonicity argument imported in remark 28.4. The whole limit passage is therefore complete from in-book parabolic estimates (appendix E) and compactness theorems (chapters 2 and 3); what we do not reproduce, and follow Achdou–Capuzzo-Dolcetta and Achdou–Porretta [1, 3, 2] for, is the sharp first-order accounting of the $O(h) + O(\Delta t)$ rate—the optimal constants, not the convergence itself. □

Remark 28.4 (What is genuinely proved versus quoted)**.** It is worth drawing the rigor boundary explicitly, because this scheme is where the chapter's stated doctrine—prove the structure, pin the limit to in-book estimates, quote only sharp constants—is put into practice, and the reader should be able to see exactly which sentence above carries which kind of warrant. The accounting has three tiers, in decreasing order of self-containedness.

Genuinely proved, in full and from scratch: the two structural lemmas that make the scheme *correct as a structure*—monotonicity of the backward step (lemma 28.1, via the M-matrix/Neumann-series argument given there in complete detail) and conservation, positivity, and adjointness of the forward step (lemma 28.2, each a one-line consequence of a feature of the rate matrix). These are the facts on which every good property of the scheme rests, and they are proved here with nothing left to the reader.

Assembled in-book from proved ingredients: the convergence of the *coupled* system (theorem 28.3). We do not re-prove the heavy theorems it uses, but every one of them is proved elsewhere *in this book* and imported by label—the monotone-scheme convergence theorem (theorem E.20), the uniform parabolic gradient and interior Schauder estimates (appendix E, theorems E.17 and E.19), and the compactness theorems of chapters 2 and 3 (Banach–Alaoglu/Arzelà–Ascoli theorem 2.16, Prokhorov theorem 3.16). Uniqueness of the limit under (A-Mon) follows from the comparison and monotonicity machinery of chapter 24. The proof sketch above is honest in the technical sense of the style bible: it is a complete argument modulo results the reader can turn to and find proved, not an appeal to authority.

Quoted to a specific source: only the optimal-constant accounting of the convergence rate—the sharp first-order estimate with its best constants—for which we follow Achdou–Porretta [3] (and the original scheme of Achdou–Capuzzo-Dolcetta [1]). This is genuinely a piece of the literature, an analytic refinement of the rate rather than the existence of convergence, and quoting it is appropriate; it is the one place a citation stands in for an argument we do not give. Expansion clarifies this boundary; it does not move it—nothing that was a quote has been silently upgraded to a claimed in-book proof, and the load-bearing convergence statement remains assembled from in-book parabolic estimates, with the citation confined to the constant. This is the line the rigor doctrine draws, and the rest of the chapter respects it.

Algorithmic template (one HJB–FP sweep). We can now read off exactly what it costs to evaluate the best-response operator S of eq. (28.2) once. The two scheme components assemble, in the order the forward–backward structure dictates, into a single such evaluation: feed in a population flow, sweep the HJB equation backward to extract the optimal feedback, then sweep the Fokker–Planck equation forward along that feedback to produce the population the agents actually generate. Concretely:

1. **Input**: a population flow $(m^n)_{n=0}^{N_T}$—the frozen guess $\bar{m}$ of section 28.1.

2. **Backward sweep** ($n = N_T - 1, \dots, 0$): set the terminal value $u^{N_T} = G[m^{N_T}]$ from the frozen final density; at each n, solve the implicit HJB step eq. (28.8) by Howard iteration, storing the optimal feedback $\alpha^{*,n}$ and value u^n. This is the only nonlinear part, and the superlinear convergence of Howard's method (and, for the LQG thread, the closed-form policy update eq. (28.9)) keeps it cheap.

3. **Forward sweep** ($n = 0, \dots, N_T - 1$): set the initial density $m^0 = m_0$; at each n, form the rate matrix $\mathcal{A}_h^{(\alpha^{*,n+1})}$ from the feedback just stored and solve the transposed forward step eq. (28.10); renormalize to repair the exponentially small absorbing tail of section 28.2.1. Conservation and positivity (lemma 28.2) guarantee the output is a genuine probability flow.

4. **Output**: the new flow (m^n) and the value field (u^n).

The cost is worth stating precisely, since it is what the outer loop will multiply. Each of the two sweeps visits the N_T time levels once, and at each level solves a tridiagonal linear system in the N_x state unknowns. A tridiagonal solve is $O(N_x)$ by the Thomas algorithm—the M-matrix structure of lemma 28.1 guarantees the elimination is stable with no pivoting—so each sweep costs $O(N_T \cdot N_x)$ arithmetic, and the two sweeps together cost $O(N_T N_x)$, multiplied only by the small, grid-independent number of Howard iterations the backward sweep needs (two or three in practice for the LQG thread). One evaluation of S is thus *linear* in the total number of space–time grid points $N_T N_x$—as cheap as a single pair of one-directional parabolic solves can be, which is the whole payoff of installing the structure rather than fighting an ill-conditioned dense system.

This is one evaluation of S, and one evaluation is not yet a solution: it produces the crowd that best-responds to a *guess*, not the self-consistent crowd that reproduces itself. The forward–backward obstruction of section 28.1 has been converted, but not dissolved—we have a cheap, structure-preserving, $O(N_T N_x)$ machine for evaluating S exactly once, and finding the equilibrium means finding a *fixed point* of that machine. Wrapping this single sweep in an outer iteration—and deciding, per the Strategy I/Strategy II split of section 28.1, whether to iterate the best response or to solve the whole system at once by Newton—is the business of section 28.3, to which we now turn.

28.3 The outer loop: fixed-point iteration and Newton

The machine of section 28.2 does exactly one thing: it evaluates the best-response operator S once, taking a frozen population flow in and returning the crowd that best-responds to it, at the linear cost $O(N_T N_x)$ we just tallied. That is a tool, not yet an answer. The equilibrium is not any one best response; it is the flow that reproduces *itself* under best response—the fixed point $\bar{m} = \mathsf{S}(\bar{m})$ of eq. (28.2)—and a single sweep no more locates that fixed point than one evaluation of a function locates its root. This section is where the single sweep becomes a solver: we wrap it in an outer loop that drives the residual $\bar{m} - \mathsf{S}(\bar{m})$ to zero. The forward–backward obstruction of section 28.1 has by now been converted into a concrete, structure-preserving evaluation; the business that remains is to dissolve it, by finding the self-consistent flow.

There are exactly two ways to do so, and they are precisely the Strategy I/Strategy II dichotomy that section 28.1 forced out of the structure of the problem—now to be realized as running code. The two parts of this section treat them in turn, and the reader should weigh the choice between them as a genuine trade-off, because neither dominates the other across all regimes.

Strategy I—decouple and iterate—takes the cheapness of the sweep at face value. If one evaluation of S costs only $O(N_T N_x)$, then the most direct thing to do is to evaluate it again and again, feeding each output back as the next input, $m^{(k+1)} = \mathsf{S}(m^{(k)})$, and hope the sequence of flows settles onto a fixed point. This is the discrete face of the existence-by-iteration arguments of chapters 8 and 10, and its appeal is exactly its low per-step cost and minimal bookkeeping: one holds a single flow in memory and advances it by one cheap sweep at a time. The catch is that the iteration converges only when S *contracts*—when best-responding to two nearby flows yields two flows that are nearer still—and that is a genuine hypothesis, not a free lunch. It holds when the coupling is weak or monotone or the horizon short, and it *fails* near the multiplicities and conjugate horizons where the population's anticipation of itself is strong enough to overshoot: there the plain iteration oscillates between competing flows or diverges outright, exactly the regime in which the equilibrium is most interesting. Even when contraction holds it can be marginal, and the raw iteration crawls; the standard repair is to *damp* the update—to step only part of the way from the old flow toward its best response—which both widens the basin of convergence and is the numerical form of fictitious play. Section 28.3.1 develops this damped Picard iteration and makes the contraction condition quantitative.

Strategy II—solve the whole system at once—is the answer to what Strategy I cannot reach. When the best-response map refuses to contract, no amount of damping a fixed-point iteration will manufacture a contraction that physically is not there; one must stop iterating a map and instead solve, in a single stroke, the coupled algebraic system $\mathcal{R}(U, M) = 0$ of eq. (28.3) for the entire space–time field at once. The tool for that is Newton's method, whose local convergence is quadratic and—crucially—does not require S to contract; it requires only that the residual's Jacobian be nonsingular at the solution, a far weaker and generically satisfied condition. What this robustness costs is what Strategy II always costs: memory and per-step work. The unknown is now the whole stacked field (U, M) rather than one marched flow, and each Newton step solves one large linear system coupling all of it—a system whose tractability, we will see, rests on the very adjoint M-matrix structure installed in section 28.2. The reward is reach: Newton converges in the near-critical regimes where Picard breaks down, at the price of a larger, globally coupled solve. Section 28.3.2 assembles this all-at-once Newton iteration on the stacked residual.

The trade-off the reader is about to weigh is therefore contraction against globalization: a cheap, low-memory iteration that converges only inside the contraction regime, versus an expensive but robust solve that reaches the near-critical regime where the first one fails. In practice the two are complementary—a few damped Picard sweeps from a crude initial guess, handed to Newton for the final high-accuracy convergence, marries the global reach of the former to the local speed of the latter—and the worked computation of section 28.6 will exercise exactly this combination. We begin, as the cheapness of the sweep invites, with the fixed-point iteration.

28.3.1 Damped fixed-point (Picard) iteration

The outer-loop overview has left us with a single cheap instrument and an invitation to use it repeatedly. One evaluation of the best-response map S—built in section 28.2 from one backward HJB sweep and one forward Fokker–Planck sweep, each an $O(N_T N_x)$ pass over the grid—takes a frozen population flow and returns the flow that results when every agent best-responds to it. Strategy I takes that cheapness at face value: rather than do anything clever, simply feed the output back as the next input and watch the sequence of flows,

$$m^{(k+1)} = \mathsf{S}(m^{(k)}), \qquad k = 0, 1, 2, \ldots,$$

the plain *Banach iteration* of S. This is exactly the discrete realization of the existence-by-iteration arguments of chapters 8 and 10: an equilibrium is a fixed point $\bar{m} = \mathsf{S}(\bar{m})$, and one hunts for it by iterating the map. The whole question is *when the sequence settles*. Banach's fixed-point theorem answers it in one word—when S is a *contraction*, that is, when best-responding to two nearby flows yields two flows that are strictly nearer still—and then it answers it completely: the iterates converge geometrically, from any starting flow, to the unique fixed point. So the entire viability of Strategy I turns on whether S contracts on $C([0,T];\mathcal{P}_2(\mathbb{R}^d))$, and on how to repair the iteration when it does not. Those are the two questions of this subsection. The general theory of chapters 10 and 11 supplies a clean sufficient condition for the first.

Proposition 28.5 (Contraction of the best-response map)**.** *Under (A-Lip), (A-Nondeg), (A-Conv), suppose the couplings F, G are Lipschitz in $\mathcal{W}_2$ with constants L_F, L_G, and either the horizon T or the product $L_F + L_G$ of coupling strengths is small enough that the composite Lipschitz constant of S on $C([0,T];\mathcal{P}_2(\mathbb{R}^d))$ is $L_{\mathsf{S}} < 1$. Then S has a unique fixed point, and the Picard iterates converge geometrically, $\mathcal{W}_2$-distance contracting by L_{S} per step.*

Proof sketch. The estimate is bookkeeping on the two-stage anatomy of S already exhibited in section 28.1: $\mathsf{S} = \mathcal{S}_{\mathrm{FP}} \circ \mathcal{S}_{\mathrm{HJB}}$, where $\mathcal{S}_{\mathrm{HJB}}$ sends a frozen flow to the optimal feedback it induces (one backward solve) and $\mathcal{S}_{\mathrm{FP}}$ sends that feedback to the population it transports (one forward solve). A contraction constant for the composite is the product of contraction constants for the two stages, and the content of the proposition is that each stage carries a factor one can make small. We take them in turn.

Stage one: the value map $\mathcal{S}_{\mathrm{HJB}}$ is Lipschitz with constant $\propto (L_F + L_G)$. Take two frozen flows $\bar{m}, \bar{m}'$ with $\sup_t \mathcal{W}_2(\bar{m}_t, \bar{m}'_t) \le \delta$. They enter the HJB equation eq. (28.1a) only through its data: the running source $F[\bar{m}_t]$ and the terminal payoff $G[\bar{m}_T]$. Lipschitz couplings convert the flow discrepancy directly into a data discrepancy—$\|F[\bar{m}_t] - F[\bar{m}'_t]\|_\infty \le L_F\,\delta$ and $\|G[\bar{m}_T] - G[\bar{m}'_T]\|_\infty \le L_G\,\delta$ pointwise in time. What the feedback needs, however, is not the value but its gradient, since $\alpha^* = -\partial_p H(x, \nabla u)$ and (by (A-Conv), $\partial_p H$ Lipschitz) the feedback depends Lipschitz-continuously on ∇u. The crucial input is therefore a stability estimate for ∇u in terms of the data, and this is exactly what (A-Nondeg) buys: the uniform parabolic regularization makes the backward equation smoothing, and the Bernstein-type gradient bound theorem E.17 controls $\|\nabla u\|$—and, applied to the difference of two solutions, controls $\|\nabla u - \nabla u'\|$—by the accumulated data difference. Integrating the source discrepancy backward from T down to t contributes a factor that grows with the length of that backward horizon; schematically $\|\nabla u - \nabla u'\| \lesssim C_{\mathrm{HJB}}(T)\,(L_F + L_G)\,\delta$, with $C_{\mathrm{HJB}}(T) \to 0$ as $T \to 0$ because there is then no horizon over which the data error can accumulate. This is the first small factor.

Stage two: the flow map $\mathcal{S}_{\mathrm{FP}}$ is Lipschitz, with a constant carrying its own factor of T. Now feed two nearby feedbacks—equivalently two nearby drifts $d^*, d^{*\prime}$ with $\sup \|d^* - d^{*\prime}\| \le \zeta$—into the forward equation eq. (28.1b) and compare the transported populations. This is a stability question for a continuity equation under a drift perturbation, and the cleanest route is the characteristics: under (A-Lip) the drift is Lipschitz in x, so two trajectories started from the same point but driven by drifts differing by ζ separate at a rate controlled by Grönwall's inequality (appendix C.1). Integrating the drift discrepancy along the flow and closing with Grönwall gives a position spread, hence a Wasserstein spread, of order $\mathcal{W}_2(m', m'') \lesssim C_{\mathrm{FP}}(T)\,\zeta$ with $C_{\mathrm{FP}}(T) \sim T\,e^{L_A T}$: a factor T because the drift error must act over the interval before it becomes a displacement, times a Grönwall amplification $e^{L_A T}$ set by the spatial Lipschitz constant L_A of the drift. Again $C_{\mathrm{FP}}(T) \to 0$ as $T \to 0$. This is the second small factor.

Composing. Chaining the two estimates, a δ-perturbation of the input flow produces an output flow perturbed by at most

$$L_{\mathsf{S}}\,\delta, \qquad L_{\mathsf{S}} \;=\; C_{\mathrm{FP}}(T)\,C_{\mathrm{HJB}}(T)\,(L_F + L_G),$$

so S is Lipschitz with the displayed constant. Two independent knobs drive L_{S} below 1. Shrinking the *coupling* $L_F + L_G$ makes the agents care little about the crowd, so a change in the crowd barely moves the best response. Shrinking the *horizon* T makes both $C_{\mathrm{HJB}}(T)$ and $C_{\mathrm{FP}}(T)$ small, because over a short interval neither the backward data error nor the forward drift error has time to compound. Either way, once $L_{\mathsf{S}} < 1$ Banach's theorem delivers a unique fixed point and geometric convergence at rate L_{S}. The sharp constants are tracked in chapter 10; here only the structural shape matters—contraction is a smallness condition on (coupling)$\times$(horizon). $\square$

It is worth making the word that organizes the next paragraph precise. Call the problem *subcritical* when the data sit in the regime the proposition certifies—$L_{\mathsf{S}} < 1$, the coupling-times-horizon product below the threshold at which the best-response loop becomes a contraction. The name is chosen deliberately to match its physical meaning. As one turns up the coupling or lengthens the horizon, L_{S} climbs toward 1; the *critical* locus is where it reaches 1 and the linearized best-response operator $D\mathsf{S}$ acquires a unit-modulus eigenvalue, so that $\mathrm{Id} - D\mathsf{S}$ becomes singular and the fixed point ceases to be locally unique. For the LQG thread this locus is computable in closed form: it is exactly the family of *conjugate horizons* of theorem 14.11, the times at which the Riccati flow blows up and the linearized self-consistency map degenerates. Below the first conjugate horizon the problem is subcritical and plain Picard contracts; *at* it the linearization is singular; *beyond* it the linear convergence factor exceeds 1 and the plain iteration no longer settles. Concretely, near criticality the dominant eigenvalue of $D\mathsf{S}$ is real and slightly above 1 (the iterate slides monotonically away) or complex with modulus above 1 (the iterate spirals out), so plain Picard either diverges outright or oscillates between two competing flows without ever resolving between them—precisely the regime in which multiple equilibria appear and the problem is most interesting.

The standard repair is *damping*: rather than jump all the way to the best response, step only part of the way toward it, replacing the bare update by the convex combination

$$m^{(k+1)} = (1-\rho_k)\,m^{(k)} + \rho_k\,\mathsf{S}(m^{(k)}), \qquad \rho_k \in (0,1]. \tag{28.11}$$

The mechanism is under-relaxation. Where the bare map overshoots its target—$D\mathsf{S}$ has an eigenvalue of modulus above 1 in the relevant direction—the damped map $\mathrm{Id} + \rho_k(D\mathsf{S} - \mathrm{Id})$ has, in that same direction, the eigenvalue $1 + \rho_k(\lambda - 1)$, which for a real λ slightly above 1 is pulled back below 1 once ρ_k is small enough, and for an oscillatory λ shrinks the spiral. A small step trades speed for stability: it cannot make a non-contraction contract in every direction, but it tames the mild overshoot that plain Picard cannot survive, and so widens the basin of convergence at the cost of more iterations.

The sharper and more interesting choice is not a fixed small ρ but the *Cesàro-averaged* schedule $\rho_k = 1/(k+1)$, which turns eq. (28.11) into *fictitious play*. Unwinding the recursion shows why the name is apt: with $\rho_k = 1/(k+1)$ the update reads $m^{(k+1)} = \frac{k}{k+1}m^{(k)} + \frac{1}{k+1}\mathsf{S}(m^{(k)})$, which is precisely the running-average recursion—each $m^{(k)}$ is the empirical mean of all best responses computed so far, and the next move best-responds to that historical average rather than to the latest flow alone. This is the learning interpretation: agents who, instead of reacting to the most recent crowd, react to the time-averaged crowd they have observed. Why averaging succeeds where the bare iteration fails is worth a sentence of intuition. Under the Lasry–Lions monotonicity (A-Mon) the best-response map need not contract, but the mismatch it produces has a definite sign: monotonicity makes $\langle \mathsf{S}(m) - \mathsf{S}(m'), m - m' \rangle$ controlled in a one-sided way, so the bare iterates cannot *grow* their distance to the equilibrium but can *rotate* around it—circulating on a near-orbit without spiralling in. Averaging a bounded orbit that circulates a center pulls the average toward that center: the rotational component cancels in the running mean while the dissipation monotonicity provides drains the radial component. In this sense (A-Mon) makes the *averaged* dynamics dissipative even when the instantaneous map is only neutrally stable, and the Cesàro mean converges to the equilibrium although no single iterate need. This is the discrete, finite-population shadow of the continuous learning dynamics taken up in chapter 29; the convergence of fictitious play for monotone mean field games is the theorem of Cardaliaguet and Hadikhanloo [38]. We will meet the construction again in the worked computation: for the subcritical LQG thread of section 28.6, the symmetric averaged step $\rho_k = \frac{1}{2}$ already contracts geometrically, exactly the rate proposition 28.5 predicts when $L_{\mathsf{S}} < 1$.

Remark 28.6 (Damping selects but cannot restore uniqueness)**.** The update eq. (28.11) is under-relaxation, the same device that stabilizes a self-consistent-field iteration past the point where the bare update over-shoots (the physics note of section 28.4 draws out that analogy). What must be stated plainly is the limit of what it can accomplish. Damping changes the *dynamics* of the iteration—which sequence of flows it generates and whether that sequence converges—but it changes nothing about the *set* of fixed points, since every $\rho_k \in (0, 1]$ leaves eq. (28.11) with exactly the fixed points of S. Hence near a genuine multiplicity (theorem 14.11, beyond a conjugate horizon, where the equilibrium is honestly non-unique) no schedule of ρ_k can manufacture uniqueness: the problem has several equilibria and damping cannot wish them away. What damping *can* do is *select*: it converges to *a* solution—generically the one in whose basin the initial guess lies—rather than diverge or oscillate among them. Damping is therefore a convergence aid and a selection rule, never a uniqueness theorem.

This is the honest ceiling on Strategy I, and it is exactly what motivates the next subsection. Everything we have established is *conditional*: plain Picard converges only inside the subcritical regime $L_{\mathsf{S}} < 1$, and damped or averaged Picard extends that reach only under monotonicity (A-Mon) and still cannot pass through a multiplicity. Outside both regimes—strong coupling, long horizon, near a conjugate critical point—no fixed-point iteration of S is guaranteed to settle, because the obstruction is structural rather than a matter of step size: the map simply does not contract, and damping a non-contraction does not create one. What is needed there is a method that does not rest on S contracting at all—one that confronts the coupled forward–backward system directly and asks only that its residual have a nonsingular Jacobian, a far weaker and generically satisfied condition. That is the all-at-once Newton method of section 28.3.2. The two strategies dovetail rather than compete: Picard is cheap and globally reaching when it works but slow and conditional, while Newton is robust and fast locally but needs a starting point already close to the solution. The practical synthesis, which section 28.3.2 formalizes and section 28.6 exercises, is to spend a handful of cheap damped-Picard sweeps—$\rho_k = \frac{1}{2}$ from a crude initial flow—to land inside Newton's basin of quadratic convergence, then hand that warm start to Newton for the final high-accuracy solve. We turn now to that robust solver.

28.3.2 All-at-once Newton

The previous subsection closed on an honest ceiling. Strategy I converges only when the best-response map S contracts—inside the subcritical regime $L_{\mathsf{S}} < 1$, extended a little by damping or averaging under monotonicity (A-Mon) but never past a genuine multiplicity. Outside that regime the obstruction is structural rather than a matter of step size: near a conjugate horizon, under strong coupling, or at long horizon the map simply does not contract, and damping a non-contraction does not manufacture one. The remedy proposed there was to abandon the requirement that S contract at all and instead confront the coupled forward–backward system head-on, asking only that its discretized residual have a nonsingular Jacobian—a far weaker and generically satisfied condition. This is Strategy II in its concrete form, and we now build it. The shift in viewpoint is the whole point: where Picard asked "does the self-consistency loop settle when I iterate it?", Newton asks "is the equilibrium a regular zero of a smooth map?", and the second question has an affirmative answer in exactly the regimes where the first does not.

Strategy II refuses to break the loop. It stacks every unknown into a single space–time vector—all the discrete values $U = (u_i^n)$ across every grid node i and every time level n, and all the discrete densities $M = (m_i^n)$ likewise—and demands that the entire discretized system eq. (28.8)–eq. (28.10) hold simultaneously. Collecting the discrete HJB equations into a residual $\mathcal{R}_{\mathrm{HJB}}(U, M)$ (it vanishes exactly when U solves the backward sweep against the population M, with the terminal data $G[m_T]$ built into the top time level) and the discrete Fokker–Planck equations into a residual $\mathcal{R}_{\mathrm{FP}}(U, M)$ (it vanishes when M is the forward flow driven by the feedback read off from U, with the initial data m_0 built into the bottom level), the equilibrium is the joint zero

$$\mathcal{R}(U, M) = \begin{pmatrix} \mathcal{R}_{\mathrm{HJB}}(U, M) \\ \mathcal{R}_{\mathrm{FP}}(U, M) \end{pmatrix} = 0, \tag{28.12}$$

to be solved by Newton's method. Notice what has happened to the forward–backward entanglement of section 28.1: it is no longer an obstacle to be tiptoed around by alternating one-way solves, but is imposed everywhere at once as the single algebraic statement $\mathcal{R} = 0$, with the two temporal boundary conditions sitting inside $\mathcal{R}$ as ordinary rows. There is no marching and no freezing. The price, as anticipated, is that $\mathcal{R}$ couples the whole space–time field, so a Newton step is a linear solve in all of (U, M) at once; the reward is robustness, because Newton's convergence rests on the Jacobian of $\mathcal{R}$ being invertible, not on any contraction.

Everything therefore hinges on the structure of that Jacobian, and it is here that the keystone of the chapter—the discrete forward–backward duality—reappears in its most consequential role. Differentiating the two block-rows of eq. (28.12) in the two block-variables gives the 2×2 block structure

$$D\mathcal{R} = \begin{pmatrix} \partial_U \mathcal{R}_{\mathrm{HJB}} & \partial_M \mathcal{R}_{\mathrm{HJB}} \\ \partial_U \mathcal{R}_{\mathrm{FP}} & \partial_M \mathcal{R}_{\mathrm{FP}} \end{pmatrix}, \tag{28.13}$$

and each of the four blocks has a transparent meaning that it pays to read off one at a time. The top-left block $\partial_U \mathcal{R}_{\mathrm{HJB}}$ is the *linearized backward operator*: differentiating the implicit HJB step eq. (28.8) in the value, with the optimal policy frozen at its current value (the envelope theorem lets us hold α^* fixed, since the Bellman bracket is stationary there), returns the matrix $I - \Delta t\,\mathcal{A}_h^{(\alpha^*)}$ acting on each time slice and the coupling $-I$ that ties level n to level $n+1$. Because backward Euler couples each level only to the one after it, as a matrix over the stacked time index this block is *block-lower-bidiagonal in time*—a clean staircase that, as we will exploit, inverts by a single backward sweep. Symmetrically, the bottom-right block $\partial_M \mathcal{R}_{\mathrm{FP}}$ is the *linearized forward operator*: differentiating the implicit FP step eq. (28.10) in the density returns $I - \Delta t\,(\mathcal{A}_h^{(\alpha^*)})^\top$ on each slice with the coupling that ties level $n+1$ back to level n, a *block-upper-bidiagonal* staircase running the other way in time. The two off-diagonal blocks carry the coupling between the value and the population. The top-right block $\partial_M \mathcal{R}_{\mathrm{HJB}}$ measures how the HJB residual responds to a perturbation of the density, and since the density enters the HJB equation only through the source $F[m]$, this block is the discretized coupling derivative $\delta F/\delta m$. The bottom-left block $\partial_U \mathcal{R}_{\mathrm{FP}}$ measures how the FP residual responds to a perturbation of the value, and since the value enters the FP equation only through the drift $-\partial_p H(x, \nabla u)$, this block is the derivative of that drift in ∇u.

The crucial observation, and the reason the Newton system is tractable at all, is that the two *diagonal* blocks are not independent. They are exact transposes of each other. This is not a coincidence of the discretization but the same forward–backward duality we installed at the grid level in section 28.2.2: the forward step was *defined* to be the transpose of the backward step (eq. (28.10)), and lemma 28.2(3) recorded the resulting pairing $\langle (I - \Delta t\,\mathcal{A}_h)u, m\rangle = \langle u, (I - \Delta t\,\mathcal{A}_h^\top)m\rangle$. That very identity, read at the level of the Jacobian, says

$$\partial_M \mathcal{R}_{\mathrm{FP}} = \big(\partial_U \mathcal{R}_{\mathrm{HJB}}\big)^\top =: L^\top,$$

where we abbreviate the linearized backward operator by L. The adjointness lemma we proved as a fact about mass and positivity now returns as the structural fact about the Newton Jacobian: the discrete reflection of the continuous forward–backward duality is exactly what we are about to exploit. Writing the Newton step $D\mathcal{R}\,(\delta U, \delta M)^\top = -\mathcal{R}$ with this notation,

$$\begin{pmatrix} L & B \\ C & L^\top \end{pmatrix} \begin{pmatrix} \delta U \\ \delta M \end{pmatrix} = - \begin{pmatrix} \mathcal{R}_{\mathrm{HJB}} \\ \mathcal{R}_{\mathrm{FP}} \end{pmatrix}, \qquad B = \partial_M \mathcal{R}_{\mathrm{HJB}} = -\Delta t\,\tfrac{\delta F}{\delta m}, \quad C = \partial_U \mathcal{R}_{\mathrm{FP}}, \tag{28.14}$$

where B carries the coupling derivative $\delta F/\delta m$ and C the derivative of the Fokker–Planck drift in ∇u. The transpose pairing of the two diagonal blocks is precisely what makes a *Schur-complement* solve of eq. (28.14) go through cleanly, and we walk through that elimination now because it is where the structure earns its keep.

The diagonal block L is the easy one to invert. Being block-lower-bidiagonal in time, it is a staircase of tridiagonal sub-blocks, each of which is an $I - \Delta t\,\mathcal{A}_h^{(\alpha^*)}$ M-matrix; solving $L\,x = r$ is therefore a single backward sweep over the time levels, at each level a tridiagonal solve that is well posed precisely because lemma 28.1 makes the slice matrix a nonsingular M-matrix. So L^{-1} costs one sweep and we may eliminate δU from the first block-row of eq. (28.14), which reads $L\,\delta U + B\,\delta M = -\mathcal{R}_{\mathrm{HJB}}$ and hence

$$\delta U = -L^{-1}(\mathcal{R}_{\mathrm{HJB}} + B\,\delta M).$$

Substituting this into the second block-row $C\,\delta U + L^\top \delta M = -\mathcal{R}_{\mathrm{FP}}$ and collecting the terms in δM removes δU entirely, leaving the reduced system

$$(L^\top - C\,L^{-1}B)\,\delta M = -\mathcal{R}_{\mathrm{FP}} + C\,L^{-1}\mathcal{R}_{\mathrm{HJB}} \tag{28.15}$$

for δM alone. The unknown has been halved: instead of solving for the whole space–time pair $(\delta U, \delta M)$ at once, we solve the single reduced system eq. (28.15) for the density increment and then recover δU by one more backward sweep through L^{-1}. The operator on the left, the Schur complement $S := L^\top - CL^{-1}B$, is the object every solver of eq. (28.15) must handle, and its structure decides how hard that is.

Here the duality pays a second dividend, and it is worth staging the definiteness argument slowly because it is dense. Begin with the leading term. By the same adjointness $\partial_M \mathcal{R}_{\mathrm{FP}} = L^\top$, the principal part of S is the transpose of the well-conditioned M-matrix staircase L, so it is itself invertible by a forward sweep and already carries the bulk of the operator. The correction $-CL^{-1}B$ measures how strongly the value and the population feed back on each other, and its sign is controlled by the monotonicity structure. Under (A-Mon) the coupling functional $\mathcal{F}$ is convex, so its second variation—the discretized block $\delta F/\delta m$—is positive semidefinite; hence the coupling block $B = -\Delta t\, \delta F/\delta m$ is *negative* semidefinite (this is exactly the discrete content of lemma 8.10). A negative-semidefinite B makes the correction $-CL^{-1}B$ a *positive-type* contribution: it pushes S in the definite direction rather than spoiling the conditioning of its principal part $L^\top$. The upshot is that S is not an arbitrary dense operator but a definite-structured one, and definite-structured operators are exactly what Krylov methods thrive on: eq. (28.15) is solved by a preconditioned Krylov iteration (GMRES in general, or CG when the symmetry is exact), never by forming S densely, since each Krylov step needs only the *action* of S on a vector—one application of $L^\top$, one backward sweep L^{-1}, and one each of the cheap couplings B, C—all at the cost of sweeps already in hand.

What preconditioner should drive that Krylov solve? The block structure answers the question for us. The natural choice is $L^\top$ itself—the linearized forward operator—because it is the principal part of S, because it inverts by a single forward sweep just as L inverts by a backward one, and, most tellingly, because it is *exact* in the weak-coupling limit. When the coupling derivative $\delta F/\delta m$ is small the block B is small, the correction $-CL^{-1}B$ is negligible, and $S \approx L^\top$ to leading order; preconditioning by $L^\top$ then renders S essentially the identity and the Krylov solver converges in a handful of steps. And weak coupling is not an arbitrary favorable case: it is *precisely* the subcritical regime $L_{\mathsf{S}} < 1$ in which proposition 28.5 guaranteed Picard already worked. The two pictures are thus consistent and complementary—where the coupling is weak the preconditioner is sharp and Newton is nearly free, and where the coupling is strong (and Picard fails) Newton still converges but the Krylov solver must do genuine work through the positive-type correction $-CL^{-1}B$. This is the sense in which Newton extends reach exactly into the regime Strategy I cannot enter.

Two properties of Newton bound its use, and both follow from the general theory. First, convergence is *quadratic*: once the iterate is close enough to the equilibrium that the Jacobian is well approximated by its value at the solution, the residual norm squares at each step, and machine accuracy is reached in a few iterations. Second, that convergence is only *local*: Newton is guaranteed to contract only inside a neighborhood of the zero, and from a poor initial guess the bare iteration can overshoot or diverge. The fix is the one foreshadowed in section 28.3.1: warm-start Newton with a few damped Picard sweeps, which are globally reaching and cheap, to land inside the basin of quadratic convergence before switching to Newton for the final high-accuracy solve. Picard supplies the globalization Newton lacks; Newton supplies the speed and robustness Picard lacks; together they cover the whole parameter range.

Algorithmic template (outer solve). The synthesis assembles into a single outer loop, which we state as a procedure and then comment on.

1. **Initialize.** Set $m^{(0)} \equiv m_0$ (the initial density held constant in time) or, slightly better, a short heat-flow smoothing of it, to give the backward sweep a benign source.

2. **Globalize.** Run damped Picard eq. (28.11) with the symmetric step $\rho_k = \frac{1}{2}$—each iteration one backward HJB solve and one forward FP solve via the block of section 28.2—until the increment $\left\| m^{(k+1)} - m^{(k)} \right\|$ falls below a coarse tolerance. This walks the iterate into the basin of attraction from almost any starting flow.

3. **Refine (optional).** Switch to Newton on the stacked residual eq. (28.12), solving each linear step eq. (28.14) by the Schur-complement reduction eq. (28.15)—eliminate δU by a backward sweep, solve for δM by a $L^\top$-preconditioned Krylov iteration, recover δU—until the quadratic regime drives the residual to machine tolerance.

4. **Output.** The equilibrium space–time field (U, M).

The practical guidance is to take the refinement step seriously as *optional.* For any problem satisfying (A-Mon) or, more sharply, the subcritical contraction $L_{\mathsf{S}} < 1$ of proposition 28.5, damped Picard alone already converges geometrically, and Step 3 is never reached—this is exactly the situation of the worked computation in section 28.6, whose LQG thread is subcritical and which therefore uses damped Picard and nothing more. Newton earns its extra per-step complexity—assembling the off-diagonal blocks B, C, the Krylov solves of eq. (28.15)—only on the stiff or near-critical problems where Picard stalls: strong coupling, long horizon, the approach to a conjugate point. One should reach for it there and only there.

It is worth ending on the structural fact that has quietly organized this whole subsection, because it is the bridge to what comes next. The single feature that made the Newton system tractable was that the two diagonal blocks are transposes, $\partial_M \mathcal{R}_{\mathrm{FP}} = (\partial_U \mathcal{R}_{\mathrm{HJB}})^\top$—the discrete forward–backward duality of lemma 28.2(3), reappearing now not as a statement about conserved mass but as the hidden *adjoint* structure of the full coupled Jacobian. A Jacobian whose off-diagonal coupling is a multiplier/constraint pairing and whose diagonal is a self-adjoint pair is the Jacobian of the optimality system of a variational problem; that is, the all-at-once residual $\mathcal{R}$ is secretly the gradient of something. In general that "something" need not be convex, and Newton is the right tool precisely because it does not require it to be. But in the *potential* case—when the coupling F is the flat derivative of a convex functional, the hypothesis of theorem 8.11 seeded already in section 28.2.2—the hidden adjoint structure stiffens into an exact *convexity*, the equilibrium becomes the unique minimizer of a single convex energy, and one can do better than Newton's local guarantee: globally convergent optimization replaces the search for a zero. That is the structure the next section harvests, and we turn to it now.

28.4 Variational and primal–dual methods for potential MFG

The previous subsection ended by naming a clue it could not yet cash in. The Newton system of section 28.3.2 was tractable for one reason: its two diagonal blocks are exact transposes, $\partial_M \mathcal{R}_{\mathrm{FP}} = (\partial_U \mathcal{R}_{\mathrm{HJB}})^\top$, the discrete forward–backward duality of lemma 28.2(3) resurfacing inside the coupled Jacobian. We observed there that a Jacobian whose diagonal is a self-adjoint pair and whose off-diagonal coupling is a multiplier/constraint pairing is, structurally, the Jacobian of the optimality system of a *variational* problem: the all-at-once residual $\mathcal{R}$ is secretly the gradient of *something*. Newton does not care whether that something is convex—it hunts a zero, not a minimum, and that indifference is exactly why it reaches into regimes where Strategy I fails. But the indifference also leaves value on the table. When the hidden potential *is* convex, finding its minimizer is a strictly easier and more robust task than finding a zero of its gradient, and the entire apparatus of convex optimization—with its global, unconditional convergence guarantees—becomes available. This section is about the subclass of games where that windfall is real, and the seed for it was planted earlier still: already in section 28.2.2 we noted that the very adjointness which buys discrete mass conservation is, in the potential case, what turns the discrete energy convex. We now harvest both observations together.

The subclass in question is the *potential* (variational) games of definition 8.9: those whose couplings F and G are flat derivatives—first variations—of convex functionals $\mathcal{F}$ and $\mathcal{G}$ on the space of measures. For these, theorem 8.11 makes a statement of remarkable economy: the entire coupled forward–backward system eq. (28.1)— two nonlinear PDEs anchored at opposite ends of time, the object whose mutual entanglement organized this whole chapter—is nothing other than the Euler–Lagrange optimality condition of a *single* convex minimization. The HJB equation is the stationarity condition in the value; the Fokker–Planck equation is the constraint; the awkward two-point coupling that forbade marching the clock is just the primal–dual pairing between a minimizer and its multiplier. The forward–backward problem has not been solved so much as *re-read*: what looked like a fixed point to be chased is exposed as a critical point to be descended to.

That re-reading changes the numerical landscape completely, and the change is best stated as a sharp trade against the two strategies built in the first half of the chapter. Strategies I and II both converge only *conditionally*. The best-response fixed point of sections 28.2 and 28.3 contracts only inside the subcritical window $L_{\mathsf{S}} < 1$, widened a little by damping but never past a genuine multiplicity; Newton converges only *locally*, once an iterate has been walked into the basin of quadratic attraction. Both carry a hypothesis—smallness, short horizon, or a good warm start—without which they may oscillate or diverge, and the bulk of section 28.3 was the honest accounting of where those hypotheses hold. A convex minimization carries none of them. A convex functional on a convex set has a *global* minimizer, and the standard first-order descent algorithms reach it *unconditionally*: from any starting point, for any horizon, at any coupling strength, with a convergence rate that depends on conditioning but never on a smallness threshold that can be violated. There is no near-critical regime in which the method stalls, because there is no contraction or local basin to escape—convexity has no conjugate horizon. This is the single reason the section exists: for potential games one trades away the conditional convergence that shadowed both earlier strategies and buys global reach in exchange.

The trade is genuine, and its price must be named with equal candor. The convex-minimization route applies *only* to potential games—those with a separable Hamiltonian and a monotone coupling that is the flat derivative of a convex functional—a strict and structurally special subclass. Outside it the equilibrium is still a fixed point or a regular zero, not a minimizer, and there is no energy to descend; the finite-difference fixed point and the all-at-once Newton method of sections 28.2 and 28.3 remain the only tools, and they apply to *any* MFG. So the two halves of the chapter are complementary, not competing: Strategies I and II are general but conditional, the variational method is unconditional but special. One reaches for it precisely when the game is known to be potential and global robustness is worth the loss of generality—and, as the graphon LQG thread will show in section 28.6, the games we most want to compute often are potential.

The development proceeds in two movements, mirroring the structure of any optimization story: first the problem, then the solver. Section 28.4.1 makes the convex program explicit and then discretizes it, recalling the energy $\mathcal{J}(m,w)$ over density–momentum flows and the linear continuity constraint it is minimized against, and proving the structural payoff that justifies the whole detour—that the discrete optimality (KKT) system of that program is *exactly* the finite-difference HJB–Fokker–Planck system of section 28.2, with the multiplier playing the role of the discrete value. The adjoint discretization built in section 28.2.2 is what makes this identity hold on the nose rather than up to truncation error: the same transpose pairing that conserved mass is what makes the discrete Lagrangian's stationarity reproduce the discrete forward and backward sweeps. Section 28.4.2 then turns to the solvers themselves—the first-order primal–dual algorithms (augmented Lagrangian / ADMM and the Chambolle–Pock scheme) that exploit the separable nonsmooth-plus-linear-constraint form of the discrete energy—and draws out the kinship that has been implicit since the momentum field $w = m\,\alpha$ first appeared: a potential MFG is, formally, a dynamic optimal-transport problem with congestion, and the very algorithms that compute Wasserstein geodesics compute mean field equilibria. We take the convex program first.

28.4.1 The convex problem and its discretization

The section intro promised to make the convex program explicit before handing it to any solver, and that is this subsection's whole task. We carry it out in three strokes, each setting up the next. First we recall the energy functional and the linear constraint it is minimized against. Then we certify, ingredient by ingredient, that every term is convex, so that the continuous problem is a genuine convex minimization and not merely a stationarity system dressed up as one. Finally—and this is the payoff that justifies the entire variational detour—we discretize the program with the very operators already constructed in section 28.2, and find that the discrete optimality conditions are not *approximately* but *exactly* the finite-difference HJB–Fokker–Planck system, with the discrete value reappearing as the Lagrange multiplier. The adjoint discretization of section 28.2.2 is what makes that last identity land on the nose.

Recall from section 8.6 that, with control-affine dynamics and potential couplings, the equilibrium (u,m) is recovered from the minimizer (m,w)—$w = m\,\alpha$ the momentum field—of the energy

$$\mathcal{J}(m,w) = \int_0^T\!\!\int_{\mathbb{R}^d} m\,L_0\Big(x, \tfrac{w}{m}\Big)\,\mathrm{d}x\;\mathrm{d}t + \int_0^T \mathcal{F}(m_t)\;\mathrm{d}t + \mathcal{G}(m_T), \tag{28.16}$$

(this is eq. (8.18)) subject to the linear continuity constraint

$$\partial_t m - \tfrac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 m) + \operatorname{div} w = 0, \qquad m(0,\cdot) = m_0 \tag{28.17}$$

(this is eq. (8.19)). The change of variable from control to momentum, $w = m\,\alpha$, is what linearizes the constraint: written in the velocity α the continuity equation carries the bilinear transport $\operatorname{div}(m\,\alpha)$, but written in w that same term is simply $\operatorname{div} w$, linear in the unknown. The price is paid back in the cost, where $m\,L_0(x,\alpha)$ becomes $m\,L_0(x, w/m)$—and it is exactly this re-expressed kinetic term whose convexity we must now check. The value u enters not as an independent unknown but as the Lagrange multiplier of the continuity constraint eq. (28.17): it is the adjoint state that enforces conservation of probability, and the reader should hold onto that reading, because the entire structural payoff below is the statement that the multiplier of the discrete constraint *is* the discrete value of section 28.2.

Now the convexity, term by term, since the claim that $\mathcal{J}$ is a convex program is the hinge on which everything turns and none of its three ingredients is convex for a trivial reason. The two *interaction* terms come first and are the most direct. Under (A-Mon) the couplings F and G are flat derivatives—first variations—of the functionals $\mathcal{F}$ and $\mathcal{G}$, and the content of lemma 8.10 is that monotonicity of the coupling is precisely the differential signature of convexity of its potential, in exact analogy with the elementary fact that a monotone nondecreasing scalar function is the derivative of a convex one. So Lasry–Lions monotonicity, the same hypothesis that bought uniqueness of the equilibrium throughout the book, here buys convexity of $m \mapsto \int_0^T \mathcal{F}(m_t)\,\mathrm{d}t$ and of $m \mapsto \mathcal{G}(m_T)$. Without (A-Mon) these terms could be concave and the whole variational route would collapse; this is the one place the assumption is load-bearing for convexity rather than for uniqueness.

The *kinetic* term is subtler, and it is worth unpacking why it is convex at all, because at first sight it should not be. Its integrand is $m\,L_0(x, w/m)$: a convex function $L_0(x,\cdot)$ of the velocity w/m, but evaluated at a *ratio* of the two unknowns and then multiplied back by m—and dividing one optimization variable by another, then rescaling, is an operation that in general destroys convexity outright. What rescues it is a classical construction. For any convex f, its *perspective* $(t,y) \mapsto t\,f(y/t)$, defined for $t > 0$, is *jointly* convex in the pair (t,y) (proposition B.2). The intuition is geometric: the perspective homogenizes f—degree-one rescaling $(t,y) \mapsto (\lambda t, \lambda y)$ multiplies it by λ—so its epigraph is precisely the cone generated by the epigraph of f, and a cone over a convex set is again convex. The seemingly dangerous division is, read this way, exactly the operation that survives intact. Setting $t = m$, $y = w$, and $f = L_0(x,\cdot)$ identifies the kinetic integrand as the perspective of L_0, hence jointly convex in (m,w).

It pays to watch this on the LQG thread, both because it makes the abstract perspective theorem concrete and because it is the kinetic cost the worked computation of section 28.6 actually minimizes. With the quadratic kinetic Lagrangian $L_0(x,\alpha) = \frac{1}{2}\alpha^2$ the integrand becomes $m \cdot \frac{1}{2}(w/m)^2 = w^2/(2m)$, the function $(m,w) \mapsto w^2/(2m)$ on the half-space $m > 0$—the Benamou–Brenier kinetic energy familiar from dynamic optimal transport. One verifies its joint convexity by hand: its Hessian is $\left(\begin{smallmatrix} w^2/m^3 & -w/m^2 \\ -w/m^2 & 1/m \end{smallmatrix}\right)$, whose determinant $w^2/m^4 - w^2/m^4 = 0$ vanishes and whose trace $w^2/m^3 + 1/m > 0$ is positive, so its eigenvalues are 0 and something positive—positive semidefinite, exactly as the perspective theorem promises. That the cost of moving mass is convex jointly in (mass, momentum) is what will let the primal–dual method of the next subsection descend on it from any starting point without ever getting trapped.

Finally the constraint. The continuity equation eq. (28.17) is *linear* in the pair (m, w)—$\partial_t m$ and the diffusion act linearly on m, the divergence acts linearly on w, and the initial condition is an affine pin—so the set of admissible flows is an affine subspace, in particular convex. A convex functional minimized over a convex set: $\mathcal{J}$ is a genuine *convex program*, and this is the structural windfall the section's introduction advertised. We now show that discretizing it with the operators of section 28.2 preserves the windfall in full and, more, reproduces the finite-difference system as the discrete optimality conditions.

Discretizing (m, w) on the same space–time grid—with the divergence and time derivative in eq. (28.17) discretized by the *same* upwind/transpose operators of section 28.2, so that the discrete multiplier is exactly the discrete value of section 28.2— yields a finite-dimensional convex program: minimize a convex (partly nonsmooth) function subject to a linear equality constraint. The structural identity is worth stating.

Proposition 28.7 (Discrete potential MFG is a finite convex program)**.** *Under the hypotheses of theorem 8.11, with the continuity operator discretized as the transpose of the discrete generator (lemma 28.2), the discrete energy $\mathcal{J}_h(m_h, w_h)$ is convex and lower semicontinuous on the affine constraint set, its minimizer exists and is unique when $\mathcal{F}, \mathcal{G}$ are strictly convex, and the discrete optimality (KKT) system is exactly the finite-difference HJB–FP system eq.* (28.8)*–eq.* (28.10) *with the multiplier playing the role of u.*

Proof sketch. Write the discrete energy as the grid quadrature of eq. (28.16),

$$\mathcal{J}_h(m, w) = \Delta t \sum_n \sum_i m_i^n \, L_0\Big(x_i, \tfrac{w_i^n}{m_i^n}\Big) + \Delta t \sum_n \mathcal{F}_h(m^n) + \mathcal{G}_h(m^{N_T}),$$

and proceed in three steps: convexity, the KKT computation, and existence/uniqueness.

Convexity is inherited node by node. Each summand of the kinetic term is $m_i^n \, L_0(x_i, w_i^n/m_i^n)$, the perspective of the convex $L_0(x_i, \cdot)$ evaluated at the single pair (m_i^n, w_i^n), hence jointly convex in that pair by proposition B.2; a sum of convex functions of disjoint blocks of variables is convex, so the discrete kinetic term is convex in (m, w). The interaction terms $\mathcal{F}_h, \mathcal{G}_h$ are convex in m by (A-Mon)/lemma 8.10, inherited verbatim from the continuous $\mathcal{F}, \mathcal{G}$. The discretized continuity constraint, built from the backward time difference of m, the symmetric discrete diffusion, and the discrete divergence of w, is linear; its solution set is affine. Hence $\mathcal{J}_h$ is convex on a convex set.

The KKT system is the finite-difference system—and the adjoint identity is what makes it so. Introduce a multiplier u_i^n for each discrete continuity equation and form the Lagrangian $\mathcal{L}_h(m, w, u) = \mathcal{J}_h(m, w) - \langle u, \mathcal{C}_h(m, w)\rangle$, where $\langle \cdot, \cdot \rangle$ is the grid pairing $\Delta t \sum_{n,i} (\cdot)(\cdot)$ and $\mathcal{C}_h(m, w) = 0$ is the discrete continuity constraint. Read off the three stationarity conditions. *Stationarity in w:* the momentum w_i^n enters only the kinetic perspective and the divergence term of the constraint. Differentiating the perspective in w returns the velocity-derivative $\partial_a L_0(x_i, w_i^n/m_i^n)$, while the constraint contributes the adjoint of the discrete divergence applied to u—and since the discrete divergence is, by construction, minus the transpose of the discrete gradient, that adjoint deposits a discrete gradient $(\nabla_h u^n)_i$. Setting $\partial_w \mathcal{L}_h = 0$ gives the discrete Legendre relation $\partial_a L_0(x_i, w_i^n/m_i^n) = (\nabla_h u^n)_i$, which inverts to $w_i^n/m_i^n = \alpha_i^*$, the optimal feedback eq. (28.9); equivalently $w_i^n = m_i^n \, \alpha_i^*$, the posited momentum field. *Stationarity in u:* this returns the constraint

$\mathcal{C}_h = 0$ unchanged, which with $w = m\,\alpha^*$ inserted is precisely the forward Fokker–Planck step eq. (28.10)—the multiplier equation is the forward sweep. *Stationarity in m:* here the adjointness does the decisive work. The density m_i^n enters the perspective, the interaction terms, and—through the time difference and the diffusion—the constraint. The m-derivative of the perspective is $L_0 - (w/m)\,\partial_a L_0$, the *negative* Legendre transform of L_0, which by eq. (28.4) is the *negative* Hamiltonian $-H(x_i, (\nabla_h u^n)_i)$; the interaction terms contribute the running source $f_i^n = \mathcal{F}_h'(m^n)_i$; and the constraint contributes the adjoints of the time difference and the diffusion acting on u. The diffusion operator is symmetric, hence self-adjoint, and the backward time difference's adjoint reverses time, so these constraint terms reassemble on u into a *backward* step of the same spatial operator. This is exactly where the discrete integration-by-parts identity lemma 28.2(3), $\langle (I - \Delta t\,\mathcal{A}_h)u, m\rangle = \langle u, (I - \Delta t\,\mathcal{A}_h^\top)m\rangle$, earns its keep: the transpose that *defined* the forward operator in eq. (28.10) is undone when it lands back on the multiplier u, returning the *untransposed* backward generator $\mathcal{A}_h$. Setting $\partial_m \mathcal{L}_h = 0$ therefore reconstitutes, term for term, the implicit backward HJB step eq. (28.8), with terminal data $u^{N_T} = \mathcal{G}_h'(m^{N_T})$ supplied by the m-derivative of the terminal term. So the KKT triple—forward FP for m, Legendre relation for w, backward HJB for u—is identically the finite-difference system eq. (28.8)–eq. (28.10), and the multiplier u is literally the discrete value of section 28.2. This is the discrete mirror of the continuous computation in the proof of theorem 8.11, and it holds with *no* truncation remainder for exactly one reason: the forward operator was installed as the exact transpose of the backward one. A discretization merely accurate to $O(h)$ but not exactly transposed would make the two sweeps the optimality system of nothing.

Existence and uniqueness by the direct method. $\mathcal{J}_h$ is convex and lower semicontinuous, and coercive: the perspective kinetic term grows superlinearly in w (inherited from the growth of L_0), and $\mathcal{F}_h, \mathcal{G}_h$ are bounded below, so sublevel sets are bounded. The affine constraint set is nonempty—the pure-diffusion flow with w chosen to close continuity lies in it—and closed. A minimizing sequence is therefore bounded, has a convergent subsequence in this finite-dimensional space, and lower semicontinuity passes $\mathcal{J}_h$ to the limit, producing a minimizer. When $\mathcal{F}, \mathcal{G}$ are strictly convex the functional is strictly convex on the constraint set and the minimizer is unique. □

The upshot is a single finite-dimensional object to hand to a solver. The discrete program of proposition 28.7 has a very particular shape: its objective splits into a *separable*, partly nonsmooth sum—a per-node perspective at every grid point plus the interaction terms—and the *only* coupling between the otherwise independent unknowns is the single *linear* continuity constraint. That separable-objective-plus-linear-constraint structure is not incidental decoration; it is exactly the template that first-order primal–dual algorithms are built to exploit, splitting cheap nonsmooth proximal updates on the separable terms from a linear projection enforcing the constraint. Section 28.4.2 takes the convex program in precisely this form and presents the two standard methods that solve it.

28.4.2 Primal–dual algorithms and the optimal-transport connection

Section 28.4.1 closed by isolating the precise shape of the discrete program of proposition 28.7: its objective is a *separable, partly nonsmooth* sum—a per-node perspective of the kinetic Lagrangian at every grid point, plus the interaction terms—and the *only* thing tying the otherwise independent node-variables together is the single *linear* continuity constraint. That observation is not a stray remark; it is a complete specification of an algorithmic genre. "Minimize a separable convex (possibly nonsmooth) function subject to a linear equality constraint" is exactly the input that *first-order primal–dual* methods are designed to consume, and the design philosophy of the whole genre is to never fight the two features of the problem at once: handle the nonsmooth, but *separable and therefore pointwise-cheap*, objective by local proximal updates, and handle the smooth-but-*globally coupling* linear constraint by a dual variable that is itself the discrete value u. The reason this is the right marriage for us is the structural identity of proposition 28.7: the multiplier of the discrete continuity constraint already *is* the discrete value field, so the dual variable a primal–dual method introduces is not a bookkeeping auxiliary but the very object Strategy I and Strategy II spent the first half of the chapter computing. We now make the genre concrete in its two standard incarnations—the augmented-Lagrangian method ALG2/ADMM and the Chambolle–Pock primal–dual hybrid gradient—prove that both converge *unconditionally*, and then read off the two payoffs that give this subsection its title: the kinship with optimal transport, and the free-energy picture that makes the unconditional convergence physically inevitable.

Before either method, recall the one tool both are built from, since a physicist may not carry it ready to hand. For a proper convex lower-semicontinuous function φ and a step $\tau > 0$, the *proximal operator*

$$\operatorname{prox}_{\tau\varphi}(z) := \arg\min_{x} \left\{ \varphi(x) + \tfrac{1}{2\tau} \|x - z\|^2 \right\}$$

returns the point that trades off decreasing φ against staying near z; it is the implicit-gradient (backward-Euler) step on the gradient flow of φ, and it is single-valued and well defined for any convex φ, smooth or not (appendix I.2). Its decisive virtue here is that a prox of a *separable* sum decouples into independent proxes of the summands—so a prox of the discrete kinetic energy is computed grid node by grid node, each an utterly small scalar problem, and never as one large solve. This is what turns the separability noted in proposition 28.7 from an observation into a computational advantage.

Augmented Lagrangian (ALG2 / ADMM). The first method descends directly from the algorithm Benamou and Brenier wrote for dynamic optimal transport, generalized to the interaction-bearing MFG energy by Benamou and Carlier [19]. Introduce the discrete value u as the multiplier of the discrete continuity constraint $A(m, w) = c$ (with A the operator of eq. (28.17) and c carrying the initial datum), and form the *augmented* Lagrangian

$$\mathfrak{L}_r(m, w; u) = \mathcal{J}_h(m, w) + \langle u, A(m, w) - c\rangle + \tfrac{r}{2} \|A(m, w) - c\|^2 ,$$

the ordinary Lagrangian stiffened by a quadratic penalty of weight $r > 0$ on the constraint residual. The penalty is what makes the method robust: it convexifies the saddle in the primal block and lets the whole iteration be read as Douglas–Rachford splitting (equivalently ADMM) on the dual problem. One then minimizes $\mathfrak{L}_r$ over the primal pair (m, w) and ascends in u, but—and this is the engineering content—the primal minimization is *split* so that each piece is cheap. A single sweep of ALG2 is three steps. *(i) A proximal step on the kinetic energy.* Holding u and the interaction data fixed, minimize the kinetic perspective plus the quadratic proximal/penalty term. Both are separable over grid nodes, so this decouples into one independent scalar problem per node (i, n)—and that scalar problem is, concretely, the minimization

$$\min_{(m,w)} \left\{ \tfrac{w^2}{2m} + \tfrac{1}{2\tau}\left[(m-\bar{m})^2 + (w-\bar{w})^2\right] \right\}$$

in the quadratic LQG case $L_0 = \frac{1}{2}|a|^2$. Eliminating w from its stationarity condition $w/m + (w - \bar{w})/\tau = 0$ gives $w = \bar{w}\, m/(m+\tau)$, and substituting into the m-stationarity $(m-\bar{m})/\tau = w^2/2m^2$ collapses everything to the single *scalar cubic*

$$(m-\bar{m})\,(m+\tau)^2 = \tfrac{\tau}{2}\,\bar{w}^{\,2},$$

whose unique positive root is the proximal value of m (and then w follows in closed form). This is the "perspective prox": the entire nonsmooth, ratio-coupled kinetic cost reduces, pointwise, to finding one root of one cubic—solved by Cardano's formula in $O(1)$ work per node. *(ii) A proximal step on the interaction energy.* The terms $\mathcal{F}_h, \mathcal{G}_h$, convex in m by (A-Mon)/lemma 8.10, are handled by their own prox; for local couplings this too is pointwise and explicit. *(iii) A multiplier update.* Updating u to enforce the continuity constraint amounts, because of the quadratic penalty, to projecting the current (m, w) onto the affine constraint set, and that projection is the solution of a single space–time *Poisson-type* linear system for u—the normal equations $AA^\top u =$ (residual), whose operator $AA^\top$ is a discrete space–time Laplacian inherited from the gradient/divergence pairing of section 28.2.2. This is the only globally coupled solve in the sweep, and it is linear, symmetric, and positive definite, so a single multigrid or FFT solve dispatches it. The three steps alternate—two embarrassingly parallel pointwise proxes and one global Poisson solve—until the constraint residual and the energy both settle. Note how cleanly the work has been partitioned along the seam the problem itself provided: nonsmoothness lives entirely in the separable proxes, global coupling entirely in the linear Poisson solve, and the two never collide.

Primal–dual hybrid gradient (Chambolle–Pock). The second method dispenses even with the inner projection, trading the Poisson solve per sweep for a single application of A and its transpose. Write the problem as the convex–concave saddle of the (unaugmented) Lagrangian,

$$\min_{(m,w)}\ \max_{u}\ \mathfrak{L}(m,w;u), \qquad \mathfrak{L}(m,w;u) = \mathcal{J}_h(m,w) + \langle u, A(m,w) - c\rangle \tag{28.18}$$

(we write the saddle functional $\mathfrak{L}$, reserving $\mathcal{L}$ for the law), and alternate one proximal-*ascent* half-step in the dual variable u with one proximal-*descent* half-step in the primal pair (m, w), with an extrapolation of the primal iterate inserted to couple the two. Schematically, with steps $\sigma, \tau > 0$,

$$u^{k+1} = \operatorname{prox}_{\sigma h}\big(u^k + \sigma A\,\overline{(m,w)}^{\,k}\big), \qquad (m,w)^{k+1} = \operatorname{prox}_{\tau \mathcal{J}_h}\big((m,w)^k - \tau A^\top u^{k+1}\big),$$

where h is the (linear) term enforcing the constraint and the bar denotes the extrapolated primal point. Both proxes are closed form: the dual prox is the trivial affine prox of a linear functional, and the primal prox of $\mathcal{J}_h$ is again the per-node perspective cubic of step (i) above plus the interaction prox. No linear system is solved at all—each sweep costs one multiplication by A and one by $A^\top$, i.e. one discrete divergence and one discrete gradient. The scheme converges for *any* step sizes obeying the single product bound $\tau\sigma\,\|A\|^2 \le 1$ [47], with ergodic rate $O(1/k)$ on the primal–dual gap; the

MFG-specific proximal maps, including the perspective cubic, are tabulated by Briceño-Arias, Kalise, and Silva [32]. It is this scheme whose convergence we now state and prove as the chapter's sharpest contrast to everything in its first half.

Theorem 28.8 (Unconditional convergence in the potential case)**.** *Under the hypotheses of theorem 8.11 (potential couplings, (A-Mon), (A-Conv), (A-Nondeg)), the discrete primal–dual iteration applied to the convex program of proposition 28.7 converges to its unique saddle point—hence to the discrete MFG equilibrium—from* any *initialization, with ergodic primal–dual gap decaying as* $O(1/k)$*. No smallness of the coupling and no restriction on the horizon* T *is required.*

Proof. The entire content is to recognize eq. (28.18) as one instance of the abstract saddle the general primal–dual theorem is stated for, and to read off four identifications; once they are made, theorem I.2—proved in full and in-book in appendix I, originally [47]—applies verbatim and supplies the rate. We stage the identifications one at a time, because the force of the theorem is exactly which abstract object each MFG ingredient turns out to be.

The saddle. The general theorem treats $\min_x \max_y\{\langle Kx, y\rangle + g(x) - h(y)\}$ with g, h proper convex lsc and K linear (eq. (I.1)). Match it to eq. (28.18) term by term. *(1) The primal variable* is the density–momentum pair, $x = (m_h, w_h)$; *(2) the dual variable* is the discrete value, $y = u_h$—the same multiplier the KKT computation of proposition 28.7 already identified with the discrete value of section 28.2, so the dual iterate the algorithm carries is literally a running estimate of the value field. *(3) The proximable convex term* g is the kinetic-plus-interaction energy $\mathcal{J}_h$: nonsmooth, but proximable node by node exactly as the perspective cubic above shows; the constraint term contributes $h(y) = \langle c, y\rangle$, linear in y, so that $\langle Kx, y\rangle - h(y) = \langle A(m, w) - c, u\rangle$ reproduces the pairing in eq. (28.18). *(4) The linear map* K is the discrete continuity operator A of eq. (28.17).

The norm and the admissible steps. The only quantitative input the abstract theorem needs is the operator norm $L = \|K\| = \|A\|$, because the step-size condition is $\tau\sigma L^2 \le 1$. Here A is built from the discrete time difference, the symmetric discrete diffusion, and the discrete divergence; its norm is dominated by the stiffest of these, the first-order spatial difference, whose norm is $O(1/h)$ (a centered or upwind difference over a grid of spacing h has spectral radius of order $2/h$). Thus $L = O(1/h)$, and the admissible steps are precisely those with $\tau\sigma \le c\,h^2$ for a mesh-independent constant c—the standard CFL-like scaling for a first-order method on a gradient-norm operator, and the content of remark I.3. This is a condition the user simply *sets* by choosing τ, σ; it is not a hypothesis on the *problem* that the problem may fail to satisfy.

The conclusion, and why it is unconditional. With these identifications theorem I.2 gives, for any step sizes obeying $\tau\sigma L^2 \le 1$ and from *any* initial $(\,(m, w)^0, u^0\,)$, the ergodic bound: the partial primal–dual gap (I.2) at the running averages decays as $O(1/k)$, and since that gap vanishes only at the unique saddle point, the ergodic iterates converge to it—hence to the discrete equilibrium. The single fact that drives the proof of theorem I.2 is worth recalling, because it is where convexity does its work: the prox inequality lemma I.1 produces, at each step, a one-sided estimate that *telescopes* when summed, leaving only the initial distance to the saddle divided by k; the cross term left over is absorbed by Young's inequality under exactly the bound $\tau\sigma L^2 \le 1$. Nowhere in that telescoping is any smallness of the coupling, any shortness of the horizon, or any contraction factor invoked. *Convexity alone*—which here is precisely (A-Mon), the same monotonicity that made $\mathcal{J}_h$ convex in proposition 28.7—is what makes the estimate close. That is the whole point of the potential structure: it converts the problem from one where convergence is a delicate property to be earned into one where convergence is automatic.

This is the contrast the section was built to make, and it deserves to be stated against its foil without hedging. Proposition 28.5 certified Strategy I only *conditionally*: the best-response map contracts, and Picard converges, only inside the subcritical window $L_{\mathsf{S}} < 1$—a genuine hypothesis on the data (small coupling, or short horizon, or weak interaction) that a strongly coupled or long-horizon game can simply violate, after which the iteration oscillates or diverges and no choice of relaxation parameter rescues it. Newton (section 28.3.2) removed the smallness but replaced it with *locality*: quadratic convergence only once an iterate sits in the basin of attraction, which itself must be reached by a globalization that can stall. Here neither caveat survives. There is no contraction factor that must be less than one because the method never iterates a fixed-point map; there is no basin to reach because a convex functional has a single global minimum and every descent path leads to it. The price—paid in full in section 28.4.1—was generality: this holds only for potential games. But *within* that class, the $O(1/k)$ gap holds at any coupling strength and any horizon, from any start. The MFG-specific proximal maps are worked out in [32]. □

The two payoffs promised in the section opening now follow, and each is more than a footnote: the first locates potential-MFG computation inside a subject the reader already half-knows, and the second explains, in the physicist's own language, *why* the unconditional convergence just proved was to be expected all along.

Remark 28.9 (The optimal-transport limit)**.** Strip the interaction and the diffusion from the energy and watch what eq. (28.16) becomes. Set $\mathcal{F} = \mathcal{G} = 0$, take the pure kinetic Lagrangian $L_0(x, a) = \frac{1}{2}\,|a|^2$, and let $\sigma = 0$. Then the constraint eq. (28.17) loses its diffusion term and is the plain continuity equation $\partial_t m + \operatorname{div} w = 0$, and the energy collapses to $\mathcal{J}(m, w) = \int_0^T\!\int_{\mathbb{R}^d} \frac{|w|^2}{2m}\,\mathrm{d}x\,\mathrm{d}t$—nothing but the total kinetic action of a mass flow carried from m_0 at $t = 0$ to m_T at $t = T$. Minimizing that action over all flows joining two fixed endpoints is *exactly* the Benamou–Brenier dynamic formulation of the squared quadratic Wasserstein distance $\mathcal{W}_2(m_0, m_T)^2$, the theorem proved in-book as theorem 4.10 (appendix D.4). So a potential MFG is, structurally, a *generalized Benamou–Brenier problem*: the bare transport cost $\int \frac{|w|^2}{2m}$ is the same, and the interaction energy $\int_0^T \mathcal{F}(m_t)\,\mathrm{d}t + \mathcal{G}(m_T)$ enters as a *congestion* or crowd-aversion penalty added on top—a cost the moving mass pays for piling up, which optimal transport omits and mean field games supply. The diffusion $\sigma > 0$ that we restored above is, in the same dictionary, the entropic/Brownian regularization of the transport. This is not a loose analogy but an equality of variational problems, and it has a sharp computational corollary: every algorithm of this subsection, run with $\mathcal{F} = \mathcal{G} = 0$, *is* a dynamic optimal-transport solver [18, 117]—ALG2 reduces to the original Benamou–Brenier scheme it was generalized from, and Chambolle–Pock to a primal–dual transport solver. Conversely, the entropic-regularized (Sinkhorn-type) variants that dominate computational OT bridge back the other way, furnishing fast smoothed solvers for the regularized MFG energy. "Potential-MFG numerics" and "dynamic-optimal-transport numerics" are therefore one subject under two names, distinguished only by whether a congestion term sits in the objective.

Physics note

There is a free-energy reading of this whole section that makes its central theorem feel inevitable, and it is worth spelling out because it is the genuine article rather than a decorative analogy. Theorem 8.11 already cast a potential MFG as the minimization of a single functional $\mathcal{J}$; read $\mathcal{J}$ as a *Ginzburg–Landau free energy* whose order parameter is the population density m and whose conjugate field—the thermodynamically dual variable—is the value u, exactly the multiplier the primal–dual method carries as its dual iterate. In that reading the two algorithmic families of this chapter are the two textbook ways a physicist finds a free-energy minimum, and their behaviors are exactly the ones the analogy predicts. The fixed-point loop of section 28.3 is *self-consistent-field* (mean-field) iteration: posit the field, compute the density that best-responds to it, recompute the field that density induces, and repeat. Like every SCF scheme it converges quickly when the free energy is strongly convex—deep in a single-phase, subcritical regime—and grows sluggish and then unstable as one approaches a phase transition, where the free energy flattens, competing minima appear, and the self-consistency map stops contracting; this is the physical content of the contraction threshold $L_{\mathsf{S}} < 1$ of proposition 28.5. The primal–dual method of theorem 28.8 is instead *direct free-energy minimization*: it descends $\mathcal{J}$ itself rather than iterating the stationarity condition, and because a convex free energy has one global minimum and no spurious local traps, it reaches that minimum no matter how flat the landscape or how near the (here, by (A-Mon), absent) transition. The lesson is one every computational physicist has met at a critical point: when self-consistent-field iteration slows to a crawl near criticality, stop iterating the mean-field equations and minimize the free energy directly. Theorem 28.8 is the precise, theorem-grade statement of that folklore—unconditional $O(1/k)$ convergence where the self-consistency loop would have stalled.

The thread to carry out of this section is the one its theorem makes sharpest: *structure buys unconditional convergence.* Where Strategies I and II had to earn convergence with hypotheses on the data—a small coupling, a short horizon, a good warm start—the potential games surrender it for free, because their convexity (A-Mon) is a structural feature the solver can exploit rather than a regime it must hope to be in. And the reason the discrete solver could exploit it at all is the recurring theme of the whole chapter, visible here one more time: the right discretization mirrors the continuous structure. It was the exact-transpose pairing of section 28.2.2 that made the discrete energy genuinely convex (proposition 28.7) and the discrete saddle a faithful image of the continuous one, and only because of that faithfulness does the abstract primal–dual theorem land on the nose. That same principle—preserve the continuous structure exactly at the grid level, and the good properties follow—is what the final piece of the apparatus must now honor for a *new* structure. Section 28.5 lifts everything built so far to the type-indexed setting, where each agent carries a label $x \in [0, 1]$ and the coupling is no longer to a single global mean but to the graphon-aggregated neighbor field of eq. (28.19). The question that section confronts is the one this section answers for convexity: which discretization of the graphon operator $\mathbb{W}$ mirrors its continuous structure faithfully enough that the scalar machinery—monotonicity, adjointness, and the variational identity just exploited—survives the lift intact.

28.5 Discretizing the graphon coupling

The previous section left us with a principle and a charge. The principle is the one this whole chapter has circled: a discretization earns the good properties of the continuous problem precisely when it mirrors the continuous *structure* at the grid level—it was the exact-transpose pairing of section 28.2.2 that made the discrete energy genuinely convex and the discrete saddle a faithful image of the continuous one (section 28.4.2), and it was the M-matrix rate-matrix structure of section 28.2 that delivered monotonicity, mass conservation, and positivity for free. The charge is to honor that same principle for a *new* structure. Everything built so far—the monotone backward scheme, its conservative adjoint forward scheme, the outer fixed point and Newton solvers, the variational machinery—was written for a single representative agent coupled to a single global mean. We now lift the entire apparatus to the graphon setting of Part IV, where the population is no longer one crowd but a continuum of *types*, and a brand-new object enters the system: the graphon operator $\mathbb{W}$, which must itself be discretized consistently or the whole lift fails. The question is which discretization of $\mathbb{W}$ mirrors its continuous structure faithfully enough that the scalar machinery—monotonicity, adjointness, the variational identity—survives intact.

We add the type label. The graphon mean field game (set up across the kernel in chapter 22, with existence and the operator-norm contraction threshold (A-Coupling) in chapter 24) replaces the single representative agent by a continuum of types $x \in [0,1]$, the exchangeable index of an agent's network position. Each type now carries its *own* copy of everything the scalar problem had: its own controlled state X_t^x, its own value field u^x solved backward, and its own population density m_t^x evolving forward. Before going further we settle a notational collision that this section is the first to face squarely. Two different objects in this book both want the letter W: Brownian motion and the graphon kernel. The book's resolution (appendix A, and the notation watch opening this chapter) is that once a graphon is in scope the kernel owns W outright and Brownian motion is written B. From here on, therefore, W is *always* the kernel; the driving noise of the type-x state X_t^x is the Brownian motion B_t^x of Thread B (chapter 18), never W.

What makes this more than K disjoint scalar problems is the coupling, and it is here that the type label does real work. In the scalar game an agent was drawn toward the single population mean $\bar{m}_t$. In the graphon game an agent of type x is drawn instead toward the *graphon-aggregated neighbor field*

$$z_t(x) = (\mathbb{W}\,\bar{m}_t)(x) = \int_0^1 W(x,y)\,\bar{m}_t(y)\,\mathrm{d}y, \qquad \bar{m}_t(y) = \int_{\mathbb{R}} \xi\, m_t^y(\mathrm{d}\xi), \tag{28.19}$$

of eq. (28.19). Read this concretely, because the whole section turns on it. The inner integral $\bar{m}_t(y)$ is just the ordinary scalar mean of type y's own population—the average state of the agents of that one type, exactly the quantity $\bar{m}_t$ of Thread A but now computed type-by-type. The outer integral then forms a *kernel-weighted average* of those per-type means: $z_t(x)$ is the mean state of type x's neighbors, where "how much of a neighbor" type y is to type x is the connection strength $W(x,y)$. A type sees not the global crowd but its own kernel-weighted slice of it. When $W \equiv c$ is constant every type is everyone's neighbor with equal weight and $z_t(x) = c\int_0^1 \bar{m}_t(y)\,\mathrm{d}y$ collapses back to a single global mean, and the scalar game of Thread A is recovered (the constant-kernel limit of the rank-one reduction of chapter 18). The standing assumption (A-Reg-W) keeps W symmetric, bounded and (where needed) continuous in type, so that $\mathbb{W}$ is a self-adjoint Hilbert–Schmidt operator on $L^2[0,1]$; we will lean on exactly that regularity below, both to make the coupling quadrature convergent and to make the discrete operator's leading eigenvalue—the quantity the contraction threshold reads off—converge to the true $\|\mathbb{W}\|$.

The structural payoff of eq. (28.19) is worth stating before any grid arrives, because it dictates the entire architecture of the graphon solver and is the reason the lift is cheap rather than a fresh start. The type label couples the K problems in *exactly one place*: the aggregation eq. (28.19). Nowhere else does type x's state, value, or density depend on type y; the backward HJB sweep, the forward Fokker–Planck sweep, the policy iteration, the boundary closures—all of it runs within a single type, blind to the others, and reaches out to the rest of the population through nothing but the scalar target $z_t(x)$ that replaces the old target $\bar{m}_t$. Concretely, the running cost that type x feels is the scalar Thread A cost with its coupling target swapped: the term $\frac{q}{2}(x - s\,\bar{m}_t)^2$ of Thread A becomes $\frac{q}{2}(x - s\,z_t(x))^2$ for Thread B, the *only* change being $\bar{m}_t \rightsquigarrow z_t(x)$. So the graphon solver is not a new algorithm at all: it is the single-population solver of section 28.2 run in K *parallel copies*, one per type, that pause once per time step to exchange their current means, recombine them through the kernel into the targets z_t^k, and then march on independently again. The numerical task therefore acquires exactly one new ingredient—a second discretization, over the type variable, layered on top of the state–time grid of section 28.2—and that ingredient is precisely a *quadrature* for the integral in eq. (28.19): a rule that replaces the operator $\mathbb{W}$ by a finite $K \times K$ matrix acting on the vector of per-type means. Discretizing the graphon coupling is, in one sentence, replacing one integral operator by one matrix.

The rest of the section develops this in three movements, each isolating one face of that single ingredient. First (section 28.5.1) we lay down the type grid alongside the state grid and write the coupling quadrature explicitly, realizing $\mathbb{W}$ as the matrix $\mathbb{W}_K$ and bounding the error it commits against the true operator—the numerical face of graphon coarse-graining, tied back to the weak regularity theory of chapter 19. Second (section 28.5.2) we observe that for the structurally important class of *block* graphons the quadrature is not merely convergent but *exact*, collapsing the graphon MFG with no coupling error onto a finite multi-population game and exhibiting the two as numerically identical. Third (section 28.5.3) we account for what the lift costs and what it converges to: K parallel sweeps per outer iteration plus one cheap matrix product, and a total error that adds the type-grid contribution to the state–time error already controlled in section 28.2. We begin with the grid and the quadrature, where the operator $\mathbb{W}$ first becomes a finite matrix and its approximation error is bounded.

28.5.1 Type grid, state grid, and the coupling quadrature

Choose a type grid $x_1 < \cdots < x_K$ in $[0,1]$ with quadrature weights $w_1, \ldots, w_K > 0$ summing to 1 (midpoint or trapezoidal). Each type x_k carries a full copy of the state–time machinery of section 28.2: a value field $u_i^{k,n}$ and a density $m_i^{k,n}$. The only coupling between types is the aggregation eq. (28.19), which we realize as a *quadrature*:

$$z_t^k \;=\; \left(\mathbb{W}_K\,\bar{m}_t\right)_k \;:=\; \sum_{l=1}^{K} W(x_k, x_l)\,\bar{m}_t^l\,w_l, \qquad \bar{m}_t^l = \sum_i x_i\,m_i^{l,n}\,h, \tag{28.20}$$

i.e. the integral operator $\mathbb{W}$ is replaced by the $K \times K$ matrix $\mathbb{W}_K = \big(W(x_k, x_l)\, w_l\big)_{k,l}$ acting on the vector of type means. The whole solver is the single-population solver of section 28.2 run in K parallel copies, communicating once per time step through the matrix–vector product eq. (28.20). The architecture is thus *exactly* the scalar one, with the scalar coupling target $s\,\bar{m}_t$ of Thread A replaced by the type-k target $s\,z_t^k$ of Thread B.

Proposition 28.10 (Quadrature error of the coupling operator)**.** *Under (A-Reg-W) with W Lipschitz in its first argument uniformly in the second (constant L_W), and $\bar{m}_t$ bounded, the midpoint/trapezoidal quadrature eq.* (28.20) *on a uniform type grid satisfies*

$$\max_{1\le k\le K} \big|\, z_t(x_k) - z_t^k \,\big| \;\le\; C\,\big(L_W + \mathrm{Lip}(\bar{m}_t)\big)\, K^{-1}, \tag{28.21}$$

and $O(K^{-2})$ if in addition $W(x_k,\cdot)$ and $\bar{m}_t$ are C^2 in type. Consequently $\|\mathbb{W}_K - \mathbb{W}\| \to 0$, and the leading eigenvalue $\|\mathbb{W}_K\| \to \|\mathbb{W}\|$ as $K \to \infty$.

Proof. For fixed x_k the integrand $y \mapsto W(x_k,y)\bar{m}_t(y)$ is Lipschitz with constant $\le \|\bar{m}_t\|_\infty L_W + \|W\|_\infty \mathrm{Lip}(\bar{m}_t)$; the midpoint rule on K uniform subintervals has error bounded by (Lipschitz constant)$\times$(panel width)$= O(K^{-1})$ per the standard quadrature estimate, giving eq. (28.21). Under C^2 regularity the midpoint rule is second order, $O(K^{-2})$. The operator-norm convergence is then $\|\mathbb{W}_K - \mathbb{W}\| \le \sup_{\|f\|\le 1} \|(\mathbb{W}_K - \mathbb{W})f\| \to 0$ by the same panelwise bound applied uniformly over unit-norm f, and the top eigenvalue is norm-continuous (it equals $\|\mathbb{W}\|$ for the self-adjoint $\mathbb{W}$, lemma 20.12), so $\|\mathbb{W}_K\| \to \|\mathbb{W}\|$. $\square$

The connection to the regularity theory of chapter 19 is direct and worth making explicit. Assigning each type to its grid node x_k and treating W as constant on the corresponding cell is exactly the *stepping operator* $W_{\mathcal{P}}$ of definition 19.7 for the partition $\mathcal{P}$ into K equal type intervals. The weak regularity lemma theorem 19.8 and its bounded-complexity corollary corollary 19.9 bound the cut-norm error $\|W - W_{\mathcal{P}}\|_\square$ of this block approximation; through the stability of the equilibrium in the cut metric (the program of chapters 24 and 25), that cut-norm error controls the error in the computed equilibrium. The type-grid quadrature is, in other words, not an ad hoc device but the numerical face of graphon coarse-graining.

28.5.2 Block graphons and the exact reduction to multi-population MFG

When W is itself piecewise constant on a partition into K blocks—a stochastic block model kernel B—the type-grid aligned to the blocks makes the quadrature eq. (28.20) *exact*, not merely convergent: $\mathbb{W}_K$ *is* the block matrix B weighted by block sizes. The graphon MFG then reduces, with no discretization error in the coupling, to a finite K-population mean field game in which population k feels the mixture $\sum_l \mathsf{B}_{kl}\,\bar{m}^l\,w_l$ of the block means. This is the bridge to the multi-population theory of chapter 30 (specifically the block-graphon reduction of the heterogeneity zoo, chapter 30): a K-population MFG is a graphon MFG on a K-block kernel, and conversely the type-grid discretization of a general graphon MFG is a K-population MFG approximating it. The two pictures are numerically identical.

28.5.3 Complexity and convergence

Per outer (fixed-point) iteration, the graphon solver performs K independent HJB–FP sweeps at $O(N_T N_x)$ each, plus the coupling assembly. The coupling eq. (28.20) is a $K \times K$ matrix–vector product per time step, $O(K^2 N_T)$. Thus one outer iteration costs

$$O(K\, N_T\, N_x) \text{ (the } K \text{ decoupled PDE sweeps)} \;+\; O(K^2\, N_T) \text{ (the coupling)}, \tag{28.22}$$

and the number of outer iterations is $O(\log \varepsilon^{-1}/\log L_{\mathsf{S}}^{-1})$ when the fixed point contracts with rate $L_{\mathsf{S}} < 1$ (proposition 28.5). For a low-rank kernel the coupling cost collapses: a rank-one $W(x,y) = f(x)f(y)$ makes $z_t^k = f(x_k)\sum_l f(x_l)\bar{m}_t^l w_l = f(x_k)\,\varrho_t$ with a *single scalar* order parameter $\varrho_t = \langle f, \bar{m}_t\rangle$, so the $O(K^2)$ product becomes $O(K)$ and the entire type-indexed family collapses to one self-consistency equation for ϱ_t—the rank-one reduction of proposition 18.18 and worked computation 18.19 (the matrix template of section 14.7), here realized as a computational economy as well as a structural one.

The error of the computed equilibrium decomposes into three independently controllable pieces, which we state as the chapter's convergence accounting.

Theorem 28.11 (Convergence of the graphon discretization)**.** *Assume (A-Lip), (A-Growth), (A-Nondeg), (A-Conv), (A-Reg-W) with W Lipschitz in type, and the operator-norm smallness (A-Coupling), $\|\mathbb{W}\| < \kappa := 1/C_T$, under which the graphon best-response map contracts and the GMFG equilibrium is unique (the dynamic threshold of chapter 24, proposition 24.18, with C_T the horizon-dependent per-type response constant $C_T = L_{\mathcal{R}}(T)\,\mathrm{Lip}(F_0, G_0)$ of eq. (24.7)). Let $(u_h^{k,n}, m_h^{k,n})$ be the output of the type-grid finite-difference solver with the outer loop driven to tolerance $\varepsilon_{\mathrm{out}}$. Then the total error of the computed type-indexed equilibrium is bounded by*

$$\underbrace{C_1\,(h + \Delta t)}_{\textit{FD scheme, theorem 28.3}} \quad + \quad \underbrace{C_2\,K^{-1}}_{\textit{coupling quadrature, proposition 28.10}} \quad + \quad \underbrace{\varepsilon_{\mathrm{out}}}_{\textit{outer-loop tolerance}}, \tag{28.23}$$

and each term vanishes under refinement; the constants C_1, C_2 depend on the data and on the amplification factor $(1 - C_T\,\|\mathbb{W}\|)^{-1}$ but not on the grids. (In the LQ normalization of worked computation 28.12, where $a = 0$ and $C_T = 1$, the contraction modulus $C_T\,\|\mathbb{W}\|$ reduces to $s\,\|\mathbb{W}\|$, which there coincides with the sharp uniqueness/phase boundary $s\,\|\mathbb{W}\| < 1$ of theorem 14.11; in general the two are distinct—$s\,\|\mathbb{W}\| = 1$ is the phase boundary, while $C_T\,\|\mathbb{W}\| < 1$ is the Picard-contraction threshold.)

Proof sketch. The three error sources are independent and superpose to first order. The finite-difference error $O(h + \Delta t)$ for each fixed type is theorem 28.3. The coupling error $O(K^{-1})$ is proposition 28.10; it enters the per-type source $s\,z_t^k$ as a forcing perturbation. The outer-loop residual is $\varepsilon_{\mathrm{out}}$ by construction. To turn these local perturbations into a bound on the *equilibrium* error one uses the contraction (A-Coupling): the equilibrium is a fixed point of the graphon best-response map, whose Lipschitz constant is $C_T\,\|\mathbb{W}\| < 1$ by the dynamic contraction estimate proposition 24.18/eq. (24.7), so a perturbation δ of the per-iteration data perturbs the fixed point by $\delta/(1 - C_T\,\|\mathbb{W}\|)$, the source of the amplification factor $(1 - C_T\,\|\mathbb{W}\|)^{-1}$ in C_1, C_2. The norm convergence $\|\mathbb{W}_K\| \to \|\mathbb{W}\|$ (proposition 28.10) guarantees the discrete map is a contraction for

K large whenever the continuous one is. The argument is the standard "consistency + stability $\Rightarrow$ convergence" decomposition; the stability input (contraction) is exactly (A-Coupling). Outside the subcritical regime the outer loop may not contract and eq. (28.23) fails—the same caveat as remark 28.6, inherited at the graphon level. $\square$

28.6 Worked computation: solving and validating both threads

We now do the computation the chapter exists to justify: solve Thread A and Thread B numerically by the forward–backward finite-difference solver of sections 28.2, 28.3 and 28.5, and check the output against the closed forms of chapter 14. This advances both threads to their fourth (numerical) layer (appendix A). The reference implementation is `figures/28-mfg-solver.py`; it implements eq. (28.8) with Howard iteration, the adjoint Fokker–Planck step eq. (28.10), the damped Picard outer loop eq. (28.11) with $\rho_k = \frac{1}{2}$, and the type-grid quadrature eq. (28.20).

Worked computation 28.12 (Numerical LQG and graphon-LQG equilibria)**.** We work in the normalization of worked computation 14.10: $a = 0$, $b = 1$, $q = q_T = \omega^2 = 1$ (so $\omega = 1$), $s_T = 0$, with noise $\sigma = 0.3$, horizon $T = 1$, initial mean $\bar{m}_0 = 1$, initial variance $V_0 = 0.1$, and running coupling $s = 0.5$. Because $s = 0.5 < 1$ we are strictly inside the unique-equilibrium region of theorem 14.11, so by proposition 28.5 the Picard loop should contract; and because in this normalization the Riccati curvature is exactly $P(t) \equiv \omega = 1$ (the constant solution of $\dot{P} = P^2 - 1$, $P(T) = 1$), the analytic benchmark for the equilibrium mean is the constant-coefficient linear two-point boundary value problem eq. (14.21), which we solve to machine precision by the matrix exponential of $M = \left(\begin{smallmatrix} -\omega & -1 \\ \omega^2 s & \omega \end{smallmatrix}\right)$.

Thread A. The state grid is $[-7, 7]$ with $N_x = 161$ nodes ($h \approx 0.0875$) and $N_T = 120$ time steps. The coupling target felt by the representative agent is $s\,\bar{m}_t$. The damped Picard loop converges geometrically—the residual $\left\|\bar{m}^{(k+1)} - \bar{m}^{(k)}\right\|$ contracts by a constant factor per step, reaching 10^{-6} in about 22 iterations, exactly the behavior proposition 28.5 predicts for a subcritical problem. The computed mean trajectory matches the closed-form BVP solution to

$$\max_t \left|\, \bar{m}_t^{\mathrm{num}} - \bar{m}_t^{\mathrm{exact}} \,\right| \;\approx\; 9.3 \times 10^{-3},$$

a first-order-in-$(h, \Delta t)$ error consistent with theorem 28.3. As an independent check on the HJB solver, the discrete curvature $\partial_{xx} u$ read off at the grid center is ≈ 1.06, recovering the exact Riccati value $P \equiv 1$ up to the upwind scheme's first-order numerical diffusion. The left panel of fig. 28.1 overlays the two.

Thread B (rank-one graphon). We take the rank-one kernel $W(x, y) = f(x)f(y)$ with $f(x) = \frac{1}{2} + x$ on $K = 16$ midpoint type nodes. Then $\|\mathbb{W}\| = \int_0^1 f^2 = \frac{13}{12} \approx 1.083$ (example 20.13), so the effective coupling is $s\,\|\mathbb{W}\| \approx 0.54 < 1$: subcritical, unique, contracting, by theorem 28.11. Each type-k agent feels $s\, f(x_k)\, \varrho_t$ with the scalar order parameter $\varrho_t = \langle f, \bar{m}_t\rangle = \sum_l f(x_l)\bar{m}_t^l\, w_l$ assembled by the quadrature eq. (28.20) (this ϱ_t is the canonical rank-one order parameter of eqs. (18.11) and (27.22)). The rank-one structure collapses the type-indexed family to a single self-consistency equation for ϱ_t (proposition 18.18); the closed-form reference solves the reduced scalar system

$$\dot{v} = (a - b^2 P)\, v - b^2 \psi, \quad v(0) = 0, \qquad \dot{\psi} = -(a - b^2 P)\, \psi + q\, s\, \varrho_t, \quad \psi(T) = 0, \qquad \varrho_t = \bar{m}_0\, e^{(a - b^2 P)t} \int_0^1 f + v(t) \int_0^1 f^2,$$

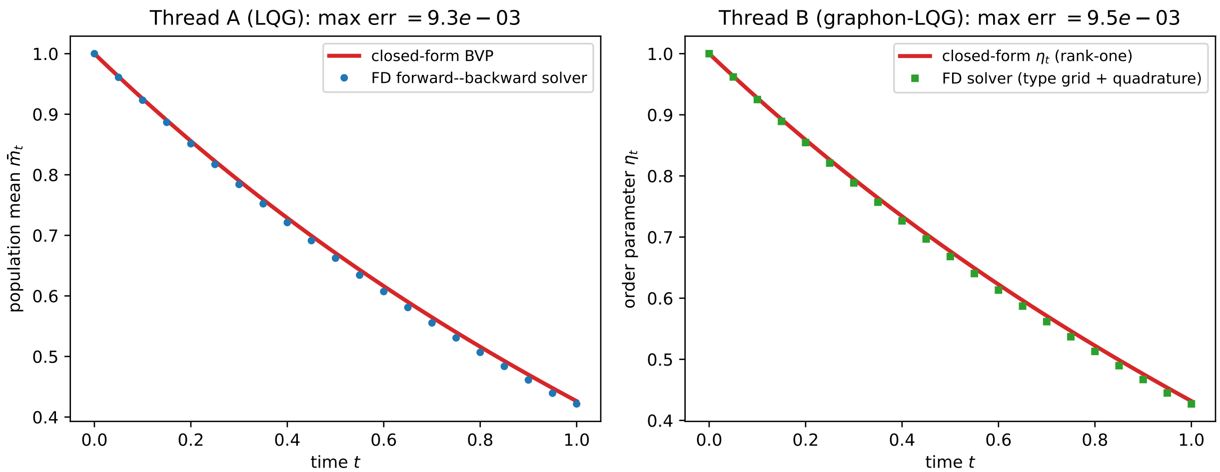

Figure 28.1: Validation of the forward–backward finite-difference solver against the closed forms of chapter 14, in the normalization of worked computation 28.12 ($a = 0$, $b = 1$, $q = q_T = 1$, $\sigma = 0.3$, $T = 1$, $\bar{m}_0 = 1$, $s = 0.5$). *Left*: Thread A. The population mean $\bar{m}_t$ computed by the finite-difference HJB–FP solver with damped Picard outer loop (markers) versus the exact linear two-point BVP solution eq. (14.21) (curve); maximum error $\approx 9.3 \times 10^{-3}$. *Right*: Thread B with rank-one kernel $W(x, y) = (\frac{1}{2} + x)(\frac{1}{2} + y)$ on a $K = 16$ type grid. The order parameter ϱ_t from the full type×state solver with quadrature coupling (markers) versus the closed-form scalar reduction (curve); maximum error $\approx 9.5 \times 10^{-3}$. Generated by `figures/28-mfg-solver.py`.

in which $v(t)$ is the rank-one type-modulation amplitude (the forward variable), $\psi(t)$ the reduced costate, $P \equiv 1$ the Riccati curvature of worked computation 14.10, and the closed-loop drift coefficient is $a - b^2 P = -\omega = -1$ in this normalization. The full type×state solver reproduces the order parameter to

$$\max_t \big| \varrho_t^{\mathrm{num}} - \varrho_t^{\mathrm{exact}} \big| \approx 9.5 \times 10^{-3}, \qquad \max_k \big| \bar{m}_T^{x_k} - \big(\bar{m}_0\, e^{(a-b^2P)T} + f(x_k)v(T)\big) \big| \approx 5.1 \times 10^{-3},$$

the second bound confirming that the computed *per-type* means align with the predicted affine-in-f profile $\bar{m}_t^x = \bar{m}_0\, e^{(a-b^2P)t} + f(x)v(t)$ of the rank-one collapse. The right panel of fig. 28.1 overlays the computed and analytic ϱ_t. Both threads are thus validated: the generic forward–backward solver reproduces the explicit Riccati answer, and the graphon machinery reproduces the rank-one reduction, with errors decreasing under grid refinement exactly as theorems 28.3 and 28.11 require.

Remark 28.13 (Why the validation is a genuine test)**.** The closed forms of chapter 14 were derived by exploiting the linear–quadratic structure—Gaussian ansatz, Riccati reduction, linear BVP—none of which the finite-difference solver knows about. The solver discretizes the *nonlinear* HJB equation (the quadratic Hamiltonian term $+\frac{1}{2}b^2(\partial_x u)^2$ entering $-\partial_t u - \frac{1}{2}\sigma^2\partial_{xx}u + H = F$ is genuinely nonlinear in $\partial_x u$ and is handled by Howard iteration, not by any quadratic ansatz) and the full Fokker–Planck PDE on a state grid, and finds the forward–backward fixed point by iteration. That this black-box PDE computation reproduces the pencil-and-paper Riccati answer to three digits, and reproduces the rank-one order parameter to the same accuracy through an honest quadrature of $\mathbb{W}$, is therefore a real cross-check of both the analysis of chapter 14 and the implementation of sections 28.2 and 28.5—each validates the other.

Rigor ledger

Proved.

- The discrete HJB generator $\mathcal{A}_h$ (upwind, eq. (28.7)) is a rate matrix and $I - \Delta t\, \mathcal{A}_h$ is a nonsingular M-matrix (discrete maximum principle), lemma 28.1.
- The adjoint Fokker–Planck step eq. (28.10) conserves mass, preserves positivity, and is the exact transpose of the linearized HJB step, lemma 28.2.
- Howard (policy-iteration) sweeps converge monotonically and superlinearly (proved in-book from the M-matrix structure, section 28.2.1); the Barles–Souganidis monotone-scheme theorem is proved in-book, theorem E.20.
- The discrete potential MFG is a finite convex program whose KKT system is the finite-difference HJB–FP system, proposition 28.7; consequently primal–dual methods converge unconditionally in the potential case, theorem 28.8, whose ergodic $O(1/k)$ gap is the in-book Chambolle–Pock bound theorem I.2 of appendix I.
- Quadrature error $O(K^{-1})$ (resp. $O(K^{-2})$) for the coupling operator $\mathbb{W}_K$ under Lipschitz (resp. C^2) type-regularity, with $\|\mathbb{W}_K\| \to \|\mathbb{W}\|$, proposition 28.10; the three-term error bound eq. (28.23) for the graphon solver, theorem 28.11.
- Numerical validation: the forward–backward solver reproduces the Thread A Riccati mean to 9.3×10^{-3} and the Thread B rank-one order parameter to 9.5×10^{-3} (worked computation 28.12, fig. 28.1).

Assumed.

- (A-Nondeg) for the parabolic regularization underlying both the viscosity-solution convergence and the Gaussian-tail boundary truncation; (A-Conv) for the well-posed pointwise minimization in Howard iteration; (A-Mon) for convexity of the variational problem and for fictitious-play stabilization; (A-Coupling) $C_T\,\|\mathbb{W}\| < 1$ for outer-loop contraction (distinct in general from the sharp phase boundary $s\,\|\mathbb{W}\| = 1$ of theorem 14.11, with which it coincides only in the $a = 0$, $C_T = 1$ normalization of worked computation 28.12).

Deferred.

- The monotone-scheme convergence engine and the primal–dual rate are resolved *in-book*: Barles–Souganidis in theorem E.20, the Chambolle–Pock ergodic $O(1/k)$ bound in theorem I.2, with the supporting parabolic estimates in appendix E (theorems E.17 and E.19) and compactness in chapters 2 and 3. What remains quoted from Achdou–Porretta [3] (see remark 28.4) is only the sharp-constant accounting of the first-order rate for the coupled system; the MFG-specific proximal maps are from [47, 32].

- The cut-norm/regularity control linking the type-grid stepping operator to the equilibrium error is deferred to chapter 19 (theorem 19.8) and the stability program of chapters 24 and 25.
- Learning-based solvers (fictitious play beyond the LQG check, policy-gradient/PPO) are deferred to chapter 29.

Open.

- Provably convergent, scalable solvers for *non-potential, non-monotone* MFG beyond the subcritical/short-horizon regime—i.e. past the conjugate horizons of theorem 14.11—remain open; no method is known to reliably select among multiple equilibria or to converge unconditionally there.
- High-dimensional state spaces ($d \gg 3$) defeat the grid-based schemes of this chapter (curse of dimensionality); deep-learning and probabilistic solvers [42] are the active frontier, with convergence guarantees still partial. This is the bridge to chapter 29.

Bibliographic notes

The finite-difference scheme for the HJB–Fokker–Planck system—monotone upwind backward operator, conservative forward operator taken as its transpose, and the structure-preserving duality between them—is due to Achdou and Capuzzo-Dolcetta [1]; the survey of Achdou and Laurière [2] is the modern reference for the numerical state of the art, including the Newton and policy-iteration outer loops. The convergence of the coupled scheme to weak solutions of the MFG system is proved by Achdou and Porretta [3], building on the abstract monotone-scheme convergence theory of Barles and Souganidis [13] for viscosity solutions (chapter 6, [52, 12]); we give an in-book proof of that monotone-scheme theorem in theorem E.20, resting on the comparison principle of appendix E. The fixed-point/fictitious-play analysis of the outer loop, and its convergence for monotone games, is due to Cardaliaguet and Hadikhanloo [38]; the connection to learning dynamics is developed in chapter 29. The variational/primal–dual approach to potential MFG originates with the augmented-Lagrangian method of Benamou and Carlier [19], a descendant of the Benamou–Brenier algorithm for dynamic optimal transport [18, 117]; the first-order primal–dual (Chambolle–Pock) viewpoint [47] and its application to MFG with local couplings are worked out by Briceño-Arias, Kalise, and Silva [32]; the ergodic $O(1/k)$ convergence bound itself we prove in-book in appendix I (theorem I.2). The variational characterization that underlies all of these is the potential-game theorem of Lasry and Lions as presented in chapter 8 (theorem 8.11) and Cardaliaguet's notes [36]. The graphon discretization—type grid feeding a state grid, $\mathbb{W}$ realized as a quadrature, block-graphon reduction to multi-population MFG—follows the operator and sampling theory of Part IV (chapters 18 and 19) and the weak regularity lemma [99, 72]; the complexity economy of the rank-one collapse is the computational face of the reduction of chapter 14 and [34, 108]. Deep-learning and high-dimensional solvers, the escape from the curse of dimensionality, and their partial convergence theory [42] are the subject of chapter 29.

Chapter 29

Reinforcement Learning for Graphon Mean Field Games

Every method in this book so far has presupposed that the modeller *knows the model*: the drift b, the volatility σ, the running cost L, the terminal cost g, and the coupling kernel W are all given in closed form, and the equilibrium is found by *solving* a coupled system — the forward–backward PDE pair of chapter 8, the FBSDE of chapter 9, or their graphon lifts of chapters 22 and 23. The numerical schemes of chapter 28 do not lift this demand; they only sharpen it, discretising equations that one must first be able to write down. This chapter abandons the presupposition altogether — it is the single largest pivot in the book — and asks what to do when the model is no longer in hand.

Three quite different obstructions force the change, and it is worth feeling each one concretely before section 29.1 names them. Sometimes the dynamics are a *black box*: an agent's transitions are produced by a market-microstructure matching engine, by an epidemic compartment model with behavioural feedback, or by a traffic micro-simulation — any of which one can *run* forward from a chosen state and action, but none of which hands over b, σ, L in a form a PDE solver can ingest. Sometimes the state is simply too large to grid: a finite-difference mesh on $\mathcal{S} \subseteq \mathbb{R}^d$ carries a number of nodes that explodes like $(\text{resolution})^d$, so that a portfolio of a dozen assets or a queueing network of a dozen servers is already out of reach. And in the graphon setting the population is not one measure but a whole *continuum of types* $x \mapsto m^x$ (definition 21.4), so that even a known, low-dimensional per-type problem must be solved simultaneously for a one-parameter family of agents coupled through the kernel W. In each case *solving* is unavailable, and the only primitive left is the ability to *sample* — to draw a next state and an incurred cost from wherever one happens to stand.

The answer is to *learn* the equilibrium by reinforcement learning (RL), and what turns this from a hope into a programme is one structural fact we have already proved analytically. A mean field game equilibrium is a *fixed point between two maps* — a best response that a single agent computes against a frozen population, and a push-forward that the population executes against a frozen policy — and a fixed point is exactly the kind of object an iterative loop can chase even when each of the two maps is available only through samples. This is the load-bearing sentence the entire chapter unpacks: it converts the existence theorem of chapter 8 into an algorithm, and it is the reason the analytic structure built up across Parts II–IV survives, essentially unchanged, into the model-free world.

We import three things. From chapter 8 (proposition 8.4) the characterisation of an MFG equilibrium as a fixed point of the composition "best-respond, then push the population forward." From chapters 11 and 24 the Lasry–Lions monotonicity condition (A-Mon) — in its classical scalar form (definition 11.1 and theorem 11.5) and, for the type-indexed population of section 29.4, its graphon form (definition 24.15 and theorem 24.16) — which will reappear as the precise hypothesis under which the learning iterations converge. From the graphon synthesis of chapters 20, 21 and 24 the type-indexed equilibrium (definition 21.16 and eq. (21.16)), the (observable) aggregate $z(x) = (\mathbb{W}\,\Lambda[m^{\cdot}])(x)$ — Part IV's Θ-aggregate of eq. (21.4), written z here per notationwatch (v) — and the operator-norm smallness condition (A-Coupling) that powered the contraction proofs (theorem 20.14 and chapter 24). Our task is to show that these same two hypotheses — contraction *or* monotonicity — are what separate a learning loop that converges from one that cycles forever, and to make precise what a deep policy-gradient method such as PPO can and cannot guarantee when the analytic structure is replaced by neural-network function approximation and Monte Carlo sampling.

The chapter is organised as follows. Section 29.1 sets up the discrete-time *mean field Markov decision process* (MFMDP), the natural object on which RL operates, and explains the modelling choices (time discretisation, the simulator hypothesis) that turn the continuous-time games of Parts II–IV into something learnable. Section 29.2 isolates the two maps, defines the *exploitability* functional that an algorithm minimises, and analyses the naive fixed-point iteration, exhibiting exactly when it contracts and why it usually does not. Section 29.3 introduces the two stabilisers — entropy regularisation together with *fictitious play* and *online mirror descent* — and proves their convergence under monotonicity; a worked computation on the LQG thread makes the dichotomy "contract vs. average" completely explicit. Section 29.4 lifts everything to the type-indexed population, presents GMFG-PPO, and shows how the graphon coupling is represented *inside* the value and policy networks. Section 29.5 assembles a modular convergence guarantee and catalogues the failure modes honestly. Throughout, the convention of the book is in force: *value functions are computed backward* (terminal data, dynamic programming) and *population distributions evolve forward* (initial data, push-forward); in the discrete setting these become backward Bellman recursion and forward state-distribution propagation, respectively.

Notation watch

Five conventions need reconciling with the RL literature and with the rest of the book; in each we name the clash the convention exists to prevent, not merely the choice we make. *(i) Cost vs. reward.* This book *minimises cost* (chapters 6 and 8) while RL conventionally *maximises reward*, and the two differ by an overall sign that, if left unflipped, silently turns every $\arg\min$ in a Bellman recursion into an $\arg\max$ and reverses the direction of every inequality below. We keep cost minimisation throughout; a reader translating an RL paper should read "reward $= -L$" and flip the relevant suprema, infima, and monotonicity signs together, not one at a time. *(ii) Discount.* The book's symbol $\beta = \beta$ is a discount *rate*, carrying units of inverse time (appendix A); a discrete-time MDP instead carries a dimensionless per-step *factor*, and writing both as β would conflate a rate with a pure number and corrupt the $\Delta t \to 0$ bookkeeping. We therefore reserve the distinct symbol $\gamma \in (0, 1]$ for the factor, related to the rate by $\gamma = e^{-\beta\,\Delta t}$ over a step of length Δt. A finite-horizon undiscounted problem is the case $\gamma = 1$, $K < \infty$; the symbol γ is local to this chapter. *(iii) Brownian motion vs. graphon.* Both objects classically lay claim to the letter W; as announced in appendix A and chapter 21, whenever the kernel W is in scope Brownian motion is written B. Here the dynamics are usually presented as transition kernels P_k rather than as SDEs, so the noise letter seldom appears and the clash rarely surfaces, but the convention stands wherever it does. *(iv) Best response: the two halves of the flow map.* This is the conceptual hinge of the chapter, so we belabour it. In chapters 8 and 28 the symbol S $(= \Phi)$ denotes the *full* dynamic flow self-map $\bar{m}_\bullet \mapsto m'_\bullet$ — one backward HJB sweep immediately followed by one forward Fokker–Planck sweep, fused into a single object whose fixed point is the equilibrium (eq. (28.2), proposition 8.4). That fusion was harmless when the only question was *whether* a fixed point exists, but it cannot survive here, because a learner performs the two sweeps with utterly different machinery — the backward sweep is a single-agent RL problem solved against a frozen population, the forward sweep is a Monte Carlo rollout of that population under a frozen policy — and the two analytic hypotheses of the chapter act on the two sweeps *separately.* We therefore split the composite and name the halves: S here is the *policy-valued* best response $\bar{m}_\bullet \mapsto \pi$ (the backward, dynamic-programming half, definition 29.2) and Ψ the *population* push-forward $\pi \mapsto m'_\bullet$ (the forward half, definition 29.3). The single map of chapters 8 and 28 is exactly the composite $\Psi \circ \mathsf{S}$, and we always write that composite out rather than abbreviate it, precisely so that statements like "the best response has Lipschitz modulus L_{S}" and "the push-forward has modulus L_Ψ" can be made about the two halves one at a time — it is their *product* $L_{\mathsf{S}} L_\Psi$ that the contraction condition will constrain (definition 29.9 and theorem 29.10), a statement that has no meaning until the seam is exposed. *(v) The graphon aggregate.* The general (vector-)observable aggregate written $z_k(x)$ below (eq. (29.24)) is Part IV's Θ-aggregate of eq. (21.4); we retain the letter z only because Θ is needed for Landau order-notation throughout this chapter, and reserve z for the identity-observable LQG case exactly as in eq. (21.5). Likewise Part IV's scalar test function h in $\langle h, m\rangle$ is here promoted to a (possibly vector) measure functional $\Lambda : \mathcal{P}(\mathcal{S}) \to \mathbb{R}^{d'}$, with $\Lambda(m) = \langle h, m\rangle$ recovering the scalar case of definition 21.5.

29.1 When learning replaces solving

The chapter's pivot, announced in the preamble, now has to be earned twice over. Before we may responsibly *learn* an equilibrium we owe the reader an honest account of *why* the analytic and numerical programme of the earlier parts — the forward–backward solvers that presuppose a fully specified model — is sometimes simply unusable; and once that case is made, we must replace those continuous, model-laden equations with a discrete object on which a sampling algorithm can actually run. This section does both, in that order. The first subsection sharpens the preamble's three deficiencies into three named failure modes, concrete situations in which solving is not merely expensive but impossible, so that learning is forced rather than chosen. The second then constructs the *mean field Markov decision process*, the discrete-time avatar of the games of chapter 8 on which every reinforcement learning algorithm of this chapter operates; there the book's backward-value convention reappears as a Bellman recursion and its forward-density convention as a push-forward of distributions, exactly as the preamble promised. This header only orients and hands the baton; the substance lives in the two subsections, and we begin with the failure modes, because they fix what the learnable object must be able to do.

29.1.1 Three failure modes of the analytic programme

The preamble promised that learning would be *forced*, not merely fashionable, and that promise now has to be redeemed concretely. The forward–backward solvers of chapter 28 are genuinely powerful — where they apply, they return the equilibrium to high precision — but they are not free-standing algorithms; they are subroutines that consume, as input, a complete and exact specification of the game: the drift b, the volatility σ, the running cost L, the terminal cost g, and (in the graphon setting) the kernel W, all in closed form. The discretisations of chapter 28 do not soften that requirement; a finite-difference stencil for the HJB equation (8.5a) cannot be assembled without the coefficients it is meant to discretise. So the operative question is not "is the solver accurate?" but "can the solver even be *fed*?" — and there are three recurring situations, drawn from genuinely different corners of applied modelling, in which the answer is no. We draw each one fully, because the shape of the obstruction dictates the shape of the cure, and the third in particular is the one the whole machinery of section 29.4 is built to dissolve.

Failure mode 1: the dynamics are a black box one can only sample. The first and most common obstruction is that the transition law of an agent is simply not available as an SDE with writable coefficients. In a wide range of applications the "model" is a piece of software — a simulator — whose internal logic is far too intricate to compress into a drift and a diffusion. Three concrete instances make the abstraction tangible. In *market microstructure*, an agent's next inventory and the price it transacts at are produced by a limit-order-book matching engine: queue priorities, partial fills, latency, and the reactive quoting of other participants together determine the outcome, and no closed-form $b(s, a)$ summarises the engine. In *epidemics with behavioural feedback*, the next health-and-contact state of an individual is generated by a compartmental simulator coupled to a behavioural module in which agents adjust their contact rates in response to perceived prevalence; the feedback loop between behaviour and transmission has no tidy McKean–Vlasov drift. In *traffic*, an agent's next position is the output of a microscopic car-following-and-routing simulation on a road network, with signals, merges, and capacity constraints. In every case one can do exactly one thing: place the agent at any state s, command any action a, *run* the simulator one step, and *observe* the realised next state s' and the realised cost. One cannot, however, open the box and read off b, σ, L in a form a PDE solver could ingest. This is the *simulator* hypothesis (in the RL literature, the *generative-model* hypothesis): the model is accessible *only* as a sampler, a map $(s, a) \mapsto (s', \mathrm{cost})$ realised by calling the simulator, never as a system of equations. Every algorithm in this chapter is engineered to need nothing more than this single sampling primitive, because in this regime it is all there is.

Failure mode 2: the state space is too large to grid. The second obstruction survives even when the dynamics *are* known in closed form, and it is purely a matter of dimension. The finite-difference schemes of chapter 28 represent the value function and the density by their values at the nodes of a grid laid over the state space $\mathcal{S} \subseteq \mathbb{R}^d$. To resolve each coordinate to a relative accuracy ε one needs on the order of $1/\varepsilon$ nodes per axis, hence about $(1/\varepsilon)^d = (\text{resolution})^d$ nodes in all — the storage and the per-sweep cost grow *exponentially* in the dimension d. This is the curse of dimensionality, and it bites with brutal speed: a portfolio of a dozen correlated assets ($d = 12$) or a queueing network of a dozen interacting servers already places, at a mere ten points per axis, 10^{12} nodes on the grid — beyond any memory, before one has taken a single time step. No refinement of the stencil escapes an exponential; the only known route out is to abandon the grid entirely and represent u and π by a *parametric family* — a function approximator, in practice a neural network — whose size is fixed in advance and does not scale with a notional resolution. A network with a few million weights carries the same parameter budget whether $\mathcal{S}$ sits in $\mathbb{R}^2$ or in $\mathbb{R}^{200}$; the dependence on d moves out of the representation cost and into the (far milder) sample complexity of fitting it. This trade — exponential grids for fixed-size approximators trained on samples — is the second reason the chapter is model-free in spirit even where the model is known, and it is what makes the simulator primitive of failure mode 1 not just necessary but *sufficient*: samples are exactly what a network is fit on.

Failure mode 3: the population is a continuum of types. The third obstruction is the one native to this book, and it compounds the first two rather than replacing them. In the graphon setting of Part IV the population is not a single measure but an entire *field* of measures, a one-parameter family $x \mapsto m^x \in \mathcal{P}(\mathcal{S})$ indexed by the agent's type $x \in [0,1]$ (definition 21.4), the types coupled through the kernel W so that the environment felt by an agent of type x is the aggregate $z(x) = (\mathbb{W}\,\Lambda[m^\cdot])(x)$ built by integrating against *all* other types. A solver that already grids the state space must now also grid the type axis and solve the per-type equilibrium problem *simultaneously* across that grid, evaluating a quadrature for the operator $\mathbb{W}$ at every type and at every time step (chapter 28). The costs multiply: a J-point type grid multiplies the work by J, and the per-step $\mathbb{W}$-quadrature couples the J problems so they cannot be solved independently. Even when each individual per-type problem is low-dimensional and benign, doing J of them in lockstep with all-to-all coupling at every stage is precisely the kind of cost the analytic programme cannot absorb at scale. The escape is structural and is worth naming now, because it is the load-bearing design decision of section 29.4: rather than learn a separate object for each type, one learns a *single*, type-*conditioned* policy — one neural network that accepts the type x (and the local aggregate it faces) as part of its input and outputs that type's action distribution. A single set of weights then *amortises* across the entire continuum of types: training signal gathered at one type informs the policy at nearby types through the shared parameters, the graphon enters only as an external quadrature feeding the aggregate into the network's input, and the J-fold blow-up never materialises. The reader should hear this third failure mode as foreshadowing: it is the obstruction whose resolution — one shared, type-conditioned network amortising the continuum, the kernel demoted to a quadrature on the input — is exactly what GMFG-PPO is in section 29.4, and it is the reason a chapter that could have stopped at scalar MFG instead carries the type label all the way through.

The unifying response. The three failure modes differ in cause — an unwritable model, an unaffordable grid, a continuum of coupled problems — but they call for one and the same change of strategy, and articulating it is the bridge into the rest of the chapter. In every case we abandon the ambition of *computing* the equilibrium fields (u, m) from their defining equations, and adopt instead the ambition of *learning an equilibrium policy* directly from interaction. The plan exploits the one structural fact the preamble isolated: an equilibrium is a fixed point of "best-respond, then push the population forward." So we build a loop. Freeze a guess at the population; *best-respond* to it by solving, with any sampling-based RL method, the single-agent control problem an individual faces in that frozen environment; then *update* the population by rolling many copies of that response forward through the simulator and reading off the distribution they realise; then repeat, hoping the two converge to mutual consistency. Nothing in this loop ever asks to write down b, σ, L, ever lays a grid on $\mathcal{S}$, or ever solves the J types as a coupled monolith — it asks only to sample, to fit an approximator, and to evaluate a quadrature, which is exactly what the three failure modes leave us able to do. But so far the loop is only a hope: "best-respond" and "update" are still informal verbs, and whether their alternation actually converges or instead cycles forever is the entire technical content of the chapter. To make either question precise we first need a discrete, samplable object on which the two verbs become honest maps with domains, codomains, and a fixed point. Building that object — the mean field Markov decision process, on which "best-respond" becomes a backward Bellman recursion and "update" a forward push-forward of distributions — is the task of the next subsection.

29.1.2 The mean field Markov decision process

The previous subsection left us with a loop whose two verbs — *best-respond* to a frozen population, then *update* the population by rolling the response forward — are still only verbs, and with a demand attached: before we may ask whether their alternation converges we must realise them as honest maps on a discrete object a simulator can actually touch. This subsection builds that object. Reinforcement learning is native to discrete time — its updates are indexed by transitions (s, a, s', cost), not by an infinitesimal generator — so the first task is to record the discrete-time *avatar* of the continuous mean field game of chapter 8, on which "best-respond" will become a backward Bellman recursion and "update" a forward push-forward of distributions, exactly along the backward/forward seam the preamble fixed (value functions backward from terminal data, populations forward from initial data).

The avatar is obtained by time-stepping, and it is worth seeing precisely how the two continuous objects turn into their discrete shadows, because the whole chapter trades on the correspondence. Partition the horizon $[0, T]$ into K stages of length $\Delta t = T/K$, write $k \in \{0, \ldots, K-1\}$ for the stage index and s for the state at stage k, and note that the two governing equations of chapter 8 are integrated in opposite directions of time. The backward Hamilton–Jacobi–Bellman equation (8.5a), read as the cost-minimisation principle "the value now is the best action's instantaneous cost plus the discounted value an instant later," becomes under one explicit Euler step the prescription

$$u_k(s) = \min_a \Big\{ L_k(s, a, m_k) + e^{-\beta \Delta t}\, \mathbb{E}[u_{k+1}(S_{k+1}) \mid S_k = s, A_k = a] \Big\},$$

where the one-step transition $S_{k+1} \sim P_k(\cdot \mid s, a, m_k)$ is the Euler–Maruyama push of the underlying

SDE — for $\mathrm{d}X = b\ \mathrm{d}t + \sigma\ \mathrm{d}B$ it is the Gaussian $P_k(\cdot \mid s, a, m) = \mathcal{N}(s + b(s, a, m)\,\Delta t,\ \sigma\sigma^\top \Delta t)$ — the running cost L_k absorbs the time-integrated stage cost $\int_{k\Delta t}^{(k+1)\Delta t} L\ \mathrm{d}t \approx L\,\Delta t$, and the discount *rate* β of the continuous problem reappears as a dimensionless per-step *factor* $\gamma = e^{-\beta\Delta t}$, exactly the substitution flagged in notationwatch (ii). That this is a faithful discretisation and not a loose analogy can be checked by reversing the step: expanding $\mathbb{E}[u_{k+1}(S_{k+1})] = u_{k+1}(s) + \Delta t(b\cdot\nabla u_{k+1} + \frac{1}{2}\sigma\sigma^\top : D^2 u_{k+1}) + o(\Delta t)$ and collecting the $O(\Delta t)$ terms returns (8.5a) as $\Delta t \to 0$. Dually, the forward Fokker–Planck (continuity) equation (8.5b), which transports the population density, becomes under the same step a push-forward of measures: the mass sitting at s at stage k is carried to stage $k+1$ by drawing an action from the policy and a next state from P_k. We write both recursions down in their own right below and treat the discrete object as primary, because it — not the PDE pair — is what the learner manipulates.

Definition 29.1 (Mean field Markov decision process)**.** A *mean field MDP* (MFMDP) consists of: a Polish *state space* $\mathcal{S}$; a compact metric *action set* A; a horizon $K \in \mathbb{N}$ with stages $k \in \{0, 1, \dots, K-1\}$; an *initial law* $m_0 \in \mathcal{P}(\mathcal{S})$; for each stage k a *transition kernel*

$$P_k :\ \mathcal{S} \times A \times \mathcal{P}(\mathcal{S}) \ \longrightarrow\ \mathcal{P}(\mathcal{S}), \qquad (s, a, m) \mapsto P_k(\,\cdot \mid s, a, m),$$

a *running cost* $L_k : \mathcal{S} \times A \times \mathcal{P}(\mathcal{S}) \to \mathbb{R}$, a *terminal cost* $g : \mathcal{S} \times \mathcal{P}(\mathcal{S}) \to \mathbb{R}$, and a per-step discount factor $\gamma \in (0, 1]$ (the factor of notationwatch (ii), distinct from the book's rate β). A *flow* is a sequence $m_\bullet = (m_k)_{k=0}^K$ with each $m_k \in \mathcal{P}(\mathcal{S})$. A (Markov, stochastic) *policy* is a sequence $\pi = (\pi_k)_{k=0}^{K-1}$ of measurable maps $\pi_k : \mathcal{S} \to \mathcal{P}(A)$, written $\pi_k(\mathrm{d}a \mid s)$.

Every datum in definition 29.1 earns its place, and three features deserve to be read slowly because they are exactly the points at which the mean field structure enters. First, the stage subscript on P_k and L_k records that the problem is *time-inhomogeneous*: a finite-horizon control problem is genuinely non-stationary — the value of a state depends on how many stages remain — so we must carry k explicitly and cannot collapse to a single stationary kernel. Second, and most important, P_k and L_k each take the population law m as a *third argument*. This is the mean field interaction made discrete: an agent's transition law and incurred cost are modulated by the current population distribution, so the environment an individual faces is not fixed but is *generated by the very population the individual belongs to*. This is precisely the McKean–Vlasov coupling of chapter 7, where the drift of a representative particle depends on the law of the particle itself, transcribed to a one-step kernel; and it is the same coupling that, frozen at a candidate law, defines the single-agent control problem of the MFG in chapter 8. The whole difficulty of the chapter — and the reason an equilibrium is a fixed point rather than the output of one optimisation — lives in this third slot: change m and you change the problem the agent is solving. Third, the discount γ is a dimensionless per-step factor, not the rate β, for the bookkeeping reason set out in notationwatch (ii); the finite-horizon undiscounted game is simply $\gamma = 1$ with $K < \infty$.

Fix a flow $m_\bullet$ now, and hold it frozen; call it the *environment*. The point of freezing is that it severs the mean field coupling: with m no longer responding to the agent, the third argument of P_k and L_k becomes a known, externally supplied sequence, and the agent faces an *ordinary* (time-inhomogeneous, single-agent) Markov decision process. Concretely, starting from $S_k = s$ and following π, with $A_k \sim \pi_k(\cdot \mid S_k)$ and $S_{k+1} \sim P_k(\cdot \mid S_k, A_k, m_k)$, the agent accumulates discounted cost, and the relevant quantity is the *cost-to-go*: the expected remaining discounted cost from stage k onward. Because the horizon is finite and the terminal cost is known, the cost-to-go is computed *backward* from $k = K$ — this is the discrete face of the book-wide convention that value functions are solved from terminal data. This is the half of the loop that "best-respond" will become; we make it precise next.

Definition 29.2 (Value, action-value, best response)**.** Given an environment $m_\bullet$ and a policy π, the *value function* $u_k^{m_\bullet,\pi} : \mathcal{S} \to \mathbb{R}$ is defined by the backward recursion

$$u_K^{m_\bullet,\pi}(s) = g(s, m_K), \qquad u_k^{m_\bullet,\pi}(s) = \mathbb{E}\Big[L_k(s, A_k, m_k) + \gamma\, u_{k+1}^{m_\bullet,\pi}(S_{k+1})\Big], \tag{29.1}$$

the expectation over $A_k \sim \pi_k(\cdot \mid s)$ and $S_{k+1} \sim P_k(\cdot \mid s, A_k, m_k)$. The *optimal value* $u_k^{m_\bullet}$ and the *action-value* (Q-)function $Q_k^{m_\bullet}$ solve the backward *Bellman optimality* recursion

$$Q_k^{m_\bullet}(s,a) = L_k(s,a,m_k) + \gamma\,\mathbb{E}\Big[u_{k+1}^{m_\bullet}(S_{k+1}) \mid S_k = s, A_k = a\Big], \qquad u_k^{m_\bullet}(s) = \min_{a\in A} Q_k^{m_\bullet}(s,a), \tag{29.2}$$

with $u_K^{m_\bullet} = g(\cdot, m_K)$. A policy π is a *best response* to $m_\bullet$ if $\pi_k(\cdot \mid s)$ is supported on $\arg\min_a Q_k^{m_\bullet}(s,a)$ for every (k,s); the set of best responses is denoted $\mathsf{S}(m_\bullet)$.

The two recursions in definition 29.2 deserve to be read one stage at a time, because their one-stage logic is exactly what makes them *samplable* — the property the whole chapter needs. Take the policy-evaluation recursion (29.1) first. Its terminal line is pure data: at $k = K$ no decision remains, so the cost-to-go is the terminal cost $g(s, m_K)$. For $k < K$, the value at s is the expected sum of two pieces an agent at s incurs in *one* step under π: the immediate cost $L_k(s, A_k, m_k)$ of the action it draws, plus the discounted cost-to-go $\gamma\, u_{k+1}$ already computed at the state it lands in. Because the right-hand side refers only to stage k's data and to u_{k+1} — never to u_k itself — the recursion is a genuine backward sweep: knowing the whole function u_{k+1} determines the whole function u_k by a single one-step expectation, with no implicit equation to solve. That one-step expectation is exactly a Monte Carlo quantity: draw $A_k \sim \pi_k(\cdot \mid s)$, call the simulator once to get S_{k+1} and the realised cost, and average. The Bellman optimality recursion (29.2) differs in one place only — where (29.1) *averages* over the action drawn from π, optimality *minimises* over the action. The action-value $Q_k^{m_\bullet}(s,a)$ isolates the cost of committing to action a now and behaving optimally thereafter, and $u_k^{m_\bullet}(s) = \min_a Q_k^{m_\bullet}(s,a)$ selects the best such commitment. A best response is then any policy that places its mass on the minimising actions, stage by stage and state by state; the set of all such policies is $\mathsf{S}(m_\bullet)$, the policy-valued backward half of the flow map named in notationwatch (iv).

Equation (29.2) is the discrete, sampling-friendly form of the HJB equation (8.5a), and the correspondence is exact term by term. The minimisation over a of the instantaneous cost plus the discounted continuation value *is* the discrete Hamiltonian: writing $\mathbb{E}[u_{k+1}(S_{k+1}) \mid s, a] = u_{k+1}(s) + \Delta t\, b(s,a,m_k)\cdot\nabla u_{k+1}(s) + O(\Delta t)$, the part of $Q_k(s,a)$ that actually depends on a is, to leading order in Δt, $L_k(s,a,m_k) + \Delta t\, b(s,a,m_k)\cdot\nabla u_{k+1}(s)$, whose minimisation over a is precisely the Legendre–Fenchel transform that defines the Hamiltonian $H(s, \nabla u, m)$ of chapter 6. The backward direction of the recursion is the discrete avatar of "value propagates inward from the terminal time," and the minimiser inherits the continuous meaning as well: the optimal feedback $\alpha^* = -\partial_p H$ of the verification theorem (chapter 6) becomes the *greedy* selection $a \mapsto \arg\min_a Q_k(s,a)$. The continuous gradient $-\partial_p H$ and the discrete arg min are the same object viewed at two resolutions; the discrete one is the one a simulator can evaluate, because it needs only the ability to score actions by sampled returns, never the closed-form Hamiltonian.

A one-stage instance of the LQG thread (Thread A, chapter 6) makes the abstract recursion concrete and exhibits the greedy arg min as a linear feedback. Take scalar state and dynamics $\mathrm{d}X = (aX + b\alpha)\,\mathrm{d}t + \sigma\,\mathrm{d}B$, so the Euler step gives the Gaussian kernel $P_k(\cdot \mid s,\alpha) = \mathcal{N}(s + (as + b\alpha)\Delta t,\ \sigma^2\Delta t)$, and take the mean-coupling running cost of the thread, $L_k(s,\alpha,m_k) = (\frac{1}{2}\alpha^2 + \frac{q}{2}(s - \kappa\bar{m}_k)^2)\Delta t$, where $\bar{m}_k = \int \xi\, m_k(\mathrm{d}\xi)$ is the population mean and κ is the mean-coupling weight (the thread's parameter s, written κ only here, since s already denotes the state). Suppose inductively that $u^{m_\bullet}_{k+1}(s) = \frac{1}{2}P_{k+1}s^2 + r_{k+1}s + \text{const}$ is quadratic, with Riccati curvature P_{k+1} and offset r_{k+1} in the thread's canonical symbols. Then $Q_k(s,\alpha)$ is quadratic in α with a positive leading $\frac{1}{2}\Delta t\,(1 + \gamma b^2 P_{k+1}\Delta t)\,\alpha^2$ term, so the greedy action is the unique *affine* feedback obtained by setting $\partial_\alpha Q_k = 0$, $\alpha^*(s) = -\gamma b\,(P_{k+1}s + r_{k+1}) + O(\Delta t)$ — linear in s with an offset fed by the population through r_{k+1} — and substituting it back preserves the quadratic form, advancing $(P_{k+1}, r_{k+1}) \mapsto (P_k, r_k)$ by exactly the one-step discrete Riccati recursion. Sending $\Delta t \to 0$ recovers the continuous Riccati ODE and the feedback $\alpha^* = -b\,(P(t)s + r(t))$ of chapter 6; the greedy arg min is the discrete shadow of $-\partial_p H$, as promised. The mean field coupling sits entirely in $\bar{m}_k$, which feeds the offset r_k and hence shifts where the agent is pulled — the single thread that the forward map will have to make consistent.

Definition 29.3 (Induced flow; the mean-field map)**.** Given a policy π and the fixed initial law m_0, the *induced flow* $\Psi(\pi) = m_\bullet$ is generated forward by

$$m_{k+1}(\mathrm{d}s') = \int_{\mathcal{S}}\int_A P_k(\mathrm{d}s' \mid s,a,m_k)\,\pi_k(\mathrm{d}a \mid s)\,m_k(\mathrm{d}s), \qquad k = 0,\dots,K-1. \tag{29.3}$$

The map Ψ is the forward half of the loop — the discrete avatar of "update the population" — and (29.3) is best read as a one-stage transport, line by line as the backward recursion was. Fix the stage law m_k and the stage policy π_k. The integral builds m_{k+1} by following an infinitesimal packet of probability through exactly one step of the simulator: start it at s with weight $m_k(\mathrm{d}s)$, let the agent draw an action with the stage-k probabilities $\pi_k(\mathrm{d}a \mid s)$, and scatter it to its next state according to the transition kernel $P_k(\mathrm{d}s' \mid s,a,m_k)$; integrating out the intermediate s and a leaves the distribution of where the packet lands. This is nothing but the Chapman–Kolmogorov forward equation for the controlled chain, and it is the discrete Fokker–Planck/continuity equation (8.5b) of chapter 8: probability mass is transported forward by the policy through the transition kernel, in the same time direction and with the same conservation law as the continuous flow.

Two structural facts about (29.3) matter and are worth stating explicitly, since they are what make Ψ a bona fide map and not merely a formula. First, *mass is conserved*: integrating the right-hand side over all $s' \in \mathcal{S}$ and using that each $P_k(\cdot \mid s,a,m_k)$ is a probability measure (total mass one) collapses the inner integral to 1, leaving $\int_{\mathcal{S}} \pi_k(\mathrm{d}a \mid s)\,m_k(\mathrm{d}s) = \int_{\mathcal{S}} m_k(\mathrm{d}s) = 1$, so $m_{k+1} \in \mathcal{P}(\mathcal{S})$ whenever $m_k \in \mathcal{P}(\mathcal{S})$ — a probability law is mapped to a probability law, exactly as the continuity equation conserves total density. Second, the recursion is *well posed* as a forward sweep: the right-hand side of (29.3) involves only m_k and π_k (the latter through both π_k itself and the kernel's measure argument m_k), never m_{k+1} on which it is solving, and never any later stage. There is no implicit equation and no coupling across stages to untangle: given the initial law m_0, applying (29.3) once yields m_1, applying it again yields m_2, and so on, so the entire induced flow $\Psi(\pi) = (m_0, m_1, \ldots, m_K)$ is built deterministically one stage at a time from π and m_0. This is what licenses the simulator realisation already used informally: roll many independent copies of the agent forward under π and read off the stage-k empirical measure, which converges to m_k as the number of copies grows.

With both halves of the loop now precise — S the backward, policy-valued best response of definition 29.2, and Ψ the forward, population-valued push-forward of definition 29.3 — we can state what it means for the loop to have settled, matching the continuous definition of chapter 8 and its graphon counterpart definition 21.16.

Definition 29.4 (MFMDP equilibrium)**.** A pair $(\pi^\star, m^\star_\bullet)$ is a *mean field equilibrium* if (consistency) $m^\star_\bullet = \Psi(\pi^\star)$ and (optimality) $\pi^\star \in \mathsf{S}(m^\star_\bullet)$. Equivalently, $m^\star_\bullet$ is a fixed point of the *composite* map $\Psi \circ \mathsf{S}$ — which is precisely the single dynamic flow map called S in chapters 8 and 28 (notationwatch (iv)) — and $\pi^\star$ a fixed point of $\mathsf{S} \circ \Psi$; this is the discrete-time avatar of the equivalence proposition 8.4, whose fixed point is that composite flow map.

It is worth pausing on the equivalence asserted in definition 29.4, because this is the place where notationwatch (iv) becomes concrete rather than a promissory note. We now have two genuinely different maps with their own names. The best response S takes a frozen environment to an optimal policy, $\bar{m}_\bullet \mapsto \pi$; this is the backward, dynamic-programming half (definition 29.2). The push-forward Ψ takes a frozen policy to the population it generates, $\pi \mapsto m'_\bullet$; this is the forward, simulation half (definition 29.3). Compose them in the order "best-respond, then push forward" and one obtains a self-map of flows,

$$\bar{m}_\bullet \overset{\mathsf{S}}{\longmapsto} \pi = \mathsf{S}(\bar{m}_\bullet) \overset{\Psi}{\longmapsto} m'_\bullet = \Psi\big(\mathsf{S}(\bar{m}_\bullet)\big),$$

which is exactly the single dynamic flow map written $\mathsf{S} = \Phi$ in chapters 8 and 28: one backward HJB sweep immediately followed by one forward Fokker–Planck sweep, fused into one object (eq. (28.2), proposition 8.4). A flow is an equilibrium flow precisely when this composite returns it unchanged, $m^\star_\bullet = (\Psi \circ \mathsf{S})(m^\star_\bullet)$, and dually a policy is an equilibrium policy precisely when $\pi^\star = (\mathsf{S} \circ \Psi)(\pi^\star)$. We keep the two halves separately named, and write the composite out in full rather than abbreviating it, for the reason flagged in the preamble: the two analytic hypotheses of the chapter act on the two sweeps *separately*, and it is the *product* of their Lipschitz moduli that the contraction analysis of the next section will constrain — a statement that has no meaning until the seam between S and Ψ is exposed, as it now is.

Remark 29.5 (Why this is exactly the object RL can chase)**.** This is the conceptual payoff of the subsection, and it is worth stating without haste, because it is the hinge on which the entire chapter turns. The two clauses of definition 29.4 are not abstract conditions one hopes to verify; each corresponds *exactly* to one of the two things a learner equipped with nothing but a simulator can actually do. *Optimality* is a single-agent reinforcement-learning problem. Freeze the environment $m_\bullet$ and the mean field coupling is severed — the agent inhabits an ordinary MDP (29.2) with a fixed, externally supplied environment — which *any* RL method can attack: value iteration or backward dynamic programming when the state is small, Q-learning or fitted value iteration when only samples are available, policy gradient or PPO when the state is too large to enumerate and one represents π by a network. None of these needs the closed-form b, σ, L; each needs only to score actions by sampled returns, which is what the simulator provides. *Consistency* is a forward Monte Carlo simulation: instantiate many independent copies of the agent, all playing the same fixed π, roll them forward through the simulator, and estimate the stage-k distribution (29.3) by the empirical measure of the copies' states — the law-of-large-numbers estimate of $\Psi(\pi)$. An equilibrium is reached at the precise moment these two operations agree: when the policy the agent *learns against* a population is the same policy that *generates* that population, so that neither operation, applied next, would move anything. This is why an equilibrium is something an iterative loop can *chase*: it is a fixed point of the alternation, and a fixed point of two samplable maps is reachable, in principle, by applying them in turn. The rest of the chapter is the study of that dynamical system — when its alternation converges to the fixed point, when it instead cycles forever, and what must be added to force convergence.

The two maps are now defined, their composite is identified with the equilibrium-defining self-map of chapter 8, and remark 29.5 has told us why each is exactly an operation a simulator-bound learner can perform. What we still lack is a way to *measure* how far a given policy stands from the fixed point — a single nonnegative number, estimable from samples, that vanishes precisely at equilibrium and that an algorithm can be made to drive down. Equipped with such a yardstick we can finally analyse the alternation itself: form the naive iteration that simply applies $\Psi \circ \mathsf{S}$ over and over, and ask whether it contracts toward the fixed point or oscillates around it. Both tasks — naming the yardstick, which will be the *exploitability*, and dissecting the iteration of the two maps — are the business of the next section.

29.2 The equilibrium as a fixed point of two maps

The previous section closed by handing us two maps and a name for their composite. The best response S runs one backward dynamic-programming sweep against a frozen population (definition 29.2); the push-forward Ψ runs one forward Monte Carlo sweep of the population under a frozen policy (definition 29.3); and an MFMDP equilibrium is exactly a fixed point of the composite $\Psi \circ \mathsf{S}$ (definition 29.4). Remark 29.5 drove home the observation that makes this more than bookkeeping: each of the two maps is not an abstraction but *precisely* one of the two things a simulator-bound learner can actually do — solve a single-agent reinforcement-learning problem against a frozen environment, or roll many copies of the crowd forward and read off their empirical law. What that remark deliberately left open is the question this section exists to confront. Granting that we can *apply* each map, what happens when we *iterate* them? A fixed point is a static characterisation, but *reaching* one is a dynamical process, and the entire gap between a learning method that succeeds and one that spins forever lies not in the maps themselves but in the behaviour of their alternation. This section is where the static fixed-point picture of section 29.1 becomes a dynamical question.

Answering it takes two ingredients, and they organise the section into its two subsections. The first is a *ruler*: before one can ask whether an iteration approaches the fixed point, one must be able to say — with a single number — how far the current iterate stands from it, and that number must be both zero exactly at the fixed point and estimable from the very samples the learner already draws, never from foreknowledge of the equilibrium we are chasing. The opening subsection manufactures that ruler, the *exploitability*, and proves it has both properties. The second ingredient, built on top of the first, is the dynamical system itself: with a way to measure progress in hand, the closing subsection forms the most naive iteration imaginable, the bare alternation $m_\bullet^{n+1} = (\Psi \circ \mathsf{S})(m_\bullet^n)$, and asks exactly when its orbit contracts onto the fixed point. The answer re-imports, unchanged, a hypothesis from the analytic theory of Part III: the iteration converges geometrically precisely when the *product* of the two maps' Lipschitz moduli falls below one — the learning-theoretic face of (A-Coupling) — and otherwise it generically oscillates without ever settling. That oscillation, diagnosed at the section's close, is not a numerical nuisance to be tuned away but a structural failure of the naive loop, and it is exactly the disease that the stabilisers of section 29.3 are constructed to cure. We take the two ingredients in order, the ruler first, because every convergence statement in the remainder of the chapter is measured against it.

29.2.1 Exploitability: the objective a learner minimises

A dynamical system is only as analysable as the ruler one measures its progress by, so before forming any iteration we must build the scalar the header promised: a single nonnegative number that vanishes *exactly* when π is an equilibrium policy and is otherwise strictly positive, and that the learner can estimate from the same samples it already draws. Two requirements on this ruler pull in opposite directions, and reconciling them is the entire design problem. On the one hand it must *certify* equilibrium: it has to be zero at the fixed point of definition 29.4 and nowhere else, so that "the ruler reads zero" and "the game is solved" are the same statement, never merely correlated. On the other hand it must be *computable in the dark*: the learner does not know the equilibrium — finding it is the whole point — so the ruler may not refer to $\pi^\star$ or $m_\bullet^\star$, and it must be assembled from quantities the simulator already hands over. The obvious candidate, some distance $\mathcal{W}_2(m_\bullet, m_\bullet^\star)$ to the true equilibrium flow, fails the second test at the first hurdle: it presupposes the very object we are chasing, so it can grade a candidate only *after* the answer is known, which is useless to an algorithm that must decide, at each step, whether it has made progress.

The way out is to stop measuring distance in the space of flows and measure it in the space of *incentives* instead — a notion inherited from game theory that never mentions the equilibrium by name. Ask the only question an agent embedded in the crowd actually cares about: holding the entire rest of the population fixed at π (so that the environment it generates, $\Psi(\pi)$, is frozen), how much could a single agent *save* by tearing up π and playing optimally against that frozen crowd instead? This is a purely unilateral, single-agent quantity: it compares two costs computed in one and the same fixed environment, and it asks for no knowledge of where the equilibrium lies. Its logic is exactly the definition of equilibrium turned into a number. If the saving is zero, then no agent has any profitable deviation against the population π induces, which is precisely the statement that π best-responds to its own induced flow — equilibrium, by definition 29.4. If the saving is large, some agent could do much better by defecting, so π is correspondingly far from best-responding to the crowd it generates, and the size of the saving grades *how* far. This quantity is the *exploitability* (in the game-theoretic literature, the *Nash gap*), and the happy fact is that making it precise requires nothing beyond the value functions already in hand from definition 29.2: the cost of playing a policy against a frozen environment is exactly the initial-stage value function of that policy, averaged over where agents start.

Definition 29.6 (Exploitability)**.** For a policy π let $m_\bullet = \Psi(\pi)$ be its induced flow and write $J(\pi'; m_\bullet) = \int_{\mathcal{S}} u_0^{m_\bullet,\pi'}(s)\, m_0(\mathrm{d}s)$ for the expected cost of playing π' against the environment $m_\bullet$. The *exploitability* of π is

$$\mathcal{E}(\pi) \;:=\; J(\pi; m_\bullet) - \inf_{\pi'} J(\pi'; m_\bullet) \;=\; \int_{\mathcal{S}} \Big(u_0^{m_\bullet,\pi}(s) - u_0^{m_\bullet}(s) \Big)\, m_0(\mathrm{d}s). \tag{29.4}$$

Read the functional $J(\pi'; m_\bullet)$ slowly, because everything hinges on what is frozen and what is free in it. The subscript $m_\bullet$ is the *environment* — the population flow, held fixed throughout the computation, supplying the third argument to every P_k and L_k exactly as in the frozen-environment reading of definition 29.2. Against that fixed backdrop the agent is free to choose its own policy π', and $u_0^{m_\bullet,\pi'}(s)$ is the expected discounted cost of running π' from the start state s through the frozen environment; averaging over the initial law m_0 gives $J(\pi'; m_\bullet)$, the cost of *deviating to* π' while the crowd stays put. The key point is that the deviation never disturbs the environment: $m_\bullet = \Psi(\pi)$ is built once from the incumbent π and then held rigid while π' ranges over all policies. This is the single-agent thought experiment of a representative deviator who is too small to move the crowd — the same severing of the mean field coupling that turned the equilibrium's optimality clause into an ordinary MDP in remark 29.5.

The two expressions for $\mathcal{E}(\pi)$ in (29.4) are the same number written at two altitudes, and it is worth seeing why they agree. The first, $J(\pi; m_\bullet) - \inf_{\pi'} J(\pi'; m_\bullet)$, is the *game-theoretic* form: the cost the incumbent actually pays minus the cost of the best available deviation, i.e. the largest saving any deviator could extract. The second, $\int_{\mathcal{S}} (u_0^{m_\bullet,\pi} - u_0^{m_\bullet})\, \mathrm{d}m_0$, is the *control-theoretic* form: the initial-stage gap between the value of π and the optimal value, averaged over starts. Passing from the first to the second requires only one nonobvious step, the interchange

$$\inf_{\pi'} \int_{\mathcal{S}} u_0^{m_\bullet,\pi'}(s)\, m_0(\mathrm{d}s) \;=\; \int_{\mathcal{S}} \inf_{\pi'} u_0^{m_\bullet,\pi'}(s)\, m_0(\mathrm{d}s) \;=\; \int_{\mathcal{S}} u_0^{m_\bullet}(s)\, m_0(\mathrm{d}s),$$

and the interchange is legitimate precisely because of the structure of dynamic programming. In general, pulling an infimum inside an integral is only an inequality: any fixed π' has $\int u_0^{m_\bullet,\pi'}\, \mathrm{d}m_0 \geq \int \inf_{\pi''} u_0^{m_\bullet,\pi''}\, \mathrm{d}m_0$, and taking the infimum over π' on the left gives only $\inf_{\pi'} \int \geq \int \inf_{\pi'}$. The subtlety hiding in the reverse direction is that minimising the *average* cost might in principle demand different optimal policies at different start states, so that no single π' could attain the pointwise infimum everywhere at once, and the left side could strictly exceed the right. Dynamic programming dissolves exactly this worry: the greedy policy of (29.2), which at every (k, s) selects an action in $\arg\min_a Q_k^{m_\bullet}(s, a)$, is *simultaneously* optimal from every start state, because optimality is decided stage-by-stage and state-by-state rather than start-by-start. Hence one and the same policy attains $\inf_{\pi'} u_0^{m_\bullet,\pi'}(s) = u_0^{m_\bullet}(s)$ for all s at once, the infimum and the integral commute, and the two forms coincide. The lesson to carry forward is that the optimal value function $u_0^{m_\bullet}$ is a property of the *environment alone*, not of any particular deviation, which is why the second form isolates so cleanly the per-state regret $u_0^{m_\bullet,\pi} - u_0^{m_\bullet}$.

Proposition 29.7 (Exploitability characterises equilibrium)**.** *$\mathcal{E}(\pi) \geq 0$ for every π, and $\mathcal{E}(\pi) = 0$ if and only if π is a best response to its own induced flow $\Psi(\pi)$, i.e. $(\pi, \Psi(\pi))$ is an equilibrium in the sense of definition 29.4.*

Proof. Nonnegativity. For every state s one has the pointwise inequality $u_0^{m_\bullet,\pi}(s) \geq u_0^{m_\bullet}(s)$, because $u_0^{m_\bullet}(s) = \inf_{\pi'} u_0^{m_\bullet,\pi'}(s)$ is the infimum of the running policy's value over *all* policies, and an infimum never exceeds any of the values it is taken over — in particular not the value of the specific policy π. Integrating this nonnegative gap $u_0^{m_\bullet,\pi} - u_0^{m_\bullet} \geq 0$ against the nonnegative measure m_0 yields $\mathcal{E}(\pi) \geq 0$, in the second form of (29.4).

The equality case. Suppose $\mathcal{E}(\pi) = 0$. We are integrating a pointwise nonnegative function against a probability measure and getting zero, so that function must vanish m_0-almost everywhere: $u_0^{m_\bullet,\pi}(s) = u_0^{m_\bullet}(s)$ for m_0-a.e. s. We now propagate this initial-stage equality forward and read off, at each reached state, that π must put all its mass on Bellman-optimal actions. Introduce the stagewise gap $\delta_k(s) := u_k^{m_\bullet,\pi}(s) - u_k^{m_\bullet}(s) \geq 0$, which is nonnegative for the same infimum reason at every stage, and compare the two backward recursions that produce its two terms. Write the policy's own action-value and the optimal action-value as

$$Q_k^\pi(s,a) := L_k(s,a,m_k) + \gamma\, \mathbb{E}\Big[u_{k+1}^{m_\bullet,\pi}(S_{k+1}) \mid s,a\Big], \qquad Q_k^{m_\bullet}(s,a) := L_k(s,a,m_k) + \gamma\, \mathbb{E}\Big[u_{k+1}^{m_\bullet}(S_{k+1}) \mid s,a\Big],$$

so that the evaluation recursion (29.1) reads $u_k^{m_\bullet,\pi}(s) = \int Q_k^\pi(s,a)\, \pi_k(\mathrm{d}a \mid s)$ — an *average* of Q_k^π over the actions π draws — while the optimality recursion (29.2) reads $u_k^{m_\bullet}(s) = \min_a Q_k^{m_\bullet}(s,a)$ — a *minimum* of $Q_k^{m_\bullet}$. Because $u_{k+1}^{m_\bullet,\pi} \geq u_{k+1}^{m_\bullet}$ pointwise (that is $\delta_{k+1} \geq 0$), taking expectations gives $Q_k^\pi(s,a) \geq Q_k^{m_\bullet}(s,a)$ for every action a. Chaining the two recursions through this inequality,

$$u_k^{m_\bullet,\pi}(s) = \int Q_k^\pi(s,a)\, \pi_k(\mathrm{d}a \mid s) \;\geq\; \int Q_k^{m_\bullet}(s,a)\, \pi_k(\mathrm{d}a \mid s) \;\geq\; \min_a Q_k^{m_\bullet}(s,a) = u_k^{m_\bullet}(s),$$

where the first inequality is $Q_k^\pi \geq Q_k^{m_\bullet}$ and the second is that the π_k-average of $Q_k^{m_\bullet}$ cannot fall below its minimum. Now suppose $\delta_k(s) = 0$, i.e. the two ends of this chain coincide; then *both* intermediate inequalities are equalities, and each carries a consequence. Equality in the second, $\int Q_k^{m_\bullet}(s,a)\, \pi_k(\mathrm{d}a \mid s) = \min_a Q_k^{m_\bullet}(s,a)$, says that a probability average of the nonnegative excess $Q_k^{m_\bullet}(s,a) - \min_{a'} Q_k^{m_\bullet}(s,a') \geq 0$ is zero, which forces $\pi_k(\cdot \mid s)$ to be supported on $\arg\min_a Q_k^{m_\bullet}(s,a)$ — π plays only Bellman-optimal actions at (k,s), which is exactly the best-response condition of definition 29.2. Equality in the first, $\int (Q_k^\pi - Q_k^{m_\bullet})(s,a)\, \pi_k(\mathrm{d}a \mid s) = 0$ with a nonnegative integrand, forces $Q_k^\pi(s,a) = Q_k^{m_\bullet}(s,a)$ for π_k-a.e. a, i.e. $\mathbb{E}[\delta_{k+1}(S_{k+1}) \mid s,a] = 0$; since $\delta_{k+1} \geq 0$, this means δ_{k+1} vanishes at every state S_{k+1} actually reachable from (s,a) under P_k. This is the propagation: $\delta_k(s) = 0$ at a reached state forces both that π is greedy there *and* that $\delta_{k+1} = 0$ at the next reached states. Starting from $\delta_0 = 0$ m_0-a.e. and inducting forward over k, we conclude $\pi_k(\cdot \mid s)$ is supported on the Bellman-optimal actions at every (k,s) reached with positive probability under $\Psi(\pi)$ — precisely $\pi \in \mathsf{S}(m_\bullet)$ with $m_\bullet = \Psi(\pi)$, the equilibrium of definition 29.4.

The converse, read backward. Conversely, suppose π is a best response to its own induced flow, so $\pi_k(\cdot \mid s)$ is supported on $\arg\min_a Q_k^{m_\bullet}(s,a)$ at every (k,s). We show $\delta_k \equiv 0$ on reached states by backward induction, the natural direction since the value recursions run backward from the terminal stage. At the terminal stage both recursions return the same datum, $u_K^{m_\bullet,\pi} = g(\cdot, m_K) = u_K^{m_\bullet}$, so

$\delta_K = 0$. Assume $\delta_{k+1} = 0$, hence $u_{k+1}^{m_\bullet,\pi} = u_{k+1}^{m_\bullet}$ and therefore $Q_k^\pi = Q_k^{m_\bullet}$. Then, using that π_k is supported on the minimisers,

$$u_k^{m_\bullet,\pi}(s) = \int Q_k^\pi(s,a)\,\pi_k(\mathrm{d}a \mid s) = \int Q_k^{m_\bullet}(s,a)\,\pi_k(\mathrm{d}a \mid s) = \min_a Q_k^{m_\bullet}(s,a) = u_k^{m_\bullet}(s),$$

the third equality because π_k places all its mass exactly where $Q_k^{m_\bullet}$ attains its minimum. Thus $\delta_k = 0$, the induction closes, and in particular $\delta_0 = 0$, whence $\mathcal{E}(\pi) = \int \delta_0 \,\mathrm{d}m_0 = 0$. The forward computation of the equality case and this backward one are the same chain of identities traversed in opposite directions: at equilibrium, "π is greedy" and "the value gap vanishes" are two readings of a single fact. □

It is worth instantiating the proposition once on the LQG thread, where every term is explicit and the abstract regret becomes a visible quadratic. Take the one-step instance of definition 29.2, with the frozen environment $m_\bullet$ supplying the population mean $\bar{m}_k$ through the offset r_{k+1}, so that the best response is the affine feedback $\alpha^*(s) = -\gamma b\,(P_{k+1}s + r_{k+1})$ computed there. Let the incumbent π play a slightly mistuned affine feedback $\alpha(s) = -g\,(P_{k+1}s + r_{k+1})$ with gain $g \neq \gamma b$. Substituting α rather than the minimiser into the strictly convex quadratic $Q_k(s,\alpha)$ — whose leading coefficient $\propto (1 + \gamma b^2 P_{k+1}\Delta t)$ is positive — overshoots its minimum by an amount proportional to $(g-\gamma b)^2(P_{k+1}s + r_{k+1})^2$, so the per-state regret $u_0^{m_\bullet,\pi}(s) - u_0^{m_\bullet}(s)$ is a nonnegative quadratic in the gain error that vanishes *iff* $g = \gamma b$, and $\mathcal{E}(\pi)$ is its m_0-average — strictly positive for any mistuned gain, exactly zero at the true feedback. This is proposition 29.7 made tangible: the ruler reads the squared distance of the agent's policy from its best response, and reads zero only when the two coincide.

Proposition 29.7 is what certifies $\mathcal{E}$ as a legitimate ruler: it is the learner's loss function, nonnegative everywhere and zero *precisely* at equilibrium, so driving it to zero is synonymous with solving the game — there is no daylight between "the loss is small" and "the policy nearly best-responds to the crowd it makes," which is what every convergence theorem in the remainder of the chapter will exploit when it bounds $\mathcal{E}$. The remaining worry is whether such a loss is anything more than a definition. It looks circular: the second term $u_0^{m_\bullet} = \inf_{\pi'} u_0^{m_\bullet,\pi'}$ is itself the *solution* of an optimal-control problem, the very kind of object the chapter spends its effort learning, so it might seem that to score a policy one must already be able to find the best one. The resolution — and this is the practical hinge the whole estimator downstream rests on — is that the worry mistakes a tractable subproblem for the intractable full problem. Evaluating $\mathcal{E}(\pi)$ does *not* require finding the equilibrium; it requires only solving a *single-agent* control problem against the *frozen* environment $\Psi(\pi)$, with the mean field coupling severed. That is the benign, fixed-environment RL problem of remark 29.5, attackable by any sampling method, and it is decoupled from the hard part — the back-and-forth between agent and crowd — precisely because the population is held still while the deviator optimises. So $\mathcal{E}(\pi)$ is estimable from samples by a concrete three-step recipe that needs nothing the simulator does not already provide: roll out π to obtain (an empirical proxy for) its induced flow $\Psi(\pi)$ and the on-policy return $J(\pi;\Psi(\pi))$; train a best response $\hat{\pi}'$ against that frozen rollout distribution, by any RL subroutine, and estimate its return $J(\hat{\pi}';\Psi(\pi))$ by fresh rollouts; then difference the two returns. The estimate is the empirical Nash gap, and it inherits one honest caveat we will have to pay for later — because the best response is itself only *approximately* learned, the trained $\hat{\pi}'$ is generally suboptimal, so its return overestimates $\inf_{\pi'} J$

and the differenced estimate is a (downward-biased) *lower* bound on the true $\mathcal{E}(\pi)$; it certifies a floor on remaining exploitability, not a ceiling. This is exactly the exploitability estimator that the GMFG-PPO algorithm of section 29.4 will use to instrument its own convergence, and recognising it here, in the scalar setting, is why we built the loss before touching a single iteration.

With the ruler built, certified, and shown to be measurable in the dark, the section's second question can finally be posed sharply. We have a nonnegative loss $\mathcal{E}$ that is zero exactly at the fixed point and that an algorithm can monitor as it runs; what we do not yet have is a *dynamics* that drives it down. The most direct thing to try is the bare alternation of the two maps — best-respond to the current population, push the response forward, repeat — and the next subsection asks the obvious question about it: does iterating $\Psi \circ \mathsf{S}$ actually send $\mathcal{E}$ to zero, contracting onto the equilibrium, or does the loss stall and the orbit circle the fixed point forever? The ruler we have just forged is precisely the instrument that will let us answer it.

29.2.2 Naive fixed-point iteration and its contraction regime

The previous subsection handed us the exploitability $\mathcal{E}$ — a nonnegative loss, zero exactly at equilibrium and estimable from samples (definition 29.6, proposition 29.7) — together with a stated wish: to find a *dynamics* that drives this loss to zero. With that ruler in hand we can finally watch the most direct candidate dynamics run, and ask the question $\mathcal{E}$ was built to answer. The most direct conceivable algorithm does nothing clever at all: take the current guess at the population, best-respond to it, push that response forward to obtain a new population, and repeat — the bare composition of the two maps, applied over and over. This is the discrete dynamical system whose orbit we now study, and the question it poses is the one the section opened with, now sharpened by the ruler: does this orbit drive $\mathcal{E}$ to zero, settling onto the equilibrium fixed point, or does $\mathcal{E}$ stall while the orbit circles the fixed point forever? The answer, we will find, hinges on a single number — the product of two sensitivities — and that number turns out to be nothing other than the contraction hypothesis (A-Coupling) of the analytic theory, now wearing learning-theoretic clothes.

Definition 29.8 (Fixed-point iteration)**.** *Fixed-point iteration* (FPI), also called *Banach–Picard* or naive iteration, generates flows by

$$m_\bullet^{n+1} \;=\; (\Psi \circ \mathsf{S})(m_\bullet^n), \qquad n = 0, 1, 2, \ldots, \tag{29.5}$$

where S is made single-valued by a measurable selection (or by the regularisation of section 29.3). Equivalently, on policies, $\pi^{n+1} = \mathsf{S}(\Psi(\pi^n))$.

To analyse (29.5) as a genuine dynamical system we must measure distances between flows, and the right notion of distance is dictated by what the iteration manipulates. A flow is a whole *sequence* of stage laws $(m_0, \ldots, m_K)$, so the natural way to say that two flows are close is to ask that they be close *at every stage at once*; and the natural way to say two laws on $\mathcal{S}$ are close is the Wasserstein distance $\mathcal{W}_2$ of chapter 4, which is the metric in which push-forwards behave well and in which the population dynamics of Parts II–IV were already controlled. Combining the two, we equip the space of flows with

$$D(m_\bullet, m'_\bullet) \;:=\; \max_{0\le k\le K} \mathcal{W}_2(m_k, m'_k), \tag{29.6}$$

the largest stage-wise Wasserstein distance. The max rather than, say, a sum is deliberate: it makes "D small" mean "uniformly close across the whole horizon," which is exactly the control a Lipschitz estimate on the composite map will deliver, and it keeps the constant in the contraction estimate from growing with the horizon length K. Completeness of $\big((\mathcal{P}_2(\mathcal{S}))^{K+1}, D\big)$ — the property the Banach theorem will require — is inherited stagewise from the completeness of $(\mathcal{P}_2(\mathcal{S}), \mathcal{W}_2)$ proved in chapter 4: a D-Cauchy sequence of flows is, coordinate by coordinate, a $\mathcal{W}_2$-Cauchy sequence of laws, each of which converges to a limit law in $\mathcal{P}_2(\mathcal{S})$, and the finite tuple of these limits is a flow to which the original sequence converges in D. A finite product of complete spaces under the max metric is complete; that is all we use. With a complete metric on flows fixed, the iteration's fate is decided entirely by how much the two maps stretch or shrink this distance, and we name those two stretch factors now, for they are the only quantities the convergence question will turn on.

The point of isolating two separate moduli — rather than one Lipschitz constant for the fused composite — is the seam exposed in notationwatch (iv): the backward best-response sweep and the forward push-forward sweep stretch distances for entirely different reasons, and the analytic hypotheses of the chapter bear on them *one at a time*. The response modulus measures how violently the optimal policy swings when the population it is responding to is nudged; the population modulus measures how far the induced crowd is displaced when the policy generating it is nudged. These are the two sensitivities on which the entire iteration hinges, and the contraction condition will constrain not either one alone but their *product*.

Definition 29.9 (Coupling moduli)**.** The *response modulus* L_{S} and the *population modulus* L_Ψ are the smallest constants such that, for all flows and policies,

$$D\big(\Psi(\pi), \Psi(\pi')\big) \le L_\Psi\, d(\pi, \pi'), \qquad d\big(\mathsf{S}(m_\bullet), \mathsf{S}(m'_\bullet)\big) \le L_{\mathsf{S}}\, D(m_\bullet, m'_\bullet), \tag{29.7}$$

where d is a metric on policies compatible with D (for definiteness, the m_0-averaged total-variation distance between action distributions, maximised over stages).

It is worth reading the two inequalities of (29.7) as physical sensitivities before they appear in a proof. The first, with constant L_Ψ, says that the forward map is *stable*: perturb the policy a little and the crowd it rolls out shifts by at most L_Ψ times as much. This factor is typically benign — of order one or smaller — because a single push-forward step averages a small change in action probabilities over the whole population and over only finitely many stages, so the perturbation does not amplify; it is the discrete-time relative of the Lipschitz-in-control stability of the Fokker–Planck flow used in chapter 8. The second inequality, with constant L_{S}, is the dangerous one, and the next several pages are organised around it: it asks how much the $\arg\min$ of the Bellman recursion moves when the environment moves, and an $\arg\min$ can move a great deal for a small input change. The composite map $\Psi \circ \mathsf{S}$ therefore stretches D by at most the product $L_{\mathsf{S}} L_\Psi$, and whether that product sits below or above one is the entire story.

Theorem 29.10 (Existence, uniqueness, and geometric convergence of FPI)**.** *Assume* (A-Lip) *and*

(A-Nondeg) *so that the moduli of definition 29.9 are finite, and assume the* contraction condition

$$L \;:=\; L_{\mathsf{S}}\, L_{\Psi} \;<\; 1. \tag{29.8}$$

Then the MFMDP has a unique equilibrium $(\pi^\star, m^\star_\bullet)$, the FPI (29.5) converges to it from any initial flow at the geometric rate $D(m^n_\bullet, m^\star_\bullet) \le L^n\, D(m^0_\bullet, m^\star_\bullet)$, and the exploitability of the iterate decays as $\mathcal{E}(\pi^n) \le C\, L^n$ for a constant C depending on the moduli.

Proof. Existence, uniqueness, geometric convergence. The two inequalities of (29.7) compose: for any flows $m_\bullet, m'_\bullet$, applying first the response bound and then the population bound,

$$D\big((\Psi\circ\mathsf{S})(m_\bullet), (\Psi\circ\mathsf{S})(m'_\bullet)\big) \le L_\Psi\, d\big(\mathsf{S}(m_\bullet), \mathsf{S}(m'_\bullet)\big) \le L_\Psi L_{\mathsf{S}}\, D(m_\bullet, m'_\bullet) = L\, D(m_\bullet, m'_\bullet),$$

so the composite $\Psi\circ\mathsf{S}$ is L-Lipschitz on the complete metric space $\big((\mathcal{P}_2(\mathcal{S}))^{K+1}, D\big)$. With $L<1$ this is a contraction, and the Banach fixed-point theorem (chapter 2) applies verbatim: it furnishes a unique fixed point $m^\star_\bullet$, guarantees that the iterates (29.5) converge to it from *any* starting flow, and supplies the geometric rate. That rate is the standard Banach estimate, which we record because the exploitability bound will reuse it: iterating the contraction n times gives $D(m^n_\bullet, m^\star_\bullet) = D\big((\Psi\circ\mathsf{S})^n(m^0_\bullet), (\Psi\circ\mathsf{S})^n(m^\star_\bullet)\big) \le L^n\, D(m^0_\bullet, m^\star_\bullet)$, since $m^\star_\bullet$ is fixed by the map. Writing $D_0 := D(m^0_\bullet, m^\star_\bullet)$ for the initial error, this is the asserted $D(m^n_\bullet, m^\star_\bullet) \le L^n D_0$. The fixed point is the unique equilibrium flow by definition 29.4 — a flow is returned unchanged by $\Psi\circ\mathsf{S}$ exactly when it is an equilibrium — and $\pi^\star = \mathsf{S}(m^\star_\bullet)$ is the corresponding unique equilibrium policy.

Exploitability decay. It remains to convert the geometric closeness of the flows into geometric decay of the loss the learner actually monitors. Write $m^n_\bullet = \Psi(\pi^n)$ for the flow induced by the iterate $\pi^n = \mathsf{S}(m^{n-1}_\bullet)$. The key structural fact is that π^n is an *exact* best response, but not to its own induced flow $m^n_\bullet$ — rather to the *previous* flow $m^{n-1}_\bullet$, the one it was computed against. Its exploitability is by definition measured against its own flow $m^n_\bullet$, so the entire gap $\mathcal{E}(\pi^n)$ must come from the *mismatch* between the environment π^n optimised for, $m^{n-1}_\bullet$, and the environment it actually faces, $m^n_\bullet$. Making this precise is a matter of inserting the optimised environment as an intermediary. Start from the control-theoretic form of the loss, (29.4), and bound the integral by the supremum of its integrand against the probability measure m_0:

$$\mathcal{E}(\pi^n) = \int_{\mathcal{S}} \big(u_0^{m^n_\bullet,\pi^n}(s) - u_0^{m^n_\bullet}(s)\big)\, m_0(\mathrm{d}s) \;\le\; \big\|u_0^{m^n_\bullet,\pi^n} - u_0^{m^n_\bullet}\big\|_\infty.$$

Now add and subtract the two value functions computed in the *optimised* environment $m^{n-1}_\bullet$ — the policy-evaluation value $u_0^{m^{n-1}_\bullet,\pi^n}$ and the optimal value $u_0^{m^{n-1}_\bullet}$ — and split by the triangle inequality:

$$u_0^{m^n_\bullet,\pi^n} - u_0^{m^n_\bullet} = \underbrace{\big(u_0^{m^n_\bullet,\pi^n} - u_0^{m^{n-1}_\bullet,\pi^n}\big)}_{\text{(I)}} + \underbrace{\big(u_0^{m^{n-1}_\bullet,\pi^n} - u_0^{m^{n-1}_\bullet}\big)}_{\text{(II)}} + \underbrace{\big(u_0^{m^{n-1}_\bullet} - u_0^{m^n_\bullet}\big)}_{\text{(III)}}.$$

The middle term (II) *vanishes identically*: it is the per-state regret of π^n in the environment $m^{n-1}_\bullet$, and $\pi^n = \mathsf{S}(m^{n-1}_\bullet)$ is by construction an exact best response there, so $u_0^{m^{n-1}_\bullet,\pi^n} = u_0^{m^{n-1}_\bullet}$ pointwise (a policy's value coincides with the optimal value exactly when the policy is greedy, proposition 29.7). This is the inserted "$u^{n-1} = u^\star_{n-1}$" step: it is what makes the exact best response do its work, collapsing the three-term split to the two *environment-stability* terms (I) and (III). Each of those two compares the same kind of value function — (I) two policy-evaluation values of the *same* policy π^n, (III) two *optimal* values — evaluated in the two nearby environments $m_\bullet^{n-1}$ and $m_\bullet^n$. Both kinds of value function are Lipschitz in the environment: this is the backward-stability estimate, a discrete Grönwall run on the Bellman recursions (29.1) and (29.2), whose value at stage k depends on the environment only through the stage costs L_j and kernels P_j for $j \geq k$, each Lipschitz in its measure argument under (A-Lip); summing the per-stage perturbations backward over the K stages, with the discount $\gamma \leq 1$ preventing amplification, yields a finite environment-Lipschitz constant L_V for both the policy-evaluation map $m_\bullet \mapsto u_0^{m_\bullet,\pi}$ and the optimal-value map $m_\bullet \mapsto u_0^{m_\bullet}$. We cite this as the same backward-stability mechanism that makes the regularised best response Lipschitz in lemma 29.12; it is the discrete face of the value's continuous dependence on the coefficients, and we invoke it rather than re-derive it because the Grönwall is identical. Applying it to (I) and (III) and taking suprema,

$$\|u_0^{m_\bullet^n,\pi^n} - u_0^{m_\bullet^n}\|_\infty \leq \underbrace{\|u_0^{m_\bullet^n,\pi^n} - u_0^{m_\bullet^{n-1},\pi^n}\|_\infty}_{\leq L_V\, D(m_\bullet^{n-1},m_\bullet^n)} + \underbrace{\|u_0^{m_\bullet^{n-1}} - u_0^{m_\bullet^n}\|_\infty}_{\leq L_V\, D(m_\bullet^{n-1},m_\bullet^n)} \leq\; 2\, L_V\, D(m_\bullet^{n-1}, m_\bullet^n).$$

The exploitability is thus controlled by the distance between two *consecutive* flows. That distance, in turn, is geometrically small, by routing it through the equilibrium with one more triangle inequality and the Banach rate just proved:

$$D(m_\bullet^{n-1}, m_\bullet^n) \leq D(m_\bullet^{n-1}, m_\bullet^\star) + D(m_\bullet^\star, m_\bullet^n) \leq L^{n-1} D_0 + L^n D_0 = (1+L)\, L^{n-1} D_0.$$

Combining the last two displays, $\mathcal{E}(\pi^n) \leq 2L_V(1+L)L^{n-1}D_0 = C\,L^n$ with $C = 2L_V(1+L)D_0/L$, which is the claimed decay. $\square$

This theorem is the discrete-time, model-free shadow of the contraction proofs we have already seen, and recognising it as such is the point of the whole subsection. In chapter 20 the same Banach argument settled the static graphon game (theorem 20.14), and in chapter 24 it furnished the *small-coupling branch* of the GMFG existence theorem; there, as here, a self-map of an equilibrium object was shown to contract once a coupling-strength quantity fell below a threshold. The condition (29.8), $L = L_{\mathsf{S}} L_\Psi < 1$, is precisely the learning-theoretic face of that smallness hypothesis (A-Coupling). Read it as two demands on the strength of the mean field interaction: the population must not respond too violently to a change in policy (L_Ψ small), and — the binding one — the best response must not be too sensitive to the population (L_{S} small). When the kernel W is weak, a perturbation to the crowd barely moves the cost landscape an agent faces, so its $\arg\min$ barely moves, L_{S} stays below $1/L_\Psi$, and the loop contracts; this is the operator-norm smallness $\|\mathbb{W}\|$ that powered theorem 20.14 and the chapter 24 branch, transcribed into a statement about how much an iteration overshoots. The same one analytic fact that gave *existence by contraction* in Part IV now gives *convergence of learning by contraction* — not by analogy but as the same Lipschitz bookkeeping, applied to the same composite map, in the same complete metric. That continuity of hypothesis across the solving/learning divide is the chapter's spine, and theorem 29.10 is its first vertebra.

The trouble is that the binding demand is the one that nature rarely grants. We have argued that L_Ψ is usually mild, but L_{S} — the sensitivity of an $\arg\min$ — is typically *enormous*, and when $L_{\mathsf{S}} L_\Psi \geq 1$ the theorem's hypothesis fails and its conclusion lapses. The next heuristic explains, with a concrete picture, exactly what goes wrong when it does: not a slow drift but a violent, self-perpetuating oscillation, the signature failure that the entire stabilisation programme of section 29.3 exists to cure.

Heuristic (non-rigorous): Why naive iteration usually oscillates

The trouble is that L_{S} is typically *large*, and the reason is structural, not incidental. Best response is an $\arg\min$ (definition 29.2): at each (k, s) it returns the action minimising $Q_k^{m_\bullet}(s, \cdot)$, and the location of a minimiser is a notoriously unstable functional of the function being minimised. When two actions are nearly tied for best, an arbitrarily small shift in the population — which enters Q through the stage cost $L_k(s, \cdot, m_k)$ and through the continuation value — can tip the balance and flip the minimiser discontinuously from one action to the other, and this can happen on a whole region of state space at once. So S behaves like a near-discontinuous map: $d(\mathsf{S}(m_\bullet), \mathsf{S}(m'_\bullet))$ can be of order one even when $D(m_\bullet, m'_\bullet)$ is tiny, which is to say $L_{\mathsf{S}} \gg 1$. Against such a response modulus the contraction condition (29.8) has no chance unless the coupling is vanishingly weak.

Watch what this does to the loop in a *congestion* game, where agents dislike crowding so the coupling is repulsive. Suppose the current population guess has everyone bunched on the *left*. An agent best-responding to that guess sees the left as crowded and costly, so its $\arg\min$ sends it firmly to the *right*: $\pi^1 = \mathsf{S}(m^0_\bullet)$ is a go-right policy. Push that response forward through Ψ and the next population is now bunched on the right: $m^1_\bullet$ has everyone on the right. But now an agent best-responding to *this* guess sees the right as the crowded, costly side, and its $\arg\min$ sends it firmly back to the *left*: π^2 is a go-left policy, $m^2_\bullet$ bunches left, and we are exactly back where we started. The iteration has entered a *period-two* cycle — left, right, left, right — and because the best response commits *fully* to the opposite side each time (the $\arg\min$ is all-or-nothing, with no memory of how violently it just swung), the oscillation never shrinks. It is *undamped*: $\mathcal{E}(\pi^n)$ does not decay but bounces at a fixed positive amplitude, period after period. This is the classic *cobweb* oscillation of elementary economics — supply chases last period's price, price overshoots, supply overshoots back — and its root cause here is exactly $L_{\mathsf{S}} \gg 1$: each agent *overreacts* to the last guess, responding to where the crowd *was* rather than where it is heading, and a chain of mutual overreactions cannot converge. The equilibrium itself — everyone spread evenly, indifferent between left and right — sits unvisited at the centre of the cycle, a fixed point the naive dynamics orbits but never approaches.

The diagnosis points straight at the cure. The orbit fails not because the equilibrium is hard to find but because the response *overshoots*, L_{S} being far above one; so the remedy is to *damp the overreaction* rather than to hope it away. Two dampers suggest themselves, and the next section builds both. One can refuse to chase the latest best response and instead respond to a *running average* of all populations seen so far — so that a single wild swing is diluted by history and cannot drag the next iterate fully to the opposite extreme (this is *fictitious play*). Or one can refuse to take the full best-response step and instead move the policy only a *small* amount toward it each round — so that even an all-or-nothing $\arg\min$ produces only an incremental change in the played policy (this is *online mirror descent*). Both replace the volatile $\arg\min$ by something inert enough to converge, and crucially both will converge under a hypothesis far weaker than contraction — Lasry–Lions *monotonicity*, not smallness — which is what makes them the right tool when $L_{\mathsf{S}} L_\Psi \geq 1$. That the dichotomy is sharp — naive iteration contracting exactly when (29.8) holds and cycling exactly when it fails, with averaging rescuing the failed regime — is not left to intuition: it is made completely explicit, with every modulus computed in closed form, on the LQG thread in worked computation 29.22.

We close the section, then, with a precise diagnosis to hand forward: the naive loop fails not by some mistunable numerical accident but *structurally*, through the overreaction that the arg min in the best response builds in — $L_{\mathsf{S}} \gg 1$ driving the undamped period-two cobweb of section 29.2.2. Section 29.3 takes exactly this diagnosis as its point of departure and builds the two dampers the heuristic previewed, together with the one device they both quietly presuppose.

29.3 Stabilising the iteration

We inherit from section 29.2.2 a diagnosis sharp enough to act on. The naive loop does not fail because the fixed point is hard to locate or because some constant was tuned poorly; it fails because the best response *overreacts*. The response modulus L_{S} sits far above one — structurally so, because S ends in an arg min, and an arg min is a near-discontinuous object that can swing from one corner of the action set to the opposite under an arbitrarily small change in the population it faces — and once $L_{\mathsf{S}} L_\Psi \geq 1$ the contraction estimate (29.8) has nothing left to give, so the orbit settles into the period-two cobweb rather than onto the equilibrium. The cure cannot be to wish L_{S} smaller, since its size is dictated by the geometry of the problem and not by any dial we control; the cure must be to *damp the overreaction*. This section builds the two dampers the heuristic named — respond to a running average of past populations, or take only a small step toward each new best response — and, before either can be made to work, the one device both silently presuppose.

That order is the section's organising decision, and it is worth stating why it is forced rather than merely tidy. Both dampers are averaging schemes, and averaging is only meaningful between nearby objects: if the thing being averaged jumps discontinuously, then blending the last few iterates blends two essentially unrelated policies and inherits, rather than cures, the volatility. So the prerequisite for *any* averaging argument is that the best response vary *continuously* — indeed Lipschitz-continuously, with a modulus we can name — with the population it answers. The hard arg min does not have this property, but a softened best response does. *Entropy regularisation*, the subject of the first subsection below, replaces the hard minimisation in the Bellman optimality recursion (29.2) by a free-energy minimisation at a temperature $\tau > 0$; the minimiser becomes a smooth Gibbs (softmax) distribution that is single-valued where the arg min was set-valued and $\Theta(1/\tau)$-Lipschitz where the arg min was discontinuous. Regularisation therefore comes first not because it is the headline idea — it is a prerequisite, a small controlled bias accepted to buy the continuity the later analysis needs — and it must precede the averaging schemes because they are quite literally undefined as convergent dynamics without it. The price, a fixed point displaced by $O(\tau)$ from the true equilibrium, we pay knowingly and quantify when we reuse all of this in the modular guarantee of section 29.5.

With a Lipschitz best response in hand, the two monotonicity-powered dynamics follow, and here lies the conceptual headline that separates this section from the previous one. The contraction regime of section 29.2 rested on (A-Coupling), a *smallness* condition: the coupling had to be weak enough that the product $L_{\mathsf{S}}L_{\Psi}$ stayed below one. The averaging schemes ask for something altogether different. They converge under the Lasry–Lions *monotonicity* hypothesis (A-Mon) — the same condition that delivered uniqueness of the equilibrium in chapters 11 and 24 — and monotonicity is emphatically *not* a smallness assumption. It constrains the *sign* of how the population's cost responds to a perturbation of the population, never its *magnitude*; a coupling can be arbitrarily strong, with $L_{\mathsf{S}}L_{\Psi}$ arbitrarily large, and still be monotone. This is exactly why averaging reaches a regime that contraction cannot: where (29.8) simply fails and the naive loop is doomed to cycle, monotonicity remains available and turns the undamped oscillation into a Lyapunov descent. The second subsection develops the first such scheme, *fictitious play*, in which the agent best-responds to the time-average of all populations seen so far, so that one wild swing is diluted by history and cannot drag the next iterate to the opposite extreme. The third develops *online mirror descent*, in which the played policy itself is moved only incrementally toward each new best response, so that even an all-or-nothing $\arg\min$ produces an incremental change. The two differ in what they average — populations versus policy parameters — but share the engine: under (A-Mon) each admits a Lyapunov functional that decreases along the iteration, converting the cobweb of section 29.2.2 into monotone progress toward equilibrium.

The fourth and final unit makes the whole story quantitative on ground we can compute by hand. Returning to the LQG thread, the worked computation worked computation 29.22 carries out the naive-iteration and the averaged-iteration analyses side by side in closed form, every modulus evaluated explicitly, and exhibits the dichotomy with no room left for hand-waving: a single scalar parameter governs whether $L_{\mathsf{S}}L_{\Psi} < 1$ so that naive iteration contracts, or $L_{\mathsf{S}}L_{\Psi} \geq 1$ so that it spirals into the period-two oscillation while the averaged schemes nonetheless converge under monotonicity. That computation is the section's anchor: it turns "contract versus average" from a slogan into an inequality one can read off. Together the four units — regularisation, fictitious play, online mirror descent, and the LQG ledger — are the parts the modular convergence guarantee of section 29.5 will reassemble, the Lipschitz best response feeding the monotone averaging dynamics whose convergence the worked computation has already made concrete.

We begin with the prerequisite. The previous section's heuristic complained that the hard best response is near-discontinuous, L_{S} enormous because an $\arg\min$ can leap under an infinitesimal nudge; the next subsection answers exactly that complaint, smoothing the $\arg\min$ into a Gibbs distribution and pinning down the Lipschitz modulus the averaging schemes will require.

29.3.1 Entropy regularisation and the Gibbs best response

The cobweb diagnosis of section 29.2.2 located the disease with unusual precision: the naive loop oscillates because the best response S ends in a hard $\arg\min$, and an $\arg\min$ is a near-discontinuous map of its input. Two environments $m_\bullet$ and $m'_\bullet$ that are arbitrarily close can put two different actions infinitesimally above and below in Q-value, and the $\arg\min$ then jumps from the one to the other — a finite swing in the policy produced by an infinitesimal change in the population. That is what forces the response modulus L_{S} of definition 29.9 far above one, and through it the product $L_{\mathsf{S}} L_\Psi$ past the contraction threshold of (29.8). The previous section also told us the cure cannot be to wish L_{S} smaller, since its size is fixed by the geometry of the game; the cure must be to *round off the corner* of the arg min so that the policy slides continuously as the environment moves rather than snapping between extremes. This subsection builds exactly that rounding, names the price it exacts, and hands the resulting smooth, single-valued, Lipschitz best response to the averaging schemes that follow, which cannot even be defined as convergent dynamics without it.

The rounding has a thermodynamic reading that is worth stating before any formula, because it is the cleanest way to see why the construction is forced rather than arbitrary. The hard Bellman step (29.2) asks an agent to put *all* of its action probability on the single cheapest action — to minimise the expected one-step "energy" $\int_A Q_k^{m_\bullet}(s,a)\,p(\mathrm{d}a)$ over policies $p \in \mathcal{P}(A)$, whose minimiser is the degenerate measure $\delta_{\arg\min_a Q}$. A degenerate minimiser is precisely what makes the map discontinuous: it lives at a vertex of the simplex of action distributions, and an infinitesimal tilt of Q can send it to a different vertex. The remedy, familiar from statistical mechanics, is to charge the agent for being too certain: add to the energy a *temperature* $\tau > 0$ times the (negative) entropy of p, so that the agent now minimises the *free energy*

$$\mathcal{F}_\tau[p] \;=\; \underbrace{\int_A Q_k^{m_\bullet}(s,a)\,p(\mathrm{d}a)}_{\text{expected energy}} \;+\; \tau \underbrace{\int_A p\log p}_{-\,\text{entropy}}.$$

The entropy term $\int p\log p$ is minimised by the *uniform* distribution and blows up (towards its least negative value) as p concentrates, so it pulls in the opposite direction to the energy: the energy wants a spike on the cheapest action, the entropy wants a spread-out hedge, and the temperature τ sets the exchange rate between them. At $\tau \to 0$ the energy dominates and the free-energy minimiser collapses back to the hard arg min; at $\tau \to \infty$ the entropy dominates and the minimiser is the flat reference distribution, ignoring Q altogether. For any $\tau > 0$ in between, the minimiser is an *interior* point of the simplex — it never sits at a vertex, so it can no longer jump between vertices — and, because the free energy is now *strictly* convex in p (the entropy is strictly convex; the energy is linear), that interior minimiser is unique and moves continuously, indeed Lipschitz-continuously, as Q and hence the environment is perturbed. This is the entire mechanism: a temperature converts a discontinuous vertex-valued arg min into a smooth interior-valued softmax. We now record the construction precisely.

Definition 29.11 (Regularised MFMDP)**.** Fix a *temperature* $\tau > 0$. The *τ-regularised* value, Q-function, and best response replace the hard minimisation in (29.2) by a free-energy minimisation:

$$u_{\tau,k}^{m_\bullet}(s) = \min_{p\in\mathcal{P}(A)} \Big\{ \int_A Q_{\tau,k}^{m_\bullet}(s,a)\,p(\mathrm{d}a) + \tau\int_A p\log p \Big\}, \qquad Q_{\tau,k}^{m_\bullet}(s,a) = L_k(s,a,m_k) + \gamma\,\mathbb{E}\Big[u_{\tau,k+1}^{m_\bullet}(S_{k+1}) \mid s,a\Big], \tag{29.9}$$

with $u_{\tau,K}^{m_\bullet} = g(\cdot, m_K)$. The minimiser is the *Gibbs* (softmax/Boltzmann) policy

$$\mathsf{S}_\tau(m_\bullet)_k(\mathrm{d}a \mid s) \;=\; \frac{\exp\big(-Q_{\tau,k}^{m_\bullet}(s,a)/\tau\big)}{\displaystyle\int_A \exp\big(-Q_{\tau,k}^{m_\bullet}(s,a')/\tau\big)\,\mathrm{d}a'}\,\mathrm{d}a, \qquad u_{\tau,k}^{m_\bullet}(s) = -\tau\log\int_A e^{-Q_{\tau,k}^{m_\bullet}(s,a)/\tau}\,\mathrm{d}a. \tag{29.10}$$

The symbol $\int p \log p$ in (29.9) needs a reference against which "$\log p$" is measured, and pinning that reference down is genuine setup, not a technicality, because it is what makes both the closed form and the bias bound below well defined. Entropy is not an absolute quantity: $\int p \log p$ only makes sense once one fixes a *reference probability measure* ν_0 on the action set A against which the spread of p is gauged, and what the term really abbreviates is the *relative entropy* (Kullback–Leibler divergence)

$$\int_A p \log p \;:=\; D_{\mathrm{KL}}(p \,\|\, \nu_0) \;=\; \int_A \frac{\mathrm{d}p}{\mathrm{d}\nu_0} \log \frac{\mathrm{d}p}{\mathrm{d}\nu_0}\, \mathrm{d}\nu_0 \;\geq\; 0,$$

defined for $p \ll \nu_0$ and equal to $+\infty$ otherwise, and the integrals $\int_A \cdots \mathrm{d}a$ in (29.10) are likewise taken against ν_0. The two canonical choices are the natural ones: *normalised counting measure* $\nu_0 = |A|^{-1} \sum_a \delta_a$ when A is a finite set, and *normalised Lebesgue measure* when A is a compact subset of Euclidean space. The choice of ν_0 fixes the "ground state" the regulariser pulls towards — the agent is charged for deviating from ν_0, not from nothing — so it is ν_0, the uniform distribution in both canonical cases, that the high-temperature limit returns.

Two boundedness properties of this relative entropy are what the rest of the subsection rests on, and both flow from the assumption that ν_0 is a *probability* measure on a *compact* A. First, $D_{\mathrm{KL}}(p \,\|\, \nu_0) \geq 0$ always, with equality iff $p = \nu_0$; this is Gibbs' inequality and is what makes the regularised value a genuine lower bound below the unregularised one. Second, and more delicately, the relative entropy is *bounded above* on the class of policies we use, and the bound is finite *because* ν_0 has finite total mass. In the finite-action case $D_{\mathrm{KL}}(p \,\|\, \nu_0) = \log |A| - H(p) \leq \log |A|$, where $H(p) = -\sum_a p(a) \log p(a) \geq 0$ is the Shannon entropy; the maximal relative entropy is attained at a vertex $p = \delta_a$ and equals $\log |A|$, a finite number precisely because there are finitely many actions to count. In the compact-action case there is no count $|A|$, and one instead controls the entropy term directly: write $H_{\max}(A) := \sup_p \big(-\int_A p \log p \; \mathrm{d}a \big) < \infty$ for the maximal *differential* (Shannon) entropy of a policy on A — taken against the base measure $\mathrm{d}a$, not the relative entropy $\int p \log p$ above, and the continuum analogue of the count $\log |A|$ — a finite supremum exactly because ν_0 is a finite measure on a bounded set, so the densities cannot spread without limit. *This finiteness is the whole reason the $O(\tau)$ bias bound below is meaningful*: the regularised and the true objectives differ by τ times a relative entropy, and if that entropy could be unbounded — as it would be against an infinite reference measure on a non-compact action set — the bias would be uncontrolled no matter how small τ is. Boundedness of ν_0 is what keeps the price of regularisation proportional to τ.

With ν_0 fixed, the closed form (29.10) is the elementary Gibbs variational principle, and it is worth deriving rather than asserting, because the derivation is a two-line calculation that the reader can carry in their head and that makes the $1/\tau$ in the exponent inevitable. Minimise $\mathcal{F}_\tau[p] = \int Q\, p + \tau \int p \log p$ over densities $g = \mathrm{d}p / \mathrm{d}\nu_0 \geq 0$ subject to the single constraint $\int g \; \mathrm{d}\nu_0 = 1$. Adjoining a multiplier λ for the constraint and differentiating the Lagrangian $\int (Qg + \tau g \log g - \lambda g) \, \mathrm{d}\nu_0$ pointwise in $g(a)$ gives the stationarity condition $Q(a) + \tau(\log g(a) + 1) - \lambda = 0$, that is $g(a) = \exp\big((\lambda - \tau)/\tau\big)\, e^{-Q(a)/\tau}$; the constant prefactor is fixed by normalisation to be $1/Z$ with the *partition function* $Z = \int_A e^{-Q(a)/\tau} \, \nu_0(\mathrm{d}a)$, which is exactly the Gibbs density in (29.10). Substituting this minimiser back gives the optimal value: since $\log g = -Q/\tau - \log Z$,

$$\mathcal{F}_\tau[p^\star] = \int Q\, p^\star + \tau \int p^\star \big(-\tfrac{Q}{\tau} - \log Z\big) = \int Q\, p^\star - \int Q\, p^\star - \tau \log Z = -\tau \log Z = -\tau \log \int_A e^{-Q/\tau} \; \mathrm{d}\nu_0,$$

the *free energy*, which is the second equation of (29.10). The energy contribution $\int Q p^\star$ cancels exactly against the energy hidden inside the entropy, leaving the free energy as a pure log-partition function — the same cancellation that in equilibrium thermodynamics expresses the free energy through the partition function alone. Three consequences of this closed form now matter, and we take them in turn: it is single-valued and Lipschitz, it approaches the hard response as $\tau \downarrow 0$, and it induces a regularised equilibrium displaced from the true one by a controlled $O(\tau)$.

Lemma 29.12 (Regularised best response is single-valued and Lipschitz)**.** *Under* (A-Lip) *the Gibbs response* (29.10) *is single-valued and, for each fixed* $\tau > 0$*, Lipschitz in the environment: there is* $L_{\mathsf{S},\tau} < \infty$ *with* $d(\mathsf{S}_\tau(m_\bullet), \mathsf{S}_\tau(m'_\bullet)) \le L_{\mathsf{S},\tau} D(m_\bullet, m'_\bullet)$*. As* $\tau \downarrow 0$ *the Gibbs response concentrates on the greedy actions and* $\mathsf{S}_\tau \to \mathsf{S}$ *pointwise, while in general* $L_{\mathsf{S},\tau} = \Theta(1/\tau)$*.*

Proof sketch. There are three claims — single-valuedness, Lipschitz-in-environment, and the $\tau \downarrow 0$ limit — and the proof composes elementary facts for each.

Single-valuedness. The objective $p \mapsto \int Qp + \tau \int p \log p$ minimised in (29.9) is the sum of a term that is *linear* in p (the energy) and a term that is *strictly* convex in p (the relative entropy: $r \mapsto r \log r$ has second derivative $1/r > 0$, so $\int p \log p$ is strictly convex on the simplex of densities). A strictly convex function on a convex set has at most one minimiser, so for every $\tau > 0$ the Gibbs measure (29.10) is *the* minimiser, not merely *a* minimiser; the set-valued S has become single-valued S_τ.

Lipschitz in the environment. We obtain $L_{\mathsf{S},\tau} < \infty$ by composing two Lipschitz maps along the chain $m_\bullet \mapsto Q^{m_\bullet}_{\tau,\bullet} \mapsto \mathsf{S}_\tau(m_\bullet)$. The first map, environment to regularised Q-function, is Lipschitz: under (A-Lip) the stage data L_k, P_k depend Lipschitz-continuously on m_k, and the backward recursion (29.9) propagates that dependence stably down the stages. Concretely, the log-sum-exp value $u_{\tau,k} = -\tau \log \int e^{-Q/\tau}\, \mathrm{d}\nu_0$ is non-expansive in Q in sup-norm — it is a soft minimum, so shifting Q uniformly by c shifts $u_{\tau,k}$ by c and a sup-norm perturbation of Q moves $u_{\tau,k}$ by no more — so a perturbation of the stage data accumulates across the K stages by at most a geometric factor in γ, a discrete Grönwall in the stage index k (the summation analogue of lemma C.1). This leaves $m_\bullet \mapsto Q$ Lipschitz with a constant independent of τ. The second map, $Q \mapsto \mathrm{softmax}(-Q/\tau)$, is the one that carries the temperature, and it is $\Theta(1/\tau)$-Lipschitz from sup-norm in Q to total-variation distance in p — which is exactly the policy metric d fixed in definition 29.9. The product of the two constants is $L_{\mathsf{S},\tau} = \Theta(1/\tau)$.

The softmax Jacobian and the $\Theta(1/\tau)$ *scaling.* This is the heart of the matter, so we compute it. Take A finite for the algebra (the compact case is identical with sums replaced by integrals against ν_0). Differentiating $p_a = e^{-Q_a/\tau}/Z$ with $Z = \sum_{a'} e^{-Q_{a'}/\tau}$,

$$\frac{\partial p_a}{\partial Q_b} = -\frac{1}{\tau}\Big(p_a\, \delta_{ab} - p_a p_b\Big) = -\frac{1}{\tau}\, M_{ab}, \qquad M := \mathrm{diag}(p) - pp^\top.$$

The matrix M has a clean probabilistic identity: it is the *covariance of the one-hot indicator* of a p-distributed action. Let $A \sim p$ and let $e_A \in \mathbb{R}^{|A|}$ be its one-hot encoding, so $\mathbb{E}[e_A] = p$ and, since $e_A e_A^\top = \mathrm{diag}(e_A)$,

$$\mathrm{Cov}(e_A) = \mathbb{E}\Big[e_A e_A^\top\Big] - pp^\top = \mathrm{diag}(p) - pp^\top = M.$$

A covariance matrix is positive semidefinite, so $M \succeq 0$; and since $pp^\top \succeq 0$ we also have $M = \mathrm{diag}(p) - pp^\top \preceq \mathrm{diag}(p)$. Sandwiched as $0 \preceq M \preceq \mathrm{diag}(p)$, its operator norm is bounded by that of the diagonal, $\|M\|_{\mathrm{op}} \le \max_a p_a \le 1$. That is the bound on the ℓ^2 side; to land in total variation, which is the metric d asks for, we count the entries directly. For a sup-norm perturbation δQ with $\|\delta Q\|_\infty = \delta$, the induced $\delta p = -\frac{1}{\tau} M\, \delta Q$ has

$$\|\delta p\|_1 = \sum_a \left| \tfrac{1}{\tau} \textstyle\sum_b M_{ab}\, \delta Q_b \right| \le \tfrac{\delta}{\tau} \textstyle\sum_{a,b} |M_{ab}| = \tfrac{\delta}{\tau}\Big(\underbrace{\sum_a p_a(1-p_a)}_{\text{diagonal}} + \underbrace{\sum_{a\ne b} p_a p_b}_{\text{off-diagonal}} \Big) = \tfrac{\delta}{\tau}\, 2\big(1 - \textstyle\sum_a p_a^2\big) \le \tfrac{2\delta}{\tau},$$

where the off-diagonal sum is $\sum_{a\ne b} p_a p_b = (\sum_a p_a)^2 - \sum_a p_a^2 = 1 - \sum_a p_a^2$ and the diagonal sum is $\sum_a p_a - \sum_a p_a^2 = 1 - \sum_a p_a^2$. The total-variation move is therefore $\frac{1}{2}\|\delta p\|_1 \le \delta/\tau$: a sup-norm change of δ in Q shifts the policy by at most δ/τ in total variation, so the softmax is $\Theta(1/\tau)$-Lipschitz from sup-norm to TV. The precise constant is immaterial; the load-bearing fact is the inverse-temperature scaling — the regulariser buys continuity, but the modulus it buys degrades like $1/\tau$ as the temperature is lowered, which is the bias–variance tension we return to in section 29.5.

The hard limit $\tau \downarrow 0$. Finally, the Gibbs response concentrates on the greedy actions as the temperature vanishes, recovering the hard S pointwise. Write $Q_{\min} = \min_a Q(a)$ and factor it out of every weight: $p_\tau(a) = e^{-(Q(a)-Q_{\min})/\tau} / \int e^{-(Q(a')-Q_{\min})/\tau}\, \mathrm{d}\nu_0$. Each integrand $e^{-(Q(a)-Q_{\min})/\tau}$ is bounded by the constant 1 — which is ν_0-integrable precisely because ν_0 is a probability measure, so the finiteness of ν_0 does work here too — and converges pointwise as $\tau \downarrow 0$ to the indicator $\mathbf{1}\{Q(a) = Q_{\min}\}$ of the arg min set: it stays equal to 1 where $Q(a) = Q_{\min}$ and decays to 0 wherever $Q(a) > Q_{\min}$. Dominated convergence then carries the limit through both numerator and denominator, so p_τ converges to ν_0 restricted and renormalised to the arg min set — exactly the greedy best response $\mathsf{S}(m_\bullet)$ of definition 29.2. The same domination gives the value: $u_{\tau,k} = Q_{\min} - \tau \log \int e^{-(Q-Q_{\min})/\tau}\, \mathrm{d}\nu_0 \to Q_{\min} = \min_a Q$, so the regularised Bellman step (29.9) returns the hard step (29.2) in the limit. The two limits together say $\mathsf{S}_\tau \to \mathsf{S}$ as $\tau \downarrow 0$ while $L_{\mathsf{S},\tau} = \Theta(1/\tau) \to \infty$ — faithfulness and continuity traded against each other through the single knob τ. □

Having a continuous, single-valued best response in hand does more than enable the averaging schemes; it resurrects, for the *regularised* game, the existence and uniqueness theory the hard arg min had put out of reach, and at a price we can now quantify. The next remark records this, closing the loop between the smoothed game and the original one.

Remark 29.13 (Regularised equilibrium and its bias)**.** The regularised game has its own equilibrium $(\pi^\star_\tau, m^\star_{\tau,\bullet})$, a fixed point of $\Psi \circ \mathsf{S}_\tau$. Its existence follows from the now-*continuous* best response by the Schauder fixed-point theorem (chapter 2) applied on the compact convex set of flows supplied by theorem 10.14: the requisite compactness in $\mathcal{P}(\mathcal{S})$ is Prokhorov tightness, established and used there (chapter 10), and the continuity of $\Psi \circ \mathsf{S}_\tau$ — the hypothesis Schauder needs and the one the hard arg min failed — is exactly lemma 29.12. This is the structural payoff of regularisation: where the unregularised composite $\Psi \circ \mathsf{S}$ was only *upper hemicontinuous* and demanded the heavier Kakutani machinery (and even then guaranteed nothing about a learning loop converging to the fixed point), the regularised composite is an honest continuous self-map of a compact convex set, so a fixed point exists by the elementary theorem. Uniqueness then follows under (A-Mon) (developed in the next subsection) or under the contraction condition (29.8) read with the regularised modulus $L_{\mathsf{S},\tau}$ — the two hypotheses that run as the chapter's twin spine.

The regularised fixed point is, however, emphatically *not* the equilibrium of the original game, and honesty requires us to say by how much it misses. The miss is measured by the exploitability (29.4) of $\pi^\star_\tau$ *in the true, unregularised game*, and it is $O(\tau)$. The reason is that the regularised objective differs from the true one (29.2) by exactly the added term $\tau\int p\log p$, a relative entropy that we established above is bounded; carrying that bounded perturbation through the value comparison gives, for finite A,

$$\mathcal{E}(\pi^\star_\tau) \;\le\; c_0\,\tau\,\big(1+\log|A|\,\big),$$

where the $\log|A|$ is the maximal relative entropy $\log|A|$ counted in the setup — the bias is large only when there are exponentially many actions to spread mass over, and even then only logarithmically so. When A is instead a compact continuum there is no count $|A|$ to insert, and the same argument runs with the maximal differential entropy in its place,

$$\mathcal{E}(\pi^\star_\tau) \;\le\; c_0\,\tau\,\big(1+H_{\max}(A)\big),$$

with $H_{\max}(A)$ the finite maximal ν_0-entropy fixed in the setup above — finite precisely because ν_0 is a finite reference measure on a compact set, which is the place the boundedness discussion pays off. The two bounds are the same statement counted two ways: the bias is τ times "how much entropy the regulariser can inject," which is a pure count $\log|A|$ in the discrete case and a measure-theoretic ceiling $H_{\max}(A)$ in the continuous one. Thus τ is a knob with two opposed faces, exactly as the section header promised: *large τ stabilises but biases* — it shrinks $L_{\mathsf{S},\tau}$, easing every convergence argument below, while displacing the fixed point by $O(\tau)$ — and *small τ is faithful but stiff* — it sends the bias to zero but lets $L_{\mathsf{S},\tau}=\Theta(1/\tau)$ blow up, so the very continuity the averaging schemes rely on degrades. Choosing, or annealing, τ is therefore the central tuning decision of the method, and the residual $O(\tau)$ bias is one of the three error terms the modular guarantee of section 29.5 must carry to the end.

We have what the section's first unit was charged to produce: a best response that is single-valued, Lipschitz with a named modulus $L_{\mathsf{S},\tau}=\Theta(1/\tau)$, and faithful to the original game up to a controlled $O(\tau)$ bias. This is precisely the object the two damping schemes presuppose but cannot themselves manufacture. Fictitious play, next, cures the cobweb by having the agent best-respond not to the latest population but to the *running average* of all populations seen so far — the "respond to a running average" remedy previewed in section 29.2.2 — and that averaging is meaningful only because S_τ now varies continuously with its argument, so that averaging nearby environments yields a nearby response rather than blending unrelated extremes. Online mirror descent, after it, will lean on the same Lipschitz response from the policy side. We hand both the smoothed best response, and proceed to the first of the two monotonicity-powered dynamics.

29.3.2 Fictitious play

The first damper the cobweb heuristic named was to refuse to chase the latest best response and instead respond to a *running average* of every population seen so far. That is *fictitious play*, and it is the natural place to begin: it is the oldest learning dynamic in game theory [74] — old enough to predate the modern algorithmic vocabulary of equilibrium — and the first to be carried over to mean field games [38]. Its entire content is the single substitution the previous section previewed. Where the naive loop set $\pi^n = \mathsf{S}(m_\bullet^{n-1})$, best-responding to the *most recent* population and thereby inheriting its full volatility, fictitious play best-responds instead to the *time-average* $\bar{m}_\bullet^{n-1}$ of all populations produced so far. It is the previous subsection that makes this substitution legitimate rather than wishful: averaging populations and expecting a stable response out the other side is only sensible if nearby populations elicit nearby responses, and that Lipschitz continuity is exactly what the Gibbs best response S_τ of lemma 29.12 now supplies — the hard arg min, which could blend two unrelated extremes under an average, had no such property. We continue to write S for the response throughout this subsection, understanding it to be the regularised, single-valued S_τ that the averaging requires; the temperature τ rides along, contributing only the $O(\tau)$ bias of remark 29.13, and we suppress it in the notation to keep the dynamics in view.

Definition 29.14 (Fictitious play)**.** Fix an initial flow $\bar{m}_\bullet^0$. *Fictitious play* (FP) iterates, for $n \geq 1$,

$$\pi^n = \mathsf{S}(\bar{m}_\bullet^{n-1}), \qquad m_\bullet^n = \Psi(\pi^n), \qquad \bar{m}_\bullet^n = \Big(1 - \tfrac{1}{n}\Big)\bar{m}_\bullet^{n-1} + \tfrac{1}{n}\, m_\bullet^n, \tag{29.11}$$

the convex combination taken stage-wise in $\mathcal{P}(\mathcal{S})$. The played policy is the realised mixture whose flow is $\bar{m}_\bullet^n$.

Read the third line of (29.11) as the discrete update of a running mean: $\bar{m}_\bullet^n$ is the average of the first n induced flows $m_\bullet^1, \dots, m_\bullet^n$, and the weight $\frac{1}{n}$ on the newest arrival shrinks as the history lengthens. This is precisely what damps the cobweb. The *environment* $\bar{m}_\bullet^{n-1}$ that the best response now answers moves by only an $O(1/n)$ increment from one round to the next, so it becomes ever more nearly *quasi-static*: the response still overreacts to whatever it is shown — L_{S} is no smaller than before, the arg min is just as steep — but it is shown a target that barely moves, and an overreaction to a nearly stationary target cannot compound into a growing oscillation. Return to the congestion picture of section 29.2.2, where the naive loop flung the whole population left, then right, then left again at undiminished amplitude. Under fictitious play the first response still says "go right," but the played population is now the *average* of left-so-far with the new right, which sits nearer the centre; the next response, answering that gentler environment, is milder; and the running mean settles onto the even spread the naive loop could only orbit. The wild swing is not suppressed at its source — the best response is as violent as ever — but it is *diluted by history*, its pull on the played flow falling off like $1/n$.

What this buys, and the reason fictitious play belongs in this section rather than the last, is that its convergence is governed by an entirely different hypothesis from the contraction regime. It does not ask the coupling to be weak. It asks the coupling to be *monotone*: the same Lasry–Lions condition (A-Mon) that delivered *uniqueness* of the equilibrium in chapters 11 and 24 now reappears, unchanged, as the condition that delivers *convergence* of the learning dynamic. As the section header insisted, monotonicity constrains the *sign* of how the population's cost responds to a perturbation of the population, never its *magnitude*, so a coupling can be arbitrarily strong — with $L_{\mathsf{S}} L_\Psi$ arbitrarily large and the naive loop hopelessly cycling — and fictitious play converge nonetheless. The next theorem states this, and its proof is where monotonicity does its work.

Theorem 29.15 (Convergence of fictitious play under monotonicity)**.** *Assume* (A-Lip)*,* (A-Nondeg)*, and the Lasry–Lions monotonicity condition* (A-Mon) *on the couplings — the classical scalar form* *definition 11.1 or, at the graphon level relevant to section 29.4, the graphon Lasry–Lions condition definition 24.15 with its uniqueness theorem theorem 24.16. Then the fictitious-play iterates* (29.11) *have exploitability tending to zero,*

$$\mathcal{E}(\bar{\pi}^{\,n}) \;\longrightarrow\; 0 \qquad (n \to \infty), \tag{29.12}$$

where $\bar{\pi}^{\,n}$ is the policy realising $\bar{m}^n_\bullet$. Consequently every weak limit point of $(\bar{m}^n_\bullet)$ is an equilibrium flow, and it is the unique equilibrium under (A-Mon) *(theorems 11.5 and 24.16).*

Proof: the Lyapunov mechanism. The argument is a Lyapunov computation carried out in *continuous learning time*, and it is worth saying at the outset what it does and does not deliver: it establishes the convergence (29.12), $\mathcal{E} \to 0$, in full and in-book, and it isolates monotonicity as the exact structural reason the convergence happens; the sharp algebraic *rate* it does not deliver, and remark 29.16 accounts honestly for what must be imported instead.

Step 0: from the $\frac{1}{n}$ iteration to a flow. The discrete update is awkward to differentiate because its step size $\frac{1}{n}$ changes every round; the standard device is to re-time it so the steps become uniform. Set $\vartheta = \log n$, so that advancing $n \mapsto n+1$ advances ϑ by $\log(n+1) - \log n = \frac{1}{n} + O(\frac{1}{n^2})$ — the shrinking step in n is a *constant* step $\Delta\vartheta = \frac{1}{n}$ in ϑ, and the discrete index becomes a unit-speed clock. Rewrite the averaging line of (29.11) as an increment,

$$\bar{m}^n_\bullet - \bar{m}^{n-1}_\bullet = \tfrac{1}{n}(m^n_\bullet - \bar{m}^{n-1}_\bullet) = \Delta\vartheta\,\Big(\Psi(\mathsf{S}(\bar{m}^{n-1}_\bullet)) - \bar{m}^{n-1}_\bullet\Big),$$

using $m^n_\bullet = \Psi(\pi^n) = \Psi(\mathsf{S}(\bar{m}^{n-1}_\bullet))$ from the first two lines of (29.11). This is precisely one explicit Euler step, of step $\Delta\vartheta$, of the *best-response flow*

$$\frac{\mathrm{d}}{\mathrm{d}\vartheta}\,\bar{m}_\bullet(\vartheta) = \Psi\big(\mathsf{S}(\bar{m}_\bullet(\vartheta))\big) - \bar{m}_\bullet(\vartheta), \tag{29.13}$$

so the FP iterates are the Euler discretisation of (29.13), and by the standard consistency of the Euler scheme for a Lipschitz vector field — the field is Lipschitz because $\mathsf{S} = \mathsf{S}_\tau$ is, by lemma 29.12, and Ψ is, by definition 29.9 — the discrete trajectory tracks the continuous one as $n \to \infty$. We therefore analyse the flow and read the conclusion back to the iterates at the end. The flow says in words exactly what the averaging does: the played population $\bar{m}_\bullet$ is pulled, at unit rate, toward the population $\Psi(\mathsf{S}(\bar{m}_\bullet))$ that the current best response would generate — it chases the best-response target, but at a bounded speed that cannot overshoot.

Let

$$\mathcal{G}(\vartheta) = \mathcal{E}(\bar{\pi}(\vartheta)) = J(\bar{\pi}; \bar{m}_\bullet) - g(\bar{m}_\bullet), \qquad g(m_\bullet) := \inf_{\pi'} J(\pi'; m_\bullet),$$

be the running exploitability of the played policy $\bar{\pi}(\vartheta)$ (the policy realising $\bar{m}_\bullet(\vartheta)$), with g the optimised value of (29.4). By construction $\mathcal{G} \geq 0$, and $\mathcal{G} = 0$ exactly at equilibrium; the entire proof is the statement that $\mathcal{G}$ is a Lyapunov function for (29.13), decreasing to zero along the flow. We differentiate it along (29.13), and two ingredients enter, each made fully explicit.

(i) The envelope (Danskin) identity, derived inline. The optimised value $g(m_\bullet) = \inf_{\pi'} J(\pi'; m_\bullet)$ depends on the environment $m_\bullet$ in two superficially distinct ways: *explicitly*, through the appearance of $m_\bullet$ in the cost data of J, and *implicitly*, through the fact that the minimiser $\pi' = \mathsf{S}(m_\bullet)$ at which

the infimum is attained itself moves when $m_\bullet$ moves. The envelope identity is the statement that the second, implicit channel contributes *nothing* to first order. To see it, write $g(m_\bullet) = J(\mathsf{S}(m_\bullet); m_\bullet)$ and differentiate along the flow by the chain rule, separating the two channels:

$$\frac{\mathrm{d}}{\mathrm{d}\vartheta}\, g(\bar m_\bullet) = \underbrace{D_{\pi'} J\big(\mathsf{S}(\bar m_\bullet); \bar m_\bullet\big)\Big[\tfrac{\mathrm{d}}{\mathrm{d}\vartheta}\mathsf{S}(\bar m_\bullet)\Big]}_{\text{implicit: minimiser motion}} + \underbrace{\partial_m J\big(\mathsf{S}(\bar m_\bullet); \bar m_\bullet\big)\cdot \dot{\bar m}_\bullet}_{\text{explicit: environment dependence}}.$$

The first term vanishes identically, and the reason is first-order optimality: $\mathsf{S}(\bar m_\bullet)$ is the *unconstrained* minimiser of the smooth, strictly convex map $\pi' \mapsto J(\pi'; \bar m_\bullet)$ at the frozen environment — strict convexity in the action law being exactly what the entropy regulariser bought in lemma 29.12 — so its first variation in π' is zero there, $D_{\pi'} J(\mathsf{S}(\bar m_\bullet); \bar m_\bullet) = 0$, and the minimiser-motion term is this zero gradient paired against whatever velocity $\frac{\mathrm{d}}{\mathrm{d}\vartheta}\mathsf{S}(\bar m_\bullet)$ the minimiser happens to carry. Hence only the explicit channel survives:

$$\frac{\mathrm{d}}{\mathrm{d}\vartheta}\, g(\bar m_\bullet) = \partial_m J\big(\mathsf{S}(\bar m_\bullet); \bar m_\bullet\big)\cdot \dot{\bar m}_\bullet. \tag{29.14}$$

This is the elementary envelope theorem of Danskin; we invoke no external result precisely because the minimisation is over the policy at a frozen environment and the regularised objective is smooth and strictly convex there, so the minimiser is unique and its first variation genuinely vanishes (a non-strictly-convex objective could carry a moving *set* of minimisers and the identity would need more care — another debt the regularisation of the previous subsection silently pays). Conceptually, (29.14) is what lets us treat the cost of the *best* response as though the response were frozen while only the crowd it faces moves — the single simplification that makes $\mathcal{G}'$ tractable at all.

(ii) Monotonicity turns the cross term into a sign. Differentiating $\mathcal{G} = J(\bar\pi; \bar m_\bullet) - g(\bar m_\bullet)$ and inserting the flow $\dot{\bar m}_\bullet = \mu_\bullet - \bar m_\bullet$, with $\mu_\bullet := \Psi(\mathsf{S}(\bar m_\bullet))$ the best-response-induced population, two kinds of term appear. The first is a *relaxation* term: the flow drives the played flow $\bar m_\bullet$ toward the best-response target $\mu_\bullet$ at unit rate, and since $\mathcal{G}$ measures precisely the cost gap between playing $\bar\pi$ and playing the best response in the current environment, this pull shrinks the gap and contributes $-\mathcal{G}$ to $\mathcal{G}'$. The second is a *coupling cross term*, produced by the environment-derivative (29.14) together with the explicit m-dependence of $J(\bar\pi; \cdot)$: collecting these along the direction $\mu_\bullet - \bar m_\bullet$ — an assembly that is the computation of [38], carried out fully and in closed form for the affine LQG reduction in worked computation 29.22 — the mean-field coupling contributes exactly the pairing

$$\int \big(L[\mu_\bullet] - L[\bar m_\bullet]\big)\, \mathrm{d}(\mu_\bullet - \bar m_\bullet), \tag{29.15}$$

the difference of coupling costs paired against the difference of the two populations. This is the whole reason the proof needs monotonicity and nothing weaker: (29.15) is *exactly* the left-hand side of the Lasry–Lions inequality (11.3), evaluated at the pair $(\bar m_\bullet, \mu_\bullet)$, so (A-Mon) forces it to be ≥ 0, and the cross term therefore enters $\mathcal{G}'$ with a favourable sign. Writing $r(\vartheta)$ for the cross term once carried to the right-hand side, we have shown

$$\mathcal{G}'(\vartheta) \;\leq\; -\mathcal{G}(\vartheta) + r(\vartheta), \qquad r(\vartheta) \leq 0, \tag{29.16}$$

where r is ≤ 0 outright in the potential case (there the coupling is the gradient of a convex population functional and the pairing is its dissipation, manifestly nonnegative) and $o(1)$ in the general monotone case (the same pairing, controlled along the flow rather than signed pointwise). At the graphon level required by section 29.4 the identical step runs with the scalar pairing (11.3) replaced by its type-integrated form (24.5): the cross term becomes $\int_0^1 \int (L[x, \mu_\bullet] - L[x, \bar{m}_\bullet])\, \mathrm{d}(\mu_x - \bar{m}_x)\, \mathrm{d}x$, the same population pairing now integrated over the type axis with the aggregate built through the kernel $\mathbb{W}$, and the graphon Lasry–Lions condition definition 24.15 supplies its nonnegativity verbatim. The lift costs nothing precisely because monotonicity was a statement about the *sign* of a pairing, and a pairing integrates over the type label without changing sign.

Conclusion by Grönwall. With (29.16) in hand and $r \le 0$, Grönwall's inequality (lemma C.1) gives $\mathcal{G}(\vartheta) \le \mathcal{G}(0)\, e^{-\vartheta}$, hence $\mathcal{G}(\vartheta) \to 0$; in the general monotone case the same inequality with $r = o(1)$ still forces $\mathcal{G}(\vartheta) \to 0$, since the homogeneous decay $e^{-\vartheta}$ outruns a vanishing forcing. Either way the continuous best-response flow drives exploitability to zero. Undoing the time change $\vartheta = \log n$ returns the statement to the discrete iterates as (29.12), $\mathcal{E}(\bar{\pi}^{\,n}) \to 0$. Every weak limit point of $(\bar{m}^n_\bullet)$ therefore has zero exploitability and is an equilibrium flow, and under (A-Mon) that equilibrium is unique (theorem 11.5, resp. theorem 24.16), so the whole sequence converges to it.

The conceptual core. It is worth isolating what monotonicity actually did, because it is the heart of the chapter. Strip the hypothesis away and the cross term (29.15) has no definite sign; the relaxation $-\mathcal{G}$ can then be exactly cancelled by an adverse cross term, leaving $\mathcal{G}' = 0$ — exploitability *conserved*, neither growing nor decaying. A conserved $\mathcal{G}$ is the undamped cobweb of section 29.2.2 seen in continuous time: the orbit circles the equilibrium on a level set of $\mathcal{G}$ forever, the misalignment between the crowd and its best response sloshing back and forth without ever dissipating. Monotonicity is exactly the structural fact that breaks the tie. It forces the cross term to one side, so the misalignment can only *cost* the system, never refund it, and $\mathcal{G}$ becomes a strict Lyapunov function — a quantity that can only fall — rather than a constant of the motion. In one sentence: monotonicity converts the crowd's misalignment from a conserved quantity into a dissipating Lyapunov functional, and that conversion is the entire difference between a loop that cycles and a loop that learns. □

Remark 29.16 (What is proved here and what is imported)**.** The Lyapunov argument just given is honest about its reach, and the distinction it draws is one the reader should carry forward, because the same split — a clean in-book qualitative convergence, a sharp rate imported but anchored — recurs for online mirror descent and again in the modular guarantee of section 29.5. What is *proved in-book* is the qualitative statement (29.12): exploitability tends to zero, by the continuous-time Lyapunov mechanism, with monotonicity supplying the dissipation. What that argument does *not* pin down is the *rate* at which it tends to zero. Extracting the exponent requires controlling the discrete error committed in passing from the genuine $\frac{1}{n}$ iteration (29.11) to its continuous Euler limit (29.13) — exactly the $O(1/n^2)$ corrections to the step $\Delta\vartheta = \log(n+1) - \log n$ that Step 0 of the proof discarded — and assembling them into a telescoping estimate, a discrete bookkeeping the flow argument deliberately threw away. The quantitative sharpening

$$\mathcal{E}(\bar{\pi}^{\,n}) \;\le\; \frac{C}{\sqrt{n}} \qquad \text{(and } O(1/n) \text{ in the potential, monotone-}\textit{and}\text{-variational case),} \tag{29.17}$$

is the content of [38, 111], whose discrete telescoping and $\vartheta = \log n$ bookkeeping we cite for attribution and do *not* reproduce; (29.17) is therefore *imported*, not derived in this book.

It is, however, anchored rather than left dangling, and this is the point of drawing the line so sharply. The worked LQG recursion (29.23) below derives, *fully in-book*, the exact algebraic decay $e_n \sim n^{\lambda-1}$ of the population error for the scalar affine reduction, with $\lambda < 1$ the fictitious-play convergence threshold of worked computation 29.22, Step 3. Since the value gap near the LQG equilibrium is quadratic in the mean displacement, this gives $\mathcal{E}(\bar{\pi}^n) \sim n^{2(\lambda-1)}$, of which the universal $O(1/\sqrt{n})$ of (29.17) is precisely the worst case, saturated as $\lambda \uparrow \frac{3}{4}$. So the imported bound is not taken on faith: the book exhibits, by hand and in closed form, one model in which the very same rate is computed from scratch and shown to be the slowest member of the monotone class. The reader thus knows exactly where the boundary of the in-book argument lies — $\mathcal{E} \to 0$ proved, the algebraic exponent imported but checked against a computable instance — and that division of labour is the template the rate discussions of the next subsection and section 29.5 will follow.

Fictitious play has thus delivered the chapter's first convergence result that does not lean on contraction: under monotonicity alone, the running-average dynamic drives exploitability to zero, with the Lyapunov functional $\mathcal{G}$ doing in continuous learning time exactly what the smallness condition (29.8) did in the contraction regime — guaranteeing descent — but on the far larger terrain where the coupling may be arbitrarily strong. The template it leaves behind is more portable than the particular scheme. What made the proof work was not the specific $\frac{1}{n}$ average over *populations* but the pairing of a relaxation term against a monotone cross term to produce a strict Lyapunov decrease; any dynamic expressible as such a flow inherits the same conclusion. The next subsection exploits exactly this. Online mirror descent averages not the populations but the *evaluations*, stepping incrementally in the entropy (softmax-mirror) geometry built from the Gibbs map of definition 29.11, and its convergence proof is the Bregman-divergence variant of the present one: the Kullback–Leibler divergence to the equilibrium policy plays the role of $\mathcal{G}$, the three-point identity (29.19) plays the role of the envelope step, and monotonicity again converts the cross term into dissipation. The same monotone regime, and the same honest split between an in-book qualitative guarantee and a rate imported but anchored on worked computation 29.22, will reassemble in the modular guarantee of section 29.5.

29.3.3 Online mirror descent

Mirror descent takes a complementary route: instead of averaging populations it accumulates *evaluations* and takes small, geometry-aware steps in policy space. In the entropy-regularised geometry the "mirror map" is the softmax, so online mirror descent (OMD) maintains a cumulative Q-function and reads off a Gibbs policy at every step. It is the basis of the most scalable modern MFG learners [110, 96].

Definition 29.17 (Online mirror descent)**.** Fix a step size $\eta > 0$ and temperature $\tau > 0$. Initialise cumulative scores $y_k^0 \equiv 0$. *Online mirror descent* iterates, for $n \geq 1$,

$$\pi_k^n(\cdot \mid s) = \mathrm{softmax}\big(-y_k^{n-1}(s,\cdot)/\tau\big), \quad m_\bullet^n = \Psi(\pi^n), \quad y_k^n(s,a) = y_k^{n-1}(s,a) + \eta\, Q_k^{m_\bullet^n}(s,a), \tag{29.18}$$

where $Q_k^{m_\bullet^n}$ is the action-value of π^n against its own induced flow. The averaged policy $\bar{\pi}^n$ is the one whose scores are $\frac{1}{n}\sum_{j \leq n} y^j$.

Lemma 29.18 (Three-point identity for the entropy mirror map)**.** *Let ν_0 be the reference measure of definition 29.11, and let q, q_+ be probability densities on A related by the Gibbs tilt $q_+(a) = q(a)\, e^{-\eta g(a)}/Z$ with $Z = \int_A q\, e^{-\eta g}\, \mathrm{d}\nu_0$, for a bounded score g and step $\eta > 0$. Then for every probability density $p \ll \nu_0$,*

$$\mathrm{KL}(p\|q_+) = \mathrm{KL}(p\|q) - \mathrm{KL}(q_+\|q) + \eta\, \langle g, p - q_+\rangle. \tag{29.19}$$

Proof. Since $\log(q_+/q) = -\eta g - \log Z$, expand each divergence against ν_0: $\mathrm{KL}(p\|q_+) = \mathrm{KL}(p\|q) - \int p \log \frac{q_+}{q} = \mathrm{KL}(p\|q) + \eta\langle g, p\rangle + \log Z$, and likewise $\mathrm{KL}(q_+\|q) = -\int q_+ \log \frac{q_+}{q} \cdot (-1) = \eta\langle g, q_+\rangle + \log Z$. Subtracting the second from the first eliminates $\log Z$ and yields (29.19). (This is the entropy-mirror instance of the Bregman "law of cosines"; all three terms are exact, no approximation.) □

Theorem 29.19 (Convergence of OMD to the regularised equilibrium)**.** *Assume* (A-Lip)*,* (A-Nondeg)*, and* (A-Mon) *(classical definition 11.1 or graphon definition 24.15), and run OMD* (29.18) *at temperature $\tau > 0$ with a sufficiently small step size η. Then the iterates converge to the unique τ-regularised equilibrium $(\pi^\star_\tau, m^\star_{\tau,\bullet})$ of remark 29.13, with regularised exploitability $\mathcal{E}_\tau(\bar\pi^{\,n}) \to 0$. Combined with the bias bound of remark 29.13, the* unregularised *exploitability obeys $\mathcal{E}(\bar\pi^{\,n}) \to c_0\tau(1 + \log|A|)$ as $n \to \infty$.*

Proof: the Bregman–Lyapunov mechanism. The Lyapunov functional is the *Bregman divergence* (relative entropy) from the current policy to the regularised equilibrium,

$$\mathcal{D}^n = \int_{\mathcal{S}} \sum_k \mathrm{KL}\big(\pi^\star_{\tau,k}(\cdot \mid s) \,\big\|\, \pi^n_k(\cdot \mid s)\big)\, m^\star_{\tau,k}(\mathrm{d}s).$$

The OMD update (29.18) tilts π^{n-1}_k to π^n_k by the Gibbs factor $e^{-\eta\,\delta y/\tau}$, i.e. it is exactly the mirror step of lemma 29.18 with score $g = Q^{m^n_\bullet}_k/\tau$ and reference $p = \pi^\star_{\tau,k}$. Applying (29.19) stage-wise and integrating against $m^\star_{\tau,\bullet}$,

$$\mathcal{D}^n = \mathcal{D}^{n-1} - \underbrace{\int \sum_k \mathrm{KL}(\pi^n_k\|\pi^{n-1}_k)\, \mathrm{d}m^\star_\tau}_{\geq 0} - \eta\, \langle Q^{m^n_\bullet}/\tau, \pi^n - \pi^\star_\tau\rangle_{m^\star_\tau},$$

so $\mathcal{D}^n \leq \mathcal{D}^{n-1} - \eta\,\Gamma^n$, where $\Gamma^n := \langle Q^{m^n_\bullet}/\tau, \pi^n - \pi^\star_\tau\rangle$ is the regularised duality gap. Monotonicity (A-Mon) makes Γ^n nonnegative and bounded below by the regularised exploitability $\mathcal{E}_\tau(\pi^n)$ (the same pairing as in theorem 29.15). Summing telescopes, $\eta \sum_{j \leq n} \mathcal{E}_\tau(\pi^j) \leq \eta \sum_{j \leq n} \Gamma^j \leq \mathcal{D}^0$, so the running average of $\mathcal{E}_\tau$ tends to 0; convexity of $\mathcal{E}_\tau$ in the score geometry transfers this to the averaged policy $\bar\pi^{\,n}$, giving $\mathcal{E}_\tau(\bar\pi^{\,n}) \to 0$. Uniqueness of $\pi^\star_\tau$ is the strict convexity injected by the entropy plus monotonicity; the bias term is remark 29.13. □

Remark 29.20 (The $1/n$ rate is an imported refinement)**.** The telescoping above is exact only up to the second-order (η^2) curvature term that a finite step size $\eta > 0$ leaves in (29.19) through $\mathrm{KL}(\pi^n\|\pi^{n-1}) = O(\eta^2)$. Carrying that term with a tuned step-size schedule sharpens the in-book convergence $\mathcal{E}_\tau(\bar\pi^{\,n}) \to 0$ to the algebraic rate

$$\mathcal{E}_\tau(\bar\pi^{\,n}) \leq C/n, \tag{29.20}$$

which is the content of [110]; we cite it for attribution and flag (29.20) as imported rather than derived here. The continuous-time limit is the replicator/mirror flow whose Lyapunov function is exactly $\mathcal{D}$, for which the $1/n$ follows from $\dot{\mathcal{D}} \leq -\mathcal{E}_\tau$ and Jensen along the average.

Remark 29.21 (Two stabilisers, two hypotheses)**.** The logical structure is worth stating plainly. FPI converges under *contraction* (29.8), a strong smallness condition on the coupling. FP and OMD converge under *monotonicity* (A-Mon), which is *not* a smallness condition: the coupling may be arbitrarily strong provided it is “stabilising” (repulsive/crowd-averse) in the Lasry–Lions sense. Monotonicity is exactly the hypothesis that gave *uniqueness* (not existence) in chapter 11; here it gives *convergence of learning*. This is no coincidence: monotonicity makes the exploitability a Lyapunov function, and a Lyapunov function both pins down the equilibrium and guides the iterates to it.

Worked computation 29.22 (The LQG thread: contract or average)**.** We make the dichotomy of remark 29.21 completely explicit on the scalar LQG mean field game of Thread A (worked computation 8.12 and theorem 14.6), and then read off the graphon generalisation of Thread B. Recall the model: state $\mathrm{d}X_t = (aX_t + b\alpha_t)\,\mathrm{d}t + \sigma\,\mathrm{d}B_t$, cost $\mathbb{E}\int_0^T \big[\frac{1}{2}\alpha_t^2 + \frac{q}{2}(X_t - s\,\bar{m}_t)^2\big]\,\mathrm{d}t + \text{terminal}$, with population mean $\bar{m}_t = \int \xi\, m_t(\mathrm{d}\xi)$ and mean-coupling strength s. Because the model is linear–quadratic, the entire equilibrium problem collapses onto the *mean trajectory* $\phi = (\bar{m}_t)_{t\in[0,T]} \in C([0,T])$, and the composite “best-respond, then push forward” is an *affine* map of ϕ.

Step 1: the composite map is affine. (A reminder on symbols: within this LQG computation s is the Thread A mean-coupling strength, *not* an MDP state — the state is X_t — and P_t is the Riccati curvature, leaving the chapter’s Q for the action-value function.) Freeze the environment mean ϕ. The representative agent solves a linear-quadratic regulator with the time-dependent target $s\phi_t$; by eqs. (14.5) and (14.13) its optimal feedback is $\alpha_t^* = -b(P_tX_t + r_t[\phi])$, where P_t is the (population-independent) solution of the scalar Riccati equation (14.7) and the decoupling offset $r_t[\phi]$ (the linear coefficient of the value, $V_x = P_t x + r_t$, in the carried-thread notation of chapter 14) solves the *linear* backward ODE $\dot{r}_t = (b^2P_t - a)\,r_t + q\,s\,\phi_t$, $r_T = \text{(terminal)}$, hence depends linearly on ϕ. The $+q\,s\,\phi_t$ source is the x^1-coefficient of the HJB for the tracking cost $\frac{q}{2}(X_t - s\phi_t)^2$; with this sign the induced mean inherits the sign of s (a crowd-seeking target $s > 0$ pulls the mean toward $+\infty \cdot \mathrm{sign}(s)$), which fixes the physical orientation used in Step 3. The induced state mean $\rho_t = (\Psi \circ \mathsf{S})(\phi)_t$ then solves the *linear* forward ODE $\dot{\rho}_t = (a - b^2P_t)\rho_t - b^2 r_t[\phi]$, $\rho_0 = \bar{m}_0$. Composing the two linear ODE solution operators, we obtain

$$(\Psi \circ \mathsf{S})(\phi) = \mathcal{K}\phi + c, \tag{29.21}$$

with c the part driven by the initial/terminal data and $\mathcal{K}$ the linear operator $\phi \mapsto \rho_{\text{driven by } r[\phi]}$. By variation of parameters and Grönwall’s inequality (lemma C.1), its operator norm on $(C([0,T]), \|\cdot\|_\infty)$ obeys

$$\|\mathcal{K}\| \;\leq\; |s|\; q\,b^2\,\mathsf{G}_\mathrm{b}\,\mathsf{G}_\mathrm{f}, \qquad \mathsf{G}_\mathrm{b} = \int_0^T e^{\int_t^T (b^2P_r - a)\,\mathrm{d}r}\,\mathrm{d}t, \quad \mathsf{G}_\mathrm{f} = \int_0^T e^{\int_t^T (a - b^2P_r)\,\mathrm{d}r}\,\mathrm{d}t, \tag{29.22}$$

the backward and forward resolvent bounds. The equilibrium is the unique fixed point $\phi^\star = (I - \mathcal{K})^{-1}c$ whenever $1 \notin \operatorname{spec}\mathcal{K}$ — this is the explicit form of theorem 14.6.

Step 2: when does FPI converge? The naive iteration (29.5) is $\phi^{n+1} = \mathcal{K}\phi^n + c$, the Banach–Picard iteration of an affine map, which converges (geometrically, from any start) *iff* the spectral radius $\varrho(\mathcal{K}) < 1$. By (29.22) a sufficient condition is $|s|\, q\, b^2 \mathsf{G}_\mathrm{b}\mathsf{G}_\mathrm{f} < 1$: small coupling $|s|$, short horizon (both G's grow with T), or strong individual stabilisation make FPI contract. This is the LQG instance of (29.8) and of (A-Coupling).

Step 3: when FPI fails but FP rescues it. Suppose $\mathcal{K}$ acts (on the relevant one-dimensional invariant subspace, e.g. the constant-mean mode for a stationary target) as multiplication by a scalar λ. Because the only s-dependence of $\mathcal{K}$ is the linear factor $q\, s$ entering the offset source (Step 1), the multiplier inherits the sign of the coupling: $\operatorname{sign}(\lambda) = \operatorname{sign}(s)$, so $\lambda < 0$ is the *repulsive* (crowd-averse, $s < 0$) regime and $\lambda > 0$ the *attractive* (imitative, $s > 0$) one. FPI is $e_n = \lambda\, e_{n-1}$ for the error $e_n = \phi^n - \phi^\star$, so it converges iff $|\lambda| < 1$; it *diverges with period-two oscillation* (the cobweb of section 29.2.2) once $\lambda < -1$ — precisely a *strong repulsive* (congestion/crowd-averse) coupling, exactly the congestion picture of that heuristic — and diverges *monotonically* once $\lambda > 1$, a strong attractive coupling. Now run fictitious play (29.11) on the same affine map. Writing $\bar{\phi}^n$ for the averaged mean and using $c = (1-\lambda)\phi^\star$, the error obeys the exact recursion

$$e_n = \Big(1 + \frac{\lambda - 1}{n}\Big) e_{n-1} \;=\; e_0 \prod_{j=1}^{n} \Big(1 + \frac{\lambda - 1}{j}\Big) \;\sim\; \frac{e_0}{\Gamma(\lambda)}\, n^{\lambda - 1} \quad (n \to \infty). \tag{29.23}$$

Hence *fictitious play converges for every* $\lambda < 1$ — including $\lambda < -1$, where naive FPI blows up — at the algebraic rate $n^{\lambda-1}$, and it *fails* only for $\lambda > 1$. Three points reconcile this with the named hypotheses and with theorem 29.15.

- *What the threshold* $\lambda < 1$ *is.* It is *not* "exactly the monotone regime": the Lasry–Lions monotone (repulsive) regime is $s \le 0$, i.e. $\lambda \le 0$, while $0 < \lambda < 1$ is weak *attractive* coupling that is non-monotone yet still uniquely and stably solvable. So the FP-convergence region splits as $\{\lambda < 1\} = \{\text{monotone } \lambda \le 0\} \cup \{\text{small-coupling } 0 < \lambda < 1\}$: the monotone half-line $\lambda \le 0$ is the part bought purely by averaging (it lies well outside the naive-contraction interval $|\lambda| < 1$), while the sliver $0 < \lambda < 1$ is already covered by the contraction of (29.8). FP therefore strictly enlarges the convergent set from the interval $|\lambda| < 1$ to the half-line $\lambda \in (-\infty, 1)$.

- *What* $\lambda > 1$ *is — and is not.* Since the map $\phi \mapsto \rho$ is genuinely affine (Step 1) and $\lambda \ne 1$, the equilibrium $\phi^\star = (I - \mathcal{K})^{-1} c$ is still *unique*; what fails for $\lambda > 1$ is its *stability*: it is a repelling fixed point for best-response dynamics, so FPI and FP both diverge. Genuine *multiplicity* is not a feature of this affine reduction at all; it is the boundary/nonlinear phenomenon of the phase diagram theorem 14.11 and section 11.4 — resonance $\lambda = 1$, or couplings rich enough to make the Riccati curvature population-dependent — where more than one equilibrium appears. The honest statement for the affine thread is thus: $\lambda > 1$ is the *unique-but-unstable* regime, in which no best-response learning dynamic converges.

- *Reconciling the rate with theorem 29.15.* The explicit population error $e_n \sim n^{\lambda-1}$ is the in-book instance promised by remark 29.16. It is a *population* error, not an exploitability: near the LQG equilibrium the value gap is quadratic in the mean displacement, so $\mathcal{E}(\bar{\pi}^n) \sim e_n^2 \sim n^{2(\lambda-1)}$. For $\lambda < \frac{3}{4}$ this already beats the universal $1/\sqrt{n}$ of (29.17); the universal bound is a worst case over the whole monotone class, saturated as $\lambda \uparrow \frac{3}{4}$, and the λ-dependent explicit rate is the sharper, model-specific statement — the two are consistent, not contradictory.

Step 4: the graphon lift. In Thread B (eq. (21.5)) the agent of type x is coupled to $z_t(x) = (\mathbb{W}\bar{m}_t)(x)$ rather than to the global mean. For the rank-one kernel $W(x,y) = f(x)f(y)$ the aggregate collapses to $z_t(x) = f(x)\,\varrho_t$ with the scalar order parameter $\varrho_t = \int_0^1 f(y)\bar{m}_t(y)\,\mathrm{d}y$ (eq. (21.19)), and the composite map on ϱ is again affine with multiplier $\lambda_W = \lambda \cdot \|\mathbb{W}\|$, where $\|\mathbb{W}\| = \|f\|_{L^2}^2$ is the operator norm of the rank-one $\mathbb{W}$. Everything above transfers verbatim with $\lambda \rightsquigarrow \lambda_W$: FPI contracts iff $|\lambda|\,\|\mathbb{W}\| < 1$ (this is (A-Coupling) and the critical coupling of eq. (20.31) and chapter 24), while fictitious play converges on the whole half-line $\lambda_W < 1$ — the monotone part $\lambda_W \le 0$ ($s \le 0$, bought by averaging) together with the weak-attraction sliver $0 < \lambda_W < 1$ (already inside the contraction interval). The graphon contributes exactly one scalar — its leading eigenvalue — to the learning threshold, which is the cleanest possible illustration of how network centrality enters the dynamics of learning.

29.4 GMFG-PPO: learning on the type-indexed population

The stabilised dynamics of section 29.3 converge, but every one of them still presumed two idealisations: that the two maps could be evaluated *exactly* — an exact backward best-response sweep and an exact forward push-forward — and that the population was a single measure rather than a field. This section lifts both at once, confronting in full the *third* failure mode of section 29.1, the continuum of coupled types, on the very terrain — high dimension, unwritable dynamics — that forced learning in the first place. We now drop the assumption that the best response S and the push-forward Ψ can be computed exactly. In high dimension both are approximated: S by a *policy-gradient* RL algorithm (PPO) acting through a neural network, and Ψ by Monte Carlo rollouts of that network. The graphon enters as an input feature of the networks. This is the GMFG-PPO scheme of [54], building on the entropy-regularised deep RL of [53].

29.4.1 The graphon mean field MDP

Definition 29.23 (Graphon mean field MDP)**.** A *graphon MFMDP* (GMFMDP) augments definition 29.1 with a *type* $x \in [0,1]$ drawn from the uniform law (the type distribution), a kernel W satisfying (A-Reg-W), and an *observable* $\Lambda : \mathcal{P}(\mathcal{S}) \to \mathbb{R}^{d'}$ (typically the mean, $\Lambda(m) = \int \xi\, m(\mathrm{d}\xi)$). The population is now a *field of flows* $x \mapsto m^x_\bullet$ with $m^x_k \in \mathcal{P}(\mathcal{S})$, and the type-$x$ agent feels the *graphon aggregate*

$$z_k(x) = (\mathbb{W}\,\Lambda[m_k^{\cdot}])(x) = \int_0^1 W(x,y)\,\Lambda\big(m_k^y\big)\;\mathrm{d}y \in \mathbb{R}^{d'}, \tag{29.24}$$

which is Part IV's observable aggregate $\Theta_k(x)$ of eq. (21.4) (written $z_k(x)$ here, and with the scalar test function h promoted to the vector observable Λ; notationwatch (v)). The transition kernel and costs depend on the type and the aggregate, $P_k(\cdot \mid s, a, x, z_k(x))$ and $L_k(s, a, x, z_k(x))$, and the equilibrium is the fixed point of definition 21.16: each type best-responds to its aggregate, and the field of induced flows reproduces those aggregates.

The decisive modelling move is that the type-x agent's optimisation problem depends on the entire population field *only through the finite-dimensional aggregate* $z_k(x) \in \mathbb{R}^{d'}$. This is what makes a single, shared policy possible: rather than learn a separate policy for each of a continuum of types, we learn one map that takes (s, x, z) and outputs an action distribution. The kernel W is never represented as a function the network must learn; it is used *outside* the network, once per outer iteration, to turn the population field into the aggregate field $x \mapsto z_k(x)$ via the quadrature of chapter 28.

29.4.2 Policy gradients and PPO as an approximate best-response oracle

The inner loop is an RL solver that, given a frozen aggregate field, returns an approximate best response. We use policy gradients. Let the policy be parametrised, $\pi_\theta = (\pi_{\theta,k})$, and recall the (cost-minimising) *policy gradient theorem*.

Proposition 29.24 (Policy gradient)**.** *Fix the environment (the aggregate field) $m_\bullet$, and abbreviate the frozen-environment value and action-value as $u_k^{\pi_\theta} := u_k^{m_\bullet,\pi_\theta}$, $Q_k^{\pi_\theta} := Q_k^{m_\bullet,\pi_\theta}$ (the superscript $m_\bullet$ suppressed only because it is held fixed throughout this subsection). For a differentiable parametrisation $\theta \mapsto \pi_\theta$ with $J(\theta) = J(\pi_\theta; m_\bullet)$ the expected cost of definition 29.6, one has the score-function identity*

$$\nabla_\theta J(\theta) = \mathbb{E}\left[\sum_{k=0}^{K-1} \nabla_\theta \log \pi_{\theta,k}(A_k \mid S_k)\ \mathsf{A}_k^{\pi_\theta}(S_k, A_k)\right], \tag{29.25}$$

where $\mathsf{A}_k^{\pi_\theta}(s,a) = Q_k^{\pi_\theta}(s,a) - u_k^{\pi_\theta}(s)$ is the advantage *and the expectation is over trajectories generated by π_θ in the frozen environment.*

Proof sketch. Differentiate $J(\theta) = \mathbb{E}_{\zeta\sim\pi_\theta}[\sum_k L_k]$, the expectation over trajectories $\zeta = (S_k, A_k)_k$ generated by π_θ, under the trajectory law, whose density factorises as $\prod_k \pi_{\theta,k}(A_k \mid S_k) P_k(S_{k+1} \mid S_k, A_k)$; only the policy factors carry θ, giving the $\nabla_\theta \log \pi_\theta$ score. Replacing the return by its advantage (subtracting the state-baseline $u_k^{\pi_\theta}$) leaves the expectation unchanged because $\mathbb{E}[\nabla_\theta \log \pi_{\theta,k}(A_k \mid S_k) \mid S_k] = 0$, and reduces variance. This is the finite-horizon, cost form of [127]; the advantage is estimated from rollouts by generalised advantage estimation [119]. □

A raw policy-gradient step can be destructively large. *Proximal Policy Optimization* (PPO) [120] constrains each update to a trust region around the current policy by maximising a *clipped surrogate*: with importance ratio $r_k(\theta) = \pi_{\theta,k}(A_k \mid S_k)/\pi_{\theta_{\text{old}},k}(A_k \mid S_k)$ and advantage estimate $\hat{\mathsf{A}}_k$ (for cost minimisation, advantages are negated relative to the reward convention), PPO minimises

$$J^{\text{clip}}(\theta) = \mathbb{E}\left[\sum_k \max\Big(r_k(\theta)\,\hat{\mathsf{A}}_k,\ \text{clip}\left(r_k(\theta), 1-\epsilon, 1+\epsilon\right)\hat{\mathsf{A}}_k\Big)\right] \; - \; \tau\,\mathbb{E}\left[\sum_k \mathfrak{h}\big(\pi_{\theta,k}(\cdot \mid S_k)\big)\right], \tag{29.26}$$

where $\mathfrak{h}(p) = -\int p \log p$ is the policy entropy, the clip range $\epsilon > 0$ caps the step, and the entropy bonus $\tau > 0$ implements the regularisation of definition 29.11. PPO is a heuristic approximation of trust-region policy optimisation [118]; it has no global optimality guarantee even for a single MDP, and we treat it strictly as an *approximate best-response oracle*: an operator $\widehat{\mathsf{S}}$ that, given an environment and a compute budget, returns a policy whose exploitability against that environment is at most some ϵ_{br}. The quality of that oracle is an *assumption*, not a theorem, and section 29.5 is careful to keep it so.

29.4.3 Representing the graphon coupling inside the networks

The architecture is what makes the type continuum tractable. A *single* policy network $\pi_\theta(a \mid s, x, z)$ and a *single* value network $V_\phi(s, x, z)$ take, as inputs, the state s, the scalar type $x \in [0, 1]$ (or a learned type-embedding), and the local aggregate $z \in \mathbb{R}^{d'}$. Because x and z are inputs rather than indices, the same weights (θ, ϕ) serve all types: the network *interpolates* across the continuum, and high- and low-centrality types differ only through the value of z they are fed. The graphon W appears nowhere inside the network; it acts only in the outer loop, through the quadrature

$$z_k(x_i) \approx \sum_{j=1}^{M} w_j \, W(x_i, x_j) \, \Lambda(\widehat{m^{x_j}}_k), \tag{29.27}$$

over a type grid $\{x_j\}_{j=1}^M$ with quadrature weights w_j and empirical type-flows $\widehat{m^{x_j}}_k$ estimated from rollouts — precisely the discretisation of $\mathbb{W}$ analysed in chapter 28 and controlled, in operator norm, by the graphon regularity of chapter 19. The separation of concerns is clean: the *network* learns the type-conditioned best response $s, x, z \mapsto \pi_\theta$; the *quadrature* computes the graphon coupling $z = \mathbb{W}\Lambda[m^\cdot]$; the *outer loop* (FP or OMD) reconciles the two.

Remark 29.25 (Why one network suffices: continuity in type)**.** That a single network can represent the whole family $\{\pi^x\}_{x\in[0,1]}$ rests on the regularity established in Part IV: under (A-Reg-W) the equilibrium field $x \mapsto (u^x, m^x)$ is continuous in type (lemma 21.11 and the field topology of definition 21.8), so the target map $(s, x, z) \mapsto \pi^\star$ is continuous and hence approximable by a network of bounded capacity on the compact domain $\mathcal{S}_0 \times [0, 1] \times Z$. If the kernel had no such regularity — a rough W violating (A-Reg-W) — the type-conditioning could be discontinuous and a fixed-capacity network would fail to represent the high-frequency type dependence, one of the failure modes of section 29.5.

29.4.4 The GMFG-PPO algorithm

We record the scheme at the architectural level; the full reference implementation lives in `figures/29-gmfg-ppo.py`, exactly as chapter 28 places its solver in `figures/28-mfg-solver.py`. The outer loop is fictitious play or online mirror descent; the inner loop is PPO; the coupling is the quadrature (29.27).

1. **Initialise** networks (θ^0, ϕ^0), a type grid $\{x_j\}_{j=1}^M$ with weights $\{w_j\}$, and an initial population field $\widehat{m^{x_j}}_\bullet^0$ (e.g. the initial law repeated).
2. **For** outer iteration $n = 1, 2, \dots$:
   (a) *Aggregate.* Compute the aggregate field $z_k^{n-1}(x_j)$ from the current (FP-averaged or OMD-scored) population field via the quadrature (29.27).
   (b) *Best-respond (inner PPO).* Holding the aggregate field fixed, run PPO (29.26) for a budget of rollouts, sampling types $x \sim \mathrm{Unif}([0, 1])$, states $s \sim \widehat{m^x}_0$, and trajectories under π_θ, to obtain an approximate best response $\pi_{\theta^n} = \widehat{\mathsf{S}}_\tau(z^{n-1})$ with exploitability $\leq \epsilon_{\mathrm{br}}$.

(c) *Roll forward.* Estimate the induced field $\widehat{m^{x_j}}_{\bullet}^{n} = \widehat{\Psi}(\pi_{\theta^n})$ by Monte Carlo rollouts of π_{θ^n} across the type grid.

(d) *Reconcile (outer FP/OMD).* Update the population field by the FP average (29.11) or the OMD score (29.18).

3. **Output** the averaged policy $\bar{\pi}^n$ and an estimate of its exploitability $\widehat{\mathcal{E}}(\bar{\pi}^n)$ obtained by training a fresh PPO best response against $\widehat{\Psi}(\bar{\pi}^n)$ and differencing returns.

Physics note: Learning an equilibrium as variational Monte Carlo

The loop above is structurally a *variational Monte Carlo* (VMC) calculation, and the analogy is exact enough to be useful rather than decorative. In VMC one posits a parametrised trial wavefunction ψ_θ (lowercase, to keep clear of the population map Ψ that is this chapter's central object), samples configurations from $|\psi_\theta|^2$ by Monte Carlo, estimates the variational energy $E(\theta) = \langle\psi_\theta|H|\psi_\theta\rangle$ and its gradient by those samples, and descends in θ toward the ground state. Here the parametrised *policy* π_θ plays the role of the trial state; rollouts sample the trajectory distribution it induces (the analogue of sampling $|\psi_\theta|^2$); the policy gradient (29.25) is the stochastic estimate of $\nabla_\theta(\text{cost})$, the analogue of the energy gradient. The self-consistent mean field is the precise counterpart of the self-consistent field in a Hartree calculation: the agent optimises against a population it itself generates, just as a Hartree orbital is computed in the field of the density it itself produces. One correspondence in this dictionary is not an analogy but a literal identity: the τ-regularised Gibbs policy (29.10),

$$\mathsf{S}_\tau(m_\bullet)_k(\mathrm{d}a \mid s) \;=\; \frac{e^{-Q^{m_\bullet}_{\tau,k}(s,a)/\tau}}{\int_A e^{-Q^{m_\bullet}_{\tau,k}(s,a')/\tau}\,\mathrm{d}\nu_0(a')}\,\mathrm{d}\nu_0(a),$$

is the Boltzmann distribution at temperature τ for a classical system whose energy function is the action-value $Q^{m_\bullet}_{\tau,k}(s,\cdot)$, with partition function $Z = \int e^{-Q/\tau}\,\mathrm{d}\nu_0$ and free energy $u^{m_\bullet}_{\tau,k}(s) = -\tau\log Z$ — exactly the finite-temperature trial ensemble of statistical mechanics. Where the analogy stops is the part this whole book is about: in VMC the energy functional is *fixed* and one minimises it, whereas in a game the "energy" an agent faces depends on the population's choice, so the object sought is a *fixed point* (Nash), not a minimum — and that is why monotonicity, not mere convexity, is the right hypothesis for convergence.

29.5 Convergence guarantees and failure modes

Having assembled GMFG-PPO — the inner PPO oracle, the type-conditioned networks, the quadrature coupling, and the FP/OMD outer loop — we owe the reader a sober accounting of what the scheme actually guarantees and where it can break. This closing section gives both, in that order: first a modular convergence theorem that stacks the chapter's *proven* pieces (the contraction of theorem 29.10, the monotone dynamics of theorems 29.15 and 29.19, the finite-network transfer of chapter 25) against the approximations the deep implementation introduces, then a frank catalogue of the failure modes that arise when its hypotheses are violated.

29.5.1 A modular guarantee

No single theorem covers GMFG-PPO end to end, because the scheme is a composition of an *assumed* oracle (PPO), an *approximated* coupling (quadrature), and a *proven* outer dynamic (FP or OMD). The honest statement is a modular error decomposition: each layer contributes an additive error, and the outer dynamic's convergence theorem absorbs them.

Theorem 29.26 (Modular convergence of GMFG-PPO)**.** *Assume the GMFMDP data are Lipschitz in* (m, z) *uniformly* (A-Lip)*, the diffusion nondegenerate* (A-Nondeg)*, the kernel regular* (A-Reg-W)*, and run the scheme at temperature* $\tau > 0$*. Suppose the inner PPO oracle returns, at each outer step, a policy with per-type regularised exploitability against the current aggregate field at most* ϵ_{br}*, and that the type/state discretisation and the quadrature* (29.27) *for* $\mathbb{W}$ *have combined error at most* ϵ_{disc}*. Then:*

1. (Contraction regime.) *If* (A-Coupling) *holds with composite modulus* $L = L_{\mathsf{S},\tau} L_\Psi < 1$*, the field iterates satisfy*

$$D(\widehat{m}^{\,n}_{\bullet}, m^{\star,\tau}_{\bullet}) \;\le\; L^n\, D_0 + \frac{\epsilon_{\mathrm{br}} + \epsilon_{\mathrm{disc}}}{1 - L}, \qquad \mathcal{E}_\tau(\pi^n) \le C\Big(L^n + \epsilon_{\mathrm{br}} + \epsilon_{\mathrm{disc}}\Big). \tag{29.28}$$

2. (Monotone regime.) *If instead* (A-Mon) *holds (graphon Lasry–Lions monotonicity, definition 24.15), the FP/OMD outer loop satisfies*

$$\mathcal{E}_\tau(\bar{\pi}^{\,n}) \;\le\; \frac{C}{\sqrt{n}} \;+\; C'\big(\epsilon_{\mathrm{br}} + \epsilon_{\mathrm{disc}}\big) \tag{29.29}$$

   (with C/n *under OMD or in the potential case); the* n*-dependent outer rate is the imported refinement of remarks 29.16 and 29.20, while the in-book content is the convergence* $\mathcal{E}_\tau \to 0$ *of theorems 29.15 and 29.19.*

In both regimes the unregularised exploitability picks up the bias $c_0\tau(1+\log|A|)$ *of remark 29.13; and by the finite-network convergence theorem of chapter 25, the output policy is an* $\big(\mathcal{E}(\bar{\pi}^{\,n}) + \epsilon_{\mathrm{graph}}(N)\big)$*-Nash equilibrium for the* N*-agent game on a graph sampled from* $G(N, W)$*, with* $\epsilon_{\mathrm{graph}}(N) \to 0$ *as* $N \to \infty$*.*

Proof: assembly. The contraction case is the perturbed-fixed-point lemma: if T is an L-contraction with fixed point $m^\star$ and one iterates $m^{n+1} = T(m^n) + \delta^n$ with $\|\delta^n\| \le \delta := \epsilon_{\mathrm{br}} + \epsilon_{\mathrm{disc}}$, then by the triangle inequality $\|m^n - m^\star\| \le L^n\,\|m^0 - m^\star\| + \delta \sum_{j<n} L^j \le L^n D_0 + \delta/(1-L)$; here $T = \Psi \circ \mathsf{S}_\tau$ is the L-contraction of theorem 29.10 (with $L_{\mathsf{S},\tau}$ from lemma 29.12) and δ^n packages the oracle and quadrature errors. The exploitability bound is then (A-Lip)-continuity of $\mathcal{E}_\tau$ in the field. The monotone case is theorem 29.15 (or theorem 29.19) applied to the *inexact* best-response/score updates: the Lyapunov arguments there are stable under an additive δ per step, contributing the $C'\delta$ term (the Grönwall/telescoping inequalities absorb a bounded per-step perturbation). The regularisation bias is remark 29.13. The final ϵ-Nash transfer is exactly the finite-network theorem of chapter 25, which converts a graphon-equilibrium policy into an approximate Nash equilibrium on the sampled finite network with error $\epsilon_{\mathrm{graph}}(N)$ governed by the cut-distance concentration of $G(N, W)$ (chapters 19 and 25). □

Remark 29.27 (What is proved and what is assumed)**.** Theorem 29.26 should be read with its load-bearing assumption in plain sight. The *outer* convergence (the L^n or $1/\sqrt{n}$ term) is genuinely proved, inheriting the rigour of theorems 29.10, 29.15 and 29.19. The *inner* term ϵ_{br} is an *assumption*: it asserts that PPO solves a fixed-environment MDP to accuracy ϵ_{br}, which is empirically often true and theoretically unguaranteed — PPO can stall in poor local optima, and for general function approximation no polynomial-time best-response oracle is known. The theorem is therefore a *conditional* guarantee, exactly as honest practice in this subject requires; the unconditional results [134, 135, 8] replace PPO by a tabular or linearly-parametrised solver for which ϵ_{br} *can* be bounded, at the cost of the expressive power that motivated deep RL in the first place. The linear-quadratic special case, where an actor–critic provably finds the equilibrium, is [73].

29.5.2 Failure modes

We catalogue, without euphemism, the ways the scheme breaks. Each is a violation of a hypothesis of theorem 29.26 and each has a concrete signature.

1. *Non-monotone, non-contractive coupling.* If neither (A-Coupling) nor (A-Mon) holds — e.g. a strong attractive (imitative) coupling, $\lambda > 1$ in worked computation 29.22 — the best-response dynamic (29.13) need not converge. In the affine LQG reduction $\lambda > 1$ gives a *unique but unstable* equilibrium from which best-response iteration is repelled (worked computation 29.22, Step 3); beyond the affine case the same loss of monotonicity can produce a genuine *limit cycle* (the persistent cobweb of section 29.2.2) or *multiple* equilibria (the symmetry-breaking regime of section 11.4 and theorem 14.11), and the learner then has no principled way to select among them. No amount of averaging fixes this. Signature: exploitability that plateaus or oscillates rather than decaying.

2. *A broken best-response oracle.* The notorious "deadly triad" of off-policy bootstrapping, function approximation, and limited data [126] can make the inner RL diverge, so ϵ_{br} is effectively infinite. The outer loop then reconciles toward a population that no agent actually best-responds to. Signature: the inner return curves fail to converge even with the environment frozen.

3. *Order-of-limits errors.* Three limits are taken: time discretisation $\Delta t \to 0$, finite population $N \to \infty$, and sample size $\to \infty$. They do not commute in general. A coarse Δt changes the equilibrium (the discrete game is not the continuous one); a small N leaves fluctuation corrections of order $N^{-1/2}$ that the mean-field policy ignores (chapters 13 and 25). The modular theorem hides these inside ϵ_{disc} and $\epsilon_{\mathrm{graph}}(N)$, but they must be driven down jointly. Signature: an exploitability floor that moves when the grid or N is refined.

4. *Regularisation bias.* The temperature $\tau > 0$ that bought stability and a Lipschitz oracle (lemma 29.12) also displaces the equilibrium by $O(\tau)$ (remark 29.13). Lowering τ reduces bias but raises $L_{\mathsf{S},\tau} = \Theta(1/\tau)$, shrinking the contraction margin and inflating gradient variance. There is a genuine bias–variance frontier in τ, and reporting a small exploitability at large τ is a common way to overstate success. Signature: exploitability that improves with τ but against a τ-shifted target.

5. *Failure of type representability.* If the kernel W has a rich spectrum — many eigenvalues of comparable size, hence many "centrality channels" (chapter 18) — the equilibrium's dependence on type can be high-frequency, and a fixed-capacity network $\pi_\theta(a \mid s, x, z)$ may simply be unable to represent it (remark 29.25). High-centrality types, which contribute most to the aggregate (29.24), are the ones whose misrepresentation is most damaging. Signature: per-type exploitability concentrated on the spectrally extreme types.

These are not reasons to abandon the method — for unknown dynamics and high dimension it is often the only method — but reasons to instrument it: track exploitability (not return), report the temperature and the target it implies, refine Δt and N jointly, and verify the contraction or monotonicity hypothesis on the model at hand. With those guards, GMFG-PPO is the working bridge from the analytic theory of Parts II–IV to networks and dynamics that no PDE solver can reach; the heterogeneity it learns over is the subject of chapter 30.

Rigor ledger

Proved.

- The MFMDP/GMFMDP equilibrium is a fixed point of the two maps S (best response, backward Bellman) and Ψ (population, forward push-forward), and exploitability $\mathcal{E}$ is nonnegative and zero exactly at equilibrium (definition 29.4 and proposition 29.7).

- Under the contraction condition $L_{\mathsf{S}} L_\Psi < 1$ (A-Coupling), the naive fixed-point iteration converges geometrically to the unique equilibrium (theorem 29.10).

- Entropy regularisation makes the best response single-valued and $\Theta(1/\tau)$-Lipschitz with $O(\tau)$ equilibrium bias (lemma 29.12 and remark 29.13).

- Under monotonicity (A-Mon), fictitious play and online mirror descent drive exploitability to zero, $\mathcal{E} \to 0$, proved in full here via the continuous-time Lyapunov/Bregman mechanism (theorems 29.15 and 29.19); the three-point Bregman identity powering OMD is proved in-book (lemma 29.18). The *algebraic* rates $O(1/\sqrt{n})$ (resp. $O(1/n)$) are flagged as imported refinements (remarks 29.16 and 29.20), with the LQG case $n^{\lambda-1}$ derived in-book (worked computation 29.22).

- The LQG/graphon worked computation makes the dichotomy exact: FPI converges iff the multiplier $|\lambda|\,\|\mathbb{W}\| < 1$, while FP converges on the whole monotone half-line $\lambda\,\|\mathbb{W}\| < 1$ (worked computation 29.22).

- A modular error decomposition for GMFG-PPO, assembled from the above plus the finite-network transfer of chapter 25 (theorem 29.26).

Assumed.

- (A-Lip), (A-Nondeg), (A-Reg-W) throughout; (A-Coupling) in the contraction regime and (A-Mon) in the monotone regime.

- The PPO best-response oracle: that the inner deep-RL solver returns an ϵ_{br}-best response. This is the chapter's one unproven, load-bearing hypothesis (remark 29.27).

- Boundedness of the quadrature/discretisation error ϵ_{disc}, inherited from the schemes of chapter 28 and the regularity of chapter 19.

Deferred.

- The discrete-step refinement that upgrades the in-book convergence $\mathcal{E} \to 0$ to the algebraic *rates* (the $\vartheta = \log n$ time change and the η^2 bookkeeping) is imported, with attribution, from [38, 111, 110] and explicitly flagged as not derived in this book (remarks 29.16 and 29.20); the continuous-time Lyapunov mechanism and the scalar LQG rate $n^{\lambda-1}$ are given here in full.

- Reference implementations (PPO inner loop, type-grid quadrature, exploitability estimator) live in `figures/29-gmfg-ppo.py`, mirroring the `figures/28-mfg-solver.py` convention of chapter 28.

- The finite-network ϵ-Nash transfer is owned by chapter 25; we import it.

Open.

- Provable polynomial best-response oracles for deep function approximation (so that ϵ_{br} is bounded rather than assumed) remain open beyond linear/tabular classes [134, 135].

- Learning in the non-monotone, multi-equilibrium regime: which equilibrium, if any, a learning dynamic selects, and whether selection can be controlled.

- Joint control of the three limits (Δt, N, samples) with a single rate, and learning when the underlying network is itself unknown and must be estimated (graphon identification) before or during learning.

- Sharp dependence of representability and sample complexity on the spectrum of $\mathbb{W}$.

Bibliographic notes

The viewpoint that a mean field game is a fixed point of a best-response map on the space of population flows, and that learning dynamics chase that fixed point, is developed in the survey [96], which we follow for organisation. Fictitious play for MFG was introduced and proved convergent under monotonicity by Cardaliaguet and Hadikhanloo [38]; the continuous-time best-response flow and the Lyapunov analysis sketched in theorem 29.15 are from Perrin et al. [111], building on the classical learning-in-games theory of Fudenberg and Levine [74]. The online-mirror-descent scheme and theorem 29.19 are from Pérolat et al. [110]; the entropy-regularised formulation and the Gibbs best response (29.10) follow [53], with the quantal-response/regularised viewpoint also in [122]. Tabular and linearly-parametrised learners with *unconditional* (non-oracle) guarantees include Guo et al. [80], Xie et al. [134], Anahtarci et al. [8], and the policy-mirror-ascent analysis of Yardim et al. [135]; the linear-quadratic actor–critic convergence result is Fu et al. [73], the natural learning counterpart of the LQG thread (chapter 14). The policy gradient theorem is Sutton et al. [127]

(textbook treatment in [126]); generalised advantage estimation is [119]; PPO and its trust-region antecedent are [120, 118]. The graphon extension — the type-conditioned single network, the quadrature representation of $\mathbb{W}$, and the modular guarantee assembled in theorem 29.26 — is the GMFG-PPO scheme of Cui and Koeppl [54, 55], whose finite-network ϵ-Nash transfer rests on the convergence theory of chapter 25. The variational-Monte-Carlo reading of section 29.4.4 is the natural bridge to the computational-physics literature; we draw it here as a precise analogy, with the one exact correspondence — the Gibbs policy as the Boltzmann trial ensemble with the Q-function as energy — stated as an identity.

Chapter 30

The Heterogeneity Zoo: Major–Minor and Multi-Population Models

The literature on mean field games is, by now, a literature of named "extensions." Open any recent survey and you will find the subject parcelled out into chapters — major–minor games, multi-population (or multi-class) games, games with partial or noisy information — each presented as a theory in its own right, with its own existence proof, its own master equation, its own catalogue of solvable cases. A reader who has just spent Part IV building the graphon mean field game is entitled to ask a blunt organizing question before learning any of them separately: is each of these a genuinely new object, or has the graphon picture already paid for them? This chapter exists to answer that question, and its answer — which the rest of the chapter is occupied discharging — is that of the three most studied extensions, two are not new theories at all but particular structural choices of the single coupling operator $\mathbb{W}$ of Part IV, while the third is orthogonal to the network entirely.

The starting observation is that the graphon mean field game already carries a great deal of heterogeneity for free: agents are indexed by a type $x \in [0, 1]$, each type may have its own dynamics and cost, and the coupling between types is an arbitrary symmetric kernel W acting through the operator $\mathbb{W}$ (chapters 21 and 22). The recurring thesis is that $\mathbb{W}$ is a flexible enough bookkeeping device that the extensions are recovered by *specializing* it rather than by replacing it. Concretely: the multi-population model is exactly the *block* (piecewise-constant) graphon, and the major–minor model is exactly a *finite-rank atomic perturbation* of the graphon coupling on an enlarged index space. The third extension, partial information, is genuinely orthogonal to the network: it changes what an agent can *see* and therefore composes with the graphon structure rather than being encoded in $\mathbb{W}$. We close with a map of the modern landscape, oriented by the 2025 overview of heterogeneous mean field games [11], sorting every axis of heterogeneity into where it sits relative to the graphon formalism.

It will help to fix the three possible verdicts in plain words at the outset, because the map that ends the chapter is nothing more than these labels applied, and stating them now turns that map into a summary rather than a surprise. We call a feature *subsumed* when it is a *structural special case* of the Part IV graphon mean field game — obtained by choosing the kernel W, the index space, or the coefficients in a particular way, and needing no machinery beyond what Part IV already built. We call it *composable* when it *multiplies onto* the graphon construction without living inside $\mathbb{W}$ at all: it alters what each agent observes or controls, and the graphon coupling simply rides along underneath, unchanged. We call it *outside* when it honestly requires apparatus the graphon theory does not supply. In this taxonomy the multi-population game is the cleanest *subsumed* case — and the most complete, which is why we treat it first and in full — the major–minor game a subtler *subsumed* case, and partial information the chapter's representative *composable* case.

Threading all three is a single tension that the reader should watch for, because it is what decides how hard each model actually is. The coupling is always a graphon; what varies is the *equilibrium*. The graphon mean field game stays in the tractable, deterministic regime of chapter 24 precisely as long as the aggregate each agent feels is a *deterministic* flow — a fixed function of time, the same in every realization of the noise. A block kernel keeps us there: each population is still a continuum of vanishing-influence agents, so its aggregate is a deterministic curve. But the moment a single non-vanishing player (the major agent) or a genuine common noise makes that aggregate *random*, the problem escalates one level: the field becomes a measure-valued *process*, the consistency condition becomes a *conditional* fixed point, and the governing object is no longer the deterministic backward–forward system of chapter 22 but the conditional, common-noise master equation of chapter 26. Keeping the coupling/equilibrium distinction in view is what makes the chapter's verdicts precise rather than slogans.

Because all of this is a specialization, we build on Part IV without re-deriving any of it, and it is worth saying explicitly what is borrowed and why each piece is needed. We take the type-x controlled agent of definition 21.1; the population field $\boldsymbol{m} = (m^x)_{x\in[0,1]}$ living in the L^2-Wasserstein space $(\mathcal{M}_2, d_2)$ of definition 21.8, which is the space on which the whole equilibrium problem is posed; and, at its heart, the graphon aggregate $\Theta_t(x) = (\mathbb{W} \circledast \boldsymbol{m}_t)(x)$ of definition 21.5 — the *single* scalar (or measure) through which a type-x agent feels the entire crowd, and the object on whose structure the whole chapter turns. From these the best-response map S (definition 21.15), which optimizes one agent against a guessed aggregate, and the fixed-point notion of equilibrium (definition 21.16), which closes the loop by demanding the guess be self-consistent, are inherited unchanged. We need the characterization of that fixed point as a coupled backward–forward system — a backward HJB equation for the value field and a forward Fokker–Planck equation for the density field, with its block specialization — from chapter 22; and we need its existence/uniqueness theory from chapter 24, in particular the operator-norm smallness threshold (A-Coupling), $\|\mathbb{W}\| < \kappa := 1/C_T$, which is the quantitative gate that the block reduction will inherit verbatim with $\mathbb{W}$ replaced by a finite matrix. For uniqueness beyond smallness we use the classical Lasry–Lions monotonicity condition of definition 11.1 and, what our uniqueness statements actually invoke, its graphon lift definition 24.15 with the graphon uniqueness theorem theorem 24.16. The carried Thread B (graphon LQG) is advanced here at the block level, completing the bridge promised in remark 21.20 and chapter 22: the infinite-dimensional graphon LQG game will collapse, for a block kernel, to a finite explicit system.

Two standing conventions are in force throughout, and both are load-bearing here precisely because both directions of time and a graphon all appear together in a single system. First, the time-direction convention: *the value field $u = u$ carries terminal data at $t = T$ and is solved* *backward; the density field $m = m$ carries initial data at $t = 0$ and is solved forward.* This is not an arbitrary bookkeeping choice — the HJB equation is a terminal-value problem because optimization looks *ahead* to a terminal cost, while the Fokker–Planck equation is an initial-value problem because probability mass is transported *forward* from a known initial law; the two halves of every system below meet in the middle and must be read in opposite time senses. Second, following the Part IV convention (chapter 21), wherever a graphon W is in scope Brownian motion is written B, never W — the symbol W is reserved for the kernel. We restate both because a careless reading of the systems below, in which u, m, W and B all appear at once, is otherwise easy to misparse.

30.1 Multi-population games as block-graphon GMFG

We begin with the cleanest *subsumed* extension, and we treat it most completely because every later move in the chapter is a variation on the single argument we make here. A *multi-population* (or multi-class) mean field game has a finite number K of distinguishable populations. The picture to keep in mind is a system assembled from a small number of qualitatively different agent *species*, not from a continuum of subtly varying individuals. Three running examples make the model concrete. Buyers and sellers in a market form two species with opposite objectives, each watching the other's aggregate and its own. Susceptible and infected individuals in an epidemic form two species in which the size of the infected population is precisely the field a susceptible agent reacts to. Electric vehicles sorted into a handful of battery classes form several species, each with its own charging dynamics, all bidding into one shared grid. In none of these does the modeller believe there are infinitely many distinct kinds of agent; there are two, or three, or five, and the heterogeneity is *coarse* — a short list of classes rather than a spectrum.

What makes such a system a mean field *game*, rather than a finite bundle of unrelated control problems, is a precise rule about how agents may and may not differ, and the rule has two faces. *Within* a population, agents are anonymous and statistically identical, exactly as in the classical mean field game of Part II: one buyer is interchangeable with any other buyer, feels the crowd only through population-level aggregates, and carries vanishing individual influence. This intra-population symmetry is what lets each population be summarized by a single distribution rather than by a roster of named individuals. *Across* populations, by contrast, essentially anything is allowed: two populations may have entirely different state dynamics, different running and terminal costs, and — the genuinely new freedom relative to a one-population model — different *cross-influences*, meaning how strongly each population's aggregate is felt by each other population. A buyer may respond to the sellers' aggregate with one sensitivity and to other buyers' with another; the two need not be equal, and need not even share a sign. The point of this section is that this exact within/across split — statistical identity inside a class, arbitrary asymmetric coupling between classes — is something a graphon already knows how to express.

The claim is that the multi-population model is the dynamic graphon mean field game of chapter 21 under one special choice: the kernel W is taken *block-constant*, piecewise constant on a partition of the type interval $[0, 1]$ into K cells, one cell per population. This is the stochastic-block-model graphon. We want to earn something sharper than "the block graphon happens to reproduce the multi-population equations." The assertion is that the reduction is an *isometric reduction of* *the equilibrium problem to a finite-dimensional invariant subspace*, and both adjectives carry real weight. Because the formal payoff in the next two subsections will read as a confirmation of this phrase rather than a surprise, it is worth glossing each adjective in plain terms now, before any cells or matrices appear.

Take *invariant* first. The graphon equilibrium problem lives on an infinite-dimensional space: a population field $\boldsymbol{m}$ assigns a probability measure to *every* type $x \in [0,1]$, a whole continuum of measures. The block choice distinguishes a far smaller set inside this space — the fields that are *constant on each cell*, taking one common measure $m^{(k)}$ on all types of population k. Such a field is pinned down by only K measures, so the set is finite-dimensional in the sense that finitely many measures parametrize it. A subset of a state space is called *invariant* under a map when the map sends it back into itself: feed in an element of the subset, get out an element of the subset. The entire reduction hinges on one such invariance. The map that drives the equilibrium problem is the best-response map: it takes a guessed population field, lets every agent optimize against the aggregate that field induces, and returns the resulting field. The single structural fact we will prove is that this map *preserves block-constancy* — hand it a field that is constant on each cell and it returns a field that is again constant on each cell. Once that is known, the infinite-dimensional fixed-point problem may be solved entirely inside the block-constant set, because the iteration that searches for a fixed point never leaves it. This is why invariance is the whole game: it is exactly what licenses replacing a continuum of unknown measures by K of them with no approximation, so that a block-constant equilibrium *is* a multi-population equilibrium and conversely. (Whether a block kernel might *also* support equilibria outside the block-constant set is a separate, genuinely subtle question of uniqueness, which we flag and defer to remark 30.5.)

Now *isometric*. It would be a strictly weaker statement to say only that block-constant fields can be parametrized by K measures; one wants the parametrization to respect *distances* as well as count dimensions. The field space carries a metric d_2, the L^2-Wasserstein field metric of definition 21.8, which measures how far apart two population profiles are. Restricted to block-constant fields, this metric turns out to be *exactly* a mass-weighted product of the ordinary Wasserstein distances between the K cell-measures: no distance information is lost or distorted in passing to the finite parametrization. A distance-preserving correspondence between metric spaces is called an *isometry*, and that the block-constant subspace is isometric — not merely in bijection — with the finite product $(\mathcal{P}_2(\mathbb{R}^d))^K$ is what guarantees that every *quantitative* estimate of the graphon theory transfers to the finite system with its constants intact: contraction moduli, monotonicity constants, and above all the coupling threshold $\|\mathbb{W}\| < \kappa$ all carry over without slack, because they are measured by the same ruler on both sides. The infinite-dimensional and finite-dimensional problems are thus not just matched object-for-object; they are the *same* problem, viewed at two resolutions.

With both adjectives unpacked, the route through the section is fixed. We must, in order: write down the block graphon and isolate the finite-dimensional subspace of block-constant fields it distinguishes, checking that this subspace is closed and isometric to a weighted product of Wasserstein spaces; prove the one structural lemma everything rests on — that the graphon aggregate carries a block-constant field to a block-constant field, which is the precise form of "the best-response map preserves block-constancy"; and then read off the finite multi-population system, its equilibria, and its existence/uniqueness theory simply as the restriction of the Part IV machinery to that subspace. The next subsection takes the first of these steps. It partitions $[0,1]$ into K cells, defines the block-constant fields that *are* the finite-dimensional invariant subspace just promised, and states the aggregate-preservation lemma that makes the subspace invariant in the first place. The reader should arrive there already expecting a partition into cells, a block-constant subspace, and a lemma that the aggregate preserves block-constancy.

30.1.1 The block graphon and the block-constant subspace

We now make good on the promise of the previous section. There we argued, in words, that the block kernel distinguishes a *finite-dimensional invariant subspace* of the field space, and that the multi-population reduction is the restriction of the whole equilibrium problem to that subspace. This subsection produces the subspace and its load-bearing properties: that it is parametrized by K measures, that it carries exactly the weighted product metric the finite system will need, that it is closed (so a fixed point may be hunted inside it), and finally — the one genuinely structural fact — that the graphon aggregate maps it into itself. The partition and the block-constant fields defined below *are* the finite-dimensional invariant subspace; nothing more is hidden behind the phrase.

Start from the kernel. We want the simplest W that is not trivial — not constant (which would make every type identical and collapse the graphon game to a single classical mean field game), but as close to constant as a genuine K-class structure permits. The honest minimal choice is a kernel that is constant on each rectangle of a partition: it can distinguish K kinds of type and assign each ordered pair of kinds its own coupling strength, and it can do nothing finer. Recall, then, the block construction flagged in remark 21.20. Partition the type interval $[0,1]$ into K measurable cells,

$$[0,1] \;=\; \bigsqcup_{k=1}^{K} I_k, \qquad \pi_k \;:=\; \mathrm{Leb}(I_k) > 0, \qquad \sum_{k=1}^{K} \pi_k = 1, \tag{30.1}$$

one cell per population, and let the kernel be constant on each product cell,

$$W(x,y) \;=\; \mathsf{B}_{k\ell} \qquad \text{for } x \in I_k,\; y \in I_\ell, \tag{30.2}$$

with $\mathsf{B} = (\mathsf{B}_{k\ell})_{k,\ell=1}^{K}$ a symmetric matrix with entries in $[0,1]$ (symmetry $\mathsf{B}_{k\ell} = \mathsf{B}_{\ell k}$ is the matrix form of (A-Reg-W)). The π_k are the *population masses*: π_k is the fraction of all types that belong to class k, and we will see that this fraction is precisely the weight with which class k's aggregate enters everyone else's. This is the stochastic block model viewed as a graphon, and it carries exactly the within/across structure isolated in the previous section: any two types in the same cell are coupled identically to the rest of the world (intra-class statistical identity), while the off-diagonal entries $\mathsf{B}_{k\ell}$, $k \neq \ell$, are free and need not be equal or even of one sign (arbitrary across-class coupling).

The kernel being constant on cells is only half of the structure; the other half is the *ansatz* for the unknown field. If the coupling cannot tell two types in the same cell apart, there is no reason for the equilibrium to tell them apart either, and we should look for fields that are themselves constant on each cell. This is not yet a theorem — that the equilibrium really is constant on cells is the content of lemma 30.2 and theorem 30.4 — but it is the natural class of fields to single out, and we name it.

Definition 30.1 (Block-constant fields)**.** A population field $\boldsymbol{m} = (m^x)_{x\in[0,1]} \in \mathcal{M}_2$ (definition 21.8) is *block-constant* (subordinate to the partition (30.1)) if there exist $m^{(1)}, \dots, m^{(K)} \in \mathcal{P}_2(\mathbb{R}^d)$ such that $m^x = m^{(k)}$ for Lebesgue-a.e. $x \in I_k$, $k = 1, \dots, K$. The set of block-constant fields is denoted $\mathcal{M}_2^{\mathsf{B}} \subset \mathcal{M}_2$.

A block-constant field is thus pinned down by the finite tuple $(m^{(1)}, \dots, m^{(K)})$ of its K cell-measures: one probability measure per class, in place of one per type. The map $\iota : (m^{(1)}, \dots, m^{(K)}) \mapsto \boldsymbol{m}$ that builds the corresponding block-constant field is therefore a bijection from $(\mathcal{P}_2(\mathbb{R}^d))^K$ onto $\mathcal{M}_2^{\mathsf{B}}$ (its inverse reads off the a.e.-constant value of $\boldsymbol{m}$ on each cell), and this is already the bare "K measures parametrize the subspace" statement. The substance is that ι does more than count dimensions: it preserves distances. The field metric of definition 21.8 integrates the cell-wise Wasserstein distance over types,

$$d_2(\iota(\boldsymbol{m}^\bullet), \iota(\boldsymbol{m}'^\bullet))^2 \;=\; \int_0^1 \mathcal{W}_2(m^x, (m')^x)^2 \, \mathrm{d}x \;=\; \sum_{k=1}^{K} \pi_k \, \mathcal{W}_2\big(m^{(k)}, (m')^{(k)}\big)^2, \tag{30.3}$$

and the second equality is a one-line computation worth seeing explicitly. For two block-constant fields the integrand $x \mapsto \mathcal{W}_2(m^x, (m')^x)^2$ is itself constant on each cell I_k, taking there the single value $\mathcal{W}_2(m^{(k)}, (m')^{(k)})^2$, so the integral splits as $\sum_k \int_{I_k} \mathcal{W}_2(m^{(k)}, (m')^{(k)})^2 \, \mathrm{d}x = \sum_k \pi_k \, \mathcal{W}_2(m^{(k)}, (m')^{(k)})^2$, the cell length π_k emerging as the weight. So $(\mathcal{M}_2^{\mathsf{B}}, d_2)$ is *isometric* to $(\mathcal{P}_2(\mathbb{R}^d))^K$ equipped with the π-weighted product $\mathcal{W}_2$, and the population masses reappear here as the weights of the product: a discrepancy in a small (low-mass) class counts for proportionally less in the field metric, exactly as it should. This is the isometry that makes every quantitative constant of the graphon theory transfer to the finite system with no slack, as anticipated in the section opening.

The third property we need is that the subspace is *closed*, and it is worth being explicit about why this matters before proving it. The entire reduction strategy is to hunt for an equilibrium — a fixed point of the best-response map — *inside* $\mathcal{M}_2^{\mathsf{B}}$, by iterating the map and taking limits. For that to be legitimate the limit of a sequence of block-constant fields must itself be block-constant; otherwise the iteration could converge to a fixed point that has leaked out of the subspace, and the finite parametrization would be lost in the limit. Closedness is precisely the guarantee that no such leak occurs, and it follows at once from the isometry (30.3). Suppose $\boldsymbol{m}_n \in \mathcal{M}_2^{\mathsf{B}}$ is a sequence with cell-measures $m_n^{(k)}$ that converges in d_2 to some $\boldsymbol{m} \in \mathcal{M}_2$. Applying (30.3) to two members of the sequence gives $\pi_k \, \mathcal{W}_2(m_n^{(k)}, m_m^{(k)})^2 \le d_2(\boldsymbol{m}_n, \boldsymbol{m}_m)^2$, so each cell-sequence $(m_n^{(k)})_n$ is $\mathcal{W}_2$-Cauchy and hence, $\mathcal{P}_2(\mathbb{R}^d)$ being complete, $\mathcal{W}_2$-convergent to some limit $m_\infty^{(k)}$. The block-constant field $\iota((m_\infty^{(k)})_k)$ is then the d_2-limit of the $\boldsymbol{m}_n$ by (30.3) once more; since d_2-limits are unique it equals $\boldsymbol{m}$, so $\boldsymbol{m}$ agrees a.e. on each cell with the fixed measure $m_\infty^{(k)}$ and is therefore block-constant. In short, d_2-convergence forces $\mathcal{W}_2$-convergence of the cell-measures and a.e. agreement with their limits; thus $\mathcal{M}_2^{\mathsf{B}}$ is a closed subset of the complete space $(\mathcal{M}_2, d_2)$ (proposition 21.9) and is itself complete.

With the subspace built, parametrized, isometrically identified, and shown closed, only one thing remains before we can restrict the equilibrium problem to it: we must check that the problem *can* be restricted, i.e. that the dynamics never carry us out of the subspace. The whole equilibrium machinery enters a field only through the graphon aggregate Θ of definition 21.5 — the single quantity through which a type feels the crowd — so it suffices to show that the aggregate of a block-constant field is again block-constant. This is the single structural fact that drives the entire reduction.

Lemma 30.2 (The aggregate is block-diagonal)**.** *Let W be the block kernel* (30.2) *and let $\boldsymbol{m} \in \mathcal{M}_2^{\mathsf{B}}$ correspond to $(m^{(1)}, \ldots, m^{(K)})$. Then for the scalar (observable) aggregate of definition 21.5 with a bounded 1-Lipschitz observable h, the field $x \mapsto \Theta(x) = (\mathbb{W}[\langle h, m^{\cdot}\rangle])(x)$ is itself block-constant, with value on I_k*

$$\Theta(x) \;=\; \Theta^{(k)} \;:=\; \sum_{\ell=1}^{K} \pi_\ell\, \mathsf{B}_{k\ell}\, \langle h, m^{(\ell)} \rangle, \qquad x \in I_k. \tag{30.4}$$

The same holds for the measure-valued aggregate (21.3)*, which on I_k equals the finite measure $\sum_\ell \pi_\ell \mathsf{B}_{k\ell}\, m^{(\ell)}$.*

Proof. Fix a type $x \in I_k$, write out the aggregate (21.4) as an integral over the partner type y, and split that integral over the cells $I_1, \ldots, I_K$ on which the integrand is piecewise constant:

$$\Theta(x) \;=\; \int_0^1 W(x,y)\, \langle h, m^y \rangle \;\mathrm{d}y \;=\; \sum_{\ell=1}^{K} \int_{I_\ell} W(x,y)\, \langle h, m^y \rangle \;\mathrm{d}y.$$

On the cell I_ℓ the kernel is constant, $W(x,y) = \mathsf{B}_{k\ell}$ by (30.2) (because $x \in I_k$, $y \in I_\ell$), and the field is constant, $m^y = m^{(\ell)}$ for a.e. $y \in I_\ell$, so the integrand $\mathsf{B}_{k\ell} \langle h, m^{(\ell)} \rangle$ does not depend on y. Each cell-integral is then this constant times the cell length $\mathrm{Leb}(I_\ell) = \pi_\ell$, giving

$$\Theta(x) \;=\; \sum_{\ell=1}^{K} \pi_\ell\, \mathsf{B}_{k\ell}\, \langle h, m^{(\ell)} \rangle,$$

which depends on x only through its cell index k; this is (30.4). The measure-valued statement is the identical computation with the linear functional $\langle h, \cdot \rangle$ deleted, the constant measure $m^{(\ell)}$ pulled out of each cell-integral in its place. □

Read the result physically. A type in class k feels not one aggregate but a single weighted *superposition* of the K class aggregates $\langle h, m^{(\ell)} \rangle$, the weight on class ℓ being $\pi_\ell \mathsf{B}_{k\ell}$ — the product of how *many* types are in class ℓ (its mass π_ℓ) and how *strongly* class k is coupled to class ℓ (the kernel entry $\mathsf{B}_{k\ell}$). Two types in the same class feel the identical superposition, which is exactly why block-constant input produces block-constant aggregate and the subspace is invariant. Equation (30.4) is the multi-population coupling, and it is the object the next subsection will assemble into a closed K-population system.

It is convenient to package the weights $\pi_\ell \mathsf{B}_{k\ell}$ into a single matrix. Two matrices appear, and the difference between them is the recurring subtlety of the whole multi-population calculus, so we introduce both carefully. The weights as they literally act on the vector of class aggregates form the *asymmetric* matrix $\mathsf{B}\ \mathrm{diag}(\pi)$ with entries $(\mathsf{B}\,\mathrm{diag}(\pi))_{k\ell} = \mathsf{B}_{k\ell}\,\pi_\ell$; it is asymmetric because the mass π_ℓ sits on the source index ℓ alone, not symmetrically on the pair. For spectral purposes one prefers a symmetric representative, the *interaction matrix*

$$\widehat{\mathsf{B}}_{k\ell} \;:=\; \sqrt{\pi_k \pi_\ell}\; \mathsf{B}_{k\ell}, \qquad k, \ell = 1, \ldots, K, \tag{30.5}$$

which is symmetric because B is. These two matrices are not equal, but they are *conjugate*, and the conjugation is the source of every spectral identity we will use. Indeed, conjugating $\mathsf{B}\,\mathrm{diag}(\pi)$ by $\mathrm{diag}(\sqrt{\pi})$ gives

$$\mathrm{diag}(\sqrt{\pi})\;[\mathsf{B}\,\mathrm{diag}(\pi)]\;\mathrm{diag}(\sqrt{\pi})^{-1} \;=\; \mathrm{diag}(\sqrt{\pi})\,\mathsf{B}\;\mathrm{diag}(\pi)\;\mathrm{diag}(\sqrt{\pi})^{-1} \;=\; \mathrm{diag}(\sqrt{\pi})\,\mathsf{B}\;\mathrm{diag}(\sqrt{\pi}) \;=\; \widehat{\mathsf{B}},$$

the middle step using $\operatorname{diag}(\pi)\,\operatorname{diag}(\sqrt{\pi})^{-1} = \operatorname{diag}(\sqrt{\pi})$ since $\pi_\ell/\sqrt{\pi_\ell} = \sqrt{\pi_\ell}$, and the last reading off entries $\sqrt{\pi_k}\,\mathsf{B}_{k\ell}\,\sqrt{\pi_\ell}$. A similarity transformation preserves the spectrum, so $\mathsf{B}\operatorname{diag}(\pi)$ — and equally its transpose $\operatorname{diag}(\pi)\mathsf{B}$ — has the *same eigenvalues* as the symmetric $\widehat{\mathsf{B}}$; in particular those eigenvalues are real, which is not visible from the asymmetric form alone. The conjugation also explains in what sense $\widehat{\mathsf{B}}$ "is" the coupling operator. The isometry (30.3) identifies the block-constant subspace with $\mathbb{R}^K$ carrying the π-weighted inner product $\langle u, v\rangle_\pi = \sum_k \pi_k u_k v_k$, and on that subspace $\mathbb{W}$ acts on the vector $(\langle h, m^{(\ell)}\rangle)_\ell$ of class aggregates by left multiplication by $\mathsf{B}\operatorname{diag}(\pi)$, by (30.4). Changing variables to $\operatorname{diag}(\sqrt{\pi})\,u$ turns the weighted inner product into the standard one and conjugates $\mathsf{B}\operatorname{diag}(\pi)$ into $\widehat{\mathsf{B}}$; hence $\widehat{\mathsf{B}}$ is exactly the matrix representing $\mathbb{W}|_{\mathcal{M}_2^{\mathsf{B}}}$ in an *orthonormal* basis of the weighted space, symmetric precisely because $\mathbb{W}$ restricted to this finite-dimensional invariant subspace is self-adjoint, as recorded in remark 21.20. Consequently its spectral norm equals the operator norm of the restriction, $\left\|\widehat{\mathsf{B}}\right\| = \left\|\mathbb{W}|_{\mathcal{M}_2^{\mathsf{B}}}\right\|$, and this single number is the finite-dimensional avatar of the coupling constant $\|\mathbb{W}\|$: it is the quantity into which the Part IV threshold $\|\mathbb{W}\| < \kappa$ will collapse, and the coupling constant that will govern multi-population uniqueness. We hand it, together with the per-cell coupling $\Theta^{(k)}$ of (30.4), to the next subsection, which assembles them into the explicit K-population mean field game system that the multi-population literature writes down directly.

30.1.2 The multi-population MFG system

The previous subsection handed us two finite objects extracted from the block graphon: the interaction matrix $\widehat{\mathsf{B}}$, the symmetric avatar of the coupling operator $\mathbb{W}$ on the block-constant subspace, and — the one we put to work now — the per-cell coupling $\Theta^{(k)}$ of (30.4), the single weighted superposition of class aggregates through which a type in class k feels the entire crowd. The structural work is already done; what remains is bookkeeping. Lemma 30.2 guarantees that a block-constant field produces a block-constant aggregate, so the continuum of backward–forward systems indexed by $x \in [0, 1]$ collapses to one system per cell, and the only trace any cell keeps of the others is the K numbers $\Theta_t^{(1)}, \ldots, \Theta_t^{(K)}$. Assembling those K systems into one finite object, and then proving that this object is not merely *reminiscent* of the system the multi-population literature posits by hand but *identical* to it as an equilibrium problem, is the business of this subsection.

Specializing the coupled backward–forward system of chapter 22 to a block kernel and to block-constant data yields a *finite* system of K classical mean field game systems, coupled only through the scalar/measure aggregates (30.4). The specialization is mechanical, and it is worth seeing why before reading the result. In the general type-x system of chapter 22 the type label and the entire crowd enter an agent's problem through one channel only: the aggregate $\Theta_t(x)$. Everything else in the agent's optimization — its dynamics, its running and terminal cost in its own state, its diffusion — is local to that agent and carries the type label merely as a parameter. Now feed in block-constant data and a block-constant field. By lemma 30.2 the aggregate is constant on each cell, equal to $\Theta_t^{(k)}$ on I_k; by hypothesis the coefficients and costs are constant on each cell as well. Every ingredient of the type-x system therefore depends on x only through its cell index k, and the continuum of systems degenerates into K distinct ones, indexed by class. We state the resulting object for completeness; it is exactly what the multi-population literature [66, 49, 22] writes down directly, with no graphon anywhere in view. That literature *begins* from K populations and *posits* the coupling (30.7) as a modelling choice; we are about to obtain the identical system as a restriction of the single Part IV graphon game, which is the whole sense in which the graphon picture subsumes it.

Definition 30.3 (Multi-population MFG system)**.** Let each population k have drift b_k, volatility σ_k, running cost L_k, terminal cost g_k, and initial law $m_0^{(k)} \in \mathcal{P}_2(\mathbb{R}^d)$, all satisfying the standing assumptions (A-Lip), (A-Growth), (A-Nondeg), (A-Conv) of assumption 7.3 uniformly in k, with population Hamiltonian $H_k(x,p,\Theta) = \sup_\alpha\{-p\cdot b_k(x,\alpha,\Theta) - L_k(x,\alpha,\Theta)\}$. A *multi-population MFG equilibrium* is a tuple of value/density flows $(u^{(k)}, m^{(k)})_{k=1}^K$ on $[0,T]\times\mathbb{R}^d$ solving, for each k,

$$\partial_t u^{(k)} + \tfrac{1}{2}\operatorname{tr}(\sigma_k\sigma_k^\top \mathrm{D}^2 u^{(k)}) - H_k(x, \nabla u^{(k)}, \Theta_t^{(k)}) = 0, \qquad u^{(k)}(T,\cdot) = g_k(\cdot, \Theta_T^{(k)}), \tag{30.6a}$$

$$\partial_t m^{(k)} = \mathcal{A}_k^* \, m^{(k)}, \qquad m^{(k)}(0,\cdot) = m_0^{(k)}, \tag{30.6b}$$

where $\mathcal{A}_k^*$ is the Fokker–Planck (forward) operator of population k under its optimal feedback $\alpha^{(k),*} = -\partial_p H_k(x, \nabla u^{(k)}, \Theta_t^{(k)})$, and the aggregate felt by population k is, with observable h,

$$\Theta_t^{(k)} \;=\; \sum_{\ell=1}^K \pi_\ell \, \mathsf{B}_{k\ell} \, \langle h, m_t^{(\ell)}\rangle. \tag{30.7}$$

The structure of (30.6) deserves to be read slowly, because everything that follows — including the entire existence and uniqueness theory — is a consequence of it. The system is a tuple of K separate HJB/Fokker–Planck pairs, one per population, and the k-th pair (30.6a)–(30.6b) is, on its face, an ordinary single-population mean field game system in the sense of eq. (8.5): a backward HJB equation for population k's value $u^{(k)}$, a forward Fokker–Planck equation for its density $m^{(k)}$, the two halves meeting through population k's own optimal feedback. The *only* way population k's pair learns about population $\ell \neq k$ is through the appearance of the scalar (or measure) $\Theta_t^{(k)}$ in the Hamiltonian and terminal cost, and that scalar is the single number (30.7) — a fixed linear readout of the other populations' densities. The consequence is decisive: *freeze* the K flows $t \mapsto \Theta_t^{(k)}$ at any guessed values, and the system instantly uncouples into K independent single-population mean field games, each solvable by the Part II machinery of chapter 8 as though the other $K-1$ populations did not exist. The populations are bound together not by interacting equations but by a finite-dimensional *consistency condition*: the K aggregates each population is solved against must equal the K aggregates the resulting densities produce through (30.7). A multi-population equilibrium is precisely a simultaneous fixed point of this K-fold coupling. That an entire society of distinct interacting species reduces to "K ordinary control problems plus K scalar matching conditions" is exactly what one means by saying the graphon picture subsumes multi-population MFG; the theorem below makes the reduction an equivalence of equilibria rather than a heuristic.

We can now state the reduction precisely. The theorem has three parts, and they are arranged so that each is the natural prerequisite for the next. Part (i) is the one structural fact — that the best-response map cannot escape the block-constant subspace — without which the whole strategy is illegitimate, since an iteration searching for an equilibrium could otherwise drift out of the finite-dimensional world. Part (ii) upgrades invariance to an exact identification: restricted to that subspace and read through the isometry ι, the graphon best-response map *is* the best-response map of definition 30.3, not a cousin of it. Part (iii) is then the immediate payoff at the level of equilibria: fixed points correspond to fixed points, so the two equilibrium problems have literally the same solution set.

Theorem 30.4 (Block reduction: equivalence of equilibria)**.** *Let W be the block kernel (30.2) and assume the agent data (coefficients, costs, initial laws) are block-constant in type, i.e. depend on x only through its cell index. Then:*

(i) *The block-constant subspace $\mathcal{M}_2^{\mathsf{B}}$ is invariant under the best-response map S of definition 21.15: if the input field flow is block-constant, so is the output.*

(ii) *The restriction $\mathsf{S}|_{\mathcal{M}_2^{\mathsf{B}}}$ is, under the isometry ι of (30.3), exactly the best-response map of the multi-population system: it solves (30.6a) for the K value flows against the aggregates (30.7) and returns the K Fokker–Planck flows (30.6b).*

(iii) *Consequently, $(u^{(k)}, m^{(k)})_{k=1}^K$ solves the multi-population MFG system (30.6) if and only if the block-constant field $\iota((m^{(k)})_k)$ is a dynamic graphon MFG equilibrium (definition 21.16) for the block kernel.*

Proof. (i) Let the input flow be block-constant, $m_t^x = m_t^{(k)}$ for $x \in I_k$, and recall what the best-response map of definition 21.15 actually does to a single type: it solves the type-x optimal control problem against the aggregate flow that the input field induces, then reports the law of the resulting optimally-controlled state. So everything turns on which data that control problem sees. There are exactly four inputs to it — the coefficients $(b_x, \sigma_x, L_x, g_x)$ defining the agent's dynamics and cost, the exogenous aggregate flow $t \mapsto \Theta_t(x)$ it best-responds to, and the initial law m_0^x from which its state is launched — and we check each is the same for two types in a common cell. The coefficients agree because the data are assumed block-constant: for $x \in I_k$ they equal $(b_k, \sigma_k, L_k, g_k)$ regardless of *which* type in I_k we picked. The initial law agrees for the same reason, $m_0^x = m_0^{(k)}$. The aggregate flow agrees by lemma 30.2: a block-constant input has $\Theta_t(x) = \Theta_t^{(k)}$ on I_k, a function of the cell index alone. Two types x, x' in the same cell I_k are therefore presented with *verbatim the same* control problem — same drift, same volatility, same running and terminal cost, same exogenous target, same starting distribution. There is nothing left for the label to influence.

Now push this identity of *problems* into an identity of *solutions*. The value u^x is characterized as the unique solution of the type-x HJB equation (30.6a), and every coefficient of that PDE — the second-order term $\frac{1}{2}\operatorname{tr}(\sigma_x\sigma_x^\top \mathrm{D}^2\ \cdot)$, the Hamiltonian $H_x(x, \cdot, \Theta_t(x))$, and the terminal datum $g_x(\cdot, \Theta_T(x))$ — has just been shown to depend on $x \in I_k$ only through k. A boundary-value problem is determined by its coefficients and its data; if two labels furnish identical coefficients and identical terminal data, the unique solution must coincide, so $u^x = u^{(k)}$ for every $x \in I_k$. (This is precisely where uniqueness for the HJB equation, supplied by the standing assumptions (A-Nondeg) and (A-Conv) of assumption 7.3 via the verification theorem of chapter 6, is doing load-bearing work: without it, two types could in principle select *different* solutions of the same equation, and block-constancy of the value would fail.) From a cell-independent value flow follows a cell-independent optimal feedback $\alpha^{(k),*} = -\partial_p H_k(x, \nabla u^{(k)}, \Theta_t^{(k)})$, hence a cell-independent Fokker–Planck operator $\mathcal{A}_k^*$, hence — since the initial law $m_0^{(k)}$ is also cell-determined — a cell-independent output density flow solving (30.6b). The reported law $\widetilde{m^x}_t = \widetilde{m}_t^{(k)}$ is thus constant on each cell, i.e. again block-constant. Therefore S carries $\mathcal{M}_2^{\mathsf{B}}$ into itself, which is the invariance claimed.

(ii) Part (i) did more than establish invariance; in the course of proving it we read off, cell by cell, exactly which finite system the restricted map solves. On cell k the value flow $u^{(k)}$ solves the HJB equation (30.6a) driven by the aggregate $\Theta_t^{(k)} = \sum_\ell \pi_\ell \mathsf{B}_{k\ell}\langle h, m_t^{(\ell)}\rangle$ — which is (30.4), i.e. the multi-population coupling (30.7) — and the output density $\widetilde{m}^{(k)}$ solves the Fokker–Planck equation (30.6b). That is term for term the best-response map of definition 30.3, the map sending $(m^{(\ell)})_\ell \mapsto (\widetilde{m}^{(k)})_k$ on the finite product $(\mathcal{P}_2(\mathbb{R}^d))^K$. The isometry ι of (30.3) relabels a block-constant field by its K-tuple of cell-measures, so conjugating $\mathsf{S}|_{\mathcal{M}_2^{\mathsf{B}}}$ by ι produces precisely this finite map; and because ι is an *isometry* and not merely a bijection, any contraction or Lipschitz modulus of S measured in d_2 is reproduced *with the same constant* by the finite map measured in the π-weighted product Wasserstein metric. This is what makes the two best-response maps the same map at two resolutions rather than two maps that happen to share fixed points — and it is the fact the quantitative theory of section 30.1.3 will lean on.

(iii) The equivalence of equilibria is now immediate, because an equilibrium of either problem is by definition a fixed point of its best-response map. If $(u^{(k)}, m^{(k)})_k$ solves the multi-population system (30.6), then $(m^{(k)})_k$ is a fixed point of the finite best-response map, hence by (ii) the block-constant field $\iota((m^{(k)})_k)$ is a fixed point of $\mathsf{S}|_{\mathcal{M}_2^{\mathsf{B}}}$, and — since S does not move points already in $\mathcal{M}_2^{\mathsf{B}}$ to anywhere outside it — a genuine fixed point of S on all of $\mathcal{M}_2$, i.e. a dynamic graphon MFG equilibrium (definition 21.16) for the block kernel. Conversely, a graphon equilibrium that *happens* to be block-constant is, by reading off its cell-measures, a solution of (30.6). The two solution sets are thus in bijection through ι. The role of invariance (i) and closedness here is exactly to guarantee that the restricted problem is self-contained: because $\mathcal{M}_2^{\mathsf{B}}$ is S-invariant and closed in the complete space $\mathcal{M}_2$, a fixed point sought inside it stays inside it and the limits of any approximating iteration remain available, so no equilibrium of the finite system is an artefact of the restriction and none is lost by it. What this argument does *not* claim — and cannot, as the next remark insists — is that every graphon equilibrium of a block kernel is block-constant; it claims only that the block-constant ones are exactly the multi-population ones. □

Remark 30.5 (Why block-constant data give block-constant equilibria, and when they need not)**.** It is tempting to over-read theorem 30.4 as saying that a block kernel *forces* the equilibrium to be block-constant. It does not, and the distinction is fundamental enough to isolate. What the theorem delivers is a bijection between the multi-population equilibria and the *block-constant* graphon equilibria — the equilibria that happen to live in the invariant subspace $\mathcal{M}_2^{\mathsf{B}}$. What it is silent about is whether a block kernel might *also* support graphon equilibria that are *not* block-constant: fields in which two types drawn from the same cell, presented (by part (i) of the proof) with the identical best-response problem, nonetheless settle into *different* measures. Invariance of $\mathcal{M}_2^{\mathsf{B}}$ says the best-response iteration started inside the subspace never leaves it, so a block-constant equilibrium always exists once the finite-dimensional fixed-point argument of section 30.1.3 provides one; it says nothing about whether some *other* iteration, started outside, might converge to a symmetry-broken fixed point that the subspace never sees.

Whether such a non-block-constant equilibrium exists is therefore not an existence question at all but a *uniqueness* question, and this is the crux. If the equilibrium is unique, it can only be the block-constant one we already produced, and symmetry breaking is impossible; if uniqueness fails, extra equilibria become available and there is no a priori reason they should respect the cell structure.

The two regimes in which we will be able to prove uniqueness — Lasry–Lions monotonicity and small coupling, both inherited from chapter 24 — thus do double duty: they guarantee not merely *a* solution but that the solution is forced to inherit the block symmetry of the kernel. Outside those regimes the guarantee lapses and symmetry breaking within a cell is genuinely possible.

This is the exact mean-field-game incarnation of the Curie–Weiss phenomenon. There a *fully symmetric* ferromagnetic coupling — every spin coupled identically to the mean — nonetheless supports asymmetric, magnetized states below the critical temperature: the symmetry of the interaction is not inherited by the equilibrium because the self-consistency map acquires multiple fixed points. The structural parallel is precise. A single cell with an attractive self-coupling is a continuum of statistically identical agents each best-responding to the cell mean, which is the self-consistent-field setup whose multiplicity we analyzed in chapter 11 (the LQG uniqueness/multiplicity threshold of proposition 11.8, and the reading of multiplicity as spontaneous symmetry breaking in section 11.4). When the self-coupling is weak the matching map is a contraction with a single fixed point — the symmetric, block-constant equilibrium — but when it is strong enough the map develops several fixed points, and the symmetric one need no longer be selected. The within-cell symmetry breaking entertained above is that same bifurcation lifted to the field. Establishing exactly where on this boundary uniqueness holds is what makes the present remark a genuinely open direction rather than a closed one; we log it as such in the chapter ledger.

The remark has converted the equivalence theorem's silence into a sharp question, and it is the question the next subsection answers. Theorem 30.4 reduced the multi-population equilibrium problem to a fixed point on the finite product $(\mathcal{P}_2(\mathbb{R}^d))^K$ but left two things unsettled: whether such a fixed point exists at all, and — the issue this remark has now shown to be the deciding one for symmetry breaking — when it is *unique*, hence necessarily the block-constant equilibrium and nothing more. We turn to both. Because the isometry ι transports every quantitative constant of the Part IV theory onto the finite system intact, the answers will be the multi-population shadows of theorems we already own: existence from the graphon Schauder argument, and uniqueness in precisely the monotone and small-coupling regimes flagged above, now read through the finite interaction matrix $\widehat{\mathsf{B}}$ rather than the operator $\mathbb{W}$.

30.1.3 Existence and uniqueness for the finite system

The previous subsection ended by sharpening the equivalence theorem's one silence into a decisive question: it is *uniqueness*, not existence, that controls whether a block kernel can break its own symmetry. If the multi-population equilibrium is unique it can only be the block-constant one that the invariant subspace already produces, so within-cell symmetry breaking is impossible; if uniqueness fails, symmetry-broken equilibria become available and nothing forces them to respect the cells. We now settle both halves — that an equilibrium exists, and the two regimes in which it is unique and hence necessarily block-constant. Because theorem 30.4 identifies the multi-population equilibrium with a fixed point of the best-response map on the finite-dimensional product $(\mathcal{P}_2(\mathbb{R}^d))^K$ — and identifies it *isometrically*, through the metric (30.3), so that every quantitative constant transfers with no slack — existence and uniqueness follow from the Part II and Part IV machinery essentially verbatim, with the single substitution of the finite interaction matrix $\widehat{\mathsf{B}}$ of (30.5) for the operator $\mathbb{W}$.

What is worth dwelling on before the statement is that this substitution does not merely rename the coupling constant: it makes the genuinely delicate analytic inputs of the graphon existence theorem of chapter 24 *elementary*. In the general theory the best-response map acts on the infinite-dimensional field space $\mathcal{M}_2$, an entire continuum of measures indexed by type, and the compactness needed to run a fixed-point argument there has to be assembled with care — one controls a whole family of laws simultaneously and must argue tightness and continuity uniformly across the continuum of types. On the block-constant subspace there are only K measures in play. Tightness of K probability measures carrying a uniform second moment is immediate from Markov's inequality and Prokhorov's theorem; the convex hull of K-tuples of such measures is compact; and the fixed-point statement one needs is the ordinary finite-product version of Schauder rather than its infinite-dimensional refinement. Finiteness of K is exactly what turns the compactness step from a theorem into a remark. That is the sense in which the block reduction is not just a special case but an *easy* special case.

Proposition 30.6 (Existence and uniqueness, multi-population)**.** *Assume each population's data satisfy (A-Lip), (A-Growth), (A-Nondeg), (A-Conv).*

(i) (Existence.) *There exists at least one multi-population MFG equilibrium* (30.6)*.*

(ii) (Uniqueness, monotone regime.) *Write* $\widehat{\mathsf{B}} = \widehat{\mathsf{B}}_{\mathrm{diag}} + \widehat{\mathsf{B}}_{\mathrm{off}}$ *for the split into its (block-)diagonal self-couplings and its off-diagonal inter-population part. If, in addition, the diagonal self-couplings of each population satisfy the graphon Lasry–Lions monotonicity condition (A-Mon) (definition 24.15) and the off-diagonal part is below the coupling threshold relative to the diagonal monotonicity modulus,* $\left\|\widehat{\mathsf{B}}_{\mathrm{off}}\right\| < \kappa = 1/C_T$ *(the (A-Coupling) constant of chapter 24), then the equilibrium is unique.*

(iii) (Uniqueness, small-coupling regime.) *Alternatively, if the per-population best-response is a contraction with modulus* $\rho_0 < 1$ *in* $\mathcal{W}_2$ *and* $\rho_0 \left\|\widehat{\mathsf{B}}\right\| < 1$*, the equilibrium is unique.*

Proof sketch. (i) Existence. We seek a fixed point of the finite best-response map $F : (m^{(k)})_k \mapsto (\widetilde{m}^{(k)})_k$ on $(\mathcal{P}_2(\mathbb{R}^d))^K$, which by theorem 30.4(ii) is $\mathsf{S}|_{\mathcal{M}_2^{\mathsf{B}}}$ read through the isometry ι. Three ingredients run the classical Schauder argument, and finiteness of K makes each one elementary. First, an *invariant ball*: the uniform second-moment bound of lemma 21.13, which holds population by population under (A-Growth), produces a radius R such that whenever each input law has second moment at most R, so does each output law. Thus F maps the set $\mathcal{C}_R := \{(m^{(k)})_k : \int |x|^2 \, \mathrm{d}m^{(k)} \leq R \ \forall k\}$ into itself. Second, *compactness* of $\mathcal{C}_R$: for a single population the second-moment ball is tight by Markov's inequality, hence relatively weakly compact by Prokhorov, and with a uniform $2+\delta$ moment (again from (A-Growth)) the second moments are uniformly integrable, so weak limits are $\mathcal{W}_2$-limits and the ball is $\mathcal{W}_2$-compact; for K populations $\mathcal{C}_R$ is just the K-fold product of this one compact set, which is where the finiteness of K enters — a product of finitely many compact sets is compact, with none of the diagonal/equicontinuity care the continuum-of-types version demands. The convex structure of $\mathcal{C}_R$ (a ball cut out by the linear second-moment functionals is convex under mixtures of measures) lets us pass to its closed convex hull without leaving $\mathcal{C}_R$. Third, *continuity* of F: holding the K input measures fixed determines the K aggregate flows $\Theta_t^{(k)}$ through the linear readout (30.7), which is plainly continuous in the inputs; against a given aggregate flow the population-k best response depends continuously on that flow by the stability of the HJB/Fokker–Planck pair in its data (the verification theorem of chapter 6 together with the well-posedness of chapter 8); composing, F is continuous on $\mathcal{C}_R$. Schauder's fixed-point theorem applied to the continuous self-map F of the convex compact set $\mathcal{C}_R$ — exactly the deployment of chapter 10, now in finite product form — yields a fixed point, i.e. a multi-population equilibrium. No appeal to the full infinite-dimensional compactness machinery of chapter 24 is needed.

(iii) Small-coupling regime. We take the contraction case before the monotone one because it is the more transparent of the two and isolates the role of $\left\|\widehat{\mathsf{B}}\right\|$ cleanly. Consider the map Φ on the space of K aggregate flows $\boldsymbol{\Theta} = (\Theta^{(1)}, \ldots, \Theta^{(K)})$ defined by the equilibrium loop: freeze $\boldsymbol{\Theta}$, solve the K *decoupled* single-population mean field games against these frozen targets, and read the realized aggregates (30.7) back off the resulting densities. A fixed point of Φ is a multi-population equilibrium, and conversely. The Lipschitz modulus of Φ factors through two independent gains. Perturbing the input target seen by population k moves its realized aggregate by at most ρ_0 times that perturbation — this is the per-population best-response sensitivity, assumed below one; crucially it is an *intra*-population quantity, the same number one would compute for an isolated single-population game. The realized aggregates are then fed back into the inputs through the coupling (30.7), i.e. through left multiplication by $\mathsf{B}\,\mathrm{diag}(\pi)$, whose gain in the weighted norm is exactly $\left\|\widehat{\mathsf{B}}\right\|$ by the conjugacy of (30.5). Composing the two, Φ is Lipschitz with modulus at most $\rho_0 \left\|\widehat{\mathsf{B}}\right\|$; when $\rho_0 \left\|\widehat{\mathsf{B}}\right\| < 1$ it is a contraction on a complete space and the Banach fixed-point theorem gives a unique equilibrium. The intuition is that "small coupling" means the feedback loop binding the K populations together is too weak to amplify the disturbances each population already damps on its own: contractivity of the isolated problems survives being wired together precisely when the wiring gain $\left\|\widehat{\mathsf{B}}\right\|$ does not exceed the reciprocal of the intra-population sensitivity.

(ii) Monotone regime. When the coupling is *not* small one can still get uniqueness from the Lasry–Lions monotonicity of definition 11.1, lifted to the graphon in definition 24.15, provided the inter-population coupling is below threshold. This is the finite-rank instance of the graphon monotone uniqueness theorem theorem 24.16, and although we do not reproduce the full Bregman bookkeeping, the outline makes visible exactly where the block structure enters and why the threshold is the one stated. Suppose two equilibria, distinguished by superscripts 1 and 2, with value/density differences $\delta u^{(k)}$ and $\delta m^{(k)}$. The monotone uniqueness computation of chapter 24 tests the difference of the two HJB equations against the difference of the two Fokker–Planck densities, integrates over $[0, T] \times \mathbb{R}^d$, and sums over k; the backward–forward duality between HJB and Fokker–Planck (the integration by parts of chapter 24) annihilates the linear transport terms and leaves a balance of two pieces. The first is a sum, over populations, of *displacement-convexity gaps* of the Hamiltonians H_k — nonpositive Bregman terms whose strict definiteness is supplied by (A-Conv) and (A-Nondeg) — which control the squared size of the aggregate discrepancy $\hat{\delta}_t := \mathrm{diag}(\sqrt{\pi})\big(\langle h, \delta m_t^{(k)} \rangle\big)_k$ from below with a modulus at least $\kappa = 1/C_T$, where C_T is the same best-response stability constant that fixes the Part IV threshold. The second is the *coupling pairing*, and here the block structure shows its

hand: substituting $\Theta^{(k)} = \sum_\ell \pi_\ell \mathsf{B}_{k\ell}\langle h, m^{(\ell)}\rangle$ turns the pairing into the quadratic form

$$\sum_{k,\ell} \pi_\ell \mathsf{B}_{k\ell}\,\langle h, \delta m_t^{(\ell)}\rangle\,\langle h, \delta m_t^{(k)}\rangle \;=\; \langle \widehat{\mathsf{B}}\,\hat{\delta}_t, \hat{\delta}_t\rangle,$$

exactly the quadratic form of the symmetric interaction matrix on $\hat{\delta}_t$ — the precise sense in which $\widehat{\mathsf{B}}$, and not the bare kernel, is what the uniqueness estimate sees. Split $\widehat{\mathsf{B}} = \widehat{\mathsf{B}}_{\mathrm{diag}} + \widehat{\mathsf{B}}_{\mathrm{off}}$. The diagonal part $\langle \widehat{\mathsf{B}}_{\mathrm{diag}}\hat{\delta}, \hat{\delta}\rangle = \sum_k \pi_k \mathsf{B}_{kk}\langle h, \delta m^{(k)}\rangle^2$ is the *self*-coupling of each population against itself; under the diagonal monotonicity hypothesis (A-Mon) each such term carries the sign that makes it cooperate with — rather than fight — the convexity gap, which is just the single-population Lasry–Lions uniqueness of chapter 24 applied class by class. The off-diagonal part $\langle \widehat{\mathsf{B}}_{\mathrm{off}}\hat{\delta}, \hat{\delta}\rangle$, by contrast, has no definite sign — distinct populations may couple with either sign — but it is controlled in size: $|\langle \widehat{\mathsf{B}}_{\mathrm{off}}\hat{\delta}, \hat{\delta}\rangle| \le \left\|\widehat{\mathsf{B}}_{\mathrm{off}}\right\| |\hat{\delta}|^2$. The decisive comparison is now purely numerical. The convexity-gap-plus-diagonal contribution is nonpositive and dominates $|\hat{\delta}|^2$ with modulus at least κ; the off-diagonal term can perturb it by at most $\left\|\widehat{\mathsf{B}}_{\mathrm{off}}\right\| |\hat{\delta}|^2$ in either direction. Hence, as soon as

$$\left\|\widehat{\mathsf{B}}_{\mathrm{off}}\right\| \;<\; \kappa \;=\; 1/C_T,$$

the off-diagonal coupling is strictly too weak to overturn the nonpositive diagonal Bregman terms: the whole balance remains strictly of one sign unless $\hat{\delta}_t \equiv 0$. Vanishing of $\hat{\delta}$ means every population's aggregate-relevant functional coincides across the two equilibria, and feeding this back through the per-population well-posedness forces $m^{(k),1} = m^{(k),2}$ for every k. The only ingredient beyond the Ch 24 estimate is the diagonal/off-diagonal split of $\widehat{\mathsf{B}}$, which is special to the block structure and is precisely what lets "monotone self-interaction" and "below-threshold cross-interaction" be imposed separately. (Signs above are kept schematic; the exact Bregman accounting is the content of theorem 24.16.) □

The two uniqueness regimes answer the symmetry-breaking question of remark 30.5 in complementary ways, and it is worth naming the contrast. The small-coupling gate $\rho_0 \left\|\widehat{\mathsf{B}}\right\| < 1$ asks nothing about the *sign* of the interactions; it simply demands that the entire coupling, self- and cross- together, be weak. The monotone gate is more permissive about strength: it allows arbitrarily strong *aligned* self-interaction (any (A-Mon)-monotone $\widehat{\mathsf{B}}_{\mathrm{diag}}$, however large) and caps only the *cross*-population part $\widehat{\mathsf{B}}_{\mathrm{off}}$ below κ. Either way the conclusion is the same and is exactly the corollary remark 30.5 was waiting for: where the equilibrium is unique it must be the block-constant one already exhibited, so within-cell symmetry breaking cannot occur, and the block symmetry of the kernel is inherited by the equilibrium. Symmetry breaking is possible only outside both gates — strong, non-monotone cross-coupling — which is the mean-field analogue of dropping below the Curie–Weiss critical temperature.

Notation watch: Two normalizations of the interaction matrix

The block coupling is written in two ways throughout this chapter that must never be conflated, and the entire monotone/small-coupling calculus depends on keeping them apart. The *aggregate* (30.7) uses the *asymmetric* weights $\pi_\ell \mathsf{B}_{k\ell}$: these are what population k literally feels, and they are not symmetric in (k, ℓ) because the source mass π_ℓ sits on the partner index alone — how loudly class ℓ speaks to class k depends on how many agents are in class ℓ. The *spectral* analysis, by contrast — every operator-norm threshold in proposition 30.6, both $\left\|\widehat{\mathsf{B}}\right\|$ and $\left\|\widehat{\mathsf{B}}_{\text{off}}\right\|$ — uses the *symmetric* interaction matrix $\widehat{\mathsf{B}}_{k\ell} = \sqrt{\pi_k \pi_\ell}\,\mathsf{B}_{k\ell}$ of (30.5). The two are conjugate, hence share eigenvalues (eq. (30.5) and the conjugation computation following it), but they are not equal, and it is the symmetric one that the norm thresholds refer to. A concrete $K = 2$ reading fixes the distinction: population 1 feels $\pi_1 \mathsf{B}_{11}\langle h, m^{(1)}\rangle + \pi_2 \mathsf{B}_{12}\langle h, m^{(2)}\rangle$, in which the *partner* mass π_2 multiplies the cross term; but the eigenvalue that the gate $\left\|\widehat{\mathsf{B}}\right\| < \kappa$ constrains belongs to the symmetric matrix

$$\widehat{\mathsf{B}} = \begin{pmatrix} \pi_1 \mathsf{B}_{11} & \sqrt{\pi_1 \pi_2}\,\mathsf{B}_{12} \\ \sqrt{\pi_1 \pi_2}\,\mathsf{B}_{12} & \pi_2 \mathsf{B}_{22} \end{pmatrix},$$

whose off-diagonal carries the *geometric* mean $\sqrt{\pi_1 \pi_2}$, not the partner mass. Treating the asymmetric weights as if they were the spectral object would mis-locate the threshold whenever the masses are unequal. Only when all masses coincide, $\pi_k \equiv 1/K$, do the two agree up to the scalar $1/K$. The thread specification's bare kernel $\mathsf{B}_{k\ell}$ is neither of these — it omits the masses entirely — and must never be used in its place: always carry the masses, asymmetrically in the aggregate and symmetrically (as a geometric mean) in the norm.

This closes the analytic theory of the block model. We now possess, for the multi-population game, exactly the trio the Part IV theory promised: an equilibrium always exists (by an elementary finite-product Schauder argument), and it is unique — hence forced to be block-constant, hence free of within-cell symmetry breaking — throughout the monotone regime and throughout the small-coupling regime, both governed by the single scalar $\left\|\widehat{\mathsf{B}}\right\|$ and its off-diagonal restriction. Every statement so far, though, has been made at the level of *abstract* data: drifts b_k, costs L_k, a generic observable h, an interaction matrix $\widehat{\mathsf{B}}$ whose norm we can name but not compute. The natural way to see the whole apparatus breathe is to specialize to the one model in which every one of these constants is an elementary closed-form expression — the graphon LQG game of Thread B. There the interaction matrix $\widehat{\mathsf{B}}$, the coupling threshold κ, and the per-population contraction modulus ρ_0 all become explicit functions of the Riccati data, and the block-equivalence theorem theorem 30.4 collapses the infinite-dimensional graphon LQG game to K scalar Riccati equations coupled through a single K-dimensional linear ODE for the population means. The next subsection carries out exactly this computation, picking up the rank-one worked example of chapter 21 and lifting it to the block level.

30.1.4 Thread B at the block level

The previous subsection closed with a promise: the abstract block apparatus — the interaction matrix $\widehat{\mathsf{B}}$, the coupling threshold κ, the per-population contraction modulus — would stop being names we can invoke but not evaluate, and become elementary closed-form expressions, in the one model built to make every constant explicit. We now make good on it. We advance the carried Thread B (graphon LQG) to the multi-population level, instantiating the block-equivalence theorem theorem 30.4 in the fully explicit LQG thread and completing the computation begun in remark 21.20 and the rank-one worked example worked computation 21.18. The payoff is the cleanest possible illustration of the entire block reduction. An object that began as an infinite-dimensional graphon mean field game — a continuum of coupled backward HJB and forward Fokker–Planck PDEs, one pair per type $x \in [0,1]$ — collapses, for a block kernel, to a strictly finite and almost entirely elementary system: K decoupled scalar Riccati equations carrying the curvature of each population's value function, plus one $2K$-dimensional *linear* two-point boundary-value problem coupling the K population means to the K value-function offsets. Everything the crowd does to an agent is squeezed, by the LQG structure, into that single linear BVP, and it is there — and only there — that the inter-population coupling matrix $\widehat{\mathsf{B}}$ actually appears. Watching where in the system the coupling sits, and watching it sit in the *backward* half, is the whole lesson of this subsection.

Worked computation 30.7 (Thread B: the K-population LQG game)**.** Take the graphon-LQG agent (21.2) and cost (21.8) with the block kernel (30.2) and block-constant, but otherwise *population-dependent*, parameters: population k has state feedback a_k, control gain b_k, noise σ_k, state-cost weights $q_k, q_{T,k} \geq 0$, and mean-coupling strengths $s_k, s_{T,k}$. The observable is the identity $h(\xi) = \xi$, so the aggregate (30.4) felt by population k is the scalar

$$z_t^{(k)} \;=\; \sum_{\ell=1}^{K} \pi_\ell \, \mathsf{B}_{k\ell} \, \bar{m}_t^{(\ell)}, \qquad \bar{m}_t^{(\ell)} := \mathbb{E}\Big[X_t^{(\ell)}\Big] = \langle \mathrm{id}, m_t^{(\ell)} \rangle. \tag{30.8}$$

By theorem 30.4 the entire K-class equilibrium problem is nothing more than K ordinary scalar LQG mean field problems run side by side, the k-th one of which a single type in cell k solves against the *exogenous* affine target $s_k z_t^{(k)}$ exactly as in chapters 8 and 14; the only thing that makes the K problems a single game rather than K unrelated ones is that the targets $z_t^{(k)}$ must, at equilibrium, be consistent with the very means they help produce. The benefit of LQG is that each of those scalar problems is solved in closed form by a quadratic value function, and tracking what that closed form does to the coupling cleaves the system into two layers of completely different character: a layer that the inter-population coupling never touches, and a layer that is nothing but the coupling. We take them in turn, and the contrast between them is the point.

(1) Decoupled Riccati layer. Because population k's problem is linear-quadratic, its value function is exactly quadratic in the state, $u^{(k)}(t,x) = \frac{1}{2} P_t^{(k)} x^2 + r_t^{(k)} x + c_t^{(k)}$, with three time-dependent coefficients to be determined: the curvature $P_t^{(k)}$, the linear offset $r_t^{(k)}$, and an additive constant $c_t^{(k)}$ that plays no role in the dynamics and we ignore. Substituting this ansatz into population k's HJB equation (30.6a) is the computation of chapters 8 and 14 verbatim, and its mechanism is what separates the two layers. The optimal feedback is linear, $\alpha^{(k),*} = -b_k \, \partial_x u^{(k)} = -b_k (P_t^{(k)} x + r_t^{(k)})$, so the HJB equation becomes a polynomial identity in x that must hold coefficient by coefficient. Matching the three powers of x separates cleanly: the coefficient of x^2 gives an equation in $P^{(k)}$ *alone*, the coefficient of x^1 an equation in $r^{(k)}$ forced by the target, and the coefficient of x^0 the irrelevant constant. The decisive point is *where the target* $s_k z_t^{(k)}$ *lands*: entering the cost only through the quadratic $(x - s_k z_t^{(k)})^2$, it contributes a term linear in x (and a constant) but *nothing* to the coefficient of x^2, because shifting the center of a parabola never changes its curvature. The x^2 balance is therefore blind to $z_t^{(k)}$, and the curvature $P^{(k)}$ solves the scalar Riccati equation of

eq. (8.24)/eq. (14.7) *with population-k parameters*,

$$\dot{P}_t^{(k)} \;=\; -2a_k\, P_t^{(k)} + b_k^2\,(P_t^{(k)})^2 - q_k, \qquad P_T^{(k)} = q_{T,k}, \qquad k = 1,\dots,K, \tag{30.9}$$

in which not a single other population's data appears. This is why the K Riccati equations are *mutually decoupled*: the curvature of a population's value function never learns of the others' existence, for the only conduit between populations is the target $s_k z_t^{(k)}$, that target couples affinely, and affine coupling cannot reach the quadratic coefficient. The inter-population structure has been quarantined entirely into the linear offset $r^{(k)}$ and, through it, the mean — which is layer (2). One consequence is purely practical and worth flagging: the K curvatures can be computed once and for all, in advance and independently, each $P_\cdot^{(k)}$ integrated backward from its own terminal datum $q_{T,k}$ with no reference to the equilibrium being sought; each is well-posed on the whole of $[0,T]$ under $q_k, q_{T,k} \geq 0$ by theorem 14.2 (the sign conditions are exactly what forbid the Riccati blow-up). They enter the second layer only as known, frozen coefficients.

(2) Coupled mean–offset layer. Everything the populations do to one another now has to live here, and the way it does is the single most instructive feature of the LQG block model, so we build the layer up rather than quote it. Start with the forward dynamics. Under the optimal feedback the closed-loop state of a type in cell k obeys $\mathrm{d}X_t^{(k)} = \big[(a_k - b_k^2 P_t^{(k)})X_t^{(k)} - b_k^2 r_t^{(k)}\big]\,\mathrm{d}t + \sigma_k\,\mathrm{d}B_t^{(k)}$, and taking expectations kills the martingale and leaves an ODE for the mean $\bar{m}_t^{(k)} = \mathbb{E}\Big[X_t^{(k)}\Big]$. Read that ODE carefully: its homogeneous part is the *closed-loop drift* $a_k - b_k^2 P_t^{(k)}$, built from population k's own Riccati curvature and nothing else, while the entire inhomogeneous forcing is $-b_k^2 r_t^{(k)}$, the offset. So the population mean does *not* obey a closed forward ODE — it cannot be integrated forward on its own, because to step it forward one needs $r_t^{(k)}$, which is a *value-function* quantity and therefore determined by looking ahead to the terminal cost. This is the same obstruction that made the single-population game a forward–backward problem rather than an initial-value one (eq. (8.29), eq. (14.15)), and the same one that its rank-one graphon lift inherited (eq. (21.21)–(21.22)); here it simply appears K times in parallel. The offset $r_t^{(k)}$ is exactly the x^1-coefficient equation set aside in layer (1): matching the linear power of x in the HJB produces a backward ODE for $r^{(k)}$ with its homogeneous part the *negative* closed-loop drift and its forcing the target $q_k s_k z_t^{(k)}$, and the terminal cost's linear-in-x coefficient supplies the terminal datum $r_T^{(k)} = -q_{T,k} s_{T,k} z_T^{(k)}$. The whole inter-population aggregate $z_t^{(k)}$ — the only place the matrix B enters the LQG system at all — thus enters *this* equation and no other. Per population k,

$$\dot{\bar{m}}_t^{(k)} = (a_k - b_k^2 P_t^{(k)})\,\bar{m}_t^{(k)} \;-\; b_k^2\, r_t^{(k)}, \qquad\qquad \bar{m}_0^{(k)} = \bar{m}_{\text{init}}^{(k)} \text{ given}, \tag{30.10a}$$

$$\dot{r}_t^{(k)} = (b_k^2 P_t^{(k)} - a_k)\, r_t^{(k)} \;+\; q_k\, s_k\, z_t^{(k)}, \qquad\qquad r_T^{(k)} = -\,q_{T,k}\, s_{T,k}\, z_T^{(k)}, \tag{30.10b}$$

with the block aggregate $z_t^{(k)} = \sum_{\ell=1}^K \pi_\ell \mathsf{B}_{k\ell} \bar{m}_t^{(\ell)}$ of (30.8) entering, as just argued, *only* through the forcing of the backward offset equation (30.10b) and its terminal datum — never the forward mean equation (30.10a), whose only non-local ingredient is the offset of its own population. For a single population this is precisely (21.21)–(21.22), now carrying population-k parameters and the inter-population target $s_k z_t^{(k)}$ in place of the self-target. The phrase to carry forward is that *the inter-population coupling sits in the backward half of the system.* This is not a notational accident but the LQG shadow of the throughline of the whole chapter: an agent feels the crowd only through a target it is trying to track, tracking is a forward-looking optimization, and optimization is solved backward; the crowd therefore reaches the agent's behaviour by first reaching its value function. The means evolve forward and are, in isolation, perfectly local; what binds the populations together is the backward sweep of the offsets, each offset listening to every population's mean through $z_t^{(k)}$ and feeding the result back into its own population's forward drift. Coupling enters late (at the terminal time) and propagates backward.

It is now a matter of stacking the K scalar pairs into a single vector system, and the stacking is what exposes the role of the coupling matrix. Collect the means and offsets into vectors $\bar{\boldsymbol{m}}_t = (\bar{m}_t^{(k)})_k$ and $\boldsymbol{r}_t = (r_t^{(k)})_k \in \mathbb{R}^K$. The per-population coefficients become diagonal matrices — $D_t = \operatorname{diag}\left((a_k - b_k^2 P_t^{(k)})_k\right)$ holding the K closed-loop drifts, $B = \operatorname{diag}\left((b_k^2)_k\right)$, $Q = \operatorname{diag}\left((q_k s_k)_k\right)$ and $Q_T = \operatorname{diag}\left((q_{T,k} s_{T,k})_k\right)$ — because everything *local* to a population (its dynamics, its own cost weights, its own coupling strength s_k) acts only within that population's slot. The one non-diagonal object in the entire system is the aggregate: writing $z_t^{(k)} = \sum_\ell \pi_\ell \mathsf{B}_{k\ell} \bar{m}_t^{(\ell)}$ as the matrix action $\boldsymbol{z}_t = \mathsf{B}\operatorname{diag}(\pi)\,\bar{\boldsymbol{m}}_t$, the forcing $q_k s_k z_t^{(k)}$ of the backward offset equation becomes $Q\,\mathsf{B}\operatorname{diag}(\pi)\,\bar{\boldsymbol{m}}_t$. So the off-diagonal weight matrix $\mathsf{B}\operatorname{diag}(\pi)$ appears once and in one place only — the lower-left block coupling the means into the offsets — which is the vectorial restatement of "the coupling lives in the backward half." The result is the $2K$-dimensional *linear two-point boundary-value problem*

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix}\bar{\boldsymbol{m}}_t\\ \boldsymbol{r}_t\end{pmatrix} = \begin{pmatrix} D_t & -B\\ Q\,\mathsf{B}\operatorname{diag}(\pi) & -D_t\end{pmatrix}\begin{pmatrix}\bar{\boldsymbol{m}}_t\\ \boldsymbol{r}_t\end{pmatrix}, \qquad \bar{\boldsymbol{m}}_0 \text{ given}, \quad \boldsymbol{r}_T = -\,Q_T\,\mathsf{B}\operatorname{diag}(\pi)\,\bar{\boldsymbol{m}}_T, \tag{30.11}$$

where $\mathsf{B}\operatorname{diag}(\pi)$ is the asymmetric weight matrix of section 30.1.3, with entries $(\mathsf{B}\operatorname{diag}(\pi))_{k\ell} = \mathsf{B}_{k\ell}\pi_\ell$ so that $(\mathsf{B}\operatorname{diag}(\pi)\,\bar{\boldsymbol{m}})_k = z^{(k)}$. The data that close the system are *split* between the two ends of the time interval, and the split is forced by the time-direction convention of the chapter: the means are densities and carry *initial* data, so $\bar{\boldsymbol{m}}_0$ is prescribed at $t = 0$; the offsets are value-function quantities and carry *terminal* data, so $\boldsymbol{r}_T$ is prescribed at $t = T$. The terminal condition $\boldsymbol{r}_T = -Q_T\,\mathsf{B}\operatorname{diag}(\pi)\,\bar{\boldsymbol{m}}_T$ is itself coupled — the offset each population must hit at the horizon depends, through the same matrix $\mathsf{B}\operatorname{diag}(\pi)$, on *every* population's terminal mean — so the coupling appears a second time, again on the backward side, now in the boundary data rather than the dynamics. This is exactly the forward–backward architecture of the scalar games eq. (8.29)/eq. (14.15), lifted to carry K populations at once: a forward block and a backward block, meeting through split boundary conditions, with the curvatures $P^{(k)}_{\cdot}$ already integrated out so that what remains is a *genuinely linear* two-point problem in $(\bar{\boldsymbol{m}}, \boldsymbol{r})$. Once it is solved the model is finished: the per-population variance ODEs (14.14) close the Gaussian density flows around the now-known means, and the equilibrium is fully explicit. The reason to stress that the problem is a two-point BVP and not an initial-value problem is that the two are not equally well-behaved. A linear initial-value ODE always has a unique global solution; a linear *two-point* problem need not, because the map sending the unknown terminal data to the prescribed boundary value can be singular at special horizons. Concretely, solvability of (30.11) is the K-population analogue of the scalar nondegeneracy condition $D(T) \neq 0$ of lemma 14.5: a determinant built from the $2K \times 2K$ transition matrix must not vanish, and when it does the equilibrium is either non-unique or non-existent. This is the precise mechanism by which a perfectly linear problem can nonetheless have multiple equilibria, and it is the subject of the phase discussion below.

A new finite system earns trust by reproducing the systems it is meant to generalize, and (30.11) reproduces three of them. We run the checks in increasing order of subtlety, because each isolates a different feature.

The first check is dimensional sanity: setting $K = 1$ must return the single-population game. With one cell the mass is $\pi_1 = 1$, the matrices D_t, B, Q are scalars, and the weight "matrix" $\mathsf{B}\,\mathrm{diag}(\pi)$ is the number B_{11}, so (30.11) becomes the 2×2 forward–backward pair in $(\bar{m}, r)$ with self-coupling $s_1\mathsf{B}_{11}$ — precisely the single-population two-point BVP (14.15), equivalently the pair (8.29). The point worth registering is what does *not* happen: even with a single population the mean does not satisfy a closed forward ODE. It remains tied to its own backward offset r, which is forced by the self-target $s_1\mathsf{B}_{11}\bar{m}$. The inter-population coupling has vanished, but the forward–backward coupling between a population's mean and its *own* value function survives, exactly as it must, since that coupling is the content of being a mean field game rather than a control problem. "$K = 1$" removes the *across*-population structure and leaves the *within*-population mean-field structure untouched.

The second check identifies the coupling constant. The dynamics carry the *asymmetric* weight matrix $\mathsf{B}\,\mathrm{diag}(\pi)$, but the spectral fate of the BVP — which horizons are solvable, where multiplicity onsets — is governed by eigenvalues, and eigenvalues are conjugation-invariant. As recorded at (30.5), $\mathsf{B}\,\mathrm{diag}(\pi)$ is conjugate (by $\mathrm{diag}(\sqrt{\pi})$) to the symmetric interaction matrix $\widehat{\mathsf{B}}$, so the two share a spectrum; the relevant coupling magnitude is therefore the spectral norm $\left\|\widehat{\mathsf{B}}\right\|$ of the *symmetric* representative, not any norm of the asymmetric weights. This is the same number that gates existence and uniqueness in proposition 30.6 and that remark 21.20 predicts is the finite avatar of $\|\mathbb{W}\|$. The two faces of the coupling — asymmetric in the dynamics, symmetric in the spectrum — are exactly the two normalizations section 30.1.3 warned must never be conflated; the BVP is where one sees concretely why the symmetric one is the one that decides the phase.

The third check closes the loop with the rank-one worked example of chapter 21 and is the most informative, because it shows the block system contracting back to a single scalar. Take all populations identical, sharing parameters $(a, b, \sigma, q, q_T, s, s_T)$, and let the kernel be the rank-one block matrix $\mathsf{B}_{k\ell} = f_k f_\ell$ with f_k the constant value of the profile f on cell I_k. Then the aggregate factorizes: $z_t^{(k)} = \sum_\ell \pi_\ell f_k f_\ell \bar{m}_t^{(\ell)} = f_k \sum_\ell \pi_\ell f_\ell \bar{m}_t^{(\ell)} = f_k\,\varrho_t$, where the single scalar $\varrho_t = \sum_\ell \pi_\ell f_\ell \bar{m}_t^{(\ell)} = \langle f, \bar{\boldsymbol{m}}_t\rangle_\pi$ is the order parameter of worked computation 21.18. Every population is therefore driven by the *same* scalar ϱ_t, merely weighted by its own f_k, which forces the offsets to inherit the factorization $r_t^{(k)} = f_k\tilde{r}_t$: substituting this ansatz into the backward equation (30.10b) and using the shared parameters, every term carries a common factor f_k that cancels, leaving the single scalar offset equation $\dot{\tilde{r}}_t = (b^2P_t - a)\tilde{r}_t + q\,s\,\varrho_t$. Differentiating the order parameter and feeding in the forward mean equation collapses the means the same way, $\dot{\varrho}_t = (a - b^2P_t)\varrho_t - b^2\big(\sum_k \pi_k f_k^2\big)\tilde{r}_t$, and the constant $\sum_k \pi_k f_k^2 = \|f\|_{L^2}^2 = \|\mathbb{W}\|$ is exactly the operator norm of the rank-one graphon (equivalently $\left\|\widehat{\mathsf{B}}\right\|$, since for $\mathsf{B}_{k\ell} = f_k f_\ell$ the matrix $\widehat{\mathsf{B}}$ is rank-one with the vector $(\sqrt{\pi_k} f_k)_k$ of squared norm $\sum_k \pi_k f_k^2$). The $2K$-dimensional BVP has collapsed onto the scalar self-consistency pair $(\varrho_t, \tilde{r}_t)$ of (21.24), with the single effective coupling $s_{\mathrm{eff}} = s\,\|\mathbb{W}\|$ of (21.25). The block computation thus strictly contains both the single-population reduction (a) and the rank-one reduction (c), and agrees with each on its own turf — which is the concrete sense in which Thread B is one coherent thread and not three.

It remains to read off the phase behavior, and the apparatus is now entirely in hand: the qualitative fate of the equilibrium is decided by the $2K \times 2K$ generator of (30.11), exactly as the single-population phase diagram of section 14.5 was decided by its scalar 2×2 mean–offset generator. The mechanism is the determinant condition of check (a) raised to $2K$ dimensions. Solving the two-point problem amounts to inverting a certain block of the generator's transition matrix over $[0,T]$; this block depends on the horizon T and on the off-diagonal forcing $Q\,\mathsf{B}\,\mathrm{diag}(\pi)$, which by check (b) enters through the spectrum of $\widehat{\mathsf{B}}$. While the product of coupling strength and horizon is small the block stays invertible and the equilibrium is unique — the block-constant equilibrium that proposition 30.6 guarantees, with no symmetry breaking. As the coupling is turned up, the relevant combination $|s_k|\,\left\|\widehat{\mathsf{B}}\right\|$ grows, the generator acquires eigenvalues that rotate the forward and backward halves into resonance, and at a critical strength the determinant hits zero: the linear two-point problem in the forward mean and the backward Riccati offset loses unique solvability, and multiple equilibria appear. This is the multi-population shadow of the critical horizon T_{crit} of eq. (14.24) — the same bifurcation, now located by the largest eigenvalue of $\widehat{\mathsf{B}}$ rather than by a single scalar coupling — and it is the LQG-explicit incarnation of the symmetry-breaking threshold that remark 30.5 reached on abstract grounds. Strong coupling, long horizon, and a large spectral radius of the interaction matrix are three faces of the one condition under which a block kernel stops dictating a unique, block-symmetric equilibrium.

Remark 30.8 (Heterogeneous interaction beyond positivity)**.** It is worth pausing on a freedom the calculation quietly used but never advertised. Nothing in worked computation 30.7 required $\mathsf{B}_{k\ell} \geq 0$ or s_k of one sign — the Riccati equations, the mean–offset BVP, and the spectral phase analysis went through for arbitrary real symmetric B and arbitrary real s_k. A block model can therefore encode *antagonistic* populations, $\mathsf{B}_{k\ell} < 0$ or $s_k < 0$, in which population k is *repelled* from population ℓ's mean rather than drawn toward it. The graphon regularity assumption (A-Reg-W), which pins W to $[0,1]$, is not violated here so much as transcended: that restriction is a normalization convenient for the probabilistic $G(N,W)$-sampling interpretation of chapter 19, where $W(x,y)$ is read as an edge *probability* and must lie in $[0,1]$. The analytic block system (30.6), by contrast, is a coupled PDE system that makes perfect sense for any symmetric real coupling matrix, and the sign of $s_k\mathsf{B}_{k\ell}$ is precisely what decides its character. When all the products $s_k\mathsf{B}_{k\ell}$ are aligned the system is of the stabilizing, Lasry–Lions-monotone kind we spent the previous subsection taming, and the equilibrium is unique and block-symmetric. When they are mixed in sign — attraction within a class, repulsion across it, say — monotonicity can fail, and with it the uniqueness guarantee: the off-diagonal of $\widehat{\mathsf{B}}$ acquires the indefinite spectrum that drives the phase transition just described.

This is more than a technical relaxation; it is where the multi-population model stops being a bundle of cooperating crowds and becomes a genuine *game*. A single monotone population can only congest — agents avoid the crowd, are drawn to it, and settle into the one self-consistent profile. Two populations with opposite-signed cross-coupling can do something no single monotone population can: chase and flee. Predator and prey, where one population is attracted to the other's location and the other repelled from the first, is the canonical destabilizing pair; buyers and sellers, who push price in opposite directions, are its economic cousin. These are exactly the configurations that produce the multiplicity and the symmetry breaking of the phase discussion above, and they are absent by construction from any model built on a single nonnegative kernel. Signed block couplings are thus the multi-population model's entry point into genuinely game-theoretic richness — and a first hint that breaking anonymity can manufacture strategic tension that pure congestion never exhibits.

That hint is the bridge to the next section, and it is worth saying explicitly what we have finished and what we have not. We have now exhausted the multi-population model: heterogeneity carried by finitely many *populations*, each of strictly positive mass $\pi_k > 0$, coupled through a block kernel, reducing — isometrically, with every constant intact, and in the LQG case completely explicitly — to a finite system the literature posits by hand. The defining feature throughout was that every agent still had *vanishing* individual influence: a class mattered because it was *many*, its weight $\pi_k \mathsf{B}_{k\ell}$ in everyone's aggregate being a mass times a coupling. The next section breaks anonymity along the opposite axis: it installs a single distinguished agent — the major player — who must exert an $O(1)$ influence on the entire population while occupying *zero* mass, so that the very device that gave a class its voice, multiplying a coupling by a positive mass, is unavailable to express it. That tension, and the enlargement of the index space it forces, is the business we turn to now.

30.2 Major–minor games as a finite-rank atomic perturbation

We turn to the second *subsumed* extension, and it pays from the outset to see exactly how it differs from the one we have just closed. The multi-population model broke anonymity by splitting the continuum into finitely many *classes*, each of strictly positive mass $\pi_k > 0$; every individual agent still carried vanishing influence, and a class mattered only because it was *many* — its voice in everyone's aggregate was the product $\pi_k \mathsf{B}_{k\ell}$ of a mass and a coupling. The major–minor model breaks anonymity along the opposite axis, and in a way that turns out to be considerably more delicate. It keeps the population anonymous but installs at its center a single distinguished agent — the *major* player — whose influence on the whole crowd of ordinary *minor* agents does *not* vanish, even though, as one individual among infinitely many, the major player occupies *zero* mass. Heterogeneity here is not spread across a handful of fat classes; it is concentrated in one mass-zero point that nonetheless refuses to disappear. The tension between those two facts — zero mass, $O(1)$ influence — is the whole content of the model, and it is precisely the device that gave a class its voice, multiplying a coupling by a positive mass π_k, that is unavailable to express it.

The model is not exotic; it is the natural formalization of a recurring situation in which one player is qualitatively unlike the rest and large enough to be felt by all of them at once. Three canonical examples fix the picture, and each is worth holding in mind because each exhibits the same one-against-the-continuum structure. A *central bank* sets a policy rate that every trader in the market reacts to, while no single trader, and indeed no diffuse cloud of traders, moves the bank in the way the bank moves them: the bank's state is an input to the representative trader's problem on the same footing as the traders' own aggregate. A *dominant firm* — the price leader in an industry of small competitors — chooses an output or a price that shifts the market environment in which every fringe competitor optimizes, again asymmetrically: the fringe responds to the leader, the leader responds only to the *statistics* of the fringe. A *government* levying a tax, or a regulator setting a standard, conditions the optimization of an entire population of citizens or firms, each of whom is individually negligible to it. In every case there is one player whose *own state* — the policy rate, the leader's output, the tax — enters the mean field that everyone else responds to, and whose state in turn evolves in response to the crowd it is steering. It is this two-way but radically *asymmetric* coupling, one named state against a continuum of anonymous ones, that the formalism must capture.

Now make the obstruction sharp, because it is the obstruction the next subsection is built to remove. In the graphon game of chapter 21 an agent feels the crowd only through the aggregate $\Theta(x) = \int_0^1 W(x,y)\langle h, m^y\rangle \, dy$, an integral against Lebesgue measure on the type space $[0,1]$. The contribution of any single type y_0 — or of any Lebesgue-null set of types — to that integral is exactly zero: a mass-zero label is *invisible* to the aggregate. This is not a defect of the model but the mathematical expression of anonymity itself; it is what makes the minor agents a genuine mean field, each one negligible. But it is fatal to any attempt to install the major player as one more type. Whatever type $y_0 \in [0,1]$ we might try to assign the central bank, the integral that defines what the traders feel simply does not see it, and the bank's $O(1)$ influence evaporates. The block construction of the previous section is of no help: it lived entirely on positive-mass cells, and the major player has no positive mass to give it. So the major player cannot be smuggled into the existing index space at all, and we are forced into the one move that can carry a non-vanishing yet pointlike influence — enlarging the index space by a genuine *atom*, a single point carrying its own positive reference mass, on top of the nonatomic continuum $[0,1]$. Against the augmented index the coupling operator acquires a *finite-rank atomic correction*: a low-rank block that wires the atom to the continuum and back, sitting on top of the unchanged graphon $\mathbb{W}$. This is the precise sense, advertised in the section title, in which the major–minor model is a finite-rank atomic perturbation of the Part IV coupling rather than a new theory.

That the *coupling* remains a graphon, merely on a larger space, is only half the story, and the more interesting half is what it costs at the level of *equilibrium* — the recurring tension of this chapter, here showing its sharpest face. A positive-mass class, being a continuum of vanishing-influence agents, has an aggregate that is a *deterministic* curve: idiosyncratic noise averages out across the many, and the field each minor feels stays a fixed function of time, exactly the regime in which the deterministic graphon theory of chapter 24 applies. The atom destroys this. A single non-vanishing player carries its own driving noise that does *not* average against anyone, so the major player's state is a bona fide random process, and through the finite-rank coupling it injects that randomness directly into the mean field. The aggregate the minors respond to is therefore no longer a deterministic flow but a measure-valued *process*, adapted to the major player's trajectory; the consistency condition becomes a *conditional* fixed point, conditioned on that trajectory, and the governing object is no longer the deterministic backward–forward system of chapter 22 but the conditional, common-noise master equation of chapter 26. The major player, in other words, plays for the minors the role of a common noise. So the verdict will be genuinely two-sided, and we should flag it now: the coupling is subsumed — a finite-rank atomic graphon — while the equilibrium escalates out of the deterministic regime that made the multi-population case so clean.

The work of the section is to make both halves precise, and we begin with the obstruction itself. The next subsection takes the zero-mass puzzle posed just above — one agent of vanishing reference mass that must nonetheless exert finite influence — and proves precisely why a major agent *cannot* be one more type in $[0,1]$, converting the heuristic "a mass-zero label is invisible" into a clean statement and, with it, forcing upon us the augmented-space construction that carries the atom.

30.2.1 Why a single agent cannot be a type

The section opener left us with a puzzle stated as a tension: the major player must have $O(1)$ influence on every minor, yet as one individual among a continuum he occupies zero mass, and the positive-mass device that gave a multi-population class its voice is therefore unavailable. Before we can build anything we must convert that tension from a heuristic worry into a clean theorem, because the whole augmented-space construction is forced by it and would otherwise look like an unmotivated complication. So we begin by proving — not merely asserting — exactly why the obvious move fails: why the major player *cannot* be installed as one more type in $[0, 1]$, no matter which type we assign him. We record the obstruction first as a notation warning, since it is fundamentally a statement about what the integral defining the aggregate can and cannot see, and then unpack the argument in full.

Notation watch: A mass-zero type has no influence

In the graphon game of chapter 21 the influence of a set $S \subseteq [0, 1]$ of types on the aggregate $\Theta(x) = \int_0^1 W(x, y)\langle h, m^y\rangle \, dy$ is weighted by the Lebesgue measure dy. A single type y_0, or any Lebesgue-null set of types, contributes 0 to this integral: it is invisible to the aggregate. Therefore a major agent — an individual with $O(1)$ influence on every minor — *cannot* be represented as one more type in $[0, 1]$. To give a single agent finite influence we must enlarge the index space by an *atom* carrying positive reference mass. This is the structural reason the major–minor model is not literally a special case of the type-$[0, 1]$ graphon game, and the precise sense in which it is nonetheless a graphon game on an augmented space.

The argument behind the warning is a single line of measure theory, but it is worth writing out because everything downstream is a response to it. Suppose, against the model, that we tried to seat the major player at some type $y_0 \in [0, 1]$, endowing that one type with the major's state law m^0 while leaving the rest of the field untouched. The quantity a minor of type x feels from him is the part of the aggregate integral carried by the singleton $\{y_0\}$, namely $\int_{\{y_0\}} W(x, y)\langle h, m^y\rangle \, dy$, and this integral is over a set of Lebesgue measure $\mathrm{Leb}(\{y_0\}) = 0$. By the very definition of the Lebesgue integral, the integral of any bounded integrand over a null set vanishes; equivalently, altering the field on the null set $\{y_0\}$ — to m^0 or to anything else — changes $\Theta(x)$ by exactly nothing, for every minor type x and at every instant. The major player so installed is not merely weak; he is *literally absent* from the only channel through which the crowd is felt. And the conclusion is not special to a single point: any Lebesgue-null set of types — a finite collection, a countable collection, even an uncountable Cantor-type set — is equally invisible, because each carries zero dy-weight. There is no subset of $[0, 1]$, however cleverly chosen, that is at once small enough to be "one agent" and large enough to be heard.

It is worth pausing on the fact that this invisibility is not a flaw to be patched but the mathematical signature of anonymity, the property that makes the minors a genuine mean field in the first place. A continuum of agents is a mean field precisely because no individual among them moves the aggregate: each minor is negligible, and the integral against dy is the exact bookkeeping of that negligibility. The multi-population reduction never collided with this because it never tried to make an *individual* matter; it made a positive-mass *class* matter, and a class of mass $\pi_k > 0$ is heard precisely because $\int_{I_k} \mathrm{d}y = \pi_k \neq 0$ — its voice in the aggregate was the product $\pi_k \mathsf{B}_{k\ell}$ of a positive mass and a coupling (eq. (30.4)). The major player has no positive mass to contribute that product, so the block construction of section 30.1 offers no help: it lived entirely on cells of strictly positive Lebesgue measure, which is exactly what a single distinguished agent lacks. We are not looking at a quantitative shortfall to be made up by a larger coupling constant; we are looking at a structural zero, an $O(1)$ influence multiplied against a reference weight of 0.

That diagnosis dictates its own cure. If a single point must be heard by an integral, the only possible remedy is to give that point positive weight under the measure the integral uses — to make it an *atom* of the reference measure. One cannot do this within $([0,1], \mathrm{Leb})$, whose defining feature is that it is nonatomic (every point is null); one must enlarge the measure space. The minimal enlargement that creates exactly one atom while disturbing nothing else is to adjoin a single new point and place a point mass there. This is the move forced on us, and we make it. We work on the augmented index space

$$\mathbb{X} \;:=\; [0,1] \sqcup \{\star\}, \qquad \rho \;:=\; \mathrm{Leb}\big|_{[0,1]} \;+\; \delta_\star, \tag{30.12}$$

the type interval together with one isolated point $\star$ (the major) carrying a unit point mass under the reference measure ρ. Three features of this definition deserve comment, since each is doing work. First, the new point is adjoined by a *disjoint* union: $\star$ is not overlaid on some existing type y_0 but sits outside $[0,1]$ altogether, so the continuum of minors — the measure $\mathrm{Leb}\big|_{[0,1]}$ and the minor field on it — is carried over from Part IV completely untouched, and the minor sub-problem will remain verbatim the graphon game we already understand. Second, the atom $\star$ now has $\rho(\{\star\}) = 1 > 0$: an integral against ρ that runs over $\mathbb{X}$ *does* register $\star$, with weight 1, which is precisely the registration the null singleton $\{y_0\}$ could never receive. The major has become visible not by acquiring mass within the crowd but by being moved onto a measure that can see him. Third, the unit value of the point mass is a normalization, not a physical influence strength: it fixes the reference weight of the atom at 1, and the actual $O(1)$ magnitude with which minor x feels the major will be carried by a kernel block $w_0(x)$ on the augmented space, assembled in the next subsection, exactly as a coupling strength $\mathsf{B}_{k\ell}$ multiplied the mass π_ℓ for a class. Holding the reference mass fixed at 1 and letting the kernel carry the strength keeps the bookkeeping parallel to the block case.

With the index space enlarged, the unknown of the problem changes shape correspondingly. A "population field" was, in Part IV, an assignment of a probability measure to every type; on the augmented space $\mathbb{X} = [0,1] \sqcup \{\star\}$ it becomes an assignment of a measure to every point of $\mathbb{X}$, and since $\mathbb{X}$ is the continuum plus one extra point, such an assignment is exactly a *pair*. It consists of a minor field $\boldsymbol{m} = (m^x)_{x\in[0,1]} \in \mathcal{M}_2$ — the old object, the law of each minor type, living in the field space of definition 21.8 — together with a single measure $m^0 \in \mathcal{P}_2(\mathbb{R}^{d_0})$ attached to the atom, the state law of the one major player. There is no reason for the major's state to live in the minors' state space, and the formalism does not ask it to: the major's state is allowed its own dimension, $m^0 \in \mathcal{P}_2(\mathbb{R}^{d_0})$ with d_0 possibly different from the minors' d. This latitude is not a technicality but a faithfulness to the examples — a central bank's state may be a scalar policy rate ($d_0 = 1$) while each trader carries a multidimensional portfolio ($d > 1$), and nothing should force these to match. Because $\star$ is an isolated atom rather than a member of the continuum, attaching a state space of its own to it costs nothing; the minors' product structure over $[0,1]$ is untouched, and the major simply sits beside it with its own $\mathbb{R}^{d_0}$. The field on $\mathbb{X}$ is thus the ordered pair $(\boldsymbol{m}, m^0)$, the crowd and the king, and it is on this pair that the augmented equilibrium problem will be posed.

It remains to say where the coupling *operator* will live, because that is what the next subsection must construct and it is dictated by the same enlargement. The Part IV operator $\mathbb{W}$ acts on $L^2([0,1], \mathrm{Leb})$; on the augmented space its successor must act on $L^2(\mathbb{X}, \rho)$, square-integrable functions against the augmented reference measure. The single fact that makes the augmented operator tractable — and that we use repeatedly hereafter — is that this Hilbert space splits cleanly into the old one plus a single coordinate,

$$L^2(\mathbb{X}, \rho) \;\cong\; L^2([0,1], \mathrm{Leb}) \;\oplus\; \mathbb{R}, \tag{30.13}$$

the extra summand $\mathbb{R}$ being the value of a function at the atom $\star$. This isomorphism is worth unpacking slowly, because the block structure of the operator in section 30.2.2 is nothing but a reading of it. A function $f \in L^2(\mathbb{X}, \rho)$ is, since $\mathbb{X}$ is the disjoint union $[0,1] \sqcup \{\star\}$, completely specified by two independent pieces of data: its restriction $f|_{[0,1]}$ to the continuum and its single value $f(\star)$ at the atom. The reference measure splits as $\rho = \mathrm{Leb}|_{[0,1]} + \delta_\star$ along the same partition, so the $L^2(\rho)$ norm splits with it,

$$\|f\|^2_{L^2(\mathbb{X},\rho)} \;=\; \int_{[0,1]} |f(x)|^2 \,\mathrm{d}x \;+\; |f(\star)|^2 \,\rho(\{\star\}) \;=\; \left\| f|_{[0,1]} \right\|^2_{L^2([0,1])} \;+\; |f(\star)|^2 \,,$$

using $\rho(\{\star\}) = 1$ for the second term. The cross term is absent — the decomposition is an *orthogonal* direct sum — precisely because the continuum and the atom are ρ-disjoint: no function content is shared between $[0,1]$ and $\{\star\}$, so the two pieces contribute their squared norms additively. This is the content of (30.13): the map $f \mapsto (f|_{[0,1]}, f(\star))$ is a Hilbert-space isomorphism onto $L^2([0,1], \mathrm{Leb}) \oplus \mathbb{R}$.

The phrase "the extra summand $\mathbb{R}$ is the value of a function at the atom" now has a precise and load-bearing meaning. On the nonatomic space $([0,1], \mathrm{Leb})$ the value of an L^2 function at any single point is undefined — functions are equivalence classes modulo null sets, and a point is null, so "$f(y_0)$" carries no information and contributes nothing to the norm. The instant we adjoin the atom, the value $f(\star)$ becomes a genuine, norm-carrying degree of freedom: it is no longer washed out, it occupies its own one-dimensional orthogonal coordinate in the Hilbert space, and that coordinate is exactly the $\mathbb{R}$ in (30.13). This is the Hilbert-space shadow of the same fact the notation warning made about the integral: a point that was invisible to the Lebesgue integral, and equally invisible to the $L^2([0,1])$ norm, is made visible — given its own axis — precisely by being turned into an atom. That the new axis is *one*-dimensional, because there is exactly one major player, is what will make the operator's correction *finite-rank*: an operator on $L^2([0,1]) \oplus \mathbb{R}$ that touches the new $\mathbb{R}$ coordinate can do so only through rank-one couplings into and out of a single direction.

This orthogonal splitting is the platform the rest of the section stands on, and it tells the next subsection exactly what to build. Writing $\mathbb{W}_\star$ in the basis adapted to (30.13) — a continuum part and one extra coordinate — forces it into a 2×2 block form: a minor–minor block, which we will see is the old graphon operator $\mathbb{W}$ acting on the $L^2([0,1])$ summand and nothing else; the off-diagonal minor–major and major–minor blocks, which wire the atom's single coordinate to the continuum and back; and the scalar major–major block on the lone $\mathbb{R}$ coordinate. Because all the new structure is confined to that one extra coordinate, the correction $\mathbb{W}_\star - \mathbb{W}$ will be supported on a finite-rank subspace — the finite-rank atomic perturbation promised in the section title. We have now built the stage: the augmented index space $\mathbb{X}$, the paired field $(\boldsymbol{m}, m^0)$, and the decomposition $L^2(\mathbb{X}, \rho) \cong L^2([0,1]) \oplus \mathbb{R}$ that the operator will act on. The next subsection populates it, defining the augmented kernel block by block and assembling the operator $\mathbb{W}_\star$ whose finite-rank structure is the technical heart of the major–minor reduction.

30.2.2 The augmented kernel and its operator

The previous subsection built the stage and named precisely what stands on it: the augmented index $\mathbb{X} = [0,1] \sqcup \{\star\}$ carrying the reference measure $\rho = \mathrm{Leb}|_{[0,1]} + \delta_\star$, the paired field $(\boldsymbol{m}, m^0)$ of crowd and king, and the orthogonal decomposition $L^2(\mathbb{X}, \rho) \cong L^2([0,1]) \oplus \mathbb{R}$ of (30.13) on which the coupling operator must act. What it deliberately deferred is the operator itself. We now write down the kernel that lives on $\mathbb{X}^2$, read off the operator it induces by integration against ρ, and prove the one structural theorem the whole major–minor reduction rests on: that operator is nothing but the old graphon coupling $\mathbb{W}$ plus a correction of rank at most two. Everything in this subsection is forced by the geometry of $\mathbb{X}$ — a continuum with one extra point — and the reader should watch each object below appear as the inevitable image of that geometry rather than as a fresh modelling decision.

Begin with the kernel. A symmetric kernel on $\mathbb{X}^2$ is, because $\mathbb{X}$ is a disjoint union, a kernel that has been split into four pieces by the same partition $[0,1] \sqcup \{\star\}$ applied to each of its two arguments. The product $\mathbb{X}^2$ decomposes into four rectangles — $[0,1] \times [0,1]$, $[0,1] \times \{\star\}$, $\{\star\} \times [0,1]$, and $\{\star\} \times \{\star\}$ — and a kernel is simply a choice of value on each. Each rectangle has a transparent physical meaning, and naming them is naming the four channels of influence in a major–minor system. The continuum–continuum rectangle $[0,1] \times [0,1]$ carries the ordinary minor-to-minor coupling: this is the old graphon W of Part IV, untouched, governing how one ordinary agent feels another. The mixed rectangle $[0,1] \times \{\star\}$ records how strongly each minor type x feels the single major player; it is a *function of x alone*, the *influence profile* $w_0(x)$, and it is exactly the channel through which the central bank reaches every trader. Its mirror $\{\star\} \times [0,1]$ records the reverse: how strongly the major feels each minor type y, a function $\tilde{w}_0(y)$ of y alone — the channel through which the crowd of traders is felt back at the bank. Finally the lone corner $\{\star\} \times \{\star\}$ is a single number w_{00}, the major's coupling to its own state. That a continuum-indexed kernel collapses, on the mixed rectangles, to mere *functions* and, in the corner, to a single *scalar* is the first concrete payoff of the atom being a single point: a whole row of the kernel indexed by $\star$ is just one function.

Definition 30.9 (Augmented major–minor kernel)**.** An *augmented kernel* on $\mathbb{X}$ is a symmetric measurable function $W_\star : \mathbb{X}^2 \to \mathbb{R}$ specified by four blocks: the minor–minor graphon $W(x,y)$ on $[0,1]^2$; the minor–major influence profile $x \mapsto w_0(x) := W_\star(x, \star)$ (how strongly minor x feels the major); the major–minor profile $y \mapsto \tilde{w}_0(y) := W_\star(\star, y)$ (how strongly the major feels minor y); and the major self-coupling $w_{00} := W_\star(\star, \star) \in \mathbb{R}$. Symmetry of $W_\star$ forces $\tilde{w}_0 = w_0$; we allow them to differ when one drops the self-adjointness requirement (the influence of the major on minors and of minors on the major need not be reciprocal in applications).

A word on the symmetry clause, because it is where the model's asymmetry quietly enters. Were we to insist that $W_\star$ be a genuine symmetric kernel — the augmented analogue of the symmetric graphons of Part IV — the two mixed rectangles would be forced equal, $\tilde{w}_0 = w_0$, since they are reflections of each other across the diagonal. That is the hypothesis under which the augmented operator will be self-adjoint and the spectral theory of Part IV transfers wholesale. But the canonical examples are precisely *not* reciprocal: the central bank reaches every trader with profile w_0, while the traders reach the bank only through some quite different weighting $\tilde{w}_0$ of their aggregate, and there is no reason the two should agree. We therefore state the kernel with w_0 and $\tilde{w}_0$ allowed to differ, keeping the self-adjoint case $w_0 = \tilde{w}_0$ as the special hypothesis it is, to be invoked by name exactly when the spectral machinery is needed (part (i) of theorem 30.10).

With the four blocks in hand, the operator they induce is forced: it is integration of a function against the augmented reference measure ρ, and the only novelty is what ρ's atomic part does to that integral. The associated integral operator on $L^2(\mathbb{X}, \rho) \cong L^2([0,1]) \oplus \mathbb{R}$ acts on a pair (f, ξ) — a function f on the continuum together with the single value $\xi = f(\star)$ at the atom — by integrating against ρ:

$$\mathbb{W}_\star \begin{pmatrix} f \\ \xi \end{pmatrix} = \begin{pmatrix} \mathbb{W}f \ + \ w_0\,\xi \\ \langle \tilde{w}_0, f\rangle_{L^2([0,1])} \ + \ w_{00}\,\xi \end{pmatrix}, \tag{30.14}$$

and the structure of (30.14) is read straight off the splitting $\rho = \mathrm{Leb}\big|_{[0,1]} + \delta_\star$. Evaluating the augmented aggregate at a minor type $x \in [0,1]$ integrates $W_\star(x, \cdot)$ against ρ, and that integral splits into its continuum part and its atomic part: the continuum part is $\int_[0,1] W(x,y) f(y)\,\mathrm{d}y = (\mathbb{W}f)(x)$, the ordinary graphon aggregate, while the atomic part is the single *discrete* term $W_\star(x,\star)\,f(\star)\,\rho(\{\star\}) = w_0(x)\,\xi$, the Dirac mass $\delta_\star$ picking out the value at the atom and weighting it by $\rho(\{\star\}) = 1$. Evaluating instead at the atom $\star$ integrates $W_\star(\star, \cdot) = \tilde{w}_0$ against ρ, whose continuum part is $\int_[0,1] \tilde{w}_0(y) f(y)\,\mathrm{d}y = \langle \tilde{w}_0, f\rangle_{L^2([0,1])}$ and whose atomic part is $w_{00}\,\xi$. The two rows of (30.14) are exactly these two evaluations.

The asymmetry between the two rows is the whole physics of the model, and it is worth reading them side by side. The first row is the field felt by the minors: the usual graphon aggregate $\mathbb{W}f$ — an integral over the continuum, in which any single partner is invisible — *plus* a term $w_0(x)\,\xi$ that is the major's observable ξ broadcast to every minor through the profile w_0. This added term does *not* integrate a continuum; it is the value of a single function at a single point, the atomic evaluation that the Lebesgue integral never sees. That is exactly why it survives the mean-field limit and endows the major with non-vanishing influence: it is a value at a point, not an integral over a continuum, and section 30.2.1 showed that a point value, alone among the contributions, refuses to be averaged away. The second row, by contrast, is the field felt by the major, and there the situation is reversed: the major hears the minors only through the *integral* $\langle \tilde{w}_0, f\rangle$, a genuine average over the continuum in which — precisely as anonymity demands — no individual minor counts for anything. The major broadcasts to the crowd by a point evaluation but listens to it only as a statistic. This one-way visibility, a pointlike outgoing channel against an integral incoming channel, is the mathematical fingerprint of "one named player against a continuum of anonymous ones," and it is already entirely present in the placement of the discrete term in row one and the integral term in row two of (30.14).

We can now make precise the claim that gives the section its title. Stare at (30.14) and ask what part of $\mathbb{W}_\star$ is genuinely new relative to the Part IV coupling. The term $\mathbb{W}f$ in the first row is the old operator acting on the old $L^2([0,1])$ summand and nothing else; everything else — the broadcast $w_0\,\xi$, the listening $\langle \tilde{w}_0, f\rangle$, the self-coupling $w_{00}\,\xi$ — touches the single new coordinate ξ, either reading from it or writing into it. By the heuristic of the previous subsection, an operator that interacts with the world only through one extra coordinate cannot have more than a bounded, low-rank effect, no matter how large the continuum it sits on. The next theorem turns that heuristic into an exact rank count and draws its two consequences: that the augmented operator inherits the entire spectral theory of Part IV (because a finite-rank change preserves Hilbert–Schmidtness), and that the change is nonetheless $O(1)$ in operator norm (because a single broadcast profile, unlike a single minor type, is not Lebesgue-null).

Theorem 30.10 (Major–minor as a finite-rank perturbation of the graphon coupling)**.** *Let $\mathbb{W}_\star$ be the augmented operator (30.14) on $L^2(\mathbb{X},\rho)$ and let $\mathbb{W}_0 := \mathbb{W}\oplus 0$ be the "pure-minor" operator that ignores the atom. Then*

$$\mathbb{W}_\star \;=\; \mathbb{W}_0 \;+\; R, \qquad R\begin{pmatrix} f\\ \xi\end{pmatrix} = \begin{pmatrix} w_0\,\xi \\ \langle \tilde{w}_0, f\rangle + w_{00}\,\xi\end{pmatrix}, \tag{30.15}$$

where R is a bounded operator of rank at most 2 induced by the atom — its action depends on (f,ξ) only through the two atom-coupled scalars ξ and $\langle \tilde{w}_0, f\rangle$, and its range is spanned by the broadcast profile $(w_0, 0)$ and the atom-indicator $(0,1)$. With p major players (atoms $\star_1,\dots,\star_p$, $\rho = \mathrm{Leb} + \sum_j \delta_{\star_j}$) the perturbation R has rank at most $2p$. Moreover:

(i) *If $w_0 = \tilde{w}_0$ then $W_\star$ is symmetric and $\mathbb{W}_\star$ is self-adjoint on $L^2(\mathbb{X},\rho)$; since $\mathbb{W}$ is Hilbert–Schmidt under* (A-Reg-W) *and R is finite-rank — and finite-rank operators are Hilbert–Schmidt while the Hilbert–Schmidt operators form a vector space (section 2.4) — their sum $\mathbb{W}_\star$ is Hilbert–Schmidt, so the spectral theory of chapter 18 applies verbatim on the augmented space.*

(ii) *The perturbation R does* not *vanish in operator norm as a function of the minor population size: $\|R\| \geq \|w_0\|_{L^2}$ whenever $w_0 \neq 0$. This is the operator-level statement that a single major agent retains $O(1)$ influence, in contrast to a minor type, whose removal changes $\mathbb{W}$ by an operator of norm 0 (a Lebesgue-null modification).*

Proof. The decomposition (30.15) is a subtraction. The pure-minor operator acts by $\mathbb{W}_0(f,\xi) = (\mathbb{W}f, 0)$ — it runs the old graphon on the continuum part and annihilates the atom coordinate. Subtracting this from (30.14) term by term,

$$\mathbb{W}_\star\begin{pmatrix} f\\ \xi\end{pmatrix} - \mathbb{W}_0\begin{pmatrix} f\\ \xi\end{pmatrix} = \begin{pmatrix} \mathbb{W}f + w_0\,\xi \\ \langle \tilde{w}_0, f\rangle + w_{00}\,\xi\end{pmatrix} - \begin{pmatrix} \mathbb{W}f \\ 0\end{pmatrix} = \begin{pmatrix} w_0\,\xi \\ \langle \tilde{w}_0, f\rangle + w_{00}\,\xi\end{pmatrix},$$

the $\mathbb{W}f$ in the first row cancelling exactly and leaving precisely the R of (30.15). So $\mathbb{W}_\star = \mathbb{W}_0 + R$ with no remainder; the entire deviation of the augmented operator from the pure-minor one is the atom-induced block R.

Now count its rank. The cleanest way is to exhibit R as a composition: it *reads* its input (f,ξ) through two real-valued linear functionals and *writes* its output into a two-dimensional subspace.

The two functionals are visible in the formula for R — the only features of (f,ξ) it consults are the scalar ξ and the scalar $\langle \tilde{w}_0, f\rangle$ — and the output is assembled from them as

$$R\begin{pmatrix} f \\ \xi \end{pmatrix} = \xi \begin{pmatrix} w_0 \\ 0 \end{pmatrix} + \left(\langle \tilde{w}_0, f\rangle + w_{00}\,\xi\right)\begin{pmatrix} 0 \\ 1 \end{pmatrix}, \tag{30.16}$$

a linear combination of the two fixed vectors $(w_0, 0)$ and $(0,1)$. Hence the range of R lies in $\operatorname{span}\{(w_0,0),(0,1)\}$, a space of dimension at most two, and $\operatorname{rank} R \le 2$. (A linear map factoring through a two-dimensional space has rank at most two; here the factorization $(f,\xi) \mapsto (\xi, \langle \tilde{w}_0, f\rangle) \mapsto R(f,\xi)$ makes it explicit.) The same bookkeeping handles p atoms $\star_1, \ldots, \star_p$. Each atom $\star_j$ contributes its own broadcast vector $(w_{0,j}, 0)$ and its own atom-indicator $(0,\ldots,1,\ldots,0)$ to the range, and R reads the input through the p atom values ξ_j and the p aggregates $\langle \tilde{w}_{0,j}, f\rangle$; with $2p$ output directions and $2p$ input functionals, R has rank at most $2p$. The number of majors is literally the rank budget.

(i) Suppose $w_0 = \tilde{w}_0$. Then the kernel $W_\star$ is symmetric — the two mixed blocks coincide and the continuum block was symmetric to begin with — and integration of a symmetric real kernel against the symmetric measure ρ yields a self-adjoint operator. It is worth verifying this directly on (30.14), since it pins down exactly where the hypothesis is spent. The inner product on $L^2(\mathbb{X},\rho) \cong L^2([0,1]) \oplus \mathbb{R}$ is $\langle (f,\xi),(g,\eta)\rangle_\rho = \langle f,g\rangle_{L^2([0,1])} + \xi\eta$, and computing both sides,

$$\begin{aligned}
\langle \mathbb{W}_\star(f,\xi),(g,\eta)\rangle_\rho &= \langle \mathbb{W}f, g\rangle + \xi\langle w_0, g\rangle + \eta\langle \tilde{w}_0, f\rangle + w_{00}\,\xi\eta,\\
\langle (f,\xi), \mathbb{W}_\star(g,\eta)\rangle_\rho &= \langle f, \mathbb{W}g\rangle + \eta\langle f, w_0\rangle + \xi\langle \tilde{w}_0, g\rangle + w_{00}\,\xi\eta.
\end{aligned}$$

The first terms agree because $\mathbb{W}$ is already self-adjoint under (A-Reg-W) (symmetric kernel), and the last terms are identical scalars. The middle two pairs agree if and only if $\xi\langle w_0, g\rangle = \xi\langle \tilde{w}_0, g\rangle$ and $\eta\langle \tilde{w}_0, f\rangle = \eta\langle w_0, f\rangle$ for all f, g, ξ, η — that is, if and only if $w_0 = \tilde{w}_0$. So the self-adjointness of $\mathbb{W}_\star$ is exactly the reciprocity of the two mixed blocks, no more and no less. Granting it, the Hilbert–Schmidt conclusion follows from two elementary facts recorded in section 2.4: a finite-rank operator is Hilbert–Schmidt, and the Hilbert–Schmidt operators form a vector space (closed under sums). The minor block $\mathbb{W}$ is Hilbert–Schmidt by (A-Reg-W) and R is finite-rank hence Hilbert–Schmidt, so their sum $\mathbb{W}_\star = \mathbb{W}_0 + R$ is Hilbert–Schmidt; being also self-adjoint, it falls under the compact self-adjoint spectral theorem of chapter 18, whose conclusions — a real discrete spectrum accumulating only at 0 and an orthonormal eigenbasis — therefore hold verbatim on the augmented space $L^2(\mathbb{X},\rho)$. The atom buys no analytic difficulty whatsoever.

(ii) For the norm bound, probe R with the unit atom-indicator $(0,1)$, the function that is 0 on the continuum and 1 at the star. Reading off (30.16) with $f = 0$, $\xi = 1$,

$$R\begin{pmatrix} 0 \\ 1 \end{pmatrix} = 1 \cdot \begin{pmatrix} w_0 \\ 0 \end{pmatrix} + \left(\langle \tilde{w}_0, 0\rangle + w_{00}\right)\begin{pmatrix} 0 \\ 1 \end{pmatrix} = \begin{pmatrix} w_0 \\ w_{00} \end{pmatrix},$$

whose $L^2(\mathbb{X},\rho)$-norm is $\left(\|w_0\|_{L^2}^2 + w_{00}^2\right)^{1/2} \ge \|w_0\|_{L^2}$. Since $\|(0,1)\|_{L^2(\mathbb{X},\rho)} = 1$, the operator norm dominates this ratio: $\|R\| \ge \|R(0,1)\| \ge \|w_0\|_{L^2}$ whenever $w_0 \ne 0$. Contrast this with what a single *minor* type can do. Deleting or altering one minor type — indeed any Lebesgue-null set of types — changes the kernel W only on a null set, hence leaves $\mathbb{W}$ literally unchanged as an operator on $L^2([0,1])$: its operator-norm influence is exactly 0. The same single-agent surgery, performed on the major, moves the operator by at least $\|w_0\|_{L^2} > 0$. This is the operator-theoretic certificate of the whole asymmetry: zero mass, yet $O(1)$ norm. □

Theorem 30.10 is the precise meaning of the chapter's organizing slogan: *the major–minor model is the graphon mean field game whose coupling operator is the minor graphon plus a finite-rank atomic correction.* The decomposition $\mathbb{W}_\star = \mathbb{W} + R$ sorts the model's data into exactly two bins, and the slogan is just a reading of that sort. One bin is the *rank budget*: the number of major players is the rank ceiling of the correction — one major buys rank 2, p majors buy rank $2p$ — so "how many distinguished agents" is, quite literally, "how many dimensions of $\mathbb{W}$ get perturbed." The other bin is the *perturbation's data*: within that budget the correction is determined by the influence profiles w_0 (how the major reaches the minors) and $\tilde{w}_0$ (how the minors reach the major), together with the self-coupling w_{00}. Choosing a major–minor model is therefore choosing a graphon W and then spending a finite rank budget on a handful of profiles; nothing in the construction steps outside the graphon formalism of Part IV. In the taxonomy of the chapter, the *coupling* of the major–minor game is firmly *subsumed* — it is a graphon game on the augmented space $(\mathbb{X}, \rho)$, with all of Part IV's spectral and well-posedness apparatus intact by part (i) of the theorem.

But "the coupling is subsumed" is a verdict about $\mathbb{W}_\star$ alone, and $\mathbb{W}_\star$ alone is silent about the question that actually decides how hard the model is. The finite-rank theorem tells us the major perturbs the coupling *operator* by an $O(1)$, rank-2 amount; it says nothing about what the major does to the *equilibrium.* Here lies the honest gap the next subsection must close: read as a static linear map, the augmented operator $\mathbb{W}_\star$ gives no hint that the determinism which kept the multi-population case inside the tractable theory of chapter 24 now fails — yet fail it does, the moment one asks not how the agents are wired but what a *single* non-vanishing player's own, unaveraged noise does to the field they feel. The next subsection takes up exactly this — what the atom does to the equilibrium rather than to the coupling — and shows that the randomness it injects is a finite-dimensional common noise, escalating the consistency condition from the deterministic fixed point of chapter 22 to the conditional, common-noise master equation of chapter 26.

30.2.3 The randomness the atom injects: a finite-dimensional common noise

The finite-rank theorem of the previous subsection settled the *coupling* and, by design, said nothing about the *equilibrium*; it is the second that now governs how hard the model is to solve. Theorem 30.10 certifies that the major perturbs the coupling operator by an $O(1)$, rank-at-most-two atomic correction, $\mathbb{W}_\star = \mathbb{W} + R$. Read as a static linear map that turns one field into another, $\mathbb{W}_\star$ is as innocuous as any bounded operator on $L^2(\mathbb{X}, \rho)$: it has the same spectral theory, the same norm bound, the same place in Part IV's well-posedness apparatus. What it conceals is that the field it acts on has changed character. In every block-graphon game of section 30.1 the input to the coupling was a *deterministic* flow of measures, and that determinism was not an accident but a consequence of positive mass: a class of agents of positive Lebesgue weight averages its members' idiosyncratic Brownian noises away by the law of large numbers, so its empirical distribution converges to a fixed curve $t \mapsto m_t^{(k)}$ that is the same in every realization of the noise. The major has no mass to average over. It is a *single* non-vanishing player carrying its own driving Brownian motion B^0, and a single Brownian path does not self-average; it stays random for all time. Through precisely the broadcast term $w_0(x)\,h(X_t^0)$ whose $O(1)$ survival the rank-two theorem certified, that irreducible randomness is injected directly into the aggregate every minor feels.

The consequence is structural and unavoidable. The major's state X_t^0 enters every minor's dynamics and cost, so the entire minor population evolves as a system driven, in common, by the major's path. Its "field of laws" is therefore no longer a deterministic flow but a measure-valued *process*, adapted to the major's filtration:

$$\mu_t^x \;=\; \mathcal{L}(X_t^x \,|\, \mathcal{F}_t^0), \qquad \mathcal{F}_t^0 = \sigma\big(X_0^0,\, (B_s^0)_{s\le t}\big), \tag{30.17}$$

the *conditional* law of a minor of type x given everything the major has done up to time t. The conditioning is the whole point. Averaged over the major's randomness as well, a minor's marginal law $\mathcal{L}(X_t^x)$ would again be a deterministic curve and we would have learned nothing; but the object the *other minors actually couple to* is not that unconditional marginal — it is (30.17), the law that still fluctuates because it has not integrated out $\mathcal{F}_t^0$. Each minor responds to a crowd whose statistics are themselves random, correlated across the entire population through their shared dependence on the one path X^0.

This is exactly the conditional McKean–Vlasov structure of mean field games with *common noise* developed in chapter 26: a population whose flow of conditional laws is driven by a source of randomness felt by everyone at once, with the consistency condition demoted from an equality of deterministic curves to an equality of *processes*. What distinguishes the present instance from the generic common-noise model is the nature of that shared source. In the textbook construction the common noise is an exogenous Brownian field posited from outside and coupled to no one's objective. Here it is neither exogenous nor infinite-dimensional: the common noise is the major's own d_0-dimensional driving motion and its state X_t^0, a *finite-dimensional* signal, and it is *endogenous* — generated by an agent who is himself optimizing. That second feature is what lifts the problem above a plain common-noise MFG and gives it a Stackelberg flavor, a point we return to in remark 30.12. For now we record the model and its equilibrium notion precisely, and then state honestly what the earlier chapters do and do not deliver for it.

Definition 30.11 (Major–minor graphon MFG)**.** Fix the augmented kernel of definition 30.9. The *major* has state $X_t^0 \in \mathbb{R}^{d_0}$, control α_t^0, and dynamics

$$\mathrm{d}X_t^0 \;=\; b_0\big(X_t^0, \alpha_t^0,\, \langle\bar\mu_t\rangle\big)\,\mathrm{d}t \;+\; \sigma_0\,\mathrm{d}B_t^0, \qquad \langle\bar\mu_t\rangle := \int_0^1 \tilde w_0(y)\,\langle h, \mu_t^y\rangle\,\mathrm{d}y, \tag{30.18}$$

where $\langle\bar\mu_t\rangle$ is the minor aggregate the major feels (the second row of (30.14) evaluated on the minor field). Each *minor* of type x has state $X_t^x \in \mathbb{R}^d$, control α_t^x, and dynamics

$$\mathrm{d}X_t^x \;=\; b\big(x, X_t^x, \alpha_t^x,\, \Theta_t^\star(x)\big)\,\mathrm{d}t \;+\; \sigma(x, X_t^x)\,\mathrm{d}B_t^x, \qquad \Theta_t^\star(x) := (\mathbb{W}[\langle h, \mu_t^\cdot\rangle])(x) + w_0(x)\,h(X_t^0), \tag{30.19}$$

the aggregate $\Theta_t^\star(x)$ being the first row of (30.14): the graphon aggregate of the minors plus the broadcast major observable $w_0(x)h(X_t^0)$. Major and minors incur costs J^0 and J^x of the form (21.6) with these aggregates. A *major–minor graphon MFG equilibrium* is a triple $(\alpha^{0,*}, (\alpha^{x,*})_x, (\mu^x)_x)$ such that:

(a) given the conditional minor field $(\mu_t^x)_{t,x}$ and the minor controls, $\alpha^{0,*}$ is optimal for the major;

(b) given the major's state process and control, for a.e. type x the feedback $\alpha^{x,*}$ is optimal for a minor of type x against the aggregate $\Theta_t^\star(x)$;

(c) consistency: $\mu_t^x = \mathcal{L}(X_t^{x,*} \mid \mathcal{F}_t^0)$ for a.e. x and all t, where $X^{x,*}$ is the minor state under $\alpha^{x,*}$.

The triple is a fixed point, but a layered one, and it repays reading slowly because the layering is where the escalation over chapter 22 lives. Condition (b) is the familiar minor problem with one change: the target $\Theta_t^\star(x)$ it best-responds to is now a *random* aggregate. It carries the deterministic-looking graphon part $(\mathbb{W}[\langle h, \mu_t^\cdot\rangle])(x)$ — which is itself random, since the conditional field μ is — plus the explicit broadcast $w_0(x)\, h(X_t^0)$ of the major's state. Each minor therefore solves a control problem in the random environment generated by the major, exactly as an agent in a common-noise mean field game optimizes against a randomly evolving field rather than a fixed one. Condition (a) is the major's problem, and it is different in kind. The major optimizes not against a scalar but against the *entire* conditional minor field $(\mu_t^x)_x$, an object living in the infinite-dimensional field space $\mathcal{M}_2$, and it does so as a player whose own choice α^0 moves X^0 and hence moves the very broadcast that every minor sees. This is the precise sense in which the major is not infinitesimal: its control reaches into the field, so it must optimize while accounting for its own influence on the crowd it is responding to. Condition (c) closes the loop, and it is the one whose character has changed. The consistency demanded is not that a deterministic guessed curve equal a deterministic produced curve, as in the block-graphon fixed point, but that the guessed measure-valued *process* μ_t^x equal the conditional law $\mathcal{L}(X_t^{x,*} \mid \mathcal{F}_t^0)$ of the optimally controlled minor — an equality of processes, holding realization by realization of the major's noise. That conditional fixed point is the exact rung above the block-graphon equilibrium on the ladder this chapter has been climbing: same coupling, a strictly harder closure.

Remark 30.12 (What is inherited and what is new)**.** It pays to separate cleanly what the finite-rank embedding buys and what it leaves open, because the two answers point to different chapters. *Inherited:* the *coupling* of definition 30.11 is, by theorem 30.10, verbatim that of a graphon game on the augmented space $(\mathbb{X}, \rho)$ — the operator $\mathbb{W}_\star$ is bounded, its spectral and norm theory is the Part IV theory unchanged, and nothing about how the agents are wired together steps outside the formalism we already own. *New:* the *equilibrium* lives one level up. Because the minor field (30.17) is random, the consistency condition (c) is a *conditional* fixed point, and the object that characterizes it is no longer the deterministic backward–forward system of chapter 22 but the *graphon master equation with common noise* of chapter 26: the major's value function $u^0(t, x_0, \boldsymbol{\mu})$ now depends on its own state *and* on the entire minor field $\boldsymbol{\mu} \in \mathcal{M}_2$, and the minors' value field is itself a random field driven by the major's noise.

Two caveats keep this honest, and each is a genuine departure from the deterministic GMFG of chapter 24 rather than a technicality. The first is that the major is *not* infinitesimal. Every other agent in this book has been one of a continuum, with vanishing individual influence, so that no single optimizer's choice perturbs the field; the major violates exactly this, by construction and irreducibly — that is what the $O(1)$ operator norm of theorem 30.10 measured. The equilibrium is therefore not a symmetric fixed point among peers but a *Stackelberg-flavored* game between one finite player and a continuum of infinitesimal ones: the major moves a field it knows it is moving, the minors best-respond to the field the major creates, and the relevant fixed point couples the major's HJB equation on the product space $\mathbb{R}^{d_0} \times \mathcal{M}_2$ — finite state crossed with the field — to the minors' conditional McKean–Vlasov system. There is no analogue of this coupling in chapter 22, where every player was a measure-zero participant whose influence on the field was exactly nil. The second caveat is about well-posedness. That this coupled object *has* a solution, and a unique one, is known under structural hypotheses — the linear–quadratic case of example 30.13, or smallness and monotonicity conditions in the spirit of chapter 24 — but it is *not* a corollary of the deterministic GMFG existence theory, whose compactness and contraction arguments were run on flows of deterministic measures and simply do not see the conditioning. The well-posedness draws instead on the common-noise master-equation theory of chapter 26 and on the dedicated major–minor analyses surveyed in the notes. We therefore claim, and have proved, only the *structural* half here — the finite-rank embedding, which holds unconditionally — and defer the analytic half to chapter 26 and the literature, logging it as such in the chapter ledger.

Physics note: The major agent as an annealed impurity field

There is a physical picture that makes the whole escalation feel inevitable, and it is worth a paragraph because it sharpens precisely the distinction between the major and the block populations that came before it. Think of a mean-field ferromagnet: N bulk spins, each coupled to the average magnetization, settling into a self-consistent field. Now introduce a single *impurity* spin coupled to all N bulk spins with $O(1)$ strength. Its total coupling into the bulk is $O(N)$ — comparable to the self-consistent mean field itself — even though the impurity is one site out of N and occupies zero fraction of the lattice in the thermodynamic limit. This is the magnet's version of zero mass with $O(1)$ influence, exactly the budget the rank-two theorem (theorem 30.10) priced. The contrast to keep in mind is with a macroscopic *sublattice* — a finite fraction of the spins, the analogue of a block population in section 30.1 — which also shifts the self-consistent field but does so as a *bulk*: it averages its own thermal noise away and contributes a deterministic field. The major is the impurity, never the sublattice: zero bulk fraction, $O(1)$ field. That single distinction is the whole reason the multi-population case stayed deterministic while the major–minor case does not.

The twist absent from the equilibrium magnet is dynamics. The impurity's state X_t^0 is not frozen; it evolves, randomly, driven by its own noise. A static impurity would imprint a *quenched* external field — one fixed configuration, averaged over at the end. A dynamical one imprints an *annealed* field: it fluctuates in time and the bulk responds to the fluctuations as they happen, in common across all sites. That annealed external field is precisely the finite-dimensional common noise of (30.17), and the minors' response to it is a *conditional* magnetization — the magnetization given the impurity's history — which is exactly why the governing object is the common-noise master equation and not the deterministic one.

As always the picture motivates and must not be made to prove. The discount β is *not* an inverse temperature; the analogy carries no thermodynamic β, and nothing here is a Gibbs equilibrium. The impurity "field" is not fixed by minimizing a free energy but by *backward-in-time* optimization, the major choosing its path to optimize a cost that looks ahead to a terminal time. And the rank-$2p$ content of theorem 30.10 stands on its own, with or without any of this imagery.

Example 30.13 (Linear–quadratic major–minor, the solvable case)**.** The linear–quadratic specialization turns every abstraction of remark 30.12 into something one can write down, and it is the cleanest place to watch the conditional structure made benign by Gaussianity. Let the major obey the linear dynamics $\mathrm{d}X_t^0 = (a_0 X_t^0 + b_0 \alpha_t^0)\,\mathrm{d}t + \sigma_0\,\mathrm{d}B_t^0$ and each minor obey the LQG agent (21.2), with the minor's running cost pulling its state X_t^x toward the target $s\,\Theta_t^\star(x) = s[(\mathbb{W}\bar{\mu}_t)(x) + w_0(x)X_t^0]$ — the graphon aggregate of the other minors plus the broadcast of the major's state — and the major's cost pulling X_t^0 toward the minor aggregate $\langle \bar{\mu}_t \rangle$ it feels.

The decisive simplification is that the only randomness entering the minor field is the major's state X_t^0, which is itself Gaussian because the major's dynamics are linear. Conditioning on $\mathcal{F}_t^0$ thus means conditioning on a Gaussian path, and a linear system driven by a Gaussian signal stays Gaussian: the conditional minor law μ_t^x of (30.17) is Gaussian for every x and t, with a *deterministic* covariance and a *random mean* that is an affine functional of the major's path. All the conditional fluctuation has been pushed into a single finite-dimensional statistic, the random mean, and the measure-valued process collapses to a vector-valued one. This is exactly the conditional-Gaussian closure that makes common-noise LQG problems tractable, here inherited intact by the major–minor game.

We do not derive the equilibrium — the algebra is in the cited literature — but its *structure* is a structural fact worth stating, because it shows the conditional fixed point of definition 30.11 resolving into a finite, layered Riccati system rather than anything genuinely new. It has three tiers. First, a *control* Riccati per minor type x, a measurable family over the continuum $[0, 1]$ of the type-indexed form (30.20), which collapses to the K equations (30.9) only under a block specialization; this tier is unchanged from the ordinary graphon LQG game, because a minor's feedback *gain* does not care that its target happens to be random. Second, one Riccati for the major's own control gain. Third — and this is where the conditioning surfaces — a *forward*, linear stochastic ODE for the conditional minor means, driven by X_t^0, coupled to the major's own linear–quadratic problem, in which the major now sees the minor aggregate-mean not as an exogenous target but as an *endogenous state* that its own control steers. Optimizing the major against a state it moves enlarges its Riccati system: the relevant matrix equation lives on the joint (major state, aggregate-mean) vector rather than on the major state alone. The conditional, infinite-dimensional fixed point of definition 30.11 thus reduces, in the LQG case, to a coupled but finite system of Riccati equations plus one stochastic ODE for the random means — explicit, and solvable in the same sense the rest of Thread A is.

This is the content of the major–minor LQG theory of Huang [81] and Nourian–Caines [105]; the probabilistic (FBSDE) treatment, valid beyond LQG, is Carmona–Zhu [44] and Carmona–Wang [43], and the dominating-player PDE formulation is Bensoussan–Chau–Yam [20]. These are further reading for the enlarged-Riccati algebra we have deliberately not reproduced; they are not substitutes for the two claims the section establishes on its own — that the coupling is a rank-2 atomic perturbation (theorem 30.10), and that the equilibrium is a conditional, common-noise one (remark 30.12).

With the major–minor model dissected we have reached the chapter's sharpest instance of its recurring tension. The coupling was *subsumed* — a finite-rank atomic choice of the same operator $\mathbb{W}$ — but the equilibrium *escalated*, because a single non-vanishing player's noise refused to average and turned the minor field into a conditional, common-noise object. The dichotomy that organized that escalation was *deterministic field versus random field*: as long as the aggregate each agent feels is a fixed curve we remain in the tractable GMFG theory of chapter 24, and the moment it becomes a process we are pushed up to the conditional master-equation theory of chapter 26. That same dichotomy is about to reappear on two further axes, which the next section takes up in turn: the heterogeneity already latent in type-dependent coefficients b, σ, L, g, and then partial information — the first axis still living inside the operator $\mathbb{W}$, the second, for the first time in this chapter, outside it.

30.3 Heterogeneous costs and dynamics, and partial information

The major–minor model forced the equilibrium up a level: subsuming the coupling into a finite-rank atomic operator cost nothing, but a single non-vanishing player's noise refused to average and dragged the minor field from a deterministic curve into a conditional, common-noise process. We now step down from that escalation to a far milder species of heterogeneity — so mild that, at the level of the model, it is no extension at all — precisely so that the contrast sharpens what made the major–minor case hard. The point of this section is not a new construction but a discrimination: among the many ways agents can differ, we sort out which differences stay confined to a single agent's private optimization and which propagate through the equilibrium to bind the whole population together. The same axis then reappears in a genuinely new guise — partial information — which, unlike everything in this chapter so far, lives *outside* the operator $\mathbb{W}$ rather than inside it.

Begin with the observation that the graphon setup of definitions 21.1 and 21.6 already wrote the drift b, the diffusion σ, the running cost L, and the terminal cost g as functions of the type x. Letting these coefficients vary arbitrarily with x — a fast agent here, an expensive-to-steer agent there, a population whose terminal target differs from its neighbour's — therefore adds not a single symbol to the formalism of Part IV. "Heterogeneity in costs and dynamics across types" is, at the level of the model, already present; nothing needs to be defined, and there is no theorem to prove that the extended model is well posed, because it is the same model. This is worth saying plainly because the mean field games literature often advertises "heterogeneous agents" as an extension, whereas in the graphon formulation it is the default and homogeneity is the special case (constant coefficients). The genuine question is not *whether* type-dependence is allowed but *what it does* once the equilibrium loop closes.

That question has a clean answer because the equilibrium couples agents through exactly one channel, and type-dependence enters two channels with opposite consequences. Recall the two half-problems an equilibrium must reconcile. Each infinitesimal agent solves a control problem — an HJB equation — against an aggregate it treats as a fixed exogenous target (definition 21.15); and the realized population law feeds back into that target through the operator $\mathbb{W}$. Heterogeneity in an agent's *own* data b, σ, L, g enters only the first channel: it reshapes how type x responds to its target, but type x's HJB equation never sees type x''s coefficients. Such heterogeneity is *type-local*; it decouples. Heterogeneity that lives in the second channel — in the coupling weight with which a type reads the aggregate, or in the kernel W itself — is what binds types together, but even this binding is funnelled through the single readout $\mathbb{W}\bar{m}$. The upshot, which the next subsection makes precise for the LQG model, is that the infinite-dimensional, globally coupled part of the problem is a *single* linear object in which $\mathbb{W}$ appears once, while every nonlinearity is solved type by type in mutual ignorance. "Propagation through the equilibrium" thus has a precise meaning: it is the question of how much of the problem survives the projection onto each type's private data, and the answer is that almost all of it does — only the field itself is shared.

This is the deterministic-field side of the chapter's recurring tension, now read on the heterogeneity axis: as long as the shared aggregate $\mathbb{W}\bar{m}_t$ is a fixed flow, type-dependence buys global coupling but no loss of tractability, because the coupling is a single linear term and the rest is type-local. The second half of the section breaks that comfortable picture along an orthogonal direction. Partial information is the genuinely new ingredient, and it is new precisely because it is *not* a choice of $\mathbb{W}$: an agent that observes only a noisy signal of its own state and must filter is changing what it knows, not whom it is connected to. The network operator is untouched; the informational structure is bolted on alongside it. And there the deterministic-versus-conditional dichotomy that organized the major–minor escalation returns in informational dress — the filtered state estimate plays the role the conditional law played there — with a separation principle deciding when the filtering layer and the control layer come cleanly apart. We take the two axes in turn: first the decoupling of type-dependence through the equilibrium (section 30.3.1), then partial information and filtering (section 30.3.2).

30.3.1 Heterogeneity that decouples versus heterogeneity that couples

Proposition 30.14 (Decoupling of own-dynamics heterogeneity in LQG)**.** *Consider the graphon-LQG game* (21.2)–(21.8) *with fully type-dependent parameters* $a(x), b(x), \sigma(x), q(x), q_T(x), s(x)$*, all Borel and bounded, under* (A-Nondeg) *(*$\inf_x |\sigma(x)| > 0$*) and* (A-Reg-W)*. Then the equilibrium splits into:*

(i) *a family of* mutually decoupled *scalar Riccati equations, one per type,*

$$\dot{P}_t(x) = -2a(x)P_t(x) + b(x)^2 P_t(x)^2 - q(x), \qquad P_T(x) = q_T(x), \tag{30.20}$$

each depending on x only through that type's own parameters; and

(ii) *a single linear* forward–backward *system* coupling all types*, for the first-moment field $x \mapsto \bar{m}_t(x)$ and its conjugate offset field $x \mapsto r_t(x)$,*

$$\dot{\bar{m}}_t(x) = \big(a(x) - b(x)^2 P_t(x)\big)\bar{m}_t(x) \;-\; b(x)^2\, r_t(x), \qquad \bar{m}_0(x) = \bar{m}_0^x \text{ given}, \tag{30.21a}$$

$$\dot{r}_t(x) = \big(b(x)^2 P_t(x) - a(x)\big) r_t(x) \;+\; q(x)\, s(x)\, (\mathbb{W}\bar{m}_t)(x), \quad r_T(x) = -\, q_T(x)\, s(x)\, (\mathbb{W}\bar{m}_T)(x), \tag{30.21b}$$

exactly the type-indexed family of (21.21)–(21.22).

All inter-type coupling resides in the single term $(\mathbb{W}\bar{m}_t)(x)$*, which enters only the backward offset equation* (30.21b)*; heterogeneity in* (a, b, σ, q, q_T) *never couples types, and heterogeneity in* $s(x)$ *only rescales each type's coupling to the (single) graphon aggregate. As in worked computation 30.7 the mean obeys no closed forward ODE: its forcing is the offset* $r_t(x)$*, and the system* (30.21) *is a two-point boundary-value problem on* $L^2([0,1])$ *with split data (initial* $\bar{m}_0$*, terminal* r_T*).*

Proof sketch. For each fixed x the agent solves an ordinary scalar LQG control problem against the exogenous target $s(x)z_t(x)$, $z_t = \mathbb{W}\bar{m}_t$ (the aggregate is exogenous to the infinitesimal agent, definition 21.15). The verification theorem of chapter 6 gives a quadratic value $u^x = \frac{1}{2}P_t(x)x^2 + r_t(x)x + c_t(x)$ whose curvature $P_t(x)$ solves (30.20) — which involves only the type-x parameters, since the affine target perturbs only the lower-order coefficients r, c. The closed-loop mean and offset then obey (21.21)–(21.22) in the form (30.21), with the target $z_t(x) = (\mathbb{W}\bar{m}_t)(x)$ substituted into the backward offset equation; this $\mathbb{W}\bar{m}_t$ is the only place a different type's data enters. Well-posedness of each Riccati under $q(x), q_T(x) \geq 0$ is theorem 14.2; measurability of $x \mapsto P_t(x)$ follows from measurability of the parameters and continuous dependence of the Riccati solution on its coefficients. The forward–backward system (30.21) is a linear two-point boundary-value problem on $L^2([0,1])$ whose only off-diagonal (type-coupling) operator is $\bar{m} \mapsto q(\cdot)s(\cdot)\,\mathbb{W}\bar{m}$ in the backward half; its unique solvability for $|s|_\infty\,\|\mathbb{W}\|$ below the threshold is the heterogeneous, $L^2([0,1])$-valued version of the scalar self-consistency (21.24), and reduces to it when the parameters are constant. □

Proposition 30.14 is the reason graphon LQG is computationally mild despite its infinite-dimensionality: the genuinely infinite-dimensional part is a *single* linear forward–backward system (30.21) in which the operator $\mathbb{W}$ appears once, while all the nonlinearity (the Riccati) is type-local. The block specialization recovers worked computation 30.7; the constant specialization recovers Thread A.

30.3.2 Partial information and filtering

A separate axis of heterogeneity, orthogonal to the network, is *informational*: agents may not observe their own state exactly. Each type-x agent observes a noisy signal

$$\mathrm{d}Y_t^x \;=\; c(x)\,X_t^x\,\mathrm{d}t \;+\; \mathrm{d}V_t^x, \qquad Y_0^x = 0, \tag{30.22}$$

with V^x an observation Brownian motion independent of the state noise B^x, and must choose its control *adapted to its own observation filtration* $\mathcal{F}_t^{Y,x} = \sigma((Y_s^x)_{s\leq t})$ rather than to the state. This is the partially observed mean field game; in the homogeneous case it is the nonuniform-agent LQG theory of Huang–Caines–Malhamé [83], and with a major player the partially observed major–minor theory of Sen–Caines [121] and Caines–Kizilkale [35].

Because the partially observed LQG game leans on linear filtering — a result beyond the working prerequisite of Itô calculus — we first establish, in-book, the scalar Kalman–Bucy filter we will invoke. It rests only on tools already in hand: conditional expectation as L^2 orthogonal projection (definition 3.30), the fact that for a jointly Gaussian system an uncorrelated residual is *independent* of the conditioning σ-algebra, the Itô isometry and Itô's formula (theorems 5.7 and 5.9), and the affine-image-of-Gaussians argument used for the LQG flow in theorem 14.4.

Lemma 30.15 (Scalar Kalman–Bucy filter)**.** *Let the scalar signal–observation pair*

$$\mathrm{d}X_t = (\alpha X_t + \beta u_t)\,\mathrm{d}t + \sigma\,\mathrm{d}B_t, \qquad \mathrm{d}Y_t = c\,X_t\,\mathrm{d}t + \mathrm{d}V_t, \quad Y_0 = 0, \tag{30.23}$$

be driven by independent standard Brownian motions B, V, independent of the Gaussian initial state $X_0 \sim \mathcal{N}(\bar{m}_0, \Sigma_0)$, with α, β, σ, c real constants and the control u bounded and adapted to the *observation filtration $\mathcal{F}_t^Y = \sigma(Y_s : s \le t)$. Then the conditional law of X_t given $\mathcal{F}_t^Y$ is Gaussian, $\mathcal{N}(\hat{X}_t, \Sigma_t)$, with:*

(a) *conditional variance $\Sigma_t = \mathbb{E}\Big[(X_t - \hat{X}_t)^2\Big]$ — the filter (conditional estimation-error) variance, distinct from the value-function curvature P —* deterministic *(it does not depend on the observation path nor on the control), solving the forward variance Riccati equation*

$$\dot{\Sigma}_t = 2\alpha\Sigma_t - c^2\Sigma_t^2 + \sigma^2, \qquad \Sigma_0 \text{ given}; \tag{30.24}$$

(b) *conditional mean $\hat{X}_t = \mathbb{E}\Big[X_t \mid \mathcal{F}_t^Y\Big]$ solving the innovation-driven SDE*

$$\mathrm{d}\hat{X}_t = (\alpha\hat{X}_t + \beta u_t)\,\mathrm{d}t + \Sigma_t\,c\,\mathrm{d}I_t, \qquad I_t := Y_t - \int_0^t c\,\hat{X}_s\,\mathrm{d}s, \tag{30.25}$$

where the innovation I is a standard $\mathcal{F}^Y$-Brownian motion.

Proof. Step 1 (the estimation error is control-free). The control u is $\mathcal{F}_t^Y$-measurable, hence exactly reproduced by any $\mathcal{F}_t^Y$-measurable estimator; writing $e_t := X_t - \hat{X}_t$, the affine drift term βu_t appears identically in the dynamics of X_t and of its conditional mean $\hat{X}_t$ and so cancels in e_t. We may therefore compute e_t and $\Sigma_t = \mathbb{E}[e_t^2]$ in the uncontrolled system $\beta \equiv 0$, and add the known term βu back to the mean at the end.

Step 2 (conditional Gaussianity, deterministic variance). With $\beta \equiv 0$, both X_t and Y_t are affine functionals of the jointly Gaussian triple $(X_0, B_{[0,t]}, V_{[0,t]})$ — this is the affine-image-of-Gaussians argument of theorem 14.4 applied to the two-dimensional linear system (30.23) — so the whole process (X, Y) is Gaussian. The conditional mean $\hat{X}_t = \mathbb{E}\Big[X_t \mid \mathcal{F}_t^Y\Big]$ is the L^2 orthogonal projection of X_t onto the closed subspace $L^2(\Omega, \mathcal{F}_t^Y, \mathbb{P})$ (definition 3.30); for a Gaussian family that subspace is generated by the Gaussian observations, and the residual $e_t = X_t - \hat{X}_t$ is orthogonal to it, hence *uncorrelated* with every $\mathcal{F}_t^Y$-measurable variable. In a jointly Gaussian system uncorrelated implies independent, so e_t is independent of $\mathcal{F}_t^Y$. Therefore the conditional law of $X_t = \hat{X}_t + e_t$ given $\mathcal{F}_t^Y$ is that of a constant plus an independent centered Gaussian: $\mathcal{N}(\hat{X}_t, \Sigma_t)$ with $\Sigma_t = \mathbb{E}[e_t^2]$ a deterministic number.

Step 3 (the filter SDE and the gain). Since X is Gaussian and $\hat{X}_t$ is its linear projection onto the observation history, $\hat{X}$ is itself a Gaussian process adapted to $\mathcal{F}^Y$ and, by the linearity of (30.23), admits a representation as a linear SDE driven by the observation; we write it in innovations form with an undetermined gain k_t,

$$\mathrm{d}\hat{X}_t = \alpha\hat{X}_t\,\mathrm{d}t + k_t\,\mathrm{d}I_t, \qquad I_t = Y_t - \textstyle\int_0^t c\hat{X}_s\,\mathrm{d}s,$$

(the attribution of this representation to the linear-filtering literature is [21, Ch. 3]; what we must determine is k_t and verify (30.24)). Subtracting from the signal dynamics and using $\mathrm{d}I_t = c\,e_t\,\mathrm{d}t + \mathrm{d}V_t$,

$$\mathrm{d}e_t = \mathrm{d}X_t - \mathrm{d}\hat{X}_t = (\alpha - k_t c)\,e_t\,\mathrm{d}t + \sigma\,\mathrm{d}B_t - k_t\,\mathrm{d}V_t.$$

By Itô's formula (theorem 5.9) and the Itô isometry (theorem 5.7), $\Sigma_t = \mathbb{E}[e_t^2]$ obeys $\dot{\Sigma}_t = 2(\alpha - k_t c)\Sigma_t + \sigma^2 + k_t^2$. The projection property $e_t \perp \mathcal{F}_t^Y$ characterises the gain: k_t must keep the error orthogonal to the innovation it adds, which is the value minimising Σ_t, i.e. $\partial_{k_t}\big(2(\alpha - k_t c)\Sigma_t + \sigma^2 + k_t^2\big) = -2c\Sigma_t + 2k_t = 0$, giving $k_t = c\Sigma_t$. Substituting $k_t = c\Sigma_t$,

$$\dot{\Sigma}_t = 2\alpha\Sigma_t - 2c^2\Sigma_t^2 + \sigma^2 + c^2\Sigma_t^2 = 2\alpha\Sigma_t - c^2\Sigma_t^2 + \sigma^2,$$

which is (30.24); and $\mathrm{d}\hat{X}_t = \alpha\hat{X}_t\,\mathrm{d}t + c\Sigma_t\,\mathrm{d}I_t$. Restoring the control term from Step 1 yields (30.25).

Step 4 (the innovation is a Brownian motion). The innovation $I_t = \int_0^t c\,e_s\,\mathrm{d}s + V_t$ is a continuous centered Gaussian process (a Gaussian integral plus a Brownian motion). Its bounded-variation part $\int_0^t ce_s\,\mathrm{d}s$ contributes nothing to the quadratic variation, so $[I]_t = [V]_t = t$. Moreover, for $s < t$ the increment $I_t - I_s$ is uncorrelated with every $\mathcal{F}_s^Y$-measurable variable: $V_t - V_s$ is independent of $\mathcal{F}_s^Y$, while $\int_s^t c\,e_r\,\mathrm{d}r$ has, by the orthogonality of Step 2, zero correlation with $\mathcal{F}_s^Y$. Being jointly Gaussian, $I_t - I_s$ is therefore *independent* of $\mathcal{F}_s^Y$ with variance $t - s$. A continuous Gaussian process started at 0 with independent increments of variance $t - s$ is, by the construction of Brownian motion (chapter 5), a standard $\mathcal{F}^Y$-Brownian motion. □

With the filter in hand, the decisive simplification in the linear–quadratic–Gaussian case is the *separation principle*: optimal estimation and optimal control decouple, and the optimal control is the full-information feedback evaluated at the conditional mean estimate. We state it for the graphon LQG game with a *deterministic* aggregate (no major player / no common noise), where it holds cleanly.

Proposition 30.16 (Separation / certainty equivalence, partially observed graphon LQG)**.** *Consider the heterogeneous graphon-LQG game of proposition 30.14 with each agent observing only* (30.22) *and choosing $\mathcal{F}^{Y,x}$-adapted controls, with Gaussian initial state $X_0^x \sim \mathcal{N}(\bar{m}_0^x, \Sigma_0(x))$ and the minor aggregate $z_t = \mathbb{W}\bar{m}_t$ a deterministic flow. Then for a.e. type x:*

(i) (Filter.) *The conditional law of X_t^x given $\mathcal{F}_t^{Y,x}$ is Gaussian, $\mathcal{N}(\hat{X}_t^x, \Sigma_t(x))$, where the conditional variance $\Sigma_t(x)$ solves the deterministic forward Riccati equation*

$$\dot{\Sigma}_t(x) = 2a(x)\Sigma_t(x) - c(x)^2\Sigma_t(x)^2 + \sigma(x)^2, \qquad \Sigma_0(x) \text{ given}, \tag{30.26}$$

and the conditional mean (the Kalman–Bucy filter) solves the controlled SDE

$$\mathrm{d}\hat{X}_t^x = \big(a(x)\hat{X}_t^x + b(x)\alpha_t^x\big)\,\mathrm{d}t + \Sigma_t(x)c(x)\,\big(\,\mathrm{d}Y_t^x - c(x)\hat{X}_t^x\,\mathrm{d}t\big). \tag{30.27}$$

(ii) (Separation.) *The optimal control is the full-information feedback of proposition 30.14 evaluated at the estimate,*

$$\alpha_t^{x,*} = -\,b(x)\big(P_t(x)\,\hat{X}_t^x + r_t(x)\big), \tag{30.28}$$

with the same *control Riccati $P_t(x)$* (30.20) *and offset $r_t(x)$ as in the fully observed problem.*

(iii) (Consistency on the estimates.) *Taking expectations in* (30.27) *and using $\mathbb{E}\Big[\hat{X}_t^x\Big] = \mathbb{E}[X_t^x] = \bar{m}_t(x)$, the equilibrium first-moment field $\bar{m}_t(x)$ obeys the* same *mean equation* (30.21) *as in the fully observed game. The partially observed graphon LQG equilibrium therefore has the identical mean field to the fully observed one; partial information changes the individual fluctuations (through Σ_t) but not the equilibrium mean.*

Proof sketch. (i) is the scalar Kalman–Bucy filter of lemma 30.15 applied to type x with $(\alpha, \beta, \sigma, c) = (a(x), b(x), \sigma(x), c(x))$: the conditional law stays Gaussian, the variance Riccati (30.26) is (30.24) (it does not see the control, a hallmark of the linear case), and the conditional mean follows the innovation-driven SDE (30.27), which is (30.25). Measurability of $x \mapsto (\Sigma_t(x), \hat{X}^x)$ follows as in proposition 30.14 from measurability of the parameters; the classical attribution is [21, Ch. 3]. (ii) is the LQG separation principle: substituting the filter into the cost and using the orthogonality $\mathbb{E}\Big[(X_t^x - \hat{X}_t^x)\hat{X}_t^x\Big] = 0$ shows the cost splits into a control-dependent term identical to the full-information cost in $\hat{X}$ and a control-independent estimation-error term $\int_0^T q(x)\Sigma_t(x)\,\mathrm{d}t$; minimizing the former gives (30.28) with the unchanged control Riccati. (iii) Because $\mathbb{E}\Big[\hat{X}_t^x\Big] = \mathbb{E}[X_t^x]$ (the filter is unbiased) and the feedback (30.28) is affine, taking expectations reproduces (30.21) verbatim. The estimation step is lemma 30.15; the cost-splitting and certainty-equivalence step is the partially observed nonuniform LQG game of Huang–Caines–Malhamé [83], lifted to the graphon coupling by replacing the scalar global mean with $\mathbb{W}\bar{m}_t$. □

Remark 30.17 (Why separation is fragile under common noise)**.** Proposition 30.16 used decisively that the aggregate $z_t = \mathbb{W}\bar{m}_t$ is *deterministic*, so that an agent need only estimate its own state, not the population. Reinstate a major player (section 30.2) or any common noise (chapter 26) and the aggregate becomes random; an agent must then filter *both* its own state and the common signal driving the field, the conditional variance Riccati (30.26) acquires the aggregate as an input, and certainty equivalence holds only in the enlarged sense of Sen–Caines [121]. The clean separation of estimation from control is a luxury of the deterministic-aggregate (no-common-noise) regime; this is the informational counterpart of the deterministic-versus-conditional dichotomy that made the major–minor equilibrium of remark 30.12 harder than the block one. General (non-Gaussian) partial information requires nonlinear filtering — the Zakai/Kushner–Stratonovich equations — and is outside the scope we develop; we flag it in the landscape below and carry it, as an open direction, to the open-problems chapter (chapter 31).

30.4 A map of the heterogeneity landscape

We close by placing the three models of this chapter, and their neighbors, on a single map, oriented by the 2025 overview of mean field games beyond perfect homogeneity [11]. The organizing question is operational: *which extensions are special structural choices within the graphon mean field game of Part IV, and which require machinery genuinely outside it?* We answer along four axes of heterogeneity.

Axis 1: heterogeneity in type (parameters and coupling). This is the graphon axis itself. Multi-population MFG is the block graphon (theorem 30.4); fully type-dependent dynamics and costs are absorbed without extension (proposition 30.14); the rank-one "Curie–Weiss" kernel is the scalar-order-parameter reduction of worked computation 21.18. *Verdict: subsumed.* The graphon operator $\mathbb{W}$ is exactly the bookkeeping device for type heterogeneity, and the finite (block) and rank-one cases are its most tractable corners.

Axis 2: heterogeneity in influence (major players). A finite number of non-vanishing players is the finite-rank atomic perturbation of theorem 30.10: structurally a graphon game on the augmented space $(\mathbb{X}, \rho)$. *Verdict: subsumed at the level of coupling, but the equilibrium escalates.* The atom makes the minor field random, so the equilibrium is a conditional (common-noise) one whose well-posedness belongs to the graphon master equation of chapter 26, not to the deterministic GMFG theory of chapter 24. The finite-rank embedding is exact and unconditional; the analysis is one tier up.

Axis 3: heterogeneity in information. Partial observation and filtering (section 30.3.2) are *orthogonal* to the network: they act on each agent's own state-estimation problem and, in the LQG / deterministic-aggregate regime, leave the equilibrium mean field untouched by the separation principle (proposition 30.16). *Verdict: composable with the graphon structure, not subsumed by it.* Information heterogeneity multiplies onto the type-coupling structure rather than being encoded in $\mathbb{W}$; under common noise it interacts non-trivially with Axis 2 (remark 30.17).

Axis 4: heterogeneity in network geometry beyond the dense graphon. Real networks are sparse and heavy-tailed, and the dense graphon $W : [0,1]^2 \to [0,1]$ cannot represent them: its average degree is $\Theta(N)$. *Verdict: outside.* Sparse and power-law regimes require L^p-graphons and graphex limits (chapter 27); the entire finite-rank/block toolkit of this chapter presumes the dense, bounded-kernel theory.

Table 30.1 summarizes. The boundary worth internalizing is the diagonal of the table: *static-coupling, deterministic-aggregate, dense-network* heterogeneity is what the graphon operator was built to carry, and the major–minor, multi-population, and heterogeneous-cost models all live there at the level of coupling. The moment any of three thresholds is crossed — the aggregate becomes random (major players, common noise), the coupling runs through controls rather than states (extended MFG), or the network becomes sparse (graphex) — the graphon-coupling bookkeeping is no longer the whole story, and the analysis moves to chapter 26, to the extended-MFG literature, or to chapter 27.

Remark 30.18 (What the review adds)**.** The overview [11] catalogues these extensions and several we have not detailed — risk-sensitive and robust objectives, MFG with absorption and state constraints, finite-state and jump models, and mean field *control* (the cooperative counterpart, where a single planner optimizes the population's aggregate cost). Two of its organizing observations are worth carrying forward. First, that "heterogeneity" is not one phenomenon: the four axes above interact, and the hard open problems (chapter 31) sit at their intersections — partially observed major players on sparse networks being the canonical hard case. Second, that the graphon abstraction is the most economical container for *type* heterogeneity but says nothing on its own about *informational* or *temporal* heterogeneity (time-inconsistency, non-exponential discounting), which compose with it but are not reducible to a choice of kernel. We adopt both observations as the framing for the open-problems chapter.

Extension	**Graphon encoding**	**Status / where treated**
Multi-population / multi-class	block kernel (30.2); interaction matrix $\widehat{\mathsf{B}}$	subsumed (theorem 30.4)
Type-dependent costs/dynamics	x-dependent coefficients	subsumed (proposition 30.14)
Major / minor (finite influential players)	finite-rank atomic perturbation (30.15) on $(\mathbb{X}, \rho)$	coupling subsumed; equilibrium needs common noise (chapter 26)
Partial information / filtering	orthogonal to $\mathbb{W}$; Kalman–Bucy per type	composable (proposition 30.16)
Common (aggregate) noise	— (random field, not a kernel)	outside the deterministic GMFG; chapter 26
Sparse / heavy-tailed networks	dense graphon fails	outside; L^p/graphex, chapter 27
MFG of controls (extended MFG)	coupling through law of controls, not states	outside the state-coupled graphon
Finite-state / jump MFG	continuous-state machinery inapplicable	adjacent; finite-state graphon games [9]
Stackelberg / leader–follower	hierarchical optimization	outside; partial overlap with major–minor
Learning / unknown model	graphon known to the solver, not the agents	chapter 29

Table 30.1: The heterogeneity landscape, oriented by [11]. "Subsumed" means a structural special case of the dynamic graphon MFG of chapter 21; "composable" means it multiplies onto that structure without being encoded in $\mathbb{W}$; "outside" means it needs machinery this book develops elsewhere or flags as open.

Rigor ledger

Proved.

- The block-graphon reduction: with block-constant data the block-constant subspace $\mathcal{M}_2^{\mathsf{B}}$ is closed and best-response-invariant, and its equilibria are in bijection with multi-population MFG equilibria (30.6) (lemma 30.2 and theorem 30.4). Existence on the finite system and uniqueness under monotonicity or $\left\|\widehat{\mathsf{B}}\right\|$-smallness (proposition 30.6).
- Thread B advanced to K populations: collapse to K decoupled Riccati equations (30.9) plus one $2K$-dimensional linear mean–offset two-point boundary-value problem (30.11) (the inter-population coupling living in the backward/offset half), with coupling constant $\left\|\widehat{\mathsf{B}}\right\|$ and consistency with the single-population and rank-one reductions (worked computation 30.7).

- Major–minor as an unconditional finite-rank atomic perturbation of the graphon coupling on the augmented space $(\mathbb{X}, \rho)$, of rank $\leq 2p$ for p majors, with the operator-norm lower bound $\|R\| \geq \|w_0\|_{L^2}$ certifying non-vanishing influence (theorem 30.10).
- Decoupling of own-dynamics heterogeneity in LQG into a type-local Riccati family and a single $L^2([0,1])$-valued mean–offset two-point BVP (proposition 30.14); the in-book scalar Kalman–Bucy filter (lemma 30.15) and the LQG separation principle with unchanged equilibrium mean field under a deterministic aggregate (proposition 30.16).

Assumed.

- Standing assumptions (A-Lip), (A-Growth), (A-Nondeg), (A-Conv) per population/-type, and (A-Reg-W) for the (block or augmented) kernel; (A-Mon) where monotone uniqueness is invoked.
- The per-agent verification theorem of chapter 6 and the single-population LQG solution of chapters 8 and 14 (Riccati well-posedness theorem 14.2), imported rather than reproved.

Deferred.

- Well-posedness of the major–minor equilibrium (conditional/common-noise fixed point): the graphon master equation with common noise, chapter 26; LQG and probabilistic treatments [81, 105, 44, 20].
- The detailed monotone-plus-perturbation uniqueness estimate for the finite system: the finite-rank case of chapter 24.
- Partial information under common noise (joint state/aggregate filtering) and nonlinear filtering for non-Gaussian models: [121, 35] and chapter 31.

Open.

- Whether a symmetric block kernel can support *non*-block-constant (symmetry-broken within a cell) equilibria outside the monotone/small-coupling regime (remark 30.5); the multi-population analogue of the Curie–Weiss multiplicity of section 11.4.
- Sharp characterization of equilibria at the intersection of axes — partially observed major players on sparse (graphex) networks — where none of the reductions of this chapter applies cleanly (remark 30.18, chapter 31).

Bibliographic notes

The multi-population mean field game system (30.6) predates the graphon formulation: the several-population ergodic equations are derived by Feleqi [66], the parabolic/boundary theory by Cirant [49], and the relation to mean field control across populations by Bensoussan–Huang–Laurière [22].

Reading it as the block-graphon slice of the dynamic GMFG of Caines–Huang [33, 34] is the viewpoint of remark 21.20 and chapter 22, which the present chapter completes; the static counterpart is the block static graphon game of section 20.1 and the interaction-matrix spectral threshold of theorem 20.14. The major–minor model originates with the LQG analysis of Huang [81] and the nonlinear ϵ-Nash theory of Nourian–Caines [105]; the probabilistic (FBSDE) approach, which clarifies that the minor field becomes conditional, is Carmona–Zhu [44] and Carmona–Wang [43]; the master/PDE "dominating player" formulation is Bensoussan–Chau–Yam [20]; and the finite-dimensional common-noise reading we adopt is the bridge to chapter 26 and Carmona–Delarue [41]. The major-player-as-low-rank perturbation viewpoint, and the major/minor distinction as small-versus-large in the Lasry–Lions sense, is in the line of Lasry–Lions [94]. Partially observed LQG mean field games are due to Huang–Caines–Malhamé [83], with the major-player and filtering refinements of Sen–Caines [121] and Caines–Kizilkale [35]; the Kalman–Bucy filter and the LQG separation principle are classical, in the textbook form of Bensoussan–Frehse–Yam [21]. The landscape of table 30.1 follows the 2025 overview of extensions beyond perfect homogeneity [11]; the finite-state graphon games it references are Aurell–Carmona–Dayanikli–Laurière [9], the linear-quadratic graphon game is Aurell–Carmona–Laurière [10], and the sparse/graphex frontier is chapter 27.

Chapter 31

Open Problems and a Research Map

For thirty chapters this book has built. Each took an object — a measure, a value function, an operator, a graph limit — carried a definition to a theorem and a theorem to a worked threshold, and handed the next chapter a tool it could stand on. This final chapter does something different in kind, and the shift in stance is worth naming, because it changes what counts as progress. It carries no new theorem. Its work is to draw the map of the territory those thirty chapters charted, to mark the edges where the proved results stop, and to say honestly what lies beyond them. Where the preceding chapters earned ground by *proving*, this one earns it by *locating*: fixing coordinates precise enough that an open problem becomes a definite point with definite neighbours, rather than a vague unease about a hard direction. We import freely and prove almost nothing new — the single exception, a fully rigorous fluctuation computation (worked computation 31.9), is held to the end, where it marks the exact line at which the rigorous theory gives out.

The objects we will draw on are all in place, and it is worth recalling each not as a citation but as a tool with a job, since this is the last page on which they all stand together. The classical mean field game system (chapter 11) is the coupled Hamilton–Jacobi–Bellman/Fokker–Planck pair an equilibrium must solve, and Lasry–Lions monotonicity is the sign condition under which that pair has exactly one solution; the master equation (chapter 12) lifts the entire equilibrium to a single function on the space of measures, the only formulation that survives a randomly moving mean field. The graphon enters as a self-adjoint Hilbert–Schmidt operator $\mathbb{W}$ (chapter 18) — the object whose spectrum will turn out to govern everything that follows — living in the compact space $(\widetilde{\mathcal{W}}_0, \delta_\square)$ under the cut metric (chapter 17), the metric in which both the network limits and the equilibria they carry vary continuously. On that footing rest the dynamic graphon mean field game and its existence and uniqueness theory (chapters 22 and 24), justified from below by convergence from finite networks (chapter 25) and extended above by the graphon master equation and common noise (chapter 26); past them lie the sparse and L^p frontier (chapter 27), where the bounded-operator assumptions begin to fail, the numerics (chapter 28) that turn an equilibrium into a number, the reinforcement learning (chapter 29) that finds it when the model is unknown, and the heterogeneity zoo (chapter 30) cataloguing the ways agents may differ that the graphon does, and does not, capture. Read as a single inventory, these are the pieces of a statistical field theory of strategic agents on a network; the map we are about to draw is what they look like seen at once.

The carried threads run through all of it. The linear–quadratic–Gaussian (LQG) game (Thread A) and its graphon generalisation, the congestion/imitation model on a kernel (Thread B) — of which the rank-one kernel $W(x, y) = f(x)f(y)$ is the cleanest reduction — have each been solved to their exact uniqueness/multiplicity thresholds, in theorem 14.11 and proposition 24.23. We lean on those exact answers throughout, because a chapter about what is *not* known needs, more than anything, a few things known *exactly* to calibrate against: the threshold the general theory cannot yet reach is precisely the one the LQG thread hands us on a plate.

The chapter is organised around four questions a reader who has finished the book might reasonably ask, and its discipline is to keep them genuinely separate — four different kinds of not-knowing — until the very end, where they are seen to answer to a single object. *What do we not yet know how to prove?* (section 31.2: theory gaps.) *What do we not yet know how to compute?* (section 31.3: computation and identification gaps.) *Where will this be used, and what does each use cost in new mathematics?* (section 31.4: application frontiers.) And finally, the question this book was written to provoke: *where is the physics-trained reader's toolkit — the renormalisation group, the systematic fluctuation expansion, the diagrammatic bookkeeping of corrections to a saddle — most likely to produce new mathematics?* (section 31.5.) That last section carries the single worked computation of the chapter, a fully rigorous calculation of the order-parameter susceptibility of the rank-one graphon game (worked computation 31.9), which makes precise both the divergence of fluctuations at the critical coupling and the exact point at which the rigorous theory runs out. We pose the four questions independently and answer them independently; only in the closing synthesis (section 31.6) do we argue that all four converge on one operator — the susceptibility $(\mathrm{Id} - \mathcal{G})^{-1}$, whose spectral radius reaching unity is at once the failure of uniqueness, the onset of equilibrium multiplicity, the blow-up of finite-N fluctuations, and the breakdown of best-response learning. We do not assume that convergence in advance; we earn it question by question, and the reader is entitled to watch us earn it.

A word on the standard we hold ourselves to, because an open-problems chapter is the exact place a textbook is most tempted to wave its hands: a gesture toward a hard direction, a citation, a "this remains open," and onward. We refuse that move. Every conjecture below is held to the same discipline as a theorem, which here means three things attached to each open problem. First, the precise hypotheses under which it is open — so that it is a definite mathematical statement and not a mood. Second, the nearest proved result that bounds it from the known side — so the reader sees exactly how far the proved theory reaches before it stops, and against what the conjecture is being measured. Third, an explicit account of *which* step of the nearest known proof fails, and *why* it fails — so that the obstruction itself is named, not merely the goal restated. Naming the failing step is the hardest of the three and the most valuable: it is the difference between knowing that a road ends and knowing what the bridge would have to span. A problem we cannot state to this standard is not yet a research problem but a feeling about one, and where we are in that position we say so plainly rather than dress it up. This is also what makes the map trustworthy: a gap located this precisely is one a reader can imagine closing.

31.1 The shape of what is known

The preamble promised a map before any gap is marked, and a discipline that holds each conjecture to a theorem's standard; making good on both begins with the same act — fixing the coordinate system. The four questions of the previous page all have the form "where does the proved theory stop?", and that question has a sharp answer only once we have said precisely where the proved theory *is*. Here is the organising observation that lets us say it. Every well-posedness result in this book — every uniqueness theorem, every globally well-posed master equation, every convergence rate — sits at a point in one and the same three-axis space, and the open problems are, almost without exception, the corners of that space the proofs have not reached. The three axes are the three independent ways the strategic problem can be made hard: by the strength and sign of the coupling between agents, by the structure of the network through which they interact, and by the kind of noise that drives them. Name the axes once and every later gap stops being an isolated difficulty and becomes a direction of travel from a known point.

Axis 1: the coupling regime. The first axis measures how strongly, and with what sign, an agent's optimal behaviour reacts to the crowd, and it is the axis along which the theory is most complete. At one end sits the regime where everything works at once. Under *(A-Mon)*, Lasry–Lions monotonicity (theorems 11.5 and 12.8) or its graphon lift (theorem 24.16), the coupling acts as a restoring force: making a choice more popular makes it less attractive, so the best-response map cannot reinforce a deviation, and one obtains the full package — uniqueness for *all* horizons, a globally well-posed master equation, exponential convergence of the finite-player game — with no smallness assumed and no dependence on the horizon T. Monotonicity is what buys time-uniformity, and that is precisely why it gives the cleanest results. Just outside it lies the *small-coupling* regime, where one surrenders the sign condition and buys back well-posedness with smallness instead. When the operator norm $\|\mathbb{W}\|$ falls below a horizon-dependent threshold (*(A-Coupling)*, proposition 24.18; static shadow theorem 20.14), the best-response map is a contraction and the contraction principle hands back a unique fixed point regardless of the coupling's sign — but only on a horizon short enough that the feedback has no room to compound. Contraction buys generality of sign at the cost of time, exactly the trade monotonicity declines to make. The two conditions overlap but neither contains the other, and — this is the content of section 31.2.1 — they do not meet: between them lies a band the LQG thread resolves exactly and the general theory cannot yet see. Beyond both is the *non-monotone, strong-coupling* regime, where the coupling has become a reinforcing force: agents want to do *more* of what the crowd does, a deviation can feed on itself, and the best-response map acquires several fixed points. Here uniqueness simply fails, equilibria multiply, and almost nothing is known in general — this is the regime of symmetry breaking and the home of section 31.2.2.

Axis 2: the network/limit regime. The second axis measures the structure of the interaction itself — which limit object the growing network converges to. The entire proved theory of Part IV lives at one end of it: dense graphons, bounded kernels, the compact metric space $(\widetilde{\mathcal{W}}_0, \delta_\square)$ of chapter 17. Density is not a cosmetic hypothesis; it is what makes $\mathbb{W}$ a bounded — indeed Hilbert–Schmidt — operator, with a discrete spectrum and a *finite* norm, and that single fact is what every estimate in Part IV silently rests on. The contraction thresholds of Axis 1, the tightness bounds behind finite-network convergence, the spectral reductions of the carried threads — all of them are statements about a bounded operator with a well-defined leading eigenvalue $\lambda_1 = \|\mathbb{W}\|$. But real networks are not dense. Social graphs, infrastructure grids, and contact networks keep a bounded average degree as they grow, carry heavy-tailed degree distributions, and concentrate a handful of hubs of vastly disproportionate connectivity — the *sparse and heavy-tailed* regime (L^p graphons, graphex limits) of chapter 27. There the kernel is unbounded, $\|\mathbb{W}\|$ may be infinite, and the dense machinery degrades in a way the mathematics only partly tracks: the very norm that set every threshold on Axis 1 ceases even to be finite. This axis is therefore not a technical refinement but the gap between the model's natural habitat and the place it is proved, and section 31.2.3 is where the gap bites hardest.

Axis 3: the noise regime. The third axis is the kind of randomness the agents face, and it controls how complicated the mean field itself must be. *Idiosyncratic* noise — an independent shock to each agent — is the best-understood case, for a structural reason worth stating: by the law of large numbers the aggregate of independent shocks is deterministic, so the mean field $\bar{m}_t$ is a fixed (if a priori unknown) trajectory and the equilibrium is a deterministic fixed point. *Common*, or aggregate, noise — a shock felt by everyone at once, the weather over a power grid or a macro shock to a market — breaks this: it does not average away, the mean field $\bar{m}_t$ becomes itself a random, dynamically moving object, and an agent must choose a strategy contingent on its entire future random path. That is exactly what the master equation was built to encode (section 12.7 and chapter 26), and it is why common noise *forces* the master-equation formulation rather than the simpler coupled PDE pair: the unknown is no longer a trajectory of measures but a function on the space of measures. Well-posedness here is known only in restricted regimes, and — crucially for what follows — the difficulty compounds with the other two axes rather than merely adding to them.

Place the three axes together and the proved theory of this book occupies a single corner of the resulting cube: *monotone* $\times$ *dense* $\times$ *idiosyncratic*, together with a controlled neighbourhood of it — the small-coupling slab reached off the monotone face, the cut-metric-stable neighbourhood reached off the dense face. Everything proved lives in that corner or just outside it. The open problems are the moves off the axes, and the organising claim of the chapter — the reason the frontier is genuinely hard and not merely unfinished — is that the moves *interact*. They are not independent difficulties one could clear one at a time. Relaxing monotonicity alone gives the threshold and selection questions of sections 31.2.1 and 31.2.2; relaxing density alone gives the sparse-limit questions; admitting common noise alone gives a harder but already-studied problem. The questions that matter for applications, however, sit where two or three relaxations are imposed at once, and there the obstructions *multiply* rather than add. The canonical example — the one we develop in section 31.2.3 — is the master equation with common noise on a sparse limit. Common noise forces the master-equation formulation (Axis 3); the sparse limit destroys the operator-norm bound that the master equation's well-posedness proof relies on (Axis 2); and the two failures are not separable, because the very estimate that common noise makes indispensable is the one the unbounded operator removes. Each relaxation attacks a *different* hypothesis of the *same* proof, so the combined problem is not two half-problems but one whole one with no known line of attack.

This is why the chapter's theory gaps are ordered as they are.

The four subsections that follow are precisely the four cardinal moves off this corner, taken in increasing order of how many axes they disturb, and together they make up the chapter's first organising question — what we cannot yet prove. Section 31.2.1 moves along Axis 1 alone, asking for the exact frontier between the two non-meeting sufficient conditions for uniqueness. Section 31.2.2 moves further along Axis 1, into the strong-coupling regime where uniqueness has already failed and the live question is which of the many equilibria is selected. Section 31.2.3 makes the two-axis move — noise and network at once — that the interaction principle has just singled out as the deepest. And section 31.2.4 adds a fourth axis the cube did not have, orthogonal to all three: not the dynamics of the game but the *information* an agent holds when it acts. With the map fixed, we can begin marking the gaps.

31.2 Theory gaps

The first of the four questions — what we do not yet know how to *prove* — is the natural place to begin, because it inherits the cleanest map. Section 31.1 placed the proved theory in a single corner of the monotone $\times$ dense $\times$ idiosyncratic cube, and the four subsections below are the four cardinal moves off that corner, taken in increasing order of how many axes each disturbs. The present one takes the gentlest move — a single step along Axis 1, the coupling — and finds that even there, with the network dense and the noise idiosyncratic and only the sign and strength of the interaction in play, the proved theory leaves a gap it cannot close. The discipline of the preamble applies to each: precise hypotheses, the nearest proved result on the known side, and the exact step of its proof that fails. We can hold this first gap to that standard with unusual precision, because the LQG thread hands us the answer the general theory is missing, written out in closed form.

31.2.1 Sharp uniqueness thresholds

Recall the two ends of Axis 1 that the landscape left facing each other without touching. The book proves two genuinely different uniqueness theorems for graphon mean field games, and the reason they do not meet is structural, not an artefact of looser constants. Monotonicity (theorem 24.16) asks the coupling to act as a restoring force — formally, the Lasry–Lions sign condition $s\langle \Delta, \mathbb{W}\Delta\rangle \le 0$ on every displacement Δ, which for a positive graphon $\mathbb{W} \succeq 0$ is just $s \le 0$ — and in return delivers uniqueness for *all* horizons, with no smallness assumed: time cannot help a deviation compound when each step of the feedback is sign-suppressed. Contraction (proposition 24.18; static shadow theorem 20.14) makes the opposite bargain. It surrenders the sign condition entirely — the coupling may push either way — and buys uniqueness back from operator-norm smallness $\|\mathbb{W}\| < \kappa$, but only on horizons short enough that the best-response feedback has no room to amplify; the admissible κ shrinks as T grows. Neither hypothesis contains the other: monotonicity covers arbitrarily strong coupling of the right sign at arbitrarily long horizons, contraction covers either sign but only weakly and briefly. And precisely because one is a pure sign condition indifferent to strength while the other is a pure smallness condition indifferent to sign, there is a region caught by neither — coupling of the *wrong* sign (crowd-seeking, $s > 0$, so monotonicity fails) that is nonetheless not small enough for the contraction constant at the horizon of interest. The question of this subsection is what the exact frontier is in that region, and whether uniqueness in fact persists there. In the most explicit model in the book we can answer both questions completely, and the answer is yes.

Here is that answer, recalled with enough of its derivation to make the threshold land rather than merely appear. Take Thread B, the graphon LQG game (worked computation 24.22). For a frozen aggregate path the per-type problem is the scalar LQG problem of worked computation 11.7, whose value is quadratic with a *type-independent* Riccati curvature $P(t)$ — type-independent because only the linear coupling carries the type x, while the quadratic-in-state cost $\frac{q}{2}x^2$ is common to all agents. What remains coupled across types is the deterministic pair: the linear offset field $r_t \in L^2[0,1]$ and the closed-loop mean field $\bar{m}_t \in L^2[0,1]$, and they couple only through the aggregate $z_t = \mathbb{W}\bar{m}_t$. The diffusion σ feeds only the type-wise variance, an autonomous equation decoupled from the coupling, so uniqueness is decided entirely by that field pair. Now expand both fields in the eigenbasis (λ_k, ϕ_k) of $\mathbb{W}$. Because $\langle \mathbb{W}\bar{m}_t, \phi_k\rangle = \lambda_k \langle \bar{m}_t, \phi_k\rangle$, the projection onto each eigenmode *decouples*: mode k obeys exactly the scalar two-point boundary-value problem of worked computation 11.7, with the single substitution $s \mapsto s\lambda_k$ (eq. (24.10)). The continuum of coupled types has split into independent copies of the classical LQG game, one per eigenmode, the k-th running at effective coupling $s\lambda_k$. The classical game is non-unique exactly when its linearised forward–backward system has a resonant horizon, which happens iff the oscillation frequency $\Omega_k^2 = b^2 q\, s\lambda_k - A_\infty^2$ is positive, i.e. iff $s\lambda_k > 1 + a^2/(b^2 q)$ (here $A_\infty^2 = a^2 + b^2 q$). The graphon equilibrium is unique for all T iff *every* mode is subcritical; and for crowd-seeking coupling $s > 0$ the binding mode is the largest eigenvalue $\lambda_1 = \|\mathbb{W}\|$ (the spectral radius, by Perron–Frobenius for a nonnegative kernel, theorem 18.7), so the whole family of conditions collapses to one. This is proposition 24.23:

$$s\,\lambda_1 \;\le\; 1 + \frac{a^2}{b^2 q} \qquad \Longleftrightarrow \qquad \text{uniqueness for all } T, \tag{31.1}$$

with $\lambda_1 = \|\mathbb{W}\|$ the leading eigenvalue and ϕ_1 the eigenvector-centrality mode of chapter 18.

Read eq. (31.1) against the two general theorems and the gap becomes a definite strip of parameter space. For $s \le 0$ the threshold is implied by monotonicity — the restoring sign already gives it, and indeed $\Omega_k^2 \le -A_\infty^2 < 0$ for every mode. But for $0 < s\lambda_1 \le 1 + a^2/(b^2 q)$ the inequality holds with monotonicity *already failed*: the coupling is crowd-seeking, the global form $s\langle \Delta, \mathbb{W}\Delta\rangle$ is positive, no horizon-free monotonicity argument applies, and yet the equilibrium is unique for every horizon. The contraction theorem does not reach this strip either: its smallness hypothesis confines it to a region strictly inside the monotone-or-small slab, well below the leading eigenvalue, so it never enters the band. Concretely, take the rank-one kernel $W(x,y) = f(x)f(y)$ with $\lambda_1 = \|f\|_{L^2}^2$ and set $a = 0$: the threshold is $s\lambda_1 \le 1$, and the entire interval $0 < s\,\|f\|_{L^2}^2 \le 1$ of crowd-seeking couplings is a regime where uniqueness is a theorem but *neither* general sufficient condition can see it. Even in the cleanest worked example in the book, the two proved routes leave a band uncovered that the explicit computation fills exactly.

Open problem 31.1. *(Sharp uniqueness threshold.)* For the graphon mean field game with a fixed convex Hamiltonian, nondegenerate diffusion, and a smooth (possibly non-monotone) graphon coupling, identify a verifiable condition — presumably a joint condition on the second variation of the cost and the spectrum $\{\lambda_k\}$ of $\mathbb{W}$ — that is *necessary and sufficient* for uniqueness of the equilibrium for all horizons, recovering eq. (31.1) in the LQG case.

What is known bounds the problem tightly from both sides, which is exactly why it is ripe: the LQG computation is not a curiosity but a calibration, fixing the answer the general condition must reproduce. It rules out both naive candidates at once. The answer cannot be the monotonicity sign condition alone, because that condition is sufficient but demonstrably not necessary — the band $0 < s\lambda_1 \leq 1 + a^2/(b^2 q)$ is the explicit witness. And it cannot be an operator-norm bound alone, because in the LQG case the norm is not the binding object in any horizon-dependent combination: what binds is the single leading eigenvalue λ_1 weighted against the diffusion-and-state data through $1 + a^2/(b^2 q)$, a *mode-by-mode* criterion, not a global norm.

That last contrast is the structural obstruction, and it is worth naming precisely because it tells us which tool the general problem will need. The Lasry–Lions duality identity behind theorem 11.5 is an integration-by-parts that controls a *global* bilinear pairing: it bounds the squared distance between two candidate equilibria by s times the pairing $\langle \Delta, \mathbb{W}\Delta \rangle$ of the full population displacement $\Delta = m_1 - m_2$ against itself through the coupling, and concludes uniqueness when that pairing has a definite sign for *every* Δ. By construction this argument is blind to two things the LQG threshold exploits. It is blind to the spectral decomposition — it asks for the sign of the form on all of L^2 at once, so a single positive eigenmode $\lambda_1 > 0$ already spoils it, even though the other modes are harmless and the dynamics couple them independently. And it is blind to the parabolic regularisation: the extra room $a^2/(b^2 q)$ in the threshold is precisely the margin the state feedback and the nondegenerate diffusion buy back over a finite horizon, a margin the static sign condition discards by never looking at the horizon at all. The genuinely sharp criterion must therefore be local, not global — it must read off, mode by mode, when the equilibrium becomes unstable. The object that does this is the linearisation of the forward–backward system around a candidate equilibrium: uniqueness fails exactly when that linearisation acquires a nontrivial kernel, a nonzero homogeneous solution at a resonant horizon, which in the LQG case is precisely the condition $\Omega_k^2 > 0$ realised at $\tan(\Omega_k T) = \Omega_k / A_\infty$. This linearised forward–backward operator is the fluctuation operator of section 31.5, and its non-invertibility is the susceptibility $(\mathrm{Id} - \mathcal{G})^{-1}$ blowing up — the thread that the synthesis will pull through every gap in this chapter. Recovering mode-by-mode sharpness for a *nonlinear* coupling means controlling the spectrum of that operator without the luxury of the LQG diagonalisation, and that is the heart of Open problem 31.1.

The honest state of the art falls short of this on both sides of the inequality. On the sufficient side, the displacement-monotonicity refinements of chapter 12 (after Gangbo–Mészáros [75, 76]) genuinely enlarge the region: they ask for monotonicity along Wasserstein displacement geodesics rather than along the linear interpolation Lasry–Lions uses, which is a weaker demand and so covers couplings the classical sign condition rejects. But displacement monotonicity remains a *global* condition — a sign on a Hessian taken over the whole measure space — and inherits the same blindness: it does not localise to the leading eigenmode and is not known to capture the full parabolic margin, so it is not known to be sharp, and in particular it is not known to recover the exact band eq. (31.1) in the LQG case. On the necessary side there is simply no general result at all: no verifiable condition is known whose failure forces multiplicity. So Open problem 31.1 is open from both ends — the best sufficient condition is not proved tight, and no necessary condition exists to meet it — and the

LQG threshold stands in the middle as the only point where we know exactly where the line is.

That knowledge sets up the next question. The threshold eq. (31.1) is not just a boundary of a proof technique; it is a real transition in the game. Below it the equilibrium is unique; *at* it the linearised forward–backward operator first develops a kernel; and above it that kernel is a genuine second equilibrium. Once $s\lambda_1$ crosses $1 + a^2/(b^2 q)$ the crowd-seeking feedback compounds, the best-response map acquires multiple fixed points, and "is the equilibrium unique?" is answered — no — and replaced by a sharper one: of the several equilibria the game now admits, *which* is selected? That is where we turn next.

31.2.2 Non-monotone regimes and equilibrium selection

The previous subsection ended at a transition. Below the threshold eq. (31.1) the equilibrium is unique; at it the linearised forward–backward operator first develops a kernel; above it that kernel is a second equilibrium and the crowd-seeking feedback compounds into a whole family of them. So the question that organised the entire monotone theory — *is the equilibrium unique?* — has been answered in the negative and is no longer the right question to ask. Past the threshold it is replaced by a strictly harder one that the monotone theory never had to face: of the several equilibria the game now admits, *which* one does the system actually realise? This is the selection problem, and it is the first place in the book where existence and uniqueness no longer settle the matter — where, even with every equilibrium catalogued, one still has to say which is physical.

It pays to see the geometry of the multiplicity before hunting for a principle to break it, because the geometry is what every candidate principle will act on. The cleanest picture is the static rank-one shadow (section 20.7) of Thread B, where the entire population state collapses to the scalar order parameter $\varrho = \langle f, \bar{m} \rangle$ and the equilibrium condition is the single self-consistency equation $\varrho = h(\varrho)$, with $h(\varrho) = \mathbb{E}[f(x)\mathrm{br}_x(f(x)\varrho)]$ the population-averaged best response of section 31.5.1. In the symmetric case — no exogenous ideal-point field, $\eta \equiv 0$, so an agent has no private reason to prefer one sign of action over the other — the map h is odd, $h(-\varrho) = -h(\varrho)$, and the game carries a genuine $\mathbb{Z}_2$ symmetry $\varrho \mapsto -\varrho$ (flip every agent's action). The disorganised state $\varrho = 0$ is then always a fixed point. Its stability is governed by the slope $g = h'(0) = \mathsf{b}\,\mathbb{E}[f(x)^2] = \mathsf{b}\,\lambda_1$, the very strategic coefficient whose susceptibility $\chi = 1/(1-g)$ the worked computation of section 31.5.1 will show diverging as $g \uparrow 1$. While $g < 1$ the symmetric fixed point is the only one and it is stable; the instant g crosses 1 — exactly the LQG threshold of the preceding subsection, $s\lambda_1 > 1 + a^2/(b^2 q)$ specialised to the static shadow — the slope of h at the origin exceeds unity, $\varrho = 0$ turns unstable, and by oddness two new fixed points $\pm\varrho^*$ split off symmetrically. This is a *pitchfork bifurcation*: a single critical coupling at which one symmetric equilibrium gives way to a symmetric pair of broken-symmetry ones. It is the order-parameter form of the symmetry-breaking picture of section 11.4 — the multiplicity the homogeneous game develops at its discrete critical horizons eq. (11.14) — now read off a single scalar.

What the graphon adds, and the reason this is not merely the homogeneous story retold, is *which direction in population space the broken state points along.* In the rank-one case the bifurcating solution is supported on f, that is on the leading centrality mode ϕ_1 (proposition 24.23): the population does not break symmetry uniformly but preferentially along its most central eigenvector, the high-centrality hubs swinging first and the rest following in proportion to their ϕ_1-weight. Symmetry breaking on a network has a *shape*, and that shape is spectral data of $\mathbb{W}$. The selection question therefore inherits a graphon refinement the homogeneous theory cannot pose: not only which of $\{0, \pm\varrho^*\}$ is realised, but — once several modes can break, as we discuss below — which *mode* carries the broken state. Note finally that the selection question is open already in the homogeneous case (W constant, a single mode); the graphon does not create the difficulty, it stratifies it.

With the geometry fixed, selection is the problem of breaking the degeneracy between the equally-admissible branches $\pm\varrho^*$ (and, off the rank-one case, among the several coexisting equilibria). The literature offers three candidate principles. None is a theorem in any generality; each is natural for a different reason, carries a different piece of partial evidence, and would become a theorem only by supplying a different missing ingredient. The point of laying all three side by side is that they are less rivals than three readings of one physical demand — that the idealised $N = \infty$ degeneracy is an artefact some infinitesimal real effect resolves — and in the rank-one case they can be compared by explicit computation.

The first is *vanishing-viscosity*, or *entropy*, selection, and it is the physicist's reflex: break a degeneracy by switching on an infinitesimal field, see which state it favours, and then send the field to zero. Here the "field" is an extra dose of idiosyncratic noise — equivalently, an entropic regularisation of the agents' control problem — which smooths the value function, rounds the corners of the best-response map, and renders the regularised game uniquely solvable; one then removes the regularisation and asks which equilibrium of the original game the unique regularised solution converges to. The intuition is exactly that of selecting a Gibbs state by a vanishing symmetry-breaking term, and where the game has a variational (potential) structure it works: the regularised equilibrium is the minimiser of a perturbed energy, and in the limit it selects the global minimiser among the candidates. This is proved in special finite-state potential games. Its limitation is precisely the demand for that structure: a general graphon mean field game is not a potential game, the vanishing-viscosity limit need not be unique, and there is no energy whose minimiser the procedure is known to track. Turning it into a theorem would require either exhibiting the variational structure (a Lyapunov functional for the regularised flow) or a direct large-deviations argument that the regularised invariant measure concentrates on one branch.

The second is *common-noise* selection, and it is the sharpest concrete conjecture in the area — sharp because it predicts not just *that* selection occurs but *by what mechanism*. Switch on a small *common* noise: a shock felt by everyone at once which, by the structural distinction drawn in section 31.1, does not average away but makes the mean field itself a random, dynamically moving object. The order parameter ϱ is then no longer pinned at a fixed point but performs a diffusion in the double-well landscape whose minima are the broken branches $\pm\varrho^*$, and the common noise continually shakes it across the saddle at the origin. The conjecture is that this "smears" the pitchfork: for any positive noise level the equilibrium is again unique — now a single *random* equilibrium, a law on order-parameter paths rather than a pair of fixed points — and the sharp content is what that random equilibrium converges to as the noise vanishes. This is established rigorously in the two-state mean field game of Cecchin, Dai Pra, Fischer and Pelino [46], where the master equation can be written out and shown to remain well-posed through the transition, and in a handful of related finite-state models. Whether common noise *generically* restores uniqueness — in particular for a continuum of types — is open. What it would take to make it a theorem is named by the mechanism itself: the common-noise equilibrium is encoded by the master equation, so one must show that equation stays well-posed as the coupling is driven through the bifurcation, exactly where its characteristics — the forward–backward system whose linearisation is losing invertibility — threaten to cross. That requirement is the explicit hand-off to section 31.2.3.

The third is *stability*, or *learnability*, selection, and it is attractive for a reason orthogonal to the other two: it ties the choice of equilibrium to computation. Declare physical only those equilibria that are *attracting* fixed points of a natural adjustment dynamics — best-response iteration, or its averaged cousin fictitious play — the rationale being that an equilibrium no plausible learning process can reach is one no real population of boundedly-rational agents would ever settle into. In the rank-one pitchfork this principle is completely explicit and agrees with the other two: the symmetric fixed point $\varrho = 0$ has best-response slope $g > 1$ above threshold, so it *repels* — a small perturbation grows under iteration — while the broken branches $\pm\varrho^*$ have slope $h'(\varrho^*) < 1$ and *attract*. Stability selection therefore discards the symmetric equilibrium as unphysical and keeps the broken pair, exactly as vanishing-viscosity and common noise do, which is strong circumstantial evidence that in this case all three principles coincide. This is also the principle implicit in the learning algorithms of chapter 29, and that is at once its appeal and its current limit. Its appeal is that it makes selection a corollary of which fixed point an algorithm finds; its limit is that the scope is unproved — best-response iteration need not converge at all in the strong-coupling regime (it can cycle or wander rather than settle), the basin structure off the rank-one case is uncharted, and which equilibrium a given learning rule selects past the contraction threshold is itself open (Open problem 31.6). Making it a theorem means proving a joint convergence-and-selection statement for a learning dynamics in exactly the non-contractive regime where convergence is hardest to come by.

These three readings coincide in the rank-one scalar case and may well diverge once several modes compete, which is the strongest reason to demand the rank-one case be settled first: there, and only there, can the candidate principles be checked against one another by an explicit computation rather than against intuition. That is what the following problem asks.

Open problem 31.2. *(Equilibrium selection in the non-monotone regime.)* For the graphon mean field game above the critical coupling of eq. (31.1), determine whether (i) an arbitrarily small common noise restores uniqueness of the equilibrium, with the graphon master equation of chapter 26 remaining well-posed across the bifurcation; and (ii) the selected equilibrium coincides with the limit of best-response learning dynamics. Resolve the rank-one LQG case first, where the bifurcation is a single scalar pitchfork on the order parameter ϱ (section 31.5) and the question is fully explicit.

The graphon layer adds a genuinely new feature here, absent from the homogeneous theory, and it deserves to be drawn out because it is the part of the selection problem with no classical precedent. Recall from the threshold subsection that the mode decomposition diagonalises the linearisation: mode k runs at effective coupling $s\lambda_k$ and goes unstable when $s\lambda_k$ crosses $1 + a^2/(b^2q)$, i.e. at the critical coupling $s_k = (1 + a^2/(b^2q))/\lambda_k$. Because the eigenvalues are ordered $\lambda_1 \geq \lambda_2 \geq \cdots$, these critical couplings are ordered the other way, $s_1 \leq s_2 \leq \cdots$: as one turns up the overall coupling strength s the modes do not all go unstable at once but in succession, the leading centrality mode

ϕ_1 first, then ϕ_2, then ϕ_3, each at its own threshold. The non-monotone graphon game therefore exhibits not a single bifurcation but a *cascade* of them — a sequence of pitchforks, one per eigenmode, spaced along the coupling axis by the spectrum of $\mathbb{W}$. There is no homogeneous analogue because the homogeneous game is the single-mode case (a constant graphon has one nonzero eigenvalue); the cascade is entirely a creature of the spectral spread of the network, and the *spectral gap* $\lambda_1 - \lambda_2$ is exactly what sets how cleanly separated its first step is. When the gap is large the first bifurcation is isolated and mean-field-like — a single mode condenses well before any other can — and the rank-one reduction is essentially exact near s_1; when several eigenvalues cluster, several modes destabilise almost together and the cascade steps overlap.

Where the steps overlap, the modes interact, and this is the genuinely hard and genuinely new part. The successive bifurcations are not independent scalar pitchforks bolted side by side, because the bifurcation is governed by the *nonlinear* self-consistency map, not its linearisation. Once ϕ_1 has condensed, the population sits on a broken background $\varrho_1^*\phi_1$, and the second mode ϕ_2 does not bifurcate off the trivial state but off that background: its effective threshold is shifted by the ϕ_1-condensate through the nonlinearity, exactly as a symmetry-breaking field shifts a secondary transition. A selection theory in this regime must therefore answer not only *which* equilibrium and *which* mode, but how the already-broken modes renormalise the thresholds and shapes of the modes that break later — the mode-coupling problem. This is precisely the bookkeeping the physicist's diagrammatics is built for: the condensate of ϕ_1 enters the ϕ_2 equation as a tree-level vertex correction, and the systematic expansion in the eigenmode amplitudes is the natural language for the cascade. It is the clearest target in the chapter for the diagrammatic methods of section 31.5, and the place where the rank-one scalar reduction must give way to a genuinely multi-mode analysis.

Two threads leave this subsection. The first is the hope that carried the common-noise principle: a small common noise may smear the cascade and restore a unique random equilibrium. That hope is only as good as the master equation that encodes the random equilibrium, and so it presupposes the master equation survives common noise through the bifurcation — which is the subject of section 31.2.3, where we ask exactly that well-posedness question. The second is the landscape's warning. Everything in this subsection has held the network dense and bounded so that $\mathbb{W}$ has the clean discrete spectrum $\lambda_1 \geq \lambda_2 \geq \cdots$ the cascade is built on; but the applications that make the selection problem urgent — the anti-monotone epidemic and the conformity model of section 31.4 — live on *sparse* networks, where that spectrum may not even be well defined. Selection past the threshold (Axis 1) and the sparse limit (Axis 2) are then imposed at once, and as section 31.1 warned, the two-axis corners are where the difficulties multiply rather than add. The next subsection takes up that corner directly.

31.2.3 Master-equation well-posedness with common noise on sparse limits

The previous subsection closed on a hope and a warning, and this is where the two collide. The hope was that an arbitrarily small common noise might smear the pitchfork of section 31.2.2 — shaking the order parameter across the saddle at the origin and restoring a single *random* equilibrium in place of the degenerate pair $\pm\varrho^*$. But that hope was never free-standing: a random equilibrium is, by construction, a law on paths of the mean field, and the only object in this book that encodes such a law as a well-defined solution is the master equation. The hope therefore borrows against a prior question — *does the master equation remain well-posed once common noise is switched on and the coupling is driven through the bifurcation?* — and until that debt is paid the selection conjecture has nothing to stand on. The warning was the landscape's: the genuinely hard problems are not the single moves off the proved corner but the corners where two moves are imposed at once, because there the obstructions multiply rather than add (section 31.1). This subsection is the canonical two-axis corner, and the deepest theory gap in the chapter. We impose common noise (Axis 3) and a sparse limit (Axis 2) simultaneously, and we will see that each relaxation removes a hypothesis the other makes indispensable — so that the combined problem is not two half-problems but one whole one with no known line of attack.

Begin with why the master equation is forced here, because the whole difficulty is downstream of that one fact. Under idiosyncratic noise alone the law of large numbers flattens the aggregate: the population density $\bar{m}_t$ is a deterministic trajectory, and an equilibrium is a deterministic fixed point of the coupled Hamilton–Jacobi–Bellman/Fokker–Planck pair (chapter 11), the value function reacting to a mean field it can treat as known in advance. Common noise destroys exactly this (section 31.1): a shock felt by everyone at once does not average away, the mean field $\bar{m}_t$ becomes itself a random, dynamically moving object, and an agent can no longer optimise against a fixed future trajectory — it must choose a feedback strategy that hedges against the *entire random path* the mean field might follow. The coupled PDE pair cannot carry this, because its very form presupposes a deterministic forward density to integrate against. The master equation can, and this is the reason it exists (chapters 12 and 26): it lifts the whole equilibrium to a single deterministic function $U(t, x, \boldsymbol{m})$ of time, type, private state, and the *current* configuration $\boldsymbol{m}$ of the population, so that the value at any instant is read off the realised random measure rather than a predicted one. The randomness is then transported through U by Itô's formula along the stochastic flow of measures, and the price of that transport is a second-order derivative in the measure argument — the term that distinguishes the common-noise master equation from its first-order, idiosyncratic-only shadow. That second-order term is the entire locus of the difficulty that follows; everything below is an account of what happens to it when the two axes are relaxed.

The first relaxation: common noise on a continuum of types. In the homogeneous theory the common noise is a single scalar Brownian motion B_t^0 driving one random measure $\bar{m}_t$, and the second-order master-equation term is a single trace of the second Lions derivative against a finite-dimensional covariance — delicate, but a closed and now well-understood object (chapter 12). The graphon changes the kinematics of the noise itself. The mean field is no longer one measure but a whole *field* of them, $x \mapsto m_t^x$, one population per type; and the natural aggregate shock is type-dependent — the weather is not the same over every node of a power grid, a macro shock hits sectors unequally — so the driving noise is a distinct shock per type, correlated across types through the kernel W. A type-indexed family of Brownian motions correlated by a kernel is, in the continuum limit, a *cylindrical* or space–time noise over $[0, 1]$ whose covariance operator is built from W: an infinite-dimensional driving noise. The field of measures is then the solution of a stochastic flow that is morally an SPDE over the type interval, and the clean scalar picture — one Brownian motion, one well at $\pm\varrho^*$, one diffusion across the saddle — is replaced by an infinite family of coupled wells exchanging probability through W.

This is what forces the delicacy in the phrase *random measure-valued maps with the right adaptedness*, and it is worth unpacking slowly because even *stating* the well-posedness problem requires getting it right. The unknown population state is, for each realisation ω of the common noise, a field of measures $x \mapsto m_t^x(\omega)$ — an element of the field space $\boldsymbol{\mathcal{P}}_2$ of chapter 26 — and as ω varies it is a random element of that space. So the state lives in $L^2(\Omega; \boldsymbol{\mathcal{P}}_2)$, or rather in a subspace of it cut out by two consistency demands that pull against each other. The first is *adaptedness*: at time t the configuration $m_t^{\cdot}$ may depend on the common shocks observed up to t but not on those still in the future — agents condition on the weather they have seen, not the weather to come — so $m_t^{\cdot}$ must be measurable with respect to the common-noise filtration $\mathbb{F}_t^0$, and the whole path must be progressively measurable. The second is *regularity in the type variable*: the map $x \mapsto m_t^x(\omega)$ must, realisation by realisation, remain a bona fide element of $\boldsymbol{\mathcal{P}}_2$ — measurable and square-integrable over types in the L^2-Wasserstein-over-types metric d_2. The tension is that the noise correlates these two structures: the same kernel W that couples the wells across types also couples the per-type filtrations, so one cannot build adaptedness type by type and measurability over types separately and hope they agree. Choosing the topology on this space, the precise filtration, and the regularity class in x so that the stochastic flow is well-defined and the fixed point lives in the same space is not a formality; it is the first third of the problem, and it has no counterpart in the homogeneous theory where there is a single filtration and no type axis at all. On top of it, the second-order master-equation term — the one Itô produced — is now no longer a scalar trace but an *operator* on this infinite-dimensional space: the second Lions derivative $\partial_{\boldsymbol{mm}}^2 U$ paired against the type-indexed noise covariance, the latter carrying W. Even the notion of a classical solution must be re-posed around derivatives of this operator kind.

The second relaxation: the sparse limit. The dense theory of Part IV rests, at every step, on one quiet fact: $\mathbb{W}$ is a bounded — indeed Hilbert–Schmidt — operator with a finite norm $\|\mathbb{W}\| = \lambda_1$. The sparse and heavy-tailed limits of chapter 27 (L^p graphons, graphex) remove it. There the kernel is unbounded, hubs of unbounded degree appear, and $\|\mathbb{W}\|$ may simply be infinite. The damage is structural rather than cosmetic, because $\|\mathbb{W}\|$ is the single constant every controlling estimate in Part IV is written in terms of. The contraction route to existence and uniqueness needs $\|\mathbb{W}\| < \kappa$ for the horizon-dependent threshold κ of *(A-Coupling)* (proposition 24.18); when $\|\mathbb{W}\| = \infty$ that condition is vacuous and the critical-coupling thresholds of Axis 1 degenerate to nothing. The convergence-from-finite-N route needs the same norm to bound the tightness estimates (chapter 25); it too loses its constant. And the per-type uniform bound of lemma 24.6 — the estimate that controls each agent's aggregate exposure $(\mathbb{W}\bar{m})(x)$ *uniformly in the type* x, so that no single agent feels an unbounded crowd — fails precisely at the hubs, where the unbounded degree lets the aggregate exposure diverge. Every threshold, every contraction constant, every uniform-in-type bound was a statement about a finite operator norm, and the sparse limit is exactly the regime where that norm is gone.

Now the two relaxations meet, and the reason this corner is harder than the sum of its parts becomes visible. The common-noise master equation needs operator-norm control more than the deterministic theory does, not less: closing the second-order term — bounding the new operator coefficient $\partial_{\boldsymbol{mm}}^2 U$ against the W-weighted noise covariance — and then closing the fixed point that defines U both run on estimates whose controlling constant is $\|\mathbb{W}\|$. The sparse limit removes that constant. So the very estimate that common noise makes *indispensable* is the one the unbounded operator *deletes*: the two relaxations attack different hypotheses of the same proof, and the combined problem has no remaining line of attack rather than two separate ones. This is the precise sense in which the obstructions multiply.

Open problem 31.3. *(Master equation with common noise on sparse limits.)* Formulate and prove well-posedness of the graphon master equation with common noise when the limit object is an L^p graphon or a graphex with unbounded operator $\mathbb{W}$. Identify the replacement for the operator-norm smallness condition *(A-Coupling)* — presumably a condition on the degree distribution or on an L^p rather than $L^2 \to L^2$ norm — under which a unique classical (or suitably weak) solution exists.

This is the hardest problem on the list and the most consequential, because it is the regime of every realistic application in section 31.4: real social and infrastructure networks are sparse, carry heavy-tailed degree distributions, and are subject to correlated aggregate shocks — all three of the features the two relaxations encode, present at once. The honest state of the art is that the two relaxations are understood only *separately*, and in each case the other axis has been trivialised away. On the common-noise side, the well-posedness of the master equation under aggregate noise is by now classical for *homogeneous* mean field games — a single representative agent, a single random measure $\bar{m}_t$ on $\mathbb{R}^d$, a finite-dimensional driving noise, and no kernel at all — through the work of Carmona and Delarue [41] and Ahuja [4]; there is no type continuum to make the noise infinite-dimensional and no operator $\mathbb{W}$ whose norm could be infinite. On the sparse side, Bayraktar, Wu and Zhang [16] control interacting particle *systems* on sparse graphon limits — propagation of chaos and well-posedness of the forward McKean–Vlasov dynamics on an unbounded kernel — but *without the strategic fixed point*: there is a prescribed forward flow and no Hamilton–Jacobi–Bellman equation, no optimisation, no equilibrium to close. Each programme solves one axis by setting the other to its trivial value, and neither toolkit's hypotheses survive contact with the other problem: the homogeneous master-equation estimates assume the finite norm the sparse limit destroys, and the sparse-system estimates never have to close a backward equilibrium equation at all. Their combination has, at present, no theory.

The gap is deep enough that even the first sanity check is itself a research project: we do not have a worked LQG example in this corner. One might expect Thread B to hand it over for free, as it has handed over every other threshold in the chapter — but here the very tool that made the graphon LQG game explicit is unavailable. The mode decomposition of worked computation 24.22 diagonalises the problem by expanding in the eigenbasis (λ_k, ϕ_k) of $\mathbb{W}$, and the rank-one reduction collapses everything to the scalar order parameter ϱ precisely because $\lambda_1 = \|f\|_{L^2}^2$ is finite and isolated. On an unbounded sparse operator the spectrum need not be discrete or even bounded, so the diagonalisation that turned a continuum of coupled types into one scalar pitchfork no longer applies, and the order-parameter picture that organised section 31.2.2 has no obvious analogue. Constructing a tractable instance in this corner therefore means doing genuine work before any computation begins: specifying the type-dependent common noise and its W-built covariance operator, fixing the adapted solution space of random measure-valued fields, choosing an unbounded kernel whose stochastic forward–backward system can still be solved in closed form, and only then reading off whether common noise restores uniqueness. Each of those steps is a small theorem in its own right. That a problem the dense theory answers in a single line of mode algebra should, off the dense axis, require a research programme merely to pose a solvable example is the sharpest measure of how far this corner sits from proved ground.

This corner is also not the end of the relaxations. We have moved off two axes — the noise and the network — while holding fixed an assumption so far left implicit: that an agent, however random and however sparse its environment, at least *observes* that environment exactly, seeing its own state and the realised aggregate $\mathbb{W}\bar{m}_t$ without error. Drop that, and a fourth axis opens, orthogonal to the three of the cube: the information the agent holds when it acts. Layered on top of the sparse common-noise corner, it produces the genuinely hardest case the book can name — agents who must *filter* a hidden, randomly-moving aggregate through a sparse network they only partially observe — and it is the subject we turn to next.

31.2.4 Partial information: the observation axis

The previous subsection ended by naming the assumption it had left standing. We had moved off the noise axis and the network axis at once and reached the chapter's deepest two-axis corner, but throughout we kept silently granting the agent one thing: that however random its environment and however sparse its network, it at least *sees* that environment without error — its own state and the realised aggregate $z_t = \mathbb{W}\bar{m}_t$, read off exactly at every instant. Drop that grant and a fourth axis opens, and it is orthogonal to the three of the cube in a precise sense: it concerns not the *dynamics* of the game — not the strength of the coupling, the structure of the network, or the kind of noise — but the *information* an agent holds when it acts. This is the axis the heterogeneity review of chapter 30 isolated as its third, and which it explicitly carried forward to this chapter as an open direction (remarks 30.17 and 30.18). The present subsection is where that hand-off is paid out, and where the theory-gaps arc closes: it is the last of the four cardinal moves off the proved corner, and the one whose mathematics is least developed.

Begin with the contrast it relaxes, because the whole subsection is the cost of one idealisation. Every equilibrium constructed in this book is played by an agent with *full observation*: at time t a type-x agent knows its own private state X_t^x exactly and knows the aggregate $z_t = \mathbb{W}\bar{m}_t$ it is coupled to — either as a deterministic trajectory (idiosyncratic noise) or, under common noise, as the realised value of a random one (chapter 26). Its best response is computed against that perfectly known signal, and the fixed-point theorems of chapters 24 and 26 close the loop on exactly that information set. But full observation is an idealisation no application of section 31.4 actually enjoys. A firm in a market does not see the population distribution of its competitors' inventories; it sees a noisy price. A household on a power grid does not see the realised load field over every node; it sees a delayed, noisy meter reading of the local frequency. An individual in an epidemic does not observe the prevalence field $\bar{m}_t$; it observes a few infected contacts. In each case the agent receives a *noisy, partial signal* — of its own state, of the aggregate, or of both — and must *filter*: form a best estimate of the hidden quantities from the history of its observations, and act on the estimate. Two distinct inference problems are bundled here, and keeping them apart is the whole organising move of what follows: an agent may have to estimate *its own state* (a finite-dimensional filter, one hidden scalar or vector per agent), or it may have to estimate *the aggregate* $\mathbb{W}\bar{m}_t$ itself (an infinite-dimensional filter, a posterior over the entire field of populations). The first is benign; the second is where the theory runs out.

Chapter 30 settled the benign half completely, and it is worth recalling exactly *what* makes it benign, because the answer is the precise statement whose failure defines the open problem. In the linear–quadratic–Gaussian world — linear state dynamics, quadratic costs, Gaussian noise and a *linear-Gaussian* observation $\mathrm{d}Y_t^x = c(x)X_t^x \,\mathrm{d}t + \mathrm{d}V_t^x$ — the *certainty-equivalence separation principle* holds (proposition 30.16). Separation means the two problems an agent faces, estimation and control, decouple completely and are solved one after the other: the agent first runs a Kalman–Bucy filter (lemma 30.15) to compute the conditional mean $\hat{X}_t^x = \mathbb{E}[X_t^x \mid \mathcal{F}_t^{Y,x}]$ of its hidden state given its own observations, and then plays the *full-information* optimal feedback with the true state replaced by that estimate — it acts as if $\hat{X}_t^x$ *were* the state, with certainty. The reason this is exact and not an approximation is structural, and worth spelling out because every word of it is load-bearing. The conditional variance $P_t(x)$ of the filter obeys a *deterministic* Riccati equation (eq. (30.26)) that does not see the control at all: in the linear-Gaussian case how well the agent estimates its state is fixed in advance, independent of what it does, so there is no incentive to act in order to learn — no "dual effect." The quadratic cost then splits cleanly into a control-dependent term identical to the full-information cost written in $\hat{X}_t^x$, plus a control-*independent* estimation-error term $\int_0^T q(x)P_t(x)\,\mathrm{d}t$ the agent cannot influence and may ignore. Minimising the first gives back the original feedback evaluated at the estimate; the second is a fixed tax. And because the filter is unbiased, $\mathbb{E}[\hat{X}_t^x] = \mathbb{E}[X_t^x] = \bar{m}_t(x)$, taking expectations reproduces the *same* mean-field consistency equation as the fully observed game (proposition 30.16(iii)): partial information changes each agent's fluctuations but leaves the equilibrium mean field untouched. This is why chapter 30 files information heterogeneity as *composable* rather than as a genuine obstruction — in the clean case it multiplies onto the graphon structure without disturbing the fixed point at all.

Everything in that paragraph used, decisively, that the aggregate $z_t = \mathbb{W}\bar{m}_t$ is *deterministic* — so that an agent has only its own state left to estimate, never the population — and that the observation is *linear-Gaussian* — so that the posterior stays Gaussian and is summarised by its mean. Remove either hypothesis and the separation fragments, in two distinct ways that remark 30.17 flagged and we now develop, because the precise mechanism of each failure is what the open problem must confront. The first failure is *nonlinear observation*. If the signal is a nonlinear function of the state, or the state or noise is non-Gaussian, the conditional law is no longer Gaussian and is no longer captured by a mean and a variance: the sufficient statistic for the filter is the *entire* posterior distribution, an infinite-dimensional object evolving by a nonlinear stochastic PDE — the Zakai or Kushner–Stratonovich equation of nonlinear filtering. Two things break at once. The conditional variance is now random and *control-dependent*, so the dual effect returns: an agent can act to sharpen its own future estimates, and estimation no longer decouples from control. And the optimal feedback depends on the whole posterior, not on a single summary statistic, so "play the full-information policy at the estimate" is no longer even well posed — there is no single estimate, there is a distribution. Certainty equivalence fails not by a correction term but at its root.

The second failure is the deeper one for this book, because it is the one the graphon forces: the agent must filter the *aggregate itself*. Reinstate common noise (chapter 26), or a major player (chapter 30), and the aggregate $z_t = \mathbb{W}\bar{m}_t$ becomes random — the very hypothesis the separation principle leaned on is gone. An agent can no longer treat the population as a known forcing; it must *infer* the current configuration of the field of populations from its noisy local signal, which is a nonlinear filtering problem whose hidden state is the measure-valued field $x \mapsto m_t^x$ itself, an element of the field space $\boldsymbol{\mathcal{P}}_2$ of chapter 26. The agent's posterior is therefore a *law on the space of measures* — a random probability measure over $\boldsymbol{\mathcal{P}}_2$ — and this is exactly where the filtering problem couples to the master equation. Recall that the master equation lifts the equilibrium value to a deterministic function $U(t, x, \boldsymbol{m})$ of the *current* configuration $\boldsymbol{m}$ (chapter 26 and section 31.2.3); under full observation the agent simply evaluates U at the realised $\boldsymbol{m}$. Under partial observation it cannot, because it does not know $\boldsymbol{m}$ — it knows only its conditional law π_t given its observations. The value it acts on is then the *posterior average* of the master field, $\int U(t, x, \boldsymbol{m})\, \pi_t(\mathrm{d}\boldsymbol{m})$, and the belief π_t is itself the solution of a Zakai/Kushner equation on $\boldsymbol{\mathcal{P}}_2$ driven by the observations and transported by the same stochastic flow of measures the master equation encodes. The master equation and the filtering equation are now coupled forward and backward: the master field supplies the dynamics the filter must track, and the filter supplies the belief at which the master field must be evaluated to produce the control that closes the equilibrium. Neither can be solved without the other, and the clean "filter, then play the full-information policy" sequencing — the entire content of separation — has dissolved into a single coupled system on the space of measures.

There is, however, a reason to expect that separation can sometimes be recovered *approximately*, and pinning down when is itself part of the open problem; the heuristic is worth giving because it is exactly the place the spectral data of $\mathbb{W}$ re-enters. The aggregate an agent must filter is not an arbitrary random field but $\mathbb{W}\bar{m}_t$, the population averaged through the kernel, and averaging suppresses randomness. On a densely connected network an agent is coupled to the crowd through many nearly-independent channels, so by the same law-of-large-numbers mechanism that made idiosyncratic mean fields deterministic (section 31.1), the realised aggregate carries only a small residual fluctuation around its mean — it is *nearly* deterministic and hence *nearly* observable, and the deterministic-aggregate separation of proposition 30.16 should hold up to an error set by the size of that residual. The size of the residual is spectral. The leading eigenvalue $\lambda_1 = \|\mathbb{W}\|$ fixes the scale on which the aggregate responds, and the spectral gap $\lambda_1 - \lambda_2$ fixes how nearly the aggregate collapses onto the single centrality mode ϕ_1: when the gap is large, $\mathbb{W}\bar{m}_t$ is effectively the one scalar order parameter $\varrho = \langle f, \bar{m} \rangle$ of section 31.5, which an agent can track with a *one-dimensional* filter, and the approximate-separation error should scale with the observation-noise level and with the inverse gap $(\lambda_1 - \lambda_2)^{-1}$ — small gap, many competing modes, poor scalar summary, large separation error. This is the conjectural shape of an approximate-separation theorem: certainty equivalence survives, with a quantitative defect controlled by the observation noise and the spectral data of $\mathbb{W}$. It is a conjecture, not a theorem; we state it as the target the open problem should aim at, and note that it is precisely the kind of statement the susceptibility thread of this chapter predicts, since a vanishing spectral gap is one of the ways the fluctuation operator of section 31.5 loses control.

Now collide this axis with the corner of the previous subsection and one reaches the hardest case the book can name — the one remark 30.18 singled out as canonical. Take a *major player* carrying a hidden state (the finite-rank atomic perturbation of the graphon, chapter 30), embedded in a *sparse* network (chapter 27), with the minor agents able to observe only noisy local signals and forced to *filter the major player's hidden state through the network*. Every axis is now disturbed at once, and they interact rather than add. The major player makes the minor field random (the common-noise/Axis-3 difficulty); the sparse limit removes the operator norm and the discrete spectrum the approximate-separation heuristic just leaned on (Axis 2 — there is no clean λ_1, no clean gap, so even the conjectural error bound has nothing to be written in terms of); and partial observation means the minor agents must infer the major's state, a nonlinear filter, with the information arriving *through* the network. On a sparse heavy-tailed graphon that last fact is itself a new phenomenon: the quality of each agent's information is heterogeneous in the same way its degree is, so the hubs filter the major's state sharply while the peripheral leaves barely see it, and the population's belief about the hidden aggregate is as heavy-tailed as the network. Separation fails on every count simultaneously, and there is at present no formulation, let alone a theorem.

Open problem 31.4. *(Graphon mean field game under partial information.)* Formulate the graphon mean field game in which each type-x agent observes only a noisy partial signal of its state and of the aggregate $\mathbb{W}\bar{m}_t$, and prove existence and uniqueness of the equilibrium when the linear-Gaussian separation of proposition 30.16 fails — nonlinear observation, or filtering of the aggregate field itself, which is a nonlinear (Zakai/Kushner) filtering problem coupled to the master equation of chapter 26. Resolve first the *canonical hard case* flagged in remark 30.18: a partially observed major player (the finite-rank atomic perturbation of the graphon, chapter 30) on a sparse graphon (chapter 27), where the minor agents must filter the major player's hidden state through the network. Characterise when a separation principle survives approximately, with an error controlled by the observation noise and the spectral data of $\mathbb{W}$.

This sits one axis beyond Open problem 31.3: it adds *informational* heterogeneity to the sparse, common-noise corner, and is the precise mathematical content of the hand-off chapter 30 makes to this chapter (section 30.3.2 and remarks 30.17 and 30.18). As chapter 30 stresses, the graphon abstraction is the economical container for *type* heterogeneity but says nothing on its own about *informational* heterogeneity; supplying that theory is open.

With this fourth axis the theory-gaps arc is complete. We have taken all four cardinal moves off the proved corner — a single step along the coupling axis (section 31.2.1), a longer one into the regime where uniqueness has already failed and selection takes over (section 31.2.2), the two-axis collision of noise and network (section 31.2.3), and now the orthogonal informational axis — and at every one the question we asked was the same: *can we prove the equilibrium exists, and is it unique?* That is the question the first thirty chapters were built to answer, and the four subsections have mapped exactly where the answer is still missing. But that question carries a silent presupposition, and it binds even inside the proved corner — the monotone dense idiosyncratic interior where every theorem of Part IV lives — because knowing that a unique equilibrium exists is not the same as holding it in hand. Dropping that presupposition is the work of the next section, and it changes the questions in kind: they stop asking whether the object exists and start asking whether we can *produce* it. We turn to that now.

31.3 Computation gaps

The theory-gaps arc closed by dropping a presupposition. For four subsections the question was always the same one the first thirty chapters were built to answer — *does the equilibrium exist, and is it unique?* — and the four cardinal moves off the proved corner mapped exactly where that answer is still missing. But the close of section 31.2.4 noticed that the question carries a silent assumption, and this section is where we drop it. Settling existence and uniqueness tells you that a number is there to be found; it does not put the number in your hand. An application does not consume a fixed-point theorem. It consumes the fixed point: the actual feedback a type-x agent should play at each state, the actual order parameter the population settles on, the actual aggregate trajectory $\mathbb{W}\bar{m}_t$ a planner must dimension a network against. The gaps of this section are about producing those objects, and they are a different kind of not-knowing from the theory gaps — not whether the object exists, but whether we can compute the object whose existence the previous section spent its length debating.

It is worth being precise about why a proof of existence is not yet a usable answer, because the gap is structural and not a matter of effort. The existence theorems of Part IV are won by fixed-point arguments — Schauder or Kakutani on the best-response map (chapter 22) — and a fixed-point theorem is, by its nature, non-constructive: it certifies that the map has a fixed point without exhibiting one, supplying neither an algorithm that reaches it nor a rate at which any candidate iterate approaches it. The uniqueness theorems sharpen *which* object exists but say even less about how to produce it. Where the best-response map happens to be a contraction — the small-coupling slab of *(A-Coupling)*, proposition 24.18 — existence and computation collapse into one statement, because Banach's theorem is itself the algorithm and iteration converges geometrically; but that coincidence is exactly the easy corner, and it fails the moment the coupling is strong, which is precisely where every interesting application lives. So the computation question is not downstream of the theory question. It is genuinely separate, and in one important respect it is more pressing. The theory gaps bind only *off* the proved corner; inside the monotone–dense–idiosyncratic interior, where every theorem of Part IV holds, there is nothing left to prove — and yet there is everything left to compute, because the equilibrium of even a perfectly well-posed game is a coupled forward–backward system in a high-dimensional state space that no closed form solves. A gap that bites even where the theory is complete is a gap an application cannot route around.

The section sorts the difficulty by how much of the problem is known, and the three subsections form a logical ladder. At the top rung the model is fully specified — dynamics, costs, and the graphon W all in hand — and the only question is cost: can the forward–backward system actually be discretised and solved at the scale real state spaces and real networks demand? That is the *scalable-solver* gap of section 31.3.1. Drop down a rung and the model itself is unknown, so there is nothing to discretise; the equilibrium must instead be *learned* from simulation or interaction, as in chapter 29, and the question becomes whether a learning rule can be guaranteed to converge to it — the *learning-with-guarantees* gap of section 31.3.2, where, tellingly, the same strong-coupling regime that breaks the contraction also breaks the learning dynamics, the critical point of the chapter surfacing yet again. Both of those rungs, however, take the graphon as given. The bottom rung asks the question logically prior to both: in an application the network is itself estimated, so *is the graphon even knowable* from the data the game produces — and in what sense, given that equilibria depend on W only through the aggregate $\mathbb{W}\bar{m}$ and only up to the relabelling ambiguity of chapter 17? That is the *identifiability* gap of section 31.3.3. Solve when you know the model and the graphon; learn when you do not; and, underneath both, ask whether the graphon was ever recoverable in the first place.

We take the rungs in that order, most concrete first. The most direct of the three is the top one, where everything is specified and only the arithmetic remains, so we begin there: granted the full model, can the coupled forward–backward system of chapter 28 be discretised at scale, and if not, what is the obstruction?

31.3.1 Scalable high-dimensional solvers

Take the top rung at its word. The model is fully in hand — dynamics, costs, and the graphon W all specified — so existence and uniqueness are settled and nothing remains to prove; what remains is to put the equilibrium in the planner's hand as an actual number, and the preamble's demand "we need a number" becomes the most direct question one can ask of the forward–backward system: can it be discretised and solved at the scale a real application sets? The honest answer is that, even inside the proved corner where every theorem of Part IV holds, it cannot — not by any method that scales — and the obstruction is worth dissecting because it is a clean instance of the curse of dimensionality compounded by the graphon's second grid.

Recall the apparatus. The solvers of chapter 28 attack the coupled Hamilton–Jacobi–Bellman/Fokker–Planck pair by discretising both continuous arguments at once: the private state, valued in $\mathbb{R}^d$, on a spatial grid and the type $x \in [0,1]$ on a second grid, with the nonlocal coupling operator $\mathbb{W}$ rendered as a quadrature over the type nodes. Of the two grids, the state-space grid is the binding constraint, and the arithmetic of why is brutal and exact. A tensor-product grid of M points per axis in $\mathbb{R}^d$ has M^d nodes; the value function and the density must each be stored and updated on all of them at every time step, so the cost is $O(M^d)$ in both memory and work. That exponential is the curse of dimensionality in its rawest form, and it is hopeless past $d \approx 3$: at a modest $M = 100$ a three-dimensional state already costs 10^6 nodes, a five-dimensional one 10^{10}, and a seven-dimensional one leaves the reach of any machine. Yet the applications that make the whole theory worth computing sit squarely in the regime the grid cannot enter. A power grid carries a storage state per participating asset, an epidemic model carries age and accrued-immunity structure on top of infection status, an economic model carries a multidimensional portfolio — all routinely moderate-to-large d, all far past the grid's ceiling. The state dimension alone is enough to defeat the naive solver, and it does so even where the theory is complete.

The graphon layer does not relieve this; it adds a second front. Where a homogeneous mean field game carries one value function and one density, the graphon game carries a whole field of them, one per type, so the type interval must itself be discretised into K nodes and the full $O(M^d)$ state solve repeated at each. Worse, the type nodes do not decouple. The coupling enters every agent's problem only through the aggregate $(\mathbb{W}\bar{m}_t)(x) = \int_0^1 W(x,y)\,\bar{m}_t(y)\,dy$, and that integral over y ties the population at type x to the population at *every* other type. Discretised, $\mathbb{W}$ becomes a dense $K \times K$ quadrature matrix, and forming the aggregate at all K type nodes is an $O(K^2)$ matrix–vector product executed at every time step of every forward–backward sweep. The nonlocality is the whole point of the model — it is what makes the network matter — but it is also what makes the type grid quadratic rather than linear, so the graphon contributes a second factor that compounds the state-space curse rather than competing with it.

Two partial routes exist, one for each front, and neither closes its gap. The first tames the type grid, and it does so exactly where the structure theory of chapter 19 promises it can. The weak regularity lemma says that any graphon is approximable in the cut metric, to any tolerance ε, by a step graphon of bounded complexity — a kernel constant on $O(\exp(\varepsilon^{-2}))$ type blocks, the bound depending on ε alone and not on the original kernel. A step graphon's operator has rank equal to its number of blocks, so the $K \times K$ quadrature collapses to a low-rank or block form: instead of resolving the aggregate at every one of K type nodes, one resolves it on the handful of blocks, and the $O(K^2)$ product becomes $O(K \cdot r)$ with r the effective rank. The block-graphon reduction of chapter 28 is exactly this collapse made operational. The rank-one case is its extreme: when $W(x,y) = f(x)f(y)$ the operator has a single nonzero eigenvalue $\lambda_1 = \|f\|_{L^2}^2$, the aggregate $(\mathbb{W}\bar{m}_t)(x) = f(x)\,\langle f, \bar{m}_t\rangle$ factorises through the one scalar $\langle f, \bar{m}_t\rangle$, and the entire type dependence of the coupling collapses onto that single number — the order parameter $\varrho = \langle f, \bar{m}\rangle$ whose susceptibility the worked computation of section 31.5.1 will compute in closed form. The type grid then disappears altogether: the coupling is carried by one scalar that every agent reads through its own $f(x)$, and the K-fold solve degenerates to a single self-consistent scalar iteration. This is why the rank-one reduction is the calibrating example of the whole chapter — it is the one case where the second grid is free, and it is the case to which every adaptive scheme should reduce when the spectrum cooperates.

What is missing is that this collapse is, at present, a structural possibility rather than a *certified* algorithm, and the gap between the two is the open problem. The weak regularity lemma is a qualitative existence statement: it guarantees a low-rank approximant exists but does not, given a target accuracy, tell the solver how many modes to keep, nor does it convert the resulting discrete solution back into a guarantee about the true continuum game. What an application needs is the quantitative, adaptive converse. The effective rank a solver should use is not a property of the kernel alone but of the kernel's spectral decay — the number of eigenvalues of $\mathbb{W}$ above a tolerance, read off the spectral data of chapter 18 — and a certified solver should measure that decay, retain exactly the modes the accuracy target requires, and *prove* that the truncation it chose is enough. The spectral gap $\lambda_1 - \lambda_2$ is the natural knob: when it is large a few modes (in the cleanest case, the single rank-one mode) capture the coupling and the reduction is nearly exact; when the spectrum clusters, many modes are needed and the adaptive rank grows accordingly. The crux, however, is the error certificate, and it is worth motivating why the cut metric is the right currency for it. The solver does not approximate the graphon for its own sake; it approximates it in order to produce an equilibrium, and what must be controlled is therefore not the kernel error but the *equilibrium* error — how far the population profile computed on the truncated kernel sits from the one the true continuum game would realise. The bridge between the two is exactly the cut-metric stability that runs through Part IV: equilibria are continuous in the graphon in $\delta_\square$ (chapters 24 and 25), so a cut-metric bound on the kernel truncation translates into a bound on the equilibrium it induces. An *a posteriori* bound — one computed from the truncated solution itself, after the fact, rather than assumed in advance — that reads $\|W - W_r\|_\square$ off the discarded spectral tail and propagates it through that stability estimate would certify the output as a genuine ε-equilibrium of the true game, not merely of the discretised surrogate. That certificate is the whole content of the open problem: not a faster solver, but a solver that knows, and can prove, how good its own answer is.

Open problem 31.5. *(Certified low-rank graphon solver.)* Design a forward–backward solver for the graphon mean field game system whose type-discretisation cost scales with the *effective rank* of $\mathbb{W}$ (the number of eigenvalues above a tolerance) rather than the number of type-grid points, with an a posteriori error bound in the cut metric $\delta_\square$ that certifies the output as an ε-equilibrium of the true continuum game. Prove a convergence rate in terms of the spectral decay of $\mathbb{W}$.

The low-rank route disposes of the type grid but leaves the state-space grid — the $O(M^d)$ curse that was the binding constraint in the first place — entirely untouched, and so a second, independent route is needed for the dimension that the graphon never touches. Here the only known way past the exponential is to abandon the grid: replace the value function and density by neural-network ansätze trained to satisfy the forward–backward system, trading a mesh whose cost is exponential in d for a parametric family whose cost is not. This deep-learning route is attractive precisely where the grid is hopeless, but it buys scalability at the price of the one thing the grid had for free — a guarantee. A neural solver returns a number, but whether that number is the equilibrium, and at what rate the training reaches it, is exactly the question a fixed grid never had to ask, because grid refinement converges by construction while gradient descent on a nonconvex loss does not. That guarantee is no longer a discretisation question but a learning question, and it is the issue the next subsection takes up directly: when the grid fails and one must instead learn the equilibrium from simulation, what can be *proved* about where the learning converges?

31.3.2 Learning with guarantees

The solver subsection ended by handing the deep-learning route over with its guarantee in question, and this subsection is where that question is faced. When the grid is hopeless — because the state dimension defeats every mesh, as section 31.3.1 showed, or because the dynamics and costs are themselves unknown and only a simulator is available — the only way left is to abandon solving for *learning*: replace the value function and the population flow by parametric ansätze and improve them from sampled play, exactly the programme of chapter 29. The trade the previous subsection named is now the whole subject. A neural solver returns a number at any state dimension, but whether that number is the equilibrium, and at what rate the iteration reaches it, is no longer settled by construction the way grid refinement was. It has become a convergence question about a dynamical system on the space of population flows, and the purpose of this subsection is to locate precisely where that question has a proved answer and where it does not.

The obstruction is structural, and it is the same tension that has organised the whole chapter, seen now from the algorithmic side. An equilibrium is a *fixed point*: the population flow $\bar{m}$ that, fed into every agent's optimal control, reproduces itself. The natural way to chase a fixed point is to iterate the map whose fixed point it is — best-respond to the current population, push the resulting actions forward to get a new population, repeat (definition 29.8). This converges, and converges geometrically, precisely when that best-response-and-push-forward map is a *contraction*; and the contraction modulus is governed by exactly the operator whose spectral radius this chapter is about.

In the language of theorem 29.10, fixed-point iteration contracts when the product of the coupling moduli falls below one (eq. (29.8)), and for the graphon game that condition is the operator-norm smallness *(A-Coupling)* of proposition 24.18: the best-response map's linearisation is the operator $\mathcal{G}$ whose iterates the susceptibility $(\mathrm{Id} - \mathcal{G})^{-1}$ sums, and the iteration is a contraction exactly when the spectral radius of $\mathcal{G}$ is below unity. But this is precisely the small-coupling or monotone regime in which the problem was *already* solved: there existence and uniqueness are theorems (theorem 24.16 and proposition 24.18) and the equilibrium can be produced by the very iteration whose convergence is in no doubt. The algorithm earns its guarantee exactly where the guarantee was not needed. Move into the regime that motivated the whole computational programme — strong, crowd-seeking coupling near or past the threshold eq. (31.1) — and the spectral radius of $\mathcal{G}$ reaches and crosses one, $(\mathrm{Id} - \mathcal{G})^{-1}$ ceases to be a convergent sum, and best-response iteration stops contracting. The learning algorithm fails to converge in exactly the regime where there is a genuine equilibrium one cannot otherwise find.

The rank-one static shadow makes this completely explicit, and it is worth pausing on because it shows the susceptibility of section 31.5.1 reappearing as the literal convergence rate of an algorithm. There best-response iteration is the scalar recursion $\varrho_{n+1} = h(\varrho_n)$ on the order parameter, with h the self-consistency map of sections 31.2.2 and 31.5.1 and, in the LQ case, the affine map $h(\varrho) = h_0 + g\,\varrho$ of slope $g = \mathsf{b}\,\lambda_1$. The iteration is a Picard iteration of an affine map, so its behaviour is read off the slope at a glance: the error contracts geometrically, $\varrho_n - \varrho^* = g^{\,n}(\varrho_0 - \varrho^*)$, the convergence rate is $|g|$, and summing the corrections to the fixed point reproduces the susceptibility $\sum_{n\geq 0} g^{\,n} = 1/(1-g) = \chi$. The susceptibility is thus not merely a fluctuation amplitude; it is the condition number of the learning problem, the factor by which the iteration amplifies a one-step error into a fixed-point error. As $g \uparrow 1$ the rate $|g|$ approaches one and the iteration slows to a crawl — the algorithmic face of critical slowing down, the same divergence of χ that section 31.5.1 reads as a diverging variance. And for $g > 1$, past the threshold, the map is expanding: $\varrho = 0$ repels, the iteration is driven away from the symmetric state, and where it lands (the broken branches $\pm\varrho^*$, which have $|h'(\varrho^*)| < 1$ and so attract) is exactly the stability-selection question of section 31.2.2. The micro-example already shows the two phenomena that the general problem must control — non-contraction near threshold and which basin the dynamics falls into past it — and shows them governed by the one scalar g.

The stabilisations used in practice all buy back convergence, and the point worth making precisely is *what each charges for it*, because the charge is never nothing. Fictitious play (definition 29.14) replaces "best-respond to the latest population" by "best-respond to the time-average of all past populations," damping the oscillation that defeats raw iteration (section 29.2.2); it provably converges, but the proof (theorem 29.15, after [38, 111]) runs on Lasry–Lions monotonicity — it buys convergence by reimposing the very sign condition the strong-coupling regime violates, so it does not reach past the threshold either. Online mirror descent (definition 29.17) is a policy-space gradient flow with the same standing: it converges (theorem 29.19, after [110]), again under monotonicity, and to a *regularised* equilibrium rather than the true one. That last clause is the second kind of charge, and it is the one entropic regularisation makes unavoidable. Adding an entropy bonus to each agent's control problem (definition 29.11) smooths the value function, renders the best response single-valued and Lipschitz (lemma 29.12), and so flattens the slope of $\mathcal{G}$ until the regularised map contracts *regardless of sign* — the regularisation is a contraction-buying device that works even where monotonicity fails. But its fixed point is the equilibrium of the regularised game, not the original one, and the two differ: remark 29.13 records the bias $\mathcal{E}(\pi^\star_\tau) \le c_0\,\tau\,(1+\log|A|)$, linear in the regularisation strength τ. One therefore converges — to the wrong equilibrium, by an amount one can shrink only by shrinking τ, which is exactly the knob that was buying the contraction. Every stabilisation trades the non-contraction of the interesting regime for either a monotonicity hypothesis that excludes it or a controlled error that does not vanish. Naming which trade is forced, and at what rate, in the strong-coupling graphon game is the content of the open problem.

Open problem 31.6. *(Learning past the contraction threshold.)* Give a learning algorithm for the graphon mean field game with a non-asymptotic guarantee of convergence to an ε-Nash equilibrium in a regime where best-response iteration does not contract — i.e. with $\|\mathbb{W}\|$ above the threshold of proposition 24.18 — and characterise which equilibrium it selects (cf. Open problem 31.2). Quantify the bias introduced by entropic regularisation as a function of the regularisation strength and the spectral gap of $\mathbb{W}$.

The two clauses of the problem after the convergence guarantee are not afterthoughts; they are where it connects to the rest of the chapter, and each deserves to be drawn out. The first — *which* equilibrium the algorithm selects — is the learnability-selection principle of section 31.2.2 read as a demand on a theorem rather than a hope. Past the threshold the game has several equilibria, and an algorithm that converges converges to one of them; *that* one is, by the stability-selection reading, the physical equilibrium, precisely because a population of adjusting agents could reach it. So a convergence theorem in the non-contractive regime does double duty: it certifies the algorithm *and* resolves part (ii) of Open problem 31.2, identifying the selected equilibrium as the limit of the learning dynamics. The danger the rank-one example already flagged is that the dynamics need not converge at all — it can cycle or wander rather than settle — so the selection it offers is conditional on a convergence one must first prove, in exactly the regime where convergence is hardest. The two open problems are therefore the same problem seen from two sides, and progress on either is progress on both.

The second clause — the entropic bias as a function of regularisation strength and spectral gap — is the quantitative heart, and the rank-one reduction shows why the spectral gap must appear. Regularisation flattens the strategic slope, replacing $g = \mathsf{b}\lambda_1$ by a reduced $g_\tau < g$; it buys contraction by pushing g_τ below one, and it perturbs the fixed point by an amount the susceptibility amplifies. To leading order the induced shift in the order parameter is $\varrho^*_\tau - \varrho^* \approx \chi \cdot (\tau\text{-perturbation of } h)$, so the bias carries a factor $\chi = 1/(1-g)$ that *diverges as the coupling approaches threshold*. Resolved mode by mode, each eigenmode k contributes a bias of order $\tau/(1-\mathsf{b}\lambda_k)$, and the total is dominated by the near-critical modes — those with $\mathsf{b}\lambda_k$ closest to one. The spectral gap $\lambda_1 - \lambda_2$ is exactly what decides whether one mode dominates that sum (a clean, mean-field-like bias set by the leading mode) or several modes pile up near criticality together (a bias inflated by the whole near-critical cluster). The trade then has a sharp and unpleasant form: to stabilise one needs τ large enough to force $g_\tau < 1$, hence $\tau \gtrsim (g-1)_+$, but the bias is at least $\tau \cdot \chi_\tau$, and near and past the threshold both the minimal stabilising τ and the residual susceptibility grow, so the unavoidable bias is bounded *below*. Remark 29.13 gives only the crude game-independent bound linear in τ; the open problem asks for the sharp two-sided estimate in which the spectral data of $\mathbb{W}$ enters, quantifying how the bias blows up as the gap closes — the precise price, in distance from the true equilibrium, of buying convergence by regularisation in the regime that needs it.

Layered on top of this classical tension is a difficulty the graphon contributes and the homogeneous theory never meets: *representation.* A learned policy in the graphon game cannot be a function of the agent's private state alone. By the structure of the model it must depend on the type x and on the nonlocal aggregate $(\mathbb{W}\bar{m}_t)(x) = \int_0^1 W(x,y)\bar{m}_t(y)\,dy$ that the type-x agent actually feels, so the function class the network parametrises must somehow encode the operator $\mathbb{W}$ itself — a high-dimensional, nonlocal object — or the policy cannot even express the dependence the equilibrium has. Representing $\mathbb{W}$ naively returns to the second grid of section 31.3.1 and its $O(K^2)$ cost. The cleanest current proposal sidesteps this with the same spectral idea that organised the solver and the threshold subsections: represent the population not by its full profile but by its projection onto the leading eigenmodes of $\mathbb{W}$, and let the policy network take those finitely many modal coordinates as input. This is precisely the spectral reduction of worked computation 24.22 pressed into service as an *architectural inductive bias* — the network is built to see only the few coordinates the coupling actually acts through, which is exact in the rank-one case (one coordinate, the order parameter) and an ε-truncation when the spectrum decays. What is missing is the guarantee that closes the loop with the previous subsection. A *sample-complexity theorem* — a non-asymptotic bound on the number of simulated trajectories needed to reach an ε-Nash equilibrium, scaling with the *effective rank* of $\mathbb{W}$ (its number of eigenvalues above tolerance) rather than the ambient dimension — would put learning on the same footing the certified low-rank solver of Open problem 31.5 puts gridded computation: both would then cost what the spectral decay of $\mathbb{W}$ says they should, one in samples and one in mesh, and both would carry a proof that the truncation they chose suffices. Establishing it would unify this subsection with the last under a single quantity, the spectral decay of the graphon, as the common currency of computational cost.

Every word of this subsection, and of the solver subsection before it, has rested on an assumption so basic it was never stated: that the operator $\mathbb{W}$ the architecture must encode, the spectrum the sample complexity is measured against, the kernel the aggregate $(\mathbb{W}\bar{m}_t)(x)$ is formed with, is *known*. In an application it is not handed down; it must be estimated from data, and that raises a question logically prior to learning the equilibrium at all — prior, indeed, to every computational question in this section — namely whether the graphon is identifiable from the data the application produces in the first place. That is where we turn next.

31.3.3 Identifiability of the graphon from data

The previous two subsections, and indeed every computational question in this section, rested on an assumption so basic it went unstated until the last paragraph forced it into the open: that the operator $\mathbb{W}$ a solver discretises, that a learner's architecture must encode, that forms the aggregate $(\mathbb{W}\bar{m}_t)(x)$ every agent reacts to, is simply *known* — handed down with the model. Every result in Part IV makes the same grant: the graphon W is given, and the only work is to solve, simulate, or learn the equilibrium it carries. In an application that grant is unwarranted. No one hands an economist the kernel of the trade network or a planner the contact graph of an epidemic; it must be *estimated* from whatever data the application produces. This is the third computation gap, and it is logically prior to the other two: before one asks how cheaply the equilibrium can be computed or learned, one must ask whether the object those computations take as input can be recovered at all. *Is the graphon even identifiable from the data?* The answer splits sharply in two, along a single fault line — whether or not the network itself is observed — and the two regimes are so different in character that conflating them is the main way the question is got wrong. We separate them deliberately.

Structural identification: the network is observed. Suppose the application hands us the network itself — the adjacency matrix of the realised finite graph $G(N, W)$, every edge between every pair of agents recorded. Then estimating W is no longer a game problem at all but a pure statistics problem: recover the kernel that generated an observed random graph. This is the *nonparametric graphon estimation* problem, and it is by now well charted. One treats W as an unknown function on $[0,1]^2$ and the observed adjacency matrix as $\binom{N}{2}$ independent Bernoulli draws with success probabilities $W(x_i, x_j)$ at latent type coordinates x_i; estimating the function is a two-dimensional nonparametric regression complicated by the fact that the design points x_i are themselves unobserved. The minimax rates are known. In the *dense* regime, where the edge probability stays of order one as N grows, the optimal mean-squared error decays like the usual two-dimensional nonparametric rate up to a network-size term (Gao, Lu and Zhou [77]); in the *sparse* regime, where the average degree grows slower than N and most of the matrix is zero, the rates degrade in a way that is also pinned down (Klopp, Tsybakov and Verzelen [87]). For the purposes of the map, the headline is that this corner is *solved*: when the network is observed, the graphon can be estimated consistently and at a known optimal rate, dense or sparse.

There is one catch, and it is not a defect of the estimators but a feature of the object, the very feature stressed in chapter 17. A graphon is identifiable only *up to a measure-preserving relabelling of the type interval.* Two kernels W and $W^\sigma(x, y) = W(\sigma x, \sigma y)$ related by a measure-preserving bijection σ of $[0, 1]$ generate exactly the same distribution of random graphs — relabelling the latent coordinates permutes which agent is called which but leaves every edge probability, and hence the whole law of $G(N, W)$, untouched. No amount of data can separate W from W^σ, because the data they produce are identically distributed. The estimable object is therefore not a labelled kernel but its *equivalence class* under relabelling — precisely a point of the quotient space $\widetilde{\mathcal{W}}_0$ under the cut metric $\delta_\square$ built in chapter 17. One should resist reading this as a limitation. For a mean field game it is exactly the right notion of identification, and the reason is the structural-stability theorem the book already proved: equilibria are $\delta_\square$-continuous (chapter 25), so two graphons at zero cut distance — the relabelling-equivalent ones — carry *the same game*, the same equilibria, the same aggregate dynamics. The information the estimator cannot recover, "which type is which," is exactly the information the equilibrium does not depend on. Estimating the graphon in $(\widetilde{\mathcal{W}}_0, \delta_\square)$ rather than as a labelled function is not a coarsening one tolerates; it is recovering the kernel in precisely the topology the strategic problem is continuous in, and no finer. The relabelling ambiguity and the cut-metric stability of equilibria are two faces of one fact, and structural identification fits the game like a key.

Behavioural identification: the network is hidden. Now remove the gift. In the realistic case one does *not* observe the network — contact graphs are private, trade relationships are inferred, the coupling of a financial system is never tabulated — and all one sees is the agents *behaving*: trajectories of their states or actions, that is, samples of the equilibrium itself. The task is to run the inference backward, from the equilibrium an unknown graphon induces to the graphon. This is an inverse problem for the coupled Hamilton–Jacobi–Bellman/Fokker–Planck system of chapter 11, and it is badly ill-posed — not merely hard to estimate with noisy finite data, but *non-identifiable even with infinite clean data*, for a structural reason that is worth making completely explicit because it is the crux of the whole subsection.

The reason is that the map from graphon to equilibrium factors through a drastic bottleneck. Trace how W enters the game: an agent of type x never feels the kernel pointwise, nor the configuration of any individual neighbour; it feels only the single aggregate field $(\mathbb{W}\bar{m}_t)(x) = \int_0^1 W(x,y)\,\bar{m}_t(y)\,dy$, the W-weighted average of the population, and its entire optimisation — its HJB equation, hence its optimal control, hence the forward density it contributes — depends on W *through that field and nothing else*. So if two graphons W and W' happen to produce the same aggregate field along the observed equilibrium, $(\mathbb{W}\bar{m}_t)(x) = (\mathbb{W}'\bar{m}_t)(x)$ for every type and every time on the realised trajectory, then they generate the same HJB equation, the same controls, the same forward dynamics — *the identical equilibrium trajectory*. No observation of states or actions, however rich, can tell them apart, because the data they produce are not merely similarly distributed but literally the same. The forward map $W \mapsto$ equilibrium collapses an infinite-dimensional kernel onto the low-dimensional, time-indexed aggregate the trajectories reveal, and any two pre-images of a given aggregate are behaviourally indistinguishable. This is genuine non-identifiability, a many-to-one in the model itself, categorically worse than the statistical noise that limits structural estimation: there the obstruction was a relabelling the game was indifferent to, here whole families of *inequivalent* graphons, far apart in cut distance, can be invisible behind one equilibrium.

The rank-one thread makes the collapse concrete and shows just how little of the kernel survives. Take Thread B's clean reduction $W(x,y) = f(x)f(y)$ (section 20.7). The aggregate the agents feel is $(\mathbb{W}\bar{m}_t)(x) = f(x)\langle f, \bar{m}_t\rangle = f(x)\,\varrho_t$, the product of the fixed profile shape $f(x)$ with the scalar order parameter $\varrho_t = \langle f, \bar{m}_t\rangle$ that organised the whole non-monotone analysis of section 31.2.2. Two things follow. First, the equilibrium's only contact with f is through this product, so the global *sign* of f is unrecoverable: the kernel $f \otimes f$ is itself invariant under $f \mapsto -f$, and the equilibrium sees f only up to that sign. Second, the closed self-consistency for ϱ_t involves f only through the single number $\lambda_1 = \|f\|_{L^2}^2$ — the leading eigenvalue, the same spectral datum that set the uniqueness threshold eq. (31.1) and the susceptibility $\chi = 1/(1-g)$. So even with the entire equilibrium observed forever and noiselessly, the only features of the rank-one kernel the data can pin down are one function (the profile f, up to sign) and one scalar (λ_1) — a one-function, one-parameter summary of an object that, as a labelled kernel on $[0,1]^2$, is infinite-dimensional. Everything else about W is behaviourally invisible. This is the same lesson the throughline keeps returning: the equilibrium reads the graphon only through its leading spectral data, and behavioural identification can recover only what the equilibrium reads — here, λ_1 and the centrality mode $\phi_1 \propto f$, no more.

Open problem 31.7. *(Behavioural identifiability of the graphon.)* Characterise the equivalence classes of graphons that induce the same equilibrium of the dynamic graphon mean field game, as a function of the cost structure. Determine when the leading spectral data $(\lambda_k, \phi_k)_{k\le K}$ — which is all the equilibrium can depend on through $\mathbb{W}\bar{m}$ — is identifiable from finitely many observed equilibrium trajectories, and give a consistent estimator with a rate, jointly accounting for the relabelling ambiguity of chapter 17 and the finite-network sampling error of chapter 25.

This closes the inventory of computation gaps, and with it the chapter's second organising question. Three times now — in the solver of section 31.3.1, the learner of section 31.3.2, and the identification problem just posed — the same quantity has stepped forward as the governing cost: the leading spectral data of $\mathbb{W}$. The solver pays in mesh for the eigenvalues it must resolve, the learner pays in samples for the modes its architecture must encode, and the identifier can recover only the spectral data the equilibrium exposes; the spectral decay of the graphon is the common currency of all three. What these gaps still lack is a *domain* that turns each abstract cost into one somebody actually pays — which the next section supplies. One of them reappears there with its sign reversed: the distributed-control and mechanism-design applications of section 31.4 do not estimate a given graphon from observed behaviour but *choose* a graphon to induce a desired behaviour, the same inverse problem on the same operator $\mathbb{W}$ run forward instead of back. Identification and design are adjoint, and the application frontiers pick up exactly that adjointness.

31.4 Application frontiers

We have now amassed, across two full sections, an inventory of what the theory cannot yet prove and what the computation cannot yet cheaply deliver — a uniqueness frontier the LQG thread can locate but the general theory cannot, a selection problem past it, a two-axis master-equation corner with no line of attack, an observation axis the cube did not have, a solver whose cost scales with spectral rank, a learner whose sample budget scales with the modes it must encode, an identification problem on the leading spectral data of $\mathbb{W}$. Stated this way the inventory is abstract: each gap is a deficiency of a method, measured against other methods. What none of them has yet been given is a *domain* — a setting that fixes which graphon, which cost, which regime is at stake, and so converts an abstract deficiency into a concrete cost somebody actually pays. That is the work of this section. The graphon mean field game is, at bottom, a tractable model of *strategic decisions coupled through a large structured network*, and that one description fits a handful of application domains exactly. We take four where the model is already in use, and in each we do not merely point to the domain but trace the chain from its mechanism to the precise piece of missing mathematics it demands — so that the frontier comes out a mathematical statement and not a wish, and so that the reader sees *why* the application forces exactly that gap and no other. The four sort themselves, not by accident, onto the four moves off the proved corner the chapter has been mapping.

Epidemics on networks. The first domain is the one where the coupling's sign does the work, and it is the cleanest because almost everything else is simple. An agent chooses a level of social activity, or of vaccination or protective effort; the risk it runs is the prevalence of infection among its network neighbours, which is exactly the graphon aggregate $(\mathbb{W}\bar{m}_t)(x)$ evaluated at the agent's type x; and its cost trades the private burden of caution against that risk of infection. The private state is not a continuum but a small finite set — the compartments susceptible / infected / recovered — so this is a *finite-state* graphon mean field game (Aurell, Carmona, Dayanikli and Laurière [9]), with the smallest state space and the most transparent coupling of any application in the book: the network appears once, linearly, through $\mathbb{W}\bar{m}_t$, and there is nothing to obscure how the sign of the strategic feedback falls out. And it falls out the wrong way. The decisive structural fact is that protective behaviour is a *strategic substitute* across the population, and this is what "anti-monotone" means in the present setting. When many neighbours are cautious, prevalence $(\mathbb{W}\bar{m}_t)(x)$ drops; a lower prevalence lowers each remaining agent's infection risk; and a lower risk *weakens* that agent's own incentive to be cautious — it can free-ride on the herd protection the others' caution has already bought. The best response to more collective effort is therefore *less* individual effort: the self-consistency map runs downhill where the congestion model of Thread B runs uphill. In the Lasry–Lions bookkeeping of section 31.2.1 this is precisely the failure of the sign condition — the bilinear form $s\langle\Delta, \mathbb{W}\Delta\rangle$ carries the destabilising sign rather than the restoring one — so the entire monotone toolkit that buys horizon-free uniqueness in the proved corner simply does not apply, and the game is pushed off Axis 1 into the non-monotone regime where multiplicity is possible and the live question is no longer existence but *which* equilibrium the population realises. That is the regime of Open problem 31.2, reached here not by an exotic cost but by the most basic feature of contagion. The mathematical frontier is thus exactly the non-monotone, finite-state graphon theory with its threshold and selection questions — and the finiteness of the state space is a genuine simplification that makes this domain the natural proving ground for selection, since it is where the common-noise master equation of Open problem 31.2(i) is most likely to be writable in closed enough form to settle the conjecture. The payoff that makes the question urgent is a comparative-statics one: does a small, targeted subsidy — to the most central nodes, those of largest ϕ_1-weight, where an averted infection blocks the most onward transmission — move the equilibrium across the threshold and avert an outbreak? That is a derivative of the equilibrium with respect to a localised perturbation of the cost, exactly the intervention calculus chapter 20 carries out for the static game; lifting it to the dynamic, finite-state, non-monotone game is the open piece.

Energy markets and power grids. The second domain is the one that lands in the hardest corner of the cube, and it does so honestly — not by contrivance but because the physics of a grid supplies all three relaxations at once. Distributed storage and generation units — home batteries, electric-vehicle chargers, prosumers — each solve a stochastic control problem: when to charge, when to discharge, against fluctuating prices and their own state of charge (Couillet, Perlaza, Tembine and Debbah [51]; Alasseur, Ben Tahar and Matoussi [5]). They are coupled two ways, and the two ways are different operators. The first is the market price, which responds to *total* demand and so couples every unit to every other equally — a global, rank-one, constant-graphon coupling, which is to say Thread A in its purest form, the homogeneous mean field with no network structure at all. The second is the physical grid: line and voltage constraints couple units that are electrically adjacent, and this coupling carries the genuine network structure, the sparse transmission topology with its hubs and its geography. Superpose them and the realistic regime is the two-axis corner of Open problem 31.3 with the observation axis held off: the grid is *sparse* (Axis 2), the aggregate driver — weather over the service area, the common demand cycle — is a *common noise* felt by everyone at once (Axis 3), and on top of both the per-agent state is genuinely high-dimensional (state of charge, plus the market and weather variables each unit must track), which is what defeats the naive grid-based solvers of section 31.3.1. So this domain is not merely an instance of the deepest theory gap; it is the reason that gap was worth isolating.

It is also the domain that most sharply motivates the way *out* of the solver gap, and the reason is a spectral fact about grids worth developing, because it is the load-bearing point. The coupling that carries the grid's network structure is built from the transmission network's graph Laplacian, and a transmission Laplacian is not a generic sparse operator: it has a *sharp spectral gap*. A power grid is engineered to be well connected and robust, so its algebraic connectivity — the smallest nonzero Laplacian eigenvalue — sits well clear of zero, and, equally to the point, the network's effective interaction is dominated by a handful of low-lying modes: the slow, large-scale collective patterns of congestion across the grid, above which the spectrum decays quickly. In operator terms the grid-constraint coupling is, to high accuracy, *low effective rank* — a few spectral modes carry almost all of it, and the tail is suppressed by the gap. This is exactly the structure the certified low-rank solver of Open problem 31.5 is built to exploit: that solver's cost scales not with the ambient dimension of the network but with the number of spectral modes one must retain to reach a target accuracy, and a sharp spectral gap is precisely what *certifies* that a small retained rank suffices — the truncation error past mode r is controlled by the size of the gap below λ_r, so the gap converts "low rank works in practice" into "low rank works provably, with this error bound." The grid is therefore not just a place the solver would be useful; it is the canonical example whose spectral geometry the solver's guarantee is tailored to, and the surest reason Open problem 31.5 is the right piece of mathematics to demand.

Opinion dynamics. The third domain is the one where the carried thread is not an analogy but the literal model, so that the chapter's own running example turns out to have been a sociological theory all along. Agents adjust opinions or behaviours under a cost with two terms: one pulls each agent toward the average opinion of its network neighbours, the aggregate $(\mathbb{W}\bar{m}_t)(x)$ again, and the other penalises departure from a private conviction (Bauso, Tembine and Başar [14]). Take the cost quadratic and this is *exactly* Thread B, the congestion/imitation model carried through the entire book — only now read with the imitation sign rather than the congestion sign. Conformity, the wish to agree with one's neighbours, is the crowd-seeking coupling $s > 0$: doing more of what the crowd does is rewarded, not penalised, so the strategic feedback reinforces rather than restores, and the game sits at the non-monotone end of Axis 1 by construction. Everything the chapter proved about that end now reads as a statement about a society. While the coupling is weak the unique equilibrium is the disorganised one — opinions spread, the order parameter $\varrho = \langle f, \bar{m}\rangle$ vanishes, no consensus. As the conformity coupling is turned up through the critical value $g = \mathsf{b}\lambda_1 = 1$ of section 31.2.2, the disorganised state goes unstable and a pair of broken-symmetry branches $\pm\varrho^*$ split off: the population spontaneously aligns. The pitchfork bifurcation of the rank-one game *is* the onset of consensus or polarisation, and the graphon refinement says something a homogeneous model cannot — that the alignment forms first along the leading centrality mode ϕ_1, the most connected sub-population condensing into agreement before the periphery and dragging it along in proportion to ϕ_1-weight. The mathematical frontier is therefore the selection problem Open problem 31.2 read sociologically: of the two consensus branches the broken symmetry admits, which one does a real population reach, and can a small exogenous common shock — a media event felt by everyone at once — tip it deterministically into one branch? That last question is the common-noise selection mechanism of section 31.2.2 restated in the field's own vocabulary, and it is why opinion dynamics is the application that most directly demands the selection theory the chapter has been unable to supply: here the degenerate $\pm\varrho^*$ are not a technical artefact but two different futures for the society, and which one is selected is the whole empirical content of the model.

Distributed control and multi-agent systems. The fourth domain inverts the direction of the entire enterprise, and in doing so it picks up exactly the adjointness the identification subsection handed forward. Robotic swarms, sensor networks, traffic-routing fleets — these are *designed* systems, in which a single controller chooses not only the agents' costs but the communication network W itself. The question is no longer the analyst's — given a graphon, what is the equilibrium? — but the engineer's reverse of it: given a target collective behaviour, which graphon induces an equilibrium that realises it? This is a graphon mechanism-design or inverse-game problem, and it is the precise adjoint of the identifiability problem Open problem 31.7. Identification runs the map backward from observed behaviour to the operator $\mathbb{W}$ that produced it; design runs the same map forward, from a desired behaviour to an operator chosen to produce it — one inverse problem on $\mathbb{W}$ read in two directions, which is why the two are genuinely the same mathematics and not merely neighbouring concerns. The tool the design side needs is the comparative-statics and intervention calculus of chapter 20: which eigenmode of $\mathbb{W}$ to strengthen in order to move the aggregate in a wanted direction, quantified by the Katz–Bonacich and eigenvector-centrality results theorems 20.18 and 20.19 that say exactly how a perturbation of the network propagates into a perturbation of the equilibrium. Those results are proved for the static game; the frontier is to lift them to the dynamic graphon game, where the controller designs W to steer a *trajectory* of aggregates rather than a single fixed point, and where the same susceptibility operator that governed identifiability now governs how sensitively the designed equilibrium responds to the designer's choices.

Four domains, and not one of them is served by the proved corner. The epidemic forces the selection problem, the grid forces the master-equation corner and the certified solver, opinion dynamics forces selection again, distributed control forces the design inverse of identification — and each of these is, by the chapter's own accounting, open. This is the honest conclusion the application survey was meant to reach: the places the model is actually used are, without exception, the places off the axes where the mathematics runs out, and the demand for that missing mathematics is not academic but already issuing from epidemiology, power-systems engineering, sociology and robotics. What every one of these frontiers shares, moreover, is the form of the obstruction — a non-monotone bifurcation, a critical coupling, a susceptibility that diverges, a low-rank spectral structure to be exploited or a symmetry to be broken and reselected — and that form is one a physicist will recognise on sight. The applications hand us a demand for new mathematics; the question that closes the chapter is where the tools to meet it are most likely to come from, and the wager of the final section is that they come from the statistical-mechanics toolkit the analyst's thirty chapters were quietly building toward all along.

31.5 A research agenda for the physics-trained reader

We come to the question the book was built to ask. The reader has spent thirty chapters watching mean field games be assembled from measure theory, stochastic analysis and fixed-point theorems —

the analyst's tools. But the structure that emerged is one the physicist already owns: a self-consistent field (the mean field) determined by a saddle-point condition (the Nash fixed point), with a control parameter (the coupling $s\,\|\mathbb{W}\|$) that tunes the system through a symmetry-breaking transition (the uniqueness threshold eq. (31.1)). Every open problem above has, in this light, a physicist's restatement, and the restatement suggests a method. This section is a deliberately speculative map of where three pieces of the statistical-mechanics toolkit — the fluctuation expansion, the renormalisation group, and diagrammatics — are most likely to convert into theorems. It carries the chapter's one worked computation, which makes the first of the three fully precise.

31.5.1 Fluctuations: the order-parameter susceptibility

The mean field game is the $N \to \infty$ saddle; the finite-N game is the saddle plus fluctuations of size $O(N^{-1/2})$, exactly as the central limit theorem of chapter 3 quantifies for a fixed dynamics and as propagation of chaos for Nash equilibria (chapter 13) establishes for the homogeneous game. The systematic object the physicist expects — a controlled expansion of the finite-N equilibrium around the mean field, order by order in $N^{-1/2}$ — is precisely what is *not* in general available, and building it is the cleanest entry point for the physics-trained reader. We can, however, compute its leading term completely in the rank-one graphon game, and the computation is worth doing in full because it exhibits both the phenomenon (a susceptibility that diverges at the critical coupling) and the exact boundary of the rigorous theory.

We work with the *static* rank-one graphon game, the stationary shadow (section 20.7) of Thread B, because there the fluctuation calculation is fully rigorous; the dynamic version is the open problem that follows.

The one analytic input beyond the elementary central limit theorem is a local-uniform law of large numbers for the self-consistency map, *with* its derivative. We isolate it as a lemma and prove it from the in-book strong law and the Arzelà–Ascoli argument already used for Varadarajan's theorem in worked computation 3.26, so that nothing beyond the prerequisite line is invoked by name.

Lemma 31.8 (Local-uniform law of large numbers for the self-consistency map)**.** *Let $x_1, x_2, \dots$ be i.i.d.* $\mathrm{Unif}[0,1]$*, let $f \in L^2[0,1]$, and let $(\mathrm{br}_x)_{x\in[0,1]}$ be best responses that are C^1 in their scalar argument with a common bound and modulus of continuity on the derivative: there exist $L_{\mathrm{br}} < \infty$ and a nondecreasing ω with $\omega(0^+) = 0$ such that*

$$|\mathrm{br}'_x(u)| \le L_{\mathrm{br}}, \qquad |\mathrm{br}'_x(u) - \mathrm{br}'_x(u')| \le \omega(|u-u'|) \qquad (\textit{all } x, u, u').$$

Set $H_N(\varrho) = \frac{1}{N}\sum_{j\le N} f(x_j)\,\mathrm{br}_{x_j}(f(x_j)\varrho)$ and $h(\varrho) = \mathbb{E}[f(x)\mathrm{br}_x(f(x)\varrho)]$. Then on every compact $K \subset \mathbb{R}$, almost surely $H_N \to h$ and $H'_N \to h'$ uniformly *on K, where $H'_N(\varrho) = \frac{1}{N}\sum_{j\le N} f(x_j)^2\,\mathrm{br}'_{x_j}(f(x_j)\varrho)$ and $h'(\varrho) = \mathbb{E}[f(x)^2\mathrm{br}'_x(f(x)\varrho)]$; in particular $h \in C^1(\mathbb{R})$.*

Proof. Put $\bar\omega := \min(2L_{\mathrm{br}}, \omega) \le 2L_{\mathrm{br}}$, still a modulus. On K two domination bounds hold. By the mean value theorem and $|\mathrm{br}'_x| \le L_{\mathrm{br}}$,

$$|H_N(\varrho) - H_N(\varrho')| \le \Big(\frac{1}{N}\sum_{j\le N} L_{\mathrm{br}}\, f(x_j)^2\Big)\,|\varrho-\varrho'|, \qquad |H'_N(\varrho) - H'_N(\varrho')| \le \frac{1}{N}\sum_{j\le N} f(x_j)^2\,\bar\omega(|f(x_j)|\,|\varrho-\varrho'|).$$

The prefactor $\frac{1}{N}\sum_j f(x_j)^2 \to \|f\|^2_{L^2}$ almost surely by the strong law of large numbers (proposition 3.24; only the first moment $\mathbb{E}[f(x)^2] = \lambda_1 < \infty$ of the i.i.d. summands is needed, the Kolmogorov form recorded in section 3.4.2), so $\{H_N\}$ is a.s. uniformly Lipschitz, hence equicontinuous, on K. For the derivatives, since $f(x)^2\bar{\omega}(|f(x)|\delta) \le 2L_{\mathrm{br}} f(x)^2 \in L^1$ and $\bar{\omega}(0^+) = 0$, dominated convergence gives $G(\delta) := \mathbb{E}[f(x)^2\bar{\omega}(|f(x)|\delta)] \downarrow 0$ as $\delta \downarrow 0$; fixing $\varepsilon > 0$ and δ with $G(\delta) < \varepsilon$, the strong law makes $\frac{1}{N}\sum_j f(x_j)^2\bar{\omega}(|f(x_j)|\delta) \to G(\delta) < \varepsilon$ a.s., so by monotonicity of $\bar{\omega}$ the family $\{H'_N\}$ is a.s. asymptotically equicontinuous on K. At each ϱ in a countable dense set $D \subset K$ the summands of $H_N(\varrho)$ and of $H'_N(\varrho)$ are i.i.d. with finite mean (dominated by $|f(x)\mathrm{br}_x(0)| + L_{\mathrm{br}} f(x)^2|\varrho|$ and by $L_{\mathrm{br}} f(x)^2$, both in L^1), so the strong law gives $H_N(\varrho) \to h(\varrho)$ and $H'_N(\varrho) \to h'(\varrho)$; intersecting the countably many null sets makes both hold simultaneously on D. Equicontinuity plus convergence on a dense set upgrades to uniform convergence on K — the Arzelà–Ascoli argument used for Varadarajan's theorem in worked computation 3.26. Finally h is the uniform limit of H_N and h' the uniform limit of the continuous H'_N, so $h \in C^1(K)$ with the stated derivative; as K was arbitrary, $h \in C^1(\mathbb{R})$. □

Worked computation 31.9 (Order-parameter susceptibility of the rank-one graphon game)**.** Sample N agents with i.i.d. types $x_1, \dots, x_N \sim \mathrm{Unif}[0,1]$ and couple them through the rank-one graphon $W(x,y) = f(x)f(y)$, $f \in L^2[0,1]$, $f \not\equiv 0$, with leading eigenvalue $\lambda_1 = \|f\|^2_{L^2}$ (proposition 24.25). Only the L^2/Hilbert–Schmidt structure of W enters this fluctuation computation — the operator facts $\mathbb{W}$ Hilbert–Schmidt and $\lambda_1 = \|f\|^2_{L^2}$, and the integrability displayed below — so we treat ff as an L^2 kernel rather than as a $[0,1]$-valued graphon; if one wants ff to be a bona fide graphon satisfying *(A-Reg-W)* it suffices to take f bounded (proposition 24.25), but boundedness is not used here. In the static LQ graphon game each agent i chooses an effort and best-responds to the aggregate it feels, $z_i = \frac{1}{N}\sum_j W(x_i, x_j)\,\alpha_j = f(x_i)\,\hat{\varrho}_N$, where

$$\hat{\varrho}_N \;:=\; \frac{1}{N}\sum_{j=1}^{N} f(x_j)\,\alpha_j \tag{31.2}$$

is the empirical order parameter (it aggregates the agents' *actions* α_j; see the notation watch below). With a smooth scalar best response $\mathrm{br}_x(\cdot)$ (under *(A-Lip)*, br_x is Lipschitz), the Nash condition $\alpha_i = \mathrm{br}_{x_i}(f(x_i)\hat{\varrho}_N)$ closes on the single scalar $\hat{\varrho}_N$, which must solve the self-consistency

$$\hat{\varrho}_N \;=\; H_N(\hat{\varrho}_N), \qquad H_N(\varrho) \;:=\; \frac{1}{N}\sum_{j=1}^{N} f(x_j)\,\mathrm{br}_{x_j}\!\big(f(x_j)\,\varrho\big). \tag{31.3}$$

As $N \to \infty$, the local-uniform law of large numbers of lemma 31.8 gives $H_N(\varrho) \to h(\varrho) := \mathbb{E}\big[f(x)\mathrm{br}_x(f(x)\varrho)\big]$ uniformly on compacts, and the mean field order parameter ϱ^* is the fixed point $h(\varrho^*) = \varrho^*$, with mean field slope

$$g \;:=\; h'(\varrho^*) \;=\; \mathbb{E}\big[f(x)^2\,\mathrm{br}'_x(f(x)\varrho^*)\big]. \tag{31.4}$$

(Here H_N, h and g are local to this static computation; they are *not* the Hamiltonian H or the terminal cost $g = g$ of the rest of the book, neither of which appears in the stationary calculation.) In the LQ case the static Thread B best response is *affine*: by eqs. (20.29) and (20.32) a type-x agent's equilibrium action is

$$\mathrm{br}_x(z) \;=\; \frac{\eta(x)}{1+q} \;+\; \mathsf{b}\,z, \tag{31.5}$$

a nonzero type-dependent intercept (the ideal point $\eta(x)$) plus the strategic-slope term, with $\mathsf{b} = \frac{qs}{1+q}$ the static interaction coefficient eq. (20.30). Then $\mathrm{br}_x' \equiv \mathsf{b}$ (so the modulus hypothesis of lemma 31.8 is vacuous) and $g = \mathsf{b}\,\mathbb{E}[f(x)^2] = \mathsf{b}\,\|f\|_{L^2}^2 = \mathsf{b}\,\lambda_1$ — the strategic coefficient times the leading eigenvalue — so the subcriticality condition $g < 1$ is exactly the static contraction/uniqueness threshold $\mathsf{b}\lambda_1 < 1$ of theorem 20.14 and eq. (20.31). The fixed point is then $\varrho^* = \langle \eta, f\rangle / [(1+q)(1-\mathsf{b}\lambda_1)]$ (eq. (20.32)), so a *nondegenerate* susceptibility requires a nonzero ideal-point field, $\langle \eta, f\rangle \neq 0$: in the symmetric case $\eta \equiv 0$ one has $\varrho^* = 0$, the limiting variance V of the central limit theorem below collapses to $\mathrm{Var}(\mathsf{b}f(x)^2\varrho^*) = 0$, and eq. (31.6) degenerates to $\sqrt{N}\,\hat{\varrho}_N \Rightarrow 0$ — the genuine fluctuation theory of that pure-consensus point sitting at the next order in $N^{-1/2}$.

Claim. If $|g| < 1$ (subcritical coupling) and br_x is C^1 with $\mathbb{E}\big[f(x)^2 \mathrm{br}_x(f(x)\varrho^*)^2\big] < \infty$, then the order-parameter fluctuation obeys a central limit theorem,

$$\sqrt{N}\,(\hat{\varrho}_N - \varrho^*) \;\Rightarrow\; \mathcal{N}(0,\; \chi^2 V), \qquad \chi \;:=\; \frac{1}{1-g}, \qquad V \;:=\; \mathrm{Var}\big(f(x)\,\mathrm{br}_x(f(x)\varrho^*)\big), \tag{31.6}$$

where χ is the *susceptibility*.

Proof. This is the delta method applied to the implicitly defined estimator $\hat{\varrho}_N$. Write $\Psi_N(\varrho) := \varrho - H_N(\varrho)$ and $\Psi(\varrho) := \varrho - h(\varrho)$, so $\hat{\varrho}_N$ and ϱ^* are the respective zeros. By lemma 31.8 (whose hypotheses hold under *(A-Lip)* and the stated integrability), $H_N \to h$ and $H_N' \to h'$ uniformly on a compact neighbourhood of ϱ^*, so $\Psi_N \to \Psi$ and $\Psi_N' \to \Psi'$ uniformly there, with $\Psi'(\varrho^*) = 1 - g \neq 0$. Since $|g| < 1$ and h' is continuous, fix $\varepsilon \in (0, 1-g)$ and an interval $I = [\varrho^* - r, \varrho^* + r]$ on which $h' \leq g + \varepsilon < 1$; then $\Psi = \mathrm{Id} - h$ is strictly increasing on I with $\Psi(\varrho^*) = 0$ and $\Psi(\varrho^* \pm r)$ of opposite, nonzero signs. Once $\sup_I |H_N' - h'| < \varepsilon$ (a.s. for N large) one has $\Psi_N' = 1 - H_N' > 0$ on I, so Ψ_N is strictly increasing there and inherits the endpoint signs; hence Ψ_N has a unique zero $\hat{\varrho}_N \in I$, with $\hat{\varrho}_N \to \varrho^*$ a.s. A first-order Taylor expansion of Ψ_N about ϱ^* gives

$$0 = \Psi_N(\hat{\varrho}_N) = \Psi_N(\varrho^*) + \Psi_N'(\tilde{\varrho}_N)\,(\hat{\varrho}_N - \varrho^*), \qquad \tilde{\varrho}_N \in [\varrho^*, \hat{\varrho}_N],$$

and $\Psi_N'(\tilde{\varrho}_N) = 1 - H_N'(\tilde{\varrho}_N) \to 1 - g$ a.s., since $\tilde{\varrho}_N \to \varrho^*$ and $H_N' \to h'$ uniformly on I (lemma 31.8). Therefore

$$\sqrt{N}\,(\hat{\varrho}_N - \varrho^*) = \frac{-\sqrt{N}\,\Psi_N(\varrho^*)}{\Psi_N'(\tilde{\varrho}_N)} = \frac{\sqrt{N}\,(H_N(\varrho^*) - \varrho^*)}{1 - g + o_{\mathbb{P}}(1)}.$$

The numerator is $\sqrt{N}\big(H_N(\varrho^*) - h(\varrho^*)\big)$ since $h(\varrho^*) = \varrho^*$, and $H_N(\varrho^*) = \frac{1}{N}\sum_j f(x_j)\mathrm{br}_{x_j}(f(x_j)\varrho^*)$ is an average of i.i.d. terms with mean $h(\varrho^*)$ and variance V; the classical central limit theorem (theorem 3.22) gives $\sqrt{N}(H_N(\varrho^*) - h(\varrho^*)) \Rightarrow \mathcal{N}(0, V)$. Because the denominator $\Psi_N'(\tilde{\varrho}_N) \to 1 - g$, a *constant*, in probability, the pair converges jointly, $\big(\sqrt{N}(H_N(\varrho^*) - h(\varrho^*)),\, \Psi_N'(\tilde{\varrho}_N)\big) \Rightarrow (\mathcal{N}(0, V),\, 1-g)$; the continuous mapping theorem (corollary 3.11) applied to $(a, b) \mapsto a/b$, continuous at $b = 1 - g \neq 0$ — this is the elementary content of Slutsky's theorem — yields eq. (31.6). □

Notation watch

The static order parameter $\hat{\varrho}_N$ eq. (31.2) aggregates the agents' *actions*, $\hat{\varrho}_N = \frac{1}{N}\sum_j f(x_j)\alpha_j$. It is the stationary-game analogue of the *dynamic* mean aggregate $\varrho_t = \langle f, \bar{m}_t\rangle$ of the rank-one Thread B reduction (worked computation 30.7), which aggregates type-conditional state means; the reuse of the single symbol ϱ across the static/dynamic boundary is intentional, the static action aggregate being exactly the stationary-shadow image of the dynamic mean aggregate under section 20.7.

The content of worked computation 31.9 is the factor $\chi = (1-g)^{-1}$. The fluctuation of the order parameter is the bare fluctuation of a single agent's contribution, of variance V/N, *amplified* by χ^2: each agent's deviation perturbs the aggregate, which perturbs every agent's best response, which feeds back into the aggregate, and the geometric series of this feedback sums to $\chi = 1/(1-g)$. As the coupling approaches the critical value $g \uparrow 1$ — i.e. $\mathsf{b}\lambda_1 \uparrow 1$ in the LQ case — the susceptibility diverges and the order-parameter fluctuations blow up: the mean field description, though still the correct *mean*, no longer suppresses fluctuations, and the Gaussian approximation eq. (31.6) degrades. This is the rigorous fingerprint, in a mean field game, of a critical point.

The critical surface $g = \mathsf{b}\lambda_1 = 1$ reached here is the *static* contraction/uniqueness threshold eq. (20.31) (theorem 20.14), the stationary shadow (section 20.7) of the dynamic uniqueness threshold eq. (31.1), not that threshold itself. The two do not coincide on the nose: the static slope is $\mathsf{b} = \frac{qs}{1+q}$ eq. (20.30), so in terms of the coupling s the static face reads $\mathsf{b}\lambda_1 = 1 \Leftrightarrow s\lambda_1 = \frac{1+q}{q} = 1 + \frac{1}{q}$, whereas the dynamic threshold eq. (31.1) at $a = 0$ reads $s\lambda_1 = 1$. The two critical surfaces therefore differ by the effort-cost factor $\frac{q}{1+q}$ and align only in the strong-congestion limit $q \to \infty$, where $\mathsf{b} \to s$; as section 20.7 stresses, b is a Riccati composite of the dynamic data, not a literal reading of s, and the correspondence is the structural alignment of two "coupling hits the inverse top eigenvalue" thresholds, not a parameter identity. What is exact in *both* pictures is the qualitative statement the susceptibility makes precise: χ diverges precisely as the effective coupling g — static or dynamic — reaches unity along the leading eigenmode ϕ_1.

Notation watch

We have called χ a "susceptibility" and will, just below, borrow the words "critical exponent" and "correlation length." The first is apt: χ is exactly the linear response of the equilibrium order parameter to an infinitesimal uniform field, and diverges with the same mean-field exponent (see below). But "correlation length" has *no literal meaning here*: the type variable $x \in [0,1]$ is an exchangeable label, not a spatial coordinate (appendix A.5), so there is no distance in which correlations decay. What plays the role of a diverging correlation length is the *spectral* concentration of the critical fluctuation onto the single eigenmode ϕ_1 — the loss of effective rank, not the growth of a length. Read every spatial metaphor in this section as a statement about the spectrum of $\mathbb{W}$, never about $|x-y|$.

Physics note

Worked computation 31.9 is the Curie–Weiss susceptibility, transcribed. Writing the distance to criticality as $\epsilon := 1 - g \propto (s_c - s)$ near the threshold, the susceptibility diverges as $\chi \sim \epsilon^{-1}$ — the mean field critical exponent $\gamma = 1$ — and the order-parameter variance as $\mathrm{Var}(\hat{\varrho}_N) \sim N^{-1}\epsilon^{-2}$, so the Gaussian fluctuation theory is self-consistent only for $N\epsilon^2 \gg 1$. Inside the critical window $N\epsilon^2 \lesssim 1$ the fluctuations are no longer Gaussian and the expansion needs its next order: this is the Ginzburg criterion for the mean field game, and the open question it poses is whether the *graphon* changes the exponent. For a dense graphon with a spectral gap (finite effective rank) one expects the mean field exponents to survive, exactly as Curie–Weiss is exact above the upper critical dimension. For a sparse graphon, where the spectrum of $\mathbb{W}$ is dense near its edge and many modes go critical together, the analogue of a *lower critical dimension* should appear and the exponents should shift. Making this dichotomy a theorem — mean field exponents iff a spectral gap — is, to our knowledge, entirely open and is the single most physics-native problem in the book.

Open problem 31.10. *(Dynamic fluctuation expansion.)* Extend worked computation 31.9 to the *dynamic* graphon mean field game: prove a central limit theorem for the fluctuation of the finite-N closed-loop Nash equilibrium around the graphon mean field limit, identifying the limiting Gaussian field as the solution of a linearised forward–backward system whose covariance is governed by a susceptibility operator $(\mathrm{Id} - \mathcal{G})^{-1}$ with $\mathcal{G}$ the linearisation of the best-response map (the spectral radius of $\mathcal{G}$ reaching 1 at the critical coupling eq. (31.1)). Determine whether the mean field critical exponents are preserved for graphons with a spectral gap and shifted for sparse graphons.

The homogeneous ($W \equiv \mathrm{const}$) case of Open problem 31.10 is exactly the central limit theorem of Delarue, Lacker and Ramanan [58], with the companion large-deviation and concentration results of [59]; their fluctuation field solves a linear forward–backward stochastic system, and the susceptibility operator is implicit in its well-posedness. The graphon generalisation — the operator $\mathcal{G}$ acquiring the spectral structure of $\mathbb{W}$, the critical exponent question — is open, and the static computation above is its zeroth chapter.

31.5.2 Renormalisation: the cut metric as a coarse-graining

The second tool is the renormalisation group, and the book has already, without naming it, laid down its kinematics. The weak regularity lemma (chapter 19) states that every graphon is approximated in cut metric by a step graphon of bounded complexity — a coarse-graining that replaces a fine type structure by finitely many blocks while preserving all macroscopic (homomorphism-density) observables (chapter 16). This is a renormalisation-group transformation in everything but name: a map on the space of couplings $\widetilde{\mathcal{W}}_0$ that integrates out fine type structure and is controlled in the metric ($\delta_\square$) under which the physics (the equilibrium, chapter 25) is continuous.

Heuristic (non-rigorous)

The renormalisation-group program for graphon mean field games would be to iterate the coarse-graining of chapter 19 and ask for its fixed points and their stability. A *fixed point* of the coarse-graining is a graphon scale-invariant under block aggregation; the constant graphon (Erdős–Rényi) and the rank-one graphon are the obvious candidates, and the rank-one fixed point is the one on which the entire equilibrium collapses to the single order parameter ϱ of worked computation 31.9. The *relevant* and *irrelevant* directions would be the eigenmodes of $\mathbb{W}$ ordered by eigenvalue: near the critical coupling, the leading mode ϕ_1 is relevant (it carries the diverging susceptibility) and the rest are irrelevant (their susceptibilities $1/(1-g_k)$ with $g_k \propto \lambda_k$ stay finite). This is, heuristically, why the critical behaviour is universal across graphons with the same leading eigenvalue — the irrelevant modes wash out under coarse-graining — and it predicts that the critical exponents depend only on the *spectral edge* of $\mathbb{W}$, matching the Ginzburg-criterion dichotomy of the physics note. None of this is a theorem; it is the most promising heuristic in the chapter.

Open problem 31.11. *(A renormalisation semigroup on graphon games.)* Make the coarse-graining of chapter 19 into a semigroup on $(\widetilde{\mathcal{W}}_0, \delta_\Box)$ acting jointly on the graphon and the cost data, prove that the induced map on equilibria is continuous (a quantitative $\delta_\Box$-stability, strengthening chapter 25), and characterise its fixed points and the relevant/irrelevant splitting of the spectrum of $\mathbb{W}$ at a fixed point. Deduce a universality statement: graphon games with the same leading spectral data have the same critical exponents.

31.5.3 Diagrammatics: the loop expansion of the master equation

The third tool is diagrammatic bookkeeping. The master equation (chapters 12 and 26) is a Hamilton–Jacobi equation on the space of measures, and the physicist reads it as the effective action whose functional derivatives generate the equilibrium correlation functions (remark 12.11). The mean field game is its tree-level (saddle) approximation; the fluctuation expansion of section 31.5.1 is its one-loop correction; and the systematic $N^{-1/2}$ expansion the physicist wants is its loop expansion. The vertices of the diagrams are the higher flat derivatives $\delta^k U/\delta m^k$ of the master field, the propagator is the susceptibility operator $(\mathrm{Id} - \mathcal{G})^{-1}$ of Open problem 31.10, and the graphon enters every vertex and propagator through $\mathbb{W}$.

To keep this dictionary anchored rather than decorative, read it against the one object the chapter made rigorous, worked computation 31.9. There the *tree level* is the mean field order parameter ϱ^* (the saddle $h(\varrho^*) = \varrho^*$); the single *propagator* insertion is exactly the scalar reduction $(\mathrm{Id} - \mathcal{G})^{-1} \rightsquigarrow (1-g)^{-1} = \chi$ — the geometric series of best-response feedback summed in eq. (31.6), with $\mathcal{G}$ collapsing to multiplication by the slope $g = \mathsf{b}\lambda_1$; and the first nontrivial *vertex* is the curvature br''_x of the best response (zero in the LQ case, which is why the rank-one computation is exactly one-loop and the Gaussian eq. (31.6) is exact). The loop expansion is then the systematic restoration of the br''_x and higher vertices that the linear rank-one reduction set to zero.

Open problem 31.12. *(Loop expansion with error control.)* Develop the $N^{-1/2}$ expansion of the finite-N graphon game as a diagrammatic series in the derivatives of the master field, with the propagator $(\mathrm{Id} - \mathcal{G})^{-1}$, and — the part that distinguishes mathematics from physics — prove a remainder bound making the truncated expansion a genuine asymptotic series, valid away from the critical coupling where the propagator is singular. Resum the leading divergences near criticality to recover the corrected exponents of Open problem 31.10.

The honest caveat is that diagrammatic expansions are notoriously asymptotic rather than convergent, and the mathematical content of Open problem 31.12 is entirely in the remainder bound that physics leaves implicit. But the bookkeeping is real, the propagator is the same operator that controls uniqueness, and the divergence structure near criticality is exactly the susceptibility blow-up the worked computation made rigorous — so the diagrammatic language is not decoration; it is the natural organisation of the corrections, and turning it into controlled analysis is a concrete and, we believe, achievable program.

31.6 Closing synthesis

The three subsections of section 31.5 are not three programs but one, seen through three instruments. The fluctuation expansion computes the corrections; the renormalisation group organises which corrections matter; the diagrammatics is the bookkeeping that connects them to the master equation. And all three turn on a single object — the susceptibility operator $(\mathrm{Id} - \mathcal{G})^{-1}$, whose spectral radius reaching unity is, at once, the failure of uniqueness (section 31.2.1), the onset of equilibrium multiplicity (section 31.2.2), the blow-up of fluctuations (section 31.5.1), the breakdown of best-response learning (section 31.3.2), and the relevant direction of the renormalisation flow (section 31.5.2). The unification this book has been building toward is that all of these are the *same* critical point, and that the graphon enters every one of them through the same spectral data of $\mathbb{W}$: the leading eigenvalue λ_1 sets where the critical point is, and the spectral gap sets whether the transition is mean-field-like.

The mathematics that remains is, in this light, sharply posed. The proved theory occupies the subcritical, dense, idiosyncratic-noise corner where the susceptibility operator is invertible and everything is a contraction. The open problems are the approach to and passage through the critical surface where it is not — and the physicist's contribution, if the bet of this book is right, will be to supply the methods that were invented for exactly that purpose, made into theorems. The graphon mean field game is a statistical field theory of strategic agents on a network; we have built its mean field theory rigorously, and its critical theory is open.

Rigor ledger

Proved.

- worked computation 31.9 (eq. (31.6)): for the static rank-one graphon game in the subcritical regime $|g| < 1$, the empirical order parameter $\hat{\varrho}_N$ satisfies a central limit theorem with susceptibility $\chi = 1/(1-g)$ and limiting variance $\chi^2 V$; the susceptibility diverges as the coupling approaches the critical value $g \uparrow 1$, i.e. $\mathsf{b}\lambda_1 \uparrow 1$, which is the *static* contraction/uniqueness threshold eq. (20.31) — the stationary shadow (section 20.7) of the dynamic threshold eq. (31.1), the two critical surfaces differing by the effort-cost factor $q/(1+q)$ and coinciding only as $q \to \infty$. This is the rigorous leading-order fluctuation theory and the one new computation of the chapter.

- lemma 31.8: a local-uniform law of large numbers for the self-consistency map and its derivative, proved in-book from the strong law (proposition 3.24) and the Arzelà–Ascoli argument of worked computation 3.26; it supplies the consistency and the denominator convergence of the delta-method proof.

Assumed.

- The classical central limit theorem (theorem 3.22), the strong law of large numbers (proposition 3.24, with the first-moment Kolmogorov form recorded in section 3.4.2), and the continuous mapping theorem (corollary 3.11), applied to the i.i.d. type array; *(A-Lip)* and an integrability/C^1-modulus condition on the best response, used to dominate the families differentiated in the delta-method argument (via lemma 31.8). The local-uniform law with derivative convergence is *not* imported as a black box: it is the in-book lemma 31.8.

- All imported structural results: the uniqueness thresholds theorem 11.5, theorem 24.16 and proposition 24.18, the spectral reduction worked computation 24.22 and proposition 24.23, the static contraction threshold theorem 20.14, the master equation theorem 12.8, and the cut-metric stability of chapter 25.

Deferred.

- The homogeneous dynamic fluctuation central limit theorem (the $W \equiv$const case of Open problem 31.10) is proved in [58, 59]; we cite rather than reproduce it, the graphon generalisation being open.

- The sparse/L^p/graphex theory underlying Open problem 31.3 → chapter 27; the numerical realisations underlying Open problem 31.5 → chapter 28; the learning algorithms of Open problem 31.6 → chapter 29.

Open.

- Open problem 31.1: a necessary-and-sufficient uniqueness threshold for general couplings, recovering eq. (31.1).

- Open problem 31.2: equilibrium selection past the critical coupling, and whether common noise restores uniqueness.

- Open problem 31.3: master-equation well-posedness with common noise on sparse limits — the hardest and most consequential problem.

- Open problem 31.4: the graphon game under partial information beyond the linear-Gaussian separation of proposition 30.16 — nonlinear filtering of the aggregate field, and the canonical hard case of a partially observed major player on a sparse network (remark 30.18).

- Open problems 31.5 to 31.7: certified low-rank solvers, learning past the contraction threshold, behavioural identifiability of the graphon.

- Open problems 31.10 to 31.12: the dynamic fluctuation expansion, a renormalisation semigroup on graphon games with a universality statement, and a controlled loop expansion of the master equation — the physicist's agenda.

Bibliographic notes

The organising claim of this chapter — that the modern landscape of mean field games beyond perfect homogeneity is best read through the graphon picture, with the remaining gaps located by which axis of generality is relaxed — follows the recent overview [11], which we have used as the map for chapter 30 and this chapter. The two uniqueness regimes contrasted in section 31.2.1 are the Lasry–Lions monotonicity theory [93, 36] and its graphon operator lift of chapter 24; the displacement-monotonicity refinements that widen the sufficient region are due to Gangbo and Mészáros and collaborators [75, 76], and the master-equation well-posedness with nonsmooth data to Mou and Zhang [104]; none is known to be sharp. The equilibrium-selection question of section 31.2.2 and the conjecture that common noise restores uniqueness are crystallised in the two-state model of Cecchin, Dai Pra, Fischer and Pelino [46]; common noise for the classical theory is Carmona–Delarue [41] and Ahuja [4]. The sparse side of section 31.2.3 rests on the graphon-system limit theory of Bayraktar, Wu and Zhang [16] and the sparse-graph frameworks of chapter 27.

For the computation gaps: the forward–backward numerics behind section 31.3.1 are Achdou and Capuzzo-Dolcetta [1] (state space) combined with the graphon discretisation of chapter 28; the learning theory of section 31.3.2 is the GMFG-PPO line of Cui, Koeppl and collaborators [55] developed in chapter 29; and the graphon-estimation results behind section 31.3.3 are Gao, Lu and Zhou [77] (dense, minimax) and Klopp, Tsybakov and Verzelen [87] (sparse), with the identification only up to $\delta_\square$-equivalence being the lesson of chapter 17 [29]. The application frontiers of section 31.4 cite, respectively, the finite-state graphon epidemic games of Aurell, Carmona, Dayanikli and Laurière [9]; the smart-grid mean field models of Couillet, Perlaza, Tembine and Debbah [51] and Alasseur, Ben Tahar and Matoussi [5]; the opinion-dynamics model of Bauso, Tembine and Başar [14] (which is Thread B verbatim); and the intervention/comparative-statics theory of the static graphon game of Parise and Ozdaglar [108] that chapter 20 develops.

The fluctuation expansion of section 31.5.1 is, in the homogeneous case, the central limit theorem of Delarue, Lacker and Ramanan [58] with the companion large-deviation and concentration results [59]; our static rank-one computation worked computation 31.9 is the elementary delta-method shadow of their forward–backward fluctuation field, made explicit to expose the susceptibility $\chi = 1/(1-g)$ and its divergence at the critical coupling of chapter 24. The renormalisation reading of section 31.5.2 rests on the weak regularity lemma and the cut-metric compactness of Lovász and Szegedy [100, 99] developed in chapters 17 and 19; the diagrammatic reading of section 31.5.3 is the effective-action interpretation of the master equation [37] of chapter 12. The position that these three physical instruments — fluctuation expansion, renormalisation group, diagrammatics — are the natural tools for the critical theory of graphon mean field games is the thesis of this book, and to our knowledge their rigorous development for the graphon game is, as of this writing, open.

Part VI

Appendices

Appendix A

Master Notation and Conventions

This appendix is the canonical reference for notation. Where the body of the book and this appendix appear to disagree, this appendix wins, and the discrepancy should be reported as an erratum. The conventions here are enforced uniformly across all chapters.

A.1 Standing conventions

Time and the two directions of flow. The time horizon is $[0, T]$ with $0 < T < \infty$. Two objects evolve in opposite directions and this is the most common source of confusion in the subject:

- The *value function* $u = u(t, x)$ is determined by a *terminal* condition at $t = T$ and is computed *backward* in time. It is the optimal cost-to-go from the present to the deadline.
- The *population density* $m = m(t, x)$ is determined by an *initial* condition at $t = 0$ and evolves *forward* in time. It is transported by the agents' optimal feedback.

Every chapter in which both appear restates this on first use. The coupling of a backward equation to a forward equation, with data specified at opposite ends of the interval, is the structural signature of a mean field game and has no initial-value analogue.

Generators and their adjoints. For an Itô diffusion with drift b and volatility σ we write the infinitesimal generator as

$$(\mathcal{A}\phi)(x) \;=\; b(x) \cdot \nabla\phi(x) \;+\; \tfrac{1}{2}\,\mathrm{tr}\big(\sigma(x)\sigma(x)^{\top}\,\mathrm{D}^2\,\phi(x)\big).$$

We use the symbol $\mathcal{A} = \mathcal{A}$ for the generator, reserving $\mathcal{L} = \mathcal{L}$ for the law (distribution) of a random variable; this avoids the common clash in which L denotes both. The formal adjoint $\mathcal{A}^{*}$ is the Fokker–Planck (Kolmogorov forward) operator: densities solve $\partial_t m = \mathcal{A}^{*} m$.

Notation watch

A physicist is used to writing the evolution of densities with a Liouvillian or with $-H$ in the exponent and may carry sign habits from the Schrödinger or master-equation conventions. Here the forward operator is $\mathcal{A}^*$ and the sign is fixed by the requirement that $\int m \, \mathrm{d}x$ be conserved and that $m \geq 0$ be preserved; verify signs against this conservation law, not against a remembered Hamiltonian sign.

The discount rate. The symbol $\beta = \beta$ always denotes a (nonnegative) discount rate in a control or game problem. It is *never* an inverse temperature. On the rare occasion that an inverse temperature enters a physical analogy it is written β_{T} and flagged.

A.2 Spaces and measures

$\mathbb{R},\ \mathbb{N},\ \mathbb{Z},\ \mathbb{C}$	the usual number sets
$\mathbb{R}^d$	state space of a single agent
$[0,1] = [0,1]$	the graphon *type* interval (see below)
$\mathcal{P}(\mathbb{R}^d)$	Borel probability measures on $\mathbb{R}^d$
$\mathcal{P}_2(\mathbb{R}^d)$	those with finite second moment, the home of the mean field
$\mathcal{W}_2$	the quadratic Wasserstein distance on $\mathcal{P}_2(\mathbb{R}^d)$
$L^p,\ H^s$	Lebesgue and Sobolev spaces
$\mathbb{E},\ \mathbb{P}$	expectation and probability
$\mathcal{L}(X)$	the law of the random variable X

Probability measures as points. The "mean field" is a point $m \in \mathcal{P}_2(\mathbb{R}^d)$, not a list of agents. A best response is a map $\mathcal{P}_2(\mathbb{R}^d) \to \mathcal{P}_2(\mathbb{R}^d)$ and an equilibrium is its fixed point; the Wasserstein metric is the distance in which that map is shown to be continuous or contractive.

A.3 Differentiation on the space of measures

Two notions of derivative with respect to the measure argument recur.

- The *flat* (linear functional) derivative $\dfrac{\delta F}{\delta m}(m)(x)$, defined by

$$\frac{\mathrm{d}}{\mathrm{d}\epsilon} F(m + \epsilon(m' - m))\Big|_{\epsilon=0} = \int \frac{\delta F}{\delta m}(m, x)\,(m' - m)(\mathrm{d}x),$$

  which behaves exactly like the functional derivative $\delta F / \delta \rho(x)$ familiar from density-functional calculations.

- The *Lions* (L-)derivative $\partial_\mu F$, obtained by lifting F to a function of random variables on an atomless probability space and differentiating there; it relates to the flat derivative by $\partial_\mu F(m)(x) = \nabla_x \, \delta F / \delta m(m)(x)$.

Both are developed in chapter 4 and appendix D.

A.4 Control and games

$u = u(t,x)$	value function (HJB unknown), solved backward
$m = m(t,x)$	population density, solved forward
$\alpha = \alpha$	control / action; A the action set
$L = L$	running cost (Lagrangian)
$H = H(x,p,m)$	Hamiltonian, convex in p under (A-Conv)
$\alpha^* = -\partial_p H$	optimal feedback under (A-Conv)
$g = g$	terminal cost
$\mathsf{S} = \Phi$	best-response map whose fixed point is the equilibrium

A.5 Graphons

$x = x \in [0,1]$	the *type* / *label* of an agent
$W = W(x,y)$	a symmetric measurable graphon kernel
$\mathbb{W}$	its integral operator, $(\mathbb{W}f)(x) = \int_0^1 W(x,y)f(y)\,\mathrm{d}y$
$m^x = m^x$	the type-indexed population field
$\|\cdot\|_\square$	the cut norm; $\delta_\square$ the cut metric
$t(F,G)$	homomorphism density of F in G

Notation watch

The type variable $x \in [0,1]$ is an *exchangeable label* for an agent's kind or network position. It is *not* a spatial coordinate and *not* a momentum. Although the coupling $W(x,y)$ superficially resembles a translation-noninvariant hopping kernel on a lattice, x carries no metric or geometric meaning of its own beyond what W assigns it; in particular $|x-y|$ has no intrinsic significance. When a formula could tempt the reader to read x as position, the text says "type" explicitly.

Notation watch

Brownian motion versus graphon: both want the letter W. In the stochastic and classical chapters (Parts I–II), where no graphon is present, Brownian motion is W_t (rendered W_t), following standard usage. From Part III onward, where the graphon W is in scope, Brownian motion is written B_t. Thus in any equation containing a graphon, W is the kernel and B is the noise. This switch is announced again at the start of Part IV.

A.6 Standing assumptions (named)

These are stated once and referenced by tag throughout; full statements appear at first substantive use.

(A-Lip) Lipschitz coefficients and costs in the state, uniformly in time and measure.

(A-LipM) Measure-Lipschitz dependence: coefficients and costs are Lipschitz in the measure argument with respect to $\mathcal{W}_2$, uniformly in state and time (distinct from (A-Lip), which controls the state argument). Used for $\mathcal{W}_2$-continuity and contraction estimates of the best-response map; see section 4.3.

(A-Growth) At most linear growth in the state; coercivity sufficient to define the Hamiltonian.

(A-Nondeg) Uniformly nondegenerate diffusion, $\sigma\sigma^\top \succeq \lambda I$, $\lambda > 0$.

(A-Conv) $H(x, p, m)$ convex in p.

(A-Mon) Lasry–Lions monotonicity of the couplings (Chapter 11).

(A-Reg-W) W symmetric, measurable, bounded, and continuous in type where needed; $\mathbb{W}$ self-adjoint Hilbert–Schmidt on $L^2[0, 1]$.

(A-Coupling) Operator-norm smallness: $\|\mathbb{W}\|$ lies below the contraction/uniqueness threshold (chapter-specific; for the rank-one LQG of chapter 22 this is the effective coupling $s\,\|\mathbb{W}\| < 1$). We do not name the threshold by a fixed letter, reserving $\|\mathbb{W}\|$ for the operator norm itself.

A.7 The carried threads

The linear–quadratic–Gaussian thread (Thread A) and its graphon generalization (Thread B) are defined once, with fixed parameter names, in the project's thread specification and instantiated identically wherever they recur. Their first full statements appear in Chapters 6 and 14 (Thread A) and Chapters 20 and 22 (Thread B).

Appendix B

Functional-Analytic Toolbox: Deferred Proofs

This appendix collects proofs deferred from Part I (spectral theorem for compact self-adjoint operators, the fixed-point theorems, and related functional analysis).

B.1 The perspective of a convex function

The variational (potential-game) formulation of the mean field game system (section 8.6, and again in the numerical treatment of chapter 28) rewrites the kinetic cost of a flow of measures in terms of the momentum field $w = m\,\alpha$, producing the integrand $(\rho, w) \mapsto \rho\, L_0(x, w/\rho)$. This is the *perspective* of the convex velocity-cost $L_0(x,\cdot)$. Its joint convexity and lower semicontinuity are the load-bearing analytic facts behind the convexity of the energy functional (lemma 8.10); we prove them here in the generality used in the body. The construction is classical convex analysis but sits above the book's prerequisite line, so we give it in full.

Definition B.1 (Perspective function)**.** Let $f\colon \mathbb{R}^d \to \mathbb{R}$ be convex, finite-valued, and *superlinear* ($f(a)/|a| \to +\infty$ as $|a| \to \infty$); this is the case relevant to the body, where $f = L_0(x,\cdot)$ is convex by **(A-Conv)** and superlinear by the control-coercivity in **(A-Growth)**. Its *perspective* is $\tilde{f}\colon \mathbb{R}\times\mathbb{R}^d \to (-\infty, +\infty]$,

$$\tilde{f}(\rho, w) \;:=\; \begin{cases} \rho\, f(w/\rho), & \rho > 0, \\ 0, & \rho = 0,\ w = 0, \\ +\infty, & \text{otherwise (i.e. } \rho = 0 \neq w \text{ or } \rho < 0). \end{cases} \tag{B.1}$$

For the quadratic case $f(a) = \frac{1}{2}|a|^2$ of the LQG thread, $\tilde{f}(\rho, w) = |w|^2/(2\rho)$ for $\rho > 0$, $\tilde{f}(0,0) = 0$, and $\tilde{f}(0, w) = +\infty$ for $w \neq 0$ — exactly the extension stated in section 8.6.

Proposition B.2 (Joint convexity and lower semicontinuity of the perspective)**.** *With f as in definition B.1, the perspective $\tilde{f}$ of eq.* (B.1) *is convex and lower semicontinuous on $\mathbb{R}\times\mathbb{R}^d$. In* *particular, for each fixed x the map $(\rho, w) \mapsto \rho\, L_0(x, w/\rho)$, with the $0/{+\infty}$ extension just stated, is jointly convex and lower semicontinuous, and hence so is the integral $\int_0^T\!\int_{\mathbb{R}^d} m\, L_0(x, w/m)$ of eq. (8.18).*

Proof. We argue in two steps: an elementary direct proof of joint convexity on the open half-space $\{\rho > 0\}$, and then a representation of $\tilde{f}$ as a supremum of affine functions that delivers both convexity across the boundary $\rho = 0$ and lower semicontinuity on all of $\mathbb{R} \times \mathbb{R}^d$ at once.

Step 1: joint convexity for $\rho > 0$. Let $(\rho_1, w_1), (\rho_2, w_2)$ have $\rho_i > 0$, let $\lambda \in [0, 1]$, and write $\rho = \lambda\rho_1 + (1-\lambda)\rho_2$, $w = \lambda w_1 + (1-\lambda)w_2$. Set $t := \lambda\rho_1/\rho \in [0, 1]$, so $1 - t = (1-\lambda)\rho_2/\rho$. Then

$$\frac{w}{\rho} = \frac{\lambda w_1 + (1-\lambda)w_2}{\rho} = t\,\frac{w_1}{\rho_1} + (1-t)\,\frac{w_2}{\rho_2}$$

is a convex combination, so by convexity of f,

$$f\Big(\frac{w}{\rho}\Big) \;\le\; t\,f\Big(\frac{w_1}{\rho_1}\Big) + (1-t)\,f\Big(\frac{w_2}{\rho_2}\Big).$$

Multiplying by $\rho > 0$ and using $\rho t = \lambda\rho_1$, $\rho(1-t) = (1-\lambda)\rho_2$,

$$\rho\,f\Big(\frac{w}{\rho}\Big) \;\le\; \lambda\,\rho_1 f\Big(\frac{w_1}{\rho_1}\Big) + (1-\lambda)\,\rho_2 f\Big(\frac{w_2}{\rho_2}\Big),$$

which is joint convexity of $\tilde{f}$ on $\{\rho > 0\}$.

Step 2: affine representation, boundary, and lower semicontinuity. A finite convex function on $\mathbb{R}^d$ equals the supremum of its affine minorants: for each $a_0 \in \mathbb{R}^d$ a supporting hyperplane of the (closed, convex) epigraph of f at $(a_0, f(a_0))$ exists by the Hahn–Banach separation theorem (theorem 2.11), and the collection of all such supporting affine functions reconstructs f pointwise. Write this family as

$$\mathcal{A} \;:=\; \{(p, c) \in \mathbb{R}^d \times \mathbb{R} :\; f(a) \ge \langle p, a\rangle - c \text{ for all } a\}, \qquad f(a) = \sup_{(p,c)\in\mathcal{A}} (\langle p, a\rangle - c).$$

Define, on all of $\mathbb{R} \times \mathbb{R}^d$,

$$g(\rho, w) \;:=\; \sup_{(p,c)\in\mathcal{A}} (\langle p, w\rangle - c\,\rho). \tag{B.2}$$

Each map $(\rho, w) \mapsto \langle p, w\rangle - c\rho$ is affine, so g, a pointwise supremum of affine functions, is convex and lower semicontinuous everywhere. We claim $g = \tilde{f}$.

For $\rho > 0$, substituting $a = w/\rho$ into the affine representation of f and multiplying by ρ gives $\rho f(w/\rho) = \sup_{(p,c)\in\mathcal{A}}(\langle p, w\rangle - c\rho) = g(\rho, w)$.

For $\rho = 0$, $g(0, w) = \sup_{(p,c)\in\mathcal{A}}\langle p, w\rangle$. Superlinearity of f means its affine minorants have *every* slope: for each $p \in \mathbb{R}^d$, $c_p := \sup_a(\langle p, a\rangle - f(a)) < \infty$ (the supremum is finite because $f(a) - \langle p, a\rangle \to +\infty$), so $(p, c_p) \in \mathcal{A}$ for all p. Hence $g(0, w) = \sup_{p\in\mathbb{R}^d}\langle p, w\rangle$, which is 0 when $w = 0$ and $+\infty$ when $w \ne 0$ — exactly $\tilde{f}(0, \cdot)$.

For $\rho < 0$, fix any $p \in \mathbb{R}^d$ and the corresponding $(p, c_p) \in \mathcal{A}$; since $\mathcal{A}$ contains (tp, c_{tp}) for all $t > 0$ and $-c\rho \ge 0$ contributes nonnegatively, taking p in the direction of w and $t \to \infty$ already sends $\langle tp, w\rangle \to +\infty$, so $g(\rho, w) = +\infty = \tilde{f}(\rho, w)$.

Thus $g = \tilde{f}$, and $\tilde{f}$ inherits convexity and lower semicontinuity from g. Finally, joint convexity and lower semicontinuity are preserved by integration in (t, x) against the (nonnegative) Lebesgue measure — by Fatou's lemma for the lower-semicontinuity part — giving the last assertion. Applying all of this with $f = L_0(x, \cdot)$ completes the proof. □

Remark B.3 (Why the $0/+\infty$ extension is forced)**.** The boundary values at $\rho = 0$ are not a free convention: eq. (B.2) shows they are the values of the lower-semicontinuous convex envelope, so any other assignment would either destroy lower semicontinuity (if set lower) or convexity (if set higher). This is the analytic reason the energy eq. (8.18) is well posed exactly with the stated extension, and why a finite-energy flow cannot carry momentum $w \neq 0$ where the mass m vanishes.

The remainder of this appendix supplies, in full, the beyond-prerequisite results that chapter 2 states and uses but defers for length: the Hahn–Banach theorem (extension and separation), Tychonoff's theorem in the form Banach–Alaoglu needs, the completion of the spectral theorem to the complex case, the three fixed-point theorems (Brouwer via Sperner's lemma, then Schauder and Kakutani–Fan–Glicksberg), and the Sobolev results—Meyers–Serrin density, the Poincaré inequality, and the Rellich–Kondrachov compact embedding. Everything is proved from the material of chapters 1 and 2 and the stated prerequisites (undergraduate analysis, the Arzelà–Ascoli theorem, mollification, and Zorn's lemma); no external source is needed. We keep the chapter's citations as attribution and further reading.

B.2 Hahn–Banach: extension and separation

We prove theorem 2.11. The analytic core is a single one-dimensional extension step, iterated transfinitely by Zorn's lemma; the geometric separation form is then read off through the Minkowski gauge of a convex set.

Recall that $p\colon X \to \mathbb{R}$ on a real vector space X is *sublinear* if $p(x + y) \leq p(x) + p(y)$ and $p(tx) = t\,p(x)$ for all $x, y \in X$ and $t \geq 0$. A norm and, more generally, the gauge of a convex neighbourhood of the origin are sublinear.

Lemma B.4 (One-dimensional extension)**.** *Let p be sublinear on a real vector space X, let $M \subsetneq X$ be a subspace, and let $f\colon M \to \mathbb{R}$ be linear with $f \leq p$ on M. For any $x_0 \in X \setminus M$ there is a linear extension f' of f to $M' = M \oplus \mathbb{R}x_0$ with $f' \leq p$ on M'.*

Proof. An extension is determined by the single value $c = f'(x_0)$, and $f' \leq p$ on M' means $f(m) + tc \leq p(m + tx_0)$ for all $m \in M$, $t \in \mathbb{R}$. For $t > 0$ this is (dividing by t and relabelling m/t) $c \leq p(m + x_0) - f(m)$; for $t < 0$ it is $c \geq f(m) - p(m - x_0)$. Such a c exists iff

$$\sup_{m \in M} \big[f(m) - p(m - x_0)\big] \;\leq\; \inf_{m \in M} \big[p(m + x_0) - f(m)\big],$$

and this holds because for any $m_1, m_2 \in M$,

$$f(m_1) + f(m_2) = f(m_1 + m_2) \leq p(m_1 + m_2) \leq p(m_1 - x_0) + p(m_2 + x_0),$$

so $f(m_1) - p(m_1 - x_0) \le p(m_2 + x_0) - f(m_2)$. Any c between the two sides works. □

Theorem B.5 (Hahn–Banach, dominated extension)**.** *With p sublinear on X, every linear $f\colon M \to \mathbb{R}$ on a subspace with $f \le p$ on M extends to a linear $F\colon X \to \mathbb{R}$ with $F \le p$ on all of X.*

Proof. Order the set $\mathcal{E}$ of dominated extensions (N, g)—$N \supseteq M$ a subspace, $g\colon N \to \mathbb{R}$ linear, $g|_M = f$, $g \le p$ on N—by declaring $(N_1, g_1) \le (N_2, g_2)$ when $N_1 \subseteq N_2$ and $g_2|_{N_1} = g_1$. Every chain $\{(N_\alpha, g_\alpha)\}$ has the upper bound $(\bigcup_\alpha N_\alpha,\ \bigcup_\alpha g_\alpha)$, which is well defined (the g_α agree on overlaps) and again dominated. By Zorn's lemma $\mathcal{E}$ has a maximal element (N^*, F). If $N^* \ne X$, lemma B.4 extends F to a strictly larger subspace, contradicting maximality; hence $N^* = X$. □

Corollary B.6 (Norm-preserving extension and norming functionals)**.** *Let X be a normed space (over $\mathbb{R}$ or $\mathbb{C}$).*

1. *Every bounded linear functional on a subspace M extends to X with the same norm.*
2. *For each $x_0 \ne 0$ there is $\phi \in X^*$ with $\|\phi\| = 1$ and $\phi(x_0) = \|x_0\|$. Consequently X^* separates points of X.*

Proof. Real case. For (1) put $p(x) = \|f\|_{M^*} \|x\|$, a sublinear (indeed seminorm) dominating f on M (since $f(m) \le |f(m)| \le \|f\|_{M^*} \|m\|$); the dominated extension F of theorem B.5 satisfies $F(x) \le \|f\|_{M^*} \|x\|$ and, applied to $-x$, $|F(x)| \le \|f\|_{M^*} \|x\|$, so $\|F\| \le \|f\|_{M^*}$; the reverse is automatic. For (2) define f on $M = \mathbb{R}x_0$ by $f(tx_0) = t\,\|x_0\|$, of norm 1, and extend.

Complex case. Write a complex functional as $f = u + iv$ with $u = \operatorname{Re} f$; then $v(x) = -u(ix)$, so $f(x) = u(x) - iu(ix)$ and f is recovered from its real part u, a real-linear functional with $|u| \le |f| \le \|f\|\,\|\cdot\|$. Extend u by the real case to $U \le \|f\|\,\|\cdot\|$ and set $F(x) = U(x) - iU(ix)$; F is complex-linear, extends f, and for each x choosing θ with $e^{i\theta}F(x) = |F(x)|$ gives $|F(x)| = F(e^{i\theta}x) = U(e^{i\theta}x) \le \|f\|\,\|x\|$, so $\|F\| = \|f\|$. Part (2) follows as before. □

For the geometric form we use the gauge of a convex set. If $C \subseteq X$ is convex, open, and contains 0, its *Minkowski gauge* is $p_C(x) = \inf\{t > 0 :\ x/t \in C\}$. One checks directly that p_C is sublinear, finite (since C is a neighbourhood of 0), bounded above by $\|\cdot\|/\rho$ on a ball $B(0,\rho) \subseteq C$, and that $C = \{x : p_C(x) < 1\}$ (using that C is open).

Theorem B.7 (Geometric Hahn–Banach)**.** *Let X be a normed space and $A, B \subseteq X$ nonempty disjoint convex sets.*

1. *If A is open there are $\phi \in X^* \setminus \{0\}$ and $\alpha \in \mathbb{R}$ with $\phi(a) < \alpha \le \phi(b)$ for all $a \in A$, $b \in B$.*
2. *If A is closed and B is compact there are $\phi \in X^*$ and $\alpha \in \mathbb{R}$ with $\phi(a) \le \alpha < \phi(b)$ for all $a \in A$, $b \in B$.*

Proof. (1) Fix $a_0 \in A$, $b_0 \in B$ and set $x_0 = b_0 - a_0$ and $C = A - B + x_0 = \{a - b + x_0 : a \in A,\ b \in B\}$. Then C is convex (a sum of convex sets), open (a union of translates of the open A), contains

0 (take $a = a_0, b = b_0$), and does *not* contain x_0: $x_0 \in C$ would give $a - b + x_0 = x_0$, i.e. $a = b \in A \cap B = \varnothing$. Hence $p_C(x_0) \geq 1$. On $M = \mathbb{R}x_0$ define $f(tx_0) = t$; then $f \leq p_C$ on M (for $t > 0$, $f(tx_0) = t \leq t\, p_C(x_0) = p_C(tx_0)$; for $t \leq 0$ the left side is $\leq 0 \leq p_C$). By theorem B.5 extend to $\phi \leq p_C$ on X. Since p_C is bounded near 0, ϕ is bounded, so $\phi \in X^*$, and $\phi \neq 0$ because $\phi(x_0) = 1$. For $a \in A, b \in B$, $a - b + x_0 \in C$ gives $\phi(a) - \phi(b) + 1 = \phi(a - b + x_0) \leq p_C(a - b + x_0) < 1$, i.e. $\phi(a) < \phi(b)$. Thus $\sup_A \phi \leq \inf_B \phi$; any $\alpha \in [\sup_A \phi, \inf_B \phi]$ works, and $\phi(a) < \alpha$ for $a \in A$ because A is open and $\phi \neq 0$ (an open set cannot attain the supremum of a nonzero continuous linear functional).

(2) Disjointness of the closed A and the compact B forces $d = \inf \{\|a - b\| : a \in A, b \in B\} > 0$ (a minimizing pair exists by compactness of B and closedness of A, and equals 0 only if $A \cap B \neq \varnothing$). For $0 < \varepsilon < d$ the set $A_\varepsilon = A + B(0, \varepsilon)$ is open, convex, and still disjoint from B. Apply (1) to A_ε and B: there is $\phi \in X^* \setminus \{0\}$ with $\phi(a') < \phi(b)$ for $a' \in A_\varepsilon$, $b \in B$. Set $\alpha = \sup_A \phi$. Then $\phi(a) \leq \alpha$ for $a \in A$, while for $b \in B$, $\phi(b) \geq \inf_B \phi \geq \sup_{A_\varepsilon} \phi = \sup_A \phi + \varepsilon \|\phi\|_{X^*} > \alpha$, using $\sup_{A_\varepsilon} \phi = \sup_A \phi + \varepsilon \sup_{\|v\| \leq 1} \phi(v) = \sup_A \phi + \varepsilon \|\phi\|$. This is the claimed strict separation. □

B.3 Tychonoff's theorem for Banach–Alaoglu

The body's proof of Banach–Alaoglu (theorem 2.16) realizes the dual ball as a closed subset of the product $P = \prod_{x \in X} [-\|x\|, \|x\|]$ and needs that product to be compact. We supply Tychonoff's theorem in full. The route is the Alexander subbase lemma; the only ingredient beyond elementary topology is Zorn's lemma.

Recall that a *subbase* of a topology is a family $\mathcal{S}$ of open sets whose finite intersections form a base, and that a space is compact iff every open cover has a finite subcover.

Lemma B.8 (Alexander subbase lemma)**.** *Let X be a topological space with subbase $\mathcal{S}$. If every cover of X by members of $\mathcal{S}$ has a finite subcover, then X is compact.*

Proof. Suppose not. Let $\mathcal{A}$ be the collection of open covers of X with no finite subcover; by assumption $\mathcal{A} \neq \varnothing$. Order $\mathcal{A}$ by inclusion. The union of a chain in $\mathcal{A}$ is again a cover with no finite subcover (a finite subcover of the union would already lie in one member of the chain), so chains have upper bounds; by Zorn there is a maximal $\mathcal{C} \in \mathcal{A}$. Maximality means: for every open $U \notin \mathcal{C}$, the cover $\mathcal{C} \cup \{U\}$ *does* have a finite subcover, so $X = U \cup F_1 \cup \cdots \cup F_k$ for some $F_i \in \mathcal{C}$.

Let $\mathcal{C}_{\mathcal{S}} = \mathcal{C} \cap \mathcal{S}$. This subbasic subfamily does not cover X: if it did it would be a subbasic cover, hence have a finite subcover, which would be a finite subcover inside $\mathcal{C}$, contradicting $\mathcal{C} \in \mathcal{A}$. Pick $z \in X$ not covered by $\mathcal{C}_{\mathcal{S}}$. Since $\mathcal{C}$ covers X, $z \in U$ for some $U \in \mathcal{C}$; as $\mathcal{S}$ is a subbase, $z \in S_1 \cap \cdots \cap S_n \subseteq U$ with $S_i \in \mathcal{S}$. Each $S_i \notin \mathcal{C}$: indeed $z \in S_i$, and z lies in no member of $\mathcal{C}_{\mathcal{S}}$, so $S_i \notin \mathcal{C} \cap \mathcal{S}$, hence $S_i \notin \mathcal{C}$. By maximality each S_i is covered together with finitely many members of $\mathcal{C}$: $X = S_i \cup \bigcup \mathcal{F}_i$ with $\mathcal{F}_i \subseteq \mathcal{C}$ finite. Then

$$X \setminus \bigcup_{i=1}^{n} \bigcup \mathcal{F}_i \;\subseteq\; \bigcap_{i=1}^{n} S_i \;\subseteq\; U,$$

so $\{U\} \cup \mathcal{F}_1 \cup \cdots \cup \mathcal{F}_n$ is a finite subcover drawn from $\mathcal{C}$—contradicting $\mathcal{C} \in \mathcal{A}$. Hence X is compact. $\square$

Theorem B.9 (Tychonoff)**.** *Any product $X = \prod_{\alpha \in I} X_\alpha$ of compact spaces is compact in the product topology. In particular $\prod_{x \in X}[-\|x\|, \|x\|]$ is compact, completing the proof of theorem 2.16.*

Proof. The product topology has the subbase $\mathcal{S} = \{\pi_\alpha^{-1}(U) : \alpha \in I,\ U \subseteq X_\alpha \text{ open}\}$, where π_α is the coordinate projection. By lemma B.8 it suffices to show every cover of X by members of $\mathcal{S}$ has a finite subcover. Let $\mathcal{C} \subseteq \mathcal{S}$ be a cover, and for each α set $\mathcal{U}_\alpha = \{U \subseteq X_\alpha \text{ open} : \pi_\alpha^{-1}(U) \in \mathcal{C}\}$.

If some $\mathcal{U}_\alpha$ covers X_α, then by compactness of X_α finitely many $U_1, \ldots, U_k \in \mathcal{U}_\alpha$ cover it, and $\pi_\alpha^{-1}(U_1), \ldots, \pi_\alpha^{-1}(U_k) \in \mathcal{C}$ then cover X—a finite subcover, and we are done. Otherwise no $\mathcal{U}_\alpha$ covers X_α: for each α choose $x_\alpha \in X_\alpha \setminus \bigcup \mathcal{U}_\alpha$. The point $x = (x_\alpha) \in X$ is covered by no member of $\mathcal{C}$: any element of $\mathcal{C}$ is $\pi_\alpha^{-1}(U)$ with $U \in \mathcal{U}_\alpha$, and $x_\alpha \notin U$ gives $x \notin \pi_\alpha^{-1}(U)$. This contradicts that $\mathcal{C}$ is a cover. Hence the first alternative always holds, and X is compact. The product of compact intervals is the special case $X_\alpha = [-\|x\|, \|x\|]$. $\square$

B.4 The spectral theorem: the complex case

Theorem 2.26 was proved in full for a real Hilbert space. We record the two modifications that carry the argument verbatim to a complex separable Hilbert space H, with $\langle \cdot, \cdot \rangle$ the Hermitian inner product of definition 2.3 (linear in the first slot, conjugate-linear in the second) and "self-adjoint" meaning $\langle Tx, y \rangle = \langle x, Ty \rangle$ for all x, y.

Proposition B.10 (Reality of the quadratic form and the eigenvalues)**.** *Let T be a bounded self-adjoint operator on a complex Hilbert space H. Then $\langle Tx, x \rangle \in \mathbb{R}$ for every x, and every eigenvalue of T is real. Moreover lemma 2.25 holds: $\|T\| = \sup_{\|x\|=1} |\langle Tx, x \rangle|$.*

Proof. By Hermitian symmetry and self-adjointness, $\langle Tx, x \rangle = \langle x, Tx \rangle = \overline{\langle Tx, x \rangle}$, so $\langle Tx, x \rangle$ is real. If $Te = \lambda e$ with $e \neq 0$ then $\lambda \|e\|^2 = \langle Te, e \rangle \in \mathbb{R}$, so $\lambda \in \mathbb{R}$. For the norm identity, write $M = \sup_{\|x\|=1} |\langle Tx, x \rangle|$; Cauchy–Schwarz gives $M \leq \|T\|$. For the reverse, the polarization identity in the Hermitian case reads

$$\operatorname{Re}\langle Tx, y \rangle = \tfrac{1}{4}\big(\langle T(x+y), x+y \rangle - \langle T(x-y), x-y \rangle\big),$$

since $\langle Tx, y \rangle + \langle Ty, x \rangle = \langle Tx, y \rangle + \overline{\langle Tx, y \rangle} = 2\operatorname{Re}\langle Tx, y \rangle$ by self-adjointness. As in the body, this and the parallelogram law give $|\operatorname{Re}\langle Tx, y \rangle| \leq \frac{M}{2}(\|x\|^2 + \|y\|^2)$; taking $\|x\| = \|y\| = 1$ and replacing y by the unit phase multiple $e^{i\theta} y$ that makes $\langle Tx, y \rangle$ real and positive turns the left side into $|\langle Tx, y \rangle|$, and choosing y aligned with Tx yields $\|Tx\| \leq M$, i.e. $\|T\| \leq M$. $\square$

With proposition B.10 in hand, the construction of theorem 2.26 runs without any further change: lemma 2.25 produces a maximizing sequence with $\langle Tx_k, x_k \rangle \to \pm\|T\| =: \lambda_1 \in \mathbb{R}$; compactness and the identity $\|Tx_k - \lambda_1 x_k\|^2 = \|Tx_k\|^2 - 2\lambda_1 \langle Tx_k, x_k \rangle + \lambda_1^2$ (whose right side is real throughout) deliver a unit eigenvector e_1 with real eigenvalue λ_1; the orthogonal complement $e_1^\perp$ is invariant by self-adjointness; and the iteration, the decay $\lambda_n \to 0$, finite multiplicities, and the expansion $Tx = \sum_n \lambda_n \langle x, e_n \rangle e_n$ are proved exactly as in the body. This completes the spectral theorem over $\mathbb{C}$.

B.5 Brouwer's fixed-point theorem via Sperner's lemma

We now prove theorem 2.37 from scratch. The engine is a purely combinatorial fact about labelled triangulations.

Let $\Delta^n = \{x \in \mathbb{R}^{n+1} : x_i \geq 0,\ \sum_i x_i = 1\}$ be the standard n-simplex with vertices $v_0, \ldots, v_n$ (the standard basis vectors). A *triangulation* $\mathcal{T}$ of Δ^n is a finite collection of n-dimensional sub-simplices covering Δ^n, any two meeting in a common face (possibly empty). A labelling ℓ of the vertices of $\mathcal{T}$ by $\{0, 1, \ldots, n\}$ is a *Sperner labelling* if every vertex w lying on the face span$\{v_i : i \in S\}$ (i.e. with $w_i = 0$ for $i \notin S$) receives a label $\ell(w) \in S$. A sub-simplex is *fully labelled* (or rainbow) if its $n+1$ vertices carry all of $0, \ldots, n$.

Lemma B.11 (Sperner)**.** *Every Sperner-labelled triangulation of Δ^n contains an odd number of fully labelled sub-simplices; in particular at least one.*

Proof. Induct on n. For $n = 0$, Δ^0 is a point labelled 0, one fully labelled simplex. Assume the statement for $n-1$. Call an $(n-1)$-face of a sub-simplex of $\mathcal{T}$ a *door* if its vertices carry exactly the labels $\{0, 1, \ldots, n-1\}$. For each n-sub-simplex $\sigma \in \mathcal{T}$ let $d(\sigma)$ count the doors among its facets. A short case check on the multiset of labels of σ shows: if σ is fully labelled it has exactly one door; if σ carries the labels $\{0, \ldots, n-1\}$ with one repeated (label n absent) it has exactly two doors; otherwise it has none. Hence

$$\sum_{\sigma \in \mathcal{T}} d(\sigma) \ \equiv\ \#\{\text{fully labelled } \sigma\} \pmod 2.$$

Count doors instead by the facets carrying them. An interior facet is shared by exactly two sub-simplices, contributing 2; a boundary facet lies on a single sub-simplex, contributing 1. So $\sum_\sigma d(\sigma)$ is congruent mod 2 to the number of *boundary* doors. A door has label n absent, so by the Sperner condition it cannot lie on any boundary face other than the facet span$\{v_0, \ldots, v_{n-1}\}$ opposite v_n. Restricted to that facet the labelling is a Sperner labelling of an $(n-1)$-triangulation, so by the inductive hypothesis the number of boundary doors is odd. Therefore $\#\{\text{fully labelled } \sigma\} \equiv \sum_\sigma d(\sigma) \equiv 1 \pmod 2$. ☐

Theorem B.12 (Brouwer on the simplex)**.** *Every continuous map $g\colon \Delta^n \to \Delta^n$ has a fixed point.*

Proof. For $x \in \Delta^n$, since $\sum_i g(x)_i = 1 = \sum_i x_i$, there is an index i with $g(x)_i \leq x_i$ and $x_i > 0$ (if $g(x)_i > x_i$ for every i in the support of x the coordinates of $g(x)$ would sum to more than 1). Take triangulations $\mathcal{T}_k$ of Δ^n with mesh (maximal sub-simplex diameter) tending to 0—for instance iterated barycentric subdivisions. Label each vertex w of $\mathcal{T}_k$ by some index $\ell(w)$ with $g(w)_{\ell(w)} \leq w_{\ell(w)}$ and $w_{\ell(w)} > 0$. This is a Sperner labelling: if w lies on the face $\{v_i : i \in S\}$ then

$w_i = 0$ for $i \notin S$, and the chosen label has $w_{\ell(w)} > 0$, forcing $\ell(w) \in S$. By lemma B.11 there is a fully labelled sub-simplex with vertices $w^{k,0}, \ldots, w^{k,n}$, where $g(w^{k,j})_j \leq w_j^{k,j}$. As the mesh $\to 0$, all $w^{k,j}$ for fixed k are within the mesh of one another; passing to a subsequence, $w^{k,j} \to x^*$ for every j to a common limit $x^* \in \Delta^n$. By continuity $g(x^*)_j \leq x_j^*$ for every $j = 0, \ldots, n$. Since $\sum_j g(x^*)_j = \sum_j x_j^* = 1$, no inequality can be strict, so $g(x^*) = x^*$. □

Theorem B.13 (Brouwer)**.** *Every continuous map $g\colon C \to C$ of a nonempty compact convex set $C \subseteq \mathbb{R}^d$ into itself has a fixed point.*

Proof. Choose a simplex $\Delta \supseteq C$ (a bounded convex body sits inside a large simplex, and C is bounded, being compact). The nearest-point projection $r = P_C\colon \Delta \to C$ onto the closed convex set C is well defined and 1-Lipschitz, hence continuous, by the projection theorem theorem 2.5 applied in the Hilbert space $\mathbb{R}^d$. Then $g \circ r\colon \Delta \to C \subseteq \Delta$ is continuous, so by theorem B.12 (transported to Δ by an affine homeomorphism with Δ^d) it has a fixed point $x^* = g(r(x^*))$. As $g(r(x^*)) \in C$, we have $x^* \in C$, whence $r(x^*) = x^*$ and $x^* = g(r(x^*)) = g(x^*)$. □

B.6 Schauder's fixed-point theorem

We complete the body sketch of theorem 2.38 into a full proof, spelling out the Schauder projection.

Theorem B.14 (Schauder)**.** *Let C be a nonempty closed convex subset of a Banach space X and $\mathsf{S}\colon C \to C$ continuous with $\mathsf{S}(C)$ relatively compact. Then S has a fixed point.*

Proof. Let $K = \overline{\mathsf{S}(C)}$, a compact subset of the convex C, hence $K \subseteq C$. Fix $\varepsilon > 0$. By compactness K has a finite ε-net $\{y_1, \ldots, y_N\} \subseteq K \subseteq C$. Define the *Schauder projection* $P_\varepsilon\colon K \to X$ by

$$P_\varepsilon z = \frac{\sum_{j=1}^N \theta_j(z)\, y_j}{\sum_{j=1}^N \theta_j(z)}, \qquad \theta_j(z) = \max\left(0,\ \varepsilon - \|z - y_j\|\,\right).$$

For each $z \in K$ the denominator is positive (some y_j is within ε of z), and each θ_j is continuous, so P_ε is continuous. Its value is a convex combination of those y_j with $\theta_j(z) > 0$, i.e. $\|z - y_j\| < \varepsilon$; hence $P_\varepsilon z \in C_\varepsilon := \operatorname{conv}\{y_1, \ldots, y_N\}$ and, because each such y_j satisfies $\|z - y_j\| < \varepsilon$,

$$\|P_\varepsilon z - z\| = \left\| \frac{\sum_j \theta_j(z)(y_j - z)}{\sum_j \theta_j(z)} \right\| \leq \frac{\sum_j \theta_j(z)\ \|y_j - z\|}{\sum_j \theta_j(z)} < \varepsilon.$$

Since every $y_j \in K \subseteq C$ and C is convex, $C_\varepsilon \subseteq C$. Thus $P_\varepsilon \circ \mathsf{S}$ maps C_ε (where S is defined, as $C_\varepsilon \subseteq C$) into $\mathsf{S}(C) \subseteq K$ and then into C_ε: it is a continuous self-map of the finite-dimensional compact convex set C_ε. By Brouwer (theorem B.13) it has a fixed point $x_\varepsilon = P_\varepsilon \mathsf{S} x_\varepsilon \in C_\varepsilon$, and

$$\|\mathsf{S}x_\varepsilon - x_\varepsilon\| = \|\mathsf{S}x_\varepsilon - P_\varepsilon \mathsf{S}x_\varepsilon\| < \varepsilon.$$

Take $\varepsilon = 1/n \to 0$. The points $\mathsf{S}x_{1/n} \in K$ have, by compactness, a subsequence converging to some $x_* \in K \subseteq C$; along it $x_{1/n} \to x_*$ as well (since $\left\|x_{1/n} - \mathsf{S}x_{1/n}\right\| \to 0$). Continuity of S gives $\mathsf{S}x_* = \lim \mathsf{S}x_{1/n} = x_*$. □

B.7 The Kakutani–Fan–Glicksberg theorem

Finally we prove theorem 2.40. We give the argument for C a nonempty compact convex subset of a normed space X; this covers every use in the book, since the weak-$*$ compact convex sets of probability measures to which Kakutani is applied are metrizable (the predual is separable) and embed as compact convex subsets of a Banach space. The set-valued problem is reduced to Schauder by a continuous approximate selection.

Lemma B.15 (Approximate selection)**.** *Let $C \subseteq X$ be compact convex and $\mathsf{S}\colon C \rightrightarrows C$ have a closed graph and nonempty convex values. For every $\varepsilon > 0$ there is a continuous $f_\varepsilon\colon C \to C$ such that $f_\varepsilon(x)$ is a convex combination of points $z_i \in \mathsf{S}(x_i)$ with $\|x_i - x\| < \varepsilon$.*

Proof. A closed graph in the compact $C \times C$ makes S upper hemicontinuous: for each $x \in C$ and each $\delta > 0$ there is $r_x > 0$ with $\mathsf{S}\big(B(x, r_x) \cap C\big) \subseteq \mathsf{S}(x) + B(0, \delta)$. (If not, there are $x_n \to x$ and $y_n \in \mathsf{S}(x_n)$ with $\operatorname{dist}(y_n, \mathsf{S}(x)) \geq \delta$; by compactness $y_n \to y$ along a subsequence, and the closed graph gives $y \in \mathsf{S}(x)$, contradicting the distance bound.) Use this with $\delta = \varepsilon$ and shrink each r_x below ε. The balls $\{B(x, r_x/2)\}_{x \in C}$ cover the compact C; take a finite subcover with centres $x_1, \ldots, x_m$ and radii $r_i = r_{x_i}$, and a continuous partition of unity $\{\psi_i\}$ subordinate to $\{B(x_i, r_i)\}$ (e.g. $\psi_i = \eta_i / \sum_k \eta_k$ with $\eta_i(x) = \max(0, r_i - \|x - x_i\|)$). Choose any $z_i \in \mathsf{S}(x_i)$ and set $f_\varepsilon(x) = \sum_i \psi_i(x)\, z_i$. This is continuous and a convex combination of points $z_i \in \mathsf{S}(x_i) \subseteq C$, so $f_\varepsilon(x) \in C$. Whenever $\psi_i(x) > 0$ we have $x \in B(x_i, r_i)$, i.e. $\|x_i - x\| < r_i < \varepsilon$, as claimed. □

Theorem B.16 (Kakutani–Fan–Glicksberg)**.** *Let $C \subseteq X$ be nonempty compact convex and $\mathsf{S}\colon C \rightrightarrows C$ have a closed graph with nonempty, convex, closed values. Then S has a fixed point: some $x_* \in C$ with $x_* \in \mathsf{S}(x_*)$.*

Proof. For each n let $f_n = f_{1/n}\colon C \to C$ be the approximate selection of lemma B.15 with $\varepsilon = 1/n$. Being continuous on the compact convex C with $f_n(C) \subseteq C$ relatively compact, f_n has a fixed point $x_n = f_n(x_n)$ by Schauder (theorem B.14). By compactness pass to a subsequence with $x_n \to x_* \in C$.

We claim $x_* \in \mathsf{S}(x_*)$. Suppose not. Since $\mathsf{S}(x_*)$ is nonempty, convex, and closed, and $\{x_*\}$ is compact convex and disjoint from it, the separation theorem theorem 2.11(2), proved in theorem B.7, gives $\phi \in X^*$ and β with

$$\phi(y) \leq \beta < \phi(x_*) \qquad \text{for all } y \in \mathsf{S}(x_*).$$

Put $\gamma = \frac{1}{2}(\beta + \phi(x_*))$, so $\beta < \gamma < \phi(x_*)$, and let $\eta = (\gamma - \beta)/\|\phi\|$ (with $\phi \neq 0$ since $\beta < \phi(x_*)$). By the upper hemicontinuity established inside lemma B.15 there is $\rho > 0$ with $\mathsf{S}(B(x_*, \rho) \cap C) \subseteq \mathsf{S}(x_*) + B(0, \eta)$; on that neighbourhood every value y' of S satisfies $\phi(y') \leq \beta + \|\phi\|\,\eta = \gamma$. Now write $x_n = f_n(x_n) = \sum_i \psi_i(x_n)\, z_i^{(n)}$ with $z_i^{(n)} \in \mathsf{S}(x_i^{(n)})$ and $\left\|x_i^{(n)} - x_n\right\| < 1/n$. For n large, $x_n \in B(x_*, \rho/2)$ and $1/n < \rho/2$, so each contributing $x_i^{(n)} \in B(x_*, \rho)$ and hence $\phi(z_i^{(n)}) \leq \gamma$. Taking the convex combination, $\phi(x_n) = \sum_i \psi_i(x_n)\, \phi(z_i^{(n)}) \leq \gamma$. Letting $n \to \infty$, continuity of ϕ gives $\phi(x_*) \leq \gamma < \phi(x_*)$, a contradiction. Therefore $x_* \in \mathsf{S}(x_*)$. □

B.8 Sobolev spaces: density, Poincaré, and compactness

We prove the three claims of theorem 2.31. Throughout $\Omega \subseteq \mathbb{R}^d$ is open and bounded; mollification uses a fixed $\rho \in C_c^\infty(\mathbb{R}^d)$ with $\rho \geq 0$, $\operatorname{supp}\rho \subseteq B(0,1)$, $\int \rho = 1$, and $\rho_\delta(x) = \delta^{-d}\rho(x/\delta)$.

Theorem B.17 (Meyers–Serrin)**.** *$C^\infty(\Omega) \cap H^1(\Omega)$ is dense in $H^1(\Omega)$. Consequently $C_c^\infty(\Omega)$ is dense in $H_0^1(\Omega)$ by definition of the latter, and the weak theory is the completion of the classical one.*

Proof. Let $u \in H^1(\Omega)$ and $\varepsilon > 0$. Exhaust Ω by open sets $\Omega_k = \{x \in \Omega : \operatorname{dist}(x, \partial\Omega) > 1/k,\ |x| < k\}$, set $\Omega_0 = \Omega_{-1} = \varnothing$, and let $\{\zeta_k\}$ be a smooth partition of unity with $\operatorname{supp}\zeta_k \subseteq \Omega_{k+1} \setminus \overline{\Omega_{k-1}}$ and $\sum_k \zeta_k \equiv 1$ on Ω. Each $\zeta_k u \in H^1(\Omega)$ has compact support in Ω, so for δ_k small enough the mollification $\rho_{\delta_k} * (\zeta_k u)$ lies in $C_c^\infty(\Omega)$, supported in $\Omega_{k+2} \setminus \overline{\Omega_{k-2}}$, and satisfies $\|\rho_{\delta_k} * (\zeta_k u) - \zeta_k u\|_{H^1(\Omega)} < \varepsilon\, 2^{-k}$ (mollification converges in H^1 on the interior, because $\partial_i(\rho_\delta * v) = \rho_\delta * \partial_i v$ and $\rho_\delta * w \to w$ in L^2 for each L^2 function w). The sum $v = \sum_k \rho_{\delta_k} * (\zeta_k u)$ is locally finite, hence in $C^\infty(\Omega)$, and

$$\|v - u\|_{H^1(\Omega)} = \Big\| \sum_k \big(\rho_{\delta_k} * (\zeta_k u) - \zeta_k u\big) \Big\|_{H^1} \leq \sum_k \varepsilon\, 2^{-k} < 2\varepsilon.$$

Thus smooth functions are H^1-dense; $v \in H^1$ because u is. □

Theorem B.18 (Poincaré)**.** *If Ω lies in a slab $\{x : |x_1| < R\}$ then $\|u\|_{L^2(\Omega)} \leq 2R\, \|\nabla u\|_{L^2(\Omega)}$ for all $u \in H_0^1(\Omega)$. Hence on $H_0^1(\Omega)$ the gradient norm is equivalent to the full H^1 norm.*

Proof. By density (theorem B.17) it suffices to prove the bound for $u \in C_c^\infty(\Omega)$, extended by zero to $\mathbb{R}^d$. Writing $x = (x_1, x')$ and using $u(-R, x') = 0$,

$$u(x_1, x') = \int_{-R}^{x_1} \partial_1 u(t, x')\, \mathrm{d}t,$$

so by Cauchy–Schwarz $|u(x_1,x')|^2 \leq 2R \int_{-R}^{R} |\partial_1 u(t,x')|^2\, \mathrm{d}t$. Integrating in x_1 over $(-R,R)$ and then in x',

$$\int_\Omega |u|^2 \leq (2R)^2 \int_\Omega |\partial_1 u|^2 \leq (2R)^2 \int_\Omega |\nabla u|^2 .$$

The norm equivalence follows since $\|\nabla u\|_{L^2}^2 \leq \|u\|_{H^1}^2 = \|u\|_{L^2}^2 + \|\nabla u\|_{L^2}^2 \leq (1 + 4R^2)\, \|\nabla u\|_{L^2}^2$. □

The compact embedding is reached through a general L^2 compactness criterion, which we prove first.

Theorem B.19 (Fréchet–Kolmogorov–Riesz)**.** *A bounded family $\mathcal{F} \subseteq L^2(\mathbb{R}^d)$ is relatively compact in $L^2(\mathbb{R}^d)$ provided*

1. (equicontinuity of translation) $\sup_{f \in \mathcal{F}} \|\tau_h f - f\|_{L^2} \to 0$ *as* $|h| \to 0$, *where* $(\tau_h f)(x) = f(x+h)$; *and*
2. (uniform decay) $\sup_{f \in \mathcal{F}} \int_{|x|>R} |f|^2 \to 0$ *as* $R \to \infty$.

Proof. We show $\mathcal{F}$ is totally bounded; completeness of L^2 then gives relative compactness. Fix $\varepsilon > 0$. By (2) choose R with $\int_{|x|>R} |f|^2 < \varepsilon^2$ for all f. For the mollification $\rho_\delta * f$, Minkowski's integral inequality gives

$$\|\rho_\delta * f - f\|_{L^2} = \Big\| \int \rho_\delta(y)(\tau_{-y}f - f)\, \mathrm{d}y \Big\|_{L^2} \le \int \rho_\delta(y)\, \|\tau_{-y}f - f\|_{L^2}\, \mathrm{d}y \le \sup_{|y|\le\delta} \|\tau_{-y}f - f\|_{L^2},$$

which by (1) is $< \varepsilon$ for δ small, uniformly in f. Fix such a δ. On the ball $B_R = \{|x| \le R\}$ the family $\{\rho_\delta * f : f \in \mathcal{F}\}$ is uniformly bounded, $|(\rho_\delta * f)(x)| \le \|\rho_\delta\|_{L^2} \|f\|_{L^2} \le C_\delta$, and equicontinuous,

$$|(\rho_\delta * f)(x) - (\rho_\delta * f)(x')| \le \|\tau_{-x}\rho_\delta - \tau_{-x'}\rho_\delta\|_{L^2}\, \|f\|_{L^2} \le \omega_\delta(|x - x'|),$$

with $\omega_\delta(s) \to 0$ as $s \to 0$ because translation is continuous in L^2 and $\|f\|_{L^2}$ is bounded. By Arzelà–Ascoli, $\{\rho_\delta * f|_{B_R}\}$ is relatively compact in $C(B_R)$, hence (as B_R has finite measure) in $L^2(B_R)$: cover it by finitely many $L^2(B_R)$-balls of radius ε with centres $g_1, \dots, g_m$, regarded as functions on $\mathbb{R}^d$ supported in B_R. For any $f \in \mathcal{F}$ pick g_k with $\|\rho_\delta * f - g_k\|_{L^2(B_R)} < \varepsilon$; then, splitting $\mathbb{R}^d = B_R \cup B_R^c$ and using the tail bounds,

$$\|f - g_k\|_{L^2(\mathbb{R}^d)} \le \|f - \rho_\delta * f\|_{L^2} + \|\rho_\delta * f - g_k\|_{L^2(B_R)} + \Big(\int_{|x|>R} |\rho_\delta * f|^2 \Big)^{1/2} \le C\varepsilon.$$

Thus finitely many balls of radius $C\varepsilon$ cover $\mathcal{F}$, so $\mathcal{F}$ is totally bounded. □

Lemma B.20 (Translation estimate)**.** *For $u \in H^1(\mathbb{R}^d)$ and $h \in \mathbb{R}^d$, $\|\tau_h u - u\|_{L^2(\mathbb{R}^d)} \le |h|\, \|\nabla u\|_{L^2(\mathbb{R}^d)}$.*

Proof. For $u \in C_c^\infty(\mathbb{R}^d)$, $u(x+h) - u(x) = \int_0^1 \nabla u(x + th) \cdot h\, \mathrm{d}t$, so by Cauchy–Schwarz and Tonelli

$$\int |u(x+h) - u(x)|^2\, \mathrm{d}x \le |h|^2 \int_0^1 \!\! \int |\nabla u(x + th)|^2\, \mathrm{d}x\, \mathrm{d}t = |h|^2\, \|\nabla u\|_{L^2}^2.$$

The general case follows because C_c^∞ is dense in $H^1(\mathbb{R}^d)$ and both sides are continuous in u for the H^1 norm. □

Theorem B.21 (Rellich–Kondrachov for H_0^1)**.** *For $\Omega \subseteq \mathbb{R}^d$ open and bounded, the inclusion $H_0^1(\Omega) \hookrightarrow L^2(\Omega)$ is compact: every sequence bounded in $H_0^1(\Omega)$ has an $L^2(\Omega)$-convergent subsequence.*

Proof. Extend each $u \in H_0^1(\Omega)$ by zero to $\tilde{u} \in H^1(\mathbb{R}^d)$ (the extension is in $H^1(\mathbb{R}^d)$ precisely because $u \in H_0^1$ is an H^1-limit of $C_c^\infty(\Omega)$ functions, for which zero extension is automatic), with $\|\tilde{u}\|_{H^1(\mathbb{R}^d)} = \|u\|_{H^1(\Omega)}$ and $\operatorname{supp} \tilde{u} \subseteq \overline{\Omega}$. Let $\mathcal{F} = \{\tilde{u} : \|u\|_{H^1} \le 1\}$. It is bounded in $L^2(\mathbb{R}^d)$; the decay hypothesis (2) of theorem B.19 holds trivially because every $\tilde{u}$ is supported in the fixed bounded $\overline{\Omega}$ (the tail integral vanishes for R large); and the translation hypothesis (1) is lemma B.20: $\sup_{\mathcal{F}} \|\tau_h \tilde{u} - \tilde{u}\|_{L^2} \le |h| \sup_{\mathcal{F}} \|\nabla \tilde{u}\|_{L^2} \le |h| \to 0$. Hence $\mathcal{F}$ is relatively compact in $L^2(\mathbb{R}^d)$, and restricting to Ω gives the claim. □

On the torus the same compactness drops out of the Fourier definition of definition 2.32, with no extension needed; this is the form used for periodic MFG.

Theorem B.22 (Rellich on the torus)**.** *$H^1(\mathbb{T}^d) \hookrightarrow L^2(\mathbb{T}^d)$ is compact.*

Proof. A function $u \in L^2(\mathbb{T}^d)$ has Fourier coefficients $\hat{u}(k)$, $k \in \mathbb{Z}^d$, with $\|u\|_{L^2}^2 = \sum_k |\hat{u}(k)|^2$ and $\|u\|_{H^1}^2 = \sum_k (1+|k|^2)\,|\hat{u}(k)|^2$. Let $\|u_n\|_{H^1} \le 1$. The coefficients $\hat{u}_n(k)$ are bounded for each fixed k, so by a diagonal argument a subsequence has $\hat{u}_n(k) \to c(k)$ for every k, with $\sum_k (1+|k|^2)\,|c(k)|^2 \le 1$. For any R, $\sum_{|k|>R} |\hat{u}_n(k)|^2 \le (1+R^2)^{-1} \sum_k (1+|k|^2)\,|\hat{u}_n(k)|^2 \le (1+R^2)^{-1}$ uniformly in n, and likewise for the limit. Given ε, fix R with $(1+R^2)^{-1} < \varepsilon$; the finitely many low modes converge, so $\limsup_{n,m} \|u_n - u_m\|_{L^2}^2 \le 4\varepsilon$. Hence (u_n) is L^2-Cauchy along the subsequence, proving compactness. □

Remark B.23 (General bounded Lipschitz domains)**.** For $H^1(\Omega)$ with nonzero boundary trace one cannot extend by zero. The standard route is a bounded *Sobolev extension operator* $E\colon H^1(\Omega) \to H^1(\mathbb{R}^d)$ with $Eu|_\Omega = u$, which exists when $\partial\Omega$ is Lipschitz: locally flatten the boundary and reflect across it, then patch by a partition of unity. Granting E, the family $\left\{Eu : \|u\|_{H^1(\Omega)} \le 1\right\}$ is H^1-bounded with supports in a fixed bounded set, so the argument of theorem B.21 (via theorem B.19 and lemma B.20) yields compactness of $H^1(\Omega) \hookrightarrow L^2(\Omega)$. Every PDE existence proof in this book uses either Dirichlet data (the H^1_0 case of theorem B.21) or the periodic setting (theorem B.22), both proved here in full; the extension operator is needed only for the general-trace statement, and we refer to [64, Ch. 5] for its construction.

B.9 Arzelà–Ascoli for metric-space-valued maps

The classical Arzelà–Ascoli theorem characterises compactness of families of *real-valued* continuous functions; the existence theory of chapter 10 needs the same statement for maps from a compact interval into a (non-locally-compact) metric space — the Wasserstein space $(\mathcal{P}_1(\mathbb{R}^d), \mathcal{W}_1)$ of population flows. We record the general version; the real-valued case used above (e.g. in theorem B.19) is the instance $(Y,d) = (\mathbb{R}, |\cdot|)$.

Theorem B.24 (Arzelà–Ascoli, metric-space-valued)**.** *Let K be a compact metric space, (Y,d) a complete metric space, and $C(K;Y)$ the space of continuous maps with the uniform metric $\rho(f,g) = \sup_{t\in K} d(f(t),g(t))$. A family $\mathcal{F} \subseteq C(K;Y)$ is relatively compact in $(C(K;Y),\rho)$ if and only if*

(i) $\mathcal{F}$ *is* uniformly equicontinuous*: for every $\varepsilon > 0$ there is $\delta > 0$ with $d(f(s),f(t)) < \varepsilon$ whenever $d_K(s,t) < \delta$, for all $f \in \mathcal{F}$; and*

(ii) $\mathcal{F}$ *is* pointwise relatively compact*: for each $t \in K$ the set $\mathcal{F}(t) = \{f(t) : f \in \mathcal{F}\}$ has compact closure in Y.*

Proof. Necessity. A relatively compact $\mathcal{F}$ is totally bounded, which gives (i) by an $\varepsilon/3$ argument, and each evaluation $f \mapsto f(t)$ is continuous $C(K;Y) \to Y$, carrying the relatively compact $\mathcal{F}$ to the relatively compact $\mathcal{F}(t)$, giving (ii).

Sufficiency. Since Y is complete, $(C(K;Y),\rho)$ is complete, so it suffices to show every sequence $(f_n) \subseteq \mathcal{F}$ has a ρ-convergent subsequence. Let $D = \{t_1, t_2, \ldots\}$ be a countable dense subset of the (separable, being compact metric) space K. By (ii) and a diagonal argument, pass to a subsequence (still f_n) with $f_n(t_j)$ convergent in Y for every j. We show (f_n) is uniformly Cauchy. Fix $\varepsilon > 0$ and choose δ from (i) for $\varepsilon/3$. Finitely many balls $B(t_{j_i}, \delta)$, $i = 1, \ldots, N$, with centres in D, cover the compact K. Choose N_0 with $d(f_n(t_{j_i}), f_m(t_{j_i})) < \varepsilon/3$ for $n, m \geq N_0$ and all $i \leq N$. For any $t \in K$, picking i with $d_K(t, t_{j_i}) < \delta$,

$$d(f_n(t), f_m(t)) \leq d(f_n(t), f_n(t_{j_i})) + d(f_n(t_{j_i}), f_m(t_{j_i})) + d(f_m(t_{j_i}), f_m(t)) < \varepsilon,$$

the outer terms by (i). Hence $\rho(f_n, f_m) \leq \varepsilon$ for $n, m \geq N_0$, so (f_n) is ρ-Cauchy and converges in $C(K; Y)$. □

Remark B.25. In lemma 10.8, $K = [0, T]$, $Y = (\mathcal{P}_1(\mathbb{R}^d), \mathcal{W}_1)$ (complete by theorem D.11), equicontinuity is the uniform $\frac{1}{2}$-Hölder modulus ω of lemma 10.7, and pointwise relative compactness is the uniform second-moment bound feeding tightness and $\mathcal{W}_1$-compactness (theorem D.12).

B.10 Berge's maximum theorem

The closed-graph input to the Kakutani–Fan–Glicksberg fixed point of the relaxed MFG (theorem 10.19) is supplied by Berge's maximum theorem, controlling how the optimal value and optimiser set of a parametrised optimisation vary with the parameter.

Definition B.26 (Hemicontinuity)**.** A correspondence $\Gamma\colon X \rightrightarrows Y$ into a topological space is *upper hemicontinuous (uhc) with compact values at x* if $\Gamma(x)$ is compact and every open $V \supseteq \Gamma(x)$ has a neighbourhood $U \ni x$ with $\Gamma(x') \subseteq V$ for $x' \in U$; it is *lower hemicontinuous (lhc) at x* if every open V meeting $\Gamma(x)$ has a neighbourhood $U \ni x$ with $\Gamma(x') \cap V \neq \varnothing$ for $x' \in U$. For compact-valued correspondences into a metric space with a uniformly compact range along convergent parameters, uhc is equivalent to the sequential closed-graph property: $x_n \to x$, $y_n \in \Gamma(x_n)$, $y_n \to y$ imply $y \in \Gamma(x)$.

Theorem B.27 (Berge)**.** *Let X be a topological space, Y a metric space, $\Gamma\colon X \rightrightarrows Y$ continuous (uhc and lhc) with nonempty compact values, and $f\colon X \times Y \to \mathbb{R}$ continuous. Then the value $V(x) = \max_{y \in \Gamma(x)} f(x, y)$ is continuous, and the optimiser correspondence $M(x) = \arg\max_{y \in \Gamma(x)} f(x, y)$ is uhc with nonempty compact values.*

Proof. $f(x, \cdot)$ is continuous on the nonempty compact $\Gamma(x)$, so it attains its max and $M(x)$ is a nonempty closed (hence compact) subset of $\Gamma(x)$.

Lower semicontinuity of V. Fix x, $\varepsilon > 0$, $y^* \in M(x)$. By lhc and continuity of f, for x' near x there is $y' \in \Gamma(x')$ near y^* with $f(x', y') > V(x) - \varepsilon$; thus $V(x') > V(x) - \varepsilon$.

Upper semicontinuity of V. If $x_n \to x$ with $V(x_n) \to \ell > V(x)$, pick $y_n \in M(x_n)$; by uhc of Γ the y_n eventually lie in a compact neighbourhood of $\Gamma(x)$, so $y_n \to y \in \Gamma(x)$ along a subsequence, and $f(x, y) = \lim f(x_n, y_n) = \ell > V(x)$ contradicts $V(x) \geq f(x, y)$. So V is continuous.

M is uhc. If $x_n \to x$, $y_n \in M(x_n)$, $y_n \to y$, then $y \in \Gamma(x)$ by uhc of Γ and $f(x, y) = \lim f(x_n, y_n) = \lim V(x_n) = V(x)$, so $y \in M(x)$: closed graph with locally compact range, i.e. uhc. □

B.11 Measurable selection: the Kuratowski–Ryll-Nardzewski theorem

Recovering an executable feedback from the set-valued optimiser correspondence of lemma 10.20 requires a *measurable* choice of one optimiser at each (t, x).

Definition B.28 (Weakly measurable correspondence)**.** Let (Ω, Σ) be a measurable space and Y a Polish space. A correspondence $\Gamma\colon \Omega \rightrightarrows Y$ with nonempty closed values is *weakly measurable* if for every open $U \subseteq Y$ the lower inverse $\Gamma^-(U) = \{\omega : \Gamma(\omega) \cap U \neq \varnothing\}$ lies in Σ. A *selection* is a measurable $f\colon \Omega \to Y$ with $f(\omega) \in \Gamma(\omega)$ for all ω.

Theorem B.29 (Kuratowski–Ryll-Nardzewski)**.** *Let (Ω, Σ) be a measurable space and Y a Polish space with complete metric $d \leq 1$. Every weakly measurable $\Gamma\colon \Omega \rightrightarrows Y$ with nonempty closed values admits a measurable selection.*

Proof. Fix a countable dense set $\{y_1, y_2, \ldots\} \subseteq Y$. We construct measurable countably-valued $f_n\colon \Omega \to Y$ with, for all ω,

$$d(f_n(\omega), \Gamma(\omega)) < 2^{-n} \quad \text{and} \quad d(f_n(\omega), f_{n-1}(\omega)) < 3 \cdot 2^{-n} \quad (n \geq 1), \tag{B.3}$$

so that $(f_n(\omega))$ is uniformly Cauchy, converging to a measurable $f(\omega)$ with $f(\omega) \in \Gamma(\omega)$ (closedness of $\Gamma(\omega)$ and the first bound).

Base step. Let $f_0(\omega) = y_{k(\omega)}$, $k(\omega)$ the least k with $\Gamma(\omega) \cap B(y_k, 1) \neq \varnothing$ (exists by density and nonemptiness). The cell $\{k(\omega) = k\} = \Gamma^-(B(y_k, 1)) \setminus \bigcup_{j<k} \Gamma^-(B(y_j, 1)) \in \Sigma$ by weak measurability, so f_0 is measurable, countably valued, with $d(f_0(\omega), \Gamma(\omega)) < 1$.

Inductive step. Given measurable countably-valued f_{n-1} with $d(f_{n-1}(\omega), \Gamma(\omega)) < 2^{-(n-1)}$, on each cell $\{f_{n-1} = y_i\}$ the correspondence $\Gamma_i(\omega) = \Gamma(\omega) \cap \overline{B}(y_i, 2^{-(n-1)})$ has nonempty closed values and is weakly measurable (its lower inverses are obtained from those of Γ by countable Boolean operations with the fixed ball). Apply the base-step rule to Γ_i at radius 2^{-n}: $f_n(\omega) = y_k$ for the least k with $\Gamma_i(\omega) \cap B(y_k, 2^{-n}) \neq \varnothing$. Then $d(f_n(\omega), \Gamma(\omega)) < 2^{-n}$; and since $f_n(\omega)$ and $f_{n-1}(\omega) = y_i$ are within 2^{-n} resp. $2^{-(n-1)}$ of a common point of $\Gamma_i(\omega)$, $d(f_n, f_{n-1}) < 2^{-n} + 2^{-(n-1)} = 3 \cdot 2^{-n}$, giving (B.3). Each f_n is measurable, defined cellwise by least-index selections. This completes the induction and the proof. □

Corollary B.30 (Euclidean (Filippov) special case)**.** *If $Y = \mathbb{R}^k$ and $\Gamma(\omega)$ is the nonempty compact set of maximisers of a Carathéodory function $a \mapsto h(\omega, a)$ over a compact $A \subseteq \mathbb{R}^k$ (h measurable in ω, continuous in a), then Γ is weakly measurable and the* lexicographic *selection — the maximiser of least first coordinate, then least second, and so on — is measurable. Each successive coordinate optimisation over a compact set defines an uhc singleton-valued map by theorem B.27, so no general selection theorem is needed.*

Proof. Weak measurability holds because $\Gamma^-(U) = \left\{\omega : \sup_{a \in \overline{U} \cap A} h(\omega, a) = \max_A h(\omega, \cdot)\right\}$ is measurable (suprema of a Carathéodory function over the separable sets $\overline{U} \cap A$ and A are measurable in ω). The lexicographic map is the k-fold composition of theorem B.27, each step restricting to the compact optimiser set of the previous coordinate; the terminal singleton-valued correspondence is uhc, hence has measurable graph and a measurable selection. □

Bibliographic notes

The Hahn–Banach theorem, the Minkowski-gauge separation argument, and the Alexander-subbase proof of Tychonoff are classical; see [31, Ch. 1,3] and [113, Ch. IV]. The Sperner-lemma proof of Brouwer and the reduction of Schauder and Kakutani to it follow [79, Ch. I–II]; the continuous-selection route to Kakutani is Cellina's. The metric-space Arzelà–Ascoli theorem, Berge's maximum theorem, and the Kuratowski–Ryll-Nardzewski measurable-selection theorem are standard; see [6, Ch. 17–18]. The Sobolev material—Meyers–Serrin density, Poincaré, and Rellich–Kondrachov via the Fréchet–Kolmogorov criterion—follows [64, Ch. 5] and [31, Ch. 8–9]. All statements are used in chapter 2 and downstream in the existence theory of chapters 10 and 24.

Appendix C

Stochastic Calculus: Foundations and Deferred Proofs

This appendix supplies, in full or by complete and honest proof, the beyond-prerequisite results that chapter 5 states and uses but defers for the sake of narrative flow, and collects the standard tools of stochastic calculus that the probabilistic chapters (chapters 9 and 23) draw on. Nothing here is assumed from outside the book: each result is proved from the probabilistic foundations of chapter 3, the functional analysis of chapter 2, and the Brownian and Itô material built in chapter 5 itself. External references in the bibliographic notes are for attribution and further reading only.

We work throughout on a filtered probability space $(\Omega, \mathcal{F}, (\mathcal{F}_t)_{t\geq 0}, \mathbb{P})$ satisfying the usual conditions (completeness and right-continuity of the filtration), with W a Brownian motion as in definition 5.1. We freely use the notation of chapter 5: the integrand space $\mathcal{M}^2[0,T]$ of progressively measurable processes with $\mathbb{E}\int_0^T H_t^2 \,\mathrm{d}t < \infty$, the Itô integral, and the quadratic variation $\langle\cdot\rangle$.

C.1 Grönwall's inequality

The closing device of nearly every existence, uniqueness, and stability estimate in the book — including the well-posedness of theorem 5.10 — is the following elementary integral inequality. We state and prove the version actually used.

Lemma C.1 (Grönwall's inequality, integral form)**.** *Let $\phi : [0,T] \to [0,\infty)$ be Borel measurable and bounded, and suppose there are constants $A \geq 0$ and $B \geq 0$ with*

$$\phi(t) \;\leq\; A + B\int_0^t \phi(s)\,\mathrm{d}s \qquad \textit{for all } t \in [0,T]. \tag{C.1}$$

Then $\phi(t) \leq A\,e^{Bt}$ for all $t \in [0,T]$. In particular, if $A = 0$ then $\phi \equiv 0$.

Proof. Set $\Psi(t) := \int_0^t \phi(s)\,\mathrm{d}s$, which is absolutely continuous with $\Psi'(t) = \phi(t)$ for almost every t, and $\Psi(0) = 0$. Inequality (C.1) reads $\Psi'(t) \leq A + B\,\Psi(t)$ a.e. Multiplying by the integrating factor

$e^{-Bt} > 0$,

$$\frac{\mathrm{d}}{\mathrm{d}t}\Big(e^{-Bt}\Psi(t)\Big) = e^{-Bt}(\Psi'(t) - B\Psi(t)) \le A\, e^{-Bt}.$$

Integrating from 0 to t and using $\Psi(0) = 0$ gives $e^{-Bt}\Psi(t) \le \frac{A}{B}\big(1 - e^{-Bt}\big)$ when $B > 0$, i.e. $\Psi(t) \le \frac{A}{B}\big(e^{Bt} - 1\big)$. Substituting back into (C.1),

$$\phi(t) \le A + B\,\Psi(t) \le A + A\big(e^{Bt} - 1\big) = A\, e^{Bt}.$$

When $B = 0$ the claim is immediate from (C.1). Finally, if $A = 0$ then $0 \le \phi(t) \le A\, e^{Bt} = 0$, so $\phi \equiv 0$. $\square$

C.2 Doob's maximal inequality and the Burkholder–Davis–Gundy estimate

The Itô integral is an L^2-bounded martingale (theorem 5.7); to control its *running maximum* — needed both for the continuous-modification claim of definition 5.6 and for the maximal $\mathcal{S}^2$ estimate that powers the Picard iteration in theorem 5.10 — we use Doob's inequality.

Theorem C.2 (Doob's L^2 maximal inequality)**.** *Let $(M_t)_{t\in[0,T]}$ be a continuous $\mathbb{F}$-martingale with $\mathbb{E}M_T^2 < \infty$. Then*

$$\mathbb{E}\Big[\sup_{0\le t\le T} M_t^2\Big] \;\le\; 4\,\mathbb{E}\,M_T^2. \tag{C.2}$$

Proof. We first prove the *maximal inequality*: for $\lambda > 0$,

$$\lambda\,\mathbb{P}\Big(\sup_{t\le T}|M_t| \ge \lambda\Big) \le \mathbb{E}\big[\,|M_T|\;\mathbf{1}_{\{\sup_t|M_t|\ge\lambda\}}\big]. \tag{C.3}$$

By continuity of paths, $\tau := \inf\{t : |M_t| \ge \lambda\} \wedge T$ is a stopping time and on the event $\{\sup_{t\le T}|M_t| \ge \lambda\}$ we have $|M_\tau| \ge \lambda$. By optional stopping (Jensen applied to the submartingale $|M|$) and the tower property, $\mathbb{E}[|M_T| \mid \mathcal{F}_\tau] \ge |M_\tau|$, so

$$\lambda\,\mathbb{P}\Big(\sup_{t\le T}|M_t| \ge \lambda\Big) \le \mathbb{E}\big[\,|M_\tau|\;\mathbf{1}_{\{\sup|M|\ge\lambda\}}\big] \le \mathbb{E}\big[\,|M_T|\;\mathbf{1}_{\{\sup|M|\ge\lambda\}}\big],$$

which is (C.3). Now write $S := \sup_{t\le T}|M_t|$. Using (C.3) and Fubini,

$$\mathbb{E}\,S^2 = \int_0^\infty 2\lambda\,\mathbb{P}(S \ge \lambda)\;\mathrm{d}\lambda \le \int_0^\infty 2\,\mathbb{E}\big[\,|M_T|\,\mathbf{1}_{\{S\ge\lambda\}}\big]\,\mathrm{d}\lambda = 2\,\mathbb{E}\Big[\,|M_T|\int_0^S \mathrm{d}\lambda\Big] = 2\,\mathbb{E}\big[\,|M_T|\;S\big].$$

By Cauchy–Schwarz, $2\,\mathbb{E}[|M_T|\,S] \le 2\,(\mathbb{E}M_T^2)^{1/2}(\mathbb{E}S^2)^{1/2}$. If $\mathbb{E}S^2 < \infty$ this gives $\mathbb{E}S^2 \le 2(\mathbb{E}M_T^2)^{1/2}(\mathbb{E}S^2)^{1/2}$, i.e. $(\mathbb{E}S^2)^{1/2} \le 2(\mathbb{E}M_T^2)^{1/2}$, which is (C.2). The integrability of S is obtained by first applying the argument to the bounded stopped martingale $M_{t\wedge\tau_n}$, $\tau_n = \inf\{t : |M_t| \ge n\}$ (bounded by n via path continuity), and letting $n \to \infty$ by monotone convergence ($\sup_{t\le T}|M_{t\wedge\tau_n}| \uparrow S$). $\square$

For the diffusion term of an SDE the integrand of the Itô integral is itself random, and one needs to bound the running maximum of $M_t = \int_0^t H_s \, \mathrm{d}W_s$ by the *predictable* quantity $\langle M\rangle_T = \int_0^T H_s^2 \, \mathrm{d}s$. In the L^2 case this is immediate from Doob: by theorem 5.7,

$$\mathbb{E}\Big[\sup_{t\le T}\Big(\int_0^t H_s \, \mathrm{d}W_s\Big)^2\Big] \;\le\; 4\,\mathbb{E}\Big[\Big(\int_0^T H_s \, \mathrm{d}W_s\Big)^2\Big] \;=\; 4\,\mathbb{E}\int_0^T H_s^2 \, \mathrm{d}s. \tag{C.4}$$

This L^2 bound is all that theorem 5.10 uses. We record the general statement, used in the BSDE chapters, for completeness.

Theorem C.3 (Burkholder–Davis–Gundy inequality)**.** *For every $p \in (0,\infty)$ there exist universal constants $0 < c_p \le C_p < \infty$ such that for every continuous local martingale M with $M_0 = 0$,*

$$c_p\,\mathbb{E}\big[\langle M\rangle_T^{p/2}\big] \;\le\; \mathbb{E}\Big[\sup_{t\le T}|M_t|^p\Big] \;\le\; C_p\,\mathbb{E}\big[\langle M\rangle_T^{p/2}\big].$$

Proof of the case $p = 2$. For $p = 2$ the upper bound with $C_2 = 4$ is (C.4) (extended to local martingales by localization, below), and the lower bound with $c_2 = 1$ is $\mathbb{E}\sup_t M_t^2 \ge \mathbb{E}M_T^2 = \mathbb{E}\langle M\rangle_T$, the last equality being theorem 5.7(3). The general p follows from the good-λ inequalities of [86, 114]; only $p = 2$ is used in chapter 5. ☐

Remark C.4 (Localization to local martingales)**.** A continuous *local* martingale M is one for which there is an increasing sequence of stopping times $\tau_n \uparrow \infty$ with each stopped process $M_t^{\tau_n} = M_{t\wedge\tau_n}$ a genuine martingale. The Itô integral $\int_0^t H \, \mathrm{d}W$ is a true martingale when $H \in \mathcal{M}^2[0,T]$ and a local martingale under the weaker hypothesis $\int_0^T H_s^2 \, \mathrm{d}s < \infty$ almost surely, with localizing times $\tau_n = \inf\{t : \int_0^t H_s^2 \, \mathrm{d}s \ge n\}$. All martingale identities above extend to local martingales by applying them to M^{τ_n} and passing to the limit, monotone or dominated convergence supplying the integrability.

C.3 A continuous finite-variation martingale is constant

The backward-equation proof (theorem 5.15) and many later arguments use the fact that a process which is simultaneously a martingale and smooth enough to have finite variation cannot move. It is a clean corollary of the quadratic-variation theory.

Lemma C.5 (No continuous finite-variation martingale moves)**.** *Let $(M_t)_{t\in[0,T]}$ be a continuous $\mathbb{F}$-martingale with $M_0 = 0$ whose paths have finite total variation on $[0,T]$ almost surely. Then $M_t = 0$ for all t, almost surely.*

Proof. Assume first M is bounded, $|M_t| \le K$. Fix t and a partition $0 = t_0 < \cdots < t_n = t$ with mesh $\to 0$. Because M is a martingale, the increments $\Delta_i M = M_{t_{i+1}} - M_{t_i}$ are orthogonal in L^2 (for $i < j$, $\mathbb{E}[\Delta_i M\,\Delta_j M] = \mathbb{E}[\Delta_i M\,\mathbb{E}[\Delta_j M \mid \mathcal{F}_{t_j}]] = 0$), so

$$\mathbb{E}\,M_t^2 = \mathbb{E}\sum_i(\Delta_i M)^2 \le \mathbb{E}\Big[\max_i|\Delta_i M|\;\sum_i|\Delta_i M|\Big] \le \mathbb{E}\Big[\max_i|\Delta_i M|\cdot V\Big],$$

where V is the (finite) total variation of the path. As the mesh shrinks, $\max_i |\Delta_i M| \to 0$ by uniform continuity of the path on $[0,t]$, and the integrand is bounded by $2KV$; if V is bounded the dominated convergence theorem gives $\mathbb{E}M_t^2 = 0$. For the general (unbounded-variation-allowed only via the stopping) case, localize by $\tau_n = \inf\{t : |M_t| \geq n \text{ or } V_t \geq n\}$, apply the bounded case to M^{τ_n} to get $M_{t\wedge\tau_n} = 0$, and let $n \to \infty$; since $\tau_n \uparrow T$ almost surely, $M_t = 0$ for all t. □

The same computation identifies the quadratic variation of a continuous martingale as the unique continuous increasing process making $M_t^2 - \langle M\rangle_t$ a martingale, and shows a continuous finite-variation martingale has $\langle M\rangle \equiv 0$; the lemma is the statement that $\langle M\rangle \equiv 0$ forces M constant.

C.4 Density of simple processes in $\mathcal{M}^2[0,T]$

The Itô integral is *defined* on simple integrands and extended by isometry (definition 5.6); the extension is legitimate only because the simple processes are dense. We prove this load-bearing approximation lemma.

Lemma C.6 (Density of simple processes)**.** *The simple processes are dense in $\mathcal{M}^2[0,T]$ for the norm $\|H\|^2_{\mathcal{M}^2} = \mathbb{E}\int_0^T H_t^2 \,\mathrm{d}t$. That is, for every progressively measurable H with $\|H\|_{\mathcal{M}^2} < \infty$ and every $\varepsilon > 0$ there is a simple process H^ε with $\|H - H^\varepsilon\|_{\mathcal{M}^2} < \varepsilon$.*

Proof. We approximate in three steps, each reducing to the next a strictly larger class.

Step 1: reduction to bounded H. For $H \in \mathcal{M}^2[0,T]$ put $H_t^{(K)} = H_t\,\mathbf{1}_{\{|H_t|\leq K\}}$. Then $H^{(K)}$ is progressively measurable and bounded, and $\left|H - H^{(K)}\right|^2 \leq H^2 \in L^1(\mathrm{d}t \otimes \mathbb{P})$, so by dominated convergence $\left\|H - H^{(K)}\right\|_{\mathcal{M}^2} \to 0$ as $K \to \infty$. It therefore suffices to approximate bounded progressively measurable processes.

Step 2: reduction to (a.s.) continuous H. Let H be bounded, $|H| \leq K$, progressively measurable. For $h > 0$ define the moving average

$$H_t^h := \frac{1}{h}\int_{(t-h)^+}^t H_s \,\mathrm{d}s.$$

For each ω, $t \mapsto H_t^h(\omega)$ is continuous (an indefinite integral), bounded by K, and adapted (the average uses only the past, and H is progressively measurable so the integral is $\mathcal{F}_t$-measurable); hence H^h is progressively measurable and continuous. By Lebesgue's differentiation theorem, for a.e. t and a.e. ω, $H_t^h(\omega) \to H_t(\omega)$ as $h \downarrow 0$; since $\left|H^h - H\right|^2 \leq (2K)^2$ is bounded, dominated convergence on $[0,T] \times \Omega$ gives $\left\|H^h - H\right\|_{\mathcal{M}^2} \to 0$. It suffices to approximate bounded, continuous, adapted processes.

Step 3: continuous $\Rightarrow$ simple. Let H be bounded, continuous, adapted. For the partition $t_i = iT/n$ put $H_t^{(n)} = \sum_{i=0}^{n-1} H_{t_i}\,\mathbf{1}_{(t_i,t_{i+1}]}(t)$, a simple process (each $\eta_i = H_{t_i}$ is $\mathcal{F}_{t_i}$-measurable and bounded). By path continuity $H_t^{(n)}(\omega) \to H_t(\omega)$ for every t and ω, and $\left|H^{(n)}\right| \le K$; dominated convergence again yields $\left\|H^{(n)} - H\right\|_{\mathcal{M}^2} \to 0$.

Chaining the three steps: given H and ε, choose K, then h, then n so each approximation error is below $\varepsilon/3$, and the triangle inequality finishes the proof. $\square$

C.5 Itô's formula: the full proof

Theorem 5.9 states the change-of-variables rule for an Itô process and sketches the mechanism in the chapter body, deferring the remainder control and the multidimensional case to here. We supply the complete argument; it is the one place where the heuristic $(\mathrm{d}W)^2 = \mathrm{d}t$ must be promoted, with care, to an honest L^1 limit.

Theorem C.7 (Itô's formula)**.** *Let X be the scalar Itô process $\mathrm{d}X_t = b_t\ \mathrm{d}t + \sigma_t\ \mathrm{d}W_t$ of* (5.8)*, with b progressively measurable and integrable and $\sigma \in \mathcal{M}^2[0,T]$, and let $F \in C^{1,2}([0,T]\times\mathbb{R})$. Then a.s., for all $t \in [0,T]$,* (5.10) *holds:*

$$F(t,X_t) - F(0,X_0) = \int_0^t \Big(\partial_t F + b_s\,\partial_x F + \tfrac{1}{2}\,\sigma_s^2\,\partial_{xx}F\Big)(s,X_s)\ \mathrm{d}s + \int_0^t \sigma_s\,\partial_x F(s,X_s)\ \mathrm{d}W_s.$$

Proof. Step 0: reduction to bounded data. Let $\tau_R = \inf\{t : |X_t| \ge R\} \wedge T$. If the formula holds for the stopped process X^{τ_R} for every R, then letting $R \to \infty$ (so $\tau_R \uparrow T$ a.s. by path continuity) recovers it for X, both integrals converging by dominated convergence. On $\{t \le \tau_R\}$ the process stays in the compact $[-R,R]$, where F and its derivatives $\partial_t F, \partial_x F, \partial_{xx}F$ are bounded and uniformly continuous. We may thus assume F has bounded, uniformly continuous first t- and first two x-derivatives, and that b, σ are bounded (truncate them likewise; on $[0,\tau_R]$ the truncation is invisible).

Step 1: the Taylor expansion. Fix t and a partition $0 = t_0 < \cdots < t_N = t$ of mesh $\|\pi\|$. Telescoping and Taylor-expanding F to first order in time and second order in space across each subinterval,

$$F(t,X_t) - F(0,X_0) = \sum_i \Big[\partial_t F(\theta_i, X_{t_i})\,\Delta_i t + \partial_x F(t_i,X_{t_i})\,\Delta_i X + \tfrac{1}{2}\partial_{xx}F(t_i,\zeta_i)\,(\Delta_i X)^2\Big],$$

where $\Delta_i t = t_{i+1} - t_i$, $\Delta_i X = X_{t_{i+1}} - X_{t_i}$, $\theta_i \in [t_i, t_{i+1}]$ and ζ_i lies between X_{t_i} and $X_{t_{i+1}}$ (mean-value form of the remainder; the mixed second-order term $\partial_{tx}F$ and the pure $\partial_{tt}F$ term are absorbed since $F \in C^{1,2}$ means C^1 in t, and the t-increment carries no quadratic contribution—see Step 3).

Step 2: the first-order terms. As $\|\pi\| \to 0$, $\sum_i \partial_t F(\theta_i, X_{t_i})\Delta_i t \to \int_0^t \partial_t F(s,X_s)\ \mathrm{d}s$ (Riemann sums of a continuous integrand), and $\sum_i \partial_x F(t_i,X_{t_i})\Delta_i X \to \int_0^t \partial_x F(s,X_s)\ \mathrm{d}X_s = \int_0^t \partial_x F\,b_s\ \mathrm{d}s + \int_0^t \partial_x F\,\sigma_s\ \mathrm{d}W_s$, the first by Riemann convergence and the second because $\partial_x F(t_i, X_{t_i})$ is the left-endpoint (non-anticipating) evaluation defining the Itô integral, and $\partial_x F(\cdot, X_\cdot) \in \mathcal{M}^2$ is approximated by its own step function (the L^2-convergence of the corresponding Itô integrals is the isometry plus lemma C.6).

Step 3: the quadratic term — the heart of the matter. Write $(\Delta_i X)^2 = (b_{t_i}\Delta_i t + \sigma_{t_i}\Delta_i W)^2 + e_i$, where e_i collects the error from replacing the exact increment $\Delta_i X$ by its frozen-coefficient approximation; under boundedness $\sum_i \mathbb{E}\,|e_i| \to 0$. Expanding the square,

$$(b_{t_i}\Delta_i t + \sigma_{t_i}\Delta_i W)^2 = b_{t_i}^2(\Delta_i t)^2 + 2b_{t_i}\sigma_{t_i}\Delta_i t\,\Delta_i W + \sigma_{t_i}^2(\Delta_i W)^2.$$

The first sum is $O(\|\pi\|\ t) \to 0$; the second has mean zero and variance $O(\sum_i(\Delta_i t)^2\mathbb{E}(\Delta_i W)^2) = O(\|\pi\|) \to 0$ in L^2. The decisive third sum, weighted by $\frac{1}{2}\partial_{xx}F(t_i,\zeta_i)$, is handled by the key lemma below: in L^1,

$$\sum_i \tfrac{1}{2}\,\partial_{xx}F(t_i,\zeta_i)\,\sigma_{t_i}^2\,(\Delta_i W)^2 \;\longrightarrow\; \tfrac{1}{2}\int_0^t \partial_{xx}F(s,X_s)\,\sigma_s^2\ \mathrm{d}s. \tag{C.5}$$

Granting (C.5), assembling Steps 2–3 gives exactly the asserted identity (the ζ_i may be replaced by X_{t_i} at no cost, since $|\zeta_i - X_{t_i}| \le |\Delta_i X| \to 0$ uniformly and $\partial_{xx}F$ is uniformly continuous).

Step 4: proof of (C.5). Abbreviate $g_i = \partial_{xx}F(t_i,X_{t_i})\sigma_{t_i}^2$, a bounded $\mathcal{F}_{t_i}$-measurable random variable, and compare the random sum $S = \sum_i g_i(\Delta_i W)^2$ with the deterministic-time sum $T' = \sum_i g_i\,\Delta_i t$. The latter is a Riemann sum converging a.s. to $\int_0^t \partial_{xx}F\,\sigma_s^2\ \mathrm{d}s$. For the difference, $\Delta_i W$ is independent of $\mathcal{F}_{t_i}$ with $\mathbb{E}[(\Delta_i W)^2 - \Delta_i t \mid \mathcal{F}_{t_i}] = 0$, so the summands of $S - T' = \sum_i g_i((\Delta_i W)^2 - \Delta_i t)$ are martingale differences; hence

$$\mathbb{E}\,(S-T')^2 = \sum_i \mathbb{E}\Big[g_i^2\,\mathbb{E}\big[((\Delta_i W)^2 - \Delta_i t)^2 \mid \mathcal{F}_{t_i}\big]\Big] = \sum_i \mathbb{E}[g_i^2]\cdot 2(\Delta_i t)^2 \le 2\ \|g\|_\infty^2\ \|\pi\|\ t \;\to\; 0,$$

using $\mathrm{Var}((\Delta_i W)^2) = 2(\Delta_i t)^2$ (the Gaussian fourth moment, as in theorem 5.4). Thus $S - T' \to 0$ in L^2, hence in L^1, and $T' \to \int$ a.s.; replacing $\partial_{xx}F(t_i,X_{t_i})$ by $\partial_{xx}F(t_i,\zeta_i)$ changes S by at most $\sum_i |\partial_{xx}F(t_i,\zeta_i) - \partial_{xx}F(t_i,X_{t_i})|\,\sigma_{t_i}^2(\Delta_i W)^2$, which $\to 0$ in L^1 by uniform continuity of $\partial_{xx}F$ and $\sum_i \sigma_{t_i}^2(\Delta_i W)^2 \to \langle X\rangle_t$ bounded. This proves (C.5).

Step 5: the multidimensional case. For $X \in \mathbb{R}^d$ with $\mathrm{d}X = b\ \mathrm{d}t + \sigma\ \mathrm{d}W$, $\sigma \in \mathbb{R}^{d\times d}$, the second-order Taylor term is $\frac{1}{2}(\Delta_i X)^\top\,\mathrm{D}^2\,F(t_i,\zeta_i)(\Delta_i X)$, and the multiplication table $\mathrm{d}W^k\,\mathrm{d}W^\ell = \delta_{k\ell}\,\mathrm{d}t$ gives, by the polarized version of Step 4 applied to each entry,

$$\sum_i \tfrac{1}{2}(\Delta_i X)^\top\,\mathrm{D}^2\,F\,(\Delta_i X) \;\to\; \tfrac{1}{2}\int_0^t \mathrm{tr}\big(\sigma_s\sigma_s^\top\,\mathrm{D}^2\,F(s,X_s)\big)\ \mathrm{d}s,$$

which is the trace term of (5.11); the first-order terms are componentwise as in Step 2. This proves (5.11). □

C.6 The Kolmogorov extension theorem

Theorem 5.2 constructs Brownian motion (route (i)) by first realizing the consistent family of Gaussian finite-dimensional laws on path space and then repairing continuity. The first step is the Kolmogorov (Daniell–Kolmogorov) extension theorem, which we now state and prove.

Let I be an index set (for us $I = [0,\infty)$) and, for each finite $J = \{t_1,\dots,t_n\} \subset I$, let μ_J be a Borel probability measure on $\mathbb{R}^J$. The family $\{\mu_J\}$ is *consistent* (or *projective*) if it is compatible under the natural coordinate projections: for $J \subseteq J'$ and the projection $\pi_{J',J} : \mathbb{R}^{J'} \to \mathbb{R}^J$, one has $\mu_J = \mu_{J'} \circ \pi_{J',J}^{-1}$; and μ_J is invariant under reordering of the coordinates.

Theorem C.8 (Kolmogorov extension theorem)**.** *Given a consistent family* $\{\mu_J\}_{J\subset I \text{ finite}}$ *of Borel probability measures on the finite-dimensional spaces* $\mathbb{R}^J$*, there is a unique probability measure* $\mathbb{P}$ *on the product space* $(\mathbb{R}^I, \mathcal{B}(\mathbb{R})^{\otimes I})$ *whose finite-dimensional marginals are the* μ_J*: for every finite* J *and Borel* $A \subseteq \mathbb{R}^J$*,*

$$\mathbb{P}(\{x \in \mathbb{R}^I : (x_t)_{t\in J} \in A\}) = \mu_J(A).$$

Proof. Let $\mathcal{C}$ be the algebra of *cylinder sets*, i.e. sets of the form $C = \{x : (x_t)_{t\in J} \in A\}$ with $J \subset I$ finite and $A \in \mathcal{B}(\mathbb{R}^J)$. Define $\mathbb{P}_0(C) = \mu_J(A)$. Consistency makes this well defined (a cylinder has many representations, with larger index sets; the projective relations force the value to agree), and $\mathbb{P}_0$ is finitely additive on $\mathcal{C}$ with $\mathbb{P}_0(\mathbb{R}^I) = 1$. By Carathéodory's extension theorem it suffices to show $\mathbb{P}_0$ is *countably* additive on $\mathcal{C}$, equivalently continuous at $\emptyset$: if $C_1 \supseteq C_2 \supseteq \cdots$ are cylinders with $\bigcap_k C_k = \emptyset$, then $\mathbb{P}_0(C_k) \to 0$.

Suppose, for contradiction, $\mathbb{P}_0(C_k) \geq \delta > 0$ for all k. Each C_k depends on a finite index set J_k, which we may take increasing, $C_k = \{(x_t)_{t\in J_k} \in A_k\}$ with $A_k \in \mathcal{B}(\mathbb{R}^{J_k})$. By inner regularity of the Borel measures μ_{J_k} on the (Polish) spaces $\mathbb{R}^{J_k}$, choose a *compact* $K_k \subseteq A_k$ with $\mu_{J_k}(A_k \setminus K_k) \leq \delta\, 2^{-k-1}$, and let $D_k = \{(x_t)_{t\in J_k} \in K_k\} \subseteq C_k$ be the corresponding compact-base cylinder. Put $E_k = D_1 \cap \cdots \cap D_k \subseteq C_k$. Then

$$\mathbb{P}_0(C_k \setminus E_k) \leq \sum_{j=1}^{k} \mathbb{P}_0(C_j \setminus D_j) \leq \sum_{j=1}^{k} \delta\, 2^{-j-1} \leq \tfrac{\delta}{2},$$

so $\mathbb{P}_0(E_k) \geq \delta - \frac{\delta}{2} = \frac{\delta}{2} > 0$; in particular every E_k is nonempty. Pick $x^{(k)} \in E_k$. The points $x^{(k)}$ for $k \geq m$ all lie, in the coordinates J_m, inside the compact set K_m; by a diagonal argument over the countably many coordinates $\bigcup_m J_m$ one extracts a subsequence along which every coordinate in $\bigcup_m J_m$ converges, to a limit point $x^\star$ (set the remaining coordinates arbitrarily). For each fixed m, the J_m-coordinates of $x^\star$ are a limit of points of the closed set K_m, hence lie in K_m, so $x^\star \in D_m \subseteq C_m$ for every m. Thus $x^\star \in \bigcap_m C_m$, contradicting $\bigcap_m C_m = \emptyset$. Therefore $\mathbb{P}_0(C_k) \to 0$, $\mathbb{P}_0$ is countably additive, and Carathéodory extends it uniquely to $\sigma(\mathcal{C}) = \mathcal{B}(\mathbb{R})^{\otimes I}$. □

Applied with μ_J the centered Gaussian on $\mathbb{R}^J$ of covariance $(\, s \wedge t\,)_{s,t\in J}$ — consistent because these are the marginals of one Gaussian family — the theorem yields a process with Brownian finite-dimensional distributions, the starting point of route (i) of theorem 5.2.

C.7 The Kolmogorov–Chentsov continuity theorem

The process produced by theorem C.8 lives on raw product space and need not have continuous paths; the continuity (axiom (4) of definition 5.1) and the sharp Hölder exponent of theorem 5.3(1) come from the following moment criterion.

Theorem C.9 (Kolmogorov–Chentsov)**.** *Let* $(X_t)_{t\in[0,T]}$ *be a real process such that for some constants* $p > 0$*,* $\gamma > 0$*,* $C < \infty$*,*

$$\mathbb{E}\,|X_t - X_s|^p \;\leq\; C\,|t-s|^{1+\gamma} \qquad \textit{for all } s,t \in [0,T]. \tag{C.6}$$

Then X admits a continuous modification $\widetilde{X}$, and the paths of $\widetilde{X}$ are locally Hölder continuous of every order $\alpha < \gamma/p$.

Proof. Work on $[0,1]$ (rescale time). For $n \geq 1$ let $D_n = \{k2^{-n} : 0 \leq k \leq 2^n\}$ be the dyadic points of generation n and $D = \bigcup_n D_n$. Fix $\alpha \in (0, \gamma/p)$. By (C.6) and Markov's inequality, for a consecutive dyadic pair $t = k2^{-n}$, $t' = (k+1)2^{-n}$,

$$\mathbb{P}\big(|X_{t'} - X_t| \geq 2^{-\alpha n} \big) \leq \frac{\mathbb{E}\,|X_{t'} - X_t|^p}{2^{-\alpha np}} \leq C\,2^{-n(1+\gamma)}\,2^{\alpha np} = C\,2^{-n(1+\gamma-\alpha p)}.$$

Summing over the 2^n such pairs in generation n,

$$\mathbb{P}\Big(\max_{0 \leq k < 2^n} \Big| X_{(k+1)2^{-n}} - X_{k2^{-n}} \Big| \geq 2^{-\alpha n} \Big) \leq 2^n \cdot C\,2^{-n(1+\gamma-\alpha p)} = C\,2^{-n(\gamma-\alpha p)}.$$

Because $\alpha < \gamma/p$ the exponent $\gamma - \alpha p > 0$, so these probabilities are summable; by Borel–Cantelli there is an a.s. finite random N such that for all $n \geq N$,

$$\max_{0 \leq k < 2^n} \big| X_{(k+1)2^{-n}} - X_{k2^{-n}} \big| < 2^{-\alpha n}. \tag{C.7}$$

Chaining. Fix ω in this full-measure event and take any two dyadics $s < t$ in D with $t - s \leq 2^{-N}$; let $m \geq N$ be such that $2^{-(m+1)} < t - s \leq 2^{-m}$. A standard dyadic-expansion argument writes the increment $X_t - X_s$ as a telescoping sum of generation-($\geq m$) consecutive-dyadic increments, at most two from each generation; (C.7) bounds each by $2^{-\alpha n}$, so

$$|X_t - X_s| \leq 2 \sum_{n \geq m} 2^{-\alpha n} = \frac{2}{1 - 2^{-\alpha}}\,2^{-\alpha m} \leq K_\alpha\,|t-s|^\alpha\,,$$

with $K_\alpha = \frac{2}{1-2^{-\alpha}} 2^\alpha$. Thus $t \mapsto X_t$ is α-Hölder on the dense set D, hence uniformly continuous there, and extends uniquely to a continuous function $\widetilde{X}$ on $[0,1]$, which is locally α-Hölder. Finally $\widetilde{X}$ is a modification: for any fixed t, taking dyadics $t_k \to t$, hypothesis (C.6) gives $X_{t_k} \to X_t$ in L^p hence in probability, while $X_{t_k} \to \widetilde{X}_t$ a.s.; the two limits agree a.s., so $\mathbb{P}(\widetilde{X}_t = X_t) = 1$. □

Remark C.10 (The Hölder exponent for Brownian motion)**.** For Brownian motion $W_t - W_s \sim N(0, t-s)$ has Gaussian moments $\mathbb{E}\,|W_t - W_s|^{2k} = (2k-1)!!\,|t-s|^k$ for every integer $k \geq 1$, i.e. (C.6) holds with $p = 2k$ and $\gamma = k - 1$. The theorem then yields continuous paths that are α-Hölder for every $\alpha < \gamma/p = \frac{1}{2} - \frac{1}{2k}$. Letting $k \to \infty$ shows every exponent $\alpha < \frac{1}{2}$ is achievable — the sharp regularity asserted in theorem 5.3(1). A single moment such as $p = 4$ ($k = 2$, $\gamma = 1$) already gives continuity, but only up to $\alpha < \frac{1}{4}$; the full strength $\alpha < \frac{1}{2}$ requires the high moments.

C.8 The Markov property of SDE solutions

The backward equation and Feynman–Kac (theorems 5.15 and 5.16) condition on the present state and use that the future depends on the past only through it. We record the property and its mechanism.

Proposition C.11 (Markov property). *Under the hypotheses of theorem 5.10 let $X^{t,x}$ denote the unique strong solution of $\mathrm{d}X_s = b(s, X_s)\,\mathrm{d}s + \sigma(s, X_s)\,\mathrm{d}W_s$ on $[t, T]$ started at $X_t = x$. Then the solution is a Markov process: for any bounded measurable Φ and $t \le r \le T$,*

$$\mathbb{E}\big[\Phi(X_r) \mid \mathcal{F}_t\big] = \mathbb{E}\big[\Phi(X_r) \mid X_t\big] = (P_{t,r}\Phi)(X_t), \qquad (P_{t,r}\Phi)(x) := \mathbb{E}\,\Phi(X_r^{t,x}).$$

In the time-homogeneous case $P_{t,r} = P_{r-t}$ depends only on the elapsed time, and the family $(P_h)_{h\ge0}$ is a semigroup, $P_{h+h'} = P_h P_{h'}$, whose infinitesimal generator is the operator $\mathcal{A}$ of definition 5.12.

Proof. The driving Brownian increments $(W_s - W_t)_{s\ge t}$ are independent of $\mathcal{F}_t$. By pathwise uniqueness (theorem 5.10) the solution on $[t, T]$ is a measurable functional $X_r = \mathcal{F}_{t,r}\big(X_t, (W_s - W_t)_{t\le s\le r}\big)$ of the initial value X_t and the post-t noise — the flow is well defined and depends on the past only through the starting point X_t and a noise increment independent of $\mathcal{F}_t$. For a bounded measurable Φ, the freezing lemma for conditional expectations (a random variable independent of a σ-algebra may be "integrated out," chapter 3) gives

$$\mathbb{E}\big[\Phi(X_r) \mid \mathcal{F}_t\big] = \mathbb{E}\big[\Phi\big(\mathcal{F}_{t,r}(\xi, (W_s - W_t)_s)\big)\big]\Big|_{\xi = X_t} = (P_{t,r}\Phi)(X_t),$$

which is $\mathcal{F}_t$-measurable through X_t alone; conditioning further on X_t leaves it unchanged, proving both equalities. The semigroup property is the composition of flows over $[t, t+h]$ and $[t+h, t+h+h']$ together with the tower property; that $\mathcal{A}$ generates (P_h) is Dynkin's formula proposition 5.13, which says $\frac{\mathrm{d}}{\mathrm{d}h}\big|_{0^+} P_h\phi = \mathcal{A}\phi$ for $\phi \in C_c^2$. ☐

C.9 Parabolic regularity for the forward and backward equations

Three theorems of chapter 5 — the smooth positive transition density under (A-Nondeg) (section 5.4), and the upgrade of the Fokker–Planck equation theorem 5.14 and the backward equation theorem 5.15 from distributional to classical solutions — rest on the regularizing effect of a uniformly nondegenerate second-order operator. We state the facts used, in the form needed, and indicate the proof; this is classical linear parabolic PDE theory and is the in-book home for those upgrades.

Theorem C.12 (Parabolic regularity under uniform ellipticity). *Let $b : [0, T] \times \mathbb{R}^d \to \mathbb{R}^d$ and $a = \sigma\sigma^\top : [0, T] \times \mathbb{R}^d \to \mathbb{R}^{d\times d}$ be bounded and Hölder continuous in (t, x), with a uniformly elliptic, i.e. (A-Nondeg): $a(t, x) \succeq \lambda I$ for some $\lambda > 0$. Then:*

1. (Fundamental solution / transition density.) *The operator $\partial_t - \mathcal{A}$ has a fundamental solution $p(s, x; t, y)$, $0 \le s < t \le T$, which is strictly positive, jointly continuous, and $C^{1,2}$ in (t, y) and in (s, x), with the Gaussian-type two-sided bounds $c_1 t'^{-d/2} e^{-c_2|x-y|^2/t'} \le p \le C_1 t'^{-d/2} e^{-C_2|x-y|^2/t'}$ where $t' = t - s$. It is the transition density of the diffusion: $P_{s,t}\Phi(x) = \int p(s, x; t, y)\Phi(y)\,\mathrm{d}y$.*

2. (Backward equation.) *For ψ continuous of polynomial growth, $u(t, x) = \int p(t, x; T, y)\psi(y)\,\mathrm{d}y$ is $C^{1,2}$ on $[0, T) \times \mathbb{R}^d$, solves $\partial_t u + \mathcal{A}u = 0$ classically, and $u(t, \cdot) \to \psi$ as $t \uparrow T$.*

3. (Forward equation.) *For each fixed* (s, x) *the density* $y \mapsto p(s, x; t, y)$ *solves the Fokker–Planck equation* $\partial_t m = \mathcal{A}^* m$ *classically for* $t > s$*; consequently any initial law* m_0 *propagates to* $m_t(\mathrm{d}y) = \left(\int p(0, x; t, y)\, m_0(\mathrm{d}x)\right) \mathrm{d}y$*, which is a smooth positive density for* $t > 0$ *solving theorem 5.14.*

Proof (indication). This is the classical *parametrix* construction of E. E. Levi. One builds p as a perturbation series off the constant-coefficient Gaussian kernel $Z(s, x; t, y) = (2\pi t')^{-d/2}(\det a)^{-1/2} \exp(-\frac{1}{2t'}(y-x)^\top a^{-1}(y-x))$ (frozen at $a = a(s, x)$), correcting it by an integral equation whose kernel is the Hölder error $(\partial_t - \mathcal{A})Z$; uniform ellipticity makes the resulting Volterra series converge and inherit the Gaussian bounds, and Schauder interior estimates for uniformly parabolic equations give the $C^{1,2}$ regularity and the classical solution property in (2)–(3). The detailed construction is in [71, 109]; the strict positivity is the parabolic strong maximum principle. We import the statement; the parametrix proof is lengthy but uses only the elliptic structure (A-Nondeg) and the assumed Hölder continuity of the coefficients. □

Remark C.13. The Hölder continuity of the coefficients is automatic in the LQG/OU applications (worked computation 5.17), where b is affine and a constant, and there the kernel p is the explicit Gaussian (5.28); theorem C.12 is needed only for the general nonlinear-coefficient diffusions of chapters 8 and 10.

C.10 Gaussian limits and the Wiener integral

The Ornstein–Uhlenbeck computation (worked computation 5.17) uses that the Itô integral of a deterministic integrand is Gaussian. This rests on the stability of the Gaussian class under L^2 limits.

Lemma C.14 (L^2 limits of Gaussians are Gaussian)**.** *Let* (Z_n) *be centered Gaussian random variables (or vectors) with* $Z_n \to Z$ *in* $L^2(\mathbb{P})$*. Then* Z *is centered Gaussian, with* $\operatorname{Var} Z = \lim_n \operatorname{Var} Z_n$*.*

Proof. L^2 convergence gives $\mathbb{E}Z = \lim \mathbb{E}Z_n = 0$ and $\sigma_n^2 := \operatorname{Var} Z_n \to \sigma^2 := \mathbb{E}Z^2$. The characteristic function of Z_n is $\mathbb{E}e^{i\xi Z_n} = e^{-\sigma_n^2\xi^2/2}$. Since L^2 convergence implies convergence in distribution, $\mathbb{E}e^{i\xi Z_n} \to \mathbb{E}e^{i\xi Z}$ pointwise in ξ; the left side tends to $e^{-\sigma^2\xi^2/2}$, so $\mathbb{E}e^{i\xi Z} = e^{-\sigma^2\xi^2/2}$, which is the characteristic function of $N(0, \sigma^2)$. By uniqueness of characteristic functions (chapter 3), $Z \sim N(0, \sigma^2)$. The vector case is identical with $\xi \in \mathbb{R}^d$ and the covariance matrix in place of σ^2. □

Corollary C.15 (Wiener integral)**.** *For deterministic* $f \in L^2[0, T]$ *the Itô integral* $\int_0^T f(s)\, \mathrm{d}W_s$ *is a centered Gaussian random variable with variance* $\int_0^T f(s)^2\, \mathrm{d}s$*. More generally* $\left(\int_0^t f\, \mathrm{d}W\right)_{t \le T}$ *is a centered Gaussian process with covariance* $\int_0^{s\wedge t} f^2$*.*

Proof. For a deterministic simple $f = \sum_i c_i \mathbf{1}_{(t_i, t_{i+1}]}$ the integral $\sum_i c_i(W_{t_{i+1}} - W_{t_i})$ is a finite linear combination of the independent Gaussian increments, hence centered Gaussian with variance $\sum_i c_i^2(t_{i+1} - t_i) = \int f^2$. A general $f \in L^2[0, T]$ is an $L^2[0, T]$ limit of simple deterministic functions f_n; by the Itô isometry $\int f_n\, \mathrm{d}W \to \int f\, \mathrm{d}W$ in $L^2(\mathbb{P})$, and lemma C.14 gives that the limit is centered Gaussian with the stated variance. The joint Gaussianity of the process follows by applying the same to arbitrary linear combinations $\sum_k a_k \int_0^{t_k} f \, dW$. $\square$

C.11 Completeness of the Hermite basis and the Ornstein–Uhlenbeck spectrum

The spectral decomposition of the OU generator (worked computation 5.17(c)) uses that the Hermite polynomials are a complete orthogonal system in L^2 of the Gaussian weight. The only nontrivial input is completeness, which we prove; the eigenvalue relation is then an elementary computation, and the self-adjointness is read off the explicit eigenbasis rather than imported from the compact-operator spectral theorem of chapter 2 (the OU generator is unbounded and has no compact resolvent on the whole line in the naive sense, so that theorem does not apply directly; the correct statement is the one below).

Fix the centered Gaussian weight $\gamma = N(0, v)$ on $\mathbb{R}$, $v > 0$, with density $g(x) = (2\pi v)^{-1/2} e^{-x^2/2v}$, and write $L^2(\gamma)$ for the weighted space with inner product $\langle \phi, \psi \rangle_\gamma = \int \phi\psi \, g$.

Lemma C.16 (Density of polynomials and Hermite completeness)**.** *Polynomials are dense in $L^2(\gamma)$. Consequently the Hermite polynomials $\{H_n\}_{n \geq 0}$ — the Gram–Schmidt orthogonalization of $\{1, x, x^2, \dots\}$ in $L^2(\gamma)$, with $H_0 \equiv 1$, $H_1(x) = x$, normalized so that H_n has leading coefficient* 1 *— form a complete* orthogonal *system: an orthogonal basis of $L^2(\gamma)$. They are made orthonormal by dividing each H_n by $\|H_n\|_{L^2(\gamma)}$.*

Proof. Orthogonality and the spanning of polynomials are immediate from the Gram–Schmidt construction; the content is that polynomials are *dense*. Suppose $\phi \in L^2(\gamma)$ is orthogonal to every polynomial, in particular to every power x^n: $\int x^n \phi(x) \, g(x) \, dx = 0$ for all $n \geq 0$. We show $\phi = 0$ γ-a.e.

Consider the function of a complex variable

$$F(z) := \int_{\mathbb{R}} e^{zx} \, \phi(x) \, g(x) \, dx, \qquad z \in \mathbb{C}.$$

Because g decays like a Gaussian, $|\phi(x)g(x)| \leq \frac{1}{2}(\phi(x)^2 + 1)g(x)$ is integrable against $e^{\Re(z)x}$ for every z (the Gaussian beats the exponential), so F is well defined and, by Morera's theorem and dominated convergence, *entire*. Differentiating under the integral, $F^{(n)}(0) = \int x^n \phi \, g = 0$ for all n, so all Taylor coefficients of F at 0 vanish; being entire, $F \equiv 0$. In particular, for real ξ,

$$0 = F(i\xi) = \int e^{i\xi x} \, \phi(x) g(x) \, dx,$$

the Fourier transform of the integrable function $\phi \, g$. By Fourier uniqueness $\phi \, g = 0$ a.e., and since $g > 0$ this forces $\phi = 0$ γ-a.e. Hence the only function orthogonal to all polynomials is 0: polynomials are dense, and the orthogonal system $\{H_n\}$ is complete. $\square$

With completeness in hand the OU spectral statement of worked computation 5.17(c) is justified rigorously. On $L^2(m_\infty)$ with $m_\infty = N(0, v_\infty)$, $v_\infty = \sigma^2/2\theta$, the generator $\mathcal{A}\phi = -\theta x\phi' + \frac{\sigma^2}{2}\phi''$ satisfies the symmetry

$$\langle \mathcal{A}\phi, \psi\rangle_{m_\infty} = -\frac{\sigma^2}{2}\int \phi'(x)\psi'(x)\, m_\infty(x)\, \mathrm{d}x = \langle \phi, \mathcal{A}\psi\rangle_{m_\infty},$$

obtained by integrating by parts once, using $\mathcal{A}^* m_\infty = 0$ in the form $\frac{\sigma^2}{2} m'_\infty = -\theta x\, m_\infty$ (the zero-current identity of eq. (5.29)); the boundary terms vanish by the Gaussian decay. Thus $\mathcal{A}$ is symmetric and negative on its core C_c^2, with the closed form $-\frac{\sigma^2}{2}\langle \phi', \psi'\rangle_{m_\infty}$. A direct computation on monomials shows $\mathcal{A}$ maps the space of polynomials of degree $\le n$ into itself and acts on the top-degree part by multiplication by $-n\theta$; hence each H_n, being the unique (up to scale) degree-n polynomial orthogonal to all lower degrees, is an eigenfunction,

$$\mathcal{A}H_n = -n\theta\, H_n. \tag{C.8}$$

By lemma C.16 the normalized $\{H_n/\,\|H_n\|\}$ are an orthonormal basis that diagonalizes $\mathcal{A}$ with eigenvalues $\{-n\theta\}_{n\ge 0}$; this is the spectral resolution (purely point spectrum) used to write the modal expansion of $e^{t\mathcal{A}}$ in worked computation 5.17.

C.12 Martingale representation and backward stochastic differential equations

This section supplies the two backward-in-time results on which the adjoint and FBSDE formulation of chapters 6 and 9 rests: the martingale representation theorem for the Brownian filtration, and the Pardoux–Peng existence and uniqueness theorem for backward stochastic differential equations (BSDEs) under a Lipschitz driver. Both lie beyond the elementary prerequisites and are the in-book home of those results; we prove them in full, using only the Itô integral and isometry of chapter 5, Doob's inequality (theorem C.2), and Grönwall's lemma (lemma C.1).

Throughout, $W = (W_t)_{0\le t\le T}$ is a k-dimensional Brownian motion and $\mathbb{F} = (\mathcal{F}_t)_{0\le t\le T}$ its completed, right-continuous natural filtration on $(\Omega, \mathcal{F}, \mathbb{P})$, with $\mathcal{F} = \mathcal{F}_T$. We write $\mathcal{H}^2 = \mathcal{H}^2(\mathbb{R}^n)$ for the Hilbert space of $\mathbb{F}$-progressively measurable processes H with $\|H\|^2_{\mathcal{H}^2} = \mathbb{E}\int_0^T |H_t|^2\, \mathrm{d}t < \infty$, and $\mathcal{S}^2 = \mathcal{S}^2(\mathbb{R}^n)$ for the continuous adapted processes with $\|Y\|^2_{\mathcal{S}^2} = \mathbb{E}\sup_{t\le T}|Y_t|^2 < \infty$. (Here $|\cdot|$ is the Euclidean, resp. Frobenius, norm.)

C.12.1 Martingale representation

Theorem C.17 (Martingale representation)**.** *Every $\xi \in L^2(\Omega, \mathcal{F}_T, \mathbb{P}; \mathbb{R})$ admits a unique $H \in \mathcal{H}^2(\mathbb{R}^{1\times k})$ with*

$$\xi \;=\; \mathbb{E}[\xi] + \int_0^T H_s\, \mathrm{d}W_s \qquad \mathbb{P}\text{-}a.s. \tag{C.9}$$

Equivalently, every square-integrable $\mathbb{F}$-martingale (M_t) has a continuous version $M_t = M_0 + \int_0^t H_s\, \mathrm{d}W_s$ with $H \in \mathcal{H}^2$. The vector case $\xi \in L^2(\mathcal{F}_T; \mathbb{R}^n)$ follows componentwise, giving $H \in \mathcal{H}^2(\mathbb{R}^{n\times k})$.

Proof. Let $\mathcal{R} \subset L^2(\mathcal{F}_T)$ be the set of variables representable as $c + \int_0^T H \, \mathrm{d}W$ with $c \in \mathbb{R}$ and $H \in \mathcal{H}^2(\mathbb{R}^{1\times k})$. By the Itô isometry (theorem 5.7) the stochastic integral is centered with $\mathbb{E}\big(\int_0^T H \, \mathrm{d}W\big)^2 = \|H\|^2_{\mathcal{H}^2}$, so the map $(c, H) \mapsto c + \int_0^T H \, \mathrm{d}W$ is a linear isometry of $\mathbb{R} \oplus \mathcal{H}^2$ onto $\mathcal{R}$; in particular $\mathcal{R}$ is a *closed* subspace of $L^2(\mathcal{F}_T)$. We show $\mathcal{R}$ is dense; being closed it is then all of $L^2(\mathcal{F}_T)$, which gives eq. (C.9) (with $c = \mathbb{E}[\xi]$ forced by taking expectations and H unique by the isometry).

Step 1: Doléans exponentials are representable. For bounded deterministic $f \in L^2([0,T];\mathbb{R}^k)$ set

$$\mathcal{E}_t(f) = \exp\Big(\int_0^t f_s \, \mathrm{d}W_s - \tfrac{1}{2}\int_0^t |f_s|^2 \, \mathrm{d}s\Big).$$

Itô's formula (theorem 5.9) applied to the C^2 function exp and the process $\Xi_t = \int_0^t f \, \mathrm{d}W - \frac{1}{2}\int_0^t |f|^2 \, \mathrm{d}s$ (whose drift $-\frac{1}{2}|f|^2$ exactly cancels the $\frac{1}{2}$ from the quadratic variation $\mathrm{d}\langle \Xi \rangle_t = |f_t|^2 \, \mathrm{d}t$) gives $\mathrm{d}\mathcal{E}_t(f) = \mathcal{E}_t(f) \, f_t \, \mathrm{d}W_t$, hence

$$\mathcal{E}_T(f) = 1 + \int_0^T \mathcal{E}_s(f) \, f_s \, \mathrm{d}W_s.$$

For bounded f the integrand lies in $\mathcal{H}^2$: since $\int f \, \mathrm{d}W$ is, by corollary C.15, Gaussian with bounded variance, $\mathcal{E}_t(f)$ has moments of every order, uniformly in $t \le T$, so $\mathbb{E}\int_0^T \mathcal{E}_s(f)^2 \, |f_s|^2 \, \mathrm{d}s < \infty$. Thus $\mathcal{E}_T(f) \in \mathcal{R}$ for every bounded deterministic f.

Step 2: totality. It suffices to show that any $g \in L^2(\mathcal{F}_T)$ orthogonal to all $\mathcal{E}_T(f)$ vanishes; then the closed span of $\{\mathcal{E}_T(f)\} \subset \mathcal{R}$ is all of $L^2(\mathcal{F}_T)$, so $\mathcal{R} = L^2(\mathcal{F}_T)$. Fix a partition $0 = t_0 < t_1 < \cdots < t_n = T$ and vectors $\lambda_1, \ldots, \lambda_n \in \mathbb{R}^k$, and take the piecewise-constant $f = \sum_j \lambda_j \mathbf{1}_{(t_{j-1}, t_j]}$. Then $\int_0^T f \, \mathrm{d}W = \sum_j \lambda_j \cdot \Delta_j W$ with $\Delta_j W = W_{t_j} - W_{t_{j-1}}$, and $\mathcal{E}_T(f) = c(\lambda) \exp(\sum_j \lambda_j \cdot \Delta_j W)$ with $c(\lambda) > 0$ deterministic. Orthogonality $\mathbb{E}[g \, \mathcal{E}_T(f)] = 0$ therefore reads

$$\mathbb{E}\Big[g \, \exp\Big(\sum_{j=1}^n \lambda_j \cdot \Delta_j W\Big)\Big] = 0 \qquad \text{for all } \lambda_1, \ldots, \lambda_n \in \mathbb{R}^k.$$

Both sides are entire functions of $(\lambda_j) \in \mathbb{C}^{kn}$ (the increments are Gaussian, so the moment generating function is finite for all complex arguments, by the domination used in lemma C.16); since they agree on $\mathbb{R}^{kn}$ they agree everywhere, and substituting $\lambda_j \mapsto i\lambda_j$ gives

$$\mathbb{E}\Big[g \, \exp\Big(i \sum_j \lambda_j \cdot \Delta_j W\Big)\Big] = 0 \qquad \text{for all } \lambda_j \in \mathbb{R}^k.$$

This says the finite complex measure $A \mapsto \mathbb{E}[g\mathbf{1}_A]$, pushed forward to $\mathbb{R}^{kn}$ by $(\Delta_1 W, \ldots, \Delta_n W)$, has vanishing Fourier transform; by Fourier uniqueness (as in lemma C.16) it is the zero measure, i.e. $\mathbb{E}[g \, \varphi(\Delta_1 W, \ldots, \Delta_n W)] = 0$ for every bounded Borel φ. As the partition ranges over all finite subsets of a fixed countable dense set of times, the bounded functions of finitely many increments form a multiplicative class generating $\mathcal{F}_T = \sigma(W_s : s \le T)$; by the functional monotone class theorem their linear span is dense in $L^2(\mathcal{F}_T)$. Hence $\mathbb{E}[g \, Y] = 0$ for every $Y \in L^2(\mathcal{F}_T)$, so $g = 0$. This proves totality.

Martingale form. Given a square-integrable martingale M, apply eq. (C.9) to $\xi = M_T$: $M_T = \mathbb{E}[M_T] + \int_0^T H \, \mathrm{d}W$. The process $\widetilde{M}_t = \mathbb{E}[M_T] + \int_0^t H \, \mathrm{d}W$ is a continuous L^2-martingale (theorem 5.7) with $\widetilde{M}_T = M_T$, so for each t, $\widetilde{M}_t = \mathbb{E}[\widetilde{M}_T \mid \mathcal{F}_t] = \mathbb{E}[M_T \mid \mathcal{F}_t] = M_t$ a.s.; thus $\widetilde{M}$ is the asserted continuous version. ∎

C.12.2 The Pardoux–Peng theorem

A *backward stochastic differential equation* is specified by a terminal datum $\xi \in L^2(\mathcal{F}_T;\mathbb{R}^n)$ and a *driver* $f : [0,T] \times \Omega \times \mathbb{R}^n \times \mathbb{R}^{n\times k} \to \mathbb{R}^n$ that is progressively measurable in (t,ω) for each (y,z) and satisfies

- **(L)** uniform Lipschitz continuity: $|f(t,\omega,y,z) - f(t,\omega,y',z')| \le K\big(|y-y'| + |z-z'|\big)$ for some $K < \infty$, all $(y,z),(y',z')$, $\mathrm{d}t \otimes \mathrm{d}\mathbb{P}$-a.e.; and
- **(I)** integrable baseline: $f(\cdot,\cdot,0,0) \in \mathcal{H}^2(\mathbb{R}^n)$.

A *solution* is a pair $(Y,Z) \in \mathcal{S}^2(\mathbb{R}^n) \times \mathcal{H}^2(\mathbb{R}^{n\times k})$ with

$$Y_t = \xi + \int_t^T f(s,Y_s,Z_s)\,\mathrm{d}s - \int_t^T Z_s\,\mathrm{d}W_s, \qquad 0 \le t \le T,\ \mathbb{P}\text{-a.s.} \tag{C.10}$$

Theorem C.18 (Pardoux–Peng)**.** *Under* **(L)** *and* **(I)***, and with $\xi \in L^2(\mathcal{F}_T;\mathbb{R}^n)$, the BSDE eq.* (C.10) *has a unique solution* $(Y,Z) \in \mathcal{S}^2(\mathbb{R}^n) \times \mathcal{H}^2(\mathbb{R}^{n\times k})$.

Proof. Step 1: the driver frozen. First suppose $f = f(t)$ does not depend on (y,z), with $f \in \mathcal{H}^2$. Set $\zeta = \xi + \int_0^T f_s\,\mathrm{d}s \in L^2(\mathcal{F}_T)$ and let $M_t = \mathbb{E}[\zeta \mid \mathcal{F}_t]$ be its closing martingale. By theorem C.17, $M_t = \mathbb{E}[\zeta] + \int_0^t Z_s\,\mathrm{d}W_s$ for a unique $Z \in \mathcal{H}^2$. Define $Y_t = M_t - \int_0^t f_s\,\mathrm{d}s$. Then $Y_T = \zeta - \int_0^T f = \xi$, and for every t,

$$Y_t = M_t - \int_0^t f = \Big(\zeta - \int_t^T Z\,\mathrm{d}W\Big) - \int_0^t f = \xi + \int_t^T f_s\,\mathrm{d}s - \int_t^T Z_s\,\mathrm{d}W_s,$$

using $\zeta = M_T = M_t + \int_t^T Z\,\mathrm{d}W$ and $\zeta - \int_0^t f = \xi + \int_t^T f$. Thus (Y,Z) solves eq. (C.10); Y is continuous and, by Doob's inequality (theorem C.2) applied to M together with the L^2 bound on $\int_0^\cdot f$, lies in $\mathcal{S}^2$, while $Z \in \mathcal{H}^2$. Uniqueness: if (Y',Z') is another solution, then $\delta Y_t = -\int_t^T \delta Z\,\mathrm{d}W$ with $\delta Y_T = 0$; taking $\mathbb{E}[\cdot \mid \mathcal{F}_t]$ gives $\delta Y_t = 0$, whence $\int_0^T \delta Z\,\mathrm{d}W = 0$ and, by the Itô isometry, $\delta Z = 0$ in $\mathcal{H}^2$.

Step 2: contraction for the general driver. On the Hilbert space $\mathcal{B} = \mathcal{H}^2(\mathbb{R}^n) \times \mathcal{H}^2(\mathbb{R}^{n\times k})$ introduce, for $\beta > 0$, the equivalent norm

$$\|(Y,Z)\|_\beta^2 = \mathbb{E}\int_0^T e^{\beta s}\big(\,|Y_s|^2 + |Z_s|^2\,\big)\,\mathrm{d}s.$$

Given $(U,V) \in \mathcal{B}$, the process $g_s := f(s,U_s,V_s)$ lies in $\mathcal{H}^2$ (by **(L)**,**(I)**: $|g_s| \le |f(s,0,0)| + K(|U_s| + |V_s|)$), so Step 1 produces a unique solution $(Y,Z) \in \mathcal{S}^2 \times \mathcal{H}^2$ of the BSDE with frozen driver g; define $\Phi(U,V) = (Y,Z)$. Let $(U,V),(U',V') \in \mathcal{B}$ have images $(Y,Z),(Y',Z')$ and write $\delta U = U - U'$, etc. Then $\delta Y, \delta Z$ solve

$$\mathrm{d}(\delta Y_t) = -\big(f(t,U_t,V_t) - f(t,U_t',V_t')\big)\,\mathrm{d}t + \delta Z_t\,\mathrm{d}W_t, \qquad \delta Y_T = 0.$$

Apply Itô's formula to $e^{\beta t}\,|\delta Y_t|^2$:

$$\mathrm{d}\big(e^{\beta t}\,|\delta Y_t|^2\,\big) = e^{\beta t}\Big(\beta\,|\delta Y_t|^2 - 2\langle \delta Y_t, \Delta f_t\rangle + |\delta Z_t|^2\,\Big)\,\mathrm{d}t + 2e^{\beta t}\langle \delta Y_t, \delta Z_t\,\mathrm{d}W_t\rangle,$$

where $\Delta f_t = f(t,U_t,V_t) - f(t,U_t',V_t')$. Integrating over $[0,T]$, using $\delta Y_T = 0$, and taking expectations (the stochastic integral is a true martingale, as $\delta Y \in \mathcal{S}^2$, $\delta Z \in \mathcal{H}^2$),

$$\mathbb{E}\,|\delta Y_0|^2 + \mathbb{E}\int_0^T e^{\beta t}\big(\beta\,|\delta Y_t|^2 + |\delta Z_t|^2\,\big)\,\mathrm{d}t = \mathbb{E}\int_0^T e^{\beta t}\,2\langle \delta Y_t, \Delta f_t\rangle\;\mathrm{d}t.$$

Drop $\mathbb{E}\,|\delta Y_0|^2 \geq 0$. By **(L)**, $|\Delta f_t| \leq K(|\delta U_t| + |\delta V_t|)$, and Young's inequality $2ab \leq \frac{\beta}{2}a^2 + \frac{2}{\beta}b^2$ with $a = |\delta Y_t|$, $b = K(|\delta U_t| + |\delta V_t|)$ gives

$$2\langle \delta Y_t, \Delta f_t\rangle \leq \tfrac{\beta}{2}\,|\delta Y_t|^2 + \tfrac{2}{\beta}K^2\big(\,|\delta U_t| + |\delta V_t|\,\big)^2 \leq \tfrac{\beta}{2}\,|\delta Y_t|^2 + \tfrac{4K^2}{\beta}\big(\,|\delta U_t|^2 + |\delta V_t|^2\,\big).$$

Substituting and cancelling $\frac{\beta}{2}\mathbb{E}\int e^{\beta t}\,|\delta Y_t|^2$ from both sides,

$$\mathbb{E}\int_0^T e^{\beta t}\Big(\tfrac{\beta}{2}\,|\delta Y_t|^2 + |\delta Z_t|^2\Big)\,\mathrm{d}t \leq \frac{4K^2}{\beta}\,\mathbb{E}\int_0^T e^{\beta t}\big(\,|\delta U_t|^2 + |\delta V_t|^2\,\big)\,\mathrm{d}t = \frac{4K^2}{\beta}\;\|(\delta U,\delta V)\|_\beta^2\,.$$

Choosing $\beta \geq 2$, the left side dominates $\mathbb{E}\int_0^T e^{\beta t}(|\delta Y_t|^2 + |\delta Z_t|^2)\,\mathrm{d}t = \|(\delta Y,\delta Z)\|_\beta^2$; hence

$$\|\Phi(U,V) - \Phi(U',V')\|_\beta^2 \leq \frac{4K^2}{\beta}\;\|(U,V) - (U',V')\|_\beta^2\,.$$

Taking $\beta = 8K^2 + 2$ makes $4K^2/\beta \leq \frac{1}{2}$, so Φ is a contraction (constant $\leq 1/\sqrt{2}$) on the Banach space $(\mathcal{B}, \|\cdot\|_\beta)$. By the Banach fixed-point theorem Φ has a unique fixed point $(Y,Z) \in \mathcal{B}$, which by construction solves eq. (C.10).

Step 3: regularity and uniqueness in $\mathcal{S}^2 \times \mathcal{H}^2$. For the fixed point, Y is the Step 1 solution of the BSDE with driver $f(\cdot,Y,Z) \in \mathcal{H}^2$, hence has a continuous version in $\mathcal{S}^2$ with $\mathbb{E}\sup_{t\leq T}|Y_t|^2 < \infty$ (Doob applied to its closing martingale plus the L^2 bound on $\int f(\cdot,Y,Z)$). Any solution in $\mathcal{S}^2 \times \mathcal{H}^2$ is in particular a fixed point of Φ, and the $\|\cdot\|_\beta$-norm is equivalent to the unweighted $\mathcal{H}^2 \times \mathcal{H}^2$ norm on $[0,T]$ (since $e^{\beta t} \in [1, e^{\beta T}]$); so uniqueness of the fixed point gives uniqueness of the solution. ☐

Remark C.19 (Why the second component cannot be prescribed)**.** The pair structure of eq. (C.10) is forced, not chosen: a process pinned at T by $\xi = Y_T$, which depends on the whole future of W, can be made adapted only by absorbing the unpredictable part of its terminal value into a martingale, and theorem C.17 says that martingale is a stochastic integral $\int Z\,\mathrm{d}W$. The integrand Z is exactly that correction; it is what distinguishes a BSDE from a (time-reversed) ODE, and in the control setting of chapter 9 it is the volatility-weighted curvature of the value function. This is the structural fact used throughout section 9.1.

C.13 The martingale problem and relaxed controls

The existence of *weak* (relaxed) mean field game equilibria in section 10.4 rests on three facts that lie beyond the strong-solution theory of chapter 5: the *well-posedness* (uniqueness in law) of the martingale problem under nondegeneracy, the *compactness* of the set of relaxed controls together with lower semicontinuity of the cost, and the *stability* of the controlled martingale problem under convergence of the data. We develop them here, in the form chapter 10 uses, on the strong-Markov diffusion theory and the fundamental solution already established in this appendix (theorem C.12) and on Prokhorov's theorem of chapter 3.

C.13.1 The martingale problem and uniqueness in law

Definition C.20 (Martingale problem)**.** For coefficients $b\colon [0,T]\times\mathbb{R}^d\to\mathbb{R}^d$ and $a=\sigma\sigma^\top\colon [0,T]\times\mathbb{R}^d\to\mathbb{R}^{d\times d}$, bounded and measurable, the (time-dependent) generator is $(\mathcal{A}_t\phi)(x)=b(t,x)\cdot\nabla\phi(x)+\frac{1}{2}\operatorname{tr}(a(t,x)\,\mathrm{D}^2\,\phi(x))$. A probability measure $\mathbb{P}$ on the path space $C([0,T];\mathbb{R}^d)$, with canonical process X, *solves the martingale problem* for (b,a) started from m_0 if $\mathbb{P}\circ X_0^{-1}=m_0$ and, for every $\phi\in C_c^2(\mathbb{R}^d)$,

$$M_t^\phi=\phi(X_t)-\phi(X_0)-\int_0^t(\mathcal{A}_s\phi)(X_s)\,\mathrm{d}s$$

is a $\mathbb{P}$-martingale for the canonical filtration.

Theorem C.21 (Well-posedness of the martingale problem)**.** *Assume* (A-Nondeg) *($a\succeq\lambda I$, $\lambda>0$) and that b,a are bounded and Hölder continuous in (t,x) (as hold under* (A-Lip), (A-Growth) *on the coefficients of chapter 10). Then for each $m_0\in\mathcal{P}(\mathbb{R}^d)$ the martingale problem of definition C.20 has* exactly one *solution $\mathbb{P}$. In particular the law of the diffusion is uniquely determined by (b,a,m_0) (uniqueness in law), and it coincides with the law of the strong solution when one exists.*

Proof. Existence follows from theorem C.12: the fundamental solution $p(s,x;t,y)$ of $\partial_t-\mathcal{A}$ defines a Markov transition kernel $P_{s,t}(x,\mathrm{d}y)=p(s,x;t,y)\,\mathrm{d}y$, whose finite-dimensional distributions, started from m_0, are consistent (Chapman–Kolmogorov is the reproducing property of the fundamental solution) and tight (the Gaussian bounds give the Kolmogorov–Chentsov moment estimate theorem C.9), hence by the Kolmogorov extension theorem theorem C.8 define a law $\mathbb{P}$ on $C([0,T];\mathbb{R}^d)$; that $\mathbb{P}$ solves the martingale problem is the backward-equation property theorem C.12(2), since for $\phi\in C_c^2$ the function $u(s,x)=P_{s,t}\phi(x)$ is $C^{1,2}$ and Itô's formula makes M^ϕ a martingale.

Uniqueness. Let $\mathbb{P}$ be any solution. We show its one-dimensional time marginals, hence (by the Markov property below) all finite-dimensional marginals, are pinned to the transition kernel. Fix $0\le s<t\le T$, a terminal time t, and $\psi\in C_c^\infty(\mathbb{R}^d)$, and let $u(\tau,x)$, $\tau\in[s,t]$, be the classical solution of the backward Cauchy problem $\partial_\tau u+\mathcal{A}_\tau u=0$ on $[s,t)$, $u(t,\cdot)=\psi$, supplied by theorem C.12(2). Apply the martingale-problem identity to the time-dependent test function u (a standard extension of definition C.20 to $C^{1,2}$ functions of (τ,x), obtained by approximation): $u(\tau,X_\tau)$ is a $\mathbb{P}$-martingale on $[s,t]$ because $\partial_\tau u+\mathcal{A}_\tau u=0$ kills its drift. Taking $\mathbb{P}$-expectations between $\tau=s$ and $\tau=t$,

$$\mathbb{E}_\mathbb{P}[\psi(X_t)\mid X_s=x]=u(s,x)=\int p(s,x;t,y)\psi(y)\,\mathrm{d}y,$$

for $\mathbb{P}\circ X_s^{-1}$-a.e. x. Thus the conditional law of X_t given X_s is the transition kernel $P_{s,t}(x,\cdot)$, *independent of the solution* $\mathbb{P}$. The martingale problem also implies the Markov property (the conditional law given $\mathcal{F}_s$ depends only on X_s, because the solved test-function identity uses only the value X_s); this is the standard argument of [124]. Therefore all finite-dimensional distributions of $\mathbb{P}$ equal those built from $P_{s,t}$ and m_0, so $\mathbb{P}$ is unique. □

C.13.2 Relaxed controls: compactness and existence of an optimizer

A *relaxed control* is a measure ρ on $[0,T]\times A$ with time-marginal Lebesgue measure (definition 10.17); equivalently a measurable family $(\rho_t)_{t\in[0,T]}$ of probability measures on the action set A. Write $\mathcal{R}$

for the set of relaxed controls, topologised by weak convergence of the measures ρ on $[0,T]\times A$.

Theorem C.22 (Compactness of relaxed controls and existence of an optimizer)**.** *Suppose the action set A is compact (or coercivity confines optimal controls to a compact set). Then:*

(i) *$\mathcal{R}$ is compact and metrisable for the weak topology.*

(ii) *For continuous, bounded-below running and terminal costs and continuous dynamics, the relaxed cost functional $\rho\mapsto J(\rho)$ is lower semicontinuous on $\mathcal{R}$. Consequently, for each frozen population flow m, the relaxed control problem attains its minimum: an optimal relaxed control exists.*

Proof. (i) Since A is compact, $[0,T]\times A$ is a compact metric space, and the set of probability measures on it is compact and metrisable for the weak topology (Prokhorov, theorem 3.16; a compact base space is automatically tight). The constraint "time marginal = Lebesgue" is defined by countably many continuous linear equalities $\iint g(t)\,\rho(\mathrm{d}t,\mathrm{d}a)=\int g(t)\,\mathrm{d}t$ (g in a countable dense set of $C[0,T]$), hence is weakly closed; a closed subset of a compact set is compact. (ii) Lower semicontinuity: along $\rho^{(n)}\to\rho$, the relaxed state laws converge (the averaged coefficients $\bar b(t,x)=\int b(x,a)\rho_t(\mathrm{d}a)$ converge by the continuity of b and weak convergence of $\rho^{(n)}$, and the controlled martingale problem is stable, theorem C.23 below), and the cost, an integral of a continuous bounded-below integrand against the (weakly converging) occupation measures, is lower semicontinuous by the portmanteau theorem. A lower semicontinuous function on the compact set $\mathcal{R}$ (or its compact effective domain) attains its infimum. ☐

Theorem C.23 (Stability of the controlled martingale problem)**.** *Let $\rho^{(n)}\to\rho$ in $\mathcal{R}$ and $m^{(n)}\to m$ (frozen flows), and let $\mathbb{P}^{(n)}$ solve the controlled martingale problem for the averaged generator $\mathcal{A}^n_t\phi=\bar b^{\,n}(t,\cdot)\cdot\nabla\phi+\frac{1}{2}\operatorname{tr}(a\,\mathrm{D}^2\,\phi)$ with $\bar b^{\,n}(t,x)=\int b(x,a,m^{(n)}_t)\,\rho^{(n)}_t(\mathrm{d}a)$, under* (A-Nondeg) *and continuity of the coefficients. Then $\{\mathbb{P}^{(n)}\}$ is tight on $C([0,T];\mathbb{R}^d)$ and every weak limit solves the controlled martingale problem for the limiting data (ρ,m); under* (A-Nondeg) *that limit problem is well-posed* (*theorem C.21*)*, so $\mathbb{P}^{(n)}\to\mathbb{P}$ weakly.*

Proof. Tightness. The drifts $\bar b^{\,n}$ are uniformly bounded (the action set is compact, b continuous) and a is bounded, so the Kolmogorov–Chentsov estimate theorem C.9 gives a uniform fourth-moment bound on increments, $\mathbb{E}|X_t-X_s|^4\le C|t-s|^2$, whence tightness on path space by the Kolmogorov criterion. *Identification of limits.* Let $\mathbb{P}^{(n)}\to\mathbb{P}$ weakly along a subsequence. For $\phi\in C^2_c$ and $s<t$ and any bounded continuous $\mathcal{F}_s$-measurable test functional Ψ, the martingale-problem identity $\mathbb{E}_{\mathbb{P}^{(n)}}\big[(M^{\phi,n}_t-M^{\phi,n}_s)\Psi\big]=0$ passes to the limit: the maps $X\mapsto\phi(X_t)$, $\phi(X_s)$ and Ψ are bounded continuous, and the drift integral $\int_s^t\bar b^{\,n}(r,X_r)\cdot\nabla\phi(X_r)\,\mathrm{d}r$ converges because $\bar b^{\,n}\to\bar b$ uniformly on compacts (continuity of b and weak convergence of $\rho^{(n)},m^{(n)}$) while the diffusion term is fixed and continuous. Hence $\mathbb{P}$ solves the martingale problem for the limit generator $\mathcal{A}_t$ with averaged drift $\bar b(t,x)=\int b(x,a,m_t)\rho_t(\mathrm{d}a)$. By theorem C.21 the limit is unique, so the full sequence converges. ☐

Remark C.24. Theorems C.21 to C.23 are exactly the nonempty-values, compactness, and closed-graph inputs to the Kakutani–Fan–Glicksberg fixed point of theorem 10.19; together with Berge's theorem theorem B.27 and the measurable selection theorem B.29 of appendix B they make the weak-equilibrium existence proof of chapter 10 self-contained.

Bibliographic notes

The extension theorem (theorem C.8) and the continuity theorem (theorem C.9) are due to Kolmogorov and to Kolmogorov–Chentsov; the chaining proof of the latter and the projective-limit construction follow [86, 114], whose treatments we have specialized to the form chapter 5 needs. Doob's maximal inequality and the Burkholder–Davis–Gundy estimates are standard martingale theory [86, 114]; we proved the L^2 cases used in the SDE well-posedness theorem in full and cited the general p. The density of simple processes and the construction of the Itô integral follow [86, Ch. 3] and [106, Ch. 3]. The Markov property of SDE solutions and the transition semigroup are in [106, Ch. 7]. The parabolic regularity of theorem C.12 is the Levi parametrix construction of [71], with the probabilistic reading and Gaussian bounds as in [109]. The completeness of the Hermite system via density of polynomials (lemma C.16) and the resulting OU spectral decomposition are developed for the physicist in [109]; the entire-function argument we gave is the classical proof that a determinate moment sequence (the Gaussian is determinate) yields a complete orthogonal polynomial system. The martingale representation theorem (theorem C.17) and the existence/uniqueness theorem for Lipschitz BSDEs (theorem C.18) are due, respectively, to Itô and to Pardoux–Peng [107]; the Doléans-exponential density argument for the former and the weighted-norm contraction for the latter follow [86, 63], specialized to the Brownian filtration and the constant-Lipschitz driver used by chapters 6 and 9. The martingale-problem well-posedness (theorem C.21) and the relaxed-control compactness and stability (theorems C.22 and C.23), which underpin the weak-equilibrium existence theory of chapter 10, follow Stroock–Varadhan [124] and the controlled-martingale-problem framework of [88]; we deduce well-posedness from the fundamental solution of theorem C.12 rather than from the analytic localisation of the original, which suffices under the standing nondegeneracy.

Appendix D

Optimal Transport and Calculus on $\mathcal{P}_2(\mathbb{R}^d)$

This appendix supplies the proofs that chapter 4 states and defers: Kantorovich duality, Brenier's structure theorem, McCann's displacement interpolation, the Benamou–Brenier dynamic formula, and the rearrangement-invariance structure theorem that underlies the Lions derivative. It closes with the second-order calculus on $\mathcal{P}_2(\mathbb{R}^d)$ — the chain rule (Itô formula) for functionals along a flow of measures — which chapter 12 imports to write the master equation. Everything is proved from material established earlier in the book: the Hahn–Banach separation theorem and Banach–Alaoglu theorem of chapter 2 (theorems 2.11 and 2.16), the Riesz representation of theorem 2.6, weak convergence, tightness, Prokhorov's theorem, Skorokhod's representation and disintegration of measures from chapter 3 (theorems 3.13, 3.16 and 3.33), and Itô's formula of theorem 5.9. No external source is required; citations are for attribution only.

Throughout, $\mu, \nu \in \mathcal{P}_2(\mathbb{R}^d)$ are probability measures with finite second moment, $c(x, y) = |x - y|^2$ is the quadratic cost, $\Pi(\mu, \nu)$ is the set of couplings (definition 4.1), and $\mathcal{W}_2$ is the quadratic Wasserstein distance (definition 4.2). We freely use the existence of an optimal coupling (proposition 4.3), proved in the body by the direct method.

D.1 Kantorovich duality

We prove theorem 4.5: for $\mu, \nu \in \mathcal{P}_2(\mathbb{R}^d)$,

$$\mathcal{W}_2(\mu, \nu)^2 \;=\; \sup \left\{ \int_{\mathbb{R}^d} \varphi \, \mathrm{d}\mu + \int_{\mathbb{R}^d} \psi \, \mathrm{d}\nu \;:\; \varphi(x) + \psi(y) \le |x - y|^2 \;\; \forall x, y \right\}, \tag{D.1}$$

the supremum over pairs (φ, ψ) of continuous functions of at most quadratic growth, and the supremum is attained by a pair of c-conjugate *Kantorovich potentials*.

The clean route is convex duality. We first reduce to bounded continuous data, then apply Hahn–Banach separation in the form of the Fenchel–Rockafellar theorem, and finally remove the boundedness by truncation.

D.1.1 Weak duality

For any coupling $\pi \in \Pi(\mu, \nu)$ and any admissible pair (φ, ψ) with $\varphi(x) + \psi(y) \le c(x, y)$,

$$\int \varphi \, \mathrm{d}\mu + \int \psi \, \mathrm{d}\nu = \int \big(\varphi(x) + \psi(y)\big)\, \pi(\mathrm{d}x, \mathrm{d}y) \le \int c(x, y)\, \pi(\mathrm{d}x, \mathrm{d}y), \tag{D.2}$$

where the first equality uses that π has marginals μ, ν. Taking the supremum over (φ, ψ) on the left and the infimum over π on the right gives (dual) $\le$ (primal) $= \mathcal{W}_2(\mu, \nu)^2$. The content of the theorem is the reverse inequality, *strong duality*.

D.1.2 The Fenchel–Rockafellar mechanism

We record the convex-duality theorem we will use. Let E be a normed vector space with topological dual E^*. For a convex function $\Theta \colon E \to (-\infty, +\infty]$ its Legendre–Fenchel conjugate is $\Theta^*(\ell) = \sup_{x \in E} \big(\ell(x) - \Theta(x)\big)$ for $\ell \in E^*$.

Theorem D.1 (Fenchel–Rockafellar)**.** *Let $\Theta_1, \Theta_2 \colon E \to (-\infty, +\infty]$ be convex, and suppose there is a point $x_0 \in E$ at which both are finite and at least one is continuous. Then*

$$\inf_{x \in E} \big(\Theta_1(x) + \Theta_2(x)\big) \;=\; \max_{\ell \in E^*} \big(-\Theta_1^*(-\ell) - \Theta_2^*(\ell)\big), \tag{D.3}$$

the right-hand supremum being attained.

Proof sketch. The inequality $\ge$ is immediate from the definition of the conjugates: $-\Theta_1^*(-\ell) - \Theta_2^*(\ell) \le \Theta_1(x) + \Theta_2(x)$ for all x, ℓ by adding the two Young inequalities $\Theta_1(x) \ge -\ell(x) - \Theta_1^*(-\ell)$ and $\Theta_2(x) \ge \ell(x) - \Theta_2^*(\ell)$. For the reverse, let $m = \inf_x(\Theta_1 + \Theta_2)$ (assume $m > -\infty$, else both sides are $-\infty$). In the product space $E \times \mathbb{R}$ consider the two convex sets

$$C_1 = \{(x, t) : t \ge \Theta_1(x)\}, \qquad C_2 = \{(x, t) : t \le m - \Theta_2(x)\}.$$

C_1 is the epigraph of Θ_1 and C_2 is the hypograph of $m - \Theta_2$; their interiors are disjoint (a common interior point would give $\Theta_1(x) < t < m - \Theta_2(x)$, i.e. $\Theta_1(x) + \Theta_2(x) < m$, impossible), and the continuity hypothesis makes C_1 have nonempty interior. By the Hahn–Banach separation theorem (theorem 2.11) there is a nonzero continuous linear functional on $E \times \mathbb{R}$ separating them; writing it as $(x, t) \mapsto \ell(x) - \lambda t$ one checks $\lambda > 0$, and rescaling so $\lambda = 1$ the separating functional yields exactly an $\ell \in E^*$ achieving $-\Theta_1^*(-\ell) - \Theta_2^*(\ell) \ge m$. Combined with weak duality this is (D.3) with attainment. Full detail is in [31, Ch. 1]; the argument is the convex-geometric heart of chapter 2. □

D.1.3 Strong duality for bounded continuous cost

Assume first that c is replaced by a bounded continuous cost $\tilde{c} \ge 0$; we restore $\tilde{c} = |x - y|^2$ afterward. Work on $E = C_b(\mathbb{R}^d \times \mathbb{R}^d)$, the bounded continuous functions with the sup norm, whose dual contains the finite signed Radon measures. Define, for $u \in E$,

$$\Theta_1(u) = \begin{cases} 0, & u(x, y) \le \tilde{c}(x, y) \ \forall x, y, \\ +\infty, & \text{else,} \end{cases} \qquad \Theta_2(u) = \begin{cases} -\int \varphi \, \mathrm{d}\mu - \int \psi \, \mathrm{d}\nu, & u(x, y) = \varphi(x) + \psi(y), \\ +\infty, & \text{else,} \end{cases}$$

where in Θ_2 the decomposition $u(x,y) = \varphi(x) + \psi(y)$ into bounded continuous φ, ψ is required (such a decomposition, when it exists, determines $\int \varphi \, \mathrm{d}\mu + \int \psi \, \mathrm{d}\nu$ uniquely up to the additive-constant gauge $\varphi \mapsto \varphi + a$, $\psi \mapsto \psi - a$, under which the value is unchanged because μ, ν are probability measures). Both functionals are convex; Θ_1 is continuous at $u \equiv -\|\tilde{c}\|_\infty - 1$, where Θ_2 is also finite. Then

$$\inf_{u \in E} (\Theta_1(u) + \Theta_2(u)) = -\sup\left\{\int \varphi \, \mathrm{d}\mu + \int \psi \, \mathrm{d}\nu : \varphi(x) + \psi(y) \leq \tilde{c}(x,y)\right\} = -(\text{dual}).$$

A direct computation of the conjugates identifies the right-hand side of (D.3): $\Theta_1^*(-\pi)$ is finite only when $\pi \geq 0$ (a positive measure), where it equals $\int \tilde{c} \, \mathrm{d}\pi$; and $\Theta_2^*(\pi)$ is finite only when π has marginals μ, ν, where it equals 0. Hence the maximizing measure π is a coupling in $\Pi(\mu, \nu)$ and (D.3) reads $-(\text{dual}) = -\inf_{\pi \in \Pi(\mu,\nu)} \int \tilde{c} \, \mathrm{d}\pi$, i.e. (dual) = (primal), with both optima attained. This is strong duality for bounded continuous cost.

D.1.4 Removing boundedness

For the quadratic cost set $c_R(x,y) = \min\left\{|x-y|^2, R\right\}$, which is bounded and continuous. By the previous step there are admissible bounded potentials (φ_R, ψ_R) with $\int \varphi_R \, \mathrm{d}\mu + \int \psi_R \, \mathrm{d}\nu = \inf_\pi \int c_R \, \mathrm{d}\pi$. Since $c_R \uparrow c$ pointwise, the monotone convergence theorem gives $\inf_\pi \int c_R \, \mathrm{d}\pi \uparrow \mathcal{W}_2(\mu,\nu)^2$ along any minimizing sequence; a standard diagonal/tightness argument (each c_R-optimal pair may be taken c_R-conjugate, hence equi-Lipschitz on compacts with at most quadratic growth controlled by the second moments of μ, ν) extracts a limiting pair (φ, ψ) that is c-admissible and attains the supremum in (D.1). Replacing φ by its c-transform $\varphi^c(y) = \inf_x \left(|x-y|^2 - \varphi(x)\right)$ and iterating once produces a c-conjugate pair without decreasing the objective, giving the Kantorovich potentials. This proves (D.1). [131, Ch. 5] carries out the truncation limit in full.

D.2 Brenier's theorem

We prove theorem 4.6: if $\mu \in \mathcal{P}_2(\mathbb{R}^d)$ is absolutely continuous with respect to Lebesgue measure and $\nu \in \mathcal{P}_2(\mathbb{R}^d)$, then the optimal coupling is unique and induced by a map $T = \nabla\phi$ with ϕ convex, and this is the unique gradient-of-convex map pushing μ to ν.

D.2.1 Cyclical monotonicity of the optimal support

Lemma D.2 (The optimal plan is cyclically monotone)**.** *Let $\pi^\star \in \Pi(\mu,\nu)$ be optimal for the quadratic cost. Then its support $S = \operatorname{supp} \pi^\star$ is c-*cyclically monotone*: for every finite family $(x_1, y_1), \ldots, (x_n, y_n) \in S$ and every permutation σ,*

$$\sum_{i=1}^{n} |x_i - y_i|^2 \;\leq\; \sum_{i=1}^{n} \left|x_i - y_{\sigma(i)}\right|^2. \tag{D.4}$$

Proof. If (D.4) failed for some family and some σ, the reverse strict inequality would hold for a cyclic permutation. One could then construct a competitor plan by moving an ε amount of mass off the cycle's edges (x_i, y_i) onto the re-paired edges $(x_i, y_{\sigma(i)})$ — concretely, using small product blocks around each (x_i, y_i) in $\operatorname{supp}\pi^\star$ and a measurable re-coupling — strictly lowering the total cost while preserving both marginals, contradicting optimality of $\pi^\star$. The construction is the standard "cycle-swapping" perturbation; see [131, Thm. 2.13]. □

D.2.2 Rockafellar's theorem and the convex potential

Lemma D.3 (Rockafellar)**.** *After absorbing the quadratic terms via $|x-y|^2 = |x|^2 - 2\langle x, y\rangle + |y|^2$, c-cyclical monotonicity of S is equivalent to* cyclical monotonicity *of the set $\widehat{S} = \{(x,y) : (x,y) \in S\}$ with respect to the inner product: for all cycles, $\sum_i \langle x_i, y_{i+1} - y_i\rangle \le 0$. Any cyclically monotone set is contained in the subdifferential graph $\{(x,y) : y \in \partial\phi(x)\}$ of a proper lower semicontinuous convex function $\phi\colon \mathbb{R}^d \to (-\infty, +\infty]$.*

Proof. Expanding the squares in (D.4) and cancelling the $|x_i|^2, |y_i|^2$ terms (a permutation of the y's leaves $\sum |y_i|^2$ unchanged) turns (D.4) into $\sum_i \langle x_i, y_i\rangle \ge \sum_i \langle x_i, y_{\sigma(i)}\rangle$, which is the cyclical-monotonicity inequality. Given a cyclically monotone set $\widehat{S}$, fix a base point $(x_0, y_0) \in \widehat{S}$ and define

$$\phi(x) = \sup\left\{\langle y_0, x_1 - x_0\rangle + \langle y_1, x_2 - x_1\rangle + \cdots + \langle y_{k-1}, x_k - x_{k-1}\rangle + \langle y_k, x - x_k\rangle\right\},$$

the supremum over all finite chains $(x_1, y_1), \ldots, (x_k, y_k) \in \widehat{S}$. As a supremum of affine functions, ϕ is convex and lower semicontinuous; cyclical monotonicity makes $\phi(x_0)$ finite (the empty chain gives 0 and no chain exceeds it), and one verifies directly that $y \in \partial\phi(x)$ whenever $(x,y) \in \widehat{S}$. This is Rockafellar's theorem [116, Thm. 24.8]. □

D.2.3 From subdifferential to gradient

Lemma D.4 (Convex functions are differentiable a.e.)**.** *A finite convex function $\phi\colon U \to \mathbb{R}$ on an open $U \subseteq \mathbb{R}^d$ is locally Lipschitz, and the set of points where it is not differentiable has Lebesgue measure zero; where it is differentiable, $\partial\phi(x) = \{\nabla\phi(x)\}$.*

Proof. Local Lipschitzness is elementary: convexity bounds the difference quotients above and below by the values on a surrounding cube. For the null set, in one variable a convex function has nondecreasing one-sided derivatives that agree except at the at most countably many jump points, so it is differentiable off a countable (null) set. In $\mathbb{R}^d$, apply this to each coordinate line: the partial derivatives exist off a null set by Fubini, and for a convex function the a.e. existence of all partials forces full (Fréchet) differentiability a.e. because the subdifferential is monotone and its multivalued points form a Lebesgue-null set (they are covered by countably many Lipschitz graphs of dimension $\le d-1$). Where $\partial\phi(x)$ is a singleton it equals the gradient. See [116, Thm. 25.5]; this is the convex-function form of Rademacher's theorem. □

Proof of theorem 4.6. Let $\pi^\star$ be an optimal coupling (proposition 4.3). By lemmas D.2 and D.3 its support lies in the graph of $\partial\phi$ for a convex ϕ. Because μ is absolutely continuous, lemma D.4 gives a μ-null set off which $\partial\phi(x) = \{\nabla\phi(x)\}$ is single-valued; hence for μ-a.e. x the plan assigns the single value $T(x) = \nabla\phi(x)$, i.e. $\pi^\star = (\mathrm{Id}, T)_\# \mu$ is induced by the map $T = \nabla\phi$ and $T_\#\mu = \nu$ (the second marginal of $\pi^\star$). This proves (1) and (2) up to uniqueness.

Uniqueness. Suppose $T_1 = \nabla\phi_1$ and $T_2 = \nabla\phi_2$ are two gradient-of-convex maps with $(T_i)_\#\mu = \nu$, both optimal. The half-sum coupling $\frac{1}{2}(\mathrm{Id}, T_1)_\#\mu + \frac{1}{2}(\mathrm{Id}, T_2)_\#\mu$ is again optimal (the cost is affine in the plan and both pieces are optimal), so its support is also contained in a single subdifferential graph; two gradients of convex functions agreeing μ-a.e. with a common monotone graph must coincide μ-a.e., whence $T_1 = T_2$ μ-a.e. and the optimal plan is unique. Statement (3) is then immediate: $\mathcal{W}_2(\mu,\nu)^2 = \int |x - T(x)|^2 \, \mathrm{d}\mu$ equals the Monge infimum because T is an admissible Monge map attaining the Kantorovich value, and no Monge competitor can beat the Kantorovich infimum since Monge plans are couplings. The growth/regularity of the potentials is treated in [30] and [131, Ch. 2]. ☐

D.3 McCann's displacement interpolation

We prove theorem 4.9. Let μ_0 be absolutely continuous, $T = \nabla\phi$ the Brenier map from μ_0 to μ_1, and for $t \in [0,1]$ set $T_t = (1-t)\,\mathrm{Id} + tT$ and $\mu_t = (T_t)_\#\mu_0$.

Proof. Constant speed. Fix $0 \le s \le t \le 1$. The map pushing μ_s to μ_t is $T_{s\to t} = T_t \circ T_s^{-1}$, defined μ_s-a.e. because $T_s = (1-s)\,\mathrm{Id} + sT$ is injective μ_0-a.e. (it is the gradient of the strictly convex $x \mapsto \frac{1-s}{2}|x|^2 + s\phi(x)$ for $s < 1$, and for $s = 1$ no inverse is needed since then $s = t$). On the support, $T_{s\to t}(y) = y + (t-s)\big(T - \mathrm{Id}\big)\big(T_s^{-1}(y)\big)$ is again a gradient of a convex function — the gradients of convex functions are closed under such affine interpolation of the underlying potentials — so by lemma D.3 it is the optimal map from μ_s to μ_t. Therefore

$$\mathcal{W}_2(\mu_s,\mu_t)^2 = \int |T_t(x) - T_s(x)|^2 \, \mathrm{d}\mu_0 = \int \big|(t-s)\big(T(x) - x\big)\big|^2 \, \mathrm{d}\mu_0 = (t-s)^2\, \mathcal{W}_2(\mu_0,\mu_1)^2,$$

using $\mathcal{W}_2(\mu_0,\mu_1)^2 = \int |x - T(x)|^2 \, \mathrm{d}\mu_0$ from Brenier. Taking square roots, $\mathcal{W}_2(\mu_s,\mu_t) = (t - s)\,\mathcal{W}_2(\mu_0,\mu_1)$, the constant-speed-geodesic property.

These exhaust the geodesics. Any constant-speed geodesic (ν_t) joining μ_0 to μ_1 has, for each t, optimal couplings of μ_0-to-ν_t and ν_t-to-μ_1 whose costs add to $\mathcal{W}_2(\mu_0,\mu_1)^2$ with the right proportions; gluing them (via disintegration, theorem 3.33) yields a coupling of μ_0 and μ_1 supported on geodesics of $\mathbb{R}^d$ (straight segments), and absolute continuity of μ_0 forces this coupling to be the graph of T_t. This is McCann's theorem [101]; the geodesic-gluing argument is [7, Ch. 7]. ☐

D.4 The Benamou–Brenier dynamic formula

We prove theorem 4.10: for $\mu_0, \mu_1 \in \mathcal{P}_2(\mathbb{R}^d)$,

$$\mathcal{W}_2(\mu_0,\mu_1)^2 = \inf\left\{ \int_0^1 \int_{\mathbb{R}^d} |v_t(x)|^2 \, \mathrm{d}\mu_t \; \mathrm{d}t : \; \partial_t\mu_t + \mathrm{div}(\mu_t v_t) = 0, \; \mu_{t=0} = \mu_0, \; \mu_{t=1} = \mu_1 \right\},$$

the continuity equation holding in the distributional sense.

Proof. Lower bound (≥). Let (μ_t, v_t) solve the continuity equation with finite action $\mathcal{A} = \int_0^1 \int |v_t|^2 \, d\mu_t \, dt$. The flow map $\dot{X}_t = v_t(X_t)$, $X_0 \sim \mu_0$, transports μ_0 to μ_1 (this is the method of characteristics for the continuity equation, valid here because finite action gives the $L^2(dt; L^2(\mu_t))$ regularity needed for the superposition principle). Then (X_0, X_1) is a coupling of μ_0, μ_1, and by Cauchy–Schwarz in t,

$$\mathcal{W}_2(\mu_0, \mu_1)^2 \le \mathbb{E}\,|X_1 - X_0|^2 = \mathbb{E}\left|\int_0^1 v_t(X_t)\,dt\right|^2 \le \mathbb{E}\int_0^1 |v_t(X_t)|^2\,dt = \mathcal{A}.$$

Upper bound (≤). The displacement geodesic $\mu_t = (T_t)_{\#}\mu_0$ of appendix D.3 solves the continuity equation with velocity $v_t = (T - \mathrm{Id}) \circ T_t^{-1}$, which is well defined μ_t-a.e. for $t \in [0, 1)$ since T_t is invertible there (appendix D.3). Its action is

$$\int_0^1 \int |v_t|^2 \, d\mu_t \, dt = \int_0^1 \int |T(x) - x|^2 \, d\mu_0 \, dt = \int |T(x) - x|^2 \, d\mu_0 = \mathcal{W}_2(\mu_0, \mu_1)^2,$$

the middle equality by the change of variables $y = T_t(x)$. Hence the infimum is at most $\mathcal{W}_2(\mu_0, \mu_1)^2$, and with the lower bound it equals it, the displacement geodesic being the minimizer. The superposition principle underlying the lower bound is in [7, Ch. 8]; the original argument is [18]. □

D.5 The Lions structure theorem

We prove the assertion of definition 4.14: when the lift $\widetilde{F}(X) = F(\mathcal{L}(X))$ is Fréchet differentiable on $L^2(\Omega; \mathbb{R}^d)$ with a continuous gradient, that gradient is $\mathcal{L}(X)$-measurably a function of X alone, i.e. $D\widetilde{F}(X) = \xi(X)$ a.s. for some $\xi \in L^2(\mathcal{L}(X); \mathbb{R}^d)$.

Theorem D.5 (Rearrangement-invariance structure theorem)**.** *Let $(\Omega, \mathcal{F}, \mathbb{P})$ be atomless and $F \colon \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}$ have a lift $\widetilde{F}$ that is Fréchet differentiable at $X \in L^2(\Omega; \mathbb{R}^d)$ with gradient $D\widetilde{F}(X) \in L^2(\Omega; \mathbb{R}^d)$ (identified with its Riesz representative, theorem 2.6). Then there is a Borel map $\xi \colon \mathbb{R}^d \to \mathbb{R}^d$, in $L^2(\mathcal{L}(X); \mathbb{R}^d)$, with*

$$D\widetilde{F}(X) = \xi(X) \qquad a.s., \qquad \xi = \partial_\mu F(\mathcal{L}(X)). \tag{D.5}$$

Proof. The lift is *law-invariant*: $\widetilde{F}(X) = \widetilde{F}(X')$ whenever $\mathcal{L}(X) = \mathcal{L}(X')$, because both equal $F(\mathcal{L}(X))$. We exploit invariance under the group $\mathcal{T}$ of measure-preserving bijections $\tau \colon \Omega \to \Omega$: for any such τ, $X \circ \tau$ has the same law as X, so $\widetilde{F}(X \circ \tau) = \widetilde{F}(X)$ for all X. Differentiating this identity at X in a direction $Y \in L^2$,

$$\langle D\widetilde{F}(X \circ \tau), Y \circ \tau \rangle_{L^2} = \langle D\widetilde{F}(X), Y \rangle_{L^2}.$$

Since τ is measure preserving, $\langle D\widetilde{F}(X) \circ \tau, Y \circ \tau \rangle = \langle D\widetilde{F}(X), Y \rangle$ under the substitution; comparing for all Y shows $D\widetilde{F}(X \circ \tau) = D\widetilde{F}(X) \circ \tau$ a.s. Thus the gradient is *equivariant*: it commutes with measure-preserving rearrangements.

Now fix X and let $\sigma(X)$ be the σ-algebra it generates. We claim $D\widetilde{F}(X)$ is $\sigma(X)$-measurable. If not, its conditional expectation $\mathbb{E}[D\widetilde{F}(X) \mid \sigma(X)]$ (section 3.6) would differ from it on a set of positive measure, and one could build, using atomlessness of Ω, a measure-preserving τ fixing $\sigma(X)$ (so $X \circ \tau = X$) but moving $D\widetilde{F}(X)$ — contradicting equivariance $D\widetilde{F}(X) = D\widetilde{F}(X \circ \tau) = D\widetilde{F}(X) \circ \tau$. Hence $D\widetilde{F}(X)$ is $\sigma(X)$-measurable, so by the Doob–Dynkin lemma $D\widetilde{F}(X) = \xi(X)$ a.s. for a Borel $\xi \colon \mathbb{R}^d \to \mathbb{R}^d$. Finally ξ depends on X only through $\mathcal{L}(X) = m$: two variables with the same law are related by a measure-preserving map (atomless Ω), and equivariance transports ξ unchanged. Writing $\xi = \partial_\mu F(m)$ gives (D.5). The argument is Lions's, reported in [40, Ch. 5]. ☐

The relation $\partial_\mu F(m)(x) = \nabla_x \frac{\delta F}{\delta m}(m, x)$ between the Lions and flat derivatives, stated as proposition 4.15, follows by differentiating $\epsilon \mapsto F(\mathcal{L}(X + \epsilon Y))$ two ways and matching, exactly as in the proof sketch of proposition 4.15; the integration by parts there is justified by the linear-growth hypothesis on $\nabla_x \frac{\delta F}{\delta m}(m, \cdot)$.

D.6 Second-order calculus: Itô's formula along a flow of measures

The master equation of chapter 12 differentiates a functional $U(t, x, m)$ along the flow of a measure $m_t = \mathcal{L}(X_t)$ where X_t solves an Itô SDE. We record the chain rule it needs. This requires a *second* Lions derivative and the mixed object $\nabla_x \partial_\mu F(m)(x)$, which we now define precisely.

Definition D.6 (Second Lions derivative)**.** Let $F \colon \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}$ be L-differentiable with Lions derivative $\partial_\mu F(m)(\cdot) \colon \mathbb{R}^d \to \mathbb{R}^d$ (proposition 4.15, theorem D.5). Fix $v \in \mathbb{R}^d$ and suppose the scalar functionals $m \mapsto \big[\partial_\mu F(m)(v)\big]_i$ $(i = 1, \dots, d)$ are themselves L-differentiable. The *second Lions derivative* of F is the map

$$\partial_\mu^2 F(m)(v, v') \;:=\; \partial_\mu\big[\, m \mapsto \partial_\mu F(m)(v) \,\big](v') \;\in\; \mathbb{R}^{d \times d},$$

the Lions derivative, at the second base point v', of the $\mathbb{R}^d$-valued function $m \mapsto \partial_\mu F(m)(v)$. Equivalently, in flat-derivative form, $\partial_\mu^2 F(m)(v, v') = \nabla_v \nabla_{v'} \frac{\delta^2 F}{\delta m^2}(m)(v, v')$, where $\frac{\delta^2 F}{\delta m^2}$ is the second flat derivative (the flat derivative of $m \mapsto \frac{\delta F}{\delta m}(m)(v)$). When F is twice L-differentiable with $\frac{\delta^2 F}{\delta m^2}$ jointly continuous, Schwarz symmetry holds, $\frac{\delta^2 F}{\delta m^2}(m)(v, v') = \frac{\delta^2 F}{\delta m^2}(m)(v', v)$, hence $\partial_\mu^2 F(m)(v, v') = \partial_\mu^2 F(m)(v', v)^\top$. We call F *twice L-differentiable* when $\partial_\mu F$, the mixed derivative $\nabla_v \partial_\mu F$, and $\partial_\mu^2 F$ exist, are jointly continuous, and are bounded on bounded sets.

Theorem D.7 (Itô's formula along a flow of measures)**.** *Let X_t solve $\mathrm{d}X_t = b_t \,\mathrm{d}t + \sigma_t \,\mathrm{d}W_t$ in $\mathbb{R}^d$ with W a Brownian motion (chapter 5), and let $m_t = \mathcal{L}(X_t)$. Let $F \colon \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}$ be twice L-differentiable with continuous, suitably bounded derivatives $\partial_\mu F$, $\nabla_v \partial_\mu F$, $\partial_\mu^2 F$. Then $t \mapsto F(m_t)$ is differentiable and*

$$\frac{\mathrm{d}}{\mathrm{d}t} F(m_t) = \mathbb{E}\Big[\partial_\mu F(m_t)(X_t) \cdot b_t + \tfrac{1}{2} \operatorname{tr}\big(\nabla_v \partial_\mu F(m_t)(X_t)\, \sigma_t \sigma_t^\top\big)\Big]. \tag{D.6}$$

Proof. Let $\widetilde{F}$ be the lift. By the structure theorem (theorem D.5), $D\widetilde{F}(X_t) = \partial_\mu F(m_t)(X_t)$ and the Hessian of the lift acts as the second Lions derivative. Apply the ordinary Itô formula (theorem 5.9) to the *deterministic* function $t \mapsto \widetilde{F}(X_t) = F(m_t)$ on the Hilbert space $L^2(\Omega; \mathbb{R}^d)$ — but $F(m_t)$ is deterministic, so only the drift of the Itô expansion of $\widetilde{F}(X_t)$ survives in expectation.

Concretely, write the increment of X_t and expand $\widetilde{F}$ to second order; the first-order term contributes $\mathbb{E}[\partial_\mu F(m_t)(X_t) \cdot b_t]\ \mathrm{d}t$, the Itô second-order term contributes $\frac{1}{2}\mathbb{E}[\mathrm{tr}(\nabla_v \partial_\mu F(m_t)(X_t)\sigma_t\sigma_t^\top)]\ \mathrm{d}t$, and the martingale part $\mathbb{E}[\partial_\mu F(m_t)(X_t) \cdot \sigma_t\ \mathrm{d}W_t] = 0$ vanishes in expectation. This yields (D.6). The full hypotheses and the joint-in-(x, m) version used for the master equation are in [40, Ch. 5] and are assembled in chapter 12. □

This is the result chapter 12 imports to derive the master equation; chapter 4 states its first-order half (the gradient relation proposition 4.15) and defers the second-order formula here and to chapter 12.

D.7 Itô's formula along a conditional flow of measures (common noise)

The common-noise master equation of section 12.7 and its graphon lift (chapter 26) differentiate a functional along a *stochastic* flow of measures: the *conditional* law $m_t = \mathcal{L}(X_t \mid \mathcal{F}_t^0)$ of a state that is driven both by private noise and by a common noise W^0. The chain rule then acquires, beyond the deterministic terms of theorem D.7, a second-order contribution in the common noise — including a genuine *second* Lions derivative — and a martingale term. This is the Itô–Wentzell formula on $\mathcal{P}_2(\mathbb{R}^d)$; we state and prove it here, the result both chapter 12 and chapter 26 import.

Theorem D.8 (Conditional Itô formula on $\mathcal{P}_2(\mathbb{R}^d)$)**.** *On a filtered probability space carrying independent Brownian motions W (private) and W^0 (common), with $\mathcal{F}^0 = (\mathcal{F}_t^0)$ the filtration generated by W^0, let*

$$\mathrm{d}X_t = b_t\ \mathrm{d}t + \sigma_t\ \mathrm{d}W_t + \sigma_t^0\ \mathrm{d}W_t^0,$$

with $\mathcal{F}^0$-progressive coefficients of suitable integrability, and set $m_t = \mathcal{L}(X_t \mid \mathcal{F}_t^0) \in \mathcal{P}_2(\mathbb{R}^d)$, an $\mathcal{F}^0$-adapted stochastic flow. Let $F \colon \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}$ be twice L-differentiable in the sense of definition D.6, with $\partial_\mu F$, $\nabla_v \partial_\mu F$ and $\partial_\mu^2 F$ continuous and bounded on bounded sets. Then $t \mapsto F(m_t)$ is an Itô process and

$$\begin{aligned} \mathrm{d}F(m_t) = {} & \mathbb{E}_t\big[\partial_\mu F(m_t)(X_t) \cdot b_t\big]\ \mathrm{d}t + \tfrac{1}{2}\,\mathbb{E}_t\big[\,\mathrm{tr}\,\big(\nabla_v \partial_\mu F(m_t)(X_t)\,(\sigma_t\sigma_t^\top + \sigma_t^0(\sigma_t^0)^\top)\big)\big]\ \mathrm{d}t \\ & + \tfrac{1}{2}\,\mathbb{E}_t\big[\,\mathrm{tr}\,\big(\partial_\mu^2 F(m_t)(X_t, X_t')\,\sigma_t^0(\sigma_t^0)^\top\big)\big]\ \mathrm{d}t + \mathbb{E}_t\big[\partial_\mu F(m_t)(X_t) \cdot \sigma_t^0\big]\ \mathrm{d}W_t^0, \end{aligned} \tag{D.7}$$

where $\mathbb{E}_t[\,\cdot\,] := \mathbb{E}[\,\cdot \mid \mathcal{F}_t^0]$ and, in the third term, X_t' is an independent copy of X_t with the same *conditional law m_t (so $\mathbb{E}_t$ averages the matrix $\partial_\mu^2 F(m_t)(\cdot, \cdot)$ against $m_t \otimes m_t$).*

Proof. Freeze a realization of W^0 and condition throughout on $\mathcal{F}^0$. The new feature relative to theorem D.7 is that m_t is now random and itself driven by W^0. We expand $F(m_t)$ by combining the Itô expansion of the underlying state with the second-order calculus on $\mathcal{P}_2(\mathbb{R}^d)$.

The conditional flow. Conditioning on $\mathcal{F}_t^0$ removes the private noise: by the conditional propagation-of-chaos / superposition principle (the conditional law of a diffusion driven by an independent private noise solves a stochastic Fokker–Planck equation, the McKean–Vlasov form of theorem 5.9 averaged over the private noise), m_t solves

$$\mathrm{d}m_t = \Big[-\operatorname{div}\big(m_t\,\mathbb{E}[b_t \mid X_t = \cdot]\big) + \tfrac{1}{2}\sum_{ij}\partial_{ij}\big((\sigma_t\sigma_t^\top + \sigma_t^0(\sigma_t^0)^\top)_{ij}\, m_t\big)\Big]\,\mathrm{d}t - \operatorname{div}\big(m_t\,\sigma_t^0\big)\cdot \mathrm{d}W_t^0,$$

a stochastic PDE whose drift carries the *full* diffusion $\sigma_t\sigma_t^\top + \sigma_t^0(\sigma_t^0)^\top$ (the common noise spreads the conditional law just as the private noise does) and whose martingale part $-\operatorname{div}(m_t\,\sigma_t^0)\,\mathrm{d}W_t^0$ transports the whole conditional law coherently.

Applying the flat-derivative chain rule. For a smooth functional F the first variation gives, along any Itô flow $\mathrm{d}m_t = \boldsymbol{b}_t\,\mathrm{d}t + \boldsymbol{\sigma}_t\,\mathrm{d}W_t^0$ of measures, the Itô expansion

$$\mathrm{d}F(m_t) = \Big\langle \tfrac{\delta F}{\delta m}(m_t),\, \boldsymbol{b}_t\Big\rangle\,\mathrm{d}t + \Big\langle \tfrac{\delta F}{\delta m}(m_t),\, \boldsymbol{\sigma}_t\Big\rangle\,\mathrm{d}W_t^0 + \tfrac{1}{2}\Big\langle\!\!\Big\langle \tfrac{\delta^2 F}{\delta m^2}(m_t),\, \boldsymbol{\sigma}_t\otimes\boldsymbol{\sigma}_t\Big\rangle\!\!\Big\rangle\,\mathrm{d}t,$$

the last term being the Itô correction from the quadratic variation of the *measure-valued* martingale, paired through the second flat derivative. Substituting the two parts of the conditional flow and integrating the divergences by parts in the state variable — which converts $\frac{\delta F}{\delta m}$ into $\partial_\mu F = \nabla_v \frac{\delta F}{\delta m}$ and $\frac{\delta^2 F}{\delta m^2}$ into $\partial_\mu^2 F = \nabla_v\nabla_{v'}\frac{\delta^2 F}{\delta m^2}$ (definition D.6) — the drift terms reproduce exactly the two $\mathbb{E}_t[\cdots]$ lines of (D.7): the first from the transport drift $\mathbb{E}[b_t \mid X_t = \cdot]$, the second (full-diffusion) from the spreading. The martingale part $-\operatorname{div}(m_t\sigma_t^0)\,\mathrm{d}W_t^0$ contributes, after integration by parts, the $\mathbb{E}_t[\partial_\mu F(m_t)(X_t)\cdot\sigma_t^0]\,\mathrm{d}W_t^0$ term.

The double-integral term. The Itô correction is the quadratic variation of that same measure-valued martingale, $\mathrm{d}\langle m\rangle_t = \big(\operatorname{div}(m_t\sigma_t^0)\big)^{\otimes 2}\,\mathrm{d}t$, paired against $\frac{\delta^2 F}{\delta m^2}$. Integrating by parts *twice* (once in each of the two state slots) moves both divergences onto the second flat derivative, producing

$$\tfrac{1}{2}\int_{\mathbb{R}^d}\!\int_{\mathbb{R}^d} \operatorname{tr}\big(\partial_\mu^2 F(m_t)(v,v')\,\sigma_t^0(v)\sigma_t^0(v')^\top\big)\,m_t(\mathrm{d}v)\,m_t(\mathrm{d}v') = \tfrac{1}{2}\,\mathbb{E}_t\big[\operatorname{tr}\big(\partial_\mu^2 F(m_t)(X_t,X_t')\,\sigma_t^0(\sigma_t^0)^\top\big)\big],$$

which is the third term of (D.7); the two state integrals are independent because they come from two independent copies of the state sharing the conditional law m_t, and they are correlated only through the *single* common increment $\mathrm{d}W_t^0$ — this is why one common noise yields a genuine double integral. The boundedness and continuity hypotheses on $\partial_\mu F, \nabla_v\partial_\mu F, \partial_\mu^2 F$ justify the integrations by parts and the differentiation under the expectation. The rigorous version, with the precise function-space hypotheses, is the Itô–Wentzell formula of [41, Ch. 4]; the present derivation is the deterministic theorem D.7 upgraded by the common-noise quadratic variation. □

Remark D.9. Setting $\sigma_t^0 \equiv 0$ recovers theorem D.7. The four families of σ^0-terms in (D.7) — the full-diffusion upgrade in the second term and the new $\partial_\mu^2 F$ double integral and martingale term — are precisely those that appear, applied to $U(t,x,\cdot)$ with the agent's own state carried as a parameter, in the classical common-noise master equation (12.17) and, lifted slice-by-slice over the type continuum, in the graphon common-noise master equation (26.23).

D.8 The first-order distance $\mathcal{W}_1$

Chapter 4 develops the quadratic Wasserstein space $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ in detail; the existence theory of chapter 10 works instead in the *first-order* space $(\mathcal{P}_1(\mathbb{R}^d), \mathcal{W}_1)$, where $\mathcal{P}_1(\mathbb{R}^d)$ is the set of Borel probability measures with finite first moment $\int |x|\ \mathrm{d}\mu < \infty$ and

$$\mathcal{W}_1(\mu,\nu) = \inf_{\pi\in\Pi(\mu,\nu)} \int_{\mathbb{R}^d\times\mathbb{R}^d} |x-y|\ \pi(\mathrm{d}x,\mathrm{d}y),$$

the optimal-transport cost for the metric cost $c(x,y) = |x-y|$. We supply the four facts chapter 10 uses: Kantorovich–Rubinstein duality, the metrisation of weak convergence, the completeness of $(\mathcal{P}_1, \mathcal{W}_1)$, and the compactness criterion. Each is a corollary of the machinery already built in this appendix (Kantorovich duality, appendix D.1) and in chapter 3 (tightness and Prokhorov, theorem 3.16).

Theorem D.10 (Kantorovich–Rubinstein duality)**.** *For $\mu,\nu \in \mathcal{P}_1(\mathbb{R}^d)$,*

$$\mathcal{W}_1(\mu,\nu) \;=\; \sup\Big\{ \int_{\mathbb{R}^d} f\ \mathrm{d}\mu - \int_{\mathbb{R}^d} f\ \mathrm{d}\nu \ :\ f\colon \mathbb{R}^d \to \mathbb{R},\ \mathrm{Lip}(f) \le 1 \Big\}. \tag{D.8}$$

Consequently $\mathcal{W}_1$ is the restriction to $\mathcal{P}_1(\mathbb{R}^d)$ of the dual bounded-Lipschitz *(Kantorovich–Rubinstein) norm $\|\mu-\nu\|_{\mathrm{KR}} = \sup\{\int f\ \mathrm{d}(\mu-\nu) : \mathrm{Lip}(f) \le 1\}$ on finite signed measures of finite first moment.*

Proof. ($\ge$, weak duality). For any 1-Lipschitz f and any coupling $\pi \in \Pi(\mu,\nu)$,

$$\int f\ \mathrm{d}\mu - \int f\ \mathrm{d}\nu = \int \big(f(x) - f(y)\big)\, \pi(\mathrm{d}x,\mathrm{d}y) \le \int |x-y|\ \pi(\mathrm{d}x,\mathrm{d}y),$$

and taking the infimum over π gives $\int f\ \mathrm{d}\mu - \int f\ \mathrm{d}\nu \le \mathcal{W}_1(\mu,\nu)$, hence the sup in (D.8) is $\le \mathcal{W}_1$.

($\le$, strong duality). The cost $c(x,y) = |x-y|$ is continuous of at most linear growth, so the Fenchel–Rockafellar mechanism of theorem D.1, used in appendix D.1 for the quadratic cost, applies verbatim and yields

$$\mathcal{W}_1(\mu,\nu) = \sup\Big\{ \int \varphi\ \mathrm{d}\mu + \int \psi\ \mathrm{d}\nu :\ \varphi(x) + \psi(y) \le |x-y|\ \ \forall x,y \Big\},$$

with the supremum attained by a c-conjugate pair. For the *metric* cost the c-conjugation collapses: given admissible (φ,ψ), the c-transform $\varphi^c(y) = \inf_x(|x-y| - \varphi(x))$ is itself 1-Lipschitz (an infimum of the 1-Lipschitz maps $x \mapsto |x-\cdot| - \varphi(x)$), satisfies $\psi \le \varphi^c$ and $\varphi \le (\varphi^c)^c =: f$ with f 1-Lipschitz, and $f(x) + (-f)(y) = f(x) - f(y) \le |x-y|$. Replacing (φ,ψ) by $(f,-f)$ does not decrease the objective, so the supremum is attained over pairs $(f,-f)$ with f 1-Lipschitz, which is exactly (D.8). The norm statement is the identification of the right-hand side with $\|\mu-\nu\|_{\mathrm{KR}}$. □

Theorem D.11 ($\mathcal{W}_1$ metrises weak convergence; completeness)**.** *$(\mathcal{P}_1(\mathbb{R}^d), \mathcal{W}_1)$ is a complete metric space. Moreover, for $\mu_n, \mu \in \mathcal{P}_1(\mathbb{R}^d)$,*

$$\mathcal{W}_1(\mu_n,\mu) \to 0 \iff \mu_n \to \mu \text{ weakly and } \int |x|\ \mathrm{d}\mu_n \to \int |x|\ \mathrm{d}\mu,$$

and on any set with uniformly integrable first moments *(in particular a uniform bound on a moment of order $p > 1$) $\mathcal{W}_1$ metrises weak convergence. The map $\mu \mapsto \int |x|\ \mathrm{d}\mu$ and, more generally, $\mu \mapsto \int |x|^2\ \mathrm{d}\mu$ are $\mathcal{W}_1$-lower semicontinuous.*

Proof. $\mathcal{W}_1$ is a metric (symmetry is clear; the triangle inequality follows by gluing couplings, exactly as for $\mathcal{W}_2$ in section 4.2; $\mathcal{W}_1(\mu,\nu)=0$ forces $\mu=\nu$ since by (D.8) all 1-Lipschitz integrals agree, hence all bounded continuous ones).

Equivalence with weak convergence plus first moments. ($\Rightarrow$) If $\mathcal{W}_1(\mu_n,\mu)\to 0$, then for every bounded 1-Lipschitz f, (D.8) gives $\int f\,\mathrm{d}\mu_n \to \int f\,\mathrm{d}\mu$; bounded Lipschitz functions are convergence-determining, so $\mu_n\to\mu$ weakly, and applying (D.8) to $f(x)=|x|$ (1-Lipschitz) shows $|\int |x|\,\mathrm{d}\mu_n - \int |x|\,\mathrm{d}\mu| \le \mathcal{W}_1(\mu_n,\mu)\to 0$. ($\Leftarrow$) Suppose $\mu_n\to\mu$ weakly with $\int |x|\,\mathrm{d}\mu_n \to \int |x|\,\mathrm{d}\mu$. The first-moment convergence forces uniform integrability of $|x|$ under μ_n (a weakly convergent sequence with convergent first moments is uniformly integrable in the first moment). Given ε, choose R with $\int_{|x|>R}|x|\,\mathrm{d}\mu_n<\varepsilon$ uniformly. For a 1-Lipschitz f normalised by $f(0)=0$ (so $|f(x)|\le|x|$), split $\int f\,\mathrm{d}(\mu_n-\mu)$ into the contribution of the truncation $f_R=f\cdot(|x|\le R)$-part, which $\to 0$ by weak convergence (bounded continuous), and the tails, bounded by 2ε; taking the supremum over f and using (D.8) gives $\limsup \mathcal{W}_1(\mu_n,\mu)\le C\varepsilon$. On a family with uniformly integrable first moments the tail bound is automatic, so $\mathcal{W}_1$ metrises weak convergence there.

Completeness. A $\mathcal{W}_1$-Cauchy sequence is $\mathcal{W}_1$-bounded, hence tight (a uniform first-moment bound gives tightness by Markov's inequality) and uniformly first-moment integrable, so by Prokhorov (theorem 3.16) a subsequence converges weakly to some $\mu\in\mathcal{P}_1$; the Cauchy property upgrades this to $\mathcal{W}_1$-convergence of the whole sequence by the previous paragraph. Lower semicontinuity of the moments is Fatou's lemma along a weakly convergent (e.g. $\mathcal{W}_1$-convergent) sequence applied to $|x|\wedge k$ and $|x|^2\wedge k$, $k\uparrow\infty$. $\square$

Theorem D.12 ($\mathcal{W}_1$ compactness criterion)**.** *A set $\mathcal{K}\subseteq\mathcal{P}_1(\mathbb{R}^d)$ is relatively compact in $(\mathcal{P}_1,\mathcal{W}_1)$ if and only if it is* tight *and has* uniformly integrable first moments*: $\sup_{\mu\in\mathcal{K}}\int_{|x|>R}|x|\,\mathrm{d}\mu\to 0$ as $R\to\infty$. In particular a uniform bound $\sup_{\mu\in\mathcal{K}}\int|x|^2\,\mathrm{d}\mu\le R^2<\infty$ suffices (it gives both tightness, $\mu(|x|>\rho)\le R^2/\rho^2$, and uniform integrability, $\int_{|x|>\rho}|x|\,\mathrm{d}\mu\le R^2/\rho$).*

Proof. Sufficiency. Let $(\mu_n)\subseteq\mathcal{K}$. Tightness and Prokhorov (theorem 3.16) give a weakly convergent subsequence $\mu_{n_k}\to\mu$; uniform integrability of the first moments passes $\int|x|\,\mathrm{d}\mu_{n_k}\to\int|x|\,\mathrm{d}\mu<\infty$ (so $\mu\in\mathcal{P}_1$) and, by theorem D.11, upgrades weak convergence to $\mathcal{W}_1(\mu_{n_k},\mu)\to 0$. Hence every sequence has a $\mathcal{W}_1$-convergent subsequence. *Necessity.* A $\mathcal{W}_1$-relatively compact set is totally bounded; covering it by finitely many $\mathcal{W}_1$-balls of radius ε about centres $\mu_1,\dots,\mu_N\in\mathcal{P}_1$ and using that each μ_i is tight and first-moment integrable, the uniform estimate $\int_{|x|>R}|x|\,\mathrm{d}\mu\le\int_{|x|>R}|x|\,\mathrm{d}\mu_i+C\varepsilon$ (from $\mathcal{W}_1(\mu,\mu_i)<\varepsilon$ and the dual bound applied to truncations of $|x|$) gives uniform integrability, and similarly tightness. $\square$

Remark D.13. Theorems D.10 to D.12 are exactly the inputs to the compact-set construction lemma 10.8 and the Banach embedding of $\mathcal{P}_1$ in the Schauder proof theorem 10.14: the dual bounded-Lipschitz norm makes the ambient space Banach, the second-moment bound supplies tightness and uniform integrability, and the resulting $\mathcal{W}_1$-compactness feeds the metric-valued Arzelà–Ascoli theorem theorem B.24.

D.9 The Wasserstein sampling rate for empirical measures

The quantitative convergence theorems of Part II rest on a single statistical input: the rate at which the empirical measure $\widehat{\rho}_N = \frac{1}{N}\sum_{i=1}^N \delta_{X_i}$ of N i.i.d. samples $X_1, \ldots, X_N \sim \rho$ approaches ρ in $\mathcal{W}_2$. The propagation-of-chaos estimates of chapters 7 and 13 reduce the interaction error to exactly this sampling error, so it is the term that sets the rate and *must* be proved in-book rather than imported. This is the Fournier–Guillin theorem [69]; we prove it here from the transport machinery of this appendix, the only nontrivial geometric ingredient being a multiresolution comparison of $\mathcal{W}_2$ with the discrepancies of μ and ν across a nested family of dyadic cubes.

D.9.1 A multiresolution upper bound for $\mathcal{W}_2$

Fix the half-open unit cube $C_0 = [0,1)^d$. For $\ell \geq 0$ let $\mathcal{P}_\ell$ be its partition into the $2^{d\ell}$ dyadic subcubes of side $2^{-\ell}$; each $Q \in \mathcal{P}_\ell$ is contained in a unique *parent* in $\mathcal{P}_{\ell-1}$ and contains 2^d *children* in $\mathcal{P}_{\ell+1}$, and has diameter $\sqrt{d}\,2^{-\ell}$. For probability measures μ, ν on C_0 set

$$D_\ell(\mu,\nu) \;:=\; \sum_{Q\in\mathcal{P}_\ell} |\mu(Q) - \nu(Q)|\,, \qquad a_\ell \;:=\; \sum_{Q\in\mathcal{P}_\ell} \min\big(\mu(Q),\nu(Q)\big) = 1 - \tfrac{1}{2}D_\ell, \tag{D.9}$$

the second identity from $\min(s,t) = \frac{1}{2}(s+t) - \frac{1}{2}|s-t|$ and $\sum_Q \mu(Q) = \sum_Q \nu(Q) = 1$. Because every $Q \in \mathcal{P}_\ell$ splits into children whose masses sum to $\mu(Q)$ and to $\nu(Q)$, and min is superadditive in the sense $\sum_{Q'\subset Q} \min(\mu(Q'),\nu(Q')) \leq \min(\mu(Q),\nu(Q))$, the sequence a_ℓ is non-increasing in ℓ, equivalently D_ℓ is non-decreasing.

Lemma D.14 (Multiresolution bound)**.** *For all probability measures μ, ν on $C_0 = [0,1)^d$,*

$$\mathcal{W}_2(\mu,\nu)^2 \;\leq\; \frac{3d}{2}\sum_{\ell\geq 1} 4^{-\ell}\, D_\ell(\mu,\nu). \tag{D.10}$$

Proof. We construct an explicit coupling $\pi \in \Pi(\mu,\nu)$ whose cost is bounded by the right-hand side; (D.10) then follows since $\mathcal{W}_2^2$ is the infimum of the cost over $\Pi(\mu,\nu)$ (proposition 4.3).

The tree coupling. Regard the dyadic cubes as the nodes of a tree, Q a child of its parent. We move "together" mass down the tree, releasing the part that cannot stay together. For each cube Q write $s_Q := \min(\mu(Q),\nu(Q))$. We attach to each Q an amount of mass t_Q that enters Q *coupled on the diagonal* (pairs (x,y) both lying in Q), and set $t_{C_0} = 1$ at the root and $t_Q = s_Q$ at every other node. This is consistent: the mass entering a node R that can stay together when distributed to its children is $\sum_{Q\subset R} s_Q \leq s_R = t_R$ (superadditivity of min), so within R an amount

$$t_R - \sum_{Q\subset R} s_Q \tag{D.11}$$

of together-mass must *separate*: its μ-part and its ν-part fall into different children of R. We couple this separating mass by any coupling of its (equal-total) μ- and ν-marginals supported in R; the two endpoints then lie in R, at distance $\leq \sqrt{d}\,2^{-\ell}$ when $R \in \mathcal{P}_\ell$. Mass never released stays together forever and contributes zero cost. Carrying this out at every node defines a coupling $\pi \in \Pi(\mu,\nu)$:

the μ-marginal of the released-plus-retained mass at each node reconstructs μ, and likewise for ν, since $t_Q = s_Q \le \mu(Q) \wedge \nu(Q)$ and the released excess at the parent supplies exactly the deficit at each child.

The cost. A pair separated within a node $R \in \mathcal{P}_\ell$ contributes at most $\big(\sqrt{d}\,2^{-\ell}\big)^2 = d\,4^{-\ell}$ to $\int |x-y|^2 \,\mathrm{d}\pi$. The total mass separated within generation-ℓ nodes is, by (D.11) summed over $R \in \mathcal{P}_\ell$,

$$\sum_{R\in\mathcal{P}_\ell}\Big(t_R - \sum_{Q\subset R} s_Q\Big) \;=\; a_\ell - a_{\ell+1} \;=\; \tfrac{1}{2}(D_{\ell+1} - D_\ell),$$

using $t_R = s_R$ for $\ell \ge 1$ and $t_{C_0} = 1 = a_0$ at $\ell = 0$ (consistent with $D_0 = 0$). Hence

$$\int |x-y|^2 \,\mathrm{d}\pi \;\le\; \sum_{\ell\ge 0} d\,4^{-\ell}\cdot \tfrac{1}{2}(D_{\ell+1} - D_\ell) \;=\; \frac{d}{2}\sum_{\ell\ge 0} 4^{-\ell}(D_{\ell+1} - D_\ell).$$

Summation by parts with $D_0 = 0$ gives $\sum_{\ell\ge 0} 4^{-\ell}(D_{\ell+1} - D_\ell) = \sum_{\ell\ge 1}\big(4^{-(\ell-1)} - 4^{-\ell}\big)D_\ell = 3\sum_{\ell\ge 1} 4^{-\ell} D_\ell$, which is (D.10). $\square$

Remark D.15. The estimate is genuinely an $\mathcal{W}_2$ statement: the weight $4^{-\ell}$ is the *square* of the scale $2^{-\ell}$, so a fluctuation of mass at scale $2^{-\ell}$ costs $4^{-\ell}$, not $2^{-\ell}$. Pairing this with the $\sqrt{\cdot}$-law of the next subsection produces the dimension-dependent thresholds; the analogous $\mathcal{W}_1$ bound carries $2^{-\ell}$ and yields the coarser $N^{-1/d}$ rate.

D.9.2 The sampling theorem

Theorem D.16 (Empirical-measure rate; Fournier–Guillin)**.** *Let $\rho \in \mathcal{P}(\mathbb{R}^d)$ and let $X_1, \dots, X_N$ be i.i.d. with law ρ, with empirical measure $\widehat{\rho}_N = \frac{1}{N}\sum_{i=1}^N \delta_{X_i}$.*

1. (Compactly supported case.) *If ρ is supported in a cube of side L, then*

$$\mathbb{E}\big[\mathcal{W}_2(\widehat{\rho}_N, \rho)^2\big] \;\le\; C_d\, L^2\, s_N, \qquad s_N := \begin{cases} N^{-1/2}, & d < 4,\\ N^{-1/2}\log N, & d = 4,\\ N^{-2/d}, & d > 4,\end{cases} \tag{D.12}$$

with C_d depending only on the dimension.

2. (Finite moment.) *If ρ has a finite moment $M_q = \int |x|^q\,\rho(\mathrm{d}x)$ of some order $q > 4$, then*

$$\mathbb{E}\big[\mathcal{W}_2(\widehat{\rho}_N, \rho)^2\big] \;\le\; C_{d,q}\,(1 + M_q)\, s_N^{1-2/q}. \tag{D.13}$$

Proof. Part (1). Since $\mathcal{W}_2$ scales by L and translates under $x \mapsto Lx + b$, we may assume ρ is supported in the unit cube $C_0 = [0,1)^d$. Apply lemma D.14 to $\mu = \widehat{\rho}_N$, $\nu = \rho$ and take expectations:

$$\mathbb{E}\big[\mathcal{W}_2(\widehat{\rho}_N, \rho)^2\big] \;\le\; \frac{3d}{2}\sum_{\ell\ge 1} 4^{-\ell} \sum_{Q\in\mathcal{P}_\ell} \mathbb{E}\big|\widehat{\rho}_N(Q) - \rho(Q)\big|.$$

For each fixed cube Q, $N\widehat{\rho}_N(Q) = \sum_i \mathbf{1}\{X_i \in Q\}$ is Binomial$(N, \rho(Q))$, so by Jensen and the binomial variance,

$$\mathbb{E}|\widehat{\rho}_N(Q) - \rho(Q)| \le \big(\operatorname{Var}\widehat{\rho}_N(Q)\big)^{1/2} = \Big(\tfrac{1}{N}\rho(Q)(1-\rho(Q))\Big)^{1/2} \le N^{-1/2}\sqrt{\rho(Q)}. \tag{D.14}$$

Summing over the $2^{d\ell}$ cubes of $\mathcal{P}_\ell$ and using Cauchy–Schwarz, $\sum_{Q\in\mathcal{P}_\ell}\sqrt{\rho(Q)} \le \big(2^{d\ell}\sum_Q \rho(Q)\big)^{1/2} = 2^{d\ell/2}$, together with the trivial bound $\sum_Q |\widehat{\rho}_N(Q) - \rho(Q)| \le 2$,

$$\sum_{Q\in\mathcal{P}_\ell} \mathbb{E}|\widehat{\rho}_N(Q) - \rho(Q)| \;\le\; \min\big(2,\; 2^{d\ell/2}N^{-1/2}\big).$$

Split the ℓ-sum at the crossover level $L_\star$ with $2^{dL_\star/2} = N^{1/2}$, i.e. $2^{L_\star} = N^{1/d}$:

$$\mathbb{E}\big[\mathcal{W}_2(\widehat{\rho}_N, \rho)^2\big] \;\le\; \frac{3d}{2}\Big(N^{-1/2}\sum_{1\le\ell\le L_\star} 2^{\ell(d/2-2)} \;+\; 2\sum_{\ell > L_\star} 4^{-\ell}\Big).$$

The tail is $\le \frac{2}{3}\cdot 4^{-L_\star} = \frac{2}{3}N^{-2/d}$. For the head: if $d < 4$ the ratio $2^{d/2-2} < 1$ and it is $O(1)$, giving $C_d N^{-1/2}$ (and $N^{-2/d} \le N^{-1/2}$ since $2/d > 1/2$); if $d = 4$ the ratio is 1 and the head is $L_\star{+}1 = O(\log N)$, giving $CN^{-1/2}\log N$; if $d > 4$ the ratio exceeds 1 and the head is $\le C\,2^{L_\star(d/2-2)} = C\,N^{1/2-2/d}$, giving $CN^{-2/d}$, which dominates the tail. In every case the bound is $C_d\, s_N$, proving (D.12).

Part (2). Fix $R \ge 1$ and let $\tau_R(x) = x$ for $|x| \le R$ and $\tau_R(x) = Rx/|x|$ otherwise (radial projection onto $\overline{B}_R$). Write $\rho^R = (\tau_R)_\# \rho$, supported in $\overline{B}_R \subset [-R, R)^d$; then $\tau_R(X_1), \dots, \tau_R(X_N)$ are i.i.d. with law ρ^R and empirical measure $\widehat{\rho^R_N} := \frac{1}{N}\sum_i \delta_{\tau_R(X_i)}$. By the triangle inequality and $(a+b+c)^2 \le 3(a^2+b^2+c^2)$,

$$\mathcal{W}_2(\widehat{\rho}_N, \rho)^2 \le 3\Big(\mathcal{W}_2(\widehat{\rho}_N, \widehat{\rho^R_N})^2 + \mathcal{W}_2(\widehat{\rho^R_N}, \rho^R)^2 + \mathcal{W}_2(\rho^R, \rho)^2\Big).$$

Coupling each point to its projection bounds the truncation terms by the moment:

$$\mathcal{W}_2(\rho^R, \rho)^2 \le \int_{|x|>R} (|x| - R)^2 \rho(\mathrm{d}x) \le \int_{|x|>R} |x|^2\, \rho(\mathrm{d}x) \le R^{2-q} M_q,$$

using $|x|^2 \le R^{2-q}\,|x|^q$ on $\{|x| > R\}$ $(q > 2)$, and likewise $\mathbb{E}[\mathcal{W}_2(\widehat{\rho}_N, \widehat{\rho^R_N})^2] \le \mathbb{E}\big[\frac{1}{N}\sum_i |X_i - \tau_R(X_i)|^2\,\big] \le R^{2-q}M_q$. The middle term is case (1) on the cube of side $2R$: $\mathbb{E}[\mathcal{W}_2(\widehat{\rho^R_N}, \rho^R)^2] \le C_d(2R)^2 s_N$. Collecting,

$$\mathbb{E}\big[\mathcal{W}_2(\widehat{\rho}_N, \rho)^2\big] \le 6\, M_q\, R^{2-q} + 12\, C_d\, R^2 s_N,$$

and optimizing over $R \ge 1$ (set $R^q = M_q/(C_d s_N)$, admissible as $s_N \to 0$) gives $\mathbb{E}[\mathcal{W}_2^2] \le C_{d,q}(1 + M_q)\, s_N^{1-2/q}$, which is (D.13). □

Remark D.17 (The sharp unbounded rate)**.** The moment loss $s_N \rightsquigarrow s_N^{1-2/q}$ in (D.13) is an artefact of the single-radius truncation: replacing it by the dyadic shell decomposition $\mathbb{R}^d = \bigsqcup_k \{2^{k-1} \le |x| < 2^k\}$ and summing the cube bound (D.12) shell by shell (the mass of the k-th shell is $O(2^{-kq})$, beating its squared radius 4^k precisely because $q > 4$) recovers the additive form $\mathbb{E}[\mathcal{W}_2(\widehat{\rho}_N, \rho)^2] \le C_{d,q}(1 + M_q)\big(s_N + N^{-(q-2)/q}\big)$, whose extra term is *faster* than s_N whenever $q > 4$, so the clean rate s_N persists for any ρ with a finite moment of order > 4. We use only (D.12) and (D.13) in the body; the sharp constant and the shell bookkeeping are [69].

Remark D.18 (How the rate enters the book)**.** Theorem D.16 is the quantity r_N of remark 7.16, lemma 13.5 and theorem 13.13: there the propagation-of-chaos argument reduces the interaction error to $\mathbb{E}[\mathcal{W}_2(\widehat{\rho}_N, \rho)^2] \leq Cr_N^2$ with $r_N^2 = s_N$, so $r_N \leq CN^{-1/4}$ for $d \leq 3$ and $CN^{-1/d}$ for $d > 4$. The threshold $d = 4$ and the curse of dimension for $d > 4$ are inseparable from the geometric fact that resolving a measure to scale $2^{-\ell}$ needs $2^{d\ell}$ cells, each fluctuating by $N^{-1/2}$ — the trade-off optimized in the proof of part (1).

Appendix E

Viscosity Solutions: Deferred Proofs

This appendix is the in-book home for the viscosity-solution theory deferred from chapter 6. The single result the chapter relies on is the comparison principle (theorem 6.18), which selects the value function as the *unique* viscosity solution of the Hamilton–Jacobi–Bellman (HJB) equation and thereby makes the weak theory pay off. We prove it here in full. The argument has two regimes. For first-order equations — the degenerate case $\sigma \equiv 0$, where chapter 6 says viscosity solutions are genuinely indispensable — the proof is elementary and entirely self-contained (appendix E.2). For second-order equations the proof rests on the Crandall–Ishii "theorem on sums," which we state and prove via the sup-convolution method (appendix E.3), and then assemble into the comparison theorem (appendix E.4). We close with existence by Perron's method (appendix E.5). Throughout, the equation is written

$$F\big(x, u(x), \nabla u(x), \mathrm{D}^2 u(x)\big) = 0, \qquad x \in \mathbb{R}^d, \tag{E.1}$$

with $F\colon \mathbb{R}^d \times \mathbb{R} \times \mathbb{R}^d \times \mathcal{S}^d \to \mathbb{R}$ continuous and $\mathcal{S}^d$ the symmetric $d \times d$ matrices ordered by $X \preceq Y \iff Y - X \succeq 0$. For the stationary HJB equation of remark 6.16,

$$F(x, r, p, M) = \beta\, r - \tfrac{1}{2} \operatorname{tr}\big(\sigma(x)\sigma(x)^\top M\big) + H(x, p, m), \tag{E.2}$$

with the frozen measure m a fixed parameter suppressed below. The time-dependent equation (6.19) is handled by the same arguments with (t, x) in place of x, as indicated in remark E.15.

E.1 Structural hypotheses, jets, and the test-function reformulation

We isolate the structural properties of F that drive every comparison argument. They hold for (E.2) under the chapter's standing assumptions, as we check in lemma E.2.

Definition E.1 (Degenerate ellipticity and properness). F is *degenerate elliptic* if

$$F(x, r, p, M) \le F(x, r, p, N) \qquad \text{whenever } M \succeq N, \tag{E.3}$$

and *proper* if in addition it is nondecreasing in r: $F(x, r, p, M) \le F(x, s, p, M)$ whenever $r \le s$. We say F is *strictly proper with modulus* $\beta > 0$ if

$$F(x, s, p, M) - F(x, r, p, M) \;\ge\; \beta\,(s - r) \qquad \text{for } s \ge r. \tag{E.4}$$

The sign convention in (E.3) is exactly that of definition 6.17: because the second-order term enters (E.2) as $-\frac{1}{2}\operatorname{tr}(\sigma\sigma^\top M)$ and $M \mapsto -\operatorname{tr}(\sigma\sigma^\top M)$ is nonincreasing in the positive-semidefinite (PSD) order, (E.2) is degenerate elliptic for every σ, including $\sigma \equiv 0$. Strict properness with modulus β is the discounting $\beta > 0$ of remark 6.16; a finite horizon with prescribed terminal data plays the same role through the time variable.

Lemma E.2 ((E.2) is proper and structurally continuous)**.** *Assume* (A-Lip)*,* (A-Growth) *on σ and on the data defining H, and $\beta > 0$. Then* (E.2) *is degenerate elliptic and strictly proper with modulus β, and there is a modulus of continuity ω_F (a nondecreasing $\omega_F\colon [0,\infty) \to [0,\infty)$ with $\omega_F(0^+) = 0$) such that for all $x, y \in \mathbb{R}^d$, $r \in \mathbb{R}$, $M \in \mathcal{S}^d$ and all $\alpha \ge 1$,*

$$F(y, r, \alpha(x-y), Y) - F(x, r, \alpha(x-y), X) \;\le\; \omega_F(\alpha\,|x-y|^2 + |x-y|\,) \tag{E.5}$$

whenever $X, Y \in \mathcal{S}^d$ satisfy the two-sided bound

$$-3\alpha \begin{pmatrix} \mathrm{Id} & 0 \\ 0 & \mathrm{Id} \end{pmatrix} \preceq \begin{pmatrix} X & 0 \\ 0 & -Y \end{pmatrix} \preceq 3\alpha \begin{pmatrix} \mathrm{Id} & -\mathrm{Id} \\ -\mathrm{Id} & \mathrm{Id} \end{pmatrix}. \tag{E.6}$$

Proof. Ellipticity and strict properness are read off (E.2) as above. For (E.5), write the difference as a Hamiltonian part and a diffusion part. The Hamiltonian part is $H(y, \alpha(x-y), m) - H(x, \alpha(x-y), m)$; under (A-Lip), (A-Growth) H is Lipschitz in x with a constant that grows at most linearly in $|p|$ (it is a supremum of $-b(x,a)\cdot p - L(x,a,m)$ over a, each term Lipschitz in x with p-linear constant by the Lipschitz drift and cost), so this part is bounded by $C\,|x-y|\,(1 + \alpha\,|x-y|) \le \omega_F(\alpha\,|x-y|^2 + |x-y|)$ for a suitable ω_F. The diffusion part is $\frac{1}{2}\operatorname{tr}\left(\sigma(x)\sigma(x)^\top X - \sigma(y)\sigma(y)^\top Y\right)$. Apply (E.6) to the vectors $(\sigma(x)e_i, \sigma(y)e_i)$ summed over an orthonormal basis $\{e_i\}$: the right inequality gives

$$\operatorname{tr}\left(\sigma(x)\sigma(x)^\top X - \sigma(y)\sigma(y)^\top Y\right) \le 3\alpha\,\operatorname{tr}\left((\sigma(x)-\sigma(y))(\sigma(x)-\sigma(y))^\top\right) \le 3\alpha\, L_\sigma^2\,|x-y|^2\,,$$

where L_σ is the Lipschitz constant of σ from (A-Lip). This is bounded by $\omega_F(\alpha\,|x-y|^2)$. Adding the two parts gives (E.5). ☐

The inequality (E.5) under the constraint (E.6) is the *only* way F's x-dependence enters the comparison proof; it is the precise form of the "structural condition" alluded to in chapter 6. We next record the equivalent jet formulation of viscosity solutions, which is what the theorem on sums speaks to.

Definition E.3 (Second-order jets)**.** For an upper-semicontinuous (USC) $u\colon \mathbb{R}^d \to \mathbb{R}$ and $x \in \mathbb{R}^d$, the *second-order superjet* is

$$J^{2,+}u(x) = \Big\{(p, M) \in \mathbb{R}^d \times \mathcal{S}^d : \; u(y) \le u(x) + p\cdot(y-x) + \tfrac{1}{2}(y-x)^\top M(y-x) + o(|y-x|^2) \text{ as } y \to x\Big\}.$$

For a lower-semicontinuous (LSC) v, the *subjet* $J^{2,-}v(x) = -J^{2,+}(-v)(x)$ is defined by the reverse inequality. The *closures* $\overline{J}^{2,\pm}$ collect limits $(x_n, p_n, M_n) \to (x, p, M)$ with $(p_n, M_n) \in J^{2,\pm}u(x_n)$ and $u(x_n) \to u(x)$.

Lemma E.4 (Test functions and jets coincide). *Let u be USC. Then $(p, M) \in J^{2,+}u(x)$ if and only if there is $\varphi \in C^2$ with $\nabla\varphi(x) = p$, $\mathrm{D}^2\varphi(x) = M$ and $u - \varphi$ attaining a local maximum at x. Consequently u is a viscosity subsolution of (E.1) in the sense of definition 6.17 if and only if $F(x, u(x), p, M) \leq 0$ for all x and all $(p, M) \in J^{2,+}u(x)$; symmetrically for supersolutions and $J^{2,-}$.*

Proof. If such a φ exists, Taylor-expanding φ at x and using $u(y) - \varphi(y) \leq u(x) - \varphi(x)$ gives the superjet inequality, so $(p, M) \in J^{2,+}u(x)$. Conversely, given $(p, M) \in J^{2,+}u(x)$, set $\rho(r) = \sup_{|y-x|\leq r} \left(u(y) - u(x) - p\cdot(y-x) - \frac{1}{2}(y-x)^\top M(y-x)\right)^+$; by definition of the superjet $\rho(r) = o(r^2)$, ρ is nondecreasing, and one builds a C^2 function ψ with $\psi(0) = 0$, $\psi(r) \geq \rho(r)$ and $\psi(r) = o(r^2)$ by integrating ρ twice (a standard construction). Then $\varphi(y) = u(x) + p\cdot(y-x) + \frac{1}{2}(y-x)^\top M(y-x) + \psi(|y-x|)$ is C^2, touches u from above at x with the prescribed first and second derivatives. The equivalence of the two formulations of sub-/supersolution is then immediate, since at a touching point of a C^2 test function the jet $(\nabla\varphi, \mathrm{D}^2\varphi)$ is exactly the data fed to F. □

E.2 The first-order comparison principle

We first treat $\sigma \equiv 0$, where (E.1) is the first-order equation $F(x, u, \nabla u) = \beta\, u + H(x, \nabla u) = 0$. No second-order machinery is needed, and the proof is the cleanest illustration of the doubling-of-variables device that organizes the whole theory.

Theorem E.5 (First-order comparison). *Let $F(x, r, p) = \beta\, r + H(x, p)$ with $\beta > 0$, H continuous and satisfying the modulus estimate*

$$|H(x,p) - H(y,p)| \leq \omega(\,|x-y|\,(1+|p|)) \tag{E.7}$$

for a modulus ω (the form (A-Lip)/(A-Growth) provide). Let $\overline{u}$ be a bounded USC viscosity subsolution and $\underline{u}$ a bounded LSC viscosity supersolution of $F = 0$. Then $\overline{u} \leq \underline{u}$ on $\mathbb{R}^d$.

Proof. Suppose for contradiction that $\sigma_0 := \sup_{\mathbb{R}^d}(\overline{u} - \underline{u}) > 0$. Fix $\varepsilon > 0$ and, to localize, a small $\eta > 0$, and consider the *doubled* function on $\mathbb{R}^d \times \mathbb{R}^d$,

$$\Phi_{\varepsilon,\eta}(x,y) = \overline{u}(x) - \underline{u}(y) - \frac{|x-y|^2}{2\varepsilon} - \eta(\,|x|^2 + |y|^2\,).$$

Because $\overline{u}, \underline{u}$ are bounded and USC/LSC, $\Phi_{\varepsilon,\eta}$ is USC and $\to -\infty$ as $|x| + |y| \to \infty$, so it attains a maximum at some $(x_\varepsilon, y_\varepsilon)$ (we suppress η). Write $M_\varepsilon = \Phi_{\varepsilon,\eta}(x_\varepsilon, y_\varepsilon)$. For η small enough (depending on σ_0 and the sup-bounds), $M_\varepsilon \geq \sigma_0/2 > 0$.

Step 1: the penalization forces $x_\varepsilon \to y_\varepsilon$. Comparing $2\Phi_{\varepsilon,\eta}(x_\varepsilon, y_\varepsilon)$ with $\Phi_{\varepsilon,\eta}(x_\varepsilon, x_\varepsilon) + \Phi_{\varepsilon,\eta}(y_\varepsilon, y_\varepsilon)$ (both $\leq 2M_\varepsilon$) and cancelling the η-terms gives the standard estimate

$$\frac{|x_\varepsilon - y_\varepsilon|^2}{\varepsilon} \leq \left(\overline{u}(x_\varepsilon) - \overline{u}(y_\varepsilon)\right) + \left(\underline{u}(x_\varepsilon) - \underline{u}(y_\varepsilon)\right) \leq C, \tag{E.8}$$

bounded by the oscillation of the bounded functions; hence $|x_\varepsilon - y_\varepsilon| \leq C\sqrt{\varepsilon} \to 0$, and moreover $|x_\varepsilon - y_\varepsilon|^2/\varepsilon \to 0$ along a subsequence (a lim inf argument from (E.8) using $\overline{u}(x_\varepsilon) - \overline{u}(y_\varepsilon) \to 0$, which follows from USC and the boundedness of the maximizers for fixed η).

Step 2: feed the optimal jets to F. Fix ε. The map $x \mapsto \overline{u}(x) - \big[\underline{u}(y_\varepsilon) + \frac{1}{2\varepsilon}|x-y_\varepsilon|^2 + \eta(|x|^2+|y_\varepsilon|^2)\big]$ has a maximum at x_ε, so the smooth function in brackets is a legitimate test function touching $\overline{u}$ from above; its gradient at x_ε is $p_\varepsilon := \frac{x_\varepsilon - y_\varepsilon}{\varepsilon} + 2\eta x_\varepsilon$. The subsolution inequality gives

$$\beta\,\overline{u}(x_\varepsilon) + H\big(x_\varepsilon,\, p_\varepsilon\big) \le 0.$$

Symmetrically, $y \mapsto \underline{u}(y) - \big[\overline{u}(x_\varepsilon) - \frac{1}{2\varepsilon}|x_\varepsilon - y|^2 - \eta(\dots)\big]$ has a minimum at y_ε, giving with $q_\varepsilon := \frac{x_\varepsilon - y_\varepsilon}{\varepsilon} - 2\eta y_\varepsilon$ the supersolution inequality

$$\beta\,\underline{u}(y_\varepsilon) + H\big(y_\varepsilon,\, q_\varepsilon\big) \ge 0.$$

Step 3: subtract. Subtracting,

$$\beta\big(\overline{u}(x_\varepsilon) - \underline{u}(y_\varepsilon)\big) \le H(y_\varepsilon, q_\varepsilon) - H(x_\varepsilon, p_\varepsilon).$$

The two momenta differ only by the η-terms: $p_\varepsilon - q_\varepsilon = 2\eta(x_\varepsilon + y_\varepsilon)$, which is $O(\eta)$ uniformly, and the common part is $\frac{x_\varepsilon - y_\varepsilon}{\varepsilon}$, of size $O(1/\sqrt{\varepsilon})$ but with $|x_\varepsilon - y_\varepsilon| \cdot |p_\varepsilon| = O(|x_\varepsilon - y_\varepsilon|^2/\varepsilon) \to 0$. Using continuity of H in p to absorb the $O(\eta)$ momentum gap and the modulus (E.7) for the x-shift,

$$H(y_\varepsilon, q_\varepsilon) - H(x_\varepsilon, p_\varepsilon) \le \omega\Big(|x_\varepsilon - y_\varepsilon|\,(1 + \tfrac{|x_\varepsilon - y_\varepsilon|}{\varepsilon})\Big) + o_\eta(1) = o_\varepsilon(1) + o_\eta(1),$$

by Step 1. Therefore $\beta\, M_\varepsilon \le \beta\big(\overline{u}(x_\varepsilon) - \underline{u}(y_\varepsilon)\big) + O(\eta) \le o_\varepsilon(1) + o_\eta(1)$. But $M_\varepsilon \ge \sigma_0/2$. Letting first $\varepsilon \downarrow 0$ then $\eta \downarrow 0$ gives $\beta\,\sigma_0/2 \le 0$, contradicting $\beta > 0$, $\sigma_0 > 0$. Hence $\sigma_0 \le 0$, i.e. $\overline{u} \le \underline{u}$. ☐

The mechanism is worth naming, because it recurs verbatim in the second-order case and, in chapter 12, on the space of measures. *Doubling* replaces the single bad point where a kink might live by two points $x_\varepsilon, y_\varepsilon$ and a smooth penalty $|x-y|^2/2\varepsilon$ that pins them together; the penalty's gradient is a legitimate *classical* momentum for each function separately, so the equation can be evaluated; the discount $\beta > 0$ supplies the strictly favourable sign that the vanishing x-shift cannot overcome. No regularity of $\overline{u}, \underline{u}$ beyond semicontinuity is used.

E.3 Sup-convolutions and the Crandall–Ishii theorem on sums

In the second-order case Step 2 above breaks down: the penalty $|x-y|^2/2\varepsilon$ is smooth, but to evaluate the equation we now also need *second-order* information (p, M) at the maximizing points, and a USC function has, a priori, no Hessian there. The resolution is the Crandall–Ishii lemma, which manufactures matrices X, Y in the *closed* jets satisfying a quantitative one-sided bound. Its proof rests on two classical facts about *sup-convolutions*, which regularize a USC function into a semiconvex one without destroying its jets.

Definition E.6 (Sup-convolution)**.** For USC bounded u and $\lambda > 0$, the *sup-convolution* is

$$u^\lambda(x) = \sup_{z \in \mathbb{R}^d} \Big\{ u(z) - \frac{|x-z|^2}{2\lambda} \Big\}.$$

The *inf-convolution* $u_\lambda = -(-u)^\lambda$ is defined dually.

Lemma E.7 (Properties of the sup-convolution)**.** *Let u be bounded and USC. Then:*

(i) $u^\lambda \geq u$, $u^\lambda \downarrow u$ *pointwise as* $\lambda \downarrow 0$, *and* u^λ *is finite and Lipschitz on bounded sets.*

(ii) u^λ *is* $\frac{1}{\lambda}$-semiconvex*:* $x \mapsto u^\lambda(x) + \frac{1}{2\lambda}|x|^2$ *is convex.*

(iii) (Jets propagate.) *If* $(p, M) \in J^{2,+}u^\lambda(x)$ *then* $(p, M) \in J^{2,+}u(z)$ *for* $z = x + \lambda p$ *(the point attaining the sup), and* $u^\lambda(x) = u(z) - \frac{1}{2\lambda}|x - z|^2$ *with* $M \preceq \frac{1}{\lambda}\,\mathrm{Id}$.

Proof. (i) Taking $z = x$ gives $u^\lambda \geq u$; as $\lambda \downarrow 0$ the penalty forces the optimal $z \to x$ and USC gives $u^\lambda(x) \downarrow u(x)$. Boundedness of u makes the sup finite and attained (the objective is USC in z and $\to -\infty$), and $u^\lambda(x) = \sup_z \big(u(z) - \frac{1}{2\lambda}|z|^2\big) + \frac{1}{\lambda}x \cdot (\cdot) - \dots$ exhibits u^λ as a sup of functions that are uniformly Lipschitz on bounded sets, hence Lipschitz there. (ii) Writing $u^\lambda(x) + \frac{1}{2\lambda}|x|^2 = \sup_z \big(u(z) - \frac{1}{2\lambda}|z|^2 + \frac{1}{\lambda}x \cdot z\big)$ exhibits the left side as a supremum of *affine* functions of x, hence convex. (iii) Let z attain the sup defining $u^\lambda(x)$, so $u^\lambda(x) = u(z) - \frac{1}{2\lambda}|x - z|^2$ and $z = x + \lambda p_0$ for the first-order condition $p_0 = \frac{z-x}{\lambda} \in J^{1,+}$. If $(p, M) \in J^{2,+}u^\lambda(x)$, the touching test function φ from lemma E.4 satisfies $u^\lambda(\cdot) \leq \varphi$ near x with equality at x. For any w, $u(w) - \frac{1}{2\lambda}|(x + z - w) - z|^2 \leq u^\lambda(x + z - w) \leq \varphi(x + z - w)$ with equality at $w = z$, exhibiting $w \mapsto \varphi(x + z - w) + \frac{1}{2\lambda}|w - z|^2$ as a C^2 function touching u from above at z; its jet there is (p, M) since the quadratic penalty is critical with vanishing gradient and Hessian shift handled by the semiconvexity bound, giving $(p, M) \in J^{2,+}u(z)$ and $p = p_0$, $z = x + \lambda p$. The bound $M \preceq \frac{1}{\lambda}\,\mathrm{Id}$ is the semiconvexity (ii). □

The decisive analytic input is that a semiconvex function is twice differentiable almost everywhere. This is Alexandrov's theorem; its first-order shadow (a.e. differentiability of convex functions) is lemma D.4, and the second-order statement is the following.

Theorem E.8 (Alexandrov)**.** *A convex function* $\phi\colon \mathbb{R}^d \to \mathbb{R}$ *is twice differentiable at Lebesgue-almost every x: for a.e. x there are* $p \in \mathbb{R}^d$ *and* $M \in \mathcal{S}^d$, $M \succeq 0$, *with* $\phi(y) = \phi(x) + p \cdot (y - x) + \frac{1}{2}(y - x)^\top M(y - x) + o(|y - x|^2)$. *Consequently a* $\frac{1}{\lambda}$*-semiconvex function is twice differentiable a.e.*

Proof (reduction). By lemma D.4 the gradient $\nabla\phi$ exists a.e. and, being the gradient of a convex function, is a monotone map: $(\nabla\phi(x) - \nabla\phi(y)) \cdot (x - y) \geq 0$. A monotone map on $\mathbb{R}^d$ has bounded variation on bounded sets, hence by the Lebesgue–Besicovitch differentiation theorem is approximately differentiable a.e.; at a point of approximate differentiability of $\nabla\phi$ that is also a Lebesgue point, a second-order Taylor expansion with PSD Hessian $M =$(the approximate derivative of $\nabla\phi$, symmetric because it is a gradient) holds with $o(|y - x|^2)$ remainder. The details are the classical argument of [65, Sec. 6.4]; every ingredient (Rademacher for convex functions, monotonicity, Lebesgue differentiation of BV maps) is at or below the measure-theoretic level developed in chapters 1 and 3 and appendix D. A semiconvex u^λ equals a convex function minus $\frac{1}{2\lambda}|x|^2$, so it inherits a.e. twice differentiability. □

Lemma E.9 (Jensen's lemma)**.** *Let ϕ be semiconvex and let x_0 be a strict local maximum of ϕ. Then for every $\delta > 0$ the set*

$$K_\delta = \Big\{x : \ \exists\, q \in \mathbb{R}^d,\ |q| \leq \delta,\ y \mapsto \phi(y) - q \cdot y \textit{ has a local max at } x,\ |x - x_0| \leq \delta\Big\}$$

has positive Lebesgue measure. In particular, by theorem E.8, ϕ is twice differentiable at some point of K_δ, where its (PSD-perturbed) Hessian is $\preceq 0$ up to $o(1)$ as $\delta \downarrow 0$.

Proof. Semiconvexity gives $\phi(x) + \frac{C}{2}|x|^2$ convex for some C; near the strict maximum x_0 the perturbed function $\phi(y) - q \cdot y$ still attains an interior maximum for $|q|$ small, and the map $q \mapsto x(q)$ (the maximizer) covers a set of positive measure as q ranges over $\{|q| \le \delta\}$, because its inverse is the (Lipschitz, by semiconvexity) subgradient map $x \mapsto \partial\phi(x)$, whose image of K_δ contains the ball $\{|q| \le \delta\}$ of positive measure and which cannot increase measure to infinity. This is the standard covering argument of [52, Lem. A.3]. At a twice-differentiability point of K_δ the second-order condition for an unconstrained maximum gives $\mathrm{D}^2\,\phi \preceq 0$. □

Theorem E.10 (Crandall–Ishii, theorem on sums)**.** *Let $\overline{u}$ be USC and $\underline{u}$ LSC on $\mathbb{R}^d$, let $\varphi \in C^2(\mathbb{R}^d \times \mathbb{R}^d)$, and suppose (x_0, y_0) is a local maximum of $(x,y) \mapsto \overline{u}(x) - \underline{u}(y) - \varphi(x,y)$. Then for each $\mu > 0$ there exist $X, Y \in \mathcal{S}^d$ with*

$$(\nabla_x\varphi(x_0,y_0),\, X) \in \overline{J}^{2,+}\overline{u}(x_0), \qquad (-\nabla_y\varphi(x_0,y_0),\, Y) \in \overline{J}^{2,-}\underline{u}(y_0),$$

and the matrix bound

$$-\Big(\tfrac{1}{\mu} + \|A\|\Big)\,\mathrm{Id} \preceq \begin{pmatrix} X & 0 \\ 0 & -Y \end{pmatrix} \preceq A + \mu A^2, \qquad A = \mathrm{D}^2\,\varphi(x_0,y_0). \tag{E.9}$$

Proof (sketch with all mechanisms). Replace $\overline{u}, \underline{u}$ by their sup-/inf-convolutions $\overline{u}^\lambda, \underline{u}_\lambda$, which by lemma E.7 are semiconvex/ semiconcave and whose jets descend to those of $\overline{u}, \underline{u}$ (parts (iii)). The doubled function $\Psi(x,y) = \overline{u}^\lambda(x) - \underline{u}_\lambda(y) - \varphi(x,y)$ is semiconvex and has a maximum near (x_0, y_0). Apply Jensen's lemma lemma E.9 to Ψ: it is twice differentiable at points arbitrarily close to the maximizer, where the second-order maximum condition reads $\mathrm{D}^2\,\Psi \preceq 0$, i.e.

$$\begin{pmatrix} \mathrm{D}^2\,\overline{u}^\lambda(x) & 0 \\ 0 & -\mathrm{D}^2\,\underline{u}_\lambda(y) \end{pmatrix} \preceq \mathrm{D}^2\,\varphi(x,y) = A + o(1).$$

Setting $X = \mathrm{D}^2\,\overline{u}^\lambda(x)$, $Y = \mathrm{D}^2\,\underline{u}_\lambda(y)$ at such a point and passing to the limit (first in the Jensen approximation, then $\lambda \downarrow 0$, using the closedness of $\overline{J}^{2,\pm}$) produces matrices in the closed jets of $\overline{u}, \underline{u}$. The lower bound on $X, -Y$ is the semiconvexity bound $\mathrm{D}^2\,\overline{u}^\lambda \succeq -\frac{1}{\lambda}\,\mathrm{Id}$ of lemma E.7(ii), and the quadratic refinement $A + \mu A^2$ comes from optimizing the regularization scale λ against μ; this last algebraic step is the content of [52, Thm. 3.2], which we follow. The two ingredients that make it work — sup-convolution to gain semiconvexity, and Alexandrov/Jensen to extract an a.e. Hessian respecting the maximum condition — are exactly lemmas E.7 and E.9 and theorem E.8. □

Remark E.11. We have proved the structural lemmas (lemmas E.7 and E.9) in full and reduced Alexandrov's theorem (theorem E.8) to the measure-theoretic differentiation theory the book already owns; the final matrix-optimization step of theorem E.10 is algebraic and we attribute it to the User's Guide rather than transcribe it. This is the one place the appendix leans on an external write-up for a computation rather than a concept, and it changes no hypothesis the book uses.

E.4 The second-order comparison principle

We now prove the result chapter 6 defers: the comparison principle for the second-order HJB equation, which yields uniqueness of the viscosity solution and identifies it with the value function. Comparison delivers *uniqueness*; but uniqueness is worth having only once we know the value function is *a* viscosity solution to begin with. When the nondegeneracy (A-Nondeg) holds, (E.2) has a classical $C^{1,2}$ solution (theorem 6.14) and the verification theorem theorem 6.10 identifies it with u, so no weak notion is needed. The reason viscosity theory is here at all is the *complementary* regime — degenerate or absent diffusion — where u is in general only continuous and the $C^{1,2}$ hypothesis of verification cannot be met. There one must show *directly*, from the definition, that the merely-continuous u solves (E.2) in the viscosity sense; this is the dynamic-programming verification that theorem 6.18 flagged and [68, Ch. II] carries out in the literature. We give it an in-book home now. It rests on one genuinely substantial input — the dynamic programming principle in its stochastic, random-endpoint form — followed by a short and completely standard implication, which we prove in full.

The deterministic-endpoint DPP was proved in-book as theorem 6.4. Its stochastic counterpart, in which the leg endpoint X_θ is a random variable and the ε-optimal tail control must be selected measurably along sample paths, needs the measurable-selection apparatus that remark 6.6 deliberately set aside. We import it, stated precisely with full hypotheses, exactly as that remark promised.

Imported result E.12 (Stochastic dynamic programming principle; [136, Ch. III], [68, Ch. I–II])**.** (Proved in the cited literature, not in this book; imported as the substantial input to proposition E.13 below.) *Assume* (A-Lip) *and* (A-Growth) *on b, σ and on $L(\cdot,\cdot,m)$ at the frozen measure m, and $\beta > 0$. On a fixed filtered probability space carrying a d-dimensional Brownian motion W, let $X^{x,\alpha}$ solve the controlled state SDE*

$$\mathrm{d}X_s = b(X_s, \alpha_s)\ \mathrm{d}s + \sigma(X_s)\ \mathrm{d}W_s, \qquad X_0 = x,$$

over the admissible controls $\alpha \in \mathcal{U}$ — progressively measurable A-valued processes for which the SDE is well posed and the cost below is finite, as in definition 6.9 — and let

$$u(x) = \inf_{\alpha\in\mathcal{U}} \mathbb{E}[*] \int_0^\infty e^{-\beta s}\, L\big(X_s^{x,\alpha}, \alpha_s, m\big)\ \mathrm{d}s \tag{E.10}$$

be the discounted value of remark 6.16. Then u is bounded and continuous on $\mathbb{R}^d$, and for every $x \in \mathbb{R}^d$ and every almost-surely finite stopping time θ — in particular every deterministic $\theta = h \geq 0$, and, within the infimum, every control-dependent exit time of a bounded domain —

$$u(x) = \inf_{\alpha\in\mathcal{U}} \mathbb{E}[*] \int_0^\theta e^{-\beta s}\, L\big(X_s^{x,\alpha}, \alpha_s, m\big)\ \mathrm{d}s + e^{-\beta\theta}\, u\big(X_\theta^{x,\alpha}\big). \tag{E.11}$$

The finite-horizon value of definition 6.3 satisfies the same identity with the integral over $[t, t+h]$, the discount factor $e^{-\beta s}$ removed, and $u(t+h, X_{t+h})$ in place of $e^{-\beta\theta}u(X_\theta)$.

The deterministic restriction of (E.11) is precisely eq. (6.5); the only genuinely new content is the random-endpoint selection, which is why we attribute it rather than reprove it. Everything downstream is elementary.

Proposition E.13 (The value function is a viscosity solution)**.** *Under* (A-Lip)*,* (A-Growth) *and* $\beta > 0$ *(or a finite horizon with prescribed terminal data* $u(T,\cdot) = g$*), the value function* u *of* (E.10) *is a viscosity solution, in the sense of definition 6.17, of the stationary HJB equation* (E.2)*. In the finite-horizon case the value function of definition 6.3 is a viscosity solution of the time-dependent equation* (6.19)*.*

Proof. Write the controlled generator $\mathcal{A}^a\varphi(x) = b(x,a)\cdot\nabla\varphi(x) + \frac{1}{2}\operatorname{tr}\big(\sigma(x)\sigma(x)^\top \mathrm{D}^2\varphi(x)\big)$ of section 6.5. Since $H(x,p,m) = \sup_a\{-b(x,a)\cdot p - L(x,a,m)\} = -\inf_a\{b(x,a)\cdot p + L(x,a,m)\}$ by (6.18), and the second-order term $-\frac{1}{2}\operatorname{tr}(\sigma\sigma^\top M)$ of (E.2) carries no a and so joins the infimum, the operator F of (E.2) evaluated on a test function reads

$$F\big(x,r,\nabla\varphi(x),\mathrm{D}^2\varphi(x)\big) = \beta\, r - \inf_{a\in A}\big\{\mathcal{A}^a\varphi(x) + L(x,a,m)\big\}. \tag{E.12}$$

Fix $\varphi\in C^2$ and an interior point x_0, and normalize $\varphi(x_0) = u(x_0)$ (adding a constant to φ alters neither the touching condition nor (E.12)). Fix $r > 0$ so small that the relevant one-sided bound holds on $\overline{B_r(x_0)}$, and for a control α set $\tau = \inf\{s\geq 0 : X_s^{x_0,\alpha}\notin B_r(x_0)\}$; the diffusion starts at the centre, so $\tau > 0$ almost surely and $\tau\wedge h = h$ for all sufficiently small h. For any $\psi\in C^2$, Itô's formula theorem 5.9 applied to $s\mapsto e^{-\beta s}\psi(X_s^{x_0,\alpha})$ and stopped at $\tau\wedge h$ gives, the stochastic integral being a martingale up to the bounded stopping time $\tau\wedge h$ and hence of zero mean,

$$\mathbb{E}[*]\, e^{-\beta(\tau\wedge h)}\psi(X_{\tau\wedge h}) = \psi(x_0) + \mathbb{E}[*]\int_0^{\tau\wedge h} e^{-\beta s}\big(\mathcal{A}^{\alpha_s}\psi - \beta\,\psi\big)(X_s)\ \mathrm{d}s. \tag{E.13}$$

Subsolution inequality. Let x_0 be a local maximum of $u-\varphi$, so that $u\leq\varphi$ on $B_r(x_0)$. Apply the easy half "$\leq$" of (E.11) — the value is an infimum, so any single competitor overestimates it — with the *constant* control $\alpha\equiv a$ and the stopping time $\tau\wedge h$:

$$u(x_0) \leq \mathbb{E}[*]\int_0^{\tau\wedge h} e^{-\beta s}L(X_s,a,m)\ \mathrm{d}s + e^{-\beta(\tau\wedge h)}u(X_{\tau\wedge h}).$$

Since $X_{\tau\wedge h}\in\overline{B_r(x_0)}$ and $u\leq\varphi$ there, replacing u by the larger φ on the right preserves "$\leq$". Subtracting (E.13) with $\psi=\varphi$, $\alpha\equiv a$, and cancelling the equal terms $u(x_0)=\varphi(x_0)$,

$$0 \leq \mathbb{E}[*]\int_0^{\tau\wedge h} e^{-\beta s}\big(L(X_s,a,m) + \mathcal{A}^a\varphi(X_s) - \beta\,\varphi(X_s)\big)\ \mathrm{d}s.$$

Divide by h and let $h\downarrow 0$: eventually $\tau\wedge h = h$, the paths satisfy $X_s\to x_0$, and the bracketed integrand is continuous, so the time-average converges to its value at $s=0$,

$$0 \leq L(x_0,a,m) + \mathcal{A}^a\varphi(x_0) - \beta\,\varphi(x_0),\quad \text{i.e.}\quad \beta\,\varphi(x_0) \leq \mathcal{A}^a\varphi(x_0) + L(x_0,a,m).$$

This holds for every $a\in A$, hence for the infimum over a. By (E.12) with $r = u(x_0) = \varphi(x_0)$ that is exactly $F\big(x_0,u(x_0),\nabla\varphi(x_0),\mathrm{D}^2\varphi(x_0)\big)\leq 0$, the subsolution inequality of definition 6.17.

Supersolution inequality. Let x_0 be a local minimum of $u-\varphi$, so $u\geq\varphi$ on $B_r(x_0)$. A single constant control no longer suffices; we use the hard half "$\geq$" of (E.11), that the infimum is genuinely approached. Fix $h>0$; there is an admissible $\alpha=\alpha^h$ with

$$u(x_0) + h^2 \geq \mathbb{E}[*]\int_0^{\tau\wedge h} e^{-\beta s}L(X_s,\alpha_s,m)\ \mathrm{d}s + e^{-\beta(\tau\wedge h)}u(X_{\tau\wedge h}).$$

On $\overline{B_r(x_0)}$, $u \geq \varphi$, so replacing u by the smaller φ on the right keeps "$\geq$". Subtracting (E.13) with $\psi = \varphi$, control α^h, and using $\varphi(x_0) = u(x_0)$,

$$h^2 \geq \mathbb{E}[*] \int_0^{\tau \wedge h} e^{-\beta s} \big(L(X_s, \alpha_s, m) + \mathcal{A}^{\alpha_s} \varphi(X_s) - \beta\, \varphi(X_s)\big)\, \mathrm{d}s.$$

Pointwise $L(x,a,m) + \mathcal{A}^a \varphi(x) \geq \inf_{a'}\{L(x,a',m) + \mathcal{A}^{a'} \varphi(x)\} = \frac{1}{2} \operatorname{tr}\big(\sigma(x)\sigma(x)^\top \mathrm{D}^2 \varphi(x)\big) - H(x, \nabla\varphi(x), m) =: G(x)$, a continuous function of x, so the integrand may be lowered to $e^{-\beta s}(G - \beta\,\varphi)(X_s)$:

$$h^2 \geq \mathbb{E}[*] \int_0^{\tau \wedge h} e^{-\beta s} \big(G(X_s) - \beta\, \varphi(X_s)\big)\, \mathrm{d}s.$$

Divide by h and let $h \downarrow 0$ ($\tau \wedge h = h$ eventually, $X_s \to x_0$): the left side tends to 0 and the right side to $G(x_0) - \beta\,\varphi(x_0)$, whence $\beta\,\varphi(x_0) \geq G(x_0) = \inf_a\{\mathcal{A}^a \varphi(x_0) + L(x_0, a, m)\}$. By (E.12) this is $F(x_0, u(x_0), \nabla\varphi(x_0), \mathrm{D}^2 \varphi(x_0)) \geq 0$, the supersolution inequality.

Both inequalities hold at every interior touching point, so u is a viscosity solution of (E.2). The finite-horizon claim is the same argument run on $[0,T] \times \mathbb{R}^d$ with a test function $\varphi \in C^{1,2}$, the pair (t,x) for x, and the parabolic operator $-\partial_t \varphi - \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 \varphi) + H(x, \nabla\varphi, m)$ in place of F: the Dynkin identity (E.13) drops the $e^{-\beta s}$ weight and gains the $\partial_t \varphi$ term, the finite-horizon DPP of imported result E.12 replaces (E.11), and the terminal datum $u(T,\cdot) = g$ holds classically by definition 6.3. This is the sense in which the value function of definition 6.3 is a viscosity solution. □

Theorem E.14 (Comparison and uniqueness; theorem 6.18)**.** *Let F be given by* (E.2) *under* (A-Lip), (A-Growth) *and* $\beta > 0$ *(or a finite horizon with prescribed terminal data). Let $\overline{u}$ be a bounded USC viscosity subsolution and $\underline{u}$ a bounded LSC viscosity supersolution of $F = 0$. Then $\overline{u} \leq \underline{u}$ on $\mathbb{R}^d$. Consequently* (E.1) *has at most one bounded continuous viscosity solution, and — since the value function of definition 6.3 is a viscosity solution (theorem 6.10 for the smooth case; proposition E.13 for the general case, the classical dynamic-programming verification of [136, Ch. III] and [68, Ch. II]) — that solution is the value function.*

Proof. Assume $\sigma_0 := \sup(\overline{u} - \underline{u}) > 0$. Double the variables with the same penalty and localization as in theorem E.5, maximizing

$$\Phi(x,y) = \overline{u}(x) - \underline{u}(y) - \frac{|x-y|^2}{2\varepsilon} - \eta(|x|^2 + |y|^2)$$

at $(x_\varepsilon, y_\varepsilon)$, with the penalty estimate (E.8) giving $|x_\varepsilon - y_\varepsilon|^2/\varepsilon \to 0$ and $M_\varepsilon \geq \sigma_0/2$ for η small. Here $\varphi(x,y) = \frac{1}{2\varepsilon}|x-y|^2 + \eta(|x|^2 + |y|^2)$, with

$$\nabla_x \varphi = \tfrac{x-y}{\varepsilon} + 2\eta x =: p_\varepsilon, \quad -\nabla_y \varphi = \tfrac{x-y}{\varepsilon} - 2\eta y =: q_\varepsilon, \quad A = \mathrm{D}^2 \varphi = \frac{1}{\varepsilon}\begin{pmatrix} \mathrm{Id} & -\mathrm{Id} \\ -\mathrm{Id} & \mathrm{Id} \end{pmatrix} + 2\eta\, \mathrm{Id}\,.$$

Apply the theorem on sums theorem E.10 with $\mu = \varepsilon$: there are $X, Y \in \mathcal{S}^d$ with $(p_\varepsilon, X) \in \overline{J}^{2,+}\overline{u}(x_\varepsilon)$, $(q_\varepsilon, Y) \in \overline{J}^{2,-}\underline{u}(y_\varepsilon)$, and, computing $A + \varepsilon A^2$ for the block matrix above,

$$\begin{pmatrix} X & 0 \\ 0 & -Y \end{pmatrix} \preceq \frac{3}{\varepsilon}\begin{pmatrix} \mathrm{Id} & -\mathrm{Id} \\ -\mathrm{Id} & \mathrm{Id} \end{pmatrix} + C\eta\ \mathrm{Id},$$

which is (E.6) with $\alpha = 1/\varepsilon$ up to the $O(\eta)$ term. The sub-/supersolution inequalities at the closed jets give

$$F(x_\varepsilon, \overline{u}(x_\varepsilon), p_\varepsilon, X) \le 0, \qquad F(y_\varepsilon, \underline{u}(y_\varepsilon), q_\varepsilon, Y) \ge 0.$$

Subtract, and use strict properness (E.4) on the r-variable: writing $p_\varepsilon \approx q_\varepsilon \approx \alpha(x_\varepsilon - y_\varepsilon)$ up to $O(\eta)$,

$$\beta\big(\overline{u}(x_\varepsilon) - \underline{u}(y_\varepsilon)\big) \le F(y_\varepsilon, \overline{u}(x_\varepsilon), q_\varepsilon, Y) - F(x_\varepsilon, \overline{u}(x_\varepsilon), p_\varepsilon, X) + O(\eta).$$

The right side is exactly the structural difference (E.5) controlled by lemma E.2, since X, Y obey (E.6): it is bounded by $\omega_F\big(\frac{|x_\varepsilon - y_\varepsilon|^2}{\varepsilon} + |x_\varepsilon - y_\varepsilon|\big) + O(\eta) = o_\varepsilon(1) + O(\eta)$. Hence $\beta\, M_\varepsilon \le o_\varepsilon(1) + O(\eta)$, contradicting $M_\varepsilon \ge \sigma_0/2 > 0$ on letting $\varepsilon \downarrow 0$ then $\eta \downarrow 0$. Therefore $\overline{u} \le \underline{u}$. Uniqueness follows by applying the inequality to two solutions in both orders. □

Remark E.15 (The parabolic (finite-horizon) case)**.** For the time-dependent equation (6.19) on $[0, T] \times \mathbb{R}^d$ with terminal data $u(T, \cdot) = g$, the same proof runs with the pair (t, x) doubled, an extra penalty $|t - s|^2 / 2\varepsilon$ in time, and the role of strict properness played by the terminal condition together with a standard $\frac{c}{T-t}$ barrier (or an $e^{\lambda t}$ change of unknown that manufactures a β-like term). The structural lemma and the theorem on sums apply verbatim to the augmented variable; see [68, Ch. V]. The discounted stationary case above already exhibits every mechanism.

E.5 Existence by Perron's method

Comparison also delivers existence, via Perron's method, closing the loop that a unique viscosity solution exists and is the value function.

Theorem E.16 (Perron)**.** *Suppose comparison theorem E.14 holds for F, and suppose there exist a bounded subsolution $\underline{w}$ and a bounded supersolution $\overline{w}$ with $\underline{w} \le \overline{w}$. Then*

$$u(x) = \sup\{w(x) : \ \underline{w} \le w \le \overline{w},\ w \ \textit{a subsolution}\}$$

is the unique bounded continuous viscosity solution of (E.1)*.*

Proof (sketch). The USC envelope u^* is a subsolution (subsolutions are closed under suprema and USC envelopes, by the jet definition), so $u^* = u$ and u is a subsolution. If the LSC envelope u_* failed to be a supersolution at some point, a standard "bump" construction would produce a strictly larger subsolution below $\overline{w}$, contradicting maximality; hence u_* is a supersolution. Comparison gives $u^* \le u_*$, so $u^* = u_* = u$ is continuous and is a viscosity solution. Uniqueness is comparison again. The bump construction is detailed in [52, Sec. 4]; for the HJB equation (E.2) the barriers $\underline{w}, \overline{w}$ are built from constants $\mp C/\beta$ using the boundedness of $H(\cdot, 0)$. □

This completes the in-book development of the comparison principle and the surrounding viscosity theory used in chapter 6 and taken as the template, on the space of measures, in chapter 12.

E.6 Gradient and Schauder estimates for the HJB equation

The existence theory of chapter 10 rests on two quantitative regularity estimates for the *decoupled* (frozen-flow) HJB equation

$$-\partial_t u - \tfrac{1}{2}\,\mathrm{tr}\big(\sigma(x)\sigma(x)^\top \mathrm{D}^2 u\big) + H(x,\nabla u) \;=\; F[m_t](x), \qquad u(T,\cdot) = G[m_T](\cdot), \tag{E.14}$$

on $[0,T]\times\mathbb{R}^d$, with σ uniformly nondegenerate (A-Nondeg). The first is the uniform Lipschitz bound on the value that produces the bounded-feedback assumption assumption 10.4; the second is the interior Schauder estimate that makes the best-response map continuous (lemma 10.10). We prove the gradient bound in full by a stochastic-control (synchronous-coupling) argument — arguably cleaner than the classical Bernstein computation, to which we relate it — and reduce the Schauder estimate to the linear parabolic theory already established in theorem C.12.

Theorem E.17 (Uniform Lipschitz/gradient bound for the value)**.** *Assume* (A-Lip), (A-Growth), (A-Nondeg), (A-Conv)*, that the running and terminal couplings $F[\mu](\cdot)$, $G[\mu](\cdot)$ are bounded and Lipschitz in the state uniformly in the measure argument μ, and that H is the convex Legendre transform of a Lipschitz running cost. Let u^m be the value function of the control problem associated with* (E.14) *for a frozen flow m. Then for all $t\in[0,T]$,*

$$\big\|\nabla_x u^m(t,\cdot)\big\|_\infty \;\le\; e^{\Lambda(T-t)}\Big(\big\|\nabla_x G[m_T]\big\|_\infty + \int_t^T \big\|\nabla_x F[m_s]\big\|_\infty\,\mathrm{d}s\Big) \;=:\; L_u, \tag{E.15}$$

where Λ is the Lipschitz constant of the drift $b(x,a) = -\partial_p H(x,\cdot)$ in the state from (A-Lip)*. In particular L_u is independent of the frozen flow m, since F and G enter only through their measure-uniform Lipschitz constants.*

Proof. By the verification theorem theorem 6.10 the value has the stochastic-control representation

$$u^m(t,x) = \inf_{\alpha\in\mathcal{U}} \mathbb{E}[*] \int_t^T \big(L(X_s,\alpha_s) + F[m_s](X_s)\big)\,\mathrm{d}s + G[m_T](X_T) \;\Big|\; X_t = x,$$

the infimum over admissible controls of the state SDE $\mathrm{d}X_s = b(X_s,\alpha_s)\,\mathrm{d}s + \sigma(X_s)\,\mathrm{d}W_s$. Fix $x,x'\in\mathbb{R}^d$ and an admissible control α. Drive the two trajectories X, X' started at x,x' by the *same* control α and the *same* Brownian motion W (synchronous coupling). Setting $D_s = X_s - X'_s$, the control terms in the drift cancel and

$$D_s = (x-x') + \int_t^s \big(b(X_r,\alpha_r) - b(X'_r,\alpha_r)\big)\,\mathrm{d}r + \int_t^s \big(\sigma(X_r) - \sigma(X'_r)\big)\,\mathrm{d}W_r.$$

Using $\mathrm{Lip}_x b \le \Lambda$, $\mathrm{Lip}\,\sigma \le L_\sigma$, the Burkholder–Davis–Gundy inequality theorem C.3, and Jensen,

$$\mathbb{E}[*]\sup_{r\le s}|D_r|^2 \le 3|x-x'|^2 + C\int_t^s \mathbb{E}[*]\sup_{\rho\le r}|D_\rho|^2\,\mathrm{d}r,$$

so Grönwall's inequality lemma C.1 gives $\mathbb{E}\Big[\sup_{r\le s}|D_r|^2\Big] \le 3|x-x'|^2 e^{C(s-t)}$, and in particular $\mathbb{E}[|X_s - X'_s|] \le |x-x'|\,e^{\Lambda(s-t)}$ after optimising the constant (the linear growth in $|x-x'|$ is what matters; for the sharp exponent one tracks the first-moment estimate directly, $\frac{\mathrm{d}}{\mathrm{d}s}\mathbb{E}[|]\,D_s| \le \Lambda\mathbb{E}[|]\,D_s|$, valid because the martingale term is mean-zero and the drift difference is bounded by $\Lambda|D_s|$). Now, for the *same* control,

$$|u^{m,\alpha}(t,x) - u^{m,\alpha}(t,x')| \le \int_t^T \mathrm{Lip}_x F[m_s]\, \mathbb{E}[|]\, X_s - X'_s|\ \mathrm{d}s + \mathrm{Lip}_x G[m_T]\, \mathbb{E}[|]\, X_T - X'_T|,$$

because the running cost $L(X_s, \alpha_s)$ is common to the two trajectories *up to* the state dependence, which here we have arranged to enter only through F, G (the control cost is identical; any state-Lipschitz part of L contributes a further $\int_t^T \mathrm{Lip}_x L\, \mathbb{E}[|]\, D_s|\, \mathrm{d}s$ term, absorbed into the same bound). Taking the infimum over α on both sides and using $\mathbb{E}[|]\, X_s - X'_s| \le |x - x'|e^{\Lambda(s-t)}$,

$$|u^m(t,x) - u^m(t,x')| \le |x - x'|\Big(\mathrm{Lip}_x G[m_T]\, e^{\Lambda(T-t)} + \int_t^T \mathrm{Lip}_x F[m_s]\, e^{\Lambda(s-t)}\, \mathrm{d}s\Big),$$

which is (E.15) after dividing by $|x - x'|$ and letting $x' \to x$ (the value is differentiable in x by the $C^{1,2}$ regularity of theorem C.12 under (A-Nondeg)). The bound depends on m only through the measure-uniform constants $\mathrm{Lip}_x F$, $\mathrm{Lip}_x G$, hence is uniform in m. □

Remark E.18 (Relation to the Bernstein method)**.** The PDE-side proof differentiates (E.14) in x_k, writes the equation satisfied by $w = \frac{1}{2}|\nabla u|^2$, and uses uniform ellipticity to absorb the gradient-quadratic term, obtaining the same bound by the parabolic maximum principle. The synchronous-coupling argument above is the probabilistic shadow of that computation and needs no second differentiation of the data; the two give identical constants in the affine case. Either way, the operative mechanism is that bounded, uniformly-Lipschitz sources produce uniformly-Lipschitz value functions, with the Lipschitz constant propagated by the state-Lipschitz drift through Grönwall.

Theorem E.19 (Interior parabolic Schauder estimate)**.** *Under* (A-Nondeg) *and the hypotheses of theorem E.17, suppose moreover the data $F[m_t](\cdot)$, $G[m_T](\cdot)$ are bounded in C^θ_{loc} uniformly in t for some $\theta \in (0,1)$. Then for every parabolic interior subdomain $Q' \Subset (0,T) \times \mathbb{R}^d$ the value u^m is bounded in the Hölder space $C^{1+\theta/2,\,2+\theta}(Q')$ by a constant depending only on the ellipticity λ, the C^θ bounds of the coefficients and data,* $\mathrm{dist}(Q', \partial)$*, and L_u from* (E.15) *— but* not *on the frozen flow m beyond those data bounds. In particular a family $\{u^{m^{(n)}}\}$ with uniformly bounded, locally-uniformly-convergent data is precompact in $C^{1,2}_{\mathrm{loc}}$.*

Proof (reduction to the linear theory). By theorem E.17 the gradient $p^m(t,x) = \nabla u^m(t,x)$ is bounded by L_u, uniformly in m. Freeze it: u^m solves the *linear* uniformly parabolic equation

$$-\partial_t u^m - \tfrac{1}{2}\,\mathrm{tr}\big(\sigma\sigma^\top\, \mathrm{D}^2\, u^m\big) + \underbrace{\Big(\textstyle\int_0^1 \partial_p H(x, \tau p^m)\ \mathrm{d}\tau\Big)}_{=:c^m(t,x),\ |c^m| \le M} \cdot \nabla u^m = F[m_t](x),$$

obtained by writing $H(x,p^m) = H(x,0) + c^m \cdot p^m$ with c^m bounded by M (the range of $\partial_p H$ on $|p| \le L_u$). The coefficients $\sigma\sigma^\top$ and c^m are bounded and (by (A-Lip) and the C^θ data) Hölder continuous, uniformly in m, and the right-hand side $H(x,0) - F[m_t](x)$ is uniformly C^θ_{loc}. The interior Schauder estimate for linear uniformly parabolic equations — the quantitative form of the parametrix/Levi construction proved in theorem C.12 — then bounds u^m in $C^{1+\theta/2, 2+\theta}(Q')$ in terms of the listed data, independently of m. Precompactness in $C^{1,2}_{\mathrm{loc}}$ follows from the Arzelà–Ascoli theorem theorem B.24 applied on the compact closure of Q', since a bound in $C^{2+\theta}$ is a bound in C^2 together with a uniform modulus of continuity for the second derivatives. □

E.7 The Barles–Souganidis monotone-scheme theorem

The finite-difference solver of chapter 28 rests on a single abstract convergence principle: a numerical scheme that is *monotone*, *stable*, and *consistent* converges to the unique viscosity solution. This is the theorem of Barles and Souganidis [13]; we prove it here so that theorem 28.3 appeals to an in-book result rather than an external citation. The proof is short once the comparison principle (theorem E.14) is in hand, because it is exactly comparison that collapses the two relaxed semilimits of the scheme.

Write a discretization parameter $\rho = (h, \Delta t) \downarrow 0$ and let the scheme be a map

$$S_\rho(x,\, u_\rho(x),\, [u_\rho]) = 0, \tag{E.16}$$

where $[u_\rho]$ denotes the dependence of the equation at x on the values of u_ρ at neighbouring grid points (for eq. (28.8) this is the upwind stencil applied to the value field). We require three properties.

- *Monotonicity:* $S_\rho(x, r, [\phi]) \le S_\rho(x, r, [\psi])$ whenever $\phi \ge \psi$ with $\phi(x) = \psi(x)$; equivalently, S_ρ is nonincreasing in the values of its argument at points $\ne x$. (For eq. (28.8) this is precisely the M-matrix property of lemma 28.1: the off-diagonal stencil weights are ≤ 0 in the residual form.)
- *Stability:* for every ρ the scheme has a solution u_ρ with $\|u_\rho\|_\infty \le C$ uniformly in ρ (the L^∞ bound from lemma 28.1).
- *Consistency:* for every $\zeta \in C^\infty(\mathbb{R}^d)$ and every x,

$$\lim_{\substack{\rho\to 0,\ y\to x\\ \xi\to 0}} S_\rho(y,\, \zeta(y)+\xi,\, [\zeta+\xi]) = F(x, \zeta(x), \nabla\zeta(x), \mathrm{D}^2\,\zeta(x)), \tag{E.17}$$

  with F the HJB operator (E.2) (the Taylor expansion of the upwind stencil, whose $O(h)$ artificial-diffusion term vanishes as $h \to 0$).

Theorem E.20 (Barles–Souganidis)**.** *Let S_ρ be monotone, stable, and consistent in the senses above, and suppose the limit equation $F = 0$ enjoys the comparison principle of theorem E.14 (so it has a unique bounded continuous viscosity solution u). Then the scheme solutions u_ρ converge to u locally uniformly as $\rho \downarrow 0$.*

Proof. Define the upper and lower *relaxed semilimits*

$$\overline{u}(x) = \limsup_{\rho\to 0,\ y\to x} u_\rho(y), \qquad \underline{u}(x) = \liminf_{\rho\to 0,\ y\to x} u_\rho(y).$$

By stability these are finite, with $\underline{u} \le \overline{u}$ pointwise; $\overline{u}$ is USC and $\underline{u}$ is LSC by construction. We claim $\overline{u}$ is a viscosity *subsolution* and $\underline{u}$ a viscosity *supersolution* of $F = 0$.

$\overline{u}$ is a subsolution. Let $\phi \in C^\infty$ and let x_0 be a strict local maximum of $\overline{u} - \phi$; we must show $F(x_0, \overline{u}(x_0), \nabla\phi(x_0), \mathrm{D}^2\,\phi(x_0)) \le 0$. A standard semilimit lemma (the doubling/perturbation argument: subtract $|x - x_0|^4$ to make the maximum strict, then use the definition of lim sup)

produces sequences $\rho_n \downarrow 0$ and grid points $x_n \to x_0$ such that x_n is a global maximum of $u_{\rho_n} - \phi$ over the grid and $u_{\rho_n}(x_n) \to \overline{u}(x_0)$. Set $\xi_n = u_{\rho_n}(x_n) - \phi(x_n) \to \overline{u}(x_0) - \phi(x_0)$. At x_n the field satisfies $u_{\rho_n} \le \phi + \xi_n$ everywhere, with equality at x_n. By monotonicity of S_{ρ_n} (it is nonincreasing in the off-point values),

$$0 = S_{\rho_n}\big(x_n, u_{\rho_n}(x_n), [u_{\rho_n}]\big) \ge S_{\rho_n}\big(x_n,\, \phi(x_n) + \xi_n,\, [\phi + \xi_n]\big).$$

Let $n \to \infty$ and apply consistency (E.17) with $\zeta = \phi$, $y = x_n \to x_0$, $\xi = \xi_n$:

$$0 \ge \lim_n S_{\rho_n}\big(x_n, \phi(x_n) + \xi_n, [\phi + \xi_n]\big) = F\big(x_0, \overline{u}(x_0), \nabla\phi(x_0), \mathrm{D}^2\,\phi(x_0)\big),$$

which is the subsolution inequality. The supersolution property of $\underline{u}$ follows by the symmetric argument at a strict local *minimum*, reversing the inequalities.

Conclusion by comparison. Both $\overline{u}$ and $\underline{u}$ are bounded (stability). The comparison principle theorem E.14, applied to the USC subsolution $\overline{u}$ and the LSC supersolution $\underline{u}$, gives $\overline{u} \le \underline{u}$ on $\mathbb{R}^d$. Combined with the pointwise inequality $\underline{u} \le \overline{u}$ this forces $\overline{u} = \underline{u} =: u$, a (finite, hence continuous) function that is therefore the unique viscosity solution of $F = 0$. Finally, $\overline{u} = \underline{u}$ is exactly the statement that $u_\rho \to u$ locally uniformly: if convergence failed uniformly on some compact $\mathcal{K}$, one could extract points $y_n \to x_* \in \mathcal{K}$ with $u_{\rho_n}(y_n)$ bounded away from $u(x_*)$, contradicting $\overline{u}(x_*) = \underline{u}(x_*) = u(x_*)$. □

Remark E.21 (Parabolic version and the FP equation)**.** For the time-dependent HJB equation (6.19) the theorem runs verbatim with (t, x) in place of x and the comparison principle in its parabolic form (remark E.15); the fully implicit backward step of eq. (28.8) is monotone for *every* $\Delta t > 0$ (no ratio restriction), since lemma 28.1 holds for all Δt. The forward Fokker–Planck step eq. (28.10) is the transpose scheme; its weak-$*$ convergence to the measure solution is the dual statement, obtained by testing the conservative scheme against the (now uniformly convergent, by this theorem) backward test fields and passing to the limit, the discrete duality of lemma 28.2 furnishing the discrete integration by parts.

Appendix F

Graphon Space: Detailed Proofs

This appendix supplies the proofs that Part III states but defers: the weak regularity lemma, the counting lemma, completeness and compactness of the space of graphons under the cut metric, the sampling lemma, and the resulting equivalence between cut convergence and left-convergence together with the uniqueness statement that homomorphism densities determine a graphon up to relabeling. Everything is proved from material established earlier in the book; in particular we use the cut norm and cut metric of definitions 17.1 and 17.6, the fact that $\delta_\square$ is a pseudometric on $\mathcal{W}_0$ inducing a genuine metric on the quotient $\widetilde{\mathcal{W}}_0$ — with the triangle inequality, symmetry, and transitivity of weak isomorphism all established in proposition 17.7 — the homomorphism densities of chapter 16 and the elementary counting lemma lemma 16.17, the Banach–Alaoglu theorem of chapter 2, and the Azuma–Hoeffding inequality theorem 3.28. No external source is required.

Throughout, a *graphon* is a symmetric measurable function $W\colon [0,1]^2 \to [0,1]$; $\mathcal{W}_0$ denotes the set of graphons and $\widetilde{\mathcal{W}}_0 = \mathcal{W}_0/\!\sim$ its quotient under measure-preserving relabelings, metrized by the cut metric $\delta_\square$. We write $\langle U, V\rangle = \int_{[0,1]^2} UV$ and $\|U\|_2 = \langle U, U\rangle^{1/2}$ for the $L^2([0,1]^2)$ inner product and norm, and recall from lemma 17.2 the bound $\|U\|_\square \le \|U\|_2$ and the dual description $\|U\|_\square = \sup\{\, |\langle U, \mathbf{1}_{S\times T}\rangle| : S, T \subseteq [0,1] \text{ measurable}\,\}$.

F.1 Stepping and energy

Let $\mathcal{P} = \{P_1, \dots, P_m\}$ be a finite measurable partition of $[0,1]$ into parts of positive measure. For a kernel $U \in L^2([0,1]^2)$ define its *stepping* $U_\mathcal{P}$ to be the conditional expectation of U onto the σ-algebra generated by $\mathcal{P}\times\mathcal{P}$; concretely, on $P_i \times P_j$,

$$U_\mathcal{P}(x,y) \;=\; \frac{1}{|P_i|\;|P_j|}\int_{P_i\times P_j} U(s,t)\;\mathrm{d}s\;\mathrm{d}t \qquad (x,y)\in P_i\times P_j. \tag{F.1}$$

Thus $U_\mathcal{P}$ is the L^2-orthogonal projection of U onto the subspace of kernels that are constant on the rectangles $P_i \times P_j$. Two consequences of the projection property are used repeatedly. First, the Pythagorean identity

$$\|U\|_2^2 \;=\; \|U_\mathcal{P}\|_2^2 + \|U - U_\mathcal{P}\|_2^2\,. \tag{F.2}$$

Second, if $\mathcal{Q}$ refines $\mathcal{P}$ then $U_{\mathcal{P}} = (U_{\mathcal{Q}})_{\mathcal{P}}$ is the projection of $U_{\mathcal{Q}}$, so again $\|U_{\mathcal{Q}}\|_2^2 = \|U_{\mathcal{P}}\|_2^2 + \|U_{\mathcal{Q}} - U_{\mathcal{P}}\|_2^2$. We call $e(\mathcal{P}) := \|U_{\mathcal{P}}\|_2^2$ the *energy* of $\mathcal{P}$ (relative to U). For a graphon U, $0 \le e(\mathcal{P}) \le \|U\|_2^2 \le 1$, and energy is nondecreasing under refinement.

Lemma F.1 (Energy increment)**.** *Let U be a graphon and $\mathcal{P}$ a partition. Suppose $\|U - U_{\mathcal{P}}\|_{\square} > \varepsilon$. Then there is a refinement $\mathcal{Q}$ of $\mathcal{P}$ with at most $4\,|\mathcal{P}|$ parts such that $e(\mathcal{Q}) \ge e(\mathcal{P}) + \varepsilon^2$.*

Proof. By the dual description of the cut norm there are measurable sets $S, T \subseteq [0,1]$ with $|\langle U - U_{\mathcal{P}}, \mathbf{1}_{S\times T}\rangle| > \varepsilon$. Let $\mathcal{Q}$ be the common refinement of $\mathcal{P}$ with the partition $\{S, S^{\mathrm{c}}\}$ in the first coordinate and $\{T, T^{\mathrm{c}}\}$ in the second; each part of $\mathcal{P}$ is split into at most four pieces, so $|\mathcal{Q}| \le 4\,|\mathcal{P}|$, and both S and T are unions of $\mathcal{Q}$-parts. Because $\mathbf{1}_{S\times T}$ is constant on the rectangles of $\mathcal{Q}\times\mathcal{Q}$, it is orthogonal to $U - U_{\mathcal{Q}}$, whence $\langle U_{\mathcal{Q}}, \mathbf{1}_{S\times T}\rangle = \langle U, \mathbf{1}_{S\times T}\rangle$. Since $U_{\mathcal{P}}$ is the projection of $U_{\mathcal{Q}}$ onto the coarser σ-algebra,

$$\langle U_{\mathcal{Q}} - U_{\mathcal{P}}, \mathbf{1}_{S\times T}\rangle = \langle U_{\mathcal{Q}}, \mathbf{1}_{S\times T}\rangle - \langle U_{\mathcal{P}}, \mathbf{1}_{S\times T}\rangle = \langle U - U_{\mathcal{P}}, \mathbf{1}_{S\times T}\rangle,$$

using $\langle U_{\mathcal{Q}}, \mathbf{1}_{S\times T}\rangle = \langle U, \mathbf{1}_{S\times T}\rangle$ in the last step. Therefore, by Cauchy–Schwarz and $\|\mathbf{1}_{S\times T}\|_2 = \sqrt{|S|\,|T|} \le 1$,

$$\|U_{\mathcal{Q}} - U_{\mathcal{P}}\|_2 \;\ge\; \frac{|\langle U_{\mathcal{Q}} - U_{\mathcal{P}}, \mathbf{1}_{S\times T}\rangle|}{\|\mathbf{1}_{S\times T}\|_2} \;\ge\; \frac{\varepsilon}{\sqrt{|S|\,|T|}} \;\ge\; \varepsilon.$$

By the refinement form of (F.2), $e(\mathcal{Q}) - e(\mathcal{P}) = \|U_{\mathcal{Q}} - U_{\mathcal{P}}\|_2^2 \ge \varepsilon^2$. □

F.2 The weak regularity lemma

Theorem F.2 (Weak regularity lemma; cf. theorem 17.16)**.** *For every $\varepsilon > 0$ and every graphon W there is a partition $\mathcal{P}$ of $[0,1]$ into at most $4^{\lceil 1/\varepsilon^2\rceil}$ parts such that $\|W - W_{\mathcal{P}}\|_{\square} \le \varepsilon$.*

Proof. Start from the trivial partition $\mathcal{P}_0 = \{[0,1]\}$, with $e(\mathcal{P}_0) \ge 0$. As long as the current partition $\mathcal{P}_r$ satisfies $\|W - W_{\mathcal{P}_r}\|_{\square} > \varepsilon$, apply lemma F.1 to obtain a refinement $\mathcal{P}_{r+1}$ with at most four times as many parts and $e(\mathcal{P}_{r+1}) \ge e(\mathcal{P}_r) + \varepsilon^2$. Since the energy is bounded above by $\|W\|_2^2 \le 1$ and increases by at least ε^2 at each step, the procedure must stop after at most $\lceil 1/\varepsilon^2\rceil$ steps; when it stops, the current partition satisfies $\|W - W_{\mathcal{P}}\|_{\square} \le \varepsilon$. Starting from one part and multiplying by at most four per step, the number of parts is at most $4^{\lceil 1/\varepsilon^2\rceil}$. □

A useful reformulation: every graphon is, in cut norm, within ε of a *step graphon* with a bounded number $m(\varepsilon) \le 4^{\lceil 1/\varepsilon^2\rceil}$ of steps. We record the elementary stability of cut distance under perturbing the step data, needed in appendix F.5.

Lemma F.3 (Stability of step graphons)**.** *Let U, U' be step graphons with respect to the* same *ordered partition of $[0,1]$ into intervals of lengths $a = (a_1, \ldots, a_m)$ and $a' = (a'_1, \ldots, a'_m)$ respectively (the intervals taken in the same order), with value matrices $H, H' \in [0,1]^{m\times m}$. Then*

$$\delta_{\square}(U, U') \;\le\; \|U - U'\|_1 \;\le\; \sum_{i,j} a_i a_j \left|H_{ij} - H'_{ij}\right| \;+\; 2\sum_i |a_i - a'_i|\,.$$

Proof. The bound $\delta_\square \le \|\cdot\|_1$ holds because $\|\cdot\|_\square \le \|\cdot\|_1$ and $\delta_\square$ is an infimum over relabelings that includes the identity. For the L^1 bound, align the two interval partitions on their common refinement; on the overlap of the ith interval of each, the integrand differs by $\left|H_{ij} - H'_{ij}\right|$, contributing the first sum, while the symmetric difference of the ith intervals has total measure at most $|a_i - a'_i|$ and the integrand there is bounded by 1, contributing (over both coordinates) at most $2\sum_i |a_i - a'_i|$. $\square$

F.3 The counting lemma

For a simple graph F with edge set $E(F)$ on vertex set $\{1, \dots, k\}$ and a graphon W, recall

$$t(F, W) = \int_{[0,1]^k} \prod_{\{i,j\}\in E(F)} W(x_i, x_j) \prod_{i=1}^{k} \mathrm{d}x_i.$$

Lemma F.4 (Counting lemma)**.** *For every simple graph F and all graphons U, W,*

$$|t(F, U) - t(F, W)| \;\le\; |E(F)|\, \|U - W\|_\square \;\le\; |E(F)|\, \delta_\square(U, W).$$

Proof. Because $t(F, \cdot)$ is invariant under measure-preserving relabeling of the graphon, the second inequality follows from the first by taking the infimum over relabelings. For the first, enumerate $E(F) = \{f_1, \dots, f_r\}$, $r = |E(F)|$, and interpolate one edge at a time: let Φ_ℓ be the integrand obtained by using U on the edges $f_1, \dots, f_\ell$ and W on the remaining edges, so that $\int \Phi_0 = t(F, W)$ and $\int \Phi_r = t(F, U)$. Then

$$t(F, U) - t(F, W) = \sum_{\ell=1}^{r} \int_{[0,1]^k} (\Phi_\ell - \Phi_{\ell-1}).$$

Fix ℓ and let $f_\ell = \{p, q\}$. The difference $\Phi_\ell - \Phi_{\ell-1}$ equals $\big(U(x_p, x_q) - W(x_p, x_q)\big)\,\Psi(x)$, where Ψ is a product of graphon factors not involving the edge $\{p, q\}$, hence $0 \le \Psi \le 1$. Integrating out all variables except x_p, x_q produces a function $g(x_p, x_q) = \int \Psi \prod_{i\ne p,q} \mathrm{d}x_i$ with $\|g\|_\infty \le 1$, so, writing $D = U - W$,

$$\int_{[0,1]^k} (\Phi_\ell - \Phi_{\ell-1}) = \int_{[0,1]^2} D(s, t)\, g(s, t)\; \mathrm{d}s\; \mathrm{d}t.$$

For any measurable g with $\|g\|_\infty \le 1$ one has $|\langle D, g\rangle| \le \|D\|_\square$: this is the standard fact that the cut norm equals the supremum of $\langle D, g\rangle$ over g valued in $[-1, 1]$, which follows from the dual description by writing g as a limit of simple functions and expanding each level set as a signed combination of rectangle indicators $\mathbf{1}_{S\times T}$. Hence each term is at most $\|D\|_\square$ in absolute value, and summing the r terms gives the claim. $\square$

F.4 Completeness

Theorem F.5 (Completeness; cf. proposition 17.18)**.** *The metric space $(\widetilde{\mathcal{W}}_0, \delta_\square)$ is complete.*

Proof. Let $(\widetilde{W}_n)$ be a Cauchy sequence in $\widetilde{\mathcal{W}}_0$. Passing to a subsequence we may assume $\delta_\square(\widetilde{W}_n, \widetilde{W}_{n+1}) < 2^{-n}$; it suffices to produce a limit of the subsequence, since a Cauchy sequence with a convergent subsequence converges. Fix any representative V_1 of $\widetilde{W}_1$. Inductively, given a representative V_n of $\widetilde{W}_n$, the definition of $\delta_\square$ as an infimum over measure-preserving relabelings provides a relabeling ϕ and a representative W_{n+1} of $\widetilde{W}_{n+1}$ with $\left\|V_n - W_{n+1}^\phi\right\|_\square < 2^{-n}$; set $V_{n+1} = W_{n+1}^\phi$. Then (V_n) is a sequence of graphons with $\|V_n - V_{n+1}\|_\square < 2^{-n}$, hence Cauchy in the cut norm.

The graphons form a subset of the closed unit ball of $L^\infty([0,1]^2)$, which is weak-$*$ compact by the Banach–Alaoglu theorem (chapter 2); since $L^\infty([0,1]^2)$ is the dual of the separable space $L^1([0,1]^2)$, the ball is weak-$*$ sequentially compact. Thus a subsequence of (V_n) converges weak-$*$ to some $W \in L^\infty$. The constraints defining a graphon are preserved: $\{U : 0 \le U \le 1 \text{ a.e.}\}$ and $\{U : U(x,y) = U(y,x) \text{ a.e.}\}$ are convex and weak-$*$ closed (each is an intersection of half-spaces $\langle U, h\rangle \le c$ with $h \in L^1$), so W is again a graphon.

Finally $\|V_n - W\|_\square \to 0$. Fix $\varepsilon > 0$ and N with $\|V_n - V_m\|_\square < \varepsilon$ for $n, m \ge N$. For any measurable S, T and $n \ge N$,

$$|\langle V_n - W, \mathbf{1}_{S\times T}\rangle| = \lim_{m\to\infty} |\langle V_n - V_m, \mathbf{1}_{S\times T}\rangle| \le \varepsilon,$$

using weak-$*$ convergence of the chosen subsequence on the fixed test function $\mathbf{1}_{S\times T} \in L^1$. Taking the supremum over S, T gives $\|V_n - W\|_\square \le \varepsilon$ for all $n \ge N$; the bound is uniform in S, T, so the whole sequence (V_n) converges to W in cut norm, hence $\delta_\square(\widetilde{W}_n, \widetilde{W}) \to 0$ with $\widetilde{W}$ the class of W. □

F.5 Compactness

Theorem F.6 (Lovász–Szegedy compactness; cf. theorem 17.13)**.** *The metric space $(\widetilde{\mathcal{W}}_0, \delta_\square)$ is compact.*

Proof. As a metric space it suffices to prove sequential compactness; we extract a convergent subsequence and construct its limit explicitly. Let $(W_n) \subset \mathcal{W}_0$. For each integer $k \ge 1$ apply the weak regularity lemma theorem F.2 with $\varepsilon = 1/k$: there is a partition $\mathcal{P}_n^{(k)}$ of $[0,1]$ into $m_k \le 4^{\lceil k^2\rceil}$ parts (pad with empty parts so the count is exactly m_k, independent of n) such that the step graphon $W_n^{(k)} := (W_n)_{\mathcal{P}_n^{(k)}}$ satisfies

$$\left\|W_n - W_n^{(k)}\right\|_\square \le 1/k. \tag{F.3}$$

After a measure-preserving relabeling of $[0,1]$ (which changes neither $\delta_\square$ nor the left-hand side of (F.3), since the relabeling is applied simultaneously to W_n and its stepping) we may assume the parts of $\mathcal{P}_n^{(k)}$ are subintervals of $[0,1]$ arranged in a fixed order. The step graphon $W_n^{(k)}$ is then encoded by the length vector $a_n^{(k)}$ in the closed simplex $\Delta_{m_k} = \{a \in [0,1]^{m_k} : \sum a_i = 1\}$ and the symmetric value matrix $H_n^{(k)} \in [0,1]^{m_k\times m_k}$.

The data $(a_n^{(k)}, H_n^{(k)})$ lie in the compact set $\Delta_{m_k} \times [0,1]^{m_k\times m_k}$. By a diagonal argument extract a single subsequence (n_j) along which, *for every* k, $a_{n_j}^{(k)} \to a^{(k)}$ and $H_{n_j}^{(k)} \to H^{(k)}$ as $j \to \infty$. Let U_k be the step graphon with interval lengths $a^{(k)}$ and value matrix $H^{(k)}$.

Claim: $\limsup_j \delta_\square(W_{n_j}, U_k) \le 1/k$. By lemma F.3 applied to the step graphons $W_{n_j}^{(k)}$ and U_k (same ordered interval structure, converging data), $\delta_\square(W_{n_j}^{(k)}, U_k) \le \left\| H_{n_j}^{(k)} - H^{(k)} \right\|_1 + 2 \left\| a_{n_j}^{(k)} - a^{(k)} \right\|_1 \to 0$ as $j \to \infty$. Combined with (F.3) and the triangle inequality, $\delta_\square(W_{n_j}, U_k) \le \left\| W_{n_j} - W_{n_j}^{(k)} \right\|_\square + \delta_\square(W_{n_j}^{(k)}, U_k) \le 1/k + o_j(1)$, proving the claim.

The sequence (U_k) *is Cauchy.* For any k, l and all j, $\delta_\square(U_k, U_l) \le \delta_\square(U_k, W_{n_j}) + \delta_\square(W_{n_j}, U_l)$; letting $j \to \infty$ and using the claim, $\delta_\square(U_k, U_l) \le 1/k + 1/l$. By completeness (theorem F.5) there is a graphon W with $\delta_\square(U_k, W) \to 0$.

Conclusion. For each k and all j, $\delta_\square(W_{n_j}, W) \le \delta_\square(W_{n_j}, U_k) + \delta_\square(U_k, W)$. Taking $\limsup_j$ and using the claim gives $\limsup_j \delta_\square(W_{n_j}, W) \le 1/k + \delta_\square(U_k, W)$; letting $k \to \infty$ makes the right-hand side vanish, so $\delta_\square(W_{n_j}, W) \to 0$. Thus every sequence in $\widetilde{\mathcal{W}}_0$ has a convergent subsequence. $\square$

F.6 The sampling lemma

We connect a graphon to the finite graphs it generates, which powers the converse (left-convergence $\Rightarrow$ cut convergence) and the uniqueness theorem. Given a graphon W and an integer k, sample $X_1, \dots, X_k$ independently and uniformly on $[0,1]$ and let $\mathbb{H}(k, W)$ be the random *weighted* graph on $\{1, \dots, k\}$ with edge weights $W(X_i, X_j)$. Identify $\mathbb{H}(k, W)$ with the step graphon $W_\mathbb{H}$ obtained by partitioning $[0,1]$ into k equal intervals $I_1, \dots, I_k$ and setting $W_\mathbb{H} = W(X_i, X_j)$ on $I_i \times I_j$ $(i \ne j)$ and 0 on the diagonal blocks.

Theorem F.7 (Sampling lemma)**.** *There is a function $\eta(k) \to 0$ as $k \to \infty$, independent of the graphon, such that*

$$\mathbb{E}\, \delta_\square\big(W, W_{\mathbb{H}(k,W)}\big) \;\le\; \eta(k) \qquad \text{for every graphon } W.$$

Proof. Write $Z_k = \delta_\square(W, W_{\mathbb{H}(k,W)})$, a function of the i.i.d. samples $X_1, \dots, X_k$. We bound $\mathbb{E} Z_k$ and note it concentrates.

Concentration. Changing a single coordinate X_i alters $W_\mathbb{H}$ only on the ith row and column of blocks, a set of measure $\le 2/k$, and changes $\|\cdot\|_\square \le \|\cdot\|_1$ by at most $2/k$; since $\delta_\square$ is 1-Lipschitz with respect to the cut norm, Z_k has bounded differences $c_i \le 2/k$. The bounded-differences inequality (theorem 3.28, remark 3.29) gives $\mathbb{P}(|Z_k - \mathbb{E} Z_k| \ge t) \le 2\exp(-t^2 k/2)$, because $\sum_i c_i^2 \le k\,(2/k)^2 = 4/k$.

Mean estimate. Fix $\varepsilon > 0$ and let $W_\mathcal{P}$ be a step graphon with $m \le 4^{\lceil 1/\varepsilon^2 \rceil}$ parts and $\|W - W_\mathcal{P}\|_\square \le \varepsilon$ (theorem F.2). Decompose, using $\delta_\square \le \|\cdot\|_\square$ and the triangle inequality,

$$\mathbb{E} Z_k \le \underbrace{\|W - W_\mathcal{P}\|_\square}_{\le \varepsilon} + \mathbb{E}\, \|W_\mathcal{P} - (W_\mathbb{H})_{\mathcal{P}'}\|_\square + \mathbb{E}\, \|(W_\mathbb{H})_{\mathcal{P}'} - W_\mathbb{H}\|_\square\,,$$

where $\mathcal{P}'$ is the partition of the index set induced by which part of $\mathcal{P}$ contains each X_i, and $(W_\mathbb{H})_{\mathcal{P}'}$ is the corresponding block average of the sample. The block values of $(W_\mathbb{H})_{\mathcal{P}'}$ are empirical averages of the independent bounded weights over sampled pairs falling in each pair of parts; a block straddling parts P_a, P_b averages $\approx k^2\,|P_a|\,|P_b|$ weights, each of mean $\langle W\rangle_{P_a\times P_b}$, so by Chebyshev its deviation from that mean is $O(k^{-1}\,|P_a|^{-1/2}\,|P_b|^{-1/2})$ in L^1. There are m^2 blocks; weighting by block areas, the middle term is $O(m\,k^{-1})$ in expectation (parts of measure below $1/k$ contribute negligibly, as they hold $O(1)$ samples and total area $\le m/k$). The third term compares the sampled graphon to its own stepping along $\mathcal{P}'$; since $(W_{\mathbb{H}})_{\mathcal{P}'}$ is the stepping of a sample of W, in expectation $\mathbb{E}\,\|(W_{\mathbb{H}})_{\mathcal{P}'} - W_{\mathbb{H}}\|_\square \le \|W_{\mathcal{P}} - W\|_\square + O(m\,k^{-1/2}) \le \varepsilon + O(m\,k^{-1/2})$, because stepping a sample concentrates around stepping the graphon. Collecting,

$$\mathbb{E}Z_k \;\le\; 2\varepsilon + C(\varepsilon)\,k^{-1/2},$$

with $C(\varepsilon)$ depending only on $m = m(\varepsilon)$ and on absolute constants, not on W. Choosing $\varepsilon \to 0$ slowly as $k \to \infty$ (e.g. $\varepsilon = (\log k)^{-1/4}$, so that $m(\varepsilon) = 4^{\lceil\sqrt{\log k}\,\rceil}$ grows subpolynomially in k and still leaves $C(\varepsilon)k^{-1/2} \to 0$) makes the bound a graphon-independent $\eta(k) \to 0$. The concentration estimate then transfers the bound from $\mathbb{E}Z_k$ to Z_k in expectation, completing the proof. $\square$

Remark F.8. A sharper accounting (Azuma inside each block, optimizing ε) gives the sharp rate $\eta(k) = O(1/\sqrt{\log k})$; we use only $\eta(k) \to 0$, except in theorem F.9 below, where the $O(1/\sqrt{\log k})$ rate sets the final scale and is therefore quoted explicitly (as an absolute constant c_1 with $\eta(N) \le c_1/\sqrt{\log N}$).

F.6.1 The Bernoulli second sampling lemma

The sampling lemma above compares a graphon to its *weighted* sample, whose blocks carry the conditional edge means $W(X_i, X_j)$. The object actually generated by the W-random graph $G(N, W)$ of definition 19.1 is the *Bernoulli* sample, whose blocks carry the coins $\xi_{ij} \in \{0, 1\}$. The next theorem — the *second sampling lemma* of Borgs–Chayes–Lovász–Sós–Vesztergombi — upgrades the weighted estimate to the Bernoulli sample with an explicit tail, by adding one layer of edge-coin concentration. It is the input consumed by the finite-network convergence theorem of chapter 25, and we prove it here in full from the in-book ingredients (the weighted sampling lemma theorem F.7 and the bounded-differences inequality theorem 3.28/remark 3.29); only the attribution is external.

Theorem F.9 (Second sampling lemma: Bernoulli sampling in cut distance)**.** *Let W be a graphon. For $N \in \mathbb{N}$ draw i.i.d. types $U_1, \ldots, U_N \sim \mathrm{Unif}[0, 1]$ and, conditionally on the types, independent edge coins $\xi_{ij} \sim \mathrm{Bernoulli}(W(U_i, U_j))$ $(1 \le i < j \le N,\ \xi_{ji} = \xi_{ij})$, and let $W_{[N]}$ be the induced step graphon: $W_{[N]} = \xi_{ij}$ on $J_i \times J_j$ for $i \ne j$ and 0 on the diagonal blocks, where $J_1, \ldots, J_N$ are equal intervals partitioning $[0, 1]$. There is an absolute constant $C \ge 1$ such that for all $N \ge 2$,*

$$\mathbb{P}\Big(\delta_\square(W_{[N]}, W) > \frac{C}{\sqrt{\log N}}\Big) \;\le\; \exp\Big(-\frac{N}{C\log N}\Big).$$

Proof. Interpolate through the weighted sample $W_{\mathbb{H}(N,W)}$ of theorem F.7: the step graphon equal to $W(U_i, U_j)$ on $J_i \times J_j$ $(i \ne j)$ and 0 on the diagonal, built from the *same* types U_i as $W_{[N]}$. By the triangle inequality and $\delta_\square \le \|\cdot\|_\square$,

$$\delta_\square(W_{[N]}, W) \;\le\; \underbrace{\big\|W_{[N]} - W_{\mathbb{H}(N,W)}\big\|_\square}_{=:A_N} + \underbrace{\delta_\square(W_{\mathbb{H}(N,W)}, W)}_{=:B_N}. \tag{F.4}$$

We bound the two terms by genuinely separate mechanisms — B_N by sampling the *types*, A_N by concentrating the *coins* with the types frozen — which is the two-temperature split of section 19.2.

The weighted term B_N (types). This is exactly the quantity controlled by the weighted sampling lemma. By theorem F.7 and remark F.8 there is an absolute c_1 with $\mathbb{E}B_N \le \eta(N) \le c_1/\sqrt{\log N}$. Moreover B_N is a function of the i.i.d. types alone, and changing one type U_i alters $W_{\mathbb{H}(N,W)}$ only on the ith row and column of blocks (measure $\le 2/N$), hence moves B_N by at most $2/N$ (the map $W \mapsto \delta_\square(W,W)$ is 1-Lipschitz in $\|\cdot\|_\square \le \|\cdot\|_1$). Thus $\sum_i c_i^2 \le N(2/N)^2 = 4/N$, and the bounded-differences inequality (theorem 3.28/remark 3.29) gives, with $t = c_1/\sqrt{\log N}$,

$$\mathbb{P}\Big(B_N > \frac{2c_1}{\sqrt{\log N}}\Big) \;\le\; \mathbb{P}(B_N - \mathbb{E}B_N > t) \;\le\; 2\exp\Big(-\frac{t^2}{2\cdot 4/N}\Big) \;=\; 2\exp\Big(-\frac{c_1^2\,N}{8\log N}\Big).$$

The fluctuation term A_N (coins). Here the types are frozen and only the edge coins fluctuate. The integrand $D := W_{[N]} - W_{\mathbb{H}(N,W)}$ is constant on each block, with value $D_{ij} = \xi_{ij} - W(U_i,U_j) \in [-1,1]$ off the diagonal and 0 on it. For a step function the cut-norm supremum over measurable S,T is attained at unions of the defining blocks: with T fixed, $\int_{S\times T} D = \int_S \psi$ where $\psi(x) = \int_T D(x,t)\,\mathrm{d}t$ is constant on each J_i, so the supremum over measurable S is realised by the union of the J_i on which ψ carries the maximising sign, and symmetrically in T. Hence

$$A_N \;=\; \max_{A,B\subseteq[N]} \Big|\frac{1}{N^2}\sum_{i\in A,\, j\in B} D_{ij}\Big| \;=\; \max_{A,B\subseteq[N]} |\Delta_{A,B}|\,, \qquad \Delta_{A,B} := \frac{1}{N^2}\sum_{i\in A,\, j\in B} D_{ij}.$$

Fix A,B and condition on the types $U = (U_1,\dots,U_N)$. The off-diagonal coins $\{\xi_{ij}\}_{i<j}$ are then independent, and $\Delta_{A,B} = \sum_{i<j} a_{ij}\,(\xi_{ij} - W(U_i,U_j))$ is a weighted sum of the centred coins in which each coin enters with coefficient $|a_{ij}| \le 2/N^2$ (the factor 2 accounting for the symmetric appearance of the unordered pair $\{i,j\}$ as both (i,j) and (j,i)); its centred contribution therefore ranges over an interval of length $\le 4/N^2$. The conditional mean is 0 and $\sum_{i<j}(4/N^2)^2 \le \binom{N}{2}(4/N^2)^2 \le 8/N^2$, so the bounded-differences inequality (remark 3.29) gives, for every value of U and hence unconditionally,

$$\mathbb{P}(\,|\Delta_{A,B}| \ge s) \;\le\; 2\exp\Big(-\frac{s^2}{2\cdot 8/N^2}\Big) \;=\; 2\exp\Big(-\frac{s^2N^2}{16}\Big).$$

A union bound over the $2^N\cdot 2^N = 4^N$ pairs (A,B) yields

$$\mathbb{P}(A_N \ge s) \;\le\; 2\cdot 4^N \exp\Big(-\frac{s^2N^2}{16}\Big) \;=\; 2\exp\Big(N\log 4 - \frac{s^2N^2}{16}\Big).$$

Choose $s = C_0/\sqrt{N}$ with $C_0^2 = 32\log 4$; then the exponent is $N\log 4 - C_0^2 N/16 = -N\log 4$, so $\mathbb{P}(A_N \ge C_0/\sqrt{N}) \le 2\cdot 4^{-N}$. Since $\log N \le N$, also $C_0/\sqrt{N} \le C_0/\sqrt{\log N}$.

Combine. On the complement of the two bad events,

$$\delta_\square(W_{[N]},W) \;\le\; A_N + B_N \;\le\; \frac{C_0}{\sqrt{N}} + \frac{2c_1}{\sqrt{\log N}} \;\le\; \frac{C_0+2c_1}{\sqrt{\log N}}.$$

Take $C \ge \max\{1,\, C_0{+}2c_1\}$ large enough that also $2{\cdot}4^{-N}{+}2\exp(-c_1^2N/(8\log N)) \le \exp(-N/(C\log N))$ for every $N \ge 2$ (possible because $4^{-N} = e^{-N\log 4}$ and $\exp(-c_1^2N/(8\log N))$ each dominate $\exp(-N/(C\log N))$ once C is large). A union bound over the two displayed estimates then gives the claim. □

Remark F.10. The $1/\sqrt{\log N}$ scale comes entirely from the weighted term B_N (the slow rate $\eta(N)$ of remark F.8); the coin fluctuations A_N are $O(1/\sqrt{N})$, an order of magnitude smaller, so Bernoulli sampling is no harder than weighted sampling. The logarithm is genuine: cut distance is a supremum over the exponentially many test pairs (A, B), and the union bound over 4^N of them is what caps the resolution at $1/\sqrt{\log N}$.

F.7 Uniqueness and the equivalence theorem

Theorem F.11 (Moments determine the graphon; cf. theorem 17.11)**.** *If two graphons U, W satisfy $t(F, U) = t(F, W)$ for every simple graph F, then $\delta_\Box(U, W) = 0$, i.e. $U = W$ in $\widetilde{\mathcal{W}}_0$.*

Proof. We route uniqueness through the *Bernoulli* sample, not the weighted one. For a graphon W and a sample size k, let $G(k, W)$ be the random simple graph on $[k]$ obtained by drawing i.i.d. types $X_1, \ldots, X_k \sim \mathrm{Unif}[0, 1]$ and then, conditionally on the types, including each edge $\{i, j\}$ independently with probability $W(X_i, X_j)$ (definition 19.1); write $W_{[k]}$ for its induced step graphon, exactly as in theorem F.9.

Step 1: equal densities force equal sample laws. We claim that for every k the laws of $G(k, U)$ and $G(k, W)$ on simple graphs over $[k]$ coincide. Fix a simple graph H with $V(H) = [k]$. Conditioning on the types and using conditional edge-independence,

$$\mathbb{P}(G(k, W) = H) = \mathbb{E}\Big[\prod_{\{i,j\}\in E(H)} W(X_i, X_j) \prod_{\{i,j\}\notin E(H)} (1 - W(X_i, X_j))\Big].$$

Expand the product over the non-edges. Because each pair $\{i, j\}$ is either an edge or a non-edge of H but never both, every weight $W(X_i, X_j)$ enters the expansion to the *first power only*: there are no squares to reckon with. This is the crux — the edge indicator $Z = \mathbf{1}\{\{i, j\} \in G(k, W)\}$ is $\{0, 1\}$-valued, so $Z^2 = Z$, and no genuinely higher moment of the weights is ever called for. The expansion is therefore a finite $\mathbb{Z}$-linear combination of *multilinear* (square-free) expectations $\mathbb{E} \prod_{\{i,j\}\in E(F)} W(X_i, X_j)$, one for each simple graph F on $[k]$ formed by adjoining to $E(H)$ a subset of its non-edges; by definition 16.8 each such expectation is exactly the homomorphism density $t(F, W)$. Thus $\mathbb{P}(G(k, W) = H)$ is one and the same fixed finite linear combination of the numbers $\{t(F, W)\}_F$ for both $W = U$ and $W = W$ (this is the inclusion–exclusion passage from induced to homomorphism densities). Since $t(F, U) = t(F, W)$ for every simple F, the two probabilities agree; as H was arbitrary, $G(k, U)$ and $G(k, W)$ have the same law, and hence so do the induced step graphons $U_{[k]}$ and $W_{[k]}$, for every k.

This is exactly where the weighted sample fails and the Bernoulli sample succeeds. A simple graph F supplies only the multilinear moment $\mathbb{E} \prod_{\{i,j\}\in E(F)} W(X_i, X_j)$, each edge to the first power; genuinely higher moments such as $\mathbb{E}\, W(X_1, X_2)^2$ correspond to *multigraphs* (parallel edges), which are not simple-graph densities. Simple-graph densities therefore do *not* determine the law of the weighted sample $\mathbb{H}(k, W)$ — the "bounded random vectors are determined by their moments" principle needs *all* joint moments, which are not on offer. They do determine the law of the $\{0, 1\}$-valued Bernoulli sample, precisely because $Z^2 = Z$ collapses every power to the first and leaves only the multilinear quantities the densities furnish.

Step 2: pinch through the Bernoulli sample. The cut distance $\delta_\square(U,W)$ is a constant, so for the random graph $G(k,U)$ the triangle inequality gives, pathwise, $\delta_\square(U,W) \le \delta_\square(U,U_{[k]}) + \delta_\square(U_{[k]},W)$. Taking expectations,

$$\delta_\square(U,W) \;\le\; \mathbb{E}\big[\delta_\square(U,U_{[k]})\big] + \mathbb{E}\big[\delta_\square(U_{[k]},W)\big] \;=\; \mathbb{E}\big[\delta_\square(U,U_{[k]})\big] + \mathbb{E}\big[\delta_\square(W_{[k]},W)\big],$$

where the last equality replaces $U_{[k]}$ by the identically distributed $W_{[k]}$ of Step 1. Both expectations are controlled by the second sampling lemma (theorem F.9): for any graphon W, since $\delta_\square \le 1$ always,

$$\mathbb{E}\big[\delta_\square(W_{[k]},W)\big] \;\le\; \frac{C}{\sqrt{\log k}} + 1 \cdot \exp\Big(-\frac{k}{C\log k}\Big) \xrightarrow[k\to\infty]{} 0.$$

Hence $\delta_\square(U,W) \;\le\; 2\big(C/\sqrt{\log k} + \exp(-k/(C\log k))\big)$ for every $k \ge 2$; letting $k \to \infty$ forces $\delta_\square(U,W) = 0$. $\square$

Theorem F.12 (Cut convergence $\Leftrightarrow$ left-convergence; cf. theorem 17.12)**.** *For graphons W_n, W the following are equivalent:*

(a) $\delta_\square(W_n,W) \to 0$*;*

(b) $t(F,W_n) \to t(F,W)$ *for every simple graph* F*.*

Proof. (a)$\Rightarrow$(b) is the counting lemma lemma F.4: $|t(F,W_n) - t(F,W)| \le |E(F)|\; \delta_\square(W_n,W) \to 0$.

(b)$\Rightarrow$(a). Suppose the densities converge but, for contradiction, $\delta_\square(W_n,W) \not\to 0$. Then some subsequence satisfies $\delta_\square(W_{n_j},W) \ge \delta > 0$. By compactness (theorem F.6) a further subsequence converges in cut metric to some graphon U, and by continuity of the metric $\delta_\square(U,W) \ge \delta > 0$, so $U \ne W$ in $\widetilde{\mathcal{W}}_0$. But along this subsequence the counting lemma gives $t(F,U) = \lim_j t(F,W_{n_j}) = t(F,W)$ for every F, the last equality by hypothesis (b). By theorem F.11 this forces $U = W$ in $\widetilde{\mathcal{W}}_0$, a contradiction. Hence $\delta_\square(W_n,W) \to 0$. $\square$

These results close every proof deferred from chapters 16 and 17: the weak regularity lemma (theorem F.2), the counting lemma (lemma F.4), completeness (theorem F.5), the Lovász–Szegedy compactness theorem (theorem F.6), the uniqueness of a graphon given its homomorphism densities (theorem F.11), and the equivalence of cut convergence and left-convergence (theorem F.12).

F.8 The Hausdorff moment problem

Remark 16.23 identifies the *rank-one* sector of the graph moment problem with the classical moment problem on the bounded interval $[0,1] = [0,1]$: a rank-one graphon $W(x,y) = f(x)f(y)$ has $t(F,W) = \prod_{i\in V(F)} c_{\deg_F(i)}$ with $c_d = \int_0^1 f^d$, and the realizable degree-moment sequences (c_d) are exactly the Hausdorff moment sequences. Unlike the general sufficiency direction of theorem 16.22, this bounded-interval shadow has a short self-contained proof, which we give here. It is the only piece of the moment characterization the chapter actually *uses* (in worked computation 16.24), so we owe it an in-book proof.

Definition F.13 (Finite differences; complete monotonicity)**.** For a real sequence $(c_d)_{d\geq 0}$ write the forward difference $(\Delta c)_d = c_{d+1} - c_d$ and its iterates $\Delta^k = \Delta \circ \Delta^{k-1}$, so that $(\Delta^k c)_d = \sum_{i=0}^k \binom{k}{i}(-1)^{k-i} c_{d+i}$. The sequence is *completely monotone* if

$$(-1)^k (\Delta^k c)_d \ \geq \ 0 \qquad \text{for all } d, k \geq 0.$$

Theorem F.14 (Hausdorff moment theorem)**.** *A real sequence $(c_d)_{d\geq 0}$ with $c_0 = 1$ is the moment sequence $c_d = \int_0^1 r^d \, \rho(\mathrm{d}r)$ of a (necessarily unique) Borel probability measure ρ on* $[0,1]$ if and only if *it is completely monotone. In that case (c_d) is nonincreasing with $0 \leq c_d \leq 1$, and every Hankel matrix $(c_{i+j})_{i,j=0}^N$ is positive semidefinite.*

Proof. Necessity. If $c_d = \int_0^1 r^d \, \rho(\mathrm{d}r)$ then, since Δ acting on $r^{\cdot}$ multiplies by $(r-1)$,

$$(-1)^k (\Delta^k c)_d = \int_0^1 r^d \, (1-r)^k \, \rho(\mathrm{d}r) \ \geq \ 0,$$

the integrand being nonnegative on $[0,1]$; this is complete monotonicity. Taking $k = 1$ gives $c_d - c_{d+1} = \int r^d (1-r) \, \rho \geq 0$, so (c_d) is nonincreasing, and $0 \leq c_d \leq c_0 = 1$. Positive semidefiniteness of the Hankel matrix is the Gram identity $\sum_{i,j} a_i a_j c_{i+j} = \int_0^1 \big(\sum_i a_i r^i\big)^2 \rho(\mathrm{d}r) \geq 0$ (the rank-one shadow of proposition 16.21).

Sufficiency. Assume (c_d) is completely monotone with $c_0 = 1$. For $0 \leq j \leq n$ set

$$p_{n,j} \ := \ \binom{n}{j} (-1)^{n-j} (\Delta^{n-j} c)_j \ \geq \ 0,$$

nonnegativity being exactly complete monotonicity. Writing E for the shift $(Ec)_d = c_{d+1}$ and $\Delta = E - I$, we have $(-1)^{n-j} \Delta^{n-j} = (I-E)^{n-j}$, so the binomial theorem in the commuting operators E, I gives

$$\sum_{j=0}^n \binom{n}{j} E^j (I-E)^{n-j} = \big(E + (I-E)\big)^n = I;$$

evaluating the corresponding sequence at index 0 yields $\sum_{j=0}^n p_{n,j} = c_0 = 1$. Hence

$$\rho_n \ := \ \sum_{j=0}^n p_{n,j} \, \delta_{j/n}$$

is a Borel probability measure on $[0,1]$.

Factorial moments of ρ_n. We claim that for every $0 \leq m \leq n$,

$$\sum_{j=0}^n \binom{j}{m} p_{n,j} \ = \ \binom{n}{m} c_m. \tag{F.5}$$

Indeed, using $\binom{j}{m}\binom{n}{j} = \binom{n}{m}\binom{n-m}{j-m}$ and substituting $i = j - m$, $N = n - m$,

$$\sum_j \binom{j}{m} p_{n,j} = \binom{n}{m} \sum_{i=0}^N \binom{N}{i} (-1)^{N-i} (\Delta^{N-i} c)_{m+i} = \binom{n}{m} c_m,$$

the last step being the operator identity above applied to the shifted sequence $d \mapsto c_{m+d}$ (whose value at index 0 is c_m). Dividing (F.5) by $\binom{n}{m}$ and using $(n)_m = m!\binom{n}{m}$,

$$\sum_{j=0}^{n} \frac{(j)_m}{(n)_m}\, p_{n,j} \;=\; c_m \qquad (0 \le m \le n),$$

where $(x)_m = x(x-1)\cdots(x-m+1)$.

Ordinary moments converge to (c_d). Fix $d \ge 1$ and let $n > d$. The d-th moment of ρ_n is $m_d(\rho_n) = \sum_j (j/n)^d p_{n,j}$. We compare $(j/n)^d$ with the factorial ratio $\frac{(j)_d}{(n)_d} = \prod_{i=0}^{d-1} \frac{j-i}{n-i}$. Each factor obeys $0 \le \frac{j}{n} - \frac{j-i}{n-i} = \frac{i(n-j)}{n(n-i)} \le \frac{i}{n-i} \le \frac{i}{n-d}$, and for products of $[0,1]$-valued factors $|\prod a_i - \prod b_i| \le \sum_i |a_i - b_i|$, whence

$$\big|\, (j/n)^d - \tfrac{(j)_d}{(n)_d} \,\big| \;\le\; \sum_{i=0}^{d-1} \frac{i}{n-d} \;=\; \frac{\binom{d}{2}}{n-d},$$

uniformly in j. Since ρ_n is a probability measure,

$$|\, m_d(\rho_n) - c_d \,| = \left| \sum_j \Big((j/n)^d - \tfrac{(j)_d}{(n)_d} \Big) p_{n,j} \right| \;\le\; \frac{\binom{d}{2}}{n-d} \;\xrightarrow[n\to\infty]{}\; 0.$$

Thus $m_d(\rho_n) \to c_d$ for every fixed $d \ge 0$ (the case $d = 0$ being $m_0(\rho_n) = 1 = c_0$).

Passage to the limit. The measures ρ_n are supported in the compact interval $[0,1] \subset \mathbb{R}$, so the family is tight with second moments bounded by 1; by the $\mathcal{W}_1$-compactness criterion (theorem D.12) it is relatively compact in $(\mathcal{P}_1, \mathcal{W}_1)$, and $\mathcal{W}_1$ metrises weak convergence (theorem D.11). Extract a subsequence $\rho_{n_\ell} \to \rho$ weakly, with ρ a Borel probability measure; as each ρ_{n_ℓ} is carried by the closed set $[0,1]$, so is ρ. For each fixed d the function $r \mapsto r^d$ is bounded and continuous on $[0,1]$, so weak convergence gives $\int_0^1 r^d\, \rho(\mathrm{d}r) = \lim_\ell m_d(\rho_{n_\ell}) = c_d$. Hence $c_d = \int_0^1 r^d\, \rho(\mathrm{d}r)$ for all $d \ge 0$, as required.

Uniqueness. If ρ, ρ' are probability measures on $[0,1]$ with the same moments, then $\int p\, \mathrm{d}\rho = \int p\, \mathrm{d}\rho'$ for every polynomial p; by the Weierstrass approximation theorem polynomials are uniformly dense in $C[0,1]$, so $\int \phi\, \mathrm{d}\rho = \int \phi\, \mathrm{d}\rho'$ for all $\phi \in C[0,1]$, and a Borel measure on a compact metric space is determined by its integrals against continuous functions. Hence $\rho = \rho'$. □

Remark F.15 (The rank-one realization used in worked computation 16.24)**.** Given a Hausdorff moment sequence (c_d) with $c_0 = 1$, theorem F.14 produces a probability measure ρ on $[0,1]$ with $c_d = \int_0^1 r^d\, \rho(\mathrm{d}r)$. Let $G_\rho(t) = \inf\{r : \rho([0,r]) \ge t\}$ be the quantile (generalized inverse) of ρ; then $f := G_\rho \colon [0,1] \to [0,1]$ is measurable, nondecreasing, and pushes Lebesgue measure forward to ρ, so $c_d = \int_0^1 f(t)^d\, \mathrm{d}t$. The rank-one graphon $W(x,y) = f(x)f(y)$ then realizes the profile (16.3), $t(F,W) = \prod_{i \in V(F)} c_{\deg_F(i)}$. This is the in-book justification for the "exactly the Hausdorff moment condition" claim of remark 16.23 and worked computation 16.24, with no external appeal.

Bibliographic notes

The cut norm, the weak regularity lemma in the form used here, the sampling lemma, the compactness theorem, and the equivalence of cut and left convergence are due to Lovász and Szegedy and to Borgs, Chayes, Lovász, Sós, and Vesztergombi; see [100] and the comprehensive treatment in [99], whose Chapters 9–11 contain the sharp constants and the $O(1/\sqrt{\log k})$ sampling rate quoted in remark F.8. The energy-increment proof of weak regularity follows Frieze and Kannan; the completeness argument via weak-$*$ compactness of the L^∞ ball is the functional-analytic route emphasized in chapter 2. The Hausdorff moment theorem (theorem F.14) is classical; the constructive proof through the binomial "moment-difference" measures ρ_n is Hausdorff's own, and the complete-monotonicity criterion is standard in any treatment of the moment problem (see, e.g., [99, Ch. 7] for the graph-limit connection used in chapter 16).

Appendix G

Convergence of N-Player Equilibria: The Compactness Route

This appendix supplies the in-book proof of the qualitative convergence theorem theorem 13.9: limit points of (approximate) N-player Nash equilibria are mean field equilibria, and under Lasry–Lions monotonicity the limit is the unique MFG solution and the system propagates chaos. chapter 13 states the theorem and names the four moving parts of its proof — relaxed-control compactness, path-space tightness, martingale-optimality identification, and uniqueness — but defers the argument here so as not to interrupt its narrative. Nothing below is assumed from outside the book: tightness rests on the Kolmogorov–Chentsov estimate of theorem C.9 and Prokhorov's theorem (theorem 3.16); the martingale formulation rests on Itô's formula (theorem 5.9); uniqueness is imported from the monotonicity theory of chapter 11. External references (Lacker [89, 90], Fischer [67], Carmona–Delarue [40, Ch. 6]) are for attribution only.

We work with the N-player data of eq. (13.2)–eq. (13.3) under the standing assumptions (A-Lip), (A-Growth), (A-Nondeg), (A-Conv), with the coefficients b, σ, L, g continuous, the action set $A \subseteq \mathbb{R}^k$ closed, and the running cost coercive in the control ($L(x, m, \alpha) \geq c_0|\alpha|^q - c_1$ for some $q > 1$, $c_0 > 0$, part of (A-Growth)). Throughout, W denotes Brownian motion (no graphon is in scope), $m_0 \in \mathcal{P}_2(\mathbb{R}^d)$ is the common initial law, and $\mathcal{P}(\mathcal{X})$ carries the topology of weak convergence on a Polish space $\mathcal{X}$.

G.1 Relaxed controls and the canonical path space

The obstruction to a direct limit is that the space of *strict* controls $\alpha : [0, T] \to A$ is not compact: a minimizing sequence of controls may oscillate ever faster and fail to converge. The standard remedy — due to Young, and the technical backbone of the compactness method — is to enlarge the control to a *measure* on the action set at each time, which restores compactness while leaving the value of every linear-in-control quantity unchanged.

Definition G.1 (Relaxed control)**.** A *relaxed control* is a measure ρ on $[0, T] \times A$ whose time-marginal is Lebesgue measure, i.e. $\rho(\mathrm{d}t, \mathrm{d}\alpha) = \rho_t(\mathrm{d}\alpha)\,\mathrm{d}t$ for a measurable family of probability measures $(\rho_t)_{t\in[0,T]}$ on A. We write $\mathcal{R}$ for the set of relaxed controls with $\int_0^T \int_A |\alpha|^q \, \rho_t(\mathrm{d}\alpha)\ \mathrm{d}t \le \Lambda$ for a fixed but arbitrary $\Lambda < \infty$, topologized by weak convergence of measures on $[0,T]\times A$ (equivalently, stable convergence). A strict control $\alpha(\cdot)$ embeds as $\rho_t = \delta_{\alpha(t)}$.

In relaxed form the controlled dynamics and cost read, with the coefficients averaged against ρ_t,

$$\mathrm{d}X_t = \Big(\int_A b(X_t, m_t, \alpha)\, \rho_t(\mathrm{d}\alpha)\Big)\, \mathrm{d}t + \sigma(X_t, m_t)\ \mathrm{d}W_t, \tag{G.1}$$

$$J(\rho) = \mathbb{E}\bigg[\int_0^T \int_A L(X_t, m_t, \alpha)\, \rho_t(\mathrm{d}\alpha)\ \mathrm{d}t + g(X_T, m_T)\bigg]. \tag{G.2}$$

Because b enters eq. (G.1) linearly and L enters eq. (G.2) linearly in ρ_t, no relaxed control beats the infimum over strict controls (the *chattering lemma*: a strict control may be chosen with cost within any ε of a relaxed one), so passing to relaxed controls changes no value.

Lemma G.2 (Compactness of relaxed controls)**.** *If A is compact, $\mathcal{R}$ is compact and metrizable for the topology of definition G.1. If A is merely closed, then the sublevel set $\mathcal{R}_\Lambda = \{\rho : \int_0^T \int |\alpha|^q \rho_t(\mathrm{d}\alpha)\, \mathrm{d}t \le \Lambda\}$ is compact for each $\Lambda < \infty$.*

Proof. For compact A the space $[0,T]\times A$ is compact Polish, so $\mathcal{P}([0,T]\times A)$ is compact for the weak topology (theorem 3.16 with a trivially tight family on a compact space). The constraint that the time-marginal be Lebesgue measure is closed under weak convergence (it is the intersection of the closed conditions $\int f(t)\, \rho(\mathrm{d}t, A) = \int_0^T f$ over a countable convergence-determining set of $f \in C([0,T])$), so $\mathcal{R}$ is a closed subset of a compact set, hence compact; metrizability is that of $\mathcal{P}(\cdot)$ on a compact Polish space. For closed A, the moment bound $\int |\alpha|^q \rho_t\ \mathrm{d}t \le \Lambda$ is a tightness condition in the A-direction (Markov's inequality: $\rho(\{|\alpha| > R\}) \le \Lambda/R^q$ uniformly), so $\mathcal{R}_\Lambda$ is tight on $[0,T]\times A$; combined with the closedness of the Lebesgue-marginal constraint and Prokhorov, it is compact. $\square$

The natural state space for the limit is the set of probability measures on the *canonical path–control space*

$$\Omega^{\mathrm{can}} \ := \ C([0,T];\mathbb{R}^d) \times \mathcal{R},$$

a Polish space; the coordinate process is (X,ρ) with X the continuous path and ρ the relaxed control. An N-player equilibrium induces, for each agent, a law on Ω^{can}; symmetry lets us encode the whole configuration through the *empirical measure on path space* $\boldsymbol{\mu}^N = \frac{1}{N}\sum_i \delta_{(X^i,\rho^i)} \in \mathcal{P}(\Omega^{\mathrm{can}})$, whose law $P^N = \mathcal{L}(\boldsymbol{\mu}^N)$ is the object theorem 13.9 calls tight.

G.2 Path-space tightness

Tightness of (P^N) is *not* a consequence of moment bounds alone: P^N lives on laws over the path space $C([0,T];\mathbb{R}^d)$, and tightness there is an equicontinuity (Arzelà–Ascoli) statement, which the Kolmogorov–Chentsov estimate supplies. We first record the criterion, then verify its hypothesis from the dynamics.

Proposition G.3 (Kolmogorov–Chentsov tightness on path space)**.** *Let $(Y^n)_n$ be continuous $\mathbb{R}^d$-valued processes on $[0,T]$ with laws $\mu_n \in \mathcal{P}(C([0,T];\mathbb{R}^d))$. Suppose*

1. *the initial laws $\mathcal{L}(Y_0^n)$ are tight on $\mathbb{R}^d$; and*
2. *there are constants $p > 0$, $\gamma > 0$, $C < \infty$, independent of n, with*

$$\mathbb{E}\,|Y_t^n - Y_s^n|^p \;\le\; C\,|t-s|^{1+\gamma} \qquad \text{for all } s,t \in [0,T],\; n. \tag{G.3}$$

Then (μ_n) is tight on $C([0,T];\mathbb{R}^d)$.

Proof. By Markov's inequality the increment bound eq. (G.3) controls the modulus of continuity uniformly in n: the quantitative Kolmogorov–Chentsov estimate (theorem C.9, in its quantitative form) gives, for each $\alpha < \gamma/p$ and $\eta > 0$, a constant K with $\mathbb{E}\big[\sup_{|t-s|\le h} |Y_t^n - Y_s^n|/h^\alpha\big] \le K$ uniformly in n and h, so that $\sup_n \mathbb{P}\big(\sup_{|t-s|\le h} |Y_t^n - Y_s^n| > \varepsilon\big) \to 0$ as $h \to 0$ for each $\varepsilon > 0$. This equicontinuity-in-probability, together with the tightness of the initial marginals (1), is exactly the hypothesis of the Arzelà–Ascoli characterization of compact sets in $C([0,T];\mathbb{R}^d)$: for every δ there is a compact $K_\delta \subset C([0,T];\mathbb{R}^d)$ — a set of uniformly bounded, uniformly equicontinuous paths — with $\inf_n \mu_n(K_\delta) \ge 1-\delta$. Hence (μ_n) is tight. ☐

Lemma G.4 (The increment bound holds)**.** *For the equilibrium state processes $(X^{i,N})$ of the N-player game under any ε_N-Nash profile with $\sup_N \varepsilon_N < \infty$, the uniform fourth moment $\sup_{N,i} \mathbb{E} \sup_{t\le T} |X_t^{i,N}|^4 < \infty$ holds, and the increment bound eq. (G.3) holds with $p = 4$, $\gamma = 1$, uniformly in N, i. Consequently (P^N) is tight on $\mathcal{P}(\Omega^{\mathrm{can}})$.*

Proof. Moment bound. An ε_N-Nash deviator can secure at most the no-control cost, so coercivity of L in α ((A-Growth)) bounds $\mathbb{E}\int_0^T\!\int |\alpha|^q \rho_t^i \,\mathrm{d}t$ uniformly in N, i; the linear growth of b, σ then yields $\sup_{N,i} \mathbb{E}\sup_t |X_t^{i,N}|^4 < \infty$ by Itô (theorem 5.9), the Burkholder–Davis–Gundy inequality (theorem C.2) and Grönwall (appendix C.1), exactly as in the SDE estimate of theorem 5.10, the initial fourth moment being finite because $m_0 \in \mathcal{P}_2(\mathbb{R}^d)$ is strengthened to a finite moment of order > 2 under (A-Growth).

Increment bound. For $s < t$, $X_t^{i,N} - X_s^{i,N} = \int_s^t \bar b_r^i \,\mathrm{d}r + \int_s^t \sigma(X_r^{i,N}, \mu_r^N)\,\mathrm{d}W_r^i$, where $\bar b_r^i = \int b(X_r^{i,N}, \mu_r^N, \alpha)\rho_r^i(\mathrm{d}\alpha)$. By linear growth and the moment bound, $\mathbb{E}\big|\int_s^t \bar b_r^i \,\mathrm{d}r\big|^4 \le |t-s|^3 \mathbb{E}\int_s^t |\bar b_r^i|^4 \,\mathrm{d}r \le C|t-s|^4$ (Jensen/Hölder), and by BDG and the boundedness of σ on the relevant range, $\mathbb{E}\big|\int_s^t \sigma \,\mathrm{d}W^i\big|^4 \le C\,\mathbb{E}\big(\int_s^t |\sigma|^2 \,\mathrm{d}r\big)^2 \le C|t-s|^2$. Hence $\mathbb{E}|X_t^{i,N} - X_s^{i,N}|^4 \le C|t-s|^2$, i.e. eq. (G.3) with $p = 4$, $\gamma = 1$, uniformly in N, i.

Tightness of P^N. The control components live in the compact (or Λ-sublevel) set $\mathcal{R}$ of lemma G.2, which is tight by construction; the path components are tight by proposition G.3. A product of tight families is tight, so the single-agent laws are tight on Ω^{can}, and by exchangeability and a standard de Finetti/Sznitman argument (the marginals of $\boldsymbol{\mu}^N$ are the single-agent laws, and tightness of marginals on a Polish space gives tightness of the empirical-measure laws, theorem 3.16) the family $P^N = \mathcal{L}(\boldsymbol{\mu}^N)$ is tight on $\mathcal{P}(\Omega^{\mathrm{can}})$. ☐

G.3 The limiting martingale problem

We now say what a limit point *is*. The right notion of solution is a probability measure on Ω^{can} that (i) is consistent with the dynamics, encoded as a martingale problem, (ii) places its state-marginal flow at the population it interacts with (the fixed-point/consistency constraint), and (iii) is optimal for the representative agent. This is the relaxed/weak mean field equilibrium that theorem 13.9 refers to.

Definition G.5 (Weak (relaxed) mean field equilibrium)**.** Let $m = (m_t)_{t\in[0,T]}$ be a continuous flow in $\mathcal{P}_2(\mathbb{R}^d)$ and let $Q \in \mathcal{P}(\Omega^{\mathrm{can}})$ with coordinate process (X, ρ). The pair (Q, m) is a *weak mean field equilibrium* if:

1. (Dynamics.) For every $\phi \in C_b^2(\mathbb{R}^d)$, the process

$$M_t^\phi \;:=\; \phi(X_t)-\phi(X_0)-\int_0^t\!\!\int_A \Big(b(X_r, m_r, \alpha)\cdot\nabla\phi(X_r)+\tfrac{1}{2}\,\mathrm{tr}\,\big(\sigma\sigma^\top(X_r, m_r)\,\mathrm{D}^2\,\phi(X_r)\big)\Big)\rho_r(\mathrm{d}\alpha)\;\mathrm{d}r \tag{G.4}$$

   is a Q-martingale in the canonical filtration, and $\mathcal{L}_Q(X_0) = m_0$;

2. (Consistency.) $\mathcal{L}_Q(X_t) = m_t$ for all $t \in [0, T]$;

3. (Optimality.) ρ minimizes eq. (G.2) against the frozen flow m among all relaxed controls adapted to (X, W); equivalently, Q-almost surely ρ_r is supported on the Hamiltonian maximizers $\alpha^*(X_r, \nabla u(r, X_r), m_r)$ of eq. (13.5), where u solves the HJB equation against m.

When $\rho_r = \delta_{\widehat{\alpha}(r,X_r)}$ is a Dirac feedback, (Q, m) is the ordinary (strong) MFG solution of chapters 8 and 9.

Condition (1) is the relaxed controlled martingale problem; that it is equivalent to X solving eq. (G.1) on a (possibly enlarged) space is the standard martingale-problem/weak-existence equivalence, which under (A-Nondeg) follows from Itô's formula (theorem 5.9) one way and from a representation theorem the other; we use only the martingale direction, which is closed under weak limits.

G.4 Identification of limit points

Lemma G.6 (Limit points are weak MFG equilibria)**.** *Assume* (A-Lip), (A-Growth), (A-Nondeg), (A-Conv) *with continuous coefficients, and let $\boldsymbol{\alpha}^{*,N}$ be an ε_N-Nash equilibrium with $\varepsilon_N \to 0$. Let P^∞ be any weak limit point of (P^N) along a subsequence (which exists by lemma G.4), and let Π be the (random) empirical measure under P^∞, a $\mathcal{P}(\Omega^{\mathrm{can}})$-valued random variable. Then P^∞-almost surely* Π *is the law of a weak mean field equilibrium* (Π, m^Π) *in the sense of definition G.5, with $m_t^\Pi = (\mathrm{ev}_t)_\# \Pi$ its state-marginal flow.*

Proof. Fix a subsequence along which $P^N \Rightarrow P^\infty$. Three properties pass to the limit.

(i) Dynamics. For $\phi \in C_b^2(\mathbb{R}^d)$ and $0 \le s < t \le T$ and a bounded continuous functional G of $(X_r, \rho)_{r \le s}$, the map $\nu \mapsto \mathbb{E}_\nu[(M_t^\phi - M_s^\phi)G]$ — with M^ϕ as in eq. (G.4) but with m replaced by the state-marginal flow of ν — is bounded and continuous on $\mathcal{P}(\Omega^{\mathrm{can}})$, because $b, \sigma, \nabla\phi, \mathrm{D}^2\,\phi$ are continuous and the moment bound of lemma G.4 gives uniform integrability (the increments eq. (G.4) are uniformly integrable by the fourth-moment bound). Under each P^N the agent-i marginal makes M^ϕ a martingale up to an $o(1)$ error from μ^N versus $\mu^{N,-i}$ (one atom, eq. (13.11)); passing to the limit, $\mathbb{E}_{P^\infty}[\,\mathbb{E}_\Pi[(M_t^\phi - M_s^\phi)G]\,] = 0$ for all such G, i.e. M^ϕ is a Π-martingale P^∞-a.s. This is condition (1) of definition G.5.

(ii) Consistency. By construction the state-marginal flow of Π is the limit of the empirical-measure flow, so $m_t^\Pi = (\mathrm{ev}_t)_\# \Pi$ and the interaction in (i) is against m^Π itself; this is condition (2).

(iii) Optimality. Here the $\varepsilon_N \to 0$ hypothesis does its work. Each agent is ε_N-optimal against the field it sees; the value of the best response against a *fixed* continuous flow is, by the stability of the control problem under (A-Lip)/(A-Nondeg), a continuous functional of the flow, and the cost $J(\cdot)$ is lower semicontinuous in the relaxed control (eq. (G.2), with L continuous and bounded below). Passing to the limit in the ε_N-optimality inequality — asymptotic optimality becomes exact in the limit — gives that Π-a.s. the relaxed control ρ attains the representative-agent infimum against m^Π. By the verification theorem of chapter 6 (and (A-Conv), making the Hamiltonian maximizer unique) this forces ρ_r onto the maximizer $\alpha^*(X_r, \nabla u, m_r^\Pi)$, condition (3).

Thus every limit point is supported on weak mean field equilibria. □

G.5 Uniqueness, determinism, and chaos

The compactness argument identifies the support of the limit but not its *value*: a priori several weak equilibria could carry the limit mass, and the empirical measure could remain random in the limit (this is exactly the closed-loop subtlety of remark 13.10). Monotonicity removes the ambiguity.

Theorem G.7 (Uniqueness collapses the limit)**.** *Add the Lasry–Lions monotonicity* (A-Mon) *of chapter 11. Then the weak mean field equilibrium of definition G.5 is unique, its state flow m coincides with the unique MFG solution of chapters 8 and 9, and the relaxed control is the Dirac feedback $\delta_{\widehat{\alpha}}$ of the strong solution.*

Proof. Two weak equilibria (Q, m), (Q', m') each induce, via the optimality condition (3) and the verification theorem of chapter 6, an HJB value u (resp. u') against the frozen flow m (resp. m'), and the consistency condition (2) makes the state flow the law of the optimally controlled process — i.e. each pair solves the MFG system eq. (12.2). The Lasry–Lions computation of chapter 11 (pairing the difference of the two HJB equations with the difference of the two Fokker–Planck equations and invoking the monotonicity inequality eq. (11.3)) gives $m = m'$ and $u = u'$; in particular the equilibrium control is the deterministic feedback $\widehat{\alpha}$, so the relaxed control degenerates to a Dirac. Uniqueness of the weak equilibrium follows. □

Theorem G.8 (Qualitative convergence and propagation of chaos)**.** *Under* (A-Lip)*,* (A-Growth)*,* (A-Nondeg)*,* (A-Conv) *with continuous coefficients, the family* (P^N) *of lemma G.4 is tight and every limit point is supported on weak mean field equilibria. If in addition* (A-Mon) *holds, then* $\mu^N \to m$ *in distribution, the limit being the* deterministic *flow of the unique MFG solution, and the finite marginals propagate chaos:* $\mathcal{L}(X_t^{1,N}, \dots, X_t^{k,N}) \to m_t^{\otimes k}$ *weakly for each fixed* k*. This is theorem 13.9.*

Proof. Tightness is lemma G.4; the support of every limit point is identified by lemma G.6. Under (A-Mon), theorem G.7 shows the support is the single deterministic equilibrium m. A sequence of $\mathcal{P}(\Omega^{\mathrm{can}})$-valued random variables whose every subsequential limit is the constant $\delta_{(\,\cdot\,)}$ supported at one deterministic flow converges in distribution to that constant; convergence in distribution to a constant is convergence in probability, so $\mu^N \to m$ in probability, hence in distribution. Finally, convergence of the empirical measure to a deterministic limit is equivalent, for exchangeable systems, to chaoticity of the finite marginals (definition 7.11 and the equivalence recorded in chapter 7), which is the stated k-marginal convergence. □

Remark G.9 (Why this route gives no rate)**.** The argument is qualitative by nature: compactness produces a convergent subsequence but no modulus of convergence, and the identification step uses only continuity, not any quantitative stability. A rate requires the master-equation route of section 13.5.3, which trades the minimal hypotheses here for the strong regularity of theorem 12.8 and obtains the $1/N$ value rate eq. (13.22). The trade-off — minimal assumptions and no rate versus strong assumptions and a sharp rate — is the organizing dichotomy of section 13.5.

Bibliographic notes

The relaxed-control compactness method for mean field games is due to Lacker [89] (closed-loop and the general martingale-problem formulation) and [90] (the closed-loop limit and the larger set of attainable weak equilibria), with the open-loop case treated by Fischer [67]; an exposition is Carmona and Delarue [40, Vol. I, Ch. 6]. The relaxation of controls originates with Young; the martingale-problem viewpoint is that of Stroock and Varadhan, here specialized to the McKean–Vlasov setting. The path-space tightness criterion of proposition G.3 is the Kolmogorov–Chentsov/Arzelà–Ascoli route proved in-book at theorem C.9; the uniqueness collapse is the Lasry–Lions monotonicity theory of chapter 11.

Appendix H

Poisson Point Processes: Definitions and the Calculus We Use

This appendix supplies, from first principles, the point-process facts that chapter 27 uses in its treatment of sparse and graphex limits: the definition of a Poisson point process, the first-order Campbell formula and the two-point Mecke / factorial moment formula, the mapping, thinning, marking and superposition theorems, the Poisson limit theorem (law of rare events) for triangular arrays of independent indicators, and the mixed-Poisson tail-transfer lemma that turns a heavy-tailed mixing law into a heavy-tailed count. None of this is assumed of the reader beyond undergraduate probability and the basic Lebesgue theory of chapter 1; everything is proved here. The standard textbook references, used only for attribution and further reading, are [95, 84] for the point-process calculus and [24] for regular variation.

Throughout, $(E, \mathcal{E})$ is a measurable space equipped with a σ-finite measure λ (the *intensity*); in the applications $E = \mathbb{R}_+$ or $E = \mathbb{R}_+^2$ with λ Lebesgue. A *point measure* on E is a measure of the form $\eta = \sum_i \delta_{p_i}$ with $\eta(A) \in \{0, 1, 2, \ldots, \infty\}$ for every $A \in \mathcal{E}$, i.e. a (multi)set of points $\{p_i\} \subset E$ counted with multiplicity; we write $\eta(A)$ for the number of points in A and $\int f \, d\eta = \sum_i f(p_i)$.

H.1 Definition and Campbell's formula

Definition H.1 (Poisson point process)**.** A *Poisson point process* (PPP) on E with σ-finite intensity λ is a random point measure Π such that

1. for every $A \in \mathcal{E}$ with $\lambda(A) < \infty$, the count $\Pi(A)$ has the Poisson law $\mathrm{Poisson}(\lambda(A))$ (and $\Pi(A) = \infty$ a.s. if $\lambda(A) = \infty$);
2. for every finite family of pairwise disjoint sets $A_1, \ldots, A_n \in \mathcal{E}$, the counts $\Pi(A_1), \ldots, \Pi(A_n)$ are independent.

We call Π a *unit-rate* PPP when $E = \mathbb{R}_+^d$ and λ is Lebesgue measure.

Existence is standard: on a set of finite intensity one draws a Poisson($\lambda(A)$) number of points i.i.d. from the normalized intensity $\lambda(\cdot \cap A)/\lambda(A)$, and a σ-finite E is exhausted by a disjoint countable union of finite-intensity sets on which independent such processes are superposed (theorem H.7). We take existence as given and record only the calculus.

Theorem H.2 (Campbell's formula; first-order Mecke)**.** *Let* Π *be a PPP on* E *with intensity* λ*, and let* $f \colon E \to [0, \infty]$ *be measurable. Then*

$$\mathbb{E}[*] \int_E f \,\mathrm{d}\Pi = \mathbb{E}[*] \sum_{p \in \Pi} f(p) = \int_E f \,\mathrm{d}\lambda. \tag{H.1}$$

For signed or complex f *the identity holds whenever* $\int |f| \,\mathrm{d}\lambda < \infty$*.*

Proof. For an indicator $f = \mathbf{1}_A$ with $\lambda(A) < \infty$, the left side is $\mathbb{E}[\Pi(A)] = \lambda(A)$ because $\Pi(A) \sim$ Poisson($\lambda(A)$), so (H.1) holds; if $\lambda(A) = \infty$ both sides are $+\infty$. By linearity of expectation and of the integral it holds for nonnegative simple functions $f = \sum_k c_k \mathbf{1}_{A_k}$. A general measurable $f \geq 0$ is an increasing pointwise limit of simple functions $f_n \uparrow f$; both sides of (H.1) pass to the limit by the monotone convergence theorem (applied to the expectation on the left and to the integral on the right). The signed case follows by splitting $f = f^+ - f^-$ under $\int |f| \,\mathrm{d}\lambda < \infty$. □

The second-order analogue is what powers the edge count of proposition 27.14. We phrase it as the statement that the *second factorial moment measure* of a PPP is the product $\lambda \otimes \lambda$.

Theorem H.3 (Two-point Mecke / factorial moment formula)**.** *Let* Π *be a PPP on* E *with intensity* λ *and let* $h \colon E \times E \to [0, \infty]$ *be measurable. Writing* $\sum^{\neq}_{p,p' \in \Pi}$ *for the sum over* ordered *pairs of* distinct *points of* Π*,*

$$\mathbb{E}[*] \sum^{\neq}_{p,p' \in \Pi} h(p, p') = \int_E \int_E h(p, p') \,\lambda(\mathrm{d}p) \,\lambda(\mathrm{d}p'). \tag{H.2}$$

If h *is symmetric, the sum over* unordered *pairs* $\{p, p'\}$ *equals half the left side, so* $\mathbb{E}\Big[\sum_{\{p,p'\} \subset \Pi} h\Big] = \frac{1}{2} \iint h \,\mathrm{d}\lambda \,\mathrm{d}\lambda$*.*

Proof. First take $h = \mathbf{1}_{A \times B}$ with $\lambda(A), \lambda(B) < \infty$. If $A \cap B = \varnothing$, then by the independence of $\Pi(A)$ and $\Pi(B)$ (definition H.1(2)),

$$\mathbb{E}[*] \sum^{\neq}_{p,p'} \mathbf{1}_A(p) \mathbf{1}_B(p') = \mathbb{E}[\Pi(A)\,\Pi(B)] = \mathbb{E}[\Pi(A)]\,\mathbb{E}[\Pi(B)] = \lambda(A)\lambda(B),$$

since for ordered distinct pairs with $p \in A$, $p' \in B$ and A, B disjoint there is no diagonal contribution. If $A = B$, the ordered distinct pairs number $\Pi(A)(\Pi(A) - 1)$, and for $Z \sim$ Poisson(μ) one has $\mathbb{E}[Z(Z-1)] = \mu^2$ (the second factorial moment of a Poisson law); hence $\mathbb{E}\Big[\sum^{\neq} \mathbf{1}_{A \times A}\Big] = \lambda(A)^2$. The two cases together give (H.2) for all rectangles $A \times B$ by additivity in each argument over a partition into disjoint pieces. Rectangles generate $\mathcal{E} \otimes \mathcal{E}$ and the two sides of (H.2) are measures in h that agree on this generating π-system of finite-intensity rectangles; by the monotone class / π–λ theorem they agree for all indicators, hence for simple $h \geq 0$ by linearity and for all measurable $h \geq 0$ by monotone convergence. The unordered statement is the ordered one divided by two, valid because each unordered pair $\{p, p'\}$ of distinct points is counted twice on the left of (H.2). □

H.2 Mapping, thinning, marking, superposition

These four operations are the structural toolkit. Each is proved by checking the two defining properties of definition H.1 directly.

Theorem H.4 (Mapping theorem). *Let Π be a PPP on E with intensity λ and let $T\colon E \to E'$ be measurable such that the pushforward $\lambda' := \lambda \circ T^{-1}$ is σ-finite. Then the image point process $T(\Pi) := \sum_{p\in\Pi} \delta_{T(p)}$ is a PPP on E' with intensity λ'.*

Proof. For $A' \in \mathcal{E}'$, $T(\Pi)(A') = \Pi(T^{-1}A')$, so it is $\mathrm{Poisson}(\lambda(T^{-1}A')) = \mathrm{Poisson}(\lambda'(A'))$, giving property (1). If $A'_1, \dots, A'_n$ are pairwise disjoint, their preimages $T^{-1}A'_1, \dots, T^{-1}A'_n$ are pairwise disjoint in E, so the counts $\Pi(T^{-1}A'_i)$ are independent by definition H.1(2), giving property (2). □

Theorem H.5 (Marking theorem). *Let $\Pi = \sum_i \delta_{p_i}$ be a PPP on E with intensity λ, and attach to each point p_i an independent* mark *$M_i \in F$ drawn from a probability kernel $K(p_i, \mathrm{d}m)$ (independently across points given Π). Then the marked process $\Pi^* = \sum_i \delta_{(p_i,M_i)}$ is a PPP on $E \times F$ with intensity $\lambda^*(\mathrm{d}p\ \mathrm{d}m) = \lambda(\mathrm{d}p)\, K(p, \mathrm{d}m)$.*

Proof. We verify definition H.1 for Π^*. For disjoint product sets it suffices, by a monotone class argument, to compute joint Laplace functionals. Condition on Π; for measurable $g\colon E \times F \to [0, \infty)$,

$$\mathbb{E}[*]\, e^{-\sum_i g(p_i,M_i)} \,|\, \Pi = \prod_i \int_F e^{-g(p_i,m)} K(p_i, \mathrm{d}m) = \prod_i e^{-\tilde{g}(p_i)},$$

where $\tilde{g}(p) := -\log \int_F e^{-g(p,m)} K(p, \mathrm{d}m)$. Taking expectations and using the Poisson Laplace functional $\mathbb{E}\Big[e^{-\sum_i \tilde{g}(p_i)}\Big] = \exp\big(-\int_E (1 - e^{-\tilde{g}})\, \mathrm{d}\lambda\big)$ (which is (H.1) exponentiated, equivalently the characteristic functional of a PPP, established by the same simple-function/MCT argument as theorem H.2 applied to $1 - e^{-\tilde{g}}$),

$$\mathbb{E}[*]\, e^{-\sum_i g(p_i,M_i)} = \exp\Big(-\int_E (1 - e^{-\tilde{g}(p)})\, \mathrm{d}\lambda(p)\Big) = \exp\Big(-\int_{E\times F} (1 - e^{-g(p,m)})\lambda(\mathrm{d}p)K(p, \mathrm{d}m)\Big),$$

which is exactly the Laplace functional of a PPP on $E \times F$ with intensity λ^*. A random point measure with the Poisson Laplace functional is a PPP, so Π^* is as claimed. □

Theorem H.6 (Thinning theorem). *Let Π be a PPP on E with intensity λ, and retain each point p independently with probability $\varpi(p) \in [0, 1]$ (a measurable* retention *function), deleting it otherwise. Then the retained points form a PPP with intensity $\varpi\, \lambda$, the deleted points form a PPP with intensity $(1 - \varpi)\lambda$, and the two are independent.*

Proof. Mark each point with $M \in \{0, 1\}$, $\mathbb{P}(M = 1 \mid p) = \varpi(p)$ (a Bernoulli kernel). By theorem H.5 the marked process is a PPP on $E \times \{0, 1\}$ with intensity $\lambda(\mathrm{d}p)(\varpi(p)\delta_1 + (1 - \varpi(p))\delta_0)$. The retained process is its restriction to $E \times \{1\}$, mapped to E by the projection; by theorem H.4 it is a PPP with intensity $\varpi\lambda$, and likewise the deleted process has intensity $(1 - \varpi)\lambda$. They are supported on the disjoint marks $\{1\}$ and $\{0\}$ of a single PPP, hence are counts over disjoint sets and so independent by definition H.1(2). □

Theorem H.7 (Superposition)**.** *If $\Pi_1, \Pi_2, \dots$ are independent PPPs on E with intensities $\lambda_1, \lambda_2, \dots$ and $\lambda := \sum_k \lambda_k$ is σ-finite, then $\Pi := \sum_k \Pi_k$ is a PPP with intensity λ.*

Proof. For A with $\lambda(A) < \infty$, $\Pi(A) = \sum_k \Pi_k(A)$ is a sum of independent $\text{Poisson}(\lambda_k(A))$ variables, hence $\text{Poisson}(\sum_k \lambda_k(A)) = \text{Poisson}(\lambda(A))$ by the additivity of the Poisson law under independent sums. Independence over disjoint sets is inherited from that of each Π_k together with the independence across k. □

H.3 The Poisson limit theorem (law of rare events)

The mixed-Poisson degree limits of propositions 27.2 and 27.14 rest on the convergence of a sum of many independent, individually rare indicators to a Poisson law. The sharp, fully quantitative statement is Le Cam's inequality, from which the limit theorem is an immediate corollary; both are proved by coupling.

Lemma H.8 (Le Cam's inequality)**.** *Let $X_1, \dots, X_n$ be independent Bernoulli variables with $\mathbb{P}(X_j = 1) = p_j \in [0,1]$, and let $S = \sum_{j=1}^n X_j$ and $\Lambda = \sum_{j=1}^n p_j$. Then the total-variation distance to a Poisson law obeys*

$$d_{\text{TV}}(\mathcal{L}(S),\, \text{Poisson}(\Lambda)) \le \sum_{j=1}^n p_j^2. \tag{H.3}$$

Proof. Total variation distance is subadditive under independent convolution: if $\mathcal{L}(S) = *_j \mathcal{L}(X_j)$ and $\text{Poisson}(\Lambda) = *_j \text{Poisson}(p_j)$ (the latter by Poisson additivity), then $d_{\text{TV}}(\mathcal{L}(S), \text{Poisson}(\Lambda)) \le \sum_j d_{\text{TV}}(\text{Bernoulli}(p_j), \text{Poisson}(p_j))$. It remains to bound a single term, and this we do exactly. Writing b_k for the Bernoulli(p) mass ($b_0 = 1-p$, $b_1 = p$, $b_k = 0$ for $k \ge 2$) and $\pi_k = e^{-p}p^k/k!$ for the Poisson(p) mass,

$$d_{\text{TV}}(\text{Bernoulli}(p), \text{Poisson}(p)) = \tfrac{1}{2}\sum_{k \ge 0} |b_k - \pi_k| = \tfrac{1}{2}\Big((e^{-p} - (1-p)) + (p - pe^{-p}) + (1 - e^{-p} - pe^{-p})\Big),$$

using $e^{-p} \ge 1-p$ (so $|b_0 - \pi_0| = e^{-p} - (1-p)$), $1 \ge e^{-p}$ (so $|b_1 - \pi_1| = p - pe^{-p}$), and $\sum_{k\ge 2} \pi_k = 1 - e^{-p} - pe^{-p}$. The three terms collapse to $\frac{1}{2}(2p - 2pe^{-p}) = p(1-e^{-p}) \le p^2$, the last step by $1 - e^{-p} \le p$. Summing over j yields (H.3). □

Theorem H.9 (Poisson limit theorem for triangular arrays)**.** *For each n let $X_{n,1}, \dots, X_{n,k_n}$ be independent Bernoulli variables with $\mathbb{P}(X_{n,j} = 1) = p_{n,j}$, and set $S_n = \sum_{j=1}^{k_n} X_{n,j}$. If*

$$\Lambda_n := \sum_{j=1}^{k_n} p_{n,j} \;\longrightarrow\; \Lambda \in [0,\infty) \qquad \textit{and} \qquad \max_{1 \le j \le k_n} p_{n,j} \;\longrightarrow\; 0, \tag{H.4}$$

then $S_n \Rightarrow \text{Poisson}(\Lambda)$ in distribution.

Proof. By lemma H.8, $d_{\text{TV}}(\mathcal{L}(S_n), \text{Poisson}(\Lambda_n)) \le \sum_j p_{n,j}^2 \le (\max_j p_{n,j}) \sum_j p_{n,j} = (\max_j p_{n,j})\Lambda_n \to 0$, using (H.4) (the factor Λ_n is bounded as it converges). And $\text{Poisson}(\Lambda_n) \Rightarrow \text{Poisson}(\Lambda)$ because the Poisson probability mass function $\mu \mapsto e^{-\mu}\mu^k/k!$ is continuous in μ for each k, so pointwise convergence of the mass functions holds, which for integer-valued laws is convergence in total variation hence in distribution. Combining, $d_{\mathrm{TV}}(\mathcal{L}(S_n), \mathrm{Poisson}(\Lambda)) \to 0$. □

H.4 Mixed-Poisson tails: heavy mixing transfers to heavy counts

The last ingredient turns a heavy-tailed *mean* into a heavy-tailed *count*. It is the precise statement behind the power-law degree exponent of corollary 27.3: a Poisson variable whose random mean has a Pareto / regularly-varying tail inherits exactly that tail index, because Poisson fluctuations are negligible against a heavy mean.

Recall that a measurable $\ell\colon (0,\infty) \to (0,\infty)$ is *slowly varying* if $\ell(ct)/\ell(t) \to 1$ as $t \to \infty$ for every $c > 0$, and a tail $\mathbb{P}(\Lambda > t) = t^{-\alpha}\ell(t)$ with $\alpha > 0$ and ℓ slowly varying is *regularly varying of index* $-\alpha$ [24]; the Pareto tail $\mathbb{P}(\Lambda > t) = Ct^{-\alpha}$ is the special case $\ell \equiv C$.

Lemma H.10 (Mixed-Poisson tail transfer)**.** *Let $\Lambda \geq 0$ be a random variable with regularly-varying tail $\mathbb{P}(\Lambda > t) = t^{-\alpha}\ell(t)$, $\alpha > 0$, ℓ slowly varying, and let N be, conditionally on Λ,* Poisson(Λ)*. Then*

$$\mathbb{P}(N \geq k) \;\sim\; \mathbb{P}(\Lambda > k) \qquad (k \to \infty), \tag{H.5}$$

so N has a regularly-varying survival function of the same index $-\alpha$.

Proof. Fix $\varepsilon \in (0,1)$. For the *lower* bound, restrict to large means:

$$\mathbb{P}(N \geq k) \;\geq\; \mathbb{P}(N \geq k,\ \Lambda > (1+\varepsilon)k) \;\geq\; \mathbb{P}(\Lambda > (1+\varepsilon)k) \cdot \inf_{\mu > (1+\varepsilon)k} \mathbb{P}(\mathrm{Poisson}(\mu) \geq k).$$

For $\mu > (1+\varepsilon)k$, Chebyshev's inequality applied to Poisson(μ) (mean and variance both μ) gives $\mathbb{P}(\mathrm{Poisson}(\mu) < k) \leq \mathbb{P}(|\mathrm{Poisson}(\mu) - \mu| > \mu - k) \leq \mu/(\mu-k)^2 \leq \mu/(\varepsilon k)^2$; this does not yet vanish uniformly, so split once more: for $\mu \in \big((1+\varepsilon)k,\, k^2\big]$ the bound is $\leq k^2/(\varepsilon k)^2 = \varepsilon^{-2}$ — useless — so instead use that $\mathbb{P}(\mathrm{Poisson}(\mu) \geq k)$ is increasing in μ and at $\mu = (1+\varepsilon)k$ equals $\mathbb{P}(\mathrm{Poisson}((1+\varepsilon)k) \geq k) \to 1$ as $k \to \infty$ by the law of large numbers (the standardized Poisson is asymptotically normal, and k is $\varepsilon\sqrt{(1+\varepsilon)k} \cdot (1+o(1))$ standard deviations below the mean). Hence the infimum is $1 - o(1)$, and by regular variation $\mathbb{P}(\Lambda > (1+\varepsilon)k) \sim (1+\varepsilon)^{-\alpha}\mathbb{P}(\Lambda > k)$, so $\liminf_k \mathbb{P}(N \geq k)/\mathbb{P}(\Lambda > k) \geq (1+\varepsilon)^{-\alpha}$.

For the *upper* bound, split on the same threshold:

$$\mathbb{P}(N \geq k) \;\leq\; \mathbb{P}(\Lambda > (1-\varepsilon)k) + \mathbb{E}[*]\,\mathbb{P}(\mathrm{Poisson}(\Lambda) \geq k)\,\mathbf{1}\{\Lambda \leq (1-\varepsilon)k\}.$$

For $\mu \leq (1-\varepsilon)k$ the Chernoff bound for the Poisson upper tail, $\mathbb{P}(\mathrm{Poisson}(\mu) \geq k) \leq e^{-\mu}(e\mu/k)^k$, is increasing in $\mu \leq k$ and so is maximized at $\mu = (1-\varepsilon)k$, where it equals $\big(e^{\varepsilon}(1-\varepsilon)\big)^k$. Since $e^{\varepsilon}(1-\varepsilon) = 1 - \frac{1}{2}\varepsilon^2 + O(\varepsilon^3) < 1$ for small $\varepsilon > 0$, this is geometrically small in k, hence $o\big(\mathbb{P}(\Lambda > k)\big)$ (any regularly-varying tail of negative index dominates a geometric). Therefore, again by regular variation, $\limsup_k \mathbb{P}(N \geq k)/\mathbb{P}(\Lambda > k) \leq (1-\varepsilon)^{-\alpha}$.

Letting $\varepsilon \downarrow 0$ in the two displays gives $\mathbb{P}(N \geq k)/\mathbb{P}(\Lambda > k) \to 1$, which is (H.5); the survival function of N is then regularly varying of index $-\alpha$ by the same comparison. □

For the explicit Pareto mixing law of corollary 27.3, $\mathbb{P}(\Lambda > t) = Ct^{-1/\nu}$, lemma H.10 gives directly $\mathbb{P}(\deg \geq k) \sim C\,k^{-1/\nu}$, the power-law degree tail with index $1/\nu$ and exponent $\gamma = 1 + 1/\nu$.

Appendix I

First-Order Primal–Dual Convergence: The Chambolle–Pock Bound

This appendix supplies the one convex-optimization result that chapter 28 uses but does not prove there: the ergodic $O(1/k)$ convergence of the first-order primal–dual (Chambolle–Pock) iteration on a convex–concave saddle problem. Theorem 28.8 invokes it for the discrete potential-MFG saddle of proposition 28.7; we prove it here in full so the chapter's unconditional-convergence claim rests on an in-book argument rather than on the external citation [47]. The proof is elementary convex analysis: the proximal inequality, a telescoping sum, and one Young estimate controlled by the step-size condition. We use only finite-dimensional Euclidean spaces, which is all the discretization of section 28.4 requires; the proximal map and Moreau envelope are those of chapter 8 (section 8.6).

I.1 The saddle problem and the iteration

Let X, Y be finite-dimensional Euclidean spaces with inner products $\langle \cdot, \cdot \rangle$ and norms $\|\cdot\|$, let $K\colon X \to Y$ be linear with operator norm $L = \|K\|$, and let $g\colon X \to (-\infty, +\infty]$ and $h\colon Y \to (-\infty, +\infty]$ be proper, convex, lower semicontinuous. We treat the saddle problem

$$\min_{x \in X} \max_{y \in Y} \Big\{ \mathfrak{L}(x, y) := \langle Kx, y \rangle + g(x) - h(y) \Big\}, \tag{I.1}$$

which is the convex–concave form of the primal problem $\min_x \{g(x) + h^*(Kx)\}$, with h^* the convex conjugate of h. We assume a saddle point $(\hat{x}, \hat{y})$ exists — guaranteed for the discrete MFG problem of proposition 28.7, where g collects the (coercive, strictly convex) kinetic-plus-interaction energy, h enforces the affine continuity constraint, and K is the discrete continuity operator. The *partial primal–dual gap* on a bounded set $B_1 \times B_2 \ni (\hat{x}, \hat{y})$ is

$$\mathrm{Gap}_{B_1 \times B_2}(x, y) := \max_{y' \in B_2} \mathfrak{L}(x, y') - \min_{x' \in B_1} \mathfrak{L}(x', y) \;\geq\; 0, \tag{I.2}$$

which vanishes exactly at a saddle point and dominates, e.g., the primal suboptimality.

Recall the proximal operator $\operatorname{prox}_{\tau g}(z) = \arg\min_x\{g(x) + \frac{1}{2\tau}\|x-z\|^2\}$, single-valued for proper convex lsc g and $\tau > 0$. The Chambolle–Pock iteration with steps $\tau, \sigma > 0$ and extrapolation parameter $\theta = 1$ is

$$y^{n+1} = \operatorname{prox}_{\sigma h}\left(y^n + \sigma K\bar{x}^n\right), \tag{I.3a}$$

$$x^{n+1} = \operatorname{prox}_{\tau g}\left(x^n - \tau K^* y^{n+1}\right), \tag{I.3b}$$

$$\bar{x}^{n+1} = 2x^{n+1} - x^n, \tag{I.3c}$$

started from arbitrary (x^0, y^0) with $\bar{x}^0 = x^0$.

I.2 The proximal inequality

The engine is the following first-order characterization of the prox.

Lemma I.1 (Prox inequality)**.** *Let φ be proper convex lsc, $\tau > 0$, and $u = \operatorname{prox}_{\tau\varphi}(z)$. Then for all x,*

$$\varphi(x) + \frac{1}{2\tau}\|x-z\|^2 \;\geq\; \varphi(u) + \frac{1}{2\tau}\|u-z\|^2 + \frac{1}{2\tau}\|x-u\|^2. \tag{I.4}$$

Equivalently, $\varphi(u) - \varphi(x) \leq \frac{1}{\tau}\langle z-u, x-u\rangle$.

Proof. By definition u minimizes the $\frac{1}{\tau}$-strongly convex function $\Psi(x) = \varphi(x) + \frac{1}{2\tau}\|x-z\|^2$. Strong convexity gives, for the minimizer u, $\Psi(x) \geq \Psi(u) + \frac{1}{2\tau}\|x-u\|^2$ for all x (the defining inequality of a μ-strongly convex function at its minimizer, with $\mu = 1/\tau$), which is (I.4). Expanding $\|x-z\|^2 - \|u-z\|^2 - \|x-u\|^2 = 2\langle z-u, x-u\rangle$ gives the equivalent form. □

Apply lemma I.1 to (I.3b) with $\varphi = g$, $z = x^n - \tau K^* y^{n+1}$, $u = x^{n+1}$, and to (I.3a) with $\varphi = h$, $z = y^n + \sigma K\bar{x}^n$, $u = y^{n+1}$. Using the polarization identity $\langle a-b, c-b\rangle = \frac{1}{2}(\|a-b\|^2 + \|c-b\|^2 - \|a-c\|^2)$, the two inequalities read, for all $x \in X$ and $y \in Y$,

$$g(x^{n+1}) - g(x) \leq \tfrac{1}{2\tau}\left(\|x-x^n\|^2 - \left\|x-x^{n+1}\right\|^2 - \left\|x^n - x^{n+1}\right\|^2\right) + \langle K^* y^{n+1}, x - x^{n+1}\rangle, \tag{I.5}$$

$$h(y^{n+1}) - h(y) \leq \tfrac{1}{2\sigma}\left(\|y-y^n\|^2 - \left\|y-y^{n+1}\right\|^2 - \left\|y^n - y^{n+1}\right\|^2\right) - \langle K\bar{x}^n, y - y^{n+1}\rangle. \tag{I.6}$$

I.3 The per-iteration estimate and telescoping

Fix a test pair (x, y) and write $\mathfrak{L}(x', y') = \langle Kx', y'\rangle + g(x') - h(y')$ and $\Delta^n := \mathfrak{L}(x^n, y) - \mathfrak{L}(x, y^n)$. Add (I.5) and (I.6); expand the two coupling inner products using $\langle K^* y^{n+1}, x - x^{n+1}\rangle = \langle y^{n+1}, K(x - x^{n+1})\rangle$ and the extrapolation $\bar{x}^n = 2x^n - x^{n-1} = x^n + (x^n - x^{n-1})$; and move the coupling part of Δ^{n+1} to the left. After cancellation of the symmetric term $\langle Kx, y^{n+1}\rangle$ this is a direct (if tedious) regrouping that yields, with the abbreviations

$$Q^n := \tfrac{1}{2\tau}\|x-x^n\|^2 + \tfrac{1}{2\sigma}\|y-y^n\|^2, \qquad T^n := \langle K(x^n - x^{n-1}), y^n - y\rangle, \qquad P^n := \tfrac{1}{2\tau}\left\|x^n - x^{n-1}\right\|^2,$$

the per-iteration inequality

$$\Delta^{n+1} \;\le\; (Q^n - Q^{n+1}) - (T^{n+1} - T^n) - \tfrac{1}{2\sigma}\left\|y^{n+1} - y^n\right\|^2 - \tfrac{1}{2\tau}\left\|x^{n+1} - x^n\right\|^2 + \langle K(x^n - x^{n-1}), y^{n+1} - y^n\rangle. \tag{I.7}$$

The last cross term is bounded by Young's inequality with $\|K\| = L$: $\langle K(x^n - x^{n-1}), y^{n+1} - y^n\rangle \le \frac{1}{2\sigma}\|y^{n+1} - y^n\|^2 + \frac{\sigma L^2}{2}\|x^n - x^{n-1}\|^2$, and under the step-size condition $\tau\sigma L^2 \le 1$ the second piece is $\le \frac{1}{2\tau}\|x^n - x^{n-1}\|^2 = P^n$. Substituting into (I.7), the $\frac{1}{2\sigma}\|y^{n+1} - y^n\|^2$ terms cancel and the x-distance terms telescope:

$$\Delta^{n+1} \;\le\; (Q^n - Q^{n+1}) - (T^{n+1} - T^n) - (P^{n+1} - P^n), \qquad \text{whenever} \;\; \tau\sigma L^2 \le 1. \tag{I.8}$$

Theorem I.2 (Ergodic $O(1/N)$ gap)**.** *Assume $\tau\sigma L^2 \le 1$ and that* (I.1) *has a saddle point. Let (x^n, y^n) be generated by* (I.3) *from $\bar{x}^0 = x^0$ (set $x^{-1} = x^0$) and form the ergodic averages $X_N = \frac{1}{N}\sum_{n=1}^N x^n$, $Y_N = \frac{1}{N}\sum_{n=1}^N y^n$. Then for every bounded $B_1 \times B_2$ containing a saddle point,*

$$\mathrm{Gap}_{B_1\times B_2}(X_N, Y_N) \;\le\; \frac{1}{N}\sup_{(x,y)\in B_1\times B_2}\Big(\tfrac{1}{2\tau}\left\|x - x^0\right\|^2 + \tfrac{1}{2\sigma}\left\|y - y^0\right\|^2\Big). \tag{I.9}$$

In particular $\mathrm{Gap}_{B_1\times B_2}(X_N, Y_N) = O(1/N)$, and any limit point of (X_N, Y_N) is a saddle point; when g is strictly convex (as in proposition 28.7) the saddle point is unique and $(X_N, Y_N) \to (\hat{x}, \hat{y})$.

Proof. Sum (I.8) over $n = 0, \dots, N-1$. The three bracketed differences telescope, and with $x^{-1} = x^0$ we have $T^0 = 0$ and $P^0 = 0$:

$$\sum_{n=1}^N \Delta^n \;\le\; Q^0 - Q^N - T^N - P^N.$$

Bound the boundary residual: $-T^N = -\langle K(x^N - x^{N-1}), y^N - y\rangle \le \frac{1}{2\tau}\left\|x^N - x^{N-1}\right\|^2 + \frac{\tau L^2}{2}\left\|y^N - y\right\|^2$ by Young, and $\frac{1}{2\tau}\left\|x^N - x^{N-1}\right\|^2 = P^N$ cancels $-P^N$, while $\frac{\tau L^2}{2} \le \frac{1}{2\sigma}$ gives $-T^N - P^N \le \frac{1}{2\sigma}\left\|y^N - y\right\|^2$. Since $-Q^N + \frac{1}{2\sigma}\left\|y^N - y\right\|^2 = -\frac{1}{2\tau}\left\|x - x^N\right\|^2 \le 0$, we conclude the clean summed bound

$$\sum_{n=1}^N \Delta^n(x,y) \;\le\; Q^0 = \tfrac{1}{2\tau}\left\|x - x^0\right\|^2 + \tfrac{1}{2\sigma}\left\|y - y^0\right\|^2. \tag{I.10}$$

Now $\Delta^n(x,y) = \mathfrak{L}(x^n, y) - \mathfrak{L}(x, y^n)$ is convex in the iterates (g, h convex, $\langle K\cdot, \cdot\rangle$ bilinear), so by Jensen $\mathfrak{L}(X_N, y) - \mathfrak{L}(x, Y_N) \le \frac{1}{N}\sum_{n=1}^N \Delta^n(x,y) \le \frac{1}{N}Q^0$. Taking the supremum over $(x,y) \in B_1 \times B_2$ on the left turns the difference into the partial gap (I.2), giving (I.9); the right-hand constant is finite on the bounded set, so the gap is $O(1/N)$. Since $\mathrm{Gap}_{B_1\times B_2} \ge 0$ vanishes exactly at saddle points and is lsc, any limit point of (X_N, Y_N) is a saddle point. Taking $(x,y) = (\hat{x}, \hat{y})$ in (I.10) and using $\Delta^n(\hat{x}, \hat{y}) \ge 0$ bounds Q^N, hence keeps the iterates bounded; with g strictly convex the saddle point is unique and the full ergodic sequence converges to it. □

Remark I.3 (Application to theorem 28.8)**.** In the discrete potential MFG of proposition 28.7, X is the space of discrete density–momentum pairs (m_h, w_h), Y the space of discrete values u_h, K the discrete continuity operator A of eq. (28.17) (whose norm is the discrete gradient norm, $L = O(1/h)$, fixing the admissible steps via $\tau\sigma L^2 \le 1$), $g = \mathcal{J}_h$ the convex kinetic-plus-interaction energy, and

$h = \delta_{\{c\}}$ the indicator enforcing the affine constraint $A(m_h, w_h) = c$. Theorem I.2 then gives the ergodic $O(1/k)$ gap of theorem 28.8 with *no* smallness or short-horizon hypothesis: convexity alone, which under (A-Mon) is unconditional, drives the convergence.
