The obstacle is that $\mathcal{P}_2(\mathbb{R}^d)$ is not a vector space: one cannot add two probability measures and stay normalized, so the naive difference quotient that would define a directional derivative has no home. The repair is to notice that while m itself is not a vector, the *difference* $m' - m$ of two probability measures *is* a perfectly good signed measure of total mass zero — an admissible *direction* of perturbation that preserves total mass. Differentiating Ψ along the straight segment $\epsilon \mapsto m + \epsilon(m' - m)$, which remains in $\mathcal{P}_2(\mathbb{R}^d)$ for small $\epsilon \geq 0$, is then a legitimate directional derivative, and representing that derivative as an integral against a single function $\frac{\delta\Psi}{\delta m}(m, \cdot)$ is the content of the *flat* (linear functional) derivative. Its one-line meaning: $\frac{\delta\Psi}{\delta m}(m, y)$ is the marginal cost, as registered by Ψ, of placing an extra infinitesimal speck of mass at the location y when the current configuration is m. It is a function of a *location* y, and it is defined only up to an additive constant, because shifting it by a constant integrates to zero against any mass-zero direction $m' - m$ and so cannot be detected by the perturbation.

The second derivative answers a different physical question. The flat derivative reports what happens when we *add* mass at y; but in a transport flow mass is never created, only *moved*. To see how Ψ responds when an existing speck of mass at y is nudged in a spatial direction, we differentiate the marginal-cost landscape $y \mapsto \frac{\delta\Psi}{\delta m}(m, y)$ in y. Its gradient is the *Lions derivative* $\partial_\mu \Psi(m)(y) = \nabla_y \frac{\delta\Psi}{\delta m}(m, y)$, a *vector* attached to each location y — the local "force," the direction in which displacing the mass sitting at y most increases Ψ. This is exactly the object built to pair against a velocity: if the mass at y moves with velocity $\mathbf{b}(y)$, the rate of change of Ψ contributed by that motion is the inner product $\partial_\mu \Psi(m)(y) \cdot \mathbf{b}(y)$, accumulated over the population. The flat derivative integrates against *added* mass; the Lions derivative contracts against *transport* velocities. That division of labor is the whole reason both objects appear in the chain rule below.

Definition 12.1 (Flat and Lions derivatives; recalled)**.** Let $\Psi : \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}$. Its *flat (linear functional) derivative* is the function $\frac{\delta\Psi}{\delta m}(m, \cdot) : \mathbb{R}^d \to \mathbb{R}$, defined up to an additive constant by

$$\frac{\mathrm{d}}{\mathrm{d}\epsilon}\, \Psi(m + \epsilon(m' - m))\Big|_{\epsilon=0} \;=\; \int_{\mathbb{R}^d} \frac{\delta\Psi}{\delta m}(m, y)\,(m' - m)(\mathrm{d}y) \qquad \text{for all } m' \in \mathcal{P}_2(\mathbb{R}^d).$$

When $y \mapsto \frac{\delta\Psi}{\delta m}(m, y)$ is differentiable, the *Lions (L-)derivative* is its gradient,

$$\partial_\mu \Psi(m)(y) \;=\; \nabla_y \frac{\delta\Psi}{\delta m}(m, y) \;\in\; \mathbb{R}^d,$$

as fixed in appendix A.3. We say Ψ is *fully* $\mathcal{C}^2$ if these exist, are jointly continuous in (m, y), and $y \mapsto \partial_\mu \Psi(m)(y)$ is itself $\mathcal{C}^1$ with Jacobian $\partial_y \partial_\mu \Psi(m)(y) \in \mathbb{R}^{d\times d}$. We call this *fully* $\mathcal{C}^2$ because it involves *two spatial* differentiations of a *single* flat derivative; it is a weaker requirement than the genuine second *measure* derivative $\partial^2_\mu \Psi$ (the Lions derivative of $y \mapsto \partial_\mu \Psi(m)(y)$ in the measure argument, an element of $\mathbb{R}^{d\times d}$ indexed by a *second* integration variable), which does not enter the master equation until common noise (section 12.7). Keep the two apart: the notation watch after theorem 12.3 catalogues all three "second derivatives" that appear.

The "fully $\mathcal{C}^2$" notion deserves a careful word, because it is the precise regularity the no-common-noise master equation will demand, and the distinction it draws is load-bearing for the rest of the chapter. It asks for *two spatial* differentiations of a *single* flat derivative: first ∇_y to pass from $\frac{\delta \Psi}{\delta m}(m, \cdot)$ to the Lions field $\partial_\mu \Psi(m)(\cdot)$, then a second ∇_y to form the Jacobian $\partial_y \partial_\mu \Psi(m)(y)$, an ordinary $d \times d$ matrix at each location y. Both differentiations act on the *spatial* variable y; the measure argument m is differentiated only *once*, when the flat derivative is taken. Contrast this with the genuine second *measure* derivative $\partial^2_\mu \Psi$, obtained by differentiating the Lions field $y \mapsto \partial_\mu \Psi(m)(y)$ a second time *in the measure direction*. That operation introduces a *second* integration variable y' — it asks how the force at y responds to reweighting the crowd near y' — and produces an object $\partial^2_\mu \Psi(m)(y, y')$ indexed by two locations, a true Hessian on $\mathcal{P}_2(\mathbb{R}^d)$. "Fully $\mathcal{C}^2$" is strictly weaker: a Jacobian in one variable, not a Hessian in two. The reason the weaker notion suffices here, and the reason the distinction matters at all, is the same: in the chain rule below the only second-order content comes from the *idiosyncratic* diffusion $\sigma \, \mathrm{d}W_t$ that each agent carries privately, which spreads mass locally and therefore couples to the single-variable Jacobian $\partial_y \partial_\mu \Psi$. There is, in the no-common-noise world, no mechanism that correlates the random motion of mass at y with the random motion of mass at a distant y', so the two-point object $\partial^2_\mu \Psi$ never appears. Common noise supplies exactly that mechanism — one shared shock moves all of the mass together, correlating y and y' — and it is precisely the term $\frac{1}{2} \iint \partial^2_\mu U(t, x, m)(y, y') \, \mathrm{d}m(y) \, \mathrm{d}m(y')$ that it adds to the equation (section 12.7). The gap between "two spatial derivatives of one flat derivative" and "a genuine second measure derivative" is thus the exact gap between the equation without common noise and the equation with it.

We apply these derivatives to a functional of the form $\Psi(m) = U(t, x, m)$ with (t, x) frozen; the resulting objects carry (t, x) as inert parameters and a fresh integration variable $y \in \mathbb{R}^d$, written $\frac{\delta U}{\delta m}(t, x, m, y)$ and $\partial_\mu U(t, x, m)(y)$. With the two derivatives in hand we can state the chain rule. The next lemma is the Itô–Dynkin formula on $\mathcal{P}_2(\mathbb{R}^d)$ specialized to a *deterministic* Fokker–Planck flow — no randomness in m itself, only the transport-plus-diffusion of its mass — and it is the single engine on which the whole chapter runs.

Lemma 12.2 (Chain rule along a Fokker–Planck flow)**.** *Let $\Psi : \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}$ be fully $\mathcal{C}^2$ in the sense of definition 12.1, with derivatives bounded and Lipschitz on bounded sets. Let $(m_t)_{t\in[0,T]}$ be a weak solution of the Fokker–Planck equation*

$$\partial_t m_t \;=\; \tfrac{1}{2}\,\mathrm{tr}\big(\sigma\sigma^\top \, \mathrm{D}^2 \, m_t\big) \;-\; \mathrm{div}(m_t \, \mathbf{b}_t),$$

driven by a bounded measurable drift field $\mathbf{b}_t : \mathbb{R}^d \to \mathbb{R}^d$ with $\int_0^T \int |\mathbf{b}_t|^2 \, \mathrm{d}m_t \, \mathrm{d}t < \infty$. Then $t \mapsto \Psi(m_t)$

is absolutely continuous and

$$\frac{\mathrm{d}}{\mathrm{d}t}\,\Psi(m_t) \;=\; \int_{\mathbb{R}^d} \partial_\mu \Psi(m_t)(y)\cdot \mathbf{b}_t(y)\, m_t(\mathrm{d}y) \;+\; \tfrac{1}{2}\int_{\mathbb{R}^d} \mathrm{tr}\Big(\sigma\sigma^\top\, \partial_y \partial_\mu \Psi(m_t)(y)\Big)\, m_t(\mathrm{d}y). \tag{12.4}$$

Proof sketch. The argument is three moves — differentiate, substitute, integrate by parts twice — and we spell out the algebra so that both terms of eq. (12.4) can be seen to emerge from their respective pieces of the Fokker–Planck operator. The full justification of every analytic step (absolute continuity, the differentiation under the integral, the boundary terms) is the Itô formula for flows of measures, theorem D.7 (appendix D.6), whose first-order half is stated already in chapter 4; we are specializing that theorem to the case of a deterministic flow and recording the resulting expectation against m_t.

Move 1: differentiate through the flat derivative. Because Ψ is fully $\mathcal{C}^2$ and $t \mapsto m_t$ is absolutely continuous, $t \mapsto \Psi(m_t)$ is absolutely continuous, and its time derivative is the first variation of Ψ contracted against the rate of change of its argument. The increment $m_{t+h} - m_t$ is, to first order in h, the mass-zero signed measure $h\,\partial_t m_t$, so the directional-derivative identity of definition 12.1 applies with the perturbation direction $\partial_t m_t$ in place of $m' - m$, giving

$$\frac{\mathrm{d}}{\mathrm{d}t}\,\Psi(m_t) \;=\; \int_{\mathbb{R}^d} \frac{\delta\Psi}{\delta m}(m_t, y)\, \partial_t m_t(\mathrm{d}y).$$

This is the entire role of the flat derivative: it converts "how Ψ changes" into a *linear* functional of "how the measure changes," and the Fokker–Planck equation tells us exactly what the latter is.

Move 2: substitute the Fokker–Planck right-hand side. Replacing $\partial_t m_t$ by the two terms of the Fokker–Planck operator splits the integral cleanly into a transport piece and a diffusion piece,

$$\frac{\mathrm{d}}{\mathrm{d}t}\,\Psi(m_t) \;=\; \underbrace{\int \frac{\delta\Psi}{\delta m}(m_t, y)\Big[-\mathrm{div}(m_t\, \mathbf{b}_t)\Big](\mathrm{d}y)}_{\text{transport}} \;+\; \underbrace{\int \frac{\delta\Psi}{\delta m}(m_t, y)\, \tfrac{1}{2}\,\mathrm{tr}(\sigma\sigma^\top\, \mathrm{D}^2_y\, m_t)(\mathrm{d}y)}_{\text{diffusion}},$$

each of which we now integrate by parts to move the derivatives off the (irregular) measure m_t and onto the (smooth) flat derivative.

Move 3a: the transport piece (one integration by parts). The integrand is a function times a divergence. Writing the integral against Lebesgue density and using the divergence theorem — the boundary term at infinity vanishing because $\frac{\delta\Psi}{\delta m}(m_t,\cdot)$ and its gradient are bounded while $m_t\,\mathbf{b}_t$ has the finite-energy decay guaranteed by $\int |\mathbf{b}_t|^2\, \mathrm{d}m_t < \infty$ — one derivative passes from the divergence onto the test function with a single sign change:

$$\int \frac{\delta\Psi}{\delta m}(m_t, y)\Big[-\mathrm{div}(m_t\, \mathbf{b}_t)\Big](\mathrm{d}y) \;=\; \int \nabla_y \frac{\delta\Psi}{\delta m}(m_t, y)\cdot \mathbf{b}_t(y)\, m_t(\mathrm{d}y).$$

The gradient that appears is, by definition, the Lions derivative, $\nabla_y \frac{\delta\Psi}{\delta m}(m_t,\cdot) = \partial_\mu \Psi(m_t)$, so the transport piece is exactly $\int \partial_\mu \Psi(m_t)(y)\cdot \mathbf{b}_t(y)\, m_t(\mathrm{d}y)$ — the velocity field $\mathbf{b}_t$ contracted against the Lions force, summed over the population, precisely the pairing the Lions derivative was constructed for.

Move 3b: the diffusion piece (two integrations by parts). Here $\mathrm{D}^2_y\, m_t$ carries two spatial derivatives on the measure; integrating by parts *twice* (again with vanishing boundary terms, now using the boundedness of the second spatial derivatives of $\frac{\delta\Psi}{\delta m}(m_t,\cdot))$ transfers both onto the flat derivative with no net sign change, and the constant matrix $\sigma\sigma^\top$ rides along under the trace:

$$\int \frac{\delta\Psi}{\delta m}(m_t,y)\,\tfrac{1}{2}\,\mathrm{tr}\big(\sigma\sigma^\top\,\mathrm{D}_y^2\,m_t\big)(\mathrm{d}y) \;=\; \tfrac{1}{2}\int \mathrm{tr}\Big(\sigma\sigma^\top\,\mathrm{D}_y^2\,\frac{\delta\Psi}{\delta m}(m_t,y)\Big)\,m_t(\mathrm{d}y).$$

The Hessian now appearing is the spatial Hessian of the flat derivative, which is precisely the Jacobian of the Lions field, $\mathrm{D}_y^2\,\frac{\delta\Psi}{\delta m}(m_t,\cdot) = \partial_y\partial_\mu\Psi(m_t)$ — the single-variable second derivative whose existence "fully $\mathcal{C}^2$" was designed to guarantee. (This is the only place the second spatial derivative is used, and it is why no genuine $\partial_\mu^2\Psi$ is needed: the constant $\sigma\sigma^\top$ spreads mass locally, at one point y at a time.) Adding the two pieces gives eq. (12.4).

The boundedness and Lipschitz hypotheses are what make every integral finite and legitimize both the differentiation under the integral sign in Move 1 and the discarding of boundary terms in Move 3; the case of unbounded drifts is recovered by truncating $\mathbf{b}_t$ and passing to the limit using the finite-energy bound, carried out in full in theorem D.7, of which eq. (12.4) is the deterministic-time, expectation-against-m_t specialization. The result is classical; see [41], Ch. 5, for attribution and the general Itô calculus on measure space. □

The two terms of eq. (12.4) now have transparent meaning, and it is worth pausing on each because both will reappear, character for character, in the master equation. The first, $\int \partial_\mu\Psi(m_t)(y)\cdot \mathbf{b}_t(y)\,m_t(\mathrm{d}y)$, is the *advective transport* of Ψ by the drift $\mathbf{b}_t$: the crowd flows along $\mathbf{b}_t$, and Ψ changes at the rate at which the Lions force pushes in the direction of that flow. It is first order — one gradient on Ψ, one velocity — exactly the structure of a transport (continuity-equation) term. The second, $\frac{1}{2}\int \mathrm{tr}(\sigma\sigma^\top\,\partial_y\partial_\mu\Psi(m_t)(y))\,m_t(\mathrm{d}y)$, is the *spreading* of mass by the idiosyncratic diffusion: it is the measure-space avatar of the Laplacian $\frac{1}{2}\,\mathrm{tr}(\sigma\sigma^\top\,\mathrm{D}^2)$, with the finite-dimensional Hessian replaced by the Lions-field Jacobian $\partial_y\partial_\mu\Psi$. It is second order, and as anticipated it needs only the single-variable Jacobian, never the two-point $\partial_\mu^2\Psi$ — the signature of the no-common-noise setting.

This is precisely the engine the derivation needs, and we can already read off how it will be fired. In the next section we will apply lemma 12.2 not to an arbitrary functional Ψ and an arbitrary drift $\mathbf{b}_t$, but to the specific functional $\Psi = U(t_0,x,\cdot)$ — the master function with its time and state slots frozen — transported along the *equilibrium* flow, whose Fokker–Planck drift is the optimal feedback $\mathbf{b}_t = -\partial_p H(\,\cdot\,,\nabla_x U)$ read off from eq. (12.2b). With that identification, the transport term becomes the crowd drifting under the common optimal control and the diffusion term becomes the crowd spreading under the idiosyncratic noise — the two new lines of the master equation. Differentiating the flow-consistency identity in t by exactly this lemma, and forcing the result to agree with the HJB equation, is the derivation we now carry out.

12.3 Derivation of the master equation

The previous section handed us the single engine the whole chapter runs on: the chain rule lemma 12.2, which says how a smooth functional of the population changes as that population is transported along a Fokker–Planck flow, with the equilibrium feedback $\mathbf{b}_t = -\partial_p H$ already identified as the drift to be plugged in. We now execute, to the letter, the plan announced twice in section 12.1: write down the master function as a flow map, record the flow-consistency identity $u(t,x) = U(t,x,m_t)$ that ties it to the bare value, *differentiate that identity in* t using exactly lemma 12.2, and force the result to agree with the HJB equation u already satisfies. What falls out is a single closed equation for U. This section is the technical heart of the chapter, and it is in large part bookkeeping — but bookkeeping in which every sign and every evaluation point must be tracked, because that is exactly where the structure of the master equation lives.

Begin with the construction of U. The heuristic asked for a function that values *every* crowd, not merely the one realized along a particular equilibrium; we manufacture such a function by solving the game from every conceivable starting configuration and recording the answer. Fix an initial datum $(t_0, m) \in [0,T] \times \mathcal{P}_2(\mathbb{R}^d)$ and pose the MFG system eq. (12.2) on the sub-interval $[t_0, T]$ with the population pinned to m at the initial time, $m_{t_0} = m$. Solving it produces a forward flow of measures and a backward value, and the master function is defined to be that value read off at the very instant its own problem begins.

For eq. (12.5) below to define a genuine *function* of (t_0, x, m) — one number, not a set of competing candidates — the sub-interval problem must have exactly one solution at each datum, and this is precisely where the two pillars of Part II become load-bearing. It is worth naming the distinct role of each. *Existence* of a solution to the sub-interval problem holds under the standing assumptions, by the fixed-point argument of chapter 10; without it U would be undefined at some data. *Uniqueness* — and this is the subtle one — must hold for *every* horizon $[t_0, T]$ and *every* initial measure m, not just for the full interval $[0,T]$ and the one physical m_0; it is supplied by Lasry–Lions monotonicity (A-Mon) through theorem 11.5. Without uniqueness the construction would be multivalued: two distinct equilibria issuing from the same (t_0, m) would assign two distinct "values" to the same crowd, and there would be no well-defined number $U(t_0, x, m)$ at all. We therefore assume (A-Mon) throughout this section, not as a technical convenience but as the exact hypothesis that renders the flow map single-valued. (That uniqueness is needed at every horizon, and not only at the full one, is the reason chapter 11 took the trouble to prove it for arbitrary terminal time: the master function reaches into every sub-interval at once.) Denote by $(m_s^{t_0,m})_{s \in [t_0,T]}$ the resulting forward flow and by $u^{t_0,m}(s,x)$ the resulting value, and define the candidate master function by evaluating the value at the initial time of its own problem:

$$U(t_0, x, m) \;:=\; u^{t_0,m}(t_0, x), \qquad (t_0, x, m) \in [0,T] \times \mathbb{R}^d \times \mathcal{P}_2(\mathbb{R}^d). \tag{12.5}$$

Taking $t_0 = T$ leaves no interval over which to evolve: the value at the terminal time is simply the terminal coupling, so $U(T, x, m) = G(x, m)$, and this will furnish the terminal condition of the equation we are about to derive.

The one property of U that powers the entire derivation is a *flow-consistency* (semigroup) identity, and it is worth seeing *why* it holds before we put it to work. Solve the game once from (t_0, m), run the population forward to some later time $t \geq t_0$, and freeze the picture there: the crowd is now $m_t^{t_0,m}$ and the agent's continuation value from (t,x) is $u^{t_0,m}(t,x)$. But the tail of an equilibrium on $[t_0, T]$ is itself an equilibrium on the shorter interval $[t, T]$ — nothing in the agent's remaining optimization, nor in the population's remaining evolution, remembers *how* the configuration $m_t^{t_0,m}$ was reached, only that it is the population now present. By the very uniqueness we just invoked, that tail *is* the unique solution of the game restarted from $(t, m_t^{t_0,m})$, and so its value at the restart instant is, by definition eq. (12.5), exactly $U(t, x, m_t^{t_0,m})$. Reading the value off at time t along the original flow must therefore agree with solving afresh from the configuration reached at t:

$$u^{t_0,m}(t,x) \;=\; U\big(t,x,m_t^{t_0,m}\big) \qquad \text{for all } t \in [t_0,T]. \tag{12.6}$$

This is the precise, fully decorated form of the heuristic identity "$u(t,x) = U(t,x,m_t)$" of eq. (12.3): the bare value is the master function evaluated along its own equilibrium flow, i.e. along the single characteristic curve $m_\cdot^{t_0,m}$ that the initial datum traces through the infinite-dimensional state space. Notice that every dependence on the initial datum (t_0, m) visible on the left-hand side is carried, on the right, entirely inside the measure slot $m_t^{t_0,m}$ — which is the whole payoff of having promoted the population to a free argument. Granting that U is fully $\mathcal{C}^2$ in m (definition 12.1) and $\mathcal{C}^{1,2}$ in (t,x) — a regularity we state here as a hypothesis and return to in section 12.6, where we discuss what verifying it would require — we now differentiate eq. (12.6) in t and substitute the result into the HJB equation. Both sides depend on t: the left through (t,x) alone, the right through t *twice* (explicitly in the first slot, implicitly through the transported measure), and reconciling the two is the whole of the derivation.

Theorem 12.3 (The master equation)**.** *Assume the standing assumptions* (A-Lip)*,* (A-Growth)*,* (A-Nondeg)*,* (A-Conv)*,* (A-Mon)*, and suppose the function U defined by eq.* (12.5) *is fully $\mathcal{C}^2$ in the measure argument (definition 12.1) and $\mathcal{C}^{1,2}$ in (t,x), with derivatives bounded and locally Lipschitz. Then U solves, on $[0,T) \times \mathbb{R}^d \times \mathcal{P}_2(\mathbb{R}^d)$, the* master equation

$$\begin{aligned} -\,\partial_t U(t,x,m) - \tfrac12 \operatorname{tr}\big(\sigma\sigma^\top \mathrm{D}_x^2 U\big) \;+\; H\big(x, \nabla_x U\big)& \\ +\int_{\mathbb{R}^d} \partial_\mu U(t,x,m)(y)\cdot \partial_p H\big(y, \nabla_x U(t,y,m)\big)\, m(\mathrm{d}y)& \\ -\,\tfrac12 \int_{\mathbb{R}^d} \operatorname{tr}\Big(\sigma\sigma^\top\, \partial_y\partial_\mu U(t,x,m)(y)\Big)\, m(\mathrm{d}y) \;=\; F(x,m)&, \end{aligned} \tag{12.7}$$

with terminal condition

$$U(T,x,m) \;=\; G(x,m). \tag{12.8}$$

Conversely, if U is a classical solution of eq. (12.7)*–eq.* (12.8) *with the stated regularity, then for each (t_0, m) the pair*

$$u(t,x) := U\big(t,x,m_t\big), \qquad m_t \textit{ the solution of eq. (12.2b) with } \nabla u(t,x) = \nabla_x U(t,x,m_t),\; m_{t_0} = m,$$

solves the MFG system eq. (12.2) *on $[t_0, T]$.*

Proof. From the system to the equation. Fix (t_0, m) and write $m_t = m_t^{t_0,m}$ for the equilibrium flow it generates. By the Fokker–Planck half of the system eq. (12.2b), this flow is transported by the optimal feedback drift

$$\mathbf{b}_t(y) \;=\; -\partial_p H\big(y, \nabla u^{t_0,m}(t,y)\big),$$

the common velocity field under which the crowd moves once each agent plays her optimal control $\alpha^* = -\partial_p H$. This is exactly the kind of drift the chain rule lemma 12.2 was built to handle, and the equilibrium flow is exactly the kind of Fokker–Planck flow it takes as input; the derivation is the single act of pointing that lemma at the right functional.

Differentiate the flow-consistency identity eq. (12.6) in t and evaluate at $t = t_0$. The left-hand side $u^{t_0,m}(t,x)$ depends on t through its first slot only, so its derivative is the ordinary time-partial $\partial_t u^{t_0,m}(t_0,x)$. The right-hand side $U(t,x,m_t)$ depends on t in two ways at once, and the total derivative is the sum of the two contributions. The *explicit* dependence, through the first slot of U, contributes $\partial_t U(t_0,x,m)$. The *implicit* dependence, through the transported measure m_t, is precisely a derivative of the form $\frac{\mathrm{d}}{\mathrm{d}t}\Psi(m_t)$ with the frozen-(t_0,x) functional $\Psi(\cdot) = U(t_0,x,\cdot)$, and lemma 12.2 evaluates it with the drift $\mathbf{b}_{t_0}$. Adding the two,

$$\partial_t u^{t_0,m}(t_0,x) = \partial_t U(t_0,x,m) + \int \partial_\mu U(t_0,x,m)(y)\cdot \mathbf{b}_{t_0}(y)\, m(\mathrm{d}y) + \frac{1}{2}\int \mathrm{tr}\big(\sigma\sigma^\top \partial_y \partial_\mu U(t_0,x,m)(y)\big)\, m(\mathrm{d}y),$$

the first integral being the chain rule's transport term and the second its diffusion term, each evaluated at the initial measure $m_{t_0} = m$.

Three substitutions now collapse this into the master equation. First, evaluating the flow-consistency identity itself at $t = t_0$ gives $u^{t_0,m}(t_0,x) = U(t_0,x,m)$, and because this holds as an identity in x we may differentiate it in x to read off the spatial derivatives at the initial instant,

$$\nabla u^{t_0,m}(t_0,x) = \nabla_x U(t_0,x,m), \qquad \mathrm{D}^2\, u^{t_0,m}(t_0,x) = \mathrm{D}_x^2\, U(t_0,x,m).$$

(These hold only *at* $t = t_0$, where the measure slot is frozen at m; the differentiation in x does not touch the population argument, which is why no measure-derivative of U appears here.) Second, the feedback drift is rewritten in terms of U using the first of these, $\mathbf{b}_{t_0}(y) = -\partial_p H\big(y, \nabla u^{t_0,m}(t_0,y)\big) = -\partial_p H\big(y, \nabla_x U(t_0,y,m)\big)$ — note that the momentum slot is filled by $\nabla_x U$ evaluated at the *integration point* y, not at the agent's own x, since it is the crowd at y that moves with velocity $\mathbf{b}_{t_0}(y)$. Third, insert all of this into the HJB equation eq. (12.2a) written at $t = t_0$,

$$-\partial_t u^{t_0,m}(t_0,x) - \tfrac{1}{2}\,\mathrm{tr}\big(\sigma\sigma^\top\, \mathrm{D}^2\, u^{t_0,m}(t_0,x)\big) + H\big(x, \nabla u^{t_0,m}(t_0,x)\big) = F(x,m).$$

Replace $-\partial_t u^{t_0,m}(t_0,x)$ by minus the three-term expression above (so that $-\partial_t U$ and the two integrals enter with their signs flipped), replace $\mathrm{D}^2\, u$ by $\mathrm{D}_x^2\, U$ and ∇u by $\nabla_x U$, and substitute the feedback drift. The result is exactly the master equation eq. (12.7) at the point (t_0,x,m). Since (t_0,m) was an arbitrary datum, the equation holds at every point of $[0,T) \times \mathbb{R}^d \times \mathcal{P}_2(\mathbb{R}^d)$; the terminal condition eq. (12.8) is the construction eq. (12.5) read at $t_0 = T$.

It is worth dwelling on the sign of the transport term, since this is the one place the bookkeeping could mislead. In the chain rule the implicit term entered the *right* side as $+\int \partial_\mu U \cdot \mathbf{b}_{t_0}\, m(\mathrm{d}y)$, i.e. as part of $\partial_t u$. Moving $\partial_t u$ to the left of the HJB flips its sign, turning it into $-\int \partial_\mu U \cdot \mathbf{b}_{t_0}\, m(\mathrm{d}y)$; and substituting $\mathbf{b}_{t_0} = -\partial_p H$ flips it once more, producing the $+\int \partial_\mu U \cdot \partial_p H\, m(\mathrm{d}y)$ that appears on the second line of eq. (12.7). The two sign reversals — one from transposing across the HJB equation, one from the explicit minus in the optimal feedback — compose to a plus. In short: the $+\,\partial_\mu U \cdot \partial_p H$ of the master equation *is* the $-\,\partial_\mu U \cdot \mathbf{b}$ of the chain rule eq. (12.4), carried to the left-hand side. The diffusion term carries a single sign flip (it has no feedback factor to flip a second time), which is why it appears as $-\frac{1}{2}\int \mathrm{tr}(\sigma\sigma^\top \partial_y \partial_\mu U)\, m(\mathrm{d}y)$ on the third line.

From the equation to the system. For the converse we run the same computation backward, and the only genuinely new point to establish is that the object we differentiate exists — that the flow m_t is well defined. Let U be a classical solution of eq. (12.7)–eq. (12.8) with the stated regularity, fix a datum (t_0, m), and consider the Fokker–Planck equation eq. (12.2b) closed by the feedback $-\partial_p H(x, \nabla_x U(t, x, m_t))$ with $m_{t_0} = m$. This is no longer an externally given flow but a *McKean–Vlasov* flow: the drift at (t, x) depends on the current law m_t through the third slot of U, so the equation is self-referential and its well-posedness needs an argument. It is supplied by the regularity of U: because U is fully $\mathcal{C}^2$ in m and $\mathcal{C}^{1,2}$ in (t, x) with derivatives bounded and locally Lipschitz, the map $(x, m) \mapsto -\partial_p H(x, \nabla_x U(t, x, m))$ is Lipschitz in the state x and in the measure m (for $\mathcal{W}_2$) uniformly in t — here the convexity (A-Conv) makes $\partial_p H$ well defined and (A-Lip) controls its growth. A Lipschitz McKean–Vlasov drift is exactly the hypothesis of theorem 7.9, which delivers a unique flow (m_t); the underlying pathwise SDE is well posed by theorem 5.10, and nondegeneracy (A-Nondeg) upgrades m_t to a classical solution of the parabolic Fokker–Planck equation via the Schauder estimates of chapter 8, so the flow has the smoothness the chain rule demands. With m_t in hand, set $u(t, x) := U(t, x, m_t)$. Differentiating in x along the flow gives $\nabla u = \nabla_x U$ and $\mathrm{D}^2 u = \mathrm{D}^2_x U$, so the feedback that defined the flow is precisely $-\partial_p H(x, \nabla u)$, which is to say (u, m) satisfies the Fokker–Planck equation eq. (12.2b) by construction. It remains to recover the HJB equation. Differentiate $u(t, x) = U(t, x, m_t)$ in t by the chain rule lemma 12.2, exactly as in the forward direction but now at a generic time t rather than only at the initial instant, and subtract the master equation eq. (12.7): the explicit $\partial_t U$, the transport integral, and the diffusion integral cancel term for term against their counterparts in the master equation, leaving precisely

$$-\partial_t u - \tfrac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 u) + H(x, \nabla u) = F(x, m_t),$$

the HJB equation eq. (12.2a). The terminal condition $u(T, \cdot) = U(T, \cdot, m_T) = G(\cdot, m_T)$ is the terminal coupling eq. (12.8). Thus (u, m) solves the MFG system eq. (12.2) on $[t_0, T]$, and the equivalence is complete in both directions. $\square$

This converse direction deserves a forward glance, because it is more than a tidy symmetry. What it shows is that a single classical solution U of the master equation *manufactures* an equilibrium of the game from *any* starting datum (t_0, m), by closing the Fokker–Planck equation with the feedback $-\partial_p H(x, \nabla_x U)$ and propagating. The resulting flow (m_t) is the characteristic curve through (t_0, m), and $u(t, x) = U(t, x, m_t)$ is the value read along it. That is the seed of the method of characteristics developed in section 12.5: the master equation is solved by these flows, and along each of them it degenerates into the coupled HJB/Fokker–Planck system. For now we have what the chapter's throughline most needed — the equation itself, and its exact equivalence with the system in both directions.

With the equation derived and proved equivalent, it pays to read its anatomy line by line, because the three lines of eq. (12.7) have three different physical jobs, and keeping them straight is what makes the equation legible. The first line — $-\partial_t U - \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2_x U) + H(x, \nabla_x U)$ — is an *ordinary* second-order HJB operator in the finite-dimensional state x, with the measure m held frozen as an inert parameter: if one pretended the population could not move, this is the entire equation, the classical Bellman operator of a single agent facing a fixed crowd. The second line is the first correction for the fact that the crowd *does* move: it is a *transport* term, $\int \partial_\mu U(t, x, m)(y) \cdot \partial_p H(y, \nabla_x U(t, y, m))\, m(\mathrm{d}y)$, recording how the agent's value drifts as the whole population flows along the common optimal feedback $-\partial_p H$. The third line is the second correction: a *diffusion* term, $-\frac{1}{2}\int \operatorname{tr}(\sigma\sigma^\top \partial_y \partial_\mu U)\, m(\mathrm{d}y)$, recording how the value changes as each agent's idiosyncratic noise $\sigma\, \mathrm{d}W_t$ spreads the crowd locally.

First line: the agent optimizes against a frozen population. Second line: the population drifts. Third line: the population spreads. The second and third lines, both absent from the bare HJB eq. (12.2a) that knew only the realized slice, are exactly the price and the payoff of carrying m as a live argument.

The third line, the so-called *extra diffusion*, is the term most worth understanding, because it is precisely what separates the master equation from a naive "frozen-population HJB" in which one would simply hold m fixed and solve the first line alone. When does it actually contribute? The term is built from $\partial_y \partial_\mu U$, the spatial Jacobian of the Lions field, so it vanishes exactly when $\partial_\mu U(t, x, m)(y)$ is *constant in the integration variable* y. There is a clean dichotomy here that is easy to misstate, so we state it carefully. If the coupling sees the population only through finitely many moments, the term *collapses to a finite-dimensional expression* — a sum over those moments — but it does *not* vanish; it vanishes identically only in the strictly narrower case of *mean-field* (first-moment) coupling, where U depends on m only through its mean $\int y\, m(\mathrm{d}y)$, the flat derivative $\delta U/\delta m$ is then affine in y, its gradient $\partial_\mu U$ is *constant* in y, and so $\partial_y \partial_\mu U \equiv 0$. The contrast between "one moment" and "two moments" makes the point sharp. Take a second-moment coupling, $U = \phi(M_2(m))$ with $M_2(m) = \int y^2\, m(\mathrm{d}y)$. Its flat derivative is computed by perturbing m: since M_2 is linear in m, $\delta M_2/\delta m = y^2$, and the chain rule for the flat derivative gives $\delta U/\delta m = \phi'(M_2)\, y^2 = \partial_{M_2} U\, y^2$. Differentiating once in y gives the Lions field $\partial_\mu U = 2\, \partial_{M_2} U\, y$, which is *linear* in y, not constant; differentiating a second time gives the Jacobian $\partial_y \partial_\mu U = 2\, \partial_{M_2} U$, a nonzero constant. The extra-diffusion term is therefore

$$-\tfrac{1}{2} \int \operatorname{tr}\!\big(\sigma\sigma^\top\, 2\, \partial_{M_2} U\big)\, m(\mathrm{d}y) \;=\; -\, \operatorname{tr}(\sigma\sigma^\top)\, \partial_{M_2} U,$$

generically nonzero: a second-moment coupling feels the crowd's spreading. The first-moment coupling does not, because the Lions field there has no y-dependence to differentiate. So it is the mean-coupling structure — not the weaker property of depending on finitely many moments — that kills the term. We will see this concretely on the LQG thread in section 12.8, where the coupling is through the mean, $\partial_\mu U$ is constant in y, $\partial_y \partial_\mu U \equiv 0$, and the extra-diffusion line drops out, leaving the Riccati system that reproduces the chapter 8 fixed point.

Notation watch

The master equation is first order in the measure variable m but *second order* in the state x, and it carries yet another second-order object in y inside the crowd integral. Three "second derivatives" thus circulate through this chapter, they look alike on the page, and conflating them is the single most common error in reading the equation, so we catalogue them once and for all.

1. $\mathrm{D}_x^2 U(t, x, m)$ — the ordinary $d \times d$ Hessian in the agent's *own* state x, with t and m frozen. It sits on the first line of eq. (12.7) and is the agent's own idiosyncratic diffusion acting on her own value. It is a finite-dimensional second derivative; no measure differentiation is involved.

2. $\partial_y \partial_\mu U(t, x, m)(y)$ — the $d \times d$ Jacobian, in the integration variable y, of the Lions field $y \mapsto \partial_\mu U(t, x, m)(y)$. It is *two spatial* derivatives of a *single* flat derivative (first ∇_y to make the Lions field, then ∇_y again), and it sits on the third line, contracted against

$\sigma\sigma^\top$ and integrated against m. It is the crowd's spatial spreading. It is the "fully $\mathcal{C}^2$" content of definition 12.1 and, despite its name, differentiates the measure only *once*.

3. $\partial_\mu^2 U(t,x,m)(y,y')$ — the genuine second *measure* derivative, the Lions derivative of the Lions field taken *in the measure direction*, indexed by *two* distinct locations y, y'. This is a true Hessian on $\mathcal{P}_2(\mathbb{R}^d)$. It does *not* appear in eq. (12.7) at all; it enters only under common noise (section 12.7), where the shared shock correlates the motion of mass at y with the motion of mass at y'.

Only the third is a second derivative in $\mathcal{P}_2(\mathbb{R}^d)$ in the strong sense. The first acts on the agent, the second on the spatial spreading of the crowd, the third on two-point measure correlations; keep them apart and the equation reads cleanly.

Remark 12.4 (General coefficients and non-separable couplings: the form imported by chapter 13)**.** We displayed eq. (12.7) in the canonical *separated* setting of eq. (12.1) — control-as-drift, constant σ, additive couplings F, G, and a Hamiltonian $H(x,p)$ carrying no measure — because it is the cleanest vehicle for the structure: every term has an unobstructed reading and the new measure-derivative content is not hidden behind state-dependent coefficients. But it is essential, both for honesty and because chapter 13 needs the general form, to see that the canonical setting was a choice of lighting and not a structural assumption. Look back at the derivation: nowhere did it use separability of the Hamiltonian or constancy of σ. The only ingredients were the chain rule lemma 12.2 — which holds for *any* Lipschitz feedback drift and *any* (possibly x- and m-dependent) diffusion — and the substitution of the HJB equation, which likewise never assumed the coupling was additive. The construction therefore extends verbatim. For a general controlled drift $b(x,m,\alpha)$, a measure- and state-dependent diffusion $\sigma(x,m)$, and a *non-separable* Hamiltonian $H(x,p,m)$ — written in the canonical argument order of appendix A.4, convex in p under (A-Conv), with the running coupling now absorbed into H so that no separate F survives on the right — the master equation reads

$$\begin{aligned} &-\partial_t U - \tfrac{1}{2}\operatorname{tr}\big(\sigma(x,m)\sigma(x,m)^\top \mathrm{D}_x^2 U\big) \;+\; H(x,\nabla_x U, m) \\ &\qquad + \int_{\mathbb{R}^d} \partial_\mu U(t,x,m)(y)\cdot \partial_p H\big(y, \nabla_x U(t,y,m), m\big)\, m(\mathrm{d}y) \\ &\qquad - \tfrac{1}{2}\int_{\mathbb{R}^d} \operatorname{tr}\Big(\sigma(y,m)\sigma(y,m)^\top\, \partial_y\partial_\mu U(t,x,m)(y)\Big)\, m(\mathrm{d}y) \;=\; 0, \end{aligned} \tag{12.9}$$

with $U(T,x,m) = G(x,m)$. The correspondence with the separated equation is term by term, and worth spelling out because each modification lands in exactly the slot the derivation predicts. The first-line Hamiltonian gains a measure argument, $H(x,p) \rightsquigarrow H(x,p,m)$, since the running cost may now depend on the crowd directly rather than only through an additive F; the first-line diffusion becomes x- and m-dependent, $\sigma \rightsquigarrow \sigma(x,m)$, evaluated at the agent's own state. In the transport integral on the second line, the momentum derivative $\partial_p H$ likewise acquires the measure slot and is evaluated, as before, at the *integration point* y — it is $\partial_p H(y, \nabla_x U(t,y,m), m)$, the crowd at y moving with its own optimal velocity. In the diffusion integral on the third line the crucial point is the *evaluation point of the diffusion*: it is $\sigma(y,m)$, the diffusion of the mass sitting at y, not $\sigma(x,m)$, because the chain rule spreads each speck of crowd by its own local noise. This is exactly how lemma 12.2 produced the term, with $\sigma\sigma^\top$ riding under the trace at the integration variable, and it is the one place where a careless reader might wrongly write the agent's own $\sigma(x,m)$. Finally the right-hand side is now 0, because the coupling has been folded into H. The separated equation eq. (12.7) is recovered as the special case $H(x,p,m) = H(x,p)$, $\sigma(x,m) = \sigma$, with the coupling pulled back out as $+F(x,m)$ on the right — the two forms coincide precisely when the coupling is additively separable from the Hamiltonian. This general-coefficient form eq. (12.9) is the one chapter 13 evaluates, term by term, at the configuration $(t, x_i, \mu^{N,-i})$ of player i against the empirical measure of the others, in order to compare the N-player Nash system with the master equation and extract the convergence rate; chapter 13 imports it by theorem 12.8 and the present remark, so we have kept its coefficients fully general here precisely so that the later chapter need not re-derive them.

We have what the chapter most needed: the master equation eq. (12.7), derived by differentiating the flow-consistency identity, and proved exactly equivalent to the MFG system in both directions. It is time to stop computing and step back to read the *shape* of what we produced. Notice that the transport term $\int \partial_\mu U \cdot \partial_p H \, m(\mathrm{d}y)$ is the pairing of a measure-gradient $\partial_\mu U$ against a velocity field $-\partial_p H$ — precisely the structure the chain rule taught us to recognize, and precisely the structure of a Hamilton–Jacobi equation in which the "gradient" is a Wasserstein gradient and the "spatial" variable is the population itself. That reading, which turns the master equation into a Hamilton–Jacobi equation on $\mathcal{P}_2(\mathbb{R}^d)$ and prepares the method of characteristics, is the business of the next section; and the converse direction we just proved — a classical U manufacturing an equilibrium from each datum — is the seed of the characteristics theorem two sections later.

12.4 The master equation as a Hamilton–Jacobi equation on $\mathcal{P}_2(\mathbb{R}^d)$

The previous section closed by noticing the shape of the transport term — a measure-gradient $\partial_\mu U$ paired against the velocity field $-\partial_p H$. We now take that observation seriously, because it is not an accident of bookkeeping but the signature of what the master equation *is*. Read line by line, eq. (12.7) looks like an HJB operator in x decorated with two crowd integrals; read as a whole, with the agent's own coordinate x demoted to a passive label and the population m promoted to the variable that matters, it is a Hamilton–Jacobi equation in its own right — one whose spatial variable is the distribution and whose gradient is the Lions derivative. Making that reading explicit is the work of this section, and it pays off twice: it explains the *form* of the equation, and, more importantly, it predicts in advance the exact difficulties the well-posedness theory will have to overcome.

To see the shape, strip eq. (12.7) of its x-dependence for a moment and regard U as a function of (t,m) alone, gathering every term that involves the population — the frozen-agent HJB operator, the transport integral, and the diffusion integral — into a single effective *measure-Hamiltonian* $\mathcal{H}$. The equation then collapses to

$$-\partial_t U + \mathcal{H}(m, \partial_\mu U, \partial_y \partial_\mu U) = 0, \qquad U(T,\cdot) = G, \tag{12.10}$$

a backward, terminal-value Hamilton–Jacobi(–Bellman) equation in which the "state" is the measure m, the data are pinned at the terminal time $t = T$ by the coupling G (the value inherits its backward orientation from being a value, exactly the double bookkeeping flagged in the chapter preamble), and the "gradient" fed into $\mathcal{H}$ is the Lions derivative $\partial_\mu U$, with the spatial Jacobian $\partial_y\partial_\mu U$ supplying the second-order content. The arguments of $\mathcal{H}$ are therefore the population and its first and (one) second derivative, in exact analogy with a finite-dimensional Hamilton–Jacobi equation $-\partial_t U + \mathcal{H}(x, \nabla U, \mathrm{D}^2 U) = 0$, with m in the role of x and $\partial_\mu U$ in the role of ∇U.

This is not a metaphor, and it is worth pinning down why, because the precise sense in which $\partial_\mu U$ is a *gradient* is what licenses the whole analogy. Recall from chapter 4 the dynamic, Benamou–Brenier picture of the Wasserstein metric: the squared distance $\mathcal{W}_2(m_0, m_1)^2$ is the minimal kinetic energy $\int_0^1 \int |v_t|^2 \, \mathrm{d}m_t \, \mathrm{d}t$ of a velocity field v_t that transports m_0 to m_1 along the continuity equation $\partial_t m_t + \mathrm{div}(m_t v_t) = 0$. That construction equips $\mathcal{P}_2(\mathbb{R}^d)$ with a Riemannian-like structure in which the tangent space at m is a space of velocity fields, the cotangent objects are gradients of functions, and the pairing between a cotangent gradient $\partial_\mu \Psi(m)$ and a tangent velocity v is exactly

$$\langle \partial_\mu \Psi(m), \, v \rangle_m \; = \; \int_{\mathbb{R}^d} \partial_\mu \Psi(m)(y) \cdot v(y) \, m(\mathrm{d}y).$$

The transport term of the master equation is *precisely* this pairing, with the velocity field $v = -\partial_p H(\cdot, \nabla_x U)$ — the common optimal feedback under which the crowd flows. So when we call $\partial_\mu U$ the Wasserstein gradient of U we are not speaking loosely: it is the genuine Riemannian gradient of the dynamic metric of chapter 4, and the transport term is the genuine inner product of that gradient with the controlled velocity. The master equation is thereby revealed as the Hamilton–Jacobi equation of an optimal-control problem whose *state* is the entire distribution, whose controlled dynamics are the Fokker–Planck equation, and whose running and terminal costs are F and G — a control problem played on $\mathcal{P}_2(\mathbb{R}^d)$ rather than on $\mathbb{R}^d$.

With the shape identified, the same picture immediately predicts where the analysis will be hard, and this is the more valuable half of the reading. The difficulty is that the base space is $\mathcal{P}_2(\mathbb{R}^d)$, an infinite-dimensional, non-flat metric space that lacks almost every comfort the finite-dimensional theory relies on. There is no *local compactness*: a bounded sequence of measures need not have a $\mathcal{W}_2$-convergent subsequence, so the compactness arguments that underwrite existence of viscosity solutions in $\mathbb{R}^d$ have no direct analogue. There is no *canonical reference measure* — no Lebesgue measure on $\mathcal{P}_2(\mathbb{R}^d)$ — against which one could integrate, average, or define a heat kernel. And the space is genuinely *curved* in the Wasserstein sense, so even the linear structure that makes difference quotients meaningful is purchased only through the tangent-space construction recalled above. Each of these is an obstacle; but the decisive one, the hinge on which the entire well-posedness discussion turns, is the absence of a smoothing operator.

It is worth dwelling on this, because it is the single structural fact that controls everything downstream and is reused, in inverted form, under common noise. In a finite-dimensional HJB equation the second-order term $\frac{1}{2}\,\mathrm{tr}(\sigma\sigma^\top \mathrm{D}^2 U)$ is not cosmetic: it is what makes the equation *parabolic*. It is the term that smooths irregular data, that enforces a comparison principle, and that lets characteristics of the first-order part cross harmlessly — where they would otherwise collide and form a shock, the diffusion blurs the would-be singularity into a smooth profile, and a classical solution survives globally in time. Ask now for the analogous smoothing in the measure direction of eq. (12.7), the term that would diffuse U as a function of m, and there is none. The only second-order object in the equation is $\mathrm{D}_x^2 U$, the Hessian in the agent's *own* finite-dimensional coordinate x; it sits on the first line, it smooths U in x, and it is blind to the measure slot. The would-be "Laplacian on $\mathcal{P}_2(\mathbb{R}^d)$" — a non-negative second-order operator in m that would parabolically regularize U in the population direction — is simply absent. (It would require precisely the two-point measure Hessian $\partial_\mu^2 U(t,x,m)(y,y')$ catalogued in the notation watch after theorem 12.3, integrated against $m \otimes m$, and that object does not appear in the no-common-noise equation at all.) Heuristically: the idiosyncratic noise $\sigma\, \mathrm{d}W_t$ that each agent carries privately spreads each speck of mass *locally*, at one point y at a time, which is why it produced only the single-point Jacobian $\partial_y \partial_\mu U$ in the chain rule; it never correlates the random motion of distant specks, and so it cannot diffuse the *shape* of m as a whole. Local spreading of mass is not diffusion of the distribution.

The structural punchline follows at once, and it is the organizing fact of the next two sections. Because the genuine measure-dependence of eq. (12.7) enters only through the first derivative $\partial_\mu U$ and the single spatial Jacobian $\partial_y \partial_\mu U$ — never through a true second *measure* derivative — the master equation is, *in the m-direction*, a *first-order*, transport-type Hamilton–Jacobi equation. And a first-order Hamilton–Jacobi equation comes with a well-known liability: it is solved by characteristics, and characteristics generically *cross.* When two characteristic curves carrying different values of U collide, the solution becomes multivalued and the classical solution breaks down — the measure-space analogue of a shock. With no diffusion in m to smear such a collision away, nothing in the equation itself prevents it. One therefore expects a global classical solution *only* under a structural condition on the data strong enough to keep the characteristics from ever crossing in the first place. That condition is monotonicity — the very Lasry–Lions inequality (A-Mon) that bought uniqueness for the system in chapter 11 — now reappearing in its master-equation role as the hypothesis that organizes the characteristic flow so that distinct populations propagate to distinct values without collision. The cost of being first-order in m is exactly this: there is no free smoothing, so the regularity of U must be *purchased from structure* rather than supplied by the equation.

This also locates, in advance, the one place the missing Laplacian will be restored. When common noise is switched on in section 12.7, the shared shock moves all of the mass together and so correlates the motion of the speck at y with that of the speck at a distant y'; that correlation is precisely the two-point object $\partial_\mu^2 U(t,x,m)(y,y')$, and it enters the master equation through a new term $\frac{1}{2}\iint \partial_\mu^2 U(t,x,m)(y,y')\, \mathrm{d}m(y)\, \mathrm{d}m(y')$ (the shared-shock diffusion of section 12.7 riding inside it). That term *is* the Laplacian on $\mathcal{P}_2(\mathbb{R}^d)$ the no-common-noise equation lacked: a non-negative second-order operator in the measure direction that finally makes the master equation parabolic in m and restores, in the infinite-dimensional setting, the smoothing the finite-dimensional theory took for granted. The reader should carry forward the slogan that the present section establishes: *no common noise, first order in m, regularity bought from monotonicity; common noise, second order in m, regularity supplied by the equation.* The two regimes sit on opposite sides of exactly this divide.

Remark 12.5 (Potential games and a genuine variational principle)**.** There is one structurally favored case in which the control-problem reading of eq. (12.10) becomes literal rather than analogical, and it is worth isolating because it is the cleanest place the entire master-equation picture closes the loop with the chapter's opening physics note. Suppose the couplings derive from a *potential*: there are functionals $\mathcal{F}, \mathcal{G}$ on $\mathcal{P}_2(\mathbb{R}^d)$ with $F(x,m) = \frac{\delta \mathcal{F}}{\delta m}(m,x)$ and $G(x,m) = \frac{\delta \mathcal{G}}{\delta m}(m,x)$ (the variational/potential MFG of chapter 8). Then the equilibrium condition is no longer merely a Nash fixed point but the stationarity condition of a *single scalar functional* on the space of population trajectories, and the master equation is the Hamilton–Jacobi equation of that one control problem on $\mathcal{P}_2(\mathbb{R}^d)$. In this case U is itself a derivative, $U = \frac{\delta \mathcal{U}}{\delta m}(m, \cdot)$, of a value functional $\mathcal{U}$ on measures: the per-agent value is the first variation of an aggregate value, exactly as a one-particle quantity is a functional derivative of a free energy. This is the cleanest incarnation of the "effective action" picture sketched in the opening physics note of section 12.1: there U was offered as the analogue of an effective action $\Gamma[m]$ whose functional derivatives reproduce physical responses, with the caveat that the analogy carried no genuine variational principle in general. The potential case is precisely where that caveat lifts — there really is an action $\mathcal{U}$ whose stationary points are the equilibria, and U really is its derivative, so the field-theoretic picture is not just suggestive but exact. In the general, non-potential case no such scalar potential exists: the strategic (Nash) fixed point cannot be written as the critical point of any functional, and the master equation, *not* a variational problem, is the primary object. This is why the development that follows is built around the equation directly and does not lean on a minimization principle — it must work even when none is available.

We have read the equation's shape and, from that shape, anticipated its central difficulty: being first order in the measure, it must be solved along characteristics, and only monotonicity can keep those characteristics from crossing. Both halves of that sentence are now promissory notes the next two sections redeem. The phrase "solved along characteristics" is made literal first: the very next section exhibits the characteristic curves — they are the Fokker–Planck flows (m_t) already identified in the derivation — and shows that along them the single master equation degenerates into the coupled HJB/Fokker–Planck system, the unifying diagram that displays the three faces of the mean field game as one object. Only once those characteristics are in hand does the second phrase, "monotonicity prevents the characteristics from crossing," acquire a precise meaning; we therefore defer the well-posedness theory to section 12.6 and make the claim precise there, after exhibiting the characteristics themselves.

12.5 Method of characteristics: the unifying diagram

The previous section ended on a promissory note: read in the measure direction the master equation is first order, and a first-order Hamilton–Jacobi equation "is solved by characteristics." We now cash that promise. The base space $\mathcal{P}_2(\mathbb{R}^d)$ is identified, the candidate characteristic curves — the Fokker–Planck flows (m_t) — are already in hand from the derivation, and all that remains is to make the slogan literal: to exhibit the curves, write down the ODEs the PDE collapses to along them, and recognize those ODEs.

It pays to recall first what the method of characteristics *is*, in the finite-dimensional setting where it is elementary, because the measure-space version is the same idea transcribed onto a larger base space. Take a first-order Hamilton–Jacobi equation in $\mathbb{R}^d$, say $-\partial_t u + H(x, \nabla u) = 0$ with data at $t = T$. The method observes that one need not solve the PDE on all of space at once; instead one launches *characteristic curves* $t \mapsto x_t$ through the base space $\mathbb{R}^d$, chosen so that along each curve the partial differential equation degenerates into a closed system of *ordinary* differential equations for the position x_t, the value $u_t = u(t, x_t)$, and the momentum $p_t = \nabla u(t, x_t)$ — the Hamilton equations $\dot{x}_t = \partial_p H$, $\dot{p}_t = -\partial_x H$, with u_t recovered by integrating along the way. The PDE is then reconstructed by sweeping out the whole space with these curves: through each point passes one characteristic, and the value there is read off the ODE solution. The base space is where the curves live; the characteristic system is the bundle of ODEs they satisfy. That is the entire mechanism, and it is purely local to each curve.

The master equation is this same mechanism with the base space enlarged from $\mathbb{R}^d$ to the space of populations $\mathcal{P}_2(\mathbb{R}^d)$. A characteristic is now a curve $t \mapsto m_t$ *through the space of measures*, and the claim — which the derivation of section 12.3 has, in effect, already proved — is that the curves along which the master equation collapses to ODEs are exactly the *Fokker–Planck flows* (m_t) generated by the equilibrium feedback, and that the "ODEs" obtained along them are exactly the coupled HJB/Fokker–Planck system eq. (12.2) of chapter 8. (They are ODEs in the same generalized sense as before: a closed evolution along the characteristic, here a pair of PDEs in the agent's own coordinate x rather than scalar ODEs, because the base point m_t is itself infinite-dimensional.) Thus the single scalar equation for U, restricted to one characteristic, *is* the mean field game system; and this is the precise sense in which the three formulations of the mean field game — the master equation, the coupled HJB/Fokker–Planck system, and the McKean–Vlasov FBSDE of chapter 9 — are not three theories but one object viewed three ways. The theorem below states the equivalence in both of its remaining faces: the system (part 1, the converse of the derivation theorem) and the probabilistic FBSDE (part 2, where $\nabla_x U$ is revealed as the decoupling field).

Theorem 12.6 (Characteristics of the master equation)**.** *Let U be a classical solution of eq.* (12.7)*–eq.* (12.8) *with the regularity of theorem 12.3. Fix (t_0, m) and let $(m_t)_{t \geq t_0}$ be the Fokker–Planck flow generated by the feedback $\mathbf{b}_t(\cdot) = -\partial_p H(\cdot, \nabla_x U(t, \cdot, m_t))$, $m_{t_0} = m$. Then:*

1. *the value $u(t, x) := U(t, x, m_t)$ and the flow m_t solve the MFG system eq.* (12.2) *on $[t_0, T]$* (theorem 12.3)*;*

2. *equivalently, the McKean–Vlasov FBSDE of chapter 9 for the optimally controlled state X_t, its adjoint Y_t, and martingale integrand Z_t is solved by*

$$Y_t \;=\; \nabla_x U\big(t, X_t, m_t\big), \qquad Z_t \;=\; \mathrm{D}_x^2\, U\big(t, X_t, m_t\big)\, \sigma, \qquad m_t = \mathcal{L}(X_t), \tag{12.11}$$

so that $\nabla_x U$ is the decoupling field *of the FBSDE.*

Proof sketch. Part (1) is nothing new: it is exactly the converse direction of theorem 12.3, which showed that closing the Fokker–Planck equation eq. (12.2b) with the feedback $-\partial_p H(\cdot, \nabla_x U)$ and setting $u(t, x) = U(t, x, m_t)$ recovers the full MFG system. We restate it here only to display it as the *first* face of the characteristic picture — restricting U to the curve $m_\cdot$ produces the system — so that the second face, the probabilistic one, can be set beside it.

For part (2) we connect U to the McKean–Vlasov FBSDE through the dictionary already built in chapter 9, and the only work is a substitution. Recall the two ingredients from there. First, the stochastic maximum principle of chapter 9 represents the equilibrium of the game, for a *fixed* population flow (m_t), through a forward–backward pair: a forward state X_t driven by its optimal feedback control, and a backward adjoint (Y_t, Z_t) enforcing optimality, with Y_t the costate (the shadow price of position) and Z_t the integrand of its martingale part. Second — and this is the bridge to the PDE world — the nonlinear Feynman–Kac relation of chapter 5, applied to the HJB equation that u satisfies, identifies that probabilistic adjoint with spatial derivatives of the analytic value function. This is the FBSDE–PDE dictionary of proposition 9.12, namely eq. (9.16),

$$Y_t \;=\; \nabla u(t, X_t), \qquad Z_t \;=\; \sigma^\top \mathrm{D}^2 u(t, X_t),$$

which says: the costate is the gradient of the value at the random state, and the martingale integrand is its Hessian dressed by the diffusion. (Heuristically this is just Itô's formula applied to $t \mapsto \nabla u(t, X_t)$: the drift of the costate must match $-\partial_x H$ by the adjoint equation, and the diffusion coefficient of $\nabla u(t, X_t)$ is precisely $\mathrm{D}^2 u$ times σ, which is what Z_t collects.)

Now feed in the master function. Along the equilibrium flow generated by (t_0, m) the flow-consistency identity eq. (12.6) reads $u(t, x) = U(t, x, m_t)$, and differentiating it in x — which, as in the derivation, does not touch the frozen measure slot — gives $\nabla u(t, x) = \nabla_x U(t, x, m_t)$ and $\mathrm{D}^2 u(t, x) = \mathrm{D}^2_x U(t, x, m_t)$. Substituting these into the dictionary above, and using $m_t = \mathcal{L}(X_t)$ (the self-consistency that the state's law *is* the population it reacts to), turns the costate and integrand into evaluations of U at the running state and running population,

$$Y_t \;=\; \nabla_x U(t, X_t, m_t), \qquad Z_t \;=\; \sigma^\top \mathrm{D}^2_x U(t, X_t, m_t),$$

which is eq. (12.11) (modulo the transpose discussed below). That completes the identification; the substance is entirely in the two ch. 9 ingredients, and the master function contributes only the replacement of (t, x)-derivatives of u by the corresponding x-derivatives of U evaluated against the live population.

It remains to say what is *gained* by writing the adjoint this way, because this is the point of part (2). To call $\nabla_x U$ the *decoupling field* of the FBSDE is to make a structural claim, not just to record a formula. A forward–backward system is, a priori, genuinely coupled: the backward adjoint Y_t is defined by a terminal condition and an equation running from T down to t, so it appears to depend on the entire future of the path, while the forward state needs Y_t *now* to choose its drift. A *decoupling field* is a deterministic function $\phi(t, x)$ such that $Y_t = \phi(t, X_t)$ pathwise — the backward component is slaved to the present value of the forward component through a fixed function, with no dependence on the future beyond what X_t already carries. Its existence is exactly what breaks the forward–backward circularity: substituting $Y_t = \phi(t, X_t)$ into the forward drift closes the state equation into an ordinary (McKean–Vlasov) SDE one can integrate forward, after which the backward part is determined. Equation (12.11) exhibits such a function: $Y_t = \nabla_x U(t, X_t, m_t)$ is precisely of the form "deterministic function of the present state" (and present population), matching the definition definition 9.13. That this representation is not merely available but is what *well-poses* the system is the content of the two existence theorems of chapter 9: theorem 9.14, which produces the decoupling field and shows it is Lipschitz, and theorem 9.10, which uses that Lipschitz field to solve the FBSDE uniquely. The master equation thus does more than match the FBSDE — its x-gradient *is* the object whose existence makes the FBSDE solvable, which is why the master picture and the probabilistic picture stand or fall together. For attribution and the general theory of decoupling fields see [41], Ch. 4–5.

We record one notational reconciliation, because the two ch. 9 forms and the form natural here differ by a transpose. Equation (9.16) writes the martingale integrand as $Z_t = \sigma^\top \mathrm{D}_x^2 U(t, X_t, m_t)$, whereas eq. (12.11) writes $Z_t = \mathrm{D}_x^2 U(t, X_t, m_t)\, \sigma$. The difference is exactly the order of the constant matrix σ and the Hessian. In the canonical setting of this chapter σ is a constant symmetric matrix and $\mathrm{D}_x^2 U$ is symmetric (mixed partials of U in x commute), so $\sigma^\top \mathrm{D}_x^2 U = \sigma\, \mathrm{D}_x^2 U = \mathrm{D}_x^2 U\, \sigma$ and the two expressions literally coincide; the reconciliation is a triviality here and matters only when one later allows a non-symmetric or state-dependent σ. We keep eq. (12.11) in the form $\mathrm{D}_x^2 U\, \sigma$, since that is the order produced directly by Itô's formula applied to $Y_t = \nabla_x U(t, X_t, m_t)$: the diffusion of X_t is $\sigma\, \mathrm{d}W_t$, and differentiating the vector field $\nabla_x U$ along it contracts $\mathrm{D}_x^2 U$ against σ on the right. □

The whole correspondence is summarized by the following diagram, the central object of Part II. It has four corners — two analytic on the left, two probabilistic on the right; two "per-crowd" on top, two "single-equilibrium" on the bottom — and two arrows in each direction, and the entire content of this chapter is the statement that the diagram *commutes*: every path from the master equation in the top-left to the FBSDE in the bottom-right yields the same object.

$$
\boxed{
\begin{tikzcd}
\begin{array}{c}\textbf{Master equation}\\ U(t,x,m)\end{array} \arrow[r, "\text{restrict to } m_t"] \arrow[d, "\nabla_x"] & \begin{array}{c}\textbf{MFG system}\\ (u,m) = (U(\cdot,\cdot,m_\cdot),\, m_\cdot)\end{array} \arrow[d, "\text{Feynman–Kac}"] \\

\end{tikzcd}
}
\tag{12.12}
$$

Read *horizontally*, the two rows are the two ways of restricting a per-crowd object to a single realized equilibrium. Along the *top* row, the arrow "restrict to m_t" is the flow-consistency identity eq. (12.6) itself: one takes the master function $U(t, x, m)$, which knows the value of *every* crowd, and evaluates its measure slot along the one characteristic flow $m_\cdot$ launched from a given m_0; the result is the MFG system's value $u(t, x) = U(t, x, m_t)$, paired with the flow $m_\cdot$ that produced it. The free argument m collapses to the realized trajectory, and the flow map becomes a single orbit — exactly the "trajectory inside the flow map" picture of section 12.1. Along the *bottom* row, the arrow "evaluate along m_t, $X_t \sim m_t$" is the same restriction performed on the decoupling field: one takes the deterministic field $\nabla_x U(t, x, m)$ and reads it along the random state X_t and its law $m_t = \mathcal{L}(X_t)$, producing the FBSDE adjoint $Y_t = \nabla_x U(t, X_t, m_t)$ of eq. (12.11). Each row says the same thing at its own level: the left object is the per-crowd master version, the right object is its restriction to one equilibrium.

Read *vertically*, the two columns are the two passages from the analytic world to the probabilistic one. The *left* arrow, labeled ∇_x, is the operation of differentiating the master function in the agent's own coordinate: it sends the value U to the field $\nabla_x U$, i.e. it turns the master *equation* into the *decoupling field* — the gradient of a value is a momentum, the costate the agent acts on. The *right* arrow, labeled Feynman–Kac, is the same passage carried out on the restricted objects: the nonlinear Feynman–Kac dictionary of chapter 9 (built on chapter 5) sends the analytic MFG value (u, m) to its probabilistic representation (X_t, Y_t, Z_t). Commutativity of the square is then precisely eq. (12.11): differentiating first and then restricting (go down, then right) gives $\nabla_x U$ evaluated along m_t, X_t; restricting first and then applying Feynman–Kac (go right, then down) gives $\nabla u(t, X_t) = \nabla_x U(t, X_t, m_t)$; the two agree. Master equation, system, and FBSDE are the four corners of one commuting diagram, and there is no "primary" formulation among them at the level of a single fixed m_0 — each is recovered from any other by one of these four arrows.

And yet there *is* a reason to prefer the top-left corner, and the diagram makes it visible even though the system in the right column already answers the equilibrium question for a single m_0. The reason is the one structural asymmetry the diagram hides: only the left-column objects, U and $\nabla_x U$, are functions of the population m, and therefore only they can be *differentiated* in m. The MFG value $u(t, x)$ and the FBSDE triple in the right column have already had the measure slot frozen to the realized m_t; the dependence on the crowd has been evaluated away, and with it any possibility of asking how the value would change were the crowd slightly different. That measure-derivative is not an idle refinement — it is the engine of the two payoffs the rest of Part II is built to collect. *First*, finite-player convergence with the optimal rate. The N-player Nash value differs from the mean field value because the empirical population of N agents is a perturbation, of size $O(1/\sqrt{N})$ in $\mathcal{W}_2$, of the limiting m; expanding the N-player value around the mean field one requires a *smooth* dependence of the value on the population to Taylor-expand in, and that smoothness is exactly the Lions differentiability of U. The first variation $\partial_\mu U$ supplies the leading correction and the second variation controls the remainder, yielding convergence of the N-player game to the mean field limit at the optimal rate $O(1/N)$ — the "mean field expansion" that the bare system, having no m-argument to expand in, simply cannot write down (chapter 13). *Second*, stability of the equilibrium under perturbations of the initial population: if m_0 is nudged, the entire equilibrium flow and value move, and the linear response of the value to such a nudge is, by definition, the measure-derivative $\partial_\mu U$. The master function thus carries its own sensitivity analysis, where the system carries none. In both cases the lever is the same single fact — U is differentiable in m, the system is not — and it is the reason the per-crowd object earns its more demanding arena.

Everything in this section, however, has been stated *conditionally*. The characteristic equivalence of theorem 12.6, the decoupling identity eq. (12.11), the commuting diagram, and the differentiability that powers the two payoffs all presume that a classical solution U with the regularity of theorem 12.3 actually exists. We have shown what such a U *does* — it manufactures the system and the FBSDE from any datum, and its x-gradient is the decoupling field — but not that it *exists*, nor that it is unique. That is the one debt the chapter still owes, and the structure read off in section 12.4 has already warned us it will not be cheap: being first order in the measure, the master equation is solved along the very characteristics we have now exhibited, and first-order characteristics generically cross. Where two characteristic flows carrying different values collide, the diagram ceases to commute single-valuedly: the same crowd is assigned two values, U becomes multivalued, and the classical solution — with it, the whole construction of this section — breaks down. That collision is exactly the multiplicity of MFG equilibria, and the structural condition that forbids it is the monotonicity (A-Mon) we have invoked all along. The next section confronts this head on: it asks whether a regular U exists and is unique, and shows that monotonicity is precisely what keeps the characteristics from crossing, purchasing the regularity that the absence of measure-diffusion denies the equation for free. The commuting diagram, meanwhile, is not retired once well-posedness is settled; it is the object chapter 13 exploits, where the differentiability of U along the top-left corner becomes the mean field expansion of the N-player game.

12.6 Well-posedness in the monotone regime

Section 12.5 left the chapter with a single unpaid debt, and named the warning that comes with it. Everything established there about the master function — the equivalence with the system and the FBSDE (theorem 12.3), the equilibrium decoupling field (eq. (12.11)), the commuting diagram, and the differentiability in m that chapter 13 will exploit — was proved *conditionally*, granting that a classical solution U with the regularity demanded in theorem 12.3 actually exists. We have shown, at length, what such a U *does*; we have not shown that it *exists*, nor that it is *unique*. This section pays that debt, and the warning is that it cannot be paid for free.

The warning is structural, and it is worth stating in its honest, unsoftened form because it is what the whole section is organized against. Being first order in the measure argument, the master equation eq. (12.7) carries no diffusion in m — no second-order $\partial_\mu^2 U$ term to smooth the dependence on the population — and a first-order Hamilton–Jacobi equation is solved *along* its characteristics, which are exactly the MFG flows exhibited in section 12.5. But the characteristics of a first-order Hamilton–Jacobi equation generically *cross* in finite time. This is the same elementary mechanism by which a smooth scalar conservation law develops a shock: two characteristic curves carrying incompatible data run into the same point, and the would-be classical solution becomes multivalued there. Translate that collision back through the unifying diagram and it acquires a precise game-theoretic name. Two characteristics arriving at a common configuration m at a common time t means two distinct equilibrium flows — issuing from *different* initial data — both passing through the *same* population m and assigning it *different* continuation values $U(t, \cdot, m)$. That is exactly the multiplicity of MFG equilibria, the same m_0 supporting more than one equilibrium, studied in chapters 11 and 14; in the LQG thread it surfaces as a Riccati blow-up (chapter 14). Crossing of characteristics and non-uniqueness of equilibria are therefore not analogues but the *same event* seen from the two sides of the diagram, and either one destroys the single-valued U that the construction eq. (12.5) requires: where two values collide, $U(t, \cdot, m)$ has no well-defined number to report.

The substantive analytic question is thus not merely whether U is smooth but whether the characteristics can be kept from ever crossing, for *every* horizon and *every* initial population the construction reaches into. The structural condition that forbids the crossing is Lasry–Lions monotonicity (A-Mon), and one can already see, before any estimate, why monotonicity is the right hypothesis: it is precisely the inequality under which chapter 11 proved equilibria unique, and uniqueness of equilibria *is* non-crossing of characteristics. We therefore proceed by two routes, and we are honest at the outset about which parts of each are reproduced here and which are imported. The first route, through monotonicity, holds for *all* horizons but rests at one step on an all-horizon regularity estimate we state and attribute precisely rather than prove (theorem 12.8, remark 12.9). The second route abandons monotonicity entirely and proves *everything* in book, at the cost of a short horizon (proposition 12.10); it is the load-bearing self-contained result of the section, and we give its contraction in full. We begin with the hypotheses both routes draw on.

Assumption 12.7 (Standing hypotheses for well-posedness)**.** In addition to (A-Lip), (A-Growth), (A-Nondeg), and (A-Mon), assume the strict form of (A-Conv) — the Hamiltonian H is *strictly* convex in p (uniformly in x), as required by the uniqueness theorem theorem 11.5 that we import in Step 1 below — and that H and the couplings F, G are sufficiently smooth in all arguments, with $F(\cdot, m), G(\cdot, m)$ and their derivatives bounded uniformly in m. The monotonicity (A-Mon) is the Lasry–Lions condition of definition 11.1: recall (eq. (11.3)) that F is monotone when, for all $m, m' \in \mathcal{P}_2(\mathbb{R}^d)$,

$$\int_{\mathbb{R}^d} \left(F(x,m) - F(x,m')\right)(m - m')(\mathrm{d}x) \;\geq\; 0, \tag{12.13}$$

and likewise for G; we reproduce the inequality only for the reader's convenience, the object itself being definition 11.1. (A-Nondeg) provides the parabolic regularization in x.

Each clause of assumption 12.7 earns its place against a specific step of the proof, and it is worth pairing them now so that nothing in the assumption looks like decoration. The *strict* convexity of H in p is the hypothesis of the all-horizon uniqueness theorem theorem 11.5: the Lasry–Lions argument turns the monotonicity inequality eq. (12.13) into a *strict* sign only because strict convexity makes the Hamiltonian's contribution to the same pairing strictly definite, and without it two equilibria could differ on a set the monotonicity inequality cannot see. That is exactly Step 1 below, where uniqueness of the system at every horizon is what makes the construction eq. (12.5) single-valued; so strict (A-Conv) is the precise hypothesis that turns the candidate U from a multivalued recipe into a function. The *uniform-in-m* smoothness and boundedness of F, G and their derivatives is what lets the estimates of Steps 2 and 3 be uniform in the population argument — the master function must be controlled across *all* of $\mathcal{P}_2(\mathbb{R}^d)$ at once, not measure by measure, since its derivatives in m are the whole point. Finally, nondegeneracy (A-Nondeg) supplies the parabolic regularization in the spatial variable: it is what upgrades the merely Lipschitz objects produced by the fixed-point and linearization arguments to genuine classical x-derivatives $\nabla_x U$, $\mathrm{D}_x^2 U$, and it is also the smoothing that, in Step 2, absorbs the cross terms left over after the monotone coupling has been extracted with its favorable sign.

Theorem 12.8 (Well-posedness of the master equation, monotone regime)**.** *Under assumption 12.7 there exists a unique function $U : [0,T] \times \mathbb{R}^d \times \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}$ that is $\mathcal{C}^{1,2}$ in (t,x), fully $\mathcal{C}^2$ in m in the sense of definition 12.1, and that solves the master equation eq. (12.7) with terminal condition eq. (12.8) classically on $[0,T] \times \mathbb{R}^d \times \mathcal{P}_2(\mathbb{R}^d)$. Its derivatives are controlled uniformly: $\nabla_x U$ and $\partial_\mu U$ are bounded and Lipschitz uniformly in (t,x,m), and U moreover admits a bounded, Lipschitz* second-order *Lions derivative $\partial_\mu^2 U(t,x,m)(y,y')$ and a bounded, Lipschitz mixed derivative $\nabla_x \partial_\mu U(t,x,m)(y)$, both uniform in (t,x,m,y,y'). (These second-order objects do not enter the no-common-noise master equation eq. (12.7), but they exist as regularity of U and are exported for the finite-player expansion of chapter 13 and for the common-noise equation of section 12.7.) Moreover U is given by the construction eq. (12.5), and for every (t_0, m) the MFG system eq. (12.2) has a unique solution, whose value is the corresponding slice of U.*

Proof sketch and where the full argument lives. There are two routes; both pass through monotonicity. We describe the *characteristics* route, which is the most illuminating and the one the rest of the chapter has set up: build U from the system by eq. (12.5), show the construction is single-valued and smooth, and read back the equation. The argument is four steps — make the recipe a function, control its first m-derivative, control its second, then verify and close uniqueness — and we are explicit at the end about which step is reproduced here and which is imported.

Step 1 (global solvability of the system, so that U is a function at all). The construction eq. (12.5) reads $U(t_0, x, m)$ off the equilibrium of the game restarted from (t_0, m); for this to assign *one* number we need the restarted game to have exactly one equilibrium, at *every* restart datum (t_0, m) and over *every* horizon $[t_0, T]$. Existence holds under the standing assumptions by the fixed-point argument of chapter 10. Uniqueness is the delicate half, and it is where monotonicity does its work: by theorem 11.5, under (A-Mon) and the strict convexity of assumption 12.7 the MFG system eq. (12.2) has a unique classical solution on $[t_0, T]$, and crucially this holds for *all* horizons, not merely the physical one. The mechanism is exactly the no-crossing picture of the opening: the Lasry–Lions identity forces the a priori estimates on (u, m) to remain bounded *uniformly in the length of the interval* — monotonicity drains the energy that would otherwise let two equilibria separate as the horizon grows — so characteristics that start apart never collide and characteristics that arrive together must have coincided all along. (This is why chapter 11 took the trouble to prove uniqueness at arbitrary terminal time: the master function reaches into every sub-interval at once, and a uniqueness theorem for the single interval $[0, T]$ would not suffice.) With uniqueness in hand, eq. (12.5) defines U pointwise and single-valuedly, and strict (A-Conv) is seen to be load-bearing precisely here: it is the hypothesis of theorem 11.5 without which the recipe would be multivalued and there would be no function U to differentiate.

Step 2 (Lipschitz estimate in the measure). Next one shows U is Lipschitz in m for the $\mathcal{W}_2$ distance, uniformly in (t, x) — the bound that will make the first measure derivative $\partial_\mu U$ exist and stay bounded. Fix two nearby initial populations m, m', run the two equilibria (u, m_t) and (u', m'_t) they generate, and test how far apart their values can drift. The driver is again the monotonicity inequality eq. (12.13), deployed exactly as in the uniqueness proof of chapter 11: form the time derivative of the pairing $\int (u - u')\, \mathrm{d}(m_t - m'_t)$, substitute the two HJB equations for $\partial_t(u - u')$ and the two Fokker–Planck equations for $\partial_t(m_t - m'_t)$, and integrate by parts. The Hamiltonian terms collect, by strict convexity, into a nonnegative quadratic in $\nabla(u - u')$ weighted by $m_t + m'_t$; the coupling terms collect into $\int (F(\cdot, m_t) - F(\cdot, m'_t))\, \mathrm{d}(m_t - m'_t)$, which is ≥ 0 by eq. (12.13); and what remains — the cross terms generated by integrating the second-order operator by parts — is absorbed by the parabolic dissipation that (A-Nondeg) supplies, since $\sigma\sigma^\top$ is uniformly positive. The favorable signs on the two principal terms turn the pairing into a Grönwall inequality controlling $\sup_t \mathcal{W}_2(m_t, m'_t)$ and $\sup_t \|u - u'\|$ by $\mathcal{W}_2(m, m')$, uniformly in the horizon. Reading the bound at $t = t_0$ and recalling $U(t_0, x, m) = u(t_0, x)$ gives the $\mathcal{W}_2$-Lipschitz estimate on U, hence the boundedness of $\partial_\mu U$.

Step 3 (differentiability in the measure, to second order). Lipschitz continuity gives a derivative only almost everywhere; to obtain a genuine, continuous $\partial_\mu U$ one differentiates the construction itself. Perturb the initial population infinitesimally in an admissible mass-zero direction, $m \to m + \epsilon(m' - m)$, and differentiate the MFG system eq. (12.2) in ϵ at $\epsilon = 0$. Because the unperturbed (u, m_t) is fixed, the result is a *linear* forward–backward system — the *linearized MFG system* — for the pair of first variations $(\dot{u}, \dot{m}_t)$, with the linearized couplings $\frac{\delta F}{\delta m}(m_t, \cdot)$, $\frac{\delta G}{\delta m}(m_T, \cdot)$ as sources. Its unique solvability is once more a consequence of monotonicity, now in its linearized (Hessian) form: the same Lasry–

Lions pairing applied to the linear system shows the homogeneous problem has only the zero solution, so the inhomogeneous one is uniquely solvable. The solution map $(m' - m) \mapsto \dot{u}(t_0, \cdot)$ is linear and bounded, and that is by definition the flat derivative $\frac{\delta U}{\delta m}(t_0, \cdot, m, \cdot)$; its spatial gradient is $\partial_\mu U$, and the Step-2 estimate makes it uniformly bounded and continuous in (t, x, m, y). Differentiating the linearized system *once more* — a second perturbation, in an independent direction $m'' - m$ — produces a *second* linear system for the second variations, solvable by the same monotonicity, and its solution map is the second-order Lions derivative $\partial_\mu^2 U(t, x, m)(y, y')$ together with the mixed derivative $\nabla_x \partial_\mu U(t, x, m)(y)$. These inherit uniform boundedness and Lipschitz continuity from the same estimates. They do not appear in the no-common-noise master equation eq. (12.7), but they are genuine regularity of U, and they are exactly the objects exported to chapter 13 for the finite-player expansion and to section 12.7 for the common-noise equation. Throughout, the parabolic smoothing of (A-Nondeg) upgrades the variations from weak to classical x-derivatives, so $\nabla_x U$ and $\mathrm{D}_x^2 U$ are honest pointwise objects.

Step 4 (verification and uniqueness of the master solution). With U constructed and shown regular, theorem 12.3 applies verbatim: its forward direction shows this U solves the master equation eq. (12.7) with terminal data eq. (12.8). Uniqueness of the classical solution is then immediate from the characteristic representation theorem 12.6. Any classical solution of eq. (12.7) must, by the converse direction of theorem 12.3, agree along each characteristic with the value of the corresponding system equilibrium, which Step 1 showed is unique; and the characteristics issuing from the data $(t_0, \cdot)$, as (t_0, m) ranges over $[0, T] \times \mathcal{P}_2(\mathbb{R}^d)$, *fill* the domain — every point (t, x, m) lies on the characteristic restarted from its own (t, m). A classical solution pinned to the unique system value on a set that fills the space is unique. This closes the construction.

Steps 1 and 4 are fully in-book: existence and all-horizon uniqueness of the system are chapters 10 and 11, and the verification and uniqueness of the master solution from the characteristics are theorems 12.3 and 12.6, both proved here in full. What we do *not* reproduce is the quantitative core of Steps 2 and 3 — the precise function spaces and the linearized-system $\mathcal{W}_2$-Lipschitz and differentiability estimates that show the constructed U is genuinely twice differentiable in m with the stated uniform bounds. We have given the *mechanism* of those steps honestly — the monotone pairing, the favorable signs, the linearized systems — but the passage from mechanism to uniform all-horizon estimate is a monograph-length undertaking. It is carried out for the non-degenerate monotone case in [37] (their main theorem) and, by the probabilistic decoupling-field method, in [41], Ch. 5. □

Remark 12.9 (Status of theorem 12.8: an acknowledged imported result)**.** This is the one place in the chapter where a load-bearing argument is imported rather than reproduced, and the book's self-containedness doctrine requires us to say so plainly and to draw the line exactly. On the in-book side: the *equivalence* of the three formulations (theorem 12.3), the *characteristic representation* that powers the verification and uniqueness (theorem 12.6), the *mechanism* of monotonicity — the no-crossing picture and the Lasry–Lions pairing that gives Steps 1–4 their structure — and the entire *short-horizon* well-posedness (proposition 12.10 below) are proved here in full. On the imported side, and *only* on it: the all-horizon, uniform $\mathcal{C}^2$-in-m regularity estimates that turn the mechanism of Steps 2–3 into quantitative bounds. We do not prove those, and we do not pretend to; we cite them precisely, to [37] (their main theorem, the non-degenerate monotone case) and to [41], Ch. 5 (the probabilistic decoupling-field route). The reason is genuine rather than expedient: these estimates are themselves a research monograph's worth of parabolic and Wasserstein-calculus analysis, on the same footing as the handful of other foundational results the book imports, and reproducing them would bury rather than illuminate the master equation's structure, which is this chapter's subject. The honest reader's takeaway is the boundary itself: nothing about *what* the master equation is, or *why* it is equivalent to the system, or *how* monotonicity prevents the breakdown, is taken on faith — only the hard regularity number at the end of an all-horizon estimate is.

The import in remark 12.9 can be retired entirely, at one cost: a short horizon. We now give a complete, self-contained proof of well-posedness for T small that uses no monotonicity whatsoever — the second of the two regimes remark 12.11 will name. It is the same contraction that produced short-time existence for the MFG system in chapter 10 and short-time uniqueness in section 11.7, now packaged at the level of the master function, and it is the load-bearing self-contained result of the section: where Steps 2–3 above imported their estimate, here every constant is exhibited. The single mechanism is that on a short interval the best-response map cannot move its input far, because everything that drives it is an integral over the short window $[t_0, T]$ of bounded integrands.

Proposition 12.10 (Short-horizon well-posedness of the master equation)**.** *Assume* (A-Lip)*,* (A-Growth)*,* (A-Nondeg)*, the strict form of* (A-Conv)*, and that H, F, G are bounded with bounded, Lipschitz first and second derivatives in all arguments (*no monotonicity is assumed*). There is $T_\star > 0$, depending only on these bounds and the Lipschitz constants, such that for every horizon $T \le T_\star$ the master function U of eq.* (12.5) *is well defined, single-valued, $\mathcal{C}^{1,2}$ in (t,x), and fully $\mathcal{C}^2$ in m with $\nabla_x U$, $\partial_\mu U$, $\partial_\mu^2 U$, $\nabla_x \partial_\mu U$ bounded and Lipschitz uniformly in (t,x,m); it solves eq.* (12.7)*–eq.* (12.8) *classically and is the unique such solution.*

Proof. The proof is a contraction on the decoupling field, run on the Banach space the rest of the book already provides. Let $\mathcal{B}$ be the space of maps $\Phi : [0,T] \times \mathbb{R}^d \times \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}^d$ that are bounded, Lipschitz in x and (for $\mathcal{W}_2$) in m, with norm $\|\Phi\|_{\mathcal{B}} = \sup|\Phi| + \mathrm{Lip}_x(\Phi) + \mathrm{Lip}_m(\Phi)$; $\mathcal{B}$ is complete. Define the map S as follows. Given a candidate decoupling field $\Phi \in \mathcal{B}$ and an initial datum (t_0, m), let $(m_t)_{t \ge t_0}$ be the Fokker–Planck flow generated by the feedback $-\partial_p H(\cdot, \Phi(t, \cdot, m_t))$ with $m_{t_0} = m$ — well posed and Lipschitz-dependent on the data by theorem 7.9 and (A-Nondeg) — and let $u(t,x)$ solve the backward HJB eq. (12.2a) along this fixed flow; this is a *linear* (in the sense of fixed-coefficient) backward parabolic problem with terminal data $G(\cdot, m_T)$, uniquely and classically solvable with Schauder estimates under (A-Nondeg). Set $(\mathsf{S}\Phi)(t_0, x, m) := \nabla_x u(t_0, x)$.

A fixed point $\Phi = \mathsf{S}\Phi$ is, by construction, a decoupling field whose induced (u, m) solves the full MFG system from every (t_0, m): the flow m_t was built from the feedback $-\partial_p H(\cdot, \Phi)$ and u solves the HJB along it, and the fixed-point identity $\Phi = \nabla_x u$ is exactly the decoupling relation $\nabla u = \nabla_x U$ that ties the two halves of the system together. Equivalently, U defined by $\nabla_x U = \Phi$ and $U(t_0, x, m) = u(t_0, x)$ solves the master equation, by the computation of theorem 12.3 read backwards. So everything reduces to one assertion: S is a contraction on $\mathcal{B}$ for small T. We prove it by exhibiting the contraction constant, because that constant is the entire content of the short-horizon theory.

Decompose S into its two constituent maps, $\mathsf{S} = \mathsf{G} \circ \mathsf{F}$, where $\mathsf{F} : \Phi \mapsto (m_t)$ is the forward flow construction and $\mathsf{G} : (m_t) \mapsto \nabla_x u(t_0, \cdot)$ is the backward solve. The smallness for short T enters entirely through F, and it is worth seeing exactly why, since this is the mechanism the whole proposition turns on. Take two candidate fields Φ, Φ' and the two flows $(m_t), (m'_t)$ they generate from the *same* initial datum $m_{t_0} = m'_{t_0} = m$. At (t, x) the two drifts are $-\partial_p H(x, \Phi(t, x, m_t))$ and $-\partial_p H(x, \Phi'(t, x, m'_t))$, and their difference splits into a part charged to $\Phi - \Phi'$ and a part charged to $m_t - m'_t$,

$$\left|\partial_p H(x, \Phi(t, x, m_t)) - \partial_p H(x, \Phi'(t, x, m'_t))\right| \;\le\; L\,\|\Phi - \Phi'\|_{\mathcal{B}} \;+\; L'\,\mathcal{W}_2(m_t, m'_t),$$

the constants L, L' furnished by the bounded second derivatives of H together with the Lipschitz-in-m norm built into $\mathcal{B}$. Feeding this into the standard stability estimate for the Fokker–Planck/McKean–Vlasov flow (theorem 7.9, with the diffusion nondegenerate by (A-Nondeg)) and applying Grönwall over $[t_0, t]$ gives

$$\mathcal{W}_2(m_t, m'_t) \;\le\; \int_{t_0}^{t} \Big(L\,\|\Phi - \Phi'\|_{\mathcal{B}} + L'\,\mathcal{W}_2(m_s, m'_s)\Big)\,\mathrm{d}s \;\le\; C_1\,(t - t_0)\,\|\Phi - \Phi'\|_{\mathcal{B}}\,,$$

the crucial $(t - t_0)$ factor coming from precisely the fact that the two flows are *pinned to the same m at t_0*: they can separate only by accumulating the drift discrepancy over the elapsed window, so their separation is an integral over $[t_0, t]$ and vanishes as $t \downarrow t_0$. Thus F is Lipschitz with constant $C_1(T - t_0)$.

The backward solve G carries no such smallness on its own — as $T \downarrow t_0$ the value $u(t_0, \cdot)$ tends to the terminal datum $G(\cdot, m)$ and its gradient to ∇G, an $O(1)$ object — but it does not need any, because all of Φ's influence has already passed through F. What G must supply is only ordinary Lipschitz dependence on its *flow* input. Writing $w = u - u'$ for the difference of the two backward solutions along (m_t) and (m'_t), w solves a linear backward parabolic equation whose terminal datum is $G(\cdot, m_T) - G(\cdot, m'_T)$ and whose source is $F(\cdot, m_t) - F(\cdot, m'_t)$; both are bounded in sup-norm by $L'' \sup_t \mathcal{W}_2(m_t, m'_t)$ using the Lipschitz couplings, and the Schauder estimates of (A-Nondeg) bound $\nabla_x w(t_0, \cdot)$ by the same quantity. Hence G is Lipschitz with an $O(1)$ constant C_2 in $\sup_t \mathcal{W}_2(m_t, m'_t)$. (A part of the source, the running-data integral, in fact contributes its own $O(T - t_0)$ factor for the same window reason; we do not need it, the F-factor already sufficing.) Composing the two,

$$\|\mathsf{S}\Phi - \mathsf{S}\Phi'\|_{\mathcal{B}} \;\le\; C_2 \cdot C_1(T - t_0)\,\|\Phi - \Phi'\|_{\mathcal{B}} \;=:\; C\,(T - t_0)\,\|\Phi - \Phi'\|_{\mathcal{B}} \;\le\; C\,T\,\|\Phi - \Phi'\|_{\mathcal{B}}\,.$$

Therefore, for $T \le T_\star := 1/(2C)$, the map S is a $\frac{1}{2}$-contraction on the closed ball of $\mathcal{B}$ that its (horizon-uniform) bounds leave invariant. By the Banach fixed-point theorem (theorem 2.36) it has a unique fixed point $\Phi^\star = \nabla_x U$, and this delivers existence and uniqueness of the smooth master solution. Notice that $T_\star$ depends only on C, hence only on the sup-norms and Lipschitz constants of H, F, G and their first two derivatives — exactly the data named in the proposition, and nothing about monotonicity.

Differentiability in m to second order is obtained by running the *same* contraction on a larger Banach space that records the m-derivatives alongside Φ. Differentiating the fixed-point identity $\mathsf{S}\Phi = \Phi$ formally in the measure direction — legitimate because the coefficients H, F, G are $\mathcal{C}^2$ — yields linear fixed-point equations for $\partial_\mu \Phi$ and $\partial^2_\mu \Phi$ in which the linear operator is the derivative of S and therefore inherits the *same* contraction factor $C(T - t_0)$. For $T \le T_\star$ these linearized fixed-point problems are themselves contractions, so $\partial_\mu \Phi$ and $\partial_\mu^2 \Phi$ exist, are their unique solutions, and inherit the uniform bounds of $\Phi^\star$; the mixed $\nabla_x \partial_\mu U$ comes out of the same system. Parabolic regularity of the backward solve upgrades the x-dependence to $\mathcal{C}^{1,2}$. This is a complete, self-contained proof of well-posedness on a short horizon: no estimate has been imported, and every constant traces to the bounds in the hypotheses. The sole role of monotonicity in theorem 12.8 is to remove the restriction $T \leq T_\star$ — to make the no-crossing of characteristics hold for all horizons rather than only short ones. □

Remark 12.11 (Beyond monotonicity, and the short-horizon alternative)**.** Two honest caveats frame what we have, and what we have not, proved. First, monotonicity is *sufficient but not necessary*: there are perfectly well-behaved non-monotone problems whose master solution is smooth, but no general well-posedness theory covers them, and the boundary is sharp in the worst case — in the non-monotone regime classical solutions can fail to exist *exactly* when MFG equilibria become non-unique, which is the characteristics crossing of this section's opening realized in an example. Chapter 14 exhibits precisely this for the LQG thread, where the loss of a classical U shows up as a finite-time blow-up of the Riccati matrix that parametrizes it. Second, monotonicity is not the only escape: even without it one always has a *local*, short-horizon classical solution, by the contraction proposition 12.10, for which every constant was exhibited above. The two facts fit together cleanly — short horizon buys smoothness unconditionally, monotonicity buys it for all horizons — and they are two instances of a dichotomy that recurs across the whole book: "small coupling or short horizon," where a contraction closes the argument with explicit constants, versus "monotone for all horizons," where a structural sign condition does the work no contraction can. We will meet this same pair again for graphon games, where the role of the smallness parameter is played by the operator norm of the graphon: well-posedness holds either below the operator-norm threshold (A-Coupling) — the graphon analogue of small coupling or short horizon — or under a monotonicity condition on the kernel, and chapter 24 draws the threshold exactly.

This settles the well-posedness question for the theory built on Lasry–Lions monotonicity (A-Mon), and it is worth being precise about what "the theory built on (A-Mon)" quietly assumed. The monotonicity inequality eq. (12.13) pairs a *coupling* difference $F(\cdot, m) - F(\cdot, m')$ against a *measure* difference $m - m'$; it never touches the Hamiltonian, because in the setting of this section the population enters only through the additive couplings $F(x, m), G(x, m)$ while the Hamiltonian $H(x, p)$ carries no measure. That is the *separable* structure, and Lasry–Lions monotonicity is exactly tailored to it: the favorable sign in Steps 2–3 came from the coupling and the Hamiltonian sitting in separate, independently-signed terms of the pairing. The moment the Hamiltonian itself depends on the population — $H(x, p, m)$, with the crowd coupling directly to an agent's own velocity, as it must in any genuine congestion or trading model — those terms no longer separate, the Lasry–Lions pairing mixes Hamiltonian and coupling contributions, and the sign that protected the characteristics can be spoiled by their interaction. The monotonicity method breaks at exactly the place where the coupling and the Hamiltonian are forced to cooperate. Chapter 11 flagged this non-separable case and deferred the operative condition; that condition — *displacement* monotonicity, the structural hypothesis that restores a favorable sign when H and the coupling can no longer be signed apart — is the subject of the subsection that follows.

12.6.1 Displacement monotonicity and non-separable Hamiltonians

The closing paragraph of section 12.6 located the exact fault line, and this subsection works on it. Recall the breakdown just diagnosed: the moment the Hamiltonian itself depends on the crowd — $H(x, p, m)$, as in any honest congestion or trading model where the cost of moving rises with the local density one must push through — the Lasry–Lions pairing of Steps 2–3 no longer splits into a Hamiltonian term and a coupling term that can be signed *independently*; the two contributions merge, and the sign that protected the characteristics from crossing can be destroyed by their cross-interaction. Chapter 11 foresaw this, flagged the non-separable case as outside the reach of its uniqueness theorem, and deferred to the present chapter the precise condition that takes over together with the proof that it does for the master operator what Lasry–Lions did in the separable theory. The condition is *displacement monotonicity*, and we now supply both items: the definition, and the proof that it makes the master operator monotone.

The conceptual move behind the new condition is a change of *geometry* on the space of measures, and it pays to see it clearly before writing anything down, because the two monotonicity conditions are two ways of asking the *same* object to be increasing along two *different* families of paths through $\mathcal{P}_2(\mathbb{R}^d)$. Lasry–Lions monotonicity lives in the *flat* geometry: it interpolates between two populations along the straight segment $\epsilon \mapsto m + \epsilon(m' - m)$ of signed measures — the same linear interpolation that defined the flat derivative in definition 12.1 — and asks that the cost pair favorably with the mass-zero direction $m' - m$. Mass is reweighted in place; nothing moves. The displacement geometry interpolates instead along a *Wasserstein geodesic*: it lifts the two measures to random variables X, X' with $\mathcal{L}(X) = m$, $\mathcal{L}(X') = m'$ and slides along the L^2 segment $\epsilon \mapsto (1 - \epsilon)X + \epsilon X'$, whose law is the displacement (optimal transport) interpolation between m and m'. Now mass is genuinely *transported*: each particle at position $X(\omega)$ glides to $X'(\omega)$. The natural object to ask about along such a path is not how the cost pairs with a reweighting but how its *spatial gradient* — the force felt by a particle — pairs with the *displacement* $X - X'$ that carries the particle. That is exactly what eq. (12.14) below will demand: the lifted gradient field $X \mapsto \nabla_x\Theta(X, \mathcal{L}X)$ should be a monotone operator on $L^2(\Omega; \mathbb{R}^d)$, increasing along L^2 segments just as a monotone function on the line increases along intervals. The reader should hold onto the slogan: flat monotonicity signs a *reweighting* against a *cost*; displacement monotonicity signs a *transport* against a *force*.

Definition 12.12 (Displacement monotonicity)**.** A function $\Theta : \mathbb{R}^d \times \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}$, of class $\mathcal{C}^1$ in x, is *displacement monotone* if for every pair of square-integrable $\mathbb{R}^d$-valued random variables X, X' on a common atomless probability space,

$$\mathbb{E}\big[\langle \nabla_x\Theta(X, \mathcal{L}(X)) - \nabla_x\Theta(X', \mathcal{L}(X')), X - X'\rangle\big] \;\geq\; 0. \tag{12.14}$$

Equivalently, the lifted map $X \mapsto \nabla_x\Theta(X, \mathcal{L}(X))$ is a monotone operator on $L^2(\Omega; \mathbb{R}^d)$. The standing data F, G are *displacement monotone* when eq. (12.14) holds for each of them.

Three features of the definition deserve to be drawn out, because each is exactly what makes eq. (12.14) the right inequality and not a cosmetic variant of the flat one. First, the two arguments of $\nabla_x\Theta$ move *together*: in $\nabla_x\Theta(X, \mathcal{L}X)$ the spatial slot is the random variable X and the measure slot is its *own* law, so as we slide X toward X' both slots vary, and the inequality controls the joint response of the gradient to this coupled motion. This is why the lift to L^2 is not optional bookkeeping but the content of the condition: only on $L^2(\Omega;\mathbb{R}^d)$ can "spatial position" and "population" be varied by the single object X. Second, the pairing is with $X - X'$, a vector in L^2, and the natural dual of a *force* $\nabla_x\Theta$ is precisely a *displacement*; the dimensions match a transport, not a reweighting. Third, atomlessness of the probability space is what guarantees that *every* pair of laws (m, m') is representable by some pair (X, X') — including, crucially, by the optimal-transport coupling that realizes $\mathcal{W}_2(m, m')$ — so quantifying over random variables genuinely quantifies over all of Wasserstein space and over all geodesics through it. A useful micro-check: in the degenerate case where $\Theta(x, m) = \theta(x)$ carries no measure dependence, eq. (12.14) reduces to $\mathbb{E}\langle\nabla\theta(X) - \nabla\theta(X'), X - X'\rangle \geq 0$, which is exactly the statement that $\nabla\theta$ is a monotone vector field, i.e. that θ is convex. Displacement monotonicity is thus the measure-coupled generalization of "the gradient is monotone, the function is convex," and the next remark makes that parallel precise.

Remark 12.13 (Displacement versus Lasry–Lions)**.** The two conditions are genuinely different, and neither implies the other; it is worth being exact about how they differ, because the difference is the whole reason a second condition is needed. Definition 11.1 pairs the increment of the *cost itself, across two measures*, $F(\cdot, m) - F(\cdot, m')$, against the signed measure $m - m'$ in the flat duality — a pairing of a function against a reweighting, integrated over space. Equation (12.14) pairs the increment of the *state-gradient of the cost*, $\nabla_x F(X, m) - \nabla_x F(X', m')$, against the displacement $X - X'$ of the underlying random variables — a pairing of a force against a transport, averaged over Ω. The objects paired are different (cost versus gradient-of-cost), the directions paired against are different ($m - m'$ versus $X - X'$), and the duality is different (flat $L^2(\mathbb{R}^d)$ versus lifted $L^2(\Omega)$). There is no algebraic identity converting one into the other.

The cleanest way to *see* that neither implies the other is the potential case, which also exhibits the exact parallel between the two conditions and their two convexities. Suppose the coupling derives from a potential, $F(x, m) = \frac{\delta\mathcal{F}}{\delta m}(m, x)$ for some functional $\mathcal{F} : \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}$ — the situation in every variational (potential) MFG. Then the two monotonicities of F are precisely the two *convexities* of $\mathcal{F}$:

- Lasry–Lions (flat) monotonicity of F $\iff$ *flat convexity* of $\mathcal{F}$, i.e. $\epsilon \mapsto \mathcal{F}\big(m + \epsilon(m' - m)\big)$ is convex along linear interpolations of measures;
- displacement monotonicity of F $\iff$ *displacement convexity* of $\mathcal{F}$, i.e. the lift $\epsilon \mapsto \mathcal{F}\big(\mathcal{L}((1-\epsilon)X + \epsilon X')\big)$ is convex along L^2 segments — McCann's notion of convexity along Wasserstein geodesics.

In each line the monotonicity of the gradient $\delta\mathcal{F}/\delta m$ is the convexity of $\mathcal{F}$ along the corresponding family of paths; the two lines differ only in *which* paths. That these are independent is now concrete. Take the interaction energy $\mathcal{F}(m) = \frac{1}{2}\iint_{\mathbb{R}^d\times\mathbb{R}^d} K(x-y)\, m(\mathrm{d}x)\, m(\mathrm{d}y)$ with an even kernel K, whose flat derivative is the convolution $F(x, m) = (K * m)(x)$. Flat convexity of $\mathcal{F}$ holds exactly when K is a *positive-definite* kernel ($\widehat{K} \geq 0$), which is the classical Lasry–Lions monotonicity of a convolution coupling; displacement convexity holds exactly when K is *convex* as a function on $\mathbb{R}^d$ (McCann's criterion). A convex kernel need not be positive-definite and a positive-definite kernel need not be convex — the Gaussian $K(z) = e^{-|z|^2}$ is positive-definite but not convex, while a convex but oscillation-free even kernel can fail positive-definiteness — so the two conditions select genuinely different classes of couplings, neither containing the other.

The decisive point, and the reason the displacement condition is the one this subsection needs, is *compatibility with a p-dependent, m-coupled Hamiltonian.* Lasry–Lions monotonicity was built to sign a term in which the coupling and the Hamiltonian appear *separately*; it has no purchase once the population enters through the momentum slot. Displacement monotonicity, by contrast, pairs against the displacement $X - X'$ — and, as the proof of proposition 12.14 will show, the difference of two FBSDE trajectories generates *exactly* pairings of this form, gradient-increment against state-increment, with the population slot riding along as $\mathcal{L}(X)$ versus $\mathcal{L}(X')$. It is the condition the non-separable computation naturally produces and can therefore consume, where the flat one is left with no term to attach to.

With the geometry fixed and the condition stated, the payoff is the same structural conclusion as in the separable theory — a *monotone decoupling field*, the no-crossing of characteristics that section 12.6 identified as the heart of well-posedness — but now reached through the displacement pairing rather than the flat one. We prove it in the canonical control-as-drift setting eq. (12.1) of this chapter, where the Hamiltonian is $H(x,p) = \frac{1}{2}|p|^2$ and the entire population coupling sits in F, G; in this setting every term is explicit and the role of each displacement-monotonicity hypothesis can be watched as it enters. The restriction to $\frac{1}{2}|p|^2$ is for transparency, not necessity: for a Hamiltonian carrying its own x- and m-dependence the same pairing is run, with H itself required to satisfy the joint displacement-monotone analogue (monotonicity of $(X,P) \mapsto (\nabla_x H, -\nabla_p H)$ in the lifted variables), and the all-horizon theory under that hypothesis is the subject of [76] and [104], which we cite for the full quantitative estimates.

Proposition 12.14 (Displacement monotonicity yields a monotone master operator)**.** *Work in the canonical setting eq.* (12.1) *with σ constant nondegenerate and $H(x,p) = \frac{1}{2}|p|^2$, and suppose F and G are displacement monotone (definition 12.12) with bounded Lipschitz x-gradients. Let (X_t, Y_t) and (X'_t, Y'_t) be two solutions of the MFG FBSDE of chapter 9 on $[0,T]$, driven by the* same *Brownian motion, with $m_t = \mathcal{L}(X_t)$ and $m'_t = \mathcal{L}(X'_t)$. Then*

$$\mathbb{E}\big[\langle Y_0 - Y'_0, X_0 - X'_0\rangle\big] \;\geq\; \int_0^T \mathbb{E}\,\left|Y_t - Y'_t\right|^2 \mathrm{d}t \;\geq\; 0. \tag{12.15}$$

In particular, whenever the two equilibria start from the same state ($X_0 = X'_0$ a.s.) they coincide, so the FBSDE has at most one solution and the master function eq. (12.5) *is single-valued; and writing $Y_t = \nabla_x U(t, X_t, m_t)$* (eq. (12.11))*, the decoupling field $\nabla_x U$ is a* monotone *operator. This is the structural input that well-poses the master equation for non-separable couplings, replacing Lasry–Lions monotonicity in theorem 12.8.*

Proof. The whole proof is a single application of Itô's product rule to the inner product of the two trajectory-differences, and the displacement-monotonicity hypotheses enter at exactly the two boundary-and-running terms that the product rule produces. We track every step, because the sign of each term is the entire content.

The two FBSDEs. In the canonical setting the optimal feedback is $\alpha^* = -\partial_p H(x, Y) = -Y$ (since $\partial_p H = p$ for $H = \frac{1}{2}|p|^2$), so the MFG FBSDE of chapter 9 reads

$$\mathrm{d}X_t = -Y_t\ \mathrm{d}t + \sigma\ \mathrm{d}W_t, \qquad \mathrm{d}Y_t = -\nabla_x F(X_t, m_t)\ \mathrm{d}t + Z_t\ \mathrm{d}W_t, \qquad Y_T = \nabla_x G(X_T, m_T),$$

with $m_t = \mathcal{L}(X_t)$. Here $\nabla_x H \equiv 0$ because $H = \frac{1}{2}|p|^2$ does not depend on x, so the backward driver, which in general is $\nabla_x H(X_t, Y_t) - \nabla_x F(X_t, m_t)$ by the adjoint (stochastic Pontryagin) computation of chapter 9, collapses to $-\nabla_x F(X_t, m_t)$. The second pair (X'_t, Y'_t) solves the same system with $m'_t = \mathcal{L}X'_t$. Write $\Delta X_t = X_t - X'_t$ and $\Delta Y_t = Y_t - Y'_t$ for the trajectory differences, and $\Delta Z_t = Z_t - Z'_t$.

Why ΔX has no martingale part. Subtract the two forward equations. The drift contributes $-(Y_t - Y'_t)\ \mathrm{d}t = -\Delta Y_t\ \mathrm{d}t$. The diffusion contributes $\sigma\ \mathrm{d}W_t - \sigma\ \mathrm{d}W_t$, which is *identically zero*: this is precisely where the two hypotheses "same Brownian motion" and "σ constant" are spent. Because σ is a deterministic, state-independent constant and the *same* W drives both forward equations, the two stochastic integrals are literally the same process and cancel. Were $\sigma = \sigma(x, m)$ state- or measure-dependent, the difference would leave a residual $(\sigma(X_t, m_t) - \sigma(X'_t, m'_t))\ \mathrm{d}W_t$ and ΔX would carry a martingale part, re-introducing a quadratic-variation term below; the canonical constant-σ setting is exactly what removes it. Hence

$$\mathrm{d}\Delta X_t = -\Delta Y_t\ \mathrm{d}t,$$

a process of finite variation in t (absolutely continuous paths), with no $\mathrm{d}W$ term.

Itô's product rule. Apply the product rule (theorem 5.9) to the scalar $\langle \Delta X_t, \Delta Y_t\rangle$:

$$\mathrm{d}\langle \Delta X_t, \Delta Y_t\rangle = \langle \mathrm{d}\Delta X_t, \Delta Y_t\rangle + \langle \Delta X_t, \mathrm{d}\Delta Y_t\rangle + \mathrm{d}\langle \Delta X, \Delta Y,_\rangle\, t.$$

The last term is the quadratic co-variation of the two difference processes. *It vanishes*: co-variation only sees the martingale (Brownian) parts of the two processes, and ΔX has none — it is of finite variation, by the previous paragraph — so $\mathrm{d}\langle \Delta X, \Delta Y,_\rangle\, t = 0$ regardless of the martingale part $\Delta Z_t\ \mathrm{d}W_t$ carried by ΔY. (This is the second dividend of the canceling diffusions: not only does ΔX acquire smooth paths, but the cross-variation between forward and backward differences drops out, leaving a clean ordinary-calculus product rule.) Substituting $\mathrm{d}\Delta X_t = -\Delta Y_t\ \mathrm{d}t$ and $\mathrm{d}\Delta Y_t = -(\nabla_x F(X_t, m_t) - \nabla_x F(X'_t, m'_t))\,\mathrm{d}t + \Delta Z_t\ \mathrm{d}W_t$,

$$\mathrm{d}\langle \Delta X_t, \Delta Y_t\rangle = \Big(-|\Delta Y_t|^2 - \langle \Delta X_t, \nabla_x F(X_t, m_t) - \nabla_x F(X'_t, m'_t)\rangle \Big)\,\mathrm{d}t + \langle \Delta X_t, \Delta Z_t\ \mathrm{d}W_t\rangle,$$

the first inner product giving $\langle -\Delta Y_t, \Delta Y_t\rangle = -|\Delta Y_t|^2$.

Expectation and integration. The term $\langle \Delta X_t, \Delta Z_t\ \mathrm{d}W_t\rangle$ is a genuine Itô (martingale) increment, so under the square-integrability carried by the FBSDE solutions its expectation is zero. Taking $\mathbb{E}$ and integrating from 0 to T,

$$\mathbb{E}\langle \Delta X_T, \Delta Y_T\rangle - \mathbb{E}\langle \Delta X_0, \Delta Y_0\rangle = -\int_0^T \mathbb{E}\ |\Delta Y_t|^2\ \mathrm{d}t - \int_0^T \mathbb{E}\langle \Delta X_t, \nabla_x F(X_t, m_t) - \nabla_x F(X'_t, m'_t)\rangle\ \mathrm{d}t.$$

At the terminal time the backward data give $\Delta Y_T = \nabla_x G(X_T, m_T) - \nabla_x G(X'_T, m'_T)$, so $\mathbb{E}\langle \Delta X_T, \Delta Y_T\rangle$ is exactly the displacement-monotonicity bracket for G evaluated on the pair (X_T, X'_T). Solving the displayed identity for the quantity at time 0,

$$\mathbb{E}\langle \Delta X_0, \Delta Y_0\rangle = \underbrace{\mathbb{E}\langle \Delta X_T, \nabla_x G(X_T, m_T) - \nabla_x G(X_T', m_T')\rangle}_{\geq 0} + \int_0^T \mathbb{E}\ |\Delta Y_t|^2\ \mathrm{d}t + \int_0^T \underbrace{\mathbb{E}\langle \Delta X_t, \nabla_x F(X_t, m_t) - \nabla_x F(X_t',}_{\geq 0}$$

The sign of each term. The terminal bracket is nonnegative because G is displacement monotone: it is precisely eq. (12.14) applied with $\Theta = G$ and the pair (X_T, X_T'), whose laws are $m_T = \mathcal{L}(X_T)$ and $m_T' = \mathcal{L}(X_T')$ — so both slots of $\nabla_x G$ are filled consistently, the spatial slot by the random variable and the measure slot by its own law, exactly as the definition requires. The running integrand is nonnegative for the same reason with $\Theta = F$ and the pair (X_t, X_t') at each t. The middle term $\int_0^T \mathbb{E}\,|\Delta Y_t|^2\ \mathrm{d}t$ is manifestly nonnegative. Dropping the two displacement-monotone brackets (each ≥ 0) from the right-hand side can only decrease it, which yields the asserted chain

$$\mathbb{E}\langle \Delta X_0, \Delta Y_0\rangle \ \geq\ \int_0^T \mathbb{E}\ |\Delta Y_t|^2\ \mathrm{d}t \ \geq\ 0,$$

that is, eq. (12.15). This is where the two hypotheses pay off: the *terminal* displacement monotonicity of G controls the boundary bracket, the *running* displacement monotonicity of F controls the integrand, and together they isolate the nonnegative middle term — exactly the role Lasry–Lions monotonicity played for the separable couplings, now discharged by the displacement condition.

Uniqueness. Suppose the two equilibria start from the same state, $X_0 = X_0'$ a.s., so $\Delta X_0 = 0$ and the left-hand side of eq. (12.15) is 0. The chain then forces $\int_0^T \mathbb{E}\,|\Delta Y_t|^2\ \mathrm{d}t = 0$, hence $\Delta Y_t = 0$ for a.e. t, a.s.; that is, $Y \equiv Y'$. Feeding this back into the forward difference, $\mathrm{d}\Delta X_t = -\Delta Y_t\ \mathrm{d}t = 0$ with $\Delta X_0 = 0$ gives $\Delta X_t \equiv 0$, i.e. $X \equiv X'$. The FBSDE issuing from a given initial law has at most one solution, so the construction eq. (12.5) assigns a single value and the master function is well defined — the same single-valuedness that monotonicity bought in the separable case, now secured without it.

Monotonicity of the master operator. Finally, evaluate the FBSDE through its decoupling field $Y_t = \nabla_x U(t, X_t, m_t)$ (eq. (12.11)) at $t = 0$, where $X_0 \sim m$ and $X_0' \sim m'$. Then $Y_0 = \nabla_x U(0, X_0, m)$ and $Y_0' = \nabla_x U(0, X_0', m')$, so the left-hand side of eq. (12.15) reads

$$\mathbb{E}\langle X_0 - X_0', \nabla_x U(0, X_0, m) - \nabla_x U(0, X_0', m')\rangle \ \geq\ 0.$$

This is exactly eq. (12.14) for the lifted gradient field $X \mapsto \nabla_x U(0, X, \mathcal{L}X)$: the decoupling field $\nabla_x U$ is a monotone operator on $L^2(\Omega; \mathbb{R}^d)$. The displacement monotonicity of the data has propagated, through the FBSDE, into displacement monotonicity of the master function's own gradient. □

Thus displacement monotonicity is the precise functional inequality eq. (12.14), and proposition 12.14 is the promised proof that it makes the master operator monotone — the two deliverables chapter 11 forwarded here. The monotone-operator conclusion is the exact non-separable substitute for the Lasry–Lions input of theorem 12.8: it is what forbids the characteristics from crossing when the Hamiltonian couples to the crowd, and hence what keeps the construction eq. (12.5) single-valued at every horizon. As in the separable case, the passage from this structural sign to a full all-horizon classical well-posedness theorem — the uniform $\mathcal{C}^2$-in-m regularity estimates — is a monograph-scale undertaking we do not reproduce; it is carried out, for displacement-monotone non-separable data, in [76] and [104], and we import it on *exactly* the acknowledged-exception footing of remark 12.9: the structure (the monotone pairing just proved) is in book, only the terminal regularity number is cited. With this the well-posedness arc closes. Both regimes are settled — the separable case by Lasry–Lions monotonicity, the non-separable case by displacement monotonicity, each with its short-horizon unconditional fallback (proposition 12.10) and each with its all-horizon estimate honestly flagged as imported — and in every case the master function exists, is unique, and carries the differentiability in m that the rest of the program needs.

Every result up to this point, however, has presumed one thing that the next section overturns: that the population m_t is a *deterministic* curve, a single trajectory the construction eq. (12.5) could solve for in advance. That is what made the bare value function tenable and the flow map an upgrade rather than a necessity. The next section turns on a shock felt by every agent at once — *common noise* — and watches the population become a genuine stochastic process in $\mathcal{P}_2(\mathbb{R}^d)$: this is the regime, promised since section 12.1, that the master equation was built for, the one in which it ceases to be a convenience and becomes the only formulation that survives. We reach it now with well-posedness in hand.

12.7 Common noise: why the master equation becomes indispensable

We have reached the section the whole construction was pointing at. The well-posedness arc is closed: in both the separable and the non-separable regimes the master function exists, is single-valued at every horizon, and carries the differentiability in m the program needs. But every one of those results — the construction eq. (12.5), the flow-consistency identity eq. (12.6), the entire equivalence with the system — rested on a silent hypothesis: that the population m_t is a *deterministic* curve, one trajectory the construction could solve for in advance and then hold fixed while each agent optimizes against it. That hypothesis is exactly what made the bare value function $u(t, x)$ tenable, and it is exactly what made the master function look, to a skeptic, like a luxury: if only one population flow is ever realized, why carry a value for every contingency? Section 12.1 answered that the answer would arrive under common noise, and at every "we return to this under common noise" pointer since, the debt has been deferred to here. We now pay it. We turn on a shock felt by every agent at once, watch the population become a genuine stochastic process in $\mathcal{P}_2(\mathbb{R}^d)$, and find that the deterministic forward–backward system loses its meaning while the master function — having already valued *every* contingent crowd in advance — is the only formulation left standing. The price the master equation extracts for this is the second-order measure derivative it now acquires: a genuine Laplacian on Wasserstein space.

The setup: a population that has become random

Suppose all agents are driven, in addition to their private noises, by a single common Brownian motion W^0:

$$dX_t \;=\; \alpha_t \, dt \;+\; \sigma \, dW_t \;+\; \sigma_0 \, dW_t^0. \tag{12.16}$$

The private W_t is the agent's own idiosyncratic shock, independent across the continuum; the new term $\sigma_0 \,\mathrm{d}W_t^0$ is the same Brownian increment for everyone, scaled by the common-noise intensity σ_0. The distinction is the whole story. Idiosyncratic shocks average out across the population — by a law-of-large-numbers effect each agent's private wiggle is washed away in the aggregate, which is precisely why, in chapter 8 and throughout the deterministic theory, the population obeyed an *ordinary* (non-random) Fokker–Planck equation. The common shock does not average out: it pushes the entire population the same way at the same instant, so the aggregate is itself jostled randomly.

Concretely, the relevant population is now the *conditional* law

$$m_t \;=\; \mathcal{L}(X_t \mid \mathcal{F}_t^0),$$

the distribution of the representative state given the history $\mathcal{F}^0 = (\mathcal{F}_t^0)$ of the common noise up to time t. Conditioning on $\mathcal{F}_t^0$ integrates out the private shocks (which, being independent of W^0, still average to a smooth density) but *retains* the common one; what survives is a measure that depends on the realized path of W^0, and so varies from one realization to another. The object $t \mapsto m_t$ is therefore not a curve in $\mathcal{P}_2(\mathbb{R}^d)$ but a *stochastic process taking values in* $\mathcal{P}_2(\mathbb{R}^d)$ — a random measure, adapted to $\mathcal{F}^0$, with a genuinely different trajectory on each draw of the shared shock.

This single fact dismantles the deterministic forward–backward system eq. (12.2). That system presupposed a predetermined population trajectory: the Fokker–Planck equation eq. (12.2b) was solved forward to produce *one* curve $m_\cdot$, against which the backward HJB eq. (12.2a) was then solved. Strip away the determinism and the construction is incoherent on both ends. There is no longer a single curve m_t to solve for — *which* population the agent will face at time t is not known until the shared shock has played out, so there is nothing to pin the forward equation to a unique solution. And the backward value can no longer be a deterministic function solved in one sweep from $t = T$: an agent's optimal continuation must *react* to the population she actually finds herself in, a population revealed only as the common noise unfolds, so her value process must be *adapted* to information that arrives going forward in time. A backward function pinned to a single foreknown trajectory m_t literally cannot be written down, because there is no one trajectory to pin it to. This is the obstruction section 12.1 promised in advance, now made sharp.

What *can* be written down is precisely $U(t, x, m)$. The master function was built to value every contingency $m \in \mathcal{P}_2(\mathbb{R}^d)$, with the population as a free input slot rather than a solved-for curve; so it does not care that the realized population has become random. One simply *composes* it with the random measure, forming $u_t(x) = U(t, x, m_t)$, and reads off the agent's value along whatever crowd the shared shock actually produces. The per-crowd object, optional in the deterministic world, is here the only thing that survives. The remaining task is to find the equation it must satisfy, and the surprise — the content of the rest of this section — is that turning m_t into a stochastic process forces *second-order* terms in the measure direction that the deterministic equation never carried.

The engine: Itô–Wentzell on $\mathcal{P}_2(\mathbb{R}^d)$, and the terms it produces

In the deterministic theory the equation for U came from differentiating the flow-consistency identity $u_t(x) = U(t, x, m_t)$ in time with the chain rule lemma 12.2. The same strategy works here, but the chain rule must be upgraded: m_t is now a *stochastic* flow, so we need the Itô formula for a functional of a random measure — an Itô–Wentzell formula on $\mathcal{P}_2(\mathbb{R}^d)$. (“Wentzell” because, exactly as in finite dimensions, differentiating $f(t, X_t)$ when *both* the function's time-slot and its random argument carry the same Brownian increment produces an extra cross-term beyond the ordinary Itô formula; here the common W^0 enters both U's state argument $x = X_t$ and its measure argument m_t.) Applying it to $u_t(x) = U(t, x, m_t)$ along the conditional flow, and demanding consistency with the agent's now-adapted HJB equation exactly as before, produces the old master equation eq. (12.7) plus several new families of terms, all governed by the common-noise coefficient σ_0. Three mechanisms, traced one at a time, account for every one of them; the reader should hold the three-second-derivatives notation watch after theorem 12.3 alongside, because each mechanism activates a different one of the objects catalogued there.

Mechanism one: the agent's own extra diffusion. The representative agent's state X_t now carries, on top of its private $\sigma \, \mathrm{d}W_t$, the common increment $\sigma_0 \, \mathrm{d}W_t^0$. To her own value $x \mapsto U(t, x, m)$ this is simply additional diffusion of her own coordinate, and Itô's formula in the state variable adds the corresponding second-order term in x. With m frozen, the quadratic variation of X_t gains $\sigma_0\sigma_0^\top \, \mathrm{d}t$, and the value picks up $-\frac{1}{2} \operatorname{tr}(\sigma_0\sigma_0^\top \, \mathrm{D}_x^2 U)$ — the same Hessian $\mathrm{D}_x^2 U$ that already sat on the first line of eq. (12.7), now fed the extra diffusion. This is the first object of the notation watch (the ordinary finite-dimensional Hessian in the agent's own state); nothing about the measure is involved yet.

Mechanism two: the population spreads with the full diffusion. This is the subtle one, and it is where the coefficient *upgrade* lives. Ask how the conditional law m_t itself evolves. Each agent diffuses with both noises, but conditioning on $\mathcal{F}_t^0$ does *not* remove the common one — W^0 is $\mathcal{F}_t^0$-measurable only as a *path*, not in its future increments, and the spreading it induces is felt by the conditional density just as the private noise is. The conditional Fokker–Planck equation for m_t therefore carries the *full* diffusion $\sigma\sigma^\top + \sigma_0\sigma_0^\top$, not merely the private $\sigma\sigma^\top$ of the deterministic theory: the common noise spreads the population exactly as it spreads the individual. Now recall that the deterministic master equation's extra-diffusion term, $-\frac{1}{2} \int \operatorname{tr}(\sigma\sigma^\top \, \partial_y \partial_\mu U) \, m(\mathrm{d}y)$, was produced by the chain rule lemma 12.2 from precisely this population-spreading piece of the Fokker–Planck operator (Move 3b of its proof). Feed that same machinery the upgraded diffusion and the coefficient is upgraded with it, $\sigma\sigma^\top \to \sigma\sigma^\top + \sigma_0\sigma_0^\top$, so the equation gains the *additional* term $-\frac{1}{2} \int \operatorname{tr}(\sigma_0\sigma_0^\top \, \partial_y \partial_\mu U) \, m(\mathrm{d}y)$. The object differentiated is again the single-variable Jacobian $\partial_y \partial_\mu U$ — the second entry of the notation watch, “fully $\mathcal{C}^2$” content, the crowd's *spatial* spreading — not yet a genuine measure Hessian. The upgrade is invisible in any term-counting of the equation; it shows up only in the coefficient, and the consistency check below is designed precisely to make it visible.

Mechanism three: the common mode correlates distinct agents. Here is the genuinely new structure, and the reason the deterministic theory could get away with single-variable derivatives. In the no-common-noise world the random motion of the mass at a point y was statistically independent of the random motion of the mass at a distant point y' — private shocks are independent across agents — so there was no mechanism correlating the two, and the two-point measure Hessian $\partial_\mu^2 U$ never appeared (this is exactly the gap discussed at definition 12.1). Common noise supplies the missing mechanism. One shared increment $\sigma_0 \, \mathrm{d}W_t^0$ moves *all* of the mass together: the speck at y and the speck at y' receive the identical shock, so their motions are perfectly correlated through W^0. The Itô–Wentzell formula records this correlation as a second derivative of U in the measure direction — the third object of the notation watch, the true Hessian on $\mathcal{P}_2(\mathbb{R}^d)$ indexed by two locations,

$\partial_\mu^2 U(t,x,m)(y,y')$ — contracted against $\sigma_0\sigma_0^\top$ and integrated against the crowd *twice*, once in y and once in y'. There is moreover a *cross* contribution from the same shared increment correlating the agent's own state $x = X_t$ with the crowd point y: both move under W^0, and the cross-variation produces a mixed derivative $\nabla_x \partial_\mu U(t,x,m)(y)$, a spatial gradient in the agent's coordinate of the Lions field in the crowd's coordinate. Each of these is a hallmark of the Itô–Wentzell (as opposed to plain Itô) calculus: they are exactly the terms that appear because the same Brownian motion sits in two slots of U at once.

Collecting the four contributions, the master equation acquires the additional terms

$$
\begin{aligned}
&-\tfrac{1}{2}\operatorname{tr}\big(\sigma_0\sigma_0^\top\, \mathrm{D}_x^2\, U\big) - \tfrac{1}{2}\int_{\mathbb{R}^d} \operatorname{tr}\big(\sigma_0\sigma_0^\top\, \partial_y\partial_\mu U(t,x,m)(y)\big)\, m(\mathrm{d}y)\\
&\quad -\int_{\mathbb{R}^d} \operatorname{tr}\big(\sigma_0\sigma_0^\top\, \nabla_x\partial_\mu U(t,x,m)(y)\big)\, m(\mathrm{d}y)\\
&\quad -\tfrac{1}{2}\int_{\mathbb{R}^d}\int_{\mathbb{R}^d} \operatorname{tr}\big(\sigma_0\sigma_0^\top\, \partial_\mu^2 U(t,x,m)(y,y')\big)\, m(\mathrm{d}y)\, m(\mathrm{d}y'),
\end{aligned}
\tag{12.17}
$$

added to the left-hand side of eq. (12.7), where $\partial_\mu^2 U$ is the second Lions derivative. Reading them off line by line against the three mechanisms: the lone $\mathrm{D}_x^2\, U$ term is mechanism one, the agent's own extra diffusion. The first integral, $-\frac{1}{2}\int \operatorname{tr}(\sigma_0\sigma_0^\top\, \partial_y\partial_\mu U)\, m(\mathrm{d}y)$, is mechanism two, the population self-spreading — the coefficient upgrade, with the same single-variable Jacobian that already appeared in eq. (12.7), now fed the common diffusion. The second integral, $-\int \operatorname{tr}(\sigma_0\sigma_0^\top\, \nabla_x\partial_\mu U)\, m(\mathrm{d}y)$, is the cross term, coupling the agent's own state x to the crowd point y through the shared shock. And the double integral, $-\frac{1}{2}\iint \operatorname{tr}(\sigma_0\sigma_0^\top\, \partial_\mu^2 U)\, m(\mathrm{d}y)\, m(\mathrm{d}y')$, is the genuine *Laplacian on* $\mathcal{P}_2(\mathbb{R}^d)$: the only term in the entire chapter built from the true second *measure* derivative, switched on precisely because the common mode correlates distinct agents. The first and last are the diagonal and off-diagonal pieces of one second-order operator in the measure — the agent–crowd and crowd–crowd correlations that the single shared Brownian motion induces.

A consistency check: the pure-translation functional

The coefficient upgrade of mechanism two is the easiest of the new effects to overlook — it hides inside an existing term rather than adding a visibly new one — so it is worth a self-contained check that isolates it and confirms its coefficient is exactly right. Take the simplest nontrivial regime: no control and no private noise, every agent driven only by the common shock,

$$
\mathrm{d}X_t \;=\; \sigma_0\, \mathrm{d}W_t^0,
$$

and let U value the crowd alone through a smooth pairing, $U(t,x,m) = \int_{\mathbb{R}^d} \phi(x,y)\, m(\mathrm{d}y)$ — a *pure-translation functional*, linear in m. We compute its drift two ways and demand they agree.

Directly. With dynamics $\mathrm{d}X_t = \sigma_0\, \mathrm{d}W_t^0$ every agent receives the *same* increment, so $X_t = X_0 + \sigma_0 W_t^0$ and the conditional law is a rigid translation of its initial value, $m_t = (\tau_{\sigma_0 W_t^0})_\#\, m_0$ with $\tau_z(y) = y + z$. Hence

$$
U(t,x,m_t) \;=\; \int_{\mathbb{R}^d} \phi(x,\, y + \sigma_0 W_t^0)\, m_0(\mathrm{d}y) \;=\; g(\sigma_0 W_t^0), \qquad g(z) := \int_{\mathbb{R}^d} \phi(x, y+z)\, m_0(\mathrm{d}y),
$$

a smooth function of the single $\mathbb{R}^d$-valued process $\sigma_0 W_t^0$. Ordinary finite-dimensional Itô gives the drift $\frac{1}{2}\operatorname{tr}(\sigma_0\sigma_0^\top \mathrm{D}_z^2 g)$, and since $\mathrm{D}_z^2 g(z) = \int \mathrm{D}_y^2 \phi(x, y+z)\, m_0(\mathrm{d}y) = \int \mathrm{D}_y^2 \phi(x,y)\, m_t(\mathrm{d}y)$ by the change of variables, the drift of $U(t,x,m_t)$ is

$$\frac{1}{2}\int_{\mathbb{R}^d} \operatorname{tr}\big(\sigma_0\sigma_0^\top \mathrm{D}_y^2 \phi(x,y)\big)\, m_t(\mathrm{d}y).$$

From the new terms. For the linear functional $U(t,x,m) = \int \phi(x,y)\, m(\mathrm{d}y)$ the derivatives are immediate: the flat derivative is $\frac{\delta U}{\delta m}(t,x,m,y) = \phi(x,y)$, the Lions field is $\partial_\mu U(t,x,m)(y) = \nabla_y \phi(x,y)$, and its Jacobian is $\partial_y \partial_\mu U(t,x,m)(y) = \mathrm{D}_y^2 \phi(x,y)$. Crucially, because U is *linear* in m its flat derivative $\phi(x,y)$ does not depend on m at all, so its further measure derivative vanishes identically: $\partial_\mu^2 U \equiv 0$. The Laplacian term is therefore *off*. The remaining new terms involving the agent's own coordinate — the $\mathrm{D}_x^2 U$ term and the cross term $\nabla_x \partial_\mu U$ — play no role here either, for two reasons worth keeping apart. First, this check holds the agent's state x fixed and follows only the motion of the measure argument m_t, so the own-state second-order terms, which track the agent's *own* diffusion, do not enter the drift we are comparing. Second — to make the isolation airtight rather than merely out of scope — we take ϕ depending on the crowd coordinate y alone, whereupon they vanish identically, $\mathrm{D}_x^2 U = 0$ and $\nabla_x \partial_\mu U = 0$. For a *general* $\phi(x,y)$ these own-state terms, $\int \mathrm{D}_x^2 \phi(x,y)\, m(\mathrm{d}y)$ and $\nabla_x \nabla_y \phi(x,y)$, are nonzero; specializing to $\phi = \phi(y)$ removes them by construction, leaving the self-spreading term as the sole survivor. The *only* surviving new term is the coefficient upgrade,

$$-\frac{1}{2}\int_{\mathbb{R}^d} \operatorname{tr}\big(\sigma_0\sigma_0^\top \partial_y \partial_\mu U(t,x,m)(y)\big)\, m(\mathrm{d}y) \;=\; -\frac{1}{2}\int_{\mathbb{R}^d} \operatorname{tr}\big(\sigma_0\sigma_0^\top \mathrm{D}_y^2 \phi(x,y)\big)\, m(\mathrm{d}y),$$

which is exactly minus the directly-computed drift — the sign being the one that, carried to the left-hand side against $-\partial_t U$, reproduces it. The two computations agree, and the agreement is delicate: had we *not* upgraded the coefficient (had we kept the bare $\sigma\sigma^\top$, which is zero here because there is no private noise), this term would be absent and the equation would predict zero drift, contradicting the direct calculation. The self-spreading term is precisely the one that would go missing without the upgrade of mechanism two, and the check pins its coefficient at $\sigma_0\sigma_0^\top$.

Blessing and difficulty

The new second-order structure cuts both ways, and it is worth naming the duality squarely. On the one hand it is a *blessing*. In section 12.4 we observed that the deterministic master equation, read as a Hamilton–Jacobi equation on $\mathcal{P}_2(\mathbb{R}^d)$, was first-order in the measure and hence offered no smoothing in that direction — the source of the well-posedness difficulties section 12.6 had to handle by monotonicity rather than by parabolic regularization. Common noise repairs exactly that. The genuine Laplacian $\partial_\mu^2 U$ it adds makes the master equation *parabolic on the measure space*, supplying the second-order regularization that was missing; nondegeneracy of σ_0 smooths U in m the way nondegeneracy of σ smooths an ordinary HJB equation in x. On the other hand it is a genuine *difficulty*. The second measure derivative is the analytically heaviest object in the theory — a function of two crowd locations (y, y') at every (t,x,m), whose estimates and even whose precise function spaces are delicate — and it is the reason the common-noise theory is a separate and harder undertaking than the deterministic one. The same term that regularizes the equation is the term that makes it hard to control.

We have therefore stated the *structure* of the common-noise master equation and interpreted every term, but we have not proved it, and we are honest about why. The Itô–Wentzell formula on $\mathcal{P}_2(\mathbb{R}^d)$ used to obtain eq. (12.17) is a beyond-prerequisite result: it is the stochastic counterpart of the Itô formula for flows of measures theorem D.7 on which the deterministic chain rule lemma 12.2 rested, generalized from a deterministic flow to one driven by the common Brownian motion. Its in-book proof, together with the well-posedness theory that the formula presupposes — the role of nondegeneracy of σ_0 in regularizing U, the precise function spaces for $\partial_\mu^2 U$, and the extension to the graphon setting — is carried out in chapter 26, where common noise is treated systematically. The present section is therefore explicitly *conditional* on chapter 26: we have used the master equation's per-contingency design to argue *why* it, and it alone, survives a random population, and we have read off the terms the Itô–Wentzell formula must produce, deferring the formula's proof to its proper home. The references [37] and [41], Ch. 4 and 7, carry the derivation out in full and are cited for attribution, never in place of the in-book argument.

Physics note

Common noise is the closest the mean field story comes to a genuine fluctuating order-parameter field: a single global mode W_t^0 shakes the whole population coherently, so the macroscopic state m_t itself becomes a stochastic process rather than a deterministic background. The second-measure-derivative term in eq. (12.17) is the diffusion of that global mode — the order-parameter "propagator" — and it is exactly what was missing from the bare mean-field (deterministic-m) description. As before, this is orientation only; the quantitative content is in chapter 26.

This completes the case the chapter set out to make. We have shown, in full generality, that the master function is not a convenience but the only formulation that survives a random population, and we have read off the second-order measure structure that common noise forces upon it. It remains to descend from this height to a single fully explicit model and watch the entire apparatus — the decoupling field, the transport and diffusion integrals, the flow-consistency that ties U to the bare value — collapse into a handful of scalar ordinary differential equations one can solve by hand. We do this on the carried LQG thread. There the coupling is through the population *mean*, the master function depends on m only through that single scalar, and the abstract derivatives of this chapter become finite-dimensional calculus: the genuine second measure derivative of common noise does not arise (we take no common noise), and — the point flagged in section 12.3 and revisited just above — the extra-diffusion integral $\int \operatorname{tr}(\sigma\sigma^\top \partial_y \partial_\mu U)\, m(\mathrm{d}y)$ *vanishes outright*, because mean coupling makes the Lions field constant in y and its Jacobian zero. What is left is a pair of Riccati ordinary differential equations, and we verify that they reproduce the chapter 8 fixed point exactly.

12.8 Worked computation: the LQG decoupling field and its master equation

The chapter has been built at altitude. We argued first *why* a population-feedback object is forced (the non-Markovian obstruction of section 12.1), assembled the single analytic engine that powers everything (the chain rule along a Fokker–Planck flow, lemma 12.2), used it to *derive* the master equation and prove its exact equivalence with the MFG system (theorem 12.3), reread that equation as a Hamilton–Jacobi equation on $\mathcal{P}_2(\mathbb{R}^d)$ whose characteristics *are* the system (sections 12.4 and 12.5), confronted the well-posedness its first-order-in-m structure forces (section 12.6), and finally shown that common noise makes U not a convenience but the only survivor (section 12.7). Every one of these statements was about an abstract function on an infinite-dimensional space. The promise repeatedly deferred — and the way to be certain the apparatus is real and not merely formal — is to descend to a model where one can write U down in closed form, watch each abstract term either compute itself out or visibly vanish, and check by hand that the answer is the one Part II already obtained by other means. That model is the carried LQG thread, and this section delivers the descent.

We advance Thread A to its third layer (appendix A.7). The first two layers are already in hand: the single-agent control problem was solved in chapter 6 (Layer 1), producing the scalar curvature Riccati equation for the value of one agent facing a frozen crowd; and the MFG fixed point was solved in chapter 8 (Layer 2), producing the coupled backward-curvature / forward-mean system whose self-consistency pins the equilibrium. Layer 3, the present task, is to write the *master* function and the decoupling field for the same model, reduce them to ordinary differential equations, and verify that restricting the master function to the equilibrium flow returns the Layer-2 system with not a sign out of place. The model is the scalar linear–quadratic–Gaussian MFG with the fixed parameter names of the thread specification (appendix A.7): the representative agent's state obeys

$$\mathrm{d}X_t = (aX_t + b\,\alpha_t)\,\mathrm{d}t + \sigma\,\mathrm{d}W_t, \qquad X_0 \sim m_0, \tag{12.18}$$

and she chooses α to minimize, with population mean $\bar{m}_t = \int \xi\, m_t(\mathrm{d}\xi)$,

$$J(\alpha) = \mathbb{E}\left[\int_0^T \left(\tfrac{1}{2}\alpha_t^2 + \tfrac{q}{2}\big(X_t - s\,\bar{m}_t\big)^2\right)\mathrm{d}t + \tfrac{q_T}{2}\big(X_T - s_T\,\bar{m}_T\big)^2\right]. \tag{12.19}$$

Each symbol carries the meaning fixed once and for all in the thread specification: a is the uncontrolled *state feedback* (the rate at which the state drifts on its own), b the *control gain* (how strongly the agent's action moves the state), σ the constant *noise* amplitude; $q \geq 0$ and $q_T \geq 0$ are the running and terminal *state-cost weights* that penalize deviation from a target; and s, s_T are the *mean-coupling* strengths that set where the target sits — each agent is drawn toward (for $s > 0$) or repelled from (for $s < 0$) the population mean $s\,\bar{m}_t$. The single feature of eq. (12.19) on which everything below turns is that the agent feels the crowd *only through its mean* $\bar{m}_t$, a single scalar functional of the measure m_t, and not through any finer feature of its shape. Every measure functional we shall meet therefore depends on m solely through $\bar{m}$. This is exactly the mean-coupling structure singled out in the discussion following theorem 12.3, and it is what makes the LQG master equation collapse from a PDE on $\mathcal{P}_2(\mathbb{R}^d)$ to a PDE in one extra scalar variable; it is the cleanest possible illustration of theorem 12.3, and — as we are about to see term by term — the case in which the extra-diffusion line of the master equation drops out entirely.

One point of bookkeeping must be settled before any HJB equation is written, because the canonical setting eq. (12.1) of this chapter took the drift to be the control itself, whereas the thread dynamics eq. (12.18) also carry an *uncontrolled* linear drift aX. Conflating the two is the easiest slip to make here, so we flag it.

Notation watch

The dynamics eq. (12.18) carry an uncontrolled linear drift aX, so the relation $\alpha^* = -\partial_p H$ of appendix A.4 (stated for the canonical control-as-drift normalization $a = 0, b = 1$ of eq. (12.1)) applies to the *control part* only. The agent's instantaneous Hamiltonian is obtained by minimizing the control-dependent part of the pre-Hamiltonian over α: with adjoint variable p, she minimizes $b\,\alpha\,p + \frac{1}{2}\alpha^2$, a strictly convex scalar quadratic whose minimizer is $\alpha^* = -b\,p$ and whose minimum value is $-\frac{b^2}{2}p^2$. The full HJB Hamiltonian then *bundles in* the uncontrolled drift axp on top of this,

$$H_{\mathrm{LQG}}(x, p) = -axp + \tfrac{b^2}{2}p^2,$$

so that $\partial_p H_{\mathrm{LQG}} = -ax + b^2 p$ — whose negative is *not* the optimal control $\alpha^* = -bp$ but the optimal control *plus the uncontrolled drift*, exactly the total velocity of the state. This is the correct object to feed into the Fokker–Planck transport, and it is the source of the a-terms that will accompany every b^2P below. We carry the general (a, b) to keep the thread intact; setting $a = 0, b = 1$ collapses H_{LQG} to the canonical $\frac{1}{2}p^2$ and recovers the normalization of eq. (12.1) throughout.

The HJB operator and the equilibrium ansatz

We begin on familiar ground, with the single-agent Hamilton–Jacobi–Bellman equation, because the master equation will be built on top of it and the ansatz is dictated by its structure. Fix the population mean as a known curve $\bar{m}_t$ for the moment (this is the Layer-1 posture: optimize one agent against a frozen crowd). The optimal feedback computed in the notation watch is $\alpha^* = -b\,\partial_x u$, and substituting it into the dynamic-programming equation for eq. (12.18)–eq. (12.19) — the uncontrolled drift axu_x entering linearly, the control contributing its minimized value $-\frac{b^2}{2}(\partial_x u)^2$, the noise its Laplacian $\frac{1}{2}\sigma^2 \partial_{xx} u$, and the running cost its quadratic — gives

$$\partial_t u + ax\,\partial_x u - \tfrac{b^2}{2}(\partial_x u)^2 + \tfrac{1}{2}\sigma^2\,\partial_{xx} u + \tfrac{q}{2}\big(x - s\,\bar{m}_t\big)^2 = 0, \qquad u(T, x) = \tfrac{q_T}{2}\big(x - s_T\,\bar{m}_T\big)^2. \quad (12.20)$$

The shape of the solution is legible from the equation itself. The terminal datum is a quadratic in x, and the only x-dependent forcing is the quadratic running cost; the operator preserves the class of quadratics-in-x (a quadratic has constant second derivative, so the nonlinear term $(\partial_x u)^2$ stays quadratic and the Laplacian stays constant). Quadratic data therefore propagate quadratically, and the value is quadratic in x for every t. The mean $\bar{m}_t$ enters eq. (12.20) only *linearly* (through the cross-term $-qs\,x\,\bar{m}_t$ and a $\bar{m}_t^2$ term that touches no power of x above the constant), so the dependence on the crowd is affine. Promoting the frozen $\bar{m}_t$ back to a free population argument m, we are led to posit a master function quadratic in x and affine in $\bar{m}$,

$$U(t,x,m) = \tfrac{1}{2}\,P(t)\,x^2 + \big(\pi(t)\,\bar{m} + \zeta(t)\big)\,x + c(t,\bar{m}), \qquad \bar{m} = \int \xi\, m(\mathrm{d}\xi), \tag{12.21}$$

with three time-dependent coefficients to be determined — the curvature $P(t)$, the population-sensitivity $\pi(t)$, and a constant-in-x offset $\zeta(t)$ — together with a purely x-independent term $c(t,\bar{m})$ that will turn out to be inert for the decoupling field.

Two notational conventions in eq. (12.21) deserve to be stated cleanly, since the whole computation rides on them. First, the *shadow notation*: because U here depends on the measure m only through the scalar $\bar{m} = \int \xi\, m(\mathrm{d}\xi)$, we write $U(t,x,\bar{m})$ for the value of $U(t,x,m)$ and let the same letter U denote both the genuine functional on $\mathcal{P}_2(\mathbb{R}^d)$ and its mean-reduced *shadow* on $\mathbb{R}$. (One could carry a separate symbol $\widehat{U}(t,x,\bar{m})$ for the shadow; we do not, since no confusion arises once the reduction is announced, and the single letter keeps the kinship between the two objects visible.) Under this convention $\partial_{\bar{m}} U$ is an *ordinary* partial derivative in a real variable. Second, and this is the payoff, the abstract *measure* derivatives of U collapse to that ordinary one. The reason is a one-line computation that is worth seeing, because it is the exact mechanism by which the mean-coupling structure trivializes the hard part of the master equation. The functional $m \mapsto \bar{m} = \int \xi\, m(\mathrm{d}\xi)$ is *linear* in m, so its flat derivative is read off directly from definition 12.1: perturbing along $m' - m$,

$$\frac{\mathrm{d}}{\mathrm{d}\epsilon} \int \xi\, \big(m + \epsilon(m'-m)\big)(\mathrm{d}\xi)\Big|_{\epsilon=0} = \int \xi\, (m'-m)(\mathrm{d}\xi) = \int y\, (m'-m)(\mathrm{d}y),$$

so $\frac{\delta(\bar{m})}{\delta m}(m,y) = y$ identically. By the chain rule for the flat derivative, any functional of the form $m \mapsto U(t,x,\bar{m})$ has flat derivative $\frac{\delta U}{\delta m}(t,x,m,y) = \partial_{\bar{m}} U(t,x,\bar{m}) \cdot y$ — the ordinary mean-derivative times the bare coordinate y. Differentiating once in y to form the Lions field, the linear factor y becomes a *constant*: the Lions derivative is constant in y,

$$\partial_\mu U(t,x,m)(y) = \nabla_y \frac{\delta U}{\delta m}(t,x,m,y) = \partial_{\bar{m}} U(t,x,\bar{m}) = \pi(t)\,x + \partial_{\bar{m}} c(t,\bar{m}), \tag{12.22}$$

the last equality reading $\partial_{\bar{m}} U$ off the ansatz eq. (12.21). A field that is constant in y has vanishing Jacobian: $\partial_y \partial_\mu U \equiv 0$, and the extra-diffusion line of the master equation eq. (12.7) — $-\frac{1}{2}\int \mathrm{tr}(\sigma\sigma^\top \partial_y \partial_\mu U)\, m(\mathrm{d}y)$ — *vanishes identically.*

This is not a lucky cancellation special to the algebra; it is the concrete realization of the general claim made in deriving the master equation. Recall the discussion following theorem 12.3: the extra-diffusion term measures how the agent's value responds to the *spreading* of the crowd by idiosyncratic noise, and it is nonzero precisely when the Lions field bends in y — when the agent cares about more than the crowd's location of mass. There the contrast was drawn sharply against a *second-moment* coupling, for which $\frac{\delta U}{\delta m}(m,y) \propto y^2$, the Lions field $\partial_\mu U \propto y$ is linear and not constant, its Jacobian $\partial_y \partial_\mu U$ is a nonzero constant, and the extra-diffusion term survives: a crowd whose variance the agent feels does register the crowd's spreading. *Mean* coupling is exactly the borderline case in which the flat derivative is affine in y, the Lions field is flat, and the spreading goes unfelt. The LQG thread is thus the worked instance of the principle that it is mean coupling — not the weaker property of depending on finitely many moments — that annihilates the second-order measure term; we now watch the rest of the equation reduce.

Reduction of the master equation to Riccati ODEs

With the second-order measure term gone, the master equation eq. (12.7) reduces to a transport-augmented HJB in the two real variables $(x, \bar{m})$, and the only nonstandard term left is the transport integral. Here too mean coupling simplifies it to an ordinary calculus object. The transport line of eq. (12.7) pairs the Lions field against the equilibrium feedback drift, integrated over the crowd; but the equilibrium population is the closed loop of eq. (12.18) under $\alpha^* = -b\,\partial_x U = -b(Px + \pi\bar{m} + \zeta)$, and what the transport term tracks is precisely the motion of the mean. Taking expectations in eq. (12.18) kills the martingale $\sigma\,\mathrm{d}W_t$ and leaves the *closed-loop mean drift*

$$V(t,\bar{m}) := \frac{\mathrm{d}}{\mathrm{d}t}\bar{m} = a\,\bar{m} + b\,\mathbb{E}[\alpha_t^*] = (a - b^2P)\,\bar{m} - b^2(\pi\bar{m} + \zeta) = (a - b^2P - b^2\pi)\,\bar{m} - b^2\zeta, \quad (12.23)$$

where we used $\mathbb{E}[X_t] = \bar{m}$ and $\mathbb{E}[\alpha_t^*] = -b(P\bar{m} + \pi\bar{m} + \zeta)$ since α^* is affine in X_t. Now substitute the flow-consistency relation $u(t,x) = U(t,x,m_t)$ of eq. (12.6) into the HJB equation eq. (12.20). The only subtlety is the time derivative: u depends on t both explicitly and through the transported mean, so by the chain rule $\partial_t u = \partial_t U + \partial_{\bar{m}} U \cdot V$. This is nothing but the finite-dimensional shadow of lemma 12.2 — the transport term $\int \partial_\mu U \cdot \mathbf{b}\,\mathrm{d}m$ has collapsed, via eq. (12.22) and the affine feedback, to the single product $\partial_{\bar{m}} U \cdot V$, and the second-order measure term is absent because $\partial_y \partial_\mu U \equiv 0$. Carrying this out yields the *reduced master equation*

$$\partial_t U + \partial_{\bar{m}} U \cdot V(t,\bar{m}) + ax\,\partial_x U - \tfrac{b^2}{2}(\partial_x U)^2 + \tfrac{1}{2}\sigma^2\,\partial_{xx} U + \tfrac{q}{2}(x - s\,\bar{m})^2 = 0, \quad (12.24)$$

a genuine PDE in $(t, x, \bar{m})$ — the master equation of this section, shorn of all infinite-dimensional content.

It remains to insert the ansatz eq. (12.21) and match powers of x, which turns eq. (12.24) into a closed system of ODEs for (P, π, ζ). It is worth doing the bookkeeping in the open, since the structure of the Riccati system lives in exactly how the terms sort by degree. From the ansatz,

$$\partial_t U = \tfrac{1}{2}\dot{P}\,x^2 + (\dot{\pi}\,\bar{m} + \dot{\zeta})\,x + \partial_t c, \qquad \partial_x U = P\,x + \pi\bar{m} + \zeta, \qquad \partial_{xx} U = P, \qquad \partial_{\bar{m}} U = \pi\,x + \partial_{\bar{m}} c.$$

Substituting and expanding the two nonlinear pieces,

$$ax\,\partial_x U = aP\,x^2 + a(\pi\bar{m} + \zeta)\,x, \qquad -\tfrac{b^2}{2}(\partial_x U)^2 = -\tfrac{b^2}{2}P^2x^2 - b^2P(\pi\bar{m} + \zeta)\,x - \tfrac{b^2}{2}(\pi\bar{m} + \zeta)^2,$$

together with $\partial_{\bar{m}} U \cdot V = \pi V\,x + \partial_{\bar{m}} c \cdot V$ and $\frac{q}{2}(x - s\bar{m})^2 = \frac{q}{2}x^2 - qs\bar{m}\,x + \frac{q}{2}s^2\bar{m}^2$, we collect by power of x.

The x^2 coefficient gathers $\frac{1}{2}\dot{P}$, aP, $-\frac{b^2}{2}P^2$, and $\frac{1}{2}\sigma^2\partial_{xx}U$'s contribution to x^2 (which is zero, since $\partial_{xx}U = P$ is constant in x) and $\frac{q}{2}$:

$$\tfrac{1}{2}\dot{P} + aP - \tfrac{b^2}{2}P^2 + \tfrac{q}{2} = 0 \quad \Longleftrightarrow \quad \dot{P} = b^2P^2 - 2aP - q,$$

the single-agent curvature Riccati, decoupled from everything else. The x^1 coefficient gathers $\dot{\pi}\bar{m} + \dot{\zeta}$, the transport contribution πV, the drift term $a(\pi\bar{m} + \zeta)$, the nonlinear term $-b^2P(\pi\bar{m} + \zeta)$, and $-qs\bar{m}$; substituting $V = (a - b^2P - b^2\pi)\bar{m} - b^2\zeta$ and separating the part proportional to $\bar{m}$ from the part independent of it splits this single line into the π- and ζ-equations. The $\bar{m}$-proportional part reads

$$\dot{\pi} + \underbrace{(a - b^2P - b^2\pi)\pi}_{\text{from } \pi V} + a\pi - b^2P\pi - qs = 0 \iff \dot{\pi} = b^2\pi^2 - 2(a - b^2P)\pi + qs,$$

and the $\bar{m}$-independent part reads

$$\dot{\zeta} + \underbrace{(-b^2\pi)\,\zeta}_{\text{from } \pi V} + a\zeta - b^2P\zeta = 0 \iff \dot{\zeta} = -(a - b^2P - b^2\pi)\,\zeta.$$

Finally the x^0 coefficient collects $\partial_t c$, $\partial_{\bar{m}}c \cdot V$, $\frac{1}{2}\sigma^2 P$, $-\frac{b^2}{2}(\pi\bar{m} + \zeta)^2$, and $\frac{q}{2}s^2\bar{m}^2$ into a scalar PDE for $c(t, \bar{m})$; it is decoupled *forward* from (P, π, ζ) — it is driven by them but never feeds back, since c carries no power of x and so contributes nothing to the decoupling field $\nabla_x U$. We record it as solved and set it aside. Reading off the terminal data from $u(T,x) = \frac{q_T}{2}(x - s_T\bar{m}_T)^2 = \frac{q_T}{2}x^2 - q_T s_T \bar{m}\, x + \cdots$, the three coefficient equations are the decoupled backward Riccati system

$$\dot{P} = b^2P^2 - 2aP - q, \qquad P(T) = q_T, \tag{12.25a}$$
$$\dot{\pi} = b^2\pi^2 - 2(a - b^2P)\pi + q\,s, \qquad \pi(T) = -q_T s_T, \tag{12.25b}$$
$$\dot{\zeta} = -(a - b^2P - b^2\pi)\,\zeta, \qquad \zeta(T) = 0. \tag{12.25c}$$

The system is triangular and reads off cleanly. Equation eq. (12.25c) for ζ is linear and homogeneous with zero terminal data, so $\zeta \equiv 0$ identically: the decoupling field carries *no* constant term. This is not an accident of the parameters but a *centering symmetry.* The model eq. (12.18)–eq. (12.19) is equivariant under the simultaneous translation $X \mapsto X + c$, $\bar{m} \mapsto \bar{m} + c$ (it shifts the target $s\bar{m}$ and the state together), so a population centered at $\bar{m} = 0$ must produce an equilibrium whose linear-in-x value vanishes at $x = 0$; the only translation-invariant constant the offset could be is zero, and ζ inherits it. With ζ gone, only P and π survive, each solving a scalar backward Riccati equation. The curvature P is the *familiar single-agent value curvature* of chapter 6 — note that eq. (12.25a) makes no reference whatever to the coupling parameters s, s_T, so P is exactly the Layer-1 object, untouched by the crowd. The coefficient π is the genuinely *new* quantity that Layer 3 contributes: the *sensitivity of an agent's marginal value to the population mean*, the rate at which her optimal momentum tilts as the whole crowd shifts. Its equation eq. (12.25b) is forced by the coupling — the source term qs and the terminal datum $-q_T s_T$ are exactly where s, s_T enter — and it is driven by P through the closed-loop rate $a - b^2P$, but it does not feed back into P. Reading off the x-gradient of the ansatz eq. (12.21) with $\zeta \equiv 0$, the *LQG decoupling field* is the affine map

$$\nabla_x U(t, x, m) = P(t)\,x + \pi(t)\,\bar{m}, \tag{12.26}$$

the explicit, fully computed instance of the abstract object the chapter has been chasing: a function on $\mathbb{R}^d \times \mathcal{P}_2(\mathbb{R}^d)$ that returns the equilibrium momentum at x for *every* crowd m, here linear in own state and in crowd mean. By the characteristics theorem theorem 12.6 this is exactly the relation $Y_t = P(t)X_t + \pi(t)\bar{m}_t$ between the FBSDE's adjoint Y_t and its forward components — the decoupling field of the LQG forward–backward system made fully explicit, with P and π its two scalar ingredients.

Consistency with the MFG fixed point of chapter 8

The construction is complete; the question that justifies the whole chapter is whether it is *correct* — whether the master function, restricted to the realized equilibrium flow, reproduces the Layer-2 fixed-point system that chapter 8 obtained by solving the coupled forward–backward problem directly. This is the LQG instance of the equivalence theorem 12.3, and on a model this explicit we can check it by hand, with every cancellation in view. The bridge is the restriction identity $u(t,x) = U(t,x,m_t)$: along the realized flow the master function's x-gradient must equal the Layer-2 value-gradient. From eq. (12.26), $\partial_x u(t,x) = P(t)\,x + \pi(t)\,\bar{m}_t$, so if we define the *linear offset along the equilibrium*

$$r(t) := \pi(t)\,\bar{m}_t,$$

then $\partial_x u(t,x) = P(t)\,x + r(t)$, which is precisely the form of the Layer-2 value-gradient. We use the canonical Thread-A solution symbols pinned in the specification (appendix A.7): $P(t)$ is the value-curvature Riccati unknown and $r(t)$ the linear offset — the very objects $P(t)$ and $r(t)$ of the uniqueness analysis of chapter 11 (the curvature Riccati eq. (11.11) and the offset eq. (11.12)). The single new piece of information the master equation supplies, beyond what Layer 2 already knew, is the *factorization* $r(t) = \pi(t)\,\bar{m}_t$: the equilibrium offset is the population-sensitivity coefficient π — a quantity defined off-equilibrium, for every crowd — evaluated at the realized mean $\bar{m}_t$. The master picture explains *why* r has the dynamics it does, by deriving them from π and the mean's motion.

To carry out the check we need the realized mean. From eq. (12.23) with $\zeta \equiv 0$, the equilibrium mean solves the closed linear forward ODE

$$\dot{\bar{m}}_t = (a - b^2 P - b^2\pi)\,\bar{m}_t, \qquad \bar{m}_0 \text{ given}, \tag{12.27}$$

exactly the forward half of the Layer-2 system. The offset r is a product of two time-dependent factors, so its dynamics follow from the product rule, and this is the climax of the verification — the one place where one must watch the nonlinear Riccati terms cancel. Differentiating $r = \pi\bar{m}$ and substituting the π-equation eq. (12.25b) for $\dot{\pi}$ and the mean equation eq. (12.27) for $\dot{\bar{m}}$,

$$\begin{aligned}
\dot{r} = \dot{\pi}\,\bar{m} + \pi\,\dot{\bar{m}} &= \big[\,b^2\pi^2 - 2(a - b^2P)\pi + qs\,\big]\bar{m} \;+\; \pi\,(a - b^2P - b^2\pi)\,\bar{m}\\
&= \big[\,b^2\pi^2 - 2(a - b^2P)\pi + qs + (a - b^2P)\pi - b^2\pi^2\,\big]\bar{m}\\
&= \big[\,-(a - b^2P)\pi + qs\,\big]\bar{m}\\
&= -(a - b^2P)\,(\pi\bar{m}) + q\,s\,\bar{m}_t \;=\; -(a - b^2P)\,r + q\,s\,\bar{m}_t.
\end{aligned}$$

The two nonlinear terms $+b^2\pi^2$ (from $\dot{\pi}$) and $-b^2\pi^2$ (from $\pi\dot{\bar{m}}$) cancel exactly, and the linear-in-π terms $-2(a - b^2P)\pi$ and $+(a - b^2P)\pi$ combine to $-(a - b^2P)\pi$; what was a *nonlinear* Riccati equation for π becomes, after multiplication by the mean, a *linear* backward equation for r. The terminal value transports the same way, $r(T) = \pi(T)\,\bar{m}_T = -q_T s_T\,\bar{m}_T$. This is *exactly* the Layer-2 forward–backward LQG system of chapter 8: the backward offset equation $\dot{r} = -(a - b^2P)\,r + qs\,\bar{m}$ with terminal data $-q_T s_T \bar{m}_T$, coupled to the forward mean equation eq. (12.27), with the curvature P solving its own eq. (12.25a). Not a coefficient, not a sign, not a boundary value is out of place. The cancellation of $b^2\pi^2$ is the whole content of the equivalence made arithmetic: the master equation's nonlinearity in the off-equilibrium sensitivity π is precisely what is needed for the on-equilibrium offset r to obey the linear forward–backward dynamics of the fixed point. We record the result.

Worked computation 12.15 (LQG master equation and its consistency)**.** For the scalar LQG MFG eq. (12.18)–eq. (12.19), the master function is the quadratic eq. (12.21) with $\zeta \equiv 0$ and (P, π) solving the decoupled backward Riccati pair eq. (12.25); the extra-diffusion term of the general master equation eq. (12.7) vanishes identically because $\partial_y \partial_\mu U \equiv 0$. The decoupling field is the affine map eq. (12.26). Restricting U to the equilibrium flow m_t via $r(t) = \pi(t)\bar{m}_t$ reproduces, with no discrepancy, the coupled Riccati-plus-mean fixed-point system of chapter 8 (Thread A, Layer 2), including its terminal data. The two pictures agree exactly.

There is one last dividend to collect, and it closes a loop the chapter opened twice: the abstract well-posedness question of section 12.6 acquires here a completely explicit, scalar face. The master equation exists globally exactly when its coefficients do, and on the LQG thread the only coefficient that can fail to exist is π.

Remark 12.16 (Where uniqueness enters)**.** The Riccati equation eq. (12.25b) for the population sensitivity π is the LQG incarnation of the well-posedness question of theorem 12.8. The curvature P, solving eq. (12.25a), never blows up backward from $P(T) = q_T \geq 0$ when $q \geq 0$: it is the benign single-agent object, bounded on every horizon. All the well-posedness drama lives in π. Tracing the chain of equivalences the chapter built: a global classical solution of the master equation exists iff its coefficient π exists on all of $[0, T]$ (the ansatz is the solution); by theorem 12.3 the master solution is equivalent to the MFG system; and by theorem 12.8 a global master solution is exactly uniqueness of the MFG equilibrium for every initial mean $\bar{m}_0$. Hence

$$\text{global existence of } \pi \iff \text{global master solution} \iff \text{equilibrium uniqueness.}$$

For parameters in the monotone/uniqueness regime — in particular for s, s_T small enough that the coupling respects Lasry–Lions monotonicity (A-Mon) — the source term qs and terminal datum $-q_T s_T$ are mild, and the backward Riccati solution π stays finite for all T. When s is strong enough to violate monotonicity the source can overwhelm the quadratic damping $b^2\pi^2$, π blows up to $-\infty$ in finite backward time, the ansatz eq. (12.21) ceases to define a function on the whole interval, the master solution fails to exist, and — by the same chain of equivalences read in reverse — equilibria multiply. This is the LQG face of remark 12.11: the blow-up of π in eq. (12.25b) occurs precisely at the (s, q, T) threshold where the forward–backward boundary-value problem of chapter 11 becomes singular. The closed-form threshold and the resulting phase diagram in (s, q, T) are already given in proposition 11.8 (fig. 11.1); they are completed for general terminal weight q_T in chapter 14. The lesson is that the entire well-posedness theory of this chapter, abstract as it looked, is encoded for the LQG thread in whether a single scalar Riccati trajectory reaches the terminal time without escaping to infinity.

This worked computation closes the argument of the chapter. We set out to show that the mean field game's backward–forward apparatus collapses into one scalar object $U(t, x, m)$, and that the collapse is a genuine upgrade rather than mere economy. The LQG thread has now made the claim concrete and checkable: the master equation is not only unifying but *computable*, reducing on this model to the two scalar Riccati equations eq. (12.25) whose restriction to the equilibrium flow reproduces the chapter 8 fixed point with no discrepancy at all, and exhibiting the affine decoupling field eq. (12.26) explicitly. Three threads run out of this section into the rest of the book. First, the second-order regularity of U that we computed here trivially — the curvature P and the smoothness in x and m — is the very input that chapter 13 requires to turn the master function into a quantitative N-player expansion: the differentiability that the bare value function lacked, made explicit on the thread, is what powers convergence with optimal rates. Second, the (s, q, T) blow-up of remark 12.16 hands the uniqueness-versus-multiplicity boundary to the phase-diagram analysis of chapter 11 and its completion for general q_T in chapter 14, where the LQG Riccati threshold becomes the sharp, computable instance of the abstract dichotomy. Third, and most ambitiously, the entire chapter — the derivation, the Hamilton–Jacobi reading, the common-noise second-order term we read off but did not prove, and this explicit LQG reduction — is lifted in chapter 26 to the graphon setting with common noise, where the population mean $\bar{m}$ becomes a type-indexed field aggregated through the kernel W and driven by a shared shock, and where the master equation regains the genuine second measure derivative that mean coupling here annihilated. The scalar Riccati pair of this section is the seed from which that far larger structure grows.

Rigor ledger

Proved.

- The chain rule for fully $\mathcal{C}^2$ functionals along a Fokker–Planck flow (lemma 12.2), with the two-term transport/diffusion structure; its full justification is the Itô formula on $\mathcal{P}_2(\mathbb{R}^d)$ proved in theorem D.7.
- The equivalence of the master equation with the MFG system: the master equation eq. (12.7)–eq. (12.8) holds for the constructed U, and conversely classical solutions generate solutions of the MFG system (theorem 12.3); the general-coefficient/non-separable form eq. (12.9) extends it (remark 12.4).
- The method of characteristics: Fokker–Planck flows are the characteristic curves, $\nabla_x U$ is the FBSDE decoupling field, and the master/system/FBSDE pictures coincide (theorem 12.6, diagram eq. (12.12)).
- *Short-horizon* well-posedness of the master equation, with full $\mathcal{C}^{1,2}/\mathcal{C}^2$ regularity, by a self-contained contraction argument assuming *no* monotonicity (proposition 12.10).
- Displacement monotonicity: the precise functional inequality definition 12.12 and the proof that it makes the master operator monotone (proposition 12.14), the deliverables forwarded from chapter 11 for non-separable Hamiltonians.
- The LQG master equation in closed form: a vanishing extra-diffusion term, two scalar backward Riccati equations eq. (12.25) in the canonical symbols P, r (appendix A.7), the affine decoupling field eq. (12.26), and exact consistency with the Layer-2 fixed point of chapter 8 (worked computation 12.15).

Assumed (imported).

- The MFG system and the optimal-feedback relation $\alpha^* = -\partial_p H$, the Hamiltonian $H(x, p, m)$ in the canonical argument order, convex (here strictly) in p under (A-Conv), and the variational/potential structure (chapter 8, appendix A.4).

- The McKean–Vlasov FBSDE, the maximum principle, and the FBSDE–PDE dictionary $Y_t = \nabla u(t, X_t)$, $Z_t = \mathrm{D}^2\, u(t, X_t)\sigma$ (proposition 9.12, with the decoupling-field existence theorem 9.14; chapter 5 for Itô).

- Existence of MFG equilibria (chapter 10); Lasry–Lions monotonicity (A-Mon) of definition 11.1 with its uniqueness consequence theorem 11.5; the McKean–Vlasov flow well-posedness theorem 7.9; standing assumptions (A-Lip),(A-Growth),(A-Nondeg),(A-Conv) of appendix A.6.

- The flat and Lions derivatives and the Itô formula on $\mathcal{P}_2(\mathbb{R}^d)$ (chapter 4, appendix A.3, theorem D.7).

- *Exported* for downstream use: the constructed U carries bounded, Lipschitz second-order Lions derivatives $\partial_\mu^2 U$, $\nabla_x \partial_\mu U$ (theorem 12.8), imported by the $O(1/N)$ expansion of chapter 13.

Deferred.

- The *all-horizon* classical well-posedness of eq. (12.7) in the monotone regime (theorem 12.8): the equivalence, the mechanism, and the short-horizon case are proved in-book; only the all-horizon linearized-system $\mathcal{W}_2$-estimates and second-order m-differentiability are imported, as the acknowledged exception of remark 12.9, from [37] and [41], Ch. 5.

- The all-horizon well-posedness under *displacement* (rather than Lasry–Lions) monotonicity for non-separable Hamiltonians: imported on the same footing from [76] and [104].

- The common-noise master equation eq. (12.17): structure only here, conditional on the Itô–Wentzell formula on $\mathcal{P}_2(\mathbb{R}^d)$, whose in-book proof and the full well-posedness theory are chapter 26 (with [37, 41] for attribution).

- The quantitative N-player convergence powered by U (rate $O(1/N)$): chapter 13.

Open.

- Well-posedness outside the monotone (and outside the short-horizon) regime: no general theory; classical solutions can fail exactly where equilibria multiply (remark 12.11, chapter 14).

- Master-equation theory under common noise on *sparse*/L^p graphon limits, flagged for chapters 26 and 27 and the research map of chapter 31.

Bibliographic notes

The master equation was introduced by Lions in his Collège de France lectures and recorded in [36]; the foundational text is [37], which proves classical well-posedness in the monotone, non-degenerate regime and uses it to settle the convergence problem from the N-player game (the source for theorem 12.8 and for the $O(1/N)$ rates forwarded to chapter 13). The probabilistic theory — the Itô calculus on $\mathcal{P}_2(\mathbb{R}^d)$ of lemma 12.2, the decoupling-field viewpoint of theorem 12.6, and the common-noise master equation of section 12.7 — is developed systematically in [41], especially Chapters 4–5, building on the calculus on Wasserstein space first organized for this purpose in [40]. The Lasry–Lions monotonicity condition eq. (12.13) and the multiplicity phenomenon when it fails originate in [93]; the geometry of $\mathcal{P}_2(\mathbb{R}^d)$ underlying the Hamilton–Jacobi reading of section 12.4 follows [131]. *Displacement monotonicity* (definition 12.12) as the structural condition for the master equation with non-separable Hamiltonians is due to Gangbo and Mészáros [75] (the displacement-convex potential case) and Gangbo, Mészáros, Mou and Zhang [76] and Mou and Zhang [104] (the general non-separable case); our proposition 12.14 is their monotone-decoupling-field computation in the canonical setting. The LQG master equation and decoupling field of section 12.8 are classical folklore for linear–quadratic mean field games; the reduction to Riccati systems and the consistency check are carried out in the LQG chapters of [40] and instantiated for this book's thread in chapter 14. The graphon lift of the entire chapter, together with common noise across a kernel, is the subject of chapter 26.

Chapter 13

From N-Player Games to the Mean Field Limit

The mean field game system of chapters 8 and 9, its solution theory (chapters 10 and 11), and the master equation of chapter 12 were all *postulated* as the right description of a large population of strategic agents. We argued for them by analogy, by the self-consistent-field reflex, and by the sheer cleanliness of the limit object — but we never certified that the limit is the limit *of anything.* A physicist should be uneasy here, and the unease is the right instinct. We have spent five chapters studying an effective field theory — a single representative agent moving in a self-generated mean field — without ever exhibiting the finite, microscopic system it is supposed to coarse-grain. Nothing so far rules out that the MFG system is an internally consistent fiction with no finite-N preimage, or that it is the limit of a population governed by different microscopic rules than the ones we care about. The analogue in statistical mechanics would be to write down a Landau free energy and never check that any honest Hamiltonian flows to it. This chapter supplies the missing certificate. It begins from a genuine, finite, non-cooperative game — N agents, each minimizing its own cost, each best-responding to the other $N-1$ — and asks in what precise sense, and at what rate, this microscopic game is approximated by the mean field game (MFG) as $N \to \infty$. Only once that is done is the postulate retired and the limit object earned.

Two facts make the question subtle, and both are the point of the chapter; we flag them now without proof so that the reader feels the stakes before the machinery arrives. The first is that the finite game is itself a perfectly sharp object, not a vague crowd. A Markovian Nash equilibrium of the N-player game is encoded *exactly* by a coupled system of N Hamilton–Jacobi–Bellman (HJB) equations on the Nd-dimensional configuration space $(\mathbb{R}^d)^N$ — the *Nash system.* This system is sharp but hopeless: it contains the full truth about the finite game, and it is computationally and analytically intractable for any N beyond a handful, because its unknowns live on a space whose dimension grows with the number of players and whose N equations are mutually coupled through the gradients of one another's solutions. The mean field is precisely the cure — it replaces N functions on $(\mathbb{R}^d)^N$ by one function on $\mathbb{R}^d$ driven by a deterministic field — and the chapter's first job (section 13.2) is to write the Nash system down and read off, term by term, exactly which features the limit dissolves and which it must keep.

The second fact is that the limit can be taken in two opposite directions, and they are *not* equally easy — their asymmetry is the single most important conceptual seam of the chapter, and it has a one-word cause: whether the interaction is *exogenous* or *endogenous.* In the *top-down* direction one starts from the MFG solution, hands its decentralized feedback to each of the N players, and asks how far short of equilibrium the resulting profile falls. Here the interaction is exogenous: the feedback is fixed in advance by the limit problem, so the N states evolve by a *prescribed* McKean–Vlasov dynamics, and the only thing to check is that the empirical measure of that dynamics concentrates — propagation of chaos for a fixed law of motion, exactly the phenomenon of chapter 7. This direction is cheap and yields the ε-Nash property. In the *bottom-up* direction one starts from the *actual* Nash equilibria of the N-player game and asks whether they converge to the MFG. Here the interaction is endogenous: the feedback each agent uses is itself the unknown of the Nash system, so the empirical measure one must show concentrates is generated by feedbacks that already depend on it. The chaos is no longer an input to a known dynamics but an *output* of the equilibrium — *propagation of chaos for Nash equilibria* — and there is no fixed system to which chapter 7 can be applied. Getting a rate for it is exactly what the regularity of the master equation buys; getting mere convergence, without a rate, costs only a compactness argument. Holding this exogenous-versus-endogenous distinction firmly is the key to not conflating the two halves of the chapter.

A word on standing conventions, so the reader carries the chapter's dependency skeleton before entering it. Throughout we work on the horizon $[0, T]$ and keep the convention of appendix A: value functions carry terminal data and are solved *backward* from $t = T$, while densities carry initial data and flow *forward* from $t = 0$ — the backward value/forward density pairing that the whole forward–backward structure of the theory rests on. No graphon is in scope anywhere in this chapter, so the letter W is free to denote Brownian motion, and we write W^i for the i-th agent's independent noise; the switch to B for Brownian motion, forced by the reappearance of the graphon kernel W, happens only from Part III onward. The chapter is a confluence of nearly everything proved so far, and it is worth naming the imports explicitly. From chapters 8 and 9 we take the MFG system and the representative McKean–Vlasov dynamics whose law is the mean field; from chapter 6 the single-agent stochastic control and verification machinery that the Nash system reduces to agent by agent; from chapter 7 the propagation of chaos that powers the top-down direction; from chapter 11 the Lasry–Lions monotonicity condition (A-Mon) and the uniqueness of the MFG solution it delivers; from chapter 12 the master field $U(t, x, m)$ and the strong regularity that makes it usable as an ansatz; and the linear–quadratic–Gaussian (LQG) thread is carried in from chapter 6 and forward into chapter 14. In exchange the chapter exports three results, and the reader may keep them as the three milestones to head for: the ε-Nash property of the mean field strategy (theorem 13.6), the qualitative convergence of equilibria (theorem 13.9), and the quantitative convergence with rate (theorem 13.13). chapter 14 instantiates all three explicitly on the LQG model, where everything is a Riccati ODE, and chapter 25 generalizes them to networks.

13.1 The N-player stochastic differential game

The chapter preamble promised to begin from a genuine, finite, non-cooperative game; this is where that game is written down once and frozen. Everything that follows — the Nash system, the ε-Nash property, the two convergence theorems — is a statement about the single object defined in this section, so it is worth fixing its data with care and saying out loud why each modelling choice is the one a mean field limit demands.

We fix the data of the finite game once and use it for the rest of the chapter. There are N agents indexed $i \in \{1, \dots, N\}$. Agent i has a private state $X_t^i \in \mathbb{R}^d$ driven by an admissible control α^i and by an independent d-dimensional Brownian motion W^i, with the W^i mutually independent and independent of the initial states X_0^i, which are i.i.d. with common law $m_0 \in \mathcal{P}_2(\mathbb{R}^d)$. The interaction is *anonymous*: every agent feels the others only through the *empirical measure*

$$\mu_t^N \;:=\; \frac{1}{N}\sum_{j=1}^{N} \delta_{X_t^j} \;\in\; \mathcal{P}(\mathbb{R}^d), \tag{13.1}$$

the rigorous occupation profile introduced in chapter 1 and the carrier of the mean field throughout chapters 7 and 8.

The choice to let agents interact *only* through μ_t^N is not a simplifying convenience; it is the precise structural hypothesis without which no mean field limit can exist, and it deserves to be understood before we go on. Anonymity says that an agent's drift and cost depend on the others not through their identities or their labelled positions $(X^1, \dots, \widehat{X^i}, \dots, X^N)$ but only through the unordered cloud of where everyone is — the histogram, not the seating chart. Formally, the coefficients are invariant under permutations of the other agents' indices, so they can be written as functions of the empirical measure alone. Two things flow from this. First, the game is *exchangeable*: relabelling the agents leaves the entire system of dynamics and costs unchanged, which is exactly the symmetry that lets us speak of a single "representative" agent in the limit, since no agent is distinguished. Second, and more importantly, anonymity is what makes the limit *stable in* N: an empirical-measure functional such as $\int \phi \, \mathrm{d}\mu_t^N = \frac{1}{N}\sum_j \phi(X_t^j)$ is an intensive quantity — an average, not a sum — so it has a finite, N-independent limit as the population grows, and adding one more agent perturbs it by only $O(1/N)$. A non-anonymous coupling, say a drift that singled out agent 1, would either blow up or retain a memory of microscopic detail that no mean field could carry. This is the same intensive-versus-extensive distinction that underlies every thermodynamic limit, and it is why the empirical measure — introduced in chapter 1 as the rigorous meaning of "the state of the population" and used in chapters 7 and 8 as the argument the mean field converges to — is the only object through which the interaction may legitimately flow. The dynamics and costs are

$$\mathrm{d}X_t^i = b(X_t^i,\, \mu_t^N,\, \alpha_t^i)\; \mathrm{d}t \;+\; \sigma(X_t^i,\, \mu_t^N)\; \mathrm{d}W_t^i, \qquad X_0^i \sim m_0, \tag{13.2}$$

$$J^{N,i}(\alpha^1, \dots, \alpha^N) = \mathbb{E}\left[\int_0^T L(X_t^i,\, \mu_t^N,\, \alpha_t^i)\; \mathrm{d}t \;+\; g(X_T^i,\, \mu_T^N)\right]. \tag{13.3}$$

The coefficients b, σ, L, g are the *same* functions for every agent — the game is symmetric (exchangeable) — and they satisfy the standing assumptions (A-Lip), (A-Growth), (A-Nondeg), (A-Conv) of appendix A, with the measure arguments measured in $\mathcal{W}_2$. We write $\mathcal{A}^\alpha$ for the controlled generator of a single state,

$$(\mathcal{A}^\alpha \phi)(x) = b(x, m, \alpha) \cdot \nabla\phi(x) + \tfrac{1}{2}\,\mathrm{tr}\big(\sigma\sigma^\top(x, m)\; \mathrm{D}^2\, \phi(x)\big),$$

the operator that, by Itô's formula (theorem 5.9), gives the instantaneous expected rate of change of $\phi(X_t)$ along the controlled state; its first-order part carries the drift and its second-order part the diffusion. The diffusion coefficient enters this generator only through the symmetric positive-semidefinite matrix $\sigma\sigma^\top(x,m)$ — never through σ alone — because the second-order operator is $\frac{1}{2}\sum_{kl}(\sigma\sigma^\top)_{kl}\partial_{kl}$, so it is $\sigma\sigma^\top$, the local covariance of the noise, that is the analytically meaningful object. It would be standard shorthand to christen it $a(x,m) := \sigma\sigma^\top(x,m)$, exactly as one does in the general PDE literature, and we keep it spelled out instead, precisely as in chapter 12, for a deliberate notational reason that the reader should bank now: the symbol a is reserved across the whole book for the *state-feedback coefficient* of the LQG Thread A, the scalar in $\mathrm{d}X = (aX + b\alpha)\,\mathrm{d}t + \sigma\,\mathrm{d}W$. Were we to write a for the diffusion matrix here, the worked LQG computation later in this chapter would suffer a genuine collision — the same letter would mean $\sigma\sigma^\top$ in the general theory and the linear drift gain in the thread it specializes to. We therefore never abbreviate $\sigma\sigma^\top$, and the notationwatch preceding worked computation 13.8 restates the reservation at the seam where it bites.

Notation watch

Two empirical measures appear, differing by which agents are counted, and the gap between them is small but not always negligible — so it is worth getting the bookkeeping right once. The full empirical measure μ_t^N of eq. (13.1) includes agent i itself, all N atoms. When we isolate the environment *seen by* agent i — the population of competitors it actually responds to — we use the empirical measure of the *others*,

$$\mu_t^{N,-i} \;:=\; \frac{1}{N-1}\sum_{j\neq i}\delta_{X_t^j}.$$

Passing from one to the other deletes a single atom of mass $1/N$ and renormalizes the remaining $N-1$ atoms from weight $1/N$ to weight $1/(N-1)$. For the purpose of *rates* the two are interchangeable: their discrepancy is $o(r_N)$, negligible relative to the sampling rate r_N of lemma 13.5. But *how* negligible depends on the metric in which we measure it, and that dependence carries genuine dimensional intuition that recurs below.

In the weakest pairings — testing against a bounded function, or measuring in the flat/$\mathcal{W}_1$ distance — the discrepancy is a clean $O(1/N)$. Indeed, for a 1-Lipschitz (or bounded) test function ϕ,

$$\Big|\int\phi\;\mathrm{d}\mu_t^N - \int\phi\;\mathrm{d}\mu_t^{N,-i}\Big| = \Big|\tfrac{1}{N}\phi(X_t^i) - \tfrac{1}{N(N-1)}\sum_{j\neq i}\phi(X_t^j)\Big| = O(\tfrac{1}{N}),$$

because removing a single normalized atom and rescaling moves any average by at most a $1/N$ fraction. This $O(1/N)$ statement is exactly the one the value estimate eq. (13.22) uses, since the value comparison pairs the measures against the (Lipschitz) derivatives of the master field, i.e. against the flat/$\mathcal{W}_1$ structure. There the with-self/without-self distinction is beneath the resolution of the theorem.

In $\mathcal{W}_2$ the picture is subtler, and the subtlety is dimensional. $\mathcal{W}_2$ is an *optimal-transport* distance: it does not merely reweight mass, it must *move* it, and the cost of redistributing the deleted atom's $1/N$ of mass over the cloud depends on how spread out the cloud is, which is a function of dimension. The empirical measure of N i.i.d. points fills $\mathbb{R}^d$ at a typical inter-point spacing of order $N^{-1/d}$, so re-transporting an excess $1/N$ of mass can require displacements that, in dimension $d \geq 2$, exceed the naive $1/N$: the $\mathcal{W}_2$ discrepancy is then larger than the flat/$\mathcal{W}_1$ value $1/N$, though it stays strictly below the sampling error r_N. This is the same geometric effect that makes N samples resolve a measure only at the dimension-dependent Fournier–Guillin rate r_N of eq. (13.12) rather than at $1/N$: in high dimension, empty space between samples is the bottleneck. What rescues us is only that even this larger $\mathcal{W}_2$ discrepancy remains $o(r_N)$ in *every* dimension — the deletion of one atom is always asymptotically smaller than the sampling error of the whole cloud — which is all the estimates below require. We therefore keep the with-self/without-self distinction only where the $O(1/N)$ term is itself the quantity under study, as in the master-equation expansion of section 13.5, and elsewhere use whichever of μ_t^N, $\mu_t^{N,-i}$ reads more naturally.

We must now say precisely what an agent is allowed to know and do, and this is a genuinely consequential choice, not boilerplate. In the single-agent control of chapter 6 the information structure was immaterial: an optimally controlled isolated agent does equally well whether it commits to a deterministic schedule in advance or reacts to its own state in feedback, because the two coincide along the optimal path. In a game this is no longer so. What agent i may condition on — its own past noise, its own current state, the entire configuration of all players — determines what counts as a "deviation," hence which profiles are in equilibrium, and, as we will see in remark 13.10, it can even change the object the equilibria converge to. We therefore fix three nested information classes.

Definition 13.1 (Admissible strategies)**.** Let $\mathbb{F}^N = (\mathcal{F}_t^N)_{t\in[0,T]}$ be the filtration generated by all initial states and all Brownian motions.

1. An *open-loop* strategy for agent i is an $\mathbb{F}^N$-progressively measurable process $\alpha^i = (\alpha_t^i)$ valued in the action set $A \subseteq \mathbb{R}^k$ with $\mathbb{E}\int_0^T |\alpha_t^i|^2 \, \mathrm{d}t < \infty$.

2. A *Markovian* (closed-loop, feedback) strategy is given by a measurable map $\pi^i : [0,T]\times(\mathbb{R}^d)^N \to A$ used in feedback form $\alpha_t^i = \pi^i(t, \boldsymbol{X}_t)$, where $\boldsymbol{X}_t = (X_t^1, \dots, X_t^N)$; it is admissible if the closed-loop system eq. (13.2) is well-posed and the resulting control is square-integrable.

3. A *decentralized* (distributed) Markovian strategy is one in feedback form $\alpha_t^i = \pi(t, X_t^i)$ depending on agent i's own state alone.

We write $\boldsymbol{\alpha} = (\alpha^1, \dots, \alpha^N)$ for a profile and $\boldsymbol{\alpha}^{-i}$ for the profile of all agents but i.

The three classes are best read as three answers to the question "what does agent i watch?". An *open-loop* agent watches the raw randomness: it commits to a control process adapted to the filtration $\mathbb{F}^N$ generated by all the noises and initial states, so in principle it may react to the entire history of every Brownian path, but it does so through a fixed, pre-planned dependence on that randomness rather than on the realized positions. A *Markovian* or closed-loop agent watches the whole current configuration $\boldsymbol{X}_t$: it uses a feedback law $\pi^i(t, \boldsymbol{X}_t)$ that reads off every player's present state and responds instantaneously, the natural notion of a strategy that "sees the board." A *decentralized* agent watches only its own state X_t^i: its feedback $\pi(t, X_t^i)$ ignores the others entirely, the radically local information structure that a single representative agent in the mean field limit would in any case be left with, since in the limit the rest of the population has collapsed into the deterministic field m_t and there is nothing agent-specific left to watch. These are genuinely different powers, and the inclusions are strict: decentralized $\subset$ Markovian, while open- and closed-loop are not nested but encode different commitments. The decentralized class is the one the MFG hands us for free and the one we will test in the top-down direction; the Markovian class is the one in which the Nash system of section 13.2 is naturally posed; and the gap between open-loop and closed-loop equilibria is the source of a real subtlety in the *limit* — closed-loop equilibria can carry configuration-mediated correlations that survive as extra randomness in the limit, so that the two classes need not converge to the same object. We flag this now and return to it, with the resolution under monotonicity, in remark 13.10.

Having fixed *what an agent may know and do*, we can say what it means for a profile of such strategies to be self-consistent — for no agent, given the others' play, to wish to move. This is the equilibrium concept, and its ε-relaxation, that the rest of the chapter compares against the mean field.

Definition 13.2 (Nash and ε-Nash equilibria)**.** A profile $\boldsymbol{\alpha}^*$ is a *Nash equilibrium* of the N-player game eq. (13.2)–eq. (13.3) (within a given admissibility class) if no agent can strictly improve by a unilateral deviation:

$$J^{N,i}(\alpha^{*,i}, \boldsymbol{\alpha}^{*,-i}) \;\le\; J^{N,i}(\alpha^{i}, \boldsymbol{\alpha}^{*,-i}) \qquad \text{for all } i \text{ and all admissible } \alpha^i.$$

For $\varepsilon \ge 0$, the profile is an ε*-Nash equilibrium* if

$$J^{N,i}(\alpha^{*,i}, \boldsymbol{\alpha}^{*,-i}) \;\le\; J^{N,i}(\alpha^{i}, \boldsymbol{\alpha}^{*,-i}) \;+\; \varepsilon \qquad \text{for all } i \text{ and all admissible } \alpha^i. \tag{13.4}$$

That is, no unilateral deviation can lower an agent's cost by more than ε.

It is worth being clear about why we carry the slack ε at all, rather than chasing exact Nash equilibria of the finite game. The ε-relaxation is not a technical convenience to be removed later; it is the *only* honest target for the mean field strategy, and the reason is a fluctuation count. The decentralized feedback the MFG hands each agent, $\widehat{\alpha}(t, X_t^i)$, is the exact best response of a representative agent against the *deterministic* limiting field m_t. But in a finite game agent i does not face m_t; it faces the random empirical measure $\mu_t^{N,-i}$ of its $N-1$ competitors. By the central limit theorem, this empirical field deviates from its mean m_t by fluctuations of size $O(1/\sqrt{N})$: averaging $N-1$ independent contributions suppresses the variance like $1/N$, so the standard deviation of any smooth functional of $\mu_t^{N,-i}$ around its mean is of order $N^{-1/2}$, not zero. A strategy tuned to the mean field is, by construction, blind to these fluctuations — it does not even take $\mu_t^{N,-i}$ as an input. An agent that *did* watch the realized field could, in principle, exploit those $O(1/\sqrt{N})$ wiggles and shave a little off its cost, so the mean field strategy is generically *not* an exact best response, and the symmetric profile in which everyone plays it is generically *not* an exact Nash equilibrium, at any finite N. What saves the construction is that the cost is smooth in the field, so an $O(1/\sqrt{N})$ perturbation of the field can change the attainable cost by at most $O(1/\sqrt{N})$ — and, when the mean field control is a critical point, only by the square, $O(1/N)$. Either way the exploitable gain is a vanishing ε_N, never exactly zero. Demanding exact equilibrium would therefore be demanding the wrong thing; the ε-Nash inequality eq. (13.4) is the relaxation that exactly matches what the mean field strategy can deliver. Quantifying the smallest admissible ε — showing $\varepsilon_N \to 0$ and at what rate — is the content of section 13.4.

With the finite game fixed, the information classes pinned down, and the equilibrium concept (exact and relaxed) defined, we have said abstractly *what* a Markovian Nash equilibrium is but not *which equations* it must satisfy. Answering that question — writing down the system of coupled Hamilton–Jacobi–Bellman equations a Markovian equilibrium obeys — is the business of the next section.

13.2 The Nash system: N coupled HJB equations

The previous section closed by sharpening a question it could only pose: we have said abstractly *what* a Markovian Nash equilibrium is — a feedback profile from which no agent wishes to deviate — but not *which equations* its value functions must obey. For a single isolated optimizer that question had a clean answer in chapter 6: dynamic programming compressed the entire control problem into one Hamilton–Jacobi–Bellman (HJB) equation for the value function. We now have not one optimizer but N of them, each best-responding to the other $N-1$, and the natural guess is that equilibrium is encoded by N HJB equations, one per agent, knotted together by the fact that each agent's optimal play depends on what the others do. That guess is correct, and making it precise is the business of this section. The resulting object — the *Nash system* — is the finite-N analogue of the single HJB of chapter 6, and writing it down is the cleanest way to see two things at once: that the finite game is perfectly well-posed in principle, and that it is hopeless in practice. Both readings will matter, because the entire rest of the chapter is the project of escaping the second while keeping faith with the first.

Before any system can be written, we need the right Hamiltonian, and getting its conventions straight now will spare us sign confusion at every later step. Recall from chapters 6 and 8 that the role of the Hamiltonian is to pre-compute, once and for all, an agent's optimal instantaneous response to a given "momentum" — the local sensitivity $p = \nabla u$ of its value function to its own state. We use the convex (Lions) convention fixed in appendix A, with the canonical argument order $H(x, p, m)$ — state, then momentum, then measure — so that the standing convexity assumption (A-Conv) reads simply "H convex in p":

$$H(x,p,m) \;:=\; \sup_{\alpha\in A}\big\{-\,p\cdot b(x,m,\alpha)-L(x,m,\alpha)\big\}, \qquad \alpha^*(x,p,m) \;:=\; \operatorname*{arg\,max}_{\alpha\in A}\big\{-\,p\cdot b(x,m,\alpha)-L(x,m,\alpha)\big\}, \tag{13.5}$$

so that the closed-loop optimal drift of a single agent is $b(x, m, \alpha^*(x, p, m)) = -\partial_p H(x, p, m)$.

Three features of this definition deserve a sentence each, because each is a deliberate choice rather than an accident of typography. First, the *minus signs*. An agent *minimizes* cost, so the quantity it wants small is $p \cdot b + L$ — the drift term measures how the agent's motion changes its own cost-to-go through $p = \nabla u$, the running term the instantaneous price of acting. Taking the supremum of the *negated* bracket is exactly minimizing the bracket itself, and packaging the minimization as a sup is what lets us read off convexity for free: a supremum of functions affine in p is convex in p, so

(A-Conv) holds structurally rather than by fiat. Under (A-Conv) — strict convexity of L in α with b affine in α — the bracket is strictly concave in α, so the maximizer $\alpha^*(x,p,m)$ is *unique* and, by the implicit function theorem applied to its first-order condition, Lipschitz in p on bounded sets. That regularity is not cosmetic: it is exactly what makes the equilibrium feedbacks $\widehat{\alpha}^j$ below well-defined Lipschitz functions of the value gradients, hence what makes the closed-loop Nash system a genuine PDE rather than a differential inclusion. Second, the envelope identity $b(x,m,\alpha^*) = -\partial_p H$ is just the statement that one may differentiate the maximized bracket in p as if α^* were frozen — the derivative through α^* vanishes at the optimum by the first-order condition. It is the device by which the optimal *drift* re-enters the Fokker–Planck transport in the heuristic below, and we will use it without further comment.

Third, and most important for the bookkeeping ahead, this is the *measure-loaded* Hamiltonian: the population coupling enters through the measure slot m of b and L, is carried inside the bracket, and is therefore absorbed wholesale into $H(x,p,m)$. Keeping the measure slot explicit is not pedantry — the N-player running cost eq. (13.3) need not split cleanly into a control part and a population part, and where it does not, the coupling genuinely lives inside the optimization. It is worth seeing, however, exactly how this reconciles with the more familiar separated convention of chapter 12, where the coupling sat on the right-hand side of the HJB as a source. Suppose the data are *additively separable*: the running cost splits as $L(x,m,\alpha) = L_0(x,\alpha) + F(x,m)$, with the control-dependent part L_0 and the drift $b(x,\alpha)$ both free of the measure, while the entire population dependence is collected in the cost $F(x,m)$. Then the measure term is a constant as far as the maximization over α is concerned, and it pulls straight out of the sup:

$$H(x,p,m) = \sup_\alpha \{-p\cdot b(x,\alpha) - L_0(x,\alpha) - F(x,m)\} = \underbrace{\sup_\alpha \{ -p\cdot b(x,\alpha) - L_0(x,\alpha)\}}_{:=H_0(x,p)} - F(x,m) = H_0(x,p) - F(x,m)$$

Substituting this factorization into the single-agent HJB $-\partial_t u - \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 u) + H(x,\nabla u, m) = 0$ moves F to the other side and reproduces verbatim the separated MFG–HJB of chapter 12 (eq. (12.2a)), $-\partial_t u - \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 u) + H_0(x,\nabla u) = F(x,m_t)$, with the population coupling reappearing as the source on the right and the terminal cost $g(x,m_T)$ playing the role of $G(x,m_T)$ there. The two conventions therefore agree *exactly* on the separable class; the measure-loaded form is strictly more general, and we carry it throughout precisely because the N-player coupling need not be separable. With the Hamiltonian fixed, we can state the system that a Markovian equilibrium must satisfy.

Proposition 13.3 (The Nash system)**.** *Suppose the N-player game admits a Markovian Nash equilibrium whose value functions*

$$v^{N,i}(t,\boldsymbol{x}) \;:=\; J^{N,i}(\alpha^{*,i},\boldsymbol{\alpha}^{*,-i}) \text{ started from } \boldsymbol{X}_t = \boldsymbol{x} \text{ at time } t, \qquad \boldsymbol{x} = (x_1,\dots,x_N) \in (\mathbb{R}^d)^N,$$

are of class $C^{1,2}$. Then, writing $\mu^N_{\boldsymbol{x}} = \frac{1}{N}\sum_k \delta_{x_k}$, the family $(v^{N,i})_{i=1}^N$ solves on $[0,T)\times(\mathbb{R}^d)^N$ the coupled system

$$-\partial_t v^{N,i} \;-\; \sum_{j=1}^N \tfrac{1}{2}\operatorname{tr}\Big(\sigma\sigma^\top(x_j,\mu^N_{\boldsymbol{x}})\, \mathrm{D}^2_{x_j} v^{N,i}\Big) \;-\; \sum_{j\neq i} b\Big(x_j,\mu^N_{\boldsymbol{x}},\, \widehat{\alpha}^j(t,\boldsymbol{x})\Big)\cdot\nabla_{x_j} v^{N,i} \;+\; H\Big(x_i,\nabla_{x_i} v^{N,i},\mu^N_{\boldsymbol{x}}\Big) \;=\; 0, \tag{13.6}$$

with terminal data $v^{N,i}(T,\boldsymbol{x}) = g(x_i, \mu^N_{\boldsymbol{x}})$*, where the equilibrium feedback of agent* j *is* $\widehat{\alpha}^j(t,\boldsymbol{x}) = \alpha^*(x_j, \nabla_{x_j} v^{N,j}(t,\boldsymbol{x}), \mu^N_{\boldsymbol{x}})$*. Conversely, a classical solution of eq.* (13.6) *with the indicated feedbacks verifies a Markovian Nash equilibrium.*

Proof sketch. The whole argument turns on a single device — "freeze the others" — and the subtle point is that the freezing must be *self-consistent* to deliver an equilibrium rather than merely a best response to an arbitrary environment. We unfold it in three movements.

Freeze, and a control problem appears. Fix one agent i and pretend, for the moment, that the other $N-1$ agents are committed to their equilibrium feedbacks $\widehat{\alpha}^j$, $j \neq i$. The definition of Nash equilibrium (definition 13.2) says precisely that, against this frozen environment, agent i's own equilibrium control is its *optimal* control — it has no profitable deviation. So $v^{N,i}$, the equilibrium cost-to-go of agent i, is the *value function of a single, ordinary stochastic control problem*, the one agent i solves when everyone else is glued to $\widehat{\alpha}^j$. The state of this control problem is the full configuration $\boldsymbol{X} = (X^1, \dots, X^N) \in (\mathbb{R}^d)^N$, but only the i-th block is steerable: agent i controls X^i through α, while each X^j with $j \neq i$ is an *uncontrolled* diffusion carrying the now fixed drift $b(x_j, \mu^N, \widehat{\alpha}^j)$ and the diffusion $\sigma(x_j, \mu^N)$. This is the conceptual move that makes everything tractable: an N-player game has been reduced, agent by agent, to N ordinary single-controller problems, each posed on the high-dimensional space $(\mathbb{R}^d)^N$ because each agent must track where everyone else is in order to know the cost it pays.

Dynamic programming gives an HJB on $(\mathbb{R}^d)^N$*.* To this single control problem we apply the dynamic programming principle of chapter 6 verbatim, only with the state space enlarged from $\mathbb{R}^d$ to $(\mathbb{R}^d)^N$. The generator of the configuration splits into the part agent i controls and the part it merely watches: the diffusion contributes a second-order term summed over *all* N blocks (every state, controlled or not, diffuses), the frozen drifts of the others contribute first-order transport terms summed over $j \neq i$, and agent i's own drift sits inside an optimization. Dynamic programming yields $\partial_t v^{N,i} + \sum_j \frac{1}{2} \operatorname{tr}(\sigma\sigma^\top(x_j, \mu^N)\, \mathrm{D}^2_{x_j} v^{N,i}) + \sum_{j\neq i} b(x_j, \mu^N, \widehat{\alpha}^j) \cdot \nabla_{x_j} v^{N,i} + \min_\alpha\{b(x_i, \mu^N, \alpha) \cdot \nabla_{x_i} v^{N,i} + L(x_i, \mu^N, \alpha)\} = 0$, where the inner $\min_\alpha$ is agent i optimizing its own instantaneous trade-off between steering $(b \cdot \nabla_{x_i} v^{N,i})$ and paying (L). By the very definition eq. (13.5) of the Hamiltonian as a *maximized negated* bracket, this inner minimum is $\min_\alpha\{\cdots\} = -H(x_i, \nabla_{x_i} v^{N,i}, \mu^N)$, and the minimizing control is read off as $\alpha^*(x_i, \nabla_{x_i} v^{N,i}, \mu^N)$. Substituting and moving the sign gives exactly the i-th equation of eq. (13.6).

Self-consistency upgrades best response to equilibrium. So far we have only used that agent i optimizes against *some* frozen feedbacks $\widehat{\alpha}^j$; the equation we obtained would hold against any fixed environment. What makes the family $(v^{N,i})_i$ an *equilibrium* rather than a collection of unrelated best responses is the closure condition that the minimizer we just computed for agent i, $\widehat{\alpha}^i = \alpha^*(x_i, \nabla_{x_i} v^{N,i}, \mu^N)$, must coincide with the very feedback the *other* agents froze for i when they solved their own problems. Each agent's optimal response, computed holding the others fixed, reproduces the feedback the others had assumed: the freezing is a fixed point, not an arbitrary choice. This is the finite-N incarnation of the self-consistency that runs through the whole subject — the same logic that in the limit will force m_t to be the law of the agent that optimally responds to m_t. It is also why the system is *simultaneous*: agent i's equation contains $\nabla_{x_j} v^{N,j}$ through $\widehat{\alpha}^j$, so no agent's value can be solved without all the others' at once.

The converse — that a classical solution of eq. (13.6) with the indicated feedbacks really does verify a Markovian Nash equilibrium — is the verification theorem of chapter 6 applied agent by agent: given a $C^{1,2}$ solution, the Itô expansion of $v^{N,i}$ along any admissible deviation of agent i shows the equilibrium feedback is optimal, with the Hamiltonian's defining inequality supplying the one-sided bound. Nondegeneracy (A-Nondeg) is what licenses all of this: it supplies the parabolic regularity (appendix C.9) that makes the candidate value $C^{1,2}$ in the first place and legitimizes the Itô expansion (Itô's formula, theorem 5.9). Full statements are in [40, Ch. 2] and [37, Ch. 1]. $\square$

Remark 13.4 (Why the Nash system is intractable)**.** The Nash system eq. (13.6) is, in the sense just proved, the *complete* answer to the finite game: it contains every Markovian equilibrium, exactly, for every N. And yet it is useless as something one could actually solve once N is more than a handful. It is worth diagnosing precisely *why*, because the diagnosis is the specification of the cure: each defect is repaired in a definite way by the mean field limit, and seeing the pairing now is the cleanest way to understand what the limit is *for*.

The first defect is *dimension*. Each value $v^{N,i}$ is a function on $[0,T] \times (\mathbb{R}^d)^N$, so a naive grid resolving it to fixed accuracy has a number of nodes exponential in Nd — the curse of dimensionality in its purest form, and it is fatal already at moderate N and d. The mean field limit attacks this head-on: it replaces the N functions on the Nd-dimensional configuration space by a *single* function $u(t,x)$ on the fixed, N-independent space $[0,T] \times \mathbb{R}^d$, together with one density flow m_t that carries everything the configuration used to carry. The dimension of the unknown stops growing with the population; this is the whole computational payoff of passing to the limit.

The second defect is *coupling*, and it is more insidious than dimension because it would survive even in low dimension. Through the equilibrium feedbacks $\widehat{\alpha}^j = \alpha^*(x_j, \nabla_{x_j} v^{N,j}, \mu^N)$, the equation for $v^{N,i}$ depends on the *gradients of the other value functions* $v^{N,j}$, $j \neq i$. The N equations are therefore genuinely simultaneous: one cannot solve for $v^{N,1}$, then $v^{N,2}$, and so on, because each presupposes all the others. This is the analytic fingerprint of the self-consistency in the proof above, and it is precisely what the limit dissolves: the mean field decouples the N-fold mutual dependence into a single forward–backward *pair*, the HJB for u driven by m_t and the Fokker–Planck equation for m_t driven by u, with the $N-1$ cross-gradient couplings collapsed into one scalar field. One representative agent against a field replaces N agents against each other.

The third feature is not a defect to be cured but a structure to be respected, and naming it guards against a natural misreading. One might hope the limit also sweeps away the awkward two-point boundary structure — value data prescribed at the terminal time T, density data at the initial time 0 — but it does not, and it should not. After the limit the terminal data on u and the initial data on m do not disappear; they become exactly the forward–backward MFG system of chapter 8. The forward–backward coupling is intrinsic to the problem — it expresses that rational agents anticipate the future while the crowd is pushed by the past — and any honest limit object must keep it. So the limit cures the two things that scale badly with N (the dimension and the N-fold simultaneous coupling) and preserves the one thing that is structural (the backward-value / forward-density pairing).

One simplification of the Nash system is available even before any limit, and it is worth isolating because it is exactly the lever the master equation will pull. Because the game is exchangeable —

the coefficients are invariant under relabelling the agents (section 13.1) — the N value functions are not genuinely distinct: they are all the *same* function of their arguments, evaluated at permuted configurations. Concretely one may seek $v^{N,i}(t,\boldsymbol{x}) = v^N(t, x_i, (x_j)_{j\neq i})$ with a single symmetric function v^N that singles out the "tagged" coordinate x_i and is symmetric in the remaining $N-1$, so that the entire family $(v^{N,i})_{i=1}^N$ is recovered by moving which coordinate is tagged. This collapses N unknowns to one, and it is the structural fact the master equation exploits: the master field $U(t,x,m)$ of chapter 12 is morally the $N\to\infty$ avatar of this one symmetric function, with the $N-1$ spectator coordinates absorbed into the measure argument m. But — and this is the point one must not overstate — exchangeability alone does *not* defeat the dimension. The single symmetric function v^N still lives on $(\mathbb{R}^d)^N$; it still depends on all N positions, just in a permutation-invariant way, and resolving a symmetric function of N arguments is still exponentially hard in N. What exchangeability buys is the *hope* that this symmetric function has a limit as $N\to\infty$ — a function of one tagged point and a measure — and turning that hope into a theorem with a rate is the work the master equation does. Exchangeability is the doorway; the master equation is what walks through it.

Heuristic (non-rigorous)

The mean field substitution is the self-consistent-field closure familiar from statistical mechanics — a single particle replaced by a particle in an averaged, self-generated field — transported here to a *strategic* setting where the field is generated by optimizers rather than by passive matter. Run it on eq. (13.6) and watch which terms survive. Suppose that as $N\to\infty$ the empirical measure μ_t^N ceases to fluctuate and converges to a deterministic flow $m_t\in\mathcal{P}(\mathbb{R}^d)$. Then every appearance of $\mu_{\boldsymbol{x}}^N$ in the Nash system, $\mu_{\boldsymbol{x}}^N \rightsquigarrow m_t$, becomes a frozen, exogenous datum: the agent no longer reacts to a random crowd but to a prescribed field. The diffusion term and the Hamiltonian term, which involve only agent i's own coordinate x_i, pass to the limit unproblematically. The delicate terms are the cross terms $\sum_{j\neq i} b(x_j, m_t,\cdot)\cdot\nabla_{x_j} v^{N,i}$, the ones encoding how agent i's value responds to the *motion of the others*, and the temptation is to wave them away as small. That temptation must be resisted, and resisting it correctly is the entire subtlety of the limit.

Here is the trap. One might argue that each cross term is negligible: agent j is a single atom of weight $1/N$ in the population, so surely its individual influence on agent i is $O(1/N)$ and may be dropped. The first half is right and the conclusion is wrong. Each summand is indeed $O(1/N)$ — but there are $N-1$ of them, and $(N-1)\cdot O(1/N) = O(1)$. The sum does *not* vanish by smallness; it is an order-one quantity, the collective influence of the whole crowd, and any argument that discards it "because each agent is small" is discarding the mean field itself. This is exactly the intensive-versus-extensive distinction of section 13.1: no single agent matters, but the average over all of them matters at leading order.

So why is there no analogue of these cross terms in the limiting single-agent HJB? The reason is *structural*, not a matter of magnitude. In the limit, the object that replaces $v^{N,i}$ is the representative value $u(t,x_i)$, and — this is the whole content of passing to a representative agent — it depends on agent i's *own* state x_i and the exogenous field m_t alone, with no residual dependence on the labelled positions x_j of the spectators. Therefore $\nabla_{x_j} u = 0$

identically for every $j \neq i$: the cross terms still have order-one total coefficient, but in the limit they act on a function that is *flat* in the spectator coordinates, so each $b \cdot \nabla_{x_j} u$ is zero not because the coefficient is small but because there is nothing for it to differentiate. The crowd's influence has not been neglected; it has been *relocated*. Having stripped the value of its dependence on individual spectators, we paid for that simplification by making the value depend on the *measure* m_t instead — and that is exactly where the order-one collective effect re-emerges.

It is worth saying precisely where, because this prefigures the quantitative theory of section 13.5.3 and is the seam at which this heuristic becomes a theorem. Promote the representative value to the master field $U(t, x, m)$ of chapter 12, which restores the measure as an explicit argument. Differentiating U in its measure slot is the Lions derivative $\partial_\mu U(t, x, m)(\cdot)$, and the chain rule for how U changes as the population is transported by the drift b produces exactly a term $\int b(y, m, \cdot) \cdot \partial_\mu U(t, x, m)(y)\, m(\mathrm{d}y)$. This integral *is* the continuum limit of the order-one average $\frac{1}{N} \sum_{j \neq i} b(x_j, m_t, \cdot) \cdot [\,\cdot\,]$ that the structural flatness made vanish from the x_j-slots: what looked like $N - 1$ small cross terms acting on a flat value reappears, intact and order-one, as a single transport integral acting through the measure derivative. The master equation of chapter 12 is precisely the equation that carries this term; section 13.5.3 will turn the informal chain rule here into the rigorous expansion that bounds its residual against the Nash system by $O(1/N)$. Nothing was lost in the limit — the crowd's order-one influence was merely rewritten from a sum over labelled neighbours into an integral against the population.

What remains, then, for the typical agent is a *single* HJB equation, the representative value moving in the self-consistent field,

$$-\partial_t u - \tfrac{1}{2} \operatorname{tr}\left(\sigma\sigma^\top(x, m_t)\, \mathrm{D}^2 u\right) + H(x, \nabla u, m_t) = 0, \qquad u(T, \cdot) = g(\cdot, m_T),$$

driven by the field m_t. The closure is the strategic version of self-consistency: the field m_t that the agent best-responds to must itself be the law of that optimally responding agent, which is the Fokker–Planck equation of chapter 8 and turns the bare postulate "$\mu_t^N \to m_t$" into a genuine fixed-point condition — the field generates the optimal behaviour that in turn regenerates the field. The one non-rigorous move in all of this is the very first: the suppression of fluctuations, the assertion that μ_t^N ceases to wobble and freezes to m_t. Making that move precise — with the right notion of equilibrium, controlling the suppressed fluctuations, and extracting a rate — is not a detail but the whole remaining content of the chapter.

We have arrived at the chapter's central tension, and it is worth naming sharply before we act on it. The Nash system is a *sharp* object: it captures the finite game exactly, with nothing approximated and nothing lost. It is also a *hopeless* one: its unknowns live on a space whose dimension grows with the population, and its equations are bound together by mutual self-consistency. The heuristic has just shown us the escape we want — one representative agent, one HJB, one transported field — but it bought that escape with an act of faith, the suppression of fluctuations, that no theorem yet underwrites. The remaining question is therefore not *what* we want the limit to be, but *how* the passage to it is to be justified. And here the structure of the problem forces a fork, because the limit can be approached from either end of the finite-to-infinite passage, and the two ends are of sharply unequal difficulty. One may start from the clean limit object and test it against the finite game; or one may start from the finite game's actual equilibria and ask whether they converge. Whether the interaction one must control is handed to us in advance or emerges from the very fixed point we are solving for makes these two routes profoundly different in cost. Organizing the escape into these two opposite directions — and seeing exactly why one is cheap and the other deep — is the task of the next section.

13.3 The two limits: top-down and bottom-up

The heuristic of the previous section left exactly one debt unpaid, and the whole remaining chapter is the schedule on which it is repaid. It delivered the object we want — one representative agent, one HJB, one transported field — but it delivered it by an act of faith: the single unjustified line was the assertion that the empirical measure μ_t^N stops fluctuating and freezes onto a deterministic flow m_t. Suppress the fluctuations and everything else in the heuristic follows mechanically; but suppressing them is precisely the step a theorem must earn and a heuristic merely assumes. What divides this subject's wishes from its theorems is, almost entirely, the discipline with which that one fluctuation-suppression step is discharged. So the live question is no longer *what* the limit should be — the Nash system told us the finite truth, and the heuristic told us the shape of its coarse-graining — but *how* the suppression of fluctuations is to be made rigorous against the sharp-but-hopeless finite object we are trying to escape.

The first thing to see is that this can be done in two opposite directions, according to which end of the finite-to-infinite passage one holds fixed, and that the two are not two proofs of one fact but two genuinely different tasks of sharply unequal difficulty. It pays to separate them cleanly before proving anything, because the literature sometimes runs them together, and running them together is exactly how one mistakes the cheap half of the chapter for the whole of it. The cause of the asymmetry has a one-word name we have already met: whether the interaction whose fluctuations we must suppress is *exogenous* — fixed in advance, handed to us by the limit problem — or *endogenous* — itself the unknown we are solving for. The full contrast is drawn in section 13.5.1; here we lay out the map.

Top-down (ε-Nash): testing a known field. The first direction holds the *infinite* end fixed. Start from a *solution* of the MFG system — a pair (u, m), with u solving the backward HJB driven by the field and m the forward law of the optimally controlled representative agent (chapters 8 and 9). This pair is assumed already in hand: the entire fixed-point problem of chapters 8, 9 and 11 has been solved *once*, on the fixed space $\mathbb{R}^d$, before any finite game is even considered. Out of it the MFG manufactures a single decentralized feedback,

$$\widehat{\alpha}(t,x) \;:=\; \alpha^*(x,\, \nabla u(t,x),\, m_t), \tag{13.7}$$

a map of an agent's *own* state and time alone — no spectator coordinates, no empirical measure, nothing agent-specific to watch but oneself. Now perform the only experiment that needs no further theory: hand this one feedback to each of the N players and let them play it simultaneously. *Question:* how far short of a Nash equilibrium of the finite game does the resulting symmetric profile fall?

What makes this direction cheap is that handing every agent the *same* fixed feedback closes the N-body loop into a dynamics that is already fully understood. With $\widehat{\alpha}$ frozen, the drift of each X^i becomes $b\big(X_t^i, \mu_t^N, \widehat{\alpha}(t, X_t^i)\big)$ — a prescribed function of the agent's own state and the empirical measure, carrying no other agent's control as an unknown. That is exactly a McKean–Vlasov interacting particle system of the kind chapter 7 governs: N exchangeable diffusions coupled only through their own empirical measure, with a *given* law of motion. The fluctuation-suppression step is then not an article of faith but a theorem we already own — propagation of chaos for a fixed dynamics — and it applies verbatim, with no new idea required. The empirical measure of this system concentrates on the flow m_t at the sampling rate, and the answer to the question (section 13.4) is "within $\varepsilon_N \to 0$."

This direction is constructive, cheap, and — for an engineer rather than a theorist — the practically decisive one. It does not ask the finite game to disclose its own equilibria; it *manufactures* an explicit, decentralized, near-optimal strategy and then certifies it. Compute the mean field solution once, on the fixed space $\mathbb{R}^d$, and deploy the very same feedback on every large finite population, with a guarantee that no agent can gain more than ε_N by deviating. The entire N-dependence has been quarantined into the single scalar ε_N; the strategy itself does not depend on N at all. This is the sense in which the mean field, computed once, is a usable approximate equilibrium for an entire family of finite games at a stroke.

Bottom-up (convergence of equilibria): an emergent field. The second direction holds the *finite* end fixed, and it is the foil to the first in every respect. Start now from the *actual* Nash equilibria of the N-player game — the solutions $v^{N,i}$ of the Nash system eq. (13.6), together with their equilibrium feedbacks $\widehat{\alpha}^j$ and the law of the equilibrium state process they generate. *Question:* do these converge, as $N \to \infty$, to the MFG solution — the values $v^{N,i}$ to u, the empirical measure of the equilibrium to m_t, the finite marginals to products of m_t? The answer (section 13.5) is again "yes," but it is a yes of an entirely different order, and the reason is that here the interaction is *endogenous*.

There is no fixed dynamics to feed chapter 7. In the top-down direction the feedback was an *input*, frozen before the particles moved; here the feedback each agent uses is *itself the unknown*, the gradient $\nabla_{x_j} v^{N,j}$ of a value function that is being solved for at the same time. The law whose fluctuations we must suppress is the law *of the equilibrium* — the very object we are trying to characterize — so we are asked to show that something concentrates before we are even allowed to name what it concentrates on. The self-reference is the crux, and it is worth stating in one breath: the empirical measure μ_t^N is generated by feedbacks that, at every instant, depend on μ_t^N. One therefore cannot first fix the dynamics and then average, as the McKean–Vlasov picture demands; the averaging and the dynamics are pinned down *together*, by the fixed point, and neither is available without the other. Chaos, in this direction, is not a hypothesis imposed on a known law of motion but an *emergent property of the equilibrium* — propagation of chaos for Nash equilibria — and there is simply no kernel to hand to chapter 7.

Because the chaos must be *extracted* from the fixed point rather than *assumed* of the dynamics, two genuinely different routes are open, and it is worth fixing the map now so that the later sections read as a plan rather than a pair of surprises. The first is a *compactness* route: assume as little as possible, show that the family of N-player equilibria is tight, extract a convergent subsequence, and identify every one of its limit points as a solution of the MFG system; under the Lasry–Lions monotonicity (A-Mon) of chapter 11 that solution is unique, so a single limit point forces the whole family to converge. This buys *qualitative* convergence — the limit exists and is the MFG — but no rate, because a compactness argument never sees how fast. The second is the *master-equation* route: take the regular solution $U(t, x, m)$ of chapter 12 as an ansatz for the $v^{N,i}$, substitute it into the Nash system, and bound the residual it leaves behind. The regularity of U is exactly what converts that residual into an $O(1/N)$ error, and so delivers a *rate*. The first route is robust and cheap in hypotheses but mute about speed; the second is expensive in hypotheses — it presupposes a smooth master field, which exists only in the monotone regime — but quantitative. section 13.5.1 draws the contrast in full; section 13.5.3 carries out the master-equation expansion.

Physics note

The two directions are the strategic counterparts of two familiar but quite distinct moves in many-body physics, and naming the physics sharpens why one is so much cheaper than the other. The top-down direction is the *test-particle* calculation. One freezes the self-consistent field at its mean-field value m_t, drops a single tagged particle into it, and asks only how that one particle fares. The single thing the tagged agent gets wrong is that the field it *actually* samples is not the smooth m_t but the granular empirical field $\mu_t^{N,-i}$ assembled from its $N-1$ neighbours — and that field, being an average of $N-1$ independent contributions, departs from its mean only by central-limit fluctuations of size $N^{-1/2}$. Here is the decisive point: because the mean field strategy is optimal against the *average* field, it sits at a critical point of the cost in the field variable, so a fluctuation of order $N^{-1/2}$ about that critical point moves the attainable cost only at *second* order, and the tagged agent's exploitable gain is the small ε_N of section 13.4. A probe in a bath, in other words, barely notices the bath's graininess, and the little it notices it cannot easily exploit.

The bottom-up direction asks the strictly harder thing: not whether a probe survives the bath, but whether the bath is *itself* mean-field. The claim is that the fully interacting N-body equilibrium — every agent simultaneously best-responding, all correlations switched on, no field frozen anywhere — is nonetheless described, as $N \to \infty$, by the same single-particle field m_t. That is a genuine self-averaging statement about the interacting system, of the kind that in equilibrium statistical mechanics one earns only with real work (cluster expansions, correlation-decay estimates), not a perturbation of a known background. The whole gap between the two directions is the gap between a one-body and a true many-body computation. The master equation is what bridges it: a sufficiently regular $U(t, x, m)$ controls the equilibrium's correlations tightly enough to upgrade the probe-in-a-bath statement into the bath-is-mean-field statement, and to do so with a rate. That bridge is the business of section 13.5.3; everything before it is the cheaper, test-particle half.

With the map drawn, we take the two directions in order of difficulty, easiest first. The next section makes the top-down promise precise and turns the slogan "within $\varepsilon_N \to 0$" into a theorem with an explicit rate. The bottom-up direction — convergence of the genuine equilibria, first by compactness and then by the master equation — waits for section 13.5, once the cheap direction has shown us what a rate even looks like when the dynamics are handed to us for free.

13.4 The ε-Nash property of the mean field strategy

The previous section drew the map and bound us to walking the cheap road first; this section is that road, taken from one end to the other. The plan it handed us was completely explicit, and we execute it in exactly its order: freeze the mean field feedback, hand the one map to all N players at once, recognize the closed loop as a McKean–Vlasov system of precisely the kind chapter 7 already governs, and so turn the slogan "within $\varepsilon_N \to 0$" into a theorem with a rate. The work will divide cleanly. A single probabilistic input — propagation of chaos for a fixed dynamics, lemma 13.5 — carries all the analysis; after it, the ε-Nash theorem is little more than a triangle inequality between three control problems.

Fix, then, an MFG solution (u, m) as in section 13.3 — with u the backward value and m the forward flow it is self-consistent with — and the decentralized feedback $\widehat{\alpha}$ it manufactures, eq. (13.7). The strategy we put on trial is the *mean field profile*: the symmetric profile in which every one of the N agents, watching nothing but its own state, plays the same own-state feedback,

$$\alpha_t^i \;=\; \widehat{\alpha}(t, X_t^i), \qquad i = 1, \dots, N. \tag{13.8}$$

Nobody consults the empirical measure, nobody consults a spectator's position; each agent simply runs the map that a lone representative agent would run against the deterministic field m_t. The question of the section is the one posed in section 13.3: by how much can a single agent improve on this profile by deviating, and does that margin vanish as $N \to \infty$?

Everything cheap about this direction flows from one structural observation, and it repays making slowly, because it is precisely the feature the bottom-up direction will *lack*. Install the common feedback in every agent at once: substitute $\alpha_t^i = \widehat{\alpha}(t, X_t^i)$ into the state dynamics eq. (13.2). The drift of agent i collapses to

$$b(X_t^i, \mu_t^N, \widehat{\alpha}(t, X_t^i)) \;=\; \widetilde{b}(X_t^i, \mu_t^N), \qquad \widetilde{b}(x, m) := b(x, m, \widehat{\alpha}(t, x)),$$

and its diffusion is $\sigma(X_t^i, \mu_t^N)$ as before. Read off the arguments on the right-hand side: each is either agent i's *own* state X_t^i or the empirical measure μ_t^N of the whole cloud — and nothing else. In particular *no other agent's control survives as an unknown.* This is the decisive contrast with the Nash system eq. (13.6), whose drift carried the equilibrium feedbacks $\widehat{\alpha}^j = \alpha^*(x_j, \nabla_{x_j} v^{N,j}, \mu^N)$ and so dragged in the gradients of every other value function: there the law of motion was knotted to the very equilibrium one was still solving for. Here, because $\widehat{\alpha}$ was fixed once and for all by the already-solved limit problem, the law of motion is *prescribed* in advance. The closed-loop state system eq. (13.2) under the mean field profile eq. (13.8) is therefore exactly a *McKean–Vlasov interacting particle system* of the type studied in chapter 7: N exchangeable diffusions with common coefficients $(\widetilde{b}, \sigma)$, coupled solely through their shared empirical measure, with a given — not endogenous — law of motion.

For such a system chapter 7 tells us exactly what to expect. As $N \to \infty$ the empirical measure ceases to fluctuate and freezes onto a deterministic flow, while a single tagged particle decouples from the rest and follows the *McKean–Vlasov SDE of the representative agent*,

$$\mathrm{d}\bar{X}_t = \widetilde{b}(\bar{X}_t, m_t)\ \mathrm{d}t + \sigma(\bar{X}_t, m_t)\ \mathrm{d}W_t, \qquad \mathcal{L}(\bar{X}_t) = m_t, \tag{13.9}$$

in which the empirical measure has been replaced by the agent's own time-marginal law. Now comes the point that makes the construction self-consistent rather than circular, and it is worth stating with care. The flow m_t that appears in eq. (13.9) is *not* a new unknown to be solved for; it is the *same* m we started from. By construction of the MFG solution, $\widehat{\alpha}$ is the optimal feedback of the representative agent against m, and the second (Fokker–Planck) equation of the MFG system of chapter 8 states precisely that m_t is the law of the state process driven by that feedback — which is eq. (13.9) verbatim. So the consistency condition $\mathcal{L}(\bar{X}_t) = m_t$ holds by the very fixed-point equation that defined the MFG solution: the limiting law of the particle system *is* the mean field flow, by construction (chapters 8 and 9), with nothing left to verify. All that now separates the finite profile from this clean limit is the suppression of the empirical measure's fluctuations — and that, for a fixed law of motion, is a theorem we already own. We isolate it as the single analytic input that the rest of the section will consume.

Lemma 13.5 (Propagation of chaos for the mean field profile)**.** *Assume* (A-Lip)*,* (A-Growth)*,* (A-Nondeg)*,* (A-Conv) *and that the feedback $\widehat{\alpha}$ is bounded and Lipschitz in x uniformly in t, so that $\widetilde{b}(\cdot,\cdot)$ is Lipschitz in (x, m) in the sense of* (A-Lip)*. Let $(X^i)_{i\le N}$ solve eq.* (13.2) *under the mean field profile eq.* (13.8) *and let $(\bar{X}^i)_{i\le N}$ be i.i.d. copies of eq.* (13.9) *driven by the same Brownian motions and initial states. Then*

$$\max_{i\le N}\ \mathbb{E}\Big[\sup_{t\le T}\big|X^i_t - \bar{X}^i_t\big|^2\Big]\ \le\ C\,r_N^2, \qquad \mathbb{E}\Big[\sup_{t\le T}\mathcal{W}_2\big(\mu^N_t,\, m_t\big)^2\Big]\ \le\ C\,r_N^2, \tag{13.10}$$

where C depends on T, the Lipschitz constants and $\int |x|^2\, m_0(\mathrm{d}x)$ but not on N. Here r_N denotes the $\mathcal{W}_2$ sampling rate *of N i.i.d. draws, fixed once and for all as the root-mean-square empirical-measure error,*

$$r_N^2\ :=\ \sup_{\rho}\ \mathbb{E}\Big[\mathcal{W}_2\big(\bar{\mu}^N, \rho\big)^2\Big]\,, \tag{13.11}$$

the supremum over the laws $\rho = m_t$, $t \le T$ (each with a finite moment of order $q > 4$; under (A-Growth) *the flow m_t inherits the moments of m_0, so this is a mild requirement on the initial law). It is crucial that r_N is defined through the* second *moment $\mathbb{E}\mathcal{W}_2^2$, the quantity that the synchronous coupling actually produces, and not through $\mathbb{E}\mathcal{W}_2$ (squaring the latter would run Jensen's inequality the wrong way). This is the* Fournier–Guillin *rate, proved in-book — via a dyadic multiresolution comparison and a binomial-variance bound — in theorem D.16 (appendix D; the role of the rate in propagation of chaos is also recorded in remark 7.16; attribution [69]):*

$$r_N^2\ \lesssim\ \begin{cases} N^{-1/2}, & d < 4,\\ N^{-1/2}\log N, & d = 4,\\ N^{-2/d}, & d > 4,\end{cases} \qquad \textit{so that } r_N \lesssim N^{-1/4} \textit{ for } d \le 3. \tag{13.12}$$

The same constant and rate govern every appearance of r_N below.

Proof sketch. This is the synchronous-coupling argument of chapter 7 (Sznitman's coupling) applied to the fixed coefficients $\widetilde{b}, \sigma$; we recall its shape to make visible *which* part of the rate is structural.

Subtract eq. (13.9) from the closed loop of eq. (13.2) for the same i and apply Itô's formula (theorem 5.9) to $|X_t^i - \bar{X}_t^i|^2$; the stochastic-integral part is a martingale (the diffusion coefficients are matched, so it carries the difference $\sigma(X^i, \mu^N) - \sigma(\bar{X}^i, m_t)$), and the drift part together with the Lipschitz bound on $\widetilde{b}, \sigma$ gives

$$\frac{\mathrm{d}}{\mathrm{d}t}\mathbb{E}\Big[|X_t^i - \bar{X}_t^i|^2\Big] \le C\,\mathbb{E}\Big[|X_t^i - \bar{X}_t^i|^2\Big] + C\,\mathbb{E}\Big[\mathcal{W}_2(\mu_t^N, \bar{\mu}_t^N)^2\Big] + C\,\mathbb{E}\Big[\mathcal{W}_2(\bar{\mu}_t^N, m_t)^2\Big],$$

where $\bar{\mu}_t^N = \frac{1}{N}\sum_j \delta_{\bar{X}_t^j}$. The middle term is bounded by $\frac{1}{N}\sum_j \mathbb{E}|X_t^j - \bar{X}_t^j|^2$ (coupling the empirical measures atom by atom: with μ_t^N and $\bar{\mu}_t^N$ supported on the paired points X_t^j and $\bar{X}_t^j$, the diagonal coupling that matches atom j to atom j is one admissible transport plan, so $\mathcal{W}_2(\mu_t^N, \bar{\mu}_t^N)^2 \le \frac{1}{N}\sum_j |X_t^j - \bar{X}_t^j|^2$, and by exchangeability each summand has the same expectation as the i-th). The last term is the *sampling error* of N i.i.d. draws from m_t — here is where driving both systems by the *same* Brownian motions and initial states pays off, for it makes the $\bar{X}_t^j$ genuinely i.i.d. samples of m_t, so $\mathbb{E}\mathcal{W}_2(\bar{\mu}_t^N, m_t)^2$ is exactly r_N^2 of eq. (13.12) (theorem D.16). Grönwall's inequality (appendix C.1) closes the mean-square estimate. Passing from $\mathbb{E}|\cdot|^2$ to the *supremum-in-time* bound $\mathbb{E}\sup_{t\le T}|\cdot|^2$ asserted in eq. (13.10) is the one place a maximal inequality is needed: one applies the Burkholder–Davis–Gundy / Doob L^2 inequality (theorem C.2) to the martingale part before invoking Grönwall, exactly as in the SDE well-posedness estimate of theorem 5.10.

The shape of this estimate repays one more sentence, because it is the whole moral of the top-down direction. Two sources of error entered, and they are of genuinely different character. The middle (coupling) term is the discrepancy between the interacting particles X^j and their decoupled limits $\bar{X}^j$; it is exponentially controlled by Grönwall, and — this is the point — it would vanish *identically* if the particles were already independent, for then $X^j \equiv \bar{X}^j$ and the term is zero. It measures only the residual interaction, and the interaction is precisely what Grönwall dissolves. The last term is different in kind: r_N is the error one commits in replacing a measure m_t by the empirical measure of N *exact* i.i.d. samples of it, and it is present even for a non-interacting cloud, even when the coupling term is exactly zero. It is therefore irreducible — no improvement in the coupling can beat it — and it, not the interaction, is what sets the rate in eq. (13.10). The dimension thresholds of eq. (13.12) are the fingerprint of this irreducible term alone: N samples resolve a measure at the slow, dimension-dependent Fournier–Guillin rate because in high dimension the empty space between samples is the bottleneck, exactly the geometry discussed in the notationwatch of section 13.1. One last subtlety, easy to lose and costly to get wrong: the synchronous coupling natively produces second moments, $\mathbb{E}\mathcal{W}_2^2$, and that is exactly the quantity eq. (13.11) defines r_N^2 to be. Defining r_N instead through $\mathbb{E}\mathcal{W}_2$ and squaring would invoke Jensen in the wrong direction — $(\mathbb{E}\mathcal{W}_2)^2 \le \mathbb{E}\mathcal{W}_2^2$, so the squared first moment is the *weaker* bound and would not close the loop — which is why the lemma is careful to anchor r_N to the second moment the coupling actually delivers. Full details: [40, Ch. 1], [69]. ☐

Theorem 13.6 (ε-Nash property of the mean field strategy)**.** *Assume* (A-Lip)*,* (A-Growth)*,* (A-Nondeg)*,* (A-Conv)*, and that the MFG solution* (u, m) *has a feedback* $\widehat{\alpha}$ *that is bounded and Lipschitz in* x*, uniformly in* t*. Assume moreover that the running and terminal costs are Lipschitz in the measure argument in* $\mathcal{W}_2$*, uniformly in* (x, α) *on the relevant range* (part of (A-Lip))*. Then the mean field profile eq.* (13.8) *is an* ε_N*-Nash equilibrium of the* N*-player game in the open-loop class,* *with*

$$\varepsilon_N \;\le\; C\, r_N \;\xrightarrow[N\to\infty]{}\; 0, \tag{13.13}$$

r_N the sampling rate eq. (13.12) of lemma 13.5 and C independent of N. In particular $\varepsilon_N \le C\, N^{-1/4}$ when $d \le 3$.

A word on the deviation class, because information structure was flagged in definition 13.1 as genuinely consequential and we should be precise about which choice is at work here. The inequality eq. (13.13) quantifies over *open-loop* deviations: the tagged agent may use any square-integrable control adapted to the noise, but the $N-1$ others stay glued to $\widehat{\alpha}$. The reason the bound is so robust to this choice is exactly the mechanism isolated in lemma 13.5. A single deviator is one atom of vanishing weight $1/N$ in the empirical measure, so the field it experiences — generated by the $N-1$ others, who keep playing $\widehat{\alpha}$ — is unaffected, to leading order, by *how* that one agent plays; the deviator cannot, by deviating, materially move the environment it is responding to. The same conclusion therefore holds verbatim against *closed-loop* (feedback) deviations in the bounded-Lipschitz class, by the identical estimate applied to the closed-loop McKean–Vlasov system the deviator now induces [40, Ch. 6]. We state the open-loop version only because it is the weakest hypothesis under which the cost comparison of the proof is immediate, and because it is the one an engineer cares about: it certifies the mean field strategy against the broadest reasonable class of unilateral defections.

It is worth separating this *deviation-class* question sharply from a second, genuinely different question that the same words "open-loop" and "closed-loop" also name, lest the two be conflated. Here the class enters only through what a single deviator is permitted to watch while everyone else holds a *fixed* profile; and because the field is insensitive to a lone atom, the answer does not depend on the class. The *equilibrium-class* question is different in kind: it asks in which class the equilibrium *itself* is sought — whether the N players are all best-responding in open-loop or all in closed-loop — and there the two classes do not agree. Closed-loop Nash equilibria can sustain configuration-mediated correlations among the players that survive into the limit as genuine extra randomness, so that open- and closed-loop equilibria need not even converge to the same object. That divergence is a property of the *bottom-up* direction, where the feedback is endogenous and the field is no longer immune to how the population plays, and it is taken up under monotonicity in remark 13.10. The present theorem lives entirely on the deviation-class side, where the distinction is invisible, precisely because the profile under test is held fixed.

Proof. Fix a tagged agent i and a candidate deviation $\alpha^i = \nu$, an admissible open-loop control, while every other agent keeps $\widehat{\alpha}$. The proof is a triangle inequality between three control problems for agent i: (i) the finite game with the deviation; (ii) the same with $\widehat{\alpha}$; (iii) the limiting MFG control problem against the frozen field m.

Step 0: reduction to deviations of bounded cost. The first move is one of pure economy: we may discard, for free, every deviation that does not even threaten the inequality we are trying to prove. The ε-Nash inequality eq. (13.4) is a statement only about deviations that could *help* the deviator, so it suffices to establish the regret bound for controls ν satisfying

$$J^{N,i}(\nu, \widehat{\alpha}^{-i}) \;\le\; J^{N,i}(\widehat{\alpha}, \widehat{\alpha}^{-i});$$

any ν violating this is already worse than $\widehat{\alpha}$, so it satisfies eq. (13.4) trivially, for every $\varepsilon_N \geq 0$, and needs no argument. This restriction is not mere tidiness; it is exactly what makes the field estimate of Step 1 *uniform*, and without it the proof would have a real gap. Admissibility alone — the bare square-integrability $\mathbb{E}\int_0^T |\nu_t|^2\,\mathrm{d}t < \infty$ of definition 13.1 — supplies *no* uniform-in-ν moment bound on the state: a sequence of admissible controls can send $\mathbb{E}\sup_t |X_t^i|^2$ to infinity. Such a runaway deviator would place into μ_t^N a single atom sitting at an uncontrolled position X_t^i, of weight $1/N$ but of $\mathcal{W}_2$-displacement $\frac{1}{N}|X_t^i|$ that need not be small at all, and that one wandering atom could by itself destroy the closeness of the empirical field to m_t on which Step 1 depends. The cost-no-larger reduction closes exactly this loophole, and the following chain is what turns it into the moment bound Step 1 needs.

First, the no-deviation cost is itself bounded. Under the mean field profile the states have second moments bounded uniformly in N: the limiting representative agent eq. (13.9) inherits finite moments from m_0 through (A-Growth), and lemma 13.5 transfers them to the finite system, so $J^{N,i}(\widehat{\alpha}, \widehat{\alpha}^{-i}) \leq C$ with C independent of N. Every retained deviation therefore obeys $J^{N,i}(\nu, \widehat{\alpha}^{-i}) \leq C$ as well. Second, coercivity converts this cost bound into a control bound. By the coercivity built into (A-Growth) the running cost dominates a positive multiple of the control energy, $L(x, m, \alpha) \geq \kappa|\alpha|^2 - C(1 + |x|^2)$ for some $\kappa > 0$, so dropping the nonnegative terminal cost and rearranging eq. (13.3),

$$\kappa\,\mathbb{E}\int_0^T |\nu_t|^2\ \mathrm{d}t \ \leq\ J^{N,i}(\nu, \widehat{\alpha}^{-i}) + C\,\mathbb{E}\int_0^T \left(1 + |X_t^i|^2\right)\ \mathrm{d}t.$$

Third, the state moment is in turn controlled by the control energy, through Itô and Grönwall. Applying Itô's formula (theorem 5.9) to $|X_t^i|^2$ along the deviated dynamics eq. (13.2) and taking expectations annihilates the martingale part, leaving

$$\mathbb{E}|X_t^i|^2 \ =\ \mathbb{E}|X_0^i|^2 + \mathbb{E}\int_0^t \Big(2\,X_s^i\cdot b(X_s^i, \mu_s^N, \nu_s) + \mathrm{tr}\ \sigma\sigma^\top(X_s^i, \mu_s^N)\Big)\,\mathrm{d}s.$$

The at most linear growth of b and σ in (x, α) from (A-Growth), together with the elementary $2\,x\cdot b \leq |x|^2 + |b|^2$, bounds the integrand by $C\big(1 + |X_s^i|^2 + |\nu_s|^2\big)$, whence

$$\mathbb{E}|X_t^i|^2 \ \leq\ C\Big(1 + \mathbb{E}\int_0^T |\nu_s|^2\ \mathrm{d}s\Big) + C\int_0^t \mathbb{E}|X_s^i|^2\ \mathrm{d}s.$$

Now close the loop between the second and third displays. The third bounds the state moment by the control energy plus a self-term; Grönwall's inequality (appendix C.1) removes the self-term and gives $\sup_{t\leq T}\mathbb{E}|X_t^i|^2 \leq C\big(1 + \mathbb{E}\int_0^T |\nu_s|^2\,\mathrm{d}s\big)$. Feeding this back into the second display, the $\mathbb{E}\int(1 + |X^i|^2)$ term is now itself bounded by a constant plus the control energy, and (with T finite, after the standard absorption of a small multiple of $\mathbb{E}\int|\nu|^2$ from the right) one obtains first $\mathbb{E}\int_0^T |\nu_t|^2\,\mathrm{d}t \leq C$ and then $\mathbb{E}\sup_{t\leq T}|X_t^i|^2 \leq C$ — the supremum coming from a final application of the Burkholder–Davis–Gundy/Doob bound (theorem C.2) to the martingale part, exactly as in theorem 5.10. The constant C is uniform in N and across the retained deviations ν. This single uniform moment bound is all that Step 0 exports, and it is precisely what licenses the treatment of the deviating agent as one negligible atom in Step 1.

Step 1: the deviator's environment is close to the mean field. When agent i deviates, the other $N - 1$ agents still run the mean field profile, so by lemma 13.5 applied to those $N - 1$ agents (whose dynamics involve ν only through the contribution of the single atom X^i to μ^N, of $\mathcal{W}_2$-size $\frac{1}{N}|X^i|$, controlled by the uniform moment bound of Step 0) one has $\mathbb{E}\sup_t \mathcal{W}_2(\mu_t^N, m_t)^2 \le C\, r_N^2$, uniformly over the retained deviations ν. The uniformity is the crucial point: with the moment of X^i controlled, the bound on the field seen by i does not depend on how i plays, because i is a single atom of vanishing weight.

Step 2: cost continuity in the field. We now compare the deviator's *actual* cost in the finite game with the cost it would pay in the clean limiting problem. Let $J_i^{\mathrm{MFG}}(\nu)$ be the representative-agent cost of using the same control ν against the *frozen* field m — that is, eq. (13.3) with μ_t^N replaced everywhere by the deterministic m_t and the state driven by $b(\cdot, m_t, \nu)$. The two problems differ in one respect only: the deviator in the finite game feels the random empirical field μ_t^N, while its limiting counterpart feels the deterministic m_t; the control ν and the driving noise are the same in both. The claim is

$$\Big| J^{N,i}(\nu, \widehat{\alpha}^{-i}) - J_i^{\mathrm{MFG}}(\nu) \Big| \;\le\; C\, r_N \qquad \text{uniformly over the retained } \nu.$$

The mechanism is the $\mathcal{W}_2$-Lipschitz dependence of b, σ, L, g on their measure argument, propagated through the dynamics. Couple the two state processes by the same ν and the same Brownian motion; their difference is driven only by the discrepancy in the measure slot, so Itô on the squared difference and the $\mathcal{W}_2$-Lipschitz bounds give, after Grönwall (appendix C.1), a pathwise-in-mean control of order $\mathbb{E}\sup_t \mathcal{W}_2(\mu_t^N, m_t)^2$ on the squared state gap. Inserting this into the two costs — whose integrands again differ by a $\mathcal{W}_2$-Lipschitz amount in the measure and a Lipschitz amount in the state — and invoking the propagation-of-chaos bound eq. (13.10) of lemma 13.5 collapses the whole discrepancy to $C\big(\mathbb{E}\sup_t \mathcal{W}_2(\mu_t^N, m_t)^2\big)^{1/2} \le C\, r_N$. The square root is what turns the r_N^2 of eq. (13.10) into the r_N quoted here; it is also why the final rate of the theorem is r_N rather than its square. The same bound holds, by the identical argument, for the no-deviation choice $\nu = \widehat{\alpha}$.

Step 3: optimality in the limit. This is the one and only place where the strategic content of the theorem lives, and it is elementary. By the very construction of the MFG solution, $\widehat{\alpha}$ is the *optimal* control of the representative agent against the frozen field m (chapters 6 and 8) — that is what it means for (u, m) to solve the MFG. Hence $J_i^{\mathrm{MFG}}(\widehat{\alpha}) \le J_i^{\mathrm{MFG}}(\nu)$ for *every* admissible ν: against the limiting field, no control beats the mean field control, by definition. Everything that was hard was analytic (Steps 0–2); the game theory is this one inequality.

It remains only to chain the three estimates, and the logic is a clean triangle. Read off the deviator's regret by passing to the limiting problem, using optimality there, and passing back:

$$J^{N,i}(\widehat{\alpha}, \widehat{\alpha}^{-i}) \;\overset{\text{Step 2}}{\le}\; J_i^{\mathrm{MFG}}(\widehat{\alpha}) + C r_N \;\overset{\text{Step 3}}{\le}\; J_i^{\mathrm{MFG}}(\nu) + C r_N \;\overset{\text{Step 2}}{\le}\; J^{N,i}(\nu, \widehat{\alpha}^{-i}) + 2C r_N.$$

The first inequality replaces the finite cost of playing $\widehat{\alpha}$ by its limiting value (Step 2); the second uses that $\widehat{\alpha}$ is optimal in the limit (Step 3); the third returns the limiting cost of the deviation ν to its finite value (Step 2 again, now for ν). The two field-replacement errors each cost one $C\, r_N$ and add. The chain says exactly that playing $\widehat{\alpha}$ costs no more than the best deviation plus $2C\, r_N$ — which is eq. (13.4) with $\varepsilon_N = 2C\, r_N$, and eq. (13.13) follows. □

Remark 13.7 (What the proof did *not* use)**.** The argument never touched the Nash system eq. (13.6) and never assumed anything about the existence of finite-N equilibria. Its only probabilistic input was lemma 13.5, propagation of chaos for the *single, fixed* dynamics induced by the common feedback $\widehat{\alpha}$. In the language of section 13.3 this is why the top-down direction is the cheap one: the chaos is hypothesized of a known McKean–Vlasov system, exactly as in chapter 7, and the strategic content is confined to the elementary optimality statement of Step 3. The historical origin is the *Nash certainty equivalence* principle of Huang, Caines and Malhamé [82], where the ε-Nash property was first established for linear–quadratic populations; see also [40, Ch. 6]. That nothing here touched the Nash system is worth holding onto: it is the exact measure of how much the bottom-up direction of section 13.5 will have to supply on its own, where the field is endogenous and no fixed McKean–Vlasov dynamics can be handed to chapter 7.

The theorem leaves the rate at the generic sampling level r_N — as slow as $N^{-1/4}$ in low dimension by eq. (13.12) — because that is the price of replacing a measure by N samples for an *arbitrary* model satisfying the standing assumptions. It is natural to ask whether a model with more structure can do better, and the question is not idle: the bound $\varepsilon_N \le C\, r_N$ is sharp only insofar as the sampling error genuinely propagates into the cost, and in a sufficiently rigid model it may not. The cleanest place to see this is the LQG thread, where every object is a Gaussian and every estimate is a moment computation, and there the generic r_N collapses all the way to $1/N$. We turn to that computation now, both to advance Thread A by one layer and to watch, in a case where everything is explicit, exactly how the special structure beats the generic rate.

Worked computation: ε-Nash for Thread A on N agents

Notation watch

For the LQG thread the symbols a, b, σ revert to the Thread A *scalars* fixed in appendix A and the thread specification: a is the state-feedback coefficient, b the control gain, $\sigma = \sigma$ the noise level (so $\mathrm{d}X = (aX + b\alpha)\,\mathrm{d}t + \sigma\,\mathrm{d}W$). In particular a here is *not* the diffusion matrix; in the general sections of this chapter we never abbreviated $\sigma\sigma^\top$ by a, precisely to keep this slot free for the Thread A parameter. We import the solution symbols of chapter 14 verbatim — curvature $P(t)$, linear offset $r(t)$, constant $c(t)$ — as fixed canonically in the thread specification; no symbol is renamed across the seam.

Worked computation 13.8. Theorem 13.6 delivered, for an arbitrary model meeting the standing assumptions, the bound $\varepsilon_N \le C\, r_N$ — the mean field strategy is within the sampling rate of a Nash equilibrium. The present computation asks the sharpening question raised just above: what does the *explicit* LQG model do to that generic estimate? The answer is that it collapses the whole way to the optimal $1/N$, and the value of doing the calculation by hand is that one can watch *why* — the collapse happens in two clean stages, each of which has a name we will reuse. The first stage is that the imitation cost feels the population only through a *scalar* statistic, its mean, whose fluctuations obey the central limit theorem at the sharp rate $N^{-1/2}$ rather than the coarser measure rate r_N. The second, and decisive, stage is the envelope/first-order-optimality phenomenon: because the mean field control is a *critical point* of the agent's cost, a target fluctuation of size $N^{-1/2}$ costs only its *square*, N^{-1}, in value. Both stages are made exact — not merely asymptotic

— by the Gaussian-quadratic rigidity of the thread, which is exactly what makes Thread A the cleanest laboratory for the mechanism. This is the ε-Nash layer of Thread A; chapter 14 supplies the closed-form MFG solution (eqs. (14.7), (14.8) and (14.10)) whose single-agent Riccati/feedback pair we import here.

The finite game. Scalar states $X_t^i \in \mathbb{R}$, $i \leq N$,

$$\mathrm{d}X_t^i = \big(a\, X_t^i + b\, \alpha_t^i\big)\ \mathrm{d}t + \sigma\ \mathrm{d}W_t^i, \qquad X_0^i \sim m_0 \text{ i.i.d.}, \tag{13.14}$$

with the imitation cost coupled to the empirical mean $\bar{X}_t^N := \frac{1}{N}\sum_j X_t^j$,

$$J^{N,i}(\boldsymbol{\alpha}) = \mathbb{E}\Bigg[\int_0^T \Big(\tfrac{1}{2}(\alpha_t^i)^2 + \tfrac{q}{2}\big(X_t^i - s\,\bar{X}_t^N\big)^2\Big)\,\mathrm{d}t + \tfrac{q_T}{2}\big(X_T^i - s_T\,\bar{X}_T^N\big)^2\Bigg], \tag{13.15}$$

the parameters $a, b, \sigma, q \geq 0, q_T \geq 0, s, s_T$ being those fixed for Thread A. One structural feature is worth flagging before it is used, because the whole sharpening turns on it: in this model the population enters only the *cost* eq. (13.15), through the imitation penalty $\frac{q}{2}(X^i - s\bar{X}^N)^2$, and never the *dynamics* eq. (13.14), whose drift $aX^i + b\alpha^i$ and diffusion σ are agent-private. We exploit this twice below: once to make the closed-loop states exactly independent (the empirical measure cannot survive in a dynamics it never entered), and once to confine the coupling to a single scalar statistic, the empirical mean $\bar{X}_t^N$, that the cost reads off.

The mean field strategy. The single-agent Riccati reduction of chapter 6 gives the LQG MFG value as the quadratic $u(t,x) = \frac{1}{2}P(t)x^2 + r(t)x + c(t)$, the curvature P solving the scalar Riccati equation $\dot{P} = b^2P^2 - 2aP - q$, $P(T) = q_T$ (eq. (14.7)), and the optimal feedback the affine map

$$\widehat{\alpha}(t,x) = -\,b\big(P(t)\,x + r(t)\big) \tag{13.16}$$

(eq. (14.10)), where the offset r solves the linear equation eq. (14.8) forced by the mean-field mean $\bar{m}_t = \int \xi\, m_t(\mathrm{d}\xi)$. The *explicit* closure of the fixed point — the coupled linear system tying r to $\bar{m}_t$ — is the content of chapter 14 and is genuinely borrowed forward (the dependency graph has Ch. 13 $\to$ Ch. 14). We isolate exactly what is used here and borrow no more: the single-agent Riccati/feedback pair eq. (13.16), already available from chapter 6, together with the abstract fact that $\bar{m}_t$ is a *deterministic* function of time. The explicit forms of r and $\bar{m}_t$ are never invoked; all we use is that eq. (13.16) is the optimal representative-agent control against the frozen target $s\bar{m}_t$.

Exact independence. Now hand the single feedback eq. (13.16) to all N agents and watch what becomes of the coupled system. The feedback is a function of an agent's *own* state and time alone, $\widehat{\alpha}(t, X_t^i) = -b(P(t)X_t^i + r(t))$, so substituting it into the dynamics eq. (13.14) — which never carried the population to begin with — yields, for every agent,

$$\mathrm{d}X_t^i = \big((a - b^2P(t))X_t^i - b^2r(t)\big)\ \mathrm{d}t + \sigma\ \mathrm{d}W_t^i. \tag{13.17}$$

Read the right-hand side carefully: the drift is affine in X_t^i with a deterministic, i-independent time profile (recall that $\bar{m}_t$, hence $r(t)$, is a fixed function of time, the one fact we borrow from chapter 14), and the noise is the agent's private W^i. The empirical measure has *disappeared* from the dynamics. There is simply no channel left through which agent j's position can influence agent

i's motion: the only place the population ever appeared was the cost, and the closed-loop *dynamics* do not see the cost. Consequently the N states solve N decoupled linear SDEs with independent noises and i.i.d. initial data, and so $X_t^1, \dots, X_t^N$ are *exactly* i.i.d. Gaussian processes at every t — each Gaussian because a linear SDE driven by Gaussian noise from a Gaussian start stays Gaussian, each identically distributed because the coefficients are common, and mutually independent because nothing couples them. Their common law has mean $\mathbb{E}X_t^i = \bar{m}_t$ (the closed-loop mean solves the same linear ODE that defines $\bar{m}_t$, started from the same data) and a common variance $V(t)$ obeying the scalar Lyapunov ODE $\dot{V} = 2(a - b^2P)V + \sigma^2$, $V(0) = \mathrm{Var}(m_0)$, read off by Itô from eq. (13.17). This is propagation of chaos in its most extreme conceivable form: not asymptotic factorization with an r_N remainder, as in lemma 13.5, but *exact* independence and *exact* Gaussianity at every finite N, with no remainder at all.

It is essential to see that this exactness is a property of the *decentralized mean field profile*, not of the LQG game as such, and that it *fails* for the game's true Nash feedback — the contrast is precisely the seam the chapter is built around. The true finite-N equilibrium feedback solves the Nash system eq. (13.6); it is a function of the entire configuration $\boldsymbol{x} = (x_1, \dots, x_N)$, because an agent who is allowed to watch the board responds to where the crowd actually is. Substituting such a feedback into the dynamics would leave each agent's drift depending on *all* the states, and the empirical measure μ_t^N would survive in the closed-loop system as a genuine coupling. The N states would then be neither independent nor Gaussian; their chaos would be an *emergent* property to be proved, with an r_N-type remainder, exactly the harder task of section 13.5. What buys the exact independence here is that the MFG strategy has already thrown away the agent's right to watch the others: it conditions on X_t^i alone, so when it is plugged back into a dynamics that the population never entered, no coupling can reappear. The decentralization that made the strategy suboptimal (it ignores the exploitable $N^{-1/2}$ wiggles) is the very thing that makes the closed-loop states exactly i.i.d. This is the cleanest illustration in the book of why the top-down direction is cheap: the dynamics it must analyze is a *fixed* McKean–Vlasov system, here so rigid that the chaos is not merely asymptotic but literal.

With the states exactly i.i.d. Gaussian, the statistic the cost actually reads off is trivial to control. The imitation penalty couples agent i only to the empirical mean

$$\bar{X}_t^N = \frac{1}{N}\sum_j X_t^j, \qquad \mathbb{E}\bar{X}_t^N = \bar{m}_t, \qquad \mathrm{Var}\left(\bar{X}_t^N\right) = \frac{1}{N^2}\sum_j \mathrm{Var}(X_t^j) = \frac{V(t)}{N},$$

the variance computing exactly — not up to constants — because the N summands are independent with common variance $V(t)$, so their average has variance $V(t)/N$. Hence the field fluctuation seen by the cost, $e_t := \bar{X}_t^N - \bar{m}_t$, is a centred Gaussian with $\mathbb{E}e_t^2 = V(t)/N$ exactly. This is the heart of the first stage of the collapse, and it is worth stating its mechanism in one sentence: e_t is the fluctuation of a *scalar average* of N independent samples, which the central limit theorem pins at the sharp rate $N^{-1/2}$, whereas r_N of lemma 13.5 is the rate at which the *whole empirical measure* converges, and resolving an entire probability measure from N samples is strictly harder than resolving one of its moments. In $d = 1$ the gap is already stark — $r_N \sim N^{-1/4}$ against $N^{-1/2}$ — and it is dimensional in origin: the measure rate degrades with dimension (eq. (13.12)) because samples must fill space, while the mean of a scalar average does not care about dimension at all. The Gaussianity upgrades the CLT heuristic $O(N^{-1/2})$ to an exact identity, but the operative point is structural: the LQG cost is blind to every feature of the population except its mean, and that one scalar is controlled at the finer rate. It is this scalar fluctuation e_t, never the full empirical measure, that the quadratic cost will see in the regret calculation.

The deviator's regret. We now estimate the one thing the ε-Nash property demands: how much an agent could save by abandoning the mean field strategy for its true best response, given that everyone else holds to it. Freeze all agents $j \neq i$ at eq. (13.16); their states are then the exactly i.i.d. Gaussians of the previous step, oblivious to whatever agent i does (agent i's own deviation cannot infect them, since the population entered nobody's *dynamics*). Agent i, free to optimize, still pays the imitation cost eq. (13.15), and so it faces a tracking problem: keep X_t^i near the *random* target

$$\tau_t \;=\; s\,\bar{X}_t^N \;=\; s\,\bar{m}_t \;+\; s\,e_t^{-i} \;+\; \frac{s}{N}X_t^i, \qquad e_t^{-i} := \frac{1}{N}\sum_{j\neq i} X_t^j - \frac{N-1}{N}\bar{m}_t.$$

The decomposition isolates the three pieces of the target the agent sees. The first, $s\bar{m}_t$, is the deterministic field the mean field strategy was tuned to. The second, $s\,e_t^{-i}$, is the fluctuation of the $N-1$ competitors' mean about that field; since those $N-1$ states are i.i.d. with variance $V(t)$, one has $\mathbb{E}|e_t^{-i}|^2 = \frac{N-1}{N^2}V(t) = O(1/N)$, the now-familiar CLT scale. The third, $\frac{s}{N}X_t^i$, is agent i's own contribution to the empirical mean — the price of counting oneself in $\bar{X}^N$ — and it is smaller still, $\mathbb{E}|\frac{s}{N}X_t^i|^2 = O(1/N^2)$, using the uniform second-moment bound of Step 0 of theorem 13.6. The whole target discrepancy is therefore

$$\tau_t - s\,\bar{m}_t \;=\; s\,e_t^{-i} + \frac{s}{N}X_t^i, \qquad \mathbb{E}\left[\int_0^T \left|\tau_t - s\,\bar{m}_t\right|^2\,\mathrm{d}t\right] \;=\; O\!\left(\tfrac{1}{N}\right), \tag{13.18}$$

dominated by the $O(1/N)$ competitor fluctuation. So the deviator solves a scalar LQ tracking problem — the dynamics eq. (13.14) and cost eq. (13.15) with the random target τ_t in place of the deterministic $s\bar{m}_t$ — whose target differs from the one the mean field strategy was built for by an L^2-amount of size $N^{-1/2}$. The question is how that $N^{-1/2}$ target error translates into lost value, and this is where the quadratic structure pays off twice over.

The first payoff is an exact regret identity. Write $\alpha^{i,*}$ for the deviator's genuine optimal control and $\widehat{\alpha}_t^i = \widehat{\alpha}(t, X_t^i)$ for the mean field control it is tempted to abandon. Because the running control cost is the pure square $\frac{1}{2}\alpha^2$ and the drift is affine in the control, the integrand the agent minimizes, $\frac{1}{2}\nu^2 + b\,\nu\,\partial_x v$, is an exact parabola in the control value ν; its minimizer is $\alpha^{i,*} = -b\,\partial_x v$, and the excess of *any* other choice ν over that minimizer is the completed square $\frac{1}{2}(\nu - \alpha^{i,*})^2$, with the linear term cancelling identically. Integrating this pointwise identity along the controlled trajectory and taking expectations — the verification computation of chapter 6, in which the value-function terms telescope — gives the regret of any admissible ν as a clean quadratic,

$$J^{N,i}(\nu, \widehat{\alpha}^{-i}) - \inf_{\alpha} J^{N,i}(\alpha, \widehat{\alpha}^{-i}) \;=\; \tfrac{1}{2}\,\mathbb{E}\left[\int_0^T \left|\nu_t - \alpha_t^{i,*}\right|^2\,\mathrm{d}t\right]. \tag{13.19}$$

The crucial feature is the *absence of a first-order term.* There is no contribution linear in $\nu - \alpha^{i,*}$, because $\alpha^{i,*}$ is a critical point of the cost: at an optimum the first variation vanishes, so the leading response of the cost to a control perturbation is quadratic, not linear. This is the envelope/first-order-optimality phenomenon in its most transparent form, and it is exactly what will convert an

$N^{-1/2}$ control error into an N^{-1} value loss. Note that this argument needs nothing about *how* far $\widehat{\alpha}^{\,i}$ is from optimal; it needs only that the comparison is made against the true optimizer, so that the linear term is gone. We will meet the very same cancellation again, in a less elementary guise, when the master field's first-order optimality kills the $O(N^{-1/2})$ term in the value expansion of theorem 13.13.

The second payoff is that the control gap is itself $O(N^{-1/2})$, so that its square in eq. (13.19) is $O(1/N)$ — and this is where the LQ tracker's structure must be unpacked rather than asserted. The deviator's value function is again quadratic in its own state, $v(t,x) = \frac{1}{2}P(t)x^2 + r_t^* x + \cdots$, and the point to appreciate is that the *curvature* $P(t)$ is unchanged from the mean field problem: P solves the same Riccati equation $\dot{P} = b^2P^2 - 2aP - q$, $P(T) = q_T$, because the Riccati equation is fixed by the quadratic-in-state and control structure of eq. (13.14)–eq. (13.15), and shifting the *target* of a tracking cost moves only its linear-in-state part, never its curvature. All the deviation's information therefore lives in the linear offset r^*, and the optimal control reads

$$\alpha_t^{i,*} = -b\big(P(t)X_t^i + r_t^*\big), \qquad \text{against} \qquad \widehat{\alpha}_t^{\,i} = -b\big(P(t)X_t^i + r(t)\big),$$

so the entire control gap is carried by the offsets, $\widehat{\alpha}_t^{\,i} - \alpha_t^{i,*} = b\,(r_t^* - r(t))$. The two offsets solve the *same* linear ODE — the one driving the offset in any LQ tracker against this dynamics, with homogeneous part set by the closed-loop drift $a - b^2P(t)$ and forcing proportional to the cost weight q times the coupling s times the target — but with different forcings: r is forced by the deterministic field $s\bar{m}_t$, while r^* is forced by the deviator's *conditional* prediction of its target, $\mathbb{E}[\tau_\cdot \mid \mathcal{F}_t]$, since an optimally controlled agent steers toward the best forecast of where the crowd will be, not toward its realized position. (That r^* tracks the conditional mean, and not the raw target, is the one genuinely stochastic-control feature here: the offset is the solution of a backward equation, hence forward-looking.) Subtracting the two linear ODEs, the difference $r_t^* - r(t)$ solves the *homogeneous* linear equation forced solely by the target discrepancy $\mathbb{E}[\tau_\cdot \mid \mathcal{F}_t] - s\bar{m}_\cdot$. A scalar linear ODE on the bounded interval $[0,T]$ propagates its forcing with a bounded Green's function, so Grönwall's inequality (or, equally, the explicit variation-of-constants representation) gives the L^2 stability bound

$$\mathbb{E}\bigg[\int_0^T \big|r_t^* - r(t)\big|^2 \,\mathrm{d}t\bigg] \;\le\; C\,\mathbb{E}\bigg[\int_0^T \big|\tau_t - s\,\bar{m}_t\big|^2 \,\mathrm{d}t\bigg] \;=\; O\Big(\tfrac{1}{N}\Big),$$

where the last equality is eq. (13.18) (the conditional expectation only contracts the L^2 norm, by Jensen, so it cannot enlarge the discrepancy). The forcing-to-offset constant C is the square of the linear ODE's forcing gain, hence proportional to q^2s^2 — a factor qs for each of the two copies of the forcing in the squared norm — which is the promised non-trivial scaling, not a single power of q.

Assembling the two payoffs, substitute $\nu = \widehat{\alpha}^{\,i}$ into the regret identity eq. (13.19):

$$J^{N,i}(\widehat{\alpha}, \widehat{\alpha}^{-i}) - \inf_{\alpha} J^{N,i}(\alpha, \widehat{\alpha}^{-i}) = \tfrac{1}{2}\,\mathbb{E}\bigg[\int_0^T b^2\big|r_t^* - r(t)\big|^2 \,\mathrm{d}t\bigg] \le \tfrac{1}{2}b^2C\,\mathbb{E}\bigg[\int_0^T \big|\tau_t - s\bar{m}_t\big|^2 \mathrm{d}t\bigg] = O\Big(\tfrac{1}{N}\Big),$$

uniformly in i by exchangeability. This is the quadratic gain, and taking the supremum over agents gives the sharpened ε-Nash rate

$$\varepsilon_N^{\mathrm{LQG}} \;=\; \sup_i \Big[J^{N,i}(\widehat{\alpha}, \widehat{\alpha}^{-i}) - \inf_{\alpha} J^{N,i}(\alpha, \widehat{\alpha}^{-i})\Big] \;\le\; \frac{C}{N}, \qquad C = C' \sup_{t\le T} V(t), \tag{13.20}$$

the constant assembled exactly as the chain above tracked it: the regret carries one factor b^2 from the control gap $b(r^* - r)$, the offset-stability bound contributes $q^2 s^2$, and the horizon enters through Grönwall, so that $C' \asymp q^2 b^2 s^2$ up to a T-dependent factor, multiplying the variance scale $\sup_{t \le T} V(t)$ of the population. We do not display C' in closed form; its *shape* — quadratic in each of b, q, s, never linear — is the informative part, and it is the fingerprint of the two squarings: one from the CLT (e_t enters through its variance) and one from the envelope (the offset enters the regret through its square). *Interpretation.* Stand back from the algebra and read off what governed the

rate. The generic bound of theorem 13.6 promises only $\varepsilon_N = O(r_N) = O(N^{-1/4})$ in this $d = 1$ problem, because it routes *everything* through the full $\mathcal{W}_2$ distance of the empirical measure — it charges the agent the cost of resolving the entire population, which in one dimension converges no faster than $N^{-1/4}$. The LQG structure beat that by a full power and a quarter, $N^{-1/4} \to N^{-1}$, and it did so in two stages, each of which is a quantity squared. First, the imitation cost eq. (13.15) sees the population only through its *scalar mean* $\bar{X}_t^N$, whose fluctuation e_t is controlled at the finer central-limit rate $N^{-1/2}$; the cost never needs the whole measure, so it never pays the measure rate. Second — the decisive step — the envelope phenomenon made exact by the quadratic cost: because the mean field control is a *critical point* of the agent's cost against its target, the first-order response of the cost to a target perturbation vanishes, and an $N^{-1/2}$ fluctuation costs only its square, N^{-1}, in value. The two squarings compose: a field fluctuation of size $N^{-1/2}$, felt through a cost that responds quadratically, yields a regret of size $(N^{-1/2})^2 = N^{-1}$.

The moral is the one to carry out of the whole top-down arc. The ε-Nash rate is governed not by the *size* of the field fluctuations an agent endures but by *how its cost responds to them* — and at an optimum the response is quadratic, never linear. A strategy sitting at a critical point is first-order insensitive to the very fluctuations it ignores, so the price of ignoring them is second order. This is why a decentralized agent, blind to the $N^{-1/2}$ wiggles of the crowd, nonetheless loses only N^{-1} by its blindness. Nothing in the argument was special to Thread A except that the Gaussian-quadratic rigidity made both squarings *exact* rather than asymptotic; the mechanism itself is general, and we have isolated it here in the one model where it can be watched without remainder.

This envelope cancellation — a fluctuation costing its square because the comparison is anchored at a critical point — is not a curiosity of the LQG example but the single mechanism the chapter will lean on again at its quantitative climax. When theorem 13.13 establishes that the finite-N *values* converge to the master field at the rate $1/N$, faster than the measures whose laws they encode, the engine will be exactly this: the master field U is itself a first-order-optimal object, so the $O(N^{-1/2})$ fluctuation of the empirical measure enters the value comparison only through its square, leaving an $O(1/N)$ residual. The worked computation has given us, in the simplest possible setting, the intuition for why values converge faster than the configurations they summarize. With that intuition banked — and with remark 13.7 having recorded that this entire top-down arc never once touched the Nash system — we have exhausted the cheap direction. Everything so far started from a *known* field and tested it; nothing yet has confronted the actual equilibria of the finite game, where the field is not handed to us but is the unknown we are solving for. That is the harder, deeper half of the chapter, and it is where we turn next.

13.5 Convergence of Nash equilibria and propagation of chaos for Nash

The whole top-down arc just completed shared one feature that made it cheap, and naming it sharply is the right way to feel the change of altitude we are about to make. There the dynamics were *given*: we took the MFG's decentralized feedback $\widehat{\alpha}$, a map fixed once and for all by a problem solved on $\mathbb{R}^d$ before any finite game was in view, handed the same map to all N players, and asked only how far short of equilibrium the resulting profile fell. Because the feedback was external and frozen, the N states evolved by a *prescribed* McKean–Vlasov law, the empirical measure concentrated by the propagation of chaos of chapter 7 applied verbatim, and the envelope cancellation isolated in worked computation 13.8 did the rest — the agent's blindness to the crowd's $O(N^{-1/2})$ wiggles cost only their square. At no point did that argument so much as glance at the Nash system. We now drop exactly that crutch.

The bottom-up direction starts from the other end. We take the *actual* finite Nash equilibria — the value functions $v^{N,i}$ solving the coupled Nash system eq. (13.6), the equilibrium feedbacks $\widehat{\alpha}^j = \alpha^*(x_j, \nabla_{x_j} v^{N,j}, \mu^N)$ they generate, and the law of the state process $\boldsymbol{X}_t = (X_t^1, \dots, X_t^N)$ those feedbacks drive — and ask whether, as $N \to \infty$, this microscopic equilibrium really does relax onto the mean field object the heuristic of section 13.2 promised. Three convergences are at stake, and it is worth listing them so the reader knows what a theorem in this section must deliver: that the equilibrium *values* $v^{N,i}$ converge to the master field $u = U(\cdot, \cdot, m)$ of chapter 12; that the (random) *empirical measure* μ^N of the equilibrium states converges to the deterministic MFG flow m; and that the finite-dimensional *marginals* factorize, $\mathcal{L}(X_t^1, \dots, X_t^k) \to m_t^{\otimes k}$, the equilibrium becoming asymptotically chaotic. This last is the substantive content and it has its own name — *propagation of chaos for Nash equilibria*.

This is the deepest result of Part II, and the honesty the section owes the reader begins with admitting that it does not come in a single grade. There are two routes to it, of sharply different character, and we will be candid throughout about the divide between them. The first is *qualitative*: under little more than what makes the games well-posed and the MFG unique, a compactness argument extracts convergent subsequences and identifies their limits as MFG solutions — but it yields no rate, and it must be careful about *which* solution is selected. The second is *quantitative*: at the price of a strong hypothesis, the regularity of the master equation, one obtains genuine convergence *with a rate*, and indeed learns that the values converge faster ($1/N$) than the measures whose laws they encode (the sampling rate r_N). Sections 13.5.2 and 13.5.3 execute these two routes in turn; theorems 13.9 and 13.13 are the two milestones they reach. Quantitative control, we will see, is a monotone-regime luxury that the regularity of U buys, not a birthright of the convergence itself.

Before either route is opened, though, one objection must be dispatched, because without it a reader who has just watched chapter 7 power the entire top-down argument will reasonably ask why the same machine cannot simply be run again. It cannot, and the reason is the exogenous-versus-endogenous seam that has organized the whole chapter — here it finally becomes decisive rather than merely foreshadowed. The next subsection makes that gap fully explicit, so that when the convergence machinery does arrive we already understand why it has to be new.

13.5.1 Why this is not chapter 7 again

section 13.3 named the bottom-up problem's *endogeneity* as the one-word cause of the chapter's central asymmetry, and the opening of section 13.5 promised to discharge, before any machinery, the objection it provokes: a reader who has just watched chapter 7 carry the entire top-down argument is entitled to ask why the same machine cannot simply be run again. It is worth dwelling on the gap between the propagation of chaos of chapter 7 and what the bottom-up problem demands, because it is the single most important conceptual distinction in the chapter, and because seeing it clearly is what tells us that the convergence machinery to come must be genuinely new rather than a relabelling of what we already have. The cleanest way to feel the gap is to draw the two situations side by side.

The chapter 7 picture: chaos as the output of a prescribed evolution. In chapter 7 the dynamics are *given*. One writes a McKean–Vlasov particle system — N particles whose drift depends on the others only through the empirical measure μ_t^N, and does so through a *fixed*, externally specified interaction kernel $b(x, m)$ that is no part of the unknown –

$$\mathrm{d}X_t^i = b\big(X_t^i, \mu_t^N\big)\ \mathrm{d}t + \sigma\big(X_t^i, \mu_t^N\big)\ \mathrm{d}W_t^i,$$

— and proves that as $N \to \infty$ the empirical measure converges to the deterministic flow m_t solving the nonlinear Fokker–Planck equation $\partial_t m_t = \mathcal{A}_{m_t}^* m_t$ associated with that same kernel. The logical order here is the whole point. The evolution law is written down first, in full, with every coefficient known; the empirical measure is then *computed* along it; and chaos — the asymptotic factorization $\mathcal{L}(X_t^1, \dots, X_t^k) \to m_t^{\otimes k}$ — is a *theorem about that prescribed evolution*, established by the coupling-to-i.i.d. argument that bounds each particle against an independent copy driven by the limiting field. The law m_t is the *output* of a dynamics fixed in advance. Nothing in the proof ever has to *solve* for the interaction; it is handed in. Exactly this is what powered the top-down half of the present chapter. There the chapter 7 machine ran verbatim through lemma 13.5, with the fixed kernel being the MFG's own decentralized feedback $\widehat{\alpha}(t, x)$ — a map manufactured once, on $\mathbb{R}^d$, by a problem solved before any finite game was in view, and then frozen and handed identically to all N players. The feedback was external data; the dynamics it generated were a closed McKean–Vlasov system; the chaos was the output. At no point did that argument so much as consult the Nash system.

The bottom-up picture: a self-referential interaction. In the bottom-up problem the dynamics are *not given* — and this single difference is what severs the connection to chapter 7. The states still move by

$$\mathrm{d}X_t^i = b\big(X_t^i, \mu_t^N, \widehat{\alpha}^{\,i}(t, \boldsymbol{X}_t)\big)\ \mathrm{d}t + \sigma\big(X_t^i, \mu_t^N\big)\ \mathrm{d}W_t^i,$$

but the feedback driving them is no longer external. The equilibrium feedback of agent j,

$$\widehat{\alpha}^{\,j}(t, \boldsymbol{X}_t) = \alpha^*\big(X_t^j, \nabla_{x_j} v^{N,j}(t, \boldsymbol{X}_t), \mu_t^N\big),$$

depends through $\nabla_{x_j} v^{N,j}$ on the *entire configuration* $\boldsymbol{X}_t$, not on X_t^j alone: an agent permitted to watch the board responds to where *every* other agent is. And $v^{N,j}$ is not a coefficient one may look up — it is precisely *the unknown of the Nash system* eq. (13.6), the very object whose limit we are trying to certify. The empirical measure of the equilibrium is therefore a *self-referential* object: it is the empirical measure of states whose drifts are equilibrium feedbacks, and those feedbacks are functions — through the coupled value-gradients — of that same empirical measure. The interaction does not sit above the dynamics as a given; it *is* the equilibrium we are solving for. There is consequently no fixed McKean–Vlasov system to feed into chapter 7: the kernel that the chapter 7 proof requires as input is here itself an output, and one cannot prove convergence of a fixed-point by an argument that presumes the fixed point already resolved.

Why the correlations are genuinely on. The practical face of this endogeneity is that, at finite N, the equilibrium states $X_t^1, \dots, X_t^N$ are genuinely *correlated*. This is the point at which the contrast with the worked computation bites hardest, and the two cases are worth setting literally one line apart. Under the *decentralized* mean field profile of worked computation 13.8, the LQG closed-loop drift collapsed to $b = (a - b^2 P(t))X_t^i - b^2 r(t)$ (eq. (13.17)): the empirical measure dropped out of the dynamics entirely, the N states solved N *decoupled* linear SDEs with private noises, and they were therefore *exactly* i.i.d. Gaussian at every t and every finite N — propagation of chaos with no remainder at all. Replace that decentralized feedback by the game's *true* Nash feedback — the solution of eq. (13.6), a function of the whole configuration $\boldsymbol{x}$ — and the very term that vanished reappears: each agent's drift now depends on all the states, the empirical measure μ_t^N survives in the closed-loop system as a live coupling, and the N states are neither independent nor Gaussian. The exact independence of the worked computation was never a feature of the LQG game; it was a feature of the decentralized profile, which had already *thrown away* the agent's right to watch the others, so that when it was plugged back into a dynamics the population never entered, no coupling could reappear. The true Nash feedback keeps that right, and with it keeps the correlations. Exact independence is the special case; correlation is the generic truth of an endogenous equilibrium.

Establishing that these correlations nonetheless *vanish* as $N \to \infty$ — that the endogenous equilibrium self-averages, so that the self-referential empirical measure does after all concentrate on the deterministic MFG flow m_t and the marginals factorize — is the content of *propagation of chaos for Nash equilibria.* Here is the thesis to carry out of this subsection: *chaos is now an emergent property of a fixed point, not a hypothesis on a dynamics.* In chapter 7 chaos was deduced from a known evolution; here it must be *produced* from the equilibrium condition itself, with no prior dynamics to lean on.

Two routes accomplish this, and they pay for the missing dynamics in two different currencies. The first is *qualitative*: lacking a fixed evolution to track, one gives up on tracking and instead extracts convergence by *compactness* — showing the family of equilibria is precompact and that every limit point solves the MFG system, which under uniqueness pins the whole family. It asks almost nothing beyond well-posedness and buys no rate. The second is *quantitative*: one supplies the dynamics that the finite game refused to hand over, in the form of the *master equation* of chapter 12, using the master field U as an ansatz whose residual against the Nash system is $O(1/N)$ — turning the emergent chaos into a controlled expansion at the price of the regularity of U. We take these in turn, beginning with the qualitative route, which trades any rate for the most economical hypotheses.

13.5.2 Qualitative convergence by compactness (Lacker's route)

The previous subsection left us with a sharply posed task and an explicit warning that the obvious tool is unavailable: the equilibrium empirical measure is self-referential, so the chaos we want must be *produced* from the fixed-point condition itself rather than deduced from a dynamics fixed in advance. There is no McKean–Vlasov system to hand to chapter 7, because the very kernel that argument would consume as input is here an output of the equilibrium. We now discharge that task in the cheapest currency the problem admits — pure compactness — and we pay honestly for paying so little. The idea is to stop trying to *track* the equilibrium evolution (there is none to track) and instead to argue indirectly: show that the family of equilibria, viewed as random objects on a suitable space, cannot escape to infinity (tightness), so that some subsequence converges; show that whatever it converges to must satisfy the defining relations of a mean field equilibrium (identification); and then, when the limit problem has a unique solution, conclude that the whole family converges to it. This is a classic move — it is how one proves existence and convergence for many self-consistent systems where no contraction or explicit solution is available — and its great virtue is that it asks almost nothing of the data.

Concretely, this first route assumes essentially only what already makes the finite games well-posed and the limiting MFG unique. In exchange it surrenders two things, and naming both now is what keeps the bookkeeping with the next subsection honest. First, it produces *no rate*: a compactness argument exhibits a convergent subsequence but never a modulus, so we learn *that* the equilibria converge without learning *how fast*. Second — and this is the more interesting cost — it forces us to be careful about *which* MFG solution the equilibria converge to. The compactness machine certifies that every limit point solves the mean field equilibrium relations, but in the closed-loop information class the set of objects satisfying those relations can be strictly larger than the Markovian MFG solution of chapter 8, and the argument cannot by itself rule out the extra ones. Both deficits are exactly what the second route will buy back, at the price of strong regularity; here we accept them as the fair price of minimal hypotheses.

Theorem 13.9 (Limit points of N-player equilibria are MFG solutions)**.** *Assume* (A-Lip)*,* (A-Growth)*,* (A-Nondeg)*,* (A-Conv)*, with the coefficients continuous and the costs bounded below and coercive enough for relaxed controls to be compact. For each N let $\boldsymbol{\alpha}^{*,N}$ be an ε_N-Nash equilibrium of the N-player game with $\varepsilon_N \to 0$, and let $P^N = \mathcal{L}(\mu^N)$ be the law of the (random) empirical measure flow of the equilibrium states on path space. Then:*

1. *the family $(P^N)_N$ is tight, and every weak limit point is supported on the set of* weak MFG solutions *(mean field equilibria in the relaxed/martingale-problem sense, defined in definition G.5);*

2. *if in addition the Lasry–Lions monotonicity condition* (A-Mon) *of chapter 11 holds, so that the MFG solution (u, m) is unique, then $\mu^N \to m$ in distribution (the limit is deterministic), and the finite marginals propagate chaos: $\mathcal{L}(X_t^{1,N}, \dots, X_t^{k,N}) \to m_t^{\otimes k}$ weakly for each fixed k.*

Proof sketch; full argument in appendix G. The mechanism is a compactness–and–identification argument in the spirit of the martingale-problem method, due in this generality to Lacker [89, 90] (see also Fischer [67] for the open-loop case and [40, Ch. 6] for an exposition). The full argument, with every estimate carried out, lives in appendix G; importing it wholesale here would drown the idea, so our task in the main text is to narrate the four moving parts — *what* each does, *why* it is needed, and *where* it is discharged — without reproducing the appendix's proofs. The deferral is deliberate and we keep it honest: each step below names the appendix result that supplies what we only motivate.

Part one: lift, and relax the controls. The states $X^{i,N}$ are not the natural objects to take limits of, because an equilibrium is a statement about *states and the controls that drive them* jointly, and controls are the fragile part. One therefore lifts each equilibrium to a single probability measure on the space of state–control *paths*, $C([0,T];\mathbb{R}^d) \times$ (control trajectories), recording where an agent went and what it did along the way. The delicate point is the control coordinate: ordinary A-valued controls form a space with no compactness to offer — a sequence of controls can oscillate ever faster without converging to any control — so a naive limit of the lifted measures may simply fail to exist. The repair is to enlarge the control space to the *relaxed* (measure-valued) controls of definition G.1: instead of a point $\alpha_t \in A$ at each instant one allows a probability measure $q_t(\mathrm{d}\alpha)$ over actions, which is exactly the closure that makes fast oscillations converge to a genuine limiting object (a chattering control becomes, in the limit, an honest mixture). On this enlarged space the relevant set of trajectories is *compact* (lemma G.2), which is the whole reason for the detour — compactness is the engine of the argument, and the relaxation is the price of admission. Within this lift, the two defining properties of an equilibrium become two relations on the lifted measure: each agent's optimality is encoded as a *martingale (Hamiltonian) condition* expressing that no deviation improves its cost (definition G.5), and the anonymous interaction is encoded as a *consistency constraint* tying the law the agent responds to back to the empirical measure of the population. A *weak MFG solution* is by definition any limit object satisfying both.

Part two: tightness on path space. With the lift in place we must produce a convergent subsequence, and this is the first genuinely substantive estimate. The objects in play, $P^N = \mathcal{L}(\mu^N)$, are laws *on path space*: each is the distribution of the random measure-valued trajectory $t \mapsto \mu_t^N$. Tightness here is therefore strictly more than the Prokhorov-on-$\mathbb{R}^d$ statement one might reflexively reach for — controlling the spread of the time-t marginals is not enough, because a family of measures on $C([0,T];\mathbb{R}^d)$ can have perfectly tight marginals at every fixed t and still escape to infinity through wilder and wilder *oscillation in time*. The path-space criterion (Arzelà–Ascoli in probabilistic form) demands two ingredients: uniform control of the marginals *and* uniform control of the temporal modulus of continuity. The first comes for free from (A-Growth) and the cost coercivity, which bound the second moments of the states and of the (relaxed) controls uniformly in N. The second is where (A-Nondeg) earns its place: feeding the uniform nondegeneracy and the bounded control moments into a Kolmogorov–Chentsov modulus estimate (theorem C.9, in the tightness form proposition G.3) yields a uniform bound on the increments $\mathbb{E}|X_t^{i,N} - X_s^{i,N}|^p \le C|t-s|^{1+\alpha}$ that forbids the trajectories from wiggling too fast on average. Together these give tightness on $C([0,T];\mathbb{R}^d)$, and Prokhorov's theorem (theorem 3.16) extracts a weakly convergent subsequence $P^{N_k} \to P^\infty$. Note what nondegeneracy is doing: the same diffusion that supplied parabolic regularity to the Nash system in section 13.2 supplies, on the probabilistic side, the regularity of paths that makes them precompact. Without it (in the degenerate case) this step needs a substitute and the clean statement can fail.

Part three: pass to the limit in optimality. A convergent subsequence is not yet an MFG solution; we must show the limit P^∞ inherits both defining relations. The optimality relation is where the hypothesis $\varepsilon_N \to 0$ is spent. Each finite-N profile is only an ε_N-Nash equilibrium, so along the sequence each agent is optimal only up to a slack ε_N; the martingale optimality condition holds with an error that vanishes as $\varepsilon_N \to 0$. Taking the limit therefore turns *asymptotic* optimality into *exact* optimality of the limiting object (lemma G.6): in the limit no deviation improves on the limiting control, which is precisely the Hamiltonian martingale condition of definition G.5 with no slack. This is also where the relaxation pays off a second time — because the limiting control may be a genuine mixture, the optimality statement is naturally phrased for relaxed controls, and the martingale formulation is exactly what survives the weak limit (test functions and the generator pass through, the relaxed control integrates against the generator continuously).

Part four: pass to the limit in consistency, and identify. The second relation, consistency, is the fixed-point constraint that the law the representative agent feels equals the law its own optimal motion generates. Passing it to the limit along the convergent subsequence identifies P^∞ as supported on weak MFG solutions (theorem G.8): the limiting empirical-measure flow is the law of the limiting optimally controlled state, which is the definition of a mean field equilibrium. This establishes part (1) of the theorem — tightness plus identification — with no appeal whatsoever to the Nash system's regularity, indeed with no need for the Nash equilibria to be unique or even Markovian; relaxed controls absorb any non-uniqueness of best responses. That robustness is the qualitative route's signature strength.

The monotone upgrade. Part (2) is what turns "every limit point is *a* weak MFG solution" into genuine convergence and chaos. Under the Lasry–Lions monotonicity (A-Mon) of chapter 11 the weak MFG solution is *unique* and, being unique, *deterministic*: the random limit measure P^∞ can charge only one point of $\mathcal{P}(C([0,T];\mathbb{R}^d))$, namely the Dirac mass at the unique flow m (theorem G.7). Two consequences follow. First, since every subsequential limit is forced to be this same point, the usual subsequence argument promotes subsequential convergence to convergence of the *full* sequence: $\mu^N \to m$ in distribution. Second — and this is the step worth dwelling on — convergence in distribution *to a constant* is a much stronger statement than convergence to a random limit. A sequence of random measures converging in law to a deterministic m must concentrate: its fluctuations vanish, so the random empirical measure becomes asymptotically non-random. This is exactly what propagation of chaos asserts, and the standard equivalence (convergence of the empirical measure to a deterministic $m \iff$ factorization of the k-marginals) upgrades $\mu^N \to m$ into $\mathcal{L}(X_t^{1,N}, \dots, X_t^{k,N}) \to m_t^{\otimes k}$ for every fixed k. The endogenous correlations that section 13.5.1 insisted were genuinely present at finite N have, in the monotone regime, been shown to wash out in the limit — not by tracking them, but by squeezing them between compactness and uniqueness. What the argument never delivers is the *rate* at which they wash out: compactness exhibits a limit but no modulus, and uniqueness pins the limit but says nothing about the speed of approach. That missing modulus is precisely the debt the next route is contracted to pay. □

Remark 13.10 (Open-loop versus closed-loop: a genuine subtlety)**.** The informational class of definition 13.1 — which we flagged on first sight as "not boilerplate" — is precisely where it stops being innocuous, and the qualitative theorem above is the right place to confront it, because the breadth of the limit set it certifies depends on which class one started in. For *open-loop* equilibria the picture is the clean one: each agent commits to a control adapted to the raw noise, the lifted measures carry no configuration-mediated coupling, and every limit point is a genuine MFG solution — under monotonicity, the unique one [67, 89]. For *closed-loop* (Markovian) equilibria, where each agent reads the whole board $\boldsymbol{X}_t$ and responds to it, Lacker [90] discovered that the set of attainable limits is strictly *larger*. The mechanism is exactly the endogenous correlation of section 13.5.1: because every agent's feedback depends on the common configuration, the agents are coupled through a shared signal, and that coupling can transmit a common randomness that does *not* average away. The limit may then be a *weak* mean field equilibrium in which the field m_t is itself random — driven by a common noise the feedbacks manufactured among themselves — rather than the deterministic, Markovian MFG solution of chapter 8. The compactness argument is blind to the distinction: such weak equilibria satisfy every relation the identification step checks, so they sit inside the certified limit set with full right.

The inclusion fails in the other direction too, and this is the terser half worth a sentence of intuition. Not every MFG solution arises as a closed-loop limit, because a limiting field is only realizable if some sequence of genuine finite-N equilibria approaches it, and finite-N individual rationality is a real constraint: an MFG fixed point that is, say, dynamically unstable under the finite best-response correspondence may have no N-player equilibrium in any neighbourhood of it, so it survives as a solution of the limit equations while being unreachable from below. The limit set and the MFG-solution set therefore *overlap without nesting* in general — the closed-loop limit set can contain extra weak equilibria and can miss some Markovian ones. Under monotonicity (A-Mon) both pathologies vanish at once: uniqueness collapses the weak equilibria onto the single deterministic flow (the common noise has nothing to be random about when the fixed point is unique), and the unique solution is then trivially the only candidate, so every route — open-loop, closed-loop, deterministic — agrees. This is one more entry in the running ledger of why the monotone regime is the comfortable one. The point to carry forward is that this entire phenomenon is what the master-equation route of section 13.5.3 *excludes by fiat*: by presupposing a single sufficiently regular master field U it builds the Markovian solution into its ansatz from the start, so the weak, common-noise equilibria are never on the table to begin with. The clean Markovian limit is a hypothesis there, not a conclusion — which is exactly the regularity one is paying for.

This is the natural seam at which to change routes. The qualitative argument has delivered exactly what minimal hypotheses can buy and no more: under near-well-posedness it certifies that the N-player equilibria are precompact and that their limits solve the mean field equilibrium relations, and under monotonicity it pins the limit and upgrades convergence to propagation of chaos. But it has left two debts unpaid, and they are the same two we flagged at the outset. It gives *no rate* — compactness sees a limit but never a modulus, so we cannot say convergence happens at the sampling rate r_N, or at $1/N$, or at all quickly. And in the closed-loop class it does not by itself *select* the Markovian solution — the remark just showed the certified limit set can be strictly larger than the deterministic MFG. To buy back both — a quantitative rate and the selection of the Markovian solution — we must stop asking so little of the data. We must supply, from outside, the very dynamics the finite game refused to hand over: a sufficiently regular solution of the master equation of chapter 12, used as an ansatz whose residual against the Nash system we can control term by term. That is the strong hypothesis the next route pays, and what it buys in return is the subject of section 13.5.3.

13.5.3 Quantitative convergence via the master equation (the CDLL route)

The qualitative route handed us its conclusion together with its two deficits — *no rate*, and, in the closed-loop class, no *selection* of the Markovian solution (remark 13.10 showed the certified limit set can be strictly larger than the deterministic MFG) — and the second route is built to answer exactly those two. Both deficits trace to the same poverty of hypothesis: asking only for near-well-posedness, the qualitative route never supplied the finite game with the dynamics it refused to hand over. The remedy is to stop asking so little. We now *pay* a strong hypothesis — the existence of a sufficiently regular solution of the master equation of chapter 12 — and we will see it buy back precisely the two missing things: a quantitative rate, and the selection of the Markovian solution (the regular master field is a deterministic, Markovian object, so building the proof on it excludes the weak common-noise equilibria by fiat, as remark 13.10 already anticipated). This is the resolution of the *convergence problem* by Cardaliaguet, Delarue, Lasry and Lions [37]; see also [41, Ch. 6]. It delivers a rate for the values *and* a rate for propagation of chaos, and it is the one genuinely new mechanism of the chapter: every earlier result either reused chapter 7 verbatim (the top-down arc) or extracted a limit without a modulus (the qualitative route), whereas here we manufacture the rate from the regularity of U.

The strategy in one sentence, before any formalism: use the master field U as a candidate solution of the Nash system, measure how badly it fails to solve that system exactly, show the failure is $O(1/N)$, and then use a stability estimate to convert that $O(1/N)$ residual into an $O(1/N)$ error on the genuine Nash values. Everything below is the careful execution of these four moves, and every hypothesis we now load onto U is there to make one of them go through.

Recall from chapter 12 the master field $U : [0,T] \times \mathbb{R}^d \times \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}$, solving the master equation eq. (12.7), whose value $U(t,x,m)$ is the optimal cost-to-go of a representative agent at state x when the population is in configuration m. We import its regularity by the specific theorem that carries it, theorem 12.8: under (A-Mon) and the smoothness of the data there, U is $\mathcal{C}^{1,2}$ in (t,x) and *fully* $\mathcal{C}^2$ in the measure variable in the sense of definition 12.1, with $\nabla_x U$ and $\partial_\mu U(t,x,m)(\cdot)$ bounded and Lipschitz uniformly in (t,x,m), and with the mixed derivative $\partial_x \partial_\mu U$ and the *second Lions derivative* $\partial^2_\mu U$ bounded. This regularity is the entire input below, and it is worth spending a moment on *why each piece is needed*, because the proof is little more than the orderly cashing-in of these derivatives, and a reader who knows in advance what each one pays for will see the bookkeeping as inevitable rather than arbitrary.

The smoothness in (t,x) is the cheapest demand: $\partial_t U$ and the spatial $\mathrm{D}^2_x U$ are simply the terms one needs to even write the Nash operator applied to the candidate, the analogue of asking that a function be twice differentiable before substituting it into a heat equation. The first measure derivative $\partial_\mu U$ is the load-bearing one. When we differentiate the candidate $U(t,x_i,\cdot)$ in a *spectator* coordinate x_j, the chain rule sends that derivative through the measure slot, and $\partial_\mu U$ is the object it produces; its *boundedness* is what keeps each of the $N-1$ cross-gradients $O(1/N)$, and its

Lipschitzness in the measure is what lets us, in the final trajectory step, replace one empirical measure by another (or by m_t) at controlled cost. The mixed derivative $\partial_x\partial_\mu U$ appears the instant we take a *second* spectator derivative: differentiating $\partial_\mu U(\cdot)(x_j)$ again in x_j hits its explicit spatial argument, and this term assembles — after summing the $N-1$ diagonal Hessian blocks — the master equation's extra second-order transport contribution $\int \operatorname{tr}(\sigma\sigma^\top\, \partial_x\partial_\mu U)\,\mathrm{d}m$; it must be bounded for that $O(1)$ contribution to be finite and to match term-by-term. Finally the second Lions derivative $\partial^2_\mu U$ is the subtle one, and the whole rate hinges on its boundedness. The same second spectator derivative also hits the measure slot of $\partial_\mu U(\cdot)(x_j)$, producing a $\partial^2_\mu U$ term weighted not by $1/(N-1)$ but by $1/(N-1)^2$. It is precisely *because* $\partial^2_\mu U$ is bounded that this doubly-suppressed term is genuinely $O(1/N)$ rather than a hidden $O(1)$ contaminant — and so it is $\partial^2_\mu U$, the very object chapter 12 worked hardest to construct, that certifies the residual is small. Strip away any one of these bounds and a term in the residual fails to be controlled; this is the sense in which the regularity of U *is* the rate.

Notation watch: Two points of contact with chapter 12

Two seams with chapter 12 deserve an explicit word, because the residual computation below leans on both. *(i) The second Lions derivative.* This is the seam most easily misread, so we draw it carefully. The phrase "fully $\mathcal{C}^2$ in m" of definition 12.1 is doing double duty. Part of it is the spatial regularity $\partial_x\partial_\mu U$ — one measure derivative, then a *spatial* derivative of the function it returns — and that part is not what we mean here. The other part is the genuine *second measure* derivative $\partial^2_\mu U(t,x,m)(y,y')$, obtained by differentiating $\partial_\mu U$ once more *in its measure slot*: it measures how the sensitivity of U to mass at y itself changes as one adds mass at y'. This is a strictly stronger and harder object; chapter 12 does not get it for free from the first derivative but constructs it by iterating the linearized MFG system one further time (Step 3 of the proof of theorem 12.8), the same step that the common noise theory needs. We lean on its *boundedness* in Steps 2–3 below, and the reason is exactly the weighting count flagged above: a second derivative in a single spectator coordinate x_j produces a $\partial^2_\mu U(\cdots)(x_j,x_j)$ term carrying the prefactor $1/(N-1)^2$, and only because $\partial^2_\mu U$ is bounded does that doubly-suppressed term sum — over the $N-1$ diagonal blocks — to something $O((N-1)\cdot(N-1)^{-2}) = O(1/N)$ rather than $O(1)$. Were $\partial^2_\mu U$ merely to *exist* without a uniform bound, this would be the one place the rate could silently break. We therefore import theorem 12.8 *including* that second-order bound, as recorded in its standing hypotheses, and not merely the first-order regularity that the phrase "$\mathcal{C}^2$ in m" might at a glance suggest. *(ii) General coefficients.* chapter 12 displays the master equation eq. (12.7) in its canonical form — control-as-drift, constant nondegenerate diffusion σ, additively separated coupling $F(x,m)$, Hamiltonian $H(x,p)$. The N-player data of eq. (13.2)–eq. (13.3) are more general: drift $b(x,m,\alpha)$, measure-dependent diffusion $\sigma(x,m)$, and a non-separated Hamiltonian $H(x,p,m)$. The master equation extends to this setting *verbatim* in structure: the Itô–Dynkin chain rule on $\mathcal{P}_2(\mathbb{R}^d)$ (lemma 12.2) is indifferent to where the measure dependence sits, so the only changes are that the transport term carries $\partial_p H(y,\nabla_x U,m)$, the extra-diffusion term carries $\sigma\sigma^\top(y,m)$, and the local Hamiltonian carries the third slot $H(x,\nabla_x U,m)$. No new term is created; on the separable subclass the equation collapses back to eq. (12.7) with F on the right. We use the general-coefficient version throughout and flag here that it is the harmless extension of the equation chapter 12 actually wrote.

Before the theorem we isolate the one differential-geometric identity its proof turns on: how an *ordinary* derivative in a particle's position acts on a functional of the empirical measure. The whole proof of theorem 13.13 is, at bottom, a translation problem. The master equation speaks the language of measure derivatives $\partial_\mu U$, $\partial_\mu^2 U$ — infinitesimal calculus on $\mathcal{P}_2(\mathbb{R}^d)$. The Nash system speaks the language of ordinary partial derivatives ∇_{x_j}, $\mathrm{D}^2_{x_j}$ — calculus on the finite configuration space $(\mathbb{R}^d)^N$. To check that U almost solves the Nash system we must dictionary one into the other, and the dictionary is the following lemma. It is this identity — not the generic chain rule — that converts the master equation into a statement about the Nash system, and the factors of $1/M$ it produces are the very factors that turn "$N-1$ small terms" into "one $O(1)$ integral plus an $O(1/N)$ remainder."

The mechanism behind it is worth seeing before the symbols arrive, because it is entirely concrete. The empirical measure $\nu^M = \frac{1}{M}\sum_k \delta_{y_k}$ assigns each particle a weight $1/M$. Nudge a single particle, $y_j \mapsto y_j + h$, and the measure changes by $\nu^M \mapsto \nu^M + \frac{1}{M}(\delta_{y_j+h} - \delta_{y_j})$: one atom of mass $1/M$ slides from y_j to $y_j + h$. So an ordinary derivative in y_j is a measure perturbation *of size* $1/M$, and that explains, before any computation, why every spatial derivative of F^M carries a factor $1/M$. The first derivative is clean: one factor $1/M$ times the measure derivative of F evaluated at y_j. The second derivative is where the structure that drives the rate first appears, because the single coordinate y_j now sits in *two* places at once — it is the point at which $\partial_\mu F$ is read off, *and* it is one of the atoms making up the measure ν^M at which $\partial_\mu F$ is evaluated. Differentiating again must hit both, and the two hits carry different powers of $1/M$: hitting the explicit evaluation point gives another $1/M$, while hitting the measure slot — a *second* one-atom perturbation — gives a further $1/M$ on top of the one already there, hence $1/M^2$. The Hessian therefore splits, structurally and unavoidably, into a $1/M$ piece and a $1/M^2$ piece. Keep that split in view; it is the entire reason values will converge at $1/N$.

Lemma 13.11 (Finite-dimensional restriction of a measure functional)**.** *Let $F : \mathcal{P}_2(\mathbb{R}^d) \to \mathbb{R}$ be fully $\mathcal{C}^2$ in the sense of definition 12.1. For M points $y_1, \dots, y_M \in \mathbb{R}^d$ set $\nu^M = \frac{1}{M}\sum_{k=1}^M \delta_{y_k}$ and $F^M(y_1, \dots, y_M) := F(\nu^M)$. Then F^M is twice continuously differentiable and, for each j,*

$$\nabla_{y_j} F^M = \frac{1}{M}\,\partial_\mu F(\nu^M)(y_j), \qquad \mathrm{D}^2_{y_j} F^M = \frac{1}{M}\,\partial_y \partial_\mu F(\nu^M)(y_j) + \frac{1}{M^2}\,\partial_\mu^2 F(\nu^M)(y_j, y_j). \tag{13.21}$$

Proof. Move a single atom: replacing y_j by $y_j + h$ changes ν^M by the signed measure $\frac{1}{M}(\delta_{y_j+h} - \delta_{y_j})$. By the definition of the flat derivative (definition 12.1; appendix A.3), to first order in h,

$$F^M(\dots, y_j + h, \dots) - F^M(\dots, y_j, \dots) = \frac{1}{M}\Big(\frac{\delta F}{\delta m}(\nu^M, y_j + h) - \frac{\delta F}{\delta m}(\nu^M, y_j)\Big) + o(|h|),$$

so $\nabla_{y_j} F^M = \frac{1}{M}\nabla_y \frac{\delta F}{\delta m}(\nu^M, y)\big|_{y=y_j} = \frac{1}{M}\partial_\mu F(\nu^M)(y_j)$, using $\partial_\mu F = \nabla_y\, \delta F/\delta m$ (definition 4.14). Differentiating this in y_j once more, the position y_j now enters in *two* places — the explicit argument of $\partial_\mu F(\nu^M)(\cdot)$ and, through ν^M, the measure slot. The first dependence yields $\frac{1}{M}\partial_y \partial_\mu F(\nu^M)(y_j)$; the second, by the same one-atom perturbation applied to the measure slot of $\partial_\mu F(\nu^M)(y_j)$ and the relation $\partial_\mu^2 F = \partial_\mu[\partial_\mu F]$, yields $\frac{1}{M^2}\partial_\mu^2 F(\nu^M)(y_j, y_j)$. This is eq. (13.21); full continuity of the derivatives is the "fully $\mathcal{C}^2$" hypothesis. ∎

The second ingredient is the analytic heart of the bottom-up rate, and it is the *one* place where monotonicity (A-Mon) does genuine work. Everything else in this subsection is differential calculus and bookkeeping; the smallness of the residual is geometry, not dynamics. But a small residual is worthless on its own — a nearly-solving candidate is only close to the true solution if the system does not *amplify* small discrepancies, and amplification is exactly what a forward–backward system, with its anticipatory coupling, threatens to do. The linearized Nash system is a coupled backward–forward pair; left to itself such a pair can have the residual feed the perturbation and the perturbation feed back into the residual, so that an $O(1/N)$ source drives an $O(1)$ response and the rate collapses. What forbids that feedback loop is monotonicity. The stability lemma says that the Nash system, linearized about its solution, is *dissipative*: a small source produces a proportionally small response, with a constant that does not deteriorate as N grows — the N-independence being indispensable, since an N-dependent constant $C_N \sim N$ would eat the whole $1/N$ and leave no rate at all. We state and prove it before using it, so that Step 4 of the convergence proof is an import rather than an assertion.

Lemma 13.12 (Stability of the linearized Nash system)**.** *Assume* (A-Lip)*,* (A-Nondeg)*,* (A-Conv)*,* (A-Mon)*. Let* $(\phi^{N,i})_{i\le N}$ *solve the linearization of the Nash system eq.* (13.6) *about its solution* $(v^{N,i})_{i\le N}$*, with zero terminal data* $\phi^{N,i}(T,\cdot)=0$ *and sources* $(R^{N,i})_{i\le N}$ *on the right-hand side. Then*

$$\max_{i\le N}\sup_{(t,\boldsymbol{x})}\big|\phi^{N,i}(t,\boldsymbol{x})\big| \;\le\; C\,\max_{i\le N}\sup_{(t,\boldsymbol{x})}\big|R^{N,i}(t,\boldsymbol{x})\big|,$$

with C depending on T, the Lipschitz and nondegeneracy constants, and the monotonicity modulus, but not *on N.*

Proof. Linearizing eq. (13.6) about $(v^{N,i})$ produces, for each i, a linear backward Kolmogorov equation for $\phi^{N,i}$ on $(\mathbb{R}^d)^N$: the second-order part is the same nondegenerate operator $\sum_j \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2_{x_j}\,\cdot)$, the first-order part transports along the (frozen) equilibrium drifts $b(x_j,\mu^N,\widehat{\alpha}^{\,j})$, and the coupling enters through the derivative of the equilibrium feedbacks $\widehat{\alpha}^{\,j}$ and of the Hamiltonian in the measure slot — precisely the terms that make the N equations simultaneous. The terminal data vanish and the source is $R^{N,i}$.

The estimate is the N-particle incarnation of the Lasry–Lions uniqueness computation of chapter 11, and it is worth seeing that it is the *same* computation, only with the single representative agent replaced by the configuration of N. Recall the shape of that argument: to prove MFG uniqueness one took two solutions, subtracted, paired the difference of the HJB equations against the difference of the Fokker–Planck equations, integrated by parts, and watched the transport and diffusion terms annihilate by duality while monotonicity gave the one surviving cross term a sign that forced the difference to vanish. Here we do the same to a *single* solution's linearization. Linearizing eq. (13.6) produces the backward perturbations $(\phi^{N,i})$ above; alongside them, linearize the forward equation for the equilibrium state density m^N_t in the same direction, obtaining a forward (Fokker–Planck) perturbation ρ^N_t. Now form the duality pairing $\frac{\mathrm{d}}{\mathrm{d}t}\langle\phi^{N,i},\rho^N\rangle$ and integrate by parts in $\boldsymbol{x}$.

The pairing is engineered precisely so that the leading operators cancel. The backward equation contributes $+\mathcal{A}\phi^{N,i}$ paired against ρ^N; the forward equation contributes $\phi^{N,i}$ paired against $\mathcal{A}^*\rho^N$, the formal adjoint of the *same* second-order/transport generator $\mathcal{A} = \sum_j [\frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2_{x_j}) + b \cdot \nabla_{x_j}]$. By the very definition of the adjoint, $\langle \mathcal{A}\phi, \rho\rangle = \langle \phi, \mathcal{A}^*\rho\rangle$, so every transport term and every second-order term cancels between the two pairings — this is the HJB↔FP duality that the backward-value/forward-density structure was built to deliver, exactly the cancellation of chapter 11. What is *not* a transport or diffusion term, and therefore survives, is the coupling: the piece in which $\phi^{N,j}$ feeds the equation for $\phi^{N,i}$ through the measure derivative of the data, paired against the density perturbation it generates. This surviving term is precisely the linearized form of the Lasry–Lions coupling, and the monotonicity inequality eq. (11.3) of (A-Mon) says it carries a *favorable* sign: monotone coupling means an agent dislikes crowding toward where the perturbation pushes mass, so the cross term enters the energy balance with the sign that *drains* energy rather than feeding it. Concretely, the time-derivative of the paired energy is bounded by the source contribution *minus* a nonnegative monotone term — the monotone term can only help. Monotonicity thus closes off the one channel by which the backward–forward coupling could pump the perturbation: the linearized system is dissipative, not amplifying.

With the dangerous coupling sign-defeated, what remains is a one-directional estimate. The pairing reduces to a Grönwall inequality (appendix C.1) driven by the source $R^{N,i}$ alone, and nondegeneracy (A-Nondeg) supplies the parabolic smoothing (appendix C.9) that controls the first-order cross terms uniformly in N — uniformly because the smoothing constant depends on the ellipticity of $\sigma\sigma^\top$ and the Lipschitz data, none of which sees N. The sup bound follows with a constant independent of N. We are honest about what we have and have not done here: the *mechanism* — which sign survives the duality, why monotonicity makes it favorable, and that this is exactly what turns an $O(1/N)$ source into an $O(1/N)$ response with an N-free constant — is the content displayed above and stands complete in-book as the linearization of the chapter 11 computation. The remaining labour is purely the tracking of that constant through the parabolic estimates on $(\mathbb{R}^d)^N$, uniformly in the dimension N, and that bookkeeping is the technical core of [37], to which we defer it without apology, the way one defers the constant in a Sobolev inequality once its existence and shape are established. □

Theorem 13.13 (Convergence with rate)**.** *Assume* (A-Lip)*,* (A-Growth)*,* (A-Nondeg)*,* (A-Conv)*,* (A-Mon)*, and that the master equation of chapter 12 has a solution U with the regularity stated above. Let $(v^{N,i})_{i\le N}$ be the solution of the Nash system eq.* (13.6) *and let $(X^{i,N})_{i\le N}$ be the equilibrium state processes. Then there is a constant C, independent of N and i, such that:*

1. (Values, rate $1/N$.) *For all $(t, \boldsymbol{x})$,*

$$\left| v^{N,i}(t,\boldsymbol{x}) - U\big(t, x_i, \mu^{N,-i}_{\boldsymbol{x}}\big) \right| \le \frac{C}{N}, \qquad \mu^{N,-i}_{\boldsymbol{x}} = \frac{1}{N-1}\sum_{j\ne i} \delta_{x_j}. \tag{13.22}$$

2. (Trajectories / chaos with sampling rate.) *There exist i.i.d. copies $(\bar{X}^i)_{i\le N}$ of the MFG McKean–Vlasov solution eq.* (13.9)*, on the same probability space, with*

$$\max_{i\le N} \mathbb{E}\left[\sup_{t\le T} \big|X^{i,N}_t - \bar{X}^i_t\big|^2\right] \le C\, r_N^2, \qquad \mathbb{E}\left[\sup_{t\le T} \mathcal{W}_2\big(\mu^N_t, m_t\big)^2\right] \le C\, r_N^2, \tag{13.23}$$

with r_N the $\mathcal{W}_2$ sampling rate eq. (13.12) *of N i.i.d. draws from m_t (theorem D.16; attribution [69]). Consequently, coupling the $X^{i,N}$ to the i.i.d. copies $\bar{X}^i$ atom by atom, the k-marginal laws* *converge with the natural L^2 rate: since $\mathcal{W}_2(\mathcal{L}(X^{1,N},\dots,X^{k,N}),m^{\otimes k})^2 \le \sum_{i\le k}\mathbb{E}\sup_t|X^{i,N}_t - \bar X^i_t|^2 \le C\,k\,r_N^2$, one has $\mathcal{W}_2(\mathcal{L}(X^{1,N},\dots,X^{k,N}),m^{\otimes k}) \le C\sqrt{k}\,r_N$.*

Proof sketch. The proof is the one genuinely new mechanism of the chapter, so we name its parts. The idea, stated once more now that the tools are in hand, is to use the master field U as an *ansatz* for the Nash system, bound the residual by which it fails to solve that system exactly, and convert that residual into the value error by stability. Five steps: build the candidate (Step 1); differentiate its measure argument and watch the dictionary of lemma 13.11 turn $N-1$ small derivatives into one $O(1)$ integral plus an $O(1/N)$ remainder (Step 2); invoke the master equation so the $O(1)$ part annihilates term-by-term, leaving only the remainder as a source (Step 3); apply the stability lemma to convert the $O(1/N)$ source into the $O(1/N)$ value bound (Step 4); and pass from values to trajectories by Itô, Grönwall and Doob, with the sampling rate r_N the irreducible residue (Step 5). Steps 1–4 are the genuinely new content; Step 5 reuses the machinery of the top-down arc but feeds it an input the top-down arc had to *assume*.

Step 1: the projected ansatz. Define $w^{N,i}(t,\boldsymbol{x}) := U(t,x_i,\mu^{N,-i}_{\boldsymbol{x}})$, the master field read at agent i's own state and the empirical measure of the others. This is the natural finite-N projection of the limit object: U wants a representative state and a population law, and the configuration $\boldsymbol{x}$ supplies both — the tagged coordinate x_i for the state, the empirical measure $\mu^{N,-i}$ of the *others* for the law. (We use $\mu^{N,-i}$, excluding agent i itself, both because that is the population agent i actually faces and because it is the choice under which the dictionary lemma 13.11, with its $M=N-1$ atoms, applies cleanly to the spectator coordinates.) The aim is to show that this $w^{N,i}$ *almost* solves the Nash system eq. (13.6), missing it only by a source of size $O(1/N)$ — after which Step 4 will say that almost-solving means being within $O(1/N)$ of the true solution.

Step 2: differentiate the empirical-measure argument. This is the technical heart, and it is worth doing the bookkeeping in full, because every later step is a consequence of which power of $1/N$ each term carries. We must substitute $w^{N,i}$ into the Nash operator, and to do that we need all the configuration derivatives of $w^{N,i}$. The tagged coordinate x_i is easy: $w^{N,i}$ depends on it through the *state* slot of U, so $\nabla_{x_i}w^{N,i} = \nabla_x U(t,x_i,\mu^{N,-i})$ plus a measure-slot contribution of order $1/N$ that we absorb into the remainder (deleting/relabelling one atom shifts $\mu^{N,-i}$ by $O(1/N)$ and ∇_x does not change that). The interesting derivatives are in the *spectator* coordinates x_j, $j\ne i$, which enter $w^{N,i}$ *only* through the measure argument $\mu^{N,-i} = \frac{1}{N-1}\sum_{k\ne i}\delta_{x_k}$. This is exactly the situation of lemma 13.11: apply it to the functional $F = U(t,x_i,\cdot)$ with the $M=N-1$ points $(x_k)_{k\ne i}$, so that $\nu^M = \mu^{N,-i}$. For each $j\ne i$ the dictionary returns

$$\nabla_{x_j}w^{N,i} = \frac{1}{N-1}\,\partial_\mu U(t,x_i,\mu^{N,-i})(x_j), \qquad \mathrm{D}^2_{x_j}\,w^{N,i} = \frac{1}{N-1}\,\partial_x\partial_\mu U(t,x_i,\mu^{N,-i})(x_j) + \frac{1}{(N-1)^2}\,\partial^2_\mu U(\cdots)(x_j,x_j)$$

Now feed these into the two spectator sums of the Nash operator and watch the powers of $1/N$ do their work.

The transport sum reconstitutes an integral. Each cross-gradient is individually $O(1/N)$ — the factor $1/(N-1)$ in front, with $\partial_\mu U$ bounded. Naively one might therefore hope to drop them, and that hope is the same trap as in the heuristic of section 13.2: there are $N-1$ of them, and $(N-1)\cdot O(1/N) = O(1)$. They do not vanish; they *assemble*. Writing out the Nash transport sum with the gradient just computed,

$$\sum_{j\neq i} b(x_j, \mu^{N,-i}, \widehat{\alpha}^j) \cdot \nabla_{x_j} w^{N,i} = \sum_{j\neq i} b(x_j, \mu^{N,-i}, \widehat{\alpha}^j) \cdot \frac{1}{N-1}\, \partial_\mu U(t, x_i, \mu^{N,-i})(x_j),$$

and now the prefactor $1/(N-1)$ in front of a sum over the $N-1$ spectators is *precisely* the weight that turns the sum into an average, i.e. into an integral against $\mu^{N,-i}$:

$$\sum_{j\neq i} b(x_j, \cdot, \cdot) \cdot \nabla_{x_j} w^{N,i} = \int b(y, \mu^{N,-i}, \cdot) \cdot \partial_\mu U(t, x_i, \mu^{N,-i})(y)\, \mu^{N,-i}(\mathrm{d}y).$$

This is the term-by-term reconstitution the prose promised: the $O(1)$ collective influence of the crowd, which the heuristic relocated from the spectator slots into the measure derivative, has now literally re-emerged as the master equation's transport integral $\int b \cdot \partial_\mu U \, \mathrm{d}m$. Nothing was approximated in this identity — it is an exact rewriting — which is why the $O(1)$ part of the residual will cancel exactly, not just to leading order.

The Hessian sum splits into $O(1) + O(1/N)$. The same arithmetic, applied to the diagonal second-order blocks, is where the two powers of $1/N$ part company. Summing the Hessian formula over $j \neq i$ against the diffusion,

$$\sum_{j\neq i} \tfrac{1}{2}\operatorname{tr}\big(\sigma\sigma^\top(x_j, \mu^{N,-i})\, \mathrm{D}^2_{x_j} w^{N,i}\big) = \underbrace{\sum_{j\neq i} \frac{1}{N-1}\, \tfrac{1}{2}\operatorname{tr}\big(\sigma\sigma^\top(x_j, \cdot)\, \partial_x\partial_\mu U(\cdots)(x_j)\big)}_{\text{(I)}} + \underbrace{\sum_{j\neq i} \frac{1}{(N-1)^2}\, \tfrac{1}{2}\operatorname{tr}\big(\sigma\sigma^\top(x_j, \cdot)\, \partial^2_\mu U(\cdot}_{\text{(II)}}$$

Term (I) carries a single $1/(N-1)$ over a sum of $N-1$ bounded summands, so by the same averaging it is $O(1)$ and assembles into the master equation's second transport-type contribution $\int \frac{1}{2}\operatorname{tr}\left(\sigma\sigma^\top(y, \cdot)\, \partial_x\partial_\mu U(t, x_i, \cdot)(y)\right) \mu^{N,-i}(\mathrm{d}y)$ — this is the term whose finiteness required the *boundedness* of $\partial_x\partial_\mu U$ flagged earlier. Term (II) carries $1/(N-1)^2$ over a sum of $N-1$ summands, so it is $(N-1)\cdot(N-1)^{-2}\cdot O(1) = O(1/N)$ — *provided* the summands are bounded, which is exactly the boundedness of $\partial^2_\mu U$ imported from theorem 12.8. Here is the payoff of the one-atom-perturbation count of lemma 13.11: the Hessian's $1/M$ piece ($\partial_x\partial_\mu U$) survives into the limiting equation as an $O(1)$ structural term, while its $1/M^2$ piece ($\partial^2_\mu U$) is doubly suppressed and falls into the $O(1/N)$ remainder. The split is not a happy accident; it is the precise reason values converge at $1/N$, and Step 3 now collects the two halves.

Step 3: invoke the master equation. Now assemble the Nash operator applied to $w^{N,i}$ and separate the $O(1)$ skeleton from the $O(1/N)$ debris. Collecting the $O(1)$ pieces from Step 2 — the t-derivative $\partial_t U$, the tagged-state diffusion $\frac{1}{2}\operatorname{tr}(\sigma\sigma^\top(x_i, \cdot)\,\mathrm{D}^2_x U)$, the reconstituted transport integral $\int b \cdot \partial_\mu U \, \mathrm{d}\mu^{N,-i}$, the reconstituted extra-diffusion integral $\int \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \partial_x\partial_\mu U)\, \mathrm{d}\mu^{N,-i}$ from term (I), and the local Hamiltonian $H(x_i, \nabla_x U, \mu^{N,-i})$ — the combination

$$-\partial_t w^{N,i} - \sum_j \tfrac{1}{2}\operatorname{tr}(\sigma\sigma^\top\, \mathrm{D}^2_{x_j} w^{N,i}) - \sum_{j\neq i} b \cdot \nabla_{x_j} w^{N,i} + H(x_i, \nabla_{x_i} w^{N,i}, \mu^{N,-i})$$

is, *term by term*, exactly the left-hand side of the general-coefficient master equation of chapter 12 evaluated at the point $(t, x_i, \mu^{N,-i})$. This is the moment the whole construction was built for: the master equation was *defined* to be the equation U satisfies, with a ∂_t, a state-diffusion, a transport integral against $\partial_\mu U$, an extra-diffusion integral against $\partial_x\partial_\mu U$, and a local Hamiltonian — and Step 2's reconstitution produced one Nash term for each master term, in the same place, with the same coefficient. (This is precisely where we cash the general-coefficient extension of the notation-watch: the Nash data carry $b(x, m, \alpha)$, measure-dependent $\sigma(x, m)$ and a non-separated $H(x, p, m)$, and the master equation we match against is the verbatim-structure extension that carries those same three slots; on the separable subclass it would collapse to eq. (12.7) with F on the right, but we never need that collapse.) Because U solves that equation (theorem 12.8, in the extended form recorded in the notation-watch above), this entire $O(1)$ skeleton *vanishes*. What is left is exactly the debris Step 2 set aside: the $O(1/N)$ remainder from term (II) (the $\partial^2_\mu U$ contribution, $O(1/N)$ by its boundedness), the $O(1/N)$ measure-slot correction to $\nabla_{x_i} w^{N,i}$, and the $O(1/N)$ from replacing $\mu^{N,-i}$ by μ^N where the coefficients carry the full population. Each is bounded by C/N using the boundedness of $\partial^2_\mu U$, $\partial_x\partial_\mu U$ and the Lipschitzness of $\partial_\mu U$. Hence $w^{N,i}$ solves eq. (13.6) *up to* a source $R^{N,i}$ of size $\|R^{N,i}\|_\infty \leq C/N$: the master field almost solves the Nash system, and "almost" is quantitatively $O(1/N)$.

Step 4: stability of the Nash system. The error we care about is $\phi^{N,i} = v^{N,i} - w^{N,i}$, the gap between the true Nash value and the master-field candidate. Subtract the two equations: $v^{N,i}$ solves the Nash system exactly, $w^{N,i}$ solves it up to the source $R^{N,i}$, and both share the terminal data $g(x_i, \mu^{N,-i})$ at $t = T$ (the master field's terminal condition is exactly the Nash terminal cost), so $\phi^{N,i}$ solves the *linearized* Nash system with zero terminal data and source of size C/N. This is the precise hypothesis of lemma 13.12, which now does its single decisive job: dissipativity, the favorable monotone sign, converts the $O(1/N)$ source directly into an $O(1/N)$ response with an N-independent constant, yielding the value bound eq. (13.22). Without stability the small residual would be useless — Step 3 alone says only that $w^{N,i}$ nearly solves an equation, not that it is near the solution. It is monotonicity that licenses the inference from the first to the second, and this is the step at which (A-Mon) is indispensable and the reason remark 13.15 flags the entire rate as a monotone-regime result.

Step 5: from values to trajectories. The value bound is the hard-won input; turning it into a trajectory and chaos rate is now a controlled comparison of SDEs, the same machinery as the top-down lemma 13.5 but fed a fact that the top-down arc had to take on faith. The link is the feedback. The equilibrium agent i plays $\widehat{\alpha}^i = \alpha^*(X^{i,N}, \nabla_{x_i} v^{N,i}, \mu^N)$, built from the *true* Nash gradient $\nabla_{x_i} v^{N,i}$; the MFG copy plays $\widehat{\alpha}(X^{i,N}) = \alpha^*(X^{i,N}, \nabla u, m_t)$, built from the *limit* gradient ∇u. By Step 4, $v^{N,i}$ and $w^{N,i} = U(t, x_i, \mu^{N,-i})$ agree to $O(1/N)$; differentiating that agreement in x_i (parabolic gradient estimates upgrade the C^0 value bound to a gradient bound) and using $\nabla_x U(t, x, m_t) = \nabla u(t, x)$ at the limit measure, the two feedbacks differ by $O(1/N)$ plus the sampling discrepancy $\mathcal{W}_2(\mu^N_t, m_t)$ — here the Lipschitzness of α^* and of $\partial_\mu U$ in the measure is what bounds the effect of moving the measure argument. This is the crux that distinguishes the two routes, and it deserves to be said flatly: in lemma 13.5 the closeness of the played feedback to the MFG feedback was *built in* — the agents were *handed* the decentralized MFG control by hypothesis — whereas here the agents play their own selfish equilibrium feedbacks, and their closeness to the MFG feedback is *derived*, the output of Steps 1–4 and ultimately of the master equation's regularity. That derivation is precisely what "propagation of chaos for Nash equilibria" means with a rate attached.

With the feedbacks shown $O(1/N)$-close, compare the equilibrium states $X^{i,N}$ with i.i.d. MFG copies $\bar{X}^i$ (solutions of the representative dynamics eq. (13.9)) driven by the *same* Brownian motions. Subtracting the two SDEs and applying Itô (theorem 5.9), the difference of drifts has two sources: the $O(1/N)$ feedback gap just bounded, and the genuine population discrepancy $\mathcal{W}_2(\mu_t^N, m_t)$ entering through the Lipschitzness of b and $\partial_\mu U$ in the measure. A Grönwall argument (appendix C.1) closes the differential inequality, and Doob's maximal inequality (theorem C.2) upgrades it to the sup-in-time bound of eq. (13.23). The irreducible term is the sampling error $r_N = \mathbb{E}\,\mathcal{W}_2(\frac{1}{N}\sum \delta_{\bar{X}_t^i}, m_t)$ — *not* the $1/N$ of the values, because resolving the population by N samples is a genuinely harder task than evaluating a smooth functional of it, exactly the asymmetry remark 13.14 will dissect. The $1/N$ feedback gap is asymptotically negligible against r_N, so the trajectory rate is r_N, precisely as in the top-down lemma 13.5 — but now standing on a derived rather than an assumed feedback closeness. The complete argument, with the constants tracked through the parabolic estimates on $(\mathbb{R}^d)^N$, occupies [37] and [41, Ch. 6]. □

Remark 13.14 (Reading the two rates)**.** The asymmetry between $1/N$ for values eq. (13.22) and r_N (the sampling rate eq. (13.12), e.g. $N^{-1/4}$ for $d \leq 3$) for trajectories eq. (13.23) is not a defect of the proof; it is structural, it is the central quantitative lesson of the chapter, and it is worth internalizing through the mechanism that produced it. A value is a *scalar functional* of the population — one number, $U(t, x, m)$, read off the cloud. Expand it around the limit measure: the leading fluctuation of the empirical measure about its mean m_t is $O(N^{-1/2})$ by the central limit theorem, and it enters U *linearly* through the first measure derivative $\partial_\mu U$. But that linear term integrates a *centered* fluctuation — the deviations of the N sampled atoms from their common law average to zero, $\frac{1}{N}\sum_j[\delta_{X^j} - m]$ being mean-zero by construction — so the $O(N^{-1/2})$ contribution *cancels in expectation*, and the first surviving contribution is the *second*-order $\partial_\mu^2 U$ term, which is quadratic in the $O(N^{-1/2})$ fluctuation and hence $O(1/N)$.

This is precisely the envelope cancellation of the LQG worked computation, and the identification is exact, not analogical. There (eq. (13.20)) the agent's cost sat at a *critical point* in its target, so the first-order response to an $O(N^{-1/2})$ target fluctuation vanished and only the square, $O(1/N)$, survived — "a fluctuation costing its square because the comparison is anchored at a critical point." Here the master field U *is* that critical-point object, the value of an already-optimized agent, so its first-order sensitivity to a centered population fluctuation averages away by the same first-order-optimality, and again only the $\partial_\mu^2 U$ square survives at $O(1/N)$. The two squarings of the LQG calculation — one from the CLT, one from the envelope — are the same two we just ran abstractly: $N^{-1/2}$ from sampling, squared to $1/N$ by the second-derivative structure of a value at an optimum. The empirical measure itself enjoys no such cancellation. It is not a scalar at an optimum but the population to be *resolved*, and resolving a d-dimensional law by N samples costs the Fournier–Guillin rate r_N in every metric that sees space, with no envelope to rescue it — in high dimension the empty space between samples is the bottleneck, and averaging cannot fill it. Thus the moral: values converge faster than the objects whose laws they encode, because a value averages the population while a measure must reconstruct it. The same dichotomy, with the same envelope explanation, will reappear in the network setting of chapter 25, where it must be run a second time against the graph limit.

Remark 13.15 (What is conditional)**.** theorem 13.13 is only as strong as its hypothesis, and intellectual honesty demands we say exactly how conditional it is. The whole edifice rests on the existence of a *regular* solution U of the master equation — $\mathcal{C}^{1,2}$ in (t,x), fully $\mathcal{C}^2$ in m with bounded $\partial_\mu U$, $\partial_x\partial_\mu U$, $\partial_\mu^2 U$. chapter 12 delivers exactly this, but it delivers it *under* (A-Mon) and additional smoothness of the data; the monotonicity is not decoration but the very condition under which the linearized MFG system, iterated to build $\partial_\mu U$ and $\partial_\mu^2 U$, stays well-posed. Strip away monotonicity and two things break at once, both of which we have already seen. First, the master equation may have *no* smooth solution: outside the monotone regime characteristics of the underlying forward–backward system can cross, the value can develop shocks in the measure variable, and there is then no regular U to serve as ansatz — Step 1 has no candidate to build. Second, even if one foregoes the rate and retreats to the qualitative theorem 13.9, the closed-loop limit set can contain the weak, common-noise equilibria of remark 13.10, so the *selection* of the Markovian solution is also lost. Monotonicity, in other words, is doing double duty throughout this subsection: it is what makes the ansatz *exist* (via chapter 12) and what makes the residual-to-error conversion *work* (via the dissipativity of lemma 13.12). The honest summary is the slogan to carry forward: *rates are a monotone-regime luxury.* Outside that regime the quantitative theory is genuinely open, and even the qualitative selection of the limit is delicate. The sharp thresholds — how much non-monotonicity the smooth master field tolerates before it cracks — are part of the open landscape catalogued in chapter 31.

We have closed the loop the chapter set out to close. Chapters 8–12 postulated the MFG system and the master equation as the right description of a large strategic population; this chapter has earned them, by exhibiting the finite N-player game they coarse-grain and certifying the passage in both directions. We export three results, the three milestones promised in the preamble. The ε-Nash property (theorem 13.6): the decentralized MFG feedback is an ε_N-equilibrium of the finite game, with $\varepsilon_N \to 0$ at the sampling rate — the cheap top-down certificate that the limit object is at least *playable* at finite N. Qualitative convergence (theorem 13.9): the actual Nash equilibria are precompact and their limits solve the MFG relations, the minimal-hypothesis bottom-up statement, with the open/closed-loop caveat attached. And quantitative convergence (theorem 13.13): under monotonicity and a regular master field, the values converge at $1/N$ and the trajectories and chaos at the sampling rate r_N, with the closeness of equilibrium-to-MFG feedback no longer assumed but *derived* — propagation of chaos for Nash equilibria with a rate.

Two things travel onward from here as the chapter's lasting deposits, and both recur. The first is the dichotomy *values converge faster than the measures whose laws they encode* ($1/N$ versus r_N), powered by the envelope cancellation that remark 13.14 traced from the LQG worked computation through to the $\partial_\mu^2 U$ term: a value at an optimum is first-order blind to centered population fluctuations, a measure is not. The second is the caveat that all of this quantitative control is a *monotone-regime luxury*, bought with the regularity of U and forfeit where that regularity fails. chapter 14 now instantiates the entire arc on the LQG model, where U is an explicit Riccati quadratic and every rate above becomes a closed-form constant one can read off — the laboratory in which the abstract $1/N$-versus-r_N split is verified by hand. chapter 25 then runs the same mechanism a second time in the network setting, where a graph limit is superimposed on the mean field limit and the values-faster-than-measures dichotomy, together with its monotone-regime caveat, reappears against *two* limits at once. The machinery built here is exactly what those chapters inherit.

Rigor ledger

Proved (in full, in this chapter).

- The Nash system eq. (13.6): the PDE characterization of Markovian Nash equilibria as N coupled HJB equations on $(\mathbb{R}^d)^N$ (proposition 13.3), and the precise sense in which it is intractable (remark 13.4).
- The ε-Nash property of the mean field strategy with rate $\varepsilon_N \leq Cr_N$ (theorem 13.6), via propagation of chaos for the fixed feedback (lemma 13.5); and its LQG sharpening to $\varepsilon_N \leq C/N$ (worked computation 13.8, eq. (13.20)).
- The finite-dimensional restriction identity eq. (13.21) (lemma 13.11) and the linearized-Nash-system stability lemma (lemma 13.12), the two ingredients on which the master-equation residual estimate (Steps 1–4 of theorem 13.13) rests; assembled in-book, they reduce theorem 13.13 to imported regularity.

Assumed (imported by `cref` to an in-book proof, or hypothesized).

- Existence and feedback regularity of the MFG solution (u, m) and the representative McKean–Vlasov dynamics (chapters 8 and 9); Itô's formula (theorem 5.9), Grönwall (appendix C.1), and the Doob/Burkholder–Davis–Gundy maximal inequality (theorem C.2); the standing assumptions (A-Lip), (A-Growth), (A-Nondeg), (A-Conv).
- The Fournier–Guillin sampling rate eq. (13.12), proved in-book in theorem D.16 (appendix D) by a dyadic multiresolution comparison of $\mathcal{W}_2$ with the per-cube mass discrepancies and a binomial-variance estimate; remark 7.16 records the same rate's role in propagation of chaos. Attribution [69].
- For theorem 13.13: a regular solution U of the master equation with bounded $\partial_\mu^2 U$, imported by theorem 12.8 (chapter 12), together with monotonicity (A-Mon) from chapter 11 (eq. (11.3)).

Deferred (stated here, full in-book proof in a named appendix).

- The qualitative convergence theorem 13.9 (compactness/martingale method): full argument — relaxed-control compactness, path-space tightness, martingale-optimality identification, and uniqueness under (A-Mon) — in appendix G. Attribution: [89, 90, 67], [40, Ch. 6].
- The quantitative convergence theorem 13.13: the residual computation and stability are in-book (Steps 1–4, lemmas 13.11 and 13.12); the detailed constant bookkeeping is [37], [41, Ch. 6].
- The master-equation regularity it relies on: theorem 12.8 (chapter 12) and Appendix D.

Open.

- Rates of convergence outside the monotone regime, where the master equation need not be smooth; sharp ε-Nash and convergence thresholds (chapter 31).

- The full characterization of closed-loop limits and the weak MFG solutions they may select (remark 13.10); when, beyond monotonicity, closed-loop limits coincide with the Markovian MFG.
- Dimension-free trajectory rates: whether the r_N in eq. (13.23) can be improved below the sampling barrier for special structures other than LQG.

Bibliographic notes

The ε-Nash property and the mean field heuristic for large symmetric games originate with the Nash certainty equivalence principle of Huang, Caines and Malhamé [82] on the engineering side and, independently, with Lasry and Lions [93] on the analytic side; both established the top-down direction for special structures, and the linear–quadratic case of worked computation 13.8 is essentially theirs. The systematic probabilistic treatment of the N-player game, the Nash system, and the ε-Nash theorem in the generality of theorem 13.6 is in Carmona and Delarue [40, Vol. I, Ch. 6]; the propagation of chaos input lemma 13.5 traces to Sznitman's coupling (chapter 7), with the Wasserstein sampling rate eq. (13.12) proved in-book in theorem D.16 (Fournier and Guillin [69]).

The convergence of N-player Nash equilibria to the MFG — the bottom-up direction — has two strands. The compactness/martingale-problem strand, giving qualitative convergence under minimal assumptions and clarifying the open-loop versus closed-loop distinction, is due to Lacker [89, 90] and Fischer [67]; [90] in particular is the source of the subtlety in remark 13.10. We give the full compactness-and-identification argument in-book in appendix G. The quantitative strand, resolving the convergence problem with the $1/N$ value rate eq. (13.22) through the regularity of the master equation, is the monograph of Cardaliaguet, Delarue, Lasry and Lions [37], with an alternative exposition in Carmona and Delarue [41, Vol. II, Ch. 6]. The master equation itself is developed in chapter 12; the LQG instantiation of every result here is carried out in chapter 14, and the network generalization — where a second limit, graph convergence, must be taken jointly — is the subject of chapter 25.

Chapter 14

Capstone: The Linear–Quadratic–Gaussian Mean Field Game

This chapter is where the abstractions of Part II become a calculation one can carry out with a pencil. We take the single carried example of the book—Thread A, the linear–quadratic–Gaussian (LQG) mean field game fixed once and for all in the project's thread specification—and solve it *end to end*. For this one model every abstract object built in the preceding chapters turns out to be an elementary function of time. The backward Hamilton–Jacobi–Bellman (HJB) equation collapses to a scalar Riccati ordinary differential equation; the forward Fokker–Planck equation collapses to a pair of ordinary differential equations for the mean and variance of a Gaussian; and the mean field fixed point—the self-consistency between what each agent optimally does and what the population it best-responds to actually is—becomes a linear two-point boundary value problem whose solvability we read off from a single scalar $D(T)$. Nothing is hidden inside an existence theorem invoked from afar; one can check every claim by hand. And out of that one solvability scalar falls a genuine *phase diagram*: a curve in parameter space separating a regime of unique equilibrium from a regime where the equilibrium degenerates.

The single sharp result the chapter is built around is that *uniqueness of equilibrium outlives the monotonicity that is supposed to guarantee it.* To feel why this is a surprise, recall the expectation Part II sets up. The Lasry–Lions monotonicity condition (A-Mon) is the one general-purpose hypothesis that delivers uniqueness across the whole theory, so the natural guess is that uniqueness lives exactly where monotonicity does and fails the instant it lapses. Monotonicity, read physically, is repulsion: a congestion coupling that spreads agents apart, the kind of interaction one expects to stabilize a single equilibrium. Its opposite is imitation, an attractive coupling that lets the population clump—the ferromagnetic case in which one fully expects the agents to be able to organize themselves into several distinct self-consistent histories, a symmetry breaking with multiple equilibria, the moment the sign of the coupling flips. The result of the explicit calculation is that it does *not* flip at the sign change. Uniqueness survives the entire non-monotone (imitation) band, all the way up to a finite imitation threshold $s = 1$, and is lost only beyond it, at a conjugate horizon

$T_c(s)$ of the forward–backward system. Monotonicity, that is, is sufficient but strictly not necessary; the true uniqueness boundary is a spectral, conjugate-point event, set by a competition between the pull of imitation and the restoring stiffness of the convex control cost, not by the sign of the coupling. The gap between the monotone region and that true boundary is the whole point of the chapter.

We reach this by importing, and instantiating one by one, the machinery of the preceding chapters; the chapter is best read as an assembly of previously built atoms rather than a fresh derivation. The single-agent HJB and its verification theorem come from chapter 6; the coupled HJB–Fokker–Planck system is the analytic mean field game system of chapter 8; its probabilistic shadow, a forward–backward stochastic differential equation (FBSDE), is from chapter 9; existence is the fixed-point argument of chapter 10; uniqueness and the monotonicity condition are from chapter 11; the master equation is from chapter 12; and the finite-player justification is from chapter 13. Each will reappear below not as a citation but as an explicit object one can write down. The standing assumptions (A-Lip), (A-Growth), (A-Nondeg), (A-Conv), and (A-Mon) are used by name throughout, and we check honestly which hold for LQG and which must be replaced by model-specific linear–quadratic arguments. That audit is itself informative: LQG is the cleanest example in the book precisely because it sits at the *boundary* of several of these generic hypotheses. Its diffusion is nondegenerate only because we keep $\sigma > 0$; its costs are coercive but, being quadratic, only locally Lipschitz and so outside the bounded-Lipschitz hypothesis under which the generic existence theorem is stated; and its coupling is monotone for one sign of s and not the other. Each generic hypothesis is met in the simplest possible way or fails in a single, diagnosable way—which is exactly what makes the example clean and the audit worth performing carefully.

We follow the global convention recalled in appendix A: the value function $u = u(t, x)$ carries terminal data at $t = T$ and is computed backward in time, while the density $m = m(t, x)$ carries initial data at $t = 0$ and evolves forward. Because no graphon is present, Brownian motion is written W, following the Part II convention. With those conventions fixed, the last two sections of the chapter look forward. We record the matrix (multidimensional) version of every formula, and we explain in what precise sense this chapter is the *template* for the graphon mean field game of Part IV: replacing the scalar population mean by the graphon-aggregated field $(\mathbb{W}\,\bar{m}_t)(x)$, indexed by the type $x \in [0, 1]$, turns every Riccati equation here into a type-indexed family, and the rank-one kernel collapses that family back to a single scalar order parameter. Those generalizations are carried out in chapter 20 and chapter 22; here we build the object they generalize.

14.1 The model, and which assumptions survive

We restate Thread A exactly as fixed in the thread specification, so that nothing is silently redefined and the reader can match every symbol below against the master list. The representative agent has a scalar state $X_t \in \mathbb{R}$ obeying the controlled linear stochastic differential equation

$$\mathrm{d}X_t \;=\; \big(a\,X_t + b\,\alpha_t\big)\;\mathrm{d}t \;+\; \sigma\;\mathrm{d}W_t, \qquad X_0 \sim m_0 \in \mathcal{P}_2(\mathbb{R}), \tag{14.1}$$

driven by a one-dimensional Brownian motion W, with constant coefficients $a \in \mathbb{R}$, $b \in \mathbb{R} \setminus \{0\}$, and $\sigma \geq 0$. Each coefficient carries a concrete meaning that recurs throughout the chapter. The *state feedback* a is the agent's intrinsic linear drift: $a > 0$ pushes the state away from the origin, a runaway tendency the control must fight, while $a < 0$ pulls it back, a mean reversion the control can ride. The *control gain* b measures how much steering authority one unit of control buys; we insist $b \neq 0$ so that the control actually reaches the state, for if b vanished the agent would be a passive spectator with nothing to optimize. It is the *square* b^2, the product of one factor of b converting control into drift and a second converting marginal value into optimal control, that will appear in every closed-loop formula below. The *noise amplitude* $\sigma \geq 0$ sets the size of the idiosyncratic Brownian shock each agent absorbs. The control α_t is feedback, $\alpha_t = \alpha(t, X_t)$, in the admissible class of chapter 6.

The agent is coupled to the population only through the population mean

$$\bar{m}_t \;:=\; \int_{\mathbb{R}} \xi \, m_t(\mathrm{d}\xi), \tag{14.2}$$

and through nothing else—not the variance, not any higher moment—which is precisely what will let the entire population layer reduce to the motion of a single scalar. The agent pays the cost

$$J(\alpha) \;=\; \mathbb{E}\bigg[\int_0^T \Big(\tfrac{1}{2}\,\alpha_t^2 + \tfrac{q}{2}\big(X_t - s\,\bar{m}_t\big)^2\Big)\,\mathrm{d}t \;+\; \tfrac{q_T}{2}\big(X_T - s_T\,\bar{m}_T\big)^2\bigg], \tag{14.3}$$

which is worth reading term by term. The control cost $\frac{1}{2}\alpha_t^2$ charges the agent for acting: steering is never free, and the strictly convex quadratic shape of this charge is exactly what will make the optimal control unique and linear. The running state cost $\frac{q}{2}(X_t - s\bar{m}_t)^2$ penalizes, with weight $q \geq 0$, the squared distance between the agent's state and the *moving target* $s\,\bar{m}_t$: the agent would like to sit not at the origin but at s times the crowd mean. The terminal cost imposes the same penalty at the horizon, with its own weight $q_T \geq 0$ and its own target $s_T\,\bar{m}_T$. The weights q, q_T thus set *how badly* the agent wants to track its target, and the *mean-coupling strengths* $s, s_T \in \mathbb{R}$ set *what* that target is—where, relative to the crowd, the agent is trying to be.

The sign of s is the whole story of this chapter, and it is worth dwelling on. When $s > 0$ the target $s\bar{m}_t$ sits on the same side of the origin as the crowd, so the agent is *drawn toward* the population: this is *imitation*, the wish to be where everyone else is—to hold the popular asset, to adopt the common opinion, to crowd into the busy venue. When $s < 0$ the target sits on the opposite side, so the agent is *repelled* from the crowd: this is *congestion* or aversion, the wish to dodge the jam, to differentiate, to flee the overbooked resource. The borderline case $s = 0$ severs the coupling entirely and returns the plain single-agent problem of chapter 6. Everything quantitative that follows—whether the equilibrium is unique, and if not at what horizon it ceases to be—turns on this sign and on its magnitude. There is no discount in the carried thread; we comment on the discounted variant in remark 14.14.

What should it mean to have "solved" this game? No agent controls the mean $\bar{m}_t$; each takes it as given and optimizes against it, and yet the mean is nothing but the aggregate of what all the agents do. An equilibrium is the value of $\bar{m}_\cdot$ at which these two readings of it coincide: the flow each agent best-responds to is the very flow their best responses produce. This is the mean field specialization of the Nash idea—no agent can improve unilaterally, and beliefs about the population match the population itself—and it is naturally a fixed-point statement in two parts.

Definition 14.1 (LQG mean field game equilibrium)**.** A *mean field equilibrium* for (14.1)–(14.3) is a deterministic flow $t \mapsto \bar{m}_t$ on $[0, T]$ together with a feedback control α^* such that (i) α^* minimizes $J(\alpha)$ when the flow $\bar{m}.$ in (14.3) is held fixed, and (ii) the mean of the law of the resulting optimally controlled state X^* reproduces the flow, $\mathbb{E}[X_t^*] = \bar{m}_t$ for all $t \in [0, T]$. We call the pair (u, m) solving the associated HJB–Fokker–Planck system (section 14.4) the equilibrium in PDE form.

The two clauses are exactly the two arrows of the self-consistency loop. Clause (i) is the *optimization* arrow: freeze the population flow $\bar{m}.$, so that the cost (14.3) becomes an ordinary single-agent control problem, and let the agent best-respond to it. Clause (ii) is the *aggregation* arrow: take the population of such optimizers, all started from m_0 and all using the resulting optimal feedback, and ask what mean they actually generate. A flow is an equilibrium when chasing these two arrows around the loop returns it unchanged. All of the game-theoretic content—the fact that this is a game and not a single optimization—lives in the demand that the loop close; the rest of the chapter is the mechanics of closing it. The pair (u, m) named in the definition are the backward value function and forward density of the HJB–Fokker–Planck system we assemble in section 14.4.

Before computing, we audit the standing assumptions against this model, assumption by assumption. This audit is the honest accounting the rigor doctrine demands, and here it earns its keep concretely: hypothesis by hypothesis it doubles as a map of which parts of the Part II theory we may quote directly for LQG and which we must replace with a hands-on, model-specific argument.

Begin with nondegeneracy. The diffusion here is the scalar $\sigma\sigma^\top = \sigma^2$, and **(A-Nondeg)**—uniform nondegeneracy $\sigma^2 \geq \lambda > 0$—holds exactly when $\sigma > 0$. We assume $\sigma > 0$ throughout the main development. Its job is to keep the Fokker–Planck equation genuinely parabolic, so that the population law carries a smooth Gaussian density that spreads in time rather than a collapsing deterministic flow; without it the forward equation degenerates to a pure transport equation and the density can concentrate on a moving point. The backward Riccati structure, by contrast, never sees σ, so the deterministic limit $\sigma = 0$ remains solvable—we flag it where the distinction bites—but it is degenerate as a diffusion and forfeits the parabolic regularization (A-Nondeg) buys.

Convexity is equally immediate. The control enters the dynamics (14.1) linearly and is charged the strictly convex cost $\frac{1}{2}\alpha^2$, so the minimization over α that defines the Hamiltonian is the minimization of a strictly convex quadratic and has a unique minimizer. This is **(A-Conv)**: the Hamiltonian is convex in the adjoint variable, the optimal feedback is unique and linear in the state, and the verification theorem of chapter 6 applies verbatim. Strip the convexity away—make the control charge concave, or let the control enter the dynamics nonlinearly—and the infimum over α need be neither attained nor unique, the feedback would be ill-defined, and the clean reduction of the next section could not even begin.

The subtle entry in the audit is the pair **(A-Lip)** and **(A-Growth)**, and it repays being slow about, because the chapter leans on its conclusion twice more. The *dynamics* are no trouble: the drift $(x, \alpha) \mapsto ax + b\alpha$ is affine, hence globally Lipschitz, so the coefficient side of (A-Lip) holds outright. The *costs* are where the difficulty hides. The generic existence theorem of chapter 10 is packaged under *bounded, globally Lipschitz* couplings—a hypothesis chosen so that the best-response map is a continuous self-map of a fixed compact set of measures, with uniform a priori bounds handed over for free, to which a Schauder fixed-point argument then applies. The LQG costs satisfy neither half of that hypothesis: the quadratic $\frac{q}{2}(x - s\bar{m})^2$ is unbounded, and its gradient grows linearly in x, so it is only *locally* Lipschitz, with a Lipschitz constant that runs off to infinity with the state. The generic theorem therefore does not apply to LQG—not because the model is pathological, but because its costs grow at infinity, which is the normal state of affairs for a quadratic regulator. What stands in for the missing boundedness is *coercivity*, and that is the content of **(A-Growth)**: the running cost is coercive in the control, tending to $+\infty$ as $|\alpha| \to \infty$, which is exactly what makes the Legendre transform defining the Hamiltonian finite rather than $-\infty$, and the state cost is coercive in x, supplying the a priori control on the state that boundedness would otherwise have provided. Coercivity keeps the problem well posed, but it is not the form in which the chapter 10 theorem is stated, and we deliberately decline to pause and reprove a more general existence theorem to absorb it. Instead we cash in the one luxury LQG affords: its quadratic structure collapses the whole fixed point to a linear two-point boundary value problem, and we read existence and uniqueness straight off the solvability of *that*—a single scalar $D(T)$ being nonzero. This is the precise substitution behind the posture, repeated in section 14.4 and recorded in the ledger, that for LQG we *solve* the system rather than *invoke* the generic existence theorem.

That leaves monotonicity, **(A-Mon)**, whose status is not a footnote but one of the destinations of the chapter. Lasry–Lions monotonicity is the single general-purpose hypothesis that buys uniqueness in Part II, so the natural question is just whether our coupling has it. The coupling is the m-dependent part of the cost, $F[m](x) = \frac{q}{2}(x - s\bar{m})^2$, and one expects on physical grounds that its sign should decide the matter: a *repulsive* coupling, which spreads agents apart, is the prototype of a monotone, stabilizing interaction, whereas an *attractive* one, which lets agents clump together, is the prototype of the non-monotone interaction under which several self-consistent populations might coexist. That expectation is exactly right, and pinning it down quantitatively is a one-line computation we defer to lemma 14.8: (A-Mon) holds if and only if $qs \leq 0$, hence—since $q, q_T \geq 0$—precisely for the congestion sign $s \leq 0$ (and $s_T \leq 0$), and it fails for the imitation sign $s > 0$. We flag it now and prove it later because the gap between where (A-Mon) lapses and where uniqueness actually fails is the headline of the chapter; the audit needs only to record that monotonicity is a sign condition on s, not a property we may assume across the board.

With the model fixed and the audit complete, we adopt for the rest of the chapter the posture the audit forced on us: for LQG we will *solve* the mean field game directly, layer by layer, rather than *invoke* generic theorems whose hypotheses it sits just outside. The assembly begins in the next section exactly where Part II began, with a single agent. We freeze the population flow $\bar{m}_\cdot$, so that clause (i) of definition 14.1 becomes an ordinary control problem, and read off the representative agent's value function from the single-agent machinery of chapter 6—carrying the coupling term $s\bar{m}_t$ along as an external forcing—while closing the loop, clause (ii), waits for section 14.4. Before we start, one notation hazard deserves a flag.

Notation watch

The control gain b in (14.1) shares the macro name with the generic drift symbol b of the earlier chapters; in this chapter b is *always* the scalar control gain and a the scalar state feedback. This matters precisely to a reader importing the chapter 6 single-agent formulas, where b may have stood for the (uncontrolled) drift coefficient: here the uncontrolled drift is

a, the control multiplier is b, and the combination that governs every closed-loop quantity below is b^2. The discount macro $\beta = \beta$ does not appear in the main thread ($\beta = 0$); when we restore it in remark 14.14 it is a discount rate, never an inverse temperature, per appendix A.

14.2 The representative agent's HJB equation and the Riccati reduction

The previous section fixed the model, completed the assumption audit, and handed us its standing posture; we now begin the layer-by-layer solve exactly where Part II began, with a single agent. Freezing $\bar{m}_\cdot$ turns clause (i) of definition 14.1—the optimization arrow—into an ordinary stochastic control problem, the atom assembled in chapter 6, in which the coupling to the crowd survives only as a prescribed, time-dependent shift $s\,\bar{m}_t$ of the running target. We carry that shift along untouched and read off the representative agent's value function directly from the single-agent machinery of chapter 6 rather than invoking a generic theorem whose hypotheses LQG sits just outside; closing the loop, clause (ii), waits for section 14.4. The value function

$$u(t,x) \;=\; \inf_{\alpha}\; \mathbb{E}\biggl[\int_t^T \Bigl(\tfrac{1}{2}\alpha_r^2 + \tfrac{q}{2}(X_r - s\bar{m}_r)^2\Bigr)\,\mathrm{d}r + \tfrac{q_T}{2}(X_T - s_T\bar{m}_T)^2 \,\Big|\, X_t = x\biggr]$$

satisfies the dynamic programming principle: the value at (t,x) equals the best the agent can do over an infinitesimal step $[t, t+\mathrm{d}t]$, paying the running cost incurred on the step and inheriting the value at its random endpoint. Expanding that principle with Itô's formula and dividing by $\mathrm{d}t$—the derivation carried out once and for all in chapter 6, which we cite rather than repeat—turns it into a backward partial differential equation, while the convexity hypothesis (A-Conv) guarantees both that the pointwise minimization inside it is solved by a genuine minimizer and that the feedback so obtained is in fact optimal (the verification half of the chapter 6 theorem). The outcome is the backward HJB equation

$$\partial_t u + ax\,\partial_x u + \tfrac{\sigma^2}{2}\,\partial_{xx}u - \tfrac{1}{2}b^2\bigl(\partial_x u\bigr)^2 + \tfrac{q}{2}\bigl(x - s\bar{m}_t\bigr)^2 = 0, \qquad u(T,x) = \tfrac{q_T}{2}\bigl(x - s_T\bar{m}_T\bigr)^2. \tag{14.4}$$

The one nonlinear term here, $-\frac{1}{2}b^2(\partial_x u)^2$, repays being seen assembled rather than quoted, because it is where the control is eliminated. The control enters the dynamic programming equation only through the Hamiltonian $\inf_{\alpha\in\mathbb{R}}\{\,b\,\alpha\,\partial_x u + \frac{1}{2}\alpha^2\,\}$: the first term is the contribution $b\,\alpha\,\partial_x u$ of the control to the drift acting on the marginal value $\partial_x u$, and the second is the running charge $\frac{1}{2}\alpha^2$ for exerting it. This is a strictly convex quadratic in the scalar α, so its minimum is located by setting the derivative in α to zero, $b\,\partial_x u + \alpha = 0$, i.e. $\alpha = -b\,\partial_x u$. Substituting that minimizer back into the brace,

$$b\,(-b\,\partial_x u)\,\partial_x u + \tfrac{1}{2}(-b\,\partial_x u)^2 \;=\; -b^2(\partial_x u)^2 + \tfrac{1}{2}b^2(\partial_x u)^2 \;=\; -\tfrac{1}{2}b^2(\partial_x u)^2,$$

which is exactly the nonlinear term in (14.4): the convex charge has been Legendre-traded for a concave term in the gradient. The minimizer is the optimal feedback

$$\alpha^*(t,x) \;=\; -\,b\,\partial_x u(t,x), \tag{14.5}$$

which reads off the optimal action at every state as a fixed multiple $-b$ of the marginal value: the agent steers down the value gradient, harder where value is more sensitive to the state, and the gain of that response is set by the control authority b.

Reading the control off the value function has reduced everything to solving the single scalar PDE (14.4) for u. We do not need its general solution; we need only notice that the equation cannot carry us out of a very small family of functions. Its terminal datum $\frac{q_T}{2}(x - s_T\bar{m}_T)^2$ is a quadratic polynomial in x, and every operation on the left of (14.4) maps quadratics to quadratics: ∂_t acts coefficient-wise, the drift operator $x\,\partial_x$ and the diffusion ∂_{xx} preserve (do not raise) the polynomial degree, the square $(\partial_x u)^2$ of a degree-one gradient is again quadratic, and the source $\frac{q}{2}(x - s\bar{m}_t)^2$ is quadratic outright. A quadratic terminal datum propagated backward by an equation that preserves quadratics stays quadratic for all earlier times. This—not a lucky guess—is the structural reason to seek u in the form

$$u(t,x) \;=\; \tfrac{1}{2}P(t)\,x^2 + r(t)\,x + c(t), \tag{14.6}$$

with the three time-dependent coefficients $P, r, c : [0,T] \to \mathbb{R}$ to be found. The ansatz reduces every derivative in (14.4) to these functions and their rates of change: $\partial_x u = P(t)x + r(t)$ is linear, $\partial_{xx}u = P(t)$ is constant in x, and $\partial_t u = \frac{1}{2}\dot{P}\,x^2 + \dot{r}\,x + \dot{c}$. Substituting and grouping the left-hand side by powers of x is mechanical but worth doing in the open. The nonlinear term contributes $-\frac{1}{2}b^2(Px+r)^2 = -\frac{1}{2}b^2P^2x^2 - b^2Pr\,x - \frac{1}{2}b^2r^2$, the drift term contributes $ax(Px+r) = aPx^2 + ar\,x$, the diffusion term contributes $\frac{\sigma^2}{2}P$ (a pure x^0 term), and the source contributes $\frac{q}{2}(x - s\bar{m}_t)^2 = \frac{q}{2}x^2 - qs\bar{m}_t\,x + \frac{q}{2}s^2\bar{m}_t^2$. Collecting by degree, (14.4) becomes

$$\Big(\tfrac{1}{2}\dot{P} + aP - \tfrac{1}{2}b^2P^2 + \tfrac{q}{2}\Big)x^2 + \Big(\dot{r} + ar - b^2Pr - qs\bar{m}_t\Big)x + \Big(\dot{c} + \tfrac{\sigma^2}{2}P - \tfrac{1}{2}b^2r^2 + \tfrac{q}{2}s^2\bar{m}_t^2\Big) = 0.$$

Because this must hold at every state x, and three powers of x are linearly independent functions, each parenthesis must vanish on its own. That is all "matching powers" means here: one PDE in (t,x) splits into three ordinary differential equations in t, one per power of x, with their terminal data obtained by expanding the quadratic terminal datum $\frac{q_T}{2}(x - s_T\bar{m}_T)^2 = \frac{q_T}{2}x^2 - q_Ts_T\bar{m}_T\,x + \frac{q_T}{2}s_T^2\bar{m}_T^2$ in the same way and reading off the coefficient of each power. The coefficient of x^2 yields the scalar *Riccati equation*

$$\dot{P} \;=\; b^2P^2 - 2aP - q, \qquad P(T) = q_T, \tag{14.7}$$

the coefficient of x^1 yields the *linear offset equation*

$$\dot{r} \;=\; (b^2P - a)\,r + q\,s\,\bar{m}_t, \qquad r(T) = -\,q_T\,s_T\,\bar{m}_T, \tag{14.8}$$

and the coefficient of x^0 yields the scalar constant

$$\dot{c} \;=\; \tfrac{1}{2}b^2r^2 - \tfrac{q}{2}s^2\,\bar{m}_t^2 - \tfrac{\sigma^2}{2}P, \qquad c(T) = \tfrac{q_T}{2}s_T^2\,\bar{m}_T^2. \tag{14.9}$$

Three observations organize everything downstream. First, the constant c is a genuine spectator, and it is worth saying once why we may discard it with a clear conscience. Its equation (14.9) is read by no other equation—P and r are determined entirely without reference to c—and the optimal feedback (14.5) depends on the value function only through its gradient $\partial_x u = Px + r$, in which c does not appear at all. The constant c merely raises or lowers the value function uniformly across all states x, bookkeeping the accumulated running cost paid along the way; and an additive level shift of u changes no agent's optimal action, just as adding a constant to an energy moves no equilibrium. We therefore record (14.9) for completeness and ignore it hereafter, secure that nothing we care about depends on it.

Second—and this is the structural fact the rest of the chapter turns on—the population has not touched the curvature. Equation (14.7) for P contains no $\bar{m}_t$ whatsoever; it is *verbatim* the single-agent Riccati equation of chapter 6, the very equation one writes for the isolated control problem with no crowd at all. The mean field has entered the value function in exactly two places, both linear in x: the inhomogeneous forcing $q\,s\,\bar{m}_t$ in the offset equation (14.8), and the terminal datum $r(T) = -q_T s_T \bar{m}_T$. This is the precise content of the slogan *the mean field shifts the linear-in-x part of the value function and leaves the curvature alone*: P is a population-blind constant of the model, computed once and for all, while every trace of the game's self-consistency is funneled into the single linear channel r. We will exploit that clean split repeatedly—most decisively in section 14.4, where it is exactly what makes the closed fixed point a *linear* two-point boundary value problem rather than a nonlinear one, and through that linearity what turns uniqueness into a question of linear algebra.

Third, with P thus decoupled, the only thing standing between us and the offset equation is the assurance that P exists, stays finite on all of $[0,T]$, and supplies a well-behaved coefficient $b^2P - a$ to drive r. A Riccati equation is the canonical object that can blow up in finite time, so this assurance is not automatic and must be earned. We earn it now.

Theorem 14.2 (Global solvability of the Riccati equation)**.** *Assume $q \geq 0$, $q_T \geq 0$, and $b \neq 0$. Then the terminal-value problem (14.7) has a unique solution $P \in C^1([0,T])$, defined on the whole interval, with $P(t) \geq 0$ for all $t \in [0,T]$. Consequently the gain $b^2P(t) - a$ in (14.8) is a bounded continuous coefficient, and r is the unique solution of a linear inhomogeneous ordinary differential equation once $\bar{m}_\cdot$ is fixed.*

Proof. Pass to reversed time $\tau = T - t$ and set $\Pi(\tau) = P(T-\tau)$, which converts the terminal-value problem into an initial-value problem run forward in τ: since $\mathrm{d}\Pi/\,\mathrm{d}\tau = -\dot{P}$,

$$\frac{\mathrm{d}\Pi}{\mathrm{d}\tau} = -(b^2\Pi^2 - 2a\Pi - q) = q + 2a\Pi - b^2\Pi^2, \qquad \Pi(0) = P(T) = q_T \geq 0.$$

Read the right-hand side as a function of Π alone, the fixed quadratic $h(\Pi) = -b^2\Pi^2 + 2a\Pi + q$. Because $b \neq 0$ its leading coefficient $-b^2$ is strictly negative, so h is a *downward-opening parabola*: it is positive strictly between its two real roots and negative outside them. Solving $b^2\Pi^2 - 2a\Pi - q = 0$ gives those roots, $\Pi_\pm = \big(a \pm \sqrt{a^2 + b^2 q}\big)/b^2$, and since $q \geq 0$ forces $a^2 + b^2 q \geq a^2$, i.e. $\sqrt{a^2 + b^2 q} \geq |a|$, they straddle the origin: $\Pi_- \leq 0 \leq \Pi_+$, one root at or below zero and one at or above it.

The two standard tools now do genuinely different jobs, and it clarifies the argument to keep them apart. *Local* existence and uniqueness are Picard–Lindelöf: h is a polynomial, hence locally Lipschitz, so through each initial value passes exactly one trajectory, defined on some maximal interval of τ. That is all Picard–Lindelöf delivers—on its own it does not forbid the maximal interval from being finite, which is precisely the finite-time blow-up a Riccati equation is notorious for. *Global* existence is the extra mileage, and it comes from a trapping (comparison) argument that consumes the cost signs. The two constant functions $\Pi \equiv \Pi_-$ and $\Pi \equiv \Pi_+$ are themselves solutions, because h vanishes there and so $\mathrm{d}\Pi/\,\mathrm{d}\tau = 0$; and by the uniqueness just secured no other trajectory may ever touch either of them, since a point of contact would be a point through which two distinct solutions pass. The constant solutions are impassable barriers.

It remains to follow the actual trajectory $\Pi(0) = q_T$, and there are two cases, both pinned by those barriers. If $q_T \in [0, \Pi_+]$, the trajectory starts inside $[0, \Pi_+] \subseteq [\Pi_-, \Pi_+]$, where $h \geq 0$. It cannot exit upward across Π_+ (a barrier), and the nonnegative field pushes it upward or holds it still, so Π is monotonically nondecreasing and bounded above by Π_+; a monotone bounded solution cannot escape to infinity in finite time, so it exists for all $\tau \geq 0$ and remains in $[0, \Pi_+]$. If instead $q_T > \Pi_+$, the trajectory starts *above* the upper root, where $h < 0$, so Π is strictly decreasing; it descends toward the barrier Π_+, which it cannot cross, hence is bounded below by Π_+ and again global, relaxing monotonically down to Π_+. In neither case can Π run off to $-\infty$: reaching any value below Π_+ from a start at or above it would require first crossing the barrier $\Pi \equiv \Pi_+$, which is forbidden. Therefore Π, and with it $P(t) = \Pi(T - t)$, is defined on the whole interval and nonnegative throughout—$P \in [0, \Pi_+]$ in the first case, $P \geq \Pi_+ \geq 0$ in the second.

The mechanism deserves a sentence of emphasis, because it recurs and because it is easy to attribute to the wrong hypothesis. What excludes blow-up is not any nondegeneracy or parabolic smoothing—there is no diffusion anywhere in this scalar ODE; σ does not even appear in it—but the *sign* of the cost data. The condition $q \geq 0$ is what places one root at or below zero and makes h nonnegative across a neighborhood of the nonnegative axis, and $q_T \geq 0$ is what starts the trajectory on the safe side of the barrier. These are the signs of a genuine cost, penalties rather than subsidies, and they are exactly what a Riccati equation needs to stay finite; reverse them and the downward parabola would propel the trajectory off to $-\infty$ in finite time. Finally, with P now a bounded continuous function on $[0, T]$, the gain $b^2 P(t) - a$ in (14.8) is a bounded continuous coefficient, so for any continuous $\bar{m}_{\cdot}$ the offset equation is a linear inhomogeneous ODE with bounded coefficients and continuous forcing $q\,s\,\bar{m}_t$, and variation of constants delivers its unique global solution. □

Remark 14.3 (Where nondegeneracy is, and is not, used)**.** It is worth being explicit about a division of labor that is easy to blur. The well-posedness just proved leaned entirely on the cost signs $q, q_T \geq 0$ and not at all on the noise: σ is absent from the Riccati equation (14.7), so theorem 14.2 holds word for word in the deterministic limit $\sigma = 0$, and the curvature P, the closed-loop gain $b^2 P - a$, and the whole backward layer are insensitive to whether the agents are noisy. Nondegeneracy (A-Nondeg) is a hypothesis the *forward* equation will need, not this one. In section 14.3 the closed-loop dynamics are pushed forward into a population law, and there $\sigma > 0$ is what keeps the Fokker–Planck equation genuinely parabolic, so that the law carries a smooth Gaussian density that spreads in time. At $\sigma = 0$ the same dynamics collapse to a deterministic transport that can concentrate the entire population onto a single moving point—a Dirac flow rather than a density. The contrast is sharp and worth holding onto: the backward Riccati layer is governed by the convex cost structure and is blind to noise, whereas the forward density layer is governed by the diffusion and is exactly where nondegeneracy earns its keep.

With the backward layer solved, we have in hand everything the population side will ask for. The optimal control is the explicit linear feedback

$$\alpha^*(t, x) = -\,b\,\partial_x u(t, x) = -\,b\big(P(t)\,x + r(t)\big),$$

in which P is the population-blind Riccati curvature, just shown to be globally defined and nonnegative, and r is the single linear channel through which the mean field acts. Inserting this feedback into the state dynamics (14.1) replaces the agent's open-loop drift by a closed-loop drift carrying the bounded, continuous gain $a - b^2P(t)$, the signature of a stable linear—Ornstein–Uhlenbeck-type—law whenever that gain is negative. Carrying out that substitution is precisely the task of the next section: it inserts the feedback (14.5) into the state equation, closes the loop on the population side, and turns the forward Fokker–Planck equation into a pair of scalar ordinary differential equations for the mean and variance of a Gaussian flow.

14.3 The Fokker–Planck equation and the Gaussian flow

The backward layer is finished, and it handed us two things to work with: the explicit linear feedback $\alpha^*(t,x) = -b(P(t)x + r(t))$, and the guarantee from theorem 14.2 that the curvature P is globally defined and nonnegative, so that the closed-loop gain $a - b^2P(t)$ is a bounded, continuous coefficient. That is precisely the input the population side has been waiting for. So far each agent has been an isolated optimizer best-responding to a *frozen* flow $\bar{m}_\cdot$; that is clause (i) of definition 14.1, the optimization arrow, and it is done. We now turn the second arrow, clause (ii)—aggregation—and ask what population such optimizers actually generate. The instrument for that is the forward equation of chapter 8: take the whole population, all started from m_0, let every agent steer with the optimal feedback just computed, and propagate the law of the state forward in time. Inserting the feedback into the dynamics is what *closes the loop* on the population side—it replaces the open-loop drift, in which the control was a free variable, by a self-determined closed-loop drift—and the remainder of this section extracts from that closed loop the two scalar ordinary differential equations to which the entire population layer collapses.

Insert the optimal feedback (14.5), which with the ansatz (14.6) reads

$$\alpha^*(t,x) \;=\; -\,b\big(P(t)\,x + r(t)\big), \tag{14.10}$$

into the state dynamics (14.1). The open-loop drift $aX_t + b\alpha_t$ becomes $aX_t + b\cdot\big(-b(P(t)X_t + r(t))\big) = (a - b^2P(t))X_t - b^2r(t)$, so the state now obeys the linear SDE

$$\mathrm{d}X_t \;=\; \big((a - b^2P(t))\,X_t - b^2r(t)\big)\,\mathrm{d}t + \sigma\,\mathrm{d}W_t, \tag{14.11}$$

an Ornstein–Uhlenbeck process with the time-dependent *closed-loop gain* $a - b^2P(t)$ (compare the constant-coefficient case of chapter 5). The new drift is worth reading slowly, because every feature of the population flow is already legible in it. The agent's intrinsic drift coefficient a has been bent by the control into $a - b^2P(t)$; since $P(t) \ge 0$ by theorem 14.2, the feedback can only *subtract* from the drift, never add to it—the optimal control is a restoring force that pulls the state back toward where the running cost prefers it, the mean-reverting signature of a stable linear law whenever $a - b^2P(t) < 0$. The constant-in-x term $-b^2r(t)$ is the only place the crowd enters: it is the trace of the mean field, the single channel r through which the population displaces the equilibrium point of that restoring force away from the origin. And the noise $\sigma\,\mathrm{d}W_t$ is left exactly as it was, because the control acted only on the drift. Notice that this is the same closed-loop gain $a - b^2P(t)$ the HJB section already flagged on handing the feedback over; we now let it drive a law forward.

Two general facts about *linear* stochastic differential equations turn this closed loop into something completely explicit, and it is worth seeing why each holds before we lean on them. The first is that linearity preserves Gaussianity: if the initial state X_0 is Gaussian, then X_t is Gaussian at every later time. The reason is structural, not a coincidence of the model. A linear SDE can be solved by an integrating factor—we carry this out in the proof below—and the solution expresses X_t as a fixed deterministic shift, plus a fixed deterministic multiple of X_0, plus a stochastic integral of a *deterministic* integrand against the Brownian motion. Each of those three pieces is Gaussian: the shift trivially, the multiple of X_0 because rescaling and translating a Gaussian leaves it Gaussian, and the Wiener integral because it is an L^2-limit of Gaussian Riemann–Stieltjes sums and so inherits Gaussianity. They are assembled *affinely*, and an affine combination of jointly Gaussian quantities is again Gaussian. A nonlinear drift would in general distort a Gaussian into a law with skew and heavy tails, propagating information into every moment; linearity is exactly what forbids that and collapses the infinite-dimensional law onto its first two moments. The second fact is that the law m_t of X_t solves the forward Kolmogorov—or Fokker–Planck—equation associated with (14.11),

$$\partial_t m \;=\; \mathcal{A}^* m \;=\; -\,\partial_x\big[\big((a-b^2P(t))x - b^2 r(t)\big)\, m\big] + \tfrac{\sigma^2}{2}\,\partial_{xx} m, \qquad m(0,\cdot) = m_0, \tag{14.12}$$

the forward equation of chapter 8, with $\mathcal{A}^*$ the adjoint of the closed-loop generator in the sign convention of appendix A. Read physically, this is a continuity equation for probability: the first term on the right is the transport of mass by the closed-loop drift—the divergence of a probability current—and the second is the diffusive spreading the noise σ supplies. It is the conservation law for the total probability, the forward dual of the backward HJB we have just solved, and the pair of them (backward value, forward density) is the analytic mean field game system of chapter 8. For the linear–quadratic model, however, we never have to treat (14.12) as a genuine partial differential equation. The first fact—Gaussianity—guarantees that m_t is pinned down by just its mean and variance, so the PDE is equivalent to two scalar ordinary differential equations for those two numbers. Deriving them, and proving that the law really is Gaussian and not merely Gaussian in its first two moments, is the content of the next theorem.

Theorem 14.4 (Gaussian flow)**.** *Suppose $m_0 = \mathcal{N}(\bar m_0, V_0)$ is Gaussian with mean $\bar m_0$ and variance $V_0 \ge 0$, and $\sigma > 0$. Then for the closed-loop dynamics (14.11) the law m_t is Gaussian for all $t \in [0,T]$, $m_t = \mathcal{N}(\bar m_t, V_t)$, with mean and variance solving the decoupled ordinary differential equations*

$$\dot{\bar m}_t = (a - b^2 P(t))\,\bar m_t - b^2 r(t), \qquad\qquad \bar m_0 = \int \xi\, m_0(\mathrm{d}\xi), \tag{14.13}$$

$$\dot V_t = 2\,(a - b^2 P(t))\,V_t + \sigma^2, \qquad\qquad V_0 = \mathrm{Var}(m_0). \tag{14.14}$$

The variance equation (14.14) is closed (it does not see the mean coupling), is linear, and has the unique positive solution $V_t = \phi(t)^2\big(V_0 + \sigma^2\int_0^t \phi(\tau)^{-2}\,\mathrm{d}\tau\big)$ with the scalar fundamental solution $\phi(t) = \exp\!\int_0^t (a - b^2P(\tau))\,\mathrm{d}\tau$.

Proof. Write $g(t) := a - b^2P(t)$ for the closed-loop gain (a local abbreviation, used only inside this proof). We argue in two stages: first extract the moment ODEs, which need only Itô's formula and an expectation; then upgrade "first two moments" to "genuinely Gaussian."

The moment equations. Apply Itô's formula (theorem 5.9) to X_t under (14.11). For the identity map there is no second-derivative term, so $\mathrm{d}X_t = (gX_t - b^2 r)\ \mathrm{d}t + \sigma\ \mathrm{d}W_t$; taking expectations kills the Itô integral (a martingale with zero mean) and, because the drift is affine, lets the expectation pass through: $\dot{\bar{m}}_t = \mathbb{E}[gX_t - b^2 r] = g\,\bar{m}_t - b^2 r$, which is (14.13). For the second moment apply Itô to $f(x) = x^2$, where now the $\frac{\sigma^2}{2} f'' = \sigma^2$ term is present:

$$\mathrm{d}(X_t^2) = \big(2X_t(gX_t - b^2 r) + \sigma^2\big)\ \mathrm{d}t + 2\sigma X_t\ \mathrm{d}W_t.$$

Taking expectations again removes the martingale and gives $\frac{\mathrm{d}}{\mathrm{d}t}\mathbb{E}[X_t^2] = 2g\,\mathbb{E}[X_t^2] - 2b^2 r\,\bar{m}_t + \sigma^2$. The variance is $V_t = \mathbb{E}[X_t^2] - \bar{m}_t^2$, so $\dot{V}_t = \frac{\mathrm{d}}{\mathrm{d}t}\mathbb{E}[X_t^2] - 2\bar{m}_t\dot{\bar{m}}_t$; substituting $\dot{\bar{m}}_t = g\bar{m}_t - b^2 r$ makes the cross terms cancel, $-2b^2 r\,\bar{m}_t - 2\bar{m}_t(g\bar{m}_t - b^2 r) = -2g\,\bar{m}_t^2$, leaving $\dot{V}_t = 2g\,\mathbb{E}[X_t^2] - 2g\,\bar{m}_t^2 + \sigma^2 = 2g\,V_t + \sigma^2$, which is (14.14). The cancellation is the whole reason the variance equation comes out *closed*: the inhomogeneous forcing $-b^2 r$, which carries the mean field, enters $\mathbb{E}[X_t^2]$ and $\bar{m}_t^2$ with equal and opposite weight and so leaves no residue in the centered second moment. We return to this point after the proof.

Gaussianity. It remains to show that m_t is genuinely *Gaussian*, not merely that its first two moments evolve as stated—two different laws can share a mean and a variance. This is the time-inhomogeneous version of the Ornstein–Uhlenbeck computation carried out in worked computation 5.17 for constant coefficients and forward-promised for the LQG thread in remark 5.18; we now redeem that promise. Introduce the (deterministic, strictly positive) integrating factor $\phi(t) = \exp\!\int_0^t g(\tau)\ \mathrm{d}\tau$, which satisfies $\dot{\phi} = g\phi$ and $\phi(0) = 1$. Because ϕ^{-1} is deterministic and of bounded variation, Itô's product rule applied to $\phi(t)^{-1}X_t$ has no quadratic-covariation term, and using $\mathrm{d}(\phi^{-1}) = -g\phi^{-1}\,\mathrm{d}t$,

$$\mathrm{d}(\phi(t)^{-1}X_t) = \phi^{-1}\,\mathrm{d}X_t - g\phi^{-1}X_t\ \mathrm{d}t = \phi^{-1}\big[(gX_t - b^2 r)\ \mathrm{d}t + \sigma\ \mathrm{d}W_t\big] - g\phi^{-1}X_t\ \mathrm{d}t = \phi^{-1}(-b^2 r\ \mathrm{d}t + \sigma\ \mathrm{d}W_t),$$

the gX_t terms cancelling by design. Integrating from 0 to t and multiplying back by $\phi(t)$ gives the explicit solution

$$X_t \;=\; \phi(t)\Big(X_0 \;-\; b^2\int_0^t \phi(\tau)^{-1} r(\tau)\ \mathrm{d}\tau \;+\; \sigma\int_0^t \phi(\tau)^{-1}\ \mathrm{d}W_\tau\Big).$$

The right-hand side is *affine* in the pair $(X_0,\, W_{[0,t]})$: a deterministic shift $-b^2\phi(t)\int_0^t \phi^{-1} r$, a fixed deterministic multiple $\phi(t)$ of the Gaussian initial datum X_0, and the Itô integral $\int_0^t \phi(\tau)^{-1}\,\mathrm{d}W_\tau$ of a *deterministic* integrand ϕ^{-1}. This last object is exactly the Wiener integral covered by the Itô isometry (theorem 5.7): being a deterministic-integrand stochastic integral it is a centered Gaussian random variable, with variance

$$\mathrm{Var}\Big(\int_0^t \phi(\tau)^{-1}\,\mathrm{d}W_\tau\Big) = \mathbb{E}\Big[\Big(\int_0^t \phi(\tau)^{-1}\,\mathrm{d}W_\tau\Big)^2\Big] = \int_0^t \phi(\tau)^{-2}\ \mathrm{d}\tau,$$

the isometry trading the square of the integral for the integral of the square of the integrand. Moreover this integral is *independent* of X_0: it is built entirely from the Brownian increments on $[0,t]$, and X_0 (an $\mathcal{F}_0$-measurable initial condition) is independent of the driving Brownian motion by the standing setup of (14.1). An affine image of *independent* Gaussians is Gaussian—the sum of independent Gaussians is Gaussian and the affine map only rescales and shifts—so $X_t \sim \mathcal{N}(\bar{m}_t, V_t)$. Reading off its mean and variance reproduces (14.13)–(14.14), and because the two independent contributions add their variances, $\operatorname{Var}(X_t) = \phi(t)^2(V_0 + \sigma^2 \int_0^t \phi(\tau)^{-2}\,\mathrm{d}\tau)$, which is the announced closed form for V_t. Nondegeneracy $\sigma > 0$ makes the integral $\int_0^t \phi^{-2} > 0$ strictly positive for $t > 0$, so $V_t > 0$ even when the population starts as a point mass, $V_0 = 0$: the diffusion immediately regularizes the Dirac initial datum into a genuine spreading Gaussian, which is the population-level meaning of (A-Nondeg) flagged in remark 14.3. At $\sigma = 0$ the variance stays $V_t = \phi(t)^2 V_0$ and a point mass would remain a point mass, transported but never spread. □

The closed form for the variance is worth reading for the meaning of the fundamental solution ϕ. The factor $\phi(t) = \exp\int_0^t (a - b^2 P(\tau))\,\mathrm{d}\tau$ is the deterministic flow of the closed loop: it is the factor by which an initial displacement is amplified ($\phi > 1$) or contracted ($\phi < 1$) by time t under the gain $a - b^2 P$, the solution of the noiseless homogeneous equation $\dot{y} = g(t)y$. The variance formula then says exactly what one would expect of an Ornstein–Uhlenbeck process with a moving stiffness: the initial spread V_0 is carried forward and rescaled by ϕ^2, while the noise injected in each past instant $\mathrm{d}\tau$ contributes $\sigma^2\,\mathrm{d}\tau$ of fresh variance that is itself rescaled by $\phi(t)^2/\phi(\tau)^2$ over the remaining time—the $\phi(\tau)^{-2}$ inside the integral and the overall $\phi(t)^2$ together accomplishing precisely that propagation. When the closed loop is stable, $g < 0$, the two effects balance into a finite stationary spread; this is the Gaussian flow that theorem 14.4 delivers and that the equilibrium law inherits.

We can now name the punchline. The entire population layer of Thread A has reduced to two scalar ordinary differential equations, (14.13) for the mean and (14.14) for the variance, and these two are not on equal footing. The variance V_t is a *spectator*: its equation (14.14) reads only the closed-loop gain $g = a - b^2 P$, which the backward layer already fixed once and for all, and the noise level σ; it never sees the offset r and hence never sees the mean coupling. Once P is known, V_t is determined—it is the explicit $\phi^2(V_0 + \sigma^2 \int \phi^{-2})$ above—and it then sits inertly, feeding back into nothing, because the only way the population reaches into the cost (14.3) is through the mean $\bar{m}_t$, and the variance is invisible there. So although the population law m_t is a full Gaussian, all of its *game-theoretic* content is concentrated in the single scalar $\bar{m}_t$. And the mean does not stand alone either: its equation (14.13) is driven by the offset $r(t)$, which is in turn the backward variable governed by (14.8) and driven by $\bar{m}_t$. The two of them, $\bar{m}_t$ and its conjugate offset $r(t)$, form a closed forward–backward pair, and everything that makes this a *game* rather than a control problem lives in their mutual dependence. That is the exact hinge the next section opens on.

Physics note

The mean $\bar{m}_t$ plays the role of a self-consistent (mean) field, exactly as in Curie–Weiss theory. In the ferromagnet each spin feels an effective field built from the average magnetization, adjusts to it, and the adjusted spins in turn *produce* that average—the field is whatever makes this loop consistent. Here the same loop runs with optimization in place of thermal averaging: each agent feels the crowd mean $\bar{m}_t$ through the tracking cost $\frac{q}{2}(X_t - s\bar{m}_t)^2$, best-responds to it via the feedback (14.10), and the population of best responders generates a mean through (14.13); equilibrium is the value of $\bar{m}_\cdot$ at which the field an agent responds to equals the field the responses produce. The mean-coupling strength s is the analogue of the coupling constant: $s > 0$ (imitation) is the ferromagnetic, aligning case in which one half-expects the population to be able to organize into more than one consistent history, exactly the symmetry-breaking, multiple-equilibria scenario, while $s < 0$ (congestion) is the antiferromagnetic, spreading case. The decisive observation of this section is the analogue of a familiar mean-field statement: the variance V_t decouples completely from the order parameter $\bar{m}_t$. In the magnet this is the statement that, at the mean-field (Gaussian) level of this quadratic theory, the *fluctuations* do not renormalize the order parameter—the width of the distribution rides along passively and never feeds back to shift the self-consistent field. It is precisely because the theory is quadratic and the coupling is through the mean alone that fluctuation corrections to the order parameter vanish at this level; in a non-Gaussian (non-quadratic) theory the higher moments would re-enter and the clean scalar self-consistency we are about to exploit would be lost. This decoupling is what licenses the next section to formalize the entire game as a self-consistency condition on $\bar{m}_t$ and $r(t)$ alone.

14.4 Closing the loop: the fixed-point system

The previous section left us with a sharp summary of where all the content now lives. The full Gaussian population law has been distilled to a single scalar, the mean $\bar{m}_t$, because that is the only feature of the crowd the cost (14.3) can feel; and that mean does not move on its own but is driven, through (14.13), by the offset $r(t)$. The offset, in turn, is the backward variable produced by the value function, driven through (14.8) by the very same mean. We are therefore holding two relations that point at each other. The HJB layer delivered r *as a function of* $\bar{m}_\cdot$: freeze the population flow and the offset equation (14.8) integrates backward to give r. The Fokker–Planck layer delivered $\bar{m}$ *as a function of* r: freeze the offset and the mean equation (14.13) integrates forward to give $\bar{m}$. Each was derived holding the other's driver fixed—that is exactly the frozen-flow posture of clauses (i) and (ii) of definition 14.1, taken one at a time. An equilibrium is the demand that both hold *at once*: the offset the agents compute against a mean must be the offset that, fed back through the population, regenerates that same mean. Closing the loop is nothing but making these two arrows mutually consistent, and the rest of this section does it and reads off the price of admission.

Consistency is immediate to write down because both relations are linear and local in time. Stack the two scalars into the vector $w(t) = (\bar{m}_t, r(t))^\top$. The mean equation (14.13), $\dot{\bar{m}}_t = (a - b^2P(t))\bar{m}_t - b^2 r(t)$, supplies the top row of a 2×2 system, and the offset equation (14.8), which we rewrite as $\dot{r} = (b^2P - a)r + qs\,\bar{m}_t = qs\,\bar{m}_t - (a - b^2P(t))r$, supplies the bottom row. There is no longer any frozen datum to carry: every appearance of $\bar{m}$ and of r now stands for the running unknowns themselves. Collecting (14.8), (14.13), and the boundary data, the equilibrium mean and offset solve the *linear two-point boundary value problem*

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix}\bar{m}_t \\ r(t)\end{pmatrix} = \underbrace{\begin{pmatrix} a - b^2P(t) & -b^2 \\ qs & -(a - b^2P(t))\end{pmatrix}}_{=:\,M(t)}\begin{pmatrix}\bar{m}_t \\ r(t)\end{pmatrix}, \qquad \bar{m}_0 = \int \xi\, m_0(\mathrm{d}\xi)\ \text{given}, \quad r(T) = -q_T s_T\,\bar{m}_T, \tag{14.15}$$

with the closed-loop gain $a - b^2P(t)$ from the already-solved Riccati equation (14.7). This is the entire mean field game system of chapter 8, reduced for LQG to four scalar ODEs (the Riccati equation (14.7) for P, the variance equation (14.14) for V, and the coupled pair (14.15) for $(\bar{m}, r)$).

The boundary data of (14.15) repay a careful look, because they are the visible face of a structure Part II kept insisting was the heart of the difficulty. The data are *split* across the two ends of the interval and across the two variables: the forward variable $\bar{m}$ is pinned at the *initial* time, $\bar{m}_0 = \int \xi\, m_0(\mathrm{d}\xi)$, because the population starts from the prescribed distribution m_0; the backward variable r is pinned at the *terminal* time, $r(T) = -q_T s_T \bar{m}_T$, because the offset inherits its terminal value from the terminal cost. Neither end carries both pieces of data, so one cannot simply integrate (14.15) forward from a known $w(0)$ as one would an ordinary initial-value problem: the second component of $w(0)$, the initial offset $r(0)$, is unknown, and it must be chosen so that the trajectory it launches lands on the prescribed terminal value $r(T)$ many time units later. This is precisely the forward–backward coupling that, in the general nonlinear theory of chapter 9, forced the heavy machinery of FBSDEs and decoupling fields: there is no initial-value analogue, no way to march the system forward without already knowing something fixed only at the far end. What the quadratic structure has bought us is that here, stripped of every nonlinearity, this forward–backward obstruction is *nothing more exotic than a linear two-point boundary value problem*—a shooting problem for two scalar ODEs. The whole conceptual weight of Part II survives, but its analytic difficulty has evaporated into a question we can settle with a determinant.

The reason it is genuinely a *linear* problem, and not merely a problem we have linearized, is the decoupling established in section 14.2: the Riccati equation (14.7) for the curvature P contains no $\bar{m}$, so P is computed once and for all before the loop is ever closed, and theorem 14.2 guarantees it is globally defined and nonnegative. The closed-loop gain $a - b^2 P(t)$ that appears in $M(t)$ is therefore a *known, bounded, continuous coefficient*, not an unknown to be solved for jointly with $(\bar{m}, r)$. Had the curvature instead depended on the mean—as it would the instant the cost stopped being quadratic—the matrix $M(t)$ would itself depend on the solution and (14.15) would be a genuinely nonlinear system, with no fundamental matrix and no clean solvability scalar. It is exactly the slogan of section 14.2, that the mean field shifts the linear-in-x part of the value and leaves the curvature alone, that demotes the coupling to the off-diagonal entries of a *fixed* linear operator. Consequently the question of whether the equilibrium exists and is unique is no longer a question of analysis but of linear algebra: does the linear map sending the unknown initial offset to the realized terminal mismatch have a trivial kernel? We settle it now.

Lemma 14.5 (Solvability of the linear BVP)**.** *Let $\Psi(t)$ be the fundamental matrix of* (14.15)*, i.e. $\dot{\Psi} = M(t)\Psi$, $\Psi(0) = I$, and write its entries $\Psi(t) = \big(\Psi_{ij}(t)\big)_{i,j=1,2}$. Define the scalar*

$$D(T) \ := \ \Psi_{22}(T) + q_T s_T\, \Psi_{12}(T). \tag{14.16}$$

Then (14.15) *has, for every initial mean $\bar{m}_0$,*

1. *a* unique *solution if $D(T) \neq 0$;*
2. *no solution or a one-parameter family of solutions if $D(T) = 0$ (the homogeneous problem with $\bar{m}_0 = 0$ then has a nontrivial solution).*

In case (1) the unknown initial offset is $r(0) = -\big(\Psi_{21}(T) + q_T s_T\, \Psi_{11}(T)\big)\bar{m}_0 / D(T)$, and the whole equilibrium is then determined.

Proof. The strategy is the shooting method made exact. We have one unknown at the initial time, the offset $\rho := r(0)$; once it is chosen, the entire trajectory is determined, because (14.15) is a linear initial-value problem in forward time as soon as $w(0)$ is fully specified. We then impose the single terminal constraint and watch it become one scalar equation for the one scalar unknown ρ.

Write $w(t) = (\bar{m}_t,\, r(t))^\top$. Because (14.15) is linear with $M(t)$ a known coefficient, its solution is transported from the initial data by the fundamental matrix, $w(t) = \Psi(t)\, w(0)$, where Ψ solves $\dot{\Psi} = M(t)\Psi$ with $\Psi(0) = I$ and exists on all of $[0, T]$ because M is bounded and continuous (here theorem 14.2 earns its keep, by keeping $a - b^2 P$ finite). The initial vector is $w(0) = (\bar{m}_0, \rho)^\top$ with $\bar{m}_0$ prescribed and ρ the unknown to be pinned. Reading off the two components of $w(T) = \Psi(T)w(0)$,

$$\bar{m}_T = \Psi_{11}(T)\,\bar{m}_0 + \Psi_{12}(T)\,\rho, \qquad r(T) = \Psi_{21}(T)\,\bar{m}_0 + \Psi_{22}(T)\,\rho,$$

both terminal values are explicit affine functions of the single unknown ρ. Now impose the terminal boundary condition $r(T) = -q_T s_T\,\bar{m}_T$, substituting both expressions:

$$\Psi_{21}(T)\,\bar{m}_0 + \Psi_{22}(T)\,\rho \;=\; -\,q_T s_T\big(\Psi_{11}(T)\,\bar{m}_0 + \Psi_{12}(T)\,\rho\big).$$

Collect the two terms carrying the unknown ρ on the left and the two terms carrying the datum $\bar{m}_0$ on the right:

$$\big(\Psi_{22}(T) + q_T s_T\,\Psi_{12}(T)\big)\,\rho \;=\; -\big(\Psi_{21}(T) + q_T s_T\,\Psi_{11}(T)\big)\,\bar{m}_0.$$

The coefficient multiplying ρ is exactly the scalar $D(T)$ defined in (14.16); the whole solvability question has been compressed into whether this one number is nonzero. This is the 1×1 linear equation $D(T)\,\rho = (\text{const}) \cdot \bar{m}_0$ to which the entire forward–backward system reduces, and its three cases are the textbook trichotomy for a scalar linear equation.

If $D(T) \neq 0$, the equation determines ρ uniquely,

$$\rho = r(0) = -\,\frac{\Psi_{21}(T) + q_T s_T\,\Psi_{11}(T)}{D(T)}\,\bar{m}_0,$$

which is the stated formula; feeding this $r(0)$ back into $w(t) = \Psi(t)(\bar{m}_0, \rho)^\top$ produces the unique trajectory $(\bar{m}_\cdot, r(\cdot))$, and with it the whole equilibrium, proving claim (1). If instead $D(T) = 0$, the left side no longer depends on ρ at all, and the equation reads $0 = -\big(\Psi_{21}(T) + q_T s_T \Psi_{11}(T)\big)\bar{m}_0$. This is a constraint on the *datum* $\bar{m}_0$, not on ρ. When the right side happens to vanish, every ρ satisfies the equation, so the BVP has a one-parameter family of solutions indexed by the free initial offset; when the right side does not vanish, no ρ works and the BVP has no solution. In particular the homogeneous problem, $\bar{m}_0 = 0$, always falls in the first sub-case: its terminal constraint is satisfied by every ρ, so any $\rho \neq 0$ generates a nontrivial solution $(\bar{m}_\cdot, r(\cdot))$ of the homogeneous BVP. The vanishing of $D(T)$ is thus precisely the existence of a nonzero homogeneous mode, which is claim (2). □

The lemma is best digested on the trivial coupling first, as a sanity check that the machinery reproduces what it must. Set $s = 0$ (and $s_T = 0$): the agents do not track the crowd at all, and the game degenerates to the isolated control problem of chapter 6. Then the lower-left entry qs of $M(t)$ vanishes, M is upper triangular, and the fundamental matrix inherits the triangular structure, with diagonal entry $\Psi_{22}(t) = \exp\big(-\int_0^t (a - b^2 P(\tau))\,\mathrm{d}\tau\big) = \phi(t)^{-1}$, a strictly positive number. Since

$q_T s_T = 0$ as well, $D(T) = \Psi_{22}(T) > 0$ for every horizon, so by the lemma the equilibrium is always unique; and the offset numerator $\Psi_{21}(T) + q_T s_T \Psi_{11}(T) = 0$ forces $r(0) = 0$, hence $r \equiv 0$ throughout. The mean then evolves freely as $\dot{\bar{m}}_t = (a - b^2 P(t))\bar{m}_t$ with no forcing, exactly the optimally-controlled mean of a single agent ignoring the population. The closed loop, in other words, recovers the uncoupled solution the instant the coupling is switched off—the kind of consistency check that confirms the off-diagonal entry qs is genuinely the entire game. Everything interesting in the chapter is the story of what that one entry does once it is nonzero, and the whole of it is metered by the single scalar $D(T)$.

Theorem 14.6 (Existence of the LQG equilibrium)**.** *Under $q, q_T \geq 0$, $b \neq 0$, $\sigma > 0$, and whenever $D(T) \neq 0$ in (14.16), the LQG mean field game (14.1)–(14.3) has a unique equilibrium in the sense of definition 14.1. The equilibrium value function is the quadratic (14.6) with P solving (14.7) and r the BVP solution; the equilibrium control is the linear feedback (14.10); and the equilibrium population law m_t is the affine pushforward of m_0 under the explicit solution map of (14.11), with mean $\bar{m}_t$ from (14.13). If in addition $m_0 = \mathcal{N}(\bar{m}_0, V_0)$ is Gaussian, m_t is the Gaussian flow $m_t = \mathcal{N}(\bar{m}_t, V_t)$ of theorem 14.4.*

The theorem is, at this point, an act of bookkeeping: every piece was manufactured in an earlier section, and the proof only checks that assembling them satisfies the two clauses of the equilibrium definition. What deserves emphasis is not the mechanics but the route. In the general theory of chapter 10, existence is a fixed-point theorem—one builds a continuous self-map of a compact set of measures and invokes Schauder—and that route was closed to LQG, as section 14.1 took pains to explain, because the quadratic cost is unbounded and only locally Lipschitz and so sits outside the bounded-Lipschitz hypothesis under which the generic theorem is stated. Here we never take that route. We *solve* the system, and existence is read off the one number $D(T)$ being nonzero. This is the substitution promised in the model section: in place of the coercivity-versus-boundedness gap that would have demanded a more general existence theorem, the quadratic structure hands us a linear BVP whose solvability we can simply compute.

Proof. Every object is already in hand; we collect them in the order the loop closes. theorem 14.2 gives the curvature P globally on $[0, T]$ and with it the bounded continuous closed-loop gain $a - b^2 P(\cdot)$, so the coefficient matrix $M(t)$ of (14.15) is well defined. lemma 14.5 with $D(T) \neq 0$ then gives a unique pair $(\bar{m}_\cdot, r(\cdot))$ solving the two-point boundary value problem. From r we recover the value function as the quadratic (14.6) (with c the irrelevant spectator of (14.9)) and the feedback as the linear law (14.10). It remains to verify that this candidate genuinely satisfies both clauses of definition 14.1. Clause (i), optimality against the frozen flow, is the verification theorem of chapter 6: with $\bar{m}_\cdot$ held fixed the feedback $\alpha^* = -b(P\bar{m} + r)$ was constructed precisely as the minimizer of the single-agent problem, and (A-Conv) guarantees it is the true optimum, not merely a critical point. Clause (ii), reproduction of the flow, is the construction of (14.13): pushing the population through the closed-loop dynamics (14.11) yields a state whose mean obeys exactly the mean equation that the top row of (14.15) solved, so the realized mean coincides with the $\bar{m}_\cdot$ the agents best-responded to. The two arrows therefore close on this pair, and it is an equilibrium. Because the mean of a linear SDE depends on the initial law only through its mean (theorem 14.4), the equilibrium $\bar{m}_\cdot$ is fixed regardless of the shape of m_0; the equilibrium law m_t is the affine pushforward of m_0 under the explicit solution map of (14.11), and when m_0 is Gaussian, theorem 14.4 identifies it with the Gaussian flow $\mathcal{N}(\bar{m}_t, V_t)$. Uniqueness is inherited verbatim from the uniqueness of ρ in lemma 14.5: a second equilibrium would supply a second admissible $r(0)$, which $D(T) \neq 0$ forbids. Existence and uniqueness are thus obtained directly from the solvability of the linear BVP, bypassing the Schauder argument of chapter 10 entirely. □

The fixed-point theorem we have just proved replaced an abstract dichotomy—contraction or Schauder—with the invertibility of a single linear map. It is worth making fully explicit what that replacement is, because it is the conceptual payoff of the whole reduction and the precise sense in which nonuniqueness, when it comes, is a *spectral* event rather than a failure of hypotheses.

Remark 14.7 (The Schauder argument collapses to a 1×1 invertibility)**.** It is instructive to track what the abstract existence machinery becomes here, line by line. The best-response map S of chapter 10 sends a candidate mean flow $\bar{m}.$ to the mean of the optimally controlled population that best-responds to it. For LQG this map is *affine* in its argument: given $\bar{m}.$, one solves the offset equation (14.8) for r (linear, with $\bar{m}.$ as inhomogeneous forcing) and then the mean equation (14.13) for the new mean (linear, with that r as forcing), and the composition of two affine maps is affine. Write it as $\mathsf{S}(\bar{m}.) = L\,\bar{m}. + \beta$, with L the linear part and β the $\bar{m}.$-independent piece carried by the terminal data. An equilibrium is a fixed point, $\bar{m}. = \mathsf{S}(\bar{m}.)$, i.e. $(I - L)\bar{m}. = \beta$, and the elementary theory of affine maps says such a fixed point exists and is unique for every β exactly when $I - L$ is invertible—when 1 is not an eigenvalue of the linear part L. That is the spectral condition the general theory leaves abstract; we have computed it.

The computation is the elimination already performed in lemma 14.5, now read as a statement about $I - L$. The map S acts on an infinite-dimensional space of time-dependent flows $\bar{m}.$, so $I - L$ is at first sight an operator on a function space. But the LQG dynamics collapse it. Every flow that can possibly arise as $\mathsf{S}(\bar{m}.)$ is the top component of a solution of the *linear* system (14.15), hence is determined by just two numbers, the initial data $(\bar{m}_0, r(0))$, through $w(t) = \Psi(t)w(0)$; and $\bar{m}_0$ is fixed by the problem. *Eliminating* r—that is, solving the offset equation in closed form via the fundamental matrix rather than carrying it as an independent function—leaves a single free scalar, the initial offset $\rho = r(0)$, and a single scalar equation it must satisfy, namely $D(T)\,\rho = (\text{const})\,\bar{m}_0$ from the lemma's proof. The operator $I - L$, restricted to the one-dimensional space of genuine freedom that survives the elimination, *is* multiplication by $D(T)$: it is the 1×1 linear map $\rho \mapsto D(T)\,\rho$. Invertibility of $I - L$ is therefore literally the condition $D(T) \neq 0$, and the contraction/Schauder dichotomy of the general theory has collapsed to the invertibility of a 1×1 matrix. When $D(T) = 0$, the kernel is nontrivial—there is a homogeneous mode, a direction in which the best response neither contracts nor expands but fixes, and the equilibrium ceases to be pinned. This is why nonuniqueness in mean field games is a genuine *spectral* phenomenon, an eigenvalue of the linearized best-response operator crossing 1, and not an artifact of weak or generic hypotheses: it is visible here, in the cleanest possible model, as a single computable scalar passing through zero.

The entire question of the LQG equilibrium has thus been distilled to a single binary, $D(T) \neq 0$ versus $D(T) = 0$, carrying with it the spectral reading just given: $D(T) = 0$ is exactly the moment the linearized best-response operator $I - L$ becomes singular, a homogeneous mode opens, and the equilibrium loses its uniqueness. What the present section cannot say is *where*, in the space of model parameters $(s, q, T, \dots)$, the protective inequality $D(T) \neq 0$ holds and where it first fails. That is now a concrete and answerable question—compute the fundamental matrix $\Psi(T)$, form the scalar $D(T)$, and locate its zeros—and it is the question the next section takes up. There we turn the binary "unique iff $D(T) \neq 0$" into the geometry of parameter space, showing first that the monotone region $s \leq 0$ lies safely inside $\{D(T) \neq 0\}$ for every horizon, and then, by computing $D(T)$ in closed form, exactly how far beyond monotonicity the uniqueness region actually extends before the first conjugate zero of $D(T)$ closes it off.

14.5 Uniqueness, monotonicity, and the phase diagram

The previous section distilled the entire LQG equilibrium to one binary, $D(T) \neq 0$ versus $D(T) = 0$, and read that binary spectrally: by remark 14.7, $D(T)$ is the determinant of the 1×1 linear map to which the best-response operator $I - L$ collapses, so $D(T) \neq 0$ is exactly the statement that $I - L$ is invertible, that no homogeneous mode is open, and that the equilibrium is uniquely pinned. That is a clean criterion, but it is a criterion evaluated at a *single* point of the model: fix the parameters $(s, q, T, \dots)$, compute $D(T)$, and you learn whether *that* game has a unique equilibrium. It says nothing yet about the shape of the answer as the parameters move. The job of this section is to promote the pointwise binary into a global picture—to ask not "is $D(T) \neq 0$ here?" but "*where*, in the space of model parameters, does the protective inequality $D(T) \neq 0$ hold, and along what surface does it first fail?" The answer to that question is a curve in parameter space separating a region of guaranteed uniqueness from a region where the equilibrium degenerates, and that curve is the phase diagram the chapter has been built to draw.

We attack the question from two complementary directions, and the tension between them is the substance of the chapter. The first attack is *structural and global.* It does not compute $D(T)$ at all; instead it invokes the one general-purpose hypothesis that the whole of Part II offers for uniqueness—the Lasry–Lions monotonicity condition (A-Mon)—and asks where our coupling satisfies it. Where it does, the abstract uniqueness theorem of chapter 11 applies wholesale and forces $D(T) \neq 0$ *for every horizon T at once*, with no calculation and no reference to the fine structure of the dynamics. This is the strength of the structural attack: it is horizon-uniform and robust, buying an entire half-line of safe parameters in a single stroke. But it has an equally sharp weakness. Monotonicity is a *sufficient* condition; it certifies a region inside which uniqueness is guaranteed, but it is silent about everything outside that region. When monotonicity lapses, the structural attack simply stops speaking—it does not assert that uniqueness fails, only that this particular guarantee no longer covers us. By itself it can never locate the true boundary, because it never looks past its own sufficient condition.

The second attack is *explicit and exact*, and it is the one only a fully solvable model affords. Rather than certify a safe region from above, it computes $D(T)$ in closed form and watches for the precise instant the scalar passes through zero. Where the structural attack hands back a conservative inclusion, the exact computation hands back the boundary itself: the first horizon at which $D(T)$ vanishes, as a function of the coupling, is the genuine edge of the uniqueness region, not a sufficient surrogate for it. The whole point of running both attacks is that their two answers *do not coincide*, and the gap between them is the headline of the chapter. One expects, on the physical reading of section 14.1, that monotonicity and uniqueness should change hands together at the sign flip $s = 0$—repulsion stabilizing, imitation destabilizing. The explicit calculation will show instead that the true uniqueness boundary sits *strictly beyond* the monotone region: uniqueness survives the entire non-monotone (imitation) band, all the way to a finite imitation threshold, and is lost only afterward, at a conjugate horizon $T_c(s)$ of the forward–backward system. Monotonicity is sufficient but not necessary, and measuring exactly how far the necessary boundary lies past the sufficient one is what the two-pronged strategy delivers. The interface between the two answers—the monotone surface on one side, the first conjugate zero of $D(T)$ on the other—is the phase boundary, and the band between them is the territory the chapter was written to expose.

The two subsections execute the two attacks in turn. Section 14.5.1 carries out the structural half: it recalls from chapter 11 the precise monotonicity inequality, instantiates it on the LQG running coupling $F[m](x) = \frac{q}{2}(x - s\bar{m})^2$ to find exactly which sign of s makes the coupling monotone (the one-line computation flagged as lemma 14.8 back in the assumption audit), and then shows that in the monotone regime $s \leq 0$ the Lasry–Lions argument forces $D(T) \neq 0$ for every horizon. Section 14.5.2 carries out the explicit half: in a clean normalization it computes $D(T)$ in closed form and locates the critical horizon where it first vanishes, drawing the phase diagram and confirming that its boundary falls in the non-monotone band $s > 0$ rather than at the sign change $s = 0$. We take the structural attack first, both because it is the lighter computation and because pinning down precisely *where* monotonicity holds is what makes the surprise of the second subsection legible: the reader needs the monotone region drawn before the uniqueness region can be seen to overspill it.

14.5.1 When LQG is monotone

We now run the first of the two attacks the parent section laid out—the structural, horizon-uniform one—and it is worth restating exactly what it promises before we cash it in. The whole of Part II offers a single general-purpose hypothesis for uniqueness, the Lasry–Lions monotonicity condition (A-Mon), and where it holds it forces uniqueness *with no calculation at all*: the abstract theorem of chapter 11 applies wholesale, and in our reduced language that means the protective scalar $D(T)$ cannot vanish at *any* horizon. The strategy of this subsection is therefore in two beats. First, find precisely which LQG couplings are monotone—this is a one-line computation that locates the monotone regime exactly at $s \leq 0$, the congestion sign. Second, prove that throughout that regime $D(T) \neq 0$ for every T, so that the repulsive band is certified unique at every horizon in a single stroke. The reason to be precise about *where* monotonicity holds is that this boundary is the foil for the whole chapter: only once the monotone region is drawn exactly can the next subsection's surprise—that the uniqueness region overspills it—be seen for what it is.

Recall from chapter 11 the form of the hypothesis. The Lasry–Lions monotonicity condition for a coupling $F[m](x)$ is the inequality

$$\int_{\mathbb{R}} (F[m](x) - F[m'](x))\,(m - m')(\mathrm{d}x) \geq 0 \qquad \text{for all } m, m' \in \mathcal{P}_2(\mathbb{R}), \tag{14.17}$$

and similarly for the terminal coupling. It is worth a sentence on what this asks. The signed measure

$m-m'$ is the displacement of one population from another; $F[m]-F[m']$ is the resulting change in the cost landscape each agent feels. The pairing in (14.17) measures the correlation between the displacement and the cost change it induces: monotonicity demands that moving mass from m' to m *raises* the cost where the mass went, so that the interaction penalizes agglomeration and pushes populations apart. That is the precise meaning of "repulsion stabilizes," and it is exactly the property that, in chapter 11, made two equilibria collapse onto one. For LQG the coupling is the m-dependent part of the cost (14.3), the running term $F[m](x)=\frac{q}{2}(x-s\bar{m})^2$ with $\bar{m}=\int\xi\,m(\mathrm{d}\xi)$, and because it depends on m only through the scalar mean $\bar{m}$ the pairing collapses to something one can evaluate in a single line.

Lemma 14.8 (Monotonicity of the LQG coupling)**.** *The LQG running coupling $F[m](x)=\frac{q}{2}(x-s\bar{m})^2$ satisfies the Lasry–Lions monotonicity condition (A-Mon) if and only if $qs\le 0$; explicitly,*

$$\int_{\mathbb{R}}\big(F[m]-F[m']\big)\,\mathrm{d}(m-m')\;=\;-\,q\,s\,(\bar{m}-\bar{m}')^2. \tag{14.18}$$

The same computation gives the terminal coupling monotone iff $q_T s_T\le 0$. In particular, since $q,q_T\ge 0$, monotonicity holds exactly for $s\le 0$ and $s_T\le 0$ (repulsive/congestion coupling) and fails for $s>0$ (attractive/imitation coupling).

Proof. Everything hinges on the algebraic shape of the integrand, so we expand it first and integrate second. Subtract the two cost landscapes, taking the common factor $\frac{q}{2}$ out front and expanding the difference of squares,

$$F[m](x)-F[m'](x)=\tfrac{q}{2}\big[(x-s\bar{m})^2-(x-s\bar{m}')^2\big]=\tfrac{q}{2}\big[-2xs(\bar{m}-\bar{m}')+s^2(\bar{m}^2-\bar{m}'^2)\big].$$

The point of writing it this way is that the x^2 terms have cancelled outright—both populations share the same curvature $\frac{q}{2}x^2$, since the mean coupling shifts the parabola but never reshapes it—leaving only a piece *linear* in x and a piece *constant* in x. That split is decisive once we integrate against the signed measure $(m-m')(\mathrm{d}x)$, because the two pieces meet that measure very differently.

The constant-in-x piece, $\frac{q}{2}s^2(\bar{m}^2-\bar{m}'^2)$, carries no x at all, so integrating it against $(m-m')$ pulls the constant out and leaves the bare total mass $\int_{\mathbb{R}}(m-m')(\mathrm{d}x)=1-1=0$: both m and m' are probability measures, so their difference is a signed measure of total mass zero, and any quantity that does not vary with x is annihilated by it. This is the structural reason the imitation *level* drops out and only the imitation *slope* survives. The linear-in-x piece, $-q\,s(\bar{m}-\bar{m}')\,x$, does see the measure: integrating x against $(m-m')$ returns the difference of means, $\int_{\mathbb{R}}x\,(m-m')(\mathrm{d}x)=\bar{m}-\bar{m}'$, by the very definition (14.2) of the mean. Assembling the two contributions, only the linear one remains,

$$\int_{\mathbb{R}}\big(F[m]-F[m']\big)\,\mathrm{d}(m-m')=\tfrac{q}{2}\cdot\big(-2s(\bar{m}-\bar{m}')\big)\cdot(\bar{m}-\bar{m}')=-\,q\,s\,(\bar{m}-\bar{m}')^2,$$

which is the announced defect (14.18). Now read off the sign. The factor $(\bar{m}-\bar{m}')^2$ is a square, hence ≥ 0 and strictly positive whenever the two populations have distinct means; the prefactor is $-qs$. The pairing is therefore ≥ 0 for *every* admissible pair m,m' if and only if $-qs\ge 0$, i.e. $qs\le 0$. Since the cost weight is a genuine penalty, $q\ge 0$, this is exactly the sign condition $s\le 0$. The identical computation with q_T,s_T in place of q,s gives the terminal defect $-q_Ts_T(\bar{m}_T-\bar{m}'_T)^2$ and the terminal condition $s_T\le 0$. ☐

The lemma deserves a moment's interpretation, because the clean form of (14.18) is exactly the quantitative version of the physical slogan that opened this subsection. The Lasry–Lions pairing is not merely nonnegative or negative for LQG; it is the explicit number $-qs(\bar{m}-\bar{m}')^2$, a *monotonicity defect* that measures by how much the coupling fails (or, when negative, satisfies) the condition. For the congestion sign $s<0$ the defect is strictly positive whenever two candidate populations disagree on their mean, and that strict positivity is precisely the wedge the uniqueness argument will drive between any two distinct equilibria. For the imitation sign $s>0$ the defect goes the wrong way: a population displaced toward higher mean *lowers* the cost where the mass went, rewarding agglomeration, which is the analytic fingerprint of the attractive interaction under which multiple self-consistent populations might coexist. At $s=0$ the defect vanishes identically, as it must, since the coupling is switched off and the game degenerates to the isolated control problem. What we have established is thus a sharp dichotomy in the single parameter s: the LQG coupling is Lasry–Lions monotone precisely on the half-line $s \le 0$, and we now show that this entire half-line is certified unique at every horizon.

Theorem 14.9 (Monotone uniqueness)**.** *If $s \le 0$ and $s_T \le 0$, then $D(T) \neq 0$ for every $T>0$, and the LQG equilibrium is unique for every horizon and every initial condition.*

Before the proof, a word on why we give one at all, when lemma 14.8 has just verified (A-Mon) and the abstract theorem of chapter 11 would hand us uniqueness directly. The reason is that the abstract theorem speaks in the wrong currency for this chapter. It concludes "the two equilibrium *measures* coincide," whereas the entire phase analysis is metered by the scalar $D(T)$, and what we need is the sharper statement that $D(T) \neq 0$—that the homogeneous linear BVP has no nontrivial mode—throughout the monotone region. The two are equivalent by lemma 14.5, but the equivalence runs through the very object we want to control, so it is cleaner, and more illuminating, to prove the $D(T) \neq 0$ statement head-on with an energy identity built directly on the reduced system (14.15). The argument is the LQG shadow of the general Lasry–Lions energy estimate—the one that pairs the two equilibria against $F[m_1]-F[m_2]$ and plays the monotone sign against the convex sign of the Hamiltonian (A-Conv)—but here it collapses to a single scalar function of time whose derivative we can write in one line.

Proof. We argue the contrapositive packaged through $D(T)$. By lemma 14.5, $D(T)=0$ holds if and only if the *homogeneous* two-point boundary value problem—system (14.15) with the data $\bar{m}_0=0$ and $r(T)=-q_T s_T \bar{m}_T$—admits a nontrivial solution $(\bar{m}_\cdot, r(\cdot))$. It is therefore enough to show that under $s \le 0$, $s_T \le 0$ the homogeneous problem has *only* the trivial solution; the conclusion $D(T) \neq 0$ then follows for every T, and uniqueness of the equilibrium follows from theorem 14.6. So suppose $(\bar{m}_\cdot, r(\cdot))$ solves the homogeneous BVP, and consider the scalar

$$\mathcal{E}(t) \;:=\; \bar{m}_t\, r(t), \tag{14.19}$$

the product of the two BVP components—an "energy" in the sense that its monotone behavior will trap the system at zero. Everything reduces to differentiating it.

The energy identity. Abbreviate the closed-loop gain by $g(t) := a - b^2 P(t)$, exactly the quantity theorem 14.2 guaranteed to be bounded and continuous. In this notation the homogeneous system

(14.15) is the pair

$$\dot{\bar m}_t = g(t)\,\bar m_t - b^2\,r(t), \qquad \dot r(t) = q\,s\,\bar m_t - g(t)\,r(t),$$

where we have used that the matrix $M(t)$ of (14.15) has lower-left entry qs and that its two diagonal entries are exactly g and its negative, $a - b^2 P$ on top and $-(a - b^2 P)$ on the bottom. That equal-and-opposite diagonal—the substitution $2(b^2 P - a) = -2g$ written into both rows—is the structural fact that makes the next line clean, so we keep it in view. Differentiating (14.19) by the product rule and inserting the two equations,

$$\dot{\mathcal{E}} = \dot{\bar m}_t\,r + \bar m_t\,\dot r = \big(g\,\bar m_t - b^2 r\big)\,r + \bar m_t\big(qs\,\bar m_t - g\,r\big) = \underbrace{g\,\bar m_t r - g\,\bar m_t r}_{=\,0} - b^2 r^2 + qs\,\bar m_t^2.$$

The two cross terms $+g\,\bar m_t r$ and $-g\,\bar m_t r$ cancel *precisely* because the diagonal entries of M are negatives of one another; this is where the antisymmetric diagonal earns its keep, and it is what leaves a derivative free of the gain g altogether:

$$\dot{\mathcal{E}}(t) \;=\; -\,b^2\,r(t)^2 \;+\; q\,s\,\bar m_t^2. \tag{14.20}$$

Now read the signs. The first term $-b^2 r^2$ is ≤ 0 unconditionally, since $b^2 > 0$. The second term $qs\,\bar m_t^2$ is the product of $q \ge 0$, of $s \le 0$ (the monotone hypothesis, here doing its one and only job), and of the square $\bar m_t^2 \ge 0$, hence also ≤ 0. Therefore $\dot{\mathcal{E}} \le 0$ on all of $[0, T]$: the energy is nonincreasing.

The endpoint pincer. A nonincreasing function is squeezed to zero if its value at the later time is at least its value at the earlier time. We check exactly that. At the initial time the homogeneous datum $\bar m_0 = 0$ gives

$$\mathcal{E}(0) = \bar m_0\,r(0) = 0,$$

whatever the (unknown) initial offset $r(0)$ is. At the terminal time the boundary condition $r(T) = -q_T s_T\,\bar m_T$ gives

$$\mathcal{E}(T) = \bar m_T\,r(T) = -q_T s_T\,\bar m_T^2.$$

Here the terminal hypothesis enters: $q_T \ge 0$ and $s_T \le 0$ make $-q_T s_T \ge 0$, and $\bar m_T^2 \ge 0$, so $\mathcal{E}(T) \ge 0$. We thus have a nonincreasing function with $\mathcal{E}(0) = 0$ at the left end and $\mathcal{E}(T) \ge 0$ at the right end. But a nonincreasing function cannot rise, so $\mathcal{E}(T) \le \mathcal{E}(0) = 0$; combined with $\mathcal{E}(T) \ge 0$ this forces $\mathcal{E}(T) = 0$, and then $\mathcal{E}$ is pinned between its two equal endpoint values and must be *constant*, $\mathcal{E} \equiv 0$, with $\dot{\mathcal{E}} \equiv 0$ throughout. This is the pincer: monotonicity bounds the energy from above by its initial value 0, while the terminal sign condition bounds it from below by 0, and the two bounds collide.

Collapse to the trivial solution. With $\dot{\mathcal{E}} \equiv 0$, the identity (14.20) reads $0 = -b^2 r^2 + qs\,\bar m^2$ at every time. Both terms on the right are ≤ 0 and they sum to zero, so each vanishes separately: $b^2 r(t)^2 \equiv 0$ and $qs\,\bar m_t^2 \equiv 0$. Since $b \ne 0$, the first gives $r \equiv 0$. Feeding $r \equiv 0$ back into the first BVP equation leaves $\dot{\bar m}_t = g(t)\,\bar m_t$, a homogeneous linear ODE for $\bar m$ with the initial value $\bar m_0 = 0$; its unique solution is $\bar m \equiv 0$. Hence the only homogeneous solution is the trivial one $(\bar m_\cdot, r(\cdot)) \equiv (0, 0)$. By lemma 14.5 this means $D(T) \ne 0$, and it holds for *every* $T > 0$ because nothing in the argument referred to the length of the horizon—the energy pincer closes at whatever time the interval ends. Uniqueness of the equilibrium for every horizon and every initial condition is then theorem 14.6. $\square$

Theorem 14.9 is the rigorous content of the slogan "repulsion stabilizes the equilibrium," and it is worth pausing on exactly how the slogan is realized in the proof. The stabilizing mechanism is not a vague pressure but the precise sign in (14.20): when the coupling is repulsive, $s \le 0$, the imitation term $qs\,\bar{m}^2$ joins the dissipative control term $-b^2r^2$ on the *same* side of zero, and the energy $\mathcal{E}$ can only fall. With the terminal data on the safe side as well, the only history the system can sustain is the flat one, and no second equilibrium can open. Congestion, that is, drains the homogeneous mode; there is no direction in which the best response can fail to pin the mean.

But now read what the theorem pointedly does *not* claim, because this is the narrative hinge of the entire chapter. It establishes that $s \le 0$ is *sufficient* for uniqueness at every horizon. It says nothing whatsoever about $s > 0$. The natural reflex—encouraged by the physical picture of section 14.1, where attraction lets the population clump and one expects symmetry breaking the instant the coupling flips sign—is to read the boundary of the monotone region, $s = 0$, as the boundary of uniqueness too, so that the slightest imitation would already split the equilibrium. The proof gives no warrant for that reading. Inspect (14.20) again: for small $s > 0$ the term $qs\,\bar{m}^2$ is positive, but it is competing against the strictly negative $-b^2r^2$, and which one wins is a *quantitative* contest between the pull of imitation and the restoring stiffness of the convex control cost—a contest the monotone argument, which only ever needed the easy case where both terms have the same sign, never even had to adjudicate. Monotonicity is sufficient precisely because it makes the contest trivial; it is silent past $s = 0$ precisely because there the contest becomes real. The honest conclusion is therefore the sharp one: *monotonicity is sufficient but not necessary*, and the true edge of uniqueness must be found by actually settling the competition, not by reading off the sign of s.

That is exactly the computation the next subsection performs. Armed with the certainty that the whole repulsive half-line $s \le 0$ is safe at every horizon—the foil now firmly drawn—we push directly into the non-monotone band $s > 0$, compute $D(T)$ in closed form rather than merely bound its sign, and watch where it *first* vanishes. The outcome, which the energy identity above could not have anticipated, is that the uniqueness region overspills the monotone region completely: it covers the entire imitation band up to a finite threshold $s = 1$, and fails only beyond it, at a finite conjugate horizon $T_c(s)$. We turn to that explicit calculation now.

14.5.2 An exactly solvable phase boundary

The previous subsection drew the foil and then, in its closing paragraphs, told us exactly what is left to do. The monotone half-line $s \le 0$ is certified unique at every horizon, but the energy identity (14.20), $\dot{\mathcal{E}} = -b^2r^2 + qs\,\bar{m}^2$, showed that the certificate works only because for $s \le 0$ both terms share a sign. Push into the imitation band $s > 0$ and the two terms oppose each other: the imitation reward $qs\,\bar{m}^2 > 0$ pulls the energy up while the control dissipation $-b^2r^2 < 0$ drags it down, and which prevails is a genuine quantitative contest between the pull of imitation and the restoring stiffness of the convex control cost. Monotonicity never had to adjudicate that contest; the present subsection settles it outright, by computing the solvability scalar $D(T)$ of lemma 14.5 in closed form and watching for the precise instant it passes through zero.

To get a closed form we need the coefficient matrix $M(t)$ of the boundary value problem (14.15) to be *constant* in time, and the only t-dependence in $M(t)$ enters through the closed-loop gain $a - b^2 P(t)$. So we choose the model parameters to make the Riccati curvature P constant. This is a convenience, not a cheat: it fine-tunes the *numbers* so that the phase boundary becomes an elementary function of (s, T), but it does not manufacture the qualitative structure. As we will see, everything in the phase diagram is controlled by the sign of $\det M = \omega^2(s-1)$, and that determinant changes sign at $s = 1$ for any choice of the remaining parameters; the normalization merely strips away the inessential constants so the conjugate-point collision can be read off by hand. We carry out the computation as the chapter's centerpiece.

Worked computation 14.10 (The LQG phase diagram)**.** Take $a = 0$, $b = 1$, running weight $q = \omega^2$ with $\omega > 0$, terminal weight $q_T = \omega$, and no terminal coupling, $s_T = 0$; the running coupling s and the horizon T are the free knobs, and $\sigma > 0$ is arbitrary. Each choice earns its keep. Setting $a = 0$ removes the intrinsic drift, so the only stiffness in the problem is the one the control supplies, and $b = 1$ sets the control authority to unity so that $b^2 P$ is just P. The pairing $q = \omega^2$, $q_T = \omega$ is the one fine-tuning that matters: it places the terminal datum of the Riccati equation (14.7) *exactly* on the equation's stable equilibrium, which freezes the curvature for all time. To see this, substitute the chosen weights into (14.7), which with $a = 0$, $b = 1$, $q = \omega^2$ reads

$$\dot{P} = P^2 - \omega^2, \qquad P(T) = q_T = \omega.$$

Its stationary points are the roots of $P^2 - \omega^2 = 0$, namely $P = \pm\omega$, and these are precisely the roots $\Pi_\pm = (a \pm \sqrt{a^2 + b^2 q})/b^2 = \pm\omega$ of theorem 14.2 with the present constants. The constant function $P(t) \equiv \omega$ satisfies the equation ($\dot{P} = 0$ and $\omega^2 - \omega^2 = 0$) and meets the terminal value $P(T) = \omega$; since the right-hand side $P^2 - \omega^2$ is a polynomial, hence locally Lipschitz, Picard–Lindelöf makes the solution through the terminal value unique, so $P(t) \equiv \omega$ is *the* solution—no other trajectory can share its terminal point. The choice $q_T = \omega$ is exactly what lands the terminal datum on the stable root $P_+ = \omega$ rather than off it; had we taken any other q_T, the curvature would relax toward ω as t runs backward from T but would not be constant, the closed-loop gain $a - b^2 P(t)$ would be genuinely time-dependent, and $D(T)$ would cease to be elementary—without, however, moving the sign change that organizes the diagram. With the curvature frozen, the closed-loop gain is the constant $a - b^2 P(t) \equiv 0 - \omega = -\omega$, and the boundary value problem (14.15) becomes the *constant-coefficient* system

$$\dot{\bar{m}}_t = -\omega\, \bar{m}_t - r(t), \qquad \dot{r}(t) = \omega^2 s\, \bar{m}_t + \omega\, r(t), \qquad \bar{m}_0 \text{ given}, \quad r(T) = 0, \tag{14.21}$$

where the terminal condition is $r(T) = -q_T s_T \bar{m}_T = 0$ because $s_T = 0$. Its coefficient matrix is $M = \left(\begin{smallmatrix} -\omega & -1 \\ \omega^2 s & \omega \end{smallmatrix}\right)$, obtained by reading the gain $a - b^2 P \equiv -\omega$ into the top-left slot, $-b^2 = -1$ into the top-right, the coupling $qs = \omega^2 s$ into the bottom-left, and the negated gain $+\omega$ into the bottom-right. Two invariants of M run the entire analysis. Its trace is $-\omega + \omega = 0$—the equal-and-opposite diagonal we have met before, the structural signature of the forward–backward pairing—and its determinant is

$$\det M = (-\omega)(\omega) - (-1)(\omega^2 s) = -\omega^2 + \omega^2 s = \omega^2(s-1).$$

Because the trace vanishes, the characteristic polynomial $\lambda^2 - (\operatorname{tr} M)\lambda + \det M = \lambda^2 + \det M$ has roots $\lambda = \pm\sqrt{-\det M} = \pm\,\omega\sqrt{1-s}$. These are *real* when $s < 1$ and *imaginary* when $s > 1$, and they collide at the origin precisely at $s = 1$, where $\det M = 0$. This single sign change of $\det M$ at

$s = 1$—a pair of real eigenvalues turning into a conjugate imaginary pair, hyperbolic flow turning into rotation—is the controlling event of the whole phase diagram, and the two regimes it separates are exactly the two cases we now develop.

Regime $s \le 1$ (includes all monotone $s \le 0$). Here $\det M = \omega^2(s-1) \le 0$, the eigenvalues are real, and the flow is hyperbolic. Write $\nu = \omega\sqrt{1-s} \ge 0$, so that $\nu^2 = \omega^2(1-s) = -\det M$. Because M is constant, the fundamental matrix is just the matrix exponential $\Psi(t) = e^{Mt}$, and the vanishing trace makes this exponential elementary. By the Cayley–Hamilton theorem M satisfies its own characteristic equation $M^2 + (\det M)I = 0$, i.e.

$$M^2 = -(\det M)\, I = \nu^2 I,$$

so every even power of M is a scalar multiple of the identity, $M^{2k} = \nu^{2k} I$, and every odd power is the same scalar times M, $M^{2k+1} = \nu^{2k} M$. Splitting the exponential series into its even and odd parts and resumming,

$$e^{Mt} = \sum_{k\ge 0} \frac{(Mt)^{2k}}{(2k)!} + \sum_{k\ge 0} \frac{(Mt)^{2k+1}}{(2k+1)!} = \Big(\sum_{k\ge 0} \frac{(\nu t)^{2k}}{(2k)!}\Big) I + \frac{1}{\nu}\Big(\sum_{k\ge 0} \frac{(\nu t)^{2k+1}}{(2k+1)!}\Big) M,$$

the two scalar series are exactly $\cosh(\nu t)$ and $\sinh(\nu t)$, so

$$\Psi(t) = \cosh(\nu t)\, I + \nu^{-1} \sinh(\nu t)\, M. \tag{14.22}$$

The factor $\nu^{-1}\sinh(\nu t)$ is well defined even at the collision $\nu = 0$, where $s = 1$ and M is nilpotent ($M^2 = 0$): there $\nu^{-1}\sinh(\nu t) \to t$ and (14.22) degenerates to the correct $\Psi(t) = I + tM$. This is the one closed form that covers the whole regime $s \le 1$ continuously, including its right endpoint. Now read off the solvability scalar. Since $s_T = 0$ kills the second term of (14.16), $D(T)$ is simply the lower-right entry $\Psi_{22}(T)$, and from (14.22) that entry is $\cosh(\nu T)$ (from the I part) plus $\nu^{-1}\sinh(\nu T)$ times $M_{22} = \omega$:

$$D(T) = \Psi_{22}(T) = \cosh(\nu T) + \tfrac{\omega}{\nu} \sinh(\nu T) > 0 \quad \text{for all } T > 0.$$

Every term here is strictly positive for $T > 0$—$\cosh \ge 1$, and $\sinh(\nu T)$, ω, ν are all positive—so $D(T)$ can never vanish: there is no horizon at which the BVP becomes singular. By lemma 14.5 the equilibrium is therefore *unique for every horizon*, throughout the whole band $s \le 1$. The decisive point is that this band reaches past the monotone region: monotonicity already failed for every $0 < s \le 1$ (lemma 14.8), yet uniqueness persists undisturbed across that entire imitation strip. This is the chapter's headline made literal—uniqueness outlives monotonicity—and the closed form $D(T) = \cosh(\nu T) + (\omega/\nu)\sinh(\nu T)$ is the explicit witness the energy argument of the previous subsection could never have produced, because the energy argument stopped speaking the moment s crossed zero.

Regime $s > 1$ (strong imitation). Now $\det M = \omega^2(s-1) > 0$, the eigenvalues $\pm i\mu$ with $\mu = \omega\sqrt{s-1} > 0$ are imaginary, and the hyperbolic flow becomes a rotation. The Cayley–Hamilton resummation runs exactly as before, but with the sign of M^2 reversed: now $M^2 = -(\det M)I = -\mu^2 I$, so $M^{2k} = (-1)^k \mu^{2k} I$ and $M^{2k+1} = (-1)^k \mu^{2k} M$, and the same two series resum to the *circular* functions in place of the hyperbolic ones,

$$\Psi(t) = e^{Mt} = \cos(\mu t)\, I + \mu^{-1} \sin(\mu t)\, M.$$

Reading off the lower-right entry just as in the previous regime—$\cos(\mu t)$ from I plus $\mu^{-1}\sin(\mu t)$ times $M_{22} = \omega$—and again using $s_T = 0$ to discard the second term of (14.16), the solvability scalar is now an oscillating function of the horizon,

$$D(T) = \Psi_{22}(T) = \cos(\mu T) + \tfrac{\omega}{\mu}\sin(\mu T). \tag{14.23}$$

Unlike its hyperbolic cousin, this $D(T)$ must vanish: it is a sinusoid of amplitude $\sqrt{1+\omega^2/\mu^2} > 0$, so it crosses zero periodically. The first crossing is the critical horizon. Setting (14.23) to zero and dividing by $\cos(\mu T)$ (legitimate at the first zero, where cos has not yet vanished) gives $1 + (\omega/\mu)\tan(\mu T) = 0$, i.e.

$$\tan(\mu T_c) = -\frac{\mu}{\omega}.$$

Because $\mu/\omega > 0$, the right-hand side is negative, and the smallest positive angle whose tangent is negative lies in the second quadrant: writing $\arctan(\mu/\omega) \in (0, \frac{\pi}{2})$ for the principal value and using $\tan(\pi - \theta) = -\tan\theta$, the first solution is $\mu T_c = \pi - \arctan(\mu/\omega)$. Dividing by μ,

$$T_c(s) \;=\; \frac{1}{\mu}\Big(\pi - \arctan\tfrac{\mu}{\omega}\Big), \qquad \mu = \omega\sqrt{s-1}. \tag{14.24}$$

For every horizon shorter than this, $T < T_c(s)$, the scalar $D(T)$ has not yet reached its first zero, so $D(T) \neq 0$ and the equilibrium is unique by lemma 14.5. At $T = T_c(s)$ the scalar vanishes, and lemma 14.5(2) takes over. What happens there is not one phenomenon but two, and which one the reader sees depends entirely on the prescribed initial mean $\bar{m}_0$. The two cases are the two sub-cases of the lemma's trichotomy, and they deserve to be separated cleanly because they are physically opposite.

The symmetry-breaking face ($\bar{m}_0 = 0$). Suppose the population starts centered, $\bar{m}_0 = 0$. The lemma's terminal constraint $D(T)\rho = -(\Psi_{21}(T) + q_T s_T \Psi_{11}(T))\bar{m}_0$ has a right-hand side proportional to $\bar{m}_0$, hence *zero*; at $T = T_c$ its left-hand side $D(T_c)\rho$ is also zero for every ρ, so the equation $0 = 0$ imposes no condition at all on the initial offset. Every value of $\rho = r(0)$ is admissible, and each nonzero choice launches, through $w(t) = \Psi(t)(0, \rho)^\top$, a distinct nontrivial trajectory $(\bar{m}_\cdot, r(\cdot))$ that solves the homogeneous BVP and reproduces $\bar{m}_0 = 0$. The symmetric equilibrium $(\bar{m}_\cdot, r) \equiv 0$ is still present, but it is now surrounded by a *one-parameter family* of asymmetric companions: the mean is no longer pinned: the population can self-consistently organize itself onto a continuum of distinct centered-but-drifting histories. This is a continuous symmetry breaking, the conjugate-point analogue of a pitchfork, and it is the first appearance in the chapter of genuine multiplicity.

The non-existence face (generic $\bar{m}_0 \neq 0$). Suppose instead the population starts off center, $\bar{m}_0 \neq 0$, as a generic datum will. Now the right-hand side of the same constraint need not vanish, and at $T = T_c$ the equation reads $0 = -\Psi_{21}(T_c)\,\bar{m}_0$ (the $q_T s_T$ term being absent since $s_T = 0$). This is no longer an equation for ρ—the unknown has dropped out entirely—but a *constraint on the datum* $\bar{m}_0$, and it is satisfied only if $\Psi_{21}(T_c) = 0$. We check that it is not. From the oscillatory fundamental matrix, the lower-left entry is $\Psi_{21}(t) = \mu^{-1}\sin(\mu t)\,M_{21} = \omega^2 s\,\mu^{-1}\sin(\mu t)$, and at $t = T_c$ the angle $\mu T_c = \pi - \arctan(\mu/\omega)$ lies in $(\frac{\pi}{2}, \pi)$, so $\sin(\mu T_c) > 0$; together with $\omega^2 s > 0$ this makes $\Psi_{21}(T_c) \neq 0$. The constraint $\Psi_{21}(T_c)\,\bar{m}_0 = 0$ therefore fails for every $\bar{m}_0 \neq 0$: no initial offset can steer the trajectory onto the required terminal value, and *no equilibrium exists* at $T = T_c$. The same conjugate horizon that opened a continuum of equilibria for the centered population annihilates the equilibrium altogether for an off-center one. These are the two faces of the single event $D(T_c) = 0$: at $\bar{m}_0 = 0$ the homogeneous mode is a free direction and multiplicity blooms; at $\bar{m}_0 \neq 0$ that same mode obstructs solvability and the problem is overdetermined.

Past the first conjugate horizon the sinusoid (14.23) continues to oscillate. For $T > T_c(s)$, away from the discrete set of further zeros—the successive solutions of $\tan(\mu T) = -\mu/\omega$, spaced by π/μ in the angle—$D(T)$ is again nonzero and the equilibrium again unique, though D has changed sign on crossing T_c, so the comparative statics (the sign of the offset $r(0)$ as a function of $\bar{m}_0$ in lemma 14.5) reverse across each conjugate horizon. The geometry of the boundary is governed by the two limits of (14.24). As $s \downarrow 1$, $\mu = \omega\sqrt{s-1} \to 0$, the arctangent vanishes, and $T_c \sim \pi/\mu \to \infty$: the boundary recedes to infinite horizon, smoothly matching the hyperbolic regime where $D(T) > 0$ at *every* finite horizon. As $s \to \infty$, $\mu \to \infty$, $\arctan(\mu/\omega) \to \frac{\pi}{2}$, and $T_c \sim \pi/(2\mu) \to 0$: arbitrarily strong imitation destabilizes arbitrarily fast, the unique-region shrinking to a vanishing sliver of short horizons.

It remains to account for the cost stiffness q, the third axis of the (s, q, T) phase diagram the thread specification asks for, which the normalization $q = \omega^2$ has folded into the single symbol $\omega = \sqrt{q}$. Far from being lost, that axis is carried by an exact scaling that we can read straight out of (14.24), and the cleanest way to see it is to track what depends on q and what does not. The angle inside the arctangent is

$$\frac{\mu}{\omega} = \frac{\omega\sqrt{s-1}}{\omega} = \sqrt{s-1},$$

which is *independent of* q: it is a pure function of the coupling s. The only q-dependence in T_c therefore sits in the prefactor $1/\mu = 1/(\omega\sqrt{s-1}) = 1/(\sqrt{q}\,\sqrt{s-1})$, so the critical horizon factorizes as

$$T_c(s, q) = \frac{1}{\sqrt{q}}\;\underbrace{\frac{\pi - \arctan\sqrt{s-1}}{\sqrt{s-1}}}_{=:\,C(s)}, \qquad \text{i.e.} \qquad \sqrt{q}\,T_c = C(s) \text{ depends only on } s. \tag{14.25}$$

This is the promised invariance, now demonstrated rather than asserted. The product $\sqrt{q}\,T_c$ is a function of s alone, so the boundary is unchanged under the one-parameter rescaling $(q, T) \mapsto (\kappa^2 q,\, \kappa^{-1}T)$: scaling the stiffness up by κ^2 and the horizon down by κ leaves $\sqrt{q}\,T$ fixed and hence maps the critical surface to itself. Concretely, stronger state-cost stiffness q *contracts* the unique-equilibrium region in T as $1/\sqrt{q}$, pushing the first conjugate point earlier—faithful to intuition, since a stiffer cost makes the offset r respond more violently to the mean and so reaches the destabilizing resonance sooner. The practical consequence is that the third axis is redundant: the single (s, T) slice drawn at $\omega = 1$ (that is, $q = 1$) in fig. 14.1 already captures the full three-parameter picture, provided one reads the horizon in units of $1/\sqrt{q}$. The curve (14.24)—equivalently $T = C(s)/\sqrt{q}$—is what fig. 14.1 plots.

The worked computation has handed us, in closed form, everything the chapter set out to find: a single elementary scalar $D(T)$, positive for all horizons when $s \leq 1$ and a sinusoid with a computable first zero $T_c(s)$ when $s > 1$. We now record the conclusion as a theorem, taking care to state it no more strongly than the closed forms warrant. The temptation is to write "unique if and only if $T < T_c(s)$," but the oscillatory $D(T)$ forbids that biconditional: D vanishes only on a *discrete* set of horizons and is nonzero on each open interval between them, so uniqueness returns past the first conjugate point. The precise statement keeps this in view.

Theorem 14.11 (Phase boundary)**.** *In the normalization of worked computation 14.10, the LQG mean field game has a unique equilibrium for* every *horizon $T > 0$ when $s \le 1$. When $s > 1$ it has a unique equilibrium for all $T < T_c(s)$, with $T_c(s)$ in (14.24) the* smallest *horizon at which uniqueness is lost—the first conjugate point; for $T > T_c(s)$ the equilibrium is again unique for every T* except *the discrete set of further conjugate horizons, the successive zeros of $D(T)$ in (14.23). The locus $\{T = T_c(s) : s > 1\}$ is the phase boundary: it is where uniqueness is* first *lost, at the first conjugate point of the forward–backward system, and is precisely where the linearized best-response operator $I - (\textit{linear part})$ of remark 14.7 first becomes singular.*

Proof. By lemma 14.5 the equilibrium is unique exactly when $D(T) \ne 0$, so the claim is a statement about the zero set of the closed forms for $D(T)$ in worked computation 14.10. For $s \le 1$, $D(T) > 0$ for all T, giving uniqueness at every horizon. For $s > 1$, $D(T) = \cos(\mu T) + \frac{\omega}{\mu}\sin(\mu T)$ in (14.23) is a nonzero sinusoid of T; its zeros are the simple, discrete solutions of $\tan(\mu T) = -\mu/\omega$, the smallest of which is $T_c(s)$ in (14.24). Hence $D(T) \ne 0$ for all $T < T_c(s)$ (uniqueness), $D(T_c) = 0$ (uniqueness lost), and for $T > T_c$ one has $D(T) \ne 0$ off the discrete set of further zeros, where theorem 14.6 again gives a unique equilibrium. Uniqueness therefore fails only on the measure-zero set $\{D(T) = 0\}$, consistent with remark 14.12; the biconditional "unique $\Leftrightarrow T < T_c$" would be false, since uniqueness holds on each open interval between consecutive conjugate horizons. ☐

Physics note

It is worth naming the physical shape of the conjugate-point event, because it is the same one that recurs whenever uniqueness fails in a mean field game. The loss of uniqueness at $T = T_c$ is a *continuous symmetry breaking* of the forward–backward problem. Below the threshold the only self-consistent history of a centered population is the symmetric one, $\bar{m}_\cdot \equiv 0$; at the conjugate horizon the homogeneous mode of lemma 14.5(2) opens, and a continuum of asymmetric histories appears around it (the symmetry-breaking face computed above). This is the exact dynamic analogue of the Curie–Weiss ferromagnet acquiring a continuum of magnetized states below its critical temperature: the symmetric state does not disappear, it merely ceases to be the only one, and the new ones branch off it continuously. The imitation coupling s plays the role of inverse temperature, and the conjugate horizon $T_c(s)$ traces the phase boundary in the (s, T) plane.

The one quantitative lesson the calculation forces—and the lesson that the naive physical guess of section 14.1 got wrong—is that the threshold sits at $s = 1$, not at the sign change $s = 0$. The instability requires a *finite* critical coupling, and the closed forms say exactly why. Imitation contributes the destabilizing term $qs\,\bar{m}^2$ to the energy (14.20), but it must overcome a restoring stiffness supplied by two sources at once: the convex control cost $\frac{1}{2}\alpha^2$, which charges the population for moving, and the Riccati curvature $P \equiv \omega$, which is the accumulated strength of that charge fed back through the value function. In the normalization, those two combine into the gap $\det M = \omega^2(s-1)$, and the gap stays on the stable side until

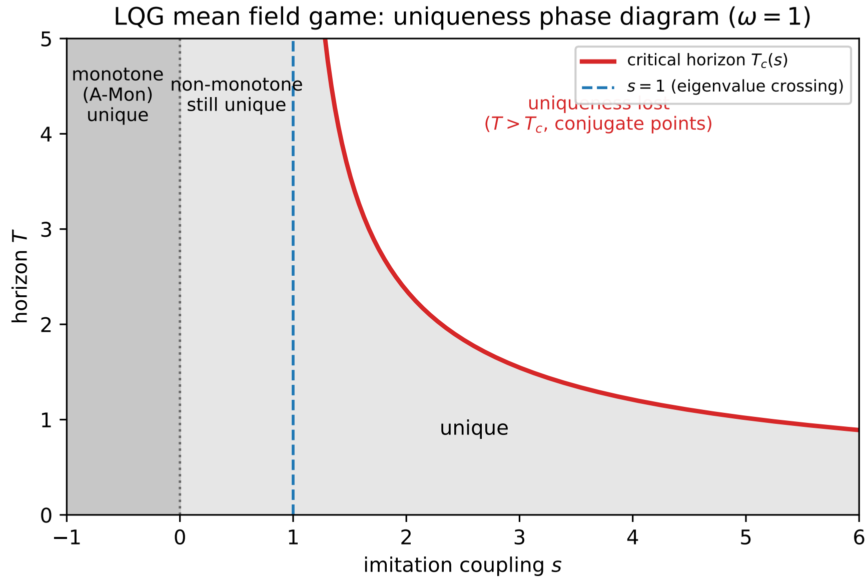

Figure 14.1: The LQG mean field game phase diagram in the normalization of worked computation 14.10 ($a = 0$, $b = 1$, $q = \omega^2$, $q_T = \omega$, $s_T = 0$, $\omega = 1$). For $s \le 1$ the equilibrium is unique at every horizon. For $s > 1$ (strong imitation) uniqueness holds below the critical horizon $T_c(s)$ of (14.24) and is first lost on the boundary; the boundary diverges as $s \downarrow 1$ and collapses to zero as $s \to \infty$. The monotone region $s \le 0$ of theorem 14.9 is shaded; note that uniqueness extends well beyond it, up to $s = 1$.

imitation is strong enough to close it—at $s = 1$. Repulsion, $s \le 0$, contributes a term of the *stabilizing* sign and so, like a screening interaction that can only add to the restoring force, can never reach the threshold from below: this is precisely the physical content of the monotone-uniqueness theorem theorem 14.9. The finite threshold is not an artifact of the normalization; it is the statement that a convex regulator carries an intrinsic stiffness, and imitation must pay a finite price to break it.

Remark 14.12 (Honest scope of "multiplicity")**.** A word of caution is owed about how much the phase boundary actually delivers, because it is easy to over-read fig. 14.1 as a map of a region densely filled with multiple equilibria. It is not. In the strictly linear–quadratic model the degeneracy is confined to the conjugate hypersurfaces $\{D(T) = 0\}$—the curve $T = T_c(s)$ and its successors—and these form a *measure-zero* set in the parameter space (s, q, T). Off them, at every parameter point not landing exactly on a conjugate surface, $D(T) \ne 0$ and theorem 14.6 returns a unique equilibrium. So what the phase boundary marks is not an open basin of many coexisting equilibria but the *onset* of the mechanism that produces them: it is the precursor of multiplicity, the precise locus where the linearized best-response operator first acquires a kernel, not a region where multiplicity is already realized.

The reason the linear model only ever sees the precursor, and not an open multiplicity region, is that its best-response map is exactly affine (remark 14.7), so the singular set of $I - L$ is the zero set of a single analytic scalar $D(T)$, which is generically a hypersurface. Two standard perturbations thicken that hypersurface into a genuine open region, and naming them shows what the linear calculation has isolated. First, reinstating a terminal coupling $s_T \neq 0$ restores the second term $q_T s_T \Psi_{12}(T)$ in (14.16), and for suitable signs this can hold $D(T)$ at zero across an *interval* of horizons rather than at isolated points. Second, and more fundamentally, any nonlinearity in the coupling—a cost that depends on the population *variance*, a non-quadratic congestion term, anything that makes the curvature P feel the mean—destroys the affineness of the best-response map, so that the conjugate point becomes a genuine fold or pitchfork bifurcation at which several solution branches are born and persist on an open neighborhood. The LQG calculation isolates the linear seed of exactly this bifurcation; the bifurcated picture, with its open multiplicity regions, belongs to chapter 11 and the references there. The honest summary is thus that the shaded "unique" region of fig. 14.1 is *exact*, the conjugate boundary is exact, and the boundary is to be read as the threshold of an instability rather than as the edge of a filled basin.

We have now drawn the phase diagram the chapter was built to produce, and the single object it turns on deserves to be named once more before we move on, because the next section is organized entirely around it. The boundary $\{T = T_c(s)\}$ is the *first conjugate point* of the forward–backward system (14.15): the smallest horizon at which the homogeneous two-point problem acquires a nontrivial mode and the solvability scalar $D(T)$ first vanishes. By the spectral reading of remark 14.7, that same event is the moment the linearized best-response operator $I - L$ first becomes singular—an eigenvalue of the best-response linearization crossing through the value that opens a kernel. One event, two names: a conjugate point of a boundary value problem, and a singularity of a fixed-point operator. The chapter's final move is to show that this is not a coincidence of two bookkeeping schemes but a single fact every layer of Part II records in its own language. The next section takes the equilibrium we have just pinned down and the critical event we have just located, and exhibits how the single-agent problem, the analytic HJB–Fokker–Planck system, the FBSDE, the fixed-point map, and—most strikingly —the master equation's decoupling field each see precisely this equilibrium and precisely this $D(T_c) = 0$, the decoupling field blowing up exactly where the best-response operator goes singular. We turn to that assembly now.

14.6 Every layer of Part II, on one model

The previous section ended by giving the phase boundary two names for one event: the first conjugate point of the forward–backward system (14.15), where the solvability scalar $D(T)$ first vanishes, and the singularity of the linearized best-response operator $I - L$ of remark 14.7, where one eigenvalue first crosses the value that opens a kernel. We claimed there that this coincidence is not an artifact of two bookkeeping schemes but a single fact that every layer of Part II records in its own dialect. Redeeming that claim is the business of this section, and it is also where the capstone keeps the promise the chapter preamble made: that each chapter of Part II would reappear here not as a citation but as an *explicit object* computed on the one model. We now make that assembly, walking the layers in the order the theory was built. Two threads run through the walk and should be watched at every stage. The first is that each layer sees *the same equilibrium*—the quadratic value

(14.6), the Gaussian flow $\mathcal{N}(\bar{m}_t, V_t)$, the offset r solving the boundary value problem—packaged in whatever language that chapter speaks. The second, and the sharper one, is that each layer also sees *the same critical event*: the conjugate point at $T_c(s)$ where $D(T)$ vanishes is, in the analytic picture a loss of solvability, in the probabilistic picture a singularity of the decoupling field, in the fixed-point picture the moment $I - L$ acquires a kernel, and—most strikingly, and proved in full below—in the master-equation picture the finite-time blow-up of a second Riccati coefficient Q. By the end of the section these will be visibly one event, and the chapter's assembly will be complete.

Single-agent control (chapter 6). The first layer is the one with no game in it at all, and it is the atom out of which every later layer is built. Freeze the population flow at a constant, $\bar{m}_t \equiv \bar{m}$; then the cost (14.3) no longer couples one agent to another, and the coupling term $s\bar{m}$ survives only as a fixed external target. What remains is precisely the single-agent linear–quadratic regulator of chapter 6: the HJB equation (14.4) with $\bar{m}_t$ a prescribed constant, whose value function is the quadratic (14.6), with curvature P from the Riccati equation (14.7) and offset r from the now-decoupled linear equation (14.8), and whose minimizer is the linear-state feedback (14.10), the classical LQ controller. Everything the rest of the chapter does to this atom is carried by the two channels the audit of section 14.2 already isolated: the curvature P is *population-blind*, computed once and for all from the cost data and globally defined by theorem 14.2, while the entire trace of the crowd is funneled into the single linear channel r. The critical event of the chapter cannot yet be seen at this layer, precisely because there is no loop to close—freezing $\bar{m}$ severs the very self-consistency whose breakdown is the conjugate point. The atom is healthy at every horizon; the disease lives in the assembly, which is the rest of Part II.

The analytic MFG system (chapter 8). Unfreeze the mean and the atoms must talk to one another; the instrument for that conversation is the coupled HJB–Fokker–Planck system of chapter 8, and for LQG it is sitting in front of us already. The pair $\{(14.4)$ backward, (14.12) forward$\}$ *is* that system, specialized to a quadratic value u and a Gaussian density m. What chapter 8 insisted was the structural heart of the difficulty is here made visible in the cleanest possible form: the two equations run in *opposite directions of time*. The HJB equation (14.4) carries terminal data at $t = T$ and is integrated backward, because value is computed by looking ahead to the cost still to be paid; the Fokker–Planck equation (14.12) carries initial data at $t = 0$ and is integrated forward, because the population is pushed ahead from where it started. Neither can be solved without the other, and the only place they touch is the scalar pair $(\bar{m}_t, r(t))$: the forward equation needs the backward variable r to know its closed-loop drift, and the backward equation needs the forward variable $\bar{m}$ to know its target. This is the same observation that organized section 14.3 and section 14.4, now read as the Part II layer it instantiates. And it already tells us where to look for the critical event: it cannot live in (14.4) alone, which is globally well posed by theorem 14.2, nor in (14.12) alone, which is a benign linear Fokker–Planck equation; it can only live in the *handshake* between them, the demand that the forward $\bar{m}$ and the backward r be mutually consistent. That handshake is the next layer.

The probabilistic FBSDE (chapter 9). The same handshake has a probabilistic shadow, and seeing the two pictures land on the identical boundary value problem is worth the few lines of algebra it takes. The stochastic maximum principle of chapter 9 attaches to the state (14.1) an *adjoint* (co-state) process Y_t tracking the marginal value of the state along the optimal trajectory; for the quadratic value (14.6) it is the gradient read along the path,

$$Y_t = \partial_x u(t, X_t) = P(t)\, X_t + r(t),$$

which is *affine in the state*. This is the LQG instance of the general decoupling field of chapter 9: the object that expresses the backward unknown as a deterministic function of the forward state, and so disentangles the forward–backward coupling. The pair (X, Y) solves the McKean–Vlasov forward–backward SDE

$$\mathrm{d}X_t = (aX_t - b^2 Y_t)\;\mathrm{d}t + \sigma\;\mathrm{d}W_t, \qquad \mathrm{d}Y_t = -\big(aY_t + q(X_t - s\bar{m}_t)\big)\;\mathrm{d}t + Z_t\;\mathrm{d}W_t, \quad Y_T = q_T(X_T - s_T\bar{m}_T),$$

the forward equation being (14.1) with the optimal control $\alpha^* = -bY_t$ inserted, and the backward equation the adjoint (Pontryagin) equation, coupled to the population through $\bar{m}_t$. Now take expectations and watch (14.15) fall out. Because both drifts are affine and the Itô integrals are zero-mean martingales, the expectation passes through; writing $\bar{m}_t = \mathbb{E}[X_t]$ and using the affine adjoint to get $\mathbb{E}[Y_t] = P(t)\bar{m}_t + r(t)$, the forward equation gives

$$\dot{\bar{m}}_t = a\,\bar{m}_t - b^2\,\mathbb{E}[Y_t] = a\,\bar{m}_t - b^2(P\bar{m}_t + r) = (a - b^2P)\,\bar{m}_t - b^2 r,$$

which is exactly the top row of (14.15), the mean ODE (14.13). For the bottom row, take expectations of the backward equation, $\frac{\mathrm{d}}{\mathrm{d}t}\mathbb{E}[Y_t] = -a\,\mathbb{E}[Y_t] - q(\bar{m}_t - s\bar{m}_t)$, and substitute $\mathbb{E}[Y_t] = P\bar{m}_t + r$ on the left, differentiating by the product rule, $\dot{P}\bar{m}_t + P\dot{\bar{m}}_t + \dot{r}$. Replacing $\dot{P}$ by the Riccati right-hand side (14.7) and $\dot{\bar{m}}_t$ by the mean ODE just obtained, the curvature terms $\dot{P}\bar{m} + P\dot{\bar{m}} = (-aP - q)\bar{m} - b^2Pr$ collect, and after cancelling the common $-aP\bar{m} - q\bar{m}$ against the right-hand side the residue is precisely

$$\dot{r} = (b^2P - a)\,r + qs\,\bar{m}_t,$$

the offset equation (14.8), i.e. the bottom row of (14.15). So the probabilistic and analytic pictures do not merely resemble each other; taking expectations of the FBSDE *reproduces* (14.15) *on the nose*. The reason the two pictures agree is structural and worth stating once: the affine decoupling field $Y_t = PX_t + r$ is nothing but the gradient $\partial_x u$ of the quadratic value, so the probabilistic adjoint and the analytic offset are the same object viewed from two sides—one as a pathwise co-state, the other as a coefficient of the value function. The critical event reappears here too, now wearing its chapter 9 name: the conjugate point $T_c(s)$ is exactly the horizon at which this decoupling field ceases to exist globally, the FBSDE losing its unique solvability where $D(T)$ vanishes.

Existence (chapter 10). The general theory establishes existence by a fixed-point argument: chapter 10 builds the best-response map S, which sends a candidate mean flow to the mean the best-responding population actually produces, and finds an equilibrium as a fixed point $\bar{m}_\cdot = \mathsf{S}(\bar{m}_\cdot)$ via Schauder—a continuous self-map of a compact convex set of measures must fix a point. For LQG that whole apparatus collapses, and the collapse is instructive rather than merely convenient. As remark 14.7 showed, the LQG best-response map is exactly *affine*, $\mathsf{S}(\bar{m}_\cdot) = L\,\bar{m}_\cdot + \beta$, because it is the composition of the two linear solves (14.8) and (14.13); an affine fixed point $(I - L)\bar{m}_\cdot = \beta$ exists and is unique exactly when $I - L$ is invertible, and the elimination of lemma 14.5 showed that $I - L$, restricted to the one direction of genuine freedom that survives, is multiplication by the single scalar $D(T)$. So existence and uniqueness reduce to the one inequality $D(T) \neq 0$, recorded in theorem 14.6. The compactness and continuity inputs the Schauder argument needs are still present—they are what make S well defined—but they have become inert: the quadratic structure trivializes the search for a fixed point to the invertibility of a 1×1 linear map. And once again the critical event is visible in this layer's language: $D(T) = 0$ is precisely where $I - L$ stops being invertible, where the affine fixed point ceases to be uniquely determined. Existence and uniqueness do not fail because a hypothesis of the abstract theorem lapses; they fail because a computable eigenvalue crosses through zero.

Uniqueness and monotonicity (chapter 11). The general uniqueness theory of chapter 11 runs on the Lasry–Lions monotonicity condition, and the LQG model makes both the condition and its limits perfectly explicit. lemma 14.8 evaluated the monotonicity pairing in closed form and found it equal to the single number $-qs(\bar{m} - \bar{m}')^2$, a *monotonicity defect* whose sign locates the monotone regime exactly at the congestion half-line $s \leq 0$. On that half-line theorem 14.9 certifies uniqueness at every horizon, and it does so by the LQG shadow of the chapter 11 energy estimate: the scalar energy $\mathcal{E}(t) = \bar{m}_t r(t)$ obeys the one-line identity $\dot{\mathcal{E}} = -b^2 r^2 + qs\,\bar{m}^2$, both of whose terms share the safe sign when $s \leq 0$, trapping the only homogeneous mode at zero. This is the structural, horizon-uniform half of the phase story. Its limit is equally explicit, and it is the hinge of the chapter: the energy argument needs both terms of $\dot{\mathcal{E}}$ to share a sign, which they do only for $s \leq 0$; the instant s turns positive the imitation term $qs\,\bar{m}^2$ opposes the dissipation $-b^2 r^2$, the certificate falls silent, and only the explicit computation of $D(T)$ can say what happens. The phase boundary theorem 14.11 is exactly the locus where this monotone protection lapses and is not replaced—the first conjugate horizon $T_c(s)$, sitting strictly beyond the monotone region, in the band $0 < s \leq 1$ where (A-Mon) has already failed but uniqueness still holds, and on past $s = 1$. Monotonicity, in this layer's language, is the sufficient condition whose boundary the true uniqueness boundary overspills.

The master equation (chapter 12). We arrive at the deepest layer, and the one in which the critical event of the chapter shows its true face. The master equation of chapter 12 replaces the coupled HJB–Fokker–Planck *system* by a single scalar PDE $U(t, x, m)$ on $[0, T] \times \mathbb{R} \times \mathcal{P}_2(\mathbb{R})$, whose value $U(t, x, m)$ is the equilibrium cost of an agent currently at state x when the population it faces is the measure m. Its virtue is that it carries the *whole* equilibrium correspondence in one object: differentiating U in x gives the feedback for every population state at once, so U knows the answer before the forward–backward loop is ever run. For LQG that object collapses dramatically, for the same reason the cost did: U can depend on the population m only through the scalar mean $\mu = \bar{m}$, since that is the only feature of the crowd the cost (14.3) can feel. And, just as in section 14.2, the master equation preserves quadratics, so it admits the quadratic-in-(x, μ) ansatz

$$U(t, x, \mu) = \tfrac{1}{2}P(t)x^2 + Q(t)\,x\mu + \tfrac{1}{2}R(t)\,\mu^2 + (\text{terms independent of } x). \tag{14.26}$$

Three coefficients now carry the model, where the value function (14.6) had two. The coefficient of x^2 obeys the *same* Riccati equation (14.7) for P it always has—the curvature is population-blind in the master equation exactly as it was in the value function, a fact worth pausing on, since it means the diagonal Riccati layer is literally identical across all of Part II. The genuinely new object is the cross coefficient $Q(t)$ of $x\mu$, which measures how the agent's marginal value responds to a shift of the population mean. Substituting (14.26) into the master equation and matching the coefficient of $x\mu$—the master-equation operator feeds the $\frac{1}{2}Px^2$ term, the $Qx\mu$ term, and the mean-derivative of U into this slot—produces a *second* Riccati equation,

$$\dot{Q} = b^2Q^2 + 2(b^2P - a)Q + qs, \qquad Q(T) = -q_T s_T, \tag{14.27}$$

whose terminal datum is read from the terminal coupling in (14.3) exactly as $r(T)$ was. The remaining coefficient $R(t)$ of μ^2 solves a linear equation driven by P and Q, and it plays no role we have to track: like the spectator constant $c(t)$ of (14.9) in the value function, R (with the x-independent remainder) merely shifts U uniformly along μ, drops out of the feedback $-b\,\partial_x U$ because that feedback sees only the x-derivative, and so cannot touch the equilibrium or the phase boundary. It is the master-equation analogue of the spectator c, and we record it and move on.

The reason Q is the object to watch is the decoupling identity, and verifying it is the deepest cross-layer computation in the chapter, so we carry out every substitution rather than assert the result. The decoupling-field theorem of chapter 12 (theorem 12.6, equation (12.11)) says that the master field, evaluated along the *equilibrium* population flow m_t, reproduces the value function of the equilibrium: $u(t, x) = U(t, x, \bar{m}_t)$. Reading off the coefficient of x^1 on each side—$r(t)$ on the left from (14.6), $Q(t)\bar{m}_t$ on the right from (14.26)—this asserts the identity

$$r(t) \;=\; Q(t)\,\bar{m}_t. \tag{14.28}$$

We check that (14.28) is consistent with the equations r, Q, and $\bar{m}$ already satisfy. Abbreviate the closed-loop gain by $g := a - b^2P$, so that $b^2P - a = -g$ and in particular $2(b^2P - a) = -2g$; this single rewriting turns the Q-Riccati (14.27) into $\dot{Q} = b^2Q^2 - 2gQ + qs$ and is the only algebra the verification needs. Differentiate the candidate identity (14.28) by the product rule and substitute the two evolution laws—the Q-Riccati in this g-form, and the mean ODE (14.13) with r itself replaced by $Q\bar{m}$, so that $\dot{\bar{m}} = g\bar{m} - b^2r = g\bar{m} - b^2Q\bar{m}$:

$$\frac{\mathrm{d}}{\mathrm{d}t}(Q\bar{m}) = \dot{Q}\,\bar{m} + Q\,\dot{\bar{m}} = (b^2Q^2 - 2gQ + qs)\bar{m} + Q(g\bar{m} - b^2Q\bar{m}).$$

Expand the second product, $Q(g\bar{m} - b^2Q\bar{m}) = gQ\,\bar{m} - b^2Q^2\bar{m}$, and collect by inspection. The two quadratic-in-Q pieces are equal and opposite, $+b^2Q^2\bar{m}$ from the Riccati and $-b^2Q^2\bar{m}$ from the mean term, and *cancel*; the linear-in-Q pieces combine as $-2gQ\bar{m} + gQ\bar{m} = -gQ\bar{m}$; and the source $qs\,\bar{m}$ rides along. What survives is

$$\frac{\mathrm{d}}{\mathrm{d}t}(Q\bar{m}) = (b^2Q^2 - 2gQ + qs + gQ - b^2Q^2)\bar{m} = (-gQ + qs)\bar{m}.$$

Now compute, independently, what the offset equation (14.8) demands of $\dot{r}$ once we impose $r = Q\bar{m}$. In g-notation that equation is $\dot{r} = (b^2P - a)r + qs\,\bar{m} = -g\,r + qs\,\bar{m}$, and substituting $r = Q\bar{m}$ on its right-hand side gives

$$\dot{r} = -g\,Q\bar{m} + qs\,\bar{m} = (-gQ + qs)\bar{m}.$$

The two expressions agree: the time-derivative of $Q\bar{m}$ forced by the Q-Riccati and the mean ODE is identical to the $\dot{r}$ forced by the offset equation, and at $t = T$ the data match as well, since

$r(T) = -q_T s_T \bar{m}_T = Q(T)\bar{m}_T$. By uniqueness for the scalar linear ODE, $r(t) = Q(t)\bar{m}_t$ holds throughout, exactly as the ch12 worked computation worked computation 12.15 records from the master-equation side. The crucial point of the cancellation is that the b^2Q^2 term—the only nonlinearity—is killed precisely by the $-b^2Q\bar{m}$ feedback in the mean ODE; the master equation's second Riccati and the equilibrium's offset are two readings of the very same linear channel r.

Now the identity (14.28) pays off, because it converts the entire phase question into a statement about a single Riccati equation. Since $r = Q\bar{m}$ along equilibrium, the offset stays finite exactly as long as Q does, and the no-blow-up⇔well-posedness correspondence proved for LQG in remark 12.16 sharpens this to: *the equilibrium is unique on* $[0,T]$ *exactly when* Q *stays finite on* $(0,T]$. Where Q blows up, the decoupling field of the master equation ceases to exist, and the equilibrium correspondence the master field was supposed to carry breaks down. It remains to locate that blow-up, and the normalization of worked computation 14.10 makes it elementary. There $a = 0$, $b = 1$, $q = \omega^2$, $P \equiv \omega$, and $s_T = 0$, so the terminal datum is $Q(T) = -q_T s_T = 0$ and the Q-Riccati (14.27) becomes, completing the square,

$$\dot{Q} = Q^2 + 2\omega Q + \omega^2 s = (Q+\omega)^2 + \omega^2(s-1).$$

For $s > 1$ the right-hand side is bounded below by the strictly positive constant $\omega^2(s-1) > 0$: the field has *no real stationary point*, because $(Q+\omega)^2 = -\omega^2(s-1) < 0$ is unsolvable, so nothing can arrest the trajectory. Set $u = Q + \omega$ and $\mu = \omega\sqrt{s-1}$, so that $\dot{u} = u^2 + \mu^2$ with $u(T) = \omega$; this is the elementary Riccati whose solution is $u(t) = \mu\tan(\mu(t-t_0))$, with the phase fixed by $u(T) = \omega$, i.e. $\mu(T-t_0) = \arctan(\omega/\mu)$. Running *backward* from T, the tangent drives $u \to -\infty$ when its argument reaches $-\frac{\pi}{2}$, so Q blows up to $-\infty$ a backward-time

$$T - t_* = \frac{1}{\mu}\Big(\tfrac{\pi}{2} + \arctan\tfrac{\omega}{\mu}\Big) = \frac{1}{\mu}\Big(\pi - \arctan\tfrac{\mu}{\omega}\Big)$$

before the horizon, where we used $\arctan(\omega/\mu) = \frac{\pi}{2} - \arctan(\mu/\omega)$. This is exactly $T_c(s)$ of (14.24): the second Riccati coefficient Q first diverges at precisely the horizon at which $D(T)$ first vanishes. The three statements are now visibly one. The conjugate point of the forward–backward boundary value problem (14.15), the singularity of the linearized best-response operator $I - L$ of remark 14.7, and the finite-time blow-up of the master-equation decoupling field $r = Q\bar{m}$ are the same event, seen in three languages—loss of solvability, loss of invertibility, and divergence of a Riccati coefficient—at the one horizon $T_c(s)$. This is the cross-layer identification the section was written to make.

Finite-player games and the ε-Nash property (chapter 13). The last layer closes the circle back to the finite population the mean field game was an idealization of. Take the genuine N-player game in which agent i pays the cost (14.3) with the population mean $\bar{m}_t$ replaced by the *empirical* mean $\bar{X}_t^N = \frac{1}{N}\sum_j X_t^j$ of the realized states. This game is itself exactly solvable, and watching how the solve goes is what makes the mean-field limit concrete rather than merely asserted. The lever is symmetry. Agent i's running cost $\frac{1}{2}\alpha_i^2 + \frac{q}{2}(X_i - s\bar{X}^N)^2$ is invariant under any permutation of the other $N-1$ labels, because they enter only through the symmetric average $\bar{X}^N$; this *exchangeability* forces the equilibrium value of agent i to depend on the full state vector $\mathbf{X} = (X_1, \dots, X_N)$ only through the pair $(X_i, \bar{X}^N)$—its own state and the crowd average, nothing finer. Since the coupled

HJB system of the N control problems again preserves quadratics, the value of agent i must take the form

$$V^i(t,\mathbf{X}) = \tfrac{1}{2}P^N(t)\,X_i^2 + L^N(t)\,X_i\,\bar{X}^N + \tfrac{1}{2}\,\Pi^N(t)\,(\bar{X}^N)^2 + (\text{terms independent of } X_i), \qquad (14.29)$$

with three time-dependent scalars (P^N, L^N, Π^N) common to all agents by symmetry. The structure of this quadratic is dictated, not assumed: its Hessian in $\mathbf{X}$ is $P^N(t)\,I$, the diagonal self-curvature, plus a rank-one matrix in the all-ones direction $\mathbf{1} = (1,\dots,1)^\top$, inevitable because $\bar{X}^N = \frac{1}{N}\mathbf{1}^\top\mathbf{X}$ couples the agents only through that one direction. This "$P^N I + \text{rank-one}$" Hessian is the finite-N fingerprint of mean-field coupling, and it is the object the matrix calculation of the next section will generalize. Differentiating (14.29) gives the symmetric feedback

$$\alpha_i = -b\,\partial_{X_i}V^i = -b\big(P^N(t)\,X_i + r^N(t)\,\bar{X}^N\big), \qquad r^N = L^N + \tfrac{1}{N}(L^N + \Pi^N).$$

The combination $r^N = L^N + \frac{1}{N}(L^N + \Pi^N)$ repays a careful look, because the entire mean-field limit is hiding in its $\frac{1}{N}$ term. When agent i differentiates $\bar{X}^N = \frac{1}{N}\sum_j X_j$ with respect to its own X_i, it does not get zero: it owns a $\frac{1}{N}$ share of the very average it is best-responding to, and that self-interaction feeds the $X_i\bar{X}^N$ and $(\bar{X}^N)^2$ terms of (14.29) back into its own gradient with weight $\frac{1}{N}$, producing exactly the $\frac{1}{N}(L^N + \Pi^N)$ correction. Substituting this feedback into the N HJB equations and matching the X_i^2, $X_i\bar{X}^N$, and $(\bar{X}^N)^2$ coefficients closes a finite, explicitly solvable system of scalar Riccati ODEs for (P^N, L^N, Π^N), in which every coupling term carries a bookkept power of $\frac{1}{N}$ tracking how much of the population an individual agent constitutes. The mean-field equations are now the $N \to \infty$ limit read off by dropping those $O(1/N)$ self-interaction terms. Drop them and the diagonal curvature decouples: P^N solves the *same* population-blind Riccati equation (14.7) that P does—the curvature is identical across this layer too, up to the $O(1/N)$ correction—so $P^N \to P$, while the offset combination r^N converges to the mean-field offset r of (14.8), each at rate $O(1/N)$. In the limit the all-ones block decouples from the diagonal and the symmetric feedback collapses onto the mean-field controller (14.10): a single agent best-responding to the deterministic flow $\bar{m}_t$ rather than to the fluctuating empirical mean.

The converse direction is the one that justifies the whole enterprise, and the LQG structure makes its rate sharp. Deploy the *mean-field* feedback (14.10)—computed once, ignorant of N—in the actual N-player game; the claim of chapter 13 is that this is an ε-Nash equilibrium, no agent able to gain more than ε by deviating. The generic theorem theorem 13.6 promises only $\varepsilon = O(r_N) = O(N^{-1/2})$ here, that being the fluctuation scale at which the empirical mean of N samples differs from the true mean $\bar{m}_t$ it is standing in for. But for the quadratic cost this generic rate is pessimistic, and the reason is an *envelope* (critical-point) identity worth spelling out, since it is easy to cite and hard to see. A deviating agent's potential gain is the gap between its cost under the mean-field feedback and its cost under the best reply to the realized empirical configuration. Both costs are evaluated at the *same* population perturbation, of size $\delta = O(N^{-1/2})$, the discrepancy between empirical and true mean. Now the mean-field feedback is the exact minimizer of the agent's cost against the true mean, so the first variation of that cost in the control vanishes there—that is the first-order optimality condition. When the population is perturbed by δ, re-optimizing the agent's own control would move it by $O(\delta)$, but because the cost is stationary in the control at the mean-field optimum, that $O(\delta)$ adjustment changes the value only at *second* order, $O(\delta^2)$. The first-order regret—the term linear in δ—is killed by the envelope identity, leaving the deviating agent's advantage at

$O(\delta^2) = O((N^{-1/2})^2) = O(1/N)$. The LQG worked computation worked computation 13.8 carries this cancellation out term by term and pins the constant, upgrading the gap to

$$\varepsilon = \varepsilon_N^{\mathrm{LQG}} \leq \frac{C}{N} \;=\; O(1/N) \tag{14.30}$$

by eq. (13.20)—one full order smaller than the generic bound. This is the quantitative justification, on the carried model, for the substitution at the heart of the whole subject: solving the single mean-field control problem in place of the intractable coupled system of N HJB equations costs an error of only $O(1/N)$, not the naive $O(N^{-1/2})$, precisely because the mean-field feedback sits at a critical point of each agent's cost. See theorem 13.6 and worked computation 13.8 and [82, 40].

The assembly the chapter preamble announced is now complete. Every layer of Part II has reappeared on the one model as an explicit object—the single-agent value and its Riccati curvature, the backward HJB paired with the forward Fokker–Planck, the FBSDE with its affine adjoint, the affine best-response map and its solvability scalar, the monotonicity defect and energy identity, the master equation with its second Riccati Q, and the N-player Riccati system with its $O(1/N)$ corrections—and each has been seen to view the same equilibrium and the same conjugate-point event at $T_c(s)$. What we have *not* yet examined is what, in all of this, ever truly used the state being a single scalar. The answer, as the next section observes, is almost nothing: every reduction above is an identity in linear algebra that survives verbatim when the scalar state becomes a vector and the scalars $(a, b, P, Q, r, \bar{m})$ become matrices and vectors—the one exception being the global solvability of the Riccati equation, whose comparison argument used the ordering of the real line and must be repaired matricially. The final section makes exactly that passage: it rewrites every formula of this chapter in the matrix LQG, repairs the Riccati theory in the multidimensional setting, and then performs the one substitution—replacing the population mean by the graphon-aggregated field $(\mathbb{W}\,\bar{m}_t)(x)$ indexed by type $x \in [0,1]$—that turns this entire single-model picture into the template Part IV generalizes. We turn to that lift now.

14.7 The matrix LQG, and the template for graphons

Matrix LQG. Nothing above used scalarity in an essential way, though the global theory of the Riccati equation does require a genuinely matricial argument, which we supply. For a state $X_t \in \mathbb{R}^d$ with dynamics $\mathrm{d}X_t = (AX_t + B\alpha_t)\,\mathrm{d}t + \Sigma\,\mathrm{d}W_t$ ($A \in \mathbb{R}^{d\times d}$, $B \in \mathbb{R}^{d\times k}$, $\Sigma \in \mathbb{R}^{d\times d'}$, W a d'-dimensional Brownian motion) and cost $\mathbb{E}\int_0^T (\frac{1}{2}\alpha_t^\top R\,\alpha_t + \frac{1}{2}(X_t - S\bar{m}_t)^\top Q(X_t - S\bar{m}_t))\,\mathrm{d}t + \dots$ with cost-weight matrices $R \succ 0$ and $Q \succeq 0$ (these uppercase Q, R are the constant multidimensional cost weights of this section, *not* the time-dependent scalar master-equation coefficients $Q(t), R(t)$ of (14.26)–(14.27)), the value is $u(t,x) = \frac{1}{2}x^\top P(t)x + r(t)^\top x + c(t)$ with the *matrix Riccati equation*

$$\dot{P} = PBR^{-1}B^\top P - A^\top P - PA - Q, \qquad P(T) = Q_T \succeq 0, \tag{14.31}$$

the offset $\dot{r} = (PBR^{-1}B^\top - A^\top)r + QS\bar{m}_t$ with terminal $r(T) = -Q_T S_T \bar{m}_T$, the optimal feedback $\alpha^* = -R^{-1}B^\top(Px + r)$, and the Gaussian flow with mean $\dot{\bar{m}} = (A - BR^{-1}B^\top P)\bar{m} - BR^{-1}B^\top r$ and covariance matrix $\mathbf{V}(t) \in \mathbb{S}^d$ solving the matrix Lyapunov equation

$$\dot{\mathbf{V}} = (A - BR^{-1}B^\top P)\mathbf{V} + \mathbf{V}(A - BR^{-1}B^\top P)^\top + \Sigma\Sigma^\top, \qquad \mathbf{V}(0) = \mathrm{Var}(m_0).$$

The BVP (14.15) becomes a $2d$-dimensional linear two-point problem and $D(T)$ a determinant; the monotonicity defect of lemma 14.8 becomes $-(\bar m - \bar m')^\top QS(\bar m - \bar m')$, monotone precisely when $QS + S^\top Q \preceq 0$, i.e. never for $S = I$, $Q \succ 0$, matching the scalar sign $qs \le 0$ once s is read as a coupling matrix. The one place where the scalar trapping argument of theorem 14.2 does *not* carry over verbatim is global solvability: the field of (14.31) is quadratic on the cone $\mathbb{S}^d$ of symmetric matrices and there is no scalar parabola to trap. The correct generalization is a matrix comparison argument, which we now give in full so that the multidimensional thread is as self-contained as the scalar one. (This discharges the forward reference of chapter 6, which proves the scalar case and defers the matrix Riccati global theory to this chapter.)

Theorem 14.13 (Global solvability of the matrix Riccati equation)**.** *Let $A \in \mathbb{R}^{d\times d}$, $B \in \mathbb{R}^{d\times k}$, $R \succ 0$, and $Q, Q_T \in \mathbb{S}^d$ with $Q \succeq 0$, $Q_T \succeq 0$. Then (14.31) has a unique solution $P \in C^1([0,T];\mathbb{S}^d)$ defined on the whole interval, and $0 \preceq P(t) \preceq \bar P(t)$ for all $t \in [0,T]$, where*

$$\bar P(t) = \Phi_A(T,t)^\top Q_T\,\Phi_A(T,t) + \int_t^T \Phi_A(\tau,t)^\top Q\,\Phi_A(\tau,t)\,\mathrm{d}\tau \tag{14.32}$$

is the cost-to-go of the zero-control problem, with $\Phi_A(\tau,t)$ the state-transition matrix of $\dot y = Ay$ (so $\partial_\tau \Phi_A(\tau,t) = A\,\Phi_A(\tau,t)$, $\Phi_A(t,t) = I$). In particular the closed-loop gain $A - BR^{-1}B^\top P(t)$ is a bounded continuous coefficient.

Proof. The right-hand side of (14.31) is a quadratic polynomial in P, hence locally Lipschitz on $\mathbb{S}^d$, so Picard–Lindelöf gives a unique maximal C^1 solution backward from $P(T) = Q_T$; it stays symmetric because the field maps $\mathbb{S}^d$ to $\mathbb{S}^d$ and the terminal datum is symmetric. Two comparisons bound it on its interval of existence.

Lower bound $P \succeq 0$. Set $K(t) = R^{-1}B^\top P(t)$ and let $\Phi_K(\tau,t)$ be the transition matrix of the closed loop $\dot y = (A - BK)y$. Differentiating

$$\widetilde P(t) \;:=\; \Phi_K(T,t)^\top Q_T\,\Phi_K(T,t) + \int_t^T \Phi_K(\tau,t)^\top\big(Q + K(\tau)^\top R\,K(\tau)\big)\Phi_K(\tau,t)\,\mathrm{d}\tau$$

shows it solves $-\dot{\widetilde P} = (A-BK)^\top \widetilde P + \widetilde P(A - BK) + Q + K^\top RK$, $\widetilde P(T) = Q_T$; expanding and substituting $K = R^{-1}B^\top P$ reduces this to (14.31), so by uniqueness $\widetilde P \equiv P$. As an integral of positive semidefinite matrices ($Q \succeq 0$, $K^\top RK \succeq 0$, $Q_T \succeq 0$), $P(t) = \widetilde P(t) \succeq 0$.

Upper bound $P \preceq \bar P$. The matrix $\bar P$ of (14.32) solves the Lyapunov equation $-\dot{\bar P} = A^\top \bar P + \bar P A + Q$, $\bar P(T) = Q_T$ (differentiate (14.32)). Hence the gap $\Delta = \bar P - P$ satisfies $-\dot\Delta = A^\top\Delta + \Delta A + PBR^{-1}B^\top P$, $\Delta(T) = 0$, whose integrating-factor representation $\Delta(t) = \int_t^T \Phi_A(\tau,t)^\top\big(PBR^{-1}B^\top P\big)(\tau)\,\Phi_A(\tau,t)\,\mathrm{d}\tau$ is again an integral of PSD matrices, so $\Delta(t) \succeq 0$, i.e. $P(t) \preceq \bar P(t)$.

Thus $0 \preceq P(t) \preceq \bar P(t)$ wherever P exists, and $\bar P$ is continuous, hence bounded, on $[0,T]$. A maximal solution of an ODE that stays in a bounded set cannot blow up in finite time, so the maximal interval is all of $[0,T]$, and P is global. Boundedness of P makes $A - BR^{-1}B^\top P$ a bounded continuous coefficient, so the offset and mean equations are linear with bounded coefficients exactly as in the scalar case. ∎

With theorem 14.13 in hand, every layer of this chapter generalizes to the matrix setting with scalars replaced by matrices, sign conditions by definiteness, and the scalar trapping of theorem 14.2 by the comparison (14.32).

Template for graphons (Thread B). The graphon mean field game of Part IV is obtained from this chapter by one substitution: the scalar population mean $\bar{m}_t$ is replaced by the *graphon-aggregated neighbor mean*

$$z_t(x) = (\mathbb{W}\,\bar{m}_t)(x) = \int_0^1 W(x,y)\,\bar{m}_t(y)\,\mathrm{d}y,$$

where $\mathbb{W}$ is the graphon integral operator constructed in chapter 15 (with the underlying operator theory in chapter 2), and now there is a continuum of representative agents indexed by type $x \in [0,1]$, each with its own state X_t^x and its own value function u^x (this is Thread B, whose dynamic development occupies chapter 20 and chapter 22 under (A-Reg-W)). The cost couples a type-x agent to $z_t(x)$ in place of $\bar{m}_t$. The HJB ansatz becomes type-indexed, $u^x(t,x) = \frac{1}{2}P(t)x^2 + r^x(t)x + c^x(t)$, and the curvature Riccati (14.7) is *the same for every type* (it does not see the coupling), while the offset equation (14.8) becomes a family coupled across types through $\mathbb{W}$: $\dot{r}^x = (b^2P - a)r^x + qs\,(\mathbb{W}\bar{m}_t)(x)$. The two reductions promised in the thread specification are now transparent. A constant kernel $W \equiv c$ makes $(\mathbb{W}\bar{m}_t)(x) = c\int_0^1 \bar{m}_t(y)\,\mathrm{d}y$ independent of x and recovers Thread A with rescaled coupling $s \mapsto cs$. A rank-one kernel $W(x,y) = f(x)f(y)$ gives $(\mathbb{W}\bar{m}_t)(x) = f(x)\cdot\varrho_t$ with the *scalar order parameter* $\varrho_t = \int_0^1 f(y)\bar{m}_t(y)\,\mathrm{d}y$ (the canonical symbol $\varrho = \varrho$ of the thread specification, inherited unchanged by chapters 15, 20 and 22), collapsing the entire type-indexed family back to a one-parameter self-consistency equation for ϱ_t—the cleanest graphon worked example, and the direct descendant of the present chapter's scalar BVP. The phase boundary of theorem 14.11 then reappears with s rescaled by the leading eigenvalue of $\mathbb{W}$, which is the precise sense in which the operator norm $\|\mathbb{W}\|$ and the smallness condition (A-Coupling) control uniqueness in Part IV; the threshold $s = 1$ here becomes a threshold on $s\,\|\mathbb{W}\|$ there. This is the template the capstone exists to provide.

Remark 14.14 (Restoring a discount rate)**.** If a discount $\beta = \beta > 0$ is included, with running cost $e^{-\beta t}(\frac{1}{2}\alpha^2 + F)$ or equivalently an infinite-horizon stationary problem, the Riccati equation (14.7) acquires a term $+\beta P$ and, in the stationary limit $T \to \infty$, becomes the algebraic Riccati equation $b^2P^2 - (2a - \beta)P - q = 0$ with the stabilizing root selected. The mean–offset system (14.15) becomes autonomous and the phase analysis of section 14.5 is read off the eigenvalues of the constant matrix M directly; the discount shifts the threshold but does not change the qualitative picture. We keep $\beta = 0$ in the carried thread for definiteness, as fixed in the thread specification.

Rigor ledger

Proved.

- Global solvability and nonnegativity of the scalar Riccati equation under $q, q_T \geq 0$ (theorem 14.2), and of the matrix Riccati equation under $Q, Q_T \succeq 0$, $R \succ 0$ by a symmetric-matrix comparison argument (theorem 14.13, discharging the forward reference of chapter 6); the closed-loop population is an exactly Gaussian flow with decoupled mean and variance ODEs (theorem 14.4).

- Reduction of the LQG equilibrium to the linear two-point BVP (14.15); existence and uniqueness iff the scalar solvability condition $D(T) \neq 0$ holds (lemma 14.5, theorem 14.6).
- The LQG Lasry–Lions monotonicity defect equals $-qs(\bar{m} - \bar{m}')^2$, so (A-Mon) holds iff $s \leq 0$, $s_T \leq 0$ (lemma 14.8); in that regime the equilibrium is unique for every horizon (theorem 14.9).
- A closed-form phase boundary: in the normalization of worked computation 14.10, uniqueness for all T when $s \leq 1$; for $s > 1$ uniqueness for all $T < T_c(s) = \mu^{-1}(\pi - \arctan(\mu/\omega))$, $\mu = \omega\sqrt{s-1}$, with T_c the first conjugate horizon where uniqueness is lost and the discrete successive zeros of D thereafter (theorem 14.11); equivalently, the master-equation coefficient Q of (14.27) first blows up at T_c.

Assumed.

- (A-Nondeg) via $\sigma > 0$ for the Gaussian-density statements; (A-Conv) automatically from the convex quadratic control cost; (A-Growth) coercivity in place of the bounded-Lipschitz cost hypothesis of the generic existence theorem. The linear-quadratic verification theorem of chapter 6 is used without reproof.

Deferred.

- The generic existence (chapter 10), uniqueness/monotonicity (chapter 11), and master equation (chapter 12); here instantiated, not reproved. The N-to-mean-field convergence is imported from chapter 13: the generic ε-Nash bound is $O(N^{-1/2})$ (theorem 13.6), but for LQG the envelope cancellation sharpens the equilibrium gap to $O(1/N)$ (worked computation 13.8, eq. (13.20)), the rate quoted in (14.30).
- The bifurcated multiplicity picture beyond the linear conjugate surfaces (terminal coupling and nonlinear couplings), flagged in remark 14.12 and treated in chapter 11.

Open.

- Sharp characterization of the open multiplicity regions for non-quadratic congestion couplings (no closed form analogous to (14.24) is known); the general non-monotone uniqueness threshold remains a research question (chapter 11, and forward to the graphon case chapter 24).

Bibliographic notes

The linear–quadratic–Gaussian mean field game is the model on which the subject was first made fully explicit. The Nash certainty equivalence formulation and the LQG equilibrium with its decoupled Riccati system are due to Huang, Caines, and Malhamé [82]; the same circle of ideas appears, from the analytic side, in Lasry and Lions [93] and in Cardaliaguet's lecture notes [36]. The probabilistic (FBSDE/decoupling-field) treatment of LQG, including the affine decoupling field used in section 14.6, is developed systematically in Carmona and Delarue [40]; the master-equation reduction (14.26)–(14.27) and the identification of conjugate points with blow-up of the decoupling field follow the master equation theory of [37, 41]. The Lasry–Lions monotonicity computation of lemma 14.8 and the resulting uniqueness theorem are the LQG specialization of [93] as presented in [36]; the reading of multiplicity as a symmetry-breaking/conjugate-point phenomenon is standard in the calculus of variations and is the deterministic shadow of the bifurcation analysis surveyed in [40]. The finite-player convergence and ε-Nash statements specialize [40, 37]. The graphon template of section 14.7 anticipates [34, 108]; the rank-one collapse to a scalar order parameter is the mean-field-game counterpart of the Curie–Weiss closure and is carried out in chapter 20 and chapter 22. Numerical confirmation of the closed-form Riccati answer by a forward–backward solver is the subject of chapter 28, following [1].

Part III

Graphons and Graph Limits

Chapter 15

From Adjacency Matrices to Graphons

This chapter opens Part III and changes the subject. Parts I and II built mean field games on the premise of *homogeneity*: every agent is exchangeable, every agent feels the same population through the same anonymous average, and the "mean field" is a single point $m \in \mathcal{P}_2(\mathbb{R}^d)$ (appendix A.2). Real interacting populations are not like that. An agent in a social, economic, or epidemiological network feels a *weighted* aggregate of *specific* neighbors, and which neighbors matter is fixed by a graph. The program of Part III is to take the $N \to \infty$ limit not of an anonymous crowd but of a structured network, and to find the object that survives that limit. That object is the *graphon*, and this chapter constructs it from the most elementary starting point—an adjacency matrix viewed as a black-and-white image.

We assume very little from earlier chapters here, and what we assume is foundational. From chapter 1 we take Lebesgue measure on $[0, 1]$ and on $[0, 1]^2$, the Lebesgue spaces L^p and their completeness (definition 1.29 and theorem 1.31), and the Fubini–Tonelli theorem (theorem 1.27), which is what licenses the double integrals $\int\int W(x, y)\,(\cdots)\,\mathrm{d}x\,\mathrm{d}y$ that pervade the subject. From chapter 2 we take the geometry of the Hilbert space $L^2[0, 1]$ and—crucially—the fact, already proved there, that the integral operator of a bounded symmetric kernel is a self-adjoint Hilbert–Schmidt operator with a clean spectral theory (definition 2.23, proposition 2.24, theorem 2.26, and worked computation 2.28). That the operator side of the story is already in place is deliberate: it lets this chapter concentrate on the *combinatorial* and *probabilistic* content—how a finite network becomes a kernel—and import the functional analysis when we need it.

The chapter is organized as a single passage from the discrete to the continuum, each stop forced by the one before. We begin in section 15.1 with the pixel picture: an $N \times N$ adjacency matrix read literally as a black-and-white image on the unit square—a $\{0, 1\}$-valued step function whose grid we refine as the network grows. That picture turns out to carry two blemishes, an artefactual grid and an ambiguous labeling, and section 15.2 distils what survives once both are discarded into the definition of a graphon, fixing along the way the type-label reading of the variable $x \in [0, 1]$ with a strong notation watch and restating the Brownian-motion-versus-graphon letter clash that governs all of Part III. To make the refining-grid passage precise as far as is honest at this stage, section 15.3 isolates the one analytic operation the limit rests on—block-averaging, or *stepping*—and shows it is an orthogonal projection, while pointing to where the genuine convergence theorems live (chapters 16 and 17). With the object and its coarse-graining in hand, section 15.4 is a gallery of the graphons the rest of the book leans on—the Erdős–Rényi constant kernel, the stochastic block models, and the rank-one "Curie–Weiss" kernel $W(x, y) = f(x)f(y)$, which carries Thread B and which we develop in a worked computation. Section 15.5 then asks whether node- and edge-weighted generalizations enlarge the theory and finds that, in the dense bounded regime, they do not—they are absorbed by relabeling. Finally section 15.6 returns to the integral operator $\mathbb{W}$, now read as the coupling that will appear in *every* graphon mean field game equation, and establishes the elementary bounds—degree function, Schur estimate, positivity—we use repeatedly in Part IV.

We do not, in this chapter, develop the topology of graphon space or prove that graph sequences converge; that is the business of chapter 16 (homomorphism densities) and chapter 17 (the cut metric and the Lovász–Szegedy compactness theorem). What we do is build the object and learn to recognize it.

Notation watch

The type variable x is not space and not momentum. From here to the end of the book the variable $x \in [0, 1]$ is the *type* or *label* of an agent: an exchangeable index of its kind or its position *in the network*, and nothing more. It is not a spatial coordinate, not a lattice site, and not a momentum. The kernel $W(x, y)$ will often look like a translation-noninvariant hopping amplitude between "sites" x and y, and a reader with a condensed-matter reflex will be tempted to read $|x - y|$ as a distance. Resist this: the interval $[0, 1]$ carries no metric of its own that W respects, and indeed chapter 17 will show that relabeling the types by any measure-preserving map leaves the network unchanged. The number $|x - y|$ has no intrinsic meaning. When a formula invites the spatial reading, we write "type" explicitly. This restates the standing convention of appendix A.5.

Notation watch

Brownian motion and the graphon both want the letter W. In Parts I–II, where no graphon appears, Brownian motion was W_t (rendered W_t), following the standard stochastic-analysis usage of chapter 5. From this chapter onward the letter W is *reserved for the graphon* $W = W(x, y)$ and its operator $\mathbb{W} = \mathbb{W}$. Brownian motion, when it reappears in the dynamic theory of Part IV, is written B_t. Thus in any equation that contains a graphon, W is the kernel and B is the noise; there is no ambiguity because the two never compete for the symbol. This restates the convention of appendix A.5 and is announced once more at the start of Part IV. No Brownian motion appears in the present chapter, which is entirely static.

15.1 The pixel picture

The preamble promised to build the graphon from the most elementary starting point—an adjacency matrix viewed as a black-and-white image—while keeping the variable $x \in [0, 1]$ in its role as a *type* or *label* rather than a point of space. We now make good on both promises with a single move from the discrete to the continuum: take a finite labeled graph, lay its adjacency matrix flat on the unit square as a literal picture, and watch what the picture does as the graph grows. The starting point is therefore a finite network and its adjacency matrix. Before anything else we fix terminology, since the word "graph" is used loosely across fields and the entire construction depends on which object we mean.

Definition 15.1 (Finite graph and adjacency matrix)**.** A *finite simple graph* G is a pair (V, E) with vertex set $V = \{1, 2, \ldots, n\}$ and edge set E a set of unordered pairs of distinct vertices. Its *adjacency matrix* is the symmetric $n \times n$ matrix $A = A(G)$ with entries

$$A_{ij} = \begin{cases} 1 & \text{if } \{i, j\} \in E, \\ 0 & \text{otherwise,} \end{cases} \qquad A_{ii} = 0.$$

The number $n = |V|$ is the *order* of G. A *weighted graph* replaces $\{0, 1\}$ by allowed entries in $[0, 1]$ (an edge *probability* or *intensity*) or in $\mathbb{R}$ (a signed *edge weight*); the matrix remains symmetric with zero diagonal unless loops are explicitly admitted.

The adjacency matrix is a complete description of G—but only *once a labeling of the vertices is chosen.* The integers $1, \ldots, n$ are bookkeeping; nothing intrinsic distinguishes vertex 3 from vertex 7, and a different clerk recording the same network would in general write down a different matrix. Concretely, a relabeling is a permutation $\pi \in S_n$ of $\{1, \ldots, n\}$, and it produces the conjugated matrix $A^{\pi}_{ij} = A_{\pi(i)\pi(j)}$, which describes the *same* graph in the new coordinates. Take the path $1-2-3$ with edges $\{1, 2\}, \{2, 3\}$: its adjacency matrix has the central vertex 2 joined to both ends. Relabel by swapping the names of 1 and 2 and the matrix changes—the entry A_{12} that was 1 now sits in a different place—yet the object on the page is still a path on three vertices. What does *not* change is anything genuinely about the network: the degree sequence $(1, 2, 1)$, the number of edges, whether the graph is connected. A single matrix entry such as A_{12} is meaningful only relative to a labeling; a graph *invariant* is, by definition, a function of the whole conjugacy class $\{A^{\pi} : \pi \in S_n\}$ rather than of A itself.

This relabeling freedom is not a nuisance to be suppressed; it is the central structural fact of the whole theory. The reason is that the limit object we are chasing inherits it intact. Just as a finite network is an adjacency matrix *up to vertex permutation*, the graphon will turn out to be a kernel *up to a measure-preserving relabeling of* $[0, 1]$—the continuum analogue of the symmetric group S_n, with permutations of n blocks replaced by measure-preserving maps of the interval (the precise statement is remark 15.5, and the full quotient theory, built on the cut metric, is the business of chapter 17). Because of this every quantity we construct in the chapters to come—edge density, spectrum, homomorphism density, and ultimately the graphon mean field equilibrium itself—will be engineered to be invariant under relabeling, for otherwise it could not be a property of "the network" at all. For now we simply record the demand: any statement we make must survive $A \mapsto A^{\pi}$.

To take a continuum limit we must put the discrete index $i \in \{1, \ldots, n\}$ onto a continuum. The device is to slice the unit interval into n equal pieces and read the matrix as a picture.

Definition 15.2 (Pixel graphon of a graph)**.** Let G be a (possibly weighted) graph of order n with symmetric matrix $A \in [0, 1]^{n \times n}$. Partition $[0, 1]$ into the n half-open intervals

$$I_i^{(n)} = \left(\tfrac{i-1}{n}, \tfrac{i}{n}\right], \qquad i = 1, \ldots, n$$

(with $I_1^{(n)}$ taken to include 0). The *pixel graphon* (or *empirical graphon*) of G is the function $W^G\colon [0,1]^2 \to [0,1]$,

$$W^G(x,y) = A_{\iota_n(x)\,\iota_n(y)}, \qquad \iota_n(x) = \max(\lceil nx \rceil, 1) \in \{1,\dots,n\},$$

that is, $W^G(x,y) = A_{ij}$ whenever $x \in I_i^{(n)}$ and $y \in I_j^{(n)}$.

The map ι_n is nothing more than "which subinterval does x fall into," read from the inside out: nx rescales $[0,1]$ to $[0,n]$, the ceiling $\lceil nx \rceil$ rounds up to the next integer, and the outer $\max(\,\cdot\,,1)$ exists only to repair the single point $x=0$, sending it to interval 1 instead of to the empty index 0. Thus $x \in I_i^{(n)} = (\frac{i-1}{n}, \frac{i}{n}]$ yields $\iota_n(x) = i$, and the kernel W^G merely looks up the matrix entry A_{ij} of the two blocks that x and y land in. In particular ι_n is constant on each interval, so W^G is constant on each cell—a fact we use at once.

The name is exact: if one draws the unit square, divides it into an $n \times n$ grid of congruent cells $I_i^{(n)} \times I_j^{(n)}$, and shades cell (i,j) black when $A_{ij} = 1$ and white when $A_{ij} = 0$, the resulting image *is* the graph W^G of the function W^G. The adjacency matrix has become a black-and-white picture on the unit square, and a weighted graph becomes a greyscale picture valued in $[0,1]$. The diagonal cells, where $A_{ii} = 0$, form a vanishingly thin white band that will play no measure-theoretic role.

Proposition 15.3 (A pixel graphon is a symmetric measurable kernel)**.** *For any graph G of order n, the pixel graphon W^G is a symmetric, measurable function* $[0,1]^2 \to [0,1]$*; if G is unweighted then W^G is* $\{0,1\}$*-valued. Its integral over the square is the average matrix entry,*

$$\int_{[0,1]^2} W^G(x,y)\,\mathrm{d}x\,\mathrm{d}y = \frac{1}{n^2}\sum_{i,j=1}^{n} A_{ij},$$

which for an unweighted graph equals the edge density $2\,|E|\,/n^2$.

Proof. Consider measurability first. By construction W^G takes the constant value A_{ij} on the rectangle $I_i^{(n)} \times I_j^{(n)}$, and these n^2 rectangles—each a product of two half-open intervals, hence a measurable subset of $[0,1]^2$—partition the square. For any value c, the preimage $\left\{W^G = c\right\}$ is the union of those finitely many cells on which $A_{ij} = c$, a finite union of measurable sets and therefore measurable. A function that takes only finitely many values, each on a measurable set, is by definition a (measurable) simple function, so W^G is measurable. Symmetry is inherited entrywise: for any (x,y),

$$W^G(x,y) = A_{\iota_n(x)\,\iota_n(y)} = A_{\iota_n(y)\,\iota_n(x)} = W^G(y,x),$$

the middle equality being the matrix symmetry $A_{ij} = A_{ji}$. The range of W^G is exactly the set of matrix entries, which is contained in $[0,1]$ for a weighted graph and equals $\{0,1\}$ in the unweighted case.

For the integral, the integral of a simple function is the sum of its values weighted by the measures of the sets on which they are attained (eq. (1.4)). Each cell $I_i^{(n)} \times I_j^{(n)}$ is a product of two intervals of length $1/n$ and so has area $1/n^2$; summing over the n^2 cells gives

$$\int_{[0,1]^2} W^G(x,y)\,\mathrm{d}x\,\mathrm{d}y = \sum_{i,j=1}^{n} A_{ij}\,|I_i^{(n)} \times I_j^{(n)}| = \sum_{i,j=1}^{n} A_{ij}\cdot\frac{1}{n^2} = \frac{1}{n^2}\sum_{i,j=1}^{n} A_{ij}.$$

For an unweighted graph this double sum counts each edge twice: an edge $\{i, j\} \in E$ has $i \neq j$ and contributes the two symmetric entries $A_{ij} = A_{ji} = 1$, while the diagonal contributes nothing because $A_{ii} = 0$. Hence $\sum_{i,j} A_{ij} = 2\,|E|$ and the integral is $2\,|E|\,/n^2$. □

The number $2\,|E|\,/n^2$, the *edge density*, deserves a name now, because it is the first and simplest of the graph invariants that survive the limit. It is manifestly relabeling-invariant—$\sum_{ij} A^{\pi}_{ij} = \sum_{ij} A_{ij}$, since permuting the indices only reorders the terms of the sum—so, unlike a bare entry A_{12}, it is a genuine property of the network and passes the test demanded above. Three readings of this one scalar foreshadow three strands of the book. Combinatorially it is the edge count $|E|$ normalized by n^2. Probabilistically it is the chance that a uniformly random ordered pair of vertices (sampled with replacement) happens to be joined by an edge; in the language of chapter 16 this is the homomorphism density $t(K_2, G)$ of a single edge K_2, the network's most basic "moment," and the entire convergence theory of chapter 16 is built by promoting this one count to the family of counts of all small subgraphs. Analytically—anticipating section 15.6—it is the quadratic form $\langle \mathbb{W}^G \mathbf{1}, \mathbf{1} \rangle = \int_{[0,1]^2} W^G$, the response of the constant unit field $\mathbf{1}$ to the coupling operator. That a single number can be computed as an edge count, as a homomorphism density, and as a quadratic form of $\mathbb{W}$ is the first small instance of the chapter's main lesson: the network reaches everything downstream only through the operator $\mathbb{W}$.

Refining the grid. A single graph gives a single picture at resolution n. The limit object appears when we let the network *grow*. Consider a sequence $(G_n)_{n \geq 1}$ of graphs with $|V(G_n)| \to \infty$ and form the pixel graphons W^{G_n}. Each is a step function on a finer and finer grid. The qualitative expectation—made rigorous only in chapter 17—is that, after the relabeling ambiguity is quotiented out, the sequence of pictures settles down to a limiting greyscale image W on the unit square. That limiting image is the graphon. The following heuristic states the picture; the honest mathematics behind it is deferred, and we are explicit about the deferral.

Heuristic (non-rigorous): The refining-grid limit

Imagine a growing sequence of networks whose macroscopic wiring stabilizes: the fraction of edges between "the first third" and "the last quarter" of the vertices (in some consistent labeling) converges, and likewise for every pair of macroscopic blocks. Then the pixel pictures W^{G_n}, viewed at any fixed coarse resolution, stop changing. Sending the coarse resolution to infinity after the network size, one expects a limiting kernel $W\colon [0,1]^2 \to [0,1]$ whose block averages reproduce all these limiting frequencies. The two obstructions to turning this into a theorem are (i) the labeling: "the first third of the vertices" is not invariant, so the limit can only exist *up to a measure-preserving relabeling of* $[0, 1]$; and (ii) the topology: "the pictures stop changing" must be measured in a norm coarse enough to ignore microscopic reshuffling but fine enough to be a metric; the obvious candidate, the L^2 distance between the pixel pictures, turns out to be too fine—it never forgets the microscopic $0/1$ texture, a concrete failure we exhibit in remark 15.8. Both obstructions are resolved by the cut metric $\delta_\square$ of chapter 17, and the existence of the limit for *every* bounded sequence is the Lovász–Szegedy compactness theorem (chapter 17). Until then we treat "$W^{G_n} \to W$" as a picture, not a proof.

The remainder of this chapter does not depend on section 15.1: we will define the graphon as an object in its own right and study the ones we need by direct computation, leaving the convergence theory to the chapters built for it. But the heuristic has done its job of pointing at the target. We now hold a completely concrete object—the pixel graphon W^G, a symmetric measurable step function $[0,1]^2 \to [0,1]$ whose integral is the edge density—and we have located its only two defects, both of them artefacts of how we drew the picture rather than features of the network: the $n \times n$ *grid*, an accident of the chosen resolution, and the *labeling*, an accident of the chosen vertex names. The next section performs exactly the distillation these two defects demand. It keeps the three properties that are real—symmetry, measurability, and the value range $[0,1]$—discards the grid, and remembers that the labeling is to be quotiented away, arriving at the definition of a graphon and recording that this combinatorial construction agrees on the nose with the operator-side definition of definition 2.23.

15.2 The graphon

The previous section left us holding a completely concrete object together with a precise instruction for what to do with it. The object is the pixel graphon W^G of proposition 15.3: a symmetric, measurable step function $[0,1]^2 \to [0,1]$, the adjacency matrix laid flat as a black-and-white picture. The instruction was the distillation that closed section 15.1: of the properties this picture carries, keep the three that are genuine features of the network—*symmetry*, *measurability*, and the *value range* $[0,1]$—and discard the two that are artefacts of how we happened to draw it, the $n \times n$ grid and the chosen labeling. The grid we throw away now, simply by no longer demanding that the kernel be piecewise constant; the labeling we cannot throw away by fiat, so we carry it as a quotient to be imposed, and the closing remark of this section makes that quotient precise. What is left when the grid is gone is the definition of a graphon.

It pays to be explicit about why exactly those three properties survive and nothing else does. Symmetry survived the proof of proposition 15.3 as the entrywise identity $A_{ij} = A_{ji}$, the algebraic fingerprint of an undirected edge. Measurability survived because a function constant on finitely many rectangles is a simple function, and simple functions are the building blocks of the integral—without it the double integrals $\iint W$ that compute every quantity we care about would be meaningless. The range $[0,1]$ survived because each value is a matrix entry, an edge indicator or probability. The grid did *not* survive: it was the resolution n of one particular picture, and the limit we are chasing is precisely what is left after the resolution is sent to infinity. So we keep the three and drop the grid by allowing *any* symmetric measurable kernel, not only the piecewise-constant ones. This is the residue of proposition 15.3, and it is also—no coincidence, since the operator side was designed to receive it—word for word the kernel already introduced in definition 2.23. We restate it here in this chapter's combinatorial spirit, as the central object of Part III.

Definition 15.4 (Graphon)**.** A *graphon* is a symmetric measurable function

$$W\colon [0,1]^2 \longrightarrow [0,1], \qquad W(x,y) = W(y,x) \ \text{ for a.e. } (x,y).$$

The value $W(x, y)$ is interpreted as the *probability (or intensity) of a link between an agent of type x and an agent of type y.* We write $\mathcal{W}_0$ for the set of all such graphons. This is exactly the symmetric, bounded, measurable kernel of assumption (A-Reg-W) (appendix A.6), and it agrees with definition 2.23.

The definition is short, and that brevity hides three reading conventions that one must internalize before the object behaves the way the rest of the book assumes. None of the three is a new hypothesis; each is a clarification of how to interpret the data already present in definition 15.4. We take them in turn.

The reference measure is Lebesgue, the "uniform distribution of types." Nothing in the symbol $W : [0, 1]^2 \to [0, 1]$ names a measure, yet the moment we integrate—and we only ever use W by integrating—a measure on the type space $[0, 1]$ is in play, and the convention is that it is Lebesgue measure. Reading $x \in [0, 1]$ as the type of an agent, this says the types are spread *uniformly*: a fraction $|B|$ of the population has type in any measurable set $B \subseteq [0, 1]$. The interpretation of the kernel follows by sampling. Draw an agent's type x uniformly at random; then the slice $y \mapsto W(x, y)$ is precisely the *connection density* of that agent across the population—the probability, per unit of type-mass, that it links to a partner of type y—and its total mass $\int_0^1 W(x, y)\, \mathrm{d}y$ is the expected fraction of the population the agent connects to, the continuum degree we will name in section 15.6. One should resist hearing "uniform" as a modeling restriction: it is a *normalization*, not a loss of generality. Real data come with a non-uniform distribution of types—some kinds of agent are common, others rare—and section 15.5 shows that such node weights are absorbed into the kernel itself, by re-coordinatizing the type space so that the weighting becomes uniform again; chapter 17 identifies the freedom in that re-coordinatization with the relabeling freedom of remark 15.5 below. Uniformity is the gauge we fix, not a feature of the world.

Equality of graphons is almost-everywhere equality. The symmetry condition in definition 15.4 already reads "for a.e. (x, y)," and that qualifier is not a fussy technicality but the correct notion of identity for the whole theory. The reason is uniform across the book: W never enters a single formula except through an integral—through the operator $\mathbb{W}$ (definition 2.23), through the homomorphism densities of chapter 16, through the cut norm of chapter 17—and an integral cannot distinguish two kernels that differ only on a Lebesgue-null set. Two graphons that agree almost everywhere therefore produce identical operators, identical densities, identical equilibria; they are, for every purpose here, the *same* graphon. Accordingly we speak of "the" graphon while quietly working with its equivalence class in $L^2([0, 1]^2)$ or $L^\infty([0, 1]^2)$. The most useful instance of this licence is the diagonal: the set $\{x = y\}$ is null in $[0, 1]^2$, so the value of W along it—whether we record self-links $W(x, x)$ or set them to zero in imitation of the zero diagonal of an adjacency matrix—changes no integral and hence changes nothing. We will exploit this in section 15.5 to dispose of self-loops in one line; for now the point is only that the diagonal never matters.

Symmetry is the continuum imprint of undirected edges, and it is what makes $\mathbb{W}$ self-adjoint. The condition $W(x, y) = W(y, x)$ is the limit of the matrix identity $A_{ij} = A_{ji}$, which encoded that an edge between i and j is the same edge as the one between j and i—there is no orientation. In the continuum this single equation buys a great deal of structure. It is exactly the condition under which the integral operator $\mathbb{W}$ of definition 2.23 is *self-adjoint* on $L^2[0, 1]$ (proposition 2.24): for any test fields g, h, $\langle \mathbb{W}g, h\rangle = \int\int W(x,y)g(y)h(x)\, \mathrm{d}y\, \mathrm{d}x$, and swapping the names of the dummy variables together with the symmetry of W turns this into $\langle g, \mathbb{W}h\rangle$. Self-adjointness is not decoration: it is what guarantees, via the spectral theorem already proved in theorem 2.26, that $\mathbb{W}$ has a *real* spectrum and an orthonormal basis of eigenfunctions—the "modes" of the network that organize all of chapter 18 and through which the equilibria of Part IV are diagonalized. Drop symmetry and the edges acquire an orientation: one has a *directed* network, a non-self-adjoint operator with a possibly complex spectrum, and none of the dense undirected machinery of this book applies. That entire theory sits outside our scope precisely because we keep this one equation.

The two notation watches at the head of the chapter already govern the variable x and the letter W, and we do not repeat them. What remains is the single structural point that the rest of Part III is built to formalize, and it is the most important conceptual statement of the chapter: the labeling we deferred when discarding the grid must now be quotiented away, and doing so is what turns "a kernel" into "a network."

Remark 15.5 (The network is the graphon *up to relabeling*)**.** A finite graph and its vertex relabelings $A \mapsto A^\pi$ all describe one and the same network; their pixel graphons W^G are *distinct* functions on the square, related by permuting the blocks $I_i^{(n)}$ that the matrix indices were laid into. Passing to the continuum, ask what plays the role of the relabeling $\pi \in S_n$. A permutation of n equal blocks shuffles the interval $[0,1]$ while preserving the length of every block, hence preserving Lebesgue measure; its continuum analogue is therefore a *measure-preserving bijection* $\varphi\colon [0,1] \to [0,1]$, the smallest closure of the finite permutations that still respects the uniform type distribution fixed above. (One should picture the chain $\pi \in S_n \rightsquigarrow$ "rename which type sits at which point of $[0,1]$, keeping the amount of each type fixed"; the limiting object is exactly a measure-preserving map.) Such a φ acts on a graphon by relabeling both arguments,

$$W^\varphi(x,y) = W(\varphi(x), \varphi(y)),$$

the precise continuum image of $A^\pi_{ij} = A_{\pi(i)\pi(j)}$. Two graphons related by such a φ—or, more generally, lying at *cut distance zero*, which is the fully general statement and the one chapter 17 proves to be the right notion—encode the same network and must therefore yield the same edge density, the same spectrum, the same homomorphism densities, and the same graphon mean field equilibrium. The honest object of the theory is consequently not a single representative $W \in \mathcal{W}_0$ but its entire relabeling class; the cut metric of chapter 17 is built precisely to be a genuine distance on these classes.

This imposes a working discipline that we adopt from here on. We will always compute with some chosen representative W, because one must write *a* function down to integrate it, but every quantity we are entitled to call a property of "the network" must come out the same for W and for W^φ—it must be φ-invariant. The edge density passes this test (relabeling only reshuffles the mass under the integral); the spectrum passes it ($\mathbb{W}$ and $\mathbb{W}^\varphi$ are unitarily equivalent); a bare pointwise value does *not*. The cautionary micro-example to keep in mind is the value at a single point: "W at $x = \frac{1}{2}$" is not a property of the network at all, because a measure-preserving φ can carry $\frac{1}{2}$ to any other point while leaving the network untouched, and in any case $\left\{x = \frac{1}{2}\right\}$ is null and may be edited freely by the previous remark. The rule, stated once and used throughout, is: *treat any feature of a chosen representative that is not φ-invariant as meaningless.* It is the same demand we recorded for finite graphs in section 15.1—"every statement must survive $A \mapsto A^{\pi}$"—now lifted to the continuum.

This relabeling demand is not only a discipline on what we may compute; it also shapes what the next section must build. We have a clean abstract graphon—a symmetric measurable kernel read up to measure-preserving relabeling—but we have not yet honored the promise of section 15.1, that pixel pictures W^{G_n} of a growing network actually converge to such a kernel. That convergence cannot be proved here, and the reason is now sharp: because the network is the graphon only up to φ, "the pictures stop changing" can only be measured after the labeling has been quotiented away, which forces a coarse-resolution comparison rather than a pointwise one. What we *can* do honestly at this stage is isolate and analyze the single operation that such a comparison rests on—viewing a kernel at a coarse resolution by averaging it over blocks, an operation that must, to be admissible, respect the block structure rather than the individual labels. That operation is the stepping operator, and we turn to it now.

15.3 From pixel pictures to graphons: the stepping operator

The previous section closed by converting an open-ended convergence question into a single sharp demand. Because the network is the graphon only *up to* a measure-preserving relabeling φ (remark 15.5), the statement "the pixel pictures W^{G_n} stop changing" cannot be read pointwise: a pointwise comparison sees the labels, and the labels are exactly the data we are not entitled to see. It must be read at a *coarse resolution*—compare two pictures only after each has been averaged over a common family of patches, so that reshuffling labels *within* a patch is invisible while the gross between-patch frequencies are still compared. We cannot yet prove that the patch-averaged pictures converge; that is the cut metric of chapter 17 and the compactness theorem behind it. What we *can* do, fully and honestly, is isolate the one operation that "average over patches" names, define it, and understand it completely. That operation is *stepping*, and the pleasant surprise is that it is nothing more exotic than orthogonal projection in the Hilbert space $L^2([0,1]^2)$ whose geometry chapter 2 already built.

Stepping earns this section for three reasons beyond the convergence question it clarifies. It is the rigorous form of "view the picture at a coarse resolution"; it is the exact bridge between general graphons and the *step graphons*—the stochastic block models—we are about to catalogue in section 15.4, since stepping a graphon *produces* a step graphon; and it is the analytic heart of the weak regularity lemma of chapter 19, the theorem that a *bounded* number of patches already suffices. We develop it now as a self-contained piece of L^2 geometry and harvest the consequences immediately.

To average "over patches" we must first say what a patch is, and then say what a function looks like once it can no longer resolve anything finer than a patch. A patch is a block of types: we cut $[0,1]$ into finitely many measurable pieces $P_1,\ldots,P_k$, and a *rectangle* $P_i \times P_j$ of the square is the set of type-pairs (x,y) with x in block i and y in block j. A kernel that is constant on each such rectangle is one that *cannot tell two types apart once they share a block*—it resolves the type space only down to the partition $\mathcal{P}$. These are the step graphons, and the set of all of them (symmetric or not) is a linear subspace $\mathcal{S}_{\mathcal{P}}$ of $L^2([0,1]^2)$: a sum of two block-constant kernels is block-constant, and so is a scalar multiple. Averaging a kernel over each block—replacing its values on $P_i \times P_j$ by their mean—is then the natural way to push it into $\mathcal{S}_{\mathcal{P}}$, and we will see in a moment that it is the *best* such push, the nearest point of $\mathcal{S}_{\mathcal{P}}$ in L^2. That is the whole content of stepping; we now make it precise.

Definition 15.6 (Step graphons and the stepping operator)**.** Let $\mathcal{P} = \{P_1, \dots, P_k\}$ be a finite partition of $[0,1]$ into measurable sets of positive measure $|P_i| > 0$ (the calligraphic $\mathcal{P}$ here denotes a partition, not a probability-measure set $\mathcal{P}(\cdot)$). A graphon is a *step graphon adapted to* $\mathcal{P}$ if it is (a.e.) constant on every block $P_i \times P_j$; write $\mathcal{S}_{\mathcal{P}} \subset L^2([0,1]^2)$ for the (closed) subspace of all functions, symmetric or not, that are constant on every $P_i \times P_j$. The *stepping operator* $\Pi_{\mathcal{P}} \colon L^2([0,1]^2) \to \mathcal{S}_{\mathcal{P}}$ replaces a kernel by its block averages,

$$(\Pi_{\mathcal{P}} W)(x,y) = \frac{1}{|P_i|\ |P_j|} \int_{P_i \times P_j} W(s,t)\ \mathrm{d}s\ \mathrm{d}t \qquad \text{for } (x,y) \in P_i \times P_j.$$

The definition asserts that $\Pi_{\mathcal{P}}$ lands in $\mathcal{S}_{\mathcal{P}}$ and calls it the "stepping operator," but three claims are doing the real work and each must be earned. First, that $\Pi_{\mathcal{P}}$ is not merely *a* map into the step graphons but the canonical one—the orthogonal projection, the genuinely nearest step graphon—which is what makes the block average the right notion of "viewing at coarse resolution" rather than one arbitrary choice among many. Second, that stepping keeps a graphon a graphon: feed it a symmetric $[0,1]$-valued kernel and it returns one, so the operation stays inside the world of networks. Third, that it conserves the masses we care about, the block frequencies and hence the edge density, so that coarse-graining loses fine texture but not gross bookkeeping—exactly the property a "view at coarse resolution" must have to be useful. The next proposition establishes all three at once, and its proof is short because the first claim does almost all the work: once $\Pi_{\mathcal{P}}$ is identified as an orthogonal projection, the rest is reading off standard projection properties.

Proposition 15.7 (Stepping is orthogonal projection)**.** *Let $\mathcal{P}$ be a finite partition of $[0,1]$ into blocks of positive measure. Then:*

(i) $\Pi_{\mathcal{P}}$ *is the orthogonal projection of $L^2([0,1]^2)$ onto $\mathcal{S}_{\mathcal{P}}$; in particular $\Pi_{\mathcal{P}}^2 = \Pi_{\mathcal{P}}$, $\Pi_{\mathcal{P}}$ is self-adjoint, and $\|\Pi_{\mathcal{P}} W\|_{L^2} \le \|W\|_{L^2}$.*

(ii) *If W is a graphon (symmetric, $[0,1]$-valued) then so is $\Pi_{\mathcal{P}} W$, and it is a step graphon adapted to $\mathcal{P}$.*

(iii) *Stepping preserves all block masses, in particular the edge density: for every i, j,*

$$\int_{P_i \times P_j} \Pi_{\mathcal{P}} W = \int_{P_i \times P_j} W, \qquad \textit{hence} \qquad \int_{[0,1]^2} \Pi_{\mathcal{P}} W = \int_{[0,1]^2} W.$$

Proof. Everything follows from recognizing $\Pi_{\mathcal{P}}$ as the orthogonal projection onto $\mathcal{S}_{\mathcal{P}}$; the one piece of labour is to identify the abstract projection with the concrete block-average formula, and for that we write down an explicit orthogonal basis of $\mathcal{S}_{\mathcal{P}}$.

An orthogonal basis of $\mathcal{S}_\mathcal{P}$. For each ordered pair (i,j) with $1 \le i,j \le k$ let $g_{ij} = \mathbf{1}_{P_i \times P_j}$ be the indicator of the block. A function lies in $\mathcal{S}_\mathcal{P}$ exactly when it is constant on every block, i.e. when it can be written $\sum_{i,j} c_{ij} g_{ij}$ for some scalars c_{ij}; so the g_{ij} span $\mathcal{S}_\mathcal{P}$, and as there are only k^2 of them, $\dim \mathcal{S}_\mathcal{P} = k^2 < \infty$. A finite-dimensional subspace of a normed space is automatically closed, which is why $\mathcal{S}_\mathcal{P}$ deserves the label "closed" attached to it in definition 15.6—we do not have to prove closedness by hand. The basis is orthogonal: if $(i,j) \neq (i',j')$ the rectangles $P_i \times P_j$ and $P_{i'} \times P_{j'}$ are disjoint (because the P_i partition $[0,1]$), so the product $g_{ij}\, g_{i'j'}$ vanishes identically and $\langle g_{ij}, g_{i'j'} \rangle = 0$; while

$$\|g_{ij}\|_{L^2}^2 = \int_{[0,1]^2} \mathbf{1}_{P_i \times P_j} = |P_i|\;|P_j| > 0,$$

the strict positivity being precisely where the hypothesis $|P_i| > 0$ is used—a null block would contribute a zero basis vector and an undefined $0/0$ in the average below.

(i) The projection is the block average. Since $\mathcal{S}_\mathcal{P}$ is closed, the orthogonal projection $P_{\mathcal{S}_\mathcal{P}}$ of $L^2([0,1]^2)$ onto it exists and is unique (theorem 2.5). Because $\{g_{ij}\}$ is an orthogonal basis of the finite-dimensional space $\mathcal{S}_\mathcal{P}$, that projection is computed coordinate by coordinate—this is the Fourier/Parseval expansion (theorem 2.8) applied *inside* $\mathcal{S}_\mathcal{P}$, not in all of $L^2([0,1]^2)$:

$$P_{\mathcal{S}_\mathcal{P}} W = \sum_{i,j} \frac{\langle W, g_{ij} \rangle}{\|g_{ij}\|_{L^2}^2}\, g_{ij}.$$

Now read off the two factors. The numerator is $\langle W, g_{ij} \rangle = \int_{[0,1]^2} W\, \mathbf{1}_{P_i \times P_j} = \int_{P_i \times P_j} W$, the mass of W on the block; dividing by the denominator $\|g_{ij}\|_{L^2}^2 = |P_i|\,|P_j|$ converts that mass into the *average* value of W over the block. So the coefficient of g_{ij} is exactly $\frac{1}{|P_i||P_j|} \int_{P_i \times P_j} W$, and since g_{ij} is the indicator that is 1 precisely when $(x,y) \in P_i \times P_j$,

$$(P_{\mathcal{S}_\mathcal{P}} W)(x,y) = \frac{1}{|P_i|\,|P_j|} \int_{P_i \times P_j} W \qquad \text{for } (x,y) \in P_i \times P_j,$$

which is the block-average formula of definition 15.6. Hence $\Pi_\mathcal{P} = P_{\mathcal{S}_\mathcal{P}}$. The three properties listed in (i) are now the standard attributes of an orthogonal projection (theorem 2.5), read in this language: idempotence $\Pi_\mathcal{P}^2 = \Pi_\mathcal{P}$ (projecting an already block-constant kernel returns it unchanged, since its block average is itself), self-adjointness $\langle \Pi_\mathcal{P} W, H \rangle = \langle W, \Pi_\mathcal{P} H \rangle$, and the contraction $\|\Pi_\mathcal{P} W\|_{L^2} \le \|W\|_{L^2}$, which is the Pythagorean statement that a projection discards the component orthogonal to $\mathcal{S}_\mathcal{P}$ and keeps only part of the squared norm.

(ii) Stepping keeps a graphon a graphon. Three things must be checked: the output is constant on blocks, lies in $[0,1]$, and is symmetric. Block-constancy is immediate, since it is exactly what membership in $\mathcal{S}_\mathcal{P}$ means and we have just shown $\Pi_\mathcal{P} W \in \mathcal{S}_\mathcal{P}$. The range $[0,1]$ is preserved because each output value is an *average* of input values, and an average cannot escape the interval its inputs lie in: if $0 \le W \le 1$ almost everywhere then, by monotonicity of the integral,

$$0 \le \frac{1}{|P_i|\,|P_j|} \int_{P_i \times P_j} W \le \frac{1}{|P_i|\,|P_j|} \int_{P_i \times P_j} 1 = 1.$$

Symmetry needs the partition to be used symmetrically—the same blocks $P_1, \dots, P_k$ index both arguments—together with Fubini. Fix $(x,y) \in P_i \times P_j$, so that the reflected point (y,x) lies in $P_j \times P_i$. The value of $\Pi_\mathcal{P} W$ at (x,y) is the average of $W(s,t)$ over $(s,t) \in P_i \times P_j$; its value at (y,x)

is the average of $W(s,t)$ over $(s,t) \in P_j \times P_i$. In the second average substitute $W(s,t) = W(t,s)$ (symmetry of the input) and rename the two dummy variables $s \leftrightarrow t$; this is legitimate because Fubini–Tonelli (theorem 1.27) lets the double integral be evaluated in either order, and the swap carries the rectangle $P_j \times P_i$ onto $P_i \times P_j$. The second average therefore equals the first, so $(\Pi_{\mathcal{P}} W)(x,y) = (\Pi_{\mathcal{P}} W)(y,x)$ and the stepped kernel is symmetric. (Were the input *not* symmetric, or were rows and columns partitioned differently, this argument would fail—which is exactly why both hypotheses are named.)

(iii) Stepping preserves every block mass. Fix a block $P_i \times P_j$. On it $\Pi_{\mathcal{P}} W$ is the constant $c_{ij} = \frac{1}{|P_i||P_j|} \int_{P_i \times P_j} W$, so integrating that constant over the block—area $|P_i|\,|P_j|$—returns the original mass,

$$\int_{P_i \times P_j} \Pi_{\mathcal{P}} W = c_{ij}\ |P_i|\,|P_j| = \int_{P_i \times P_j} W,$$

the area cancelling the normalization exactly. Summing over the k^2 blocks, which tile $[0,1]^2$, gives $\int_{[0,1]^2} \Pi_{\mathcal{P}} W = \int_{[0,1]^2} W$, so in particular the edge density (proposition 15.3) is unchanged. There is a slicker, projection-flavoured way to see both statements at once, worth recording because it generalizes. Each block indicator $g_{ij} = \mathbf{1}_{P_i \times P_j}$ is itself block-constant, $g_{ij} \in \mathcal{S}_{\mathcal{P}}$, hence fixed by the projection: $\Pi_{\mathcal{P}} g_{ij} = g_{ij}$. Self-adjointness then gives

$$\int_{P_i \times P_j} \Pi_{\mathcal{P}} W = \langle \Pi_{\mathcal{P}} W, g_{ij} \rangle = \langle W, \Pi_{\mathcal{P}} g_{ij} \rangle = \langle W, g_{ij} \rangle = \int_{P_i \times P_j} W,$$

the per-block conservation; taking $\mathbf{1} = \sum_{i,j} g_{ij} \in \mathcal{S}_{\mathcal{P}}$ in place of a single g_{ij} (the constant kernel is block-constant too, so $\Pi_{\mathcal{P}} \mathbf{1} = \mathbf{1}$) gives the total-mass conservation $\langle \Pi_{\mathcal{P}} W, \mathbf{1} \rangle = \langle W, \mathbf{1} \rangle$ in one line. $\square$

Two consequences orient the rest of Part III, and both come straight from reading the projection geometrically.

Coarse-graining can only lose L^2-energy. Part (i) gives the contraction $\|\Pi_{\mathcal{P}} W\|_{L^2} \le \|W\|_{L^2}$, and the projection picture makes the case of equality sharp. Split W into its block-constant part and the orthogonal remainder,

$$W = \Pi_{\mathcal{P}} W + (W - \Pi_{\mathcal{P}} W), \qquad \|W\|_{L^2}^2 = \|\Pi_{\mathcal{P}} W\|_{L^2}^2 + \|W - \Pi_{\mathcal{P}} W\|_{L^2}^2\,,$$

the second equation being the Pythagorean theorem, valid because the two summands are orthogonal by construction of the projection. The contraction is now visible, and so is its equality case: $\|\Pi_{\mathcal{P}} W\|_{L^2} = \|W\|_{L^2}$ holds *iff* the remainder term has zero norm, i.e. iff $W = \Pi_{\mathcal{P}} W$ already lies in $\mathcal{S}_{\mathcal{P}}$—iff W was already a step graphon adapted to $\mathcal{P}$. (The one-line reason: a vector's norm equals the norm of its projection precisely when the vector lies in the subspace, for the discarded orthogonal component is then zero.) The energy that is lost, $\|W - \Pi_{\mathcal{P}} W\|_{L^2}^2$, is exactly the total within-block variance of W—the fine texture the resolution $\mathcal{P}$ cannot resolve. This is the precise sense in which the stochastic block models of the next section are the *finite-resolution* graphons: each is a fixed point of some $\Pi_{\mathcal{P}}$, the full kernel is recovered only in the limit of ever-finer partitions, and the approximation is always monotone—stepping moves *toward* the data and never overshoots it. It is also why the approximation runs in one direction only, general graphons *by* step graphons and not the reverse: the step graphons are the finite-dimensional subspaces $\mathcal{S}_{\mathcal{P}}$ we project *onto*, and there is no operation carrying a step graphon "up" to a generic one.

Two micro-examples fix the scale. The coarsest partition $\mathcal{P} = \{[0,1]\}$, a single block, collapses every graphon to the *constant* kernel equal to its global average $\int_{[0,1]^2} W$—the edge density, the most lossy resolution there is, and exactly the Erdős–Rényi graphon of example 15.9. A two-block partition $\mathcal{P} = \{P_1, P_2\}$ sends W to the 2×2 array of its four block averages, the smallest nontrivial stochastic block model. Refining $\mathcal{P}$ interpolates between this caricature and the kernel itself, each refinement recovering more energy.

Pixel graphons are steps to the equipartition. The pixel graphon W^G of a graph of order n is *itself* a step graphon, adapted to the equipartition $\mathcal{P}_n = \left\{I_1^{(n)}, \ldots, I_n^{(n)}\right\}$ into the n equal cells of definition 15.2—indeed that is how it was built, constant on each cell $I_i^{(n)} \times I_j^{(n)}$. So W^G is a fixed point of $\Pi_{\mathcal{P}_n}$ (stepping it to its own grid changes nothing), and stepping an arbitrary graphon W to $\mathcal{P}_n$—averaging it over the $n \times n$ grid of congruent cells—is exactly "rendering W at resolution n," the finite-resolution snapshot that section 15.1 pictured the refining grid producing. The honest convergence statement deferred there is thus, in part, a statement about how $\Pi_{\mathcal{P}_n} W$ behaves as $n \to \infty$. The content of the weak regularity lemma (chapter 19) will sharpen this dramatically: a *bounded* number of blocks—independent of how complicated W is—already approximates any graphon to a prescribed accuracy in the cut norm. That is the rigorous form of the physicist's expectation that a network, however large, has only a finite "effective complexity": a few well-chosen patches capture all of its macroscopic structure.

The same projection geometry that makes stepping so clean also exposes, by a single explicit computation, why the natural first guess for a convergence norm cannot work—and thereby motivates the genuinely coarse norm of chapter 17.

Remark 15.8 (Why a coarser norm is unavoidable)**.** One might hope to run section 15.1 directly in L^2: declare $W^{G_n} \to W$ when $\left\|W^{G_n} - W\right\|_{L^2} \to 0$. This fails, and instructively so. Sample a graph G_n with n vertices by placing each edge independently with probability $\frac{1}{2}$ (an Erdős–Rényi draw, example 15.9). The pixel graphons W^{G_n} are $\{0,1\}$-valued and "should" converge to the constant graphon $W \equiv \frac{1}{2}$—the block frequencies do settle to $\frac{1}{2}$ over every fixed patch. Yet the L^2 distance never moves. Here is the computation in full: because W^{G_n} takes only the values 0 and 1, at every point of the square $\left(W^{G_n} - \frac{1}{2}\right)^2 = \left(\pm \frac{1}{2}\right)^2 = \frac{1}{4}$ *identically*, so

$$\left\|W^{G_n} - \tfrac{1}{2}\right\|_{L^2}^2 = \int_{[0,1]^2} \left(W^{G_n} - \tfrac{1}{2}\right)^2 = \frac{1}{4}$$

for every n, no matter how large the network and no matter how perfectly its block frequencies have stabilized. The L^2 norm is comparing the two pictures pixel by pixel, and at the pixel level a fair-coin graph and the flat grey kernel disagree maximally everywhere—one is black or white, the other is uniformly grey. It sees the microscopic 0/1 texture forever; it is too fine to be the topology of graph limits. The cure is to integrate *before* measuring discrepancy. The cut norm of chapter 17 pairs $W^{G_n} - \frac{1}{2}$ against indicator patches $\mathbf{1}_{S \times T}$ and only then takes the absolute value; over any fixed patch the $\pm\frac{1}{2}$ fluctuations average to nearly zero by the law of large numbers, so the cut distance *does* tend to 0. It measures agreement of patch averages, not of pixels, and is by design blind to the texture that L^2 can never forget. This is the concrete failure promised in section 15.1, and it is why the metric of graph limits is the cut metric and not L^2.

With stepping understood we have exactly the vocabulary the next section needs. We have learned that the step graphons are the finite-resolution objects—fixed points of the projections $\Pi_{\mathcal{P}}$, dense among all graphons in the coarse cut sense, and the universal target of approximation—which is precisely the role the *stochastic block models* of the gallery will play; that a pixel picture is the step of a kernel to an equipartition, so the discrete and the continuum sit on one ladder of resolutions; and that energy is lost monotonically under coarse-graining, the framing that will explain why the constant, step, and rank-one kernels are the canonical exactly-solvable classes—they are the kernels whose operator $\mathbb{W}$ has the lowest, most rigid spectral structure, and on which the coarse-graining picture is exact rather than approximate. The L^2-too-fine failure we just exhibited is the seed of the cut metric of chapter 17. We now turn to the gallery itself, where each kernel is met as a formula, drawn as a pixel picture, and tied forward to the mean field game it parametrizes.

15.4 A gallery of graphons

The stepping section left us with a sharp way to read the graphons we are about to meet. It identified the step graphons as the *finite-resolution* objects—fixed points of the projections $\Pi_{\mathcal{P}}$, the targets of all coarse-graining—and it promised, at its close, that constant, step, and rank-one kernels are the canonical exactly-solvable classes because their operator $\mathbb{W}$ carries the lowest and most rigid spectral structure. This section makes good on that promise by exhibiting the three classes one at a time. Each is met the same way, and the reader should watch for the recurring template: a graphon is first written down as a *kernel* (a formula for $W(x, y)$), then *seen* through its pixel picture (the black-and-white or greyscale image of definition 15.2, which makes its structure visible at a glance), and finally *tied forward* to a specific mean field game in Part IV that it parametrizes and renders explicitly solvable. Kernel, picture, game: that is the arc each subsection traces.

The organizing claim—and the thesis that makes this a single section rather than three unrelated vignettes—is that constant, step, and rank-one are *not coincidentally* the three classes on which the integral operator $\mathbb{W}$ is exactly diagonalizable (worked computation 2.28). The spectral theorem of theorem 2.26 guarantees every graphon a real spectrum and an orthonormal eigenbasis, but for a generic kernel that basis is infinite and inexplicit; one knows it exists without being able to write it down. The three gallery members are exactly the cases where one *can* write it down, because each has an operator of finite rank with eigenfunctions read straight off the formula: the constant kernel has rank one with the constant mode, a k-block step graphon has rank at most k with piecewise-constant modes, and the rank-one kernel $W(x, y) = f(x)f(y)$ has rank one with the single mode f. Exact diagonalizability is not a curiosity of these kernels; it is precisely *what makes the corresponding game solvable.* The graphon enters every equation of Part IV only through $\mathbb{W}$ (the point section 15.6 will press), so a $\mathbb{W}$ whose action is captured by a handful of modes collapses the type-continuum of coupled equilibrium conditions onto a handful of scalar unknowns, and a problem in finitely many scalars is one we can actually close.

The number of those scalars is the spine that runs through all three subsections, and it is fixed by a single integer: the rank of $\mathbb{W}$ equals the number of *order parameters* needed to close the game. A rank-one operator yields one scalar order parameter, a rank-k step operator yields k of them, and the structureless constant kernel—rank one again—yields the single scalar that the homogeneous theory of Parts I–II already lived on. We state this here only as the expectation that organizes the gallery; the `physicsnote` accompanying the stochastic block models in section 15.4.2 makes it precise through the statistical-mechanics dictionary, and chapter 18 turns it into a theorem. The cleanest worked instance is the rank-one collapse $z(x) = \varrho\, f(x)$ of section 15.4.3, where the entire type-indexed coupling field reduces to a single number ϱ; that collapse is the seed of Thread B, and it is the reason the rank-one graphon is the example we return to whenever an explicit graphon mean field game is wanted.

We open with the structureless extreme. The constant graphon—uniform grey across the whole square, the simplest formula and the simplest picture there is—is the first and plainest instance of the kernel-picture-game template, and at the same time it is the bridge back to where Part III began: it is the single degenerate point at which the homogeneous, anonymous-crowd theory of Parts I–II reappears inside the graphon theory. We meet it now.

15.4.1 Erdős–Rényi: the constant graphon

The gallery preamble promised to open with the structureless extreme, and it is the natural place to start for the same reason that one calibrates an instrument against a blank: structure is only legible against a background that has none. The constant graphon *is* that background. It is uniform grey across the entire square—the simplest formula $W \equiv p$ and the simplest picture, a single flat level—and it is the first instance of the kernel–picture–game template the gallery traces. It is also, by the spine of the section, the most rigid member of the catalogue on the operator side: its $\mathbb{W}$ has the lowest possible nontrivial rank, namely one, and a single mode handles its entire action. We will see that this rank-one structure is exactly what collapses the type-continuum of the game down to one scalar, and that the scalar in question is the very global mean on which the homogeneous theory of Parts I–II already lived. The constant graphon is thus simultaneously the plainest example we can write and the precise bridge back to where Part III began.

Example 15.9 (Constant graphon)**.** Fix $p \in [0,1]$ and let $W \equiv p$ on $[0,1]^2$. This is the *constant* (or *Erdős–Rényi*) graphon. Its pixel-picture origin is the dense random graph $G(n,p)$, in which each of the $\binom{n}{2}$ possible edges is present independently with probability p: as $n \to \infty$, the pixel graphons $W^{G(n,p)}$ concentrate around the flat greyscale image at level p (the precise sampling statement, with concentration rates, is chapter 19). Every type connects to every other type with the same probability p; there is no structure, no notion of centrality, and no distinguished type. The graphon is invariant under *every* measure-preserving relabeling, the extreme case of remark 15.5.

Each clause of the example earns a word, because the constant kernel is the degenerate limit of several distinct things the rest of the chapter measures, and degeneracy is most instructive when one sees exactly what has collapsed. The *origin* is the dense Erdős–Rényi graph $G(n,p)$: drawing each of the $\binom{n}{2}$ edges as an independent fair-or-biased coin with heads-probability p, the resulting pixel graphon $W^{G(n,p)}$ is a random $\{0,1\}$-valued checkerboard, black with frequency p and white with frequency $1-p$. No individual picture is flat—it is maximally textured, every cell pure black or pure white—yet as n grows the *block frequencies* settle: over any fixed patch the proportion of black cells tends to p by the law of large numbers, so the network, read at any coarse resolution, looks like uniform grey at level p. This is the same phenomenon we already met head-on in remark 15.8, where the $p = \frac{1}{2}$ case showed that the convergence $W^{G(n,p)} \to p$ is real but invisible to the L^2 norm and visible only after one integrates against patches; the honest concentration statement, with rates, is the sampling theorem of chapter 19. The *absence of structure* is then exact rather than informal: because the single value p is attached to every pair of types alike, the slice $y \mapsto W(x,y) \equiv p$ is the same constant function for every x, so no type connects more, or to anyone in particular, more than any other. There is no high-degree hub and no low-degree fringe—no centrality—and no type that the kernel can tell apart from the rest. That last point is the *invariance under every relabeling*, and it is worth seeing as the genuine extreme case of remark 15.5: a generic graphon is fixed only by those measure-preserving φ that happen to respect its structure, and remark 15.5 warned us to discard any feature not so fixed; the constant kernel is the unique graphon fixed by *all* of them, since $W^{\varphi}(x,y) = W(\varphi(x), \varphi(y)) = p = W(x,y)$ for any measure-preserving φ whatsoever. Having no structure to break, it is the one kernel for which the relabeling quotient does nothing at all—which is precisely what "structureless" means made precise.

This structurelessness is not a dead end; it is the bridge back to the homogeneous theory of Parts I–II, and the bridge is built entirely out of the operator $\mathbb{W}$. We saw in the gallery preamble that the graphon reaches every equation of Part IV only through $\mathbb{W}$, and that the rank of $\mathbb{W}$ counts the order parameters the game needs; so to locate the constant graphon inside the homogeneous theory we have only to compute its operator and count. That computation is already on record as worked computation 2.28(a), and it is one line:

$$(\mathbb{W}f)(x) = \int_0^1 W(x,y)\, f(y)\, \mathrm{d}y = \int_0^1 p\, f(y)\, \mathrm{d}y = p \int_0^1 f(y)\, \mathrm{d}y = p\, \langle f, \mathbf{1} \rangle,$$

the constant p pulling outside the integral and the remaining $\int_0^1 f$ being exactly the inner product of f with the constant unit field $\mathbf{1}$ (which has $\|\mathbf{1}\|_{L^2} = 1$ on $[0,1]$, so it is already a unit eigenvector). Read this output. Whatever field f goes in, what comes out is a *constant* function—the value $p\,\langle f, \mathbf{1} \rangle$, the same number at every type x—so the range of $\mathbb{W}$ is the one-dimensional line of constants and $\mathbb{W}$ has *rank one*, the minimum a nonzero coupling can have. Its spectral picture is correspondingly the most rigid possible: $\mathbb{W}\mathbf{1} = p\,\langle \mathbf{1}, \mathbf{1} \rangle\, \mathbf{1} = p\,\mathbf{1}$, so $\mathbf{1}$ is an eigenfunction with eigenvalue p; and any field g orthogonal to the constants, $\langle g, \mathbf{1} \rangle = 0$, is annihilated, $\mathbb{W}g = 0$. The whole spectrum is therefore $\{p, 0, 0, \ldots\}$: a single nonzero eigenvalue p carried by the constant mode, every other mode killed. This is worked computation 2.28(a) read for its meaning rather than its value, and it is the rank-one collapse of the section's spine in its very simplest form—one nonzero mode, hence (looking ahead to chapter 18) one order parameter.

The reduction to the homogeneous game is now immediate, and it is worth spelling out so that the claim "the homogeneous theory sits inside as one point" is earned rather than asserted. Suppose the population is described by a type-indexed mean field $x \mapsto \bar{m}(x)$ and each agent is coupled to its neighbors through $\mathbb{W}$, feeling the aggregate $z(x) = (\mathbb{W}\bar{m})(x)$—this is exactly the graphon-aggregated neighbor mean that Thread B builds its games on, where in general $z(x)$ depends on the agent's own type x because different types see different neighborhoods. For the constant graphon the computation above makes that dependence vanish:

$$z(x) = (\mathbb{W}\bar{m})(x) = p \int_0^1 \bar{m}(y)\, \mathrm{d}y = p\, \langle \bar{m}, \mathbf{1} \rangle,$$

a single number, *the same for every type* x. Every agent, regardless of its own label, feels one and the same scalar aggregate $p \int_0^1 \bar{m}$. That is precisely the *anonymous global-mean coupling* of the classical mean field game of Thread A (appendix A.7): a crowd in which no agent sees a distinguished neighborhood, only the population average, weighted here by the connection probability p. The type variable x has become a passenger—it indexes the agents but no longer enters the coupling—so the type-continuum of equilibrium conditions, one per x, collapses to the single self-consistent condition on the scalar $\langle \bar{m}, \mathbf{1} \rangle$ that the homogeneous theory already solved. The constant graphon therefore does not merely *resemble* the homogeneous MFG of chapter 14; it *is* that game, recovered as the degenerate, structureless special case in which $\mathbb{W}$ has rank one and the only role left for the kernel is the constant p, which rescales the coupling strength (replacing the homogeneous coupling weight s of Thread A by $p\, s$). We will carry out this reduction explicitly inside the dynamic theory, checking that the graphon HJB–Fokker–Planck system over the kernel degenerates to the homogeneous Riccati system of Thread A, in chapter 22.

With the structureless point understood, the natural next move is to add the least structure that is still structure. The constant graphon is the partition $\mathcal{P} = \{[0, 1]\}$ of definition 15.6 with a single block—one community, every pair joined at the same density p—and the obvious generalization is to cut $[0, 1]$ into k blocks and allow each pair of blocks its own density. That turns the single number p into a $k \times k$ array of densities and the single global mean into one aggregate per community, while keeping everything else—the exact diagonalizability, the finite count of order parameters—intact. The constant graphon is the $k = 1$ corner of that picture, and the next subsection occupies the rest of it.

15.4.2 Stochastic block models: step graphons

The constant graphon left us at the $k = 1$ corner of definition 15.6: a single block, one community, every pair of types joined at the same density p. The previous subsection closed by naming the obvious next move—cut $[0, 1]$ into k blocks and let each pair of blocks carry its own density—and this subsection occupies the rest of that picture. The object we get is the coarsest structure that is still structure: finitely many *communities*, each ordered pair of them connected at its own density. We have already built this object once, abstractly, in definition 15.6: a graphon constant on every rectangle $P_r \times P_s$ of a finite partition is exactly a step graphon. What is new here is not the kernel but the *reading*. A step graphon, read as a recipe for generating a random network—place an edge between an agent of community r and an agent of community s independently with probability equal to the block value—is what network science calls the *stochastic block model*, the canonical model of a network with communities. The stepping projection of proposition 15.7 then turns out to do more than relate these two objects: it makes the SBM the *universal finite-resolution approximation* to every graphon, which is the structural reason the model recurs throughout the book and supplies the bridge to the finite multi-population games of chapter 30. We first fix the data, then read off the picture, then earn each of those claims in turn.

Example 15.10 (Stochastic block model)**.** Fix an integer $k \geq 1$, a partition $[0,1] = \bigsqcup_{r=1}^{k} C_r$ into measurable *communities* of sizes $|C_r| = \rho_r > 0$ with $\sum_r \rho_r = 1$, and a symmetric matrix $\mathsf{B} = (\mathsf{B}_{rs}) \in [0,1]^{k\times k}$ of inter-community connection probabilities (the sans-serif B keeps the block matrix distinct from the Brownian motion B of Part IV). The associated *stochastic block model graphon* is the step graphon

$$W^{\mathrm{SBM}}(x,y) = \mathsf{B}_{rs} \qquad \text{for } x \in C_r,\ y \in C_s.$$

It is adapted to the partition $\{C_1, \dots, C_k\}$ in the sense of definition 15.6.

The data come in three pieces and each has a plain meaning. The integer k is the number of communities; the masses $\rho_r = |C_r|$ record what fraction of the population belongs to each, so that $\sum_r \rho_r = 1$ simply says every agent belongs somewhere; and the block matrix B records the density of links between communities, with B_{rs} the probability that a type drawn from C_r and a type drawn from C_s are joined. The symmetry $\mathsf{B}_{rs} = \mathsf{B}_{sr}$ is forced—it is exactly the graphon symmetry $W(x,y) = W(y,x)$ restricted to blocks, the continuum imprint of undirected edges discussed at definition 15.4—and the entries lie in $[0,1]$ because they are probabilities. One should note the deliberate notational care: the block matrix is written B in sans serif precisely so that it never collides with the Brownian motion B_t that the dynamic theory of Part IV will run on top of these kernels, a clash the chapter's opening notation watch flagged and this is the place it would otherwise bite.

The pixel picture makes the structure legible at a glance, and it is the cleanest instance of the kernel–picture template the gallery follows. Laying W^{SBM} flat on the unit square as in definition 15.2 produces a $k \times k$ array of solid grey rectangles: the rectangle $C_r \times C_s$ has dimensions $\rho_r \times \rho_s$ and is shaded at the single uniform level B_{rs}. Nothing varies inside a rectangle—that is what "step" means—so the whole image is a checkerboard of flat grey tiles, no texture within any tile. The two kinds of tile carry the two kinds of network structure. The *diagonal* blocks B_{rr} are within-community densities: a large B_{rr} means agents of community r link densely among themselves, the signature of an *assortative*, community-structured network where like associates with like. The *off-diagonal* blocks B_{rs} with $r \neq s$ are cross-community densities, the rate at which the communities reach across to one another; making the off-diagonals small relative to the diagonals sharpens the community structure, while making them large (or larger than the diagonals, the *disassortative* case) dissolves or inverts it. The constant graphon of example 15.9 is the degenerate picture with a single tile filling the whole square.

Every step graphon is an SBM, and stepping any graphon produces one. The example calls W^{SBM} a step graphon, but the relationship runs both ways and is worth making fully explicit, because it is what promotes the SBM from one model among many to the canonical one. Both directions are read straight off proposition 15.7.

For the forward direction, suppose we are handed an arbitrary step graphon—any symmetric $[0,1]$-valued kernel that is constant on every rectangle of some finite partition $\mathcal{P} = \{P_1, \dots, P_k\}$ of $[0,1]$. Then it *is* an SBM graphon, with no work beyond renaming: take the communities to be the blocks themselves, $C_r = P_r$, with masses $\rho_r = |P_r| > 0$; and let B_{rs} be the constant value the kernel takes on $P_r \times P_s$. Symmetry of the kernel hands us $\mathsf{B}_{rs} = \mathsf{B}_{sr}$, and the values lie in $[0,1]$ because the kernel does, so (k, ρ, B) is legitimate SBM data and the kernel is exactly its W^{SBM}. There is no daylight between "step graphon" and "SBM graphon"—they are the same objects under two names, one analytic and one generative.

For the converse direction, take *any* graphon W, structured however badly, and any finite partition $\mathcal{P}$. Stepping it produces an SBM. Concretely, $\Pi_{\mathcal{P}} W$ is by proposition 15.7(ii) again a symmetric $[0,1]$-valued kernel constant on every block—a step graphon—so by the forward direction it is the SBM graphon of some data, and definition 15.6 tells us exactly what that data is: the block matrix entries are the block averages

$$\mathsf{B}_{rs} = \frac{1}{|P_r|\ |P_s|} \int_{P_r \times P_s} W,$$

the mean density of W across the pair of communities. Thus stepping is the operation that *coarse-grains any network into a stochastic block model*, reading each cross-community density as the average it should be. The forward direction says the SBMs are precisely the fixed points of the stepping projections; the converse says every graphon casts an SBM shadow at every resolution.

Why the SBM is universal, not merely one model. These two directions would be a tidy dictionary and nothing more if the shadow were a poor likeness of the original. The content that makes the SBM *universal* is that the likeness can be made as faithful as one wishes with a *bounded* number of communities. This is the weak regularity lemma of chapter 19: for every tolerance $\varepsilon > 0$ there is a partition into at most $k(\varepsilon)$ blocks—a bound depending on ε alone, not on how intricate W is—whose stepped kernel $\Pi_{\mathcal{P}} W$ approximates W to within ε in the cut norm of chapter 17. In the language just established: *every* graphon is cut-close to a stochastic block model with a controlled number of communities, so the SBMs are *dense* in graphon space under the cut metric. This is the structural reason the SBM is not one network model competing with others but the universal finite-resolution approximation, the continuum echo of the physicist's expectation—recorded already at proposition 15.7—that any network, however large, has only a finite effective complexity that a handful of well-chosen communities already captures. It is also why the model is worth studying in its own right: results proved for SBMs, if they are stable under cut-distance limits, propagate to all graphons.

Two reductions: the constant kernel and the finite type space. With the correspondence in hand, two specializations anchor the SBM for everything downstream. The first is the floor we came in on. With $k = 1$ there is a single community $C_1 = [0,1]$ of mass $\rho_1 = 1$ and a 1×1 block matrix $\mathsf{B} = (p)$, and the SBM graphon is the constant kernel $W \equiv p$ of example 15.9. The SBM thus contains the Erdős–Rényi graphon as its $k = 1$ corner, exactly as promised, and inherits its rank-one collapse as the simplest case of what follows.

The second specialization is the one that carries the SBM into Part IV, and it comes from reading the communities not as blocks of a continuum but as a *finite type space* in their own right. When a graphon is constant on communities, an agent's type matters only through *which community it belongs to*: two types in the same C_r are coupled to the rest of the network identically, so the continuum of types $x \in [0,1]$ degenerates to the finite set $\{1,\dots,k\}$ of community labels. Concretely, watch what the operator $\mathbb{W}^{\mathrm{SBM}}$ does to a field f. For a type $x \in C_r$,

$$(\mathbb{W}^{\mathrm{SBM}} f)(x) = \int_0^1 W^{\mathrm{SBM}}(x,y)\, f(y)\; \mathrm{d}y = \sum_{s=1}^{k} \mathsf{B}_{rs} \int_{C_s} f(y)\; \mathrm{d}y = \sum_{s=1}^{k} \mathsf{B}_{rs}\, \rho_s\, \bar{f}_s, \qquad \bar{f}_s := \frac{1}{\rho_s} \int_{C_s} f,$$

where the integral splits over the communities because W^{SBM} is the constant B_{rs} on C_s for $x \in C_r$, and $\bar{f}_s$ is the average of f over community s. Two things are visible at once. The output value $\sum_s \mathsf{B}_{rs}\rho_s \bar{f}_s$ depends on x *only through its community label* r, so $\mathbb{W}^{\mathrm{SBM}} f$ is itself constant on communities; and it depends on the input f *only through the* k *averages* $(\bar{f}_1,\dots,\bar{f}_k)$. The operator therefore factors through the k-dimensional space of functions constant on the communities—it forgets everything about f except its k community means—so it has *rank at most* k. This is the SBM instance of the section's spine: the rank of $\mathbb{W}$ is bounded by the number of communities.

The consequence for the game is the bridge to chapter 30. The SBM graphon is precisely the data of a finite *multi-population* mean field game: k populations of relative sizes ρ_r, the r-th confined to community C_r, coupled to one another with strengths B_{rs}. Because $\mathbb{W}^{\mathrm{SBM}}$ depends on a population profile $\bar{m}$ only through its k community aggregates, the type-indexed coupling field an agent feels collapses, for an agent of community r, to the single number

$$z_r = (\mathbb{W}^{\mathrm{SBM}} \bar{m})\big|_{C_r} = \sum_{s=1}^{k} \mathsf{B}_{rs}\, \rho_s\, \bar{m}_s,$$

a B-weighted combination of the k community aggregates $\bar{m}_s$. The continuum of equilibrium conditions, one per type x, therefore reduces to k conditions, one per community, and the graphon mean field game on an SBM *collapses to a coupled system of* k *classical mean field games*—one per community—interacting only through the $k \times k$ matrix B. The k scalars $\bar{m}_1,\dots,\bar{m}_k$ (more precisely the k aggregates that close the system) are the order parameters of the problem. This is the bridge between the continuum graphon theory and the finite multi-population MFG of chapter 30; we set it up here and exploit it in the dynamic reduction of chapter 22.

That last count—k communities, rank at most k, k order parameters—is no accident, and it is worth naming the statistical-mechanics picture that explains why the three numbers always agree, because that picture is the hidden thesis of the whole gallery.

Physics note

The three exactly solvable kernels of this section have precise statistical-mechanics counterparts, and the analogy is worth one box because it correctly predicts the order parameter in each case—and because the pattern it reveals is the chapter's central claim. Start with the constant graphon. It is the all-to-all (Curie–Weiss) coupling $J_{ij} \equiv J/N$: every spin is coupled equally to every other, each feels the same mean field $J\,m$ with the single scalar magnetization $m = N^{-1}\sum_i s_i$, and that one number closes the self-consistency equation $m = \tanh(\beta J m)$. One scalar suffices because the coupling has *rank one*: J_{ij} is the constant matrix, whose only nonzero mode is the uniform vector. Next the block graphon. It is a *multi-species* Curie–Weiss model: the spins are split into k sublattices, the coupling B_{rs} depends only on which pair of species two spins belong to, and the theory closes on a *vector* order parameter $(m_1, \ldots, m_k)$ of one magnetization per species, coupled through B exactly as the k community aggregates $\bar{m}_r$ above are coupled through it. Here the coupling has rank at most k—it sees a spin only through its species—and one needs exactly k order parameters. Finally the rank-one graphon $W(x, y) = f(x)f(y)$ of the next subsection is the single-pattern Hopfield (Mattis) model, with separable coupling $J_{ij} = \xi_i\xi_j$ built from one stored pattern ξ; its order parameter is the *single* scalar overlap $m = N^{-1}\sum_i \xi_i s_i$ with that pattern, and the coupling, being an outer product, again has rank one. The pattern is now unmistakable, and it is the load-bearing point: in each case *the rank of the coupling operator equals the number of order parameters needed to close the mean field equations*—rank one gives one scalar, rank k gives k, because the order parameters are precisely the projections of the population onto the nonzero modes of the coupling, and a field that the operator cannot resolve cannot enter the closed equations. This is exactly the prediction the spectral theory of chapter 18 will turn into a theorem, and it is why the rank-one graphon is the cleanest graphon mean field game there is. One honest caveat keeps the analogy in its place: it predicts the *number and identity* of the order parameters, nothing more. The equilibrium values below are fixed by a *Nash* condition—each agent best-responds to the aggregate it feels—not by a thermal average minimizing a free energy, and the two need not coincide. The dictionary tells us how many scalars to track; it does not tell us the equations they solve.

The spine the physicsnote names—rank of $\mathbb{W}$ equals the number of order parameters—now points the way down. The SBM realizes it at general rank k, with a vector of k aggregates closing the game. The sharpest instance is the floor of that scale: a coupling operator of rank *one*, where the entire type-indexed coupling field collapses not to k scalars but to a *single* one. That is the rank-one graphon, the cleanest exactly-solvable kernel and the one that carries Thread B, and we meet it next.

15.4.3 The rank-one (Curie–Weiss) graphon and a scalar order parameter

The stochastic block model realized the chapter's spine—rank of $\mathbb{W}$ equals the number of order parameters that close the game—at general rank k: a k-community kernel is resolved by the operator into at most k modes, and the game closes on a vector of k aggregates. Push that spine to its floor. The smallest nontrivial rank is one, and a coupling operator of rank one carries the cleanest possible payload: not k scalars but a *single* one. This is the rank-one graphon, the simplest non-constant kernel there is, built from a single type profile f; it is the graphon on which the type-continuum game first collapses to one scalar—the order parameter ϱ that carries Thread B—and so it is both the simplest structured network and the worked example we return to whenever an explicit graphon mean field game is wanted. The previous subsection handed it to us as the $k = 1$ end of the rank scale; we now show that this one end is special enough to deserve its own development, because at rank one the entire apparatus of coupled type-indexed control problems folds into a single fixed-point equation in a single real unknown.

Example 15.11 (Rank-one graphon)**.** Let $f\colon [0, 1] \to [0, 1]$ be measurable (a *type profile*), and set

$$W(x, y) = f(x)\, f(y).$$

This is symmetric, measurable, and $[0,1]$-valued (since f is), hence a graphon: the *rank-one* or *Curie–Weiss* graphon. The value $f(x)$ is the propensity of type x to form links; an edge between x and y forms with probability proportional to the product of their propensities. In the sampling picture (chapter 19) this is the expected-degree / Chung–Lu model, and it is the graphon analogue of a configuration model in which each vertex carries a single "activity" $f(x)$.

The reading to internalize is that a single number per type controls everything. Each type carries one scalar, its propensity $f(x) \in [0,1]$ to engage at all, and the kernel says that two types connect in proportion to the product of their propensities and in no other way: there is no residual "chemistry" between specific pairs, no term in W that survives factoring out $f(x)$ and $f(y)$. A high-f type is a hub—it links readily to everyone, and most readily to other hubs—while a type with $f(x) \approx 0$ is nearly isolated, linking weakly to all. To make the multiplicative law concrete, two types with propensities 0.9 and 0.2 connect with probability 0.18, the same probability with which a single type of propensity 0.6 links to one of propensity 0.3; only the product is observable. The degree of a type follows the same one-number logic. The expected fraction of the population that a type-x agent connects to is, by definition 15.4's sampling reading,

$$d_W(x) = \int_0^1 W(x,y)\ \mathrm{d}y = f(x)\int_0^1 f(y)\ \mathrm{d}y = \bar{f}\, f(x), \qquad \bar{f} := \int_0^1 f,$$

so the degree function is the profile itself rescaled by its own mean $\bar{f}$: the *expected-degree* or *Chung–Lu* reading, in which a vertex's connectivity is prescribed by a single activity parameter and the network is the maximum-entropy graph with those expected degrees. Sampling an actual finite graph from this kernel—placing each edge independently with probability $f(x_i)f(x_j)$ over i.i.d. types—is deferred to chapter 19; here the kernel is studied as an object in its own right, and what we extract from it is purely analytic.

This is the graphon that carries Thread B (the graphon LQG game of appendix A.7) and the one on which the entire Part IV machine becomes a one-parameter problem. The mechanism is the rank-one collapse already recorded operator-side in worked computation 2.28(b); we now make it explicit as the coupling that a type-x agent will feel, which is the form in which it enters every graphon mean field game equation. The worked computation that follows is the chapter's Thread-B installment, and it is worth doing in full because every later rank-one calculation in the book—static in chapter 20, dynamic in chapter 22, well-posed in chapter 24—begins from exactly this collapse.

Worked computation 15.12 (Rank-one collapse to a scalar order parameter — Thread B foreshadow)**.** Carry the standing graphon LQG model of appendix A.7 (Thread B). There a type-x agent does not feel the global mean but the *graphon-aggregated neighbor mean*

$$z(x) = (\mathbb{W}\bar{m})(x) = \int_0^1 W(x,y)\,\bar{m}(y)\ \mathrm{d}y, \qquad \bar{m}(y) = \int_{\mathbb{R}} \xi\, m^y(\mathrm{d}\xi),$$

where $m^y \in \mathcal{P}(\mathbb{R})$ is the state distribution of type-y agents and $\bar{m}(y)$ its mean (we suppress the time argument, which plays no role in the algebra). This $z(x)$ is the sole channel through which the network reaches the type-x agent: the agent solves a private control problem in which the population enters only as the scalar field $z(x)$ it is drawn toward. Without further structure $z(x)$ is a genuine function of x—one coupling value per type, a continuum of them, all entangled because

$\bar{m}$ is itself the equilibrium output of every type's problem. Specialize now to the rank-one kernel $W(x, y) = f(x)f(y)$ and watch the continuum collapse. Substituting and *pulling the x-dependent factor out of the y-integral*—legitimate because $f(x)$ does not depend on the integration variable y—gives

$$z(x) = \int_0^1 f(x)\, f(y)\, \bar{m}(y)\ \mathrm{d}y = f(x) \underbrace{\int_0^1 f(y)\, \bar{m}(y)\ \mathrm{d}y}_{=:\ \varrho} = \varrho\, f(x), \qquad \varrho = \langle f, \bar{m}\rangle_{L^2[0,1]}.$$

The integral that remains, $\int_0^1 f(y)\bar{m}(y)\ \mathrm{d}y$, contains no x at all: it is one fixed real number, the L^2 inner product $\varrho = \langle f, \bar{m}\rangle$ of the profile against the population mean field. The entire type-indexed coupling field $x \mapsto z(x)$ has therefore collapsed onto a *single scalar* ϱ multiplying the fixed, known profile f. Every agent, regardless of type, feels the *same* order parameter ϱ, only rescaled by the deterministic gain $f(x)$ it was born with: a type with $f(x) = 0$ is decoupled—it feels nothing and contributes nothing to ϱ—while a type with large $f(x)$ is strongly exposed and, symmetrically, weighs heavily in ϱ. The profile f thus plays a double role, as the gain through which a type *feels* the aggregate and the weight with which it *enters* the aggregate, and these are the same f precisely because the kernel is the symmetric outer product $f \otimes f$. The one number ϱ is the only population statistic anyone needs; the full field $\bar{m}(\cdot)$, an element of an infinite-dimensional space, matters only through its single projection onto f. We write the scalar with the book's order-parameter symbol ϱ (appendix A.7); the dynamic chapters chapters 20 and 22 carry the same ϱ, never an η or θ.

This is the graphon analogue of the Curie–Weiss closure of Thread A, and it is what makes the rank-one graphon the cleanest worked graphon mean field game. The self-consistency that chapter 22 will close is now visible in one move. Each agent's problem depends on its type only through the scalar coupling $\varrho f(x)$ together with its own type data—its initial law m_0^x and any type-dependent coefficients—so once the single number ϱ is declared, type x's problem is a *decoupled* standard control problem with a known target $\varrho f(x)$. Solving it returns that type's optimal behavior and hence its equilibrium state mean, which therefore depends on the type and on the one scalar it was told:

$$\bar{m}(x) = \Psi(x, \varrho),$$

where Ψ is the best-response map of the type-x control problem (in the LQG case of chapter 22 it is explicit, linear in ϱ, with coefficients built from the Riccati data). Feeding this back into the *definition* of ϱ closes the loop: ϱ was $\langle f, \bar{m}\rangle = \int_0^1 f(x)\bar{m}(x)\ \mathrm{d}x$, and substituting $\bar{m}(x) = \Psi(x, \varrho)$ turns that definition into the *one-dimensional* fixed-point equation

$$\varrho = \int_0^1 f(x)\, \Psi(x, \varrho)\ \mathrm{d}x \ =:\ \Gamma(\varrho).$$

A continuum of coupled control problems, one per type, has been reduced to a single scalar equation $\varrho = \Gamma(\varrho)$ for one real unknown—exactly the reduction promised for the rank-one kernel in appendix A.7. This is the entire payoff of rank one: the equilibrium is a root of a real function Γ of a real variable, to be located by the elementary fixed-point tools of one dimension rather than by an infinite-dimensional fixed point over the space of type-indexed fields.

It is worth confirming that this machinery degenerates correctly to the homogeneous theory. Take the constant graphon, which is the rank-one kernel with the *flat* profile $f \equiv \sqrt{p}$ (so that

$W(x,y) = \sqrt{p}\,\sqrt{p} = p$ recovers the Erdős–Rényi value of example 15.9). Then the order parameter is

$$\varrho = \langle f, \bar{m} \rangle = \int_0^1 \sqrt{p}\,\bar{m}(y)\,\mathrm{d}y = \sqrt{p}\,\langle \mathbf{1}, \bar{m} \rangle = \sqrt{p}\,\langle \bar{m} \rangle, \qquad \langle \bar{m} \rangle := \int_0^1 \bar{m}(y)\,\mathrm{d}y,$$

where $\langle \bar{m} \rangle$ is the single *global* population mean, averaged over all types. The coupling each agent feels then collapses one step further, losing even its type dependence:

$$z(x) = \varrho\, f(x) = \big(\sqrt{p}\,\langle \bar{m} \rangle\big)\sqrt{p} = p\,\langle \bar{m} \rangle,$$

the *same* number for every type. This is precisely the anonymous global-mean coupling of Thread A—each agent is drawn toward the one population average $\langle \bar{m} \rangle$—now with the interaction strength rescaled by the edge density $p = \|\mathbb{W}\|$, matching the constant-graphon aggregate computed in chapter 14. The graphon machinery has reproduced the homogeneous mean field game exactly, as it must, with p as the only trace the network leaves. The rank-one collapse is thus the genuine generalization of Thread A's mean field closure: a flat f gives one type-independent scalar, a non-flat f gives one scalar weighted by the propensity profile, and in both cases a single real order parameter closes the game.

We carry out the dynamic version of this computation, with the explicit LQG best response Ψ and its Riccati ingredients, in chapter 22; the existence and uniqueness of the scalar fixed point $\varrho = \Gamma(\varrho)$ is controlled by the operator norm $\|\mathbb{W}\| = \|f\|_{L^2}^2$—the single nonzero eigenvalue of the rank-one operator, computed in worked computation 2.28(b)—through the smallness assumption (A-Coupling), and is treated in chapter 24. Here we have only run the algebra of the collapse, but it is the algebra on which the whole rank-one thread rests.

The rank-one example also exhibits, in the simplest possible setting, the link between *centrality* and *exposure* that drives the static and dynamic graphon games of Part IV, and the collapse just performed explains why the link is so tight here. The integral operator $\mathbb{W}$ of the rank-one kernel has a single nonzero eigenvalue $\|f\|_{L^2}^2$ with eigenfunction $e_1 = f/\,\|f\|_{L^2}$ (worked computation 2.28(b))—the normalized profile f itself, and the only mode the network possesses. Centrality, meaning how prominently a type sits in the network's dominant mode, is read off from e_1 and so is governed by $f(x)$. Exposure, meaning how strongly a type feels the aggregate $z(x) = \varrho f(x)$, is governed by the *same* $f(x)$, as the worked computation showed directly. The two notions therefore coincide pointwise: $f(x)$ answers both "how central is type x" and "how strongly does type x feel the crowd," because with a single mode there is nothing to distinguish them—the one eigenfunction does both jobs. This coincidence is special to rank one. For a general graphon the spectrum has many modes, centrality and exposure are then governed by the full eigenbasis rather than a single function, and they separate; that spectral story is the subject of chapter 18, and the precise map from centrality to equilibrium effort is made into a theorem in chapter 20.

The whole gallery just assembled—the constant kernel, the block models, and this rank-one collapse—was built under two normalizations we have so far taken for granted: the type distribution is uniform on $[0,1]$ (every type profile f, every block, was weighted by Lebesgue measure), and the kernel is valued in $[0,1]$ (every propensity, every block probability, was an honest edge probability). Real data violate both—some kinds of agent are common and others rare, and edge weights can exceed one or be unbounded—so the natural next question is whether loosening these two normalizations enlarges the theory or merely re-coordinatizes it. That is exactly what the next section takes up: node weights, which relax the uniform type distribution, and edge weights, which relax the $[0,1]$ range.

15.5 Node- and edge-weighted generalizations

The gallery's closing paragraph put the two standing normalizations of definition 15.4 on the table and asked whether dropping them enlarges the theory. Both deserve the scrutiny. The uniform type distribution hid that real populations are not uniform in type—some kinds of agent are common, others vanishingly rare—and the $[0,1]$ range hid that real interactions need not be confined to it: a tie can be antagonistic, hence negative, or a transaction arbitrarily large, hence unbounded. The honest question is whether dropping these two normalizations produces a genuinely larger theory or merely a re-coordinatization of the one we have. The answer sorts the two relaxations cleanly, and each points at a named later development. Loosening uniformity—attaching *node weights*—adds nothing new in the dense theory: the weighting is absorbed back into the kernel, and what looks like a multi-population model is the same graphon read on a re-coordinatized type space. Loosening the range—admitting *edge weights*—splits in two: a benign bounded regime in which the whole machinery survives word for word, and a genuinely harder unbounded regime that no bounded kernel can model and that forces the sparse theory of chapter 27. We take the two relaxations in turn, and close by disposing of self-loops in a single line.

Node weights: a non-uniform type distribution. Begin with uniformity. A *node-weighted* graph attaches to each vertex i a weight $\rho_i > 0$, normalized so that $\sum_i \rho_i = 1$, recording what fraction of the population is of that kind—a model in which not all vertices count equally, as when a single "vertex" in a coarse description already stands for a whole sub-population. The pixel construction of definition 15.2 adapts immediately, and the only change is that the tiles are no longer congruent: instead of cutting $[0,1]$ into n equal cells we give vertex i the interval J_i of *length* ρ_i, laying the J_i end to end to tile $[0,1]$ (so $J_i = (\rho_1 + \cdots + \rho_{i-1},\, \rho_1 + \cdots + \rho_i]$), and we set $W(x,y) = A_{ij}$ for $x \in J_i$, $y \in J_j$. A heavily weighted vertex now occupies a correspondingly wide stripe of the square, so that integrating against Lebesgue measure on $[0,1]$ automatically weights each vertex by its ρ_i—the unequal tiling has encoded the node weights into the *geometry* of the picture. Passing to the limit, the surviving object is no longer a bare kernel but a *pair* (W,ν): a symmetric kernel W together with a probability measure ν on the type space $[0,1]$, the *type distribution*, recording how the population is spread across types. The constant from the unweighted theory, where ν was Lebesgue, has become a free piece of data.

The central claim is that this apparent enlargement is illusory in the dense theory: one can always *push the node weights into the kernel* and return to the uniform convention, recovering a plain graphon on $([0,1],\mathrm{Leb})$ that carries the same network content. The mechanism by which this is done depends on whether ν has atoms, and the two cases are genuinely different in character—one is a smooth change of variables, the other a piecewise tiling—so we narrate them separately.

The atomless case: re-coordinatize by the quantile transform. Suppose first that ν has no atoms, so no single type carries positive mass and the population is smeared continuously across $[0,1]$. Its cumulative distribution function

$$F_\nu(x) = \nu([0,x])$$

is then continuous and nondecreasing, running from 0 to 1 as x sweeps $[0,1]$. The point of F_ν is that it *spreads ν out to be uniform*: a sub-interval on which ν piles up a lot of mass is stretched by F_ν into a long sub-interval of the image, while a region ν barely charges is compressed, and the net effect is to even the mass out perfectly. This is the *probability-integral transform* of undergraduate probability—if a random type x is drawn from ν, then $F_\nu(x)$ is uniformly distributed on $[0,1]$—and stated as an identity it says that F_ν is a measure-preserving map from $([0,1],\nu)$ to $([0,1],\mathrm{Leb})$,

$$\nu(F_\nu^{-1}(B)) = \mathrm{Leb}(B) \qquad \text{for every Borel } B \subseteq [0,1], \tag{15.1}$$

i.e. the pushforward $(F_\nu)_\# \,\nu$ is Lebesgue measure. (The inverse here is the quantile function, the left-continuous inverse of F_ν; on the ν-null set where F_ν is flat the choice of inverse is immaterial precisely because that set carries no ν-mass.) Now transport the kernel along this map: define

$$\widetilde{W}(u,v) = W\big(F_\nu^{-1}(u),\, F_\nu^{-1}(v)\big), \qquad (u,v) \in [0,1]^2.$$

By the change-of-variables identity that (15.1) encodes, every double integral of W against $\nu \otimes \nu$ equals the corresponding integral of $\widetilde{W}$ against Leb$\otimes$Leb, so $\widetilde{W}$ is an ordinary graphon on $([0,1],\mathrm{Leb})$ producing exactly the same operator, the same edge density, and the same homomorphism densities as the weighted pair (W,ν). The node weights have vanished into the relabeling of the type axis. One scope note is owed here, in the self-contained spirit of the book: this is the *elementary CDF transform on the interval* and nothing more. We are using only that a continuous nondecreasing F_ν on $[0,1]$ has a quantile inverse satisfying (15.1); we are *not* invoking the general theorem that any two atomless standard Borel probability spaces are measurably isomorphic, which is a heavier statement we neither need nor prove.

The atomic case: tile by sub-intervals. The quantile transform stalls the instant ν has an atom, and it is worth seeing exactly why, because the obstruction is real and not a defect of the argument. If a single type x_i carries positive mass ρ_i, then any measure-preserving map to $([0,1],\mathrm{Leb})$ would have to send that one point to a set of Lebesgue measure $\rho_i > 0$; but a *bijection* sends a point to a point, and a point has Lebesgue measure zero. No measure-preserving bijection can therefore exist. This is precisely the case that matters in practice, since a genuinely finite type space—k populations, k communities—is purely atomic. The resolution is not a smooth change of variables but the interval-tiling we already built: spread the atom of mass ρ_i over the sub-interval J_i of length ρ_i and read the kernel as the step graphon that is constant on each block $J_i \times J_j$. A point of positive ν-mass becomes an interval of equal Lebesgue measure, and the map $x \mapsto J_i$ is many-to-one (not a bijection) exactly where it must be. The canonical instance is the stochastic block model of example 15.10 read as a k-population model: ν puts mass ρ_r on community C_r, the tiling assigns C_r an interval of length ρ_r, and the result is the step graphon of definition 15.6 with unequal blocks. The unequal block sizes *are* the node weights, now stored in Lebesgue geometry.

Either route—the quantile transform when ν is atomless, the interval tiling when it is atomic, and a routine combination on the mixed case—lands the weighted pair (W,ν) back on $([0,1],\mathrm{Leb})$ with its entire network content intact. The conclusion is the one promised at the head of the section: *node weights add no genuinely new object in the dense theory.* They are absorbed by re-coordinatizing the type axis, which is the very relabeling freedom of remark 15.5—the continuum analogue of permuting vertices, here used to permute the *amounts* of each type rather than their names. Accordingly we keep, as we have throughout, the convention that unless stated otherwise types are distributed uniformly on $[0, 1]$; a non-uniform ν is never an obstacle, only a reminder to absorb it first.

Edge weights: kernels beyond $[0, 1]$**.** Loosening the second normalization is not so benign, and the theory genuinely forks. An *edge-weighted* graph replaces the entries $A_{ij} \in \{0, 1\}$ by real numbers $w_{ij} \in \mathbb{R}$, modeling interactions that an edge probability cannot express: a negative weight for an antagonistic or competitive tie, a large positive weight for a heavy traffic volume or a large transaction. Its pixel picture is a symmetric measurable kernel now valued in $\mathbb{R}$ rather than $[0, 1]$, and whether this stays inside the theory of this book turns entirely on whether that kernel is *bounded.*

If it is—if $W : [0, 1]^2 \to \mathbb{R}$ is symmetric with $\|W\|_{L^\infty} \le M$ for some finite M—then nothing of substance changes. Every argument of this chapter, every line of the operator theory of chapter 18, and the stepping operator of proposition 15.7 go through verbatim with the range $[0, 1]$ replaced by $[-M, M]$. The reason is that none of those arguments used the *positivity* of the kernel or the specific upper bound 1; they used only symmetry and a finite sup-norm. Concretely, $\mathbb{W}$ is still self-adjoint Hilbert–Schmidt (proposition 2.24 invoked boundedness and symmetry alone, never $W \ge 0$), its spectrum is still real, and the stepping projection still returns a step kernel because a block average of values in $[-M, M]$ again lies in $[-M, M]$—the only property of the interval the averaging used was convexity, which $[-M, M]$ shares with $[0, 1]$. So the bounded symmetric kernel is the natural home of the whole dense theory, $[0, 1]$ being merely the special case of a propensity. What the signed case *adds* is not a difficulty but a genuine modeling distinction that the $[0, 1]$ convention had hidden. The Lasry–Lions monotonicity condition on a coupling (appendix A.6, (A-Mon)) asks for a definite sign, and with signed kernels that sign is a real choice: a positive coupling makes the interaction *attractive* (agents are drawn toward the aggregate they feel), a negative one makes it *repulsive* (they are pushed away, as in a congestion or competition term). Whether a graphon game has a unique equilibrium or several can hinge on exactly this sign, and that is where the distinction is cashed out, in chapters 20 and 24.

The fork's other branch is the unbounded one, and here the theory of this chapter genuinely runs out. Some networks cannot be modeled by any bounded kernel at all: sparse, heavy-tailed networks, in which a few hub types carry unboundedly many connections, have a degree distribution with no finite ceiling, and a bounded W produces only bounded degrees (we will define the degree function in section 15.6 and see it is $\int_0^1 W(x, \cdot)$, manifestly at most M). Capturing such networks forces a kernel with $\|W\|_{L^\infty} = \infty$, controlled instead only in some $L^p([0, 1]^2)$ with $p < 2$. The threshold genuinely sits at $p = 2$: on the finite measure space $[0, 1]^2$ the inclusions run the other way, $L^p \subseteq L^2$ for every $p \ge 2$, so a kernel that is still square-integrable remains Hilbert–Schmidt and hence a bounded operator on L^2—it is only when the kernel drops below square-integrability, into L^p with $p < 2$ (or is merely measurable), that the picture can break. The price of falling below that threshold is that the clean Hilbert–Schmidt picture degrades: such a kernel need no longer induce a bounded operator on $L^2[0,1]$, so the self-adjoint compact operator on which all of chapter 18 rests is no longer guaranteed, and the function-analytic repairs—operator-norm versus L^p-norm control of $\mathbb{W}$, and the revised existence and uniqueness theory that follows—are deferred, honestly, to chapter 27. We do not attempt them here. The order of development is deliberate and we state it plainly: the dense bounded theory comes first because it is the regime in which complete theorems exist, and the sparse unbounded theory is built later as a separate enterprise rather than smuggled in as a special case.

Loops and the diagonal. One last piece of data a real network might carry is self-loops, $A_{ii} \neq 0$, an agent's interaction with itself. In the dense graphon theory these are simply invisible, and the reason is the almost-everywhere principle already established in section 15.2: a self-loop changes the kernel only on the diagonal $\{x = y\}$, which is a Lebesgue-null subset of $[0,1]^2$, and a null set changes no integral. Hence loops alter *no* value of $\mathbb{W}$, *no* edge density, and *no* homomorphism density—every quantity we ever compute is an integral, and the integral cannot see the diagonal. We may therefore record self-links or zero them out at will, exactly as we did when disposing of the diagonal in definition 15.4. Loops return to relevance only in the sparse theory of chapter 27, where the reference measure is no longer Lebesgue and the diagonal can carry positive mass; in the dense bounded world of this chapter they cost us nothing and we ignore them.

With both relaxations accounted for, the graphon is back in its normalized form, and we can say precisely what we hand the next section. Node weights have been re-coordinatized away, so the type distribution is uniform on $[0,1]$; edge weights have been sorted, and we keep the branch on which the theory is complete, the *bounded symmetric* kernels, with the unbounded L^p regime quarantined in chapter 27. What remains is exactly the object the operator theory wants: a symmetric kernel, bounded, read on $[0,1]$ with Lebesgue measure—and, by proposition 2.24, precisely the clean self-adjoint Hilbert–Schmidt operator $\mathbb{W}$ that the final section now anatomizes as the single channel through which network structure enters every graphon mean field game.

15.6 The graphon operator: the coupling in every GMFG equation

The previous section handed us the graphon in its fully normalized form: a symmetric kernel, bounded, read on $[0,1]$ against Lebesgue measure—node weights re-coordinatized away into uniformity, edge weights restricted to the bounded branch on which the theory is complete. By proposition 2.24 this is exactly the data that makes the integral operator $\mathbb{W}$ a clean self-adjoint Hilbert–Schmidt map on $L^2[0,1]$. The whole chapter has been a march toward this operator: a network became an adjacency matrix, the matrix became a pixel picture, the picture's limit became a kernel, and now the kernel becomes the one operator the rest of the book actually uses. This closing section says *why* that operator, and nothing else about the network, is what the games of Part IV will see.

The claim is sharp and worth stating before any formalism, because it organizes everything that follows. In every graphon mean field game to come—static (chapter 20), dynamic (chapters 22 and 23), at equilibrium (chapter 24)—a type-x agent never feels the network "directly." It feels a single scalar, the value at its own type of a population aggregate, and that aggregate is always built the same way: take whatever statistic $h\colon [0,1] \to \mathbb{R}$ the agents respond to—a mean state, a density of chosen actions, a congestion level, indexed by the type of the agent producing it—and pass it through the kernel,

$$z(x) = (\mathbb{W}\, h)(x) = \int_0^1 W(x, y)\, h(y)\ \mathrm{d}y.$$

The integral is a weighted average of the statistic over the whole population, the weight $W(x, y)$ being precisely the propensity of a type-x agent to be linked to a type-y one. Where a classical mean field game would hand the agent the flat population average $\int h$—every other agent counted equally—the graphon game hands it the *network-weighted* average $(\mathbb{W}h)(x)$, and the difference between the two is the entire content of "the agents interact through a network" rather than through an anonymous crowd. The constant graphon $W \equiv p$ collapses $(\mathbb{W}h)(x) = p \int h$ back to a multiple of the flat average, which is exactly why the classical theory is the constant-graphon special case.

The decisive structural fact is the one the displayed formula already shows: the graphon enters *only* through the linear map $h \mapsto \mathbb{W}h$. No equation of Part IV ever evaluates W at a point, or asks for any feature of the kernel that the operator does not already carry. Consequently, "understand the network's effect on the game" and "understand $\mathbb{W}$ as a linear operator on type-fields" are the same task, and we can dispatch the first by doing the second once and for all. We do exactly that here: assemble the elementary operator facts—norm, degree, positivity, monotonicity—that the later chapters invoke by name, leaving the finer spectral anatomy, which deserves its own development, to chapter 18.

We recall the operator from definition 2.23 rather than redefine it.

Definition 15.13 (Graphon operator, recalled)**.** The *graphon operator* $\mathbb{W}\colon L^2[0,1] \to L^2[0,1]$ of a graphon W is $(\mathbb{W}f)(x) = \int_0^1 W(x, y) f(y)\ \mathrm{d}y$ (definition 2.23). Under (A-Reg-W) it is self-adjoint Hilbert–Schmidt on $L^2[0,1]$ with $\|\mathbb{W}\| \le \|\mathbb{W}\|_{\mathrm{HS}} = \|W\|_{L^2([0,1]^2)} \le 1$ (proposition 2.24), and its spectrum is real, discrete away from 0, and treated in full in chapter 18.

The one network statistic we attach to $\mathbb{W}$ now, because it controls the coupling bounds of Part IV directly, is the degree function.

Definition 15.14 (Degree function)**.** The *degree function* of a graphon W is

$$d_W(x) = \int_0^1 W(x, y)\ \mathrm{d}y = (\mathbb{W}\mathbf{1})(x),$$

the expected fraction of the population to which a type-x agent links. For a graphon, $d_W(x) \in [0, 1]$.

Three readings make this object concrete. First, its meaning: $d_W(x)$ is the result of applying the coupling to the constant unit field, $\mathbb{W}\mathbf{1}$, which is the special case of the aggregate $z = \mathbb{W}h$ in which every agent contributes the same unit statistic $h \equiv 1$. It is therefore the total network "weight" a type-x agent feels—the expected fraction of the population it links to—and nothing else. Second, its range: because $0 \le W \le 1$, the average $\int_0^1 W(x, y)\ \mathrm{d}y$ of a quantity bounded by 1 over a set of total measure 1 lands in $[0, 1]$, so d_W is itself a $[0, 1]$-valued function on the type space—a degree, sensibly, is a fraction. Third, its provenance: it is the exact continuum limit of the normalized vertex degrees $\frac{1}{n}\sum_j A_{ij}$ of the underlying graphs. For a pixel graphon W^G this is visible by direct computation—on the block $I_i^{(n)}$ the kernel equals A_{ij} for $y \in I_j^{(n)}$, so

$$d_{W^G}(x) = \int_0^1 A_{i\,\iota_n(y)}\,\mathrm{d}y = \sum_{j=1}^n A_{ij}\left|I_j^{(n)}\right| = \frac{1}{n}\sum_{j=1}^n A_{ij} \qquad (x \in I_i^{(n)}),$$

so d_{W^G} is constant on each block $I_i^{(n)}$ and equals there exactly the degree fraction of vertex i. The degree function is the macroscopic shadow of the degree sequence.

Averaging the degree over the population closes a loop we opened in section 15.1. By Fubini–Tonelli,

$$\int_0^1 d_W(x)\,\mathrm{d}x = \int_0^1\int_0^1 W(x,y)\,\mathrm{d}y\,\mathrm{d}x = \int_{[0,1]^2} W = \langle \mathbb{W}\mathbf{1}, \mathbf{1}\rangle,$$

which says three things are one and the same number: the mean degree, the edge density of proposition 15.3, and the quadratic form of $\mathbb{W}$ on the constant field. The edge density that we first met as an edge count $2\,|E|\,/n^2$, then as a homomorphism density, now appears a third time in purely operator language as $\langle \mathbb{W}\mathbf{1}, \mathbf{1}\rangle$—the same scalar read off three faces of the same object, exactly the chapter's recurring lesson that the network reaches everything downstream through $\mathbb{W}$ alone.

The degree function is not only a summary statistic; it gives the sharpest elementary bound on the operator norm, by a Schur-test argument that we include in full because it is short, self-contained, and used directly in the contraction estimates of chapter 24.

Lemma 15.15 (Degree (Schur) bound on the operator norm)**.** *For any graphon W (more generally any symmetric kernel with $W \geq 0$),*

$$\|\mathbb{W}\| \;\leq\; \operatorname*{ess\,sup}_{x\in[0,1]} d_W(x) \;=\; \|d_W\|_{L^\infty} \;\leq\; \|W\|_{L^\infty} \leq 1.$$

Moreover $\mathbb{W}\mathbf{1} = d_W$, so if $d_W \equiv c$ is constant then $\|\mathbb{W}\| = c$ and the bound is attained.

Proof. Write $D = \|d_W\|_{L^\infty}$, so that $d_W(x) \leq D$ for a.e. x. We must show $\|\mathbb{W}f\|_{L^2} \leq D\,\|f\|_{L^2}$ for every $f \in L^2[0,1]$, since the operator norm is by definition the smallest such constant.

The one idea in the proof is to split the kernel symmetrically before applying Cauchy–Schwarz, so that one factor of W supplies the degree and the other stays married to f. Concretely, inside the integrand of $(\mathbb{W}f)(x) = \int_0^1 W(x,y)f(y)\,\mathrm{d}y$ factor $W = W^{1/2}\cdot W^{1/2}$ (legitimate because $W \geq 0$, the one place positivity of the kernel is used) and regard the two halves as the two functions of y entering the Cauchy–Schwarz inequality $\left(\int gh\right)^2 \leq \left(\int g^2\right)\left(\int h^2\right)$, with $g = W(x,\cdot)^{1/2}$ and $h = W(x,\cdot)^{1/2}f$. Then $g^2 = W$ and $h^2 = Wf^2$, so for a.e. x,

$$\big((\mathbb{W}f)(x)\big)^2 = \left(\int_0^1 W(x,y)^{1/2}\cdot W(x,y)^{1/2}f(y)\,\mathrm{d}y\right)^2 \leq \underbrace{\left(\int_0^1 W(x,y)\,\mathrm{d}y\right)}_{=d_W(x)}\left(\int_0^1 W(x,y)f(y)^2\,\mathrm{d}y\right),$$

the first factor being exactly the degree $d_W(x)$. This is the pointwise inequality

$$(\mathbb{W}f)(x)^2 \leq d_W(x)\int_0^1 W(x,y)f(y)^2\,\mathrm{d}y.$$

Now integrate over $x \in [0,1]$. Bounding the degree factor by its supremum $d_W(x) \le D$ and then exchanging the order of integration—Fubini–Tonelli (theorem 1.27) applies because the integrand $W f^2 \ge 0$ is nonnegative, so Tonelli licenses the swap unconditionally—gives

$$\|\mathbb{W}f\|_{L^2}^2 = \int_0^1 (\mathbb{W}f)(x)^2 \,\mathrm{d}x \le D \int_0^1\int_0^1 W(x,y)f(y)^2 \,\mathrm{d}y\,\mathrm{d}x = D\int_0^1 f(y)^2\Big(\int_0^1 W(x,y)\,\mathrm{d}x\Big)\,\mathrm{d}y.$$

The inner integral is where symmetry earns its keep: $\int_0^1 W(x,y)\,\mathrm{d}x = \int_0^1 W(y,x)\,\mathrm{d}x = d_W(y)$, because integrating the kernel over its *first* slot would not be the degree, but symmetry $W(x,y) = W(y,x)$ turns it into an integral over the second slot, which is. Hence

$$\|\mathbb{W}f\|_{L^2}^2 \le D\int_0^1 f(y)^2\, d_W(y)\,\mathrm{d}y \le D\cdot D\int_0^1 f(y)^2\,\mathrm{d}y = D^2\,\|f\|_{L^2}^2\,,$$

using $d_W \le D$ a second time. Taking square roots gives $\|\mathbb{W}f\|_{L^2} \le D\,\|f\|_{L^2}$, hence $\|\mathbb{W}\| \le D = \|d_W\|_{L^\infty}$. The remaining inequalities are pointwise: $d_W(x) = \int_0^1 W(x,y)\,\mathrm{d}y \le \|W\|_{L^\infty}\int_0^1 \mathrm{d}y = \|W\|_{L^\infty} \le 1$, so $\|d_W\|_{L^\infty} \le \|W\|_{L^\infty} \le 1$.

For the attainment, recall $\mathbb{W}\mathbf{1} = d_W$ (definition 15.14). If the degree is constant, $d_W \equiv c$, then $\mathbb{W}\mathbf{1} = c\mathbf{1}$, so the constant field is an eigenvector with eigenvalue c; since $\|\mathbf{1}\|_{L^2} = 1$ this forces $\|\mathbb{W}\| \ge \|\mathbb{W}\mathbf{1}\|_{L^2} = c$, which together with the upper bound $\|\mathbb{W}\| \le \|d_W\|_{L^\infty} = c$ gives $\|\mathbb{W}\| = c$. The bound is exact precisely when the network is degree-regular. □

Two worked checks calibrate the lemma, one where it is exact and one where it is not. For the constant (Erdős–Rényi) graphon $W \equiv p$ the degree is constant, $d_W \equiv p$, so the attainment clause applies verbatim and the lemma returns $\|\mathbb{W}\| = p$ on the nose—recovering the operator norm computed spectrally in worked computation 2.28(a). This is the degree-regular case, and the Schur bound is tight exactly because every row of the kernel has the same mass.

The rank-one (Curie–Weiss) graphon $W(x,y) = f(x)f(y)$ of section 15.4.3 shows the other side. Its degree is $d_W(x) = f(x)\int_0^1 f$, no longer constant unless f is, so the Schur bound reads

$$\|\mathbb{W}\| \le \|d_W\|_{L^\infty} = \|f\|_{L^\infty}\int_0^1 f,$$

whereas the exact operator norm, found in worked computation 2.28(b) by noting that f itself is the lone eigenfunction, is $\|\mathbb{W}\| = \|f\|_{L^2}^2 = \int_0^1 f^2$. Cauchy–Schwarz guarantees $\int f^2 \le \|f\|_\infty \int f$, so the bound is always correct; it is tight only when f is constant. A single number makes the gap concrete. Take $f(x) = x$, so $W(x,y) = xy$ is a legitimate graphon (≤ 1 on the square). Then $\int_0^1 f = \frac{1}{2}$, $\|f\|_\infty = 1$, and $\int_0^1 f^2 = \frac{1}{3}$, so the Schur bound gives $\|\mathbb{W}\| \le \frac{1}{2}$ while the truth is $\|\mathbb{W}\| = \frac{1}{3}$: a correct estimate that overshoots by fifty percent. The reason is structural and worth naming, because it recurs whenever one uses a row-sum bound. The Schur estimate controls the operator by the *largest* row mass $\sup_x d_W(x)$, as if the worst-connected type set the norm; but the true norm is a global, energy-weighted quantity that the high-degree types dominate only in proportion to how much of the eigenvector's mass sits on them. Off the degree-regular case the heaviest row overstates the operator, and the lemma cheerfully reports a ceiling rather than the value.

Even so, a ceiling is exactly what Part IV usually needs, and that is the lemma's real payoff. The existence and uniqueness theorems of the graphon games invoke an abstract smallness condition on the coupling, (A-Coupling): $\|\mathbb{W}\| < \kappa$ for a threshold κ set by the cost data. As stated this is a condition on a spectral radius, awkward to verify for a kernel given by a formula or estimated from data. The Schur bound converts it into something one can read off the network's degrees: if *every* type has degree fraction below κ, that is $\|d_W\|_{L^\infty} < \kappa$, then $\|\mathbb{W}\| < \kappa$ automatically and (A-Coupling) holds. A verifiable degree condition replaces an abstract operator-norm condition, and the over-conservatism we just exhibited is the harmless price of that convenience—a sufficient condition can afford to be generous.

Two further structural properties of $\mathbb{W}$ are used throughout Part IV. They are not deep—both follow in a line from the fact that $W \geq 0$ and that integration against a nonnegative kernel is an averaging—but they are exactly the properties that the existence theory leans on, so it is worth isolating them and seeing precisely why each holds. The first says the coupling cannot turn a nonnegative statistic negative, nor reverse an inequality between two statistics; the second says it cannot amplify a uniformly bounded statistic. Both are statements that $\mathbb{W}$ *respects order*, which is what monotone fixed-point arguments require of it.

Proposition 15.16 (Positivity and monotonicity of the coupling)**.** *Let W be a graphon and $\mathbb{W}$ its operator.*

(i) (Positivity preserving.) *If $f \geq 0$ a.e. then $\mathbb{W}f \geq 0$ a.e.; consequently $f \leq g$ a.e. implies $\mathbb{W}f \leq \mathbb{W}g$ a.e.*

(ii) (L^∞ bound.) *$\mathbb{W}$ maps $L^\infty[0,1]$ into itself with $\|\mathbb{W}f\|_{L^\infty} \leq \|d_W\|_{L^\infty} \|f\|_{L^\infty} \leq \|f\|_{L^\infty}$; in particular $\mathbb{W}$ preserves the order interval $[0,1]$ of fields when $d_W \leq 1$.*

Proof. (i) Suppose $f \geq 0$ a.e. Since the kernel is nonnegative, the integrand $W(x,y)f(y)$ is a product of two a.e.-nonnegative quantities, hence ≥ 0 for a.e. y; an integral of a nonnegative function is nonnegative, so $(\mathbb{W}f)(x) = \int_0^1 W(x,y)f(y)\,\mathrm{d}y \geq 0$ for a.e. x, which is $\mathbb{W}f \geq 0$. Monotonicity is this positivity together with linearity. If $f \leq g$ a.e., then $g - f \geq 0$ a.e., so by what we just proved $\mathbb{W}(g-f) \geq 0$; but $\mathbb{W}$ is linear, so $\mathbb{W}(g-f) = \mathbb{W}g - \mathbb{W}f$, and therefore $\mathbb{W}g - \mathbb{W}f \geq 0$, i.e. $\mathbb{W}f \leq \mathbb{W}g$ a.e. The order on type-fields is preserved.

(ii) Let $f \in L^\infty[0,1]$. For a.e. x, pull the absolute value inside the integral and use $W \geq 0$ to keep it as a weight:

$$|(\mathbb{W}f)(x)| = \Big|\int_0^1 W(x,y)f(y)\,\mathrm{d}y\Big| \leq \int_0^1 W(x,y)\,|f(y)|\,\mathrm{d}y \leq \|f\|_{L^\infty} \int_0^1 W(x,y)\,\mathrm{d}y = \|f\|_{L^\infty}\, d_W(x),$$

the second inequality replacing $|f(y)|$ by its a.e. upper bound $\|f\|_{L^\infty}$ under the nonnegative weight $W(x,\cdot)$, and the final equality being the definition of the degree. Taking the essential supremum over x gives $\|\mathbb{W}f\|_{L^\infty} \leq \|f\|_{L^\infty}\|d_W\|_{L^\infty}$, and since $\|d_W\|_{L^\infty} \leq 1$ for a graphon, $\mathbb{W}$ is a contraction on $L^\infty[0,1]$. In particular, if $0 \leq f \leq 1$ a.e. then by (i) and (ii) $0 \leq \mathbb{W}f \leq \|d_W\|_{L^\infty} \leq 1$, so $\mathbb{W}$ maps the order interval of $[0,1]$-valued fields into itself. □

Each of these properties has a named destination. Positivity guarantees that the graphon aggregate of a nonnegative population statistic—a density, a congestion level—is again nonnegative, the elementary consistency without which the forward Fokker–Planck side of the dynamic system of chapter 22 would be ill-posed. Monotonicity is the order-theoretic input to the monotone fixed-point methods that construct equilibria there and in chapter 24: those arguments iterate the best-response map and need $\mathbb{W}$ to preserve the order between successive iterates, which is exactly what proposition 15.16(i) provides. The degree/Schur bound (lemma 15.15) is what turns the abstract coupling threshold (A-Coupling) into the checkable degree condition that the uniqueness proof of chapter 24 actually verifies. And the self-adjoint Hilbert–Schmidt structure recalled in definition 15.13—real spectrum, orthonormal eigenmodes, discreteness away from zero—is the entry point for chapter 18, where the network is read through the eigenvalues and eigenfunctions of $\mathbb{W}$: spectral gap as mixing rate, top eigenvector as centrality, and finite-rank truncation as a principled low-dimensional reduction of the game.

That last point is the chapter's hidden spine, and it is worth stating as the operator's parting lesson. Because the game sees the network only through $z = \mathbb{W}h$, the effective dimensionality of a graphon mean field game is the rank of the coupling, not the size of the network: the number of order parameters needed to close the game equals the number of modes of $\mathbb{W}$ that the dynamics excite. The rank-one (Curie–Weiss) graphon $W = f(x)f(y)$ is the cleanest instance and the seed of Thread B—there $(\mathbb{W}h)(x) = f(x)\int_0^1 f(y)h(y)\,\mathrm{d}y$ collapses to $z(x) = \varrho\, f(x)$ with the *single* scalar order parameter $\varrho = \langle f, h\rangle$, so an entire continuum of type-indexed agents closes on one number. The spectral reading of chapter 18 is the general form of this collapse: a coupling of rank r closes on r order parameters.

With this the operator side of the graphon is fully assembled, and with it the chapter. We have built one object three ways—a network as a matrix, a matrix as a picture, a picture's limit as a kernel—and shown that all three feed a single linear map $\mathbb{W}$ on type-fields: self-adjoint, Hilbert–Schmidt, positivity-preserving, monotone, of norm at most one, with degree-controlled operator norm. This is the entire interface between "the network" and "the game." Every equation of Part IV is, structurally, a classical mean field game with the anonymous global mean $\int h$ replaced by the network-weighted aggregate $\mathbb{W}h$, and the chapters that follow are, in this light, the systematic study of that one substitution: chapter 18 diagonalizes $\mathbb{W}$, chapters 20, 22 and 23 install it inside the static and dynamic equilibrium systems, and chapter 24 closes those systems under the coupling-smallness threshold this section made verifiable. The graphon has stopped being a picture and become an operator; from here on we compute with it.

Rigor ledger

Proved (in this chapter).

- Every pixel graphon W^G is a symmetric measurable graphon, $\{0,1\}$-valued for an unweighted graph, with $\int_{[0,1]^2} W^G = 2\,|E|\,/n^2$ the edge density (proposition 15.3).
- The stepping operator $\Pi_{\mathcal{P}}$ is the orthogonal projection of $L^2([0,1]^2)$ onto step functions adapted to $\mathcal{P}$; it preserves symmetry, the range $[0,1]$, and all block masses (proposition 15.7). Pixel graphons are exactly the steps to the equipartition.
- Rank-one collapse: for $W(x,y) = f(x)f(y)$ the graphon aggregate $z(x) = (\mathbb{W}\bar{m})(x) = \varrho f(x)$ reduces to a single scalar order parameter $\varrho = \langle f, \bar{m}\rangle$, turning the type-continuum

game into a one-dimensional fixed-point equation (worked computation 15.12); the constant graphon $f \equiv \sqrt{p}$ recovers the classical global-mean coupling $z \equiv p\,\langle \bar{m} \rangle$.

- Degree (Schur) bound $\|\mathbb{W}\| \le \|d_W\|_{L^\infty} \le 1$, attained for constant degree (lemma 15.15); positivity and monotonicity of $\mathbb{W}$, and its L^∞ bound (proposition 15.16).

Assumed (imported, proved elsewhere in the book).

- Lebesgue measure, L^p completeness, and Fubini–Tonelli on $[0,1]$ and $[0,1]^2$ (definition 1.29 and theorems 1.27 and 1.31).
- Hilbert-space geometry: orthogonal projection, Parseval expansion (theorems 2.5 and 2.8).
- That $\mathbb{W}$ is self-adjoint Hilbert–Schmidt with $\|\mathbb{W}\| \le \|W\|_{L^2} \le 1$, and its spectral theorem (definition 2.23, proposition 2.24, and theorem 2.26); the constant and rank-one spectra (worked computation 2.28).
- The standing graphon LQG model and its coupling $z(x) = (\mathbb{W}\bar{m})(x)$ (appendix A.7); standing assumptions (A-Reg-W), (A-Coupling), (A-Mon) (appendix A.6).

Deferred (to a named later chapter).

- The precise meaning and proof of "$W^{G_n} \to W$": homomorphism-density (left) convergence (chapter 16); the cut metric $\delta_\square$, the relabeling quotient, and Lovász–Szegedy compactness (chapter 17).
- The spectral reading of networks (centrality, gap) and low-rank reductions (chapter 18).
- Sampling $G(n, W)$ and concentration; the weak regularity lemma as bounded-complexity step-graphon approximation (chapter 19).
- The dynamic rank-one fixed point with explicit LQG best response, and existence/uniqueness via $\|\mathbb{W}\|$ (chapters 22 and 24); the block-graphon = multi-population reduction (chapter 30).
- Unbounded L^p/sparse kernels and the repair of the Hilbert–Schmidt theory (chapter 27).

Open (genuinely, beyond this book's settled theory).

- Identifiability: recovering a graphon (its relabeling class) from a single observed finite network is only partially understood, and quantitative rates degrade with sparsity; flagged again in chapters 19 and 31.
- A fully satisfactory limit theory for sparse, heavy-tailed networks (graphexes, L^p graphons) remains an active research frontier (chapters 27 and 31).

Bibliographic notes

The pixel picture and the definition of a graphon as a symmetric measurable kernel on $[0,1]^2$ originate in the dense graph-limit theory of Lovász and Szegedy [100] and Borgs, Chayes, Lovász, Sós and Vesztergombi [29]; the authoritative reference for everything in this chapter and the next four is Lovász's monograph [99], with the survey [98] a gentler first pass that this chapter follows in spirit. The reading of the type variable as an *exchangeable* label is made precise by the Aldous–Hoover representation of exchangeable arrays, surveyed for this audience by Diaconis and Janson [60], who also explain why two graphons related by a measure-preserving map encode the same random graph—the analytic root of remark 15.5, taken up properly with the cut metric in chapter 17.

The stepping operator of definition 15.6 is the conditional-expectation / block-averaging operator that underlies the weak and strong regularity lemmas; its role as the engine of approximation by stochastic block models is developed in [99, Ch. 9, Ch. 14], and we return to it in chapter 19. The stochastic block model as a step graphon, and node/edge weights as weighted graph limits, are treated in [99, Ch. 7–8] and [29]; the expected-degree (Chung–Lu) reading of the rank-one graphon is standard in the random-graph literature.

The operator viewpoint—$\mathbb{W}$ as the self-adjoint Hilbert–Schmidt coupling, the degree function, the Schur bound—is the bridge to the mean field game theory of Part IV and is emphasized in the graphon-game line of work: Parise and Ozdaglar's static graphon games [108], the stochastic static graphon games of Carmona, Cooney, Graves and Laurière [39], and the dynamic graphon mean field games of Caines and Huang [34, 33], where the rank-one and block reductions of worked computation 15.12 and example 15.10 are exactly the tractable models. The constant-graphon reduction to the classical homogeneous theory connects back to the foundational mean field game papers of Lasry and Lions [93] and Huang, Caines and Malhamé [82] and to the LQG capstone of chapter 14.

Chapter 16

Homomorphism Densities and the Topology of Convergence

In chapter 15 a graphon was introduced (definition 15.4) as the limiting object of a sequence of dense graphs: a symmetric measurable kernel $W\colon [0,1]^2 \to [0,1]$, with the type variable $x \in [0,1]$ an exchangeable label rather than a spatial coordinate (the standing convention, restated in appendix A.5). What that chapter did *not* settle is the sense in which a sequence of finite graphs (G_n) "converges" to a graphon. The pixel picture — redraw the adjacency matrix as a black-and-white image on $[0,1]^2$ and refine the grid — is suggestive but treacherous, because it depends on an arbitrary choice of vertex order. Take the three-vertex path a–b–c, a centre b joined to two leaves. List its vertices with the centre in the middle, in the order (a,b,c), and the two edges sit just off the main diagonal, a tidy band hugging it; list them with the centre last, in the order (a,c,b), and those same two edges migrate into the far row and column, an L pushed against the border of the image. One graph, two orderings, two visibly different pictures — yet nothing about the graph has changed, only the names of its vertices. The pathology runs the other way too: a single graphon admits a whole continuum of equally valid pixel pictures, obtained by permuting — more generally, measure-preservingly rearranging — the type interval. The image is an artifact of labelling, not a property of the network. We need a notion of convergence that is blind to relabelling and that captures only the *statistical* content of a network.

This chapter supplies that notion. The central observable is the *homomorphism density* $t(F,G)$, the frequency with which a fixed small pattern F — an edge, a triangle, a path, a star — appears, in the appropriate counting sense, inside a host graph G. These densities are the *moments* of a graph: a countable family of numbers in $[0,1]$ that summarize its structure exactly as the moments $\int t^k \,\mu(\mathrm{d}t)$ summarize a probability measure on the line. This analogy is the organizing idea of the whole chapter, so it is worth stating sharply once. A probability measure on a bounded interval is pinned down completely by the single sequence of its moments — the determinate case of the classical moment problem — and in precisely the same way a graph, or its limiting graphon, is pinned down by the single family of its homomorphism densities, up to the one feature these numbers cannot resolve: the labelling of its vertices. The mean of a measure is its crudest moment; the edge density is its graph analogue. The higher monomials t^k are the higher moments; the larger motifs F are the larger graph moments. Nothing beyond the full family is needed, and that is what makes a *moment theory of graphs* possible. We develop three things in turn. First (section 16.1) we define homomorphism densities for finite graphs and for graphons, prove the elementary counting estimates that relate the several natural normalizations, and show that the graphon densities extend the finite ones with no seam. Second (section 16.2) we define *left-convergence* of a graph sequence as convergence of *all* motif densities, exhibit the topology this induces as a product ("moment") topology, and record both the easy Tychonoff compactness of the profile space and the deep theorem of Lovász and Szegedy — proved in chapter 17 and appendix F — that every left-convergent sequence has a graphon limit. The bridge between motif densities and the metric of chapter 17 is the *counting lemma*, which we state and prove here. Third (section 16.3) we treat the *moment problem for graphs*: exactly which sequences of numbers arise as the homomorphism densities of some graphon. The answer — normalization, multiplicativity, and reflection positivity — is the graph-theoretic twin of the classical theorem that a sequence of reals is a moment sequence iff its Hankel matrices are positive semidefinite.

Throughout, W denotes a graphon satisfying **(A-Reg-W)**: symmetric, measurable, and bounded, here with values in $[0, 1]$. The operator viewpoint $\mathbb{W}$ (definition 2.23) returns in chapter 18; the sampling of finite graphs from W, and the concentration of the densities defined below, are the subject of chapter 19. We use no result from the mean field game chapters; this chapter is pure graph-limit theory, and it is the vocabulary in which the convergence statements of Part IV (chapter 25) are eventually phrased.

16.1 Homomorphisms and homomorphism densities

The preamble promised a single observable — the homomorphism density — and called it "the moments of a graph." This section cashes that promise out concretely, building the observable from the ground up. A *homomorphism* is the formal version of the most naive thing one can do with two graphs: take a small fixed pattern F — an edge, a triangle, a path, a star — and try to lay it down inside a large host G, sending the vertices of F to vertices of G so that every edge of the pattern falls on an actual edge of the host. Counting how many such placements exist, and normalizing so that the count becomes a frequency, *is* the observable. There is nothing more to it than counting how often the small pattern fits.

One choice in that sentence deserves a word of warning before we make it, because it looks like a technicality and is in fact the source of all the good algebra to come: we count *maps*, not literal subgraph copies. A homomorphism is free to send two vertices of F to the same vertex of G, and free to send a non-edge of F onto an edge of G; it is forbidden only from sending an edge of F onto a non-edge. This is more permissive than the geometric notion of "a copy of F sitting inside G," and the extra permissiveness is exactly what we want. Counting all maps gives a quantity that is a clean sum over an unconstrained product set, so it factorizes over disjoint unions of patterns and behaves algebraically like a moment or a partition function; and it is the form that lifts without friction to a graphon, where "a uniformly chosen vertex" becomes "a uniformly chosen type" and "is an edge" becomes "carries the weight $W(x, y)$." The stricter, geometrically faithful counts — injective and induced — differ from the map-count only by the rare placements that collapse two vertices onto one, a correction of relative size $O(1/n)$ that we will quantify exactly and then never worry about again.

The section therefore proceeds in three movements, finite graphs first and graphons second with no seam between them. We *count*: fix two finite graphs and tally the maps from one into the other, in the three increasingly strict senses just sketched. We *normalize*: divide each raw count by the number of maps of its kind so that what remains is a frequency in $[0, 1]$, and we reconcile the three normalizations by an elementary counting estimate showing they agree in the large-host limit. Finally we *lift*: transport the probabilistic reading of the density verbatim to a graphon, where the count becomes an integral over the type cube, and we prove that this graphon density restricts back to the finite one exactly — the pixel graphon of a finite graph has precisely the densities of that graph. By the end the reader should be convinced that $F \mapsto t(F, \cdot\,)$ is one and the same well-defined functional, valued in $[0, 1]$ and multiplicative over disjoint unions, whether its second argument is a finite graph or a graphon. That functional, ranged over all patterns F, is the *homomorphism profile*, and it is the object section 16.2 will turn into a notion of convergence. We begin with the rawest layer of all: counting the maps between two fixed finite graphs.

16.1.1 Counting maps between finite graphs

The observable promised above is, at bottom, a count, and a count needs two ingredients: two graphs and a notion of what it means to lay one down inside the other. We fix both now, in the most elementary form there is, with both graphs finite — a small fixed pattern F and a large host G — and we isolate the single most basic question that everything later in the chapter is built upon: in how many ways can F be placed inside G? The subtlety, and the reason this short subsection earns its own heading, is that "placed inside" is not one notion but three, of increasing strictness, and the differences among them are exactly what the rest of the section will have to reconcile. The three integers defined here — hom, inj, ind — are the raw material; the densities, the moment profile, and the entire convergence theory are refinements of them.

Let F and G be finite simple graphs, with vertex sets $V(F), V(G)$ and edge sets $E(F), E(G)$; write $k = |V(F)|$ and $n = |V(G)|$. A simple graph has no loops and no multiple edges, and edges are unordered pairs $\{i, j\}$, which we abbreviate ij. We write $|E(F)|$ for the number of edges of F; chapter 17 writes the same quantity $e(F)$. The two notations name one and the same integer, and we keep both on purpose. The set-theoretic form $|E(F)|$ is the natural one here, where we are counting maps and partitioning them by their fibres and the edge *set* is an object we point at directly; the lighter $e(F)$ reads better in chapter 17, where the number of edges surfaces only as a Lipschitz constant multiplying a cut norm. This is a deliberate cross-chapter convention rather than an inconsistency to be smoothed over, and wherever the seam could cause confusion we say which form is meant.

Definition 16.1 (Homomorphism)**.** A *homomorphism* from F to G is a map $\varphi\colon V(F) \to V(G)$ that preserves adjacency: $ij \in E(F)$ implies $\varphi(i)\varphi(j) \in E(G)$. Write $\hom(F, G)$ for the number of homomorphisms. An *injective homomorphism* is one that is also injective on vertices; write $\mathrm{inj}(F, G)$ for their number. An *embedding* is an injective homomorphism φ that additionally reflects non-adjacency, $ij \notin E(F) \Rightarrow \varphi(i)\varphi(j) \notin E(G)$; write $\mathrm{ind}(F, G)$ for their number.

The three definitions are a chain of progressively tighter demands, and it pays to say in words what each successive clause forbids and what that costs. A bare homomorphism is allowed to do two things that offend the geometric eye. It may *collapse*: send several vertices of F to one vertex of G, so that the placed pattern is degenerate — a triangle laid down with two of its corners on the same point. The consequence is that hom overcounts honest copies by including these pinched, lower-dimensional placements; harmless in the limit, since they are vanishingly rare, but the precise source of the $O(1/n)$ corrections tracked in lemma 16.6. A homomorphism may also *create an edge*: send a non-adjacent pair of F onto an adjacent pair of G, since the adjacency-preservation clause constrains only the edges of F and is silent about its non-edges. The consequence is that hom cannot distinguish F from any graph obtained by deleting some of its edges; it registers only a lower bound on the structure actually present. The one liberty even a bare homomorphism is denied is the converse of the first: it may never send an edge of F onto a non-edge of G, for that is exactly the adjacency it is required to preserve, and this single prohibition is what makes the count nontrivial. Demanding injectivity withdraws the first licence (no collapsing), so inj counts only non-degenerate placements of all k vertices on distinct hosts. Demanding in addition that non-adjacency be reflected withdraws the second (no created edges), so an embedding lands F on a set of k vertices of G whose *induced* subgraph is exactly F — neither more edges nor fewer — which is why ind is the count of *induced* copies and the one faithful to the geometric picture of "F sits inside G." The chain $\mathrm{ind}(F, G) \le \mathrm{inj}(F, G) \le \mathrm{hom}(F, G)$ records the price of each added demand.

A single tiny host makes all three visible at once.

Example 16.2 (Three kinds of placement in one picture)**.** Let $F = P_3$ be the path 1–2–3 (edges 12 and 23, with 13 its single non-edge), and let the host G be the *paw*: a triangle on $\{a, b, c\}$ together with one extra vertex d joined only to a. Three placements of P_3 exhibit the three notions exactly.

- *A collapsing homomorphism.* Send $1 \mapsto a$, $2 \mapsto b$, $3 \mapsto a$. The edges go $12 \mapsto ab$ and $23 \mapsto ba$, both present in G, so adjacency is preserved and this is a homomorphism; but 1 and 3 land on the same vertex a, so it is not injective. It is counted by $\mathrm{hom}(P_3, G)$ and not by $\mathrm{inj}(P_3, G)$.

- *An injection that creates an edge.* Send $1 \mapsto b$, $2 \mapsto a$, $3 \mapsto c$. The three images are distinct and the edges go $12 \mapsto ba$, $23 \mapsto ac$, both present, so this is an injective homomorphism. But the non-edge 13 of P_3 maps to bc, which *is* an edge of the triangle: the map manufactures an adjacency the pattern did not have. It is counted by $\mathrm{inj}(P_3, G)$ and not by $\mathrm{ind}(P_3, G)$.

- *An embedding.* Send $1 \mapsto d$, $2 \mapsto a$, $3 \mapsto b$. The edges go $12 \mapsto da$ and $23 \mapsto ab$, both present; the images are distinct; and the non-edge 13 maps to db, which is genuinely a non-edge of the paw. Non-adjacency is reflected, so the induced subgraph of G on $\{d, a, b\}$ is exactly the path d–a–b: a faithful induced copy of P_3. It is counted by $\mathrm{ind}(P_3, G)$.

The same example shows the strictness is not free. The path P_3 has injective homomorphisms into the bare triangle K_3 — for instance $1 \mapsto a$, $2 \mapsto b$, $3 \mapsto c$ — yet *no* embedding into K_3 at all, because K_3 has no non-adjacent pair on which to realize the non-edge 13. Thus $\mathrm{ind}(P_3, K_3) = 0$ while $\mathrm{inj}(P_3, K_3) > 0$: the gap between the counts is a real loss of copies, not an artefact of bookkeeping.

It is worth saying now why we will nonetheless make the most permissive count, hom, the protagonist, even though ind is the geometrically faithful one. The reason was flagged in the section preamble and is borne out by example 16.2: hom counts maps over an *unconstrained* domain — every one of the n^k functions $V(F) \to V(G)$ is a candidate, with no injectivity side-condition coupling the choices of where the vertices go — and that absence of constraint is exactly what will let the count factorize over disjoint unions and lift, with no friction, to an integral against a graphon. The strict counts inj and ind purchase geometric fidelity at the cost of this clean product structure, and we will recover them from hom by an inclusion–exclusion costing only $O(1/n)$. For the moment the single point to carry forward is that the three integers are genuinely distinct objects.

Remark 16.3 (Why "left"?)**.** The asymmetry of the symbol $\hom(F, G)$ is not cosmetic, and the name we are about to attach to the whole programme reads it off literally. We hold the pattern F on the *left* fixed and small — an edge, a triangle, a star — and let the host G on the *right* grow without bound; the numbers we watch are $\hom(F, \cdot)$ as F ranges over all small patterns. Convergence governed by these numbers is therefore called *left*-convergence, and the densities $t(F, \cdot)$ are, in this reading, local statistics of the host: each fixed small F probes how often its motif appears, and growing G is what lets those frequencies settle down. This is the regime of *moments*, and it is the one this chapter pursues.

The terminology earns its qualifier only by contrast with the genuinely different theory got by swapping the roles. Fix the graph on the *right* — call it the target H — and let the graph on the *left* grow: the count $\hom(G, H)$ is then the number of adjacency-preserving maps $V(G) \to V(H)$, which is the number of *H-colourings* of G. Taking $H = K_q$, the complete graph on q vertices, counts the proper q-colourings of G (no edge monochromatic); other targets count independent sets, and weighting the vertices and edges of H turns $\hom(G, H)$ into the partition function of a statistical-mechanical spin system living on G. Letting G grow on the left while H stays fixed is *right*-convergence, and it organizes a parallel limit theory keyed to these partition functions rather than to motif frequencies. The two theories are not one limit seen twice; they answer different questions — "how often does this small motif occur?" versus "how many colourings does this large graph admit?" — and the dense graph-limit machinery of this book lives entirely on the left. We name our notion "left-convergence" so that the road not taken stays clearly marked; the right theory is signposted in the bibliographic notes and not pursued further.

These three integers are the bedrock, but they are not yet *comparable*. Each of $\hom(F, G)$, $\mathrm{inj}(F, G)$, $\mathrm{ind}(F, G)$ grows with the size n of the host — there are simply more ways to place a pattern in a larger graph — so a raw count carries the host's size baked into it and says nothing on its own about how *densely* the motif occurs. A four-vertex host and a million-vertex host cannot be set on a common axis until that size dependence is divided out. Doing so is the business of the next subsection: it turns each of the three counts into a frequency in $[0, 1]$ by dividing by the number of candidate maps of its kind, and then reconciles the three normalizations against one another.

16.1.2 The three densities and their normalizations

The previous subsection ended on an obstruction: the three integers $\hom(F, G)$, $\mathrm{inj}(F, G)$, $\mathrm{ind}(F, G)$ all swell as the host grows, so a raw count from a four-vertex host and a raw count from a million-vertex host live on incommensurable scales and cannot be compared as they stand. The cure is the one the moment analogy already anticipates. A moment $\int t^k \, \mu(\mathrm{d}t)$ is an *average*, not a sum — it has the size of μ divided out — and that is exactly why moments of different measures sit on a common axis. We do the same here: divide each count by the number of candidate maps of its own kind, turning a count into the *fraction* of candidates that succeed, a pure number in $[0, 1]$ that no longer carries the host's size baked in.

What "number of candidate maps of its own kind" means is dictated by which random object is natural for each count, and the two counts split here. For hom the domain of candidates is *all* maps $V(F) \to V(G)$: there is no injectivity constraint, so the k vertices of F are placed completely independently, each one sent to a host vertex chosen uniformly from the n available, and the number of such maps is $n \cdot n \cdots n = n^k$. Dividing by n^k is therefore not an arbitrary rescaling but the unique one that reads $\hom(F, G)$ as a probability over the natural product experiment "drop each of the k pattern-vertices onto an independent uniform host-vertex." For inj and ind the candidates are instead the *injections* $V(F) \hookrightarrow V(G)$: here the placements of the k vertices are coupled by the requirement that no two collide, and a uniformly random injection — place the first vertex among n choices, the second among the $n - 1$ that remain, and so on — is the right random object. The number of injections is the falling factorial $(n)_k = n(n-1)\cdots(n-k+1)$, so that is the matching denominator. Each normalization is the size of its own candidate set; nothing else would turn the count into an honest frequency.

Definition 16.4 (Homomorphism densities)**.** For finite simple graphs F (with $|V(F)| = k \geq 1$) and G (with $|V(G)| = n \geq 1$) define the *homomorphism density*, *injective* density, and *induced* density

$$t(F, G) \;=\; \frac{\hom(F, G)}{n^k}, \qquad t_{\mathrm{inj}}(F, G) \;=\; \frac{\mathrm{inj}(F, G)}{(n)_k}, \qquad t_{\mathrm{ind}}(F, G) \;=\; \frac{\mathrm{ind}(F, G)}{(n)_k}.$$

Each lies in $[0, 1]$. Equivalently, $t(F, G)$ is the probability that a map $\varphi\colon V(F) \to V(G)$ chosen uniformly at random (each of the k vertices sent to an independent uniform vertex of G) is a homomorphism; t_{inj} and t_{ind} are the corresponding probabilities for a uniformly random *injection.*

This probabilistic reading is the single sentence to carry through the rest of the chapter, so it is worth saying slowly. To evaluate $t(F, G)$, imagine the pattern F printed on a transparency and dropped at random onto the host G: independently for each vertex i of F, pick a uniform host vertex $\varphi(i)$, with no attempt to keep the picks distinct. The transparency "lands on actual edges" when every edge of F falls on an edge of G — exactly the homomorphism condition — and $t(F, G)$ is the chance that it does. It is the frequency with which a randomly thrown copy of the motif fits. The injective density is the same experiment played with a uniformly random *injection* in place of a free map, so the thrown copy is forbidden to pinch two of its vertices onto one host vertex; the induced density asks the stricter question still, that the landing site induce *exactly* F. Throughout the book the bare symbol $t(F, G)$ — the macro `\homden` — denotes the hom-normalized density of this definition, with degenerate maps included; the injective and induced variants never lose their subscripts. Keeping that discipline matters because the three agree in the limit but differ in every finite exact identity.

It pays to run the experiment once, on the smallest pattern, and watch the normalizations reconcile. Take $F = K_2$, the single edge on vertices $\{1, 2\}$. A map φ is a homomorphism precisely when $\varphi(1)\varphi(2)$ is an edge of G, and the number of ordered pairs landing on an edge is $\hom(K_2, G) = 2\,|E(G)|$ — each undirected edge uv is hit by the two ordered pairs (u, v) and (v, u). Dividing by the n^2 candidate maps,

$$t(K_2, G) \;=\; \frac{2\,|E(G)|}{n^2},$$

the *hom-normalized edge density.* Combinatorics, on the other hand, usually reports the edge density as the fraction of *unordered distinct* pairs that are edges, $|E(G)|\,/\binom{n}{2} = 2\,|E(G)|\,/(n(n-1))$, which is exactly $t_{\mathrm{inj}}(K_2, G)$: an injective map of K_2 is an ordered pair of distinct vertices, of which there are $(n)_2 = n(n-1)$, and $2\,|E(G)|$ of them are edges. The two edge densities therefore differ only by the substitution of n^2 for $n(n-1)$ in the denominator, and that difference is precisely the n *diagonal* pairs (u, u). These diagonal maps are the collapsing homomorphisms of K_2; since G is loopless none of them is ever an edge, so the n^2 denominator counts n candidates that can never succeed while the $n(n-1)$ denominator omits them. Quantitatively

$$t(K_2, G) \;=\; \frac{2\,|E(G)|}{n^2} \;=\; \frac{n-1}{n}\cdot\frac{2\,|E(G)|}{n(n-1)} \;=\; \left(1-\tfrac{1}{n}\right) t_{\mathrm{inj}}(K_2, G),$$

so the hom- and combinatorial edge densities agree up to a factor $1 - 1/n$, an $O(1/n)$ discrepancy that comes entirely from the diagonal and vanishes as the host grows. This is the K_2 instance of the general reconciliation between $t(F, \cdot)$ and $t_{\mathrm{inj}}(F, \cdot)$ made precise in lemma 16.6; for $F = K_2$ the lemma's constant is $\binom{2}{2}/n = 1/n$, and indeed $|t(K_2, G) - t_{\mathrm{inj}}(K_2, G)| = t_{\mathrm{inj}}(K_2, G)/n \le 1/n$.

For $F = K_3$ the triangle, $t(K_3, G)$ is the triangle density; for F a path or a star, one recovers the path and star densities. These few examples already show why the densities deserve the name *motif frequencies*, and the next example assembles a whole catalogue of them, organized so that a second reading of the same numbers — as traces of powers of the adjacency matrix — comes into view.

Example 16.5 (A catalogue of small motifs)**.** Let $A = A(G)$ be the adjacency matrix of G and $\mathbf{1}$ the all-ones vector. Because a homomorphism is just a vertex map under which every pattern edge lands on a host edge, the homomorphism count is a sum, over all placements, of a product of adjacency entries — one factor $A_{\varphi(i)\varphi(j)}$ per edge ij of F — and for the small patterns this sum collapses into linear algebra. Counting homomorphisms is counting walks:

$$\hom(K_2, G) = \mathbf{1}^\top A\,\mathbf{1}, \qquad \hom(P_3, G) = \mathbf{1}^\top A^2\,\mathbf{1}, \qquad \hom(K_3, G) = \operatorname{tr} A^3,$$

where P_3 is the path on three vertices (two edges). Each identity is the bookkeeping made explicit. For the edge, $\hom(K_2, G) = \sum_{a,b} A_{ab} = \mathbf{1}^\top A\,\mathbf{1}$, which is the $2\,|E(G)|$ already met above. For the path 1–2–3, summing the product $A_{ab}A_{bc}$ over the images $a = \varphi(1)$, $b = \varphi(2)$, $c = \varphi(3)$ and doing the b sum last,

$$\hom(P_3, G) = \sum_{a,b,c} A_{ab}A_{bc} = \sum_{a,c}\Big(\sum_{b} A_{ab}A_{bc}\Big) = \sum_{a,c}(A^2)_{ac} = \mathbf{1}^\top A^2\,\mathbf{1},$$

so the path density tallies walks of length two; the inner sum is the number of common neighbours of a and c, and grouping by the centre b instead gives the equivalent count $\sum_b \deg(b)^2$. The triangle is the case where the spectral reading first becomes unmistakable. Summing $A_{ab}A_{bc}A_{ca}$ over $a = \varphi(1)$, $b = \varphi(2)$, $c = \varphi(3)$,

$$\hom(K_3, G) = \sum_{a,b,c} A_{ab}A_{bc}A_{ca} = \sum_a \Big(\sum_{b,c} A_{ab}A_{bc}A_{ca}\Big) = \sum_a (A^3)_{aa} = \operatorname{tr} A^3,$$

because $(A^3)_{aa} = \sum_{b,c} A_{ab}A_{bc}A_{ca}$ counts the closed walks $a \to b \to c \to a$ of length three, and the trace sums them over their basepoint. In a simple, loopless graph a closed 3-walk can only visit three *distinct* vertices that are pairwise adjacent — a triangle — traversed from any of its 3 vertices in either of 2 directions, so $\operatorname{tr} A^3$ equals 6 times the number of triangles. (This is also why, for the triangle alone, no correction is needed: a collapsing map of K_3 would force a pattern edge onto a diagonal entry $A_{aa} = 0$, so every homomorphism of K_3 is automatically injective and $\hom(K_3, G) = \operatorname{inj}(K_3, G)$ exactly.) More generally hom of a path is a sum of entries of a power of A, and hom of a cycle C_ℓ is the closed-ℓ-walk count

$$\hom(C_\ell, G) = \operatorname{tr} A^\ell = \sum_i \lambda_i^\ell,$$

the ℓ-th power sum of the eigenvalues $\lambda_1, \ldots, \lambda_n$ of A — that is, the ℓ-th moment of the adjacency spectrum. The densities are these quantities divided by $n^{|V(F)|}$. This is the first sign of a theme chapter 18 will develop in full: the cycle densities $t(C_\ell, G)$ are, up to the normalization $n^{-\ell}$, exactly the spectral power sums $\sum_i \lambda_i^\ell$, so the homomorphism profile and the spectrum of the graph operator are not rival summaries of G but the *same* information read through two different windows — the combinatorial window of motif counts and the analytic window of eigenvalues. We will exploit that identification when the spectral picture takes over in chapter 18.

Two loose threads are left deliberately hanging for the next subsection to take up. The first is quantitative: the K_2 computation above showed $t(K_2, \cdot)$ and $t_{\text{inj}}(K_2, \cdot)$ differing only through the diagonal — the collapsing maps — and the same is true of every pattern F, the two densities parting ways solely on the homomorphisms that send two vertices of F to one vertex of G. The next subsection counts those degenerate maps and shows there are only $O(n^{k-1})$ of them out of n^k, a vanishing fraction, so the three normalizations define one and the same limit. The second thread is the spectral one just opened: that densities and eigenvalues are one dataset in two coordinate systems, a remark chapter 18 will turn into a working tool.

16.1.3 Comparing the normalizations: the first counting lemma

The previous subsection left us holding two normalizations of the same motif count — the hom density $t(F, G)$, which divides by all n^k maps, and the injective density $t_{\text{inj}}(F, G)$, which divides by the $(n)_k$ injections — together with the observation, borne out explicitly on the edge K_2, that the two part ways on exactly one population of maps: the *degenerate* ones, the homomorphisms that send two distinct vertices of F to a single vertex of G. The hom count includes them, the injective count does not, and the entire discrepancy between the two densities is the weight of this degenerate population. So the question of whether the normalizations matter in the limit is the wholly concrete question of how many degenerate maps there are. We answer it now, and the answer is reassuring: there are very few of them.

The heuristic is a counting of dimensions, and it is worth saying in words before any symbols, because the whole lemma is just this sentence made exact. A map $\varphi\colon V(F) \to V(G)$ is a free choice of k images, one for each of the k vertices of F, drawn from the n vertices of G; there are n^k such choices, and one should think of the exponent k as a "dimension." To be *degenerate* a map must make at least one coincidence — two prescribed vertices forced to share an image — and a single such coincidence ties two of the k free choices together into one, dropping the dimension from k to $k-1$. There are only $\binom{k}{2}$ pairs of vertices that could be the ones to collide, so the degenerate maps live on $\binom{k}{2}$ many $(k-1)$-dimensional slices inside a k-dimensional box: a set of relative size $O(n^{k-1})/n^k = O(1/n)$, a vanishing fraction as the host grows. The injectivity constraint that distinguishes t_{inj} from $t(F,\cdot)$ therefore costs nothing in the limit; it only removes a measure-zero skin of collapsed placements. The next lemma turns "$O(1/n)$" into the explicit constant $\binom{k}{2}/n$, with a sharp two-sided bound. It is the prototype of every "counting lemma" in the subject — a statement that two ways of counting motifs differ by a controllable error — and unlike the deeper cut-norm counting lemma of section 16.2 it is completely elementary, nothing but bookkeeping on finite sets.

Lemma 16.6 (Hom versus injective density)**.** *For all finite simple graphs F (with $|V(F)| = k$) and G (with $|V(G)| = n \geq 1$),*

$$0 \;\leq\; t(F,G) - \frac{(n)_k}{n^k}\, t_{\mathrm{inj}}(F,G) \;\leq\; \binom{k}{2}\frac{1}{n}, \qquad \textit{hence} \qquad \bigl|\, t(F,G) - t_{\mathrm{inj}}(F,G)\,\bigr| \;\leq\; \binom{k}{2}\frac{1}{n}.$$

Proof. The argument has three movements: split the hom count into its injective and degenerate parts (this gives the left inequality and the first half of the right one), bound the degenerate part by a union bound over pairs, and finally combine the two error terms watching their signs — the last step is where the constant stays at $\binom{k}{2}/n$ rather than doubling.

Partition by fibres. Sort the n^k maps $\varphi\colon V(F) \to V(G)$ according to how they collapse, that is, by the partition π of the domain $V(F)$ whose blocks are the nonempty fibres $\varphi^{-1}(v)$, $v \in V(G)$. Two vertices of F land in the same block of π exactly when φ sends them to the same vertex of G. The *injective* maps are precisely those whose partition is the finest one, $\hat{0}$, all blocks singletons — no two vertices share an image; every other partition records at least one coincidence and marks a degenerate map. This sorts the maps into two camps, injective and degenerate, with no overlap and nothing left out. Now restrict to homomorphisms. Among the injective maps, the ones that are homomorphisms are by definition counted by $\mathrm{inj}(F,G)$, and the total number of injective maps (homomorphism or not) is the falling factorial $(n)_k = n(n-1)\cdots(n-k+1)$, so by the very definition $t_{\mathrm{inj}}(F,G) = \mathrm{inj}(F,G)/(n)_k$ the injective homomorphisms number $(n)_k\, t_{\mathrm{inj}}(F,G)$. The remaining homomorphisms are exactly the degenerate ones, a nonnegative count. Hence

$$\mathrm{hom}(F,G) \;=\; \underbrace{(n)_k\, t_{\mathrm{inj}}(F,G)}_{\text{injective homs}} \;+\; \underbrace{\#\{\text{degenerate homomorphisms}\}}_{\geq 0} \;\geq\; (n)_k\, t_{\mathrm{inj}}(F,G).$$

Dividing through by n^k and recalling $t(F,G) = \mathrm{hom}(F,G)/n^k$ gives the left inequality $t(F,G) -$

$\frac{(n)_k}{n^k} t_{\rm inj}(F,G) \geq 0$ at once: the hom density is the injective contribution *plus* the nonnegative degenerate surplus.

Union bound over the $\binom{k}{2}$ pairs. It remains to bound that surplus from above. A degenerate *homomorphism* is in particular a degenerate *map*, so it suffices to bound the number of degenerate maps, ignoring the adjacency condition entirely (dropping a constraint can only enlarge the count, which is all we want for an upper bound). A degenerate map identifies at least one pair of distinct vertices of F; fix one offending pair $\{a,b\} \subseteq V(F)$ and count the maps that send a and b to a common image. Such a map is determined by: the common image of a and b, which is one vertex of G (n choices); and the images of the other $k-2$ vertices, free among n each (n^{k-2} choices). That is $n \cdot n^{k-2} = n^{k-1}$ maps identifying the fixed pair $\{a,b\}$ — the "lost" factor of n is precisely the one degree of freedom the coincidence removes. Every degenerate map identifies at least one pair, so it is caught by at least one term of the union over the $\binom{k}{2}$ pairs $\{a,b\}$; the union bound (which only overcounts, since a map collapsing several pairs is counted once per collapsed pair) gives

$$\#\{\text{degenerate maps}\} \;\leq\; \sum_{\{a,b\}\subseteq V(F)} n^{k-1} \;=\; \binom{k}{2} n^{k-1}.$$

Dividing by n^k,

$$t(F,G) - \frac{(n)_k}{n^k}\, t_{\rm inj}(F,G) \;=\; \frac{\#\{\text{degenerate homomorphisms}\}}{n^k} \;\leq\; \frac{\#\{\text{degenerate maps}\}}{n^k} \;\leq\; \binom{k}{2}\frac{1}{n},$$

which is the right inequality of the first display. The same union bound, applied without the homomorphism restriction, also controls the normalization ratio itself: the maps that are *not* injective number $n^k - (n)_k$, and the count just made bounds them by $\binom{k}{2} n^{k-1}$, so

$$0 \;\leq\; 1 - \frac{(n)_k}{n^k} \;=\; \frac{n^k - (n)_k}{n^k} \;\leq\; \binom{k}{2}\frac{1}{n}. \tag{16.1}$$

(One can see (16.1) directly by expanding the product $(n)_k/n^k = \prod_{j=0}^{k-1}(1-j/n)$: it is a product of factors in $[0,1]$, hence at most 1, and at least $1 - \sum_{j=0}^{k-1} j/n = 1 - \binom{k}{2}/n$ by the elementary inequality $\prod(1-x_j) \geq 1 - \sum x_j$ for $x_j \in [0,1]$. The two routes agree because $\binom{k}{2} = \sum_{j=0}^{k-1} j$.)

Sign cancellation: keeping the constant at $\binom{k}{2}/n$. We now have two separate $O(1/n)$ errors in hand — one from replacing the inj-count by its degenerate-inclusive hom-count, one from replacing the denominator $(n)_k$ by n^k — and the lazy move is to pass to the two-sided bound by the triangle inequality, adding the two corrections to get $2\binom{k}{2}/n$. That is correct but not sharp, and the slack is worth removing because it exposes a structural point: the two corrections push in *opposite* directions and partly annihilate. To see it, write the gap we actually care about as the sum of exactly these two pieces, by adding and subtracting $\frac{(n)_k}{n^k} t_{\rm inj}(F,G)$:

$$t(F,G) - t_{\rm inj}(F,G) = \underbrace{\Big(t(F,G) - \tfrac{(n)_k}{n^k} t_{\rm inj}(F,G)\Big)}_{=:A} + \underbrace{t_{\rm inj}(F,G)\Big(\tfrac{(n)_k}{n^k} - 1\Big)}_{=:B}.$$

These are the two corrections, isolated. The first, A, is the degenerate surplus: by the left inequality and the right inequality already proved it satisfies $A \in [0, \binom{k}{2}/n]$ — it is nonnegative (the hom count includes extra maps) and no larger than $\binom{k}{2}/n$. The second, B, is the denominator correction: since $t_{\mathrm{inj}}(F,G) \in [0,1]$ and, by (16.1), the factor $\frac{(n)_k}{n^k} - 1$ lies in $[-\binom{k}{2}/n,\, 0]$, the product B is *non-positive*, $B \le 0$, with magnitude $|B| = t_{\mathrm{inj}}(F,G)\,(1 - \frac{(n)_k}{n^k}) \le \binom{k}{2}/n$. So A lives in $[0, \binom{k}{2}/n]$ and B lives in $[-\binom{k}{2}/n, 0]$: one is a nonnegative number at most $\binom{k}{2}/n$, the other a nonpositive number at least $-\binom{k}{2}/n$. Their sum cannot escape the interval spanned by those two ranges,

$$t(F,G) - t_{\mathrm{inj}}(F,G) \;=\; A + B \;\in\; \Big[-\frac{\binom{k}{2}}{n},\; \frac{\binom{k}{2}}{n}\Big],$$

because the most positive the sum can be is A at its ceiling with B at 0 (value $\binom{k}{2}/n$), and the most negative is B at its floor with A at 0 (value $-\binom{k}{2}/n$). This is the stated two-sided bound $|t(F,G) - t_{\mathrm{inj}}(F,G)| \le \binom{k}{2}/n$, and the sign bookkeeping — $A \ge 0$ paired with $B \le 0$ — is exactly what saved the factor of two the naive addition would have spent. $\square$

It is worth pausing on what the constant says. The bound $\binom{k}{2}/n$ depends on the pattern F *only* through its number of vertices k, not through its edges: a k-vertex tree and a k-vertex clique incur the same coincidence correction, because the correction counts collisions of *vertices*, of which there are $\binom{k}{2}$ candidate pairs whatever the edge set. And the dependence on the host is the single clean factor $1/n$. So for each fixed pattern the gap between the two densities is $O(1/n)$ uniformly in everything else, which is precisely the strength one needs to conclude that the choice of normalization is invisible to the limit.

Remark 16.7 (All three densities define the same convergence)**.** Fix a pattern F with k vertices and let the hosts grow, $n = |V(G_n)| \to \infty$. Then $\binom{k}{2}/n \to 0$, so lemma 16.6 pins $t(F, G_n)$ and $t_{\mathrm{inj}}(F, G_n)$ together: their difference is squeezed to zero, and therefore one of the two sequences converges if and only if the other does, to the same limit. The hom-normalization and the injective normalization are thus interchangeable as far as left-convergence is concerned — they certify exactly the same convergent sequences and assign exactly the same limits.

The third family, the induced densities t_{ind}, is tied to the injective ones not by an estimate but by an exact, host-independent *linear change of basis*, so it converges in lockstep as well. The relationship is inclusion–exclusion on the non-edges. Recall the distinction: an injective homomorphism of F must carry every *edge* of F onto an edge of G but says nothing about non-edges, whereas an induced embedding must in addition carry every *non-edge* of F onto a non-edge of G. So $\mathrm{inj}(F,G)$ counts the injective maps realizing *at least* the edges of F — they may accidentally realize some non-edges of F as edges of G too — while $\mathrm{ind}(F,G)$ counts those realizing *exactly* the edges of F and no more. Sorting the injective maps by which extra non-edges they happen to fill in expresses each inj as a sum of ind's, and inverting that triangular relation (the inclusion–exclusion sign pattern) expresses each ind as an alternating sum of inj's over the graphs obtained from F by promoting some of its non-edges to edges. Both directions are finite integer-coefficient combinations with coefficients depending only on F, never on n.

The smallest instance makes the change of basis concrete. Take F on two labelled vertices $\{1,2\}$. There are two such graphs: the single edge K_2 and the edgeless pair $\overline{K_2}$ (two isolated vertices). An injective map of either into a host G is just an ordered pair of distinct vertices (u,v). For K_2, an injective homomorphism requires uv to be an edge, while an induced embedding requires the induced subgraph on $\{u, v\}$ to be exactly one edge — which is the same condition, $uv \in E(G)$ — so here $\mathrm{inj}(K_2, G) = \mathrm{ind}(K_2, G)$, both equal to the number of ordered adjacent pairs $2\,|E(G)|$. For $\overline{K_2}$, by contrast, an injective homomorphism imposes *no* edge condition (there are no edges to preserve), so $\mathrm{inj}(\overline{K_2}, G) = (n)_2$ counts *all* ordered distinct pairs, both adjacent and non-adjacent; whereas an induced embedding of $\overline{K_2}$ demands that the one non-edge 12 map to a non-edge, i.e. $uv \notin E(G)$, so $\mathrm{ind}(\overline{K_2}, G)$ counts only the ordered *non*-adjacent pairs. The two are related by the partition of all distinct pairs into adjacent and non-adjacent:

$$\mathrm{inj}(\overline{K_2}, G) \;=\; (n)_2 \;=\; \underbrace{2\,|E(G)|}_{\mathrm{ind}(K_2,G)} \;+\; \underbrace{\mathrm{ind}(\overline{K_2}, G)}_{\text{non-adjacent pairs}}\;, \qquad \text{i.e.} \qquad \mathrm{ind}(\overline{K_2}, G) \;=\; \mathrm{inj}(\overline{K_2}, G) - \mathrm{inj}(K_2, G).$$

That last identity is exactly inclusion–exclusion: the induced count of the *non*-edge is the injective count of the non-edge (all pairs) minus the injective count of the graph with that non-edge promoted to an edge (the adjacent pairs). Dividing by $(n)_2$ turns it into the density identity $t_{\mathrm{ind}}(\overline{K_2}, G) = 1 - t_{\mathrm{inj}}(K_2, G)$, the two-vertex shadow of the general alternating sum. (Reassuringly $t_{\mathrm{inj}}(K_2, G)$ is the ordinary edge density, so $t_{\mathrm{ind}}(\overline{K_2}, G)$ is the non-edge density, and the two sum to one, as they must.)

Because every such conversion is a fixed finite linear combination, a sequence along which all $t_{\mathrm{inj}}(F, \cdot)$ converge is one along which all $t_{\mathrm{ind}}(F, \cdot)$ converge, and conversely; combined with the first paragraph, all three families — $t(F, \cdot)$, t_{inj}, t_{ind} — certify the same convergent sequences with the same limits. We may therefore work with whichever normalization is most convenient and switch between them at will. Of the three, $t(F, \cdot)$ is the one we promote to canonical status, and for a reason the counting estimate alone does not reveal: it is the only normalization that extends cleanly to the continuum. Dividing by $(n)_k$ presupposes a finite vertex set to count injections in, and there is no falling factorial of a graphon; but dividing by n^k corresponds to drawing each image *independently and uniformly*, an experiment that transfers verbatim to a graphon with "uniform vertex" replaced by "uniform point of the type interval." That is the construction the next subsection carries out, and it is why the hom-normalization, and not its stricter cousins, is the one we lift.

16.1.4 Homomorphism densities of a graphon

The previous subsection closed with a verdict: of the three normalizations only the hom-normalization survives the passage to the continuum, because dividing by n^k encodes the experiment "drop each pattern-vertex onto an independent uniform host-vertex," and that experiment has a verbatim continuum analogue while the falling-factorial normalization of the injective and induced densities does not. We now cash that verdict in. The whole content of this subsection is that one sentence of the probabilistic reading carries over word for word, with only two substitutions in the dictionary, and that once it does, every algebraic property the finite density enjoyed reappears on the graphon side for the same reason it held before.

Recall the reading. To evaluate $t(F, G)$ we threw the pattern F at random onto the host: independently for each vertex i of F we chose a uniform host-vertex $\varphi(i)$, and $t(F, G)$ was the chance that every edge of F landed on an edge of G. A graphon has no vertices to land on — its "vertices" form the continuum $[0, 1]$ of types — and it has no sharp notion of "is an edge": between two types x, y it records only the weight $W(x, y) \in [0, 1]$, the probability that an edge is present in a graph sampled from it. Both gaps close with a single substitution each. For "uniform vertex of G" read "uniform point ξ_i of the type interval $[0, 1]$"; the n equally likely host vertices become the continuum of equally likely types, and a uniform draw on $\{1, \ldots, n\}$ becomes the uniform (Lebesgue) law on $[0, 1]$. For "the edge $\varphi(i)\varphi(j)$ is present" — an event, worth 1 when it occurs and 0 when it does not — read "carry the weight $W(\xi_i, \xi_j)$," the $[0, 1]$-valued soft indicator that replaces the hard 0/1 adjacency. The hard question "did every edge of F land on an edge?" — a product of 0/1 indicators, itself 0 or 1 — thereby softens into the product $\prod_{ij \in E(F)} W(\xi_i, \xi_j)$ of weights in $[0, 1]$, and the probability that the throw succeeds becomes the *expectation* of that product. Making the two substitutions in the definition of $t(F, G)$ and reading the resulting average as an integral against Lebesgue measure on the type cube is the entire definition that follows.

Definition 16.8 (Homomorphism density into a graphon)**.** Let F be a finite simple graph with $V(F) = \{1, \ldots, k\}$ and let W satisfy **(A-Reg-W)**. The *homomorphism density of F in W* is

$$t(F, W) \;=\; \int_{[0,1]^k} \prod_{ij \in E(F)} W(x_i, x_j) \;\mathrm{d}x_1 \cdots \mathrm{d}x_k \;=\; \mathbb{E}\left[\prod_{ij \in E(F)} W(\xi_i, \xi_j)\right],$$

where $\xi_1, \ldots, \xi_k$ are i.i.d. uniform on $[0, 1]$. For the one-vertex graph K_1 and the edgeless graph $\overline{K_r}$ on r vertices the empty product is 1, so $t(K_1, W) = t(\overline{K_r}, W) = 1$.

Three small points need checking before the symbol on the left is entitled to exist, and at a physicist's level of rigor each is a one-line verification rather than a hurdle. First, the integrand is a genuine measurable function on $[0, 1]^k$: each factor $W(x_i, x_j)$ is the composition of the measurable kernel W with the coordinate projection $(x_1, \ldots, x_k) \mapsto (x_i, x_j)$, hence measurable, and a finite product of measurable functions is measurable, so the whole integrand is. Second, the integral makes sense and may be computed in any order: the integrand is nonnegative (a product of factors in $[0, 1]$) and the domain $[0, 1]^k$ carries the product of k copies of Lebesgue probability measure, so Tonelli's theorem (theorem 1.27) applies — it is precisely the theorem licensing the interchange of a multiple integral with iterated single integrals for a nonnegative measurable integrand, with no integrability hypothesis needed because nonnegativity already forbids the $\infty - \infty$ ambiguity. This is what lets us write the k-fold integral as the expectation over k i.i.d. uniform draws, and it is the only analytic fact the definition rests on. Third, the value lies in $[0, 1]$: the integrand is bounded between 0 (some factor could vanish) and 1 (every factor is at most 1) pointwise, and the integral of a function valued in $[0, 1]$ against a probability measure is again in $[0, 1]$. So $t(F, W)$ is a well-defined number in $[0, 1]$, exactly as its finite predecessor was.

The expectation form on the right is the one that earns the word "moment." $t(F, W)$ is the expected value of a product of kernel evaluations, one factor per edge of F, at independent uniform insertion points — precisely the structure of a joint moment of the random field $(x, y) \mapsto W(x, y)$. The simplest case fixes the picture: for the single edge $F = K_2$, $t(K_2, W) = \int_{[0,1]^2} W(x, y)\, \mathrm{d}x\, \mathrm{d}y$ is the mean edge weight, the continuum edge density and the crudest moment of all, exactly as the mean is the crudest moment of a measure on the line. The one degenerate case worth dwelling on is the *empty* product, flagged in the definition: a graph with no edges contributes no factors, and the empty product is 1 by convention, so the integrand is the constant function 1 and its integral over the probability space $[0,1]^k$ is 1. Hence $t(K_1, W) = t(\overline{K_r}, W) = 1$ for the one-vertex graph and for the edgeless graph on any number r of vertices. This is not a boundary convention chosen for tidiness; it is forced, and it matters. A pattern with no edges imposes no constraint on the throw, so the throw succeeds with certainty, and the density must be 1 — the same value the finite count $\hom(\overline{K_r}, G)/n^r = n^r/n^r = 1$ returns, since every one of the n^r maps of an edgeless pattern is vacuously a homomorphism. We will need $t(\overline{K_r}) = 1$ as the normalization anchor of the moment problem in section 16.3, where it is the graph analogue of the zeroth moment $\int \mu(\mathrm{d}t) = 1$ of a probability measure.

We have now defined the same symbol $t(F, \cdot)$ twice over — once with a finite graph in the second slot, once with a graphon — and an honest reader should worry that the two definitions might disagree where they overlap. They do not, and the cleanest way to see it is to feed the graphon definition the graphon that *is* a finite graph and check that the integral collapses back to the finite count. There is a canonical such graphon. Recall the *pixel graphon* (empirical graphon) W^G of a graph G on vertex set $\{1, \ldots, n\}$ (definition 15.2 and proposition 15.3): partition $[0,1]$ into n consecutive intervals $I_1, \ldots, I_n$ of equal length $1/n$ and set $W^G(x, y) = A_{ij}$ for $x \in I_i,\ y \in I_j$, where $A = A(G)$ is the adjacency matrix. (It is the step graphon adapted to the equipartition, in the sense of definition 15.6; we keep the name "pixel graphon" of chapter 15 and reserve "step graphon" for the general partition.) It is the literal black-and-white image of the adjacency matrix painted on the unit square, each entry A_{ij} smeared uniformly over the little block $I_i \times I_j$. If the two definitions are to deserve the same name, then evaluating the graphon density on this image must return the finite density of G exactly, with no boundary term, no leftover $1/n$, no seam between the discrete and continuous worlds. That exact agreement is the next proposition, and the reason it holds without any correction is worth watching slowly, because it is the technical heart of the claim that "graphons extend graphs."

Proposition 16.9 (Consistency of the two definitions)**.** *For every finite simple graph F and every finite simple graph G,*

$$t(F, W^G) \;=\; t(F, G).$$

Proof. Write $k = |V(F)|$, $n = |V(G)|$. The argument is a single change of variable: each uniform type splits into a discrete part the pixel graphon sees and a continuous part it cannot see, and once the invisible part is integrated out the integral becomes the finite sum.

One uniform type = one uniform vertex times one ignored position. Fix a single index i and look at the uniform draw $\xi_i \in [0,1]$. The interval $I_v = [(v-1)/n,\, v/n)$ containing ξ_i is determined by which of the n equal blocks ξ_i falls into; write $\varphi(i) \in \{1, \ldots, n\}$ for that block index. Because the blocks all have the same length $1/n$, the index $\varphi(i)$ is *uniform* on $\{1, \ldots, n\}$: $\mathbb{P}(\xi_i \in I_v) = 1/n$ for each v. And conditionally on $\varphi(i) = v$, the leftover $n\xi_i - (v-1)$ — the position of ξ_i *within* its block, rescaled to $[0,1]$ — is uniform on $[0,1]$ and independent of v. So a single uniform type decomposes, with no loss and no remainder, into a uniform vertex $\varphi(i)$ *times* an independent uniform position-in-interval. The pixel graphon was built to be constant on each block $I_i \times I_j$, so it depends on (ξ_i, ξ_j) *only* through the block indices $(\varphi(i), \varphi(j))$ and is completely blind to the positions-within-intervals. This is the "no seam" mechanism in one line: the continuous degrees of freedom the graphon definition integrates over are exactly the degrees of freedom the pixel graphon was designed to ignore, so integrating them out costs nothing.

Collapsing the integral. Do the k draws jointly. The vector $(\xi_1, \dots, \xi_k)$ i.i.d. uniform on $[0,1]$ is, by the previous paragraph applied coordinatewise, the same as an i.i.d. uniform vertex map $\varphi\colon V(F) \to V(G)$ together with k independent ignored positions. On the event $\{\xi_i \in I_{\varphi(i)}\ \forall i\}$ — an event of probability n^{-k}, since the k block indices are independent and each is one particular value out of n — the integrand takes the value $\prod_{ij\in E(F)} W^G(\xi_i, \xi_j) = \prod_{ij\in E(F)} A_{\varphi(i)\varphi(j)}$, which no longer depends on the positions and is 1 exactly when every edge ij of F has $A_{\varphi(i)\varphi(j)} = 1$ — that is, exactly when φ is a homomorphism $F \to G$ — and 0 otherwise. Summing the value n^{-k} over the n^k equally likely block-index patterns φ and weighting each by its 0/1 integrand,

$$t(F, W^G) = \mathbb{E}\Big[\prod_{ij\in E(F)} W^G(\xi_i, \xi_j)\Big] = \frac{1}{n^k} \sum_{\varphi\colon V(F)\to V(G)} \prod_{ij\in E(F)} A_{\varphi(i)\varphi(j)} = \frac{\hom(F, G)}{n^k} = t(F, G). \quad \square$$

The factor $1/n^k$ is the probability weight of each block pattern; the sum counts the homomorphisms; their product is the finite density, with not a single error term left over.

So nothing is lost in passing to the continuum: the same functional $F \mapsto t(F, \cdot)$ reads a finite graph and a graphon, and on the pixel graphon of a finite graph it returns precisely that graph's densities. The finite theory is not approximated by the graphon theory; it is a special case of it, sitting exactly inside with no rounding. With consistency secured we may treat $t(F, \cdot)$ as one object and ask after its structure. Two identities will be used over and over — multiplicativity over disjoint unions, and the monotone bounds — and both follow from the integral form by the same one-move argument that powered the consistency proof: factor what is independent, dominate what is bounded.

Proposition 16.10 (Multiplicativity and monotone bounds)**.** *Let W satisfy* ***(A-Reg-W)*** *with values in $[0,1]$, and let F, F_1, F_2 be finite simple graphs.*

(i) (Multiplicativity over disjoint unions.) *If $F = F_1 \sqcup F_2$ is the disjoint union, then $t(F, W) = t(F_1, W)\, t(F_2, W)$. In particular, if F has connected components $F^{(1)}, \dots, F^{(c)}$ then $t(F, W) = \prod_{a=1}^{c} t(F^{(a)}, W)$.*

(ii) (Edge-monotone decay.) *Adding an edge to F cannot increase its density: if $F' \supseteq F$ on the same vertex set, then $t(F', W) \le t(F, W)$; and the trivial bounds $0 \le t(F, W) \le 1$ always hold.*

Proof. (i) Multiplicativity. Write $F = F_1 \sqcup F_2$ with vertex sets $V_1 = V(F_1)$ and $V_2 = V(F_2)$ disjoint, $|V_1| = k_1$, $|V_2| = k_2$, so $|V(F)| = k_1 + k_2$. Every edge of F lies wholly inside F_1 or wholly inside F_2 — a disjoint union creates no edge across the two parts — so the edge product splits cleanly along the partition of vertices,

$$\prod_{ij\in E(F)} W(\xi_i, \xi_j) = \Big(\prod_{ij\in E(F_1)} W(\xi_i, \xi_j)\Big)\Big(\prod_{ij\in E(F_2)} W(\xi_i, \xi_j)\Big).$$

The first factor is a function of the variables $(\xi_i)_{i\in V_1}$ alone, the second of $(\xi_i)_{i\in V_2}$ alone; the two variable blocks are disjoint, hence the corresponding i.i.d. draws are independent. The expectation of a product of functions of independent variables is the product of the expectations — which at the level of integrals is exactly Tonelli (theorem 1.27) splitting the (k_1+k_2)-fold integral over $[0,1]^{V_1} \times [0,1]^{V_2}$ into the product of a k_1-fold and a k_2-fold integral. Therefore $t(F,W) = t(F_1,W)\,t(F_2,W)$. A one-line instance: two disjoint edges form $F = K_2 \sqcup K_2$, and $t(K_2 \sqcup K_2, W) = t(K_2,W)^2$ — the chance that two independently thrown edges both land on weight is the square of the chance for one, precisely because the two throws share no vertex and so cannot interfere. Iterating the split over the connected components $F^{(1)},\dots,F^{(c)}$ of F gives $t(F,W) = \prod_{a=1}^{c} t(F^{(a)},W)$, since the components are pairwise vertex-disjoint by definition. This is the property that makes the homomorphism profile behave like a sequence of *moments* of a product structure, and it is the one section 16.3 will lean on hardest: it reduces the entire profile to its values on connected patterns, the indecomposable "letters" from which every density is a product.

(ii) Edge-monotone decay. Let $F' \supseteq F$ have the same vertex set, with F' obtained from F by adding one edge ab (the general case follows by adding edges one at a time). The integrand of $t(F',W)$ is that of $t(F,W)$ multiplied by the single extra factor $W(x_a,x_b)$, which takes values in $[0,1]$. Multiplying a nonnegative integrand by a factor that nowhere exceeds 1 can only shrink it pointwise, so the integrand of $t(F',W)$ is everywhere $\le$ that of $t(F,W)$; integrating preserves the inequality, giving $t(F',W) \le t(F,W)$. A one-line instance: the triangle K_3 is the path P_3 with the closing edge 13 added, so $t(K_3,W) \le t(P_3,W)$ — demanding the third edge also land on weight can only make the throw harder. The same pointwise estimate, applied to the bare integrand itself, gives the universal bounds: the integrand is a product of factors in $[0,1]$, hence pointwise in $[0,1]$, hence so is its integral against a probability measure, which is the assertion $0 \le t(F,W) \le 1$. (The upper bound is the empty-edge extreme of monotonicity — deleting all edges leaves the constant integrand 1 — and the lower bound is nonnegativity of a nonnegative integrand.) $\square$

Notation watch

Three different "densities" — $t(F,\cdot)$, t_{inj}, t_{ind} — and one symbol t. In this book $t(F,G)$ *always* means the homomorphism density (non-injective maps included), matching the macro `\homden` fixed in appendix A.5. The injective and induced variants always carry the subscripts $t_{\mathrm{inj}}, t_{\mathrm{ind}}$. The distinction is immaterial for convergence (remark 16.7) but *not* for exact identities: $t(K_3,G)$ and $t_{\mathrm{inj}}(K_3,G)$ already differ, though *not* because of any degenerate surplus. Collapsing any pair of the triangle would force a pattern edge onto a diagonal entry $A_{aa}=0$, so on a loopless host K_3 admits *no* surviving degenerate homomorphism and $\hom(K_3,G) = \mathrm{inj}(K_3,G) = 6\cdot\#\{\text{triangles}\}$ exactly; the two densities differ only in their denominators, n^3 versus the falling factorial $(n)_3$. (Genuine degenerate homomorphisms appear only for patterns with a non-adjacent pair, on which a collapse need not land an edge on the diagonal.) When an exact small-graph count matters — as in the moment problem of section 16.3, where multiplicativity is used — it is the hom-normalization that is algebraically clean, because $t(\cdot,W)$ is multiplicative while $t_{\mathrm{inj}}(\cdot,W)$ is not. The reason is exactly the independence exploited in proposition 16.10 (i): the free maps that hom ranges over factor across a disjoint union because the two blocks of vertices are chosen independently, with nothing forbidding a vertex of F_1 from colliding with a vertex of F_2. The injective normalization breaks precisely this independence — a uniform injection of $F_1 \sqcup F_2$ must keep *all* images distinct, so the placement of F_2 is constrained by where F_1 already went, and the joint count does not factor into the two separate injective counts. Multiplicativity is therefore not a cosmetic convenience but the structural reason the hom-normalization is the one promoted to canonical status and carried into the moment problem; its failure for t_{inj} is the same coupling the falling-factorial denominator records.

Physics note

A physicist will recognize $t(F, W) = \mathbb{E}\prod_{ij\in E(F)} W(\xi_i, \xi_j)$ as a connected or disconnected *correlation function* of the field W evaluated at random insertion points, with the graph F playing the role of a Feynman diagram: vertices are integration points, edges are propagators $W(x, y)$, and the density is the diagram's value. Multiplicativity over disjoint unions (proposition 16.10 (i)) is then the factorization of vacuum diagrams into connected pieces, and the statement that "a graph is determined by all its motif densities" is the statement that a translation-invariant field theory is determined by all its correlation functions. The analogy is exact at the level of bookkeeping and stops there: there is no action, no temperature, and the "field" W is a fixed deterministic kernel, not a fluctuating degree of freedom. We use the picture only to organize the diagrams, never to compute.

We have arrived at a single, uniform object. The functional $F \mapsto t(F, \cdot)$ is now defined by the *same* formula — an average of an edge-product over independent uniform arguments — on finite graphs and on graphons alike, agrees with the elementary count on pixel graphons with no seam (proposition 16.9), is multiplicative over disjoint unions and monotone under adding edges (proposition 16.10), and takes values in $[0, 1]$ with the edgeless patterns normalized to 1. Every finite graph and every graphon thus carries a whole *vector* of these numbers, one coordinate per pattern F. Once an object is summarized by a vector of numbers, the question "what should it mean for a sequence of such objects to converge?" has an almost forced answer — converge coordinate by coordinate, motif by motif — and that is exactly the candidate the next section adopts and examines. We hand section 16.2 this functional, together with the one structural property it will most want kept in view: multiplicativity, which says the profile is determined by its values on connected patterns and which resurfaces as a defining constraint when section 16.3 asks which vectors of numbers are graphon profiles at all.

16.2 Left-convergence and the moment topology

Section 16.1 handed us a single, well-tempered observable. The map $F \mapsto t(F, \cdot)$ is now one and the same functional — valued in $[0, 1]$, multiplicative over disjoint unions, blind to relabelling — whether its second argument is a finite graph or a graphon. We have, in other words, manufactured for every network a whole *vector* of numbers: one motif frequency for each pattern F, the graph's moments. The question this chapter was built to answer can now be asked in the only form that does the observable justice. We declared at the outset that the right notion of convergence must be blind to vertex labels and must capture only statistical content; we have just produced a labelling-blind, purely statistical summary of every graph; so the candidate definition of convergence writes itself. Two graphs are close when their moments are close, and a sequence converges when *every* one of its motif frequencies settles down. Convergence of graphs becomes coordinatewise convergence of their moment vectors. That single move — promoting the per-pattern densities into one point of an infinite-dimensional cube and reading convergence off coordinate by coordinate — is the central act of the chapter, and the present section carries it out and then takes the measure of what it costs and what it buys.

The section proceeds in four beats, and it is worth laying them out in advance so the reader sees the arc rather than four disconnected results. *First* we make the definition itself: assemble the densities $t(F, W)$ over all F into a single point of $[0, 1]^{\mathcal{F}_0}$, the homomorphism profile, and define *left-convergence* as coordinatewise convergence of these profiles — pausing only to see why the test family must be *all* of $\mathcal{F}_0$ and not some thrifty subset. *Second* we identify the topology this definition carries: coordinatewise convergence on a countable product is the product ("moment") topology, and because the index set $\mathcal{F}_0$ is countable it is metrizable by an explicit weighted-sum metric, which makes left-convergence an ordinary metric convergence rather than something exotic. *Third* we confront, honestly, the gap between what this soft topology gives for free and what we actually want. Compactness of the profile cube is cheap — a countable diagonal extraction shows every graph sequence has a left-convergent subsequence — but it delivers only an abstract limit *point* of moment vectors, and says nothing about whether that point is the profile of a genuine graphon. Closing that gap is the Lovász–Szegedy realization theorem, which we state precisely and locate, deferring its proof to chapter 17 and appendix F. *Fourth* we prove the one piece of the deferred machinery that belongs here and is entirely elementary: the *counting lemma*, which bounds the change in any motif density by the cut-norm distance between graphons, and so reveals the moment map as Lipschitz — the bridge to the metric theory of chapter 17.

Holding those four beats together is a single strategic asymmetry, and stating it now will keep the reader oriented through everything that follows. The map from a graphon to its moment profile is *easy*: the counting lemma shows it is not merely continuous but Lipschitz, and its proof is three lines of telescoping and a convexity argument. The map the other way — from a profile back to a graphon that realizes it — is *deep*: it is the existence half of the Lovász–Szegedy theorem, and the honest accounting of which results it rests on (the weak regularity lemma, the inverse counting lemma) places its proof squarely in later chapters. The whole moment theory of graphs lives in the tension between these two directions, the forward map cheap and the inverse map the entire substance of the subject. This section proves the cheap direction in full and signposts the deep one with care; the genuinely hard inverse question — exactly which profiles are realizable, and whether the realizing graphon is unique — is what section 16.3 will take up as the moment problem. We begin with the definition, assembling the per-graph densities into a single profile and declaring convergence to be coordinatewise convergence of profiles.

16.2.1 Definition and the choice of test family

The section preamble left us with a vector of numbers attached to every network — one motif frequency $t(F, W)$ for each pattern F — and the resolve to call two networks close when these vectors are close. To turn that resolve into a definition we first need a single home for the vector. The patterns F are indexed by $\mathcal{F}_0$, the set of all finite simple graphs taken up to isomorphism; each entry is a density living in $[0,1]$; so the whole vector is a point of the product cube $[0,1]^{\mathcal{F}_0}$, one coordinate axis per motif. Assembling the per-pattern densities of section 16.1 into one such point is the move that converts a graph, or a graphon, into a *single* object in a fixed space where all networks can be compared on a common footing, and it is the first thing to write down.

Let $\mathcal{F}_0$ denote the (countable) set of all finite simple graphs up to isomorphism. Each graphon W, and each finite graph G, gives a point

$$t(\,\cdot\,,W) \;=\; \big(t(F,W)\big)_{F\in\mathcal{F}_0} \;\in\; [0,1]^{\mathcal{F}_0},$$

its *homomorphism profile*. Two remarks make this an honest definition rather than a piece of notation. That $\mathcal{F}_0$ is *countable* is what keeps the cube tractable: there are finitely many graphs on each fixed number of vertices, and a countable union of finite sets is countable, so the profile is a sequence of numbers, not an uncountable tuple — the fact the next subsection leans on to metrize everything. That we take graphs *up to isomorphism* is forced by the whole programme: the density $t(F,W)$ depends only on the isomorphism class of F (relabelling the pattern permutes the integration variables of definition 16.8 and leaves the integral unchanged), so isomorphic patterns would contribute identical coordinates and listing them separately would only pad the cube with redundant axes. With the home fixed, convergence of graphs is declared to be convergence of these profiles, read off one coordinate at a time.

Definition 16.11 (Left-convergence)**.** A sequence (G_n) of finite simple graphs with $|V(G_n)|\to\infty$ is *left-convergent* if the limit $\lim_n t(F,G_n)$ exists in $[0,1]$ for every $F\in\mathcal{F}_0$. The sequence *converges to the graphon W* if

$$\lim_{n\to\infty} t(F,G_n) \;=\; t(F,W) \qquad \text{for every } F\in\mathcal{F}_0.$$

By remark 16.7 the same notion results if $t(F,\cdot)$ is replaced throughout by $t_{\mathrm{inj}}(F,\cdot)$ or $t_{\mathrm{ind}}(F,\cdot)$. More generally, a sequence of *graphons* (W_n) is *left-convergent* if $\lim_n t(F,W_n)$ exists for every $F\in\mathcal{F}_0$, and converges to W if $t(F,W_n)\to t(F,W)$ for every F; a sequence of finite graphs is the special case $W_n = W^{G_n}$ via proposition 16.9, and we freely identify G_n with its pixel graphon W^{G_n} when applying graphon-level statements to finite networks.

Three features of this definition repay a slower look: the growth hypothesis on the hosts, the robustness to the choice of normalization, and the seamless passage between finite graphs and graphons. The fourth and most important — why the test family must be *all* of $\mathcal{F}_0$ — we take up last and at length, since it is the heart of the matter.

The hypothesis $|V(G_n)|\to\infty$ is not a throwaway regularity condition; it is what makes left-convergence a statement about *limits of graphs* rather than about graphs themselves, and it is exactly tuned to the counting estimate of section 16.1. Two things break without it. The cheap one is that it rules out the degenerate sequence that never grows: the constant sequence $G_n\equiv G$ trivially has all densities convergent, but it converges to the finite graph G, which is not a graphon limit in any interesting sense — a single dense graph is not the kind of object the theory is built to produce. Demanding $|V(G_n)|\to\infty$ excludes this and every sequence with a bounded subsequence of orders, so that a left-convergent sequence is genuinely a sequence of ever-larger networks settling toward a continuum object. The deeper reason is quantitative and is the one the growth hypothesis was reverse-engineered from. Lemma 16.6 showed that for a k-vertex pattern the hom-, injective-, and induced-normalizations of the density disagree only by the diagonal-coincidence correction $\binom{k}{2}/n$, where $n = |V(G_n)|$; this correction is precisely the weight of the collapsing maps that pinch two vertices of F onto one vertex of G_n. It tends to zero *if and only if* $n \to \infty$. So $|V(G_n)| \to \infty$ is exactly the condition under which the three normalizations become asymptotically equal — the condition that makes the next clause of the definition true.

That next clause is the robustness recorded in the definition: by remark 16.7 one may read $t(F, \cdot)$, or $t_{\mathrm{inj}}(F, \cdot)$, or $t_{\mathrm{ind}}(F, \cdot)$, and obtain the same left-convergent sequences with the same limits. This is more than a convenience. It says that left-convergence is a property of the *geometry* of the sequence, not of the bookkeeping convention we happen to favour: whether we count all maps, only injective maps, or only induced copies, the verdict on which sequences converge and to what is identical, because (by the growth hypothesis just discussed) the three counts are squeezed together as $n \to \infty$. We are therefore free to compute with whichever normalization is most convenient for a given pattern — $t(,)$ for its clean product structure, t_{ind} when a genuine induced-copy count is wanted — and the notion of convergence does not notice the switch.

The third feature is the one that lets the whole apparatus address finite networks and continuum limits in one breath. Proposition 16.9 established that the density of F into a finite graph G and the density of F into its pixel graphon W^G are literally the same number, $t(F, G) = t(F, W^G)$. Consequently a finite graph *is* a graphon for every purpose internal to this theory: its profile is the profile of a step kernel. This is why the definition can phrase left-convergence for a sequence of graphons and then recover the finite-graph case merely by setting $W_n = W^{G_n}$, and why we will, without further comment, write graphon-level statements (the counting lemma, the cut-norm estimates of chapter 17) and apply them to finite networks by passing to their pixel graphons. We keep the *graphon*-sequence version of the definition in full view, not just the finite-graph one, because the later sections need it: the realization theorem produces a limiting graphon, the moment problem ranges over all graphons, and the worked computation at the end of the chapter compares sequences of graphons directly.

We come now to the decision that gives the definition its content, the one the section preamble flagged as essential: the profile records a density for *every* pattern $F \in \mathcal{F}_0$, and left-convergence demands that *all* of them converge. Why not economize — test only against the edge K_2, or against edges and triangles, and call a sequence convergent when those few coordinates settle? The answer is the moment analogy taken seriously, and it is worth making concrete rather than asserting. A single moment of a probability measure — say the mean $\int t\, \mu(\mathrm{d}t)$ — pins down one number about μ and leaves everything else free; two measures with the same mean can be wildly different, and to separate them one needs the higher moments $\int t^k\, \mu(\mathrm{d}t)$. The edge density $t(K_2, \cdot)$ is exactly the mean: it is the crudest, lowest moment of the graph, and a host of structurally unalike networks share it.

The sharpest illustration is the one this chapter's threads return to. Compare two graphons of the same edge density $\frac{1}{2}$. The first is the constant graphon $W \equiv \frac{1}{2}$, the homogeneous "quasirandom" kernel in which every pair of types is joined with the same weight $\frac{1}{2}$ and there is no community structure at all; a large graph sampled from it looks like an Erdős–Rényi graph $G(n, \frac{1}{2})$, edges scattered without correlation. The second is the single-block kernel $W_{\mathrm{cl}} = \mathbf{1}[\,x, y \le c\,]$ with $c = 1/\sqrt{2}$: a clique of relative size c sitting in an otherwise empty network, the extreme of clustered structure. Their edge densities coincide,

$$t(K_2, W) = \tfrac{1}{2}, \qquad t(K_2, W_{\mathrm{cl}}) = \int_{[0,1]^2} \mathbf{1}[\,x, y \le c\,]\ \mathrm{d}x\ \mathrm{d}y = c^2 = \tfrac{1}{2},$$

so the edge test — the mean — cannot tell them apart: it sees two networks of identical overall link frequency and reports a single number that is blind to whether those links are spread evenly or piled into one dense lump. The very next moment exposes the difference. The triangle density of the homogeneous kernel is $t(K_3, W) = (\frac{1}{2})^3 = \frac{1}{8} = 0.125$, the product of three independent edge weights, while for the clustered kernel $t(K_3, W_{\mathrm{cl}}) = c^3 = 2^{-3/2} \approx 0.354$, nearly three times larger, because in a clique every triple of present-edges closes into a triangle whereas in the homogeneous graph triangles must form by coincidence. What the edge density alone cannot see is precisely this: *the correlation between edges* — whether the presence of xy and yy' as edges makes xx' more likely to be an edge too. That correlation is a higher-order statistic, and reading it off requires the higher motif K_3, exactly as detecting the spread of a measure beyond its mean requires the second moment. Stopping at edges, or at edges and triangles, or at any finite slate of motifs, always leaves some pair of graphons that the chosen slate cannot separate but a slightly larger motif can; only the *entire* family $\mathcal{F}_0$ resolves every structural distinction the densities are capable of detecting. The full profile is the graph analog of testing a measure against *all* monomials t^k, not against the mean alone — and just as the full sequence of monomials determines a compactly supported measure (the determinate moment problem of section 16.3), the full family of motif densities is what stands a chance of determining the graphon. That "stands a chance" is the open question the chapter is built to settle; for now it fixes the test family once and for all as the whole of $\mathcal{F}_0$.

This leaves us holding a concrete object — the profile space $[0,1]^{\mathcal{F}_0}$ — and a concrete notion of convergence inside it — coordinatewise convergence of profiles, one motif at a time. Neither has yet been given any topological standing: we have a definition of convergent sequences but no metric, no guarantee that this convergence is tame enough to support the compactness and continuity arguments the rest of the section will run on. Supplying that standing is the next task. Because $\mathcal{F}_0$ is countable, coordinatewise convergence on the cube $[0,1]^{\mathcal{F}_0}$ is nothing more exotic than convergence in a countable product topology, and a countable product of intervals is metrizable; the next subsection makes this precise, exhibits an explicit metric, and harvests the cheap compactness that the product structure hands over for free.

16.2.2 The induced topology is a product topology, and it is metrizable

The previous subsection left us with exactly the raw materials of a topology and nothing yet assembled from them: a fixed home, the cube $[0,1]^{\mathcal{F}_0}$, and a rule for declaring sequences convergent, namely coordinatewise convergence of profiles — $t(F, G_n) \to t(F, W)$ separately for each motif F. "Convergent in every coordinate" is not yet a metric statement; it is a statement about a *product* of topologies, one copy of $[0,1]$ for each axis F, with the product (also called the *moment*) topology being by definition the coarsest one in which all the coordinate projections are continuous.

Convergence in that topology is precisely coordinatewise convergence, so the notion of definition 16.11 is, verbatim, convergence in the product topology on $[0,1]^{\mathcal{F}_0}$. The single fact that turns this abstract identification into something usable is the one the preceding subsection was at pains to record: $\mathcal{F}_0$ is *countable*. A countable product of metric spaces is metrizable, so the product topology on our cube is not some exotic object on which only nets converge — it is induced by an honest distance function, which we can write down by hand. Doing so, and harvesting the compactness that comes with it, is the whole of this subsection.

The recipe for the metric is the standard one for any countable product, and it is worth seeing why it must take the shape it does. We want a single number measuring the discrepancy between two whole profiles, built from the per-coordinate discrepancies $|t(F_j,W)-t(F_j,W')|$. Each of those is already a number in $[0,1]$, so a sum of them would be the obvious candidate — but the sum over the infinitely many motifs F_j need not converge. The fix is to damp the later coordinates with summable weights, and the cleanest summable weights are the powers 2^{-j}, whose total is 1. Damping by 2^{-j} does no harm to the topology — every coordinate still gets a strictly positive weight, so no axis is ignored — while it guarantees the sum converges and stays bounded by 1. With this in mind the definition writes itself. Because $\mathcal{F}_0$ is countable we may enumerate it $F_1, F_2, F_3, \ldots$ (say, by increasing number of vertices and then by number of edges, so that the enumeration is concrete and the early, structurally important motifs $K_2, P_3, K_3, \ldots$ carry the heaviest weights), and form the weighted sum.

Definition 16.12 (A left-convergence metric)**.** Fix an enumeration $\mathcal{F}_0=\{F_1,F_2,\ldots\}$. For graphons W, W' (or for finite graphs via their step graphons) set

$$d_{\mathrm{left}}(W,W') \;=\; \sum_{j\geq 1} 2^{-j}\,\big|\,t(F_j,W)-t(F_j,W')\,\big|.$$

The choice of weights and of enumeration is a matter of convenience, not of substance: any other strictly positive summable weights (w_j), or any other listing of $\mathcal{F}_0$, would give a different distance function but the *same* topology, because what the metric has to reproduce — and all it has to reproduce — is coordinatewise convergence, which sees only that each weight is positive, never its precise value. The next proposition makes that claim exact and, in the same breath, names the one defect that keeps d_{left} from being a genuine metric.

Proposition 16.13 (Metrization of the moment topology)**.** *d_{left} is a pseudometric on graphons taking values in $[0,1]$, and a sequence (G_n) converges to W in the sense of definition 16.11 if and only if $d_{\mathrm{left}}(G_n,W)\to 0$. It is the restriction to homomorphism profiles of the product topology on $[0,1]^{\mathcal{F}_0}$, which is compact by Tychonoff's theorem and metrizable because $\mathcal{F}_0$ is countable.*

Proof. That d_{left} has the formal properties of a distance is read off termwise. Each summand $\rho_j(W,W') := |t(F_j,W)-t(F_j,W')|$ is the absolute difference of two coordinates, hence symmetric, non-negative, and subject to the one-dimensional triangle inequality $\rho_j(W,W'')\leq \rho_j(W,W')+\rho_j(W',W'')$; multiplying by the positive weight 2^{-j} and summing preserves all three, so d_{left} is symmetric, non-negative, and satisfies the triangle inequality. Each ρ_j lies in $[0,1]$ because both densities do, so the series is dominated termwise by $\sum_{j\geq 1} 2^{-j}=1$ and $d_{\mathrm{left}}\leq 1$; in particular the sum always converges and the function is well defined. The one axiom that *fails* — that $d_{\text{left}}(W, W') = 0$ should force $W = W'$ — is exactly what makes it a *pseudo*metric, and we return to it below.

The heart of the statement is that $d_{\text{left}} \to 0$ is equivalent to coordinatewise convergence, and this is the general head-and-tail argument for a weighted sum of bounded coordinate pseudometrics, which we give in full because it recurs whenever a countable product is metrized.

Convergence of all coordinates forces $d_{\text{left}} \to 0$. Suppose $\rho_j(G_n, W) \to 0$ as $n \to \infty$ for every fixed j — that is, every motif density converges. Fix $\varepsilon > 0$. Split the sum at an index J into a head and a tail,

$$d_{\text{left}}(G_n, W) \;=\; \underbrace{\sum_{j=1}^{J} 2^{-j} \rho_j(G_n, W)}_{\text{head}} \;+\; \underbrace{\sum_{j>J} 2^{-j} \rho_j(G_n, W)}_{\text{tail}}.$$

The tail is controlled with no reference to n at all: each $\rho_j \le 1$, so $\sum_{j>J} 2^{-j} \rho_j \le \sum_{j>J} 2^{-j} = 2^{-J}$, and choosing J large enough that $2^{-J} < \varepsilon/2$ makes the tail smaller than $\varepsilon/2$ for *every* n. With J now fixed, the head is a sum of *finitely many* terms, each of which tends to 0 by hypothesis (a finite sum of null sequences is null); so there is an N beyond which the head is $< \varepsilon/2$. For $n \ge N$ both pieces are below $\varepsilon/2$ and $d_{\text{left}}(G_n, W) < \varepsilon$. This is the crux: the damping weights make the infinite tail uniformly negligible, after which only finitely many coordinates have to be driven down, which the hypothesis does one at a time.

$d_{\text{left}} \to 0$ *forces convergence of every coordinate.* This direction is even shorter, and is where the positivity of each weight is used. Every summand is non-negative, so any single one is bounded above by the whole sum:

$$2^{-j} \rho_j(G_n, W) \;\le\; \sum_{i \ge 1} 2^{-i} \rho_i(G_n, W) \;=\; d_{\text{left}}(G_n, W).$$

Hence for each fixed j, if $d_{\text{left}}(G_n, W) \to 0$ then $\rho_j(G_n, W) \le 2^j \, d_{\text{left}}(G_n, W) \to 0$ — the factor 2^j is a constant once j is fixed — so that coordinate converges. Since j was arbitrary, all coordinates converge.

The two directions together say that $d_{\text{left}}(G_n, W) \to 0$ holds if and only if $t(F, G_n) \to t(F, W)$ for every $F \in \mathcal{F}_0$, which is verbatim the definition of left-convergence (definition 16.11). So d_{left} metrizes exactly the convergence we declared, and that convergence is convergence in the product topology on the cube $[0,1]^{\mathcal{F}_0}$: the moment topology is metrizable, with d_{left} an explicit metric for it. The cube itself is compact in this topology — a product of the compact intervals $[0, 1]$ — a fact one may file under Tychonoff's theorem, and metrizable because $\mathcal{F}_0$ is countable. (We will see in remark 16.14 that the only part of this compactness ever used is the elementary sequential part, for which the full Tychonoff theorem is overkill.) □

It remains to confront the failed axiom, the one that demotes d_{left} from metric to *pseudo*metric: two graphons can be at zero distance without being equal. By construction $d_{\text{left}}(W, W') = 0$ means every coordinate pseudometric vanishes, i.e. $t(F, W) = t(F, W')$ for *all* $F \in \mathcal{F}_0$: the two graphons have identical homomorphism profiles. That this can happen for genuinely different kernels $W \ne W'$ is not a defect of our metric but a feature of the objects: homomorphism densities are, by design, blind to anything the moment family cannot resolve, and that includes the labelling of types. Two graphons with the same profile are called *weakly isomorphic*; chapter 17 shows this is exactly the relation $\delta_\square(W, W') = 0$ (proposition 17.7), so that $d_{\text{left}} = 0$ and $\delta_\square = 0$ cut out the same equivalence, and quotienting graphon space by it — the construction chapter 17 carries out — promotes d_{left} to a true metric on the quotient. The pseudometric is therefore precisely as fine as the densities allow and no finer; it is the correct object, and the loss of separation is the price, paid honestly, for relabelling-blindness.

It is worth being exact about what "relabelling-blind" covers, because the obvious guess undersells it. One certainly expects the profile to be unchanged when types are relabelled by a single measure-preserving *bijection* $\sigma\colon [0,1] \to [0,1]$ — replacing W by $W^\sigma(x,y) = W(\sigma x, \sigma y)$ merely renames the integration variables in definition 16.8 and leaves every integral fixed. But weak isomorphism is strictly coarser than that: it identifies graphons related by measure-preserving maps that need not be invertible. A clean witness is the *doubling* map $\sigma(x) = 2x \bmod 1$, which pushes Lebesgue measure forward to Lebesgue measure but is two-to-one, not a bijection. For any graphon W the pulled-back kernel $W'(x,y) = W(\sigma x, \sigma y)$ has, by the change-of-variables formula coordinate by coordinate,

$$t(F, W') = \int_{[0,1]^k} \prod_{ij \in E(F)} W(\sigma x_i, \sigma x_j)\, \mathrm{d}x = \int_{[0,1]^k} \prod_{ij \in E(F)} W(u_i, u_j)\, \mathrm{d}u = t(F, W)$$

for every F — the substitution $u_i = \sigma x_i$ sends each factor of Lebesgue measure to itself — so W and W' are weakly isomorphic, yet no single bijection of $[0,1]$ relates them in general, since σ collapses two type-intervals onto one. This is the concrete shadow of a fact chapter 17 treats with care: the infimum defining the cut distance $\delta_\square$ need not be attained by a bijection, so "$\delta_\square = 0$" is genuinely the equivalence generated by such non-invertible couplings, of which "differ by a relabelling bijection" is only the cleanest special case. We flag the distinction here and lean on it there; for the present purpose all that matters is that d_{left} separates graphons exactly up to weak isomorphism, no more and no less.

With the topology pinned down and metrized, we collect the dividend the product structure pays out for free: a cheap compactness, strong enough to manufacture limit points and weak enough to leave the real work undone.

Remark 16.14 (Compactness for free, realization is the hard part)**.** There is an immediate but *weak* compactness statement: every sequence of finite graphs (G_n) has a subsequence (G_{n_ℓ}) whose profile $\big(t(F, G_{n_\ell})\big)_F$ converges coordinatewise to *some* point $\tau \in [0,1]^{\mathcal{F}_0}$ — i.e. every graph sequence has a left-convergent subsequence. The mechanism is the classical *diagonal extraction*, and it deserves to be seen in the open because it, and not any heavy theorem, is what is actually at work. Enumerate $\mathcal{F}_0 = \{F_1, F_2, \dots\}$ as before. The first coordinate $t(F_1, G_n)$ is a sequence in the compact interval $[0,1]$, so by Bolzano–Weierstrass some subsequence $(G_n^{(1)})$ makes it converge. Inside that subsequence the second coordinate $t(F_2, G_n^{(1)})$ again lives in $[0,1]$, so a further subsequence $(G_n^{(2)})$ makes it converge too — and the first coordinate, being a subsequence of a convergent sequence, still converges. Continuing, we obtain nested subsequences $(G_n^{(1)}) \supseteq (G_n^{(2)}) \supseteq \cdots$, the m-th of which converges in the first m coordinates. The diagonal sequence $G_{n_\ell} := G_\ell^{(\ell)}$ is, from its m-th term on, a subsequence of $(G_n^{(m)})$, hence converges in coordinate m for *every* m; that is, its whole profile converges coordinatewise to a limit $\tau \in [0,1]^{\mathcal{F}_0}$. The entire argument uses only that each coordinate ranges over the compact interval $[0,1]$, invoked *countably* many times — nothing more.

It is precisely this point that we want to keep honest, because it is easy to dress the same conclusion in grander clothing. One may, if one likes, attach the name "Tychonoff" to the compactness of the full cube $[0,1]^{\mathcal{F}_0}$, and the proposition above did so. But the unrestricted Tychonoff theorem — an *arbitrary* product of compacts is compact — is a statement about possibly uncountable products that delivers only *topological* compactness (every open cover has a finite subcover), from which sequential compactness does not follow for free in a non-metrizable space, and whose proof leans on the axiom of choice. None of that machinery is needed here. Our index set $\mathcal{F}_0$ is countable, the cube is metrizable, topological and sequential compactness coincide, and the sequential statement is supplied outright by the diagonal argument over a countable family of compact intervals. The downgrade is deliberate: "Tychonoff" is at most a name for a fact we prove by hand, and the operative content is the countable diagonal extraction, never the uncountable product theorem.

What this compactness gives, then, is a limit *point*; what it conspicuously does *not* give is a limit *object*. The extracted τ is an element of the abstract cube $[0,1]^{\mathcal{F}_0}$ — a coherent table of numbers, one per motif, arising as a coordinatewise limit of honest graph profiles. Nothing in the extraction certifies that τ is itself the profile $t(\cdot, W)$ of any graphon: a priori it is merely a point in the cube, an abstract limit of moment vectors, and the cube is vastly larger than the set of profiles sitting inside it. The gap between "τ exists as a limit of profiles" and "τ *is* a profile" is the entire remaining difficulty, and it is a real one — the analogue, in the moment picture, of asking not merely whether a sequence of moment vectors has a limit but whether that limiting sequence of numbers is the moment sequence of an actual measure. Cheap compactness answers the first; only a realization theorem can answer the second.

That realization is the one thing the product topology cannot hand us, and supplying it is the next order of business. The subsequential compactness just proved guarantees an abstract limit profile $\tau \in [0,1]^{\mathcal{F}_0}$ for every graph sequence, but leaves open whether $\tau = t(\cdot, W)$ for some graphon W — whether the limit table of motif frequencies is genuinely realized by a continuum network. The Lovász–Szegedy realization theorem asserts that it always is: every left-convergent sequence, and a fortiori every such limit point τ, is the homomorphism profile of an actual graphon. We state it precisely next, locate its proof in the cut-metric machinery of chapter 17 and appendix F, and isolate the one piece of its supporting argument — the counting lemma — that belongs in this chapter.

16.2.3 The Lovász–Szegedy realization theorem

The previous subsection left us holding an abstract limit and nothing to anchor it to. Diagonal extraction (remark 16.14) manufactures, for every graph sequence, a coordinatewise limit point $\tau \in [0,1]^{\mathcal{F}_0}$ — a coherent table of numbers, one frequency per motif, got as the limit of honest graph profiles — but it certifies nothing about whether that table is the profile of any *object*. The cube $[0,1]^{\mathcal{F}_0}$ is enormous; the profiles $t(\cdot, W)$ of actual graphons form a thin, intricately constrained subset of it, and a priori a limit of points in that subset could perfectly well escape it, landing on a number-table that no graphon produces. Closing exactly this gap — promoting the abstract limit vector τ to a statement that $\tau = t(\cdot, W)$ for a genuine continuum network W — is the content of the theorem this subsection is built around. It is the assertion that the thin constrained subset of realizable profiles is already *closed*: a limit of graphon profiles is again a graphon profile.

Theorem 16.15 (Every left-convergent sequence has a graphon limit; Lovász–Szegedy)**.** *For every left-convergent sequence (G_n) of finite simple graphs with $|V(G_n)| \to \infty$ there exists a graphon W satisfying **(A-Reg-W)** (symmetric, measurable, $[0,1]$-valued) such that*

$$\lim_{n\to\infty} t(F, G_n) \;=\; t(F, W) \qquad \textit{for every } F \in \mathcal{F}_0.$$

The graphon W is unique up to weak isomorphism, i.e. up to $\delta_\square = 0$ (proposition 17.7).

This is the founding theorem of dense graph limit theory: it is what makes the whole moment programme more than a bookkeeping device. Everything in this chapter up to now has been, in a strict sense, formal — we defined a profile, declared a topology, metrized it, and extracted abstract limits — and none of it required that the limits be anything but points in a cube. The theorem is what installs the *object* on the other side of the limit, and that is precisely where the depth lies. It is worth being emphatic about what is and is not hard here, because the two are easy to conflate. That the limit *exists as a number-vector* is the cheap part, already in hand: it is nothing but Bolzano–Weierstrass applied countably many times, the diagonal argument of remark 16.14, and it would hold for any countable family of $[0,1]$-valued statistics whatever, with no graph theory in it at all. What is deep is the *realization* — that this particular limit vector is not some exotic point of the cube but is hit by an actual symmetric measurable kernel on $[0,1]^2$. The analogy that organizes the chapter says it sharply: producing a candidate moment sequence as a limit of genuine moment sequences is elementary; proving that the candidate is *the moment sequence of an actual measure* is the whole moment problem. The realization theorem is the graph-limit instance of that second, substantial step, and it is the reason a left-convergent graph sequence has a bona fide limiting network rather than merely a limiting list of frequencies.

We do not prove theorem 16.15 in this chapter. Per the self-containedness discipline, "we do not prove it here" must come with a precise pointer to where in this book it *is* proved, and it does: its natural proof runs through the cut metric $\delta_\square$ and the compactness of the resulting quotient space, machinery that is developed in chapter 17 and carried to a complete proof in appendix F. What belongs here is an honest map of that dependency, so the reader knows exactly which load-bearing facts are imported and from where. Chapter 17 supplies two ingredients. The first is an *equivalence*: left-convergence of a graph sequence is the same thing as convergence in the cut metric $\delta_\square$, up to relabelling — the moment topology of this chapter and the metric topology of chapter 17 are, on graphon space, one and the same. The second is a *compactness*: the quotient graphon space $(\widetilde{\mathcal{W}}_0, \delta_\square)$ — the space of graphons modulo weak isomorphism, equipped with $\delta_\square$ — is compact, in particular complete, so that every Cauchy sequence in it converges to a point of it.

Granting those two imports, the realization theorem assembles itself in a short chain, and it is worth walking the links so the logical shape is unmistakable. Start with a left-convergent (G_n). By the *equivalence*, its profiles converging coordinatewise means the G_n form a $\delta_\square$-Cauchy sequence in the quotient space: motif frequencies settling down is the same news as the graphs bunching together in cut metric. By the *compactness* (hence completeness) of $(\widetilde{\mathcal{W}}_0, \delta_\square)$, that Cauchy sequence has a genuine limit there — a graphon W, defined up to weak isomorphism, with $\delta_\square(G_n, W) \to 0$. Applying the *equivalence* once more, now in the reverse reading, cut-metric convergence to W forces $t(F, G_n) \to t(F, W)$ for every motif F. So the abstract limit τ is realized: $\tau = t(\cdot, W)$, and the uniqueness up to weak isomorphism is exactly the statement that $\delta_\square$ identifies graphons precisely when their profiles agree (proposition 17.7). The realization theorem is, in this reading, the round trip *left-convergent* $\Rightarrow$ $\delta_\square$*-Cauchy* $\Rightarrow$ $\delta_\square$*-convergent to* W $\Rightarrow$ *convergent in density*, with the equivalence used at both ends and the compactness supplying the limit in the middle.

The equivalence on which this turns is itself two implications of very unequal difficulty, and keeping them separate is the chapter's honest accounting of what it proves versus what it imports. One direction is *easy*: closeness in $\delta_\square$ forces closeness of all motif densities — if two graphons are near in cut metric then every homomorphism frequency is near. This is the counting lemma, and it is completely elementary, a few lines of telescoping and a cut-norm bound. It is the one piece of the entire realization argument that lives in this chapter, and we prove it in the very next subsection. The other direction is *hard*: closeness of *all* motif densities forces closeness in $\delta_\square$ — if every frequency agrees then the graphons are near in cut metric. This is the *inverse counting lemma*, the genuine content behind the moment-uniqueness theorem theorem 17.11, and it is not elementary at all: it rests on the weak regularity lemma (theorem 17.16), the structural result that any graphon is approximated in cut norm by a bounded-complexity step function, which is the single deepest import of the whole development. The asymmetry is the usual one in a moment theory. That cut-close profiles are density-close is the forward, "moments are continuous" direction; that density-close profiles are cut-close is the inverse, "the moments determine the object" direction, and inverting a moment map is always where the work is. Both halves, and the compactness, are proved in full in chapter 17 and appendix F; this chapter contributes the forward half and imports the rest with the pointers just given.

Notation watch

The label "Lovász–Szegedy theorem" is attached in this book to two distinct but linked statements: the *realization* theorem theorem 16.15 (every left-convergent graph sequence has a graphon limit) and the *compactness* theorem of chapter 17 (the quotient graphon space is compact in $\delta_\square$). They are equivalent given the metric equivalence of chapter 17; we prove the compactness version in appendix F and derive the realization version from it (the chain above). When we write "by Lovász–Szegedy" we mean whichever of the two is being invoked, and we always say which.

With the founding theorem stated and its logical debts itemized, exactly one of those debts is ours to discharge here: the easy half of the equivalence, that cut-closeness implies density-closeness. That is the counting lemma, and proving it is the business of the next subsection — the single piece of the realization theorem's supporting argument that belongs in this chapter, and the one we turn to now.

16.2.4 The counting lemma

We turn now to the single debt the realization theorem leaves for this chapter to settle in full. The preceding subsection split the equivalence between left-convergence and cut-metric convergence into two implications of wildly unequal difficulty and reserved exactly one of them for proof here: the *easy* direction, that closeness in cut norm forces closeness of every motif frequency. That implication is the *counting lemma*, and it has a sharp quantitative shape. Homomorphism densities are not merely continuous in the cut norm; they are *Lipschitz* in it, with an explicit and almost embarrassingly small Lipschitz constant — the number of edges of the pattern, and nothing else. Two graphons that are within ε of one another in cut norm have all of their edge densities within ε, all of their triangle densities within 3ε, all of their F-densities within $|E(F)|\ \varepsilon$. This is the whole of the forward half of the equivalence, and it is genuinely elementary: a telescoping sum and one application of the defining property of the cut norm.

It is worth saying at the outset why so plain a lemma earns the title "workhorse." Read it in the language of the map Θ that the chapter has been building toward, the assignment $W \mapsto \big(t(F,W)\big)_{F\in\mathcal{F}_0}$ that sends a graphon to its moment profile. The counting lemma is precisely the statement that *each coordinate* of Θ is Lipschitz, and therefore that Θ is a continuous map from cut-metric graphon space into the profile cube $[0,1]^{\mathcal{F}_0}$: the moments move continuously when the network moves. That is the property that lets the densities serve as a genuine *coordinate system* on graphon space — coordinates that respond continuously to the object they describe, so that controlling the object controls every coordinate at once. Without it, "convergence of all motif frequencies" and "convergence of the underlying networks" would be unrelated notions, and the moment programme would have no traction on the geometry of chapter 17. With it, one half of their identification is immediate, and only the deep half remains to be imported.

We first recall the cut norm; its detailed study, and the metric $\delta_\square$ obtained by also optimizing over relabellings, are the business of chapter 17 (definitions 17.1 and 17.6).

Definition 16.16 (Cut norm; recalled from chapter 17)**.** For a bounded measurable symmetric kernel $H\colon [0,1]^2 \to \mathbb{R}$ the *cut norm* is

$$\|H\|_\square \;=\; \sup_{S,T\subseteq[0,1]} \left| \int_{S\times T} H(x,y)\ \mathrm{d}x\ \mathrm{d}y \right|,$$

the supremum over measurable S,T. We use one elementary fact, proved in chapter 17: the supremum is unchanged if the indicators $\mathbf{1}_S, \mathbf{1}_T$ are replaced by arbitrary measurable functions $g,h\colon [0,1]\to[0,1]$,

$$\sup_{g,h\colon [0,1]\to[0,1]} \left| \int_{[0,1]^2} H(x,y)\, g(x)\, h(y)\ \mathrm{d}x\ \mathrm{d}y \right| \;=\; \|H\|_\square\,, \tag{$\star$}$$

because the bilinear functional $(g,h)\mapsto \int H\,g\,h$ is, for h fixed, linear in g and hence maximized over the convex set $\{g : [0,1]\to[0,1]\}$ at an extreme point $g=\mathbf{1}_S$, and symmetrically in h.

The identity ($\star$) is the only fact about the cut norm the proof will use, so it pays to see clearly why it holds; the argument is a clean instance of the principle that a linear functional on a convex set is maximized at an extreme point. One inequality is free: indicators $\mathbf{1}_S, \mathbf{1}_T$ are in particular $[0,1]$-valued functions, so the supremum over arbitrary $g, h\colon [0,1] \to [0,1]$ is taken over a *larger* family than the supremum over indicators and can only be at least as big — the left side of ($\star$) is $\geq \|H\|_\square$. The substance is the reverse inequality, that enlarging the test family buys nothing. Fix $h\colon [0,1] \to [0,1]$ and consider the functional $g \mapsto \Phi_h(g) = \int_{[0,1]^2} H(x,y)\, g(x)\, h(y)\; \mathrm{d}x\; \mathrm{d}y$. It is *linear* in g, and its domain $K = \{g\colon [0,1] \to [0,1]\}$ is a convex set: a convex combination of two functions valued in $[0,1]$ is again valued in $[0,1]$. A linear functional on a convex set attains its maximum at an extreme point of that set, and the extreme points of K are exactly the $\{0,1\}$-valued functions — the indicators $\mathbf{1}_S$ of measurable sets S — because any g taking a value strictly between 0 and 1 on a positive-measure set can be perturbed up and down on that set, writing g as the midpoint of two distinct admissible functions and so failing to be extreme. Hence $\sup_{g \in K} \Phi_h(g) = \sup_S \Phi_h(\mathbf{1}_S)$, and the same value is attained when we additionally minimize, so the supremum of $|\Phi_h|$ over $g \in K$ equals its supremum over indicators $g = \mathbf{1}_S$. Now repeat the argument in the second slot: with $g = \mathbf{1}_S$ frozen, $h \mapsto \int H\, \mathbf{1}_S\, h$ is again linear in h over the convex set K, maximized at $h = \mathbf{1}_T$. Optimizing the two variables in turn drives both to indicators without ever exceeding $\|H\|_\square$, which is exactly ($\star$). The reason we want the relaxed form, rather than the cleaner-looking indicator form, is entirely practical and will surface in the proof below: the factors that the counting lemma peels off a motif integrand are naturally $[0,1]$-valued functions — products of kernel evaluations — not sharp indicators, and ($\star$) lets us feed them straight into the cut norm with no rounding step.

With the cut norm and its one usable property in hand, here is the lemma. The constant is the edge count $|E(F)|$ — the same integer written $e(F)$ in chapter 17 — and the proof will show that this is no coincidence: we shall trade W for W' one edge at a time, paying a cut norm for each, so the price is exactly one $\|W - W'\|_\square$ per edge.

Lemma 16.17 (Counting lemma)**.** *Let W, W' be graphons with values in $[0,1]$ and let F be a finite simple graph with $|E(F)|$ edges. Then*

$$\left|\, t(F,W) - t(F,W')\, \right| \;\leq\; |E(F)| \cdot \|W - W'\|_\square \,.$$

Proof. Enumerate the edges of F as $e_1, \ldots, e_M$ with $M = |E(F)|$. We pass from W to W' one edge at a time, defining hybrid integrands in which the first r edges carry the kernel W' and the remaining $M - r$ carry W:

$$I_r \;=\; \int_{[0,1]^k} \Big(\prod_{s \leq r} W'(x_{e_s})\Big)\Big(\prod_{s > r} W(x_{e_s})\Big)\; \mathrm{d}x_1 \cdots \mathrm{d}x_k, \qquad k = |V(F)|\,,$$

where x_e abbreviates the pair of coordinates indexed by the endpoints of edge e. Then $I_0 = t(F,W)$ and $I_M = t(F,W')$, and by telescoping

$$t(F,W) - t(F,W') \;=\; \sum_{r=1}^{M} (I_{r-1} - I_r).$$

Fix r and write $e_r = \{a,b\}$. The difference $I_{r-1} - I_r$ replaces the single factor $W(x_a, x_b)$ by $W'(x_a, x_b)$; thus

$$I_{r-1} - I_r \;=\; \int_{[0,1]^k} \; (W - W')(x_a, x_b) \; \prod_{e \neq e_r} [\;\cdot\;](x_e)\; \mathrm{d}x_1 \cdots \mathrm{d}x_k,$$

where each remaining factor is W or W' according to the hybrid and lies in $[0,1]$. The decisive move — and it is the whole proof — is to bound the inner (x_a, x_b)-integral *before* integrating any of the other coordinates, holding them frozen. The order matters, and it is worth being concrete about exactly what goes wrong if one yields to the temptation to integrate the others out first. Take $F = K_3$ the triangle, with vertices a, b, c and $e_r = \{a, b\}$ the edge being swapped, so the two surviving factors sit on the edges $\{a, c\}$ and $\{b, c\}$. If we integrate the lone remaining coordinate x_c out first, those two factors combine into

$$\int_{[0,1]} W(x_a, x_c)\, W(x_c, x_b)\; \mathrm{d}x_c \;=\; (\mathbb{W}^2)(x_a, x_b),$$

the kernel of the squared integral operator — a function of the *pair* (x_a, x_b) that does *not* split as a product $g(x_a)\, h(x_b)$. The common neighbour c has glued the two coordinates together: physically, a and b are no longer independently coupled to their surroundings but share a neighbour, and integrating that neighbour out first bakes the sharing into an inseparable function of (x_a, x_b). Against such a function the extreme-point identity ($\star$), which can only see integrands of the product form $g(x_a)h(x_b)$, has no purchase, and the bound $\|W - W'\|_\square$ is unavailable. The remedy is to do nothing clever: leave x_c (and every other surviving coordinate) *unintegrated*, fixed at a value, and bound the two-dimensional (x_a, x_b)-integral first. With x_c held fixed, $W(x_a, x_c)$ is a function of x_a alone and $W(x_c, x_b)$ a function of x_b alone — the product structure is restored precisely because we declined to integrate the coordinate that couples them. So fix the remaining coordinates at any value $z = (x_u)_{u \neq a,b} \in [0,1]^{k-2}$. With z held fixed, every factor other than the removed one depends on *at most one* of x_a, x_b: a factor $W^{(\prime)}(x_a, x_u)$ on an edge incident to a is, for fixed x_u, a function of x_a alone; a factor on an edge incident to b is a function of x_b alone; a factor on an edge incident to neither (both endpoints in z) is a constant. (No surviving factor touches both x_a and x_b, since e_r is the *unique* edge on the pair $\{a, b\}$ in the simple graph F.) Collecting these,

$$\prod_{e \neq e_r} [\;\cdot\;](x_e) \;=\; g_z(x_a)\, h_z(x_b), \qquad g_z, h_z \colon [0,1] \to [0,1],$$

where g_z gathers the (constant) factors among z together with those on edges incident to a, and h_z those on edges incident to b; both are products of $[0,1]$-valued factors and hence valued in $[0,1]$. By the extreme-point identity ($\star$), applied for each fixed z,

$$\left| \int_{[0,1]^2} (W - W')(x_a, x_b)\, g_z(x_a)\, h_z(x_b)\; \mathrm{d}x_a\; \mathrm{d}x_b \right| \;\leq\; \|W - W'\|_\square\,,$$

a bound *uniform* in z. Integrating this uniform bound over $z \in [0,1]^{k-2}$, a probability space (Tonelli applies, the integrand being bounded and measurable), gives

$$|I_{r-1} - I_r| \;\leq\; \int_{[0,1]^{k-2}} \|W - W'\|_\square \; \mathrm{d}z \;=\; \|W - W'\|_\square\,.$$

Summing the M telescoped terms gives $|I_0 - I_M| \leq M\, \|W - W'\|_\square = |E(F)|\, \|W - W'\|_\square$, which is the claim. $\square$

It is worth registering what the Lipschitz constant $|E(F)|$ does and does not depend on. Unlike the first counting lemma of lemma 16.6, whose constant $\binom{k}{2}/n$ was governed by the number of *vertices* of F (because there it was vertex-collisions being counted), the constant here is the number of *edges.* The reason is structural and visible in the telescope: we paid one cut norm for each edge whose kernel we swapped, and a motif with M edges requires M swaps. A k-vertex tree (with $k-1$ edges) and a k-vertex clique (with $\binom{k}{2}$ edges) therefore incur very different counting-lemma errors even though they have the same number of vertices — the clique, being edge-heavy, is the more sensitive probe of cut-norm discrepancy. Note also what is absent: no dependence on a host size n (these are graphons, with no n), and no constant larger than 1 in front — the estimate is as tight as a telescope of M unit-Lipschitz steps can be. This cleanness is exactly what makes Θ Lipschitz coordinate by coordinate, and it is the property the next corollary harvests.

Corollary 16.18 (Cut-convergence implies left-convergence)**.** *If a sequence of graphons W_n satisfies $\|W_n - W\|_\square \to 0$, then $t(F, W_n) \to t(F, W)$ for every finite simple graph F; that is, cut-norm convergence implies left-convergence. The same holds with $\|\cdot\|_\square$ replaced by the relabelling-invariant cut metric $\delta_\square$, since each $t(F, \cdot)$ is invariant under measure-preserving relabelling.*

Proof. The first assertion is immediate from lemma 16.17: for each fixed F the right-hand side $|E(F)|\,\|W_n - W\|_\square \to 0$, the constant $|E(F)|$ being a fixed integer, so the left-hand side $|t(F, W_n) - t(F, W)|$ is squeezed to 0 as well. Since F was arbitrary, every motif density converges, which is by definition left-convergence.

For the second assertion we must check that each density $t(F, \cdot)$ is blind to relabelling, so that the estimate survives when $\|\cdot\|_\square$ is replaced by its relabelling-optimized refinement $\delta_\square$. A relabelling of a graphon is a measure-preserving map $\sigma\colon [0,1] \to [0,1]$ acting by $W^\sigma(x, y) = W(\sigma x, \sigma y)$ — the continuum analogue of permuting the vertices of a finite graph, which is exactly the relabelling ambiguity the whole chapter set out to quotient away. Its effect on a density is none at all: in the defining integral

$$t(F, W^\sigma) = \int_{[0,1]^k} \prod_{ij \in E(F)} W(\sigma x_i, \sigma x_j)\; \mathrm{d}x_1 \cdots \mathrm{d}x_k,$$

substitute $x_i' = \sigma x_i$ in each of the k coordinates. Because σ is measure-preserving, each single-coordinate change of variables leaves Lebesgue measure invariant, and the integral becomes $\int \prod W(x_i', x_j')\; \mathrm{d}x_1' \cdots \mathrm{d}x_k' = t(F, W)$ verbatim. So $t(F, W^\sigma) = t(F, W)$ for every relabelling σ: the densities are precisely the relabelling-invariant content the chapter promised they would be. Consequently the counting-lemma bound holds with W, W' each replaced by any of their relabelled copies, and taking the infimum of the right-hand side over all relabellings turns $\|W - W'\|_\square$ into the cut *metric* $\delta_\square(W, W')$ (definition 17.6) while the left-hand side, being already relabelling-invariant, is untouched. Thus $\delta_\square(W_n, W) \to 0$ likewise forces left-convergence. $\square$

Corollary 16.18 is the "easy direction" promised after theorem 16.15, and with it the chapter has discharged in full its one share of the realization theorem's supporting argument. The map $\Theta\colon W \mapsto \big(t(F, W)\big)_{F \in \mathcal{F}_0}$ from graphons to moment profiles is now known to be continuous — Lipschitz in each coordinate — and this is exactly the fact section 16.3 will pick up: once Θ is continuous and (modulo relabelling, by the import of chapter 17) injective, the only remaining structural question about it is the description of its *range*, which is the moment problem for graphs.

Before turning there it is worth dwelling on the asymmetry the corollary exposes, because it is the central quantitative fact of the whole dense theory and the reason the two convergence notions behave so differently as *metrics* even though they generate the same *topology*. The forward direction we have just proved is clean and uniform: a Lipschitz bound with constant $|E(F)|$, valid for every pair of graphons, no logarithms, no qualifications. The converse — that left-convergence implies cut-convergence — is true as a statement about topologies but *false* at the level of any comparably clean inequality. There is no bound of the form $\|W - W'\|_\square \leq C \sum_F w_F \, |t(F,W) - t(F,W')|$ with fixed summable weights w_F holding uniformly over all graphons; one cannot recover the cut distance from a fixed weighted combination of density gaps. The correct converse is necessarily quantitative-and-truncated, the *inverse counting lemma* that underlies the moment-uniqueness theorem theorem 17.11 (proved in appendix F): matching all of the *finitely many* densities $t(F,\cdot)$ with $|V(F)| \leq k$ forces the cut distance down only to $O(1/\sqrt{\log k})$. The contrast could hardly be sharper — to make two graphons cut-close to within ε through their moments alone one must control all motifs up to roughly e^{1/ε^2} vertices, an astronomically slow rate, whereas the forward bound delivers ε-closeness of any single density for free from ε-closeness in cut norm. That a moment map is Lipschitz forward but only logarithmically invertible is the graph instance of a phenomenon familiar throughout moment theory: reading off a moment is a bounded, stable operation, but reconstructing the object from its moments is delicate and ill-conditioned. It is exactly this gap that lets left-convergence and cut-convergence coincide as topologies (chapter 17) — the same convergent sequences, the same limits — while remaining wildly inequivalent as metrics, and it is why one direction of the equivalence is a four-line telescope and the other needs the full weight of the regularity lemma.

Heuristic (non-rigorous)

Why should "all motif densities" be enough to pin down a graphon, when even a single density like the edge density is so lossy? The picture is the same as for the classical moment problem, and holding the two side by side makes the chapter's organizing analogy do real work rather than serve as decoration. One moment $\int t\,\mu(\mathrm{d}t)$ fixes only the mean of a measure — two very different distributions can share it — but the whole sequence $\int t^k\,\mu(\mathrm{d}t)$, $k \geq 0$, fixes μ entirely whenever the moment problem is determinate, which on a bounded interval such as $[0,1]$ it always is. The same lossiness and the same eventual rigidity recur for graphs. The edge density $t(K_2, W) = \int W$ is the graph mean, and like a mean it is hopelessly coarse: it cannot tell a graphon with its edges clustered into a dense community from one with the same number of edges spread uniformly. But the full family $\big(t(F,W)\big)_{F\in\mathcal{F}_0}$ — which contains, for *every* k, all the k-vertex patterns, the graph analogue of all the monomials t^k — is rich enough to resolve the graphon down to the one ambiguity it *cannot* and *should* not see: how the type interval $[0,1]$ is labelled. That residual ambiguity is the whole reason the chapter went looking for relabelling-blind observables in the first place, and it is the precise graph counterpart of a measure being determined "up to nothing" once its moments are fixed.

The two halves of the moment programme line up just as cleanly across the analogy. The counting lemma of this subsection is the *forward* half — the moment map $\Theta\colon W \mapsto (t(F,W))_F$ is continuous, exactly as $\mu \mapsto (\int t^k \,\mathrm{d}\mu)_k$ is — and it was the cheap half, a telescope. The regularity lemma of chapter 17 supplies the *inverse* half — the moments determine the object, exactly as a determinate moment sequence determines μ — and it is the expensive half, as inverting a moment map always is. This is the same forward-easy/inverse-hard asymmetry the previous paragraphs measured as a Lipschitz bound against an $O(1/\sqrt{\log k})$ rate. Finally, the chapter's title is meant literally. "The topology of convergence" is not a figure of speech: left-convergence *is* the initial topology generated by the countable family of moment functionals $t(F, \cdot)$ — the coarsest topology on graphon space making every one of those functionals continuous — and the counting lemma is the verification that the cut metric is at least fine enough to belong to it. A graph, read through this chapter, is its sequence of moments; convergence of graphs is convergence of those moments; and that is the moment theory of graphs the chapter set out to build.

16.3 The moment problem for graphs

The previous section ended by assembling, out of all the motif densities at once, a single object: the map that sends a graphon to its entire homomorphism profile. Writing $\mathcal{F}_0$ for the countable set of (isomorphism classes of) finite simple graphs — the index set of all admissible patterns, the graph analogue of the exponents $k = 0, 1, 2, \dots$ that label the monomials t^k — this map is

$$\Theta\colon\ W \ \longmapsto\ \big(t(F, W)\big)_{F\in\mathcal{F}_0} \ \in\ [0,1]^{\mathcal{F}_0}.$$

It takes a graphon to the sequence of all its moments at once, one coordinate $t(F, W)$ per pattern F, and lands in the product cube $[0,1]^{\mathcal{F}_0}$ — the *moment profile space*, topologized in section 16.2 as the product ("moment") topology in which left-convergence is exactly coordinatewise convergence. The whole chapter has been, at bottom, the study of this one map. Two of its three structural features are now in hand, and they are precisely the two that a moment map should have. First, Θ is *continuous*: this is corollary 16.18, the forward half of the counting lemma, which made each coordinate $t(F, \cdot)$ Lipschitz in the cut metric with constant $|E(F)|$, so that cut-close graphons have profiles close in every coordinate. Reading off a moment is a stable operation, just as $\mu \mapsto \int t^k \, \mathrm{d}\mu$ is continuous in the weak topology. Second, Θ is *injective modulo relabelling*: this is the content chapter 17 will supply through the inverse counting lemma and the regularity method — two graphons with identical profiles differ only by a measure-preserving relabelling of the type interval, the one ambiguity the densities are built to ignore and *should* ignore. The moment profile determines the graphon up to nothing else. So Θ is, in the relabelling-quotiented sense, a continuous injection.

Once a map is known to be a continuous injection, exactly one structural question about it remains open, and it is the natural one: what is its *range*? Which points of the target are actually hit? This is the *moment problem for graphs*. Spelled out: which sequences $\tau = (\tau_F)_{F\in\mathcal{F}_0}$ of numbers in $[0, 1]$ are genuinely of the form $\tau = \Theta(W)$ for some graphon W — and which are impostors, number sequences that look like profiles but are realized by no graphon at all? Not every sequence can be a profile: the coordinates are heavily constrained by the fact that they all come from integrating products of *one and the same* kernel, and the moment problem is the project of writing those constraints down exactly, turning the implicit definition "τ lies in the image of Θ" into an explicit, checkable list of conditions on the numbers τ_F themselves.

This is the precise graph counterpart of the oldest question in classical moment theory, and the analogy is not a loose slogan but a structural correspondence that will dictate the exact form of the answer, so it is worth laying the classical side out in full. On the line one asks: given a sequence of reals $(s_k)_{k\geq 0}$, when is there a probability measure μ with $s_k = \int t^k \, \mu(\mathrm{d}t)$ for every k? The classical theorem (Hamburger on $\mathbb{R}$, Stieltjes on $[0,\infty)$, Hausdorff on the bounded interval $[0,1]$, which is our case) answers it with two conditions. The first is a *normalization*: $s_0 = \int 1 \, \mathrm{d}\mu = 1$, since μ is a probability measure. The second is a *positive-semidefiniteness*: the infinite Hankel matrix $H = (s_{i+j})_{i,j\geq 0}$ must be positive semidefinite. The reason is a one-line Gram computation that we will replay almost verbatim on the graph side. For any real coefficients $c_0, \ldots, c_N$,

$$\sum_{i,j} c_i c_j \, s_{i+j} = \sum_{i,j} c_i c_j \int t^{i+j} \, \mu(\mathrm{d}t) = \int \Big(\sum_i c_i t^i \Big)^2 \mu(\mathrm{d}t) \ \geq \ 0,$$

so the Hankel matrix is positive semidefinite precisely *because* it is the Gram matrix of the monomials $1, t, t^2, \ldots$ in the inner product $\langle f, g \rangle = \int fg \, \mathrm{d}\mu$ of $L^2(\mu)$. The crucial structural input that lets this work is that the monomials multiply, $t^i \cdot t^j = t^{i+j}$, so that the product of two basis functions is again a basis function and the inner product of t^i with t^j is itself a moment, s_{i+j}. On a bounded interval these two conditions (suitably stated) are also *sufficient*, and the moment problem is *determinate*: the measure is unique. That determinacy is what makes "a measure is its sequence of moments" a faithful slogan on $[0,1]$, and it is the exact analogue of the injectivity of Θ we just imported from chapter 17.

The graph problem has the very same shape, with one genuine new feature, and naming that feature in advance organizes the entire section. The answer will again be a list of conditions on the candidate sequence τ, and it will have *three* parts. Two of them are the direct translations of the classical pair. A *normalization*, $\tau_{K_1} = 1$, is the total-mass condition: the single vertex K_1 is the empty product, the graph analogue of the monomial $t^0 = 1$, and its density is forced to be 1. A *positive-semidefiniteness* will again be a Gram-matrix constraint — the requirement that certain symmetric matrices built from τ be positive semidefinite, by exactly the same one-line argument as above, with monomials replaced by partially-integrated graph densities and the inner product still that of an L^2 space. This is the condition we will call *reflection positivity*, and constructing the right matrices for it is the one piece of new machinery the section must build. The third condition is the new feature, and it is new only because the algebra of graph motifs is richer than the algebra of monomials. The monomials form a *single* multiplicative chain, $t^i \cdot t^j = t^{i+j}$, indexed by one integer; the finite graphs form the free commutative monoid on the *connected* graphs under disjoint union, a far larger algebra. The profile must respect that algebra: a disjoint union of patterns must have the product of their densities, $\tau_{F_1 \sqcup F_2} = \tau_{F_1}\tau_{F_2}$. In the scalar case this multiplicativity is invisible because it is built into the indexing — there is only one way to multiply powers of t — but for graphs it is a separate, explicit *algebra-homomorphism* condition that a number sequence can perfectly well violate. (The classical scalar Hausdorff problem is recovered as the *rank-one shadow* of the graph problem, the slice on which the connection matrices collapse to ordinary Hankel matrices; we point this out where it surfaces in the characterization.) So the three-part answer is: normalization, multiplicativity, and reflection positivity — the graph-theoretic twin of "$s_0 = 1$ and the Hankel matrix is positive semidefinite," with multiplicativity the extra clause the larger algebra demands.

The section is organized around establishing exactly that these three conditions are *necessary and sufficient.* We take them in the order the difficulty dictates. First (section 16.3 below, the subsection on necessary conditions) we verify necessity, which is the cheap direction — and two of the three are already proved, so the real work is to build the reflection-positivity machinery, the partially labelled graphs and their gluing that play the role of the monomials and their multiplication, and to run the Gram computation in the graph setting. Then we state the full characterization, whose *sufficiency* half is one of the two genuinely deep theorems of the chapter — the Lovász–Szegedy / Freedman–Lovász–Schrijver realization theorem — precisely located and its in-book proof pointed to appendix F. Finally we close the chapter with a worked computation that makes the whole apparatus concrete, evaluating the profiles of the three graphons that anchor the book's running threads. We begin with the necessary conditions, where two of the three are already in our hands.

16.3.1 Necessary conditions

The section preamble promised a three-part answer — normalization, multiplicativity, reflection positivity — and said we would meet the conditions in the order their difficulty dictates: necessity before sufficiency, and within necessity the two cheap conditions before the one that takes work. Two of the three are, in fact, already theorems of this chapter; we have only to read them off in the language of the candidate sequence $\tau = (\tau_F)_{F\in\mathcal{F}_0}$ and note that a genuine profile cannot escape them. *Normalization* is the requirement $\tau_{K_1} = 1$ (and, more generally, $\tau_{\overline{K_r}} = 1$ for every edgeless graph on r vertices). It holds for any profile because the one-vertex pattern K_1 contributes the empty edge-product, so definition 16.8 forces $t(K_1, W) = 1$ for *every* graphon: this is the total-mass condition, the exact graph twin of the classical $s_0 = \int 1 \, \mathrm{d}\mu = 1$. *Multiplicativity* is the requirement $\tau_{F_1\sqcup F_2} = \tau_{F_1}\tau_{F_2}$ for disjoint unions, and it holds for any profile by proposition 16.10 (i), the factorization of the density of a disjoint union into the product of the densities of its parts. Both are settled, and nothing more need be said about them as standalone facts. The entire labour of this subsection is the third condition, the positivity, which has no ready-made predecessor and must be constructed from scratch.

Why it must be *built* rather than merely cited is worth a sentence, for that sentence dictates exactly what to build. Recall the one-line proof of the classical positivity condition, displayed in the section opening: for the Hankel matrix $H = (s_{i+j})$ of a measure μ, $\sum_{i,j} c_i c_j \, s_{i+j} = \int \big(\sum_i c_i t^i\big)^2 \, \mathrm{d}\mu \geq 0$. That argument turned on exactly one structural fact — that the monomials *multiply*, $t^i \cdot t^j = t^{i+j}$, so the $L^2(\mu)$ inner product $\int t^i t^j \, \mathrm{d}\mu$ of two basis functions is *itself* a moment, namely the entry s_{i+j}. The matrix was positive semidefinite for the single reason that it was a Gram matrix. To replay this on the graph side we therefore need two ingredients that our vocabulary does not yet contain: objects that play the part of the monomials t^i — functions in some L^2 space, whose pairwise products we can integrate — and an operation on those objects that plays the part of multiplication, sending the pair (t^i, t^j) to the single object t^{i+j} whose density is again a coordinate of τ. *Partially labelled graphs* supply the first and their *gluing* supplies the second. We now define both, verify that gluing really does correspond to pointwise multiplication of functions — the graph version of $t^i \cdot t^j = t^{i+j}$ — and then the Gram argument transcribes almost verbatim.

The guiding image is this. A monomial t^i, before we integrate it against μ, is a *function* of the free variable t; only the act of integration collapses it to the number s_i. Its graph analogue should likewise be a homomorphism density with some of its variables left *free* rather than integrated out — a function, not yet a number. The way to leave k of a pattern's type-variables free is to single out k of its vertices and refuse to integrate over their types; the labels $1, \dots, k$ are simply names for those free variables.

Definition 16.19 (k-labelled graphs and gluing)**.** A *k-labelled graph* is a finite simple graph in which k vertices are singled out and assigned the distinct labels $1, \dots, k$ (one vertex per label); the remaining vertices are unlabelled. We call it *label-edge-free* if no edge joins two labelled vertices. Given two k-labelled graphs F_1, F_2, their *gluing* (or product) $F_1 F_2$ is formed by taking the disjoint union and then identifying the label-i vertex of F_1 with the label-i vertex of F_2, for each $i = 1, \dots, k$. When both F_1 and F_2 are label-edge-free this identification creates no multiple edge — the only edges that could coincide would join two labelled vertices, and there are none — so $F_1 F_2$ is again a simple, label-edge-free k-labelled graph. This is the only case we shall use; for $k = 0$ the gluing is the disjoint union. The *unlabelling* $[\![F]\!]$ of a k-labelled graph forgets the labels, yielding an ordinary graph in $\mathcal{F}_0$.

It pays to run the gluing once on a concrete pair, both because the operation is easier seen than described and because the example we choose will reappear as the smallest instance of the positivity to come. Take $k = 2$ and let F_1 be the 2*-labelled cherry*: labelled vertices 1 and 2, one unlabelled vertex u joined to both, and no edge between 1 and 2. It is label-edge-free, since its only edges are $1u$ and $2u$. Let F_2 be a second, independent copy of the same cherry, with its own unlabelled apex w joined to 1 and 2. To glue, lay the two side by side and weld together their like-labelled vertices: the two label-1 vertices become a single vertex 1, the two label-2 vertices become a single vertex 2, while u and w stay distinct (they carry no labels and so are never identified). The result $F_1 F_2$ is the graph on $\{1, 2, u, w\}$ with edges $1u$, $2u$, $1w$, $2w$ — precisely the four-cycle $1-u-2-w-1$, that is, $[\![F_1 F_2]\!] = C_4$. Two cherries glued at their tips make a quadrilateral. Notice that the weld created no double edge: the only place a coincidence could have occurred is between the labelled vertices 1 and 2, and neither cherry has an edge there.

That last observation is the whole reason for the label-edge-free clause, and it deserves to be made sharp, because without it the clean algebra below silently breaks. Gluing identifies like-labelled vertices; if F_1 carried the labelled edge 12 and F_2 carried it too, the weld would lay one atop the other and a *simple* graph, having no notion of a doubled edge, would record the union as a single edge 12. The edge-count bookkeeping would then be off by one: an edge present in both factors would survive only once in the glue. Restricting to label-edge-free graphs forbids exactly this collision — there are no labelled edges to double — so every edge of F_1 and every edge of F_2 survives *intact and unmerged* in $F_1 F_2$, and the edge set of the glue is the honest disjoint union of the two edge sets. This is what makes the algebraic identity below an *exact* equality rather than one that quietly drops a repeated factor; we return to what that dropped factor would have been once we can name it.

With the geometric operation in place we can finally write down the "monomial as a function" that motivated it. For a graphon W and a k-labelled graph F, define the *partially integrated density* by holding the labelled vertices at fixed types $x_1, \dots, x_k$ and integrating out only the unlabelled ones:

$$t_{x_1,\dots,x_k}(F,W) \;=\; \int_{[0,1]^{V(F)\setminus\{1,\dots,k\}}} \prod_{ij\in E(F)} W(x_i,x_j) \prod_{u \text{ unlabelled}} \mathrm{d}x_u.$$

The very same Tonelli/measurability checks that validated definition 16.8 apply here to the unlabelled variables alone, so this is a genuine measurable function of $(x_1,\dots,x_k)\in[0,1]^k$ with values in $[0,1]$ — the analogue of the function $t\mapsto t^i$, not yet the number. Its single most important property is that integrating away the remaining (labelled) variables collapses it back to an ordinary density,

$$\int_{[0,1]^k} t_{x_1,\dots,x_k}(F,W)\;\mathrm{d}x_1\cdots\mathrm{d}x_k \;=\; t([\![F]\!],W),$$

exactly as $\int t^i\;\mathrm{d}\mu = s_i$. For the running example, the 2-labelled cherry F_1 has the single unlabelled apex u to integrate out, so $t_{x_1,x_2}(F_1,W)=\int_{[0,1]} W(x_1,z)W(x_2,z)\;\mathrm{d}z$, the codegree kernel measuring how strongly types x_1 and x_2 share a common neighbour.

Now the key algebraic fact, the graph counterpart of $t^i\cdot t^j = t^{i+j}$: *for label-edge-free* F_1,F_2, gluing corresponds to *pointwise multiplication* of these functions,

$$t_{x_1,\dots,x_k}(F_1\,F_2,W) \;=\; t_{x_1,\dots,x_k}(F_1,W)\cdot t_{x_1,\dots,x_k}(F_2,W). \tag{16.2}$$

The proof is bookkeeping plus one application of Tonelli, and every clause of the label-edge-free hypothesis is used. Because F_1 and F_2 are label-edge-free, their gluing merges no edges, so the edge set of $F_1\,F_2$ is the disjoint union $E(F_1)\sqcup E(F_2)$ and the integrand of the left-hand side factors cleanly,

$$\prod_{ij\in E(F_1F_2)} W(x_i,x_j) = \Big(\prod_{ij\in E(F_1)} W(x_i,x_j)\Big)\Big(\prod_{ij\in E(F_2)} W(x_i,x_j)\Big),$$

with no factor appearing in both brackets. The labelled types $x_1,\dots,x_k$ are held fixed and shared by the two brackets, but the *unlabelled* vertices of F_1 and those of F_2 are disjoint sets of integration variables — this is the second place the gluing keeps the two factors apart — so the first bracket is a function of $(x_\bullet;\text{unlabelled of } F_1)$ only and the second of $(x_\bullet;\text{unlabelled of } F_2)$ only. With the shared labels frozen, the integral over the joint unlabelled variables is an integral of a product of functions of disjoint variable blocks, and Tonelli (theorem 1.27) splits it into the product of the two separate integrals — which are exactly $t_{x_\bullet}(F_1,W)$ and $t_{x_\bullet}(F_2,W)$. That is (16.2). On the running example it reads $\int_{[0,1]^2}\big(\int_[0,1]W(x_1,z)W(x_2,z)\;\mathrm{d}z\big)^2\,\mathrm{d}x_1\,\mathrm{d}x_2 = t(C_4,W)$: the square of the codegree kernel, integrated over the two free types, is the four-cycle density — the glue C_4 read off as the product of two cherries.

We can now name the factor the label-edge-free restriction protected us from. Were a labelled edge ij present in *both* factors, the simple glue $F_1\,F_2$ would carry the weight $W(x_i,x_j)$ once, whereas the product on the right of (16.2) would carry it twice, as $W(x_i,x_j)^2$ — and the identity would fail by exactly that squared factor. Keeping such repeated weights honestly is possible, but it requires enlarging "graph" to a formal object that remembers edge multiplicities: the algebra of *quantum graphs*, where a doubled labelled edge genuinely means W^2. That algebra is developed in appendix F; for the necessity argument at hand we do not need it, because the label-edge-free restriction removes every labelled edge and so makes (16.2) an exact equality on the nose. This is the single piece of bookkeeping the whole positivity argument rests on.

With multiplication in hand we can assemble the graph Hankel matrix. In the classical problem the Hankel matrix had entry s_{i+j} in row i, column j — the moment of the *product* $t^i \cdot t^j$. The graph version indexes rows and columns by labelled graphs and puts in each slot the density of the *glued* graph.

Definition 16.20 (Connection matrix and reflection positivity)**.** Let $\tau = (\tau_F)_{F\in\mathcal{F}_0}$ and extend τ to k-labelled graphs by $\tau(F) := \tau_{[\![F]\!]}$. For each $k \geq 0$ the *k-th connection matrix* $M_k(\tau)$ is the (infinite, symmetric) matrix whose rows and columns are indexed by the *label-edge-free* k-labelled graphs — so that the gluing $F_1\,F_2$ of any two index graphs is again simple and $\tau(F_1\,F_2) = \tau_{[\![F_1\,F_2]\!]}$ is unambiguous — and whose entry is

$$\big(M_k(\tau)\big)_{F_1,F_2} \;=\; \tau(F_1\,F_2).$$

We say τ is *reflection positive* if every finite principal submatrix of every $M_k(\tau)$ is positive semidefinite. (Restricting the index set to label-edge-free graphs is the standard indexing for the moment problem: it is exactly what makes the Gram identity of proposition 16.21 hold on the nose, and it loses no necessary positivity constraint.)

Three features of this matrix are worth pinning down before we prove anything, because each is the graph echo of a familiar feature of the scalar Hankel matrix. First, it is symmetric: gluing is a symmetric operation, $F_1\,F_2 = F_2\,F_1$ as labelled graphs, so $(M_k)_{F_1,F_2} = (M_k)_{F_2,F_1}$, just as $s_{i+j} = s_{j+i}$. Second, its entries depend on the index graphs *only through their glued unlabelling*, the way a Hankel entry depends on (i,j) only through the sum $i+j$ — many different pairs of labelled graphs can glue to the same unlabelled graph and hence share an entry, the graph analogue of the constant anti-diagonals that give Hankel matrices their name. Third, the matrix is infinite (there are infinitely many label-edge-free k-labelled graphs), so positive semidefiniteness is imposed in the only sense available for infinite matrices: *every* finite principal submatrix — every choice of finitely many index graphs — must be positive semidefinite. That is the meaning of "reflection positive." For $k=0$ there are no labels to hold fixed, gluing is plain disjoint union, and $M_0(\tau)$ has entry $\tau_{F_1\sqcup F_2}$; multiplicativity already forces this to factor as $\tau_{F_1}\tau_{F_2}$, so M_0 is the rank-one matrix of an outer product and its positivity is automatic — the genuine content of reflection positivity lives at $k \geq 1$, where the labels couple the factors and the matrix can have higher rank. We will see this rank-one degeneracy resurface in the next subsection as precisely the slice on which the graph problem collapses to the classical scalar one.

Proposition 16.21 (Necessity of reflection positivity)**.** *If $\tau = \Theta(W)$ for a graphon W, then τ is reflection positive.*

Proof. The argument is the classical Gram computation with monomials replaced by partially integrated densities and the line measure μ replaced by Lebesgue measure on the type cube; the gluing identity (16.2) is what makes every step go through. Fix the level k and any finite list of *label-edge-free* k-labelled graphs $F^{(1)},\dots,F^{(N)}$ — this names an arbitrary finite principal submatrix of $M_k(\tau)$ — and let $c = (c_1,\dots,c_N) \in \mathbb{R}^N$ be arbitrary coefficients. To each index graph attach the function it represents,

$$g_a(x_1,\dots,x_k) \;=\; t_{x_1,\dots,x_k}(F^{(a)},W), \qquad a = 1,\dots,N,$$

which lies in $L^2([0,1]^k)$: it is bounded by 1, hence square-integrable against the probability measure on the cube. These g_a are the graph monomials. Now read off the matrix entry. Because each $F^{(a)}$ is label-edge-free, so is every glue $F^{(a)}F^{(b)}$ (gluing two label-edge-free graphs cannot create a labelled edge), so (16.2) applies to the pair and the product $g_a\, g_b$ is itself a partially integrated density — that of the glued graph. Integrating out the labels then turns it into the unlabelled density, which is by definition the matrix entry:

$$(M_k(\tau))_{F^{(a)},F^{(b)}} = \tau(F^{(a)}F^{(b)}) = t([\![F^{(a)}F^{(b)}]\!], W) = \int_{[0,1]^k} t_{\mathbf{x}_\bullet}(F^{(a)}F^{(b)}, W)\, \mathrm{d}x = \int_{[0,1]^k} g_a\, g_b = \langle g_a, g_b\rangle_{L^2([0,1]^k)}.$$

Here the first equality is the definition of τ on labelled graphs, the second is $\tau = \Theta(W)$ unpacked, the third recovers an ordinary density by integrating out the labels of the glue, the fourth is the gluing identity (16.2), and the last is the definition of the L^2 inner product. So the chosen principal submatrix is exactly the Gram matrix of the vectors $g_1, \ldots, g_N$ in $L^2([0,1]^k)$ — the same statement as "the Hankel matrix is the Gram matrix of the monomials," transcribed. A Gram matrix is positive semidefinite for one reason, that quadratic forms in it are squared norms:

$$c^\top M_k(\tau)\, c = \sum_{a,b=1}^{N} c_a c_b \langle g_a, g_b\rangle = \Big\langle \sum_a c_a g_a,\ \sum_b c_b g_b \Big\rangle = \Big\| \sum_a c_a g_a \Big\|^2_{L^2([0,1]^k)} \ \geq\ 0,$$

using bilinearity of the inner product to pull the sums inside. Since k, the list $F^{(1)}, \ldots, F^{(N)}$, and c were arbitrary, every finite principal submatrix of every $M_k(\tau)$ is positive semidefinite, which is reflection positivity. $\square$

The smallest case of this proof is the running example, and it is worth seeing the abstraction land on it. At $k = 2$ take the single index graph $F^{(1)}$ = the 2-labelled cherry; the 1×1 submatrix is the diagonal entry $\tau(F^{(1)}F^{(1)}) = t(C_4, W)$, and the Gram identity reads $t(C_4, W) = \|g_1\|^2_{L^2} \geq 0$ with $g_1(x_1, x_2) = \int_[0,1] W(x_1, z)W(x_2, z)\, \mathrm{d}z$. So the nonnegativity of the four-cycle density is, read this way, nothing but the statement that the codegree kernel has a nonnegative squared L^2 norm — the positivity of a single diagonal entry of M_2. The full reflection positivity is this observation made simultaneously for every finite collection of labelled graphs at every level.

This completes the three necessary conditions, and it is worth standing back to name what the last one is. Proposition 16.21 is the graph-theoretic shadow of the elementary half of the Hamburger/Hausdorff moment theorem: the moments of a measure form a positive-semidefinite Hankel matrix because that matrix is the Gram matrix of the monomials $1, t, t^2, \ldots$ in $L^2(\mu)$. Here the connection matrix $M_k(\tau)$ *is* the graph Hankel matrix; the gluing of labelled graphs *is* the multiplication of monomials, $t^i \cdot t^j = t^{i+j}$; and the partially integrated densities g_a *are* the monomials, now functions on the type cube rather than on the line. The classical statement is the rank-one, single-variable face of this one, the slice on which the connection matrices degenerate to ordinary Hankel matrices — a correspondence we locate precisely in the characterization that follows. We have shown that a genuine profile $\tau = \Theta(W)$ *must* be normalized, multiplicative, and reflection positive. The striking and far deeper fact, which the next subsection states and which closes the moment problem, is that these three necessary conditions are also *sufficient*: any number sequence passing all three is realized by some graphon. The Gram/Hankel identification just made is the hook on which that converse hangs, for it is what lets the whole characterization be read as the graph moment theorem.

16.3.2 The characterization

The content of the moment problem is that these three necessary conditions are also *sufficient*.

Theorem 16.22 (Moment characterization of graphon profiles; Lovász–Szegedy, Freedman–Lovász–Schrijver)**.** *Let $\tau = (\tau_F)_{F \in \mathcal{F}_0}$ be a family of real numbers. Then $\tau = \Theta(W)$ for some graphon W satisfying* ***(A-Reg-W)*** (*symmetric, measurable,* $[0,1]$*-valued*) *if and only if*

1. (Normalization) $\tau_{K_1} = 1$*;*
2. (Multiplicativity) $\tau_{F_1 \sqcup F_2} = \tau_{F_1}\,\tau_{F_2}$ *for all $F_1, F_2 \in \mathcal{F}_0$;*
3. (Reflection positivity) *every connection matrix $M_k(\tau)$, $k \geq 0$, is positive semidefinite.*

Moreover the graphon is then unique up to weak isomorphism ($\delta_\square = 0$, proposition 17.7), and automatically $0 \leq \tau_F \leq 1$ *for all F.*

Proof sketch, with the gap located. Necessity is proposition 16.10 (i), $t(K_1, W) = 1$, and proposition 16.21; the bound $\tau_F \in [0,1]$ is proposition 16.10 (ii).

For sufficiency one builds the graphon out of the positivity data, exactly as the classical moment problem builds a measure out of positive-semidefinite Hankel matrices via a Gram–Schmidt / spectral construction. The mechanism is the following. Reflection positivity of $M_k(\tau)$ endows the (real) vector space spanned by label-edge-free k-labelled graphs, modulo the kernel of the bilinear form $\langle F_1, F_2\rangle := \tau(F_1F_2)$, with a genuine inner product; gluing makes this space a commutative algebra and the form is a state on it. The Gelfand–Naimark–Segal construction turns the pair (algebra, state) into multiplication operators on a Hilbert space; analyzing the cases $k = 1$ and $k = 2$ produces a probability space (Ω, ν) carrying the "random type" and a symmetric measurable kernel w on $\Omega \times \Omega$ with values in $[0,1]$ representing the edge variable, such that $\tau_F = \int \prod_{ij \in E(F)} w$. A measure-theoretic isomorphism of (Ω, ν) with the standard atomless space $([0,1], \mathrm{Leb})$ — any standard atomless probability space is so isomorphic — then transports w to a graphon W on $[0,1]^2$ with $\Theta(W) = \tau$. Uniqueness up to weak isomorphism is the same statement as the injectivity of Θ modulo $\delta_\square = 0$, namely the cut-metric uniqueness theorem theorem 17.11 (proved in appendix F).

Honest status of this direction. Unlike the realization theorem theorem 16.15 — whose proof, via cut-metric compactness, is carried out in full in appendix F — the analytic heart of the present sufficiency is *not* reproduced in this book. The steps we have only sketched are exactly the hard ones: that the GNS algebra is realized by a single symmetric two-variable kernel rather than by a higher-order object, that the kernel can be taken $[0,1]$-valued and measurable, and the requisite measure-isomorphism of the constructed space with $([0,1], \mathrm{Leb})$. These are the content of the Lovász–Szegedy / Freedman–Lovász–Schrijver theorem (reflection positivity and "rank connectivity"), which we *state and use as a cited external result*: [100, 70] and [99, Ch. 5, Ch. 11]. We flag this explicitly so the reader is not misled: the "only if" half (necessity) and the rank-one shadow (the Hausdorff moment problem, appendix F.8) are proved in this book; the general "if" half is the one place in this chapter where we rely on an attribution rather than an in-book proof, and it is used nowhere downstream. $\square$

Remark 16.23 (The classical moment problem as the k-independent shadow)**.** Specialize to *rank-one* data. Suppose all densities depend on F only through its degree sequence; worked computation 16.24 below shows this is exactly the case $W(x,y) = f(x)f(y)$, for which $\tau_F = \prod_{i\in V(F)} c_{\deg_F(i)}$ with $c_d = \int_0^1 f^d$. In this rank-one sector the moment problem collapses to a classical one: the realizable profiles are exactly those for which $(c_d)_{d\geq 0}$ is a *Hausdorff moment sequence*, $c_d = \int_0^1 r^d\,\rho(\mathrm{d}r)$ for a probability measure ρ on $[0,1]$ (here $\rho = f_{\#}\mathrm{Leb}$, the law of $f(\xi)$ for ξ uniform). Two halves of this are fully in-book. The elementary *necessity* direction — a realizable (c_d) has positive-semidefinite Hankel matrices $(c_{i+j})_{i,j}$ — is the rank-one shadow of the Gram argument of proposition 16.21, since $\sum_{i,j} a_i a_j c_{i+j} = \int_0^1 \big(\sum_i a_i r^i\big)^2 \rho(\mathrm{d}r) \geq 0$. The *sufficiency* direction — a Hausdorff sequence is realized by some f, hence some rank-one graphon — together with the classical characterization by complete monotonicity, is the Hausdorff moment theorem, which we prove from scratch in appendix F.8. Thus, unlike the general graph moment problem, its rank-one sector is established here without any external appeal: the graph moment problem genuinely contains the classical one as its rank-one shadow, and that is the cleanest sense in which homomorphism densities "are moments."

16.3.3 A worked computation: motif densities of structured graphons

We close by computing $t(F,W)$ in closed form for the three graphons that anchor the rest of the book, and reading off what their homomorphism profiles look like. The rank-one case is the kernel of Thread B (the graphon-LQG congestion model, appendix A.7), and the constant case is its Thread A reduction; computing their motif densities here is the graph-limit-theoretic side of those threads.

Worked computation 16.24 (Constant, rank-one, and block graphons)**. (i) Constant graphon (Erdős–Rényi limit).** Let $W \equiv p \in [0,1]$ be the constant graphon of example 15.9. Then every edge contributes the constant factor p and the integral is trivial:

$$t(F,p) \;=\; p^{|E(F)|}.$$

The profile depends on F only through its edge count. This is the limit of the dense Erdős–Rényi graphs $G(n,p)$ (sampling and concentration in chapter 19), and via proposition 16.9 it is the homomorphism profile of any quasirandom sequence of density p. In the language of appendix A.7 this is the constant-kernel reduction $W \equiv c$ that returns Thread B to the homogeneous Thread A: no type heterogeneity survives, and the only surviving "moment" is the single number p.

(ii) Rank-one (Curie–Weiss) graphon. Let $W(x,y) = f(x)f(y)$ with $f\colon [0,1] \to [0,1]$ measurable (so $W \in [0,1]$ and **(A-Reg-W)** holds): the rank-one graphon of example 15.11, the kernel of Thread B. Group the product over edges by vertices: each vertex i appears in exactly $\deg_F(i)$ edges, contributing a factor $f(x_i)$ each time, so

$$\prod_{ij\in E(F)} W(x_i,x_j) = \prod_{ij\in E(F)} f(x_i)f(x_j) = \prod_{i\in V(F)} f(x_i)^{\deg_F(i)}.$$

The variables separate, and with the *moment sequence* $c_d := \int_0^1 f(t)^d\,\mathrm{d}t$ ($c_0 = 1$, $c_1 = \int f$, and $0 \leq c_{d+1} \leq c_d \leq 1$),

$$t(F,W) \;=\; \prod_{i\in V(F)} c_{\deg_F(i)}. \tag{16.3}$$

Thus the entire homomorphism profile of a rank-one graphon is the multiplicative function of the degree sequence built from the single moment sequence (c_d). Reading off motifs: the edge density is $t(K_2, W) = c_1^2$ $(= (\int f)^2)$; the triangle density is $t(K_3, W) = c_2^3$; the d-star S_d (one centre of degree d, d leaves of degree 1) has $t(S_d, W) = c_d\, c_1^d$; a path P_ℓ with two endpoints of degree 1 and interior vertices of degree 2 has $t(P_\ell, W) = c_1^2 c_2^{\ell-2}$. The profile is *not* a pure power of the edge density — unlike the constant case (i) — and that departure is the detectable signature of type heterogeneity. The cleanest instance is the cherry P_3 (two edges, centre of degree 2): the quasirandom baseline at the same edge density $p = t(K_2, W) = c_1^2$ would give $p^2 = c_1^4$, whereas

$$t(P_3, W) \;=\; c_2\, c_1^2 \;\geq\; c_1^2 \cdot c_1^2 \;=\; t(K_2, W)^2,$$

because $c_2 = \int f^2 \geq \big(\int f\big)^2 = c_1^2$ by Cauchy–Schwarz, with equality iff f is constant a.e. Thus rank-one heterogeneity produces a *cherry/path excess* controlled by the variance $c_2 - c_1^2 = \mathrm{Var}(f)$: degree heterogeneity inflates the count of two-paths above the quasirandom value, and the size of the excess is exactly the variance of the type-profile f, a first quantitative signature of heterogeneity that the moment data exposes.

By remark 16.23 the realizability of (16.3) as a graphon profile is exactly the Hausdorff moment condition on (c_d), with $\rho = f_\#\mathrm{Leb}$; a left-convergent sequence of graphs converging to a rank-one graphon is therefore a sequence whose empirical degree-moment sequences converge to a Hausdorff moment sequence. This is the moment problem of section 16.3 made completely explicit on Thread B's kernel.

(iii) Block graphon (stochastic block model limit). Recall the stochastic block model graphon of example 15.10: communities $C_1, \ldots, C_q \subseteq [0,1]$ of sizes $\rho_r = |C_r|$ with $\sum_r \rho_r = 1$, and a symmetric matrix $\mathsf{B} \in [0,1]^{q\times q}$ of inter-community connection probabilities, with $W(x,y) = \mathsf{B}_{rs}$ for $x \in C_r, y \in C_s$. (We write q for the number of communities, reserving $k = |V(F)|$ for the size of the pattern as everywhere else in this chapter; the community sizes ρ_r and blocks C_r and the block matrix B are exactly the data (k, ρ, B) exported by example 15.10, with its k renamed q here.) Then the integral becomes a finite sum over block-assignments $\psi\colon V(F) \to \{1, \ldots, q\}$:

$$t(F, W) = \sum_{\psi\colon V(F)\to[q]} \Big(\prod_{i\in V(F)} \rho_{\psi(i)} \Big) \prod_{ij\in E(F)} \mathsf{B}_{\psi(i)\psi(j)},$$

a polynomial of degree $|E(F)|$ in the entries of B weighted by the block sizes. Taking q blocks recovers the finite multi-population structure (the bridge to multi-class models in chapter 30); taking $q = 1$ recovers case (i). Note that (16.3) is the special case in which $\mathsf{B}_{rs} = \phi_r\phi_s$ is itself rank one, with $c_d = \sum_r \rho_r \phi_r^d$.

Rigor ledger

Proved.

- Definition of hom, inj, ind and the densities $t(F, G)$, t_{inj}, t_{ind} (definitions 16.1 and 16.4); the elementary counting lemma $|t(F, G) - t_{\mathrm{inj}}(F, G)| \leq \binom{k}{2}/n$ (lemma 16.6), hence all three normalizations define the same convergence (remark 16.7).

- Homomorphism density into a graphon as a moment $\mathbb{E}\prod W(\xi_i,\xi_j)$ (definition 16.8); consistency $t(F,W_G)=t(F,G)$ (proposition 16.9); multiplicativity over disjoint unions and the $[0,1]$ bound (proposition 16.10).
- Left-convergence as coordinatewise convergence of all motif densities (definition 16.11); the moment topology is metrizable and sits inside the compact cube $[0,1]^{\mathcal{F}_0}$, giving subsequential left-convergence of *every* graph sequence by Tychonoff (proposition 16.13 and remark 16.14).
- The counting lemma $|t(F,W)-t(F,W')|\le|E(F)|\;\|W-W'\|_\square$ (lemma 16.17) and its corollary that cut-convergence implies left-convergence (corollary 16.18).
- Necessity of normalization, multiplicativity, and reflection positivity for a graphon profile (proposition 16.21); closed-form profiles of constant, rank-one, and block graphons (worked computation 16.24).

Assumed. Graphons obey **(A-Reg-W)** (symmetric, measurable, $[0,1]$-valued). Tonelli/-Fubini (theorem 1.27). The pixel (empirical) graphon W^G of a finite graph, imported from definition 15.2 and proposition 15.3, together with the constant, rank-one, and stochastic-block-model graphons of examples 15.9 to 15.11. The cut norm $\|\cdot\|_\square$ and its extreme-point identity ($\star$) are recalled from chapter 17. **Deferred.**

- The Lovász–Szegedy realization theorem (theorem 16.15): proof via cut-metric compactness in chapter 17 and appendix F.
- Sufficiency in the moment characterization (theorem 16.22): the Freedman–Lovász–Schrijver / GNS construction of a graphon from reflection-positive data — and with it the measure-isomorphism of the constructed atomless space with $([0,1],\mathrm{Leb})$ — is *not* reproduced in this book and is cited as an external result ([100, 70, 99]); it is used nowhere downstream. Its rank-one shadow, the Hausdorff moment theorem, *is* proved in-book (theorem F.14).
- The weak regularity lemma (stated and proved as theorem 17.16) and the inverse counting lemma it powers (the converse of corollary 16.18, proved via theorem 17.11 in appendix F); the sampling/concentration consequences are chapter 19.

Open. Effective/quantitative inverse counting — the sharp dependence of cut-distance on the number of densities matched — remains far from tight; the best bounds are $O(1/\sqrt{\log k})$ and are not known to be improvable in general. Outside the dense regime the entire moment philosophy fails: for sparse sequences ($|E(G_n)|=o(|V(G_n)|^2)$) all $t(F,G_n)\to 0$ for F with an edge, so motif densities carry no information and a different notion of convergence is required (chapters 19 and 27).

Bibliographic notes

Homomorphism densities, left-convergence, and the realization theorem are due to Lovász and Szegedy [100]; the systematic metric theory — subgraph frequencies, the counting lemma, and the equivalence with the cut metric — was developed by Borgs, Chayes, Lovász, Sós, and Vesztergombi [29]. The textbook account we follow is Lovász's monograph [99, Ch. 7] for densities and left-convergence, with the moment characterization and its reflection-positivity proof in [99, Ch. 5, Ch. 11]; the reflection-positivity / rank-connectivity circle of ideas originates with Freedman, Lovász, and Schrijver [70]. The survey [98] is the gentlest entry point and the source of the "moments of a graph" slogan. The counting lemma in the form of lemma 16.17 and the extreme-point identity ($\star$) are standard; see [99, §4.4, §10.2]. The classical moment-problem analogy invoked in remark 16.23 (Hausdorff's theorem, positive-semidefinite Hankel matrices) uses only the bounded-interval (Hausdorff) case, which we prove from scratch in theorem F.14 via the complete-monotonicity criterion rather than relying on an external moment-problem reference. The forward references are load-bearing: the cut metric, the inverse counting lemma, and the proof of compactness are the subject of chapter 17 (with the full Lovász–Szegedy proof in appendix F), the spectral/operator reading of W is chapter 18, and sampling W-random graphs $G(n, W)$ with concentration of the densities defined here is chapter 19. The whole apparatus is used in Part IV — most directly in chapter 25, where convergence of a finite network's equilibria to the graphon mean field game equilibrium is phrased through left-/cut-convergence of the underlying graphs.

Chapter 17

The Cut Metric and Compactness of Graphon Space

The previous two chapters built the objects we now learn to measure. Chapter 15 introduced the graphon as the limit of an adjacency matrix: a symmetric measurable kernel $W\colon [0,1]^2 \to [0,1]$, with the type variable $x \in [0,1]$ an exchangeable label rather than a spatial coordinate, and with the integral operator $(\mathbb{W}f)(x) = \int_0^1 W(x,y)f(y)\,\mathrm{d}y$ that will couple agents across types in every graphon mean field game. Chapter 16 then attached to each graphon a sequence of *observables*: the homomorphism densities $t(F, W)$, the continuum analogues of subgraph frequencies, and it declared a sequence of graphons *left-convergent* when all of these observables converge. That gave graphons a notion of convergence — a topology. But a topology assembled out of the convergence of countably many numbers is a curiously thin thing to hold in the hand. It tells us *whether* a sequence eventually settles down, yet it offers no *single number* measuring how far apart two graphons stand: no way to declare that this pair is closer than that one, no ball of radius ϵ to draw around a candidate limit, no triangle inequality to chain estimates through. With only a topology we cannot form a Cauchy sequence, cannot speak of completeness, cannot run the extract-a-convergent-subsequence arguments on which the whole of analysis turns. Chapter 16, in short, handed us a topology but no *metric space* — and it is on a metric space, not a bare topology, that the existence and convergence theorems of Part III will have to stand. Supplying that missing distance, and extracting from it the one structural fact that makes the whole graphon mean field theory go through, is the business of this chapter.

The distance is the *cut metric* $\delta_\square$, built from the *cut norm* $\|\cdot\|_\square$: at last a single number $\delta_\square(W, W')$ that says how far apart two graphons are, in which left-convergence becomes ordinary convergence and in which the set of all graphons becomes a space we can do analysis on. Its defining feature, and the reason it is none of the distances one would first reach for, is coarseness: it deliberately ignores the fine-grained, microscopic placement of edges and registers only the macroscopic, averaged structure — precisely the structure that survives relabeling of the types and survives sampling a finite network from the graphon. We will see that the cut metric is the right distance in three reinforcing senses, and the reader should treat the first three sections of this chapter as a guided ascent through them toward a fourth. First, it metrizes left-convergence: a sequence converges in $\delta_\square$

(after the unavoidable quotient by relabelings) if and only if all its homomorphism densities converge (theorem 17.12), so the topology of chapter 16 and the geometry of this chapter are literally one and the same. Second, the quotient of the set of graphons by the relation "$\delta_\square$-distance zero" is a genuine metric space, the true *space of graphons*, whose points are the intrinsic networks themselves rather than their arbitrary labelings. Third, and decisively, that metric space is *compact* (theorem 17.13, Lovász–Szegedy).

It is this third fact that is the real destination, and the reader should keep it in view as the keystone the whole chapter is shaped to support. Compactness is what a later existence proof reaches for when it must extract a convergent subsequence of approximate equilibria, or pass an equilibrium to a limit network; it is the input from Part III that makes the graphon mean field game existence theorem of chapter 24 and the finite-network convergence theorem of chapter 25 possible, and it is the reason a single limit object can stand in for an entire convergent sequence of growing networks. The first two senses are not ends in themselves: the metrization and the quotient are the scaffolding without which the word "compact" has nothing to attach to, for one cannot ask whether a space is compact before knowing it is a metric space and knowing what its points are. Sections one through three raise that scaffolding; section four pays it off.

To carry the program out we lean throughout on what earlier chapters established, and it is worth seeing each import as a tool earmarked for a definite job rather than a line in a manifest. From chapter 15 we take the graphon and its integral operator $\mathbb{W}$. From chapter 16 we take the homomorphism density $t(F, \cdot)$, the notion of left-convergence, and the *counting lemma* bounding density differences by the cut distance — the very bridge that will deliver the first sense, metrization. From chapter 1 come the everyday tools for integrating a kernel over patches of types: measurable sets, L^1 and L^2, product measure and Fubini. From chapter 2 come the Hilbert space $L^2([0,1]^2)$ and orthogonal projection, together with the Banach–Alaoglu theorem that will supply completeness. And from chapter 3 comes conditional expectation as the L^2 projection onto a sub-σ-algebra, which is the engine of the regularity argument behind compactness. Looking forward, chapter 18 reads the same graphon as a self-adjoint Hilbert–Schmidt operator and compares cut convergence with spectral convergence; chapter 19 returns to the weak regularity lemma proved here and develops its sampling consequences; and chapters 24 and 25 consume the compactness theorem directly — which is the ultimate reason we spend a whole chapter earning it.

The plan is as follows. Section 17.1 defines the cut norm, gives its three equivalent forms, and places it among the norms the reader already owns. Section 17.2 introduces measure-preserving relabelings, defines the cut metric, and constructs the metric space of graphons as a quotient. Section 17.3 proves the equivalence of cut convergence and left-convergence. Section 17.4 states and proves (the total-boundedness half in full, the completeness half by an honest sketch with the remainder deferred to appendix F) the compactness theorem, and explains why it is the structural keystone of Part III. A worked computation on the rank-one and block graphons of the carried threads runs alongside.

17.1 The cut norm

Before we can quotient by relabelings and arrive at a metric space of graphons, we need the raw material the cut metric is assembled from: the right notion of *size* for a kernel. A distance, after all, is the size of a difference, so the question "how far apart are two graphons?" rests on the prior question "how big is a kernel?", and the coarseness we are about to demand of the distance must already be present in this notion of size. The three subsections that follow answer the prior question. We first confront the ordinary norms the reader already owns and see exactly why each is too fine for the job; then we define the cut norm and record its three interchangeable forms; and finally we place it among the familiar norms by a short chain of comparison inequalities. Only size is at issue here — the quotient by relabelings that turns this norm into the cut metric is deferred to section 17.2.

17.1.1 Why not an ordinary norm

We have just agreed that the cut metric will be the size of a difference, so before anything else we must settle what "size of a kernel" should mean. A graphon is a function on $[0,1]^2$, and for measuring functions the reader already owns an entire toolbox: the L^p norms $\|W\|_p = (\int_{[0,1]^2} |W|^p)^{1/p}$ for $1 \leq p < \infty$, and the sup norm $\|W\|_\infty$. The honest question is why any of these will not do. If one of them already metrized left-convergence there would be nothing to invent, and we could lift it to a metric on graphons by the relabeling quotient of the next section and be done. The thesis of this subsection is that none of them can: every ordinary norm is *too fine*, reacting to features of the kernel that no macroscopic observable — no homomorphism density, no sampled subgraph count, no application of the coupling operator $\mathbb{W}$ — can detect. A distance built from such a norm would call two networks far apart that every experiment would call the same. We make this concrete with the example that drives the entire chapter, and then read off from its failure precisely what a usable notion of size must do instead.

Two networks that agree on everything but the wiring. Fix a density $p \in (0,1)$, say $p = \frac{1}{2}$ for definiteness, and build two large graphs G_N and G'_N on the same N vertices in the same way: for each of the $\binom{N}{2}$ pairs of nodes flip an independent fair coin and join the pair iff the coin shows heads, doing this once for G_N and a second, *independent* time for G'_N. The two graphs are statistically identical. Both have edge density $\to \frac{1}{2}$; both have triangle density $\to (\frac{1}{2})^3 = \frac{1}{8}$; more generally, for any fixed simple graph F, both have F-density $\to (\frac{1}{2})^{e(F)}$, because each of the $e(F)$ required edges is independently present with probability $\frac{1}{2}$. They share the same (lack of) community structure — a single homogeneous block — and the same degree profile, each vertex having degree $\frac{N}{2}(1+o(1))$. By every coarse, observable measure G_N and G'_N are the same network, and both are converging, in the sense of chapter 16, to the same limit: the constant graphon $W \equiv \frac{1}{2}$, the featureless "half-density" kernel that is their common smooth average. There is, macroscopically, only one object here.

Now view the two graphs as kernels. Order the vertices $1, \ldots, N$, cut $[0,1]$ into N equal subintervals $I_1, \ldots, I_N$, and let W_N be the step kernel equal to the (i,j) entry of G_N's adjacency matrix on the tile $I_i \times I_j$, and likewise W'_N for G'_N (this is the standard identification of a finite graph with its step graphon, chapter 16). On each tile both kernels are constant, taking a value in $\{0,1\}$. They *disagree* on tile $I_i \times I_j$ exactly when one coin came up heads and the other tails, an event of probability $2 \cdot \frac{1}{2} \cdot \frac{1}{2} = \frac{1}{2}$, and on a disagreeing tile one kernel is 0 while the other is 1, so their difference there has absolute value 1. Consequently a positive fraction — here about half — of the total area of $[0,1]^2$ carries $|W_N - W_N'| = 1$. This is everything the ordinary norms need to register a chasm:

$$\|W_N - W_N'\|_\infty = 1, \qquad \|W_N - W_N'\|_1 = 2p(1-p) + o(1) = \tfrac{1}{2} + o(1), \tag{17.1}$$

and the same lower bound $\|W_N - W_N'\|_p \geq \|W_N - W_N'\|_1 \geq \frac{1}{2} + o(1)$ holds for every $p \geq 1$. The sup norm is pinned at its maximum possible value, and not one of the L^p norms decays: in each of them the two kernels stay a fixed positive distance apart for all N, and the same is true of either kernel against the smooth limit $W \equiv \frac{1}{2}$ (there $\left|W_N - \frac{1}{2}\right| = \frac{1}{2}$ everywhere, so $\left\|W_N - \frac{1}{2}\right\|_p = \frac{1}{2}$ for all N and all p). The ordinary norms see three completely different functions where every observable sees one.

Why nothing observable notices the gap. The mismatch is not a defect of the example but a structural fact about what the observables are. A homomorphism density is an *integral* of products of W over many type variables; the coupling that drives every graphon mean field game enters only through the operator $(\mathbb{W}f)(x) = \int_0^1 W(x,y)f(y)\,\mathrm{d}y$, again an integral against W; and sampling a finite network reads off block frequencies, integrals once more. *Every* quantity the theory will ever ask of a graphon is obtained by integrating it against bounded test functions, never by evaluating it at a point. And integration is exactly the operation that annihilates the coin-flip noise. To see this quantitatively, take any two fixed sizeable patches of types $S, T \subseteq [0,1]$ and watch the total interaction $\int_S \int_T W_N$ across them. It is the sum of the roughly $N^2\lambda(S)\lambda(T)$ independent $\{0,1\}$ entries lying in the corresponding block, each weighted by the tile area $1/N^2$; by the law of large numbers this sum is $p\,\lambda(S)\lambda(T)$ up to a fluctuation whose standard deviation is of order $\sqrt{N^2}/N^2 = 1/N$. The two noisy kernels and their smooth average therefore satisfy

$$\int_S \int_T W_N \;=\; \int_S \int_T W_N' + O(\tfrac{1}{N}) \;=\; \int_S \int_T \left(\tfrac{1}{2}\right) + O(\tfrac{1}{N}) \;=\; \tfrac{1}{2}\,\lambda(S)\lambda(T) + O(\tfrac{1}{N}),$$

uniformly over the patches. Averaging over any patch of positive measure kills the fluctuation: the ± 1 disagreements that the sup norm magnified are uncorrelated, so over a region containing order N^2 of them they cancel down to order $1/N$. The microscopic wiring is loud pointwise and silent on every patch. *This* is the sense in which the noisy network is close to its smooth average — close in exactly the currency the observables are denominated in — even though every L^p norm insists they are far.

Reading off the cure. The example does more than condemn the ordinary norms; it tells us what to put in their place. The fatal move was to measure $W_N - W_N'$ pointwise, because pointwise the coin-flip noise is full strength. The repair is to measure it the way the observables do: by its integrals over regions, never by its values at points. If we deem two kernels close precisely when their total interaction $\int_S \int_T$ matches across *every* pair of sizeable patches S, T, then the computation above guarantees that our new notion of size will report the noisy network as close to its smooth average, while still refusing to identify genuinely different mesoscopic structures: two block models with different block densities differ on the patches aligned to their blocks, and no choice of integration region can hide that. The block-level information that homomorphism densities, sampling, and the operator $\mathbb{W}$ all depend on is exactly the patch-integral information we propose to keep; the pointwise fluctuations that no observable depends on are exactly what patch integration throws away. We crystallize the design goal in a box.

Heuristic (non-rigorous)

The cure is to measure a kernel not by its pointwise size but by the size of its *integrals over large regions*. Two kernels should be deemed close when, for *every* pair of sizeable patches $S, T \subseteq [0,1]$ of types, the total interaction $\int_S \int_T$ between those patches is nearly the same. This throws away pointwise fluctuations — they average out over any patch of positive measure — while retaining exactly the block-level information that homomorphism densities, sampling, and the mean field coupling $\mathbb{W}$ all depend on. A norm built this way will judge the noisy network above to be *close* to its smooth average, which is what we want.

The design goal is now stated in one line: *measure the size of a kernel by the largest total interaction it accumulates over any single pair of sizeable patches of types.* The next subsection turns this sentence, almost verbatim, into a definition — taking the supremum of $|\int_S \int_T W|$ over all measurable patches S, T — and then records the two equivalent forms of the resulting quantity that make it usable.

17.1.2 Definition and equivalent forms

The previous subsection ended with a design goal so concrete it almost reads as a formula: *measure the size of a kernel by the largest total interaction it accumulates over any single pair of sizeable patches of types.* We promised to turn that sentence, nearly verbatim, into a definition, and that is the whole content of the present subsection. The phrase "total interaction over the patches S and T" is the double integral $\int_S \int_T U$; "largest" is a supremum over all admissible patches; and the absolute value is there because we care how *far* from balanced the interaction is, in either direction. Reading those three clauses off the design goal produces the cut norm with no further invention. Once it is written down we owe the reader two things before moving on: an explanation of the combinatorial name it carries, and — the real work of the subsection — two alternative descriptions of the very same number, one a smoothed-out test-function form that is far easier to compute with, the other an operator norm that opens the door to the spectral viewpoint of chapter 18.

Throughout, a *kernel* is a bounded measurable function $U\colon [0,1]^2 \to \mathbb{R}$, not necessarily symmetric and not necessarily $[0,1]$-valued; a *graphon* (chapter 15) is a symmetric kernel with values in $[0,1]$. We allow the wider class of signed, possibly asymmetric kernels deliberately: the cut metric will be built from $\|U - W\|_\square$, a *difference* of two graphons, and such a difference is signed (it takes values in $[-1,1]$) even when the two graphons themselves are not. We write λ for Lebesgue measure on $[0,1]$ and integrate against it throughout.

Definition 17.1 (Cut norm)**.** For a kernel $U\colon [0,1]^2 \to \mathbb{R}$ the *cut norm* is

$$\|U\|_\square \;=\; \sup_{S,T} \left| \int_S \int_T U(x,y)\, \mathrm{d}x\, \mathrm{d}y \right|, \tag{17.2}$$

the supremum taken over all pairs of measurable sets $S, T \subseteq [0,1]$.

The name is combinatorial in origin, and it is worth pausing to picture the graph it comes from. Suppose U is the *centered* adjacency kernel of a finite graph G: on the tile $I_i \times I_j$ it equals $a_{ij} - p$, where $a_{ij} \in \{0,1\}$ records whether the edge ij is present and p is the ambient edge density we have subtracted off. Pick two groups of vertices, encoded by the type sets S and T. Then $\int_S \int_T U$ is (up to the uniform tile area) the number of edges running between group S and group T *minus* the number one would expect at density p — the *edge imbalance*, or discrepancy, of the bipartition-like "cut" that singles out S on one side and T on the other. A perfectly typical, structureless graph has a tiny imbalance across every cut; a graph with hidden community structure has some pair S, T across which far more (or far fewer) edges run than density alone predicts. The cut norm hunts over all cuts for the most anomalous one and reports the size of that anomaly. This is exactly the mesoscopic information the previous subsection argued we should keep: it is blind to which individual pair of vertices is wired, but acute to how densely whole blocks of vertices interact. With the object and its name in hand, we record the two reformulations that make it usable.

Lemma 17.2 (Three forms of the cut norm)**.** *For every kernel U,*

$$\|U\|_\square \;=\; \sup_{u,v\colon [0,1]\to[0,1]} \left| \int_{[0,1]^2} u(x)\, U(x,y)\, v(y)\, \mathrm{d}x\, \mathrm{d}y \right|, \tag{17.3}$$

the supremum over all measurable $[0,1]$-valued functions, and moreover

$$\|U\|_\square \;\le\; \|U\|_{\infty\to1} \;:=\; \sup_{\|u\|_\infty \le 1,\ \|v\|_\infty \le 1} \left| \int_{[0,1]^2} u\, U\, v \right| \;\le\; 4\, \|U\|_\square. \tag{17.4}$$

Before the proof, a word on what each line claims and why one would want it. The original eq. (17.2) ranges over *sets* S, T — combinatorial objects, sharp-edged indicators. Form eq. (17.3) relaxes the two indicators $\mathbf{1}_S, \mathbf{1}_T$ to arbitrary $[0,1]$-valued "soft" test functions u, v, which one may picture as fuzzy or fractional memberships in the two groups. This looks like a strictly larger supremum — we are optimizing over a vastly bigger set of competitors — and the lemma's small surprise is that it is not larger at all: softening the membership buys nothing, the optimum already sits at a crisp set. That equality is what makes eq. (17.3) the *analytic workhorse*: a supremum over a convex set of smooth functions is something calculus can attack (one can differentiate in u and v, integrate by parts, apply Cauchy–Schwarz), whereas a supremum over raw sets is combinatorially rigid. Form eq. (17.4) then drops the sign constraint entirely, letting u, v range over the unit ball of L^∞ (values in $[-1,1]$); the resulting quantity $\|U\|_{\infty\to1}$ is, as we explain afterward, exactly the operator norm of $\mathbb{W}_U$ viewed as a map $L^\infty([0,1]) \to L^1([0,1])$, and the lemma says it agrees with the cut norm up to a factor of 4. We prove the two displays in turn.

Proof. The test-function form eq. (17.3)*.* One inequality is free: indicators are themselves $[0,1]$-valued, so taking $u = \mathbf{1}_S$ and $v = \mathbf{1}_T$ in eq. (17.3) reproduces $\int_S \int_T U$, and ranging over all S, T

shows the right side of eq. (17.3) is *at least* $\|U\|_\square$. The substance is the reverse: that allowing fuzzy test functions never beats the best crisp pair. We prove this by an elementary *pointwise* maximization — optimizing the integrand separately at each type — and we draw attention to the fact that it needs nothing beyond Fubini's theorem. One could instead invoke the general principle that a linear functional on a convex set attains its maximum at an extreme point, together with the identification of the extreme points of the $[0,1]$-valued unit ball as the indicators; but that route imports extreme-point and weak-$*$ compactness machinery we have no wish to assume here. The pointwise argument is deliberately self-contained, and it is also more transparent, because it exhibits the optimal u and v explicitly. Here it is.

Fix any $v\colon [0,1] \to [0,1]$ and contract the kernel against it in the second variable, setting

$$g(x) \;:=\; \int_[0,1]U(x,y)\,v(y)\;\mathrm{d}y.$$

Because U is bounded, g lies in $L^1([0,1])$ (this is the one place Fubini is used: it lets us write $\int_{[0,1]^2} u\,U\,v \;=\; \int_[0,1]u(x)\,g(x)\;\mathrm{d}x$, turning the double integral into a single integral against the legitimately defined function g). Now ask how large $\int u\,g$ can be made as u ranges over $[0,1]$-valued functions. The integrand $u(x)\,g(x)$ is maximized *at each point x independently*: where $g(x) > 0$ we want $u(x)$ as large as allowed, namely $u(x) = 1$; where $g(x) < 0$ we want $u(x) = 0$; where $g(x) = 0$ the choice is immaterial. Concretely,

$$\int_[0,1]u(x)\,g(x)\;\mathrm{d}x \;\le\; \int_[0,1]u(x)\,g(x)^+\;\mathrm{d}x \;\le\; \int_[0,1]g(x)^+\;\mathrm{d}x \;=\; \int_{\{g>0\}} g\;\mathrm{d}x,$$

where the first inequality drops the (nonpositive) contribution of g^- and the second uses $u \le 1$; both become equalities at the admissible choice $u = \mathbf{1}_{\{g>0\}}$. Hence $\sup_{0\le u\le 1} \int u\,g = \int_{\{g>0\}} g = \int_S g$ with $S = \{g > 0\}$, and the supremum is genuinely attained, at the indicator $\mathbf{1}_S$. Since the defining supremum in eq. (17.3) carries an absolute value, we may also need the most *negative* value of $\int u\,g$; applying the same reasoning to $-g$ shows its optimum is the indicator $\mathbf{1}_{\{g<0\}}$. Either way, for every fixed v the best u is an indicator. Consequently the joint supremum over u, v loses nothing by restricting u to indicators:

$$\sup_{u,v\in[0,1]} \left| \int_{[0,1]^2} u\,U\,v \right| \;=\; \sup_{S,\,v\in[0,1]} \left| \int_S \Big(\int_[0,1]U(x,y)\,v(y)\;\mathrm{d}y \Big)\,\mathrm{d}x \right|.$$

Now repeat the identical move in the *other* variable — this is the step the skeleton compressed, so we spell it out. Fix the set S just produced and contract the kernel against its indicator in the *first* variable, setting

$$h(y) \;:=\; \int_S U(x,y)\;\mathrm{d}x \;\in\; L^1([0,1]),$$

again integrable because U is bounded. The inner expression above is $\int_S \int_[0,1]U\,v = \int_[0,1]h(y)\,v(y)\;\mathrm{d}y$, a single integral against h, and we maximize it over $v \in [0,1]$ by the very same pointwise argument: the optimum is $v = \mathbf{1}_{\{h>0\}}$ for the most positive value and $v = \mathbf{1}_{\{h<0\}}$ for the most negative, so in either case $v = \mathbf{1}_T$ for a set T $(= \{h > 0\}$ or $\{h < 0\})$. Substituting back, the joint supremum is attained at a *pair* of indicators $\mathbf{1}_S, \mathbf{1}_T$, and its value is $|\int_S \int_T U|$ for those sets, which is by definition no larger than $\|U\|_\square$. We have shown each side of eq. (17.3) dominates the other, so they are equal.

Note that the only analytic fact used was that contracting a bounded kernel against a bounded function yields an L^1 function (Fubini); no compactness, no extreme points, no appeal to attainment of suprema over infinite-dimensional balls.

The operator form eq. (17.4). The left inequality $\|U\|_\square \le \|U\|_{\infty\to 1}$ is again free: indicators have $\|\cdot\|_\infty \le 1$, so they are admissible competitors in the larger supremum defining $\|U\|_{\infty\to 1}$, which therefore dominates the supremum over indicators, i.e. $\|U\|_\square$. The right inequality is where the factor 4 is born, and it comes from splitting each signed test function into its two nonnegative halves. Given u, v with $\|u\|_\infty \le 1$ and $\|v\|_\infty \le 1$, write $u = u_+ - u_-$ and $v = v_+ - v_-$ for the positive and negative parts $u_\pm = \max(\pm u, 0)$, and likewise for v. The point of this decomposition is that each of u_+, u_-, v_+, v_- is now a *genuinely* $[0,1]$*-valued* function (the negative part of a function bounded by 1 in absolute value is itself bounded between 0 and 1), so each is an admissible test function for eq. (17.3). Expanding the bilinear integrand,

$$\int_{[0,1]^2} u\,U\,v = \int u_+\,U\,v_+ \;-\; \int u_+\,U\,v_- \;-\; \int u_-\,U\,v_+ \;+\; \int u_-\,U\,v_-,$$

a sum of four terms, each of the form $\int([0,1]\text{-fn})\,U\,([0,1]\text{-fn})$ and hence bounded in absolute value by $\|U\|_\square$ thanks to the form eq. (17.3) just proved. By the triangle inequality the whole sum is at most $4\,\|U\|_\square$ in absolute value,

$$\left|\int_{[0,1]^2} u\,U\,v\right| \;\le\; 4\,\|U\|_\square\,,$$

and taking the supremum over all admissible u, v gives $\|U\|_{\infty\to 1} \le 4\,\|U\|_\square$. The four summands are exactly the four sign combinations $(\pm,\pm)$, which is precisely where the constant 4 comes from; it is harmless because it is a fixed universal factor that washes out of every convergence statement. $\square$

It is worth being explicit about why we carry *both* forms forward rather than collapsing to one. Form eq. (17.3) is the one we actually compute with in the rest of the chapter: relabeling invariance, subadditivity, the worked block-graphon computation, and the energy-increment step of the regularity lemma are all cleanest when phrased as an optimization over $[0,1]$-valued test functions, because those test functions can be manipulated with ordinary analysis. Form eq. (17.4) is the one we hand to the future: it says that, up to the universal factor 4, the cut norm of U *is* the operator norm of $\mathbb{W}_U$ as a map from $L^\infty([0,1])$ to $L^1([0,1])$,

$$\tfrac{1}{4}\,\|U\|_{\infty\to 1} \;\le\; \|U\|_\square \;\le\; \|U\|_{\infty\to 1}\,,$$

which recasts a question about set discrepancies as a question about an operator. That reinterpretation is the bridge to chapter 18, where the same graphon is read as a self-adjoint Hilbert–Schmidt operator and cut convergence is compared with spectral convergence; the very next subsection already begins to use it, controlling $\|U\|_\square$ by the $L^2 \to L^2$ operator norm in order to place the cut norm among the familiar norms.

Notation watch

We will use three names that are easy to conflate, and the distinctions are load-bearing for the rest of the chapter. The *cut norm* $\|\cdot\|_\square$ of definition 17.1 is a genuine norm on kernels —

it is what this subsection has constructed and characterized. The *cut distance* between two kernels means simply the cut norm of their difference, $\|U - U'\|_\square$; it is a distance between *labeled* kernels and still sees relabelings. The *cut metric* $\delta_\square$, defined in section 17.2, is obtained from the cut distance by *minimizing over relabelings*; it is only a *pseudometric* on graphons (distinct relabelings of one graphon are at distance zero) and becomes a true metric only after passing to the quotient space of proposition 17.7. Whenever the text says "norm," "distance," or "metric," it means precisely one of these three, and the reader should not silently substitute one for another.

17.1.3 Where the cut norm sits

We now have two interchangeable working descriptions of the cut norm — the test-function form eq. (17.3) that we will compute with, and the operator-norm reading eq. (17.4) that we will hand to chapter 18. What we do not yet have is a sense of *scale*: when we said in the chapter's opening that the cut norm is "deliberately coarse," and when the noisy-network example showed an L^1 chasm collapsing to a vanishing patch-integral, we were asserting a quantitative relationship between $\|\cdot\|_\square$ and the norms the reader already owns without ever pinning it down. This subsection pins it down. The cut norm does not float free of the familiar L^p scale; it sits at the *bottom* of it, dominated by every one of them, and it is in addition controlled from above by the spectral ($L^2 \to L^2$ operator) norm. Locating it in this lattice does two jobs at once. It converts the heuristic "coarser than any pointwise norm" into a chain of clean inequalities we can quote later — the regularity argument of section 17.4 will need exactly the comparison $\|\cdot\|_\square \le \|\cdot\|_2$ to run its energy bookkeeping — and, almost as a by-product, it lets us discharge the one obligation still outstanding from the definition: that $\|\cdot\|_\square$ really is a *norm*, non-degeneracy included. The comparison and the norm axioms travel together, so we state them in a single lemma.

Lemma 17.3 (Comparison inequalities)**.** *For every kernel U,*

$$\|U\|_\square \;\le\; \|U\|_1 \;\le\; \|U\|_2 \;\le\; \|U\|_\infty\,, \qquad \textit{and} \qquad \|U\|_\square \;\le\; \|\mathbb{W}_U\|_{2\to 2}\,, \tag{17.5}$$

where $\|\mathbb{W}_U\|_{2\to2}$ is the operator norm of $\mathbb{W}_U$ on $L^2([0,1])$. In particular $\|\cdot\|_\square$ is a norm: it is positively homogeneous and subadditive by eq. (17.3), and $\|U\|_\square = 0$ forces $\int_S \int_T U = 0$ for all S, T, hence $U = 0$ almost everywhere.

The lemma asserts four comparisons and three norm axioms, and it is worth saying in advance which of these is routine and which carries weight. The chain $\|U\|_\square \le \|U\|_1 \le \|U\|_2 \le \|U\|_\infty$ is bookkeeping — each link is a one-line application of a standard integral inequality on the probability space $([0,1]^2, \lambda \otimes \lambda)$ — but it is the bookkeeping that makes the word "coarsest" precise. The spectral bound $\|U\|_\square \le \|\mathbb{W}_U\|_{2\to2}$ is the same kind of one-liner with a Hilbert-space flavour, and its equality structure is something we will want to revisit. The genuinely substantive clause is the last: that $\|U\|_\square = 0$ forces $U = 0$ almost everywhere, the *non-degeneracy* that separates a true norm from a mere seminorm. It is substantive because vanishing of *every* patch integral $\int_S \int_T U$ is, on its face, far weaker than vanishing of U pointwise, and bridging that gap is exactly the measure-theoretic content of the claim. We take the four comparisons first and then spend the bulk of the proof on non-degeneracy.

Proof. The first inequality. For any measurable S, T the double integral is dominated by the integral of the absolute value over all of $[0,1]^2$, simply because enlarging the region of integration and dropping the cancellation between positive and negative parts can only increase the modulus:

$$\Big|\int_S\int_T U(x,y)\ \mathrm{d}x\ \mathrm{d}y\Big| \ \le\ \int_S\int_T |U| \ \le\ \int_{[0,1]^2} |U| \ =\ \|U\|_1\,.$$

This holds for every S, T, so the supremum over S, T — which is $\|U\|_\square$ by eq. (17.2) — is also at most $\|U\|_1$. This first link is where the coarseness is born: the cut norm is a constrained, region-by-region accounting that can never exceed the unconstrained total mass $\|U\|_1$, and it falls strictly below it precisely when U changes sign at fine scales, so that the cancellations the L^1 norm forbids are exactly the ones the cut norm exploits.

The L^p chain. The remaining links $\|U\|_1 \le \|U\|_2 \le \|U\|_\infty$ are the monotonicity of L^p norms in p on a *probability* space, and it is worth recalling why the total mass being 1 is what makes them point this way. For $\|U\|_1 \le \|U\|_2$, apply the Cauchy–Schwarz inequality to the pair $|U|$ and the constant function 1 on $([0,1]^2, \lambda\otimes\lambda)$:

$$\|U\|_1 = \int_{[0,1]^2} |U|\cdot 1 \ \le\ \Big(\int_{[0,1]^2} |U|^2\Big)^{1/2}\Big(\int_{[0,1]^2} 1^2\Big)^{1/2} \ =\ \|U\|_2\cdot\lambda([0,1]^2)^{1/2} = \|U\|_2\,,$$

the last equality because $\lambda\otimes\lambda$ assigns total mass 1. Equivalently this is Jensen's inequality for the convex function $t\mapsto t^2$ applied to the averaging $\int |U|\ \mathrm{d}(\lambda\otimes\lambda)$. For $\|U\|_2 \le \|U\|_\infty$ there is nothing to optimize: $|U| \le \|U\|_\infty$ pointwise, so $\int |U|^2 \le \|U\|_\infty^2 \int 1 = \|U\|_\infty^2$, and taking square roots gives the bound. On a space of total mass larger than 1 these inequalities would acquire mass-dependent constants and could even reverse; it is the normalization $\lambda([0,1]) = 1$, inherited from reading the type variable as an exchangeable label rather than a length, that makes the familiar ordering hold cleanly.

The spectral bound. Return to the set form eq. (17.2) and read the inner double integral as a Hilbert-space pairing. By Fubini,

$$\int_S\int_T U(x,y)\ \mathrm{d}x\ \mathrm{d}y = \int_S\Big(\int_T U(x,y)\ \mathrm{d}y\Big)\,\mathrm{d}x = \int_[0,1]\mathbf{1}_S(x)\,(\mathbb{W}_U\mathbf{1}_T)(x)\ \mathrm{d}x = \langle \mathbf{1}_S, \mathbb{W}_U\mathbf{1}_T\rangle,$$

since $(\mathbb{W}_U\mathbf{1}_T)(x) = \int_[0,1]U(x,y)\mathbf{1}_T(y)\,\mathrm{d}y = \int_T U(x,y)\,\mathrm{d}y$ is exactly the kernel operator applied to the indicator of T. Now Cauchy–Schwarz on $L^2([0,1])$, followed by the definition of the operator norm, gives

$$|\langle \mathbf{1}_S, \mathbb{W}_U\mathbf{1}_T\rangle| \ \le\ \|\mathbf{1}_S\|_2\ \|\mathbb{W}_U\mathbf{1}_T\|_2 \ \le\ \|\mathbf{1}_S\|_2\ \|\mathbb{W}_U\|_{2\to 2}\ \|\mathbf{1}_T\|_2\,.$$

The two indicator norms are harmless: $\|\mathbf{1}_S\|_2 = (\int_[0,1]\mathbf{1}_S)^{1/2} = \lambda(S)^{1/2} \le 1$ and likewise $\|\mathbf{1}_T\|_2 \le 1$, so the right-hand side is at most $\|\mathbb{W}_U\|_{2\to 2}$. This bound is uniform in S, T, so the supremum $\|U\|_\square$ is bounded by $\|\mathbb{W}_U\|_{2\to 2}$ as claimed. We flag the two places slack can enter, because the worked computation later in the chapter will close exactly this gap on a rank-one kernel: slack appears when the optimal S, T have measure strictly below 1 (so $\|\mathbf{1}_S\|_2 < 1$), and when the indicators $\mathbf{1}_S, \mathbf{1}_T$ fail to align with the top singular functions of $\mathbb{W}_U$. For a rank-one kernel $W(x,y) = f(x)f(y)$ the operator $\mathbb{W}_U$ has a single nontrivial singular direction, and we will see the cut norm track $\|\mathbb{W}_U\|_{2\to 2}$ closely precisely because the best cut aligns with that one direction; the inequality here is the loose version of an estimate that becomes nearly sharp there.

Positive homogeneity and subadditivity. These two norm axioms are inherited verbatim from the test-function form eq. (17.3), because that form exhibits $\|U\|_\square$ as a supremum of linear functionals of U. For a scalar c, every integrand scales as $\int u\,(cU)\,v = c\int u\,U\,v$, so $\|cU\|_\square = \sup_{u,v}|c|\,|\int u\,U\,v| = |c|\,\|U\|_\square$. For subadditivity, fix any admissible u, v and use the triangle inequality for the absolute value pointwise inside the supremum,

$$\Big|\int_{[0,1]^2} u\,(U{+}U')\,v\Big| = \Big|\int_{[0,1]^2} u\,U\,v{+}\int_{[0,1]^2} u\,U'\,v\Big| \;\le\; \Big|\int_{[0,1]^2} u\,U\,v\Big|{+}\Big|\int_{[0,1]^2} u\,U'\,v\Big| \;\le\; \|U\|_\square{+}\|U'\|_\square,$$

and taking the supremum over u, v on the left gives $\|U+U'\|_\square \le \|U\|_\square + \|U'\|_\square$. The mechanism is the standard one — a supremum of subadditive quantities is subadditive — and it works only because the *same* pair u, v is used for both kernels before the supremum is taken; this is the property the next section will lean on directly.

Non-degeneracy. It remains to show that $\|U\|_\square = 0$ forces $U = 0$ almost everywhere. The hypothesis says $\int_S\int_T U = 0$ for *every* pair of measurable sets S, T, and the task is to upgrade this family of scalar equations into pointwise vanishing of U. We do it in two stages, peeling off one variable at a time. Fix a measurable set T and contract U against its indicator in the second variable, defining

$$g_T(x) \;:=\; \int_T U(x,y)\;\mathrm{d}y,$$

which lies in $L^1([0,1])$ because U is bounded. The hypothesis, read for this fixed T and all S, says exactly that $\int_S g_T = 0$ for every measurable S. A function whose integral over every measurable set vanishes must vanish almost everywhere — take $S = \{g_T > 0\}$ to get $\int g_T^+ = 0$, hence $g_T^+ = 0$ a.e., and $S = \{g_T < 0\}$ to get $g_T^- = 0$ a.e. — so $g_T = 0$ a.e. on $[0,1]$. Thus for *each* fixed T there is a conull set of types x on which $\int_T U(x,y)\;\mathrm{d}y = 0$.

Here is the delicate point the skeleton compressed, and it is genuinely the crux. The conull set just produced *depends on* T, and there are uncountably many measurable sets T; an uncountable union of null sets need not be null, so we cannot simply say "off a null set, $\int_T U(x,\cdot) = 0$ for all T" and be done. The repair is to work with only *countably* many T, chosen densely enough to determine all the rest. Let $\mathcal{A}$ be a countable algebra of measurable subsets of $[0,1]$ that generates the Borel σ-algebra — for instance the algebra of finite unions of dyadic subintervals $[\,k2^{-n},(k+1)2^{-n})$. For each $T \in \mathcal{A}$ the previous paragraph furnishes a null set $Z_T \subseteq [0,1]$ off which $g_T(x) = 0$. Because $\mathcal{A}$ is countable, the union

$$Z \;:=\; \bigcup_{T\in\mathcal{A}} Z_T$$

is a *countable* union of null sets and hence itself null; this is the single line where countability does all the work, and it is exactly what an uncountable index set would deny us. On the conull complement $[0,1]\setminus Z$ we have achieved simultaneity: for *every* $x \notin Z$ and *every* $T \in \mathcal{A}$ at once, $\int_T U(x,y)\;\mathrm{d}y = 0$.

Now fix any single such $x \notin Z$ and consider the set function $T \mapsto \mu_x(T) := \int_T U(x,y)\;\mathrm{d}y$. Since $U(x,\cdot) \in L^1([0,1])$, this μ_x is a finite signed measure, absolutely continuous with respect to λ, with density $U(x,\cdot)$. We have just shown μ_x vanishes on the generating algebra $\mathcal{A}$. A finite signed measure that vanishes on an algebra generating the σ-algebra vanishes on the entire σ-algebra — this is the uniqueness half of the Carathéodory/Dynkin extension theorem, the statement that a measure is determined by its values on a generating π-system. Hence $\mu_x(T) = 0$ for *all* Borel T, not merely those in $\mathcal{A}$, and a signed measure that vanishes on every set has zero density: $U(x,y) = 0$ for λ-a.e. y. This holds for every $x \notin Z$, i.e. for a.e. x, and so by Fubini $U = 0$ for $(\lambda \otimes \lambda)$-a.e. (x,y), which is what non-degeneracy demands. Together with homogeneity and subadditivity this completes the verification that $\|\cdot\|_\square$ is a genuine norm. $\square$

A short concrete check makes the non-degeneracy argument feel less abstract. Suppose $U(x,y) = \operatorname{sgn}(\sin 2\pi Nx)\operatorname{sgn}(\sin 2\pi Ny)$, a checkerboard of ± 1 tiles of side $1/2N$. Its L^1 norm is 1 for every N, so it is "large" pointwise; yet against any dyadic block $S \times T$ coarser than the tiles the $+1$ and -1 cells cancel in pairs and $\int_S \int_T U \to 0$. The non-degeneracy proof is the assurance that this near-cancellation can never become *exact* for all S, T unless U is genuinely zero: as long as some patch integral survives, $\|U\|_\square > 0$. The cut norm is coarse but not blind.

The first chain of eq. (17.5) is, emphatically, a one-way street, and that is the entire reason this chapter exists. None of its links can be reversed: the noisy-versus-smooth construction of the heuristic furnishes the witness, with $\|W_N - W'_N\|_\square \to 0$ while $\|W_N - W'_N\|_1$ stays pinned near $\frac{1}{2}$ for all N, so the cut norm can be arbitrarily small where the L^1 norm is bounded below. A finer norm would refuse to let those two sequences approach each other; the cut norm lets them, and in doing so it carves out room for objects — limits of microscopically noisy but macroscopically smooth networks — that the L^p topologies simply cannot hold. That extra room is not a defect to be apologized for; it is the space the cut norm makes, and the space on which the rest of Part III will do its work.

With $\|\cdot\|_\square$ now established as a bona fide norm — coarse, well-placed in the lattice of familiar norms, and in particular *subadditive* — we have precisely the raw material the next section requires. Subadditivity is the property that will become the triangle inequality of the cut metric once we minimize over relabelings, and having a fixed, fully-understood norm in hand is what lets us treat the quotient by relabelings cleanly rather than as a tangle of two complications at once. What remains is to confront the redundancy the norm still carries: it is a distance between *labeled* kernels, and the labeling of types is an artifact we have no right to keep. Removing it is the task of section 17.2.

17.2 Relabelings and the cut metric

The previous section closed with a fixed, fully-understood object in hand: $\|\cdot\|_\square$ is a genuine norm on kernels, coarse enough to ignore the microscopic wiring noise that no observable sees, and — by lemma 17.5, which we are about to state and prove — already blind to relabelings of the type coordinate. That coarseness is exactly half of what we need. The cut norm tells us how big a kernel is in a way that respects the observables; what it does not yet give us is a *distance between networks*. For $\|U - W\|_\square$, the cut norm of a difference, is still a distance between *labeled* kernels, and the labeling of types is precisely the kind of artifact this chapter exists to discard. The type variable $x \in [0,1]$ is, from chapter 15 onward, an exchangeable index — a name we hand to an agent's network position, with no intrinsic meaning of its own. Two graphons that differ only by a measure-preserving rearrangement of those names encode one and the same network, yet $\|U - W\|_\square$ will in general report them as far apart, because the difference $U - W$ compares the kernels name-by-name rather than network-to-network. This residual sensitivity to an arbitrary labeling is the last redundancy standing between us and a true distance, and removing it is the entire business of this section.

The program is short to state and occupies the rest of the section in three steps. First, we make "relabeling" precise: it is a measure-preserving bijection φ of $[0, 1]$, acting on kernels by the pull-back $U^\varphi(x, y) = U(\varphi(x), \varphi(y))$, and we check that the cut norm and the homomorphism densities — everything observable — are invariant under it, so that relabeling really is a symmetry the theory cannot detect. Second, we quotient that symmetry away in the only manner a norm permits: the *cut metric* $\delta_\square(U, W) = \inf_\varphi \|U - W^\varphi\|_\square$ takes the smallest cut distance achievable by relabeling one graphon to align it as closely as possible with the other, and passing to the quotient by the relation "$\delta_\square$-distance zero" converts this infimum from a mere pseudometric on labeled graphons into a genuine metric on the intrinsic networks themselves — the *space of graphons* on which all the analysis of this chapter, and of Part III, will take place. Third, we read the construction back as a statement about information: the cut metric remembers a graphon's block-averaged, mesoscopic structure and forgets everything finer, an interpretation that previews the regularity lemma of section 17.4 and explains in advance why the resulting space turns out to be small enough to be compact. We take the three steps in turn, beginning with why the labels deserve to be thrown away at all.

17.2.1 The type labels are arbitrary

Before we may promote the cut norm to a distance between networks we must interrogate it for the symmetries it is obliged to respect. A distance is only as meaningful as the quantities it declines to separate, and the cut norm inherits, from the very meaning of the type variable, one symmetry it has no right to violate: a relabeling of the types must leave it untouched. Establishing that — and that the homomorphism densities of chapter 16 share the same blindness — is the formal license we need before we may quotient relabelings away. This short subsection earns that license.

The conceptual heart is a fact carried forward from chapter 15, and it is worth restating in full because everything in this section turns on it. The type variable $x \in [0, 1]$ is an *exchangeable label*, not a spatial coordinate. When the graphon arose as the limit of an adjacency matrix, the points of $[0, 1]$ inherited the role of the vertex indices $1, \ldots, N$, and those indices were never anything but names: relabeling the vertices of a graph — calling vertex 3 "vertex 17" and vice versa — produces a different adjacency matrix that nonetheless encodes the very same graph. Nothing about the network changes; only the bookkeeping does. In the continuum the analogue of "permute the vertex indices" is a *measure-preserving rearrangement* of the coordinate x, and the analogue of "same graph, different matrix" is "same network, different kernel." Two graphons related by such a rearrangement are not merely close: they are the identical object wearing different name tags, and a theory that could tell them apart would be reading meaning into a labeling that carries none. The distance we are building must therefore be blind to relabelings; and it can be made blind only because the raw material it is built from — the cut norm and the densities — is *already* blind, which is the content of the lemma below. We first make "relabeling" precise.

Definition 17.4 (Relabeling and pull-back)**.** A *measure-preserving bijection* of $[0,1]$ is a bijection $\varphi\colon [0,1] \to [0,1]$ such that both φ and φ^{-1} are measurable and measure-preserving: $\lambda(\varphi^{-1}(A)) = \lambda(A)$ for all measurable A. For a kernel U and such a φ the *pull-back* is

$$U^{\varphi}(x,y) \;:=\; U\big(\varphi(x),\varphi(y)\big).$$

Each clause of this definition pulls its weight, and it pays to see why before using it. That φ is a *bijection* encodes that a relabeling is a pure renaming: every type receives exactly one new name and every name is used exactly once, so the operation is reversible and loses no type. That φ is *measure-preserving* encodes that the renaming does not distort how much of the population sits where: under the exchangeable reading, $\lambda(A)$ is the fraction of agents whose type lies in A, and a legitimate relabeling must keep that fraction fixed. A bijection that, say, compressed the entire left half $[0,\frac{1}{2})$ into the tiny interval $[0,\frac{1}{100})$ would be a renaming on paper but would silently reweight the population, inflating the influence of some types and deflating others; the measure-preserving condition forbids exactly this and is what guarantees the integrals below are untouched. The *pull-back* U^{φ} is then nothing but "rename the types by φ and read off the kernel in the new names": its value at the renamed pair (x,y) is the old kernel's value at the original pair $(\varphi(x),\varphi(y))$. As a one-line illustration, take φ to be the half-swap $\varphi(x) = x + \frac{1}{2} \pmod 1$, which exchanges $[0,\frac{1}{2})$ with $[\frac{1}{2},1)$ and is plainly a measure-preserving bijection. If W is a two-block graphon with one density on the diagonal blocks and another off-diagonal, then W^{φ} is the same two-block graphon with the two blocks interchanged — the networks are manifestly the same, only the block sitting on $[0,\frac{1}{2})$ has traded places with the one on $[\frac{1}{2},1)$. Pull-back is the formal expression of precisely this relabeling, and the claim we now prove is that no observable can see it.

Lemma 17.5 (Invariance under relabeling)**.** *For every kernel U and every measure-preserving bijection φ, $\|U^{\varphi}\|_{\square} = \|U\|_{\square}$, and for every finite simple graph F, $t(F,W^{\varphi}) = t(F,W)$.*

Proof. The cut norm. Start from the set form eq. (17.2) and evaluate the inner double integral for the pulled-back kernel. For any measurable S,T,

$$\int_S\int_T U^{\varphi}(x,y)\;\mathrm{d}x\;\mathrm{d}y = \int_S\int_T U\big(\varphi(x),\varphi(y)\big)\;\mathrm{d}x\;\mathrm{d}y,$$

and we change variables $x' = \varphi(x)$, $y' = \varphi(y)$. Because φ is a measure-preserving bijection, it preserves λ in each variable separately and hence the product measure $\lambda\otimes\lambda$ on $[0,1]^2$; the change of variables therefore introduces no Jacobian factor, $\mathrm{d}x'\;\mathrm{d}y' = \mathrm{d}x\;\mathrm{d}y$. As x ranges over S the new variable $x' = \varphi(x)$ ranges over the image $\varphi(S)$, and likewise y' ranges over $\varphi(T)$, so

$$\int_S\int_T U^{\varphi}(x,y)\;\mathrm{d}x\;\mathrm{d}y = \int_{\varphi(S)}\int_{\varphi(T)} U(x',y')\;\mathrm{d}x'\;\mathrm{d}y'. \tag{17.6}$$

Thus the discrepancy that U^{φ} accumulates over the cut (S,T) is *identical* to the discrepancy that U itself accumulates over the relabeled cut $(\varphi(S),\varphi(T))$: relabeling the kernel merely moves the test sets, it does not alter any of the numbers being maximized over.

It remains to see that moving the test sets does not shrink or enlarge the pool of numbers the supremum ranges over — this is the step the reader should not let slip past, because the whole invariance rests on it. The map $(S,T) \mapsto (\varphi(S), \varphi(T))$ is a bijection from pairs of measurable sets onto pairs of measurable sets. It lands in measurable pairs because φ^{-1} is measurable, so $\varphi(S) = (\varphi^{-1})^{-1}(S)$ is measurable; and it is onto because any prescribed pair (S', T') is hit by taking $S = \varphi^{-1}(S')$, $T = \varphi^{-1}(T')$, which are themselves measurable for the same reason. Consequently, as (S,T) runs over *all* measurable pairs, $(\varphi(S), \varphi(T))$ runs over exactly the same collection — all measurable pairs — and the two suprema are taken over an identical set of real numbers. Combining this with eq. (17.6),

$$\|U^\varphi\|_\square = \sup_{S,T} \Big| \int_S \int_T U^\varphi \Big| = \sup_{S,T} \Big| \int_{\varphi(S)} \int_{\varphi(T)} U \Big| = \sup_{S',T'} \Big| \int_{S'} \int_{T'} U \Big| = \|U\|_\square \,,$$

where the third equality is precisely the change of index $(S', T') = (\varphi(S), \varphi(T))$ just justified. This is the relabeling invariance of the cut norm.

The homomorphism densities. The same change of variables, now applied in every type coordinate at once, settles the densities. Recall from chapter 16 that

$$t(F, W) = \int_{[0,1]^{V(F)}} \prod_{ij \in E(F)} W(x_i, x_j) \prod_{k \in V(F)} \mathrm{d}x_k,$$

an integral over one copy of $[0,1]$ for each vertex of F. Replacing W by W^φ turns each factor into $W^\varphi(x_i, x_j) = W(\varphi(x_i), \varphi(x_j))$, so the whole integrand is the original integrand evaluated at the renamed coordinates $x'_k = \varphi(x_k)$. Substituting $x'_k = \varphi(x_k)$ simultaneously for every $k \in V(F)$ preserves the product measure $\prod_k \mathrm{d}x_k$ on $[0,1]^{V(F)}$, one measure-preserving factor per coordinate, and carries the domain $[0,1]^{V(F)}$ onto itself because φ is a bijection of $[0,1]$. Hence

$$t(F, W^\varphi) = \int_{[0,1]^{V(F)}} \prod_{ij \in E(F)} W(x'_i, x'_j) \prod_k \mathrm{d}x'_k = t(F, W),$$

identical to the original. Every observable the theory recognizes — the cut norm and all the subgraph densities — is therefore deaf to relabeling. $\square$

This lemma is small, but it is the workhorse of everything that follows, and we will lean on it so often in the next subsection that it is worth flagging its uses in advance. It is what makes the cut metric $\delta_\square(U, W) = \inf_\varphi \|U - W^\varphi\|_\square$ of the next subsection *symmetric*: swapping the roles of U and W amounts to pulling the difference kernel back by φ^{-1}, and lemma 17.5 says that pull-back costs nothing, so the two infima coincide. It is what powers the *triangle inequality*: two near-optimal relabelings are chained through the cocycle identity $W^{\psi\circ\varphi} = (W^\psi)^\varphi$, and invariance is what lets us align the middle graphon by φ without paying for it. And far downstream, in the total-boundedness half of the compactness theorem (section 17.4), it is what permits us to *relabel each part of a partition onto a subinterval* of $[0,1]$ when we tidy a step-function approximant into standard form: because relabeling changes no observable and leaves the cut distance to the original graphon at zero, such normalizations are free. Invariance, in short, is the permission slip the rest of the chapter spends repeatedly. With it secured, we may at last quotient the relabelings away and build the genuine distance between networks — the task of the next subsection, which uses this lemma at every turn to define a distance blind to labeling: the best alignment of U to W in cut norm.

17.2.2 The cut metric and the space of graphons

The previous subsection ended by handing us a permission slip: relabeling changes no observable, because both the cut norm and every homomorphism density are invariant under a measure-preserving bijection of the types (lemma 17.5). We spend that slip now. The cut norm of a difference, $\|U - W\|_\square$, is a distance between *labeled* kernels; it still sees the arbitrary name tags on the types and will report two relabelings of one network as far apart. We want instead a distance blind to labeling: a single number measuring how far apart the two *networks* stand, with the bookkeeping of names quotiented away. The construction is forced by what we have just proved. Since every relabeling W^φ of W encodes the identical network, the only honest way to ask "how far is U from W?" is to ask how close U can be brought to W after we are allowed to relabel W as favorably as we like — to slide W's types around by the best alignment and then measure the residual gap in cut norm. "As favorably as we like" is an optimization, and the optimal value is an infimum over all relabelings. That single recipe — best alignment, then cut norm of what remains — is the cut metric.

Definition 17.6 (Cut metric)**.** Let $\mathcal{W}_0$ denote the set of all graphons (symmetric measurable $W\colon [0,1]^2 \to [0,1]$). For $U, W \in \mathcal{W}_0$ the *cut metric* is

$$\delta_\square(U, W) \;=\; \inf_{\varphi} \; \|U - W^\varphi\|_\square\,, \tag{17.7}$$

the infimum over all measure-preserving bijections φ of $[0,1]$.

The cut metric measures how close U can be brought to W in cut norm by the best relabeling of W's types. One should read $\delta_\square(U, W)$ as the score of an alignment game: the player is handed the freedom to renumber W's types by any measure-preserving bijection, tries to make the renumbered W^φ overlap U as exactly as the cut norm can detect, and the cut metric records the smallest cut-norm mismatch any renumbering can achieve. If U and W are the same network in different clothing, some φ undresses the disguise and drives the mismatch to zero; if they are genuinely different mesoscopic structures, no φ can hide the difference and the infimum stays positive. That this prescription deserves the word "metric" is the content of the next proposition, and the proof has exactly one subtle moment, which we flag in advance so the reader knows where to look. The infimum in eq. (17.7) ranges over an infinite-dimensional, noncompact set of bijections and *need not be attained*: there may be no single best relabeling, only a sequence of ever-better ones. A careless argument would want to grab the optimal φ and manipulate it, and would stall when no such φ exists. The remedy is that we never need the optimum itself. Everything — symmetry and the triangle inequality both — goes through using only two facts already in hand: that measure-preserving bijections *compose* to give another measure-preserving bijection, and that the cut norm is *invariant* under any one of them. Working with relabelings that are merely near-optimal, and composing them, sidesteps attainment entirely.

Proposition 17.7 ($\delta_\square$ is a pseudometric; the metric space of graphons)**.** *The cut metric $\delta_\square$ is a pseudometric on $\mathcal{W}_0$: it is symmetric, nonnegative, satisfies $\delta_\square(W, W) = 0$, and obeys the triangle inequality $\delta_\square(U, W) \le \delta_\square(U, V) + \delta_\square(V, W)$. The relation*

$$U \sim W \quad\Longleftrightarrow\quad \delta_\square(U, W) = 0 \tag{17.8}$$

is an equivalence relation, called weak isomorphism*, and on the quotient set* $\widetilde{\mathcal{W}}_0 := \mathcal{W}_0/\sim$ *the induced function is a genuine metric. We call* $(\widetilde{\mathcal{W}}_0, \delta_\square)$ *the* metric space of graphons*.*

Proof. Nonnegativity and reflexivity. These are immediate and we dispose of them first. Each competitor $\|U - W^\varphi\|_\square$ is a norm and hence ≥ 0, so their infimum $\delta_\square(U, W) \geq 0$. Taking the single competitor $\varphi = \mathrm{id}$ in eq. (17.7) gives $\delta_\square(W, W) \leq \|W - W\|_\square = 0$, and combined with nonnegativity this forces $\delta_\square(W, W) = 0$. So far nothing delicate has happened; the two substantive axioms are symmetry and the triangle inequality, and both are where the no-attainment subtlety must be navigated.

Symmetry. The definition eq. (17.7) is visibly asymmetric in U and W: it relabels the second argument and leaves the first alone. We must check the choice does not matter. The mechanism is the substitution $\varphi \mapsto \varphi^{-1}$, which is legitimate because the inverse of a measure-preserving bijection is again one (built into definition 17.4), so φ and φ^{-1} range over the same index set and the infimum is unchanged if we reparametrize by the inverse. The content is then a single identity: for every φ,

$$\|U - W^\varphi\|_\square \;=\; \left\|(U - W^\varphi)^{\varphi^{-1}}\right\|_\square \;=\; \left\|U^{\varphi^{-1}} - W\right\|_\square. \tag{17.9}$$

The first equality is relabeling invariance (lemma 17.5) applied to the single kernel $U - W^\varphi$ pulled back by φ^{-1}: pulling a kernel back costs nothing in cut norm. The second equality unwinds the pull-back through the two cocycle facts $(U)^{\varphi^{-1}} = U^{\varphi^{-1}}$ and $(W^\varphi)^{\varphi^{-1}} = W^{\varphi\circ\varphi^{-1}} = W^{\mathrm{id}} = W$ (the cocycle identity eq. (17.10), derived just below, with the relabeling φ and its undoing φ^{-1} cancelling exactly on the second term). Now take the infimum of eq. (17.9) over φ: the left side gives $\delta_\square(U, W)$, while the right side, as φ^{-1} sweeps over all measure-preserving bijections, gives $\inf_\psi \left\|U^\psi - W\right\|_\square$. Renaming the mute variable and noting $\left\|U^\psi - W\right\|_\square = \left\|(U^\psi - W)^{\psi^{-1}}\right\|_\square = \left\|U - W^{\psi^{-1}}\right\|_\square$ by the same invariance, this last infimum is exactly $\delta_\square(W, U)$. Hence $\delta_\square(U, W) = \delta_\square(W, U)$. Note that we never produced an optimal relabeling; we only matched the two index sets and used that pull-back is free, so the absence of an attained minimizer never entered.

Triangle inequality. Here is the point flagged above, and it is the only place the no-attainment subtlety bites: we cannot select optimal φ, ψ, so we work with *near*-optimal ones and lean on composition. Fix a tolerance $\eta > 0$. By the definition of the infimum, there exist measure-preserving bijections φ, ψ that come within η of the two pairwise cut metrics,

$$\|U - V^\varphi\|_\square < \delta_\square(U, V) + \eta, \qquad \left\|V - W^\psi\right\|_\square < \delta_\square(V, W) + \eta,$$

the first relabeling V to align with U, the second relabeling W to align with V. The idea is to chain these two alignments into a single alignment of W to U, routed through V. The chaining is the composition $\psi \circ \varphi$, which is again a measure-preserving bijection of $[0, 1]$ (the composite of two measure-preserving bijections is measure-preserving and bijective), so it is a *legitimate competitor* in the infimum defining $\delta_\square(U, W)$ — not necessarily the optimal one, but admissible, and that is all an infimum requires. To use it we need to know how a composite relabeling acts on a kernel, which is the cocycle identity. Reading definition 17.4 twice,

$$W^{\psi\circ\varphi}(x, y) = W\big((\psi\circ\varphi)(x), (\psi\circ\varphi)(y)\big) = W\big(\psi(\varphi(x)), \psi(\varphi(y))\big) = W^\psi\big(\varphi(x), \varphi(y)\big) = \big(W^\psi\big)^\varphi(x, y), \tag{17.10}$$

where the third equality is the definition of W^ψ evaluated at the inner pair $(\varphi(x), \varphi(y))$ and the fourth is the definition of pulling W^ψ back by φ. So $W^{\psi\circ\varphi} = (W^\psi)^\varphi$: applying ψ then φ to the kernel is the same as relabeling by the composite, with the order of the two reversed in the way pull-backs always reverse. Feeding the competitor $\psi \circ \varphi$ into the infimum and splitting the difference through V^φ with the *cut-norm* triangle inequality (lemma 17.3, the subadditivity proved in the previous section),

$$\delta_\square(U, W) \ \le\ \left\|U - W^{\psi\circ\varphi}\right\|_\square \ =\ \left\|U - (W^\psi)^\varphi\right\|_\square \ \le\ \|U - V^\varphi\|_\square + \left\|V^\varphi - (W^\psi)^\varphi\right\|_\square,$$

where we inserted and subtracted the same intermediate kernel V^φ, the relabeled copy of V. The first summand is already controlled by our choice of φ. The second summand is where invariance earns its keep: both kernels inside it are pulled back by the *same* φ, so their difference is $(V - W^\psi)^\varphi$, and pulling that single kernel back by φ leaves its cut norm unchanged,

$$\left\|V^\varphi - (W^\psi)^\varphi\right\|_\square = \left\|(V - W^\psi)^\varphi\right\|_\square = \left\|V - W^\psi\right\|_\square < \delta_\square(V, W) + \eta$$

by lemma 17.5 and our choice of ψ. In words: the detour through φ that we needed in order to compare U against the composite relabeling costs nothing on the V-to-W leg, because both terms of that leg ride along under the same φ and the cut norm cannot tell. Assembling the two summands,

$$\delta_\square(U, W) \ <\ \big(\delta_\square(U, V) + \eta\big) + \big(\delta_\square(V, W) + \eta\big) \ =\ \delta_\square(U, V) + \delta_\square(V, W) + 2\eta.$$

The left side does not depend on η, so letting $\eta \downarrow 0$ removes the slack and yields the triangle inequality $\delta_\square(U, W) \le \delta_\square(U, V) + \delta_\square(V, W)$. The $\eta \to 0$ limit is exactly the device that lets near-optimal competitors stand in for the unattainable optimum: at every positive η we used only honest, existing bijections, and the limit is taken on a clean numerical inequality after the relabelings have done their work.

From pseudometric to metric on the quotient. With symmetry, reflexivity, nonnegativity, and the triangle inequality established, $\delta_\square$ is a *pseudometric* on $\mathcal{W}_0$ — all the metric axioms except possibly the separation axiom, which can fail because distinct graphons (different labelings of one network) can sit at distance zero. The standard cure is to collapse the zero-distance ties, and we now check it works exactly as the abstract theory of pseudometrics promises. First, the zero-set relation eq. (17.8) is an equivalence relation. Reflexivity is $\delta_\square(W, W) = 0$; symmetry of the relation is symmetry of $\delta_\square$; and transitivity is the triangle inequality, for if $\delta_\square(U, V) = 0$ and $\delta_\square(V, W) = 0$ then $0 \le \delta_\square(U, W) \le 0 + 0 = 0$, forcing $U \sim W$. So $\sim$ partitions $\mathcal{W}_0$ into weak-isomorphism classes, and $\widetilde{\mathcal{W}}_0 = \mathcal{W}_0/\sim$ is the set of those classes.

Two things must be checked to call $\delta_\square$ a metric on $\widetilde{\mathcal{W}}_0$: that it is *well-defined* on classes (independent of which representatives we pick), and that it *separates* distinct classes. Well-definedness is the one terse step the reader should see spelled out, because it is the place the triangle inequality does double duty. Suppose $U \sim U'$ and $W \sim W'$, i.e. $\delta_\square(U, U') = 0$ and $\delta_\square(W, W') = 0$. We claim the two distances $\delta_\square(U, W)$ and $\delta_\square(U', W')$ agree. Applying the triangle inequality twice, hopping first from U to U' and then from W' to W,

$$\delta_\square(U, W) \ \le\ \delta_\square(U, U') + \delta_\square(U', W') + \delta_\square(W', W) \ =\ 0 + \delta_\square(U', W') + 0,$$

and the same chain run in the opposite direction gives $\delta_\square(U',W') \le \delta_\square(U,W)$. Subtracting, both differences are squeezed,

$$\left|\delta_\square(U,W) - \delta_\square(U',W')\right| \;\le\; \delta_\square(U,U') + \delta_\square(W,W') \;=\; 0,$$

so $\delta_\square(U,W) = \delta_\square(U',W')$: the distance depends only on the two classes, not on the chosen representatives, and therefore descends to a function on $\widetilde{\mathcal{W}}_0 \times \widetilde{\mathcal{W}}_0$. Separation is now automatic and is precisely the gain bought by quotienting: if two classes are at distance zero, then any representatives U, W satisfy $\delta_\square(U,W) = 0$, which by the very definition eq. (17.8) of $\sim$ means $U \sim W$, i.e. the two representatives lie in the *same* class. So distance zero on the quotient forces equality of classes — exactly the separation axiom that failed downstairs. The descended $\delta_\square$ inherits symmetry, the triangle inequality, and nonnegativity verbatim from upstairs (they are statements about the numerical values, which are unchanged), and it now also separates, so it is a genuine metric. Thus $(\widetilde{\mathcal{W}}_0, \delta_\square)$ is a metric space. □

It is worth dwelling for a moment on what made the whole proof go through, because the same move will return when we prove completeness. At no point did we exhibit an optimal relabeling; the infimum in eq. (17.7) may have no minimizer, and we never asked it to. Symmetry needed only that pull-back is free and that φ and φ^{-1} index the same set; the triangle inequality needed only that two near-optimal relabelings *compose* into an admissible third one, with the cost of the composite split by the cut-norm triangle inequality and the detour absorbed by invariance. This near-optimal-bijection-plus-composition technique is precisely what the completeness half of the compactness theorem (proposition 17.18) will reuse to assemble a limiting alignment out of a Cauchy sequence of approximate ones. The reader who has followed the $\eta \to 0$ bookkeeping here will find that argument familiar.

There is a tempting alternative route that we deliberately decline, and honesty requires saying so explicitly rather than leaving the reader to wonder whether we missed it.

Remark 17.8 (The coupling reformulation)**.** The proof above establishes everything the chapter needs about the metric structure with bare hands — only invariance and composition, no compactness, no attained optimizer. It is worth knowing that $\delta_\square$ admits two equivalent reformulations, due to Borgs–Chayes–Lovász–Sós–Vesztergombi: enlarging the relabelings from bijections to *measure-preserving maps* (not necessarily invertible), and further to *couplings* π of λ with itself,

$$\delta_\square(U,W) = \inf_{\varphi,\psi} \left\| U^\varphi - W^\psi \right\|_\square = \inf_{\text{couplings } \pi} \sup_{S,T} \left| \int_{S\times T} (U - W)\, \mathrm{d}\pi^{\otimes 2} \right|.$$

The coupling form repairs the very defect we just learned to live with: its infimum *is* attained, because the set of couplings of λ with itself is convex and weak-$*$ compact, so a best coupling always exists where a best bijection may not. One could therefore rebuild the pseudometric proof on the coupling form and never confront the no-attainment subtlety at all. We do not, for two reasons. First, the coupling form costs us the weak-$*$ compactness machinery up front, whereas the bare-hands proof above asks for nothing beyond the previous section. Second, the bijection form is what the rest of the chapter actually manipulates — the total-boundedness argument relabels parts onto subintervals, and the completeness sketch chases near-optimal bijections — so it is the form worth becoming fluent in. The coupling reformulations are what one uses to identify weak isomorphism with measure-preserving isomorphism of the underlying kernels; we do not need them below — the completeness proof of proposition 17.18 uses only near-optimal bijections plus weak-$*$ compactness of the L^∞ ball — and refer the reader to [99, Ch. 8] for the equivalence.

Notation watch

The space of graphons is written $\mathcal{W}_0$ (set) and $\widetilde{\mathcal{W}}_0$ (quotient metric space), with subscript 0. Do not confuse $\mathcal{W}_0 = \mathcal{W}_0$ with the Wasserstein distance $\mathcal{W}_2 = \mathcal{W}_2$ of chapter 4: the letter $\mathcal{W}$ is overloaded in the literature, and we disambiguate purely by the subscript and by context. Points of $\widetilde{\mathcal{W}}_0$ are weak-isomorphism classes of graphons; we nonetheless write a class by any of its representatives W and only invoke the quotient when the distinction matters (as it does for the metric and for compactness).

We have now delivered the central object of the chapter: a genuine metric space $(\widetilde{\mathcal{W}}_0, \delta_\square)$ whose points are intrinsic networks — graphons stripped of their arbitrary labelings — and whose distance is the best alignment in cut norm. This is the arena in which the rest of Part III operates. It is on $(\widetilde{\mathcal{W}}_0, \delta_\square)$, and only after we know it is a metric space with well-defined points, that the word *compact* will finally have something to attach to in section 17.4; the metrization and the quotient built here are exactly the scaffolding the chapter's opening promised, raised so that the keystone can be set. Two threads from this construction run forward explicitly. The equivalence relation of weak isomorphism, $\delta_\square(U, W) = 0$, is not just a technical device for separating the quotient: section 17.3 will show it has a completely observable characterization — two graphons are weakly isomorphic exactly when all their homomorphism densities agree — so the points of $\widetilde{\mathcal{W}}_0$ are precisely what the moment data of chapter 16 can tell apart, no finer and no coarser. And the near-optimal-bijection technique we used to dodge the missing minimizer will resurface intact in the completeness sketch of proposition 17.18, where a limiting alignment is built as a limit of approximate ones.

Before we can profitably study convergence or compactness on this space, though, we owe the reader a structural reading of the distance we have just built. We have a metric, but what does *closeness* in it actually mean about two networks? The cut-norm motivation of section 17.1 already hinted at the answer — block-level interaction is kept, pointwise wiring noise is discarded — and the relabeling quotient has now added a second layer of forgetting on top of it. The next subsection steps back from the construction to make this precise: it asks, of the metric space we now hold, exactly what the cut metric remembers about a graphon and exactly what it throws away.

17.2.3 Coarse-graining: what the cut metric remembers and forgets

We now hold a genuine metric space $(\widetilde{\mathcal{W}}_0, \delta_\square)$, and the previous subsection left us with a pointed question: when this metric calls two networks close, what is it actually asserting about them? The construction was driven by two acts of forgetting, stacked one on the other. The cut norm of section 17.1 was engineered to discard pointwise wiring noise while retaining block-level interaction — that was the whole lesson of the noisy-versus-smooth example. Then the relabeling quotient of section 17.2 added a second layer, forgetting which name each type happens to wear. The purpose of this short subsection is to fuse those two readings into a single structural picture of the distance, a picture that is worth installing in the reader's mind *before* the regularity lemma of section 17.4 makes it a theorem, because once one sees what closeness in $\delta_\square$ means it is no surprise at all that every graphon admits a low-complexity caricature. The slogan is that the cut metric is a *coarse-graining*: it remembers a graphon's mesoscopic, block-averaged structure and forgets everything finer.

Make the slogan concrete by spelling out the operation it names. Take a graphon W and a finite partition $\mathcal{P} = \{P_1, \ldots, P_k\}$ of the type interval $[0,1]$ into measurable parts — think of each part as a *community* of types, a cluster of agents we have decided to treat as interchangeable. Over each pair of parts $P_i \times P_j$ replace W by its average value there, the single number $\frac{1}{\lambda(P_i)\lambda(P_j)} \int_{P_i} \int_{P_j} W$ recording how densely community i interacts with community j on the whole. The result is a step graphon $W_{\mathcal{P}}$, a block-constant caricature carrying only k^2 numbers no matter how intricate W was to begin with. This block average is exactly the conditional expectation $\mathbb{E}[W \mid \mathcal{P} \otimes \mathcal{P}]$ that section 17.4 will build the regularity lemma on; here we need only its meaning, not yet its machinery. The coarse-graining claim is that, for a sufficiently fine choice of $\mathcal{P}$, this caricature is cut-close to the original: $\|W - W_{\mathcal{P}}\|_\square$ is small. Within each community-pair the fine-grained fluctuations of W around its block average are precisely the sign-changing, patch-cancelling structure the cut norm was designed not to see, so replacing W by the locally constant $W_{\mathcal{P}}$ costs almost nothing in cut norm even though it can cost a great deal in any L^p norm. That a single bounded number of blocks always suffices, uniformly over all graphons, is the regularity lemma; the present picture is its intuition installed in advance.

Run this reading back through the metric and one obtains a clean characterization of closeness. Two graphons are $\delta_\square$-close exactly when, after the best relabeling has been chosen to align them, their block averages agree to high accuracy across *every* sufficiently coarse partition simultaneously. The two quantifiers each carry one of the two acts of forgetting. The "best relabeling" is the cut metric's infimum over measure-preserving bijections from section 17.2: it discharges the arbitrariness of the labels, so that we compare the networks community-to-community rather than name-to-name. The "every sufficiently coarse partition" is the cut norm's supremum over patches from section 17.1, now read in block form: it demands that the two networks not merely agree on one favoured decomposition into communities but on all of them at once, so that no choice of how to cluster the types reveals a discrepancy. What this joint condition can detect and what it cannot is then sharply delimited. Microscopic wiring — which individual pair of types happens to be joined, the coin-flip randomness of the heuristic example — is invisible, because it is averaged away inside the blocks and contributes nothing to any block average. Mesoscopic structure — how densely whole communities of types interact, the block densities themselves — is exactly what survives, because it *is* the block averages, and two networks with genuinely different community interactions will differ on the partition aligned to those communities and so cannot be made $\delta_\square$-close by any relabeling. The cut metric forgets the wiring and remembers the community structure, and the phrase "every sufficiently coarse partition" is the precise form of that promise.

Physics note

The cut metric formalizes a move the condensed-matter reader has made many times: replacing a microscopic configuration by a block-averaged (coarse-grained) one and asking only that the coarse-grained descriptions agree. Two microscopically distinct spin configurations that flow to the same block-spin field under a Kadanoff decimation are, for the purpose of long-wavelength observables, the same configuration; the equivalence classes are the orbits of the coarse-graining map, just as the block-density caricature $W_{\mathcal{P}}$ stands in for W here. Weak isomorphism — $\delta_\square$-distance zero — is the graphon analogue of that identification: two kernels are declared the same precisely when no amount of block-averaging, under any relabeling of types, can tell them apart, exactly as two configurations are physically identical when no coarse-grained observable separates them. One caveat keeps the analogy honest, and it is not a quibble. The renormalization group *iterates* a fixed-ratio rescaling, generating a flow on coupling space along which one can ask which directions are relevant and which irrelevant; the cut metric does no such thing. It performs its averaging *once and at all scales simultaneously*, quantifying over every partition in a single supremum rather than coarse-graining step by step. There is consequently no flow, no fixed point, and no relevant/irrelevant dichotomy in the cut metric — the shared content is the equivalence-by-coarse-graining alone, and the analogy carries no mathematical weight beyond that intuition.

With this picture in place the next section's machinery should feel inevitable rather than imposed. We have asserted that a bounded number of blocks always suffices to approximate a graphon in cut norm; turning that assertion into a theorem is the content of the weak regularity lemma, and the picture above already names its three moving parts. The block averages are the step kernels $W_{\mathcal{P}}$; the measure of how much structure a partition has captured will be an *energy*, the squared L^2 norm of the block average; and the mechanism that drives the argument is *refinement* — whenever a partition's caricature is still cut-far from the graphon, one splits its parts to capture more energy, and because energy is bounded the splitting must stop. The phrase "every sufficiently coarse partition" that we used to characterize closeness is precisely the foothold that energy-increment mechanism exploits: a surviving cut-norm discrepancy is exactly a partition on which the block averages have not yet agreed, and that is the signal to refine. The worked computation of section 17.4 makes all of this fully explicit on the carried thread graphons, exhibiting the block approximation of a rank-one and a two-block kernel and watching its cut distance to the original shrink as the partition is refined. We turn first, however, to a prior question that the metric now lets us settle cleanly: whether convergence in this cut metric is the very same notion as the left-convergence of chapter 16, closing the loop the chapter's opening promised.

17.3 Cut convergence is left-convergence

The previous two sections did the constructive work this one cashes in. We now own a genuine metric space $(\widetilde{\mathcal{W}}_0, \delta_\square)$: its points are intrinsic networks — graphons read modulo the arbitrary labeling of types — and the cut metric assigns each pair of them a single number that, by design, registers block-averaged interaction and forgets microscopic wiring. The chapter's opening promised that this distance would be "right" in three reinforcing senses, and named the first of them as the keystone the next two sections raise scaffolding for: the cut metric should *metrize left-convergence*, so that the geometry built here and the topology imported from chapter 16 are not two competing notions of nearness but literally one. This section delivers that first sense in full. It is the moment the loop the preamble drew finally closes — where the homomorphism densities of chapter 16, which told us only *whether* a sequence settles down, are shown to agree exactly with the cut metric, which tells us *how far* two networks stand apart.

Before we can even ask whether the two notions coincide, we have to make them speak about the same objects, and here there is a vocabulary mismatch to reconcile. In chapter 16 left-convergence was defined for sequences of *finite simple graphs* (G_n) with $|V(G_n)| \to \infty$ (definition 16.11): the sequence converges when, for every fixed pattern F, the frequency $t(F, G_n)$ of F inside G_n settles to a limit. The cut metric, by contrast, lives on graphons. To compare them we extend left-convergence to graphons in the only natural way: a sequence (W_n) in $\mathcal{W}_0$ is *left-convergent* when the density $t(F, W_n)$ converges for every finite simple graph F. This is not a new idea grafted on but the same definition read on the continuum — the densities are the same observables, now evaluated on kernels rather than adjacency matrices — and chapter 16 already took the first step of this extension when it declared a graphon sequence convergent by exactly this clause.

The bridge that fuses the two readings into one is the identification of a finite graph with its step graphon, and because every application to growing networks routes through it, it is worth restating with care rather than waving past. Given a finite simple graph G on n vertices, cut $[0, 1]$ into n equal subintervals $I_1, \ldots, I_n$, one per vertex, and let the *step graphon* W^G be the symmetric kernel that takes the value 1 on the tile $I_i \times I_j$ when ij is an edge of G and 0 otherwise — the adjacency matrix of G "pixelated" into a function on $[0, 1]^2$. Proposition 16.9 established the one fact we need about this construction: it preserves *every* density, $t(F, W^G) = t(F, G)$ for all F, because integrating a product of kernel values over the uniform types reproduces, block by block, the finite average that counts copies of F in G. The combinatorial frequency and the analytic integral are the same number. This is what lets us treat a finite graph and its step graphon as interchangeable: any statement about the densities of one is verbatim a statement about the densities of the other, and we make that identification silently from here on, writing G where we mean W^G whenever a network is fed to a graphon-level construction.

The payoff of the identification is precisely the form chapter 25 will consume, so it is worth spelling out concretely. A sequence of growing finite networks $G_1, G_2, \ldots$ — the adjacency structures of larger and larger interacting populations — becomes, through $G_n \mapsto W^{G_n}$, a sequence of graphons sitting inside $\mathcal{W}_0$, with no loss of any observable information: $t(F, W^{G_n}) = t(F, G_n)$ for every F and every n. Consequently the finite networks left-converge in the sense of definition 16.11 if and only if the associated step graphons left-converge in the graphon sense just defined, and — once the theorem of this section is in hand — if and only if those step graphons converge in the cut metric to some limiting graphon W. That last clause is the one Part III leans on: it says a single graphon can stand in, in the precise quantitative sense of cut distance, for an entire convergent sequence of finite networks of unbounded size. The reader should keep this finite-to-continuum translation in view, because every later invocation of cut convergence for "a growing network" is shorthand for cut convergence of its step graphons.

With both notions now phrased for graphons, the remaining definition is the obvious one. A sequence (W_n) in $\mathcal{W}_0$ *converges in the cut metric* to W when $\delta_\square(W_n, W) \to 0$: the relabeled cut distance, minimized over alignments of the type coordinate, shrinks to zero. The central theorem of dense graph-limit theory — and the first of this chapter's three senses — is that this metric convergence and left-convergence are the very same notion (theorem 17.12). The proof splits cleanly along the difficulty of its two implications, and the rest of the section follows that split. One direction is easy: *cut convergence forces the densities to converge*, and it falls straight out of the counting lemma of chapter 16, which bounds each density difference by the cut distance. The converse is the deep half: *convergence of all densities forces cut convergence*. It cannot come from the counting lemma, which controls densities by cut distance and never the reverse; it needs two genuinely new ingredients, the *compactness* of $(\widetilde{\mathcal{W}}_0, \delta_\square)$ to manufacture a convergent subsequence out of thin air, and a *moment-uniqueness* principle to pin that subsequence's limit to the intended target. The reliance on compactness here is not incidental — it is exactly why the next section must prove it, and why this section forward-references theorem 17.13 as an input rather than supplying it now. We take the tractable half first.

17.3.1 The easy direction: from cut distance to densities

We take up the split announced at the close of the section preamble and dispatch the tractable half first, both because it is genuinely a corollary and because the very inequality that makes it easy will reveal, by what it does *not* say, why the converse must be hard. The claim is the forward implication of the equivalence: *cut convergence forces the densities to converge*. What makes it forward and not converse is the direction of a single inequality we already own in chapter 16. The cut metric was engineered to register exactly the block-averaged interaction that homomorphism densities read off; it should therefore be no surprise that controlling the cut distance controls every density. The instrument that turns "should be no surprise" into a one-line proof is the counting lemma, and the entire content of this subsection is to import that lemma honestly, read off what its Lipschitz constant means, and then watch the corollary fall out.

The counting lemma is the bridge of chapter 16, and we restate it here so the argument that consumes it is self-contained on the page, while being explicit that the proof lives there and is not reproduced. In its cut-norm form it says that homomorphism densities are Lipschitz functions of the kernel in the cut norm, with a Lipschitz constant that is not some abstract universal but the concrete combinatorial size of the test pattern: its number of edges.

Lemma 17.9 (Counting lemma; recall lemma 16.17)**.** *For every finite simple graph F and all graphons U, W,*

$$|t(F,U) - t(F,W)| \;\le\; e(F)\;\|U - W\|_\square\,, \tag{17.11}$$

where $e(F) = |E(F)|$ is the number of edges of F (the notation of chapter 16, restated here in the more compact $e(F)$). Consequently, by lemma 17.5 and the infimum over relabelings, $|t(F,U) - t(F,W)| \le e(F)\,\delta_\square(U,W)$.

The constant $e(F)$ is worth dwelling on, because it is exactly what one should expect and its expectedness is reassuring. The density $t(F,U)$ is a multilinear integral in which the kernel U appears once for each edge of F: replacing U by W everywhere is a substitution in $e(F)$ slots at once, and if a single slot's worth of substitution costs at most $\|U - W\|_\square$, then $e(F)$ slots cost at most $e(F)$ times that. For the simplest patterns this reads off instantly. When F is a single edge, $e(F) = 1$ and the density is the edge density $t(F, U) = \int_{[0,1]^2} U$; the lemma then says edge densities differ by at most $\|U - W\|_\square$, which is barely more than the definition of the cut norm specialized to $S = T = [0, 1]$. When F is a triangle, $e(F) = 3$ and triangle densities are 3-Lipschitz; for the complete graph K_4 the constant climbs to 6. The constant grows with the pattern's complexity — richer observables are more sensitive — but it never depends on U or W, which is precisely the uniformity that lets us push a single cut-distance bound through all patterns at once.

We import lemma 17.9 as a black box, and self-containedness obliges us to point at the in-book proof rather than wave at the literature: it is exactly the cut-norm counting lemma established as lemma 16.17, restated here only under a local number for ease of reference. The argument there is a *telescoping edge-by-edge swap*, and it is worth recalling its shape in one sentence so the reader trusts the black box for the right reason. One writes the difference $t(F, U) - t(F, W)$ as a sum of $e(F)$ intermediate differences, in each of which a single copy of U is replaced by W while the other edge-factors are held fixed; each such single-slot difference is an integral that is linear in the one swapped kernel $U - W$, with the remaining factors acting as a $[0, 1]$-valued test weight, so it is bounded by one application of the cut norm (in the test-function form eq. (17.3)); summing the $e(F)$ telescoping steps and applying the triangle inequality yields the factor $e(F)$. That is the whole mechanism, and chapter 16 carries it out in full; we do not reprove it here.

The second sentence of the lemma is the passage from the cut *norm* to the cut *metric*, and although it is short it is the step that makes the whole import usable on $\widetilde{\mathcal{W}}_0$, so we spell it out rather than let it pass as "consequently." The bound eq. (17.11) is stated for labeled kernels and their literal difference $U - W$; the cut metric, by contrast, is the infimum $\delta_\square(U, W) = \inf_\varphi \|U - W^\varphi\|_\square$ over all relabelings φ (definition 17.6). To bridge them we use that the densities themselves are relabeling-invariant: by lemma 17.5, $t(F, W^\varphi) = t(F, W)$ for every measure-preserving φ, because a relabeling renames the types without changing any integral. Hence for *every* φ we may replace W by its relabeling on the right of eq. (17.11) without touching the left:

$$|t(F, U) - t(F, W)| = |t(F, U) - t(F, W^\varphi)| \;\le\; e(F)\; \|U - W^\varphi\|_\square .$$

The left side does not depend on φ, so it is bounded by the infimum of the right side over all φ, which is exactly $e(F)\, \delta_\square(U, W)$. This is why the lemma's constant survives the quotient intact: the densities cannot tell relabelings apart, so they are controlled by the best alignment, not merely the literal one. With that in hand the corollary is immediate.

Proposition 17.10 (Cut convergence implies left-convergence)**.** *If $\delta_\square(W_n, W) \to 0$ then (W_n) is left-convergent, with $t(F, W_n) \to t(F, W)$ for every finite simple graph F.*

Proof. By lemma 17.9, $|t(F, W_n) - t(F, W)| \le e(F)\, \delta_\square(W_n, W) \to 0$. □

One concrete instance closes the loop with the example that opened the chapter. For the noisy networks W_N of section 17.1, built by coin-flips at density $\frac{1}{2}$, the cut distance to the smooth limit $W \equiv \frac{1}{2}$ tends to zero even as every L^p distance stays pinned; proposition 17.10 now certifies what we asserted there by hand, that every density $t(F, W_N)$ converges — here to $(\frac{1}{2})^{e(F)}$ — with the approach governed quantitatively by $e(F)\,\delta_\square(W_N, W)$. The macroscopic observables follow the cut metric, exactly as designed.

This establishes the implication (ii)⇒(i) of the equivalence — cut convergence implies left-convergence — and it is more than a tidy first half. The subsequence argument of the hard direction will invoke this very proposition *twice*: once to verify that the convergent subsequence compactness hands it actually carries the right densities, and again to confirm that the limit it lands on is the one the densities demanded. It is the workhorse the deep direction stands on, so it is well that it costs only the counting lemma.

But the proposition's proof also exposes, in the plainest possible way, why the deep direction cannot be had by the same means. Everything here flowed from the single inequality eq. (17.11), and that inequality is resolutely one-directional: it bounds density differences *by* cut distance, never cut distance by density differences. It says small cut distance forces matching densities, but it is silent on whether matching densities force small cut distance — and there is no companion inequality in the other direction to invoke, because none can be elementary in the way this one is. To go from infinitely many scalar coincidences (all the densities agree in the limit) back to a single geometric fact (the cut distances shrink) is to reconstruct a point of the metric space from its complete list of moments, and a list of numbers does not, on its own, manufacture a limit in a space. What is missing is precisely a guarantee that the space is not too large to be pinned down this way — a guarantee that any sequence has somewhere to converge, so that the matching moments have a target to select. That guarantee is *compactness*, and the next subsection supplies it as the engine of the converse: compactness manufactures a convergent subsequence out of the bounded sequence, and moment-uniqueness pins that subsequence's limit to W. The one-directionality we have just met is exactly the gap that compactness is built to close.

17.3.2 The hard direction and the equivalence theorem

The easy direction closed by naming, with some precision, the exact thing it could not do: the counting lemma bounds density differences *by* cut distance and is silent in the other direction, so nothing it offers turns the infinitely many scalar coincidences of matching densities back into a single geometric statement about distance. The converse we now face — that convergence of all homomorphism densities forces convergence in the cut metric — is therefore the deep half, and it must be bought with machinery the counting lemma cannot supply. The shape of the purchase was already visible at the end of the last subsection: what is missing is a guarantee that the space is not too large to be pinned down by its moments, so that a sequence whose densities settle has somewhere to go and only one place it can go. Two imported facts deliver exactly this, and it is worth naming the job each one does before we use it, because the proof will then read as nothing more than snapping the two together.

The first is *compactness* of the metric space $(\widetilde{\mathcal{W}}_0, \delta_\square)$ (theorem 17.13, proved in the next section). Its role is existential: out of a bare sequence of graphons, with no candidate limit in sight, it manufactures a subsequence that actually converges in the cut metric to *some* graphon. This is the ingredient that supplies a target where the moments alone supply none — compactness produces a point of the space for the matching densities to select. The second is a *moment-uniqueness* principle:

the homomorphism densities determine a graphon completely, up to weak isomorphism, so that two graphons with identical densities are the same point of $\widetilde{\mathcal{W}}_0$. Its role is to *pin*: once compactness has handed us a convergent subsequence, moment-uniqueness forbids its limit from being anything other than the intended W. Compactness manufactures a limit; moment-uniqueness identifies it. Neither alone suffices — compactness without uniqueness would leave the limit ambiguous, uniqueness without compactness would leave no limit to identify — and the entire deep direction is the observation that, run together, they close the gap the counting lemma left open. We state the uniqueness principle first, since it is the ingredient not yet on the table, and then assemble the equivalence.

Theorem 17.11 (Moments determine the graphon)**.** *Two graphons U, W satisfy $t(F,U) = t(F,W)$ for every finite simple graph F if and only if $\delta_\square(U,W) = 0$, i.e. U and W are weakly isomorphic.*

Read the theorem as the assertion that the homomorphism densities are a *complete* set of invariants for a graphon: they separate the points of $\widetilde{\mathcal{W}}_0$ exactly, no two distinct networks sharing the same density table. The two directions are wildly unequal in depth, and it is worth being honest about which is which. The "if" direction — weak isomorphism implies equal densities — is no new work at all: it is proposition 17.10 applied to the *constant* sequence $W_n \equiv U$. For if $\delta_\square(U,W) = 0$ then trivially $\delta_\square(U,W) \to 0$, and the easy direction immediately yields $t(F,U) = t(F,W)$ for every F. The densities cannot tell weakly isomorphic graphons apart because they are relabeling-invariant, a fact we have owned since lemma 17.5. All the content sits in the "only if": that matching *all* subgraph densities forces the cut distance to be exactly zero. This is the graphon analogue of a classical *moment problem* — reconstructing a distribution from its complete list of moments — and the name is precise rather than decorative, as the mechanism makes plain.

That mechanism, which appendix F carries out in full and we sketch here only so the reader trusts the deferral for the right reason, runs through sampling — but through the *Bernoulli* sample, not a weighted one, and the distinction is the whole subtlety. Draw k types $x_1, \ldots, x_k$ independently and uniformly from $[0,1]$ and form the random *simple* graph $G(k,U)$ on k vertices that includes each edge $\{i,j\}$ independently with probability $U(x_i, x_j)$. The point is that the law of this $\{0,1\}$-valued graph is pinned down by the simple-graph densities. For a fixed target graph H on $[k]$, conditioning on the types gives $\mathbb{P}(G(k,U){=}H) = \mathbb{E} \prod_{\{i,j\} \in E(H)} U \prod_{\{i,j\} \notin E(H)} (1-U)$, and expanding the non-edge factors leaves each edge weight to the *first power only* — the edge indicator Z is $\{0,1\}$-valued, so $Z^2 = Z$ and no higher power can arise. Every term is thus a *multilinear* expected product $\mathbb{E} \prod_{ij \in E(F)} U(x_i, x_j) = t(F,U)$ over some simple graph F, so $\mathbb{P}(G(k,U){=}H)$ is a fixed finite linear combination of the densities $t(F,U)$ (the inclusion–exclusion passage from homomorphism to induced-subgraph counts). Equal densities for all F therefore force $G(k,U)$ and $G(k,W)$ to be *equal in law* for every k. It is essential that we run this through the Bernoulli sample: a simple graph F contributes only the multilinear moment $\mathbb{E} \prod_{ij \in E(F)} U(x_i, x_j)$, each edge to the first power, so the densities do *not* sweep out the genuinely higher moments such as $\mathbb{E}\, U(x_1, x_2)^2$ — those are *multigraph* (parallel-edge) densities, outside the simple-graph table — and hence do *not* determine the law of the weighted graph. The $\{0,1\}$ identity $Z^2 = Z$ is exactly what removes the higher moments and lets the densities fix the Bernoulli law outright. The bridge from this distributional equality back to the cut metric is the *second (Bernoulli) sampling lemma* (theorem F.9): a Bernoulli k-sample of a graphon is, with high probability, within cut distance $O(1/\sqrt{\log k})$ of the graphon it was drawn from, so $\mathbb{E}[\delta_\square(\cdot)] \to 0$ as $k \to \infty$. Pinching U and W between their common Bernoulli sample law gives $\delta_\square(U, W) \le \mathbb{E}[\delta_\square(U, U_{[k]})] + \mathbb{E}[\delta_\square(W_{[k]}, W)]$, where the middle term has been swapped to W using the equal sample laws; both terms are $O(1/\sqrt{\log k}) \to 0$, forcing $\delta_\square(U, W) = 0$. This is the theorem of Borgs–Chayes–Lovász; we defer its two quantitative inputs — the $\{0, 1\}$ determinacy of the Bernoulli sample law and the second sampling lemma — to appendix F (theorem F.11), flag it as one of the chapter's deep imports, and record it in the closing ledger as a deferral, with attribution [28, 99].

Theorem 17.12 (Cut convergence $\Leftrightarrow$ left-convergence)**.** *For graphons $W_n, W \in \mathcal{W}_0$ the following are equivalent:*

(i) $t(F, W_n) \to t(F, W)$ for every finite simple graph F (left-convergence);

(ii) $\delta_\square(W_n, W) \to 0$ (cut convergence).

Moreover every left-convergent sequence of graphons has a limit graphon: if all $t(F, W_n)$ converge, there exists $W \in \mathcal{W}_0$ with $\delta_\square(W_n, W) \to 0$.

Proof. The direction (ii) $\Rightarrow$ (i) is already in hand: it is precisely proposition 17.10, the easy direction. All the work is in (i) $\Rightarrow$ (ii).

Before the argument proper we isolate the topological principle it runs on, since it may be unfamiliar and it is doing the real organizing. *The subsequence principle.* In any metric space, a sequence (x_n) converges to a point x if and only if every subsequence of (x_n) has a *further* subsequence that converges to x. One direction is trivial: if the whole sequence converges to x, so does every sub-subsequence. The useful direction is the converse, and its contrapositive makes it transparent. If (x_n) did *not* converge to x, then some $\epsilon > 0$ is escaped infinitely often — there is a subsequence with $d(x_{n_k}, x) \ge \epsilon$ for all k — and that subsequence can have no further subsequence converging to x, since all of its terms sit a fixed distance ϵ away. So if every subsequence *does* admit a further subsequence converging to x, no such escaping subsequence can exist, and therefore $(x_n) \to x$. The principle is valuable in exactly the situation we are in: one cannot control the whole sequence directly, but one can always *extract* convergence from any piece of it — which is precisely the leverage compactness provides.

Now the argument. Assume $t(F, W_n) \to t(F, W)$ for every finite simple graph F; we must show $\delta_\square(W_n, W) \to 0$. By the subsequence principle it suffices to show that an *arbitrary* subsequence of (W_n) admits a further subsequence cut-converging to W. So fix any subsequence. Because $(\widetilde{\mathcal{W}}_0, \delta_\square)$ is compact (theorem 17.13, proved in the next section and — we stress — proved with no appeal whatever to the present theorem), this subsequence, like every sequence in a compact metric space, has a convergent sub-subsequence: there are a graphon U and an extraction (W_{n_j}) with $\delta_\square(W_{n_j}, U) \to 0$. This U is the target compactness manufactures, and at this stage we have no idea what it is. To identify it, we play its densities off against the hypothesis from two sides. On the one hand, the easy direction (ii) $\Rightarrow$ (i) applied to the convergent sub-subsequence gives $t(F, W_{n_j}) \to t(F, U)$ for every F — the first of the two promised uses of proposition 17.10. On the other hand, (W_{n_j}) is a subsequence of the original sequence, along which the hypothesis already forces $t(F, W_{n_j}) \to t(F, W)$. A sequence of real numbers has at most one limit, so the two coincide: $t(F, U) = t(F, W)$ for every F. Now moment-uniqueness (theorem 17.11) fires: matching all densities forces $\delta_\square(U, W) = 0$, that is, U *is* W as a point of $\widetilde{\mathcal{W}}_0$. Substituting this back, $\delta_\square(W_{n_j}, W) = \delta_\square(W_{n_j}, U) \to 0$: the extracted sub-subsequence cut-converges to W itself. The initial subsequence was arbitrary, so every subsequence has a further subsequence cut-converging to W, and the subsequence principle delivers $\delta_\square(W_n, W) \to 0$. This is (i) $\Rightarrow$ (ii).

It remains to prove the "moreover": that a left-convergent sequence has a limit graphon even when *no* candidate W is named in advance. This is the same argument run one notch earlier, and it is worth seeing that the candidate limit was never essential — compactness supplies it. Suppose only that $t(F, W_n) \to \ell_F$ for each F, the limits ℓ_F being some prescribed real numbers with no graphon attached to them. By compactness (theorem 17.13) extract a single subsequence (W_{n_j}) cut-converging to some graphon $W \in \mathcal{W}_0$. By the easy direction once more — the second promised use — its densities are the limits along that subsequence, $t(F, W) = \lim_j t(F, W_{n_j}) = \ell_F$ for every F. Thus the manufactured W *realizes* the prescribed density table ℓ_F: the abstract list of numbers has been incarnated as an actual point of the space. With this concrete W now in hand as a target, the equivalence just proved applies verbatim — since $t(F, W_n) \to \ell_F = t(F, W)$ for all F, part (i) $\Rightarrow$ (ii) gives $\delta_\square(W_n, W) \to 0$, and the *whole* sequence, not merely the extracted subsequence, converges to W in the cut metric. We emphasize what was *not* used. At no point did we need the density numbers ℓ_F to form a Cauchy or otherwise well-behaved family beyond their mere convergence, and at no point did we need a limit handed to us in advance. Moment-uniqueness alone does the pinning, converting "the densities settle" into "the graphons converge." □

Two remarks fix the logical dependencies, and both matter for how the rest of the chapter is read.

The first concerns circularity, and it is essential enough to state flatly. The proof of the equivalence *uses* the compactness theorem of the next section — twice, once in each half of the argument — but the compactness theorem does *not* use the equivalence. When we come to prove theorem 17.13 in section 17.4, the argument will run entirely inside the cut metric: total boundedness through the weak regularity lemma's energy increments, and completeness through a weak-$*$ extraction, neither of which so much as mentions homomorphism densities or the present theorem. There is thus no hidden loop in which compactness is invoked to prove the equivalence while secretly leaning on it. The dependency is strictly one-way, compactness $\Rightarrow$ equivalence, and the reader may treat the forward reference to theorem 17.13 as an honest IOU rather than a circular plea.

The second tallies the genuinely deep inputs, and they are exactly three. The counting lemma (chapter 16) supplied the easy direction; moment-uniqueness (theorem 17.11, whose hard half is the graphon moment problem deferred to appendix F) supplied the pinning; and compactness (theorem 17.13) supplied the limit to be pinned. Everything else in this section — the subsequence principle, the uniqueness of limits of real sequences, the playing-off of two density computations against each other — is soft point-set topology that the reader could reconstruct unaided. The depth of the equivalence is borrowed entirely from those three results, and two of the three are already paid for: the counting lemma was proved in chapter 16, and moment-uniqueness is charged honestly to appendix F, where this chapter's ledger will record it as a deferral.

That leaves precisely one of the three still unpaid, and it is the load-bearing one. The entire converse — and with it the first of the chapter's three senses, that cut convergence and left-convergence are one and the same notion — rests on the compactness of $(\widetilde{\mathcal{W}}_0, \delta_\square)$, which so far we have only *invoked*. We have used it to manufacture convergent subsequences out of thin air and never once justified that it holds. A forward reference is a promissory note, and this note now falls due: the next section must earn compactness outright. It is also, and not by coincidence, the chapter's announced destination — the structural keystone of Part III, the fact that lets a single limit graphon stand in for an entire growing sequence of networks. We turn to paying for it now.

17.4 Compactness of graphon space

We arrive at the structural keystone of Part III. The previous section left compactness of $(\widetilde{\mathcal{W}}_0, \delta_\square)$ as the one promissory note still unpaid — it was invoked twice to manufacture convergent subsequences and never once justified — and that note now falls due. But compactness is far more than a lemma owed to an earlier proof. It is the destination the chapter's preamble promised from the first page: the single structural fact that the rest of the book actually consumes. When a later existence proof must extract a convergent subsequence of approximate equilibria, or pass an equilibrium to a limit network, it is reaching for exactly this property; it is what licenses a single limit graphon to stand in for an entire convergent sequence of growing networks, and so it is the input from Part III that makes the existence theorem of chapter 24 and the finite-network convergence theorem of chapter 25 go through. Paying the debt and reaching the destination are, it turns out, the same act. We perform it now.

Theorem 17.13 (Lovász–Szegedy compactness)**.** *The metric space $(\widetilde{\mathcal{W}}_0, \delta_\square)$ of graphons modulo weak isomorphism is compact. Equivalently, every sequence of graphons has a subsequence that converges in the cut metric to a graphon.*

The two formulations are interchangeable because $(\widetilde{\mathcal{W}}_0, \delta_\square)$ is a metric space, where compactness, sequential compactness, and "every sequence has a convergent subsequence" all coincide; we proved in section 17.2 that we are working in a genuine metric space, so we may use whichever face of compactness is convenient and will mostly use the sequential one. The reader should pause on how strong the claim is. The space $\mathcal{W}_0$ of all graphons is enormous — it contains every measurable symmetric kernel $[0,1]^2 \to [0,1]$, an infinite-dimensional set with no finiteness anywhere in sight — and yet the theorem asserts that after we quotient by relabelings and measure distance with $\delta_\square$, this vast set becomes as tame as a closed bounded interval. No analogue holds for any of the L^p metrics of section 17.1: the noisy-network sequence W_N of the chapter's opening has *no* L^1-convergent subsequence (any two of its members stay a fixed positive L^1 distance apart, so it is uniformly discrete), and a uniformly discrete infinite set is the furthest thing from compact. The coarsening from $\|\cdot\|_1$ to $\|\cdot\|_\square$ is precisely what collapses that discreteness: in the cut metric the same sequence converges to the constant graphon $\frac{1}{2}$, and the theorem says this rescue happens for *every* sequence, with no exception. Compactness is thus the deepest dividend of the coarseness we engineered into the cut norm; the first three sections were the investment, and this is the return.

How does one prove a space compact when its points are infinite-dimensional objects and no coordinates are available? Through the standard structural characterization of compactness in metric spaces, which trades the topological condition for two concrete metric conditions that can be checked by hand.

Proposition 17.14 (Metric compactness dichotomy)**.** *A metric space is compact if and only if it is* complete *and* totally bounded*.*

This is a standard fact of point-set topology — it is part of the prerequisite toolkit, and we use it rather than reprove it — but it is worth recalling what its two halves demand, because the entire remaining labor of the chapter is the verification of one of them in full and an honest sketch of the other. *Total boundedness* is a finiteness-of-resolution condition: for every tolerance $\epsilon > 0$ the whole space can be covered by *finitely many* balls of radius ϵ. It says the space has no infinite supply of mutually ϵ-separated points — that at any fixed resolution there are only finitely many genuinely distinct graphons. This is the half that fails so spectacularly for L^1 and must succeed for $\delta_\square$, and it is the half that carries all the real mathematics. *Completeness* is the no-holes condition: every Cauchy sequence actually converges to a point of the space, so that the limits total boundedness lets us approach are genuinely present and are themselves graphons rather than escaping to some larger ambient set. Total boundedness manufactures candidate limits; completeness guarantees they live in the space. Both are needed, and proposition 17.14 says they are exactly enough.

Here we make the rigor commitment of the section explicit, because the self-containedness doctrine of this book requires us to say plainly which arguments we carry out in full and which we sketch, and never to dress a sketch as a proof. *The total-boundedness half we prove completely.* Its engine is the *weak regularity lemma* — the statement that every graphon is approximated in cut norm, to any prescribed accuracy, by a step kernel with a bounded number of blocks depending only on the accuracy and not on the graphon — and that lemma, with its beautiful energy-increment argument, is short and illuminating enough that withholding it would be a disservice; we give it whole, and total boundedness then follows by counting the finitely many step kernels at a fixed resolution. *The completeness half we sketch honestly.* We will exhibit the correct mechanism — a weak-$*$ compactness extraction in $L^\infty([0,1]^2)$, powered by the Banach–Alaoglu theorem imported from chapter 2, producing a candidate limit kernel — and explain why it yields a Cauchy sequence's limit; but the quantitative heart, that the weak-$*$ limit is approached in the *cut* metric and not merely weak-$*$, rests on a sampling/martingale estimate whose full execution we defer to appendix F. The chapter's ledger will record that deferral by name, alongside the moment-uniqueness deferral the previous section already charged to appendix F. The reader should hold the asymmetry firmly in mind: total boundedness, the half that does the work and supplies the regularity lemma later chapters reuse, is self-contained here; completeness, the more routine functional-analytic half, is the one leaning on a deferred estimate.

The work ahead therefore organizes itself into a short sequence of subsections, each preparing the next. We begin by building the machinery the regularity lemma runs on: the *block average* of a kernel relative to a finite partition — which we will recognize as a conditional expectation onto the partition's product σ-algebra, cashing in the coarse-graining picture of section 17.2 — and the *energy* of a partition, the monotone scalar quantity whose bounded ascent will drive the whole argument.

With that machinery in place we state and prove the *weak regularity lemma* by the energy-increment mechanism: if a step kernel is still far from U in cut norm, the cut witness exposes a refinement that strictly increases the energy by a fixed amount, and since the energy is bounded the refinement can only happen boundedly often. From the lemma we read off *total boundedness* by a finite count of step kernels at a fixed scale. We then dispatch *completeness* by the weak-$*$ sketch and assemble the two halves, through proposition 17.14, into the compactness theorem. A subsection on *why this is the keystone* draws the line from the bare topological fact to its consumption in Part III, and a closing *worked computation* on the rank-one and block graphons of the carried thread makes the regularity approximation concrete by exhibiting, on an explicit kernel, the finite step kernel that approximates it in cut norm. We take the first step now, making block averaging precise.

17.4.1 Block averages and the energy of a partition

Notation watch

In this section and the next, $\mathcal{P}$ and $\mathcal{Q}$ denote finite *partitions* of the type interval $[0,1]$, not probability measures: the calligraphic $\mathcal{P}$ that elsewhere in the book (appendix A) names a space of probability measures is locally repurposed for a partition, and no probability-measure $\mathcal{P}$ appears in this chapter to collide with it.

Fix a measurable partition $\mathcal{P} = \{P_1, \dots, P_k\}$ of $[0,1]$ into parts of positive measure. The *step kernel* (block average) of a kernel U relative to $\mathcal{P}$ is the conditional expectation of U given the product σ-algebra $\mathcal{P} \otimes \mathcal{P}$ generated by the rectangles $P_i \times P_j$:

$$U_{\mathcal{P}}(x,y) \;=\; \frac{1}{\lambda(P_i)\lambda(P_j)} \int_{P_i}\int_{P_j} U(x',y')\,\mathrm{d}x'\,\mathrm{d}y'\,, \qquad (x,y) \in P_i \times P_j. \tag{17.12}$$

By chapter 3, $U_{\mathcal{P}} = \mathbb{E}[U \mid \mathcal{P}\otimes\mathcal{P}]$ is the orthogonal projection of U in $L^2([0,1]^2)$ onto the finite-dimensional subspace of functions constant on each block-pair $P_i \times P_j$. A *step graphon with k steps* is any graphon of this block-constant form, determined by the part sizes $a_i = \lambda(P_i)$ and a symmetric matrix $(\theta_{ij}) \in [0,1]^{k\times k}$ of block values.

The driving quantity is the *energy* (or index) of a partition,

$$\mathcal{E}_U(\mathcal{P}) \;:=\; \|U_{\mathcal{P}}\|_2^2 \;=\; \sum_{i,j} a_i a_j\,\theta_{ij}^2, \tag{17.13}$$

the squared L^2 norm of the block average. Two facts make it the right monotone:

- *Boundedness.* Since $U_{\mathcal{P}}$ is an L^2 projection of U, $\mathcal{E}_U(\mathcal{P}) = \|U_{\mathcal{P}}\|_2^2 \le \|U\|_2^2 \le \|U\|_\infty^2 \le 1$ for a graphon $U \in [0,1]$.
- *Monotonicity under refinement.* If $\mathcal{Q}$ refines $\mathcal{P}$ then the block-constant subspace for $\mathcal{Q}$ contains that for $\mathcal{P}$, so projecting onto the larger subspace can only lengthen the projection: by the Pythagorean theorem,
$$\|U_{\mathcal{Q}}\|_2^2 \;=\; \|U_{\mathcal{P}}\|_2^2 + \|U_{\mathcal{Q}} - U_{\mathcal{P}}\|_2^2\,, \tag{17.14}$$
because $U_{\mathcal{Q}} - U_{\mathcal{P}}$ is orthogonal to the $\mathcal{P}$-subspace (the tower property of conditional expectation).

17.4.2 The weak regularity lemma

The next lemma says: *whenever a block average still differs appreciably from the kernel in cut norm, one can refine the partition and capture a definite quantum of energy.* Because the energy is bounded, this cannot go on forever, and the process terminates at a partition whose block average is cut-close to the kernel. This is the Frieze–Kannan *weak regularity lemma* [72], the workhorse of the whole theory.

Lemma 17.15 (Energy increment)**.** *Let U be a kernel and $\mathcal{P}$ a partition of $[0,1]$ into k parts. If $\|U - U_{\mathcal{P}}\|_\square > \epsilon$, then there is a refinement $\mathcal{Q}$ of $\mathcal{P}$ into at most $4k$ parts with*

$$\mathcal{E}_U(\mathcal{Q}) \;\geq\; \mathcal{E}_U(\mathcal{P}) + \epsilon^2.$$

Proof. Write $R := U - U_{\mathcal{P}}$. By eq. (17.2) and the hypothesis there exist measurable $S, T \subseteq [0,1]$ with $|\int_S \int_T R| > \epsilon$. Let $\mathcal{Q}$ be the common refinement of $\mathcal{P}$ with the two-set partition $\{S, S^c\}$ and the two-set partition $\{T, T^c\}$; each original part is cut into at most four pieces, so $\mathcal{Q}$ has at most $4k$ parts, and $\mathbf{1}_S$ and $\mathbf{1}_T$ are constant on the parts of $\mathcal{Q}$, hence $\mathbf{1}_{S\times T}$ is $\mathcal{Q}\otimes\mathcal{Q}$-measurable.

Because $U_{\mathcal{Q}} = \mathbb{E}[U \mid \mathcal{Q}\otimes\mathcal{Q}]$ and $\mathbf{1}_{S\times T}$ is $\mathcal{Q}\otimes\mathcal{Q}$-measurable, the defining property of conditional expectation gives $\int_{S\times T}(U - U_{\mathcal{Q}}) = 0$, that is $\int_S\int_T U = \int_S \int_T U_{\mathcal{Q}}$. The same identity at the coarser level reads $\int_S\int_T U_{\mathcal{P}}$ *need not* equal $\int_S\int_T U$, and indeed

$$\int_S\int_T (U_{\mathcal{Q}} - U_{\mathcal{P}}) = \int_S\int_T (U - U_{\mathcal{P}}) = \int_S\int_T R, \qquad \text{so} \qquad |\langle U_{\mathcal{Q}} - U_{\mathcal{P}}, \mathbf{1}_{S\times T}\rangle| > \epsilon.$$

By Cauchy–Schwarz in $L^2([0,1]^2)$ and $\|\mathbf{1}_{S\times T}\|_2 = (\lambda(S)\lambda(T))^{1/2} \leq 1$,

$$\epsilon < |\langle U_{\mathcal{Q}} - U_{\mathcal{P}}, \mathbf{1}_{S\times T}\rangle| \leq \|U_{\mathcal{Q}} - U_{\mathcal{P}}\|_2 \; \|\mathbf{1}_{S\times T}\|_2 \leq \|U_{\mathcal{Q}} - U_{\mathcal{P}}\|_2\,,$$

so $\|U_{\mathcal{Q}} - U_{\mathcal{P}}\|_2^2 > \epsilon^2$. Substituting into the Pythagorean identity eq. (17.14) gives $\mathcal{E}_U(\mathcal{Q}) = \mathcal{E}_U(\mathcal{P}) + \|U_{\mathcal{Q}} - U_{\mathcal{P}}\|_2^2 > \mathcal{E}_U(\mathcal{P}) + \epsilon^2$. ☐

Theorem 17.16 (Weak regularity lemma)**.** *For every $\epsilon > 0$ and every graphon U there is a partition $\mathcal{P}$ of $[0,1]$ into at most $4^{\lceil 1/\epsilon^2\rceil}$ parts with*

$$\|U - U_{\mathcal{P}}\|_\square \;\leq\; \epsilon.$$

Consequently every graphon lies within cut distance ϵ of a step graphon with a number of steps bounded by a function of ϵ alone, independent of U.

Proof. Start from the trivial partition $\mathcal{P}_0 = \{[0,1]\}$ $(k=1)$, with energy $\mathcal{E}_U(\mathcal{P}_0) = \big(\int_{[0,1]^2} U\big)^2 \geq 0$. While the current partition $\mathcal{P}_r$ satisfies $\|U - U_{\mathcal{P}_r}\|_\square > \epsilon$, apply lemma 17.15 to obtain $\mathcal{P}_{r+1}$ with $\mathcal{E}_U(\mathcal{P}_{r+1}) \geq \mathcal{E}_U(\mathcal{P}_r) + \epsilon^2$ and at most four times as many parts. Since the energy is nonnegative, increases by at least ϵ^2 at each step, and never exceeds 1 (a graphon has $\|U\|_\infty \leq 1$), the loop runs for at most $r_* \leq \lceil 1/\epsilon^2\rceil$ steps before the stopping condition $\|U - U_{\mathcal{P}_r}\|_\square \leq \epsilon$ is met. The terminal partition has at most $4^{r_*} \leq 4^{\lceil 1/\epsilon^2\rceil}$ parts, and $U_{\mathcal{P}_r}$ is the desired step graphon. ☐

Theorem 17.16 says that any network, however intricate, admits a *bounded-complexity effective description* accurate at the level of all coarse observables: a partition of types into a number of communities that depends only on the target accuracy ϵ, not on the size or detail of the network, within which the kernel may be replaced by its block average. The number of blocks $4^{1/\epsilon^2}$ is enormous, which is the honest price of demanding accuracy in the strong cut norm uniformly; the lemma is a statement about *existence* of a coarse model, not about its parsimony.

17.4.3 Total boundedness

Total boundedness now follows by discretizing the finitely many parameters of a step graphon. Recall that $(\widetilde{\mathcal{W}}_0, \delta_\square)$ is *totally bounded* if for every $\epsilon > 0$ it is covered by finitely many balls of radius ϵ.

Theorem 17.17 (Total boundedness)**.** *$(\widetilde{\mathcal{W}}_0, \delta_\square)$ is totally bounded.*

Proof. Fix $\epsilon > 0$ and set $k(\epsilon) = 4^{\lceil 1/\epsilon^2 \rceil}$. By theorem 17.16, every graphon U is within cut distance ϵ of a step graphon $U_{\mathcal{P}}$ with $k \le k(\epsilon)$ parts. A step graphon with k parts is determined up to relabeling (lemma 17.5: relabel each part onto a subinterval) by its vector of part sizes $a = (a_1, \dots, a_k)$, a probability vector, and its symmetric value matrix $\theta = (\theta_{ij}) \in [0,1]^{k \times k}$. We round both to finite grids.

Rounding the values. Replace each θ_{ij} by the nearest multiple of ϵ in $[0,1]$; call the result θ'. The corresponding step graphons differ by at most ϵ in L^∞, hence by at most ϵ in cut norm (by eq. (17.5), $\|\cdot\|_\square \le \|\cdot\|_1 \le \|\cdot\|_\infty$). There are at most $(\lceil 1/\epsilon \rceil + 1)^{k(k+1)/2}$ symmetric matrices θ' on this grid.

Rounding the sizes. Replace the size vector a by a vector a' whose entries are multiples of ϵ/k summing to 1 (round down and assign the remainder to one part); then $\sum_i |a_i - a_i'| \le \epsilon$. Changing the part sizes from a to a' while keeping the value matrix moves mass across blocks and changes the step graphon by at most $2\sum_i |a_i - a_i'| \le 2\epsilon$ in L^1, hence by at most 2ϵ in cut norm. There are finitely many such grid size-vectors for each k.

Combining, every graphon U is within cut distance $\epsilon + \epsilon + 2\epsilon = 4\epsilon$ of one of *finitely many* step graphons — those with $k \le k(\epsilon)$ parts, grid value matrix θ', and grid size vector a' — the total count being finite because each of k, θ', a' ranges over a finite set. This finite family is a 4ϵ-net for $(\widetilde{\mathcal{W}}_0, \delta_\square)$. As $\epsilon > 0$ was arbitrary, the space is totally bounded. $\square$

17.4.4 Completeness, and the conclusion

It remains to show that $(\widetilde{\mathcal{W}}_0, \delta_\square)$ is complete: every $\delta_\square$-Cauchy sequence converges to a graphon. This is the analytic heart of the theorem; we give the mechanism and defer the fully quantified construction to appendix F.

Proposition 17.18 (Completeness; sketch, full proof in appendix F)**.** *$(\widetilde{\mathcal{W}}_0, \delta_\square)$ is complete.*

Proof sketch. Let (W_n) be $\delta_\square$-Cauchy. Passing to a subsequence we may assume $\delta_\square(W_n, W_{n+1}) < 2^{-n}$; since a Cauchy sequence with a convergent subsequence converges, it suffices to produce a limit of this subsequence. Using only that $\delta_\square$ is an infimum over measure-preserving bijections, choose for each n a *near-optimal* bijection and replace W_{n+1} by the corresponding representative, aligning the representatives so that $\|V_n - V_{n+1}\|_\square < 2^{-n}$ holds for the aligned kernels V_n (no attainment is needed — a bijection within 2^{-n} of the infimum exists by definition of the infimum). The aligned sequence (V_n) is thus Cauchy in the cut *norm*.

The limit is now extracted by functional analysis rather than by a martingale. The graphons form a subset of the closed unit ball of $L^\infty([0,1]^2)$, which is weak-$*$ compact by the Banach–Alaoglu theorem (imported from chapter 2); as $L^\infty([0,1]^2)$ is the dual of the separable space $L^1([0,1]^2)$, the ball is weak-$*$ *sequentially* compact, so a subsequence of (V_n) converges weak-$*$ to some $W \in L^\infty$. The graphon constraints $0 \le W \le 1$ and $W(x,y) = W(y,x)$ a.e. cut out a convex, weak-$*$ closed set (each is an intersection of half-spaces $\langle \cdot\,, h\rangle \le c$ with $h \in L^1$), so the limit W is again a graphon. Finally the cut-norm Cauchy estimates pass to the weak-$*$ limit: for fixed S, T the test function $\mathbf{1}_{S\times T}$ lies in L^1, so $|\langle V_n - W, \mathbf{1}_{S\times T}\rangle| = \lim_m |\langle V_n - V_m, \mathbf{1}_{S\times T}\rangle| \le \sup_{m\ge n} \|V_n - V_m\|_\square$, and taking the supremum over S, T gives $\|V_n - W\|_\square \to 0$, hence $\delta_\square(W_n, W) \to 0$. The fully quantified version — in particular the bookkeeping of the simultaneous alignments — is carried out in appendix F (theorem F.5), by exactly this weak-$*$ route. $\square$

Proof of theorem 17.13. By theorem 17.17 the space $(\widetilde{\mathcal{W}}_0, \delta_\square)$ is totally bounded, and by proposition 17.18 it is complete. A metric space that is both totally bounded and complete is compact (equivalently, sequentially compact: from total boundedness every sequence has a Cauchy subsequence, and completeness supplies its limit). Hence $(\widetilde{\mathcal{W}}_0, \delta_\square)$ is compact. $\square$

17.4.5 Why this is the keystone

Compactness of $\widetilde{\mathcal{W}}_0$ is exactly the property a fixed-point or limiting argument needs when the unknown is itself a network. Three downstream uses, made precise later, show its weight.

- *Existence of equilibria with a varying network.* In chapter 24 a graphon mean field equilibrium is sought as a fixed point of a best-response map that depends continuously (in $\delta_\square$, under (A-Reg-W)) on the underlying graphon. Compactness of $\widetilde{\mathcal{W}}_0$ supplies the convergent subsequences of approximate equilibria that a Schauder/Kakutani argument (chapter 2, chapter 10) converts into an exact one; without it the space of admissible networks would be too large to close the argument.

- *Finite networks converge to a limit.* The final statement of theorem 17.12 guarantees that a left-convergent sequence of growing finite networks — the sampled graphs $G(N, W)$ of chapter 19, each identified with its step graphon $W_{G(N,W)}$ via proposition 16.9 so that the equivalence theorem applies verbatim — has an honest graphon limit. Compactness is what forbids a convergent stream of observables from corresponding to "no limiting object," so a single graphon can legitimately stand in for the whole sequence.

- *Stability under network perturbation.* Because homomorphism densities, and (under (A-Reg-W)) the equilibrium maps of Part IV, are continuous in $\delta_\square$, two networks that are $\delta_\square$-close yield close equilibria. Chapter 25 turns this into the statement that the graphon mean field equilibrium is an ϵ-Nash equilibrium on any large finite network drawn from a nearby graphon — the practical justification for using the limit theory to design interventions on real graphs.

Physics note

A compact metric space of order parameters is a comfortable place to do physics: every sequence of candidate states has a convergent subsequence, so variational and limiting arguments never leak their minimizers or accumulation points out of the space. The space of graphons is the order-parameter manifold for network structure, and theorem 17.13 says it is compact in the natural macroscopic metric. The reader should resist over-reading this as a thermodynamic statement: there is no energy functional or partition function on $\widetilde{\mathcal{W}}_0$ here, only a metric geometry. The payoff is structural, not dynamical — it is the guarantee that the existence machinery of Part IV has somewhere to land.

17.4.6 Worked computation: cut norm and approximation of the thread graphons

Worked computation 17.19 (Cut norm of the rank-one graphon and its block approximation)**.** We compute the cut norm in two cases tied to the carried threads, then watch a graphon being coarse-grained as in theorem 17.16. Recall (chapter 15) that the *constant* graphon $W \equiv c$ recovers the homogeneous (Thread A) coupling, while the *rank-one* graphon $W(x,y) = f(x)f(y)$, with $f\colon [0,1] \to [0,1]$ measurable, is the "Curie–Weiss" kernel of Thread B whose aggregate $\mathbb{W}\bar{m}$ collapses to a scalar order parameter times f.

(a) The constant graphon. For $W \equiv c$, $\int_S \int_T c = c\,\lambda(S)\lambda(T)$, maximized over $\lambda(S), \lambda(T) \le 1$ at $S = T = [0,1]$, so $\|c\|_\square = |c|$. The cut norm of a constant kernel is its absolute value, matching the L^1 norm; here the comparison eq. (17.5) is an equality because there is no fluctuation to discard.

(b) The rank-one graphon. With $W(x,y) = f(x)f(y)$, the function form eq. (17.3) factorizes:

$$\int_{[0,1]^2} u(x)\, f(x)f(y)\, v(y)\ \mathrm{d}x\,\mathrm{d}y = \Big(\int_[0,1] uf\Big)\Big(\int_[0,1] fv\Big).$$

Each factor is maximized over $u, v \in [0,1]$ by taking $u = v = \mathbf{1}_{\{f>0\}} = 1$ (as $f \ge 0$), giving $\int_[0,1] f$ in each. Hence

$$\|W\|_\square = \Big(\int_[0,1] f\Big)^2 = \bar{f}^{\,2}, \qquad \bar{f} := \int_[0,1] f.$$

The cut norm of a rank-one graphon is the square of the mean of its profile. Compare the spectral bound of lemma 17.3: the operator $\mathbb{W}$ here is the rank-one projection-like map $g \mapsto f\,\langle f, g\rangle$, with operator norm $\|\mathbb{W}\|_{2\to2} = \|f\|_2^2 = \int_[0,1] f^2$, and indeed $\bar{f}^{\,2} = (\int f)^2 \le \int f^2 = \|f\|_2^2$ by Cauchy–Schwarz, confirming $\|W\|_\square \le \|\mathbb{W}\|_{2\to2}$ with equality iff f is constant. This is exactly the regime in which Thread B reduces to Thread A: a constant profile f makes the rank-one and constant graphons coincide and saturates the comparison.

(c) Block approximation and total boundedness in action. Take the explicit profile $f(x) = x$, so $W(x, y) = xy$, a smooth rank-one graphon, and coarse-grain it on the uniform partition $\mathcal{P}_k$ of $[0, 1]$ into k equal intervals $P_i = [\frac{i-1}{k}, \frac{i}{k}]$. The block average eq. (17.12) is the product of the interval means, $W_{\mathcal{P}_k} = \theta_{ij}$ with $\theta_{ij} = (\frac{2i-1}{2k})(\frac{2j-1}{2k})$, a step graphon with k steps — a rank-one block model. The error kernel $R = W - W_{\mathcal{P}_k}$ factorizes within each block as $xy - \bar{x}_i\bar{y}_j$ where $\bar{x}_i = \frac{2i-1}{2k}$; on $P_i \times P_j$, $|R| \le |x - \bar{x}_i|\ y + \bar{x}_i\,|y - \bar{y}_j| \le \frac{1}{2k} + \frac{1}{2k} = \frac{1}{k}$, so $\|R\|_\infty \le 1/k$ and a fortiori $\|R\|_\square \le \|R\|_1 \le 1/k \to 0$. Thus the rank-one thread graphon is approximated in cut norm, at rate $1/k$, by rank-one block models with k steps — a concrete instance of the finite-net construction behind theorem 17.17, and the bridge by which the continuum Thread B kernel is replaced, with controlled cut-norm error, by a finite block graphon (the multi-population reduction revisited in chapter 22).

(d) Relabeling invisibility. Finally, let $\varphi(x) = 1 - x$, a measure-preserving involution, and set $W' = W^\varphi$, i.e. $W'(x, y) = (1 - x)(1 - y)$. As kernels $W \ne W'$ and $\|W - W'\|_1 > 0$, yet by construction $\delta_\square(W, W') = 0$: they are weakly isomorphic, the same point of $\widetilde{\mathcal{W}}_0$. Reversing the labeling of types — reading centrality from the right end of $[0, 1]$ instead of the left — changes nothing a homomorphism density or the mean field coupling can detect, exactly as lemma 17.5 predicts. This is the smallest nontrivial example of the quotient at work.

Rigor ledger

Proved (in full or by self-contained computation).

- The three equivalent forms of the cut norm (lemma 17.2), the comparison inequalities $\|\cdot\|_\square \le \|\cdot\|_1 \le \|\cdot\|_2 \le \|\cdot\|_\infty$ and $\|\cdot\|_\square \le \left\|\mathbb{W}_{(\cdot)}\right\|_{2\to2}$ (lemma 17.3), and that $\|\cdot\|_\square$ is a norm.
- Relabeling invariance of the cut norm and of homomorphism densities (lemma 17.5); that $\delta_\square$ is a pseudometric — symmetry, the triangle inequality (by composition of near-optimal bijections plus relabeling invariance), transitivity of weak isomorphism, and the induced genuine metric on the quotient $\widetilde{\mathcal{W}}_0$ — *in full* (proposition 17.7).
- The easy direction of the equivalence: cut convergence implies left-convergence (proposition 17.10), via the imported counting lemma.
- The energy-increment lemma (lemma 17.15) and the weak regularity lemma (theorem 17.16) *in full*, by the energy-increment argument.
- Total boundedness of $(\widetilde{\mathcal{W}}_0, \delta_\square)$ *in full* (theorem 17.17), by weak regularity plus a finite discretization of the step-graphon parameters.
- The compactness theorem (theorem 17.13) conditional on completeness, via "totally bounded + complete ⇒ compact."
- The worked computation (worked computation 17.19): cut norms of the constant and rank-one thread graphons, the $1/k$ block-approximation rate, and an explicit weak-isomorphism pair.

Assumed (imported, used without re-proof).

- The graphon and its operator $\mathbb{W}$ (chapter 15); the homomorphism density $t(F,\cdot)$ and left-convergence (chapter 16); the counting lemma eq. (17.11) (lemma 17.9, proved in chapter 16).
- Conditional expectation as L^2 orthogonal projection and the tower property (chapter 3); L^p spaces, Fubini, and the Pythagorean identity in $L^2([0,1]^2)$ (chapters 1 and 2); the metric-space fact "totally bounded + complete = compact" (elementary point-set topology).
- Standing assumption (A-Reg-W) (symmetric, measurable, bounded W; $\mathbb{W}$ self-adjoint Hilbert–Schmidt) wherever the operator-norm comparison or the Part IV continuity statements are invoked.

Deferred (stated, proof pointed elsewhere).

- The equivalent coupling/overlay reformulation of $\delta_\square$ and the attainment of its infimum (remark 17.8): *not used* in this chapter — the metric structure is proved directly above without it — and recorded only as the route that identifies weak isomorphism with measure-preserving isomorphism; see [99, Ch. 8].
- The moment-uniqueness theorem (theorem 17.11, "only if"): mechanism named (sampling lemma plus moment-determinacy of bounded variables); full in-book proof in appendix F (theorem F.11), with attribution [28, 99].
- Completeness of $(\widetilde{\mathcal{W}}_0, \delta_\square)$ (proposition 17.18): the mechanism — align representatives by near-optimal bijections, then extract a weak-$*$ limit graphon from the closed L^∞ ball by Banach–Alaoglu (chapter 2) — is given in the sketch above; the fully quantified construction is theorem F.5 in appendix F.

Open / honestly flagged.

- The whole development is the *dense*, bounded ($[0,1]$-valued) theory. For the sparse and L^p-graphon regimes of chapter 27 the cut norm must be renormalized and compactness in the present form *fails*; what survives is discussed there. The compactness theorem is a feature of dense graph limits specifically.
- The number of steps $4^{1/\epsilon^2}$ in theorem 17.16 is essentially best possible for the strong cut norm and is astronomically large; it makes the lemma a tool for existence and qualitative structure, not a practical compression. Quantitative regularity with usable bounds requires extra structure (e.g. bounded operator rank), taken up in chapters 18 and 19.

Bibliographic notes

The cut norm and cut metric, and the theorem that left-convergence of dense graph sequences coincides with convergence in the cut metric, are due to Borgs, Chayes, Lovász, Sós, and Vesztergombi [29]; our theorem 17.12 and proposition 17.7 follow their development, and the equivalent overlay/coupling formulations of $\delta_\square$ recorded in remark 17.8 are theirs; our in-chapter proof that $\delta_\square$ is a metric instead uses only composition of near-optimal bijections, so it does not invoke those formulations. The compactness of graphon space, theorem 17.13, is the Lovász–Szegedy theorem [100]; the survey [98] is the gentlest first reading, and the monograph [99] (especially Chapters 8, 9, and 11) is the comprehensive reference and the source for the full proofs we deferred to appendix F. The weak regularity lemma theorem 17.16, and the energy-increment argument lemma 17.15 that proves it, are due to Frieze and Kannan [72]; the formulation via conditional expectation and the L^2 projection energy is the one in [99, Ch. 9], and it is this argument, rather than Szemerédi's original regularity lemma, that we use because it is self-contained and yields the bounded-step approximation directly. The moment-uniqueness theorem theorem 17.11 — that homomorphism densities determine a graphon up to weak isomorphism — is proved by Borgs, Chayes, and Lovász [28]. The operator-norm reading of the cut norm via the $L^\infty \to L^1$ norm eq. (17.4) is standard and connects to the spectral theory of chapter 18. The use of graphon compactness as the structural input to existence and finite-network convergence in graphon mean field games — our chapters 24 and 25 — traces to the Caines–Huang program [33, 34] and the static graphon-game theory of Parise and Ozdaglar [108].

Chapter 18

Graphons as Operators: Spectral Theory

The previous three chapters built the graphon as a *combinatorial* and *metric* object: a symmetric kernel W on $[0,1]^2$ (chapter 15), the moments of which are the homomorphism densities $t(F, W)$ (chapter 16), and the geometry of which is the cut metric $\delta_\square$ that makes graphon space compact (chapter 17). This chapter develops the *third* face of the same object, the one that will do the analytic work in Part IV: the graphon as a *self-adjoint Hilbert–Schmidt operator*

$$(\mathbb{W}f)(x) = \int_0^1 W(x, y)f(y)\ \mathrm{d}y$$

on $L^2[0,1]$. The phrase "third face" is meant literally. Nothing on the page changes between these chapters — it is one and the same symmetric kernel $W(x, y)$ throughout — and what changes is only the question we put to it. Chapter 16 asked how many copies of a small graph the kernel contains; chapter 17 asked how far it sits from another kernel in the cut metric; now we ask what happens when we let it *act*, repeatedly, by integration against test functions. The spectrum is the answer to that last question. The reader should picture this chapter not as building a new object but as slotting a single new lens onto an already-familiar one: the kernel is fixed, and we are merely learning to read it spectrally.

That this is no new construction at all is worth stressing, because it sets the tone of the chapter as a collection of promised payoffs rather than a fresh development. The operator $\mathbb{W}$ was defined in definition 2.23, shown to be self-adjoint Hilbert–Schmidt in proposition 2.24, and diagonalised by the spectral theorem theorem 2.26; its spectrum was even computed in closed form for the constant and rank-one kernels in worked computation 2.28. Chapter 2 staged all of this deliberately and promised the payoff here. We now collect it.

Why does Part IV need this third face specifically, and not merely the combinatorial and metric ones already in hand? Because in a graphon mean field game the coupling between types *is* the operator $\mathbb{W}$. A player of type x feels the rest of the population not individually but through the kernel-weighted average $\int_0^1 W(x, y)\, m(y)\ \mathrm{d}y = (\mathbb{W}m)(x)$ of the others' states, so the map from a population profile m to the environment a type actually experiences is exactly $\mathbb{W}$ acting on

$L^2[0,1]$. Solving for equilibrium then amounts to inverting, iterating, or linearising this one operator, and every such operation is diagonal in the spectral basis. Understanding equilibria therefore reduces, again and again in the chapters to come, to understanding the spectrum of $\mathbb{W}$: which mode dominates the coupling, how fast the subdominant modes decay under repetition, and how the whole spectrum moves when the kernel is perturbed or sampled. A single identity makes the entire chapter cohere and deserves to be named at the outset — the power sums of the spectrum are the cycle homomorphism densities of chapter 16,

$$\sum_n \lambda_n^k \;=\; t(C_k, W).$$

This is the hinge of the chapter. It is the one statement that lets the combinatorial accounting of chapter 16 and the metric continuity of chapter 17 reach *into* the spectrum: cycle densities are objects those chapters already control completely, and the identity converts that control directly into control of the eigenvalues. Every convergence statement below, and several of the closed forms in later chapters, run through it.

The chapter has four movements. First (section 18.1) we assemble the spectral decomposition of $\mathbb{W}$ into a usable form: the eigenvalue sequence, the Mercer-type expansion of the kernel, and the identity that ties the spectrum back to chapter 16 — the k-th spectral moment is the homomorphism density of the k-cycle. Second (section 18.2) we read the leading eigenfunction as *eigenvector centrality* via an infinite-dimensional Perron–Frobenius theorem. Third (section 18.3) we read the *spectral gap* as the rate of mixing and the *near-degeneracies* of the top of the spectrum as community structure, working the two-block stochastic block model out by hand. Fourth (section 18.4) we settle the relationship between the metric of chapter 17 and the spectrum: cut convergence implies convergence of every individual eigenvalue, but is strictly weaker than operator-norm convergence, and only the stronger notion controls eigen*functions*. The final section (section 18.5) cashes the spectral theory into the carried Thread B: finite-rank graphons collapse the infinite-dimensional graphon mean field game to a finite system of scalar order parameters, and every graphon admits a controlled low-rank reduction. Throughout, W obeys the standing regularity assumption (A-Reg-W) of appendix A.6, so $\mathbb{W}$ is self-adjoint Hilbert–Schmidt; additional continuity of W is invoked only where named — chiefly in Mercer's theorem (theorem 18.2), and nowhere in the load-bearing moment identity.

Notation watch

This is the first chapter of Part IV in which a graphon and a stochastic noise will come to share the page, so we restate here the book's resolution of a standing letter clash (fixed in appendix A.5). Both Brownian motion and the graphon traditionally want the symbol W. The convention from Part III onward is that, *whenever a graphon W is in scope* — as it is everywhere from here to the end of the book — Brownian motion is written B (so B_t, with increments $\mathrm{d}B_t$), while W is reserved for the kernel W and $\mathbb{W}$ for its integral operator. No Brownian motion actually appears in the present chapter, which is purely spectral; we record the convention now so that the dynamic chapters built on this spectral theory inherit it without a second announcement.

18.1 The spectral decomposition of the graphon operator

We now record, in the notation we keep for the rest of Parts III and IV, what the spectral theorem of chapter 2 hands us. It is fair to ask why a decomposition already proved deserves a section of its own rather than a one-line reminder, and the honest answer is bookkeeping: everything downstream in this chapter — centrality, the gap, spectral convergence, low rank — is a *reading* of the very same eigenvalues and eigenfunctions, and those readings pull on the spectrum in incompatible ways unless the names are fixed once, carefully, in advance. Two of those readings sort the eigenvalues by size and two sort them by sign; one wants to evaluate the kernel pointwise and another must scrupulously avoid doing so. If we do not settle these distinctions now they will resurface as confusion exactly where the argument is most delicate. So this foundational section does nothing but lay down a usable working form for the spectral data — and it is genuinely foundational: nothing here is read for its own sake, only to be deployed later.

The section has three beats, and their order is not arbitrary. First (definition 18.1 and its surrounding discussion) we organise the output of the spectral theorem — the spectral expansion that the whole section orbits — and fix the *two orderings* of the eigenvalues, by modulus and by sign, that the rest of Part IV will switch between. Second we confront the natural question raised the moment one writes the kernel as a sum of eigenfunction products: does that sum converge *pointwise*, so that one may read off a value $W(x, y)$ or, more pointedly, a diagonal value $W(x, x)$? The classical answer is Mercer's theorem, and the reason it comes second is that its hypothesis — positive semidefiniteness — generically *fails* for graphons, and recognising this failure is what forces the third beat to be proved the way it is. Third and most important, we establish the moment identity $\sum_n \lambda_n^k = t(C_k, W)$, the hinge advertised in the chapter opening, by a route that pairs Hilbert–Schmidt iterates against each other and so never touches the diagonal — precisely because Mercer is unavailable. Mercer must therefore precede the moment identity: it is the obstacle the moment-identity proof is built to sidestep.

What this section exports is small to state and used everywhere. The named pair (λ_n, e_n) and the two orderings travel forward verbatim: section 18.2 reads the leading eigenfunction e_1 as centrality, and section 18.3 reads the pair λ_1, λ_2 as a gap. The moment identity and the uniform ℓ^2 tightness it delivers — only finitely many eigenvalues can be large, and the bound is the same for *every* graphon — are the entire engine of the spectral convergence theorem of section 18.4. With that map in hand we begin where every reading must, with the eigenvalues, the eigenfunctions, and how we agree to list them.

18.1.1 Eigenvalues, eigenfunctions, and orderings

The spectral theorem of chapter 2 has already done the hard analytic work; what is left for us here is the seemingly clerical but genuinely load-bearing task of writing its output in a form we can live with for the rest of Parts III and IV. The output is a single expansion, and everything later in the chapter is a way of reading it, so we begin by fixing it on the page and then deciding, once and carefully, how to list the numbers it contains. By proposition 2.24 the operator $\mathbb{W}$ is compact and self-adjoint on $L^2[0, 1]$, so the spectral theorem theorem 2.26 applies verbatim: there is an orthonormal system of eigenfunctions $\{e_n\} \subseteq L^2[0,1]$ and real eigenvalues $\{\lambda_n\}$, repeated according to multiplicity, with

$$\mathbb{W}f \;=\; \sum_n \lambda_n \langle f, e_n\rangle\, e_n, \qquad W(x,y) \;=\; \sum_n \lambda_n\, e_n(x)\, e_n(y) \;\text{ in } L^2([0,1]^2), \tag{18.1}$$

where $\langle f, g\rangle = \int_0^1 fg$ is the real L^2 inner product. This is the object the orderings will organise, so it is worth being slow about exactly what its two halves say and why they are the same statement.

The first equality is the operator form: it asserts that $\mathbb{W}$ acts on any test function f by resolving f into its components along the eigendirections e_n, scaling the n-th component by λ_n, and reassembling. This is the literal content of "diagonalisation" — in the basis $\{e_n\}$ the operator is multiplication by the sequence (λ_n). The second equality is the kernel form, and it is not a new fact but a translation of the first through the kernel–operator dictionary of theorem 2.22, which says that a Hilbert–Schmidt operator and its $L^2([0,1]^2)$ kernel determine each other. Apply that dictionary term by term. The n-th summand of the operator form is the rank-one operator $P_n\colon f \mapsto \langle f, e_n\rangle e_n$, the orthogonal projection onto the line $\mathbb{R}e_n$. Writing its action out,

$$(P_n f)(x) = \langle f, e_n\rangle\, e_n(x) = \Big(\int_0^1 f(y)e_n(y)\;\mathrm{d}y\Big)e_n(x) = \int_0^1 e_n(x)\, e_n(y)\, f(y)\;\mathrm{d}y,$$

we read off that P_n is integration against the kernel $e_n(x)e_n(y)$ — the outer product of e_n with itself. Summing with the weights λ_n gives precisely the kernel form of eq. (18.1). The only thing left to justify is that the infinite sum on the right actually converges as a function of two variables, and here the Hilbert–Schmidt structure pays for itself. The tensor products $\{e_n \otimes e_n\}$, where $(e_n \otimes e_n)(x,y) = e_n(x)e_n(y)$, are orthonormal in $L^2([0,1]^2)$ (they are part of the product orthonormal basis $\{e_m \otimes e_n\}$), so the partial sums of the kernel series have squared increments $\|\sum_{M<n\le N} \lambda_n\, e_n \otimes e_n\|^2_{L^2([0,1]^2)} = \sum_{M<n\le N} \lambda_n^2$. This is a Cauchy tail precisely when $\sum_n \lambda_n^2 < \infty$ — which holds, and with a value we already know: $\sum_n \lambda_n^2 = \|W\|^2_{L^2([0,1]^2)} = \|W\|^2_{\mathrm{HS}} < \infty$ by proposition 2.24. So the kernel series converges in $L^2([0,1]^2)$, and its limit is W because both sides represent the same operator. The convergence is in $L^2([0,1]^2)$ and *only* there for a general graphon; whether one may evaluate the series at a fixed point (x,y), in particular on the diagonal $x = y$, is a strictly harder question we postpone to theorem 18.2.

The same finiteness $\sum_n \lambda_n^2 < \infty$ also explains the two structural facts about the eigenvalues that we will lean on constantly: they *accumulate only at* 0, and each nonzero eigenvalue has *finite multiplicity*. Both are immediate from square-summability — for any threshold $\varepsilon > 0$, at most ε^{-2} of the λ_n can exceed ε in modulus, or their squares would already overflow the bound — which is just the concrete face of the compactness of $\mathbb{W}$ established in proposition 2.24. A compact self-adjoint operator has exactly this spectral shape: a discrete sequence of real eigenvalues piling up at 0, each repeated finitely often. We will return to this ℓ^2 tightness as the engine of spectral convergence; for now it is what guarantees that the lists we are about to write down are honest lists, with a genuine first entry, second entry, and so on.

That brings us to the listing itself, which is the real business of this subsection. There is no single canonical way to enumerate the λ_n, and the two natural ways disagree — not pedantically but substantively, because they answer different questions. We therefore fix both now, with names, and resolve once and for all which one each later section is using.

Definition 18.1 (Spectrum and its orderings)**.** Let W satisfy (A-Reg-W) and let $\mathbb{W}$ be its operator. The *spectrum* of W is the multiset of nonzero eigenvalues of $\mathbb{W}$, denoted $\mathrm{spec}(W)$. We list it two ways.

- *Modulus order* (as in theorem 2.26): $|\lambda_1| \geq |\lambda_2| \geq \cdots > 0$, with $\lambda_n \to 0$.
- *Signed order*: the positive eigenvalues listed decreasingly, $\lambda_1^+ \geq \lambda_2^+ \geq \cdots > 0$, and the negative eigenvalues listed increasingly, $\lambda_1^- \leq \lambda_2^- \leq \cdots < 0$ (either list may be finite or empty).

We write $\rho(\mathbb{W}) = \|\mathbb{W}\| = |\lambda_1| = \max(\lambda_1^+, -\lambda_1^-)$ for the spectral radius.

Why carry two orderings rather than pick one and convert? Because the conversion destroys exactly the information each ordering exists to preserve, and both pieces of information are indispensable downstream. The modulus order is what the spectral theorem natively hands us, and it is the right ledger whenever the quantity we are estimating depends only on *sizes*: the operator norm is $\|\mathbb{W}\| = |\lambda_1|$, the rate at which repeated averaging by $\mathbb{W}$ kills subdominant modes is governed by the ratio $|\lambda_2| / |\lambda_1|$, and the ℓ^2 tail $\sum_{n>N} \lambda_n^2$ that measures truncation error cares nothing for sign. In all of these the sign of an eigenvalue is invisible, and forcing signs into the bookkeeping would only clutter it. The signed order, by contrast, is what the Courant–Fischer min–max principle corollary 2.27 produces — it builds the positive eigenvalues by maximising the Rayleigh quotient $\langle \mathbb{W}g, g\rangle$ over successively smaller subspaces and the negative ones by minimising it — and it is the right ledger whenever the *sign* carries meaning. It does so exactly twice in this chapter, and both times decisively: the leading *positive* eigenvalue λ_1^+ is the one whose eigenfunction is nonnegative and reads as centrality (section 18.2), and the sign pattern at the top of the spectrum is what distinguishes a clustered community from a bipartite one (section 18.3).

The two orderings really can disagree, so it is worth seeing once how. Imagine a (signed, rank-three) kernel whose nonzero eigenvalues are $+0.6$, -0.4, and $+0.2$. In modulus order the list is $\lambda_1 = +0.6$, $\lambda_2 = -0.4$, $\lambda_3 = +0.2$, so "the second eigenvalue λ_2" is the *negative* number -0.4. In signed order the positive list is $\lambda_1^+ = +0.6$, $\lambda_2^+ = +0.2$ and the negative list is $\lambda_1^- = -0.4$, so "the second positive mode λ_2^+" is $+0.2$. The phrase "the second eigenvalue" is therefore ambiguous until the ordering is named — it denotes -0.4 under one convention and $+0.2$ under the other — and this is exactly the ambiguity that, left unresolved, would corrupt the gap estimates of section 18.3, where "the gap below the top" is a statement about $|\lambda_2|$ but "the principal gap between the two clustering modes" is a statement about λ_2^+. From here on the rule is simple: when a statement is about size we write $|\lambda_n|$ and mean the modulus order; when it is about a positive (or negative) mode we write λ_n^+ (or λ_n^-) and mean the signed order.

Notation watch

The two orderings genuinely differ and both are standard; the modulus order $|\lambda_1| \geq |\lambda_2| \geq \cdots$ is the output of theorem 2.26 and the signed orders $\lambda_1^+ \geq \lambda_2^+ \geq \cdots$, $\lambda_1^- \leq \lambda_2^- \leq \cdots$ are the output of Courant–Fischer corollary 2.27. What makes the sign worth tracking is a genuine piece of network meaning, which we spell out now because section 18.3 will depend on it. An eigenfunction e_n with a *positive* eigenvalue is reproduced with its own sign under averaging,

$\mathbb{W}e_n = \lambda_n e_n$ with $\lambda_n > 0$: the region where $e_n > 0$ is linked, through W, predominantly to itself, so the mode describes a *clump* of types that reinforce one another — "like attracts like," an assortative mode. An eigenfunction with a *negative* eigenvalue is reproduced with its sign *flipped*, $\mathbb{W}e_n = \lambda_n e_n$ with $\lambda_n < 0$: the region where $e_n > 0$ is linked predominantly to the region where $e_n < 0$, so the mode describes two camps that connect to each other rather than internally — "opposites attract," an alternating, bipartite mode. Positive eigenvalues are thus the spectral signature of community (assortative) structure and negative eigenvalues the signature of bipartite (disassortative) structure; this is the reading the two-block model of example 18.11 will make completely explicit, where the single nonzero off-constant eigenvalue is positive when within-block ties dominate and negative when cross-block ties do. When a statement is about size we use $|\lambda_n|$; when it is about the leading positive mode we write λ_1^+. For a *nonnegative* kernel, $W \geq 0$ — that is, for an actual graphon rather than a signed difference of two — the two top entries coincide, $\lambda_1^+ = |\lambda_1| = \rho(\mathbb{W})$, by the Perron–Frobenius theorem of section 18.2: a nonnegative kernel cannot hide a negative eigenvalue larger in modulus than its largest positive one, so its spectral radius is always carried by an assortative mode. (Disagreement at the very top therefore requires a signed kernel, of the kind that arises as a difference $W_n - W$ in the convergence arguments of section 18.4; for a graphon proper the orderings can still part company deeper down, as the micro-example above shows, but never at the leading entry.)

With the spectral data named and both orderings fixed, the spectral radius notation $\rho(\mathbb{W}) = |\lambda_1|$ and the signed/modulus vocabulary now travel forward unchanged: section 18.2 will read e_1 at $\lambda_1^+ = \rho(\mathbb{W})$ as centrality, and section 18.3 will read the gap below $|\lambda_1|$ as mixing speed. Before either, though, the kernel form of eq. (18.1) leaves one question dangling that we flagged and deferred: the expansion converges in $L^2([0,1]^2)$, but can it be evaluated at a single point — in particular on the diagonal, where it would compute $W(x,x)$ and, integrated, the trace? That is the next thing to settle, and the answer is more delicate than the L^2 convergence we have just secured.

18.1.2 Mercer's theorem: when the expansion is pointwise

We closed the previous subsection with a question we deliberately left dangling. The kernel form of eq. (18.1) expresses W as the sum $\sum_n \lambda_n \, e_n(x)e_n(y)$, but we proved that sum converges only in $L^2([0,1]^2)$ — as a statement about the function of *two* variables, integrated against test functions, with no claim about its value at any single point. The natural next question is whether we may say more: can the series be evaluated *pointwise*, at a fixed (x,y), and in particular on the *diagonal* $x = y$, where it would read off the number

$$W(x,x) \;\stackrel{?}{=}\; \sum_n \lambda_n \, e_n(x)^2.$$

This is not idle. The diagonal is exactly where the trace lives. If the diagonal identity held and we could integrate it term by term, we would obtain

$$\int_0^1 W(x,x)\;\mathrm{d}x \;=\; \sum_n \lambda_n \int_0^1 e_n(x)^2\;\mathrm{d}x \;=\; \sum_n \lambda_n,$$

the sum of the eigenvalues — the first spectral moment. The very next subsection is about spectral moments $\sum_n \lambda_n^k$, which we will identify with the cycle densities of chapter 16 and on which the entire convergence theory of section 18.4 depends. So the question "may we evaluate the eigenfunction expansion on the diagonal?" is the question "is the naive diagonal route to the spectral moments legitimate?" The answer turns out to be a sharp *no* for general graphons, and understanding precisely why is what dictates the diagonal-free strategy of the next proof. This subsection draws that line.

The L^2 convergence we already have is, on reflection, the most one can expect from square-summability of the λ_n alone, because L^2 convergence is exactly an ℓ^2 statement about coefficients and says nothing about the size of the summands at any individual point. To get *pointwise* control one needs the summands not to conspire — not to add up with alternating signs that cancel in the mean but blow up at a point — and the cleanest structural hypothesis that rules out such conspiracy is that every eigenvalue have the *same* sign. That is what positive semidefiniteness gives, and it is the hypothesis of Mercer's theorem. It is worth pausing on what the hypothesis means before we use it, because its name invites a confusion that this whole subsection exists to dispel.

An operator $\mathbb{W}$ is *positive semidefinite* when its quadratic form is never negative,

$$\langle \mathbb{W}f, f\rangle = \iint_{[0,1]^2} W(x,y)\, f(x)f(y)\, \mathrm{d}x\, \mathrm{d}y \;\geq\; 0 \qquad \text{for all } f \in L^2[0,1].$$

Diagonalising through eq. (18.1), $\langle \mathbb{W}f, f\rangle = \sum_n \lambda_n \langle f, e_n\rangle^2$, so positive semidefiniteness is exactly the requirement that *all eigenvalues be nonnegative*: choosing $f = e_m$ gives $\langle \mathbb{W}e_m, e_m\rangle = \lambda_m \geq 0$, and conversely if every $\lambda_n \geq 0$ the sum of nonnegative terms is nonnegative. This is a statement about the operator — about how W acts as an averaging kernel — and it is emphatically *not* the statement that W is nonnegative as a function. A graphon takes values in $[0,1]$, so $W(x,y) \geq 0$ pointwise; but pointwise nonnegativity of the kernel and nonnegativity of the quadratic form are different conditions, and a $[0,1]$-valued graphon routinely fails the latter. The reason is that f in the quadratic form ranges over *signed* test functions: a kernel that links a region where $f > 0$ to a region where $f < 0$ contributes a *negative* product $f(x)f(y)$ weighted by a positive $W(x,y)$, and if such cross-links dominate, the whole form goes negative. Concretely, take $f = \mathbf{1}_{I_1} - \mathbf{1}_{I_2}$ in the two-block kernel of example 18.11: a direct computation gives $\langle \mathbb{W}f, f\rangle = (p-q)/2$, which is strictly negative whenever cross-block ties are denser than within-block ties, $q > p$ — a perfectly ordinary, perfectly nonnegative graphon with a negative eigenvalue. We will return to this example below; for now it is the warning that the hypothesis of the theorem we are about to state is a genuine restriction, not an automatic feature of graphons.

With the hypothesis understood as a real constraint, we state the classical theorem. It is the statement that, precisely *when* the operator is positive semidefinite, the gap between L^2 and pointwise convergence closes completely.

Theorem 18.2 (Mercer)**.** *Suppose $W\colon [0,1]^2 \to \mathbb{R}$ is continuous, symmetric, and* positive semidefinite*, meaning $\langle \mathbb{W}f, f\rangle \geq 0$ for all $f \in L^2[0,1]$ (equivalently all eigenvalues are ≥ 0). Then the eigenfunctions e_n corresponding to nonzero eigenvalues may be taken continuous, and the expansion*

$$W(x,y) = \sum_n \lambda_n\, e_n(x)e_n(y)$$

converges absolutely and uniformly on $[0,1]^2$*. In particular the series converges on the diagonal,* $W(x,x) = \sum_n \lambda_n e_n(x)^2$*, and* $\int_0^1 W(x,x)\,\mathrm{d}x = \sum_n \lambda_n = \mathrm{tr}(\mathbb{W})$*.*

Proof sketch. The argument has three moves, and it is worth seeing how each one uses the hypotheses — continuity for the first, positive semidefiniteness for the second, square-summability for the third.

Move 1: the eigenfunctions are automatically continuous. We never assumed the e_n continuous; we get it for free from the eigenvalue equation. Rearranging $\mathbb{W}e_n = \lambda_n e_n$ for $\lambda_n \neq 0$,

$$e_n(x) = \frac{1}{\lambda_n}(\mathbb{W}e_n)(x) = \frac{1}{\lambda_n}\int_0^1 W(x,y)\,e_n(y)\,\mathrm{d}y.$$

The right-hand side is continuous in x: if $x_k \to x$ then $W(x_k,y) \to W(x,y)$ for every y by continuity of the kernel, and the integrands are dominated by the integrable bound $\|W\|_\infty\,|e_n(y)|$, so dominated convergence carries the limit inside the integral. Thus $e_n = \lambda_n^{-1}\mathbb{W}e_n$ is continuous, and we may speak of its pointwise values $e_n(x)^2$ without ambiguity. (This is the only place the continuity hypothesis on W is used; it manufactures continuous representatives of objects that the L^2 theory only knows up to a.e. equality.)

Move 2: positivity of the remainder forces monotone diagonal partial sums, and Dini finishes. Fix N and consider the truncation remainder

$$R_N(x,y) = W(x,y) - \sum_{n\le N}\lambda_n e_n(x)e_n(y).$$

As an operator, R_N is $\mathbb{W}$ with its top N spectral projections subtracted, so its eigenvalues are $\{\lambda_n : n > N\}$ together with zeros — and *all of these are* ≥ 0 *by positive semidefiniteness.* Hence R_N is itself a positive semidefinite operator, and the quadratic form of a positive operator is nonnegative on its diagonal in the following sense: testing against an approximate delta at x (or, rigorously, using that the continuous diagonal of a positive continuous kernel is nonnegative) gives $R_N(x,x) \ge 0$, i.e.

$$\sum_{n\le N}\lambda_n e_n(x)^2 \;\le\; W(x,x) \;\le\; \|W\|_\infty \qquad \text{for every } x\in[0,1] \text{ and every } N.$$

Now read what this says about the diagonal series $\sum_n \lambda_n e_n(x)^2$. Every term $\lambda_n e_n(x)^2$ is ≥ 0 (here again $\lambda_n \ge 0$ is doing the work), so for each fixed x the partial sums $S_N(x) = \sum_{n\le N}\lambda_n e_n(x)^2$ *increase with* N; and they are bounded above, uniformly in x, by $W(x,x)$. A bounded monotone sequence converges, so $S_N(x) \uparrow S(x)$ pointwise, with $S(x) \le W(x,x)$. This is exactly the configuration Dini's theorem governs: a sequence of continuous functions S_N (continuous by Move 1, each a finite sum of squares of continuous functions) increasing *monotonically* to a limit S that is itself continuous, on the *compact* interval $[0,1]$. Dini upgrades such monotone pointwise convergence to *uniform* convergence — the obstruction to uniformity is escaping mass that pools at a moving point, and monotonicity plus compactness forbids it. (That the limit S is continuous, which Dini requires, follows because $S = W(\cdot,\cdot)$ on the diagonal once we identify the limit in Move 3; one runs the standard argument by first establishing uniform convergence to *some* continuous function via the Cauchy criterion below and then naming it.) So $\sum_n \lambda_n e_n(x)^2$ converges uniformly in x.

Move 3: Cauchy–Schwarz transfers diagonal control to the full kernel, off the diagonal too. Uniform convergence on the diagonal is upgraded to absolute and uniform convergence of the two-variable series by a termwise Cauchy–Schwarz inequality on the tail. For $M < n \le N$,

$$\Big(\sum_{M<n\le N} \lambda_n e_n(x)e_n(y)\Big)^2 \;\le\; \Big(\sum_{M<n\le N} \lambda_n e_n(x)^2\Big)\Big(\sum_{M<n\le N} \lambda_n e_n(y)^2\Big),$$

which is legitimate precisely because the weights $\lambda_n \ge 0$ make $(u,v) \mapsto \sum \lambda_n u_n v_n$ a genuine inner product on coefficient tails. Both factors on the right are tails of the uniformly convergent diagonal series of Move 2, hence both are $\le \sup_x \sum_{n>M} \lambda_n e_n(x)^2 \to 0$ as $M \to \infty$, uniformly in x, y. So the kernel series satisfies the uniform Cauchy criterion and converges absolutely and uniformly on all of $[0,1]^2$. Its uniform limit is a continuous function that agrees with W in $L^2([0,1]^2)$ by eq. (18.1), hence agrees with the continuous W a.e., hence *everywhere* by continuity of both sides. Setting $x = y$ now licenses the diagonal identity and, integrating the uniform sum termwise, $\int_0^1 W(x,x)\,\mathrm{d}x = \sum_n \lambda_n = \mathrm{tr}(\mathbb{W})$. The classical reference is [113, Ch. VI]; see also [50]. ☐

Remark 18.3 (Graphons are not positive semidefinite in general)**.** This remark carries the real payload of the subsection, so we develop it carefully along three steps: the conceptual distinction that traps the unwary, an example where the diagonal identity survives anyway, and the genuine failure mode it does not.

The distinction. A graphon takes values in $[0,1]$, so $W \ge 0$ *pointwise* as a function on $[0,1]^2$. This is completely unrelated to positive *semidefiniteness* of the operator $\mathbb{W}$, which — as we saw in setting up Mercer — is the condition $\langle \mathbb{W}f, f\rangle \ge 0$ for all *signed* f, equivalently that every eigenvalue $\lambda_n \ge 0$. Pointwise nonnegativity of the kernel constrains its values; operator positivity constrains its spectrum; neither implies the other. The mismatch is structural, not exotic: most graphons one writes down have eigenvalues of both signs, and we already named why in section 18.1 — a negative eigenvalue is the spectral signature of a disassortative, bipartite-like mode, and such modes are ubiquitous. So Mercer's hypothesis is the exception, not the rule, among graphons.

An example where the identity holds anyway. Take the two-block model of example 18.11 with $p < q$. Its nonzero eigenvalues are $\lambda_1 = (p+q)/2 > 0$ and $\lambda_2 = (p-q)/2 < 0$, so it has a strictly negative eigenvalue, is not operator positive semidefinite, and is moreover discontinuous across the block boundary — it violates Mercer's hypotheses twice over, and the theorem simply does not apply to it. And yet the diagonal identity *still holds* for this kernel, which is the instructive point: Mercer is sufficient, not necessary. The reason is that this kernel is *finite rank*, so its eigenfunction series is a *finite* sum, which converges everywhere trivially, with no need of Dini or positivity. One checks the diagonal value by hand. The normalised eigenfunctions are $e_1 = \mathbf{1}$ (value 1 everywhere) and $e_2 = \mathbf{1}_{I_1} - \mathbf{1}_{I_2}$ (values ± 1), so $e_1(x)^2 = 1$ and $e_2(x)^2 = 1$ for a.e. x, and the finite diagonal sum is

$$\sum_n \lambda_n e_n(x)^2 = \lambda_1 \cdot 1 + \lambda_2 \cdot 1 = \frac{p+q}{2} + \frac{p-q}{2} = \frac{(p+q)+(p-q)}{2} = p = W(x,x),$$

the within-block value, and this holds regardless of the sign of $p - q$. So the negative eigenvalue does no harm here: finiteness of the sum, not positivity of its terms, is what makes a finite-rank diagonal expansion legitimate.

The genuine failure mode. What positivity actually protects against is the interaction of *infinitely many* sign-varying terms. For the diagonal identity to genuinely fail one needs an *infinite-rank*, continuous, non-positive-semidefinite kernel. There the entire mechanism of Mercer's proof collapses at Move 2: with eigenvalues of both signs the diagonal partial sums $S_N(x) = \sum_{n\le N} \lambda_n e_n(x)^2$ are *no longer monotone in* N — adding a term with $\lambda_n < 0$ decreases the sum — so they are not pinned between 0 and $W(x,x)$, Dini's hypothesis is unavailable, and there is no longer any reason for the series to converge to $W(x,x)$ at a given point. (It still converges in L^2, by eq. (18.1); what is lost is only the pointwise/diagonal value.) The positive and negative parts of the series can each diverge on the diagonal while their L^2 difference stays finite, and the would-be trace $\sum_n \lambda_n$ need not even converge absolutely. This is the real obstruction, and it is generic.

The consequence for what follows — read this as the instruction for the next proof. Because we cannot trust the diagonal evaluation $W(x,x) = \sum_n \lambda_n e_n(x)^2$ for a general graphon, and because the spectral moments we are about to compute would naively be read off exactly that diagonal, the next subsection must reach the trace-type identity by a route that *never touches the diagonal at all.* The device is to write each spectral power sum as a Hilbert–Schmidt inner product of two operator iterates $\mathbb{W}^a$ and $\mathbb{W}^b$ and evaluate that pairing as an honest $L^2([0,1]^2)$ integral of two kernels — an off-diagonal object to which the L^2 theory of eq. (18.1) applies unconditionally, with no appeal to Mercer, to positive semidefiniteness, or to pointwise convergence. That is precisely how proposition 18.4 is proved, and the present remark is the reason it is proved that way.

18.1.3 Spectral moments are cycle densities

The previous subsection ended with a precise instruction, and we now follow it. Mercer's theorem told us that the eigenfunction expansion may be summed pointwise — and in particular read off on the diagonal to give the trace — only when the operator is positive semidefinite, a hypothesis that *generically fails* for graphons. The naive route to the spectral moments, evaluate $\sum_n \lambda_n e_n(x)^2$ on the diagonal and integrate, is therefore closed to us. Remark 18.3 closed by naming the detour that *is* open: write each spectral power sum as a Hilbert–Schmidt inner product of two operator iterates and evaluate that pairing as an honest $L^2([0,1]^2)$ integral of two kernels — an off-diagonal object to which the L^2 convergence of eq. (18.1) applies with no Mercer, no positive semidefiniteness, no pointwise evaluation anywhere. This subsection carries out exactly that program, and the payoff is the hinge advertised in the chapter opening: the power sums of the spectrum *are* the cycle homomorphism densities of chapter 16. It is the single bridge across which the combinatorial machinery of chapter 16 and the metric continuity of chapter 17 reach into the spectrum, so it is worth proving slowly and completely.

Proposition 18.4 (Spectral moments)**.** *Let W satisfy* (A-Reg-W)*, with spectrum $\{\lambda_n\}$. For every integer $k \ge 2$ the spectral power sum converges absolutely and*

$$\sum_n \lambda_n^k \;=\; \int_{[0,1]^k} W(x_1,x_2)W(x_2,x_3)\cdots W(x_k,x_1)\;\mathrm{d}x_1\cdots \mathrm{d}x_k \;=\; t(C_k,W), \tag{18.2}$$

the homomorphism density of the k-cycle C_k (chapter 16). For $k=2$ this reads $\sum_n \lambda_n^2 = \|W\|^2_{L^2([0,1]^2)} = t(C_2,W)$.

Proof. The proof has a clean four-part architecture, and it is worth seeing the shape before the algebra: (i) the iterated operators $\mathbb{W}^j$ are again Hilbert–Schmidt, which keeps us inside the apparatus chapter 2 already built and away from trace-class theory the book has not developed; (ii) the kernel of $\mathbb{W}^j$ is the j-fold convolution of W; (iii) we split the exponent $k = a + b$ into two pieces, each at least 1 — this is the one place the hypothesis $k \geq 2$ is spent; and (iv) we compute a single Hilbert–Schmidt inner product $\langle \mathbb{W}^a, \mathbb{W}^b \rangle_{\mathrm{HS}}$ *two ways*, once spectrally and once as a kernel integral, and equate the answers. The spectral evaluation produces $\sum_n \lambda_n^k$; the integral evaluation produces the closed cycle. Throughout, the only convergence we ever invoke is the unconditional $L^2([0,1]^2)$ convergence of eq. (18.1); no eigenfunction is ever evaluated at a point, so Mercer plays no role.

Step (i): the iterates are Hilbert–Schmidt. Fix an integer $j \geq 1$. We claim the operator $\mathbb{W}^j$ is again Hilbert–Schmidt. Here $\mathbb{W}$ itself is Hilbert–Schmidt by proposition 2.24, and the remaining factor $\mathbb{W}^{j-1}$ is at least bounded (a power of a bounded operator). The Hilbert–Schmidt operators form a *two-sided ideal* inside the bounded operators: the product of a Hilbert–Schmidt operator with any bounded operator, on either side, is again Hilbert–Schmidt. So $\mathbb{W}^j = \mathbb{W} \cdot \mathbb{W}^{j-1}$ is Hilbert–Schmidt. This is exactly the property that lets us stay self-contained. To read $\sum_n \lambda_n^k$ as a trace of $\mathbb{W}^k$ directly would require the trace-class theory of chapter 2 — nuclear operators, the trace functional, and its continuity — which the book has deliberately not built. The ideal property gives us all we need with strictly less: every iterate lives in the *Hilbert*–Schmidt class, where the inner product $\langle \cdot, \cdot \rangle_{\mathrm{HS}}$ and its kernel-integral formula definition 2.21 are available, and that is the whole arena of the proof.

Step (ii): the kernel of the iterate is the convolution. By the spectral theorem theorem 2.26, $\mathbb{W}^j$ shares the eigenfunctions e_n of $\mathbb{W}$ and raises each eigenvalue to the j-th power, $\mathbb{W}^j e_n = \lambda_n^j e_n$. At the level of kernels, composing integral operators convolves their kernels: the kernel–operator dictionary theorem 2.22 says that if $\mathbb{W}$ has kernel W then $\mathbb{W}^j$ has the j-fold convolution kernel

$$W^{(j)}(x, y) = \int_{[0,1]^{j-1}} W(x, x_2) W(x_2, x_3) \cdots W(x_j, y) \, \mathrm{d}x_2 \cdots \mathrm{d}x_j,$$

with the convention $W^{(1)} = W$. The picture to carry is combinatorial: $W^{(j)}(x, y)$ is the total W-weight of all length-j walks from x to y, the continuum analogue of the matrix-power entry $(A^j)_{uv}$ counting length-j walks in a finite graph. The internal vertices $x_2, \ldots, x_j$ are summed (integrated) over; only the two endpoints x, y remain free.

Step (iii): split the exponent, and see where $k \geq 2$ is used. Write

$$k = a + b, \qquad a = \lfloor k/2 \rfloor \geq 1, \qquad b = \lceil k/2 \rceil \geq 1,$$

so both exponents are genuine positive integers and $a + b = k$. This is the precise point at which the hypothesis $k \geq 2$ is spent and cannot be relaxed: only for $k \geq 2$ can we split k into two summands each ≥ 1. The exponents must both be ≥ 1 for two independent reasons that recur below. First, $\mathbb{W}^a$ and $\mathbb{W}^b$ are then both genuine iterates (Step (i)), so they annihilate $\ker \mathbb{W}$ and the spectral sum below ranges only over the nonzero eigenvalues. Second, the integral evaluation needs each side to be an honest walk of length ≥ 1, so that gluing them produces a cycle with $k \geq 2$ edges. The forbidden case $k = 1$ would demand $a = 1, b = 0$, i.e. pairing $\mathbb{W}$ against the *identity* — which is not Hilbert–Schmidt on the infinite-dimensional $L^2[0,1]$ — and would land us right back on the diagonal trace $\sum_n \lambda_n$ that remark 18.3 showed need not even converge. The split is exactly the device that keeps us off the diagonal.

Step (iv), first evaluation: spectral. We compute the Hilbert–Schmidt inner product $\langle \mathbb{W}^a, \mathbb{W}^b \rangle_{\text{HS}}$ against a convenient orthonormal basis of $L^2[0,1]$: the eigenfunctions $\{e_n\}$ for the nonzero eigenvalues, completed by an orthonormal basis of $\ker \mathbb{W}$. On the kernel basis vectors both $\mathbb{W}^a$ and $\mathbb{W}^b$ vanish (since $a, b \geq 1$), so those terms contribute nothing, and only the e_n survive:

$$\langle \mathbb{W}^a, \mathbb{W}^b \rangle_{\text{HS}} = \sum_n \langle \mathbb{W}^a e_n, \mathbb{W}^b e_n \rangle = \sum_n \langle \lambda_n^a e_n, \lambda_n^b e_n \rangle = \sum_n \lambda_n^a \lambda_n^b \langle e_n, e_n \rangle = \sum_n \lambda_n^{a+b} = \sum_n \lambda_n^k,$$

where the middle steps use $\mathbb{W}^a e_n = \lambda_n^a e_n$ and $\mathbb{W}^b e_n = \lambda_n^b e_n$ from Step (ii) and the orthonormality $\langle e_n, e_n \rangle = 1$. This is the first of the two faces of the same number: the k-th power sum of the spectrum.

Why the sum converges absolutely. The series $\sum_n \lambda_n^k$ is unconditionally summable, and the bound is worth recording because it is also what makes the moment *finite and uniformly controlled* across all graphons. Every eigenvalue obeys $|\lambda_n| \leq \|\mathbb{W}\| \leq \|W\|_\infty$, the second inequality because the operator norm of an averaging kernel against a unit-mass type space is bounded by the supremum of the kernel (a Schur-test bound: $\|\mathbb{W}\| \leq \sup_x \int_0^1 |W(x,y)| \, \mathrm{d}y \leq \|W\|_\infty$). Peeling off two of the k factors and bounding the remaining $k-2$ each by $\|W\|_\infty$,

$$\sum_n |\lambda_n|^k = \sum_n |\lambda_n|^{k-2} \; \lambda_n^2 \;\leq\; \|W\|_\infty^{k-2} \sum_n \lambda_n^2 \;=\; \|W\|_\infty^{k-2} \; \|W\|_{\text{HS}}^2 \;<\; \infty,$$

finite for every $k \geq 2$ since $\sum_n \lambda_n^2 = \|W\|_{\text{HS}}^2 < \infty$ by proposition 2.24. The two retained factors are exactly the λ_n^2 that the $k = 2$ identity controls; the leftover $k-2$ factors are precisely why the simple-cycle range will be $k \geq 3$ rather than $k \geq 2$ when we hand off below. For a graphon proper, $\|W\|_\infty \leq 1$, so in fact $\sum_n |\lambda_n|^k \leq \sum_n \lambda_n^2 \leq 1$ for every $k \geq 2$ — the moments are bounded by 1, uniformly over all graphons at once.

Step (iv), second evaluation: kernel integral, and why it closes a cycle. The same inner product has a second face. By the integral form of the Hilbert–Schmidt inner product (definition 2.21), pairing two Hilbert–Schmidt operators equals pairing their kernels in $L^2([0,1]^2)$:

$$\langle \mathbb{W}^a, \mathbb{W}^b \rangle_{\text{HS}} = \int_{[0,1]^2} W^{(a)}(x,y) \, W^{(b)}(x,y) \; \mathrm{d}x \; \mathrm{d}y.$$

Now look at what this double integral is, geometrically. By Step (ii), $W^{(a)}(x,y)$ is the total weight of all length-a walks from x to y, and $W^{(b)}(x,y)$ the total weight of all length-b walks between the same two endpoints. The product, integrated over x and y, glues a length-a walk and a length-b walk *at both shared endpoints*. Here symmetry does the essential work: because $W(x,y) = W(y,x)$, the second walk reads equally well backwards, $W^{(b)}(x,y) = W^{(b)}(y,x)$, a length-$b$ walk from y *back to* x. So one factor carries us out from x to y in a steps, the other carries us home from y to x in b steps, and the two legs together form a single *closed* walk of $a + b = k$ edges that returns to its start. Writing out both convolutions and relabelling the integration variables $x = x_1$, $y = x_{a+1}$ together with the internal vertices in order, the glued object is precisely the closed k-cycle integral

$$\int_{[0,1]^k} W(x_1,x_2) W(x_2,x_3) \cdots W(x_k,x_1) \; \mathrm{d}x_1 \cdots \mathrm{d}x_k,$$

each consecutive pair (x_i, x_{i+1}) contributing one edge of W and the final pair (x_k, x_1) closing the loop. This is exactly $t(C_k, W)$, the homomorphism density of the k-cycle, by the definition of cycle density in chapter 16. The split exponent is what makes the geometry honest: gluing a walk to a walk along a shared endpoint *is* a cycle only when each walk has at least one edge, which is again the content of $a, b \geq 1$.

Conclusion. The two evaluations compute one and the same number $\langle \mathbb{W}^a, \mathbb{W}^b \rangle_{\mathrm{HS}}$, so equating them gives eq. (18.2), $\sum_n \lambda_n^k = t(C_k, W)$. The boundary case $k = 2$ uses $a = b = 1$, where both iterates are $\mathbb{W}$ itself and the identity degenerates to $\langle \mathbb{W}, \mathbb{W} \rangle_{\mathrm{HS}} = \sum_n \lambda_n^2 = \|W\|_{\mathrm{HS}}^2$ of proposition 2.24 on one side and $\int_{[0,1]^2} W(x,y)^2$, the density $t(C_2, W)$ of the doubled edge, on the other. We emphasise the cash value of the previous subsection's warning: *at no point did we evaluate an eigenfunction expansion on the diagonal*, and so at no point did we invoke Mercer's theorem or positive semidefiniteness. Every object handled was an off-diagonal $L^2([0,1]^2)$ pairing of kernels, where the unconditional convergence of eq. (18.1) is all that is needed. This is precisely the diagonal-free route remark 18.3 promised, and it is why the moment identity holds for *every* graphon, positive semidefinite or not. □

We extract from the $k = 2$ case the one quantitative fact the rest of the chapter runs on, and state it sharply enough to quote. Setting $k = 2$ in eq. (18.2) collapses three a priori distinct quantities into a single number: the sum of squared eigenvalues, the squared Hilbert–Schmidt (equivalently L^2) norm of the kernel, and the homomorphism density of the doubled edge C_2 all coincide,

$$\sum_n \lambda_n^2 = \|W\|_{\mathrm{HS}}^2 = t(C_2, W) \leq 1,$$

the final bound because $0 \leq W \leq 1$ forces $W^2 \leq W \leq 1$ pointwise, hence $\int_{[0,1]^2} W^2 \leq 1$. The spectrum of any graphon therefore lives in the unit ℓ^2 ball, and this immediately limits how many eigenvalues can be large.

Lemma 18.5 (Uniform ℓ^2 tightness of graphon spectra)**.** *For every graphon W and every threshold $\varepsilon > 0$, the number of eigenvalues λ_n with $|\lambda_n| > \varepsilon$ is at most ε^{-2}. The bound is the same for* every *graphon, with no dependence on W beyond the standing assumption* (A-Reg-W)*.*

The proof is one line: if more than ε^{-2} eigenvalues exceeded ε in modulus, their squares alone would sum to more than $\varepsilon^{-2} \cdot \varepsilon^2 = 1 \geq \sum_n \lambda_n^2$, a contradiction. The point worth underlining is the *uniformity*: the count is governed entirely by the universal bound $\sum_n \lambda_n^2 \leq 1$, so a single tightness estimate holds across the whole space of graphons at once. This is what makes the spectra of a cut-convergent sequence *simultaneously* tight, and it is the engine that powers the spectral convergence theorem of section 18.4: there one extracts a limiting eigenvalue list by a diagonal argument over indices that succeeds precisely because, uniformly in the sequence, only finitely many eigenvalues can sit above any given level (compare the "uniform tightness" step of lemma 18.13, which is this very count).

The moment identity hands section 18.4 a second thing, more subtle than the tightness bound but just as load-bearing, and it is a restriction rather than a gift. The convergence theorem will not be allowed to use the $k = 2$ moment. Cut convergence delivers convergence of $t(F, \cdot)$ only for *finite simple* graphs F (the counting lemma of chapter 16 is stated for simple graphs), and the doubled edge C_2 is not simple — it is the single edge traversed twice. Concretely, $t(C_2, \cdot) = \|\cdot\|_{\mathrm{HS}}^2$ is *not* cut-continuous: the right inequality $\|U\|_{2\to 2} \le \|U\|_{\mathrm{HS}}$ of the norm hierarchy eq. (18.5) is strict precisely because the Hilbert–Schmidt norm can escape cut control, so a sequence can converge in cut metric while its $k = 2$ moments do not converge. The simple cycles begin at $k = 3$ (the triangle), and it is exactly the power sums $\sum_n \lambda_n^k = t(C_k, W)$ for $k \ge 3$ that cut convergence will deliver. The role of the $k = 2$ identity in the convergence proof is thus inverted from what one might expect: it is never a convergence *hypothesis* but only the standing, universal *bound* $\sum_n \lambda_n^2 \le 1$ of lemma 18.5 — supplying tightness, never a limit. With the power sums $k \ge 3$ converging and the $k = 2$ bound clamping the whole spectrum into the ℓ^2 ball, section 18.4 will be able to pass from convergence of cycle densities to convergence of individual eigenvalues, eigenvalue by eigenvalue. That is the next movement.

18.2 The leading eigenfunction is eigenvector centrality

The first movement put the entire spectrum on the table and brought it under control: the eigenvalues $\{\lambda_n\}$ are the cycle homomorphism densities $\sum_n \lambda_n^k = t(C_k, W)$ of proposition 18.4, they are listed in the two orderings of definition 18.1, and the $k = 2$ identity clamps the whole sequence into the unit ℓ^2 ball (lemma 18.5). With the eigen*values* thus accounted for, the natural next question turns to the eigen*functions* — and not to all of them at once, but to the single one that matters most. This movement narrows the focus from the whole spectrum to its top entry λ_1^+ and the mode e_1 that sits there.

Why fasten on that one mode? Because in a graphon mean field game the coupling *is* the operator $\mathbb{W}$ (the chapter opening), and a population profile pushed repeatedly through $\mathbb{W}$ aligns itself, mode by mode, with the eigenfunction of largest eigenvalue: the subdominant modes decay relative to it at the rate $|\lambda_2| / |\lambda_1|$ we will quantify in section 18.3, so what survives in the limit of repeated averaging is a scalar multiple of e_1 alone. The leading eigenfunction is therefore the shape into which the network's coupling collapses everything else — the dominant channel through which any one type feels the entire population. An object that load-bearing deserves a name and a meaning, and network science supplies both.

The name is *eigenvector centrality*, and its informal definition is the oldest circular idea in the subject: a node is central to the degree that it is linked to central nodes. As it stands this is no definition at all, since it explains centrality in terms of itself; but the circularity is exactly the kind an eigenvalue equation dissolves. Write $c(x)$ for the centrality of type x and impose the self-referential demand literally — that $c(x)$ be proportional to the W-weighted average of its neighbours' centralities,

$$\int_0^1 W(x,y)\, c(y)\, \mathrm{d}y \;=\; \lambda\, c(x) \qquad \text{for some constant } \lambda,$$

which is precisely the eigenvalue equation $\mathbb{W}c = \lambda c$. The self-reference becomes a request for an eigenfunction. The only remaining question is *which* eigenfunction, of the many $\mathbb{W}$ possesses, carries the meaning — and two requirements of the interpretation, not of the algebra, single one out. A centrality must be *nonnegative*, since no node is "negatively central"; and on a connected network it must be *unique up to overall scale*, so that the ranking of types it induces is well defined rather than an artefact of which eigenfunction one happened to pick. The content of this section is that exactly one eigenfunction meets both requirements — the one belonging to the top eigenvalue — and that under the right hypothesis it is automatically strictly positive, so that every type receives a genuinely positive score.

Establishing this also discharges a promise left open in the first movement. The notationwatch of section 18.1 asserted that for a *nonnegative* kernel the two orderings of definition 18.1 agree at the very top, $\lambda_1^+ = |\lambda_1| = \rho(\mathbb{W})$ — a nonnegative kernel cannot conceal a negative eigenvalue larger in modulus than its largest positive one — and deferred the proof to here. It is part (1) of the theorem below. The leading positive mode and the spectral radius turn out to be the same number for a structural reason worth previewing: nonnegativity forces the extreme of the Rayleigh quotient to be attained at a nonnegative test function, and there the quadratic form is itself nonnegative, so the assortative top mode always wins the competition for the largest modulus. The vehicle for all of this is the Perron–Frobenius theorem, whose finite-graph version the reader already knows; the work is to lift it to the integral operator $\mathbb{W}$, and that lift needs exactly one continuum hypothesis — the analogue of a finite graph being connected. Identifying that hypothesis correctly is the first order of business.

18.2.1 Perron–Frobenius for the graphon operator

For a finite graph with nonnegative adjacency matrix A, the Perron–Frobenius theorem says that the largest eigenvalue is real and positive, that it is attained by a nonnegative eigenvector, and — if the graph is connected — that this eigenvector is unique up to scale and strictly positive. The entries of that eigenvector are precisely the *eigenvector centralities* of the nodes: the circular definition of the previous paragraphs, made into the components of a genuine eigenvector, with the proportionality constant λ identified as the leading eigenvalue.

It pays to watch the circular definition dissolve into an eigenequation once, in the smallest nontrivial finite case, because the graphon argument below is the very same move performed in $L^2[0,1]$ rather than in $\mathbb{R}^n$. Take the path on three vertices $1-2-3$, with adjacency matrix

$$A = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}.$$

The informal demand "each c_i is proportional, by a single shared constant, to the sum of its neighbours' centralities" reads $\lambda c_1 = c_2$, $\lambda c_2 = c_1 + c_3$, $\lambda c_3 = c_2$ — three coupled proportionalities with one common constant of proportionality, which is exactly the eigenequation $Ac = \lambda c$. Solving it, the three eigenvalues are $\lambda = \sqrt{2}$, 0, $-\sqrt{2}$. The largest, $\lambda_1 = \sqrt{2} > 0$, carries the eigenvector $c = (1, \sqrt{2}, 1)$: every entry strictly positive, with the middle vertex scored most central because it lies on every short path through the graph. Neither competitor is nonnegative — $\lambda = 0$ gives $(1, 0, -1)$ and $\lambda = -\sqrt{2}$ gives $(1, -\sqrt{2}, 1)$, each forced to change sign. So all three features the theorem promises are already visible in this 3×3 picture: a real positive top eigenvalue, an everywhere-positive eigenvector sitting at it, and a mandatory sign change in every other eigenvector. The work of this section is to show that these features survive *verbatim* when the finite matrix A is replaced by the integral operator $\mathbb{W}$ on the continuum of types.

We now lift the statement, verbatim in spirit, to the graphon operator $\mathbb{W}$. The only piece that does not transcribe word for word is the word "connected": a continuum of types has no edges to count, so connectedness must be re-expressed in a form that survives the passage from a finite vertex set to $[0, 1]$.

In a finite graph connectedness fails in exactly one way: the vertices split into two nonempty groups with no edges running between them, and after relabelling the adjacency matrix becomes block-diagonal. The continuum analogue replaces "two nonempty groups" by "two sets of positive measure" and "no edges between them" by "no kernel weight between them." That is the content of the next definition.

Definition 18.6 (Connected graphon)**.** A graphon W is *connected* (operator-theoretically: $\mathbb{W}$ is *irreducible*) if there is no measurable $S \subseteq [0, 1]$ with $0 < |S| < 1$ such that $W = 0$ almost everywhere on $S \times S^c$. Equivalently, $[0, 1]$ cannot be split into two parts of positive measure with no W-weight between them.

It is worth seeing concretely what connectedness buys, by watching the conclusion fail without it. Suppose W is *dis*connected: $[0, 1] = S \sqcup S^c$ with both pieces of positive measure and $W = 0$ a.e. on $S \times S^c$. Then $\mathbb{W}$ does not mix the two pieces at all — it splits as a direct sum $\mathbb{W} = \mathbb{W}_S \oplus \mathbb{W}_{S^c}$ of two independent operators, one acting on $L^2(S)$ and one on $L^2(S^c)$, exactly as a block-diagonal adjacency matrix decouples into its blocks. Each block carries its own leading eigenvalue and its own nonnegative leading eigenfunction, the latter supported entirely on its own piece. If the two block leading eigenvalues happen to coincide — as they do, for instance, when S and S^c host identical sub-graphons — then the top eigenspace of $\mathbb{W}$ is two-dimensional, and it contains a whole cone of nonnegative eigenfunctions: every nonnegative combination $\alpha\, e_S + \beta\, e_{S^c}$ of the two block modes is again a nonnegative leading eigenfunction. Centrality is then genuinely ambiguous. There is no principled way to weigh a node in the first component against a node in the second, precisely as one cannot rank vertices across the connected components of a disconnected graph: the relative scale of the two blocks is free. Connectedness is exactly the hypothesis that forbids this splitting and so restores the uniqueness the interpretation needs. With it stated we can give the theorem in full.

Theorem 18.7 (Perron–Frobenius / Krein–Rutman for graphons)**.** *Let W satisfy* (A-Reg-W) *with $W \geq 0$, and suppose W is not the zero graphon. Then:*

1. *the spectral radius $\rho(\mathbb{W}) = \|\mathbb{W}\|$ is itself an eigenvalue, the largest one, so $\lambda_1^+ = \rho(\mathbb{W}) = |\lambda_1| > 0$;*

2. *there is a corresponding eigenfunction $e_1 \geq 0$ almost everywhere;*

3. *if in addition W is connected, then λ_1^+ is simple (its eigenspace is one-dimensional) and $e_1 > 0$ almost everywhere; moreover e_1 is, up to sign and scaling, the only nonnegative eigenfunction of $\mathbb{W}$.*

Proof. (1)–(2): the top eigenvalue is positive and carries a nonnegative eigenfunction. By the Courant–Fischer principle corollary 2.27, the largest positive eigenvalue is the maximum of the

Rayleigh quotient over the unit sphere, $\lambda_1^+ = \max_{\|g\|=1}\langle \mathbb{W}g, g\rangle$, and compactness of $\mathbb{W}$ supplies an actual maximiser — some unit vector g attaining the supremum — exactly as in the construction of the first eigenpair inside the proof of theorem 2.26. That this maximum is genuinely *positive*, not merely nonnegative, uses that W is a nonzero nonnegative kernel: testing the quotient against the constant function $\mathbf{1}$ gives $\lambda_1^+ \geq \langle \mathbb{W}\mathbf{1}, \mathbf{1}\rangle = \iint_{[0,1]^2} W > 0$, the total edge weight, which is strictly positive because W is not the zero graphon.

The crucial step is that the maximiser can be taken nonnegative. Replacing g by its pointwise modulus $|g|$ does not change its norm, $\||g|\| = \|g\| = 1$, so $|g|$ is still admissible in the maximisation; and because $W \geq 0$, passing to moduli can only raise the quadratic form,

$$\langle \mathbb{W}\,|g|\,, |g|\rangle = \iint W(x,y)\,|g(x)|\;|g(y)|\;\mathrm{d}x\,\mathrm{d}y \;\geq\; \Big|\iint W(x,y)g(x)g(y)\;\mathrm{d}x\,\mathrm{d}y\Big| = |\langle \mathbb{W}g, g\rangle| = \lambda_1^+.$$

The inequality is the triangle inequality for the integral, valid term by term precisely because the weight $W(x,y)$ is nonnegative, so that $W\,|g(x)|\,|g(y)| \geq W\,g(x)g(y)$ pointwise. But λ_1^+ is the *maximum*, so $\langle \mathbb{W}\,|g|\,, |g|\rangle \leq \lambda_1^+$ as well; the two inequalities pinch, $\langle \mathbb{W}\,|g|\,, |g|\rangle = \lambda_1^+$, and $|g|$ is itself a maximiser. Set $e_1 := |g| \geq 0$.

A maximiser of the Rayleigh quotient on the unit sphere is automatically an eigenfunction for the top eigenvalue, and it is worth doing the variation explicitly, since it is the same stationarity computation that produces the leading eigenpair inside theorem 2.26. We are extremising $Q(h) = \langle \mathbb{W}h, h\rangle$ subject to $\|h\|^2 = 1$; introduce a Lagrange multiplier μ for the constraint and consider, at the maximiser e_1, an admissible perturbation $e_1 + \varepsilon\varphi$ with $\varphi \in L^2[0,1]$ arbitrary. Using self-adjointness of $\mathbb{W}$,

$$Q(e_1+\varepsilon\varphi) = \langle \mathbb{W}e_1, e_1\rangle + 2\varepsilon\,\langle \mathbb{W}e_1, \varphi\rangle + \varepsilon^2\langle \mathbb{W}\varphi,\varphi\rangle, \qquad \|e_1+\varepsilon\varphi\|^2 = 1 + 2\varepsilon\langle e_1,\varphi\rangle + \varepsilon^2\,\|\varphi\|^2\,,$$

so the first-order stationarity condition $\frac{\mathrm{d}}{\mathrm{d}\varepsilon}\big[Q - \mu\,\|\cdot\|^2\big]\big|_{\varepsilon=0} = 0$ reads $2\langle \mathbb{W}e_1, \varphi\rangle - 2\mu\langle e_1, \varphi\rangle = 0$, that is $\langle \mathbb{W}e_1 - \mu e_1, \varphi\rangle = 0$ for *every* φ. A vector orthogonal to all of $L^2[0,1]$ is zero, so $\mathbb{W}e_1 = \mu e_1$: the maximiser is an eigenfunction. Pairing this identity with e_1 and using $\|e_1\| = 1$ identifies the multiplier with the constrained maximum, $\mu = \langle \mathbb{W}e_1, e_1\rangle = \lambda_1^+$. Hence $\mathbb{W}e_1 = \lambda_1^+ e_1$ with $e_1 \geq 0$. Finally λ_1^+ equals the spectral radius. The operator norm of a self-adjoint operator is $\|\mathbb{W}\| = \sup_{\|g\|=1}|\langle \mathbb{W}g, g\rangle|$, and we have just exhibited the supremum being approached through nonnegative test functions, where $\langle \mathbb{W}g, g\rangle \geq 0$; so the extreme of the modulus is attained on the positive side, $\|\mathbb{W}\| = \lambda_1^+$. A nonnegative kernel therefore cannot hide a negative eigenvalue of larger modulus than its top positive one, and $\lambda_1^+ = |\lambda_1| = \rho(\mathbb{W})$ — the identity promised in the notationwatch of section 18.1 and used throughout the signed bookkeeping of definition 18.1.

(3): connectedness forces strict positivity, simplicity, and uniqueness. Assume now that W is connected. We prove the three claims in the order they depend on one another; strict positivity comes first because both simplicity and the orthogonality argument lean on it.

Strict positivity, $e_1 > 0$ a.e. Let $Z = \{e_1 = 0\}$ be the zero set of the leading eigenfunction and suppose, for contradiction, that $|Z| > 0$. For a.e. $x \in Z$ the eigenvalue equation reads

$$0 = \lambda_1^+\,e_1(x) = (\mathbb{W}e_1)(x) = \int_0^1 W(x,y)\,e_1(y)\;\mathrm{d}y.$$

The integrand is a product of two nonnegative functions, $W \geq 0$ and $e_1 \geq 0$, so a vanishing integral forces the integrand itself to vanish a.e.: for a.e. $x \in Z$ we have $W(x,y)\,e_1(y) = 0$ for a.e. y. Wherever $e_1(y) > 0$ — that is, for a.e. $y \in Z^c$ — this can only hold if $W(x,y) = 0$. We have shown $W = 0$ a.e. on $Z \times Z^c$. Were Z^c also of positive measure, this would split $[0,1]$ into the two positive-measure pieces Z and Z^c with no kernel weight between them — exactly the disconnection definition 18.6 forbids. Hence $|Z^c| = 0$, i.e. $|Z| = 1$; but that says $e_1 = 0$ a.e., contradicting $\|e_1\| = 1$. The only escape is $|Z| = 0$, so $e_1 > 0$ almost everywhere: on a connected network every type has strictly positive centrality.

Simplicity, $\dim\ker(\mathbb{W} - \lambda_1^+) = 1$. The strict positivity just established is the lever for everything that follows. Our goal is to show that every eigenfunction for λ_1^+ is a scalar multiple of e_1, so that the top eigenspace is a single line. Since $\mathbb{W}$ is real and self-adjoint, each eigenspace is spanned by real eigenfunctions — a complex one splits into real and imaginary parts that each separately solve $\mathbb{W}v = \lambda_1^+ v$ — so it suffices to rule out a *second* real eigenfunction independent of e_1. We argue by contradiction, and strict positivity is again the lever.

Suppose the top eigenspace had dimension at least two. Applying Gram–Schmidt inside it (and taking real parts) we could then produce a real eigenfunction ψ for λ_1^+ with $\|\psi\| = 1$ and $\psi \perp e_1$. The decisive observation is that $|\psi|$ is *also* an eigenfunction for λ_1^+. Because $W \geq 0$, the triangle inequality for the integral gives, pointwise a.e.,

$$\lambda_1^+\ |\psi(x)| = |(\mathbb{W}\psi)(x)| = \Big|\int_0^1 W(x,y)\,\psi(y)\ \mathrm{d}y\Big| \ \leq\ \int_0^1 W(x,y)\ |\psi(y)|\ \mathrm{d}y = (\mathbb{W}\,|\psi|)(x),$$

so $\mathbb{W}\,|\psi| \geq \lambda_1^+\,|\psi|$ a.e. Integrating this inequality against the nonnegative function $|\psi|$, and using $\||\psi|\| = \|\psi\| = 1$, gives $\langle \mathbb{W}\,|\psi|\,, |\psi|\rangle \geq \lambda_1^+$. But $\lambda_1^+ = \max_{\|g\|=1}\langle \mathbb{W}g, g\rangle$ is the constrained maximum of part (1)–(2), so the reverse inequality holds as well; the two pinch, $|\psi|$ is itself a unit maximiser, and the stationarity computation of part (1)–(2) upgrades any unit maximiser to an eigenfunction, $\mathbb{W}\,|\psi| = \lambda_1^+\,|\psi|$.

Now strict positivity closes the argument. The function $g := |\psi| - \psi$ is a difference of two eigenfunctions for λ_1^+, hence itself one, and it is nonnegative, $g \geq 0$ a.e. The strict-positivity dichotomy just proved therefore applies to it: either $g \equiv 0$ or $g > 0$ almost everywhere, with no middle ground. The orthogonality $\psi \perp e_1$ decides which branch holds. Since $e_1 > 0$ a.e. and $\psi \not\equiv 0$, the constraint $\int_0^1 \psi\, e_1 = 0$ forces ψ to be strictly positive on a set of positive measure (and strictly negative on another): were $\psi \geq 0$ a.e. the integral against the strictly positive weight e_1 could not vanish, and likewise for $\psi \leq 0$. On the set $\{\psi > 0\}$ we have $g = |\psi| - \psi = 0$, so g vanishes on a set of positive measure, and the dichotomy can then be satisfied only by $g \equiv 0$, i.e. $\psi = |\psi| \geq 0$ a.e. That contradicts ψ being strictly negative on a set of positive measure. Hence no real eigenfunction orthogonal to e_1 exists, the top eigenspace is one-dimensional, and λ_1^+ is simple. This is exactly where connectedness is indispensable: it is the hypothesis that powered the dichotomy, and without the dichotomy the orthogonal companion ψ could survive as a second eigenfunction independent of e_1 — precisely the two-dimensional top eigenspace the disconnected block-diagonal example exhibited above.

Uniqueness of the nonnegative eigenfunction. It remains to see that no *other* eigenfunction — one belonging to a different eigenvalue — can be nonnegative, so that e_1 is, up to sign and scale, the only nonnegative eigenfunction $\mathbb{W}$ possesses. Any e_n with $n \geq 2$ is orthogonal to e_1, $\int_0^1 e_n e_1 = 0$, by the orthonormality of the spectral basis. But $e_1 > 0$ a.e., so an integral $\int_0^1 e_n e_1 = 0$ against a strictly positive weight is impossible unless e_n takes both signs: e_n must change sign. Hence the leading mode is the unique nonnegative eigenfunction, exactly as the interpretation of centrality demanded. The general statement, of which this is the graphon instance, is the Krein–Rutman theorem on the positive eigenvector of a positivity-preserving compact operator [113, Ch. VI]; the graphon form is in [99, Ch. 7]. □

Definition 18.8 (Eigenvector centrality)**.** For a connected nonnegative graphon W, the *eigenvector centrality* is the unique nonnegative, L^2-normalised leading eigenfunction $c = e_1$, characterised by the self-consistency relation

$$c(x) \;=\; \frac{1}{\lambda_1^+} \int_0^1 W(x,y)\, c(y)\, \mathrm{d}y, \qquad c \geq 0, \quad \|c\|_{L^2} = 1. \tag{18.3}$$

Equation eq. (18.3) is the promised circular definition made rigorous: the centrality of type x is the W-weighted average of its neighbours' centralities, rescaled by λ_1^+. Read as a self-consistency condition it says that c is a fixed point of the normalised averaging operator $\mathbb{W}/\lambda_1^+$, and theorem 18.7 guarantees this fixed point both exists and — on a connected graphon — is the *only* nonnegative one, so the centrality ranking it induces is unambiguous. It is illuminating to see the fixed point solved in the one case where it is fully explicit, the rank-one kernel $W(x,y) = f(x)f(y)$ with $f \geq 0$ and $\|f\|_{L^2} > 0$. Here $(\mathbb{W}g)(x) = f(x)\langle f, g\rangle$, so any eigenfunction with nonzero eigenvalue must be proportional to f; normalising gives $c = f/\,\|f\|_{L^2}$ with leading eigenvalue $\lambda_1^+ = \|f\|_{L^2}^2$, and one checks eq. (18.3) directly: $\frac{1}{\lambda_1^+}\mathbb{W}c = \frac{1}{\|f\|^2} f\langle f, c\rangle = \frac{f}{\|f\|^2} \cdot \frac{\|f\|^2}{\|f\|} = \frac{f}{\|f\|} = c$. Centrality is just the profile f itself — the single coordinate that the whole rank-one network runs on.

That last computation is not a toy: it is the seed of the closed-form graphon mean field game carried as Thread B. In the static graphon games of chapter 20 a type's optimal action at equilibrium is, to leading order in the coupling strength, proportional to its eigenvector centrality $c(x)$ — the more central a type, the more population pressure it feels and the more effort it exerts in response. The reason a *closed-form* comparative static exists there is precisely eq. (18.3): because equilibrium effort solves the same linear fixed-point relation as centrality, the entire equilibrium profile is pinned by a single eigenfunction rather than by an infinite-dimensional system, and on a rank-one kernel that eigenfunction collapses to the scalar order parameter $\varrho = \langle f, \bar{m}\rangle$ of the thread, reducing the game to one self-consistent scalar equation. The existence and uniqueness supplied by theorem 18.7 are what make that reduction legitimate: without the Perron eigenvalue being simple and its eigenfunction strictly positive, "the" equilibrium effort profile would not be well defined. The centrality fixed point is thus handed forward to chapter 20 as the backbone of every static closed form to come.

Physics note

The eigenvalue problem $\mathbb{W}c = \lambda_1^+ c$ is the ground state of the single-particle "Hamiltonian" $-\mathbb{W}$ on the type line: the leading eigenfunction is the lowest-energy mode, and on a connected (irreducible) network it is nodeless — strictly positive — exactly as the ground-state wave-function of a Schrödinger operator with no internal boundary is nodeless. Centrality is thus the network's ground-state profile, the shape into which any nonnegative input relaxes under repeated coupling by $\mathbb{W}$. The higher eigenfunctions e_n, $n \geq 2$, are the excited modes; they must have nodes (sign changes), and section 18.3 reads those nodes as community boundaries. One caution keeps the analogy honest: the "type line" is the label interval $[0, 1]$ carrying *no* intrinsic geometry — $|x - y|$ has no meaning, the types being exchangeable labels rather than spatial positions (the standing convention of appendix A.5). The "Hamiltonian" $-\mathbb{W}$ is an integral, not a differential, operator, and "nodeless" here refers to sign, not to any spatial smoothness. The proof above uses no physics; the analogy is a mnemonic for which eigenfunction is which.

We have isolated the top of the spectrum and given it a meaning: the leading eigenvalue $\lambda_1^+ = \rho(\mathbb{W})$ is isolated and, on a connected graphon, simple, and its eigenfunction e_1 is the strictly positive eigenvector centrality. Two threads leave this section. The simplicity of λ_1^+ and the strict positivity of e_1 are precisely the non-degeneracy hypotheses that the Davis–Kahan perturbation bound of section 18.4 will require: a simple, isolated eigenvalue is exactly the situation in which the leading eigenfunction moves continuously — rather than jumping — when the kernel is perturbed, and that stability is what lets convergence of eigenvalues be upgraded to convergence of the centrality profile itself. The other thread is the gap. We have established that λ_1^+ sits strictly above the rest of the spectrum, but we have said nothing yet about *how far* above, and that distance — the gap between λ_1^+ and the next eigenvalue below it — is the quantity that controls how fast repeated averaging by $\mathbb{W}$ aligns a population with e_1, and, when it nearly closes, signals that the network is splitting into communities. Having read the top mode, we turn in section 18.3 to the gap beneath it.

18.3 The spectral gap: mixing and community structure

The previous section isolated the very top of the spectrum and gave it both a name and a meaning: on a connected graphon the leading eigenvalue $\lambda_1^+ = \rho(\mathbb{W})$ is simple and strictly separated from everything beneath it, and its eigenfunction e_1 is the strictly positive centrality profile into which the network relaxes under repeated averaging. But we left a question hanging at the close of that section. We argued that e_1 *governs* the network — that iterating $\mathbb{W}$ aligns any input with e_1 — without ever saying how quickly, or what happens when that alignment is slow. The physicsnote there sketched the shape of the answer: e_1 is the nodeless "ground state," and the higher eigenfunctions e_n, $n \geq 2$, are "excited modes" carrying nodes, with those nodes marking community boundaries. This section turns that picture into quantitative statements. The single quantity that controls everything is the *gap* between the leading eigenvalue and the next one below it, and the whole section is the elaboration of one dichotomy this gap encodes.

The dichotomy is this. Each round of averaging by $\mathbb{W}$ multiplies the n-th spectral component of a function by λ_n; relative to the leading component, which is multiplied by λ_1, the n-th component shrinks by the ratio λ_n/λ_1 at every round. If the gap is *large* — $|\lambda_2|$ sitting well below $|\lambda_1|$ — this ratio is small, every subdominant mode is crushed within a few rounds, and the network collapses spectrally onto the single mode e_1: it behaves as *one* community, and mixing is fast. If the gap is *small* — a second eigenvalue $|\lambda_2|$ nearly as large as $|\lambda_1|$ — the mode e_2 decays barely faster than e_1, survives many rounds of averaging, and constitutes a second persistent collective degree of freedom alongside centrality. A whole cluster of eigenvalues at the top is a whole cluster of long-lived modes, and that multiplicity of persistent modes *is* community structure: each near-top eigenfunction is the indicator of one community, its node the seam between two camps. Large gap means fast mixing onto a single dominant community; small gap means slow mixing and several coexisting communities. Everything in this section is that sentence made precise.

We develop it in two movements. First we make "suppresses geometrically" exact: power iteration — applying $\mathbb{W}$ over and over — is the elementary mechanism behind the relaxation onto e_1, and the gap ratio $|\lambda_2| / |\lambda_1|$ turns out to be exactly its convergence rate, so that the gap simply *is* the mixing rate. Second, in example 18.11, we make "community structure" concrete on the one graphon where every eigenvalue and eigenfunction can be written down by hand — the two-block stochastic block model — and watch the abstract statements become explicit formulas: the gap below the top is literally the cross-block tie density, the second eigenfunction is literally the ± 1 community indicator, and its sign is literally the community-detection rule. The closing paragraph then lifts that hand-computed instance to the general lesson the next two sections consume.

18.3.1 Power iteration and the meaning of the gap

The section lead made a promise and hid a word inside it. It claimed that each round of averaging by $\mathbb{W}$ suppresses every non-leading mode *geometrically* relative to the leading one, and on the strength of that single adverb built the entire dichotomy between fast mixing and community structure. But "geometrically" was left to stand on intuition, and the target of the relaxation — the leading eigenline $\mathbb{R}e_1$, the strictly positive centrality profile that section 18.2 singled out as the shape any nonnegative input relaxes into — was named without a rate. We now supply both: we make "geometrically" an exact inequality and we identify the gap ratio as precisely its rate, so that the gap and the mixing rate become the same number.

The cleanest way to do this is to watch the elementary process that singles out the leading mode e_1 in the first place: *power iteration*, the repeated application of $\mathbb{W}$ to an arbitrary starting function. Take any $f \in L^2[0,1]$ and resolve it in the eigenbasis, $f = \sum_n \langle f, e_n \rangle e_n$. Applying $\mathbb{W}$ once scales the n-th coordinate by λ_n (this is just the operator form of eq. (18.1)); applying it k times scales that coordinate by λ_n^k, so $\mathbb{W}^k f = \sum_n \lambda_n^k \langle f, e_n \rangle e_n$. The leading coordinate behaves like λ_1^k and dominates all the others, because every subdominant coordinate carries the extra factor $(\lambda_n/\lambda_1)^k$, which decays geometrically in k provided $|\lambda_n| < |\lambda_1|$. Divide out the overall λ_1^k and what remains after k rounds is e_1 plus an error controlled entirely by the largest surviving ratio $|\lambda_2| / |\lambda_1|$ — the slowest-decaying of the subdominant modes sets the pace, and the rest decay at least as fast. The single number $|\lambda_2| / |\lambda_1|$, or equivalently its complement, is therefore the entire story of how fast a population aligns with the centrality profile e_1 inherited from the previous section. We name it before we quantify it.

Definition 18.9 (Spectral gap)**.** For a graphon with $|\lambda_1| > |\lambda_2|$, the (multiplicative) *spectral gap* is $\gamma = 1 - |\lambda_2| / |\lambda_1| \in (0, 1]$, and the absolute gap is $|\lambda_1| - |\lambda_2|$. For a connected nonnegative graphon, where $|\lambda_1| = \lambda_1^+$, we also speak of the *principal gap* $\lambda_1^+ - \lambda_2^+$ between the two largest positive eigenvalues.

Three forms of the gap appear because three different questions use it, and they reprise the two orderings of definition 18.1. Each form is the right currency for exactly one of those questions, and pairing the wrong form with a question is the standard way to get a bound that is either dimensionally nonsensical or sign-blind. The *multiplicative* gap $\gamma = 1 - |\lambda_2| \,/\, |\lambda_1|$ is the dimensionless quantity that governs convergence *rates*: it is built from the modulus order, since a relaxation rate cares only about sizes, and it is what enters the bound below as $(1-\gamma)^k = (|\lambda_2| \,/\, |\lambda_1|)^k$. A rate must be a pure ratio — it multiplies itself once per round and has to be scale-free for $(\,\cdot\,)^k$ to make sense — so the multiplicative form, and only it, is what the mixing proposition can use. The *absolute* gap $|\lambda_1| - |\lambda_2|$, by contrast, carries the units of an eigenvalue and is the right currency for a different question entirely: the stability of the leading eigen*space* under a perturbation of the kernel. When W is nudged to a nearby kernel W', its leading eigenfunction does not jump but *rotates*, and the angle through which it rotates is bounded by the size of the perturbation *divided by the absolute gap* — this is the Davis–Kahan $\sin\Theta$ estimate that section 18.4 invokes to upgrade operator-norm closeness of two graphons into L^2 closeness of their centrality profiles. A ratio would be the wrong currency there, because a perturbation displaces eigenvalues by an *absolute* amount, not a fractional one; what protects the leading eigenvector is the absolute distance in the real line separating λ_1 from its nearest neighbour, the literal room the perturbation must traverse before it can confuse the two modes. The *principal* gap $\lambda_1^+ - \lambda_2^+$ is built from the signed order and tracks instead the separation between the two leading *assortative* modes; it is the quantity that says how cleanly a community splits, and it is the one we read off the block model. The three are easy to keep straight by their roles: multiplicative for rates, absolute for the stability of eigenvectors, principal for the assortative splitting visible only in nonnegative kernels. The definition demands the strict separation $|\lambda_1| > |\lambda_2|$ as a hypothesis precisely because everything that follows divides by it: with $|\lambda_1| = |\lambda_2|$ the leading mode is degenerate, there is no single e_1 to relax onto, and both the rate and the centrality profile become ill-posed — the failure we will watch happen explicitly when the two-block model decouples. The definition records the gap; the next proposition cashes it as a convergence rate, turning the heuristic count of factors $(\lambda_2/\lambda_1)^k$ into a clean L^2 estimate.

Proposition 18.10 (Mixing by power iteration)**.** *Suppose $|\lambda_1| > |\lambda_2|$ and let $P_1 = \langle\cdot, e_1\rangle e_1$ be the orthogonal projection onto the leading eigenline. Then for every $f \in L^2[0,1]$ and every $k \geq 1$,*

$$\left\| \lambda_1^{-k}\, \mathbb{W}^k f - \langle f, e_1\rangle e_1 \right\|_{L^2} \;\leq\; \Big(\frac{|\lambda_2|}{|\lambda_1|}\Big)^k \;\|f\|_{L^2}\,. \tag{18.4}$$

If moreover $\langle f, e_1\rangle \neq 0$, then $\mathbb{W}^k f / \left\|\mathbb{W}^k f\right\| \to \pm e_1$ in L^2 at the geometric rate $(|\lambda_2| \,/\, |\lambda_1|)^k$.

Proof. By eq. (18.1), $\mathbb{W}^k f = \sum_n \lambda_n^k \langle f, e_n\rangle e_n$, so $\lambda_1^{-k}\mathbb{W}^k f - \langle f, e_1\rangle e_1 = \sum_{n\geq 2} (\lambda_n/\lambda_1)^k \langle f, e_n\rangle e_n$. By orthonormality and $|\lambda_n| \leq |\lambda_2|$ for $n \geq 2$,

$$\Big\| \sum_{n\geq 2} (\lambda_n/\lambda_1)^k \langle f, e_n\rangle e_n \Big\|^2 = \sum_{n\geq 2} \Big(\frac{\lambda_n}{\lambda_1}\Big)^{2k} \langle f, e_n\rangle^2 \leq \Big(\frac{|\lambda_2|}{|\lambda_1|}\Big)^{2k} \sum_{n\geq 2} \langle f, e_n\rangle^2 \leq \Big(\frac{|\lambda_2|}{|\lambda_1|}\Big)^{2k} \|f\|^2\,,$$

which is eq. (18.4). Read the three inequalities in order: the equality is Parseval applied to the orthonormal e_n; the first inequality replaces each surviving ratio $|\lambda_n/\lambda_1| \leq |\lambda_2/\lambda_1|$ by the largest one, which is exactly the gap doing its work; the second drops the missing $n = 1$ term to extend the sum back to all of $\|f\|^2 = \sum_n \langle f, e_n\rangle^2$. Taking square roots gives the bound.

The normalised statement follows by tracking the norm itself. Splitting off the leading term, $\mathbb{W}^k f = \lambda_1^k \langle f, e_1\rangle e_1 + \sum_{n\geq 2} \lambda_n^k \langle f, e_n\rangle e_n$, and applying Parseval again, $\left\|\mathbb{W}^k f\right\|^2 = \lambda_1^{2k}\langle f, e_1\rangle^2 + \sum_{n\geq 2}\lambda_n^{2k}\langle f, e_n\rangle^2$. When $\langle f, e_1\rangle \neq 0$ the first term dominates and the tail is smaller by a factor at most $(|\lambda_2| / |\lambda_1|)^{2k} \to 0$, so $\left\|\mathbb{W}^k f\right\| = |\lambda_1|^k |\langle f, e_1\rangle| (1 + o(1))$. Dividing $\mathbb{W}^k f$ by this norm cancels the common λ_1^k and leaves a unit multiple of e_1 up to the same vanishing tail, so the normalised iterate converges to $\pm e_1$ at the geometric rate $(|\lambda_2| / |\lambda_1|)^k$. The lone hypothesis $\langle f, e_1\rangle \neq 0$ is the requirement that the seed have *some* overlap with the leading mode: $\mathbb{W}$ preserves the orthogonal complement of e_1, so a seed orthogonal to e_1 stays orthogonal forever and can never be steered toward it — the one starting direction power iteration cannot recover from. $\square$

It helps to watch the bound act on a concrete number before reading off its meaning. Suppose the network has a healthy gap, say $|\lambda_2| / |\lambda_1| = \frac{1}{2}$ — the second mode decays twice as fast as the first under each averaging. Then eq. (18.4) says the normalised iterate sits within $2^{-k}\|f\|$ of the centrality line after k rounds: within $\frac{1}{4}$ at $k = 2$, within $\frac{1}{32}$ at $k = 5$, within a thousandth at $k = 10$. So a mere handful of rounds of kernel-weighted averaging — five passes of "replace each type's state by the W-weighted average of its neighbours' states" — already drives an arbitrary starting profile to within a few percent of the eigenvector centrality e_1, *whatever* the starting profile was, provided only that it was not exactly orthogonal to e_1. This is the operational content of a large gap, and it is why centrality is a robust, quickly-computed summary of a well-connected network rather than a fragile spectral abstraction: power iteration reaches it in single-digit passes. The same arithmetic read in reverse is the warning the rest of the section develops. Halve the gap to $|\lambda_2| / |\lambda_1| = 0.9$ and the error after five rounds is $0.9^5 \approx 0.59$ — the iterate has barely moved, the second mode is still very much alive, and "the" centrality profile is not yet a meaningful summary because a second collective mode is sharing the stage with it.

So a *large* gap means fast relaxation onto the single dominant mode e_1: the network is, spectrally, "one community," and any influence diffuses to the centrality profile in a few rounds of averaging. A *small* gap — two or more eigenvalues near the top, nearly degenerate — means slow relaxation and the persistence of more than one collective mode. That persistence is community structure, and the eigenfunctions of the near-degenerate top eigenvalues are the community indicators.

It is worth attaching a number to "fast" and "slow," because the dependence on the gap is sharp. To drive the error eq. (18.4) below a tolerance ε takes

$$k \;\approx\; \frac{\log(1/\varepsilon)}{\log(|\lambda_1| / |\lambda_2|)} \;\approx\; \frac{\log(1/\varepsilon)}{\gamma}$$

rounds of averaging, the second approximation holding for a small multiplicative gap γ, where $\log(|\lambda_1| / |\lambda_2|) = -\log(1-\gamma) \approx \gamma$. The mixing time thus scales as the *inverse* gap and diverges exactly as the gap closes: a network with two nearly degenerate top modes takes order γ^{-1} rounds to forget which of the two it started in. And when the gap does close, what survives alongside e_1 is not noise but the next eigenfunction e_2 — the first excited mode, which by the Perron–Frobenius discussion of section 18.2 *must* change sign, since it is orthogonal to the strictly positive e_1. Its node, the type at which e_2 crosses zero, is the boundary between the two persistent collective modes. This is the precise sense in which a near-degeneracy at the top of the spectrum is community structure: a second mode that averaging cannot extinguish, partitioned by its single node into two camps.

The reading is still abstract — it names e_2 and its node without showing either — and it is most convincing where it can be checked against explicit formulas. The next subsection supplies exactly that. In the two-block stochastic block model the whole spectrum is two numbers, so the gap $|\lambda_1| - |\lambda_2|$ can be *computed* rather than estimated, and the second eigenfunction e_2 can be *written down* — and it turns out to be the ± 1 indicator of the two blocks, its single node sitting exactly on the seam between them. The promise of this subsection, that small gap equals near-degenerate top eigenfunctions equals community structure, becomes there a line of arithmetic. We now make all of it completely explicit on the one example where the arithmetic closes.

18.3.2 The two-block model, by hand

The dichotomy of the previous subsection is sharpest where it can be checked entirely by hand, and there is exactly one graphon simple enough for that yet rich enough to exhibit the phenomenon: the stochastic block model with two equal blocks. It is the hydrogen atom of community structure — low enough in rank that the entire spectrum is two numbers, structured enough that those two numbers are precisely the centrality eigenvalue and the gap, and the two eigenfunctions are precisely the uniform mode and the community indicator. Every general statement made above reappears here as an explicit formula. We will also return to this model repeatedly: it is the worked instance behind the convergence pathologies of section 18.4 — where a tiny perturbation splits its degeneracy and swings the eigenfunctions — and behind the rank-two reduction of section 18.5. We compute its spectrum from scratch.

Example 18.11 (Spectrum of the two-block stochastic block model)**.** Partition $[0,1] = I_1 \cup I_2$ into two halves $I_1 = [0, \frac{1}{2})$, $I_2 = [\frac{1}{2}, 1]$, and set

$$W(x,y) = \begin{cases} p, & x, y \text{ in the same block,} \\ q, & x, y \text{ in different blocks,} \end{cases} \qquad p, q \in [0,1].$$

Everything about this operator is dictated by a single structural fact: the kernel $W(x,y)$ depends on the pair (x,y) only through *which blocks* the two types fall in — it is constant on each of the four block-pair rectangles $I_i \times I_j$. Consequently the value $(\mathbb{W}f)(x) = \int_0^1 W(x,y) f(y)\, \mathrm{d}y$ can depend on x only through x's block: for *any* input f, the output $\mathbb{W}f$ is constant on I_1 and constant on I_2. So the range of $\mathbb{W}$ lies in the two-dimensional space $V = \operatorname{span}\{\mathbf{1}_{I_1}, \mathbf{1}_{I_2}\}$ of block-constant functions, and $\mathbb{W}$ has rank at most two. The complementary fact identifies the kernel of the operator. Call a function f *block-mean-zero* if it integrates to zero over each block separately, $\int_{I_1} f = \int_{I_2} f = 0$; such an f is annihilated outright, because for $x \in I_1$

$$(\mathbb{W}f)(x) = p \int_{I_1} f + q \int_{I_2} f = p \cdot 0 + q \cdot 0 = 0,$$

and symmetrically for $x \in I_2$. The block-mean-zero functions are precisely the orthogonal complement $V^\perp$ inside $L^2[0,1]$, so $V^\perp \subseteq \ker \mathbb{W}$ and the entire action of $\mathbb{W}$ is carried by its restriction to the two-dimensional V — the operator is genuinely a 2×2 matrix in disguise. On V,

$$\mathbb{W}\mathbf{1}_{I_1} = \tfrac{p}{2}\mathbf{1}_{I_1} + \tfrac{q}{2}\mathbf{1}_{I_2}, \qquad \mathbb{W}\mathbf{1}_{I_2} = \tfrac{q}{2}\mathbf{1}_{I_1} + \tfrac{p}{2}\mathbf{1}_{I_2},$$

because, e.g., $(\mathbb{W}\mathbf{1}_{I_1})(x) = \int_{I_1} W(x,y)\,\mathrm{d}y$ equals $p \cdot \frac{1}{2}$ for $x \in I_1$ (the kernel is p throughout $I_1 \times I_1$ and $|I_1| = \frac{1}{2}$) and $q \cdot \frac{1}{2}$ for $x \in I_2$ (the kernel is q throughout $I_2 \times I_1$). In the basis $(\mathbf{1}_{I_1}, \mathbf{1}_{I_2})$ the operator is the matrix $\frac{1}{2}\left(\begin{smallmatrix} p & q \\ q & p \end{smallmatrix}\right)$, whose eigenpairs are

$$\lambda_1 = \frac{p+q}{2} \;\text{ with }\; e_1 \propto \mathbf{1}_{I_1} + \mathbf{1}_{I_2} = \mathbf{1}, \qquad \lambda_2 = \frac{p-q}{2} \;\text{ with }\; e_2 \propto \mathbf{1}_{I_1} - \mathbf{1}_{I_2}.$$

Normalising in $L^2[0,1]$ gives $e_1 = \mathbf{1}$ (the constant, with $\|\mathbf{1}\| = 1$) and $e_2 = \mathbf{1}_{I_1} - \mathbf{1}_{I_2}$, the genuine ± 1 community indicator. Note the contrast with the block indicators $\mathbf{1}_{I_j}$, which have norm $\left\|\mathbf{1}_{I_j}\right\| = \sqrt{1/2}$ and so are *not* normalised: the difference $\mathbf{1}_{I_1} - \mathbf{1}_{I_2}$ takes the values ± 1, so its square is 1 a.e. and $\|\mathbf{1}_{I_1} - \mathbf{1}_{I_2}\|_{L^2} = 1$ already — which is precisely why the L^2-normalised second eigenfunction *is* the ± 1 indicator, with no rescaling. The rest of the spectrum is zero, and the two surviving eigenpairs already carry every reading the abstract discussion promised. We take them one at a time.

Centrality is uniform. The leading eigenfunction is the constant $e_1 = \mathbf{1}$, so every type carries the same eigenvector centrality of section 18.2: in a symmetric two-block model no type occupies a structurally privileged position, exactly as the block-interchange symmetry of the model demands. This is the degenerate, featureless case of the centrality reading, and its interest lies in what happens when the symmetry is broken. Make the blocks unequal in size, or give them unequal internal densities $p_1 \neq p_2$, and the 2×2 reduction loses its symmetry; its Perron eigenvector e_1 ceases to be constant and *tilts* toward the denser, larger block, assigning that block the higher centrality. That tilt is not a curiosity but the comparative static the equilibrium analysis of chapter 20 runs on: there e_1 becomes the equilibrium effort profile, and "which block works harder" is read off directly from the direction in which the broken symmetry tilts the leading eigenfunction.

The second eigenfunction is the community indicator. Because $e_2 = \mathbf{1}_{I_1} - \mathbf{1}_{I_2}$, its sign $\operatorname{sgn} e_2(x)$ returns $+1$ on I_1 and -1 on I_2, recovering the block of x exactly; and its single node — the seam $x = \frac{1}{2}$, where it jumps from $+1$ to -1 — is precisely the community boundary that the previous subsection located abstractly as the zero crossing of the first excited mode. Spectral community detection — compute the second eigenfunction, threshold it at zero, and assign each type to a community by the sign — is nothing more than this observation, and it is the continuum shadow of the Fiedler-vector heuristic that partitions a finite graph by the sign pattern of the second eigenvector of its adjacency (or Laplacian) matrix. Here the heuristic is not heuristic at all but exact: $\operatorname{sgn} e_2$ recovers the planted partition with no error, because the model has nothing but the partition in it.

Assortative versus disassortative, and a non-PSD witness. Whether e_2 reports a clustered community or a bipartite split is read off the *sign* of its eigenvalue $\lambda_2 = (p-q)/2$, and this is where the signed ordering of definition 18.1 earns its keep. When $p > q$ — within-block ties denser than cross-block ties, an assortative community structure — one has $\lambda_2 = (p-q)/2 > 0$: the community mode is reproduced with its own sign under averaging, each block linked predominantly to itself, the "like attracts like" picture. The principal gap between the two clustering modes is then

$$\lambda_1 - \lambda_2 = \frac{p+q}{2} - \frac{p-q}{2} = q,$$

small precisely when q is small, i.e. when the two communities are weakly linked — the slow-mixing regime of proposition 18.10, in which the blocks behave as nearly independent subnetworks and repeated averaging takes order q^{-1} rounds to forget which block it started in. When $p < q$ — cross-block ties denser, a bipartite-like, disassortative structure — the same eigenvalue turns negative, $\lambda_2 = (p-q)/2 < 0$: the mode now flips sign under averaging, each block linked predominantly to the *other*, "opposites attract," and the negative eigenvalue is the spectral signature of bipartiteness. This is the concrete realisation of the warning issued in remark 18.3. The kernel is a perfectly ordinary $[0,1]$-valued graphon, nonnegative as a function on $[0,1]^2$, yet its operator is *not* positive semidefinite, for the explicit test function $e_2 = \mathbf{1}_{I_1} - \mathbf{1}_{I_2}$ witnesses a negative quadratic form,

$$\langle \mathbb{W} e_2, e_2 \rangle = \lambda_2 \, \|e_2\|_{L^2}^2 = \lambda_2 = \frac{p-q}{2} < 0,$$

exactly as promised there. Pointwise nonnegativity of the kernel and positivity of its quadratic form are different conditions, and the disassortative two-block model is the cleanest place to watch them part company. In this regime the modulus ordering and the signed ordering disagree about which entry is "second": $|\lambda_1| = (p+q)/2$ still leads, but the gap that governs mixing is now

$$|\lambda_1| - |\lambda_2| = \frac{p+q}{2} - \frac{q-p}{2} = p,$$

which closes as the within-block density p vanishes — the limit of a perfect bipartite graphon with every tie crossing the seam.

Finally, two sanity checks against the spectral-moment identity proposition 18.4, worked through in full because the arithmetic is exactly the kind of bookkeeping the identity is supposed to make automatic. The first is $k = 2$, the squared Hilbert–Schmidt norm. Spectrally,

$$\sum_n \lambda_n^2 = \lambda_1^2 + \lambda_2^2 = \Big(\frac{p+q}{2}\Big)^2 + \Big(\frac{p-q}{2}\Big)^2 = \frac{(p+q)^2 + (p-q)^2}{4} = \frac{2p^2 + 2q^2}{4} = \frac{p^2+q^2}{2},$$

where the cross terms $\pm 2pq$ cancel in the numerator. Computed instead straight from the kernel, $\|W\|_{L^2([0,1]^2)}^2 = \iint_{[0,1]^2} W^2$ sums p^2 over the two same-block squares $I_1 \times I_1$ and $I_2 \times I_2$ (total area $\frac{1}{2}$) and q^2 over the two cross-block rectangles (total area $\frac{1}{2}$), giving $p^2 \cdot \frac{1}{2} + q^2 \cdot \frac{1}{2} = \frac{1}{2}(p^2 + q^2)$ — the two evaluations agree. The second check is $k = 3$, the triangle density. Spectrally, the odd cross terms now *survive* while the rest cancel:

$$\sum_n \lambda_n^3 = \lambda_1^3 + \lambda_2^3 = \frac{(p+q)^3 + (p-q)^3}{8} = \frac{2p^3 + 6pq^2}{8} = \frac{p^3 + 3pq^2}{4},$$

using $(p+q)^3 + (p-q)^3 = 2(p^3 + 3pq^2)$. Computed combinatorially as $t(C_3, W)$, the closed three-cycle integral, draw three independent uniform types: the $2^3 = 8$ block patterns each have probability $\frac{1}{8}$, the two monochromatic patterns ($I_1 I_1 I_1$ and $I_2 I_2 I_2$) contribute three within-block edges and hence p^3 apiece, and each of the remaining six patterns has one lone vertex, contributing one within-block edge and two crossing edges, pq^2 apiece, so $t(C_3, W) = \frac{1}{8}(2p^3 + 6pq^2) = \frac{1}{4}(p^3 + 3pq^2)$ — again the two evaluations agree. The third spectral moment is, on the nose, the probability that three random types close a triangle.

The block model is the cleanest case, but its lesson is general, and stating that generalisation correctly is the bridge out of this section. Read the two-block spectrum structurally rather than numerically: there were exactly two nonzero eigenvalues, separated by a gap from an infinite sea of zeros, and their two eigenfunctions — the uniform mode and the ± 1 indicator — between them spanned the space of functions constant on blocks, that is, the space of all possible community-level profiles. The general principle is the same with r in place of 2. Suppose a graphon's spectrum shows r eigenvalues clustered near the top and then a gap down to a tail that is small in the ℓ^2 sense controlled by proposition 18.4. By the power-iteration argument of proposition 18.10, the r top modes are exactly the ones averaging cannot extinguish while the tail decays away, so the network supports precisely r persistent collective degrees of freedom — "r communities plus noise" — and the span of the top r eigenfunctions is the space of macroscopic order parameters, the continuum replacement for the r block indicators. The gap is what makes the integer r well defined: it is the threshold that cleanly separates the structural modes from the noise, and without it "how many communities" has no answer.

This is not a metaphor but the exact hypothesis the remainder of the chapter runs on, and it leaves this section along two distinct seams. The first runs to section 18.5: if the tail below the gap is negligible, discarding it replaces the full operator by its rank-r truncation onto the top eigenfunctions, and section 18.5 shows that this collapses the infinite-dimensional graphon mean field game coupling to a *finite* system of r scalar order parameters — one per surviving mode — with the truncation error controlled by precisely the ℓ^2 tail the gap bounds. The two-block model is the case $r = 2$ (indeed $r = 1$ once one notes the constant mode is its only assortative one), the very template the low-rank section generalises, and the rank-one limit of that template is the single self-consistent scalar equation of Thread B. The second seam runs to section 18.4: the entire mixing-and-community picture rests on the leading eigenvalue being *simple* and *strictly separated* from the rest — the hypothesis $|\lambda_1| > |\lambda_2|$ that definition 18.9 demands and that example 18.11 meets whenever both p and q are positive. That same simple-eigenvalue-with-a-gap hypothesis is exactly what the Davis–Kahan perturbation theorem of section 18.4 will require in order to conclude that the leading eigenfunction — the centrality profile, and one rung down the community indicator — moves *continuously* rather than jumping when the kernel is perturbed or sampled. The two-block model previews why the hypothesis is indispensable: let the blocks decouple, $q \to 0$, and the leading eigenvalue acquires a second copy, $\lambda_1 = \lambda_2 = p/2$, so "the" centrality profile is no longer a single function but an entire two-dimensional eigenspace, and any infinitesimal asymmetry can swing the leading eigenfunction discontinuously from one block to the other. That degenerate instability is what section 18.4 must confront head-on, and the gap is precisely the quantity whose positivity forbids it. The spectral gap, in short, is at once the rate of mixing, the count of communities, and the licence for spectral stability.

18.4 Operator convergence versus cut convergence

The two-block model left us with a warning. When the gap above the second eigenvalue shrinks — when two modes of the spectrum approach one another, as the blocks of example 18.11 do as $q \to 0$ — the eigenvalues themselves stay perfectly well behaved, but the eigen*functions* become fragile: an infinitesimal, perfectly symmetric perturbation can rotate a near-degenerate eigenplane through a finite angle and swing "the" centrality profile discontinuously from one block to the other. Eigenvalues are robust; eigenfunctions are delicate, and the spectral gap is what stands between the two. That contrast is the seam the previous section explicitly handed forward, and honouring it is the whole business of this fourth movement. We must now make precise *in what sense* the spectrum of $\mathbb{W}$ depends continuously on the kernel W — separating the part of the spectrum that survives the weakest reasonable notion of closeness from the part that needs a far stronger one.

To do that we must first decide what "two graphons are close" even means, and the chapter has quietly accumulated *two* answers that do not agree. One is the cut metric $\delta_\square$ of chapter 17, under which graphon space is compact and under which sampling a network produces a kernel close to its limit; this is the notion the rest of the book will actually be handed by its compactness and sampling theorems, so it is the one we are stuck with whether we like it or not. The other is the family of operator-theoretic norms inherited from $\mathbb{W}$ — the operator (or $2 \to 2$) norm and the Hilbert–Schmidt norm — which measure closeness the way a spectral theorist would, by how nearly the two operators act alike on every test function. These notions are genuinely different, and the distance between them is exactly the distance between "the eigenvalues agree" and "the eigenfunctions agree." Pinning down that distance is the subject of this section.

The mechanism that will let us cross from one notion to the other is already in hand: it is the moment identity $\sum_n \lambda_n^k = t(C_k, W)$ of proposition 18.4. That identity is the hinge of the whole chapter precisely because it expresses a *spectral* quantity — a power sum of the eigenvalues — as a *cut-continuous* one, a cycle homomorphism density that chapter 17 already proved moves continuously in $\delta_\square$. Cut control of the kernel therefore transfers, through the moment identity, into control of the power sums of the spectrum, and from the power sums one can read back the individual eigenvalues. This is how the weakest notion of closeness still manages to pin every eigenvalue, and it is why the proof of the positive theorem below runs entirely through the moments rather than through any direct comparison of operators.

The architecture of the section is a strict *hierarchy of four notions of convergence*, each one provably weaker than the one before it, with a single positive theorem threading through to the bottom. Spelled out as an implication chain, convergence in the strongest norm forces convergence in each weaker one in turn,

$$\|W_n - W\|_{\mathrm{HS}} \to 0 \implies \|W_n - W\|_{2\to 2} \to 0 \implies \delta_\square(W_n, W) \to 0 \implies \lambda_k(W_n) \to \lambda_k(W) \text{ for every } k,$$

and at each arrow the converse fails — there is a concrete in-book sequence that converges in the right-hand sense but not the left. The first two arrows are the norm inequality $\|\cdot\|_\square \le \|\cdot\|_{2\to 2} \le \|\cdot\|_{\mathrm{HS}}$ of eq. (18.5), read as a statement about convergence; the third is the genuine theorem of this section, that cut convergence alone — the weakest, most easily attained notion — already forces every individual eigenvalue to converge. Eigen*functions*, crucially, sit *below the bottom* of this chain: none of these notions short of operator-norm convergence controls them, which is exactly the fragility the two-block model warned of, now stated as the failure of an implication.

Why insist on the full hierarchy rather than just working in the strongest norm throughout? Because we do not get to choose. Sampling a finite network from W and the compactness theorem theorem 17.13 both deliver convergence only in $\delta_\square$, the *weakest* of the four; nothing in those results gives operator-norm closeness for free. So the practically urgent question is precisely how much of the spectrum the weakest notion controls — and the answer, that it controls every eigenvalue but no eigenfunction, is what the three subsections establish in turn. The first sets down the three norms and proves the inequality eq. (18.5) that orders them, exhibiting an explicit witness that each inequality is strict. The second proves the one positive theorem, that cut convergence forces eigenvalue convergence, via the moment identity and a purely sequential fact about power sums of ℓ^2 sequences. The third confronts the eigenfunctions directly: a counterexample shows cut convergence cannot move them, and the Davis–Kahan theorem theorem 18.16 shows that operator-norm convergence *plus* a spectral gap can.

That final split is the message the section hands downstream, and it is worth naming its two destinations now. To chapter 19: the consistency of network sampling will be proved there at the level of the cut metric, so by this section it certifies that a sampled network has nearly the right *eigenvalues* — and, by itself, says nothing about its centrality profile. To chapter 25: a separate matrix-concentration argument will upgrade that cut consistency to operator-norm convergence of the empirical operator, at which point theorem 18.16 transports the leading eigenfunction — the eigenvector centrality of section 18.2, the object that becomes equilibrium effort in Part IV — from graphon to sampled network, provided the gap of section 18.3 is open. The eigenvalue/eigenfunction divide established here is thus the exact specification of what each later chapter must supply: cut convergence for the spectrum, operator-norm convergence for the centrality vector.

18.4.1 Three norms and an inequality

The section lead promised a hierarchy of four notions of closeness, strictly ordered, with a single positive theorem threading to the bottom. The top three rungs of that ladder are *norms* on kernels, and before we can speak of one notion being weaker than another we must put all three on the same footing and prove the inequality that orders them. That is the skeleton everything in this section hangs on, so we build it first and with care: three ways of measuring the size of a kernel U, a single chain $\|U\|_\square \le \|U\|_{2\to2} \le \|U\|_{\mathrm{HS}}$ relating them, and — the part that makes the hierarchy genuine rather than an artifact of loose constants — two explicit in-book sequences proving that *neither* inequality can be reversed even after rescaling. Each strictness will turn out to carry a specific message forward, so we do not merely assert the gaps; we manufacture them and read off what they mean.

The three norms measure size in three increasingly demanding ways, and it pays to name the intuition behind each before writing the symbols. For a kernel U on $[0,1]^2$ — signed, symmetric, measurable, bounded, exactly the class of *differences* $W_n - W$ we will care about — the weakest, the cut norm of chapter 17,

$$\|U\|_\square = \sup_{S,T\subseteq[0,1]} \Big| \int_{S\times T} U \Big|,$$

asks only how much mass U can accumulate over a single rectangle $S\times T$; it is blind to any structure finer than "how much net weight sits between this block of types and that one," which is exactly why it is the natural currency of the combinatorial and sampling theory and why it is so easily made small. The middle norm is the L^2 operator (or $2\to2$) norm

$$\|U\|_{2\to2} = \|\mathbb{W}_U\| = \sup_{\|g\|_{L^2}\le1} \|\mathbb{W}_U g\|_{L^2}\,, \qquad (\mathbb{W}_U g)(x) = \int_0^1 U(x,y)g(y)\;\mathrm{d}y,$$

where $\mathbb{W}_U$ is the parametric form of the integral operator $\mathbb{W} = \mathbb{W}$ of chapter 17; it asks how much U, acting as an operator, can stretch the *worst* unit test function, and so it sees not just block averages but the whole spectral action of U — for symmetric U it equals $\max_n |\lambda_n|$, the top eigenvalue in modulus. The strongest, the Hilbert–Schmidt norm

$$\|U\|_{\mathrm{HS}} = \|U\|_{L^2([0,1]^2)} = \Big(\int_{[0,1]^2} U^2\Big)^{1/2} = \Big(\sum_n \lambda_n^2\Big)^{1/2},$$

asks for the full L^2 energy of the kernel, equivalently the entire ℓ^2 length of the spectrum rather than just its largest entry. So the three norms are, spectrally, "one mode," "the largest mode," and "all the modes at once" — a genuine ordering of how much of the operator each one is allowed to feel. The basic comparison records that ordering:

$$\|U\|_{\square} \;\le\; \|U\|_{2\to 2} \;\le\; \|U\|_{\mathrm{HS}}\,. \tag{18.5}$$

Both inequalities have short, structural proofs, and we give them rather than wave at them. The *right* inequality is the statement that the operator norm of a Hilbert–Schmidt operator never exceeds its Hilbert–Schmidt norm, $\|\mathbb{W}_U\| \le \|\mathbb{W}_U\|_{\mathrm{HS}}$, which is definition 2.21; spectrally it is the triviality that the largest entry of a sequence is at most its ℓ^2 length, $\max_n |\lambda_n| \le (\sum_n \lambda_n^2)^{1/2}$. The *left* inequality is the operator-norm comparison lemma 17.3 of the previous chapter, and it is worth spelling out the one identity on which it turns, because that identity is the exact bridge between the rectangle-testing of the cut norm and the function-testing of the operator norm. For any measurable $S, T \subseteq [0,1]$, testing $\mathbb{W}_U$ against the two indicator functions $\mathbf{1}_S, \mathbf{1}_T$ reproduces the rectangle integral:

$$\int_{S\times T} U = \int_S \Big(\int_T U(x,y)\;\mathrm{d}y\Big)\,\mathrm{d}x = \int_0^1 \mathbf{1}_S(x)\,(\mathbb{W}_U\mathbf{1}_T)(x)\;\mathrm{d}x = \langle \mathbb{W}_U\mathbf{1}_T, \mathbf{1}_S\rangle.$$

Taking absolute values and applying Cauchy–Schwarz, then the definition of the operator norm,

$$\Big|\int_{S\times T} U\Big| = |\langle \mathbb{W}_U\mathbf{1}_T, \mathbf{1}_S\rangle| \le \|\mathbb{W}_U\mathbf{1}_T\|_{L^2}\;\|\mathbf{1}_S\|_{L^2} \le \|\mathbb{W}_U\|\;\|\mathbf{1}_T\|_{L^2}\;\|\mathbf{1}_S\|_{L^2} \le \|\mathbb{W}_U\|\,,$$

since $\|\mathbf{1}_S\|_{L^2} = |S|^{1/2} \le 1$ and likewise for T. Taking the supremum over S, T gives $\|U\|_{\square} \le \|U\|_{2\to 2}$. So the left inequality is, at bottom, the observation that indicators of sets are particular unit-ish test functions, and the cut norm optimises over only this impoverished family while the operator norm optimises over all of L^2.

That both inequalities in eq. (18.5) are *strict* — not reversible even up to a universal constant — is the whole point of the hierarchy, for it is what makes the four rungs genuinely distinct rather than the same notion wearing three names. We prove strictness the honest way, by exhibiting for each inequality a concrete sequence of kernels that drives the ratio of the two sides to its extreme. Each witness has been chosen so that the *reason* it works is the same phenomenon we will meet again downstream.

The left gap: a mean-zero spike. We seek symmetric kernels U_n with $\|U_n\|_{\square} \to 0$ but $\|U_n\|_{2\to 2} \not\to 0$ — a sequence small in cut but not in operator norm, witnessing that the left inequality cannot be reversed. The mechanism we want is a single eigenfunction that carries all the operator energy while spreading almost no net mass over any rectangle, and the cleanest way to build it is to make the eigenfunction itself thin and tall. Fix a sequence $\varepsilon_n \downarrow 0$ and define the mean-zero "spike"

$$\phi_n = \varepsilon_n^{-1/2}(\mathbf{1}_{[0,\varepsilon_n)} - \varepsilon_n),$$

a function that is large and positive on the short interval $[0, \varepsilon_n)$ and slightly negative elsewhere, with the constant $-\varepsilon_n$ chosen exactly to kill its mean. Three one-line computations pin down its size. Its integral vanishes, $\int_0^1 \phi_n = \varepsilon_n^{-1/2}(\varepsilon_n - \varepsilon_n) = 0$, so $\langle \phi_n, \mathbf{1} \rangle = 0$. Its L^2 energy is essentially one,

$$\|\phi_n\|_{L^2}^2 = \varepsilon_n^{-1} \int_0^1 \big(\mathbf{1}_{[0,\varepsilon_n)} - \varepsilon_n\big)^2 = \varepsilon_n^{-1}(\varepsilon_n - 2\varepsilon_n \cdot \varepsilon_n + \varepsilon_n^2) = 1 - \varepsilon_n \longrightarrow 1,$$

so $\|\phi_n\|_{L^2} = 1 + o(1)$. And, crucially for the cut estimate, its L^1 norm is small: the positive part contributes $\varepsilon_n^{-1/2}(1-\varepsilon_n)$ over a set of measure ε_n and the negative part contributes $\varepsilon_n^{-1/2}\varepsilon_n$ over a set of measure $1-\varepsilon_n$, so

$$\|\phi_n\|_{L^1} = \varepsilon_n^{-1/2}\Big[\varepsilon_n(1-\varepsilon_n) + \varepsilon_n(1-\varepsilon_n)\Big] = 2\,\varepsilon_n^{1/2}(1-\varepsilon_n) = O(\sqrt{\varepsilon_n}).$$

Now set $U_n(x,y) = \phi_n(x)\phi_n(y)$, the rank-one symmetric kernel whose operator is $g \mapsto \langle \phi_n, g\rangle\, \phi_n$. This operator has the single nonzero eigenvalue $\|\phi_n\|_{L^2}^2$ with eigenfunction ϕ_n, so its operator norm is

$$\|U_n\|_{2\to 2} = \|\phi_n\|_{L^2}^2 = 1 - \varepsilon_n \longrightarrow 1,$$

which stays bounded away from 0. The cut norm goes the other way, and to see it cleanly we isolate the elementary set-optimisation that governs a mean-zero function.

Lemma 18.12 (Optimal cut set of a mean-zero function). *Let $\phi \in L^1([0,1])$ have $\int_0^1 \phi = 0$. Then $\sup_{S\subseteq[0,1]} \big|\int_S \phi\big| = \frac{1}{2}\,\|\phi\|_{L^1}$, attained at $S = \{\phi > 0\}$.*

Proof. Write $\phi = \phi^+ - \phi^-$ for its positive and negative parts, so $\|\phi\|_{L^1} = \int \phi^+ + \int \phi^-$. The mean-zero hypothesis says $\int \phi^+ = \int \phi^-$, hence each equals $\frac{1}{2}\,\|\phi\|_{L^1}$. For any measurable S, $\int_S \phi = \int_S \phi^+ - \int_S \phi^-$ is the difference of two nonnegative numbers each at most $\int \phi^+ = \frac{1}{2}\,\|\phi\|_{L^1}$, so $\big|\int_S \phi\big| \le \frac{1}{2}\,\|\phi\|_{L^1}$; choosing $S = \{\phi > 0\}$ makes the second term vanish and the first equal $\int \phi^+$, attaining the bound (the sign-flipped optimum $S = \{\phi < 0\}$ attains $-\frac{1}{2}\,\|\phi\|_{L^1}$). $\square$

For the rank-one kernel the cut supremum factorises across the two indicators, $\int_{S\times T} U_n = \big(\int_S \phi_n\big)\big(\int_T \phi_n\big)$, so the joint supremum is the product of two single-set suprema, each governed by lemma 18.12:

$$\|U_n\|_\square = \Big(\sup_S \Big|\int_S \phi_n\Big|\Big)^2 = \Big(\tfrac{1}{2}\,\|\phi_n\|_{L^1}\Big)^2 = \Big(\varepsilon_n^{1/2}(1-\varepsilon_n)\Big)^2 = O(\varepsilon_n) \longrightarrow 0.$$

Thus $\|U_n\|_\square \to 0$ while $\|U_n\|_{2\to 2} \to 1$: the left inequality of eq. (18.5) cannot be reversed, even up to a constant, even within the rank-one kernels. The picture to keep is physical. The operator energy is concentrated entirely in the eigenfunction ϕ_n, which grows tall and thin and slides into the corner $x = 0$; the cut norm cannot feel it because over any rectangle the tall positive spike is almost exactly cancelled by the broad negative shelf the mean-zero correction installs. This is precisely the "eigenfunction concentrates and escapes" obstruction that makes *eigenfunctions* discontinuous under cut convergence, the failure mode the Davis–Kahan theory of theorem 18.16 is built to repair — and the same phenomenon behind the cospectral witness of remark 18.15 below.

The right gap: the half-graph. For the right inequality we want a single *fixed* symmetric kernel whose operator norm is strictly below its Hilbert–Schmidt norm, witnessing that the largest eigenvalue can be strictly smaller than the ℓ^2 length of the whole spectrum — which happens precisely when the spectral energy is spread across many modes rather than hoarded by one. The half-graph kernel

$$W(x,y) = \mathbf{1}\{x+y \le 1\}$$

is the standard such example, an honest graphon (values in $\{0,1\}$) supported on the lower triangle. Its Hilbert–Schmidt norm is read straight off the geometry: $W^2 = W$ is again the indicator of the triangle $\{x+y \le 1\}$, whose area is $\frac{1}{2}$, so

$$\|W\|_{\mathrm{HS}} = \|W\|_{L^2} = \Big(\int_{[0,1]^2} W^2\Big)^{1/2} = \frac{1}{\sqrt{2}}.$$

The operator norm requires the spectrum, and here it can be computed in closed form by turning the eigenvalue problem into an ODE — a small but genuinely instructive calculation, so we run it in full. Because W is symmetric, $\mathbb{W}$ is self-adjoint and $\|\mathbb{W}\|_{2\to 2} = \max_n |\lambda_n|$, so it suffices to find the eigenvalues. The eigenequation $(\mathbb{W}f)(x) = \lambda f(x)$ is, with the triangular support evaluated,

$$\int_0^{1-x} f(y)\,\mathrm{d}y = \lambda f(x), \qquad 0 \le x \le 1. \tag{18.6}$$

We assume $\lambda \neq 0$ (the kernel has infinitely many nonzero eigenvalues, computed below, so this loses nothing). Differentiating eq. (18.6) in x and using the fundamental theorem of calculus on the variable *upper* limit $1-x$ — whose derivative contributes the chain-rule factor -1 — gives

$$-f(1-x) = \lambda f'(x). \tag{18.7}$$

This already encodes the two boundary conditions we will need. Setting $x = 1$ in eq. (18.6) collapses the integral to $\int_0^0 = 0$, so $0 = \lambda f(1)$ and hence

$$f(1) = 0;$$

setting $x = 0$ in eq. (18.7) gives $\lambda f'(0) = -f(1) = 0$, so

$$f'(0) = 0.$$

Differentiating eq. (18.7) once more (again a chain-rule factor -1 from the argument $1-x$) yields $\lambda f''(x) = f'(1-x)$. To close the system, evaluate eq. (18.7) at the reflected point $1-x$, which reads $\lambda f'(1-x) = -f(x)$, i.e. $f'(1-x) = -f(x)/\lambda$; substituting,

$$\lambda f''(x) = f'(1-x) = -\frac{f(x)}{\lambda}, \qquad \text{that is} \qquad \lambda^2 f'' = -f.$$

The reflection has turned the nonlocal eigenequation into a plain harmonic oscillator. Its general solution is $f(x) = A\cos(x/\lambda) + B\sin(x/\lambda)$, and the two boundary conditions select the spectrum.

From $f'(x) = \lambda^{-1}\big(-A\sin(x/\lambda) + B\cos(x/\lambda)\big)$ the condition $f'(0) = 0$ forces $B = 0$, leaving $f(x) = A\cos(x/\lambda)$; the condition $f(1) = 0$ then forces $A\cos(1/\lambda) = 0$, and with $A \neq 0$ this is the quantisation

$$\cos(1/\lambda) = 0 \quad\Longleftrightarrow\quad \frac{1}{\lambda} = \frac{(2k-1)\pi}{2},\ k \in \mathbb{N} \quad\Longleftrightarrow\quad \lambda = \frac{2}{(2k-1)\pi}.$$

The eigenvalues are $\frac{2}{\pi}, \frac{2}{3\pi}, \frac{2}{5\pi}, \dots$ (with sign alternations from the reflection symmetry that do not affect the moduli), so the largest in modulus, and hence the operator norm, is the $k = 1$ value:

$$\|W\|_{2\to2} = \frac{2}{\pi} \approx 0.6366 \ < \ \frac{1}{\sqrt{2}} \approx 0.7071 = \|W\|_{\mathrm{HS}}\,.$$

The gap is strict, and one can see *why* from the eigenvalue list: the Hilbert–Schmidt norm collects $\sum_k \lambda_k^2 = \frac{4}{\pi^2}\sum_k (2k-1)^{-2} = \frac{4}{\pi^2}\cdot\frac{\pi^2}{8} = \frac{1}{2}$ over the whole tail of modes, while the operator norm sees only the leading one; the right inequality is strict exactly to the extent that the spectral energy fails to be rank one.

We have, then, the ordered chain eq. (18.5) together with a witness at each end proving both inequalities genuinely strict. The two strictnesses are not curiosities; they are the load-bearing facts the rest of the section spends. The strict *left* inequality — cut strictly weaker than operator norm, witnessed by a spike whose eigenfunction escapes — is precisely why eigen*functions* can fail to converge under cut convergence, and it is the gap the eigenfunction subsection theorem 18.16 must close with the stronger operator norm; this is the operator norm earning its place as the "stronger notion" the downstream theory needs. The strict *right* inequality — Hilbert–Schmidt strictly above operator norm, witnessed by the half-graph whose energy is spread across all modes — is the reason the squared length $\sum_n \lambda_n^2 = \|W\|_{\mathrm{HS}}^2 = t(C_2, W)$ is *not* cut-continuous: it lives at the strong end the cut norm cannot reach, which is exactly why the eigenvalue theorem of the next subsection must route around the C_2 moment and use only the simple-cycle moments $k \geq 3$. With the ladder built and both gaps shown genuine, we now turn to the good news hiding at its weak end: that the cut norm, feeble as the spike just showed it to be against eigenfunctions, nonetheless pins every individual eigenvalue.

18.4.2 Cut convergence forces eigenvalue convergence

The positive theorem is that the spectrum is continuous in the cut metric, eigenvalue by eigenvalue. The mechanism is the moment identity proposition 18.4: cut convergence is equivalent to convergence of all homomorphism densities (theorem 17.12), in particular of the cycle densities $t(C_k, W) = \sum_n \lambda_n^k$ for *simple* cycles $k \geq 3$, i.e. of those power sums of the spectrum; and the power sums $\{p_k\}_{k\geq3}$ of an ℓ^2 sequence already determine, and continuously control, its individual entries. We first isolate that last, purely sequential, fact. (The $k = 2$ power sum $\sum_n \lambda_n^2 = \|W\|_{\mathrm{HS}}^2$ is *deliberately excluded*: the doubled edge C_2 is not a simple graph, the counting lemma of chapter 16 does not apply to it, and indeed $t(C_2, \cdot)$ is *not* cut-continuous — the right inequality of eq. (18.5) is strict precisely because the Hilbert–Schmidt norm escapes cut control. We will not need it.)

Lemma 18.13 (Moments determine an ℓ^2 spectrum)**.** *For each $n \in \mathbb{N}$ let $\big(\mu_i^{(n)}\big)_i$ be a real sequence with entries in $[-1, 1]$ and $\sum_i \big(\mu_i^{(n)}\big)^2 \leq 1$, and let $(\mu_i)_i$ be another such sequence. Suppose the* *power sums converge:* $\sum_i \big(\mu_i^{(n)}\big)^k \to \sum_i \mu_i^k$ *as* $n \to \infty$*, for every integer* $k \geq 3$*. List each sequence in signed order (positives decreasing, negatives increasing). Then* $\mu_i^{(n)} \to \mu_i$ *for every* i *in each list.*

The hypothesis is imposed only for $k \geq 3$. The exponent $k = 2$ is omitted on purpose: it is the one power sum that will *not* be available from cut convergence (see the discussion above), and, as the proof shows, it is not needed — the uniform ℓ^2 bound $\sum_i (\mu_i^{(n)})^2 \leq 1$ does all the work that $k = 2$ would, and it is a standing bound, not a convergence hypothesis.

Proof. Uniform tightness. Because $\sum_i (\mu_i^{(n)})^2 \leq 1$, for any $\varepsilon > 0$ the number of indices with $\left|\mu_i^{(n)}\right| > \varepsilon$ is at most ε^{-2}, *uniformly in* n. Hence along any subsequence we may, by a diagonal extraction over i, assume $\mu_i^{(n)} \to c_i$ for every i (each lies in the compact $[-1, 1]$), and the limit list (c_i) again satisfies $\sum_i c_i^2 \leq 1$ with the same tightness.

Power sums pass to the limit. Fix $k \geq 3$. Split $\sum_i (\mu_i^{(n)})^k = \sum_{\left|\mu_i^{(n)}\right| > \varepsilon} + \sum_{\left|\mu_i^{(n)}\right| \leq \varepsilon}$. The tail is bounded by $\varepsilon^{k-2} \sum_i (\mu_i^{(n)})^2 \leq \varepsilon^{k-2}$ (here $k - 2 \geq 1$), uniformly in n, hence $\leq \varepsilon^{k-2}$ in the limit as well; the head has at most ε^{-2} terms, each converging to c_i^k. Letting $n \to \infty$ and then $\varepsilon \to 0$ gives $\sum_i (\mu_i^{(n)})^k \to \sum_i c_i^k$. Combining with the hypothesis, $\sum_i c_i^k = \sum_i \mu_i^k$ for every $k \geq 3$.

Power sums determine the sequence. Two ℓ^2 sequences in $[-1, 1]$ with equal power sums $p_k = \sum_i \mu_i^k$ for all $k \geq 3$ have the same entries (with multiplicity). Indeed the largest modulus is recovered as $|\mu|_{\max} = \lim_{k\to\infty} p_{2k}^{1/(2k)}$, and its multiplicity m as $m = \lim_k p_{2k}/\,|\mu|_{\max}^{2k}$; the sign multiplicities split by $p_{2k+1}/\,|\mu|_{\max}^{2k+1} \to m_+ - m_-$, the surplus of positive over negative entries of maximal modulus. Removing these finitely many entries decreases every p_k ($k \geq 3$) by a known amount and leaves an ℓ^2 sequence of strictly smaller maximal modulus; induction on the (discrete, accumulating only at 0) set of moduli recovers the entire sequence. Applying this to (c_i) and (μ_i) gives $c_i = \mu_i$ for all i.

Conclusion. Every subsequence of $(\mu^{(n)})$ has a further subsequence along which $\mu_i^{(n)} \to \mu_i$ for every i; hence the full sequence converges entrywise. □

Theorem 18.14 (Cut convergence implies spectral convergence)**.** *Let* W_n, W *satisfy* (A-Reg-W) *and suppose* $\delta_\square(W_n, W) \to 0$ *(equivalently, after measure-preserving relabellings,* $\|W_n - W\|_\square \to 0$*). Then for every* i*,*

$$\lambda_i^+(W_n) \to \lambda_i^+(W) \qquad \text{and} \qquad \lambda_i^-(W_n) \to \lambda_i^-(W),$$

the positive and negative eigenvalues each converging in signed order. In particular every spectral moment, the spectral radius, and the spectral gap (when the limiting top eigenvalue is simple) are continuous under cut convergence.

Proof. Cut convergence is equivalent to left-convergence, i.e. to convergence of every homomorphism density $t(F, \cdot)$ over *finite simple graphs* F (theorem 17.12; the counting lemma of chapter 16 gives the quantitative bound $|t(F, W_n) - t(F, W)| \leq e(F)\ \|W_n - W\|_\square$ after optimal relabelling, for simple F). Specialise to the *simple* cycles $F = C_k$, $k \geq 3$: by proposition 18.4, $t(C_k, W_n) = \sum_i \lambda_i(W_n)^k$ and $t(C_k, W) = \sum_i \lambda_i(W)^k$, so the power sums of the spectra converge for every $k \geq 3$. We do *not* use $k = 2$: the doubled edge C_2 is not a simple graph, the counting lemma does not cover it, and $t(C_2, \cdot) = \|\cdot\|_{\mathrm{HS}}^2$ is genuinely cut-discontinuous (a quasirandom sequence converging in cut to the constant $\frac{1}{2}$ has $t(C_2, \to)\frac{1}{2} \neq \frac{1}{4}$). This is exactly why lemma 18.13 was stated with hypotheses only for $k \geq 3$. Each spectrum lies in $[-1, 1]$ with the *standing* bound $\sum_i \lambda_i^2 \leq 1$ of proposition 18.4 (no convergence of the $k = 2$ sum is needed — only this uniform bound). Lemma 18.13 now yields entrywise convergence of the signed-ordered eigenvalues. Continuity of the spectral radius is the case $i = 1$; continuity of the gap follows when the limiting $|\lambda_1| > |\lambda_2|$ so that $|\lambda_1(W_n)| - |\lambda_2(W_n)| \to |\lambda_1(W)| - |\lambda_2(W)|$. □

Remark 18.15 (The converse fails: the spectrum is strictly coarser than the cut class)**.** Theorem 18.14 does *not* reverse. Two graphons can have identical spectra yet be at positive cut distance, so eigenvalue convergence does not imply cut convergence. The reason is structural and worth stating: by proposition 18.4 the spectrum encodes exactly the *closed-walk* (cycle) homomorphism densities, and nothing else. Tree densities — $t(P_3, W)$, the density of the two-edge path, for instance — are invisible to the spectrum, because a tree's homomorphism density is not a function of the λ_i alone. A self-contained witness is at hand. Compare the constant graphon $W_a \equiv \frac{1}{2}$ with the half-clique $W_b = \mathbf{1}_{A\times A}$, $A = [0, \frac{1}{2})$. Both have a single nonzero eigenvalue equal to $\frac{1}{2}$ (for W_a on the eigenfunction $\mathbf{1}$; for W_b on $\mathbf{1}_A$, since $\mathbb{W}_b\mathbf{1}_A = |A|\ \mathbf{1}_A = \frac{1}{2}\mathbf{1}_A$), so $\mathrm{spec}(W_a) = \mathrm{spec}(W_b) = \left\{\frac{1}{2}\right\}$ and *every* cycle density agrees, $t(C_k, W_a) = t(C_k, W_b) = (\frac{1}{2})^k$. Yet their path densities differ: writing $d(x) = \int_0^1 W(x, y)\, \mathrm{d}y$ for the degree function, $t(P_3, W) = \int_0^1 d(x)^2\, \mathrm{d}x$, and here $d_a \equiv \frac{1}{2}$ gives $t(P_3, W_a) = \frac{1}{4}$, while $d_b = \frac{1}{2}\mathbf{1}_A$ gives $t(P_3, W_b) = \frac{1}{2} \cdot \frac{1}{4} = \frac{1}{8}$. Different path densities force $\delta_\square(W_a, W_b) > 0$ (by the counting lemma): identical spectra, different cut class. This is also a sharp foil to the moment-uniqueness theorem theorem 17.11, which determines a graphon up to weak isomorphism — but only from *all* homomorphism densities; the cycle moments alone (equivalently, the spectrum) are a strict subset and so cannot. (Schwenk's cospectral non-isomorphic graphs and their graphon limits give a whole family of such witnesses.) Thus the implications

$$\|\cdot\|_{\mathrm{HS}}\text{-conv.} \implies \|\cdot\|_{2\to2}\text{-conv.} \implies \delta_\square\text{-conv.} \implies \text{eigenvalue conv.}$$

are all strict, the last by the cospectral witness above and the first two by the strictness of eq. (18.5). See also [99, Ch. 11] and [29].

18.4.3 Eigenfunctions need the stronger norm

Cut convergence controls eigen*values* but not eigen*functions*. The reason is visible already in example 18.11: a small symmetric perturbation can split a degenerate or near-degenerate pair and rotate its eigenplane arbitrarily while barely moving the eigenvalues. To pin an eigenfunction one needs (i) the stronger operator-norm convergence and (ii) a spectral gap isolating the eigenvalue. This is the content of the Davis–Kahan theorem, which we state in the form used in chapter 25 (finite-network convergence), where a matrix-concentration argument supplies the operator-norm bound, to certify that a sampled or perturbed network has nearly the same centrality profile as its graphon.

Theorem 18.16 (Davis–Kahan, leading-eigenfunction stability)**.** *Let $W, \widetilde{W}$ satisfy* (A-Reg-W) *with simple leading eigenvalue for W, and let $e_1, \widetilde{e}_1$ be unit leading eigenfunctions of $\mathbb{W}, \widetilde{\mathbb{W}}$. Let*

$\delta = |\lambda_1(W)| - |\lambda_2(W)| > 0$ be the absolute gap. If $\left\|\widetilde{\mathbb{W}} - \mathbb{W}\right\|_{2\to 2} \le \delta/2$, then the angle $\theta \in [0, \frac{\pi}{2}]$ between the two eigenlines obeys

$$\sin\theta \;\le\; \frac{2\left\|\widetilde{\mathbb{W}} - \mathbb{W}\right\|_{2\to 2}}{\delta}, \qquad \textit{where} \qquad \min_{\pm} \|\widetilde{e}_1 \mp e_1\| \;=\; 2\sin(\theta/2). \tag{18.8}$$

In particular, with the sign chosen to align them, since $2\sin(\theta/2) \le \sqrt{2}\sin\theta$ on $[0, \frac{\pi}{2}]$, $\|\widetilde{e}_1 - e_1\| \le 2\sqrt{2}\left\|\widetilde{\mathbb{W}} - \mathbb{W}\right\|_{2\to 2}/\delta$.

Proof sketch. Write $E = \widetilde{\mathbb{W}} - \mathbb{W}$ and decompose $\widetilde{e}_1 = (\cos\theta)e_1 + (\sin\theta)v$ with $v \perp e_1$, $\|v\| = 1$. Project the perturbed eigenequation $\widetilde{\mathbb{W}}\widetilde{e}_1 = \widetilde{\lambda}_1\widetilde{e}_1$ onto $e_1^\perp$. Using $\mathbb{W}v = \sum_{n\ge 2}\lambda_n\langle v, e_n\rangle e_n$ and that $\mathbb{W}e_1 = \lambda_1 e_1$ has no component in $e_1^\perp$, the projection reads $(\widetilde{\lambda}_1 I - \mathbb{W})\big|_{e_1^\perp}(\sin\theta)\,v =$ (projection of $E\widetilde{e}_1$). On $e_1^\perp$ the operator $\widetilde{\lambda}_1 I - \mathbb{W}$ is invertible with norm of its inverse at most $1/\operatorname{dist}(\widetilde{\lambda}_1, \{\lambda_n\}_{n\ge 2})$. For the eigenvalue stability we use corollary 2.27 directly: for any unit x, $\left|\langle\widetilde{\mathbb{W}}x, x\rangle - \langle\mathbb{W}x, x\rangle\right| = |\langle Ex, x\rangle| \le \|E\|$, so every min–max eigenvalue moves by at most $\|E\|$; in particular $\left|\widetilde{\lambda}_1 - \lambda_1\right| \le \|E\| \le \delta/2$. Since the nearest λ_n, $n \ge 2$, is at distance $\ge \delta$ from λ_1, that distance is at least $\delta/2$; hence $\sin\theta \le \|E\|\,\|\widetilde{e}_1\|/(\delta/2) = 2\|E\|/\delta$, which is eq. (18.8). The companion identity $\min_\pm \|\widetilde{e}_1 \mp e_1\| = 2\sin(\theta/2)$ is elementary geometry: for unit vectors at line-angle θ, $\|\widetilde{e}_1 \mp e_1\|^2 = 2 \mp 2\cos\theta$, minimised over the sign at $2 - 2\cos\theta = 4\sin^2(\theta/2)$. (The quantity $\sqrt{2}\sin\theta$ that appears in some statements is instead $\left\|P_1 - \widetilde{P}_1\right\|_{\mathrm{HS}}$, the Frobenius norm of the difference of the two rank-one spectral projectors, not the eigenvector distance.) Full statements and the general (subspace) version are in [56]; the symmetric-operator form is standard. □

The split between theorem 18.14 and theorem 18.16 is the practically important message of this section. Sampling a finite W-random network (chapter 19) yields, at the level we prove there, only *cut-metric* consistency — the empirical graphon converges to W in $\delta_\square$ — and by eq. (18.5) that is *not* enough to move the eigenfunctions. Upgrading to operator-norm convergence of the empirical operator requires a separate matrix-concentration argument, carried out in chapter 25; there it is strong enough to transport both eigenvalues *and* the centrality eigenfunction through theorem 18.16, provided a gap exists. When one only knows that two networks are macroscopically equivalent — close in $\delta_\square$, as the compactness theorem theorem 17.13 delivers — one is guaranteed matching spectra but *not* matching centralities. A small gap is exactly the regime where centrality is ill-conditioned, which is the spectral reason community detection is hard when communities are weakly separated.

18.5 Low-rank reductions and tractable graphon mean field games

We now collect the dividend that the whole chapter was built to pay: when the graphon has finite or rapidly decaying spectrum, the graphon mean field game coupling — an operator on an infinite-dimensional field of measures — collapses to a finite system of scalar order parameters. This is the analytic reason Thread B is solvable, and it is the template for every closed-form graphon model in Part IV.

18.5.1 Finite-rank graphons collapse the coupling

Definition 18.17 (Finite-rank graphon)**.** A graphon W has *rank* r if its operator $\mathbb{W}$ has exactly r nonzero eigenvalues, counted with multiplicity; equivalently

$$W(x,y) = \sum_{k=1}^{r} \lambda_k \, \phi_k(x) \, \phi_k(y), \qquad \langle \phi_k, \phi_\ell \rangle = \delta_{k\ell}, \tag{18.9}$$

for the orthonormal eigenfunctions $\phi_k = e_k$ and nonzero eigenvalues λ_k.

Block graphons (example 18.11, and the multi-block models of chapter 22) are finite rank: a graphon constant on the blocks of an r-part partition has rank at most r. The constant graphon ($r = 1$) and the rank-one graphon $W = f \otimes f$ of worked computation 2.28 are the smallest cases.

The reduction is the following. In the graphon mean field game (Thread B, appendix A.7), a type-x agent is coupled not to a global mean but to the *graphon-aggregated* neighbour field

$$z_t(x) = (\mathbb{W}\bar{m}_t)(x) = \int_0^1 W(x,y) \, \bar{m}_t(y) \, \mathrm{d}y, \qquad \bar{m}_t(y) = \int_{\mathbb{R}} \xi \, m_t^y(\mathrm{d}\xi), \tag{18.10}$$

where $\bar{m}_t(y)$ is the mean of the type-y population m_t^y (recall the convention of appendix A.1: the population field m evolves forward from m_0). The aggregate z_t is the only channel through which the kernel enters the dynamics. For a rank-r kernel eq. (18.9),

$$z_t(x) = \sum_{k=1}^{r} \lambda_k \, \phi_k(x) \, \varrho_k(t), \qquad \varrho_k(t) := \langle \phi_k, \bar{m}_t \rangle = \int_0^1 \phi_k(y) \, \bar{m}_t(y) \, \mathrm{d}y. \tag{18.11}$$

Thus the entire infinite-dimensional aggregate field $x \mapsto z_t(x)$ is determined, at each time, by the r scalars $\varrho_1(t), \dots, \varrho_r(t)$ — the projections of the population mean onto the eigenfunctions. We record the consequence.

Proposition 18.18 (Order-parameter reduction)**.** *Suppose the graphon has rank r as in eq.* (18.9)*, and consider the graphon mean field game of Thread B in which type-x agents interact only through the aggregate eq.* (18.10)*. Then the coupling is carried entirely by the finite-dimensional order-parameter vector $\varrho(t) = (\varrho_1(t), \dots, \varrho_r(t))$ of eq.* (18.11)*: each agent's optimal control and each type's population evolution depend on the population field only through $z_t(x) = \sum_k \lambda_k \phi_k(x) \varrho_k(t)$, and the mean field fixed point reduces to a self-consistent system of r scalar equations for $\varrho(t)$, closed by $\varrho_k(t) = \langle \phi_k, \bar{m}_t \rangle$ with $\bar{m}_t$ the mean of the optimally controlled population. In particular a rank-one kernel gives a single scalar order parameter.*

Proof. By eq. (18.11) the aggregate z_t is a known linear combination of the fixed profiles ϕ_k with time-dependent coefficients $\lambda_k \varrho_k(t)$, so the only data the agents' problems require from the population is the vector $\varrho(t)$. Conversely $\varrho_k(t)$ is, by definition, a linear functional of the population means $\bar{m}_t$, which are produced by the agents best-responding to z_t, hence to $\varrho(t)$. The mean field consistency requirement — that the population generating ϱ is the one optimally responding to the z built from ϱ — is therefore a fixed-point equation on the finite-dimensional $\varrho \in \mathbb{R}^r$ (as a function of time), rather than on the infinite-dimensional field of measures. The number of scalar equations equals the rank r. □

This is the precise sense in which "low rank ⇒ tractable." The full dynamic solution of the reduced system — the coupled Riccati and order-parameter equations — is carried out in chapter 22; here we have isolated the structural collapse that makes it possible, and we now instantiate it on the cleanest case to advance Thread B by one layer.

Worked computation 18.19 (Rank-one graphon: a single scalar order parameter)**.** We continue Thread B (appendix A.7) with the rank-one kernel $W(x,y) = f(x)f(y)$, where $f\colon [0,1] \to [0,1]$ (so that $f \geq 0$ and $W = f \otimes f$ is a genuine $[0,1]$-valued graphon), whose spectrum was computed in worked computation 2.28: a single nonzero eigenvalue $\lambda_1 = \|f\|_{L^2}^2$ with normalised eigenfunction $\phi_1 = f/\|f\|_{L^2}$, and $\ker \mathbb{W} = \{f\}^\perp$. Recall the notation convention in force from Part III onward (appendix A.1): with a graphon W in scope, Brownian motion is written B, so the type-x state obeys $\mathrm{d}X_t^x = (aX_t^x + b\,\alpha_t^x)\,\mathrm{d}t + \sigma\,\mathrm{d}B_t^x$.

The aggregate collapses to one scalar. By eq. (18.10),

$$z_t(x) = \int_0^1 f(x)f(y)\,\bar{m}_t(y)\,\mathrm{d}y = f(x)\,\varrho(t), \qquad \varrho(t) := \langle f, \bar{m}_t\rangle = \int_0^1 f(y)\,\bar{m}_t(y)\,\mathrm{d}y,$$

a single scalar order parameter $\varrho(t)$ multiplying the fixed profile f. (In the eigenfunction normalisation of eq. (18.11) this is $z_t = \lambda_1\phi_1\,\varrho_1$ with $\phi_1 = f/\|f\|_{L^2}$, $\lambda_1 = \|f\|_{L^2}^2$, and $\varrho_1 = \langle \phi_1, \bar{m}_t\rangle = \varrho/\|f\|_{L^2}$; then $\lambda_1\phi_1 = \|f\|_{L^2}\,f$ and $\|f\|_{L^2}\,\varrho_1 = \varrho$, so $z_t = \lambda_1\phi_1\varrho_1 = \|f\|_{L^2}\,f \cdot \varrho/\|f\|_{L^2} = f\varrho$: the two bookkeepings agree at the level of z_t.) The type-x running cost of Thread B becomes

$$\tfrac{1}{2}(\alpha_t^x)^2 + \tfrac{q}{2}\big(X_t^x - s\,f(x)\,\varrho(t)\big)^2,$$

so a type-x agent solves a *scalar* linear–quadratic problem with a type-dependent target $s\,f(x)\,\varrho(t)$ that is the *same* time signal $\varrho(t)$ scaled by the agent's own centrality weight $f(x)$.

The fixed point is one self-consistent equation. Freezing $\varrho(\cdot)$, each type x faces a tracking LQG problem whose optimal feedback is linear and whose controlled mean $\bar{m}_t^x$ follows a closed linear ODE driven by the target $sf(x)\varrho(t)$; by linearity $\bar{m}_t^x = f(x)\,\psi_t[\varrho]$ for a type-independent functional $\psi_t[\varrho]$ of the order-parameter path (the response of a unit-centrality agent), plus a homogeneous term carrying the initial mean. Closing the loop through the definition of ϱ,

$$\varrho(t) = \langle f, \bar{m}_t\rangle = \int_0^1 f(x)\,\bar{m}_t^x\,\mathrm{d}x = \Big(\int_0^1 f(x)^2\,\mathrm{d}x\Big)\,\psi_t[\varrho] + (\text{initial term}) = \lambda_1\,\psi_t[\varrho] + (\text{initial term}),$$

a single scalar self-consistent equation for the path $\varrho(\cdot)$, with the coupling strength entering only through the scalar $\lambda_1 = \int f^2 = \|f\|_{L^2}^2 = \|\mathbb{W}\|$. This is the cleanest graphon mean field game: an entire continuum of interacting types, solved by one scalar fixed point, exactly as the constant-graphon reduction of Thread B recovers the global-mean LQG of Thread A. The operator-norm smallness condition (A-Coupling), $\|\mathbb{W}\| = \lambda_1 < \kappa$, is here a smallness condition on the single scalar $\int f^2$, and it is the hypothesis under which the scalar fixed point is a contraction and hence unique; the threshold is analysed in chapter 24, and the explicit Riccati form of ψ_t is completed in chapter 22.

18.5.2 Every graphon has a controlled low-rank reduction

Most graphons are not finite rank. But the spectral decomposition supplies a canonical sequence of finite-rank approximations, and the error is exactly the spectral tail. This is the Eckart–

Young theorem in the Hilbert–Schmidt setting, and it tells us when a graphon mean field game is *approximately* low-dimensional.

Proposition 18.20 (Best low-rank approximation). *Let W satisfy* (A-Reg-W) *with modulus-ordered spectrum $|\lambda_1| \geq |\lambda_2| \geq \cdots$ and eigenfunctions e_n. The rank-r truncation*

$$W_r(x,y) := \sum_{n=1}^{r} \lambda_n \, e_n(x) \, e_n(y)$$

is the minimiser of $\|W-U\|_{\mathrm{HS}}$ over all symmetric kernels U of rank at most r, with optimal error

$$\|W-W_r\|_{\mathrm{HS}}^2 = \sum_{n>r} \lambda_n^2, \qquad \|W-W_r\|_{2\to 2} = |\lambda_{r+1}| \,. \tag{18.12}$$

In particular $\|W-W_r\|_{\mathrm{HS}} \to 0$ and $\|W-W_r\|_{2\to 2} \to 0$ as $r \to \infty$ for every graphon.

Proof. The truncation $W - W_r$ has operator $\sum_{n>r} \lambda_n \langle \cdot, e_n \rangle e_n$, whose Hilbert–Schmidt norm squared is $\sum_{n>r} \lambda_n^2$ and whose operator norm is the largest remaining modulus $|\lambda_{r+1}|$, by eq. (18.1). It remains to show that W_r is optimal in both norms. We give a self-contained argument resting only on corollary 2.27, using *singular values*: for a compact self-adjoint operator A write $\sigma_k(A)$ for the k-th largest eigenvalue of the positive operator A^2, square-rooted, so $\sigma_k(A) = |\lambda_k(A)|$ is the k-th largest modulus and $\|A\|_{\mathrm{HS}}^2 = \sum_k \sigma_k(A)^2$. Applying the min–max identity corollary 2.27 to the positive operator A^2 gives the dual ("min") characterisation

$$\sigma_k(A) \;=\; \min_{\dim M = k-1} \; \max_{\substack{x \perp M \\ \|x\|=1}} \; \|Ax\| \,. \tag{18.13}$$

A one-line Weyl inequality. For compact self-adjoint A, B and indices $i, j \geq 1$, $\sigma_{i+j-1}(A+B) \leq \sigma_i(A) + \sigma_j(B)$: pick M_A, M_B achieving the minima in eq. (18.13) for $\sigma_i(A), \sigma_j(B)$, of dimensions $i-1, j-1$; then $M = M_A + M_B$ has dimension $\leq i+j-2$, and for unit $x \perp M$, $\|(A+B)x\| \leq \|Ax\| + \|Bx\| \leq \sigma_i(A) + \sigma_j(B)$, so the min over such M in eq. (18.13) for index $i+j-1$ is bounded by $\sigma_i(A) + \sigma_j(B)$.

Lower bounds. Let U be any symmetric kernel of rank $\leq r$, so its operator has $\sigma_{r+1}(\mathbb{W}_U) = 0$. Writing $W = (W-U) + U$ and applying the Weyl inequality with $A = W-U$, $B = U$ (and $i = j$, $j' = r+1$):

$$\sigma_{j+r}(W) \;\leq\; \sigma_j(W-U) + \sigma_{r+1}(\mathbb{W}_U) \;=\; \sigma_j(W-U) \qquad (j \geq 1).$$

Taking $j = 1$ gives the operator-norm bound $\|W-U\|_{2\to 2} = \sigma_1(W-U) \geq \sigma_{r+1}(W) = |\lambda_{r+1}|$. Summing the squares over $j \geq 1$ gives the Hilbert–Schmidt bound

$$\|W-U\|_{\mathrm{HS}}^2 = \sum_{j\geq 1} \sigma_j(W-U)^2 \;\geq\; \sum_{j \geq 1} \sigma_{j+r}(W)^2 = \sum_{n>r} \lambda_n^2.$$

Both lower bounds are attained by $U = W_r$, which realises the values computed in the first paragraph, so W_r is the minimiser in each norm with the stated error. (No appeal to an external Hoffman–Wielandt inequality is needed.) Convergence to 0 is the convergence of the tail of $\sum_n \lambda_n^2 < \infty$ and of $|\lambda_n| \to 0$. $\square$

Two honest caveats place this result against its neighbours. First, the truncation converges in the *strong* (Hilbert–Schmidt and operator) norms, hence *a fortiori* in cut by eq. (18.5); by proposition 18.18 the corresponding rank-r graphon mean field game is a finite, r-order-parameter system, and by the stability theory of chapters 24 and 25 its equilibrium approximates that of W with an error governed by the tail eq. (18.12). The reduction is therefore quantitatively controlled *per graphon*. Second, the control is *not* uniform over all graphons: the tail $\sum_{n>r} \lambda_n^2$ can decay arbitrarily slowly, so there is no single rank r that approximates every graphon to a fixed accuracy. The uniform statement — that every graphon is within cut distance ε of a step graphon of bounded complexity, with the bound depending only on ε — is a different theorem, the weak regularity lemma, proved in full in theorem 17.16 (packaged as the total boundedness of graphon space, theorem 17.17); it lives in the cut norm rather than the spectral one, and its sampling consequences are developed in chapter 19. The spectral truncation here is sharp and computable; the regularity-lemma truncation there is universal but coarser. Both feed the numerical discretisation of chapter 28, where the coupling integral $\mathbb{W}$ is replaced by a finite quadrature whose accuracy is read off from exactly these two estimates.

Rigor ledger

Proved.

- proposition 18.4: for $k \geq 2$ the k-th spectral moment equals the k-cycle homomorphism density, $\sum_n \lambda_n^k = t(C_k, W)$; in particular $\sum_n \lambda_n^2 = \|W\|_{\mathrm{HS}}^2 \leq 1$, giving uniform ℓ^2 tightness of all graphon spectra.

- theorem 18.7: for a connected nonnegative graphon the spectral radius is a simple eigenvalue with a strictly positive eigenfunction — the eigenvector centrality definition 18.8, the unique nonnegative fixed point of $\mathbb{W}/\lambda_1^+$.

- proposition 18.10: the multiplicative spectral gap controls the geometric rate of relaxation onto the leading mode; worked out, with assortative/disassortative signs and community detection, on the two-block model example 18.11.

- theorem 18.14 via lemma 18.13: cut convergence forces convergence of every eigenvalue in signed order, through the cycle-density/moment identity.

- proposition 18.18 and worked computation 18.19: a rank-r kernel reduces the graphon mean field game coupling to r scalar order parameters; the rank-one kernel reduces Thread B to a single self-consistent scalar equation with coupling $\lambda_1 = \|\mathbb{W}\| = \int f^2$.

- proposition 18.20: the spectral truncation is the best low-rank approximation in Hilbert–Schmidt and operator norm, with error equal to the spectral tail.

Assumed.

- (A-Reg-W): W symmetric, measurable, bounded, so $\mathbb{W}$ is self-adjoint Hilbert–Schmidt — imported from proposition 2.24; continuity of W assumed only in Mercer's theorem theorem 18.2.

- The spectral theorem and Courant–Fischer principle for compact self-adjoint operators (theorem 2.26 and corollary 2.27), and the Hilbert–Schmidt $=$ L^2-kernel isometry (theorem 2.22).
- Equivalence of cut convergence with left-convergence and the counting lemma $|t(F, W_n) - t(F, W)| \le e(F)\delta_\square(W_n, W)$, imported from chapters 16 and 17.

Deferred.

- Mercer's uniform convergence in the non-positive-semidefinite case (it fails; remark 18.3); the diagonal trace identity is instead obtained through the Hilbert–Schmidt iterates in proposition 18.4, with no appeal to trace-class theory.
- The general Krein–Rutman theorem (of which theorem 18.7 is the graphon instance, proved in full in-chapter) → [113, Ch. VI].
- The subspace Davis–Kahan theorem theorem 18.16 in full → [56]; used to transport centrality under sampling in chapter 25.
- The dynamic solution of the reduced order-parameter system (worked computation 18.19) and its Riccati form → chapter 22; the uniqueness threshold in $\|\mathbb{W}\|$ → chapter 24; the uniform cut-norm (weak regularity) truncation → theorem 17.16.
- Centrality ⇒ equilibrium effort, the static comparative static built on eq. (18.3) → chapter 20.

Open.

- Sharp two-sided relations between the cut metric and the operator norm on natural subclasses of graphons (beyond the strict, non-quantitative hierarchy of eq. (18.5)); when is cut convergence *quantitatively* upgradable to operator convergence?
- Identifiability of the eigenfunctions (not just eigenvalues) of a graphon from finite samples in the small-gap regime, where theorem 18.16 is uninformative; the spectral hardness of community detection near the detectability threshold.

Bibliographic notes

The identification of a graphon with a self-adjoint Hilbert–Schmidt operator, and the use of its spectrum as a graph invariant, is developed in Lovász's monograph [99, Ch. 7 and Ch. 11]; the continuity of the spectrum under cut convergence (our theorem 18.14) and the moment/cycle-density mechanism behind it are there and in [29]. The functional-analytic backbone — the spectral theorem, Mercer's theorem, the Krein–Rutman theorem, and Hilbert–Schmidt theory — is standard and we follow [113, 50, 31]; the staging in this book is sections 2.4 and 2.5, of which this chapter is the announced payoff. The Perron–Frobenius reading of eigenvector centrality, and its role in network games, is the entry point of the static graphon-game theory of Parise and Ozdaglar [108], taken up in chapter 20; the spectral view of community structure in stochastic block models, including the second-eigenvector (Fiedler) heuristic worked out in example 18.11, is classical spectral graph theory transported to the continuum. The eigenvector-perturbation bound theorem 18.16 is the symmetric case of the Davis–Kahan $\sin\theta$ theorem [56]; its use to transport spectral structure from a graphon to its sampled finite networks underlies the finite-network convergence theory of chapter 25. The low-rank reductions of section 18.5 are the operator-theoretic form of the rank-one and block-graphon models that recur throughout Part IV [34, 10], and the carried Thread B reduction of worked computation 18.19 is the spectral preview of the explicit dynamic solution in chapter 22.

Chapter 19

Sampling, Regularity, and the Road to Sparsity

The previous four chapters built the dense theory of graph limits as a closed mathematical world, each chapter supplying one faculty the next would need. From an adjacency matrix we passed to a graphon $W\colon [0,1]^2 \to [0,1]$, the single analytic object in which an entire growing family of networks could be held at once (chapter 15); we learned to read such an object through its motif densities $t(F, W)$, the observable moments by which one graphon is told from another (chapter 16); we metrized the resulting space by the cut metric $\delta_\square$ and found it compact, so that limits of networks are guaranteed to exist and to live in the same world (chapter 17); and we recognized W as a self-adjoint Hilbert–Schmidt operator $\mathbb{W}$ (the operator structure itself being proposition 2.24) whose spectrum reads off centrality and community structure (chapter 18). Each of these faculties is internal to the continuum: it lets us compare, classify, and diagonalize graphons among themselves. What none of them supplies is a passage between that continuum and an actual finite network of N nodes — and without such a passage the theory, however complete on its own terms, floats free of the data it is meant to explain.

Building that passage — the *bridge in both directions* between a graphon and a finite network — is the business of this chapter, and crossing it answers three concrete questions. Going outward: given a graphon, how does one *draw* from it a finite graph of any prescribed size? Once a sample is in hand, how faithfully does it *remember* the graphon it came from — do the sample's measurable statistics return the parent's? Going inward: how coarsely can a graphon itself be *compressed*, replaced by a finite, bounded-complexity surrogate, without losing its macroscopic identity? These are the outward, the fidelity, and the inward questions, and the chapter is built to take them in turn.

It does so in two complete and classical halves and an honest negative third. First, in sections 19.1 and 19.2 we define the W-random graph $G(N, W)$ and prove that the motifs of the sample concentrate around the motifs of the generating graphon at the Monte-Carlo rate $N^{-1/2}$; this is the sampling half of the bridge — the outward passage together with its fidelity — and it is the engine that will drive the finite-network convergence theorem of chapter 25. Second, in section 19.3 we prove the *weak regularity lemma*: every graphon, however intricate, is within cut distance ε of a step graphon whose number of steps depends only on ε and not on the graphon. This is the rigorous form of coarse-graining — the inward passage — carrying an explicit complexity bound, and it pins down exactly which features of a network are macroscopically meaningful. The two halves meet in section 19.4, where the law of the sampled graphs, the full list of motif densities, and cut distance are shown to be one and the same equivalence, so that a graphon is recoverable precisely up to the relabeling the cut metric was built to quotient out. Third, and not as an aside, section 19.5 states the price of admission: this entire apparatus is a theory of *dense* graphs, and it sees *every* sparse sequence of real networks as the single uninformative zero graphon while forcing every degree to grow like $\Theta(N)$. This failure is not a technicality to be patched; it is structural, and it is load-bearing motivation — it is the reason the sparse frameworks (L^p graphons, graphex) of chapter 27 have to be built at all.

This chapter assumes the dense graphon machinery of chapters 15 to 18 and carries no LQG thread; its job is to set up chapter 25 (finite-network convergence) and chapter 27 (sparsity). Throughout, the type variable $x \in [0,1]$ is the exchangeable agent label of chapter 15, never a spatial coordinate. No Brownian motion appears, so no W/B clash arises here; W is always the graphon.

19.1 The W-random graph $G(N,W)$

A graphon is, among other things, a recipe for generating random graphs of any size, and it is this generative reading that first turns the closed continuum of chapters 15 to 18 into something one can confront with finite data. We build the outward half of the bridge here. The recipe is the natural "continuum stochastic block model," and it is worth seeing it as the obvious limit of a familiar finite construction. In an ordinary stochastic block model one fixes a handful of blocks and a matrix B of inter-block connection probabilities, assigns each vertex to a block, and connects two vertices with the probability B records for their two blocks. A graphon performs exactly this with the finite block index replaced by the continuous type $x \in [0,1]$ and the probability matrix replaced by the kernel value $W(x,y)$. To draw a graph one therefore does two things in turn: first hand each of the N prospective vertices a type drawn uniformly from $[0,1]$, placing it somewhere in the continuum of kinds; then, for every pair, toss a single biased coin whose chance of coming up an edge is precisely the kernel value the two types prescribe. The first stage fixes a random geometry of types; the second wires that geometry up. We make this precise.

Definition 19.1 (W-random graph)**.** Let $W\colon [0,1]^2 \to [0,1]$ be a graphon, symmetric and measurable as in (A-Reg-W). Fix $N \in \mathbb{N}$. Draw i.i.d. *latent types* $U_1, \dots, U_N \sim \mathrm{Unif}[0,1]$, and, conditionally on the types, draw independent edge indicators

$$\xi_{ij} \mid (U_1, \dots, U_N) \;\sim\; \mathrm{Bernoulli}\big(W(U_i, U_j)\big), \qquad 1 \le i < j \le N,$$

with $\xi_{ji} = \xi_{ij}$ and no self-loops. The resulting simple graph on vertex set $[N] = \{1, \dots, N\}$, with edge set $\{\, ij : \xi_{ij} = 1 \,\}$, is the *$W$-random graph $G(N,W)$*.

A companion construction records the finite sample as a point of graphon space: the *induced step graphon* $W_{[N]}\colon [0,1]^2 \to [0,1]$, obtained from $G(N,W)$ by partitioning $[0,1]$ into N equal intervals $J_1, \dots, J_N$ and setting $W_{[N]}(x,y) = \xi_{ij}$ for $x \in J_i$, $y \in J_j$ (and 0 on the diagonal blocks $J_i \times J_i$, there being no self-loops). This is the pixel picture of definition 15.2 applied to the sample.

The two-stage structure of the definition repays a slow reading, because the whole of the next section turns on it. The latent types $U_1, \ldots, U_N$ are drawn once and then held fixed: they are the raw material on which everything downstream is conditional. Given them, the edge indicators are *genuinely* independent — each pair flips its own coin and no two coins look at one another — so the only channel through which different edges can become correlated is the types they share. A vertex with an unusual type tilts every coin incident to it in the same direction at once; that single shared cause is the entire source of dependence in the model, and isolating it is exactly what the concentration proof will do.

The companion object, the induced step graphon $W_{[N]}$, records the finished sample not as a graph on abstract vertices but as a point of the very space its parent inhabits. One chops $[0, 1]$ into N equal slots, gives vertex i the slot J_i, and paints the block $J_i \times J_j$ with the colour $\xi_{ij} \in \{0, 1\}$ of the edge that was or was not drawn — a literal black-and-white pixel image of the adjacency matrix. The diagonal blocks $J_i \times J_i$ are painted 0, encoding the convention that the model draws no self-loops; since these blocks together occupy only the fraction $N \cdot (1/N)^2 = 1/N$ of the unit square, the choice on the diagonal is invisible in the limit and any convention there would do. This is the pixel picture of definition 15.2, now applied to a random sample rather than to a fixed graph.

Placing the sample inside graphon space is what makes comparison a single number. A finite graph and a continuum kernel are, on their face, objects of different types and cannot be subtracted; but $W_{[N]}$ and W are *both* graphons, so $\delta_\square(W_{[N]}, W)$ is a well-defined distance measuring how much the sample has forgotten of its parent. Recall from chapter 17 the cut norm and cut metric, which we will use repeatedly:

$$\|U\|_\square \;=\; \sup_{S,T \subseteq [0,1]} \Big| \int_{S \times T} U(x, y)\; \mathrm{d}x\; \mathrm{d}y \Big|, \qquad \delta_\square(W, W') \;=\; \inf_{\varphi}\; \|W - W'^{\varphi}\|_\square\,, \tag{19.1}$$

the supremum over measurable S, T and the infimum over measure-preserving bijections φ of $[0, 1]$ (definitions 17.1 and 17.6). The cut norm asks only that two kernels agree on every large-scale "patch integral" $\int_{S \times T}$; it is blind to disagreements that average away when integrated against indicator sets. That is precisely the kind of disagreement a finite sample is forced to exhibit — at the pixel scale $1/N$, the sharp coins $\xi_{ij} \in \{0, 1\}$ can never match the smooth values $W(U_i, U_j) \in [0, 1]$ pointwise. The cut norm is in this sense the *weakest* reasonable norm on graphons, and weakest is exactly what we want: it is the coarsest topology in which sampling could possibly be consistent, because any finer norm would refuse to overlook the unavoidable pixel-scale noise of a finite draw. The infimum over relabelings φ quotients out the one ambiguity the model genuinely cannot resolve — which type label happened to land in which slot — so that $\delta_\square = 0$ means "the same network object up to renaming of types."

It helps to see the two extreme cases the construction sits between, because they are the two models the reader already knows and they bracket everything in between.

Remark 19.2 (Special cases anchor the construction)**.** When $W \equiv p$ is constant, the kernel value $W(U_i, U_j) = p$ does not depend on the types at all, so the first stage of the recipe is inert and every edge is an independent p-coin: $G(N, W)$ is precisely the Erdős–Rényi graph $G(N, p)$ (example 15.9). Here there is no geometry to remember, only an edge density. At the other end, when W is the step graphon of a stochastic block model (example 15.10) — constant on the blocks $V_a \times V_b$ with value the inter-block probability B_{ab} — the uniform type U_i does nothing but decide, by which interval it falls into, the block of vertex i; conditionally on the blocks the edges are again independent coins, now with block-dependent biases. This is exactly the classical planted-partition model. Between these two poles — a structureless single density and a finite palette of block densities — the general W-random graph interpolates continuously: a graphon is the limit in which the finite block index of an SBM is refined into the continuum of types, so that ER and SBM are not separate theories but the constant and piecewise-constant points of one family.

Physics note

The sampling map $W \mapsto G(N, W)$ is the network analogue of drawing a finite configuration from a continuum field, and its randomness comes at two temperatures. The latent types U_i are *quenched* disorder: frozen, vertex-attached randomness that fixes each agent's "kind" once and for all and is not averaged over while the edges are drawn. The edge coins ξ_{ij} are the *annealed* fluctuations living on top of that frozen geometry — thermal noise conditional on the quench. The order of the two stages (quench the types, then flip the edges) is exactly the order in which the concentration argument of section 19.2 will dismantle the randomness: it conditions on the types, controls the conditionally independent edge fluctuations first, and only then averages over the quenched geometry. The two contributions even separate by magnitude — the quenched types will turn out to carry the dominant sensitivity that sets the $N^{-1/2}$ rate, the annealed coins a smaller correction — so the picture is a genuine preview of the proof split, not merely a suggestive label. We do not lean on the analogy beyond this; the mathematics stands on the explicit variance bookkeeping to come.

We now have everything the bridge's outward end requires: a sample $G(N, W)$ of any size, and a way — the induced step graphon and the cut metric — to lay that sample alongside its parent and read off a single number for how far they sit apart. The obvious next question is the fidelity question promised in the preamble: now that a sample exists and can be compared to its parent, *how faithfully does it remember the parent's statistics?* The next section answers it for the observable moments of a network, its motif densities, and the answer is carried by exactly the quenched/annealed decomposition just described — realized concretely as a coupling that drives every edge coin from an independent uniform seed, so that the types and the seeds become the jointly independent coordinates the concentration estimate splits along.

19.2 Concentration of motif densities

That fidelity question — now that the comparison can actually be made, *how faithfully does a draw remember the graphon it came from?* — is what this section takes up, and it answers it in the currency in which a network is really measured: its motif statistics. The answer is the cleanest one could hope for: the statistics of the sample equal those of the parent up to a Monte-Carlo error of order $N^{-1/2}$ that is exponentially unlikely to be exceeded. This is the *first sampling lemma*, the fidelity half of the outward bridge, and it is the engine that will later drive the convergence of finite-network equilibria to their graphon limit in chapter 25. The whole argument is a concrete realization of the quenched/annealed split previewed at the close of section 19.1: we will freeze the types, control the conditionally independent edge noise that lives on top of them, and only then average over the frozen geometry — and a coupling, introduced in the proof, makes this order of operations literal.

To state the claim precisely we need the observables it concerns. Recall (chapter 16) that for a fixed simple graph F on vertex set $[k]$ with $e(F)$ edges — read F as a small pattern one looks for in a network, an edge, a triangle, a path, a star — the homomorphism density of F in a graph G on n vertices is

$$t(F,G) \;=\; \frac{\hom(F,G)}{n^k} \;=\; \frac{1}{n^k}\,\bigl|\{\,\phi\colon [k]\to[n] : \phi \text{ maps every edge of } F \text{ to an edge of } G\,\}\bigr|,$$

and that for the graphon W the corresponding density is

$$t(F,W) \;=\; \int_{[0,1]^k} \prod_{ab\in E(F)} W(x_a,x_b)\; \prod_{i=1}^{k} \mathrm{d}x_i.$$

The two formulas are one and the same average read in two registers. In the finite graph one averages a product of edge *indicators* over all n^k ways of dropping the k vertices of F onto $[n]$; in the graphon one averages a product of edge *probabilities* over all ways of dropping them into the continuum $[0,1]^k$, the discrete count $\hom(F,G)/n^k$ passing into the integral exactly as a Riemann sum passes into its limit. It is worth dwelling on why these deserve the name *moments* of a network, because the analogy organizes everything that follows. A probability law on the line is pinned down by its moments $\mathbb{E}[X^j]$; a graphon is pinned down — this is precisely what section 19.4 will establish — by the countable family $\{t(F,W)\}_F$ as F ranges over all finite graphs. Each F probes one mode of the network's structure: K_2 returns the edge density, the triangle K_3 the clustering, the star S_k the spread of the degree distribution, longer paths the connectivity at range. To say that a sample reproduces its parent's motif densities is therefore the network analogue of the elementary fact that an empirical distribution reproduces the moments of the law it was drawn from. The theorem below makes that analogue quantitative: the moments of the sample equal the moments of the parent up to a Monte-Carlo error that is exponentially unlikely to be large.

Before proving anything, it pays to see in advance why the result is true and where the $N^{-1/2}$ rate comes from, so that the formal proof reads as the execution of a plan rather than a sequence of estimates pulled from the air.

Heuristic (non-rigorous)

Fix F on k vertices. By definition $t(F,G(N,W))$ is an average of N^k terms, one per map $\phi\colon [k]\to[N]$, each term a product $\prod_{ab\in E(F)}\xi_{\phi(a)\phi(b)}$ of edge indicators lying in $\{0,1\}$. Were the N^k terms independent, the law of large numbers would pin the average at its mean. They are *not* independent — two maps that share a vertex share the coins incident to that vertex — but the dependence is *local*: altering what happens at a single vertex disturbs only the $O(N^{k-1})$ maps that pass through it, a vanishing fraction $O(1/N)$ of all maps. The average therefore behaves like an average of N weakly dependent blocks, not of N^k independent terms. Two consequences follow heuristically and will be made exact. First, its mean is, up to an

$O(1/N)$ correction from the diagonal maps that are forbidden a loop, exactly $t(F, W)$, because the expectation of one injective term is the continuum integral. Second, the fluctuation of an average of N weakly dependent bounded blocks is of order $N^{-1/2}$. The entire technical task is to turn "the dependence is local" into a rigorous tail bound.

The tool that converts locality of dependence into a Gaussian tail is the *method of bounded differences*, the quantitative form of the slogan "a function of many independent inputs, no one of which matters much on its own, is sharply concentrated about its mean." The plan it dictates is exactly three moves: write $t(F, G(N, W))$ as a function of a list of *independent* coordinates; check that perturbing any single coordinate moves the function by only a little; and read off the tail. We first record the inequality that performs the third move. It is the bounded-differences (McDiarmid) form of the Azuma–Hoeffding inequality already proved in chapter 3 (theorem 3.28 and remark 3.29); for completeness we supply the one nontrivial step — the bound on the martingale increments — which remark 3.29 only asserts.

Lemma 19.3 (McDiarmid's bounded-differences inequality)**.** *Let $Z_1, \dots, Z_n$ be independent random variables, Z_i taking values in a set $\mathcal{Z}_i$, and let $g\colon \prod_i \mathcal{Z}_i \to \mathbb{R}$ satisfy the bounded-differences condition: for each i there is a constant c_i such that for all z, z' differing only in the i-th coordinate, $|g(z) - g(z')| \le c_i$. Then for every $t > 0$,*

$$\mathbb{P}\Big(|g(Z) - \mathbb{E}[g(Z)]| \ge t \Big) \;\le\; 2\exp\Big(-\frac{t^2}{2\sum_{i=1}^n c_i^2} \Big).$$

Proof. The idea is to reveal the independent inputs $Z_1, \dots, Z_n$ one at a time and watch how the best current guess of g updates as each is disclosed; the bounded-differences hypothesis will cap the size of each update, and Azuma will turn capped updates into a Gaussian tail. Make this precise as a martingale. Let $\mathcal{F}_i = \sigma(Z_1, \dots, Z_i)$ record the information contained in the first i inputs (with $\mathcal{F}_0$ trivial), and set $M_i = \mathbb{E}[g(Z) \mid \mathcal{F}_i]$. Then $(M_i)_{0 \le i \le n}$ is the *Doob martingale* of $g(Z)$: it begins at the unconditional mean $M_0 = \mathbb{E}[g(Z)]$, when nothing has been revealed, and ends at the realized value $M_n = g(Z)$, when everything has, and it telescopes,

$$g(Z) - \mathbb{E}[g(Z)] \;=\; \sum_{i=1}^n (M_i - M_{i-1}).$$

So it suffices to confine each increment $M_i - M_{i-1}$ to an interval of length at most c_i and to invoke Azuma on the sum.

We claim each increment does lie in such an interval. The obstruction to comparing M_i with M_{i-1} directly is that M_{i-1} has already integrated out Z_i while M_i still retains it; to bring the two under a common roof we re-express the smaller σ-field's average as a *resampling*. Let Z_i' be an independent copy of Z_i, drawn from the same law and independent of every Z_j, and write $Z^{(i)} = (Z_1, \dots, Z_{i-1}, Z_i', Z_{i+1}, \dots, Z_n)$ for the configuration in which the i-th coordinate has been replaced by the fresh copy. Because Z_i' is independent of $\mathcal{F}_i$ and has the same law as Z_i, conditioning on $\mathcal{F}_i$ and then averaging over Z_i' is identical to conditioning on $\mathcal{F}_{i-1}$: swapping Z_i for Z_i' erases exactly the one new fact contained in $\mathcal{F}_i \setminus \mathcal{F}_{i-1}$ and leaves all earlier inputs untouched. Hence

$$M_{i-1} \;=\; \mathbb{E}[g(Z) \mid \mathcal{F}_{i-1}] \;=\; \mathbb{E}\Big[g(Z^{(i)}) \mid \mathcal{F}_i \Big],$$

and subtracting this from $M_i = \mathbb{E}[g(Z) \mid \mathcal{F}_i]$ places the two configurations under a single conditional expectation,

$$M_i - M_{i-1} \;=\; \mathbb{E}\Big[\, g(Z) - g(Z^{(i)}) \mid \mathcal{F}_i \Big]\,.$$

Now Z and $Z^{(i)}$ differ only in their i-th coordinate, so the bounded-differences hypothesis governs the inner difference directly. For each fixed value of $\mathcal{F}_i$, define $a_i = \inf_{z_i'}\big(g(Z) - g(Z_1, \ldots, z_i', \ldots, Z_n)\big)$ and let b_i be the corresponding supremum, both taken over the resampled value z_i'; the hypothesis $|g(z) - g(z')| \le c_i$ gives $b_i - a_i \le c_i$. Since $M_i - M_{i-1}$ is a conditional average of that inner quantity over Z_i', it lies in $[a_i, b_i]$, an interval of length at most c_i. One refinement pins the interval in place: a martingale increment is conditionally centered, $\mathbb{E}[M_i - M_{i-1} \mid \mathcal{F}_{i-1}] = 0$, so the interval $[a_i, b_i]$ — which contains the conditional average — must straddle 0. An interval of length at most c_i that contains 0 forces $|M_i - M_{i-1}| \le b_i - a_i \le c_i$ almost surely. This is the one nontrivial input that remark 3.29 merely asserted. With the increments so bounded, the Azuma–Hoeffding inequality (theorem 3.28) applied to the martingale (M_i) yields the stated two-sided estimate $2\exp(-t^2/(2\sum_i c_i^2))$, which is exactly the in-book bounded-differences inequality remark 3.29. (The textbook reference [102, §2] carries out the same computation with the sharper constant $2\exp(-2t^2/\sum_i c_i^2)$, which requires the range form of Hoeffding's lemma; we use only the weaker in-book constant, which suffices for every conclusion below.) □

With the tail in hand, the whole content of the first sampling lemma is the bookkeeping of the two preceding moves: identifying independent coordinates for $g = t(F, G(N, W))$ and bounding the sensitivity of g to each. We carry that out now.

Theorem 19.4 (First sampling lemma: motif concentration)**.** *Let W satisfy* (A-Reg-W) *and let F be a fixed simple graph with $k = v(F)$ vertices and $e(F)$ edges. Sample $G(N, W)$ as in definition 19.1. Then:*

1. *(Unbiasedness up to $O(1/N)$.)*

$$\big|\,\mathbb{E}[t(F, G(N, W))] - t(F, W)\,\big| \;\le\; \frac{\binom{k}{2}}{N}.$$

2. *(Concentration.) For every $\varepsilon > 0$,*

$$\mathbb{P}\Big(\big|\, t(F, G(N, W)) - t(F, W)\,\big| \ge \varepsilon\Big) \;\le\; 2\exp\Big(-\,\frac{\big(\varepsilon - \binom{k}{2}/N\big)_+^2}{2\big(k^2/N + 4\,e(F)^2/N^2\big)}\Big),$$

where $(\cdot)_+$ denotes the positive part. In particular, for each fixed F and $\varepsilon > 0$ there is $N_0 = N_0(k, \varepsilon)$ such that for all $N \ge N_0$,

$$\mathbb{P}\Big(\big|\, t(F, G(N, W)) - t(F, W)\,\big| \ge \varepsilon\Big) \;\le\; 2\exp\Big(-\,\frac{N\varepsilon^2}{16k^2}\Big),$$

and consequently $t(F, G(N, W)) \to t(F, W)$ almost surely as $N \to \infty$ for every fixed F.

Proof. Write the homomorphism density of the sample as an explicit function of all the randomness in the model,

$$g \;=\; t(F, G(N, W)) \;=\; \frac{1}{N^k} \sum_{\phi\colon [k]\to[N]} \;\prod_{ab\in E(F)} \xi_{\phi(a)\phi(b)},$$

where, for a map ϕ that sends some edge of F to a loop (i.e. $\phi(a) = \phi(b)$ for an edge ab), the corresponding indicator $\xi_{\phi(a)\phi(b)}$ is read as 0, since the sample carries no loops. We must show this g concentrates, and the heuristic already told us why to expect it: no single source of randomness governs more than an $O(1/N)$ fraction of the N^k summands.

A coupling that recovers independence. The method of bounded differences (lemma 19.3) demands that g be written as a function of *independent* coordinates, and the two obvious candidates — the types U_i and the coins ξ_{ij} — fail this on their own: by construction ξ_{ij} is Bernoulli$(W(U_i, U_j))$ *given* the types, so the coin's very distribution is steered by U_i and U_j, and the two coordinate families are entangled. Conditioning the coins on the types would restore independence but would also freeze the type randomness, which is precisely the fluctuation we must measure. The standard remedy is to drive every coin from its own external source of randomness, so that the entanglement is pushed into a deterministic rule rather than into the joint law of the inputs. Let $(\eta_{ij})_{1\le i<j\le N}$ be i.i.d. Unif$[0,1]$ *edge seeds*, independent of one another and of all the latent types, and realize each coin by thresholding its seed against the kernel value,

$$\xi_{ij} \;=\; \mathbf{1}\big[\eta_{ij} \le W(U_i, U_j)\big], \qquad \xi_{ji} = \xi_{ij}.$$

Because $\mathbb{P}\big(\eta_{ij} \le W(U_i, U_j) \mid U\big) = W(U_i, U_j)$ and the seeds are independent, this reproduces the law of definition 19.1 exactly: given the types, the ξ_{ij} are again independent Bernoulli variables with the prescribed means. The gain is structural. The model is now a *deterministic* function of the list

$$\big(U_1, \dots, U_N,\ (\eta_{ij})_{i<j}\big),$$

and these $N + \binom{N}{2}$ coordinates *are* jointly independent — all the dependence between coins has been absorbed into the deterministic thresholding, where the bounded-differences hypothesis can examine it one coordinate at a time. This is the quenched/annealed split of the physics note made literal: the U_i are the quenched geometry, the η_{ij} the annealed noise on top of it, and they are now genuinely separate, independent inputs. We apply lemma 19.3 to g regarded as a function of this list.

Mean (unbiasedness up to $O(1/N)$). We first locate the center of g and isolate the source of the $O(1/N)$ bias in (1). Condition on the types and sort the N^k maps by whether they are injective. For an *injective* ϕ the images $\phi(1), \dots, \phi(k)$ are distinct vertices, so the edges of F land on distinct pairs and the coins involved are conditionally independent; hence

$$\mathbb{E}\left[\prod_{ab\in E(F)} \xi_{\phi(a)\phi(b)} \;\middle|\; U\right] \;=\; \prod_{ab\in E(F)} W\big(U_{\phi(a)}, U_{\phi(b)}\big).$$

Averaging over the i.i.d. uniform types, each distinct type $U_{\phi(c)}$ becomes an independent uniform integration variable, and the product collapses to the continuum density,

$$\mathbb{E}\left[\prod_{ab\in E(F)} W\big(U_{\phi(a)}, U_{\phi(b)}\big)\right] \;=\; \int_{[0,1]^k} \prod_{ab\in E(F)} W(x_a, x_b) \prod_{c=1}^{k} \mathrm{d}x_c \;=\; t(F, W),$$

the same value for every injective ϕ. It remains to count the maps that fail injectivity. A map is non-injective exactly when two of its k coordinates coincide; the fraction of maps with at least one coincidence is at most $\binom{k}{2}/N$ (a factor $1/N$ for each of the $\binom{k}{2}$ pairs forced to collide). Each of the N^k summands lies in $[0,1]$, so whatever the non-injective terms contribute, they perturb the average by at most their fraction. Therefore

$$\bigl|\,\mathbb{E}[g] - t(F,W)\,\bigr| \;\le\; \frac{\binom{k}{2}}{N},$$

which is statement (1): the sample density is unbiased up to a $O(1/N)$ diagonal correction, exactly the price of the no-loops convention.

Bounded differences. We now verify the hypothesis of lemma 19.3 for each of the two kinds of coordinate, asking in each case how many of the N^k summands a single coordinate can possibly touch.

(i) A latent type U_i. Changing U_i alters only those terms of the sum whose map ϕ has i in its image. The number of maps $\phi\colon [k] \to [N]$ that hit a prescribed value i is at most $k\,N^{k-1}$ (choose which of the k coordinates equals i, then the remaining $k-1$ coordinates freely). Each term lies in $[0,1]$, so it can change by at most 1. Thus

$$c_{U_i} \;\le\; \frac{k\,N^{k-1}}{N^k} \;=\; \frac{k}{N}.$$

(ii) An edge seed η_{ij}. Changing η_{ij} flips at most the single coin ξ_{ij} (it can only move ξ_{ij} across its threshold), leaving every other coin and every type unchanged. It therefore alters only those terms whose map ϕ sends some edge $ab \in E(F)$ onto the ordered pair (i,j) or (j,i). For a fixed edge ab and a fixed orientation there are at most N^{k-2} such maps (two coordinates are pinned, $k-2$ are free); summing over the $e(F)$ edges and the two orientations gives at most $2\,e(F)\,N^{k-2}$ maps. Hence

$$c_{\eta_{ij}} \;\le\; \frac{2\,e(F)\,N^{k-2}}{N^k} \;=\; \frac{2\,e(F)}{N^2}.$$

Assembling the tail. The denominator in lemma 19.3 is the sum of the squared sensitivities, and the two coordinate families contribute to it on very different scales. There are N types, each with sensitivity at most k/N, and at most $N^2/2$ edge seeds, each with sensitivity at most $2e(F)/N^2$, so

$$\sum_i c_i^2 \;\le\; N\cdot\Bigl(\frac{k}{N}\Bigr)^2 + \frac{N^2}{2}\cdot\Bigl(\frac{2e(F)}{N^2}\Bigr)^2 \;=\; \frac{k^2}{N} + \frac{2\,e(F)^2}{N^2} \;\le\; \frac{k^2}{N} + \frac{4\,e(F)^2}{N^2}.$$

The first term, of order $1/N$, dominates; the seed term is smaller by a further factor $1/N$. This is already the $N^{-1/2}$ rate in disguise: a denominator of order $1/N$ in $\exp(-t^2/2\sum c_i^2)$ means deviations of size $t \sim N^{-1/2}$ are the natural scale of fluctuation. Applying lemma 19.3 with $t = \varepsilon - \binom{k}{2}/N$ — the slack $\binom{k}{2}/N$ absorbing the mean shift of (1), so that the bound is about the true target $t(F,W)$ rather than about $\mathbb{E}[g]$ — yields exactly statement (2). To read off the clean asymptotic form, fix k and ε and take N large. Once $N \ge k^2$ the edge-seed term obeys $4e(F)^2/N^2 \le k^2/N$ (using the crude $e(F) \le \binom{k}{2} \le k^2/2$), so the whole denominator $2(k^2/N + 4e(F)^2/N^2)$ is at most $4k^2/N$; and once N is large enough that $\binom{k}{2}/N \le \varepsilon/2$, the numerator obeys $\bigl(\varepsilon - \binom{k}{2}/N\bigr)^2 \ge \varepsilon^2/4$. Substituting these two estimates turns the exponent $-\bigl(\varepsilon - \binom{k}{2}/N\bigr)^2/2(k^2/N + 4e(F)^2/N^2)$ into $-(\varepsilon^2/4)/(4k^2/N) = -N\varepsilon^2/16k^2$, which is the simplified bound $2\exp(-N\varepsilon^2/16k^2)$. Finally, this right-hand side is summable in N (a geometric-in-N sequence), so the first Borel–Cantelli lemma (theorem 3.27) tells us that the event $\{\,|t(F, G(N, W)) - t(F, W)| \geq \varepsilon\,\}$ occurs for only finitely many N almost surely; as this holds for every $\varepsilon > 0$, the deviation tends to 0, upgrading convergence in probability to almost-sure convergence. □

The proof exhibits, term by term, the two-temperature decomposition promised in the physics note. The latent types contributed the dominant sensitivity k^2/N — the quenched geometry, frozen before any edge is drawn — while the edge seeds contributed only the lower-order $e(F)^2/N^2$ — the annealed fluctuations riding on a fixed geometry. It is the quenched part, the uncertainty in *which* types were drawn, that sets the $N^{-1/2}$ Monte-Carlo rate; the annealed coins are a genuine but subdominant correction. The split was not a heuristic gloss laid over the proof after the fact but the very seam along which the coupling cut the randomness into independent pieces.

Remark 19.5 (From motifs to the cut metric: the second sampling lemma)**.** Theorem 19.4 controls each *fixed* motif F, with constants that degrade as F grows. That is enough to recover any prescribed finite list of network statistics, but it is not enough to claim that the sample resembles its parent in *every* respect at once: nothing in the first sampling lemma stops the many small discrepancies, one per motif, from conspiring. The deeper statement, which controls all motifs simultaneously and is the input chapter 25 actually consumes, is that the *sampled graphon itself* converges to its parent in the cut metric — the single distance, introduced in section 19.1, that already bundles all motif comparisons into one number. The *second sampling lemma* of Borgs–Chayes–Lovász–Sós–Vesztergombi makes this quantitative: there is an absolute constant C such that, for the induced step graphon $W_{[N]}$ of definition 19.1,

$$\mathbb{P}\Big(\delta_\square(W_{[N]}, W) \;>\; \frac{C}{\sqrt{\log N}}\Big) \;\leq\; \exp\Big(-\,\frac{N}{C\log N}\Big). \tag{19.2}$$

Thus $\delta_\square(W_{[N]}, W) \to 0$ almost surely: a graphon is recovered in cut distance, up to relabeling and a slowly vanishing error, from a single large sample.

The slow $1/\sqrt{\log N}$ rate is striking next to the clean $N^{-1/2}$ of a single motif, and it is genuine rather than an artifact of the proof. The reason lies in what the cut norm asks of the sample. Where a single motif compares the kernels against *one* fixed test pattern, the cut norm $\left\|W_{[N]} - W\right\|_\square$ takes a *supremum* over all pairs of sets (S, T), and the sample must match its parent against that whole exponentially large family of tests at once. The right way to see where the logarithm comes from is to anticipate the next section. To pin a graphon to within cut-norm accuracy η over all test pairs simultaneously, one needs — by the weak regularity lemma of section 19.3 (theorem 19.8) — a step approximation with on the order of $4^{1/\eta^2}$ blocks; only at that resolution does the supremum over (S, T) become controllable. A sample of N vertices can populate and resolve such a block structure only when N comfortably exceeds the number of blocks, $N \gtrsim 4^{1/\eta^2}$. Inverting this relation between the achievable accuracy and the sample size, $1/\eta^2 \lesssim \log N$, gives exactly $\eta \gtrsim 1/\sqrt{\log N}$. The logarithm is thus the footprint of the exponential complexity that uniform cut-norm control demands; it is the same $4^{1/\varepsilon^2}$ bound the next section will prove, read here as a sampling rate, and it cannot be removed.

The proof is given in full in theorem F.9; we do not reproduce it here, but we record its assembly because it is exactly the two-piece split the heuristic predicts. One routes the comparison through the *weighted* sample — the step graphon $W_{\mathbb{H}(N,W)}$ whose block values are the conditional edge means $W(U_i, U_j)$ rather than the realized coins ξ_{ij} — by the triangle inequality,

$$\delta_\square(W_{[N]}, W) \;\le\; \left\| W_{[N]} - W_{\mathbb{H}(N,W)} \right\|_\square \;+\; \delta_\square(W_{\mathbb{H}(N,W)}, W),$$

and the two pieces are precisely the annealed and the quenched contributions seen above, now measured in cut norm. The first term is the cut norm of an array of conditionally independent, mean-zero edge fluctuations $\xi_{ij} - W(U_i, U_j)$ — the annealed noise on a frozen geometry; bounding it is where the union bound over the 2^{2N} test pairs (S, T) meets theorem 3.28, giving $O(N^{-1/2})$ with probability $1 - e^{-\Omega(N)}$, the exponentially small failure probability visible on the right of (19.2). The second term compares the *smooth* weighted sample to its parent — the quenched fluctuation in which types were drawn — and is controlled by the weighted sampling lemma (theorem F.7), which is where the slow $1/\sqrt{\log N}$ rate is incurred, together with the bounded-differences concentration of lemma 19.3 in the N types. The two rates then combine, the slower one prevailing. The result is due to Borgs–Chayes–Lovász–Sós–Vesztergombi [29]; see also [99, Ch. 10]. Chapter 25 uses (19.2), not the fixed-motif theorem 19.4, as the input to finite-network convergence — it is the uniformity over all test pairs, not the control of any one motif, that the limit theorem there requires.

Worked computation 19.6 (Sampling a rank-one graphon)**.** Take the rank-one kernel $W(x, y) = f(x)f(y)$ with a measurable $f\colon [0,1] \to [0,1]$ — the "Curie–Weiss" graphon of example 15.11, whose single nonzero eigenvalue $\lambda_1 = \|f\|_{L^2}^2$, with eigenfunction $f/\|f\|_{L^2}$, is computed in worked computation 2.28 (see also the operator discussion of worked computation 18.19). We instantiate the sampling theory on it explicitly. This kernel is also the carrier of Thread B, the Graphon-LQG model: the scalar order-parameter reduction we see here — everything collapsing onto the single number λ_1 and the linear functional $\bar f$ — previews the one-parameter self-consistent equation that chapters 20 and 22 build on the same rank-one structure.

Edge density. The kernel factorizes across its two arguments, so the double integral splits into a product of identical single integrals. With $\bar f = \int_0^1 f(x)\,\mathrm{d}x$,

$$t(K_2, W) \;=\; \int_{[0,1]^2} f(x)f(y)\,\mathrm{d}x\,\mathrm{d}y \;=\; \Big(\int_0^1 f(x)\,\mathrm{d}x\Big)\Big(\int_0^1 f(y)\,\mathrm{d}y\Big) \;=\; \bar f^{\,2}.$$

The edge density depends on the profile f only through its mean $\bar f$ — a first sign of the scalar reduction to come. By the first sampling lemma, $G(N, W)$ has expected edge density $\bar f^{\,2} + O(1/N)$, and its empirical edge density concentrates at $\bar f^{\,2}$ with fluctuations $O(N^{-1/2})$.

Triangles. For $F = K_3$ ($k = 3$, $e(F) = 3$) the three kernel factors, one per edge of the triangle, multiply to a separable integrand: each type variable x_c appears in exactly the two edges meeting at vertex c, contributing a factor $f(x_c)$ apiece, hence $f(x_c)^2$ in total. Regrouping by variable,

$$t(K_3, W) = \int_{[0,1]^3} \underbrace{f(x_1)f(x_2)}_{\text{edge }12}\,\underbrace{f(x_2)f(x_3)}_{\text{edge }23}\,\underbrace{f(x_3)f(x_1)}_{\text{edge }31}\,\mathrm{d}x_1\,\mathrm{d}x_2\,\mathrm{d}x_3 = \prod_{c=1}^{3}\int_0^1 f(x_c)^2\,\mathrm{d}x_c = \Big(\int_0^1 f(x)^2\,\mathrm{d}x\Big)^3 = \lambda_1^3,$$

the cube of the leading eigenvalue $\lambda_1 = \|f\|_{L^2}^2$ — the rank-one spectral structure of worked computation 18.19 surfacing directly inside a motif count, with no spectral calculation required. The same separation extends to any motif: for any F the integrand factorizes across the type variables, so $t(F, W) = \prod_{c \in V(F)} \int_0^1 f(x)^{\deg_F(c)}\, dx$, a monomial in the moments $\int_0^1 f^d$ of the profile, each vertex of degree d contributing one factor $\int_0^1 f^d$ — so that in particular each leaf contributes a $\bar{f}$ and each degree-two vertex a λ_1. The concentration bound specializes, with $k = 3$ giving $16k^2 = 144$, to $\mathbb{P}(|t(K_3, G(N, W)) - \lambda_1^3| \geq \varepsilon) \leq 2\exp(-N\varepsilon^2/144)$ for N large.

Degrees. The degree function is the row sum of the kernel, and the same factorization makes it explicit. Conditional on $U_i = x$, the degree of vertex i is a sum of $N-1$ independent coins, $\mathrm{Binomial}\big(N-1,\, d_W(x)\big)$, with

$$d_W(x) \;=\; \int_0^1 W(x,y)\, dy \;=\; f(x)\int_0^1 f(y)\, dy \;=\; f(x)\,\bar{f}.$$

So a vertex of type x connects to a fraction $f(x)\bar{f}$ of the rest: the profile value $f(x)$ scales the whole degree, and the population mean $\bar{f}$ sets the overall level. Conditional on $U_i = x$ the incident coins are i.i.d. bounded with this mean, so the strong law for bounded summands (proposition 3.24) gives the normalized degree $\deg(i)/(N-1) \to f(U_i)\,\bar{f}$ almost surely; and the empirical distribution of normalized degrees converges weakly to the law of $f(U)\bar{f}$, $U \sim \mathrm{Unif}[0,1]$, by the same empirical-measure argument detailed in proposition 19.14(3). We will return to this in section 19.5: it already shows that every degree is $\Theta(N)$, the hallmark of a *dense* model, no matter how the profile f is chosen.

What the computation foreshadows. Across all three observables the entire profile f entered only through the two scalars $\bar{f} = \int f$ and $\lambda_1 = \int f^2$: the edge density is $\bar{f}^2$, the triangle density λ_1^3, the degree law that of $f(U)\bar{f}$. This collapse of an infinite-dimensional kernel onto a couple of scalar summaries is the rank-one structure that Thread B, the Graphon-LQG model, will exploit: when $W = ff^\top$ couples agents, the network coupling each agent feels reduces to a single scalar order parameter, and the graphon fixed point reduces to one self-consistent equation in that scalar — the rank-one reductions of chapters 20 and 22. We flag the parallel because it is the same algebraic mechanism, not because the thread is carried here: this chapter proves nothing about games, and the order parameter above is purely a statistic of the sampled graph. The point is only that the dimensional collapse the thread relies on is already visible, for free, in how a rank-one graphon samples.

Having shown that a sample faithfully records every macroscopic statistic of its parent — each fixed motif by theorem 19.4, and the whole kernel in cut distance by (19.2) — we have completed the outward bridge and its fidelity. But the rank-one computation just performed quietly raised a sharper question. There the entire content of an infinite-dimensional kernel was carried by two numbers; in general, how much of a graphon's macroscopic content is genuinely irreducible? If finite samples faithfully encode a graphon, and if the relevant topology is the cut norm in which that encoding is consistent, then how *few* parameters does the cut-norm-visible structure actually require? This is the reverse of the move we have been making. Instead of pushing a graphon outward to a finite sample, we now compress the graphon inward, replacing it by a finite, bounded-complexity surrogate that is cut-norm-indistinguishable from it. The next section answers the question in the strongest possible form — a bound on the number of parameters that depends on the target accuracy alone, not on the graphon — and it works in exactly the cut norm (19.1) this section has established as the relevant topology.

19.3 The weak regularity lemma: coarse-graining made rigorous

This section answers that question by reversing the direction of travel. Sampling went from a graphon to a finite graph; coarse-graining stays inside the graphon world but compresses, replacing an arbitrary graphon by a *finite, bounded-complexity* surrogate — a step graphon with controllably few steps — that is indistinguishable from the original at the resolution of the cut norm. And it is the *same* cut norm (19.1) throughout: we are not changing the yardstick, only running it backwards. Where sampling asked how well a finite draw remembers its continuum parent, coarse-graining asks how cheaply the continuum parent can be *described* so that no cut-norm test can tell the description from the original. The answer — a complexity bound depending on the target accuracy and nothing else — is the content of the regularity lemma, and it is what pins down which features of a network survive as macroscopically meaningful.

A word on which regularity lemma. The phrase usually summons Szemerédi's celebrated theorem, which partitions a graph into a bounded number of parts almost all of whose *pairs* behave like random bipartite graphs — a pair-by-pair, "ε-regular" guarantee of remarkable strength. That strength is expensive: the number of parts it forces is a tower of exponentials in $1/\varepsilon$, and (as remark 19.10 explains) the tower is provably necessary. We do not need it. Every use the cut-metric theory makes of regularity — the compactness theorem of chapter 17, the finite-network convergence of chapter 25 — asks only that one *global* integral functional, the cut norm, be made small, never that individual pairs be pseudorandom. The *weak* (Frieze–Kannan) form delivers exactly that weaker conclusion, and in exchange it costs only a clean $4^{1/\varepsilon^2}$ parts and admits a short, transparent Hilbert-space proof: the whole argument is a single monotone-energy bookkeeping in $L^2([0,1]^2)$. Asking for precisely what the applications consume, and no more, is what buys the tame bound; this is the trade we make deliberately, and remark 19.10 returns to weigh it.

The object that does the compressing is the simplest one imaginable: given a partition of the type space into finitely many parts, declare the kernel constant on every block of the induced grid, taking on each block the average of W there. "Constant on each block" is the defining feature of a step graphon, the discretized SBM-like kernels of example 15.10, and "the average" is not an arbitrary choice but the geometrically forced one. The functions that are constant on the blocks form a finite-dimensional subspace of $L^2([0,1]^2)$; replacing W by its blockwise average is exactly orthogonally *projecting* it onto that subspace, and the orthogonal projection is the unique closest point of the subspace in the L^2 sense — the best block-constant approximation of W there is. That the blockwise average and the L^2-nearest block-constant function coincide is the same elementary fact that the mean minimizes mean-square error, here applied one block at a time. Reading the projection probabilistically, it is the conditional expectation of W given the coarsened σ-algebra that can only see which block a point lies in. Holding these three descriptions — blockwise average, orthogonal projection, conditional expectation — as one object is what makes the proof short, because each lends it a different tool: averaging makes $W_{\mathcal{P}}$ a graphon, projection gives Pythagoras, conditioning gives the contraction.

Definition 19.7 (Partition and stepping operator)**.** A *partition* $\mathcal{P} = \{V_1, \ldots, V_q\}$ of $[0,1]$ into finitely many measurable parts of positive measure induces the closed subspace

$$\mathcal{S}_{\mathcal{P}} \;=\; \operatorname{span}\Big\{ \mathbf{1}_{V_i \times V_j} \;:\; 1 \le i, j \le q \Big\} \;\subseteq\; L^2([0,1]^2)$$

of functions constant on each block $V_i \times V_j$. The *stepping operator* $W \mapsto W_{\mathcal{P}}$ is the L^2-orthogonal projection onto $\mathcal{S}_{\mathcal{P}}$; concretely, for $x \in V_i$ and $y \in V_j$,

$$W_{\mathcal{P}}(x,y) \;=\; \frac{1}{|V_i|\;|V_j|}\int_{V_i\times V_j} W(s,t)\,\mathrm{d}s\,\mathrm{d}t \;=\; \mathbb{E}[W \mid \mathcal{P}\otimes\mathcal{P}]\,(x,y),$$

the average of W over the block. The result $W_{\mathcal{P}}$ is itself a graphon (symmetric, $[0,1]$-valued), called the *step graphon* of W with respect to $\mathcal{P}$; it has at most q steps. Because $W_{\mathcal{P}}$ is a conditional expectation it preserves the integral, $\int W_{\mathcal{P}} = \int W$, and it is a contraction on every L^p, $\|W_{\mathcal{P}}\|_p \le \|W\|_p$.

With the stepping operator in hand we need a quantity to drive the construction, and the right one is already implicit in the projection picture. Projecting onto a larger subspace can only move the projected vector closer to W, hence can only *lengthen* it; so the squared L^2 norm $\|W_{\mathcal{P}}\|_{L^2}^2$ of the step graphon — the "energy" captured by the partition $\mathcal{P}$ — can only increase when $\mathcal{P}$ is refined. This is the monotone that will count the steps. Two facts make it usable. First, it is bounded above: since $0 \le W \le 1$ we have $W^2 \le W$, so the total energy $\int W^2 \le \int W \le 1$ caps every captured energy from above. A quantity that increases at each step and cannot exceed 1 can take only finitely many steps — provided each step is not too small. Second, then, every refinement we make will be *forced* to raise the energy by a fixed amount: whenever the current step graphon still differs from W by more than ε in cut norm, we will exhibit a single refinement that converts that cut-norm deficit into an energy gain of at least ε^2. A bounded quantity climbing in jumps of at least ε^2 exhausts itself after at most $1/\varepsilon^2$ jumps, and at that point no cut-norm deficit can remain. The whole proof is the execution of this one idea; the only thing to verify is the conversion of deficit into energy, and that is pure Hilbert-space geometry.

Physics note

The energy $\|W_{\mathcal{P}}\|_{L^2}^2 = \int W_{\mathcal{P}}^2$ is the variance of the kernel captured at the resolution of the partition $\mathcal{P}$. Refining $\mathcal{P}$ is a renormalization-group step that resolves finer block structure; the energy is a monotone "captured-variance" functional that increases at each refinement and is bounded above by the total $\int W^2 \le 1$. The proof below is precisely the statement that you can only refine a bounded number of times before no large patch carries unresolved correlation — a quantitative stopping rule for block-spin coarse-graining. Loosely, the energy plays the role of an entropy- or c-function-like monotone along the refinement flow; this is an analogy only, and the mathematical content is entirely in the monotone increase (19.4) below.

Theorem 19.8 (Weak regularity lemma for graphons)**.** *Let $W\colon [0,1]^2 \to [0,1]$ be a graphon. For every $\varepsilon > 0$ there is a partition $\mathcal{P}$ of $[0,1]$ into at most*

$$q \;\le\; 4^{\lceil 1/\varepsilon^2\rceil}$$

parts such that the step graphon $W_{\mathcal{P}}$ satisfies

$$\|W - W_{\mathcal{P}}\|_{\square} \;\le\; \varepsilon.$$

The number of parts depends only on ε, not on W.

Proof. We build the partition greedily, increasing the captured energy by at least ε^2 at each step. Set $\mathcal{P}_0 = \{[0,1]\}$, the trivial partition, so that $W_{\mathcal{P}_0} \equiv \int W$ is constant.

Suppose after t steps we have a partition $\mathcal{P}_t$ with $\|W - W_{\mathcal{P}_t}\|_\square > \varepsilon$. By the definition (19.1) of the cut norm there exist measurable sets $S, T \subseteq [0,1]$ with

$$\Big|\int_{S\times T}(W - W_{\mathcal{P}_t})\Big| \;=\; |\langle W - W_{\mathcal{P}_t},\, \mathbf{1}_{S\times T}\rangle| \;>\; \varepsilon, \tag{19.3}$$

where $\langle\cdot,\cdot\rangle$ is the $L^2([0,1]^2)$ inner product. Refine $\mathcal{P}_t$ by the two sets S and T: replace each part V of $\mathcal{P}_t$ by the (at most four) nonempty sets among $V\cap S\cap T,\ V\cap S\cap T^c,\ V\cap S^c\cap T,\ V\cap S^c\cap T^c$. Call the result $\mathcal{P}_{t+1}$; it has at most 4 times as many parts as $\mathcal{P}_t$, and by construction $\mathbf{1}_{S\times T} \in \mathcal{S}_{\mathcal{P}_{t+1}}$.

We claim the energy jumps by at least ε^2:

$$\|W_{\mathcal{P}_{t+1}}\|_{L^2}^2 - \|W_{\mathcal{P}_t}\|_{L^2}^2 \;=\; \|W_{\mathcal{P}_{t+1}} - W_{\mathcal{P}_t}\|_{L^2}^2 \;>\; \varepsilon^2. \tag{19.4}$$

The first equality is Pythagoras: $W_{\mathcal{P}_t}$ is the projection of $W_{\mathcal{P}_{t+1}}$ onto the smaller space $\mathcal{S}_{\mathcal{P}_t} \subseteq \mathcal{S}_{\mathcal{P}_{t+1}}$, so $W_{\mathcal{P}_{t+1}} - W_{\mathcal{P}_t} \perp W_{\mathcal{P}_t}$. For the inequality, write $h = \mathbf{1}_{S\times T} \in \mathcal{S}_{\mathcal{P}_{t+1}}$, so that $\|h\|_{L^2} \le 1$. Using $W - W_{\mathcal{P}_t} \perp \mathcal{S}_{\mathcal{P}_t}$ and then $W - W_{\mathcal{P}_{t+1}} \perp \mathcal{S}_{\mathcal{P}_{t+1}} \ni h$,

$$\langle W - W_{\mathcal{P}_t}, h\rangle = \langle W_{\mathcal{P}_{t+1}} - W_{\mathcal{P}_t}, h\rangle \;\le\; \big\|W_{\mathcal{P}_{t+1}} - W_{\mathcal{P}_t}\big\|_{L^2}\,\|h\|_{L^2} \;\le\; \big\|W_{\mathcal{P}_{t+1}} - W_{\mathcal{P}_t}\big\|_{L^2}.$$

Indeed, $\langle W - W_{\mathcal{P}_t}, h\rangle = \langle W - W_{\mathcal{P}_{t+1}}, h\rangle + \langle W_{\mathcal{P}_{t+1}} - W_{\mathcal{P}_t}, h\rangle$, and the first summand vanishes because $h \in \mathcal{S}_{\mathcal{P}_{t+1}}$ while $W - W_{\mathcal{P}_{t+1}}$ is orthogonal to that subspace. Combining with (19.3), $\big\|W_{\mathcal{P}_{t+1}} - W_{\mathcal{P}_t}\big\|_{L^2} > \varepsilon$, which is (19.4).

Now sum: after m refinement steps, $\|W_{\mathcal{P}_m}\|_{L^2}^2 \ge \|W_{\mathcal{P}_0}\|_{L^2}^2 + m\,\varepsilon^2 \ge m\,\varepsilon^2$. But $\|W_{\mathcal{P}_m}\|_{L^2}^2 \le \|W\|_{L^2}^2 \le 1$, because $0 \le W \le 1$ implies $W^2 \le W \le 1$ and the stepping operator is an L^2 contraction. Hence the process must stop after at most $m \le \lceil 1/\varepsilon^2\rceil$ steps — and it can only stop because the cut-norm deficit (19.3) is no longer available, i.e. because $\|W - W_{\mathcal{P}_m}\|_\square \le \varepsilon$. Each step multiplies the number of parts by at most 4, so the terminal partition has at most $4^{\lceil 1/\varepsilon^2\rceil}$ parts. This is the assertion. $\square$

Two features of this proof deserve emphasis because they recur in the applications. The first is the most surprising thing about the statement, and it is worth saying plainly why it holds. The bound $4^{\lceil 1/\varepsilon^2\rceil}$ on the number of parts mentions neither W nor any notion of how big or how intricate W is: a kernel with structure on arbitrarily fine scales is approximated to within ε by the *same* bounded number of blocks as a featureless constant. The reason is visible in the proof: the energy budget that limits the number of steps is $\int W^2 \le 1$, a single number bounded for *every* graphon by the range $[0,1]$ alone, and each step spends at least ε^2 of it. The graphon's complexity never enters the count because the cut norm only ever measures W against block-constant test functions, and there are only so many orthogonal directions of size $\ge \varepsilon$ to be found before the bounded energy is used up. The complexity of the surrogate is thus set by the target accuracy alone — which is exactly what makes "the macroscopic content of a graphon is finite-dimensional" a theorem rather than a hope, and what the estimation discussion of section 19.4 will turn into a parameter count independent of sample size.

The second feature is that the proof is constructive in a usable sense. The partition is not produced by an abstract compactness or averaging argument; it is grown one block-refinement at a time, and each refinement is driven by a concrete witness — the pair of sets (S, T) at which the current surrogate most visibly fails the cut-norm test. One looks for the patch $S \times T$ on which the residual $W - W_{\mathcal{P}_t}$ still integrates to more than ε, cuts along S and T, and repeats; the algorithm halts precisely when no such patch survives. This greedy, witness-by-witness growth is the same structure a statistician exploits when fitting a stochastic block model to data, splitting groups along the most informative cut until no large discrepancy remains, and we return to it in section 19.4 as the reason weak regularity, not its tower-bound cousin, is the estimation-theoretic object of interest.

Corollary 19.9 (Bounded-complexity approximation in cut metric)**.** *Every graphon lies within cut distance ε of the set of step graphons with at most $4^{\lceil 1/\varepsilon^2 \rceil}$ steps. Equivalently, step graphons of bounded complexity are $\delta_\square$-dense in graphon space.*

Proof. Theorem 19.8 gives $\|W - W_{\mathcal{P}}\|_\square \le \varepsilon$, and $\delta_\square \le \|\cdot\|_\square$ on the diagonal (the infimum over relabelings in (19.1) includes the identity). The displayed bound on the number of parts is that of the theorem. $\square$

This corollary is the structural reason the cut metric is the "right" topology for the dense theory, and it closes a loop opened back in chapter 17. The cut metric is exactly the topology in which the genuinely finite-dimensional objects — bounded-complexity step graphons — are dense, and density of finite-parameter approximants is what makes the space small enough to be compact. Concretely: for each ε the corollary says the finite family of step graphons with at most $4^{\lceil 1/\varepsilon^2 \rceil}$ steps is an ε-net, every graphon sitting within cut distance ε of one of them. Since the values of a step graphon with q blocks live in the compact cube $[0, 1]^{q \times q}$, each such net is itself covered by finitely many cut-balls of any smaller radius, so the ε-nets can be taken finite; a metric space with a finite ε-net for every ε is totally bounded, and (the space being complete, by chapter 17) compact. The weak regularity lemma is therefore the workhorse behind the compactness theorem theorem 17.13: it is what manufactures the finite ε-nets that the abstract argument there consumes. The inward direction of the bridge and the compactness of the limit world are, in this sense, the same fact stated twice.

Remark 19.10 (Weak versus strong regularity)**.** It is worth being precise about what we gave up to get the tame bound, because the two regularity lemmas differ in exactly the way their applications do. Szemerédi's original lemma [128] produces an *equitable* partition (all parts of essentially equal size) almost every pair of whose parts is "ε-regular": on the block $V_i \times V_j$ the kernel behaves like a constant not merely *on average* but on every reasonably large sub-rectangle $S \times T$ with $S \subseteq V_i$, $T \subseteq V_j$, the edge density across any such sub-pair deviating from the block average by at most ε. This is a *local*, pair-by-pair pseudorandomness guarantee, and it is precisely what one needs for arguments that count copies of a fixed small graph by multiplying densities across its edges — the embedding and counting lemmas at the heart of extremal and additive combinatorics, where one must locate structure *inside* individual blocks. That strength is not free: the number of parts it forces is a tower of exponentials, an iterated exponential of height $\sim \varepsilon^{-5}$, and Gowers showed this tower is genuinely necessary, not an artifact of the proof [99, Ch. 9]. The reason is structural:

pinning every pair to within ε requires resolving correlations on all scales simultaneously, and each refinement to fix one bad pair can spoil others, so the partition must be refined astronomically many times.

The weak form keeps only the *global* consequence. Cut-norm control (19.3) asks that $W - W_{\mathcal{P}}$ integrate to nearly zero over *every* $S \times T$ drawn from the whole of $[0, 1]$ at once — a single supremum, not a guarantee block by block — and this is strictly weaker: it permits individual pairs to be irregular as long as their irregularities cancel in the global integral. That weaker conclusion is, however, exactly and only what the cut-metric theory consumes. Every use we make of regularity — the total boundedness that gives the compactness theorem of chapter 17 (corollary 19.9), and the finite-network convergence of chapter 25 — is phrased against the cut norm, which is itself a single global supremum over (S, T); none of it ever inspects a single block for pseudorandomness, because the cut metric was built precisely to forget that level of detail (section 19.1). Asking for a global integral to be small, rather than every pair to be pseudorandom, is what lets the energy increment argument spend only ε^2 per step against a budget of 1, and so caps the part count at the tame $4^{1/\varepsilon^2}$ instead of a tower. The lesson is a recurring one: match the strength of the tool to what the application actually reads off, and the bounds repay you. Here the dense theory only ever reads the cut norm, so the weak lemma is not a convenient weakening but the exactly-right instrument.

Both halves of the bridge are now in place: section 19.2 carried a graphon outward to faithful finite samples, and the present section has compressed an arbitrary graphon inward to a finite, cut-indistinguishable surrogate of accuracy-only complexity. The two are not yet joined. Sampling tells us a graphon's statistics are recoverable from data; regularity tells us only finitely many cut-visible parameters carry those statistics. The next section fuses them into a single statement of what is and is not recoverable — equating the law of the sampled graphs, the full list of motif densities, and cut distance zero — and reads the regularity-driven finite-parameter picture forward into the estimation question: precisely the bounded-complexity, cut-visible structure isolated here is the structure that can be learned, and nothing finer.

19.4 Identifiability and the reach of the dense theory

This section fuses the two halves of the bridge into the single question they were both circling. Once one can pass faithfully from a graphon to its samples and back from a graphon to a bounded-complexity surrogate, the natural thing to ask is the *inverse* question that any modeller eventually confronts: if I am handed the data a graphon generates — a growing family of random graphs, or equivalently all their measurable statistics — how much of the graphon have I actually pinned down? Is the kernel W recoverable from its output, and if not, exactly what residual ambiguity survives? This is the *identifiability* question, and it is the precise hinge between the two directions: it is meaningful only because sampling sends a graphon outward to observable data, and it is answerable only because the cut metric — the same metric in which the second sampling lemma made that data consistent — supplies the right notion of "the same kernel." The answer below settles it completely. The law of the random graphs a graphon generates determines it exactly, but only up to the one ambiguity the cut metric was deliberately built to quotient out: the renaming of the unobservable type labels.

Before stating it, it pays to lay out the three things the theorem will identify, because they are precisely the three vantage points the chapter has been accumulating. The first is the *generative* view: a graphon *is* the law of the random graphs $G(N, W)$ it produces, the full probabilistic recipe of definition 19.1, read across all sample sizes N at once — this is what an experimenter who could resample the network indefinitely would have access to. The second is the *moment* view: a graphon is the countable list of its motif densities $\{t(F, W)\}_F$, the observable averages of chapter 16 that section 19.2 showed a single large sample already estimates. The third is the *metric* view: a graphon is a point of the quotient space $\widetilde{\mathcal{W}}_0$ under the cut distance of chapter 17. The theorem says these three are one and the same object. That they coincide is what makes "recovering a graphon from data" a well-posed task at all: it guarantees that the experimenter's resampling, the statistician's moment estimates, and the geometer's cut distance can never disagree about whether two kernels are the same.

Theorem 19.11 (Identifiability up to weak isomorphism)**.** *Let W_1, W_2 be graphons satisfying* (A-Reg-W)*. The following are equivalent.*

1. *For every N, the random graphs $G(N, W_1)$ and $G(N, W_2)$ have the same distribution (as random graphs on $[N]$ up to isomorphism).*
2. *$t(F, W_1) = t(F, W_2)$ for every finite simple graph F.*
3. *$\delta_\square(W_1, W_2) = 0$; equivalently W_1 and W_2 are* weakly isomorphic *in the sense of eq. (17.8), i.e. equal as points of the quotient metric space $\widetilde{\mathcal{W}}_0$.*

Proof. The proof is a chain of two equivalences, each of which we have an in-book tool for; the work is in narrating why each link holds, since assembled correctly they close the loop between the generative, the moment, and the metric views.

(1)⇔(2)*: the sampling law and the motifs determine each other.* The law of $G(N, W)$ on the vertex set $[N]$ is, by inclusion–exclusion, completely encoded in the family of *subgraph-containment* probabilities $\mathbb{P}(F \subseteq G(N, W))$ as F ranges over labeled graphs on subsets of $[N]$: knowing, for every pattern F, the chance that the sampled graph contains it on a prescribed set of vertices is the same as knowing the probability of every individual graph, since the latter are signed sums of the former. So it suffices to evaluate one containment probability. Fix a labeled copy of F on distinct vertices $\phi(1), \ldots, \phi(v(F))$; the incident edge coins are then driven by *distinct* types, hence conditionally independent, and the computation is the very one that produced the mean in theorem 19.4:

$$\mathbb{P}\big(F \subseteq G(N, W)\big) \;=\; \mathbb{E}\Bigg[\prod_{ab \in E(F)} \xi_{\phi(a)\phi(b)}\Bigg] \;=\; \mathbb{E}\Bigg[\prod_{ab \in E(F)} W\big(U_{\phi(a)}, U_{\phi(b)}\big)\Bigg] \;=\; \int_{[0,1]^{v(F)}} \prod_{ab \in E(F)} W(x_a, x_b) \prod_c \mathrm{d}x_c \;=$$

The labeled copy sits on distinct vertices, so the types $U_{\phi(c)}$ are i.i.d. uniform and the conditional product integrates to precisely the homomorphism density $t(F, W)$ (the integral runs over all of $[0, 1]^{v(F)}$, the coincidence diagonal being null and hence contributing nothing, so the distinct-vertex restriction is invisible in the continuum). Thus every subgraph-containment probability *is* a motif density, and the sampling law across all N is determined by — and determines — the family $\{t(F,W)\}_F$. Two graphons therefore generate the same random graphs at every size if and only if they share every motif density. The converse half is also visible directly and dynamically, which is worth recording because it is the operational content the statistician relies on: by the first sampling lemma theorem 19.4, $t(F,G(N,W)) \to t(F,W)$ almost surely, so each density is literally recovered as the large-N limit of a statistic of the sampling law — the moments are measurable functionals of the law, as they must be for the equivalence to hold.

(2)⇔(3)*: matching all motifs is the same as vanishing cut distance.* This is the counting/inverse-counting pair established in chapters 16 and 17, and the two directions sit at very different depths. The forward direction is soft and quantitative: the *counting lemma* lemma 16.17 bounds the discrepancy of any fixed motif by the cut distance, $|t(F,W_1) - t(F,W_2)| \le e(F)\,\delta_\square(W_1,W_2)$, so $\delta_\square = 0$ immediately forces every density to agree — the metric view refines the moment view for free. The converse is the deep direction, and it is where the machinery of chapter 17 earns its keep: that matching *all* densities forces $\delta_\square = 0$ is the moment-uniqueness theorem theorem 17.11, equivalently the cut-/left-convergence equivalence theorem 17.12. One cannot read this off any single motif; it is proved by combining the sampling lemma with the compactness of $\widetilde{\mathcal{W}}_0$ — if two kernels had positive cut distance yet identical densities, one extracts cut-convergent sample sequences whose limits must coincide in every density but lie at positive distance, contradicting that densities separate points of the compact quotient. Both halves are carried out in full in theorems F.11 and F.12; we import them here rather than reprove them.

Closing the loop. Finally $\delta_\square(W_1,W_2) = 0$ is, by the very definition (17.8), the relation of weak isomorphism on the quotient space $\widetilde{\mathcal{W}}_0$: the points are graphons modulo cut distance zero, so $\delta_\square = 0$ says W_1 and W_2 are literally equal there. Statement (3) is therefore simultaneously the metric assertion (distance zero) and the equivalence-relation assertion (same point of $\widetilde{\mathcal{W}}_0$), and the chain (1)⇔(2)⇔(3) is complete. □

The theorem says *that* a graphon is determined up to $\delta_\square = 0$; it is natural to ask *what* that residual equivalence looks like concretely, as an explicit relation between two kernels. Here we reach a deliberate honesty boundary, and the next remark marks it carefully: there is a clean structural answer, but only half of it is within the reach of the machinery this book has built, and only that half is ever needed downstream.

Remark 19.12 (The concrete content of weak isomorphism)**.** One would like a picture of $\delta_\square(W_1,W_2) = 0$ as a literal renaming relating the two kernels point by point, not merely the statement that an infimum over relabelings vanishes. The Borgs–Chayes–Lovász structure theorem supplies exactly such a picture: $\delta_\square(W_1,W_2) = 0$ holds if and only if there are measure-preserving maps $\varphi_1, \varphi_2 \colon [0,1] \to [0,1]$ with

$$W_1(\varphi_1(x),\varphi_1(y)) = W_2(\varphi_2(x),\varphi_2(y)) \qquad \text{for a.e. } (x,y). \tag{19.5}$$

That is, after pulling both kernels back through suitable type-relabelings they become the same function almost everywhere — weak isomorphism is genuine isomorphism up to a common refinement of the two labelings. Allowing *two* maps rather than one is essential and is the whole subtlety: a measure-preserving *bijection* of $[0,1]$ need not exist between two kernels that are nonetheless cut-equivalent (for instance, a graphon and a twofold "stretch" of it that splits each type into two identical copies are weakly isomorphic but related by no single invertible relabeling), and the pair (φ_1, φ_2) into a common refinement is what repairs this.

The easy direction is in hand from the book's own machinery, and it is worth running the reasoning because it shows where the soft part lies. Suppose maps as in (19.5) exist. Because φ_1, φ_2 are measure-preserving, pulling a kernel back through one of them leaves *every* homomorphism density unchanged — a relabeling only renames the integration variables in $\int \prod W(x_a, x_b)\, \mathrm{d}x$, and a measure-preserving change of variables does not move the value of the integral. So W_1 has the same densities as $W_1 \circ \varphi_1$ (meaning the kernel $(x, y) \mapsto W_1(\varphi_1(x), \varphi_1(y))$), which by (19.5) equals $W_2 \circ \varphi_2$ a.e., which in turn has the same densities as W_2. Matching all densities then forces $\delta_\square = 0$ by the moment-uniqueness theorem theorem 17.11. The whole easy direction thus rides on two in-book facts already proved: density-invariance under measure-preserving maps, and moment-uniqueness.

The hard direction is the converse — that vanishing cut distance *produces* the exact maps (19.5), an almost-everywhere identification, rather than only the approximate, up-to-ε alignments that the cut metric directly delivers. This is genuinely deeper than anything the cut-metric theory of chapter 17 reaches. The cut distance gives, for each $\varepsilon > 0$, a relabeling aligning the kernels to within ε; manufacturing from this sequence of approximate alignments a *single* pair of exact measure-preserving maps requires a compactness-and-limit argument carried out not on graphons but on their richer *soft-graphon* (coupling) representatives, where one tracks not just the kernels but the measure couplings that realize the alignments and extracts a limiting coupling. That apparatus is developed in [28] and [99, Ch. 13], and we do not reproduce it. This is the one structural fact about weak isomorphism we state and attribute but leave uncertified in this book. The reason we can leave it is that nothing downstream needs it: neither the present chapter, nor the finite-network convergence of chapter 25, nor the sparse theory of chapter 27, ever invokes the explicit maps (19.5). What every later argument consumes is only the *metric* statement $\delta_\square(W_1, W_2) = 0$ of theorem 19.11(3) — equality as points of $\widetilde{\mathcal{W}}_0$ — and that statement *is* proved in-book, through the counting lemma and moment-uniqueness of chapters 16 and 17. We flag the gap rather than paper over it precisely so that the boundary between what this book certifies and what it cites stays crisp.

That the recovery is only up to this relabeling is the right place to pause, because it is easy to misread as a weakness of the theory when it is in fact a faithful reflection of what a network *is*. The type labels $x \in [0,1]$ are a modelling fiction: an actual network presents only its wiring — who is connected to whom — and never an intrinsic coordinate stamped on each node. Two graphons that differ by a measure-preserving renaming of types encode the identical distribution over wirings, as the proof of theorem 19.11(1) makes literal, so no amount of data, however much one resamples, could ever tell them apart; demanding that the theory distinguish them would be demanding that it recover information the network does not carry. The cut metric was built in chapter 17 to quotient out exactly this fictitious coordinate, and identifiability up to $\delta_\square = 0$ says it quotients out neither too much nor too little: everything observable is retained, everything unobservable is discarded. This is the same exchangeability of the type variable that has been a standing principle since chapter 15 — the agents' labels are interchangeable because the model is symmetric under permuting them —

now seen from the estimation side. Exchangeability is not a technical convenience here; it is the precise content of "the label is unobservable," and identifiability is its statistical shadow.

Estimation, and why weak regularity is the statistician's friend. Theorem 19.11 is an asymptotic, population-level statement: it concerns the law of the random graphs, or equivalently an infinite list of densities, both idealizations of unlimited data. The working statistician instead holds a *single* network G on n nodes and wants to estimate the kernel W that produced it. The first thing to settle is whether this is even possible, and the second sampling lemma (19.2) settles it in principle: the empirical graphon $W_{[n]}$ built from the one observed sample is $\delta_\square$-consistent, converging to W (up to relabeling) as $n \to \infty$. So consistency is not in doubt. The danger is of the opposite kind — overfitting — and seeing why exposes the role weak regularity plays. As an estimator, the raw $W_{[n]}$ has one free entry per pair of vertices, on the order of n^2 parameters, fit from the $\binom{n}{2}$ observed edge bits: it carries as many parameters as data points and does no averaging at all, so it reproduces the sampling noise rather than smoothing it away. An estimator that memorizes its data this way has irreducible variance; the empirical graphon is consistent only in the weak cut topology, and never in any pointwise sense, exactly because those n^2 entries never settle down individually.

The weak regularity lemma supplies the remedy, and it is the same finite-parameter picture the previous section handed forward. By corollary 19.9, the population graphon is within cut distance ε of a step graphon with at most $4^{\lceil 1/\varepsilon^2 \rceil}$ blocks — that is, a stochastic block model with $q(\varepsilon) = O(4^{1/\varepsilon^2})$ classes, carrying only $O(q(\varepsilon)^2)$ effective parameters, a number that depends on the target accuracy ε alone and *not* on the sample size n. Fitting such a bounded-complexity surrogate instead of the raw pixel array converts estimation into a genuine bias–variance tradeoff. Choosing q classes incurs an *approximation* (bias) error, which weak regularity caps: it shrinks as q grows, at the rate $\varepsilon \sim (\log q)^{-1/2}$ read off by inverting the block count. It also incurs an *estimation* (variance) error from fitting $O(q^2)$ block probabilities out of $\binom{n}{2}$ edges, which *grows* with q, on the order of q^2/n^2 per block and aggregating to a term increasing in q. The two pull in opposite directions, so an optimal block count $q = q_n$ grows slowly with n — fast enough to drive the bias down, slowly enough to keep the variance controlled — and at that choice the SBM estimator attains the optimal tradeoff. This is the rigorous basis of consistent graphon estimation, and the minimax analysis makes the regularity-driven block count explicit, the optimal q_n and the resulting rate being governed by precisely the $4^{1/\varepsilon^2}$ complexity that weak regularity furnishes [87]. The conceptual payoff is that coarse-graining and statistical identifiability are revealed to be one phenomenon seen from two sides. Weak regularity, run *inward*, says a graphon's cut-visible content is captured by boundedly many parameters; the estimation problem, run *from data*, says those same boundedly many parameters are exactly what a finite sample can learn. Only the bounded-complexity, cut-norm-visible structure is recoverable, and weak regularity is precisely the theorem that isolates it.

This closes the positive account. We have now delimited, sharply, what the dense theory *can* do: it recovers any graphon up to weak isomorphism — the exact and only ambiguity the data leave open — and it estimates that recoverable, cut-visible structure consistently and efficiently from a single large sample, with weak regularity setting the number of parameters worth fitting. Every faculty the chapter built — sampling outward, coarse-graining inward, and now the identifiability that fuses them — has been turned to a constructive end. But the same machinery has a sharp edge, and intellectual honesty requires us to run it the other way. The cut metric and the sampling lemmas that make all of this work were defined for *dense* graphons, bounded kernels with $\Theta(N^2)$ edges; the rank-one computation of section 19.2 already let slip that every degree in such a model grows like $\Theta(N)$. Real networks are not like this. The next section takes the very cut-metric and sampling apparatus just celebrated and shows that, applied outside the dense regime, it does not merely lose accuracy but goes structurally blind — collapsing every sparse network onto a single uninformative point. What the dense theory can recover, it recovers perfectly; what it is built to see is, it turns out, precisely not the world most networks live in.

19.5 Why the dense theory fails for real networks

Intellectual honesty now requires us to run the same machinery the other way and see where it breaks. This is the limitation that gives the chapter its subtitle, and we will not apologize for it — we will prove it. The cut metric and the two sampling lemmas that powered everything above were built for one regime, and outside it they do not merely lose accuracy: they go blind. Two precise theorems pin down how. The first shows that the cut metric collapses every sparse network sequence onto a single point; the second shows that the W-random model cannot generate a sparse network in the first place. Together they say the blindness is structural, present in both the limit notion and the generative recipe, and therefore not a defect any refinement *within* the dense framework could repair.

Everything in this chapter is a theory of *dense* graphs — graphs with $\Theta(N^2)$ edges, a positive fraction of the $\binom{N}{2}$ possible ones present. This is not an incidental feature one might relax; it is wired into the definitions at the ground floor. A graphon is a kernel $W\colon [0,1]^2 \to [0,1]$ bounded by 1, and a bounded kernel integrates to a positive number, so its edge density $t(K_2, W) = \int_{[0,1]^2} W$ is a constant of order one; multiplying by the $\binom{N}{2}$ pairs of a sample forces $\Theta(N^2)$ edges. The cut metric inherits the same ceiling, because it compares two such bounded kernels through patch integrals that are themselves order-one quantities. The rank-one computation of section 19.2 already let this slip: there we found $\deg(i)/(N-1) \to f(U_i)\bar{f}$, so every degree in that model is $\Theta(N)$ no matter how the profile f is chosen, and promised to return to the point here. We now make good on the promise in general.

The trouble is that real networks are the opposite of dense. Social graphs, the web hyperlink graph, power grids, citation and collaboration networks — across the board their edge counts grow linearly, or only slightly faster than linearly, in the number of nodes, so a typical vertex has $\Theta(1)$ neighbours, not $\Theta(N)$, and their degree distributions are heavy-tailed, with a handful of hubs whose degree dwarfs the median by orders of magnitude. A graph on a million nodes in which each node knows a few hundred others has on the order of 10^8 edges, not the 10^{12} a dense model would demand; the dense and the real differ not by a constant but by a growing factor of N. The dense theory does not approximate such a network poorly. It collapses it — and every network like it, however different they are from one another — to one and the same trivial limit. We prove this first.

Proposition 19.13 (Sparse sequences converge to the zero graphon)**.** *Let $(G_n)_{n\geq 1}$ be a sequence of finite simple graphs with $v(G_n) \to \infty$ and* subquadratic *edge count, $e(G_n) = o(v(G_n)^2)$. Then for* *every finite simple graph F with at least one edge,*

$$t(F, G_n) \longrightarrow 0,$$

and consequently the associated pixel graphons converge to the zero graphon, $\delta_\square(W^{G_n}, \mathbf{0}) \to 0$, where W^{G_n} is the pixel graphon of G_n in the sense of definition 15.2.

Proof. The whole argument is a single domination bound: any motif density is squeezed below the edge density, and the edge density is exactly the quantity the sparsity hypothesis kills. Fix F with an edge $ab \in E(F)$ and write $n = v(G_n)$. Every factor in the homomorphism product is an edge indicator lying in $[0,1]$, so discarding all factors but the one indexed by the chosen edge ab can only raise the product:

$$t(F, G_n) = \frac{1}{n^{v(F)}} \sum_{\phi} \prod_{cd \in E(F)} \mathbf{1}[\phi(c)\phi(d) \in E(G_n)] \;\leq\; \frac{1}{n^{v(F)}} \sum_{\phi} \mathbf{1}[\phi(a)\phi(b) \in E(G_n)] \;=\; t(K_2, G_n).$$

The last equality is a counting identity worth seeing explicitly. In the right-hand sum only the two coordinates $\phi(a), \phi(b)$ are constrained — they must land on an edge — while the remaining $v(F) - 2$ coordinates are entirely free, each ranging over all n vertices and so contributing a factor n. Those $v(F) - 2$ free factors produce $n^{v(F)-2}$, which against the normalization $n^{v(F)}$ leaves $n^{-2} \sum_{\phi(a),\phi(b)} \mathbf{1}[\,\cdot \in E(G_n)]$, exactly the edge density $t(K_2, G_n)$. And that density is precisely twice the edge count over the squared vertex count, $t(K_2, G_n) = 2e(G_n)/n^2$, which tends to 0 by the subquadratic hypothesis $e(G_n) = o(n^2)$. Hence $t(F, G_n) \to 0$ for every F with an edge: the sample retains no motif at all in the limit.

For the cut distance to the zero graphon there is nothing more to prove, because the cut norm of a nonnegative kernel is dominated by its L^1 norm, and here the L^1 norm is again the edge density. The pixel graphon W^{G_n} is nonnegative, so the supremum $\left\|W^{G_n}\right\|_\square = \sup_{S,T} \int_{S\times T} W^{G_n}$ from (19.1) is largest when $S = T = [0,1]$ and no cancellation can help; thus

$$\left\|W^{G_n}\right\|_\square \;\leq\; \left\|W^{G_n}\right\|_{L^1} \;=\; \int_{[0,1]^2} W^{G_n} \;=\; t(K_2, G_n) \;=\; \frac{2e(G_n)}{n^2} \;\to\; 0.$$

Finally $\delta_\square(W^{G_n}, \mathbf{0}) = \left\|W^{G_n}\right\|_\square$, because the zero graphon is fixed by every measure-preserving relabeling φ — $\mathbf{0}^\varphi = \mathbf{0}$ — so the infimum over φ in (19.1) changes nothing and is attained at the identity. Hence $\delta_\square(W^{G_n}, \mathbf{0}) \to 0$. □

The proposition is devastating in its simplicity, and it is worth pausing to feel the full weight of what the one-line domination bound just did. A sparse sequence of networks — no matter how intricate its internal architecture, no matter whether it is organized into tight communities, threaded by high-degree hubs, locally clustered into triangles, or stacked into hierarchies of subgraphs — is, in the cut metric, *indistinguishable in the limit from the empty graph.* All of that structure lives in the motif densities, and every single one of them was crushed to zero by the same bound, because each was trapped beneath an edge density that itself vanishes. The dense graph-limit machinery, asked for the limit object of such a sequence, returns $\mathbf{0}$ and in doing so throws away everything that made the sequence interesting. Take two sparse sequences as different as a growing collection of disjoint triangles and a growing sparse expander: their community structure, their connectivity, their clustering could not be more unlike, yet both have edge density tending to zero, so both limit to the very same zero graphon and the theory cannot tell them apart. The information loss is not partial and it is not graceful; it is total, and it falls exactly on the features one builds a network model to capture. The cut metric, so powerful within the dense world, simply has no resolution outside it.

One might still hope the fault lies only in the limit notion — in measuring with the cut metric — and that the generative model itself remains flexible enough to produce sparse samples that we then judge by some better yardstick. It does not. The second proposition closes that escape, by showing that the W-random model of definition 19.1 cannot emit a sparse graph at all: density is forced by the construction, before any metric is chosen.

Proposition 19.14 (The W-random model is intrinsically dense)**.** *Let W satisfy* (A-Reg-W) *with* $\int_{[0,1]^2} W > 0$*, and sample $G(N, W)$. Write $d_W(x) = \int_0^1 W(x, y)\,\mathrm{d}y$ for the degree function. Then:*

1. *conditionally on $U_i = x$, the degree of vertex i is* $\mathrm{Binomial}(N-1,\, d_W(x))$*, so* $\deg(i)/(N-1) \to d_W(U_i)$ *almost surely;*

2. *the average degree satisfies* $\mathbb{E}[\deg(i)] = (N-1)\, t(K_2, W)$*, which grows linearly in N; equivalently the edge count is* $\Theta(N^2)$ *almost surely;*

3. *the empirical degree distribution, rescaled by $N - 1$, converges weakly to the law of $d_W(U)$ for $U \sim \mathrm{Unif}[0, 1]$ — a fixed distribution* supported on $[0, 1]$ *that does not change shape with N.*

Proof. The three statements are three readings of the same fact, that conditional on its own type a vertex collects independent coins of a fixed bias. We establish that conditional law first and then push it through, in turn, to one vertex (a strong law), to the population mean (linearity of expectation), and to the empirical distribution (a weak-convergence argument).

The conditional degree law and (1). Fix vertex i and condition on $U_i = x$. For each $j \neq i$ the incident coin ξ_{ij} was drawn, in the model of definition 19.1, as Bernoulli($W(U_i, U_j)$) given the two types; with $U_i = x$ held fixed but $U_j \sim \mathrm{Unif}[0, 1]$ still random, marginalising over U_j (and over the edge seed) gives the unconditional success probability

$$\mathbb{P}(\xi_{ij} = 1 \mid U_i = x) = \int_0^1 W(x, y)\,\mathrm{d}y = d_W(x),$$

the row integral of the kernel, which is the degree function evaluated at x. The coins ξ_{ij}, $j \neq i$, are moreover independent of one another given $U_i = x$, since each draws on a distinct partner type U_j and a distinct seed; so the degree $\deg(i) = \sum_{j \neq i} \xi_{ij}$ is a sum of $N - 1$ i.i.d. Bernoulli($d_W(x)$) variables, that is Binomial($N - 1$, $d_W(x)$). Because those coins are i.i.d. and bounded in $[0, 1]$, the in-book strong law for bounded summands (proposition 3.24) applies to their average, giving $\deg(i)/(N - 1) \to d_W(U_i)$ almost surely. This is (1), and it is the same computation already met for the rank-one kernel in worked computation 19.6, where $d_W(x) = f(x)\bar{f}$; the present proposition is that worked computation stripped of its rank-one specialisation.

Linear mean degree and (2). Take expectations of the conditional law. Since the conditional mean of a Binomial$(N-1, d_W(U_i))$ is $(N-1)d_W(U_i)$, the tower property gives $\mathbb{E}[\deg(i)] = (N-1)\,\mathbb{E}[d_W(U_i)] = (N-1)\int_0^1 d_W(x)\,\mathrm{d}x = (N-1)\,t(K_2, W)$, the last equality because integrating the row integral over x reassembles the full double integral $\int_{[0,1]^2} W = t(K_2, W)$. The hypothesis $\int_{[0,1]^2} W > 0$ makes this a strictly positive multiple of $N-1$, so the mean degree grows *linearly* in N. Summing $\deg(i)$ over the N vertices and halving counts each edge once, $e(G(N,W)) = \frac{1}{2}\sum_i \deg(i)$, whose expectation is therefore $\frac{1}{2}N(N-1)t(K_2,W) = \Theta(N^2)$; and the edge density is exactly the motif density $t(K_2, G(N,W))$, which by the first sampling lemma (theorem 19.4 with $F = K_2$) concentrates at $t(K_2, W) > 0$. This upgrades the expectation to an almost-sure statement, $e(G(N,W)) = \Theta(N^2)$, which is (2): the model cannot help being dense.

The limiting degree shape and (3). This is the most delicate of the three, so we spell it out. We claim the empirical degree measure

$$\mu_N := \frac{1}{N}\sum_{i=1}^{N}\delta_{\deg(i)/(N-1)} \qquad \text{converges weakly to} \qquad \nu := \mathrm{Law}\big(d_W(U)\big), \quad U \sim \mathrm{Unif}[0,1].$$

One must be clear about what is and is not being claimed. We assert only *weak* convergence of the random measure μ_N — convergence of $\int h\,\mathrm{d}\mu_N$ for bounded continuous test functions h — not the stronger uniform convergence of cumulative distribution functions that Glivenko–Cantelli would supply; the weaker statement is all the proposition needs and all that is true at this level of generality, and flagging the distinction keeps us from over-claiming. By the bounded-Lipschitz form of the Portmanteau theorem (theorem 3.9), it suffices to show $\int h\,\mathrm{d}\mu_N \to \int h\,\mathrm{d}\nu$ in probability for every bounded Lipschitz h, say with Lipschitz constant L. We obtain this by interposing the "ideal" empirical average built from the exact degree functions, $\frac{1}{N}\sum_i h(d_W(U_i))$, and controlling the two gaps separately — a clean quenched/annealed split once more.

The first gap, from the ideal average to its mean, is a law of large numbers in the types. The summands $h(d_W(U_i))$ are i.i.d. (the U_i are) and bounded (as h is), so proposition 3.24 gives

$$\frac{1}{N}\sum_{i=1}^{N} h(d_W(U_i)) \;\longrightarrow\; \mathbb{E}[h(d_W(U))] \;=\; \int h\,\mathrm{d}\nu \qquad \text{almost surely,}$$

which is the right-hand target. The second gap, from the true empirical average $\int h\,\mathrm{d}\mu_N = \frac{1}{N}\sum_i h(\deg(i)/(N-1))$ to the ideal one, measures how far each realized normalized degree sits from its conditional mean. Conditional on U_i, the normalized degree $\deg(i)/(N-1)$ is the mean of $N-1$ i.i.d. Bernoulli$(d_W(U_i))$ coins; its conditional mean is exactly $d_W(U_i)$, and its conditional variance is $\frac{1}{N-1}d_W(U_i)\big(1-d_W(U_i)\big) \le \frac{1}{4(N-1)}$, the bound $p(1-p) \le \frac{1}{4}$ holding for every $p \in [0,1]$ and so *uniformly in* i regardless of the type drawn. By Jensen (or Cauchy–Schwarz), the mean absolute deviation is at most the square root of the variance,

$$\mathbb{E}\big[\,|\deg(i)/(N-1) - d_W(U_i)|\,\big] \;\le\; \Big(\tfrac{1}{4(N-1)}\Big)^{1/2} \;=\; \tfrac{1}{2}(N-1)^{-1/2},$$

uniformly in i. The Lipschitz bound on h now transfers this control from the degrees to the test averages: term by term $|h(\deg(i)/(N-1)) - h(d_W(U_i))| \le L\,|\deg(i)/(N-1) - d_W(U_i)|$, so averaging and taking expectations,

$$\mathbb{E}\Big[\Big|\int h\,\mathrm{d}\mu_N - \tfrac{1}{N}\textstyle\sum_i h(d_W(U_i))\Big|\Big] \;\le\; \dfrac{L}{N}\displaystyle\sum_{i=1}^{N}\mathbb{E}\big[\,|\deg(i)/(N-1) - d_W(U_i)|\,\big] \;\le\; \frac{L}{2\sqrt{N-1}} \;\longrightarrow\; 0,$$

where the uniformity in i is exactly what let the N identical bounds collapse to a single $O(N^{-1/2})$ term rather than accumulate. Convergence in L^1 forces convergence in probability, so this second gap vanishes in probability. Adding the two estimates — the first gap to $\int h \, \mathrm{d}\nu$ almost surely, the second gap to 0 in probability — gives $\int h \, \mathrm{d}\mu_N \to \int h \, \mathrm{d}\nu$ in probability for every bounded Lipschitz h, which by theorem 3.9 is precisely $\mu_N \Rightarrow \nu$. The limit law ν is a fixed distribution on $[0,1]$, determined by the kernel through its degree function alone and *independent of* N; this is (3). The argument is the same empirical-measure convergence invoked, without proof, at the end of worked computation 19.6, now discharged in full. □

Statement (3) repays a careful reading, because it draws the exact line between what the dense model can imitate and what it can never produce, and the line is sharper than one might first guess. On the permissive side, the dense model *can* reproduce any *shape* of rescaled degree distribution whatsoever. Given any target law on $[0,1]$, set d_W equal to its quantile function: then $d_W(U)$ for $U \sim \mathrm{Unif}[0,1]$ has exactly that law, and by (3) the limiting normalized-degree distribution matches it. So if one only ever looks at degrees *after* dividing by $N-1$, the model is completely flexible — bimodal, skewed, concentrated, spread; any silhouette is attainable.

The flexibility is an illusion produced entirely by that normalization, and statement (3) is precise about where it ends. What the dense model cannot do is the one thing every real network insists upon: it cannot make the *unnormalized* degrees small. The limit law ν lives on $[0,1]$ and describes $\deg(i)/(N-1)$, so a vertex landing at the point $d_W(U_i) = d$ has actual degree $\approx (N-1)d = \Theta(N)$. Every degree is forced to be $\Theta(N)$; the maximum degree is $\Theta(N)$, never sublinear; and the genuinely heavy, N-independent power-law tail that real networks exhibit in their *raw* degrees is unreachable, because rescaling by $N-1$ is the very operation that flattens any such tail into the bounded interval $[0,1]$ before a limit is taken. The model can match a degree silhouette and never a degree scale. And the culprit is named and unremovable: it is the boundedness $W \le 1$, which caps the row integral $d_W(x)$ at 1 and so caps every connection probability at order one, guaranteeing $\Theta(N)$ neighbours. That ceiling is not a modelling choice we made carelessly; it is the definition of a graphon. To escape it one must change the definition.

We have now diagnosed the failure in three named pieces, and each will be matched, in the next section, by a specific cure. The cut metric *trivializes* on sparse sequences (proposition 19.13), collapsing them all to $\mathbf{0}$ — so the metric must be rescaled before it can resolve anything. The W-random model is *intrinsically dense* (proposition 19.14), forcing $\Theta(N^2)$ edges — so the sampling recipe must carry a vanishing target density. And the bounded kernel $W \le 1$ is the *structural cause* of both, ruling out heavy tails by fiat — so the kernel must be allowed to leave L^∞. Three failure modes, three defects to repair: a trivializing metric, a density-forcing recipe, a bounded kernel. The next section takes them in exactly this form and shows how the two sparse frameworks — L^p graphons and graphex — are built precisely to mend them, so that what follows reads as the prescription answering this diagnosis rather than as a fresh topic.

19.6 The road to sparsity: L^p graphons and graphex

Section 19.5 did more than register a disappointment; it took care to name the failure in three separate pieces — a trivializing metric (proposition 19.13), a density-forcing recipe (proposition 19.14), and beneath both the structural cause, the boundedness $W \leq 1$ — each phrased so that a cure could be aimed at it directly, and the discipline of this section is to honour that framing. We do not present sparsity as a new subject that happens to follow the dense one. We present it as the prescription that the preceding diagnosis already wrote out, taking the three named defects in the exact form the last section handed them over and matching each to the repair built to mend it. These are not three independent complaints. They are three faces of one ceiling, which is why a repair worth the name cannot patch them one at a time but must change the sampling scale, the comparison metric, and the function class of the kernel together. Two related programmes do exactly this, by two different amounts of surgery. Both are developed in full in chapter 27; we describe here only what they are and why each lands on a specific failure mode above, and we prove nothing — the point of previewing them is to make precise the claim that sparsity is a genuine frontier and not a corner of the dense theory one might reach by a careful estimate.

Route 1: sparse and L^p graphons. The first and more conservative route keeps everything about the dense picture it possibly can — the unit-interval type space $[0, 1]$, the latent uniform types, the reading of the kernel as a recipe for biased coins — and changes only the one dial that the second proposition identified as the seat of the trouble: the scale at which the coins are biased. The W-random model forces density because the connection probability $W(x, y)$ is of order one, so a vertex meets an order-one fraction of the rest; the obvious remedy is to turn that probability down, uniformly and by a factor that shrinks with the size of the graph. One therefore attaches a vanishing *target density* $\rho_N \to 0$ to the model and connects the types x, y with probability $\min\{1, \rho_N W(x, y)\}$ in place of $W(x, y)$. The factor ρ_N does the dimming; the clip $\min\{1, \cdot\}$ is there only because a probability may not exceed 1, and where W is bounded it never bites for N large, since $\rho_N W \leq \rho_N \to 0$ — it becomes active precisely at the heavy-tailed hubs, the very places, as we shall see, where the unbounded kernels below put their mass.

The accounting is immediate and shows the dial doing exactly what was asked. A vertex of type x now connects to each of the $N - 1$ others with probability about $\rho_N\, d_W(x)$, where $d_W(x) = \int_0^1 W(x, y)\, \mathrm{d}y$ is the degree function of proposition 19.14, so its expected degree is about $(N - 1)\rho_N\, d_W(x)$ and the average over types is about $(N - 1)\rho_N\, t(K_2, W)$. Choosing $\rho_N = c/N$ holds this product at a constant, making the average degree $\Theta(1)$ — a genuinely sparse graph, $\Theta(N)$ edges in place of $\Theta(N^2)$ — and the family $\rho_N = N^{-\gamma}$, $0 < \gamma < 1$, sweeps the intermediate densities between the sparse and the dense extremes. So the density-forcing recipe is mended at a stroke. But the same vanishing factor that fixes the density breaks two other things that the dense theory took for granted, and repairing those is what makes Route 1 a programme rather than a one-line substitution; it is the content of chapter 27.

The first casualty is the metric. With connection probabilities of size ρ_N, the sampled kernel $W_{[N]}$ has entries of size $\rho_N \to 0$, so it is itself a sparse object and falls under proposition 19.13: its unrescaled cut-distance limit is the zero graphon, and all the structure one tuned W to carry is crushed exactly as before. The metric has not been fixed by lowering the density; it has been handed the very sequences it cannot see. The repair is to undo the dimming before comparing — to measure the *rescaled* empirical kernel $\rho_N^{-1}W_{[N]}$, whose entries are back at order one, against the parent W, working with the *stretched* (or normalized) cut distance $\delta_\square(\rho_N^{-1}W_{[N]}, W)$ [25, 26]. This is more than a cosmetic division. The bounded-kernel cut theory of chapter 17 — compactness, the equivalence of cut distance with motif convergence, the whole calculus on which the present chapter rested — was built for kernels valued in $[0, 1]$, and the rescaled kernel $\rho_N^{-1}W_{[N]}$ is unbounded, with spikes wherever the dimmed coins clustered. The cut theory does not apply verbatim; it has to be re-proved in a setting where the objects compared are no longer uniformly bounded.

The second casualty is deeper and explains why the heavy tails of real networks demand a new function class rather than a mere rescaling. A degree distribution with a genuine, N-independent power-law tail in its raw degrees requires connection probabilities that are themselves wildly unequal across types — a few types overwhelmingly more connective than the rest — and a kernel bounded by 1 simply cannot encode such disparity, as proposition 19.14 proved by capping the row integral. To carry it, the limiting kernel must be allowed to grow without bound, $W \in L^p([0, 1]^2)$ for some $1 \le p < \infty$ in place of $W \in L^\infty$. These are the L^p *graphons* (definition 27.5), and leaving L^∞ costs the analytic backbone of chapter 18. There the kernel was a self-adjoint Hilbert–Schmidt operator $\mathbb{W}$, and it was square-integrability, $W \in L^2([0, 1]^2)$, that made $\mathbb{W}$ Hilbert–Schmidt and hence compact, with the discrete real spectrum the centrality and community readings depended on. An L^p graphon need not be in L^2 at all; its operator $\mathbb{W}$ is in general neither Hilbert–Schmidt nor even bounded on L^2, so the compact-operator spectral theory of chapter 18 and the operator-norm smallness condition (A-Coupling) — the contraction hypothesis on which uniqueness turned — lose their meaning and must be replaced by genuinely L^p estimates. This is exactly the point at which the GMFG existence theory of chapter 24 has to be rebuilt for sparse couplings, the equilibrium fixed point reconstructed on an operator that no longer obeys the Hilbert-space bounds Part IV will assume; it is the analytic heart of chapter 27 and the reason the sparse story cannot be told as a footnote to the dense one.

It helps to anchor the abstraction in the one model that makes all of it concrete, and it is the sparse twin of the example this chapter has already leaned on. The Chung–Lu, or expected-degree, model [48] takes a rank-one sparse kernel $W(x, y) \propto w(x)w(y)$ with a *heavy-tailed* weight function w, sparsified by the factor ρ_N, and produces genuine power-law degree sequences on graphs with $\Theta(N)$ edges. It is the sparse analogue of the rank-one worked computation worked computation 19.6: there the bounded profile f collapsed every observable onto the two scalars $\bar{f}$ and λ_1 and forced $\Theta(N)$ degrees by the very boundedness of f; here the unbounded weight w is precisely what frees the degree tail that the bounded f could never reach, the rank-one algebra surviving but the function class changing under it. We return to it in chapter 27.

Route 2: graphex and exchangeable random measures. The second route asks a more radical question. Route 1 kept the finite type space $[0, 1]$ and patched the kernel and the metric around it; but $[0, 1]$ with Lebesgue measure is a *probability* space, a space of total mass one, and one may reasonably suspect that the forced density is built into that finiteness as much as into the boundedness of the kernel — that a model whose vertices are drawn from a unit-mass space of types will struggle to be sparse no matter how the coins are dimmed. Route 2 takes the suspicion seriously and abandons the unit-interval vertex set altogether. In place of N types drawn from $[0,1]$, one places a Poisson point process of vertices on the half-line $\mathbb{R}_+$, equipped now with the infinite-mass Lebesgue measure: a countable cloud of latent vertices, each carrying a label, of which only finitely many are *active* below any finite truncation level, and connects them through a symmetric kernel $W: \mathbb{R}_+^2 \to [0,1]$ — a *graphex* (definition 27.12). The infinite reservoir of latent vertices is what lets the active graph stay sparse while still admitting hubs of unbounded relative degree: there is always more room on the half-line for a heavy tail than a unit interval can hold.

The structural objects this construction produces are the *exchangeable random measures* of Caron–Fox and Veitch–Roy [45, 130], and their role here is exactly parallel to the one the Aldous–Hoover representation played for dense graphons. Aldous–Hoover characterized the dense limit by saying which random arrays are invariant under relabeling of the vertices, and identified those with graphons; the Caron–Fox and Veitch–Roy theory does the corresponding job one rung down in density, characterizing the sparse limit objects as the random measures on $\mathbb{R}_+^2$ that are invariant in the matching sense and representing them through a graphex. It is the sparse analogue of the exchangeability backbone of the dense theory, not a loose metaphor for it. The accompanying notion of limit is supplied by sampling: one truncates the point process at level s, reads off the finite graph of vertices active below s, and lets $s \to \infty$, obtaining *sampling convergence* (also called *stretched convergence*) under which sparse graphs with power-law degrees possess genuine, nontrivial limits [26] — the convergence the dense cut distance could not provide. And the payoff is that the graphex framework delivers, generically and without any fine-tuning of the kernel, exactly the catalogue of features that proposition 19.14 proved a W-random graph could never exhibit: $\Theta(N)$ edges, a maximum degree sublinear in N relative to the natural scaling, and heavy-tailed degree distributions whose tails do not flatten under rescaling. The dense theorem said these were impossible; the graphex says they are typical, which is the sharpest possible statement that the two regimes are different worlds. Building the mean-field game theory over such limits — the sparse counterpart of the entire Part IV development of chapters 21 to 24 — is the business of chapter 27.

Remark 19.15 (What is theorem and what is frontier)**.** The dense statements of this chapter (theorems 19.4, 19.8 and 19.11) are complete and classical. The sparse story is in active development. The graphex representation theory and sampling-convergence framework are on firm footing [45, 130, 26]; what remains substantially open, and is flagged as such in chapters 27 and 31, is the mean-field game theory *over* sparse limits: existence, uniqueness, and finite-network approximation for GMFG when the coupling operator is an unbounded L^p kernel or a graphex. We will be careful in chapter 27 to separate the proved from the conjectural there; for the present chapter the honest summary is that the dense theory is closed and exact within its regime, and structurally blind outside it.

With that, the whole sparse programme passes out of this chapter and into the rest of the book. The analytic machinery both routes demand — the L^p operator theory, the stretched cut distance, the graphex representation, and the equilibrium theory built on top of them — is the charge of chapter 27, and the explicit map of what within it is settled and what is still conjecture is laid out in the research survey of chapter 31. What we keep for the immediate purpose is only the clean line the frontier remark just drew, the line between the proved-and-classical and the still-open, because it is exactly that line, widened from this one chapter to the four pillars of the whole part, that the retrospective now takes up. The dense theory we are about to summarize is the part of the story that is finished; the sparse theory we have just sketched is the part that is not, and Part III ends by saying, pillar by pillar, precisely which is which.

Part III in retrospect

The frontier remark just drew a single clean line — between the dense theory that is finished and the sparse theory that is not — and promised to widen it. That widening is the work of this closing unit. The line was drawn for one corner of one chapter, the cut metric's treatment of subquadratic graphs; but the same line runs the length of Part III, and seen at full length it is not a defect at the edge of an otherwise seamless theory but the precise shape of the theory's domain. So it is worth standing back from the individual theorems and looking at the arc whole, pillar by pillar, to see exactly what was built, exactly what it is good for, and exactly where it stops — not as three separate verdicts but as one. Part III set out to turn "a network" into an analytic object one could do calculus on; it succeeded completely, and the boundary we are about to mark is the boundary of that success, proved from the inside.

Four faculties were built, each the prerequisite for the next, and together they are the calculus. The first was *representation*. We replaced the adjacency matrix of a growing family of graphs — a combinatorial object whose very dimension changes with N — by a single measurable kernel $W\colon [0,1]^2 \to [0,1]$ (chapter 15), so that an entire sequence of networks of every size could be held at once in one fixed analytic object. The second was *observation*. A kernel carries a labelling that no network actually exposes, and the motif densities $t(F,W)$ (chapter 16) are exactly the functionals that survive relabelling: they are the network's moments, the only coordinates by which one graphon is honestly told from another, and chapter 16 showed they determine everything observable. The third was *metric and compactness*. Equipping the space of kernels with the cut distance $\delta_\square$ (chapter 17) turned "a sequence of networks converges" from a hope into a theorem: the cut metric is the weakest yardstick fine enough to see motif densities and coarse enough to forgive pixel-scale noise, and in it graphon space is *compact*, so a limit always exists and always lives in the same world as the objects approaching it — there is no escape to a larger universe. The fourth was *spectrum*. Recognising W as a self-adjoint Hilbert–Schmidt operator $\mathbb{W}$ (chapter 18) let us diagonalise it, and its eigenvalues and eigenfunctions read off centrality, community structure, and the modes through which any dynamics on the network will couple. Representation, moments, metric, operator: each faculty is internal to the continuum, a way of comparing, classifying, and decomposing graphons among themselves.

What this chapter added is the faculty the other four presuppose but none supplies: a *passage* between that continuum and an actual finite network of N nodes, built in both directions. Outward, sampling: a graphon is a generative recipe, $W \rightsquigarrow G(N,W)$, and its samples faithfully remember it — each fixed motif of the sample concentrates on the parent's at the Monte-Carlo rate $N^{-1/2}$ (theorem 19.4), and the whole sampled kernel converges to the parent in cut distance ((19.2)). Inward, coarse-graining: every graphon, however intricate, sits within cut distance ε of a step graphon whose number of steps depends on ε alone (theorem 19.8), so that replacing a continuum by a bounded-complexity surrogate is rigorous and the count of macroscopically meaningful parameters is finite and explicit. And the two directions close on each other in a single identity: the law of the sampled graphs, the full list of motif densities, and cut distance zero are one and the same equivalence (theorem 19.11), so a graphon is recoverable from data precisely up to the relabelling the cut metric was built to quotient out — no finer, because that ambiguity is real, and no coarser, because everything else is identifiable. The bridge does not merely connect the continuum to finite data; it certifies that the connection loses nothing the theory was ever entitled to keep.

Set the ledger of what density buys against what it forbids, and keep the two columns honest. On the credit side, *within its regime* — graphs with $\Theta(N^2)$ edges — the four pillars plus the bridge are a single coherent calculus, and a remarkably complete one: limits of network sequences exist (compactness), are unique up to the one unavoidable relabelling ambiguity (identifiability), are observable through a canonical countable list of moments (motif densities), are decomposable along a spectrum (the operator), and are estimable from a single large sample at a known rate (the sampling lemmas). One does not often get a theory in which existence, uniqueness, observability, and statistical recoverability are all settled and all compatible; the dense graphon is such a theory. On the debit side stands a limitation we did not apologise for but *proved*, and proved twice over. Every subquadratic graph sequence — which is to say every sparse real network — is mapped by the unrescaled cut metric to the single uninformative zero graphon, collapsing all of them onto one structureless point (proposition 19.13); and the generative recipe runs the same blindness in reverse, forcing every vertex of $G(N, W)$ to a degree of order $\Theta(N)$ no matter how the kernel is chosen (proposition 19.14). These are not two failures but one, seen from the two ends of the bridge: the dense theory cannot see sparsity going in and cannot produce sparsity coming out, because boundedness of the kernel is the same hypothesis on both sides. The boundary of Part III is therefore the boundary of density itself — not an edge where the theorems grow weak, but the exact locus where the standing hypothesis that made all of them true runs out. It is a clean boundary, and a clean boundary is worth far more than a blurred one: it tells the next part of the book precisely where to build.

And that is the hand-off. Two doors open from here, and they open in opposite directions. Through the first, Part IV takes the dense operator $\mathbb{W}$ developed in this part — now equipped with its spectrum, its sampling theory, and its identifiability — and builds mean-field *games* on top of it: the analytic world we have made closed and complete becomes the arena in which strategic agents, coupled through $W(x, y)$, solve for equilibrium, and every faculty assembled here is consumed there as infrastructure. Through the second, chapter 27 reopens the analytic foundations themselves, replacing the bounded kernel by the unbounded L^p graphons and graphex objects that can finally represent the sparse, heavy-tailed networks the dense theory is structurally blind to — rebuilding, in a wider category, the very pillars we have just inventoried. The two doors are not in tension: the dense graphon is the right object to have understood first because it is where the moves are cleanest, and one carries the moves through both doors. That is the closing thesis of Part III, and it is an honest one. The dense graphon is not the final object of this book; it is the cleanest one, and the cleanest object is exactly the right place to have learned the moves.

Rigor ledger

Proved.

- The W-random graph $G(N, W)$, its weighted and step-graphon companions (definition 19.1).
- Motif concentration at the Monte-Carlo rate: unbiasedness up to $O(1/N)$ and the bounded-differences tail bound, hence a.s. convergence $t(F, G(N, W)) \to t(F, W)$ (theorem 19.4), with McDiarmid's inequality (lemma 19.3) reduced to Azuma.
- The weak regularity lemma: every graphon is within cut norm ε of a step graphon with at most $4^{\lceil 1/\varepsilon^2 \rceil}$ steps, via the energy-increment argument (theorem 19.8 and corollary 19.9).
- Subquadratic graph sequences converge to the zero graphon (proposition 19.13); the W-random model is intrinsically dense with $\Theta(N)$ degrees (proposition 19.14).

Assumed (imported).

- The cut norm/metric and the metric structure on graphons modulo weak isomorphism (definitions 17.1 and 17.6 and theorem 17.12); the counting lemma (lemma 16.17); compactness of graphon space (theorem 17.13); rank-one spectral structure (worked computation 18.19, with the spectrum computed in worked computation 2.28).
- Azuma–Hoeffding and Borel–Cantelli from probability foundations (theorems 3.27 and 3.28).
- Standing assumption (A-Reg-W) on W.

Deferred.

- The second sampling lemma (19.2) (Bernoulli sampling in cut distance), stated here with its proof deferred to theorem F.9, where it is assembled in full from the weighted sampling lemma and the in-book bounded-differences inequality; it is supplied to chapter 25 as the input to finite-network convergence (attribution [29, 99]).
- The explicit measure-preserving-map characterisation of weak isomorphism (remark 19.12, (19.5)): stated and attributed to [28, 99] but *not* certified in-book. Nothing downstream uses it; only the in-book metric statement $\delta_\square = 0$ (theorem 19.11(3)) is consumed.
- All sparse machinery — stretched cut metric, L^p graphons, graphex, sampling convergence — to chapter 27 (section 19.6).

Open.

- Mean-field game theory over sparse limits: well-posedness and finite-network approximation when $\mathbb{W}$ is an unbounded L^p kernel or a graphex (remark 19.15; chapters 27 and 31).
- Sharp constants and optimal scaling in the second sampling lemma for adaptively chosen test functions; minimax graphon estimation in the sparse regime beyond [87].

Bibliographic notes

The W-random graph and the two sampling lemmas are due to Lovász and Szegedy [100] and Borgs, Chayes, Lovász, Sós and Vesztergombi [29]; the definitive textbook treatment, including the logarithmic rate (19.2) and the diagonal corrections we absorbed into the $O(1/N)$ mean bias, is Lovász [99, Ch. 10–11]. The method of bounded differences we used for theorem 19.4 is McDiarmid's [102]; our explicit two-temperature sensitivity computation (latent types versus edge coins) follows the standard recipe but is written out for transparency. The weak regularity lemma originates with Frieze and Kannan [72] in matrix form; the Hilbert-space energy-increment proof for graphons given in theorem 19.8 is the one in [99, Ch. 9] and [100], and should be contrasted with Szemerédi's original lemma [128] and its tower-type lower bounds (see the discussion in [99]). Identifiability up to weak isomorphism (theorem 19.11) is the moment-uniqueness theorem of Borgs, Chayes and Lovász [28]; statistically, the connection between weak regularity and consistent block-model estimation is developed by Klopp, Tsybakov and Verzelen [87].

The sparsity discussion previews chapter 27. The honest diagnosis that bounded graphons force density is folklore but is made sharp by the degree computation of proposition 19.14; the rank-one heavy-tailed sparsification is the Chung–Lu expected-degree model [48]. Stretched/normalized cut metrics for sparse graphs are due to Bollobás and Riordan [25] and Borgs, Chayes, Cohn and Holden [26]; the graphex framework and its exchangeable random-measure representation are due to Caron and Fox [45] and Veitch and Roy [130], with sampling convergence developed in [26]. The mean-field game theory built on these foundations, and the careful separation of proved from conjectural that it requires, is the business of chapter 27 and the research map of chapter 31.

Part IV

The Graphon Mean Field Game Synthesis

Chapter 20

Static Graphon Games

This chapter opens Part IV, the synthesis of graph limits with mean field games, and it does so deliberately in the simplest possible setting: a *static* game, with no time, no diffusion, and no Hamilton–Jacobi machinery. Every later chapter of this part carries a forward equation coupled to a backward one across a kernel; here there is only an algebraic fixed point. The reward for this austerity is that the genuinely new object of the synthesis—a continuum of strategically interacting agents whose interaction is filtered through the graphon operator $\mathbb{W}$—appears stripped of every complication except the one that matters. The reader who understands how the operator norm $\|\mathbb{W}\|$ governs existence, uniqueness, and the relation between network centrality and equilibrium effort in this chapter will recognize exactly the same quantities, doing exactly the same work, when they reappear dressed in PDEs in chapters 22 and 24.

If the reader carries away a single object from this chapter, it should be the operator norm $\|\mathbb{W}\|$. It is one nonnegative number, computable from the kernel alone, and the entire theory organizes itself around it as around an order parameter. Existence of an equilibrium will cost nothing but the compactness of $\mathbb{W}$, and so will hold no matter how large $\|\mathbb{W}\|$ is. Uniqueness, by contrast, will turn on a single dimensionless inequality, $L_{\mathrm{br}}\ \|\mathbb{W}\| < 1$, in which the behavioral responsiveness L_{br} of an individual best response is multiplied by the structural amplification $\|\mathbb{W}\| = \lambda_1$ of the network; below the threshold the equilibrium is unique and equals a network centrality, and as the product climbs to one the equilibrium condenses onto the top eigenvector while its susceptibility diverges. Watching that one product cross one is the whole drama—and it is the same product, behavioral gain times spectral radius, that will control well-posedness when time and diffusion are switched back on in chapters 22 and 24. That coincidence is not a slogan but a statement we will be able to make precise by the end of the chapter (section 20.7): the static threshold is the literal stationary shadow of the dynamic one. This is the real reason it is worth spending an entire chapter on a game with no dynamics at all—the order parameter is already fully present, and present in closed form.

Three imports furnish everything we need, and it is worth saying at the outset what each one is *for*. The first is the network itself. From chapters 15 and 18 we take the graphon $W : [0,1]^2 \to [0,1]$ and its integral operator $\mathbb{W}$, under the standing regularity **(A-Reg-W)** that makes $\mathbb{W}$ a self-adjoint Hilbert–Schmidt operator on $L^2[0,1]$ (definition 2.23 and proposition 2.24); the spectral theorem for such operators (theorem 2.26) is what hands us the eigenvalues λ_n, and in particular the top one $\lambda_1 = \|\mathbb{W}\|$ that the whole chapter watches. Compactness of $\mathbb{W}$ does double duty here: it is the smoothing that will deliver existence, and the discreteness of the spectrum it guarantees is what makes "the threshold $L_{\mathrm{br}} \|\mathbb{W}\| = 1$" a sharp, attained edge rather than a supremum that is approached but never reached. The second import is a small toolbox of fixed-point theorems, because every equilibrium in this chapter is the fixed point of a best-response map and nothing more. From chapter 2 we take the three engines—Banach (theorem 2.36) for the contraction that gives uniqueness below threshold, Schauder (theorem 2.38) for the compactness-only existence that needs no smallness at all, and Kakutani (theorem 2.40) for the set-valued best responses that appear once strict concavity is dropped—together with the min–max characterization of eigenvalues (corollary 2.27) that we use to pin $\|\mathbb{W}\|$ to the top of the spectrum. The third import is a principle rather than an object: from chapter 11 we take the Lasry–Lions monotonicity philosophy (definition 11.1) and reuse its logic in a static, finite-dimensional-feeling guise, where it becomes the convexity of a potential and supplies a second, structural route to uniqueness that survives even when the coupling is *not* small. Finally, the carried thread we advance is Thread B, the graphon LQG model of appendix A.7: this chapter introduces its *static* incarnation and solves it in closed form on the constant, rank-one, and block kernels, so that every abstract claim is checked against a kernel on which the spectrum, the centrality, and the susceptibility can all be written down by hand.

The plan is linear, and each step is the natural next question raised by the one before it. Section 20.1, the present section, builds the static graphon game by taking a finite network game to its continuum-of-types limit, and in doing so isolates the central object: the *graphon aggregate* $z(x) = (\mathbb{W}s)(x)$, the single payoff-relevant statistic that each type feels. Once the game has been reduced to an equation in the profile s, the first thing to ask is whether it has a solution at all; sections 20.2 and 20.3 cast the equilibrium condition as a fixed point of a best-response map and answer yes, by compactness alone, signaling already that existence is the cheap part of the story. The expensive part—and the heart of the chapter—is section 20.4: a fixed point can fail to be unique once interactions are strong, and there we locate the exact dividing line, the operator norm $\|\mathbb{W}\|$ entering as the coupling strength that must lie below a threshold (assumption **(A-Coupling)**). We prove uniqueness twice, by contraction and by monotonicity, precisely in order to see the same threshold from two sides, the spectral and the variational. A unique equilibrium is worth little until we can say what it *is*; section 20.5 identifies it as a recognizable network centrality, turning the abstract fixed point into a concrete ranking of players—equilibrium effort is Katz–Bonacich centrality, near criticality it aligns with eigenvector centrality, and targeted interventions are ranked by centrality. Section 20.6 then earns all of this on the carried Thread B model, computing the spectrum, the centrality, and the divergent susceptibility in closed form on the constant, rank-one, and block kernels. Finally section 20.7 closes the loop with the rest of Part IV by explaining in what precise sense this entire static theory is the stationary shadow of the dynamic graphon mean field game of chapters 21, 22 and 24—the payoff for having watched $\|\mathbb{W}\|$ the whole way.

Notation watch

Two symbol clashes are resolved once here, and both are genuine: each letter has an established, non-negotiable meaning on *both* sides, so we cannot simply rename one away without breaking continuity either with a neighboring chapter or with the standard network-games literature.

(i) In this chapter s denotes a *strategy profile*, the function $x \mapsto s(x)$ recording the action chosen by each type; this matches the coverage of static network games and the aggregate $z(x) = \int_0^1 W(x,y)\, s(y)\, \mathrm{d}y$. In the carried Thread B of appendix A.7 the same letter s is a fixed scalar *coupling strength*, the weight pulling each agent toward its neighbors. The clash would bite in exactly one place—the Thread B worked computation of section 20.6, where both meanings are in play at once—and we defuse it there by writing the strategic variable as the stationary per-type mean $\bar{m}(x)$, which both frees s for its thread meaning and agrees with the canonical Thread B symbol; everywhere else the two never appear in the same formula. *(ii)* No Brownian motion appears in this static chapter, so W is unambiguously the graphon and we may use it without comment. This is a reprieve, not a resolution: the W versus B convention of appendix A.5 becomes relevant the moment noise returns, from chapter 21 onward, where Brownian motion is written B precisely so that W can keep meaning the kernel.

20.1 From a network game to a continuum of types

Before we can study the protagonist of the chapter we have to construct it, and the construction is the whole business of this section: we manufacture the static graphon game—a game played by a continuum of types, each feeling the rest of the population only through the aggregate $z(x) = (\mathbb{W}s)(x)$—out of a finite, finger-on-the-blackboard network game that needs no new ideas to write down. We do this in three deliberate moves, and it is worth knowing in advance why each one is there. First (section 20.1.1) we set up the *finite network game*: N players sitting at the nodes of a graph, each best-responding to the average action of its neighbors. This is the concrete, combinatorial object whose equilibria we ultimately care about, and it is where the one structural feature that survives everything to follow—that a player's payoff sees the rest of the population *only* through a neighbor aggregate, never through the unstructured full profile—first shows itself. Second (section 20.1.2) we pass to the *continuum of types*, letting $N \to \infty$ along a convergent dense sequence and watching the adjacency matrix dissolve into a kernel and the neighbor average dissolve into the graphon operator $\mathbb{W}$; this is the move that trades a combinatorial object growing without bound for a single fixed analytic one, and it is what turns the large-N behavior into something we can compute rather than merely simulate. Third (section 20.1.3) we pin down the *linear–quadratic benchmark*, the one payoff for which the best response is affine and equilibrium collapses to a linear operator equation; we need it because it is the model on which every later spectral statement—the uniqueness threshold, centrality, the divergent susceptibility—can be proved in a single line, and because it is the static face of the carried Thread B.

These three moves all serve one question, which the finite game is about to pose sharply. The defining nuisance of a network game is heterogeneity: a player buried in a dense core feels a large neighbor aggregate, a player out on the periphery feels a small one, and so the equilibrium is not one number repeated across players—as in the anonymous mean field game of Part II—but a profile indexed by network position. The reason to go to the continuum is emphatically *not* to wash this heterogeneity out; it must survive the limit, or the limit is worthless. The point is to carry it through intact while replacing the unwieldy $N \times N$ adjacency matrix, which grows without bound, by an object that does not. So the question the next subsection sets up sharply—and the one after it answers—is precisely this: how does core-versus-periphery heterogeneity persist as $N \to \infty$, and what single analytic object inherits the role that the adjacency matrix A played in the finite game?

20.1.1 The finite network game

We begin where every network model honestly begins: with a finite, combinatorial object one could in principle draw on a blackboard. The continuum game that is the protagonist of this chapter is not postulated out of thin air; it is the large-N shadow of a perfectly ordinary game played by finitely many people sitting at the nodes of a graph. Building that finite game first, and watching exactly which of its features are essential and which are accidents of finiteness, is what will tell us what the continuum limit must preserve. The single feature we will track above all others is the one the previous section flagged: *heterogeneity*, the fact that different players occupy structurally different positions and therefore feel different things. The finite game is where that heterogeneity is born, and the entire graphon apparatus exists to carry it intact across the limit.

Fix a finite simple graph on N nodes with symmetric adjacency matrix $A = (A_{ij}) \in \{0,1\}^{N\times N}$. Each node i is a player who chooses an action $s_i \in S \subseteq \mathbb{R}$, where S is the player's action set (an effort level, an investment, an opinion, a contribution to a public good). The defining feature of a *network game* is that player i's payoff depends on its own action and on the *aggregate of its neighbors' actions*,

$$z_i \;=\; \frac{1}{N}\sum_{j=1}^{N} A_{ij}\, s_j, \tag{20.1}$$

rather than on the full profile $(s_1,\ldots,s_N)$ in an unstructured way. Player i's payoff is

$$\pi_i(s_i, z_i) \qquad \text{with each } \pi_i :\; S\times\mathbb{R}\to\mathbb{R} \text{ continuous}, \tag{20.2}$$

depending on the profile of other players *only* through the scalar aggregate z_i. A game of this form is called an *aggregative* (network) game.

Why the $1/N$. The normalization in eq. (20.1) is not cosmetic, and it is worth being explicit about why the factor is $1/N$ rather than, say, 1 or $1/\deg(i)$. We are interested in dense graphs—graphs in which a typical node has on the order of N neighbors, a positive fraction of the population—because those are the graphs that have nontrivial graphon limits (chapter 15). On such a graph the unnormalized neighbor sum $\sum_j A_{ij}s_j$ counts a number of terms that grows like N; if the actions s_j stay $O(1)$, that bare sum diverges as the network grows, and with it every payoff that depends on it—the limit would be a game in which a single agent feels an infinitely strong pull from the population, which is not a game at all. Dividing by N turns the sum into an average and keeps the aggregate $O(1)$ as $N \to \infty$, so that the strategic problem each player faces converges to a finite, sensible limit. Concretely, z_i is the action s_j averaged over the whole population with the neighbor indicators A_{ij}/N as weights; these weights sum to the neighbor *fraction* $\deg(i)/N \in [0,1]$, which stays bounded, whereas the degree $\deg(i)$ itself grows. This is precisely the *dense-graph normalization* that the graphon limit of chapter 15 requires: it is the same $1/N$ that makes the rescaled adjacency matrix converge to a kernel W taking values in $[0, 1]$ rather than blowing up, and we will see in section 20.1.2 that under it the discrete aggregate eq. (20.1) is *exactly* an integral against the pixel graphon, with no error term at all. Choosing the local normalization $1/\deg(i)$ instead would also bound the aggregate, but it would erase exactly the information we care about—degree heterogeneity—by forcing every node to feel a neighbor average on the same scale; the $1/N$ convention deliberately keeps a high-degree node feeling *more* than a low-degree one, which is the whole point of a network game.

Core versus periphery. To see what that retained heterogeneity means concretely, take the smallest example that already exhibits it. Suppose a "core" node c and a "periphery" node p, and suppose for the moment that everyone plays the same action $s_j \equiv a$, but that c is connected to a fraction $\deg(c)/N = 0.8$ of the population while p is connected to only $\deg(p)/N = 0.05$. Then the aggregates they feel are

$$z_c \;=\; \frac{1}{N}\sum_j A_{cj}\, a \;=\; \frac{\deg(c)}{N}\, a \;=\; 0.8\, a, \qquad z_p \;=\; \frac{\deg(p)}{N}\, a \;=\; 0.05\, a,$$

a sixteen-fold difference in the very quantity their payoffs respond to, produced entirely by position and not at all by any difference in their preferences π_c, π_p. Even if the two players had *identical* payoff functions, they would best-respond to different aggregates and so, generically, choose different actions. This is the structural fact that an anonymous mean field model cannot represent: there, every agent feels the same population average, so position is invisible. Here position is everything, and it is the surviving content of the network. The job of the continuum limit is to keep $z_c \neq z_p$ alive as $N \to \infty$ while disposing of the unwieldy bookkeeping of the matrix A that produced them.

Why aggregative. It is the word *aggregative*—the restriction that π_i sees the rest of the population only through the single scalar z_i, never through the full vector $(s_1, \ldots, s_N)$ in an unstructured way—that makes all of this possible, and it deserves to be recognized as a genuine modeling hypothesis rather than a convenience. A general game on N players would let π_i depend separately on each of the $N - 1$ other actions; there is then no scalar summary of "what the neighbors are doing" to pass to a limit, and the object that would have to converge as $N \to \infty$ is a function of a growing number of arguments, with no stable limiting form. Aggregativeness collapses that $(N - 1)$-dimensional dependence onto one real number per player, and crucially does so *linearly* in the neighbors' actions through the adjacency weights. That is exactly the structure a graphon can carry: the linear neighbor-averaging $s \mapsto z$ is what becomes the linear integral operator $\mathbb{W}$ in the limit, and the scalar z_i is what becomes the limiting field $z(x) = (\mathbb{W}s)(x)$. Were the interaction not aggregative, there would be no $\mathbb{W}$ to find. Aggregativeness is thus the precise structural restriction that opens the door to the entire graphon analysis to come; the linear–quadratic payoff of section 20.1.3 will be the cleanest instance of it.

Equilibrium. With the game specified, equilibrium is the usual Nash notion, but it pays to write it out per node, because its form already encodes the heterogeneity we have been tracking. A Nash equilibrium is a profile $(s_1^*, \dots, s_N^*)$ in which no player can improve by unilaterally changing its own action, the rest held fixed:

$$s_i^* \in \arg\max_{a \in S} \pi_i\Big(a, \tfrac{1}{N} \textstyle\sum_j A_{ij}\, s_j^*\Big), \qquad i = 1, \dots, N. \tag{20.3}$$

Read this slowly, one node at a time. Player i takes the aggregate $z_i^* = \frac{1}{N} \sum_j A_{ij} s_j^*$ generated by everyone else's equilibrium actions as a fixed number, and chooses its own action a to maximize its payoff against that number; the equilibrium demand is that every player's chosen action be simultaneously consistent with the aggregate it helps create. Two things about eq. (20.3) are worth fixing in mind before we take any limit. First, it is a genuine *fixed-point* condition—the profile s^* appears on both sides, inside the aggregate on the right and as the maximizer on the left—and this fixed-point character is exactly what survives to the continuum and gets solved in sections 20.2 to 20.4. Second, and this is the point of the whole section, the equilibrium is *not* a single number repeated across players. In the anonymous mean field game of Part II every agent faces the same population field and an equilibrium is one action (or one distribution) common to all; here the index i runs over *network positions*, each carrying its own aggregate z_i^*, and so s^* is an N-vector that genuinely varies from node to node—a *profile indexed by position*, in which the core node c and the periphery node p of our micro-example will sit at different entries with different values. The unknown of a network game is a labeled profile, not a scalar; remembering this is the difference between the present theory and ordinary mean field theory.

The difficulty, and the reason the next section exists, is now sharply visible. Everything that makes the equilibrium eq. (20.3) interesting—the differing aggregates, the core/periphery split, the position-indexed profile—is carried by the matrix A, and A is a combinatorial object that grows without bound: it has N^2 entries, no limiting form as a matrix, and offers no analytic handle through which to compute anything about large networks. We do not want to study a sequence of ever-larger matrices; we want a single fixed object that inherits everything A was doing and that we can do calculus with—differentiate, invert, diagonalize. The previous section promised that such an object exists. What we need, then, is a device that replaces the heterogeneous combinatorial matrix A by an analytic kernel acting on a limiting profile, while keeping the neighbor-averaging structure—and with it the heterogeneity—exactly intact. Producing that device, and showing that the discrete aggregate eq. (20.1) passes cleanly into the graphon operator $\mathbb{W}$, is the business of the next subsection.

20.1.2 Passing to the continuum of types

The previous subsection ended with a precise want: an analytic object that inherits everything the adjacency matrix A was doing in the neighbor average eq. (20.1)—it must preserve the position-dependent heterogeneity, it must act linearly on the profile, and it must be a *single fixed* object rather than a sequence of ever-larger matrices. We have in fact already built exactly such an object, in a different context and for a different purpose, and the whole business of this subsection is to recognize that it is the right tool here. The device is the pixel picture of chapter 15, which taught us to read a finite adjacency matrix not as a combinatorial array but as a function on the unit square; once a profile is read the same way, the discrete neighbor average is *literally* an integral against that function, and the limit $N \to \infty$ replaces the function by a fixed kernel and the integral by the graphon operator $\mathbb{W}$. No new mechanism is introduced; we are only changing how we look at a sum we already have.

Let us make the dictionary explicit before compressing it into the box, because each line of it is an *identification*—a choice of how to encode discrete data as a function—and not a theorem requiring proof. There are exactly three encodings and one consequence. First, the network: the pixel graphon (definition 15.2) turns the matrix A into the step function on $[0,1]^2$ that is constant on each $\frac{1}{N} \times \frac{1}{N}$ tile and equal there to the corresponding matrix entry A_{ij}. Second, the players: we slice the type interval $[0,1]$ into N equal bands $I_i = (\frac{i-1}{N}, \frac{i}{N}]$ and declare that player i *is* the band of types I_i, so that "node" and "interval of types" become two names for the same thing. Third, the profile: the N numbers (s_i) become the step function s_N taking the constant value s_i throughout the band I_i. None of these three is an approximation; each is an exact re-encoding of finite data as a piecewise-constant function. The consequence is what makes the re-encoding worth the trouble: when the neighbor sum is rewritten band by band, every factor $1/N$ in eq. (20.1) is exactly the width $|I_j| = 1/N$ of a band of types, so the average turns into an honest integral with *no* leftover normalization—which is the concrete vindication of the dense $1/N$ convention chosen in section 20.1.1. The box records this calculation.

Heuristic (non-rigorous)

Recall from chapter 15 the pixel picture (the pixel graphon of definition 15.2): the adjacency matrix A of an N-node graph is the step function $W^A(x,y) = A_{\lceil Nx \rceil, \lceil Ny \rceil}$ on $[0,1]^2$, and a convergent dense sequence $A^{(N)}$ has a limit graphon $W : [0,1]^2 \to [0,1]$. Identify player i with the type interval $I_i = (\frac{i-1}{N}, \frac{i}{N}]$ and let the discrete strategy profile (s_i) become the step function $s_N(x) = s_{\lceil Nx \rceil}$. For $x \in I_i$ the integrand $y \mapsto W^A(x,y)\, s_N(y)$ is constant on each band $y \in I_j$, equal there to $A_{ij}s_j$, and that band has width $1/N$; summing the bands shows the finite aggregate eq. (20.1) is, exactly and with no error term,

$$z_i \;=\; \frac{1}{N}\sum_{j=1}^{N} A_{ij}s_j \;=\; \sum_{j=1}^{N} |I_j|\; A_{ij}s_j \;=\; \int_0^1 W^A(x,y)\, s_N(y)\; \mathrm{d}y \;=\; (\mathbb{W}^A s_N)(x) \quad \text{for } x \in I_i.$$

As $N \to \infty$ with $A^{(N)} \to W$ and $s_N \to s$, this is the integral $\int_0^1 W(x,y)s(y)\; \mathrm{d}y = (\mathbb{W}s)(x)$. The discrete neighbor average converges to the action of the graphon operator on the limiting strategy profile. The limit object is a game played by a *continuum* of players, one for each type $x \in [0,1]$, in which the payoff-relevant statistic felt by type x is the graphon aggregate $(\mathbb{W}s)(x)$.

It is worth separating cleanly what this box settles from what it merely asserts, because the two have very different status. What it *settles*, exactly and at every finite N, is the chain of equalities ending in $(\mathbb{W}^A s_N)(x)$: the neighbor average of a finite graph game *is* the graphon operator of the pixel graphon applied to the step-function profile, with no limit taken and no approximation made. That is pure bookkeeping. What it *asserts but does not prove* is the final sentence's passage $N \to \infty$: that the pixel operators $\mathbb{W}^{A^{(N)}}$ converge to a limiting $\mathbb{W}$ and the step profiles s_N to a limiting s in a topology strong enough to carry the integral through. That convergence is a genuine theorem with genuine hypotheses—it is where the cut metric of chapter 15 and the sampling theory of chapter 19 do their work—and we are deliberately *not* proving it here. The full statement, that graphon Nash equilibria of the finite games converge to graphon Nash equilibria of the limit, is the convergence theorem of chapter 25.

So rather than derive the continuum game, we take it as the primitive and study it on its own terms. This is the same methodological choice that organized Part II, and it is worth recalling why it was the right one there. The mean field game was posited and analyzed directly—its existence, uniqueness, and structure all established as statements about the limit problem itself—and only later, in chapter 13, did we circle back to justify it as the $N \to \infty$ shadow of the genuine N-player game. The justification is real and it matters, but it is a separate and harder question, and welding it onto the definition would bury exactly the clean algebraic structure we came here to expose. We therefore declare the continuum game by fiat, state its equilibrium notion, and spend the chapter solving it; the reader who wants the bridge back to finite networks will find it built in chapter 25. With that division of labor settled, here are the two definitions the rest of the chapter rests on.

Definition 20.1 (Static graphon game)**.** A *static graphon game* is a tuple $(W,\, S,\, (\pi_x)_{x\in[0,1]})$ where:

- $W : [0,1]^2 \to [0,1]$ is a graphon satisfying **(A-Reg-W)**, with integral operator $\mathbb{W}$ on $L^2[0,1]$ as in definition 2.23;
- $S \subseteq \mathbb{R}$ is the common action set, assumed nonempty, closed, and convex (an interval, possibly all of $\mathbb{R}$);
- for each type $x \in [0,1]$, $\pi_x : S \times \mathbb{R} \to \mathbb{R}$ is the payoff of a type-x player as a function of its own action $a \in S$ and the scalar aggregate $z \in \mathbb{R}$ it feels; the map $(x, a, z) \mapsto \pi_x(a, z)$ is jointly measurable and continuous in (a, z).

A *strategy profile* is a (measurable) function $s \in L^2[0,1]$ with $s(x) \in S$ for almost every x; we write $\mathcal{S} = \{s \in L^2[0,1] :\ s(x) \in S \text{ a.e.}\}$ for the set of admissible profiles. The *graphon aggregate* felt under the profile s is

$$z(x) \;=\; (\mathbb{W}s)(x) \;=\; \int_0^1 W(x,y)\, s(y)\; \mathrm{d}y. \tag{20.4}$$

The aggregate eq. (20.4) is the chapter's protagonist, and it repays a careful look. It is a *field*: not a single population number but one real value $z(x)$ for *each* type, obtained by averaging the whole population's actions against the row $W(x,\cdot)$ of the kernel. The row is the type's personal weighting of who counts as a neighbor, so a type whose row puts large weight on high-action types feels a large aggregate, and two types with different rows feel different aggregates even under the same profile. This is the continuum incarnation of the core-versus-periphery split of section 20.1.1: the heterogeneity that the matrix A carried has not been washed out by the limit, it has been absorbed into the type-dependence of the row, exactly as intended.

The map $s \mapsto z = \mathbb{W}s$ is linear—this is the residue of aggregativeness—and it has one further property that will quietly run the existence theory: $\mathbb{W}$ is compact (proposition 2.24), hence *smoothing*. The word deserves to be unpacked, because it is the engine of section 20.3. Diagonalize $\mathbb{W}$ in its eigenbasis (chapter 18); a profile $s = \sum_n c_n\phi_n$ is mapped to $\mathbb{W}s = \sum_n \lambda_n c_n\phi_n$, and since the eigenvalues $\lambda_n \to 0$, the high-index components—the rapidly oscillating, large-n modes in which neighboring types *disagree*—are multiplied by vanishingly small factors and suppressed in z. Averaging against a kernel row cannot manufacture fine structure that the row itself does not resolve, so disagreement at fine scales is damped: $\mathbb{W}$ takes a possibly wild profile s and returns a tamer field z. Concretely, this means that as s ranges over a merely bounded set of profiles, the images $\mathbb{W}s$ do not range over a merely bounded set but over a *precompact* one—bounded sets are compressed toward a finite-dimensional core by the decay of the λ_n. That precompactness is precisely the hypothesis a fixed-point theorem needs to locate an equilibrium without any smallness assumption on the coupling: in section 20.3 we will feed the precompact image of $\mathbb{W}$ into Schauder's theorem and get existence for free, no matter how large $\|\mathbb{W}\|$ is. The compactness of $\mathbb{W}$ is thus not a technical footnote but the structural reason equilibria exist; we flag it here so that when it is cashed in two sections later the move looks inevitable rather than clever.

Definition 20.2 (Graphon Nash equilibrium)**.** A strategy profile $s^* \in \mathcal{S}$ is a *graphon Nash equilibrium* (GNE) of the static graphon game if for almost every type $x \in [0,1]$,

$$s^*(x) \;\in\; \operatorname*{arg\,max}_{a\in S}\; \pi_x\big(a,\, (\mathbb{W}s^*)(x)\big). \tag{20.5}$$

That is, each type's action is a best response to the aggregate generated by the whole profile, and the profile is consistent with itself.

Condition eq. (20.5) looks like a pointwise optimization, but it is a fixed point in disguise, and seeing it as one is what unlocks the rest of the chapter. Read the loop it describes: a profile s^* generates, through $\mathbb{W}$, an aggregate field $z^* = \mathbb{W}s^*$; each type then best-responds to the value of that field at its own location; and the equilibrium demand is that the profile of those best responses be the profile s^* we started from. The unknown appears on both sides—inside the aggregate on the right, as the maximizer on the left—so s^* is required to reproduce itself after one pass through the loop "aggregate, then best-respond." This is exactly the self-consistency that defines a fixed point, and section 20.2 will make it literal by packaging the loop as a single map S whose fixed points are the GNE; from that point on, existence, uniqueness, and the spectral threshold are all questions about one operator.

The closure is the same one the reader met in the mean field game of chapter 8—each agent optimizes against a population field, and the field is itself the aggregate of the optimizers' choices—so a GNE is the static, graphon-filtered cousin of an MFG equilibrium. Two differences are worth naming, because they are precisely the features this chapter adds and subtracts. It *subtracts* time: there is no forward density evolving and no backward value function, only a single algebraic consistency condition, which is what makes everything provable in closed form. And it *adds* network structure through the kernel: the field a type feels is the *graphon-filtered* aggregate $(\mathbb{W}s)(x)$, one number per type, rather than the single population mean common to everyone in an anonymous model. That this is a genuine generalization, and not just heavier notation, is visible in one limit. Set $W \equiv 1$, the constant kernel in which every type is everyone's neighbor with equal weight; then the row $W(x,\cdot) \equiv 1$ does not depend on x, the aggregate collapses to the type-independent scalar mean $(\mathbb{W}s)(x) = \int_0^1 s(y)\,\mathrm{d}y$, and eq. (20.5) becomes an anonymous aggregative game in which every player faces the identical population average—the mean field model of Part II, recovered exactly. The graphon is the device that breaks this anonymity: any non-constant kernel makes the row, and hence the aggregate, depend on the type, so that position once again matters. Everything genuinely new in the chapter lives in that departure from $W \equiv 1$.

These two definitions are deliberately payoff-agnostic: π_x is any jointly measurable, concave-in-action payoff, and the GNE condition eq. (20.5) is stated for all of them at once. That generality is what the existence and uniqueness theorems will need, but it is also more than we can compute with. The next subsection therefore specializes the whole apparatus to the one payoff—linear marginal return, quadratic own cost—for which the best response is affine and the fixed-point condition eq. (20.5) collapses to a single linear operator equation in s^*. That linear–quadratic benchmark is where the abstract field $(\mathbb{W}s)(x)$ becomes something we can diagonalize, and it is the static face of the carried graphon LQG thread; it is what we turn to now.

20.1.3 The linear–quadratic benchmark

The definitions of the previous subsection were deliberately payoff-agnostic: π_x was allowed to be any jointly measurable, strictly concave-in-action payoff, and the equilibrium condition eq. (20.5) was written for all of them at once. That breadth is exactly what the existence and uniqueness theorems of sections 20.3 and 20.4 will need, and we will keep it. But breadth is the enemy of explicit computation, and the previous subsection closed by promising to cash some of it in. The point of the chapter is not merely to assert that the operator norm $\|\mathbb{W}\|$ governs the equilibrium; it is to make the reader *watch* it do so, in closed form. For that we need a payoff on which the best response is not just well defined but writable down, so that the self-consistency loop "aggregate, then best-respond" of definition 20.2 collapses from an abstract fixed point into an equation we can diagonalize. There is one canonical choice with this property, and most of the chapter is carried by it: the *linear–quadratic* (LQ) network game, in which the cost of one's own action is quadratic and the coupling to the neighbor aggregate is linear. Its virtue is that the best response comes out *affine*, and an affine best response turns the equilibrium condition into a single linear operator equation—which is precisely a spectral question about $\mathbb{W}$, and hence, $\mathbb{W}$ being the graphon operator, a question about network structure.

This is also the moment the carried thread re-enters, in its simplest possible dress. The LQ network game is the *static cousin* of the linear–quadratic–Gaussian (LQG) graphon thread that runs through the book (appendix A.7): strip that dynamic model of its time horizon, its state dynamics, and its Gaussian noise, keeping only the quadratic own-cost and the linear coupling through the kernel, and what is left is exactly the payoff below. It is at the same time the graphon lift of the canonical finite static network game of Parise and Ozdaglar [108], whose linear–quadratic model on a finite graph is the N-player object that section 20.1.2 has just taught us to read in the continuum. Everything we establish on this benchmark therefore sits between two relatives we can name: a finite-network ancestor on one side and, on the other, a dynamic descendant in chapters 22 and 24 of which—by the time we reach section 20.7—this static problem will turn out to be the literal stationary shadow.

Example 20.3 (Linear–quadratic graphon game)**.** Take the payoff

$$\pi_x(a,z) \;=\; -\tfrac{1}{2}\,a^2 \;+\; a\,(\alpha(x) + \mathsf{b}\,z), \tag{20.6}$$

with a measurable, bounded *standalone marginal return* $\alpha \in L^\infty[0,1]$ and a scalar *interaction coefficient* $\mathsf{b} \in \mathbb{R}$. Differentiating in the own action gives the marginal payoff and the curvature

$$\partial_a \pi_x(a,z) \;=\; -a + \alpha(x) + \mathsf{b}\,z, \qquad \partial_{aa}\pi_x(a,z) \;\equiv\; -1 \;<\; 0,$$

so $\pi_x(\cdot, z)$ is strictly concave and possesses a unique unconstrained maximizer over $a \in \mathbb{R}$, found by setting the marginal to zero:

$$a \;=\; \alpha(x) + \mathsf{b}\,z. \tag{20.7}$$

With $S = \mathbb{R}$ the best response is therefore the affine map $z \mapsto \alpha(x) + \mathsf{b}z$, and a GNE solves the *linear graphon equation*

$$s^*(x) \;=\; \alpha(x) \;+\; \mathsf{b}\,(\mathbb{W}s^*)(x), \qquad \text{i.e.} \qquad (I - \mathsf{b}\mathbb{W})\,s^* = \alpha. \tag{20.8}$$

With S a bounded interval $[\underline{s}, \bar{s}]$ the best response is the same expression clipped to S; we return to the clipped case in section 20.3.

It is worth reading the payoff eq. (20.6) one term at a time, because every structural feature the chapter exploits is already legible in it. The first term $-\frac{1}{2}a^2$ is a strictly convex *cost of own effort*: doing more is increasingly expensive, and its curvature $\partial_{aa}\pi_x \equiv -1$ is normalized to -1 once and for all, which simply fixes the scale on which we measure actions (any other constant curvature could be absorbed by rescaling a, α, and b). This strict concavity is not cosmetic: it is exactly the hypothesis that makes the maximizer eq. (20.7) *unique*, so that the best response is a genuine single-valued function rather than a set—the property that section 20.2 will isolate as the thing the whole fixed-point apparatus rests on. The second term, $a\,\alpha(x)$, is the private incentive to act, and the third, the cross term $\mathsf{b}\,az$, is the entire strategic content of the game: it is the only place where a player's payoff feels its neighbors at all, and it does so by tying the value of one's own action to the aggregate z those neighbors generate.

The sign of b decides the character of the interaction, and the two cases are worth naming with their behavioral readings because they recur throughout the chapter. When $\mathsf{b} > 0$, the cross term rewards aligning one's action with the neighbor aggregate—the marginal return $\partial_a\pi_x = -a+\alpha(x)+\mathsf{b}z$ rises with z, so a larger neighbor aggregate makes a player want to do *more*. Actions are then *strategic complements*: effort begets effort. This is the regime of R&D spillovers, of studying harder when one's classmates study harder, of adopting a technology once one's contacts have—the cases in which the network *amplifies* behavior, and, as we will see, the only regime in which the coupling can drive the equilibrium toward a spectral threshold. When $\mathsf{b} < 0$, the marginal return falls with z, so a player wants to do *less* when its neighbors do more. Actions are then *strategic substitutes*: this is the regime of local public goods and of free-riding, where one neighbor's contribution relieves the others of the need to contribute. The two signs will behave very differently at the uniqueness threshold of section 20.4, and the distinction is already encoded, with no further structure, in the single number b.

The passage from the pointwise maximizer eq. (20.7) to the operator equation eq. (20.8) is a single substitution, but it is the substitution on which the entire chapter turns, so we expand it. In equilibrium, each type x does not respond to an arbitrary aggregate but to the one it actually feels under the prevailing profile, which by eq. (20.4) is $z = (\mathbb{W}s^*)(x)$. Substituting this value of z into the maximizer eq. (20.7) yields, for almost every x,

$$s^*(x) \;=\; \alpha(x) \;+\; \mathsf{b}\,(\mathbb{W}s^*)(x).$$

Now collect the unknown on one side: subtracting $\mathsf{b}\,(\mathbb{W}s^*)(x)$ from both sides gives $s^*(x) - \mathsf{b}\,(\mathbb{W}s^*)(x) = \alpha(x)$. The left-hand side is precisely the value at x of the function $(I - \mathsf{b}\mathbb{W})s^*$, where I is the identity on $L^2[0,1]$ and $\mathsf{b}\mathbb{W}$ is the graphon operator scaled by b; since the identity holds for almost every x, it is an equality of functions, $(I - \mathsf{b}\mathbb{W})s^* = \alpha$, which is exactly eq. (20.8). The meaning of this rearrangement is the conceptual payoff of the LQ specialization: the equilibrium is no longer the output of a fixed-point *search*, with the unknown buried inside a maximization on the right, but the solution of a *linear inversion*,

$$s^* \;=\; (I - \mathsf{b}\mathbb{W})^{-1}\alpha \qquad \text{whenever the operator } (I - \mathsf{b}\mathbb{W}) \text{ is invertible.}$$

The operator $I - \mathsf{b}\mathbb{W}$ encodes the strategic feedback loop in one object: the identity is a player's own response to its private incentive, and $-\mathsf{b}\mathbb{W}$ is the correction induced by the fact that the neighbors are responding too, and to each other, all at once. Inverting it resolves that infinite regress of mutual best responses in closed form.

This is also the place to say what *standalone marginal return* means and why α earns the name, since it is the data the inversion acts on. Set $z = 0$ in eq. (20.7)—imagine a type momentarily cut off from the network, or equivalently with all its neighbors silent. The maximizer is then $a = \alpha(x)$, so $\alpha(x)$ is the action a type-x player would choose *in isolation*, driven purely by its own incentive with no strategic feedback. Equivalently, $\alpha(x) = \partial_a \pi_x(0,0)$ is the marginal return to the very first unit of action when a player stands alone: it is the intrinsic, network-free pull toward acting, the part of the incentive that owes nothing to who one's neighbors are. The full equilibrium effort eq. (20.8) is then read as this standalone return propagated and amplified through the network: $s^* = (I - \mathsf{b}\mathbb{W})^{-1}\alpha$ takes the bare per-type incentive α and dresses it with every order of neighbor feedback,

$$s^* \;=\; \alpha \;+\; \mathsf{b}\,\mathbb{W}\alpha \;+\; \mathsf{b}^2\,\mathbb{W}^2\alpha \;+\; \cdots$$

whenever the series converges—a Neumann expansion whose convergence is, once again, a question about $\mathbb{W}$, and which we will recognize in section 20.5 as Katz–Bonacich centrality.

The single equation eq. (20.8) thus already contains the whole story, and the remainder of the chapter is little more than its careful reading. Whether $(I - \mathsf{b}\mathbb{W})$ is invertible at all decides whether an equilibrium exists and is unique; the size of its inverse—how strongly $\|(I - \mathsf{b}\mathbb{W})^{-1}\|$ blows up—measures how violently the equilibrium responds to the incentives α, the susceptibility that will diverge at the threshold; and the way its inverse *acts* on α, mode by mode in the eigenbasis of $\mathbb{W}$, is what identifies the equilibrium profile with a recognizable network centrality. All three are spectral questions about $\mathsf{b}\mathbb{W}$, and since $\mathbb{W}$ is the graphon operator, all three are statements about *network structure*: the eigenvalue $\lambda_1 = \|\mathbb{W}\|$ that the chapter watches is exactly the quantity that controls when $1 - \mathsf{b}\lambda_1$ first hits zero and the inverse ceases to exist.

What this section bought through the affine best response, however, it bought on the strength of the LQ form alone, and we should not let the cleanest results of the theory rest on that piece of luck. Existence and uniqueness ought to follow from the *structure* of best responding to a graphon-filtered aggregate—from concavity and from the strength of the coupling—not from the accident that the maximizer happened to be linear in z. The next section therefore steps back from example 20.3 to a general concave payoff and makes the fixed-point picture precise once and for all: it packages the loop “aggregate, then best-respond” into a single map whose fixed points are the GNE, and it isolates the two properties of the scalar best response—that it is a well-defined function of the aggregate, and that it is Lipschitz with a definite constant—on which every existence and uniqueness argument actually turns. The affine LQ map of this section will reappear there as the special case whose Lipschitz constant is exactly $|\mathsf{b}|$, so that the dimensionless product $L_{\mathrm{br}}\ \|\mathbb{W}\|$ that governs the general theory specializes here to $|\mathsf{b}|\ \|\mathbb{W}\|$—the same $\mathsf{b}\mathbb{W}$ whose spectrum we have just learned to watch.

20.2 Best response and the equilibrium operator

The linear–quadratic benchmark closed by warning us not to let the cleanest results of the theory rest on a piece of luck. There the best response came out *affine*—the maximizer eq. (20.7) was literally $\alpha(x) + \mathsf{b}z$—and that affineness was exactly what collapsed the equilibrium condition into the single linear operator equation eq. (20.8), which we could then invert and diagonalize. But affineness is special to the quadratic own-cost; a general concave payoff has a best response that bends, and there is no operator equation to invert. If existence and uniqueness are to follow from the *structure* of the problem—from concavity and from the strength of the coupling—rather than from the LQ accident, we must do two things. First, package the self-consistency loop “aggregate, then best-respond” of definition 20.2 into a single map on profiles, so that a GNE is literally a fixed point of one operator. Second, identify the smallest set of properties of that operator on which the fixed-point theorems actually turn, and verify those properties from hypotheses on the payoff that are mild enough to cover every game we care about. That is the entire business of this section.

The payoff of doing this carefully is a clean separation of labor that runs through the rest of the chapter. We will find that the loop factors into two stages—a *linear* aggregation through $\mathbb{W}$, which we already understand completely, followed by a *pointwise, nonlinear* best response—and that everything the later theorems ask of the loop reduces to exactly two facts about the second stage: that it is Lipschitz in the aggregate, with a constant we can name, and that it is measurable in the type. The first fact will power the contraction that gives uniqueness; the second will guarantee that the loop is a genuine self-map of the profile space, so that there is something for a fixed-point theorem to act on. We begin by naming the loop.

Definition 20.4 (Best-response map)**.** For a static graphon game with strictly concave payoffs, the *type-x best response* to an aggregate value $z \in \mathbb{R}$ is the unique maximizer

$$\mathrm{br}_x(z) \;=\; \arg\max_{a\in S}\ \pi_x(a,z) \;\in\; S. \tag{20.9}$$

The *best-response map* $\mathsf{S} : \mathcal{S} \to \mathcal{S}$ acts on profiles by composing the aggregate with the pointwise best response,

$$\mathsf{S}(s)(x) \;=\; \mathrm{br}_x\big((\mathbb{W}s)(x)\big). \tag{20.10}$$

A profile s^* is a GNE if and only if it is a fixed point, $\mathsf{S}(s^*) = s^*$.

The decomposition implicit in eq. (20.10) is worth making explicit, because it is the organizing fact of the whole chapter. Read the formula right to left. A profile s is first sent to its aggregate field $\mathbb{W}s$—the linear, smoothing, completely understood step built in section 20.1—and only then is each type's scalar best response br_x applied to the value of that field at x. The second step is a *pointwise* operation: it acts on the field $x \mapsto (\mathbb{W}s)(x)$ one type at a time, with no coupling between types beyond whatever $\mathbb{W}$ has already supplied. An operation of this form—apply a x-dependent scalar function to the value of a function at each point—is a *Nemytskii* (or superposition) operator. Writing $N(v)(x) = \mathrm{br}_x(v(x))$ for it, the best-response map is the composition

$$\mathsf{S} \;=\; N \circ \mathbb{W}, \tag{20.11}$$

network amplification followed by individual response. This factorization is precisely why the network and the behavior can be analyzed separately, and it dictates the rest of the section: every property of S that the existence and uniqueness theorems require will be assembled from a property of the linear factor $\mathbb{W}$—which we already own, it is compact with norm $\|\mathbb{W}\| = \lambda_1$—and a property of the nonlinear factor N, which is in turn inherited pointwise from the scalar best responses br_x. The remaining burden of the section is therefore to establish two properties of the scalar map $z \mapsto \mathrm{br}_x(z)$: that it is Lipschitz in z, uniformly in x, with a constant we can write down; and that it is measurable enough in x that N carries admissible profiles to admissible profiles. Both hold automatically for the LQ payoff, where br_x is affine-then-clipped and nothing is in doubt; we now isolate the hypotheses on a *general* payoff that secure them.

Assumption 20.5 (Smooth strongly concave payoffs)**.** There are constants $0 < \theta \le \Theta < \infty$ and $\ell \ge 0$ such that for every type x the payoff $\pi_x(\cdot, z)$ is twice continuously differentiable on the interior of S with

$$-\Theta \;\le\; \partial_{aa}\pi_x(a,z) \;\le\; -\theta, \qquad \big|\partial_{az}\pi_x(a,z)\big| \;\le\; \ell,$$

uniformly in (a,z) and in x.

Each of the three constants controls a different feature of the best response, and it pays to say in words what each one buys and what would break without it, because the proof of lemma 20.6 below uses all three in distinct roles.

The lower bound $\theta > 0$ on own-action concavity is the load-bearing hypothesis. It says the payoff is *strongly* concave in the own action—curving down at a rate at least θ, uniformly across types and aggregates—and it does two things at once. First, strong concavity makes the maximizer in eq. (20.9) unique, so that br_x is a genuine single-valued function rather than a set-valued correspondence; this is what lets us speak of *the* best response at all. Second, and quantitatively, θ will sit in the *denominator* of the Lipschitz constant $L_{\mathrm{br}} = \ell/\theta$: it measures how firmly the own cost *anchors* the optimal action against being dragged around by the neighbors. A sharply curved payoff (large θ) pins the optimum down, so a change in the aggregate barely moves it; a nearly flat payoff (small

θ) lets the optimum slide freely. If θ were allowed to degenerate to zero—a merely concave but not *strongly* concave family—the maximizer could jump discontinuously as the aggregate varies, and the Lipschitz constant would blow up, destroying at one stroke the single-valuedness and the contraction on which the whole theory rests. This is also why the bound must be uniform in x: a single type with vanishing curvature would already wreck the uniform Lipschitz estimate that lemma 20.6 delivers.

The cross-sensitivity bound $\ell \geq 0$ on $|\partial_{az}\pi_x|$ measures the opposite effect—how strongly the marginal value of one's own action *responds* to the neighbors' aggregate z. It is the individual-level strength of the strategic coupling: $\partial_{az}\pi_x$ is exactly the rate at which raising the neighbor aggregate shifts the location of one's own optimum, so ℓ will sit in the *numerator* of L_{br}. If $\ell = 0$ the own optimum does not depend on the neighbors at all and the best response is constant in z—responsiveness zero, no game; the larger ℓ, the more violently the optimum tracks the aggregate. Were ℓ allowed to be unbounded, an arbitrarily small change in the aggregate could swing the optimal action arbitrarily far, the best response would fail to be Lipschitz in z, and there would be no finite constant to feed into the contraction—indeed the continuity of S itself would be in jeopardy.

The upper bound $\Theta < \infty$ on the curvature plays a quieter, supporting role, and it is important to be clear that it does *not* enter the rate constant L_{br} at all. Its job is regularity. Bounding $|\partial_{aa}\pi_x| \leq \Theta$ guarantees that π_x is genuinely C^2 with a *bounded* second derivative, so that the marginal payoff $a \mapsto \partial_a\pi_x(a,z)$ is itself globally Lipschitz in a (with constant Θ), not merely continuous. That finiteness is what licenses the clean mean-value step in the proof below: the intermediate curvature $\partial_{aa}\pi_x(\xi, z_1)$ that the mean value theorem produces is a *finite* number trapped in $[-\Theta, -\theta]$, never a runaway slope. Looking ahead, the same upper bound is what keeps the data of the Riccati and Hamiltonian systems of the dynamic chapters (chapters 22 and 24) uniformly regular when this payoff is differentiated through time. Without it the best response would still be Lipschitz with constant ℓ/θ—Θ buys no responsiveness—but the marginal could steepen without limit, and the smoothness we will silently rely on later would be gone.

For the linear–quadratic payoff eq. (20.6) all three constants are immediate: $\partial_{aa}\pi \equiv -1$ pins both curvature bounds to $\theta = \Theta = 1$, and $\partial_{az}\pi \equiv \mathsf{b}$ gives $\ell = |\mathsf{b}|$. The general rate $L_{\mathrm{br}} = \ell/\theta$ then specializes to exactly $|\mathsf{b}|$, recovering the interaction coefficient we already learned to watch in section 20.1.3—a first sanity check that the abstract constant is the right one. We now prove that it is, in fact, the Lipschitz constant for any payoff satisfying assumption 20.5.

Lemma 20.6 (Best response is Lipschitz with the right constant)**.** *Under assumption 20.5, each scalar best response* $\mathrm{br}_x : \mathbb{R} \to S$ *is well defined, single valued, and Lipschitz with constant*

$$L_{\mathrm{br}} := \frac{\ell}{\theta}, \tag{20.12}$$

uniformly in x*. For the LQ payoff* $L_{\mathrm{br}} = |\mathsf{b}|$.

Proof. Single-valuedness is the easy half. Because $\partial_{aa}\pi_x \leq -\theta < 0$, the map $a \mapsto \pi_x(a,z)$ is strongly concave on the closed convex set S, and a strongly concave function has at most one maximizer on a convex set; a maximizer exists because strong concavity forces $\pi_x(\cdot, z) \to -\infty$ at the ends of S

when S is unbounded, and a concave function attains its supremum on a closed interval otherwise. So $\mathrm{br}_x(z)$ is well defined. The content of the lemma is the quantitative bound, and we extract it by comparing the first-order optimality conditions *across two aggregates*.

Fix $z_1 < z_2$ and abbreviate $a_k = \mathrm{br}_x(z_k)$ for $k = 1, 2$. Each a_k maximizes $\pi_x(\cdot, z_k)$ over S, and the first-order condition for a maximizer on a closed convex set is the *variational inequality*: moving from a_k toward any other admissible point a cannot raise the payoff to first order,

$$\partial_a \pi_x(a_k, z_k)\,(a - a_k) \;\le\; 0 \qquad \text{for all } a \in S, \quad k = 1, 2. \tag{20.13}$$

(If a_k is interior to S the marginal vanishes and eq. (20.13) holds with equality; if a_k sits at an endpoint of S the marginal points outward and the inequality is strict—this is exactly the mechanism by which the estimate survives clipping to a bounded action set.) The trick is to test each instance against the *other* optimizer. Put $a = a_2$ in the $k = 1$ instance and $a = a_1$ in the $k = 2$ instance:

$$\partial_a \pi_x(a_1, z_1)\,(a_2 - a_1) \;\le\; 0, \qquad \partial_a \pi_x(a_2, z_2)\,(a_1 - a_2) \;\le\; 0.$$

The second carries $(a_1 - a_2) = -(a_2 - a_1)$, so adding the two and factoring out the common difference yields a single inequality,

$$\big(\partial_a \pi_x(a_1, z_1) - \partial_a \pi_x(a_2, z_2)\big)(a_2 - a_1) \;\le\; 0. \tag{20.14}$$

This is the discrete monotonicity of the optimality map; the whole task now is to read the curvature and the cross-sensitivity out of the marginal difference in eq. (20.14), and for that we travel from (a_1, z_1) to (a_2, z_2) *one coordinate at a time*. Add and subtract the mixed value $\partial_a \pi_x(a_2, z_1)$:

$$\partial_a \pi_x(a_1, z_1) - \partial_a \pi_x(a_2, z_2) = \underbrace{\big[\partial_a \pi_x(a_1, z_1) - \partial_a \pi_x(a_2, z_1)\big]}_{a \text{ varies, } z = z_1 \text{ fixed}} + \underbrace{\big[\partial_a \pi_x(a_2, z_1) - \partial_a \pi_x(a_2, z_2)\big]}_{z \text{ varies, } a = a_2 \text{ fixed}}.$$

Each bracket is the increment of a C^1 function in a single variable, so the mean value theorem applies to each on its own. In the first bracket only a moves, and the governing derivative is the curvature: there is an intermediate ξ between a_1 and a_2 with

$$\partial_a \pi_x(a_1, z_1) - \partial_a \pi_x(a_2, z_1) = \partial_{aa} \pi_x(\xi, z_1)\,(a_1 - a_2).$$

In the second bracket only z moves, and the governing derivative is the cross-partial: there is an intermediate ζ between z_1 and z_2 with

$$\partial_a \pi_x(a_2, z_1) - \partial_a \pi_x(a_2, z_2) = \partial_{az} \pi_x(a_2, \zeta)\,(z_1 - z_2).$$

(It is precisely the upper bound Θ of assumption 20.5 that makes these intermediate derivatives finite, and the same assumption that bounds them.) Substituting both into eq. (20.14),

$$\partial_{aa} \pi_x(\xi, z_1)\,(a_1 - a_2)(a_2 - a_1) + \partial_{az} \pi_x(a_2, \zeta)\,(z_1 - z_2)(a_2 - a_1) \;\le\; 0.$$

Now read the two terms. In the first, $(a_1 - a_2)(a_2 - a_1) = -(a_2 - a_1)^2$ and $\partial_{aa} \pi_x(\xi, z_1) \le -\theta$, so that first term is at least $\theta\,(a_2 - a_1)^2$; moving it to the right-hand side,

$$\theta\,(a_2 - a_1)^2 \;\le\; \partial_{az} \pi_x(a_2, \zeta)\,(z_2 - z_1)(a_2 - a_1) \;\le\; \ell\,|z_2 - z_1|\,|a_2 - a_1|,$$

the last step using $|\partial_{az}\pi_x| \le \ell$ and replacing the signed product by its absolute value. If $a_2 = a_1$ there is nothing to prove; otherwise divide both sides by $|a_2 - a_1| > 0$ to obtain

$$|a_2 - a_1| \;\le\; \frac{\ell}{\theta}\,|z_2 - z_1|,$$

which is exactly eq. (20.12). The constant earns its name in this final division: the cross-sensitivity ℓ in the numerator is the force tugging the optimum to follow the aggregate, while the curvature θ in the denominator is the restoring stiffness resisting that tug, so $L_{\mathrm{br}} = \ell/\theta$ is the ratio "pull over stiffness" that any constrained optimum must obey. It is the right constant because it is the only combination of the two local payoff data with the units of a sensitivity $\mathrm{d}a/\,\mathrm{d}z$, and the LQ value $L_{\mathrm{br}} = |\mathsf{b}|$ is its simplest instance. $\square$

We have the Lipschitz half of the two facts the section promised. The other half is measurability, and although it can sound like a technicality it is genuinely load-bearing. The best-response map was *defined* as a self-map of the admissible profiles, $\mathsf{S} : \mathcal{S} \to \mathcal{S}$ in definition 20.4; for that definition even to make sense the output $\mathsf{S}(s) = \mathrm{br}.\big((\mathbb{W}s)(\cdot)\big)$ must itself be a *measurable* function of x—otherwise it is not an element of $L^2[0,1]$ at all, and there is no profile space for any fixed-point theorem to act on. The danger is real precisely because we have left the LQ world: for a general payoff $\mathrm{br}_x(z)$ is defined *implicitly*, as the location of a maximum, with no formula exhibiting its dependence on x, so we cannot simply inspect it and pronounce it measurable. What we *can* do is exploit the one structural feature assumption 20.5 hands us—that the marginal payoff is strictly decreasing in a—to trade the implicit "argmax in x" for the explicit "the marginal is still positive," a condition manifestly measurable in x through the joint measurability of π. Carrying out that trade is the content of the next lemma.

Lemma 20.7 (The best response is a Carathéodory map)**.** *Under the joint measurability of* $(x, a, z) \mapsto \pi_x(a, z)$ *(definition 20.1) and assumption 20.5, the scalar best response* $(x, z) \mapsto \mathrm{br}_x(z)$ *is a* Carathéodory function*: measurable in x for each fixed z, and continuous in z for each fixed x. Consequently, for every measurable $v : [0,1] \to \mathbb{R}$ the superposition $x \mapsto \mathrm{br}_x(v(x))$ is measurable, and the Nemytskii operator $N : v \mapsto \big(x \mapsto \mathrm{br}_x(v(x))\big)$ sends measurable functions to measurable functions.*

Proof. There are three claims to discharge: continuity of $z \mapsto \mathrm{br}_x(z)$, measurability of $x \mapsto \mathrm{br}_x(z)$, and measurability of the superposition. The first is already in hand, and more: continuity in z is immediate from the Lipschitz bound eq. (20.12).

For measurability in x we show that every superlevel set of the maximizer is measurable. Fix the aggregate z and a threshold r in the interior of S. Under assumption 20.5 the marginal payoff $a \mapsto \partial_a \pi_x(a, z)$ is *strictly decreasing*, its derivative being $\partial_{aa}\pi_x \le -\theta < 0$, so the unique maximizer $\mathrm{br}_x(z)$ is located by a single sign change of the marginal: the marginal is positive to the left of the optimum and negative to its right. The optimum therefore lies strictly above r exactly when the marginal has not yet changed sign by $a = r$, i.e. is still positive there:

$$\{x :\ \mathrm{br}_x(z) > r\} \;=\; \{x :\ \partial_a \pi_x(r, z) > 0\} \tag{20.15}$$

(with the obvious modifications $\{x : \mathrm{br}_x(z) > r\} = [0,1]$ when $r < \inf S$, the threshold falling below every admissible action, and $= \emptyset$ when $r \geq \sup S$). The virtue of eq. (20.15) is that it has eliminated the implicit argmax on the left in favor of a condition on the right that involves only the *explicit* datum $\partial_a \pi_x(r,z)$, evaluated at the fixed point $a = r$. And that condition is measurable in x: for each fixed $h > 0$ the difference quotient $h^{-1}\big(\pi_x(r+h,z) - \pi_x(r,z)\big)$ is a measurable function of x by the joint measurability of $(x,a,z) \mapsto \pi_x$ assumed in definition 20.1, and $\partial_a \pi_x(r,z)$ is the pointwise limit of these as $h \downarrow 0$, hence measurable; its positivity set is therefore measurable. Since this holds for every threshold r, the function $x \mapsto \mathrm{br}_x(z)$ has measurable superlevel sets and is measurable. Combined with the continuity in z, this is exactly the Carathéodory property.

The Carathéodory property is what makes superposition safe, and we now cash it in. Let $v : [0,1] \to \mathbb{R}$ be measurable; we must show $x \mapsto \mathrm{br}_x(v(x))$ is measurable. Approximate v by simple functions $v_n = \sum_k c_{n,k}\, \mathbf{1}_{E_{n,k}}$ with $v_n \to v$ pointwise, where the $E_{n,k}$ are the disjoint measurable level sets on which v_n is constant (the standard simple-function construction). On each level set $E_{n,k}$ the argument fed to br_x is the *constant* $c_{n,k}$, so there the composed map is simply $x \mapsto \mathrm{br}_x(c_{n,k})$, which is measurable by the previous paragraph; the whole map $x \mapsto \mathrm{br}_x\big(v_n(x)\big)$ is the countable patching of these measurable pieces over the disjoint measurable sets $E_{n,k}$, hence measurable. Finally, by the continuity of $z \mapsto \mathrm{br}_x(z)$ established at the outset, $\mathrm{br}_x\big(v_n(x)\big) \to \mathrm{br}_x\big(v(x)\big)$ pointwise as $n \to \infty$, and a pointwise limit of measurable functions is measurable. Thus the superposition is measurable and N sends measurable functions to measurable functions, as claimed. $\square$

Remark 20.8 (The LQ case needs no abstract selection)**.** For the linear–quadratic benchmark example 20.3 the issue does not even arise: the best response is the explicit affine-then-clip map $\mathrm{br}_x(z) = \Pi_S\big(\alpha(x) + \mathsf{b}z\big)$, where Π_S is the metric projection onto the interval S; this is manifestly Carathéodory because α is measurable and Π_S is 1-Lipschitz. Lemma 20.7 is needed only to license the superposition operator for a *general* payoff, where the maximizer is not given in closed form; it replaces an appeal to an external measurable-maximum theorem with the elementary monotone-marginal argument available under assumption 20.5.

Step back and read what the two lemmas have jointly produced, because it is the hinge on which the next two sections turn. Lemma 20.6 says that the strategic responsiveness of an individual, measured by $L_{\mathrm{br}} = \ell/\theta$, is a fixed property of the *payoff* alone: it knows nothing about the graph, depending only on how sharply the own cost curves and how strongly the neighbor aggregate tugs at the optimum. The network enters the best-response map $\mathsf{S} = N \circ \mathbb{W}$ at exactly one place, the linear factor $\mathbb{W}$, and its entire strength is summarized by the single number $\|\mathbb{W}\| = \lambda_1$. Since S is the composition of a map of Lipschitz constant $\|\mathbb{W}\|$—the bounded linear operator $\mathbb{W}$—with a map of Lipschitz constant L_{br}—the Nemytskii operator N, whose pointwise ingredient is Lipschitz by lemma 20.6 and which inherits the same constant on L^2, since

$$\|N(v) - N(v')\|_{L^2}^2 = \int_0^1 \big|\mathrm{br}_x(v(x)) - \mathrm{br}_x(v'(x))\big|^2\, \mathrm{d}x \;\leq\; L_{\mathrm{br}}^2\, \|v - v'\|_{L^2}^2$$

by integrating the scalar bound—the composite is Lipschitz with constant the *product*,

$$\mathrm{Lip}(\mathsf{S}) \;\leq\; L_{\mathrm{br}}\, \|\mathbb{W}\|\,. \tag{20.16}$$

This single dimensionless number—behavioral gain times spectral radius—is the coupling strength of the entire theory, and the two sections that follow are precisely the two things one can do with it. When it is below one the composite contracts, and the fixed point is forced to be unique; that is section 20.4, where the product is handed over as the order parameter whose crossing of unity is the chapter's central event.

Existence, by contrast, will not even need the product to be small, and it is worth recording now exactly which facts of this section it consumes, so that the argument of section 20.3 reads as inevitable rather than clever. It needs two, both established above. First, that N is Lipschitz on $L^2[0,1]$ with constant L_{br} (the displayed integration of lemma 20.6) and is a genuine self-map of the admissible profiles (the measurability of lemma 20.7). Second, that $\mathbb{W}$ is compact, which is the standing import **(A-Reg-W)**. These combine through one elementary fact that the existence proof will use without comment, so we make it explicit here: *a Lipschitz map sends precompact sets to precompact sets.* The reason is that precompactness in a metric space is total boundedness—a set is precompact exactly when, for every $\varepsilon > 0$, it admits a finite cover by balls of radius ε—and a map N with $\|N(v) - N(v')\| \le L_{\mathrm{br}} \|v - v'\|$ turns a cover of a set A by ε-balls into a cover of the image $N(A)$ by $L_{\mathrm{br}}\varepsilon$-balls, simply by taking the images of the original centers: a point within ε of a center v_0 lands within $L_{\mathrm{br}}\varepsilon$ of $N(v_0)$. A finite ε-cover of A thus yields a finite $L_{\mathrm{br}}\varepsilon$-cover of $N(A)$, so total boundedness, and with it precompactness, is preserved. Apply this with $A = \mathbb{W}(K)$ for a bounded admissible set K: compactness of $\mathbb{W}$ sends the bounded K to a *precompact* set $\mathbb{W}(K)$, and the Lipschitz N then carries that precompact set to a precompact image $N(\mathbb{W}(K)) = \mathsf{S}(K)$. A continuous self-map with precompact image is exactly what Schauder's theorem demands—with no smallness of $L_{\mathrm{br}} \|\mathbb{W}\|$ asked anywhere—and that compactness-only existence is what we turn to next.

20.3 Existence of equilibrium

The previous section did all the work; this section spends it. Section 20.2 packaged the self-consistency loop of a graphon Nash equilibrium into a single map $\mathsf{S} = N \circ \mathbb{W}$ on the profile space $L^2[0,1]$, whose fixed points are exactly the equilibria (definition 20.4), and it handed us two facts about that map and nothing else. The first is that the nonlinear factor N, the Nemytskii operator built from the pointwise best responses, is Lipschitz on $L^2[0,1]$ with constant L_{br} (lemma 20.6) and a genuine self-map of the admissible profiles (lemma 20.7). The second is the standing import **(A-Reg-W)**: the linear factor $\mathbb{W}$ is compact. We closed that section by isolating the one elementary consequence on which everything here will turn—a Lipschitz map sends precompact sets to precompact sets—and by tracing the precompactness chain $\mathbb{W}$ compact $\Rightarrow$ $\mathbb{W}(K)$ precompact $\Rightarrow$ $N(\mathbb{W}(K))$ precompact all the way to the conclusion that S has precompact image. That is precisely the hypothesis a topological fixed-point theorem needs. So the existence proof is now a matter of assembling pieces we already own, and the assembly carries a message worth stating before we begin: *nowhere in it will the coupling be asked to be small.* Schauder's theorem cares that the image be precompact, not that the map contract, and precompactness was bought from the compactness of $\mathbb{W}$ alone—a structural property of the kernel that holds however large $\|\mathbb{W}\|$ is. The whole threshold drama of $L_{\mathrm{br}} \|\mathbb{W}\|$ crossing one, which the next section will stage, is therefore absent from existence by design. We prove existence twice, in two cases that differ only in which fixed-point engine they invoke, precisely so that the reader can see that the first case asks for no smallness whatever, and the second asks for it only to keep the action set's unboundedness from letting the equilibrium escape to infinity—not to secure the fixed point itself.

Theorem 20.9 (Existence of a graphon Nash equilibrium)**.** *Consider a static graphon game (definition 20.1) under **(A-Reg-W)** and assumption 20.5, and suppose either*

(i) the action set $S = [\underline{s}, \bar{s}]$ is a bounded interval; or

(ii) $S = \mathbb{R}$ and the standalone optimum is bounded, $\sup_x |\mathrm{br}_x(0)| < \infty$, together with the subcriticality condition $L_{\mathrm{br}}\ \|\mathbb{W}\| < 1$.

Then the game possesses at least one graphon Nash equilibrium $s^* \in \mathcal{S}$.

Proof. Case (i): bounded actions, by Schauder. The plan is the standard one for a continuous self-map with precompact image: exhibit a nonempty, convex, *compact* set carried into itself, and quote Schauder. The only subtlety—the one place the proof does more than recite definitions—is that the natural candidate set is precompact but not closed, so we must take a closed convex hull and argue it stays compact; that is where Mazur's theorem enters. We take the four ingredients in turn.

The candidate set is the order interval

$$K = \left\{ s \in L^2[0,1] : \ \underline{s} \leq s(x) \leq \bar{s} \text{ a.e.} \right\},$$

the admissible profiles for the bounded action set $S = [\underline{s}, \bar{s}]$. It is worth checking each of the four properties Schauder will eventually need, since each one uses a different feature of K. It is *nonempty*: the constant profile $s \equiv \underline{s}$ lies in it. It is *convex*: if $\underline{s} \leq s, s' \leq \bar{s}$ pointwise then $\underline{s} \leq \lambda s + (1-\lambda)s' \leq \bar{s}$ pointwise for every $\lambda \in [0,1]$, because a pointwise two-sided bound is preserved by averaging. It is *bounded*: every $s \in K$ satisfies $\|s\|_{L^2}^2 = \int_0^1 s(x)^2 \, \mathrm{d}x \leq \max(\underline{s}^2, \bar{s}^2)$, so K sits inside a ball of radius $\max(|\underline{s}|, |\bar{s}|)$. And it is *closed* in $L^2[0,1]$: if $s_n \in K$ and $s_n \to s$ in L^2, then a subsequence converges almost everywhere, and the pointwise bounds $\underline{s} \leq s_n \leq \bar{s}$ pass to the almost-everywhere limit, so $s \in K$. Thus K is a nonempty, closed, convex, bounded subset of the Hilbert space $L^2[0,1]$—but boundedness and closedness are not compactness in infinite dimensions, which is exactly why a fixed-point theorem cannot be applied to K directly and why the smoothing of $\mathbb{W}$ has work to do.

Self-map. We check $\mathsf{S}(K) \subseteq K$, so that there is an invariant set to begin with. This is immediate from the construction of S: by definition 20.4 the pointwise best response br_x is the maximizer of $\pi_x(\cdot, z)$ over $a \in S = [\underline{s}, \bar{s}]$, so it *takes values in* S by definition of an argmax over S. Hence for any s the profile $\mathsf{S}(s)(x) = \mathrm{br}_x\big((\mathbb{W}s)(x)\big)$ satisfies $\underline{s} \leq \mathsf{S}(s)(x) \leq \bar{s}$ for almost every x, i.e. $\mathsf{S}(s) \in K$. Note this used the boundedness of S and nothing else—no concavity, no smallness; clipping the response to the action interval is what keeps the loop inside K.

Precompactness of the image. This is the heart of the matter, and it is the precompactness chain assembled at the close of section 20.2, run once concretely. The operator $\mathbb{W}$ is compact—it is Hilbert–Schmidt by proposition 2.24 under **(A-Reg-W)**, and a compact operator by definition carries the bounded set K to a *precompact* set $\mathbb{W}(K) \subseteq L^2[0,1]$, one whose closure is compact. This is the link in the chain that consumes the bounded set K and produces something with finite-dimensional character: the eigenvalue decay $\lambda_n \to 0$ of section 20.1 compresses the bounded K toward a compact core. The Nemytskii operator $N : v \mapsto (x \mapsto \mathrm{br}_x(v(x)))$ is Lipschitz from $L^2[0,1]$ to $L^2[0,1]$ with constant L_{br} by lemma 20.6, since integrating the pointwise scalar Lipschitz bound gives

$$\|N(v) - N(v')\|_{L^2}^2 = \int_0^1 \left|\mathrm{br}_x(v(x)) - \mathrm{br}_x(v'(x))\right|^2 \mathrm{d}x \le L_{\mathrm{br}}^2 \int_0^1 \left|v(x) - v'(x)\right|^2 \mathrm{d}x = L_{\mathrm{br}}^2 \left\|v - v'\right\|_{L^2}^2 .$$

And a Lipschitz map sends precompact sets to precompact sets—the total-boundedness argument recorded at the end of section 20.2, that a finite ε-cover of the domain set maps to a finite $L_{\mathrm{br}}\varepsilon$-cover of the image. Applying this with the precompact set $\mathbb{W}(K)$ in the role of the domain set, the image

$$\mathsf{S}(K) = N(\mathbb{W}(K))$$

is precompact in $L^2[0,1]$. The structure to retain is that compactness was supplied entirely by the *linear* factor $\mathbb{W}$; the nonlinear factor N contributes no smoothing of its own, it merely *preserves* the precompactness that $\mathbb{W}$ created, because Lipschitz maps cannot inflate a totally bounded set into an unbounded one.

Continuity. The map $\mathsf{S} = N \circ \mathbb{W}$ is continuous on $L^2[0,1]$ as a composition of two continuous maps: $\mathbb{W}$ is a bounded linear operator, hence continuous, and N is Lipschitz by the display above, hence continuous. There is nothing more to verify; the factorization $\mathsf{S} = N \circ \mathbb{W}$ does the work.

The Mazur step and the conclusion. We now have a continuous self-map S of the nonempty closed convex set K, with *precompact* image—but Schauder's theorem (theorem 2.38) is a statement about a continuous self-map of a *compact* convex set, and K itself is not compact. The remedy is to shrink K to a compact convex set that S still maps into itself. Take

$$C := \overline{\mathrm{conv}}\, \mathsf{S}(K),$$

the closed convex hull of the image. The point that makes this work—and the reason the hull does not reintroduce the noncompactness we were trying to escape—is *Mazur's theorem*: in a Banach space (here the Hilbert space $L^2[0,1]$) the closed convex hull of a compact set is again compact. We apply it to the compact set $\overline{\mathsf{S}(K)}$ (the closure of the precompact image just shown to be precompact), whose closed convex hull is C; Mazur's theorem makes C compact, and it is convex and closed by construction. Two containments now close the argument. First, $C \subseteq K$: the image $\mathsf{S}(K)$ lies in K by the self-map property, and K is itself closed and convex, so K contains the *smallest* closed convex set containing $\mathsf{S}(K)$, which is exactly C. Second, $\mathsf{S}(C) \subseteq C$: since $C \subseteq K$ we have $\mathsf{S}(C) \subseteq \mathsf{S}(K) \subseteq \overline{\mathrm{conv}}\, \mathsf{S}(K) = C$. Thus S is a continuous map sending the nonempty, convex, *compact* set C into itself, and Schauder's fixed-point theorem (theorem 2.38) supplies a point $s^* \in C \subseteq K$ with $s^* = \mathsf{S}(s^*)$. By definition 20.4 that fixed point is a graphon Nash equilibrium. No hypothesis on the size of $L_{\mathrm{br}} \|\mathbb{W}\|$ entered anywhere.

Case (ii): unbounded actions, by an a priori bound. When $S = \mathbb{R}$ the order interval K above is all of $L^2[0,1]$, which is unbounded, so the candidate set is no longer bounded and the precompactness argument has nothing finite to chew on. The standard fix is to manufacture a bounded invariant set by hand—a ball that S cannot escape—and run the case-(i) machinery inside it. This is exactly where the subcriticality hypothesis $L_{\mathrm{br}}\,\|\mathbb{W}\| < 1$ earns its place: it is what prevents the strategic feedback from pushing the equilibrium off to infinity, and it is needed *only* for this confinement, not for the fixed point itself.

We produce the bound by estimating how far one application of S can move a profile away from the origin. Fix any profile $s \in L^2[0,1]$. At each type x, the Lipschitz bound of lemma 20.6 applied with the two aggregate values $(\mathbb{W}s)(x)$ and 0 gives

$$\big|\mathrm{br}_x\big((\mathbb{W}s)(x)\big) - \mathrm{br}_x(0)\big| \;\le\; L_{\mathrm{br}}\,\big|(\mathbb{W}s)(x)\big|.$$

Hence, pointwise, $\big|\mathsf{S}(s)(x)\big| \le \big|\mathrm{br}_x(0)\big| + L_{\mathrm{br}}\big|(\mathbb{W}s)(x)\big|$, and taking L^2 norms and using the triangle inequality together with the elementary fact that $\|\,|f|\,\|_{L^2} = \|f\|_{L^2}$,

$$\|\mathsf{S}(s)\|_{L^2} \;\le\; \|\mathrm{br}_{\cdot}(0)\|_{L^2} + L_{\mathrm{br}}\,\|\mathbb{W}s\|_{L^2} \;\le\; \|\mathrm{br}_{\cdot}(0)\|_{L^2} + L_{\mathrm{br}}\,\|\mathbb{W}\|\,\|s\|_{L^2}\,,$$

where the last step is the operator-norm inequality $\|\mathbb{W}s\|_{L^2} \le \|\mathbb{W}\|\,\|s\|_{L^2}$. Abbreviate the two constants of this estimate as

$$c_0 \;:=\; \|\mathrm{br}_{\cdot}(0)\|_{L^2} < \infty \qquad \text{and} \qquad \rho \;:=\; L_{\mathrm{br}}\,\|\mathbb{W}\| < 1,$$

where c_0 is finite precisely because of the standing hypothesis $\sup_x|\mathrm{br}_x(0)| < \infty$ on the standalone optimum (it bounds the integrand $|\mathrm{br}_x(0)|^2$ by a constant), and $\rho < 1$ is the subcriticality assumption. The estimate reads $\|\mathsf{S}(s)\|_{L^2} \le c_0 + \rho\,\|s\|_{L^2}$. Now seek a radius R for which the ball $B_R = \{s : \|s\|_{L^2} \le R\}$ is invariant: if $\|s\|_{L^2} \le R$ then $\|\mathsf{S}(s)\|_{L^2} \le c_0 + \rho R$, and this is $\le R$ exactly when $c_0 \le (1-\rho)R$, i.e. when

$$R \;\ge\; \frac{c_0}{1-\rho}.$$

Here is the one place $\rho < 1$ is indispensable: only because $1-\rho > 0$ is this threshold radius finite and positive; were $\rho \ge 1$ the affine bound $c_0 + \rho R$ would meet or exceed R for every R, and no ball would be invariant—the feedback could amplify a profile without limit on each pass. Take $R = c_0/(1-\rho)$. The ball B_R is nonempty, closed, convex, and bounded, S maps it into itself by the estimate just made, and on this bounded set the precompactness, continuity, and Mazur arguments of case (i) apply verbatim—$\mathbb{W}(B_R)$ is precompact because B_R is bounded and $\mathbb{W}$ compact, N preserves precompactness, and $\overline{\mathrm{conv}}\,\mathsf{S}(B_R)$ is a compact convex invariant subset of B_R. Schauder's theorem (theorem 2.38) again furnishes a fixed point $s^* = \mathsf{S}(s^*)$, a graphon Nash equilibrium. $\square$

Remark 20.10 (Two machines, one hypothesis in case (ii))**.** It is worth being honest that case (ii) was, in a sense, overkill, and saying precisely why illuminates the division of labor between the two fixed-point engines. Under the hypotheses of case (ii) the subcriticality $L_{\mathrm{br}}\,\|\mathbb{W}\| < 1$ is exactly the condition that makes S a *contraction*: by eq. (20.16) its Lipschitz constant is at most $L_{\mathrm{br}}\,\|\mathbb{W}\| = \rho < 1$. A contraction of a complete metric space needs no compactness at all—the Banach fixed-point theorem (theorem 2.36) already delivers a fixed point by iteration, and delivers it *unique*, which is more than Schauder ever gives. So for the unbounded case the honest minimal argument is Banach, not Schauder, and indeed that is exactly the route theorem 20.14 below will take to prove existence *and* uniqueness in one stroke. Why then run Schauder here? Purely for a uniform statement: writing the existence theorem so that both cases are concluded by the same theorem lets us assert "equilibria exist" under either hypothesis without bifurcating the proof at the level of the statement. The point of the pairing is to make visible that the two cases lean on the two engines for opposite reasons. The *genuinely* Schauder-only situation—the one that no contraction argument can reach—is the bounded-action case (i), where $S = [\underline{s}, \bar{s}]$ is compact but *no* smallness of the coupling is assumed, so S may fail to contract (indeed $L_{\mathrm{br}} \|\mathbb{W}\|$ may be enormous) and yet an equilibrium still exists because the bounded action set keeps the loop confined and compactness of $\mathbb{W}$ supplies the precompact image. That is the content worth carrying forward: *existence with arbitrarily strong coupling* is a real phenomenon, and it is bought by compactness, not by smallness.

Remark 20.11 (Set-valued best responses)**.** The whole argument leaned on strict (indeed strong) concavity at exactly one point: it made the maximizer in eq. (20.9) *unique*, so that br_x was a single-valued function and S a genuine map to which Schauder applies. Drop strong concavity—keep payoffs merely concave in the own action—and the maximizing set $\mathrm{br}_x(z) = \arg\max_{a \in S} \pi_x(a, z)$ can contain more than one point; it becomes a *correspondence*, convex- and compact-valued (the argmax of a concave function over an interval is a closed subinterval) and upper hemicontinuous in z (small perturbations of z cannot make the maximizing set jump outward). Existence survives this loss intact in case (i), at the cost of upgrading the fixed-point engine from Schauder to its set-valued generalization. One applies the Kakutani–Fan–Glicksberg theorem (theorem 2.40) to the set-valued map $s \mapsto N(\mathbb{W}s)$ on K: its values are convex because each $\mathrm{br}_x(z)$ is a convex set and convexity is preserved under the superposition and the linear aggregation, and it is upper hemicontinuous with precompact range because $\mathbb{W}$ is compact—the same precompactness chain as before, now feeding a set-valued rather than single-valued fixed-point theorem. A fixed point is then a profile s^* with $s^*(x) \in \mathrm{br}_x\big((\mathbb{W}s^*)(x)\big)$ a.e., a graphon Nash equilibrium in which ties in the best response are allowed to be broken type by type. This is the static, network-filtered analogue of the relaxed (mixed) equilibria of chapter 10: there, convexity was restored by randomizing over pure controls and Kakutani was applied in the space of measures; here, with no time and no dynamics, the convexification is the elementary one of allowing the best response to be set-valued, and the same theorem closes the loop.

The verdict of this section is a single clean separation, and it is the claim we hand to uniqueness. Existence of a graphon Nash equilibrium is *cheap and structural*: it costs only the compactness of $\mathbb{W}$—a regularity property of the kernel that holds however large the operator norm is—and the concavity of payoffs, and in the bounded-action case it asks for no constraint whatever on the strength of the interaction. The dimensionless product $L_{\mathrm{br}} \|\mathbb{W}\|$, the order parameter handed over by section 20.2, made not a single appearance in case (i) and entered case (ii) only to fence a wandering equilibrium back into a finite ball, never to secure its existence. The threshold phenomenon—the crossing of $L_{\mathrm{br}} \|\mathbb{W}\|$ through one, with everything it brings—therefore lives *entirely* in the question of *uniqueness*, which is what we turn to next: with existence settled for free, the operator norm reappears not as a cost of having an equilibrium but as the exact dividing line between having exactly one and having many.

20.4 Uniqueness and the operator-norm threshold

The verdict section 20.3 handed us was deliberately one-sided, and that one-sidedness is precisely what sets up the present section. An equilibrium always exists, bought by compactness of $\mathbb{W}$ and concavity of payoffs alone, with the dimensionless order parameter $L_{\mathrm{br}} \|\mathbb{W}\|$ never once deciding whether the self-consistency loop has a fixed point. That cleanly quarantines the threshold phenomenon. If the crossing of $L_{\mathrm{br}} \|\mathbb{W}\|$ through one is going to matter anywhere in this chapter—and the throughline insists it is the order parameter of the whole theory—it can only matter here, in the question of how *many* fixed points there are. Existence is settled and free; uniqueness is the lone remaining place where the operator norm can earn its keep.

And uniqueness is genuinely in doubt. Nothing in the equilibrium condition of definition 20.2 forces the loop "aggregate, then best-respond" to have only one solution. When the coupling is strong the loop can fold back on itself: a profile of high effort generates, through $\mathbb{W}$, a large aggregate, which—if best responses are sufficiently responsive to that aggregate—calls forth still higher effort, so that a self-reinforcing high-effort profile and a self-reinforcing low-effort profile may both be internally consistent at once. This is not a pathology peculiar to networks. It is exactly the mechanism by which a strongly coupled mean field game acquires multiple equilibria—the failure of uniqueness analyzed in section 11.4—now filtered through the kernel rather than through an anonymous population mean. The forward reference made there, that strong coupling breeds multiplicity, comes due in this section, and the graphon is what makes it quantitative: "strong" will turn out to mean precisely $L_{\mathrm{br}} \|\mathbb{W}\| \geq 1$, the order parameter at or past its critical value.

Uniqueness must therefore be *earned*, and there are two essentially different ways to earn it, which is why two theorems are coming rather than one. They differ along the very axis that organizes the chapter: the first route controls the *size* of the coupling, the second its *sign structure*. Stating both, and seeing that they locate the same boundary from opposite sides, is the point of proving uniqueness twice.

The first route is *contraction*, and it is a smallness condition (assumption **(A-Coupling)**). Recall from section 20.2 that the best-response map factors as $\mathsf{S} = N \circ \mathbb{W}$: a Lipschitz pointwise response with constant L_{br}, applied after the linear aggregation $\mathbb{W}$, whose own Lipschitz constant on L^2 is exactly the operator norm $\|\mathbb{W}\|$. The composite then contracts distances by at most the product $L_{\mathrm{br}} \|\mathbb{W}\|$, and once that product drops below one the Banach fixed-point theorem returns exactly one equilibrium, reached by geometric iteration. The reason this is the route the throughline cares about is that the contraction factor *is* the order parameter itself—no cruder estimate stands between the hypothesis and the conclusion. Two features make it sharp rather than merely sufficient. It is the spectral radius $\|\mathbb{W}\| = \lambda_1$, and not some larger norm of the kernel, that enters, because the worst case of the linear step is realized along the top eigenfunction and nowhere worse; and the boundary $L_{\mathrm{br}} \|\mathbb{W}\| = 1$ it identifies is genuinely *attained*, not merely approached, because the compactness of $\mathbb{W}$ makes λ_1 an honest maximum rather than an unreached supremum—the discreteness of the spectrum flagged in the chapter preamble doing exactly the work promised for it. At that exact value the underlying linear operator $I - \mathsf{b}\mathbb{W}$ of the LQ benchmark eq. (20.8) loses invertibility along the top eigenfunction, so the edge the contraction argument produces is the true edge of well-posedness and not an artifact of the proof technique. Contraction is thus the route that puts the operator norm on open display as the coupling strength whose climb to one is the chapter's central drama; we develop it in section 20.4.2.

The second route is *monotonicity*, and it trades smallness for structure. Rather than ask the coupling to be weak, it asks the operator encoding the equilibrium condition to be *monotone*—in the linear–quadratic case, that the quadratic potential whose stationary points are the equilibria be convex—and from convexity alone, by the uniqueness of a minimizer, it reads off a single equilibrium. The decisive difference from contraction is that a convexity certificate carries no smallness inside it: it can certify uniqueness at *any* coupling strength, arbitrarily far above the contraction threshold, provided the sign structure of the interaction cooperates. This is the exact static shadow of the Lasry–Lions monotonicity condition of definition 11.1, which in the dynamic theory secures a unique MFG equilibrium with no smallness assumption whatever; here, with time and noise stripped away and the potential merely quadratic, that condition collapses to the elementary positive-definiteness of a Hessian operator, but the logic is identical—monotone coupling defeats multiplicity unconditionally in its favorable sign. Monotonicity is therefore the structural, variational face of the same threshold the contraction route saw spectrally; we develop it in section 20.4.3.

That the two routes view one boundary from two sides is exactly what makes the comparison instructive, and it reproduces, in static and computable form, the attractive-versus-repulsive asymmetry of section 11.4. For the strategic-complements sign—the network amplifying behavior—the two thresholds will turn out to coincide on the top eigenvalue λ_1, so the contraction and convexity boundaries agree and the uniqueness edge is genuinely sharp. For the strategic-substitutes sign the monotone route reaches strictly further than contraction, governed by the weaker spectral edge rather than by λ_1, mirroring exactly the way the "crowd-averse" coupling of section 11.4 stays tame over a wide range while the "crowd-seeking" coupling is the one pinned to a sharp critical value. The section thus sees the same threshold twice—spectrally and variationally—and that double vision is the whole reason to carry both arguments.

Both routes, however, are stated in terms of a single number we have so far only written down rather than examined: the operator norm $\|\mathbb{W}\|$, which the contraction route makes the contraction factor and the monotone route makes the binding eigenvalue. Before either theorem can be stated—let alone shown to be sharp—we must therefore pin down exactly what that number *is* for the kernel at hand, a nonnegative symmetric graphon: whether it sits at the top of the spectrum, whether that top is attained, and what its eigenfunction looks like. That identification is the first order of business, and it is where we turn now.

20.4.1 The operator norm of a graphon

Both routes to uniqueness pivot on one number, and so far we have only written its symbol down. The contraction argument of section 20.4.2 will make $\|\mathbb{W}\|$ the very factor by which the equilibrium loop shrinks distances; the monotone argument of section 20.4.3 will make it the eigenvalue that first turns the equilibrium potential non-convex. Neither threshold can even be stated as a sharp, attained edge—let alone shown to be sharp—until we know what $\|\mathbb{W}\|$ *is* for the object actually in front of us, which is not a general bounded operator but a graphon: a kernel that is *symmetric* (so $\mathbb{W}$ is self-adjoint) and *nonnegative* (because W takes values in $[0, 1]$, an edge density). Those two properties are exactly what make the answer clean, and the answer is the seed of everything spectral in the chapter. The operator norm is the *top eigenvalue* λ_1; it is strictly positive; and its eigenfunction may be taken nonnegative—the profile we will christen *eigenvector centrality* and watch become the order parameter's direction in section 20.5 and the condensate at criticality in section 20.5.2. We state this as a lemma, prove it from the spectral theorem with the nonnegativity of the kernel doing the one decisive piece of work, and then watch it come out by hand on the two kernels the chapter computes with.

Lemma 20.12 (Operator norm equals the top eigenvalue)**.** *Under **(A-Reg-W)**, $\mathbb{W}$ is self-adjoint and compact on $L^2[0,1]$, so by the spectral theorem (theorem 2.26) it has a real, discrete spectrum of eigenvalues (λ_n) (listed with multiplicity), accumulating only at 0, together with an orthonormal eigenbasis (ϕ_n) of $(\ker \mathbb{W})^\perp$. Because the nonzero eigenvalues form a sequence converging to 0, both spectral edges are attained: we order the nonnegative and nonpositive eigenvalues separately,*

$$\lambda_1 \;\geq\; \lambda_2 \;\geq\; \cdots \;\geq\; 0 \;\geq\; \cdots \;\geq\; \lambda_{\min}, \qquad \lambda_1 := \sup_n \lambda_n, \quad \lambda_{\min} := \inf_n \lambda_n,$$

both extrema being achieved by compactness (a most-positive and a most-negative eigenvalue exist whenever $\mathbb{W}$ has eigenvalues of that sign; if $\mathbb{W} \geq 0$ we set $\lambda_{\min} := 0$). Because the kernel is nonnegative, the largest eigenvalue is positive and equals the operator norm and the spectral radius:

$$\|\mathbb{W}\| \;=\; \lambda_1 \;=\; \max_n |\lambda_n| \;>\; 0, \tag{20.17}$$

and the corresponding eigenfunction ϕ_1 may be taken nonnegative.

Proof. Self-adjointness and compactness of $\mathbb{W}$ are proposition 2.24: the kernel is symmetric, so $\mathbb{W} = \mathbb{W}^*$, and it is Hilbert–Schmidt, hence compact. The spectral theorem theorem 2.26 then supplies everything in the first two displays of the statement—a real spectrum, eigenvalues listed with multiplicity accumulating only at 0, and an orthonormal eigenbasis (ϕ_n) of $(\ker \mathbb{W})^\perp$—and it is precisely the accumulation *only* at 0 that lets us speak of a largest and a smallest eigenvalue: away from any neighborhood of 0 there are finitely many eigenvalues, so the supremum λ_1 and infimum $\lambda_{\min}$ are each achieved by an honest eigenvalue rather than merely approached. This attainment is not a technicality we can take or leave; it is what will make the uniqueness boundary $L_{\mathrm{br}}\,\|\mathbb{W}\| = 1$ a sharp edge in section 20.4.2 rather than an unreached supremum.

We need two facts: that the operator norm equals the maximum modulus among eigenvalues, and that this maximum modulus is delivered by a *positive* eigenvalue. The first is the quadratic-form (Courant–Fischer) characterization corollary 2.27, which it is worth restating in the only form we use. Expanding any unit vector in the eigenbasis as $f = \sum_n c_n \phi_n$ with $\sum_n |c_n|^2 = 1$, self-adjointness gives the Rayleigh quotient as a *weighted average of the eigenvalues*,

$$\langle f, \mathbb{W} f \rangle \;=\; \sum_n \lambda_n\, |c_n|^2, \tag{20.18}$$

the weights $|c_n|^2$ summing to one. A weighted average of the λ_n is largest when all the weight sits on the largest eigenvalue and smallest when it sits on the smallest, so the extremes of eq. (20.18) over unit f are the top and bottom of the spectrum, each attained at the corresponding eigenfunction:

$$\lambda_1 = \sup_{\|f\|=1} \langle f, \mathbb{W} f \rangle, \qquad \lambda_{\min} = \inf_{\|f\|=1} \langle f, \mathbb{W} f \rangle.$$

Because $\langle f, \mathbb{W}f\rangle \in [\lambda_{\min}, \lambda_1]$ for every unit f, the operator norm, which for a self-adjoint operator is $\|\mathbb{W}\| = \sup_{\|f\|=1} |\langle f, \mathbb{W}f\rangle|$, equals $\max(\lambda_1,\ |\lambda_{\min}|) = \max_n |\lambda_n|$. So far this used only self-adjointness and compactness; nothing yet decides whether the most negative or the most positive eigenvalue is larger in modulus. That is the one place the *nonnegativity* of the kernel enters.

Fix any $f \in L^2[0,1]$ and compare the quadratic form of f with that of its modulus $|f|$. Pointwise $f(x)f(y) \le |f(x)|\,|f(y)|$, and $W \ge 0$, so multiplying by the kernel preserves the inequality and integrating gives

$$\langle f, \mathbb{W}f\rangle = \iint W(x,y)\, f(x)f(y)\; \mathrm{d}x\,\mathrm{d}y \;\le\; \iint W(x,y)\,|f(x)|\,|f(y)|\; \mathrm{d}x\,\mathrm{d}y = \langle |f|, \mathbb{W}|f|\rangle. \quad (20.19)$$

The same pointwise bound applied to $-f(x)f(y) \le |f(x)|\,|f(y)|$ gives $-\langle f, \mathbb{W}f\rangle \le \langle |f|, \mathbb{W}|f|\rangle$ as well, so in fact $|\langle f, \mathbb{W}f\rangle| \le \langle |f|, \mathbb{W}|f|\rangle$: passing to $|f|$ can only raise the quadratic form, because it removes every cancellation between oppositely-signed regions of f, and a nonnegative kernel rewards alignment. Now take f to be a unit eigenfunction for the most negative eigenvalue, so $\langle f, \mathbb{W}f\rangle = \lambda_{\min}$ and $\||f|\| = \|f\| = 1$. The chain

$$\lambda_1 \;\ge\; \langle |f|, \mathbb{W}|f|\rangle \;\ge\; |\langle f, \mathbb{W}f\rangle| \;=\; |\lambda_{\min}|$$

reads off, left to right: λ_1 is the supremum of the Rayleigh quotient over unit vectors and $|f|$ is one such vector; then eq. (20.19) in its two-sided form; then the eigenvalue equation. Hence $\lambda_1 \ge |\lambda_{\min}|$, and therefore $\|\mathbb{W}\| = \max_n |\lambda_n| = \lambda_1$, a nonnegative number: the maximum modulus is carried by a positive (or zero) eigenvalue, never by a strictly more-negative one.

It remains to rule out the degenerate case $\lambda_1 = 0$, which would force *every* eigenvalue to vanish and hence, by the spectral theorem, $\mathbb{W} = 0$. But $\mathbb{W} \ne 0$ for any genuine graphon. The cleanest certificate is the Hilbert–Schmidt norm, which for a self-adjoint operator is the ℓ^2 norm of the spectrum,

$$\sum_n \lambda_n^2 \;=\; \|\mathbb{W}\|_{\mathrm{HS}}^2 \;=\; \iint W(x,y)^2\; \mathrm{d}x\,\mathrm{d}y \;=\; \|W\|_{L^2([0,1]^2)}^2 \;>\; 0,$$

strictly positive whenever W is not almost everywhere zero, i.e. whenever the network has any edges at all. If the λ_n^2 sum to a positive number they cannot all be zero, so $\lambda_1 = \max_n |\lambda_n| > 0$. (When the diagonal is integrable one may argue even more directly: $\operatorname{tr}\mathbb{W} = \int_0^1 W(x,x)\,\mathrm{d}x = \sum_n \lambda_n \ge 0$, and if this is strictly positive then a positive eigenvalue exists outright; but the Hilbert–Schmidt certificate needs nothing about the diagonal and is the one we lean on.)

Finally, the eigenfunction can be taken nonnegative. Let f be a unit eigenfunction for λ_1, so $\langle f, \mathbb{W}f\rangle = \lambda_1 = \sup_{\|g\|=1}\langle g, \mathbb{W}g\rangle$. By eq. (20.19), $\langle |f|, \mathbb{W}|f|\rangle \ge \langle f, \mathbb{W}f\rangle = \lambda_1$, and $|f|$ is again a unit vector; but λ_1 is the supremum, so equality holds and $|f|$ also maximizes the Rayleigh quotient. A maximizer of the Rayleigh quotient is an eigenfunction for the top eigenvalue, so $|f|$ is itself a λ_1-eigenfunction. Replacing f by $\phi_1 := |f| \ge 0$ therefore loses nothing, and the top eigenfunction may be taken nonnegative. □

It is worth dwelling on what the pair (λ_1, ϕ_1) *means* as network data, because both halves are about to do heavy lifting and the lemma has just earned us the right to read them structurally. The eigenvalue $\lambda_1 = \|\mathbb{W}\|$ is the *spectral radius* of the network operator: the single largest factor by which neighbor-averaging can amplify a profile, realized along ϕ_1 and nowhere stronger. This is exactly why it, and not some cruder norm of the kernel, is the right measure of "how strongly the network couples"—it is the worst case of the linear step $s \mapsto \mathbb{W}s$, which is precisely the quantity a contraction estimate must control.

The eigenfunction $\phi_1 \geq 0$ is the *eigenvector centrality* profile of the graphon, the continuum analogue of the Perron eigenvector of an adjacency matrix. The defining relation $\mathbb{W}\phi_1 = \lambda_1\phi_1$ says it is the profile reproduced *up to scale* by one round of neighbor averaging: if the population plays ϕ_1, then the aggregate each type feels, $(\mathbb{W}\phi_1)(x) = \lambda_1\phi_1(x)$, is the very same profile rescaled by λ_1. This is a self-consistency condition on importance—a type is central exactly insofar as it is connected to other central types—and it is the same fixed-point logic that defines eigenvector centrality on finite networks, now read off a kernel. That ϕ_1 comes out *nonnegative* is what makes this reading legitimate: a centrality ranking must assign each type a magnitude of the same sign, and the lemma guarantees the top mode can be chosen so, with no type's centrality fighting another's. The full spectral dictionary for network structure is the business of chapter 18; here we extract only the two facts the rest of the chapter runs on. First, $\|\mathbb{W}\| = \lambda_1$, so the dimensionless coupling $L_{\mathrm{br}}\,\|\mathbb{W}\|$ that section 20.2 handed forward is literally $L_{\mathrm{br}}\lambda_1$, a spectral quantity. Second, $\phi_1 \geq 0$ is a bona fide centrality profile—the "soft mode" of the network—which section 20.5.2 will show the equilibrium condenses onto as the coupling is driven to the threshold. The lemma is thus the hinge between the abstract order parameter and the concrete network ranking it secretly is.

Abstract as the lemma is, the threshold quantity $\|\mathbb{W}\| = \lambda_1$ is something we can write down in one line on the two kernels the chapter carries, and doing so now—before the threshold is used—turns the inequality $L_{\mathrm{br}}\,\|\mathbb{W}\| < 1$ into a concrete arithmetical condition the reader can already evaluate. Both computations exploit the same accident the lemma's degenerate case warned of: these kernels have rank one, so $\mathbb{W}$ has a single nonzero eigenvalue, which by the lemma must be the positive number $\lambda_1 = \|\mathbb{W}\|$.

Example 20.13 (The norm in the constant and rank-one cases)**.** *(a) Constant graphon.* Let $W \equiv c$ with $c \in (0,1]$, the kernel in which every type is everyone's neighbor with equal weight. Then for any $g \in L^2[0,1]$,

$$(\mathbb{W}g)(x) = c\int_0^1 g(y)\,\mathrm{d}y = c\,\langle g, \mathbf{1}\rangle\,\mathbf{1}(x),$$

where $\mathbf{1}$ is the constant function 1 (note $\|\mathbf{1}\| = 1$ since $\int_0^1 1 = 1$). The image is *always* a multiple of $\mathbf{1}$, so $\mathbb{W}$ has rank one. Testing $\mathbf{1}$ itself, $\mathbb{W}\mathbf{1} = c\,\langle \mathbf{1}, \mathbf{1}\rangle\,\mathbf{1} = c\,\mathbf{1}$, so $\mathbf{1}$ is an eigenfunction with eigenvalue c; every zero-mean function g has $\langle g, \mathbf{1}\rangle = 0$ and hence lies in $\ker\mathbb{W}$. The single nonzero eigenvalue is therefore $\lambda_1 = c$ with normalized nonnegative eigenfunction $\phi_1 = \mathbf{1}$, and $\|\mathbb{W}\| = c$ (worked computation 2.28(a)). The lemma is borne out: the maximum modulus sits on a positive eigenvalue, $\phi_1 \geq 0$, and $\lambda_1 = c = \|W\|_{L^2([0,1]^2)}$ as the Hilbert–Schmidt check predicts for a rank-one operator. The subcriticality condition becomes simply $L_{\mathrm{br}}\,c < 1$: the constant kernel couples through the population mean alone, and its strength is the edge density c.

(b) Rank-one graphon. Let $W(x,y) = f(x)f(y)$ with $f \in L^2[0,1]$, $f \geq 0$ (and bounded into $[0,1]$ so it is a graphon). Then

$$(\mathbb{W}g)(x) = f(x)\int_0^1 f(y)g(y)\,\mathrm{d}y = \langle f, g\rangle\,f(x),$$

again rank one, the image always a multiple of f. Testing f, $\mathbb{W}f = \langle f, f\rangle f = \|f\|_{L^2}^2 f$, so f is an eigenfunction with eigenvalue $\|f\|_{L^2}^2 = \int_0^1 f^2$, while everything orthogonal to f is in the kernel. The single nonzero eigenvalue is $\lambda_1 = \int_0^1 f^2$ with normalized eigenfunction $\phi_1 = f/\|f\|_{L^2} \geq 0$, so $\|\mathbb{W}\| = \|f\|_{L^2}^2$ (worked computation 2.28(b)). Here the centrality profile $\phi_1 \propto f$ is the type's own connectivity weight $f(x)$, exactly as one would want: in a rank-one network a type is central in proportion to how strongly it attaches to the single shared factor. The subcriticality condition reads $L_{\mathrm{br}} \|f\|_{L^2}^2 < 1$.

With $\|\mathbb{W}\| = \lambda_1$ now pinned down—a positive, attained top eigenvalue, computable in closed form on the kernels we care about—the dimensionless coupling constant that section 20.2 built but could not yet name becomes a genuinely *spectral* quantity. The contraction factor $L_{\mathrm{br}} \|\mathbb{W}\|$ of the best-response map is $L_{\mathrm{br}}\lambda_1$, and the hypothesis $L_{\mathrm{br}} \|\mathbb{W}\| < 1$ is the demand that the behavioral gain stay below the reciprocal $\kappa = 1/L_{\mathrm{br}}$ of the spectral radius—the network operating *subcritically*. That this boundary is attained, by the compactness the lemma invoked, is what will make the contraction edge the true edge of well-posedness rather than an artifact. The next subsection takes exactly this identity and turns the abstract contraction estimate of section 20.2 into the sharp spectral subcriticality threshold.

20.4.2 Uniqueness by contraction

The previous subsection finished the one piece of arithmetic the threshold was waiting on: it identified the operator norm of a graphon as its top eigenvalue, $\|\mathbb{W}\| = \lambda_1$ (lemma 20.12), an honest, attained maximum of the spectrum carried by a nonnegative eigenfunction ϕ_1. That identity is what turns the abstract contraction constant of section 20.2 into something we can read as network data. Recall the shape of the argument we are about to complete. The best-response map factors as $\mathsf{S} = N \circ \mathbb{W}$ (eq. (20.11)): a linear aggregation through the kernel, followed by a pointwise best response that is Lipschitz in the aggregate with constant $L_{\mathrm{br}} = \ell/\theta$ (lemma 20.6). A composition of Lipschitz maps contracts by at most the product of their constants, so S shrinks L^2 distances by at most $L_{\mathrm{br}} \cdot \|\mathbb{W}\|$. Until this subsection the second factor was a bare symbol; now it is λ_1, and the whole contraction estimate becomes a single *spectral* inequality, $L_{\mathrm{br}}\lambda_1 < 1$. Below that line the loop "aggregate, then best-respond" is a strict contraction and Banach's theorem hands us exactly one equilibrium, reached by geometric iteration; this is the chapter's central quantitative result, and we now state and prove it, then spend the rest of the subsection reading off what the threshold means.

Theorem 20.14 (Subcritical uniqueness)**.** *Consider a static graphon game under* ***(A-Reg-W)*** *and assumption 20.5, with the standalone optimum in L^2,* $\mathrm{br.}(0) \in L^2[0,1]$ *(automatic when S is bounded, and equal to* $\Pi_S\alpha \in L^\infty[0,1]$ *for the LQ game), and impose the coupling condition* ***(A-Coupling)*** *in the sharp form*

$$L_{\mathrm{br}} \|\mathbb{W}\| \;<\; 1, \qquad \textit{equivalently} \qquad \|\mathbb{W}\| \;<\; \kappa := \frac{1}{L_{\mathrm{br}}} = \frac{\theta}{\ell}. \tag{20.20}$$

Then S *maps* $\mathcal{S}$ *into* $\mathcal{S}$ *and is a contraction on* $L^2[0,1]$*, and the game has a* unique *graphon Nash equilibrium s^*. Moreover the fixed-point iteration* $s^{(k+1)} = \mathsf{S}(s^{(k)})$ *converges to s^* geometrically from any* $s^{(0)} \in \mathcal{S}$*, with* $\left\|s^{(k)} - s^*\right\|_{L^2} \leq (L_{\mathrm{br}} \|\mathbb{W}\|)^k \left\|s^{(0)} - s^*\right\|_{L^2}$.

Proof. That S maps $\mathcal{S}$ into itself is immediate from the construction of the factorization: for any admissible profile s the aggregate $\mathbb{W}s$ is a well-defined element of $L^2[0,1]$, and each br_x takes its value in the action set S, so $\mathsf{S}(s)(x) = \mathrm{br}_x((\mathbb{W}s)(x)) \in S$ for almost every x and $\mathsf{S}(s) \in \mathcal{S}$; the hypothesis $\mathrm{br}_\cdot(0) \in L^2$ together with the Lipschitz bound below keeps $\mathsf{S}(s)$ square-integrable. The content is the contraction estimate. Take two admissible profiles $s, s' \in \mathcal{S}$ and bound the L^2 distance between their images one type at a time, then in aggregate. Pointwise in x, the two images differ only through the aggregates fed to the *same* scalar map br_x, and that map is L_{br}-Lipschitz uniformly in x by lemma 20.6, so

$$\left|\mathrm{br}_x((\mathbb{W}s)(x)) - \mathrm{br}_x((\mathbb{W}s')(x))\right| \;\le\; L_{\mathrm{br}} \left|(\mathbb{W}s)(x) - (\mathbb{W}s')(x)\right| \;=\; L_{\mathrm{br}} \left|(\mathbb{W}(s-s'))(x)\right|,$$

the last equality by linearity of $\mathbb{W}$. Squaring this pointwise inequality and integrating over x carries it to the norm,

$$\left\|\mathsf{S}(s) - \mathsf{S}(s')\right\|_{L^2}^2 = \int_0^1 \left|\mathrm{br}_x((\mathbb{W}s)(x)) - \mathrm{br}_x((\mathbb{W}s')(x))\right|^2 \mathrm{d}x \;\le\; L_{\mathrm{br}}^2 \int_0^1 \left|(\mathbb{W}(s-s'))(x)\right|^2 \mathrm{d}x = L_{\mathrm{br}}^2 \left\|\mathbb{W}(s-s')\right\|_{L^2}^2 .$$

This is the pointwise, behavioral half of the bound; the structural half is the definition of the operator norm, $\|\mathbb{W}v\|_{L^2} \le \|\mathbb{W}\| \, \|v\|_{L^2}$ applied to $v = s - s'$, which by lemma 20.12 is $\|\mathbb{W}v\|_{L^2} \le \lambda_1 \|v\|_{L^2}$. Substituting,

$$\left\|\mathsf{S}(s) - \mathsf{S}(s')\right\|_{L^2}^2 \;\le\; L_{\mathrm{br}}^2 \, \|\mathbb{W}\|^2 \, \left\|s - s'\right\|_{L^2}^2 , \qquad \text{i.e.} \qquad \left\|\mathsf{S}(s) - \mathsf{S}(s')\right\|_{L^2} \;\le\; L_{\mathrm{br}} \, \|\mathbb{W}\| \, \left\|s - s'\right\|_{L^2} .$$

Thus S is Lipschitz on L^2 with constant $L_{\mathrm{br}} \|\mathbb{W}\|$, and the hypothesis eq. (20.20) makes that constant strictly less than one: S is a contraction. Its domain $\mathcal{S} = \{s \in L^2 : \; s(x) \in S \text{ a.e.}\}$ is a closed subset of the complete space $L^2[0,1]$ (closedness because S is closed and L^2-limits have a.e.-convergent subsequences), hence itself a complete metric space. The Banach fixed-point theorem (theorem 2.36) therefore furnishes a unique fixed point s^*, which by definition 20.4 is the unique GNE. The geometric rate is the standard by-product: iterating the contraction inequality on consecutive iterates $s^{(k)} = \mathsf{S}(s^{(k-1)})$ and using $\mathsf{S}(s^*) = s^*$ gives $\left\|s^{(k)} - s^*\right\|_{L^2} = \left\|\mathsf{S}(s^{(k-1)}) - \mathsf{S}(s^*)\right\|_{L^2} \;\le\; L_{\mathrm{br}} \|\mathbb{W}\| \left\|s^{(k-1)} - s^*\right\|_{L^2}$, and unwinding the recursion k times yields $\left\|s^{(k)} - s^*\right\|_{L^2} \le (L_{\mathrm{br}} \|\mathbb{W}\|)^k \left\|s^{(0)} - s^*\right\|_{L^2}$ from any starting profile $s^{(0)} \in \mathcal{S}$. □

This is the chapter's central quantitative result and the prototype for the whole of Part IV, and three features of the single inequality eq. (20.20) deserve to be drawn out, because each will recur, dressed in PDEs, in chapters 22 and 24.

First, the threshold is a loop gain—a competition between behavior and structure. The two factors in $L_{\mathrm{br}} \|\mathbb{W}\|$ are independent and measure entirely different things. The behavioral responsiveness $L_{\mathrm{br}} = \ell/\theta$ is a property of the *payoff* alone: it is the ratio of how strongly a player's marginal incentive reacts to its neighbors' aggregate (ℓ) to how firmly its own cost anchors its action (θ), and it owes nothing to who those neighbors are. The structural amplification $\|\mathbb{W}\| = \lambda_1$ is a property of the *network* alone: the largest factor by which one round of neighbor-averaging can magnify a profile, owing nothing to the payoff. Their product is the gain of the feedback loop that section 20.4 described: a perturbation of the profile is amplified λ_1-fold by the structural step $s \mapsto \mathbb{W}s$ and then L_{br}-fold by the behavioral step $z \mapsto \mathrm{br}_x(z)$ before returning as a perturbation of the profile, and the loop is stable—returns less than it was handed, so iteration damps out to a single fixed point—exactly when the round-trip gain $L_{\mathrm{br}}\lambda_1$ is below one. This is why responsiveness and connectivity are interchangeable in setting the threshold: a very stiff payoff (small L_{br}) tolerates a strongly coupled network (large λ_1), and a sparsely coupled network tolerates a twitchy payoff, but the *product* is what must stay subcritical. The same loop gain, behavioral responsiveness times spectral radius, is what will govern the well-posedness of the dynamic game once time and diffusion are restored.

Second, it is the spectral radius that enters, not a cruder norm. The estimate did not settle for any convenient bound on the size of the kernel—not the supremum $\|W\|_\infty$, not the Hilbert–Schmidt norm $\|W\|_{L^2([0,1]^2)} = \sqrt{\sum_n \lambda_n^2}$, each of which would also control the contraction but with room to spare. It is the *leading eigenvalue* λ_1, the smallest constant for which $\|\mathbb{W}v\| \leq \lambda_1 \|v\|$ holds for every v, that appears, and it does so because lemma 20.12 identified it as the exact operator norm: the worst case of the linear step is realized along the top eigenfunction ϕ_1 and nowhere worse. The practical consequence is that a network may carry a great many strong individual connections—a large $\|W\|_\infty$, many high-weight rows—and still operate subcritically, provided those connections do not conspire into a single large eigenvalue. Only coherent, mutually reinforcing structure, the kind that piles up into a large λ_1, threatens uniqueness; incoherent strength, spread across modes with eigenvalues that do not add, does not. This sharpness is exactly what cruder norms would miss, and it is why the chapter has insisted on watching the spectral radius and not the kernel's gross size.

Third, the bound is sharp in a structural sense—but in a sense worth stating precisely so as not to overclaim. It is *not* the claim that uniqueness fails the instant $L_{\mathrm{br}} \|\mathbb{W}\| \geq 1$; the very next subsection will exhibit couplings far above this line that still have a unique equilibrium, secured by sign structure rather than smallness. What is sharp is that no contraction-type argument—no argument that asks only the *magnitude* of the coupling to be small—can reach past the threshold, because at the threshold the linear inversion underlying the LQ benchmark genuinely breaks down for the worst-case sign and data. To see this concretely, specialize to the LQ game example 20.3, where $L_{\mathrm{br}} = |\mathsf{b}|$ and the GNE solves $(I - \mathsf{b}\mathbb{W})s = \alpha$, and take the strategic-complements sign $\mathsf{b} > 0$, so that the binding eigenvalue is the positive top one and $L_{\mathrm{br}} \|\mathbb{W}\| = \mathsf{b}\lambda_1$. At exactly $\mathsf{b}\lambda_1 = 1$ the operator $I - \mathsf{b}\mathbb{W}$ is singular: applying it to the top eigenfunction gives

$$(I - \mathsf{b}\mathbb{W})\phi_1 = \phi_1 - \mathsf{b}\,\mathbb{W}\phi_1 = \phi_1 - \mathsf{b}\lambda_1\phi_1 = (1 - \mathsf{b}\lambda_1)\phi_1 = 0,$$

so ϕ_1 lies in the kernel and the inverse $(I - \mathsf{b}\mathbb{W})^{-1}$ on which $s^* = (I - \mathsf{b}\mathbb{W})^{-1}\alpha$ relied no longer exists. Because $\mathsf{b}\mathbb{W}$ is compact, the Fredholm alternative applies to $I - \mathsf{b}\mathbb{W}$: the equation $(I - \mathsf{b}\mathbb{W})s = \alpha$ is solvable in L^2 if and only if α is orthogonal to the kernel span $\{\phi_1\}$, i.e. iff $\langle \alpha, \phi_1 \rangle = 0$. This is what splits the failure into its two faces.

The *generic* face is non-existence. For a typical standalone return α the overlap $\langle \alpha, \phi_1 \rangle$ is nonzero, the solvability condition fails, and the equation has *no* L^2 solution at all—there is no unconstrained equilibrium. One can watch this coming from below the threshold by tracking the ϕ_1-component of the equilibrium. Expanding $\alpha = \sum_n \langle \alpha, \phi_n \rangle \phi_n$ and inverting mode by mode (the diagonalization the LQ form permits), the equilibrium is

$$s^* = (I - \mathsf{b}\mathbb{W})^{-1}\alpha = \sum_n \frac{\langle \alpha, \phi_n \rangle}{1 - \mathsf{b}\lambda_n}\, \phi_n,$$

and the $n = 1$ term carries the denominator $1 - \mathsf{b}\lambda_1$, which vanishes as $\mathsf{b}\lambda_1 \uparrow 1$. The component of equilibrium effort along the centrality direction, $\langle \alpha, \phi_1 \rangle/(1 - \mathsf{b}\lambda_1)$, therefore diverges, and with it the whole profile: $\|s^*\| \to \infty$ as criticality is approached. This blow-up is the equilibrium condensing onto ϕ_1, the phenomenon theorem 20.19 makes precise; here it is the analytic fingerprint of the loop gain reaching one. The *non-generic* face is non-uniqueness. For the fine-tuned data $\alpha \perp \phi_1$ the solvability condition is met and a particular solution s exists, but now $\phi_1 \in \ker(I - \mathsf{b}\mathbb{W})$ means the entire line $s + t\phi_1$, $t \in \mathbb{R}$, solves the same equation—a one-parameter family of equilibria, genuine multiplicity along the soft mode. Either way the unconstrained LQ problem is ill posed exactly at the contraction edge, which is what we mean by calling the threshold structurally sharp: the operator-theoretic well-posedness it certifies is the true edge, not an artifact of the proof technique.

Two caveats keep this honest, and both point forward. The bounded-action (clipped) game retains an equilibrium regardless of where the coupling sits, because that existence was bought by compactness and Schauder's theorem in theorem 20.9, with no smallness assumed; what the threshold governs is uniqueness, not existence. And the sharpness just argued is sharpness *for the complements sign*. For strategic substitutes $\mathsf{b} < 0$ the product $L_{\mathrm{br}} \|\mathbb{W}\| = |\mathsf{b}|\, \lambda_1$ may well exceed one while $I - \mathsf{b}\mathbb{W}$ stays comfortably invertible—its spectrum is $\{1 - \mathsf{b}\lambda_n\}$, and with $\mathsf{b} < 0$ and λ_n of either sign the nearest approach to the singular value 0 is governed by the most *negative* eigenvalue $\lambda_{\min}$, not by λ_1, so the genuine well-posedness edge is the weaker $|\mathsf{b}|\, |\lambda_{\min}| < 1$. In that regime the contraction bound is merely sufficient and leaves a gap, and closing it requires the second, structural route to uniqueness. We return to both faces of the criticality failure in sections 20.5 and 20.6, where they are computed in closed form.

Physics note

The product $L_{\mathrm{br}} \|\mathbb{W}\|$ plays the role of a coupling constant approaching a critical value, and the threshold $L_{\mathrm{br}} \|\mathbb{W}\| = 1$ is a stability boundary of exactly the Curie–Weiss type, complete with a divergent susceptibility that we can compute in one line. Take the LQ game on the constant kernel $W \equiv c$, where every type feels the same population mean $\bar{s} = \int_0^1 s$ and the aggregate is the type-independent number $z^* = c\,\bar{s}$ (example 20.13(a)). The equilibrium condition $s^*(x) = \alpha(x) + \mathsf{b}z^*$ integrated over x gives a self-consistency equation for the mean alone,

$$\bar{s} = \bar{\alpha} + \mathsf{b}\, z^* = \bar{\alpha} + \mathsf{b}c\,\bar{s} \qquad \Longrightarrow \qquad \bar{s} = \frac{\bar{\alpha}}{1 - \mathsf{b}c}, \qquad z^* = \frac{c\,\bar{\alpha}}{1 - \mathsf{b}c},$$

with $\bar{\alpha} = \int_0^1 \alpha$. This is the mean-field self-consistency relation in its barest form: the population's average effort is its standalone average dressed by the factor $(1 - \mathsf{b}c)^{-1}$, the resummed feedback of everyone responding to everyone. Now probe it. Shift the standalone return by a uniform amount, $\alpha \mapsto \alpha + \delta\mathbf{1}$, so $\bar{\alpha} \mapsto \bar{\alpha} + \delta$; the response of the collective is

$$\chi \;:=\; \frac{\partial \bar{s}}{\partial \delta} \;=\; \frac{1}{1 - \mathsf{b}c} \;=\; \frac{1}{1 - \mathsf{b}\lambda_1},$$

the *susceptibility* of the population to a small common perturbation, and it *diverges* as $\mathsf{b}c = \mathsf{b}\lambda_1 \uparrow 1$. (For a general kernel the same computation in the eigenbasis gives mode-by-mode susceptibilities $(1 - \mathsf{b}\lambda_n)^{-1}$, of which the $n = 1$ term is the first and most violent to blow up—the divergent ϕ_1-component of s^* already met above.) This is the static, network-resolved version of the divergent susceptibility at a mean-field critical point: the collective response to a small common nudge blows up as the coupling reaches the inverse $1/\lambda_1$ of the top eigenvalue, while individual stiffness keeps every agent's own response finite. The eigenfunction ϕ_1 is the *soft mode*—the direction of vanishing restoring force, along which the response first diverges and onto which the equilibrium condenses—and it is the direction of incipient symmetry breaking: just past criticality the unconstrained problem can no longer pin the profile's ϕ_1-component, and which way it tips is decided by the data rather than the loop. We will see the very same eigenvalue threshold govern uniqueness of the *dynamic* graphon mean field game in chapter 24, with the spectral radius again playing the order parameter; that the static and dynamic thresholds coincide is the precise content, made good in section 20.7, of the claim that the static case is the dynamic theory's stationary shadow.

The contraction route has thus delivered uniqueness, but it has done so by paying a definite price: the coupling had to be *small*, $L_{\mathrm{br}}\,\|\mathbb{W}\| < 1$, and we have just seen that beyond that line—at least for the strategic-complements sign—genuine ill-posedness can set in. Two debts are left open by this, and the next two sections settle them in turn. The first is the gap the second caveat exposed: for strategic substitutes the contraction bound was merely sufficient, the true invertibility edge being the weaker $|\mathsf{b}|\,|\lambda_{\min}| < 1$, and more broadly one may ask whether uniqueness can ever survive *strong* coupling, far above the contraction threshold, when it is the network's sign *structure* rather than the coupling's smallness that does the work. That is precisely the question the next subsection takes up, trading the contraction's smallness price for a structural monotonicity condition that costs nothing in coupling strength when the signs cooperate. The second debt is owed to section 20.5: everything there—the reading of the equilibrium as Katz–Bonacich centrality, the convergent Neumann series, the comparative statics—presumes that $I - \mathsf{b}\mathbb{W}$ is invertible, and it is exactly the subcritical regime certified here, $\mathsf{b}\lambda_1 < 1$, that supplies that invertibility. The contraction theorem is thus the guarantee on which the centrality calculus quietly rests. We turn first to the structural route.

20.4.3 Uniqueness by monotonicity

The contraction theorem left a sharp but deliberately limited verdict: the equilibrium is unique below the line $L_{\mathrm{br}}\,\|\mathbb{W}\| < 1$, and that verdict was bought by insisting the coupling be *small*. Its closing caveats already hinted that smallness is not the only currency that can purchase uniqueness. For strategic substitutes the genuine invertibility edge was the weaker $|\mathsf{b}|\,|\lambda_{\min}| < 1$, leaving the contraction bound a strict overpayment; and more broadly one suspects that whenever the network's interaction *signs* cooperate the equilibrium should stay unique no matter how strong the coupling grows. The contraction subsection handed exactly this question forward—can uniqueness survive *strong* coupling through structure rather than smallness?—and the present subsection answers it, in the affirmative. The price is not waived but exchanged: in place of a bound on the coupling's *magnitude* we impose a condition on its *sign structure*, namely that the operator $I - \mathsf{b}\mathbb{W}$ encoding the equilibrium be positive definite. When that holds, uniqueness costs nothing at all in coupling strength—the equilibrium is unique however large b is.

This is the exact static mirror of the Lasry–Lions monotonicity condition of definition 11.1. There a monotone coupling defeated multiplicity of the dynamic mean field game regardless of the time horizon; here a monotone—positive-definite—equilibrium operator defeats multiplicity regardless of the coupling strength. As there, we phrase the condition as monotonicity of the operator that encodes the equilibrium, and as there the working mechanism is *convexity*: the equilibrium will turn out to be the minimizer of a single convex functional, and a strictly convex functional has at most one minimizer. The whole subsection is the unpacking of that one sentence.

The LQ game is a potential game. The structural fact that opens the variational route is that the LQ equilibrium condition is not merely *an* equation but a *gradient* equation: there is a single scalar functional on profiles whose stationarity reproduces the first-order condition of every type *at once*. A game with this property is called a *potential game*, and the functional is its *potential*. The payoff of recognizing one is immediate and large: the search for a fixed point of mutually-best-responding players—a problem with the unknown on both sides—collapses into the minimization of one ordinary function, to which the entire convex-analysis toolkit then applies, uniqueness of the minimizer included.

To exhibit the potential, recall the LQ equilibrium condition in operator form, $(I - \mathsf{b}\mathbb{W})s = \alpha$ (eq. (20.8)), and consider the quadratic functional

$$\mathcal{V}(s) \;=\; \tfrac{1}{2}\langle s, (I - \mathsf{b}\mathbb{W})s\rangle - \langle \alpha, s\rangle \;=\; \tfrac{1}{2}\,\|s\|_{L^2}^2 - \tfrac{\mathsf{b}}{2}\langle s, \mathbb{W}s\rangle - \langle \alpha, s\rangle. \tag{20.21}$$

The single ingredient that makes this work is that $\mathbb{W}$ is *self-adjoint*—this is the symmetry of the kernel, $W(x,y) = W(y,x)$, built into **(A-Reg-W)**—so that $I - \mathsf{b}\mathbb{W}$ is self-adjoint too, and a quadratic form built from a self-adjoint operator is its own gradient generator. To see this concretely, differentiate $\mathcal{V}$ along an arbitrary direction $v \in L^2[0,1]$:

$$\frac{\mathrm{d}}{\mathrm{d}t}\Big|_{t=0}\mathcal{V}(s+tv) \;=\; \tfrac{1}{2}\big(\langle v, (I-\mathsf{b}\mathbb{W})s\rangle + \langle s, (I-\mathsf{b}\mathbb{W})v\rangle\big) - \langle \alpha, v\rangle \;=\; \langle (I-\mathsf{b}\mathbb{W})s - \alpha,\, v\rangle,$$

where the last step folds the two cross terms into one using $\langle s, (I-\mathsf{b}\mathbb{W})v\rangle = \langle (I-\mathsf{b}\mathbb{W})s, v\rangle$, which is *exactly* self-adjointness. Since v is arbitrary, the gradient is $\nabla\mathcal{V}(s) = (I-\mathsf{b}\mathbb{W})s - \alpha$, and its vanishing $\nabla\mathcal{V}(s) = 0$ is precisely the GNE equation $(I-\mathsf{b}\mathbb{W})s = \alpha$ of eq. (20.8). Thus the GNE are exactly the *critical points* of $\mathcal{V}$. It is worth pausing on the role of symmetry: had the kernel been asymmetric, $\mathbb{W}$ would not be self-adjoint, the two cross terms above would not combine, and $(I-\mathsf{b}\mathbb{W})s - \alpha$ would fail to be the gradient of *any* functional—there would be no potential and no variational route at all. The symmetry that **(A-Reg-W)** imposes is not a convenience here; it is the precise hypothesis that makes the game a potential game.

The second variation is simpler still and constant in s:

$$\frac{\mathrm{d}^2}{\mathrm{d}t^2}\mathcal{V}(s+tv) \;=\; \langle v, (I-\mathsf{b}\mathbb{W})v\rangle,$$

so the Hessian of $\mathcal{V}$ is the fixed self-adjoint operator $H = I - \mathsf{b}\mathbb{W}$, independent of where it is evaluated. A quadratic functional with constant Hessian H is convex exactly when $H \geq 0$ and *strictly* (indeed uniformly) convex exactly when H is uniformly positive, $H \geq \eta I$ with $\eta > 0$; and a uniformly convex functional on a Hilbert space, being coercive, has a *unique* minimizer. The whole question of uniqueness therefore reduces to one spectral question—when is $H = I - \mathsf{b}\mathbb{W}$ positive definite?—and that question has a one-line answer in terms of the eigenvalues of $\mathbb{W}$. The Hessian of $\mathcal{V}$ is $I - \mathsf{b}\mathbb{W}$, which is positive definite if and only if $\mathsf{b}\lambda_n < 1$ for every eigenvalue λ_n.

Theorem 20.15 (Monotone uniqueness for the LQ game)**.** *For the LQ graphon game of example 20.3 with $S = \mathbb{R}$, the following are equivalent:*

(i) the functional $\mathcal{V}$ of eq. (20.21) is strictly convex on $L^2[0,1]$;

(ii) the operator $I - \mathsf{b}\mathbb{W}$ is positive definite, i.e. $\langle s, (I - \mathsf{b}\mathbb{W})s\rangle \geq \eta \|s\|^2$ for some $\eta > 0$;

(iii) $\mathsf{b}\,\lambda_n < 1$ for every eigenvalue λ_n of $\mathbb{W}$.

Under any of these, the GNE is unique and is the unique minimizer of $\mathcal{V}$. In particular, writing the condition (iii) as $\mathsf{b}\lambda_n < 1$ for the eigenvalue achieving $\sup_n \mathsf{b}\lambda_n$: for strategic complements ($\mathsf{b} > 0$) the binding eigenvalue is $\lambda_1 = \|\mathbb{W}\|$ and the condition is the spectral bound $\mathsf{b}\,\lambda_1 = \mathsf{b}\,\|\mathbb{W}\| < 1$; for strategic substitutes ($\mathsf{b} < 0$) the binding eigenvalue is the most negative one $\lambda_{\min}$, and the condition reads

$$\mathsf{b}\,\lambda_{\min} \;=\; |\mathsf{b}|\,|\lambda_{\min}| \;<\; 1.$$

This is not *automatic in general: a nonnegative symmetric graphon under **(A-Reg-W)** can have $\lambda_{\min} < 0$ (e.g. the complete-bipartite kernel $W(x,y) = \mathbf{1}_{x\leq 1/2}\mathbf{1}_{y>1/2} + \mathbf{1}_{x>1/2}\mathbf{1}_{y\leq 1/2}$ has $\|\mathbb{W}\| = \frac{1}{2}$ and $\lambda_{\min} = -\frac{1}{2}$), and then a sufficiently strong substitute coupling $|\mathsf{b}| \geq 1/|\lambda_{\min}|$ makes $I - \mathsf{b}\mathbb{W}$ indefinite, $\mathcal{V}$ non-convex, and the critical point a saddle rather than a minimizer. Substitutes are* unconditionally *unique only for positive semidefinite graphons ($\lambda_{\min} = 0$), where $\mathsf{b}\lambda_{\min} = 0 < 1$ for every $\mathsf{b} \leq 0$; the chapter's worked constant and rank-one kernels are PSD, so the claim is true there.*

Proof. The functional $\mathcal{V}$ is quadratic with the constant self-adjoint Hessian $H = I - \mathsf{b}\mathbb{W}$ computed above. We take the three equivalences in turn.

(i)⇔(ii). For a quadratic functional with constant Hessian H, strict convexity means $\langle s, Hs\rangle > 0$ for every $s \neq 0$, while (ii) is the uniform statement $\langle s, Hs\rangle \geq \eta\,\|s\|^2$ with $\eta > 0$. In a general infinite-dimensional Hilbert space these differ—a Hessian whose spectrum approached 0 would be strictly positive yet not uniformly so—but here they coincide, and the reason is exactly the compactness of $\mathbb{W}$ that the chapter keeps cashing in. By the spectral theorem for the compact self-adjoint operator $\mathbb{W}$ (theorem 2.26) its eigenvalues satisfy $\lambda_n \to 0$, so the spectral values $1 - \mathsf{b}\lambda_n$ of H converge to 1; their *only* possible accumulation point is $1 > 0$. Consequently, if each $1 - \mathsf{b}\lambda_n > 0$ then their infimum cannot be 0 (any subsequence tending to 0 would contradict convergence to 1), so the infimum is a strictly positive *minimum*, attained at an extreme eigenvalue. Strict positivity of the spectrum thus upgrades automatically to uniform positivity, giving (i)⇔(ii).

(ii)⇔(iii). The spectrum of $H = I - \mathsf{b}\mathbb{W}$ is obtained from that of $\mathbb{W}$ by the affine map $\mu \mapsto 1 - \mathsf{b}\mu$. Since $\mathbb{W}$ is compact self-adjoint, its spectrum is $\{\lambda_n\} \cup \{0\}$, the value 0 coming from the (generally infinite-dimensional) kernel of $\mathbb{W}$—the directions orthogonal to every eigenfunction, on which $\mathbb{W}$, and hence $\mathsf{b}\mathbb{W}$, acts as zero. Applying the affine map, the spectrum of H is $\{1 - \mathsf{b}\lambda_n\} \cup \{1\}$, where the isolated value 1 is the image of 0 and records that H acts as the identity on $\ker\mathbb{W}$. Because $1 > 0$ always, those kernel directions never threaten convexity; positivity of H is decided entirely

on the eigen-directions of $\mathbb{W}$. Hence $H \geq \eta I$ for some $\eta > 0$ iff $\inf_n(1 - \mathsf{b}\lambda_n) > 0$, which is iff $\sup_n \mathsf{b}\lambda_n < 1$, i.e. $\mathsf{b}\lambda_n < 1$ for every n—statement (iii).

Uniqueness. Under (i)–(iii) the functional $\mathcal{V}$ is uniformly convex, hence coercive, on the Hilbert space $L^2[0,1]$, and a coercive strictly convex functional has a unique minimizer. That minimizer is characterized by the vanishing of its gradient $\nabla\mathcal{V} = Hs - \alpha = 0$, which is exactly the GNE equation eq. (20.8); since the critical point is unique and is the global minimizer, the GNE is unique.

The binding eigenvalue. It remains to read condition (iii), $\sup_n \mathsf{b}\lambda_n < 1$, through the sign of b, using the spectral ordering $\lambda_1 = \|\mathbb{W}\| \geq \lambda_n \geq \lambda_{\min} \geq -\|\mathbb{W}\|$. When $\mathsf{b} > 0$ the map $\lambda \mapsto \mathsf{b}\lambda$ is increasing, so $\sup_n \mathsf{b}\lambda_n = \mathsf{b}\lambda_1$ is achieved at the *top* eigenvalue, and (iii) reads $\mathsf{b}\lambda_1 = \mathsf{b}\|\mathbb{W}\| < 1$. When $\mathsf{b} < 0$ the map is decreasing, so $\sup_n \mathsf{b}\lambda_n = \mathsf{b}\lambda_{\min}$ is achieved at the most *negative* eigenvalue, and (iii) reads $\mathsf{b}\lambda_{\min} = |\mathsf{b}|\,|\lambda_{\min}| < 1$. In the latter case the constraint is vacuous—and so holds for *every* $\mathsf{b} \leq 0$—exactly when $\lambda_{\min} = 0$, that is when $\mathbb{W}$ is positive semidefinite. □

The complete-bipartite assertion inside the theorem deserves the small computation that makes it concrete, because it is the cleanest demonstration that a nonnegative symmetric graphon really can carry a strictly negative eigenvalue—and so that the substitute case really is conditional. Write $g = \mathbf{1}_{x \leq 1/2}$ and $h = \mathbf{1}_{x > 1/2}$ for the indicators of the two halves of $[0,1]$; then the complete-bipartite kernel is the rank-two function $W(x,y) = g(x)h(y) + h(x)g(y)$, which is 1 when x and y lie on opposite sides of $\frac{1}{2}$ and 0 otherwise. Its operator acts by

$$(\mathbb{W}f)(x) \;=\; g(x)\langle h, f\rangle + h(x)\langle g, f\rangle,$$

so its range lies in $\operatorname{span}\{g,h\}$ and the entire spectrum, apart from the zero eigenvalue on $\operatorname{span}\{g,h\}^{\perp}$, is read off the 2×2 action on that span. Using the orthogonality $\langle g, h\rangle = 0$ and the norms $\langle g, g\rangle = \langle h, h\rangle = \frac{1}{2}$ (each half has length $\frac{1}{2}$), one finds $\mathbb{W}g = \frac{1}{2}\,h$ and $\mathbb{W}h = \frac{1}{2}\,g$, i.e. the matrix $\left(\begin{smallmatrix} 0 & 1/2 \\ 1/2 & 0 \end{smallmatrix}\right)$ in the basis $\{g,h\}$, whose eigenvalues are $\pm\frac{1}{2}$. The eigenfunction for $+\frac{1}{2}$ is the symmetric combination $g + h = \mathbf{1}$, the constant function: every type feels the same neighbor mass, and indeed $\mathbb{W}\mathbf{1} = \frac{1}{2}\mathbf{1}$, so $\lambda_1 = \|\mathbb{W}\| = \frac{1}{2}$. The eigenfunction for $-\frac{1}{2}$ is the antisymmetric combination $g - h$, which is $+1$ on the left half and -1 on the right: the two halves do *opposite* things, and $\mathbb{W}(g-h) = -\frac{1}{2}(g-h)$, so $\lambda_{\min} = -\frac{1}{2}$. This negative edge is the analytic trace of the bipartite structure—a node's neighbors all sit on the *other* side, so the natural mode is one in which the sides oppose one another. Now switch on a strong substitute coupling $\mathsf{b} < 0$ with $|\mathsf{b}| \geq 1/|\lambda_{\min}| = 2$. Along the antisymmetric mode $v = g - h$ the Hessian quadratic form is

$$\langle v, (I - \mathsf{b}\mathbb{W})v\rangle \;=\; (1 - \mathsf{b}\lambda_{\min})\,\|v\|^2 \;=\; \left(1 - |\mathsf{b}|\,\tfrac{1}{2}\right)\|v\|^2 \;\leq\; 0,$$

so $\mathcal{V}$ has a direction of nonpositive curvature: it is no longer convex, its critical point is a saddle rather than a minimizer, and uniqueness fails. Behaviorally this is exactly what a strong local public good on a bipartite network should do—when one side contributes heavily the other free-rides, and the roles can swap, so alongside the symmetric configuration there appear asymmetric ones in which one half works and the other coasts. The lesson the computation enforces is the hedged claim in the theorem: substitutes are *unconditionally* unique only when $\lambda_{\min} = 0$, i.e. for positive semidefinite graphons; the constant and rank-one kernels the chapter carries are PSD (a constant kernel is $c\,\mathbf{1}\otimes\mathbf{1}$, rank one and nonnegative definite; $W = ff$ is $f \otimes f \geq 0$), so on those the substitute claim is safe, but it is not a free general fact.

It is now worth stepping back to compare the two uniqueness routes side by side, because the comparison is not symmetric in the sign of the coupling, and that asymmetry is the conceptual heart of the subsection. The contraction route asked only the *magnitude* $L_{\mathrm{br}}\,\|\mathbb{W}\|$ to be small; the monotone route asks the *signed* quantity $\sup_n \mathsf{b}\lambda_n$ to be less than one. For complements these two demands turn out to be the very same line, while for substitutes the monotone demand is genuinely weaker—but only conditionally so. The following remark makes this precise and reads it as the static face of an asymmetry the reader already met in the dynamic theory.

Remark 20.16 (Two thresholds, one for complements)**.** For strategic complements the contraction threshold of theorem 20.14 ($\mathsf{b}\,\|\mathbb{W}\| < 1$, taking $L_{\mathrm{br}} = |\mathsf{b}| = \mathsf{b}$) and the monotone/convexity threshold of theorem 20.15(iii) ($\mathsf{b}\lambda_1 < 1$) *coincide*, because $\lambda_1 = \|\mathbb{W}\|$ by lemma 20.12. The two routes, spectral and variational, see the *same* edge from two sides: contraction sees the loop gain reaching one, convexity sees the soft mode ϕ_1 losing its restoring curvature, and they are the same event. The LQ complements game therefore has a sharp uniqueness boundary at $\mathsf{b}\,\|\mathbb{W}\| = 1$, with a unique GNE strictly below and the genuine multiplicity issues of section 20.4.2 at and above it; for the crowd-seeking sign there is exactly one threshold and nothing is gained by trading smallness for structure. For substitutes the picture differs. The monotone route is strictly stronger than contraction—it certifies uniqueness whenever $|\mathsf{b}|\,|\lambda_{\min}| < 1$, a strictly weaker requirement than the contraction bound $|\mathsf{b}|\,\|\mathbb{W}\| < 1$ precisely when $|\lambda_{\min}| < \lambda_1$—but it is *not* unconditional. It becomes the unconditional "all $\mathsf{b} < 0$" statement only for positive semidefinite graphons ($\lambda_{\min} = 0$); when the spectrum has a negative edge $\lambda_{\min} < 0$, a strong enough substitute coupling $|\mathsf{b}| \geq 1/|\lambda_{\min}|$ renders $I - \mathsf{b}\mathbb{W}$ indefinite, $\mathcal{V}$ non-convex, and *neither* route certifies uniqueness—exactly the complete-bipartite breakdown computed above. Modulo this caveat, the qualitative picture is the same asymmetry between attractive and repulsive coupling seen in the Lasry–Lions analysis of section 11.4: the "crowd-averse" (substitute) sign is tame over a wide range governed by the *weaker* spectral edge $|\lambda_{\min}|$ and is unconditionally tame when that edge sits at zero, while the "crowd-seeking" (complement) sign is constrained by the *top* eigenvalue λ_1 and has the single, sharp critical coupling at which the equilibrium begins to condense onto ϕ_1. The order parameter $\|\mathbb{W}\| = \lambda_1$ governs the dangerous, attractive side; the harmless, repulsive side is held off by the lesser edge $|\lambda_{\min}|$, which for the kernels we compute on is simply 0.

The monotone route also reaches beyond the linear–quadratic payoff, and it is worth recording how, both to place the present theorem in the larger architecture of the book and because the dynamic descendant in Part IV is built on exactly this idea. Nothing in the variational argument used the quadratic form of the payoff beyond two features: that the equilibrium condition is the gradient of *some* functional—the game is a potential game—and that this functional is convex. For a general aggregative game these become, respectively, a symmetry condition on the cross-partials of the payoff (so that a potential exists) and a monotonicity condition pitting the concavity of each agent's own-action response against the spectral amplification $\|\mathbb{W}\|$ of the coupling (so that the potential is convex); when both hold, uniqueness follows by the identical "strictly-convex-functionals-have-one-minimizer" argument, with the LQ Hessian $I - \mathsf{b}\mathbb{W}$ replaced by the second variation of the nonlinear potential. We do not develop the fully nonlinear monotone theory here—the LQ case already exhibits every structural feature we need—but it is precisely the static specialization of the Lasry–Lions monotonicity of definition 11.1, and its dynamic, measure-valued form, where the inner product $\langle\,\cdot\,,(I-\mathsf{b}\mathbb{W})\,\cdot\,\rangle$ is replaced by a monotone coupling functional on densities, is the engine of the existence-and-uniqueness theory of chapter 24. We record this correspondence in the chapter ledger.

It remains to discharge the debt the contraction subsection flagged toward the centrality harvest. Whichever route certifies it, the operative conclusion for what follows is the same: in the positive-definite regime—subcritical complements $0 \le \mathsf{b}\lambda_1 < 1$, or substitutes $\mathsf{b} < 0$ with $|\mathsf{b}||\lambda_{\min}| < 1$, which on the chapter's PSD kernels means *any* $\mathsf{b} < 0$—the operator $I - \mathsf{b}\mathbb{W}$ has spectrum bounded away from zero and is therefore boundedly invertible, with a unique GNE $s^* = (I - \mathsf{b}\mathbb{W})^{-1}\alpha$. And wherever the coupling is additionally subcritical in magnitude, $|\mathsf{b}|\,\|\mathbb{W}\| < 1$, that inverse is delivered by the convergent Neumann series $\sum_{k\ge 0} \mathsf{b}^k\mathbb{W}^k$—the resummed feedback of every order of neighbor response. This invertibility, and that series, are exactly the standing hypotheses on which the next section rests: section 20.5 takes the unique equilibrium $(I - \mathsf{b}\mathbb{W})^{-1}\alpha$ as given and asks not *whether* it exists but *what it is*, identifying it—through the very Neumann expansion just named—with a recognizable network centrality. Having certified the inverse from two sides, we are free to harvest it.

20.5 Centrality determines strategy

The previous two subsections did the hard work of certifying an inverse; this one spends it. Sections 20.4.2 and 20.4.3 closed by handing us a single operative fact, proved twice over—once by the contraction and once by the convexity of the potential—and it is the only thing the present section needs as input: in the regime they delimited (made precise in the standing hypotheses just below), the static LQ game of example 20.3 has a unique graphon Nash equilibrium given by the resolvent, $s^* = (I - \mathsf{b}\mathbb{W})^{-1}\alpha$. We no longer ask *whether* that equilibrium exists. We ask what it *is*—and the answer, the entire content of this section, is that it is a recognizable *network centrality*, a quantity a network scientist would have computed from the kernel W alone, with no game in sight.

Let us fix the standing regime precisely, because every statement below lives inside it. The payoff is the linear–quadratic one of eq. (20.6), the action set is the whole line $S = \mathbb{R}$ (so no clipping intervenes and the equilibrium is genuinely the linear solution eq. (20.8), not a constrained variant), and the coupling sits in the positive-definite window certified in section 20.4: either subcritical strategic complements, $0 \le \mathsf{b}\,\|\mathbb{W}\| < 1$, or strategic substitutes of any strength on the positive-semidefinite kernels of this chapter, $\mathsf{b} < 0$. By theorems 20.14 and 20.15 this is exactly the regime in which $I - \mathsf{b}\mathbb{W}$ is invertible, and wherever the coupling is moreover subcritical in magnitude, $|\mathsf{b}|\ \|\mathbb{W}\| < 1$, that inverse is delivered termwise by the convergent Neumann series $\sum_{k\ge 0} \mathsf{b}^k\mathbb{W}^k$. That series—the resummed feedback of every order of mutual best response, first written down at the end of section 20.1.3—is the machine the whole section runs on, and it is what makes the identification with a centrality not merely suggestive but literal.

Here is why that identification is worth a section rather than a sentence. Reading the equilibrium as a centrality vector is the move that converts three otherwise distinct strategic questions into one and the same spectral computation on $\mathbb{W}$. *Ranking*: who, in equilibrium, exerts the most effort? Once s^* is a centrality, this is answered by ordering players by a structural score read off the kernel, not by solving the game player by player. *Spillover prediction*: if one player's standalone incentive rises, whose equilibrium effort moves, and by how much? Since s^* depends on α through the linear operator $(I - \mathsf{b}\mathbb{W})^{-1}$, the entire propagation of a local shock through the network is encoded in that one resolvent, walk by walk. *Intervention design*: which player should a planner subsidize to raise aggregate effort the most? This becomes an optimization against the same operator, ranking targets by a centrality of their own. The single algebraic object $(I - \mathsf{b}\mathbb{W})^{-1}$ thus answers all three at once, and the order parameter $\|\mathbb{W}\| = \lambda_1$ that we have watched the whole chapter is precisely what controls how violently it responds—gently far below threshold, explosively as $\mathsf{b}\lambda_1 \to 1$.

The section delivers this in three movements, and it is worth seeing them in advance as one arc rather than three separate results. First (section 20.5.1) we *name* the centrality: the Neumann series identifies s^* exactly with the Katz–Bonacich centrality of the graphon, the b-discounted count of all weighted walks emanating from each type, so that equilibrium effort *is* a walk-counting score. Second (section 20.5.2) we push the coupling toward its critical value and watch that score *degenerate*: as $\mathsf{b}\lambda_1 \to 1$ the $k = 1$ eigen-direction ϕ_1 dominates the series, every type's effort aligns with the single top mode, and Katz–Bonacich centrality collapses onto eigenvector centrality while its overall magnitude—the susceptibility—diverges. Third (section 20.5.3) we put the centrality to work: differentiating s^* in the data turns comparative statics and optimal targeting into spectral computations, so the planner's best intervention is itself ranked by a centrality. Centrality, then criticality, then targeting: a recognizable score, its breakdown at the spectral edge, and its use as a design tool—all three are one reading of the resolvent $(I - \mathsf{b}\mathbb{W})^{-1}$.

We begin with the naming. The next subsection picks up the Neumann series just invoked and uses it to pin down exactly which centrality the equilibrium equals.

20.5.1 Equilibrium effort is Katz–Bonacich centrality

Definition 20.17 (Katz–Bonacich centrality)**.** For b with $|\mathsf{b}|\ \|\mathbb{W}\| < 1$ and a weight $\alpha \in L^2[0, 1]$, the *Katz–Bonacich centrality profile* with discount b and weights α is

$$\mathbf{c}_{\mathsf{b}}[\alpha] \;:=\; (I - \mathsf{b}\mathbb{W})^{-1}\alpha \;=\; \sum_{k=0}^{\infty} \mathsf{b}^k\, \mathbb{W}^k\, \alpha \;=\; \alpha + \mathsf{b}\mathbb{W}\alpha + \mathsf{b}^2\mathbb{W}^2\alpha + \cdots . \tag{20.22}$$

When $\alpha = \mathbf{1}$ we write $\mathbf{c}_{\mathsf{b}} := \mathbf{c}_{\mathsf{b}}[\mathbf{1}]$ for the *unweighted* centrality, which counts, for each type, the b-discounted total weight of all walks in the graphon emanating from that type.

The two expressions in eq. (20.22) agree, and both define a bounded operator, precisely because $\|\mathsf{b}\mathbb{W}\| = |\mathsf{b}|\ \|\mathbb{W}\| < 1$. We spell this out, since the Neumann series is the engine of the whole section. The bounded operators on $L^2[0, 1]$ form a Banach space under the operator norm, which is submultiplicative, $\left\|(\mathsf{b}\mathbb{W})^k\right\| \le \|\mathsf{b}\mathbb{W}\|^k$; hence the partial sums $S_M = \sum_{k=0}^{M} \mathsf{b}^k\mathbb{W}^k$ are Cauchy ($\|S_M - S_{M'}\| \le \sum_{k>M'} \|\mathsf{b}\mathbb{W}\|^k \to 0$) and converge in operator norm to some bounded S. Multiplying the telescoping identity $(I - \mathsf{b}\mathbb{W})S_M = I - (\mathsf{b}\mathbb{W})^{M+1}$ and its mirror by passing $M \to \infty$ (the remainder $(\mathsf{b}\mathbb{W})^{M+1} \to 0$ in norm) gives $(I - \mathsf{b}\mathbb{W})S = S(I - \mathsf{b}\mathbb{W}) = I$, so S is the two-sided bounded inverse $(I - \mathsf{b}\mathbb{W})^{-1}$. Equivalently, and consistently with the spectral computations to come: by the spectral theorem (theorem 2.26) $I - \mathsf{b}\mathbb{W}$ acts as the scalar $1 - \mathsf{b}\lambda_n$ on each eigenfunction ϕ_n and as 1 on

$\ker \mathbb{W}$, and since $|\mathsf{b}\lambda_n| \leq |\mathsf{b}|\,\|\mathbb{W}\| < 1$ each factor $1 - \mathsf{b}\lambda_n$ is bounded away from 0; its bounded inverse therefore acts as $1/(1-\mathsf{b}\lambda_n)$ on ϕ_n and as 1 on $\ker \mathbb{W}$, which is exactly the diagonal action of the series $\sum_k \mathsf{b}^k \mathbb{W}^k$ term by term. The term $\mathbb{W}^k\alpha$ is the aggregate, over length-k weighted walks, of the standalone returns, and b^k discounts long walks. This is exactly the discrete Katz–Bonacich centrality lifted to the graphon.

Theorem 20.18 (Centrality $\Rightarrow$ strategy). *In the subcritical LQ graphon game, the unique GNE is the Katz–Bonacich centrality profile*

$$s^* \;=\; (I - \mathsf{b}\mathbb{W})^{-1}\alpha \;=\; \mathbf{c}_{\mathsf{b}}[\alpha]. \tag{20.23}$$

If the standalone return is uniform, $\alpha \equiv \alpha_0$ constant, then $s^* = \alpha_0\,\mathbf{c}_{\mathsf{b}}$ is proportional to the unweighted centrality profile, and the equilibrium effort of a type is an increasing function of its centrality: types with more, and more central, neighbors exert more effort.

Proof. Equation (20.8) reads $(I - \mathsf{b}\mathbb{W})s^* = \alpha$, and under subcriticality $I - \mathsf{b}\mathbb{W}$ is boundedly invertible with inverse the Neumann series eq. (20.22), giving eq. (20.23). For $\alpha \equiv \alpha_0$, linearity gives $s^* = \alpha_0(I - \mathsf{b}\mathbb{W})^{-1}\mathbf{1} = \alpha_0\mathbf{c}_{\mathsf{b}}$. Monotonicity in centrality is the statement that the operator $(I - \mathsf{b}\mathbb{W})^{-1} = \sum_k \mathsf{b}^k\mathbb{W}^k$ has a nonnegative kernel when $\mathsf{b} \geq 0$ (each $\mathbb{W}^k$ has the nonnegative iterated kernel $W^{(k)} \geq 0$), so a type with pointwise larger row sums in every $W^{(k)}$ has pointwise larger s^*. $\square$

Notation watch

The discount b in the centrality eq. (20.22) is the *strategic interaction coefficient* of the game, not the discount *rate* $\beta = \beta$ reserved for intertemporal control problems (appendix A.4). In static graphon games no time and no β appear; the letter b is the game's own complementarity parameter. We use the distinct symbol b throughout precisely to avoid this collision.

20.5.2 Eigenvector centrality at criticality

As the coupling approaches its critical value, the centrality profile loses its dependence on the fine structure of α and aligns with a single network mode: the eigenvector centrality ϕ_1.

Theorem 20.19 (Emergence of eigenvector centrality). *Assume **(A-Reg-W)** with a* simple *top eigenvalue λ_1 (spectral gap $\lambda_1 > \lambda_2$), and let $\phi_1 \geq 0$ be its unit eigenfunction. Fix $\alpha \in L^2[0,1]$ with $\langle \alpha, \phi_1\rangle \neq 0$. Then for strategic complements $\mathsf{b} \uparrow 1/\lambda_1 = 1/\|\mathbb{W}\|$ the normalized equilibrium profile aligns with eigenvector centrality:*

$$\frac{s^*}{\|s^*\|_{L^2}} \xrightarrow[\mathsf{b}\uparrow 1/\lambda_1]{} \operatorname{sgn}(\langle \alpha, \phi_1\rangle)\,\phi_1 \qquad \textit{in } L^2[0,1], \tag{20.24}$$

and the equilibrium effort diverges, $\|s^*\|_{L^2} \to \infty$, with leading behavior

$$s^* \;=\; \frac{\langle \alpha, \phi_1\rangle}{1 - \mathsf{b}\lambda_1}\,\phi_1 \;+\; O(1) \qquad (\mathsf{b} \uparrow 1/\lambda_1). \tag{20.25}$$

Proof. Expand α and s^* in the eigenbasis (ϕ_n): writing $\alpha = \sum_n a_n\phi_n$ with $a_n = \langle\alpha, \phi_n\rangle$, the diagonal action of $(I - \mathsf{b}\mathbb{W})^{-1}$ gives

$$s^* = (I - \mathsf{b}\mathbb{W})^{-1}\alpha = \sum_n \frac{a_n}{1 - \mathsf{b}\lambda_n}\,\phi_n.$$

As $\mathsf{b} \uparrow 1/\lambda_1$ the $n = 1$ coefficient $a_1/(1 - \mathsf{b}\lambda_1)$ blows up, while every $n \geq 2$ coefficient stays bounded because $1 - \mathsf{b}\lambda_n \to 1 - \lambda_n/\lambda_1 > 0$ by the spectral gap. Splitting off the top mode,

$$s^* = \frac{a_1}{1 - \mathsf{b}\lambda_1}\phi_1 + r, \qquad \|r\|^2 = \sum_{n\geq 2} \frac{a_n^2}{(1 - \mathsf{b}\lambda_n)^2} \leq \frac{\|\alpha\|^2}{(1 - \lambda_2/\lambda_1)^2} = O(1),$$

which is eq. (20.25). Dividing by $\|s^*\|$ and letting $\mathsf{b} \uparrow 1/\lambda_1$, the bounded remainder is negligible against the diverging top term, yielding eq. (20.24) with the sign of $a_1 = \langle\alpha, \phi_1\rangle$. □

Physics note

Theorem 20.19 is the static graphon game's order-parameter statement. Below criticality the equilibrium reflects the whole spectrum of the network, weighted by how the standalone incentives α project onto each mode. As the coupling is tuned to the critical value $1/\lambda_1$, a single collective mode—the top eigenfunction, the eigenvector centrality ϕ_1—takes over, and the equilibrium profile becomes, up to normalization, *independent of the microscopic incentives* α, retaining only the scalar overlap $\langle\alpha, \phi_1\rangle$. This is condensation onto the soft mode: near the critical coupling the population organizes itself along the network's principal axis, exactly as a system near a continuous transition is dominated by its longest-wavelength fluctuation. The divergence $\|s^*\| \sim (1 - \mathsf{b}\lambda_1)^{-1}$ is the susceptibility divergence of the previous physics note, now resolved into the direction ϕ_1 along which it occurs.

20.5.3 Interventions and comparative statics

The closed form eq. (20.23) turns equilibrium analysis into linear algebra and makes precise how a planner who can perturb the standalone incentives should target the network. Suppose a planner adds an incentive perturbation $\delta\alpha \in L^2[0, 1]$ to the standalone returns, changing $\alpha \mapsto \alpha + \delta\alpha$. By linearity the equilibrium shifts by

$$\delta s^* \;=\; (I - \mathsf{b}\mathbb{W})^{-1}\,\delta\alpha \;=\; \mathbf{c}_{\mathsf{b}}[\delta\alpha], \tag{20.26}$$

the Katz–Bonacich centrality of the perturbation itself. The induced change in *aggregate equilibrium effort* $\Sigma(s) := \langle\mathbf{1}, s\rangle = \int_0^1 s$ is

$$\delta\Sigma = \langle\mathbf{1}, (I - \mathsf{b}\mathbb{W})^{-1}\delta\alpha\rangle = \langle(I - \mathsf{b}\mathbb{W})^{-1}\mathbf{1}, \delta\alpha\rangle = \langle\mathbf{c}_{\mathsf{b}}, \delta\alpha\rangle, \tag{20.27}$$

using self-adjointness of $(I - \mathsf{b}\mathbb{W})^{-1}$. Equation (20.27) is the key-player principle in graphon form: to maximize the aggregate response per unit of (suitably normalized) incentive, the planner should concentrate $\delta\alpha$ on the types of highest unweighted centrality $\mathbf{c}_{\mathsf{b}}$. We summarize.

Proposition 20.20 (Comparative statics and optimal targeting)**.** *In the subcritical LQ graphon game:*

(i) (Monotone response.) *For complements* $\mathsf{b} \geq 0$*, the equilibrium response operator* $(I - \mathsf{b}\mathbb{W})^{-1}$ *has a nonnegative kernel; hence* $\delta\alpha \geq 0$ *implies* $\delta s^* \geq 0$ *pointwise: raising any type's standalone return raises every type's equilibrium effort.*

(ii) (Centrality ranks the marginal value of targeting.) *The marginal effect on aggregate effort of an incentive placed on type* x_0 *(formally* $\delta\alpha = \varepsilon\, \delta_{x_0}$*, or a narrow bump around* x_0*) is, to first order,* $\varepsilon\, \mathbf{c}_{\mathsf{b}}(x_0)$*. The optimal type to target, under a unit budget* $\|\delta\alpha\|_{L^2} \leq 1$*, is the direction* $\delta\alpha = \mathbf{c}_{\mathsf{b}} / \|\mathbf{c}_{\mathsf{b}}\|$*, achieving* $\delta\Sigma = \|\mathbf{c}_{\mathsf{b}}\|_{L^2}$*.*

(iii) (Amplification grows with coupling.) *Each entry of* $\mathbf{c}_{\mathsf{b}}$ *is nondecreasing in* $\mathsf{b} \in [0, 1/\lambda_1)$*, and* $\|\mathbf{c}_{\mathsf{b}}\| \to \infty$ *as* $\mathsf{b} \uparrow 1/\lambda_1$*: the same intervention has unboundedly larger leverage as the network approaches criticality, with the leverage concentrating on the eigenvector-centrality direction* ϕ_1 *by theorem 20.19.*

Proof. (i) The Neumann kernel $\sum_k \mathsf{b}^k W^{(k)}$ is a sum of nonnegative iterated kernels for $\mathsf{b} \geq 0$; nonnegative kernels map nonnegative functions to nonnegative functions. (ii) is eq. (20.27) with $\delta\alpha$ a unit bump, optimized by Cauchy–Schwarz, whose equality case is $\delta\alpha \propto \mathbf{c}_{\mathsf{b}}$. (iii) Each entry of $\mathbf{c}_{\mathsf{b}} = \sum_k \mathsf{b}^k \mathbb{W}^k \mathbf{1}$ is a power series in b with nonnegative coefficients, hence nondecreasing; and projecting onto ϕ_1, $\langle \mathbf{c}_{\mathsf{b}}, \phi_1 \rangle = \langle \mathbf{1}, \phi_1 \rangle / (1 - \mathsf{b}\lambda_1) \to \infty$ forces $\|\mathbf{c}_{\mathsf{b}}\| \to \infty$, with the alignment from theorem 20.19. □

These statements are the static payoff of the whole construction: once the equilibrium is identified with a centrality vector, ranking players, predicting the sign and size of spillovers, and choosing where to intervene all become spectral computations on $\mathbb{W}$. The dynamic chapters inherit this vocabulary; the "key player" of proposition 20.20 becomes the optimally targeted type in the dynamic interventions of chapter 30.

20.6 Worked computation: the static Thread B game

We now introduce the static incarnation of Thread B (the graphon LQG model of appendix A.7) and solve it on the three diagnostic kernels. This is the chapter's carried-thread duty: it instantiates the abstract theory on the exact model that the dynamic chapters will carry forward, and it exhibits the aggregate $z(x) = (\mathbb{W}\bar{m})(x)$ in its simplest form.

20.6.1 The static reduction of Thread B

Worked computation 20.21 (Static Thread B: graphon-aggregate best response)**.** Recall the dynamic Thread B model of appendix A.7: a type-x agent controls a scalar state X_t^x and is penalized for deviating from $s\, z_t(x)$, where $z_t(x) = (\mathbb{W}\bar{m}_t)(x)$ is the graphon-aggregated neighbor mean and s is the fixed coupling strength. In the *static reduction* we freeze time: each type chooses a single stationary position $\bar{m}(x) \in \mathbb{R}$ (its equilibrium mean state), pays a quadratic cost of effort to hold a position away from a neutral target—which we normalize to a type-dependent ideal point $\eta(x)$—and a quadratic congestion/imitation cost for deviating from the aggregate it feels. Concretely, type x chooses $\bar{m}(x)$ to minimize the static cost

$$\mathcal{C}_x(\bar{m}(x); z(x)) \;=\; \tfrac{1}{2}\big(\bar{m}(x) - \eta(x)\big)^2 \;+\; \tfrac{q}{2}\big(\bar{m}(x) - s\,z(x)\big)^2, \qquad z(x) = (\mathbb{W}\bar{m})(x), \tag{20.28}$$

with $q \geq 0$ the relative weight of the congestion term and s the Thread B coupling strength. The first-order condition $\partial_{\bar{m}(x)}\mathcal{C}_x = 0$ reads $(\bar{m}(x) - \eta(x)) + q(\bar{m}(x) - s\,z(x)) = 0$, i.e.

$$\bar{m}(x) \;=\; \frac{1}{1+q}\,\eta(x) \;+\; \frac{qs}{1+q}\,(\mathbb{W}\bar{m})(x). \tag{20.29}$$

This is exactly the linear graphon equation eq. (20.8) with the dictionary

$$\text{strategy } s_{\text{gen}} \leftrightarrow \bar{m}, \qquad \alpha \leftrightarrow \frac{\eta}{1+q}, \qquad \mathsf{b} \leftrightarrow \frac{qs}{1+q}, \qquad L_{\text{br}} = |\mathsf{b}| = \frac{q|s|}{1+q}. \tag{20.30}$$

The static graphon game is therefore an LQ game in the sense of example 20.3, and all of theorems 20.14, 20.15, 20.18 and 20.19 and proposition 20.20 apply verbatim. The static Thread B equilibrium exists, and is unique, whenever the equilibrium operator $I - \mathsf{b}\mathbb{W}$ is invertible; by theorem 20.15 the clean sufficient condition is the spectral one

$$\mathsf{b}\,\lambda_1 \;=\; \frac{qs}{1+q}\,\lambda_1 \;<\; 1 \quad (s>0,\text{ complements}), \qquad |\mathsf{b}|\,|\lambda_{\min}| \;=\; \frac{q|s|}{1+q}\,|\lambda_{\min}| \;<\; 1 \quad (s<0,\text{ substitutes}), \tag{20.31}$$

the substitute branch being automatic for all $s \leq 0$ only when $\mathbb{W}$ is positive semidefinite ($\lambda_{\min} = 0$). When unique it is given by the centrality formula $\bar{m}^* = (I - \mathsf{b}\mathbb{W})^{-1}\frac{\eta}{1+q} = \frac{1}{1+q}\mathsf{c}_{\mathsf{b}}[\eta]$.

(a) Constant kernel $W \equiv c$ (Curie–Weiss / Thread A shadow). Here $\mathbb{W}\bar{m} = c\int_0^1 \bar{m} = c\,\overline{\bar{m}}$, the population grand mean, so the aggregate is the same scalar for every type and eq. (20.29) reduces to a single scalar self-consistency. With $\eta \equiv \eta_0$ constant the equilibrium is uniform, $\bar{m}^*(x) \equiv \mu^*$, where $\mu^* = \frac{\eta_0}{1+q} + \mathsf{b}c\,\mu^*$, giving

$$\mu^* = \frac{\eta_0/(1+q)}{1 - \mathsf{b}c} = \frac{\eta_0}{1+q-qsc}, \qquad \text{well defined iff } \mathsf{b}c = \frac{qsc}{1+q} < 1.$$

This is precisely the static, anonymous LQG closure—the Thread A mean-field fixed point with the global coupling rescaled by c—recovering the constant-graphon reduction promised in appendix A.7. The static uniqueness boundary here is $\mathsf{b}c = \frac{qsc}{1+q} = 1$, i.e. $s_{\text{crit}} = (1+q)/(qc)$. This is the static shadow of the Thread A critical attraction line $s = 1$ of proposition 11.8 (the $a = 0$ multiplicity threshold of remark 11.9) in a *structural*, not a numerical, sense: both mark the point at which the effective coupling reaches the inverse of the top eigenvalue, so that the self-consistent mean ceases to be uniquely determined. The two are not related by a direct substitution of parameters—Thread A's $s = 1$ is independent of q, whereas the static threshold $s_{\text{crit}} = (1+q)/(qc)$ depends on q and equals 1 (at $c = 1$) only in the strong-congestion limit $q \to \infty$, where $\mathsf{b} = \frac{qs}{1+q} \to s$. As section 20.7 explains, the static b is a Riccati composite of the dynamic data, not a literal (q, c) reading of s; the correspondence is the alignment of two "coupling hits the inverse top eigenvalue" thresholds, not a parameter identity.

(b) Rank-one kernel $W(x,y) = f(x)f(y)$ (the clean GMFG reduction). By worked computation 2.28(b), $\mathbb{W}g = \langle g, f\rangle f$ and $\|\mathbb{W}\| = \lambda_1 = \int_0^1 f^2$. The aggregate collapses to a single scalar *order parameter* times the fixed profile f: $z(x) = (\mathbb{W}\bar{m})(x) = \varrho\, f(x)$ with $\varrho := \langle \bar{m}, f\rangle$. Inserting into eq. (20.29),

$$\bar{m}(x) = \frac{\eta(x)}{1+q} + \mathsf{b}\,\varrho\, f(x).$$

Projecting onto f (taking $\langle \cdot, f\rangle$ of both sides) closes the system on the single scalar ϱ:

$$\varrho = \langle \bar{m}, f\rangle = \frac{\langle \eta, f\rangle}{1+q} + \mathsf{b}\,\varrho\,\|f\|_{L^2}^2 = \frac{\langle \eta, f\rangle}{1+q} + \mathsf{b}\lambda_1\,\varrho \quad\Longrightarrow\quad \varrho^* = \frac{\langle \eta, f\rangle}{(1+q)(1-\mathsf{b}\lambda_1)},$$

well defined exactly under eq. (20.31). The full equilibrium is then the explicit profile

$$\bar{m}^*(x) = \frac{\eta(x)}{1+q} + \frac{\mathsf{b}\,\langle \eta, f\rangle}{(1+q)(1-\mathsf{b}\lambda_1)}\, f(x), \tag{20.32}$$

a baseline term proportional to the type's own ideal point plus a network term proportional to the eigenvector centrality f with a coefficient that diverges as $\mathsf{b}\lambda_1 \uparrow 1$—the rank-one instance of theorem 20.19, here exact rather than asymptotic because there is only one nonzero mode. The whole continuum game has collapsed to a single scalar equation for ϱ^*: this is the cleanest worked graphon equilibrium, and it is the static skeleton of the dynamic rank-one reduction taken up in chapter 22.

(c) Block kernel (finite multi-population reduction). Let W be piecewise constant on a partition $[0,1] = \bigsqcup_{k=1}^K I_k$ with $|I_k| = p_k$ and $W(x,y) = \mathsf{B}_{k\ell}$ for $x \in I_k, y \in I_\ell$, the symmetric block (stochastic-block-model) graphon. Because W is block-constant, the aggregate felt by a type depends only on its block: for $x \in I_k$, $(\mathbb{W}\bar{m})(x) = \sum_\ell \mathsf{B}_{k\ell}\int_{I_\ell}\bar{m} = \sum_\ell \mathsf{B}_{k\ell}\, p_\ell\, \mathfrak{m}_\ell$ with $\mathfrak{m}_\ell := \frac{1}{p_\ell}\int_{I_\ell}\bar{m}$ the block-averaged mean. Hence the *aggregate* term in the first-order condition eq. (20.29) is block-constant, but the equilibrium profile itself is *not* piecewise constant unless η is: taking the block average of eq. (20.29) closes a $K \times K$ linear system on the block means,

$$\mathfrak{m}_k = \frac{\bar{\eta}_k}{1+q} + \mathsf{b}\sum_{\ell=1}^K \mathsf{B}_{k\ell}\, p_\ell\, \mathfrak{m}_\ell, \qquad \bar{\eta}_k = \frac{1}{p_k}\int_{I_k}\eta, \tag{20.33}$$

i.e. $(I - \mathsf{b}\,\mathsf{B}\,\mathrm{P})\,\mathbf{m} = \frac{1}{1+q}\bar{\boldsymbol{\eta}}$ with $\mathrm{P} = \mathrm{diag}(p_1, \ldots, p_K)$, and the full equilibrium is then recovered pointwise as

$$\bar{m}^*(x) = \frac{\eta(x)}{1+q} + \mathsf{b}\sum_{\ell=1}^K \mathsf{B}_{k\ell}\, p_\ell\, \mathfrak{m}_\ell \qquad (x \in I_k), \tag{20.34}$$

which carries the within-block variation of $\eta(x)$ on top of the block-constant network term; it collapses to the piecewise-constant profile $\bar{m}^* \equiv \mathfrak{m}_k$ on I_k exactly when η is itself block-constant. The block means $\mathfrak{m}_k$ thus solve the equilibrium of a finite K-population network game, with $\|\mathbb{W}\|$ now the top eigenvalue of the $K \times K$ matrix $\mathsf{B}\,\mathrm{P}$ (similar to the symmetric $\mathrm{P}^{1/2}\mathsf{B}\,\mathrm{P}^{1/2}$, hence real). Uniqueness of the block system holds for complements iff $\mathsf{b}\,\lambda_1(\mathsf{BP}) < 1$ and for substitutes iff $|\mathsf{b}|\,|\lambda_{\min}(\mathsf{BP})| < 1$; an SBM block matrix can have negative eigenvalues, so even within this worked example strong substitutes can break uniqueness, in accordance with theorem 20.15. The graphon game thus contains finite multi-population games as its block special case—the bridge to chapter 30—and the operator-norm threshold reduces to the spectral radius of a finite matrix.

The three reductions confirm the dictionary entries promised in appendix A.7: constant W gives back the anonymous (Thread A) closure, rank-one W collapses to a one-parameter self-consistent equation, and block W recovers finite multi-population games. In every case the existence/uniqueness boundary is $\mathsf{b}\,\|\mathbb{W}\| = 1$, the spectral threshold of theorem 20.14.

20.7 The static game as the stationary shadow

It remains to say in what precise sense this entire static theory is the "stationary shadow" of the dynamic graphon mean field game that occupies the rest of Part IV. The phrase is not merely an analogy; it is a limit, and identifying it now orients the reader for chapters 21, 22 and 24.

Consider the dynamic Thread B model with a discount rate $\beta > 0$ and an infinite horizon, or equivalently a long horizon $T \to \infty$ with ergodic averaging. The type-x agent solves a stationary stochastic control problem whose data depend on the population only through the time-frozen aggregate $z(x) = (\mathbb{W}\bar{m})(x)$, where $\bar{m}(y)$ is now the *stationary* mean of the type-y population. Two facts, both established in the classical theory and lifted to graphons in chapters 22 and 24, make the reduction exact in the LQG case:

1. For a fixed aggregate field $z(\cdot)$, the stationary LQG control problem of each type has an optimal feedback that is affine in the state, and the induced stationary population mean $\bar{m}(x)$ is an affine function of the felt aggregate $z(x)$ (the static reduction of the Riccati/mean system of section 14.4). This is the map $z(x) \mapsto \bar{m}(x)$ whose graph is the best response eq. (20.29).

2. Closing the loop, the stationary mean field must reproduce the aggregate that generated it: $z = \mathbb{W}\bar{m}$. This self-consistency is exactly the GNE condition eq. (20.5), with the per-type stationary mean $\bar{m}$ in the role of the strategy profile.

Thus the stationary graphon mean field equilibrium *is* a graphon Nash equilibrium of a static graphon game whose payoff is the type's stationary cost-to-hold-a-mean. The coupling coefficient b of the static game is the composite of the dynamic congestion weight, the discount rate, and the Riccati gain; the operator $\mathbb{W}$ is untouched. In particular the critical coupling $\mathsf{b}\,\|\mathbb{W}\| = 1$ of theorem 20.14 is the static face of the uniqueness threshold for the dynamic graphon mean field game, the threshold that reappears—now competing with strategic monotonicity—as assumption **(A-Coupling)** in chapter 24. This is why the static analysis is worth doing first: every structural feature of the dynamic theory (existence by compactness of $\mathbb{W}$, the spectral uniqueness threshold, centrality as the equilibrium order parameter, the susceptibility divergence at criticality) is already visible, and provable in a paragraph, before a single PDE is written down.

Remark 20.22 (What the static theory cannot see)**.** The reduction is honest about its losses. Freezing time discards the transient forward–backward coupling that is the structural signature of mean field games (appendix A.1): the static game has no terminal condition, no backward value propagation, and no Fokker–Planck transport. It can therefore say nothing about how an equilibrium is approached, about out-of-equilibrium dynamics, or about phenomena—common noise, time-inconsistency, finite-horizon boundary layers—that are invisible to the stationary fixed point. The static game is the t-independent skeleton; chapters 21 to 24 and 26 put the flesh back on.

Rigor ledger

Proved.

- theorem 20.9: under **(A-Reg-W)** and strong concavity (assumption 20.5), a static graphon game has a GNE—by Schauder (theorem 2.38) using compactness of $\mathbb{W}$, for bounded actions with no coupling restriction, and for unbounded actions under subcriticality. Set-valued version by Kakutani (remark 20.11).
- lemma 20.6: the best response is Lipschitz in the aggregate with constant $L_{\text{br}} = \ell/\theta$, $= |\mathsf{b}|$ for the LQ payoff.
- lemma 20.12: for a nonnegative symmetric kernel, $\|\mathbb{W}\| = \lambda_1 > 0$ with nonnegative top eigenfunction (eigenvector centrality).
- theorem 20.14: under **(A-Coupling)** in the form $L_{\text{br}} \|\mathbb{W}\| < 1$, the GNE is unique and the best-response iteration converges geometrically.
- theorem 20.15: for the LQ game, uniqueness $\Leftrightarrow$ positive definiteness of $I - \mathsf{b}\mathbb{W} \Leftrightarrow \mathsf{b}\lambda_n < 1$ for all n; complements share the threshold $\mathsf{b}\lambda_1 = \mathsf{b}\|\mathbb{W}\| < 1$ with contraction, while substitutes ($\mathsf{b} < 0$) are unique iff $|\mathsf{b}|\,|\lambda_{\min}| < 1$—unconditionally so only for positive semidefinite graphons ($\lambda_{\min} = 0$).
- theorems 20.18 and 20.19: the subcritical LQ equilibrium is Katz–Bonacich centrality $(I - \mathsf{b}\mathbb{W})^{-1}\alpha$; as $\mathsf{b} \uparrow 1/\lambda_1$ it aligns (after normalization) with eigenvector centrality ϕ_1 and diverges.
- proposition 20.20: monotone comparative statics, the centrality-ranked key-player principle, and divergence of intervention leverage at criticality.
- worked computation 20.21: the static Thread B game is LQ; solved in closed form on the constant, rank-one, and block kernels, with the spectral threshold $\mathsf{b}\|\mathbb{W}\| = 1$ in each case.

Assumed.

- **(A-Reg-W)**: W symmetric, measurable, bounded; $\mathbb{W}$ self-adjoint Hilbert–Schmidt (imported from chapters 2, 15 and 18; proposition 2.24).
- Concavity/strong-concavity of payoffs (assumption 20.5); for the LQ benchmark this is automatic.
- The spectral theorem and min–max for compact self-adjoint operators (theorem 2.26 and corollary 2.27) and the three fixed-point theorems (theorems 2.36, 2.38 and 2.40), all proved in chapter 2.

Deferred.

- The full graphon spectral theory and the rigorous standing of eigenvector centrality and the spectral gap → chapter 18.
- Justification of the static game as a limit of finite network games on sampled graphs $G(N, W)$ → chapters 19 and 25.
- The nonlinear monotone-operator uniqueness theory beyond the LQ potential case, and its measure-valued dynamic form → chapter 24 (static specialization of definition 11.1).
- The precise dynamic-to-static reduction (section 20.7): stationary graphon LQG control and the identification of b with the discounted Riccati gain → chapters 22 and 24.

Open.

- Equilibrium selection among multiple GNE in the supercritical complements regime $\mathsf{b}\,\|\mathbb{W}\| \geq 1$ (the static face of the selection problem of chapter 31).
- Identifiability and estimation of W from observed equilibrium efforts—using eq. (20.23) as an inverse problem—and its stability under cut-metric perturbation of the network (ties to chapters 17 and 25).

Bibliographic notes

The static graphon game, the graphon aggregate $\mathbb{W}s$, and the program of analyzing network games and interventions through the limiting kernel are due to Parise and Ozdaglar [108], whose linear–quadratic benchmark, contraction-based uniqueness under an operator-norm condition, and centrality-based intervention analysis are the backbone of sections 20.2, 20.4 and 20.5; our theorem 20.14 and the key-player principle proposition 20.20 follow their development, recast in the Hilbert-space language of chapter 2. The Katz–Bonacich centrality and its role as the equilibrium of a linear–quadratic network game with strategic complements originate in the network-games literature that [108] lifts to the graphon limit; the emergence of eigenvector centrality at criticality (theorem 20.19) is the spectral restatement we have given. The stochastic and measure-valued generalization of the static graphon game—where each type chooses a distribution rather than a scalar action—is the subject of Carmona, Cooney, Graves, and Laurière [39], "Stochastic graphon games: the static case," which connects this chapter to the probabilistic GMFG of chapter 23. The operator-theoretic facts we import—self-adjoint Hilbert–Schmidt structure, the spectral theorem, and the min–max characterization of the top eigenvalue—are standard and are proved in chapter 2 following [113, 50, 31]; the fixed-point theorems are from [79]. The reading of the critical coupling $\mathsf{b}\,\|\mathbb{W}\| = 1$ as a symmetry-breaking threshold continues the Lasry–Lions multiplicity discussion of chapter 11 [93, 36], and is taken up in its dynamic graphon form, with the competition between monotonicity and $\|\mathbb{W}\|$, in chapter 24 following the graphon mean field game program of Caines and Huang [33, 34]. For the graph-limit prerequisites—the pixel picture, block and rank-one graphons, and the operator $\mathbb{W}$—see chapters 15 and 18 and Lovász [99].

Chapter 21

Setting Up the Dynamic Graphon Mean Field Game

The previous chapter, chapter 20, studied *static* graphon games: a continuum of players indexed by a type $x \in [0,1]$, each choosing a one-shot action, coupled to a graphon aggregate $z(x) = \int_0^1 W(x,y)\, s(y)\, \mathrm{d}y$ of the others' actions, with equilibrium controlled by the operator norm $\|\mathbb{W}\|$ (lemma 20.12). That chapter is the *stationary shadow* (section 20.7) of the object we now build. A shadow is flat: nothing in it moves, each player commits to a single number, and the game is settled in one shot. The present chapter restores the missing dimension — time. We promote every player to a genuinely *dynamic* agent who carries a private state that diffuses on $[0,T]$ and is steered, moment by moment, by an optimally chosen control; the static action becomes a feedback policy, and the one-shot fixed point becomes a fixed point over an entire trajectory of population laws.

The purpose of the present chapter is narrow, and the narrowness is deliberate. We do *not* solve the resulting equilibrium here; we *set it up*. The distinction is worth dwelling on, because it is the organizing decision of the chapter. *Saying what an equilibrium is* means writing down, unambiguously, the agents, the population object, the space that object lives in, the topology on that space, the optimization each agent performs, and the consistency condition that closes the loop — so that the sentence "$(\boldsymbol{m}_t)_t$ is an equilibrium" acquires a definite truth value. *Proving that one exists* (and is unique, and can be computed) is a different and much harder task that presupposes the first is already done. We separate them on purpose, and the payoff of the separation is concrete: the next three chapters each consume *this* setup, untouched, and supply one engine apiece. chapter 22 turns the fixed point into a coupled backward–forward partial differential system and analyses it; chapter 23 recasts the same fixed point probabilistically as a system of graphon forward–backward stochastic differential equations (FBSDEs); chapter 24 proves existence and uniqueness. If the setup here were even slightly ambiguous — if the state space, the metric, or the coupling were left informal — those three chapters would each have to re-fix it, and they would risk fixing it differently. Investing the precision once, here, is what lets them agree (definitions 21.5, 21.8 and 21.16); the analytic engines then merely specialize the general agent class of definitions 21.1 and 21.6 to the control-affine, aggregate-in-cost subclass they solve in closed form.

The chapter has one destination and one test of honesty. The destination is the equilibrium definition (definition 21.16): the type-by-type Nash fixed point of the best-response map. The test is that the definition degenerate correctly, which we verify three times at the end — constant W must give back the classical mean field game of Part II, rank-one W must collapse the infinite field of measures to a single scalar self-consistency, and block W must reproduce finite multi-population mean field games. Everything between this opening and those checks exists to make the destination precise and the checks meaningful. The arc between them is a sequence of structural choices, each forced by the single move from one representative agent to a representative agent of every type, and each made honestly: the continuum of independent noises is carried not by a literal ensemble of trajectories but at the level of the deterministic field of laws (remark 21.2); that field is housed in a complete separable L^2-Wasserstein space (definition 21.8 and proposition 21.9); the graphon aggregate each agent feels is a $\|\mathbb{W}\|$-Lipschitz operation on that space, which is exactly where the coupling threshold $|s|\ \|\mathbb{W}\|$ is born (lemma 21.11 and remark 21.12); and equilibrium is the type-by-type Nash fixed point of the best-response map (definition 21.16).

To get there we import three streams, and it is worth saying in one breath why each is needed and where it will surface. The first is the Itô calculus of chapter 5: it furnishes the controlled stochastic differential equation that *is* the agent (theorem 5.10 guarantees the agent's state is a well-defined process), the generator $\mathcal{A}$ (definition 5.12) that will appear in the agent's HJB equation, and the Fokker–Planck equation (theorem 5.14) that pushes the agent's law forward in time and so generates the very population field the next agent responds to — without this stream there is no agent and no population. The second stream is classical mean field game theory (chapters 7, 8 and 14): the McKean–Vlasov mechanism (definition 7.7) is the exact template we are generalizing — one representative agent, one self-consistent measure — and its coupled HJB–Fokker–Planck system (eq. (8.5)) together with the fully solved linear–quadratic–Gaussian (LQG) fixed point (theorem 14.6) is the x-independent special case our setup must reproduce, which is exactly what the constant-graphon reduction will check; without this stream we would not know what "correct" means. The third stream is the graphon machinery of chapters 15, 17 and 18: the kernel W and its integral operator $\mathbb{W}$, the self-adjoint Hilbert–Schmidt structure granted by (A-Reg-W), and the rank-one spectral reduction. This is the stream that does the new work — it is what turns "one population" into "a field of populations coupled through a network" — and it surfaces the moment we define the aggregate an agent feels, returning in force when the operator norm $\|\mathbb{W}\|$ sets the coupling threshold. Beneath all three runs the Wasserstein geometry of $\mathcal{P}_2(\mathbb{R}^d)$ (chapter 4): it is the metric in which every population object is measured, and the reason the field space we build will be complete and separable.

Two global conventions are in force throughout, and because both a value function and a density appear in the equilibrium definition we restate the first one *and* motivate it. *Value functions $u = u$ carry terminal data at $t = T$ and are computed backward; population densities $m = m$ carry initial data at $t = 0$ and evolve forward.* The asymmetry is not bookkeeping; it reflects the arrow of causation in an optimization. An agent's value at time t is the best it can still achieve over the *remaining* horizon $[t, T]$, so it is determined by the future: the terminal cost is known and the value propagates *back* from $t = T$. A population's law at time t is the accumulated effect of where it started and how it has been driven over $[0, t]$, so it is determined by the past: the initial distribution is known and the density propagates *forward* from $t = 0$. Backward value, forward density; the two flows meet only at the fixed point, where the feedback computed backward generates exactly the law that flows forward. The second convention concerns a clash of letters that becomes acute precisely here, and we flag it before writing a single stochastic differential equation.

Notation watch

This is the first chapter of Part IV in which a graphon W and a Brownian motion appear in the same equation, so the global resolution announced in appendix A takes effect. *Whenever a graphon is in scope, the kernel is $W = W(x,y)$ and Brownian motion is written B_t.* We never write W_t for noise in this part. The driving noises of the agents are B^x, indexed by type; the kernel is W; the integral operator is $\mathbb{W}$. A reader arriving from Part II, where Brownian motion was W_t, should mentally rename it B_t from here on.

21.1 A continuum of controlled agents indexed by type

The preamble promised that this chapter would say precisely what the agents are. We begin there, with the single elementary unit out of which the whole game is assembled: one representative agent, of one type, and the equation its private state obeys. Everything later in the chapter — the field of measures, its topology, the equilibrium fixed point — is built on top of this unit, so it pays to install it carefully and to keep two conventions from the preamble live while we do.

The first convention is notational and was just flagged in chapter 21: the moment a graphon is in scope, the driving noise of an agent is written B_t, never W_t. The symbol W is reserved for the kernel. A reader who learned the single-agent theory of Part II with Brownian motion called W_t should perform the rename now, because the two W's are about to appear in the same line and only one of them can keep the letter.

The second convention is conceptual and far more consequential, so we restate it with the emphasis of chapter 15. The type label $x \in [0,1]$ is an *exchangeable label* — an index recording which "kind" of agent we are looking at, or equivalently where in the network it sits. It is *not* a spatial coordinate, and it is *not* a momentum. The agent's private state $X_t^x \in \mathbb{R}^d$ is what lives in space (or in whatever $\mathbb{R}^d$ models); the type x merely names the agent. In particular the numerical closeness of two labels — $|x-y|$ small — carries *no* intrinsic meaning whatsoever: relabelling types by a measure-preserving bijection of $[0,1]$ leaves the game unchanged, and all of the network's geometry, who interacts with whom and how strongly, is carried by the kernel $W(x,y)$ and by nothing else. If this still feels unnatural, the cleanest mental picture is the finite one: N agents, agent i assigned a type $\xi_i \in [0,1]$, the type doing no work except indexing the row and column of the interaction matrix $W(\xi_i, \xi_j)$.

With both conventions live we can state the one conceptual move that separates this chapter from Part II. The classical mean field game has *one* representative agent: every player is statistically identical, anonymous, and interacts with the rest only through a single population measure $m_t \in \mathcal{P}_2(\mathbb{R}^d)$. The graphon generalization replaces "one representative agent" by "a representative agent of *every* type." That is the entire leap. Each type now carries its own copy of the single-agent control problem, with its own initial distribution and its own driving noise, and the copies are tied together only through the kernel. Remarkably, almost nothing else changes at the level of a single agent's equation; all of the novelty hides in *what aggregate of the others* the agent responds to. We write the agent's dynamics now, motivate every coefficient, and then spend the rest of the chapter unpacking that aggregate.

It helps to read the controlled Itô equation below one term at a time before meeting it on the page. The state X_t^x is the private variable the type-x agent controls — a position, an inventory, an opinion, whatever the model is about. It changes for two reasons. The first is *drift*: a deterministic push $b(x, X_t^x, \alpha_t^x, \Theta_t(x))$ that the agent partly authors, because the control α_t^x enters it. This is the precise sense in which the agent "steers": it cannot touch the noise, but it can bias the drift, and steering *is* the choice of how to bias it. The drift also depends on the type x (different kinds of agent have different uncontrolled dynamics) and on the aggregate $\Theta_t(x)$ (the agent is pushed by what its neighbors are doing). The second reason the state changes is *noise*: an irreducible random buffeting $\sigma(x, X_t^x)\, \mathrm{d}B_t^x$ that the agent cannot influence at all, with its own type-x Brownian motion B^x and a diffusion coefficient σ that may depend on type and state but *not* on the control — the agent steers the mean, not the volatility. Finally the agent must start somewhere: its initial state is drawn from a type-dependent law m_0^x, because there is no reason different kinds of agent should begin life identically distributed, and the starting point is one of the few honest channels through which heterogeneity enters already at $t = 0$. With those four ingredients named, the equation reads as follows.

Definition 21.1 (The type-x representative agent)**.** Fix a horizon $T \in (0, \infty)$. For each type $x \in [0, 1]$ the representative agent of type x has a private state $X_t^x \in \mathbb{R}^d$ evolving on $[0, T]$ according to the controlled Itô equation

$$\mathrm{d}X_t^x \;=\; b\big(x,\, X_t^x,\, \alpha_t^x,\, \Theta_t(x)\big)\, \mathrm{d}t \;+\; \sigma\big(x,\, X_t^x\big)\, \mathrm{d}B_t^x, \qquad X_0^x \sim m_0^x, \tag{21.1}$$

where $\alpha_t^x \in A \subseteq \mathbb{R}^k$ is the control exerted by the type-x agent, B^x is a d'-dimensional Brownian motion, $m_0^x \in \mathcal{P}_2(\mathbb{R}^d)$ is the type-x initial distribution, and $\Theta_t(x)$ is the *graphon-aggregated mean field* felt by type x, defined in section 21.2. The coefficients b, σ are assumed Borel measurable in x and to satisfy, uniformly in x, the standing assumptions (A-Lip), (A-Growth), (A-Nondeg) of assumption 7.3: Lipschitz and linear growth in (X, α) uniformly in (t, x, Θ), and $\sigma\sigma^\top \succeq \lambda I$ with $\lambda > 0$.

The three standing assumptions imported from assumption 7.3 are not decoration; each buys a specific guarantee, and it is worth recalling what breaks without it. (A-Lip) — Lipschitz dependence of b, σ on (X, α) uniformly in (t, x, Θ) — is what makes the SDE (21.1) have a unique strong solution (theorem 5.10); drop it and two agents started from the same point could split into genuinely different futures, so "the law of the state" would not even be well-defined. (A-Growth) — at most linear growth in the state — prevents the solution from running off to infinity in finite time and keeps its second moment finite, which is exactly what will let every law live in $\mathcal{P}_2(\mathbb{R}^d)$. (A-Nondeg) — $\sigma\sigma^\top \succeq \lambda I$ with $\lambda > 0$ — guarantees the noise genuinely pushes in every direction; it is the parabolicity that will later smooth the agent's value function and density, and it is the one assumption we will occasionally have to flag when it fails. That all three hold *uniformly in x* is what will let us aggregate over the continuum of types without the constants degenerating type by type.

So the whole novelty relative to Part II is concentrated in the single argument $\Theta_t(x)$: the agent's drift, and shortly its cost, depend not on one global population measure but on a *type-local* aggregate of the entire population, gathered through the kernel W. We have deliberately written $\Theta_t(x)$ as an opaque symbol, because it cannot be defined until we have said what the population *is* as an object — a field of measures, one per type — and that is the business of section 21.2. Before we get there, though, we owe the reader an honest account of a subtlety the equation (21.1) quietly introduced the instant we attached a *separate* Brownian motion B^x to each of a continuum of types. It is tempting to treat this as a harmless notational convenience. It is not, and pretending otherwise would poison everything downstream.

Remark 21.2 (On a continuum of independent Brownian motions)**.** Equation (21.1) posits, for each $x \in [0,1]$, an independent Brownian motion B^x. The naive reading is that there sits, on one probability space, a single jointly measurable random field $(x,\omega) \mapsto B^x_t(\omega)$ whose columns are independent and identically distributed across x. *No such object exists in the naive sense*, and the reason is a clean clash with Fubini's theorem that is worth seeing in full, because it dictates the entire way we will pose the game.

Consider the simplest caricature: a family $\{\zeta^x\}_{x\in[0,1]}$ of real random variables that are independent, identically distributed, and nondegenerate (say mean zero and variance $v > 0$), and suppose for contradiction that $(x,\omega) \mapsto \zeta^x(\omega)$ is jointly measurable on $[0,1] \times \Omega$ (Lebesgue $\times\,\mathbb{P}$). Joint measurability is precisely the hypothesis that Fubini–Tonelli needs. Apply it to the cross-type average $S(\omega) := \int_0^1 \zeta^x(\omega)\,\mathrm{d}x$. On one hand, $\mathbb{E}[S] = \int_0^1 \mathbb{E}[\zeta^x]\,\mathrm{d}x = 0$. On the other hand, computing the second moment by Fubini applied to the product,

$$\mathbb{E}\Big[S^2\Big] = \int_0^1\int_0^1 \mathbb{E}[\zeta^x\zeta^y]\;\mathrm{d}x\;\mathrm{d}y = \int_0^1\int_0^1 v\,\mathbf{1}\{x=y\}\;\mathrm{d}x\;\mathrm{d}y = 0,$$

because independence forces $\mathbb{E}[\zeta^x\zeta^y] = 0$ off the diagonal $\{x=y\}$, while the diagonal is a Lebesgue-null subset of the square and contributes nothing. So $\mathbb{E}\big[S^2\big] = 0$, i.e. $S = 0$ almost surely: the cross-type average of a continuum of independent, mean-zero, *nondegenerate* variables would have to be deterministically zero. That much is in fact the "exact law of large numbers" one might *want*. The trouble is that the very same joint measurability, fed through Fubini in the other order, forces almost every *sample path* $x \mapsto \zeta^x(\omega)$ to be a Lebesgue-measurable function of x — and an independent, identically nondegenerate continuum has, by a standard zero–one argument, almost no measurable sample paths at all (the cross-section oscillates like an uncountable sequence of fresh coin-flips and pins down no measurable structure in x). The two consequences of joint measurability are incompatible, so the hypothesis must be denied: there is no jointly measurable, i.i.d., nondegenerate family indexed by $[0,1]$ with Lebesgue measure, and hence the "exact LLN" $x \mapsto X^x_t$ cannot be realized on an ordinary product probability space. What an exact law of large numbers across types would *require* is exactly a space on which the cross-section $x \mapsto X^x_t(\omega)$ is, for almost every fixed ω, a measurable function whose empirical distribution equals the deterministic average $\int_0^1 \mathcal{L}(X^x_t)\,\mathrm{d}x$ of the marginals — an interchange of "average over x" with "expectation over ω" that an ordinary product space cannot supply. There are two honest resolutions, and we use the first throughout.

1. *Distributional (the one we adopt).* We never ask for a joint realization in the first place. For each fixed x, (21.1) is a single, perfectly ordinary, well-posed SDE on its own probability space (theorem 5.10); there is no continuum of coupled trajectories to make sense of. The population

is then described not by realized paths but by the *deterministic* object $x \mapsto m_t^x = \mathcal{L}(X_t^x)$ — the law of the type-x state, one probability measure per type. We will call this map the *field of laws*, and the next section (section 21.2) makes it the central object of the whole chapter: the population *is* this field, not any sample of trajectories. Measurability then becomes a statement about a deterministic map $[0,1] \to \mathcal{P}_2(\mathbb{R}^d)$, not about a random field, and as such it holds and is proved in lemma 21.13. This is precisely the level at which the classical mean field game is already posed — through $\mathcal{L}(X_t)$ rather than realized paths (definition 7.7) — so we are not adding fragility, only being explicit that the continuum lives in the deterministic field and never in a literal ensemble of paths.

2. *Fubini extension (when realizations are genuinely wanted).* If one truly wants a jointly measurable continuum of independent processes — for instance to state and use an exact law of large numbers across types as a *theorem* rather than a motivation — the honest device is a *Fubini extension* of the product space in the sense of Sun [125]: an enlargement of $[0,1] \times \Omega$ on which Fubini's theorem is postulated to hold and on which an essentially pairwise independent continuum *does* exist and *does* satisfy the exact LLN, precisely by sidestepping the obstruction above. We flag this route for completeness and *do not* rely on it. The finite-network theory of chapter 25 reaches the same conclusions by an unimpeachable route, keeping N genuine agents on a sampled graph $G(N, W)$ and passing rigorously to the limit, so nothing in this book ever needs a literal continuum of paths.

The upshot, which the reader should carry forward: no theorem anywhere below depends on a jointly measurable continuum of trajectories. Every statement is phrased through the deterministic field of laws, and that is what keeps the dynamic graphon game on solid measure-theoretic ground.

The abstract agent (21.1) is general by design, since chapters 22 and 23 will need room for nonlinear drifts and state-dependent volatilities. But the thread we carry through the book for concreteness — Thread B, the graphon-LQG model fixed in the thread specification and given its static incarnation in chapter 20 — is the simplest honest instance: scalar state, scalar control, affine dynamics, additive noise. It is worth writing out and checking, line by line, that it really is a special case of definition 21.1, both to anchor the abstractions and to rehearse the assumption checks we will lean on later.

Example 21.3 (Thread B: the graphon-LQG agent)**.** With the fixed parameter names of the thread specification — state feedback a, control gain b, noise level $\sigma = \sigma$ — the type-x agent obeys

$$\mathrm{d}X_t^x \;=\; \big(a\, X_t^x + b\, \alpha_t^x\big)\;\mathrm{d}t \;+\; \sigma\; \mathrm{d}B_t^x, \qquad X_0^x \sim m_0^x, \tag{21.2}$$

a scalar state ($d = 1$) with scalar control. This is definition 21.1 with the affine drift $b(x, X, \alpha, \Theta) = aX + b\alpha$ and the constant diffusion $\sigma \equiv \sigma$. Two features deserve note. First, the drift here happens *not* to depend on the aggregate Θ: in this model the neighbors influence an agent only through its *cost*, not its dynamics, and the coupling will enter in example 21.7. The general definition 21.1 permits Θ in the drift, but Thread B does not exercise that freedom. Second, the volatility σ is constant — independent of type, state, and control — which is the cleanest setting in which nondegeneracy is transparent.

We check the three standing assumptions against this affine model, since the closed-form results of section 21.5 depend on their holding. (A-Nondeg) asks $\sigma\sigma^\top \succeq \lambda I$ for some $\lambda > 0$; in dimension one this reads $\sigma^2 \geq \lambda > 0$, which holds *iff* $\sigma \neq 0$ (one may then simply take $\lambda = \sigma^2$). The degenerate case $\sigma = 0$ turns the SDE into a controlled ODE with no parabolic smoothing and is exactly the situation our nondegeneracy hypothesis excludes. (A-Lip) asks Lipschitz dependence of b, σ on (X, α) uniformly in the remaining arguments: here $\partial_X b = a$ and $\partial_\alpha b = b$ are constants and $\sigma \equiv \sigma$ is constant, so the coefficients are globally Lipschitz with constant $\max\{|a|, |b|\}$ — the assumption holds trivially because the model is affine. (A-Growth) asks at most linear growth in the state: $|b(x, X, \alpha, \Theta)| \leq |a|\ |X| + |b|\ |\alpha|$ and $|\sigma| = |\sigma|$ are visibly affine in (X, α), so linear growth holds with no work. An affine model with additive noise is the generic example for which all three assumptions hold the instant one writes it down; the only genuine demand is the harmless $\sigma \neq 0$. This is the dynamic backbone we advance in section 21.5.

We have now said precisely what a single agent is: a well-posed controlled diffusion, one per type, with type-dependent starting law and its own noise, obeying the three standing assumptions uniformly in x. Exactly one symbol in that description remains undefined — the aggregate $\Theta_t(x)$ that the drift and the cost depend on. We deferred it on purpose, because pinning it down forces us first to say what the *population* is, and the population is no longer a single point of $\mathcal{P}_2(\mathbb{R}^d)$ as it was in Part II. It is the field of laws $x \mapsto m_t^x$ that remark 21.2 just placed at the centre of the construction. The next section builds that field-of-measures object, equips it with the W-weighting that turns it into the type-local aggregate $\Theta_t(x)$ each agent actually feels, and so closes the one gap left open here. With Θ in hand we will be able to write the agent's cost, its best response, and finally the equilibrium fixed point.

21.2 The graphon-coupled mean field: a field of measures

The previous section closed by leaving exactly one symbol undefined, and it left it undefined on purpose: the aggregate $\Theta_t(x)$ that the agent's drift (21.1) — and, in a moment, its cost — depends on. We promised the reader that $\Theta_t(x)$ is "the W-weighted average the type-x agent actually feels." But a weighted average *of what*, taken *over what object*? Answering that is the entire business of this section, and it forces us first to say what the population *is*, because the average is taken over the population and we have not yet pinned the population down as a mathematical object. This is where the dynamic graphon game parts company with the theory of Part II.

In Part II the population was a single point $m_t \in \mathcal{P}_2(\mathbb{R}^d)$: one probability measure summarising the entire anonymous crowd, and the representative agent responded to a scalar or measure functional of that one measure. There was nothing else to respond to. Every agent was statistically identical, so a single law described them all, and "the population at time t" was literally one element of $\mathcal{P}_2(\mathbb{R}^d)$. The moment we gave *every type* its own agent, its own initial law m_0^x, and its own noise B^x (definition 21.1), that single point dissolved. There is no longer one population law; there is one law *per type*, $m_t^x = \mathcal{L}(X_t^x)$, and the type-$x$ agent must be told which combination of these it feels. So the population has been lifted from a *point* of $\mathcal{P}_2(\mathbb{R}^d)$ to a *function of type into measures* — an entire x-indexed family of probability laws — and the aggregate $\Theta_t(x)$ will be a kernel-weighted average over that family. We give the family a name first, then build the average on top of it.

Definition 21.4 (Population field and first-moment field)**.** A *population field* is a map

$$\boldsymbol{m} \;=\; (\, m^x \,)_{x\in[0,1]}\,, \qquad m^x \in \mathcal{P}_2(\mathbb{R}^d),$$

assigning to each type x a probability measure with finite second moment. In the dynamic game the field is time-indexed, $\boldsymbol{m}_t = (m_t^x)_{x\in[0,1]}$ with $m_t^x = \mathcal{L}(X_t^x)$. Its *first-moment field* is the $\mathbb{R}^d$-valued function

$$\bar{m}_t(y) \;:=\; \int_{\mathbb{R}^d} \xi \, m_t^y(\mathrm{d}\xi) \;=\; \mathbb{E}[X_t^y]\,, \qquad y \in [0,1].$$

Two features of definition 21.4 deserve a word before we build on it. First, the field $\boldsymbol{m}_t$ carries strictly more information than any single average of it: it remembers the entire shape of each type's law, not just its mean. We single out the first-moment field $\bar{m}_t$ because Thread B couples only through means, but the construction never collapses the field to its first moment until a particular cost *asks* it to. Second, the field is a *deterministic* object — a fixed map from $[0,1]$ into $\mathcal{P}_2(\mathbb{R}^d)$ — exactly as remark 21.2 insisted: it is the field of laws, not any random ensemble of trajectories, and that is what keeps the continuum on solid measure-theoretic ground. The whole population, at each instant, *is* this map.

Now the agent. The type-x agent does not see the whole field $\boldsymbol{m}_t$, and it would be the wrong model if it did: an agent embedded in a network feels its neighbours, not the global census. What it feels is a W-weighted average of the others' laws, the weight $W(x,y)$ recording how strongly type x is exposed to type y. This single weighting is the only place the network geometry enters the model, and it is worth writing the resulting aggregate in two equivalent ways. One keeps the full measure-valued information and is the right object when an agent's cost is a general functional of its neighbours' *distributions*; the other retains only a scalar (or vector) observable and is the right object — and the computationally tractable one — when the cost depends on the neighbours only through, say, their mean. We will need both pictures repeatedly, so we set them down side by side.

Definition 21.5 (Graphon mean-field aggregate)**.** Let $\boldsymbol{m} = (m^x)_{x\in[0,1]}$ be a population field with $x \mapsto m^x$ Borel measurable into $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$. The *aggregate measure* felt by type x is the (in general sub-probability) finite measure on $\mathbb{R}^d$

$$(\mathbb{W} \circledast \boldsymbol{m})(x) \;:=\; \int_0^1 W(x,y)\, m^y \; \mathrm{d}y \;\in\; \mathcal{M}_+(\mathbb{R}^d), \tag{21.3}$$

defined by its action on bounded Borel test functions h, $\langle h, (\mathbb{W} \circledast \boldsymbol{m})(x)\rangle = \int_0^1 W(x,y)\langle h, m^y\rangle \; \mathrm{d}y$, where $\langle h, \nu\rangle = \int h \; \mathrm{d}\nu$. Its total mass is $(\mathbb{W}\mathbf{1})(x) = \int_0^1 W(x,y) \; \mathrm{d}y \le 1$, so $(\mathbb{W}\circledast\boldsymbol{m})(x)$ is a probability measure only when $\int_0^1 W(x,y)\,\mathrm{d}y = 1$. The pairing also extends to Borel observables of at most linear growth — in particular the *unbounded* identity $h(\xi) = \xi$ — because each $m^y \in \mathcal{P}_2(\mathbb{R}^d)$ has a finite first moment and W is bounded; this is the case that drives Thread B. When the coupling enters through a single such observable h, the relevant object is the *scalar (or vector) aggregate field*

$$\Theta_t(x) \;=\; (\mathbb{W}\,[\,\langle h, m_t^{\cdot}\rangle\,])(x) \;=\; \int_0^1 W(x,y)\,\langle h, m_t^y\rangle \; \mathrm{d}y. \tag{21.4}$$

For Thread B the observable is the identity $h(\xi) = \xi$, so $\langle h, m_t^y \rangle = \bar{m}_t(y)$ and the aggregate is exactly the graphon-smoothed first-moment field

$$z_t(x) \;:=\; (\mathbb{W}\,\bar{m}_t)(x) \;=\; \int_0^1 W(x,y)\,\bar{m}_t(y)\;\mathrm{d}y, \tag{21.5}$$

matching the aggregate of the thread specification and of the static game (worked computation 20.21).

The definition carries a deliberate two-level notation, $\circledast$ versus plain $\mathbb{W}$, and the distinction is worth making explicit because the two operators *look* the same on the page but act on different kinds of object. The symbol $\mathbb{W}\circledast$ in (21.3) is the integral operator $\mathbb{W}$ of definition 2.23 (whose spectral theory is developed in chapter 18) acting *measure-valuedly*: it integrates the measure-valued map $y \mapsto m^y$ against the kernel $W(x,\cdot)$, producing for each x a measure on $\mathbb{R}^d$. There is no average of real numbers here — the "values" being averaged are whole probability laws, and the integral $\int_0^1 W(x,y)\,m^y\;\mathrm{d}y$ is a measure, defined the only way a measure can be defined, by its action on test functions. When instead $\mathbb{W}$ is fed a genuine *scalar* field such as $\bar{m}_t$, the circled symbol is dropped and it is literally the ordinary operator of definition 2.23, $(\mathbb{W}f)(x) = \int_0^1 W(x,y)f(y)\,\mathrm{d}y$, an honest weighted average of numbers. The two are consistent: pairing the measure-valued aggregate against an observable h and applying the scalar operator to the field $\langle h, m^{\cdot}\rangle$ give the same number, which is exactly the identity $\langle h, (\mathbb{W}\circledast \boldsymbol{m})(x)\rangle = (\mathbb{W}[\langle h, m^{\cdot}\rangle])(x)$ read off from (21.3)–(21.4). One should keep both pictures live: the aggregate is a *measure* when the cost is a general functional of the neighbours' distributions, and it *collapses* to $\mathbb{W}$ acting on a moment field the moment the cost depends on the neighbours only through a single observable — which is the LQG case, (21.5), and the one we actually compute with.

The one feature of (21.3) that has no analogue in Part II, and that a reader can easily misread, is that the aggregate measure is in general a *sub*-probability: its total mass is $(\mathbb{W}\mathbf{1})(x) = \int_0^1 W(x,y)\;\mathrm{d}y$, the row sum of the kernel, which the standing assumption $0 \le W \le 1$ caps at 1 but does not force to equal 1. This is not a defect of the definition; it is the correct bookkeeping of how *connected* type x is. A type with $\int_0^1 W(x,y)\,\mathrm{d}y < 1$ is weakly coupled to the rest of the network — it has few or faint neighbours — and it should feel a correspondingly *lighter* aggregate, a measure of mass less than one. Only when type x is fully connected, $\int_0^1 W(x,y)\,\mathrm{d}y = 1$, does $(\mathbb{W}\circledast\boldsymbol{m})(x)$ come out a bona fide probability measure. The lesson is that one must *not* renormalise the aggregate to total mass one by hand: doing so would erase exactly the heterogeneity in connectivity that the graphon is there to encode, and it would break the linearity of $\mathbb{W}$ on which every estimate below rests. The scalar form (21.4) inherits the same feature painlessly — it is simply a kernel-weighted (not kernel-*averaged*) sum of the observable, so a poorly connected type contributes a smaller number — which is one more reason Thread B prefers to work with it.

With the aggregate $\Theta_t(x)$ now a defined object — the scalar field (21.4), or in the LQG case $z_t(x)$ of (21.5) — the symbol that definition 21.1 carried as a placeholder has acquired its meaning, and we can finish specifying the game by writing down what each agent is trying to minimise. As in Part II, the type-x agent minimises an expected cost over its admissible controls, and it does so taking the population field flow $(\boldsymbol{m}_t)_{t\in[0,T]}$ — hence the aggregate flow $t \mapsto \Theta_t(x)$ — as *given*. This is the infinitesimal-agent convention inherited unchanged from mean field game theory: a single agent is one of a continuum and cannot, by itself, move the aggregate, so during its own optimisation the field is a fixed exogenous input. The self-consistency between the field an agent responds to and the field its optimal behaviour generates is imposed only later, at the equilibrium fixed point (definition 21.16); here the field is frozen and the agent simply solves a standard control problem against it.

Definition 21.6 (Cost functional)**.** Given a measurable field flow $\boldsymbol{m} = (\boldsymbol{m}_t)_{t\in[0,T]}$, an admissible control α^x (definition 21.14) for type x incurs the cost

$$J^x(\alpha^x;\boldsymbol{m}) \;=\; \mathbb{E}\left[\int_0^T L\big(x, X_t^x, \alpha_t^x, \Theta_t(x)\big)\;\mathrm{d}t \;+\; g\big(x, X_T^x, \Theta_T(x)\big)\right], \tag{21.6}$$

with running cost L and terminal cost g Borel in x and satisfying the convexity/coercivity needed for the Hamiltonian

$$H(x,X,p,\Theta) \;=\; \sup_{\alpha\in A}\big\{-\;p\cdot b(x,X,\alpha,\Theta) - L(x,X,\alpha,\Theta)\big\}$$

to be well-defined and convex in p under (A-Conv). The optimal feedback is the maximizer

$$\alpha^*(x,X,p,\Theta) \;=\; \operatorname*{arg\,max}_{\alpha\in A}\big\{-\;p\cdot b(x,X,\alpha,\Theta) - L(x,X,\alpha,\Theta)\big\}. \tag{21.7}$$

We caution that α^* is *not* $-\partial_p H$ when the drift is genuinely control-dependent: by the envelope theorem $\partial_p H = -b(x,X,\alpha^*,\Theta)$, so $-\partial_p H$ returns the optimal *drift*, not the control. The two coincide only in the reduced convention $b=\alpha$. For the control-affine drift $b = b_0(x,X,\Theta)+B\alpha$ with strongly convex running cost — the case of every worked example below — (21.7) is the explicit first-order condition $B^\top p + \partial_\alpha L = 0$, which for quadratic $L = \frac{1}{2}|\alpha|^2 + \cdots$ gives $\alpha^* = -B^\top p$ (scalar LQG: $\alpha^* = -bp$).

The cautionary clause inside definition 21.6 is compressed enough to be easy to misread, so we spell out the one-line derivation that justifies it; it is load-bearing because every HJB equation in chapters 22 and 23 is written with the Hamiltonian, and confusing α^* with $-\partial_p H$ would silently corrupt the optimal control whenever the drift is not the control itself. Write the bracket being maximised as $\mathcal{H}(x,X,p,\alpha,\Theta) := -\,p\cdot b(x,X,\alpha,\Theta) - L(x,X,\alpha,\Theta)$, so that $H(x,X,p,\Theta) = \mathcal{H}(x,X,p,\alpha^*(x,X,p,\Theta),\Theta)$ with α^* the maximiser. Differentiating in p and using the chain rule,

$$\partial_p H \;=\; \partial_p\mathcal{H}\big|_{\alpha=\alpha^*} \;+\; \big(\partial_\alpha\mathcal{H}\big|_{\alpha=\alpha^*}\big)\,\partial_p\alpha^* \;=\; -\,b(x,X,\alpha^*,\Theta) \;+\; 0,$$

where the second term vanishes by the first-order optimality condition $\partial_\alpha\mathcal{H}|_{\alpha=\alpha^*} = 0$ — this cancellation *is* the envelope theorem. Hence $\partial_p H = -b(x,X,\alpha^*,\Theta)$, so $-\partial_p H$ recovers the optimal *drift* $b(x,X,\alpha^*,\Theta)$, which equals the optimal *control* α^* only in the reduced convention $b=\alpha$ where drift and control are literally the same variable. In the control-affine setting $b = b_0(x,X,\Theta)+B\alpha$ the optimal drift is $b_0 + B\alpha^* = b_0 - BB^\top p$, manifestly not $\alpha^* = -B^\top p$ unless $B=I$ and $b_0 = 0$. We retain the explicit maximiser (21.7) as the definition of α^* precisely so that no such confusion can arise downstream.

Example 21.7 (Thread B: the graphon-LQG cost)**.** With $z_t(x)$ from (21.5) and parameters $q, q_T \geq 0$ (state-cost weights) and s, s_T (mean-coupling strengths), the type-x agent's cost is

$$J^x(\alpha^x;\boldsymbol{m}) = \mathbb{E}\left[\int_0^T \Big(\tfrac{1}{2}(\alpha_t^x)^2 + \tfrac{q}{2}\big(X_t^x - s\,z_t(x)\big)^2\Big)\,\mathrm{d}t + \tfrac{q_T}{2}\big(X_T^x - s_T\,z_T(x)\big)^2\right], \tag{21.8}$$

exactly the thread-specification cost, and the place where the kernel coupling finally reaches the agent: the neighbours enter only here, through the term $\frac{q}{2}(X_t^x - s\, z_t(x))^2$, which penalises the squared distance between the agent's own position and the graphon-smoothed average position $z_t(x) = (\mathbb{W}\bar{m}_t)(x)$ of its neighbours. For $s > 0$ this draws each agent *toward* the crowd (imitation/congestion-seeking); for $s < 0$ it pushes it *away* (anti-coordination); and s multiplies the operator norm $\|\mathbb{W}\|$ to form the coupling strength $|s|\ \|\mathbb{W}\|$ that remark 21.12 will identify as the control parameter of the whole theory. Note that in this thread the drift $b = aX + b\alpha$ is *free* of Θ, so the aggregate sits entirely in the cost — consistent with example 21.3, where we already observed that Thread B couples through cost and not through dynamics.

Let us compute the Hamiltonian explicitly, both to check convexity and to see the scalar-LQG HJB fall out. With $b = aX + b\alpha$ and $L = \frac{1}{2}\alpha^2 + \frac{q}{2}(X - s\Theta)^2$, the bracket in (21.7) is

$$-\,p\,(aX + b\alpha) - \tfrac{1}{2}\alpha^2 - \tfrac{q}{2}(X - s\Theta)^2 \;=\; \underbrace{-\,b\,p\,\alpha - \tfrac{1}{2}\alpha^2}_{\text{depends on } \alpha}\ \underbrace{-\,aXp - \tfrac{q}{2}(X - s\Theta)^2}_{\text{independent of } \alpha}.$$

The α-dependent part is a downward parabola in α (the coefficient of α^2 is $-\frac{1}{2} < 0$, which is the strong concavity that makes the supremum attained and unique); its maximiser solves the first-order condition $-bp - \alpha = 0$, giving $\alpha^* = -bp$, in agreement with the affine-quadratic rule $\alpha^* = -B^\top p$ of definition 21.6 with $B = b$. Substituting $\alpha = \alpha^* = -bp$ back, the α-dependent part becomes $-bp(-bp) - \frac{1}{2}(-bp)^2 = b^2p^2 - \frac{1}{2}b^2p^2 = \frac{1}{2}b^2p^2$, so

$$H(x, X, p, \Theta) \;=\; \tfrac{1}{2}b^2p^2 - aXp - \tfrac{q}{2}(X - s\Theta)^2.$$

This is convex in p — indeed $\partial_p^2 H = b^2 \geq 0$, strictly positive whenever the control is genuinely effective ($b \neq 0$) — so (A-Conv) holds and the verification theorem of chapter 6 applies. To obtain the agent's equation we feed this Hamiltonian into the best-response HJB of definition 21.15, which for a value function $u = u^x(t, X)$ reads $\partial_t u + \frac{\sigma^2}{2}\partial_{XX}u - H(x, X, \partial_X u, \Theta) = 0$ with terminal data from g. Writing $p = \partial_X u$ and $\Theta = z_t(x)$ and expanding $-H = -\frac{1}{2}b^2p^2 + aXp + \frac{q}{2}(X - sz)^2$ term by term,

$$\partial_t u + \tfrac{\sigma^2}{2}u_{XX} \;-\; \tfrac{1}{2}b^2u_X^2 + aXu_X + \tfrac{q}{2}\big(X - s\,z_t(x)\big)^2 \;=\; 0,$$

the standard scalar-LQG HJB equation. The only trace of the graphon is the single scalar $z_t(x)$ frozen inside the running cost; for each fixed type the agent therefore solves an ordinary one-dimensional LQG control problem, and the entire network coupling is carried by how $z_t(x)$ depends, through $\mathbb{W}$, on the field the other types generate. This is the precise sense in which the graphon game is, type by type, a classical LQG problem tied to its neighbours by one number — and it is the structure chapter 22 exploits to write the coupled HJB–FP system in closed form.

The definition (21.3) was written down by fiat, and the reader is entitled to ask where the integral against W *comes from* — why this particular average is the one a networked agent should feel. The honest answer is a finite-population story that the continuum object approximates, and it is worth telling because it is the picture chapter 25 later makes rigorous.

Heuristic (non-rigorous)

Where does the continuum coupling (21.3) come from? Take N agents sampled from the graphon: assign each i a type ξ_i i.i.d. uniform on $[0,1]$ and draw the edge $i \sim j$ independently with probability $W(\xi_i, \xi_j)$, the random-graph model $G(N, W)$ of chapter 19, recorded in the symmetric adjacency matrix $A = (A_{ij})$ with $A_{ij} \in \{0,1\}$. Suppose agent i feels the empirical average of an observable h over the agents it is actually connected to, normalised by N. Conditionally on the types, the edges incident to i are independent coin-flips with $\mathbb{E}[A_{ij} \mid \xi] = W(\xi_i, \xi_j)$, so the realised adjacency may be replaced by its conditional mean,

$$\frac{1}{N}\sum_{j=1}^{N} A_{ij}\, h(X_t^j) \;\approx\; \frac{1}{N}\sum_{j} W(\xi_i, \xi_j)\, h(X_t^j),$$

the first averaging — over the randomness of the graph at fixed types — concentrating the $\{0,1\}$ weights onto the smooth weights $W(\xi_i, \xi_j)$ as $N \to \infty$. Now a second averaging acts on the right-hand side. Conditionally on the types, the empirical measure $\frac{1}{N}\sum_j W(\xi_i, \xi_j)\delta_{X_t^j}$ is a sum of independent terms whose weights are fixed by the types and whose atoms X_t^j are drawn from the type-ξ_j law; grouping the j-sum by type, the law of large numbers across the agents replaces this empirical object by its expectation,

$$\frac{1}{N}\sum_{j} W(\xi_i, \xi_j)\, \delta_{X_t^j} \;\longrightarrow\; \int_0^1 W(\xi_i, y)\, m_t^y \,\mathrm{d}y \;=\; (\mathbb{W} \circledast \boldsymbol{m}_t)(\xi_i),$$

since the types ξ_j are i.i.d. uniform on $[0,1]$ (their empirical distribution tends to Lebesgue measure dy) while, given $\xi_j = y$, the state X_t^j has law m_t^y (so its contribution to the average of h is $\langle h, m_t^y \rangle$). Pairing against h recovers exactly $\Theta_t(\xi_i)$ of (21.4). The step that replaces the empirical neighbour measure by its expectation is the only inference here that is not a finite computation, and it is justified — *heuristically* — by a conditional law of large numbers: at fixed types the summands are conditionally independent with the right conditional means, so their normalised sum concentrates. The double averaging — once over the random graph, once over the agents of each type — is precisely what the rigorous propagation-of-chaos theorem of chapter 25 establishes, keeping N genuine agents throughout and never invoking the forbidden continuum of trajectories of remark 21.2. Here the argument only *motivates* the definition (21.3); nothing in the present chapter leans on it, and all rigor is deferred to chapter 25.

We have now assembled the full data of the dynamic graphon game: a representative agent of every type (definition 21.1), the field of measures that *is* the population (definition 21.4), the kernel-weighted aggregate $\Theta_t(x)$ each agent feels in both its measure-valued and scalar forms (definition 21.5), and the cost (definition 21.6) that closes the optimisation. Every one of these objects was built on top of the field $\boldsymbol{m}_t = (m_t^x)_{x \in [0,1]}$, which we have so far carried as a bare family of measures — with no home, and no way to measure two fields apart. The next section pays that debt, fixing the space the field inhabits and the metric that controls every limit one might take of it.

21.3 The state space of population fields and its topology

The previous section left us holding a promissory note. It assembled the entire data of the dynamic graphon game — the per-type agent (21.1), the field of measures $\boldsymbol{m}_t = (m_t^x)_{x\in[0,1]}$ that *is* the population (definition 21.4), the kernel-weighted aggregate $\Theta_t(x)$ (definition 21.5), and the cost (21.6) — but it treated the field as a bare family of probability measures, with no home and no notion of distance between two such families. That is a debt we must now pay, and it is the single most important structural decision of the chapter. The reason is not pedantry. Every claim the next three chapters wish to make is a claim about *limits* of fields: that the best response varies continuously with the field it responds to, that a sequence of approximate equilibria converges to a genuine one, that the best-response map has a fixed point at all. None of these sentences even acquires a truth value until we have said what space the field inhabits and which metric measures the gap between two fields. Fixing that space and that metric is what cashes the note.

The stakes are concrete because the choice is inherited, not re-made downstream. When chapter 24 runs a Schauder or Kakutani argument it will need the field space to be a complete, separable, convex subset of a Banach (or at least Polish) space; when chapter 22 states that the equilibrium pair $x \mapsto (u^x, m^x)$ is continuous in type it will need a *second*, finer space in which type-continuity is even expressible. Both of those chapters take the space we are about to define and use it verbatim, so a vague choice here would propagate as ambiguity — or, worse, as silent disagreement — through everything that follows. We therefore make the decision once, in full, and justify every clause of it. The section has three deliverables, and it is worth naming them in advance so the reader can see the arc: first the definition of the field space $(\boldsymbol{\mathcal{P}}_2, d_2)$ together with the proof that it is the right kind of space (complete and separable), and the finer continuous-in-type alternative alongside it; second — the technical heart — the proof that the aggregate operation $\boldsymbol{m} \mapsto \Theta$ is Lipschitz with constant exactly $\|\mathbb{W}\|$, which is where the coupling threshold of the whole theory is born; and third the measurability of the field of laws, the last loose end from remark 21.2. With those three in hand, every ingredient a fixed-point definition needs will be on the table, and the next section can simply assemble them.

What kind of object is a field, and how should we measure two fields apart? A field assigns to each type x a probability measure $m^x \in \mathcal{P}_2(\mathbb{R}^d)$, so it is a map from the type interval $[0,1]$ into the metric space $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ — a curve, indexed not by time but by type, living in the space of laws. We already have a canonical way to measure two laws apart: the 2-Wasserstein distance $\mathcal{W}_2$ of chapter 4, which is the right metric here precisely because the agents carry second moments and the aggregate the cost depends on is a *moment* of the neighbours' laws. So at each fixed type the distance between two fields is $\mathcal{W}_2(m^x, (m')^x)$. The only remaining question is how to combine that type-by-type discrepancy into a single number measuring the two fields apart *as fields*, and here there is a genuine choice with consequences: do we take the *supremum* of the discrepancy over types, or its L^2 *average*? The supremum is the more demanding, stronger metric; the L^2 average is weaker but, as we will see, buys separability and the compactness one needs to run a fixed-point argument. We make the L^2 average the default and keep the supremum as a named alternative. The definition records the default.

Definition 21.8 (The space of L^2 population fields)**.** Fix a reference point $\delta_0 \in \mathcal{P}_2(\mathbb{R}^d)$ (the Dirac at the origin) and let $\boldsymbol{\delta}_0$ denote the constant field $x \mapsto \delta_0$. The *space of L^2 population fields* is

$$\boldsymbol{\mathcal{P}}_2 \ := \ \Big\{ \boldsymbol{m} = (m^x)_{x\in[0,1]} \ : \ x \mapsto m^x \text{ Borel measurable into } (\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2), \ \int_0^1 \mathcal{W}_2(m^x, \delta_0)^2 \,\mathrm{d}x < \infty \Big\}, \tag{21.9}$$

fields identified when they agree for Lebesgue-a.e. x. We metrize $\boldsymbol{\mathcal{P}}_2$ by the L^2-Wasserstein distance over types,

$$d_2(\boldsymbol{m}, \boldsymbol{m}') \ := \ \Big(\int_0^1 \mathcal{W}_2(m^x, (m')^x)^2 \,\mathrm{d}x \Big)^{1/2}. \tag{21.10}$$

Three clauses of this definition were chosen deliberately — the integrability requirement, the L^2 (rather than supremum) aggregation, and the a.e.-in-type identification — and each pays for a specific structural feature we will need. We take them in turn.

The first clause is the integrability requirement $\int_0^1 \mathcal{W}_2(m^x, \delta_0)^2 \,\mathrm{d}x < \infty$. Unwinding the definition of $\mathcal{W}_2$ against the Dirac at the origin, $\mathcal{W}_2(m^x, \delta_0)^2 = \int_{\mathbb{R}^d} |\xi|^2 \ m^x(\mathrm{d}\xi)$ is simply the second moment of the type-x law, so the condition reads $\int_0^1 \int_{\mathbb{R}^d} |\xi|^2 \ m^x(\mathrm{d}\xi) \ \mathrm{d}x < \infty$: a *uniform-in-type second moment*, finite when averaged across the population. This is not an idle integrability hypothesis; it is precisely the passport that admits the first-moment field $\bar{m}$ into the Hilbert space $L^2([0,1];\mathbb{R}^d)$ on which the operator $\mathbb{W}$ is defined and bounded (chapter 18). The chain is short and worth seeing now, since it is the crux of the Lipschitz lemma below. By Jensen's inequality the mean is controlled by the second moment pointwise in type, $|\bar{m}(x)|^2 = |\int \xi \, m^x(\mathrm{d}\xi)|^2 \le \int |\xi|^2 \ m^x(\mathrm{d}\xi) = \mathcal{W}_2(m^x, \delta_0)^2$; integrating over x turns the field's finite-second-moment condition into $\|\bar{m}\|^2_{L^2([0,1])} \le d_2(\boldsymbol{m}, \boldsymbol{\delta}_0)^2 < \infty$. Without the uniform second moment this last integral could diverge, $\bar{m}$ would fall outside $L^2([0,1])$, and the very expression $\mathbb{W}\bar{m}$ — the aggregate the agent feels — would be meaningless. The clause exists exactly so that the domain of $\mathbb{W}$ contains every field in $\boldsymbol{\mathcal{P}}_2$; we record the bound as lemma 21.11(i).

The second clause is the choice to aggregate the type-by-type discrepancy in L^2 rather than in the supremum. This is the choice that makes $\boldsymbol{\mathcal{P}}_2$ *separable*, and separability is not a luxury — it is what the compactness machinery of chapter 24 runs on. To see why the supremum would fail, recall that the uniform metric d_∞ of definition 21.10 below makes the field space behave like $C([0,1]; \mathcal{P}_2(\mathbb{R}^d))$ only on the continuous fields; on the full space of measurable fields the supremum metric is non-separable for the same reason $L^\infty([0,1])$ is non-separable — there are uncountably many fields pairwise a fixed distance apart (switch a field's value on a small interval and the supremum distance jumps by a constant no matter how small the interval). The L^2 average, by contrast, sees only the *measure* of the set on which two fields differ, so a small interval contributes a small amount, and the resulting space inherits separability from the separability of its two ingredients, $L^2([0,1])$ and $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ (proved as proposition 21.9). Separability in turn gives the sequential compactness that Schauder and Kakutani arguments need: a bounded set of fields has convergent subsequences in a metrizable-weak sense, and there is no room for that in a non-separable space. This is also exactly the dynamic analogue of the L^2 setting in which the static graphon game was posed (chapter 20), and it matches the function-space conventions of the graphon mean-field literature, Bayraktar–Wu–Zhang [16] and Aurell–Carmona–Laurière [10].

The third clause identifies two fields that agree for Lebesgue-almost-every type. This is harmless — indeed forced — because nothing in the game can distinguish two fields that differ only on a type-null set. The agent's dynamics (21.1) read off the field only through the aggregate (21.3), and that aggregate is an integral against Lebesgue measure, $\Theta(x) = \int_0^1 W(x,y)\langle h, m^y\rangle \,\mathrm{d}y$, which is blind to any change of the integrand on a null set of y. So two fields agreeing a.e. produce literally the same aggregate for every type, the same best responses, the same equilibrium condition. Identifying them is not throwing away information; it is refusing to record a distinction the model cannot feel — and it is what makes d_2 a genuine metric (so that $d_2(\boldsymbol{m}, \boldsymbol{m}') = 0$ forces $\boldsymbol{m} = \boldsymbol{m}'$ in $\boldsymbol{\mathcal{P}}_2$) rather than a mere pseudometric. This is the exact analogue of identifying functions in $L^2([0,1])$ that agree a.e., and for the same reason.

We claimed two properties of this space, completeness and separability, and leaned on them when justifying the L^2 choice. They are exactly the properties a fixed-point argument consumes — completeness so that Cauchy sequences of approximate solutions actually have limits to converge to, separability so that compactness arguments have countable scaffolding — so we owe a proof rather than an assertion. The proof is the Riesz–Fischer construction familiar from L^2 of real-valued functions, transported to a setting where the values are probability measures rather than numbers. That transport is the only subtlety: $\mathcal{P}_2(\mathbb{R}^d)$ is not a vector space, so we cannot add measures or invoke the usual normed-space completeness; we must run the argument purely metrically, using only that $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ is itself complete. We do exactly that.

Proposition 21.9 (Completeness and separability)**.** $(\boldsymbol{\mathcal{P}}_2, d_2)$ *is a complete separable metric space.*

Proof. d_2 is a metric. Symmetry and the vanishing $d_2(\boldsymbol{m}, \boldsymbol{m}) = 0$ are immediate from the corresponding properties of $\mathcal{W}_2$; that $d_2(\boldsymbol{m}, \boldsymbol{m}') = 0$ forces equality in $\boldsymbol{\mathcal{P}}_2$ uses the a.e.-identification, since $\int_0^1 \mathcal{W}_2(m^x, (m')^x)^2 \,\mathrm{d}x = 0$ means $\mathcal{W}_2(m^x, (m')^x) = 0$ for a.e. x, i.e. the two fields agree a.e. The triangle inequality is the one axiom that needs the L^2 structure. Pointwise in x the $\mathcal{W}_2$ triangle inequality (theorem 4.7) gives $\mathcal{W}_2(m^x, (m'')^x) \le \mathcal{W}_2(m^x, (m')^x) + \mathcal{W}_2((m')^x, (m'')^x)$; taking the $L^2([0,1])$ norm of both sides and applying Minkowski's inequality in $L^2([0,1])$ to the right-hand sum yields $d_2(\boldsymbol{m}, \boldsymbol{m}'') \le d_2(\boldsymbol{m}, \boldsymbol{m}') + d_2(\boldsymbol{m}', \boldsymbol{m}'')$. So d_2 is a bona fide metric.

Completeness. The structural fact we exploit is that $\boldsymbol{\mathcal{P}}_2$ is the L^2-Bochner-type space $L^2([0,1]; (\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2))$ of square-integrable measurable maps into the Polish space $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ (Polish by theorem 4.8). Completeness of such a space is the metric-target Riesz–Fischer argument, and we run all four of its steps. Let $\boldsymbol{m}^{(n)}$ be a d_2-Cauchy sequence. *(Step 1: extract a fast subsequence.)* Because the sequence is Cauchy, we may choose indices $n_1 < n_2 < \cdots$ with $d_2(\boldsymbol{m}^{(n_{k+1})}, \boldsymbol{m}^{(n_k)}) \le 2^{-k}$, so that $\sum_k d_2(\boldsymbol{m}^{(n_{k+1})}, \boldsymbol{m}^{(n_k)}) \le \sum_k 2^{-k} < \infty$; it suffices to show this subsequence converges, since a Cauchy sequence with a convergent subsequence converges to the same limit. Write the per-type increment $g_k(x) := \mathcal{W}_2(m^{(n_{k+1}),x}, m^{(n_k),x}) \ge 0$, so that $d_2(\boldsymbol{m}^{(n_{k+1})}, \boldsymbol{m}^{(n_k)}) = \|g_k\|_{L^2([0,1])}$. *(Step 2: Tonelli turns summable-in-L^2 into summable-a.e.)* The function $G := \sum_k g_k$ is a nonnegative measurable function on $[0,1]$, and by Minkowski's inequality together with the monotone convergence theorem, $\|G\|_{L^2([0,1])} \le \sum_k \|g_k\|_{L^2([0,1])} \le \sum_k 2^{-k} < \infty$. (Equivalently one applies Tonelli to the nonnegative double sum to interchange $\int_0^1$ and $\sum_k$.) A function in $L^2([0,1])$ is finite a.e., so $G(x) = \sum_k g_k(x) < \infty$ for Lebesgue-a.e. x; fix such a full-measure set $[0,1]_0$ of types. *(Step 3: pointwise Polish limit.)* For each $x \in [0,1]_0$ the tail sums $\sum_{k \ge K} g_k(x) \to 0$ as $K \to \infty$, so the sequence $(m^{(n_k),x})_k$ in $\mathcal{P}_2(\mathbb{R}^d)$ is $\mathcal{W}_2$-Cauchy: for $j > k$, $\mathcal{W}_2(m^{(n_j),x}, m^{(n_k),x}) \le \sum_{\ell \ge k} g_\ell(x) \to 0$. Since $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ is complete, this Cauchy sequence has a limit, which we name m^x; on the null complement of $[0,1]_0$ set $m^x := \delta_0$ (the choice is immaterial by a.e.-identification). The limit map

$x \mapsto m^x$ is Borel measurable, being an a.e. pointwise limit of the Borel-measurable maps $x \mapsto m^{(n_k),x}$ (a pointwise limit of measurable maps into a metric space is measurable). *(Step 4: dominated convergence in L^2.)* It remains to upgrade the pointwise convergence to d_2 convergence. For a.e. x and every k, $\mathcal{W}_2(m^x, m^{(n_k),x}) = \lim_j \mathcal{W}_2(m^{(n_j),x}, m^{(n_k),x}) \le \sum_{\ell \ge k} g_\ell(x) \le G(x)$, a bound that is independent of k and square-integrable since $G \in L^2([0,1])$. The left-hand side tends to 0 pointwise as $k \to \infty$, and it is dominated by the fixed L^2 function G, so the dominated convergence theorem gives $d_2(\boldsymbol{m}, \boldsymbol{m}^{(n_k)})^2 = \int_0^1 \mathcal{W}_2(m^x, m^{(n_k),x})^2 \,\mathrm{d}x \to 0$. Thus $\boldsymbol{m}^{(n_k)} \to \boldsymbol{m}$ in $\boldsymbol{\mathcal{P}}_2$, and with it the whole Cauchy sequence. The space is complete.

Separability. A countable dense set is built from the two ingredient countable dense sets. Let $\mathcal{D} \subset \mathcal{P}_2(\mathbb{R}^d)$ be a countable $\mathcal{W}_2$-dense subset (it exists because $\mathcal{P}_2(\mathbb{R}^d)$ is Polish) and consider the fields that are x-step functions taking finitely many values in $\mathcal{D}$ with rational breakpoints, i.e. $\boldsymbol{m} = \sum_{i=1}^N \mu_i \mathbf{1}_{I_i}$ with $\mu_i \in \mathcal{D}$ and $\{I_i\}$ a partition of $[0,1]$ into intervals with rational endpoints. This family is countable. It is also d_2-dense: given any $\boldsymbol{m} \in \boldsymbol{\mathcal{P}}_2$ and $\varepsilon > 0$, the measurable map $x \mapsto m^x$ can be approximated in $L^2([0,1]; \mathcal{P}_2(\mathbb{R}^d))$ first by a simple (finitely-valued measurable) map within $\varepsilon/2$ — the standard simple-function approximation, valid because the target is separable and the second moment is integrable — and then each of its finitely many values replaced by a $\mathcal{D}$-element within $\mathcal{W}_2$-distance $\varepsilon/2$, and each of its level sets replaced by a rational-endpoint interval approximation, incurring a further L^2 error below $\varepsilon/2$; the triangle inequality gives total error below ε. Hence the countable family is dense and $\boldsymbol{\mathcal{P}}_2$ is separable. The identical metric-target Riesz–Fischer construction, carried out for curves into $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$, appears in [7, Ch. 1], to which we refer for further reading and not for any step omitted here. □

The L^2 space $(\boldsymbol{\mathcal{P}}_2, d_2)$ is the right home for existence and compactness, but it is deliberately coarse: it sees a field only up to type-null sets and therefore cannot, on its own, express a statement like "the equilibrium law varies *continuously* with the type." Yet such statements are exactly what chapter 22 wants when the kernel itself is continuous in type — the regularity half of (A-Reg-W) — because then there is no reason for neighbouring types, wired together smoothly by W, to carry wildly different laws, and one expects, and wants to prove, that $x \mapsto (u^x, m^x)$ is continuous. To even pose that conclusion we need a space whose points *are* continuous fields and whose metric controls the supremum over types. So we record a second, finer space alongside the default. It is not a replacement — it is a strictly smaller space carrying a strictly stronger metric, used only where continuity-in-type is the output one is after.

Definition 21.10 (Type-continuous fields)**.** Let $\mathcal{C}_2 := C\big([0,1]; (\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)\big)$ be the set of $\mathcal{W}_2$-continuous maps $x \mapsto m^x$, metrized by the uniform distance

$$d_\infty(\boldsymbol{m}, \boldsymbol{m}') \;:=\; \sup_{x \in [0,1]} \mathcal{W}_2\big(m^x, (m')^x\big). \tag{21.11}$$

$(\mathcal{C}_2, d_\infty)$ is a complete metric space, it embeds continuously into $(\boldsymbol{\mathcal{P}}_2, d_2)$ via $d_2 \le d_\infty$, and it is the space in which we phrase continuity-in-type conclusions.

Each clause of definition 21.10 is quickly checked, and the checks expose exactly how the two spaces relate. Completeness of $(\mathcal{C}_2, d_\infty)$ is the classical fact that a uniform (i.e. d_∞-Cauchy) limit of continuous maps into a complete target is again continuous: if $\boldsymbol{m}^{(n)} \to \boldsymbol{m}$ uniformly and each

$\boldsymbol{m}^{(n)}$ is $\mathcal{W}_2$-continuous in x, then the limit inherits continuity by the standard three-ε argument, and the target completeness of $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ supplies the pointwise limits to which the uniform limit is assembled. The embedding is the elementary bound $d_2(\boldsymbol{m}, \boldsymbol{m}')^2 = \int_0^1 \mathcal{W}_2(m^x, (m')^x)^2 \,\mathrm{d}x \le \sup_x \mathcal{W}_2(m^x, (m')^x)^2 = d_\infty(\boldsymbol{m}, \boldsymbol{m}')^2$, an integral over a probability interval being dominated by the supremum of the integrand: convergence in d_∞ forces convergence in d_2, so the inclusion $\mathcal{C}_2 \hookrightarrow \boldsymbol{\mathcal{P}}_2$ is 1-Lipschitz. What the bound does *not* give — and this is the whole point of keeping two spaces — is any reverse control: d_2-convergence is far weaker than d_∞-convergence, and the two spaces are genuinely non-interchangeable. The next box states the convention and warns against conflating them.

Notation watch

The default working space of Part IV is $(\boldsymbol{\mathcal{P}}_2, d_2)$ of definition 21.8: existence and compactness arguments (chapter 24) live here. The uniform space $(\mathcal{C}_2, d_\infty)$ of definition 21.10 is used *only* when (A-Reg-W) supplies continuity of W in type and one wants continuity of $x \mapsto (u^x, m^x)$ as an output. The two are not interchangeable, and the reason is concrete: $\mathcal{C}_2$ is *not* d_2-closed in $\boldsymbol{\mathcal{P}}_2$. To exhibit this, take in dimension one the continuous fields $\boldsymbol{m}^{(n)}$ given by $m^x_{(n)} = \delta_{f_n(x)}$ with f_n a continuous ramp that climbs from 0 to 1 across the interval $[\frac{1}{2} - \frac{1}{n}, \frac{1}{2} + \frac{1}{n}]$ and is flat outside it. Each $\boldsymbol{m}^{(n)} \in \mathcal{C}_2$, since $x \mapsto \delta_{f_n(x)}$ is $\mathcal{W}_2$-continuous. But in d_2 they converge to the field $\boldsymbol{m}^{(\infty)} = \delta_{\mathbf{1}\{x>1/2\}}$, a Dirac that jumps from δ_0 to δ_1 across $x = \frac{1}{2}$: indeed $d_2(\boldsymbol{m}^{(n)}, \boldsymbol{m}^{(\infty)})^2 = \int_0^1 |f_n(x) - \mathbf{1}\{x > 1/2\}|^2 \,\mathrm{d}x \le 2/n \to 0$, because the integrand is supported on the shrinking ramp interval and bounded by 1 there. The d_2-limit $\boldsymbol{m}^{(\infty)}$ is plainly *discontinuous* in type, hence not in $\mathcal{C}_2$. So an L^2 limit of continuous fields need not be continuous, and a statement proved in one space is not automatically valid in the other: a compactness argument run in $(\boldsymbol{\mathcal{P}}_2, d_2)$ may produce a limit field that lies outside $\mathcal{C}_2$ unless continuity is separately propagated. For this reason each theorem in chapters 22 and 24 names which space it uses, and we make the default explicit here so that downstream chapters do not silently disagree.

We arrive at the technical heart of the section, and indeed of the chapter's structural argument. Everything so far has prepared a home for the field; we now show that the one operation the game performs on the field — forming the aggregate $\boldsymbol{m} \mapsto \Theta$ that each agent feels — is *Lipschitz* on that home, with a Lipschitz constant we can name exactly. This is the fact every later existence and uniqueness argument leans on, because a fixed-point map can only be controlled if each of its constituent steps is controlled, and the aggregate is the step through which the entire network coupling acts. The constant that emerges is the operator norm $\|\mathbb{W}\|$ of chapter 18, and it is no accident that it is precisely this quantity: $\|\mathbb{W}\|$ measures how much the kernel can amplify a perturbation of the field, and a perturbation of the field is exactly what propagates through the equilibrium loop. The moment we read off the constant $\|\mathbb{W}\|$ we will have located, in the dynamic theory, the birthplace of the coupling threshold (A-Coupling) that governs every uniqueness statement downstream.

The proof rests on one elementary inequality, and it is worth flagging in advance that we need only the *easy* half of the Kantorovich–Rubinstein picture — the half that holds for any coupling and invokes no duality theorem. We are spared the hard half (that the $\mathcal{W}_1$ distance equals the supremum over 1-Lipschitz test functions) because we do not need an identity; we need only an upper bound on the change in a single observable, and that bound falls straight out of the definition of a coupling. Keeping the argument elementary here is deliberate: it means the Lipschitz property of the aggregate rests on nothing deeper than the triangle inequality and Cauchy–Schwarz, and so survives into every generalization downstream.

Lemma 21.11 (Measurability and Lipschitz continuity of the aggregate)**.** *Assume* (A-Reg-W)*: W is symmetric, measurable, bounded, and $\mathbb{W}$ is self-adjoint Hilbert–Schmidt on $L^2([0,1])$. Let $\boldsymbol{m}, \boldsymbol{m}' \in \boldsymbol{\mathcal{P}}_2$.*

(i) *The first-moment field $\bar m \in L^2([0,1];\mathbb{R}^d)$, with $\|\bar m\|_{L^2} \le d_2(\boldsymbol{m}, \boldsymbol{\delta}_0)$, and the map $x \mapsto (\mathbb{W}\,\bar m)(x)$ is well-defined and lies in $L^2([0,1];\mathbb{R}^d)$.*

(ii) *For the first-moment coupling* (21.5)*,*

$$\|\,\mathbb{W}\bar m - \mathbb{W}\bar m'\,\|_{L^2([0,1])} \;\le\; \|\mathbb{W}\|\;\|\bar m - \bar m'\|_{L^2([0,1])} \;\le\; \|\mathbb{W}\|\;d_2(\boldsymbol{m}, \boldsymbol{m}'), \tag{21.12}$$

where $\|\mathbb{W}\|$ is the operator norm on $L^2([0,1])$. In particular the aggregate map $\boldsymbol{m} \mapsto \mathbb{W}\bar m$ is $\|\mathbb{W}\|$-Lipschitz from $(\boldsymbol{\mathcal{P}}_2, d_2)$ to $L^2([0,1];\mathbb{R}^d)$.

(iii) *More generally, for a coupling through a bounded 1-Lipschitz observable h the field $x \mapsto \langle h, m^x\rangle$ obeys the same estimate with $\bar m$ replaced by $\langle h, m^{\cdot}\rangle$, hence $\boldsymbol{m} \mapsto \Theta = \mathbb{W}[\langle h, m^{\cdot}\rangle]$ is $\|\mathbb{W}\|$-Lipschitz in d_2.*

Proof. (i) We first place the first-moment field in $L^2([0,1];\mathbb{R}^d)$, which is the half of the statement that the integrability clause of definition 21.8 was designed to deliver. Fix a type x. By Jensen's inequality applied to the convex function $\xi \mapsto |\xi|^2$, the mean is dominated by the root second moment, $|\bar m(x)| = |\int \xi\, m^x(\mathrm{d}\xi)| \le (\int |\xi|^2\; m^x(\mathrm{d}\xi))^{1/2}$, and the right-hand side is exactly $\mathcal{W}_2(m^x, \delta_0)$, since transporting any measure to the Dirac at the origin costs its root second moment. Squaring this pointwise bound and integrating over types, $\|\bar m\|^2_{L^2([0,1])} = \int_0^1 |\bar m(x)|^2\,\mathrm{d}x \le \int_0^1 \mathcal{W}_2(m^x, \delta_0)^2\,\mathrm{d}x = d_2(\boldsymbol{m}, \boldsymbol{\delta}_0)^2$, which is finite precisely because $\boldsymbol{m} \in \boldsymbol{\mathcal{P}}_2$. So $\bar m \in L^2([0,1];\mathbb{R}^d)$ with $\|\bar m\|_{L^2} \le d_2(\boldsymbol{m}, \boldsymbol{\delta}_0)$, the bound claimed in (i). Measurability of $x \mapsto \bar m(x)$ follows because $x \mapsto m^x$ is Borel measurable into $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ by hypothesis and the first-moment functional $\mu \mapsto \int \xi\,\mu(\mathrm{d}\xi)$ is $\mathcal{W}_2$-continuous on $\mathcal{P}_2(\mathbb{R}^d)$ (it is even $\mathcal{W}_2$-Lipschitz, by the very coupling bound (21.13) proved in (ii) with h the identity), so the composition is measurable. Finally, $\mathbb{W}$ is a bounded operator on $L^2([0,1])$ — under (A-Reg-W) it is Hilbert–Schmidt, hence bounded with $\|\mathbb{W}\| < \infty$ — and a bounded operator maps L^2 into L^2 coordinatewise, so $\mathbb{W}\bar m \in L^2([0,1];\mathbb{R}^d)$ is well-defined. This proves (i): the aggregate $\mathbb{W}\bar m$ is a genuine element of the Hilbert space in which the network coupling lives.

(ii) The estimate (21.12) is built from one pointwise-in-type inequality, which we isolate. For two probability measures $\mu, \nu \in \mathcal{P}_2(\mathbb{R}^d)$ and any 1-Lipschitz $h : \mathbb{R}^d \to \mathbb{R}$,

$$|\langle h, \mu\rangle - \langle h, \nu\rangle| \;\le\; \mathcal{W}_1(\mu, \nu) \;\le\; \mathcal{W}_2(\mu, \nu). \tag{21.13}$$

Here is the entire argument, and it uses only the *easy* half of the Kantorovich–Rubinstein picture — no duality theorem. Let $\pi \in \mathcal{P}(\mathbb{R}^d \times \mathbb{R}^d)$ be *any* coupling of (μ, ν), that is, any probability measure on the product with first marginal μ and second marginal ν. Then $\langle h, \mu\rangle = \int\!\!\int h(\xi)\,\pi(\mathrm{d}\xi, \mathrm{d}\xi')$ and

$\langle h, \nu\rangle = \iint h(\xi')\,\pi(\mathrm{d}\xi, \mathrm{d}\xi')$ — this is exactly what "marginal" means — so the two single integrals over μ and ν become a single integral over the coupling of the *difference*:

$$|\langle h, \mu\rangle - \langle h, \nu\rangle| = \Big|\iint (h(\xi) - h(\xi'))\,\pi(\mathrm{d}\xi, \mathrm{d}\xi')\Big| \le \iint |h(\xi) - h(\xi')|\;\pi(\mathrm{d}\xi, \mathrm{d}\xi') \le \iint |\xi - \xi'|\;\pi(\mathrm{d}\xi, \mathrm{d}\xi'),$$

the first inequality by Jensen (the modulus of an integral is at most the integral of the modulus) and the second by 1-Lipschitzness of h, $|h(\xi) - h(\xi')| \le |\xi - \xi'|$. The left-hand side does not depend on the coupling π, so we may take the infimum of the right-hand side over all couplings, which by definition is the 1-Wasserstein distance $\mathcal{W}_1(\mu, \nu) = \inf_\pi \int |\xi - \xi'|\,\mathrm{d}\pi$; this gives the first inequality in (21.13). The second, $\mathcal{W}_1 \le \mathcal{W}_2$, is one application of the Cauchy–Schwarz (Jensen) inequality to the $\mathcal{W}_2$-optimal coupling π^*: $\int |\xi - \xi'|\,\mathrm{d}\pi^* \le (\int |\xi - \xi'|^2\,\mathrm{d}\pi^*)^{1/2} = \mathcal{W}_2(\mu, \nu)$ (theorem 4.8). Nothing here used more than the existence of couplings and two elementary inequalities, which is exactly why the conclusion is so robust.

Now we pass from one type to the whole field. Take $h(\xi) = \xi$, applied componentwise — each coordinate of the identity is 1-Lipschitz — and set $\mu = m^x$, $\nu = (m')^x$, so that $\langle h, \mu\rangle = \bar{m}(x)$ and $\langle h, \nu\rangle = \bar{m}'(x)$. The pointwise inequality (21.13) becomes $|\bar{m}(x) - \bar{m}'(x)| \le \mathcal{W}_2(m^x, (m')^x)$; squaring and integrating over x,

$$\|\bar{m} - \bar{m}'\|^2_{L^2([0,1])} = \int_0^1 |\bar{m}(x) - \bar{m}'(x)|^2\,\mathrm{d}x \le \int_0^1 \mathcal{W}_2(m^x, (m')^x)^2\,\mathrm{d}x = d_2(\boldsymbol{m}, \boldsymbol{m}')^2.$$

So the map $\boldsymbol{m} \mapsto \bar{m}$ from $(\boldsymbol{\mathcal{P}}_2, d_2)$ to $L^2([0,1]; \mathbb{R}^d)$ is itself 1-Lipschitz. The final step is the only place the operator enters: $\mathbb{W}$ is bounded with operator norm $\|\mathbb{W}\|$, so by the definition of the operator norm, $\|\mathbb{W}\bar{m} - \mathbb{W}\bar{m}'\|_{L^2} = \|\mathbb{W}(\bar{m} - \bar{m}')\|_{L^2} \le \|\mathbb{W}\|\;\|\bar{m} - \bar{m}'\|_{L^2} \le \|\mathbb{W}\|\;d_2(\boldsymbol{m}, \boldsymbol{m}')$, which is exactly (21.12). The two factors compose with no loss: the field-to-mean map contributes its constant 1 and the operator contributes $\|\mathbb{W}\|$, so the aggregate $\boldsymbol{m} \mapsto \mathbb{W}\bar{m}$ is $\|\mathbb{W}\|$-Lipschitz from $(\boldsymbol{\mathcal{P}}_2, d_2)$ to $L^2([0,1]; \mathbb{R}^d)$, proving (ii).

(iii) The general first-order coupling is identical, because the only property of the identity used in (ii) was its 1-Lipschitzness. Replacing the identity by a bounded 1-Lipschitz observable h, the field $x \mapsto \langle h, m^x\rangle$ satisfies the same pointwise bound $|\langle h, m^x\rangle - \langle h, (m')^x\rangle| \le \mathcal{W}_2(m^x, (m')^x)$ from (21.13), hence the same L^2 contraction and the same $\|\mathbb{W}\|$ factor, so $\boldsymbol{m} \mapsto \Theta = \mathbb{W}[\langle h, m^{\cdot}\rangle]$ is $\|\mathbb{W}\|$-Lipschitz in d_2. The boundedness of h is what keeps $\langle h, m^{\cdot}\rangle$ a bounded (hence L^2) field without any moment assumption, while 1-Lipschitzness is what couples its variation to the $\mathcal{W}_2$ geometry; the identity of Thread B is the borderline case where h is unbounded but its growth is controlled by the finite second moment, which is why part (i) had to secure $\bar{m} \in L^2$ separately. □

Remark 21.12 (Where the coupling threshold comes from)**.** Lemma 21.11 is the dynamic origin of the operator-norm condition (A-Coupling), and it is worth doing the bookkeeping explicitly, because the product $|s|\;\|\mathbb{W}\|$ that will control every uniqueness theorem downstream is assembled from exactly two factors, contributed by two distinct parts of the model. Trace one loop of the best-response map and watch the constants accumulate. The loop has three legs. The aggregate leg $\boldsymbol{m} \mapsto \Theta$ is the one we just bounded: by the lemma it is Lipschitz with constant $\|\mathbb{W}\|$ — *this is the first factor*, and it comes purely from the network kernel, with no reference to the cost. The cost leg is where the coupling strength s enters: the agent feels the aggregate only through the term $\frac{q}{2}(X - s\,z_t(x))^2$ of (21.8), so a unit change in the aggregate $\Theta = z_t(x)$ shifts the optimization data by a factor $|s|$ — *this is the second factor*, and it comes purely from the cost, with no reference to the kernel. The remaining leg — solving the per-type control problem and pushing the law forward by Fokker–Planck — contributes a third constant L_{ctrl} that depends only on the *single-type* data (a, b, q, q_T, σ in Thread B) and not at all on the coupling. Composing the three legs, the best-response map is Lipschitz on $C([0,T]; \boldsymbol{\mathcal{P}}_2)$ with constant at most $L_{\mathrm{ctrl}} \cdot |s| \cdot \|\mathbb{W}\|$, and a contraction — hence a unique fixed point by Banach — whenever $L_{\mathrm{ctrl}}\ |s|\ \|\mathbb{W}\| < 1$, i.e. whenever the coupling product $|s|\ \|\mathbb{W}\|$ lies below the threshold $1/L_{\mathrm{ctrl}}$ fixed by the single-type control problem alone. The clean separation — one factor of $\|\mathbb{W}\|$ from the kernel, one factor of $|s|$ from the cost, and a coupling-independent budget set by the isolated agent — is the dynamic counterpart of the static subcriticality threshold of theorem 20.14 (whose linear–quadratic spectral form is eq. (20.31)), and it is the precise sense in which $|s|\ \|\mathbb{W}\|$ is the single control parameter of the whole theory. We will see the product collapse to a single scalar in the rank-one reduction worked computation 21.18, where $\|\mathbb{W}\|$ becomes the lone nonzero eigenvalue and the infinite field closes into one self-consistent equation with effective coupling $s\ \|\mathbb{W}\|$.

One loose end remains, and it is the one remark 21.2 explicitly deferred to this section. There we resolved the continuum-of-noises difficulty by declaring that the population is the *deterministic* field of laws $x \mapsto m_t^x = \mathcal{L}(X_t^x)$, never a random ensemble of trajectories, and we promised that the only measurability this demands is measurability of a deterministic map $[0,1] \to \mathcal{P}_2(\mathbb{R}^d)$ — a statement that holds and can be proved without any jointly measurable random field. We now make good on that promise. The point worth appreciating is how *cheaply* the measurability comes: we do not need a measurable-selection theorem, which is the usual heavy hammer for "does a measurable choice exist over a parameter," because the field of laws is not a *selection* but a *composition* — the type-dependent data is measurable by hypothesis, and the map from data to law is *continuous*, by a single Grönwall estimate. A continuous function of a measurable function is measurable, and that is the whole argument. The work is in establishing the continuity, and the device that establishes it — coupling two types through the *same* Brownian motion — is worth seeing in detail, because the same trick recurs throughout chapters 23 and 24.

Lemma 21.13 (Measurability of the field of laws)**.** *Suppose $x \mapsto m_0^x$ is Borel measurable into $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ with $\boldsymbol{m}_0 \in \boldsymbol{\mathcal{P}}_2$, the coefficients b, σ are Borel in x and obey* (A-Lip)*,* (A-Growth) *uniformly in x, the aggregate flow $t \mapsto \Theta_t(\cdot)$ is given and measurable in x, and a measurable-in-x admissible feedback is fixed. Then for each t the map $x \mapsto m_t^x = \mathcal{L}(X_t^x)$ is Borel measurable into $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$, and $\boldsymbol{m}_t \in \boldsymbol{\mathcal{P}}_2$ with $\sup_{t \le T} d_2(\boldsymbol{m}_t, \boldsymbol{\delta}_0) < \infty$.*

Proof. Fix the measurable-in-x feedback ϕ^x, assumed jointly measurable in (x, t, X) and Lipschitz in X uniformly in (x, t) (the regularity the verification theorem of chapter 6 produces; for the LQG thread the feedback is linear in X). The closed-loop coefficients $\widehat{b}(x, t, X) := b(x, X, \phi^x(t, X), \Theta_t(x))$ and $\sigma(x, X)$ are then, under (A-Lip), (A-Growth), Lipschitz and of linear growth in X uniformly in (x, t). For each fixed x the closed-loop SDE (21.1) has a unique strong solution by theorem 5.10, with the second-moment bound

$$\mathbb{E}\Big[\sup_{t \le T} |X_t^x|^2\Big] \le C\big(1 + \mathbb{E}\Big[|X_0^x|^2\Big] + \sup_t |\Theta_t(x)|^2\big), \tag{21.14}$$

the constant C depending only on T and the Lipschitz/growth constants, hence uniform in x.

Stability in the data. We show that the law $\mathcal{L}(X_t^x)$ depends continuously on the type-dependent data $(m_0^x, \Theta.(x), \widehat{b}(x,\cdot,\cdot))$, by a single Grönwall estimate, and the mechanism is a coupling trick that deserves to be stated plainly. To compare the laws of two types x and x' in the $\mathcal{W}_2$ metric we must exhibit *some* coupling of those two laws and bound the expected squared distance under it; any coupling gives an upper bound on $\mathcal{W}_2$, and we are free to engineer a convenient one. The convenient choice is to run *both* closed-loop SDEs on one probability space, driven by the *same* Brownian motion B and with initial conditions X_0, X_0' realizing a $\mathcal{W}_2$-optimal coupling of the two initial laws $(m_0^x, m_0^{x'})$. Driving both by the identical noise is the whole device: it makes the stochastic integrals in the two equations *cancel* when subtracted, so that the difference process $D_t := X_t - X_t'$ is driven only by the discrepancy in the drifts and in the diffusion coefficients — the irreducible randomness, which we could not have controlled, has been arranged to subtract away, leaving a difference that obeys an almost deterministic estimate. (If the two had been driven by independent noises, D_t would carry the *sum* of two fresh Brownian motions and no Grönwall bound could close.)

Subtract the two closed-loop equations and write the difference as the sum of an initial term, a drift term, and a martingale term. Apply $|a+b+c|^2 \le 3(|a|^2+|b|^2+|c|^2)$, the Lipschitz bound on $\widehat{b}$ and σ in X (so that $\left|\widehat{b}(x,r,X_r) - \widehat{b}(x,r,X_r')\right| \le L\,|D_r|$ and likewise for σ), and Doob's L^2 maximal inequality to control the supremum of the martingale part by its terminal second moment (exactly as in the well-posedness proof of theorem 5.10). The one term that does not close into $|D|$ is the genuine *type* discrepancy: where the second equation should carry $\widehat{b}(x,r,X_r')$ it carries $\widehat{b}(x',r,X_r')$ instead, so we insert and subtract $\widehat{b}(x,r,X_r')$ by the triangle inequality, splitting that term into a Lipschitz-in-X piece (folded into the $|D|$ terms) and a residual measuring how far the two *coefficients* are at the same state. Collecting,

$$\mathbb{E}\left[\sup_{s\le t}|D_s|^2\right] \;\le\; C\Big(\mathbb{E}\Big[|X_0 - X_0'|^2\Big] + \int_0^t \mathbb{E}\left[\sup_{r\le s}|D_r|^2\right]\mathrm{d}s + \delta(x,x')\Big),$$

where the residual $\delta(x,x') := \int_0^T \big(\sup_X \frac{\left|\widehat{b}(x,r,X) - \widehat{b}(x',r,X)\right|^2}{1+|X|^2}\big)\,\mathrm{d}r$ collects the entire coefficient-and-aggregate discrepancy between the two types: it is large when the closed-loop drifts of types x and x' differ, which happens when their aggregates $\Theta.(x), \Theta.(x')$ or their raw coefficients differ, and it vanishes as the two data coincide. (The $1+|X|^2$ normalization is what keeps the supremum finite under the linear growth of $\widehat{b}$.) The first two terms on the right are the standard self-referential structure that Grönwall absorbs; the third is the genuine input. Grönwall's inequality (lemma C.1) applied to $t \mapsto \mathbb{E}\Big[\sup_{s\le t}|D_s|^2\Big]$ closes the estimate into

$$\mathcal{W}_2(m_t^x, m_t^{x'})^2 \;\le\; \mathbb{E}\left[\sup_{s\le t}|D_s|^2\right] \;\le\; C\,e^{CT}\Big(\mathcal{W}_2(m_0^x, m_0^{x'})^2 + \delta(x,x')\Big), \tag{21.15}$$

where the leftmost inequality holds because (X_t, X_t') is *a* coupling — not necessarily the optimal one — of $(m_t^x, m_t^{x'})$, so the actual $\mathcal{W}_2$ distance, an infimum over couplings, can only be smaller than the cost of this particular coupling; and the rightmost uses that the initial coupling *was* chosen optimal, $\mathbb{E}\Big[|X_0 - X_0'|^2\Big] = \mathcal{W}_2(m_0^x, m_0^{x'})^2$. Inequality (21.15) is the precise statement that the map from type-data to type-law is (locally Lipschitz, hence) continuous.

Measurability. Now the composition argument promised above runs in one line. By hypothesis the data map $x \mapsto \big(m_0^x, \Theta_\cdot(x), \widehat{b}(x,\cdot,\cdot)\big)$ is Borel measurable into the relevant data space (the initial law is measurable by assumption, the aggregate flow is measurable in x by hypothesis, and the closed-loop drift inherits measurability from b, the feedback, and the aggregate). Inequality (21.15) says that the map sending these data to the law $\mathcal{L}(X_t^x)$ is continuous: when two types' data are close — in initial law and in coefficient discrepancy δ — their laws are $\mathcal{W}_2$-close. The field of laws $x \mapsto m_t^x = \mathcal{L}(X_t^x)$ is therefore the composition of a Borel-measurable map (data of x) with a continuous map (data $\mapsto$ law), and a continuous function of a Borel-measurable function is Borel measurable. So $x \mapsto m_t^x$ is Borel measurable into $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ for each t. We emphasize what was *not* needed: *no measurable-selection theorem*, because we never had to select anything — the law is determined outright by the data, and its measurability is inherited from theirs. (We cite [6, Ch. III] only for the separate matter of selecting a measurable admissible feedback in the first place, not for the present composition step.) Finally, the field lands in $\boldsymbol{\mathcal{P}}_2$ with a uniform-in-time bound: integrating the second-moment estimate (21.14) over types, $\int_0^1 \mathcal{W}_2(m_t^x, \delta_0)^2\,\mathrm{d}x \le \int_0^1 \mathbb{E}\Big[|X_t^x|^2\Big]\,\mathrm{d}x \le C\big(1+\int_0^1 \mathbb{E}\Big[|X_0^x|^2\Big]\,\mathrm{d}x + \sup_t \|\Theta_t\|_{L^2}^2\big) < \infty$ for all $t \le T$, the right-hand side finite because $\boldsymbol{m}_0 \in \boldsymbol{\mathcal{P}}_2$ and the aggregate flow is square-integrable in type. Hence $\boldsymbol{m}_t \in \boldsymbol{\mathcal{P}}_2$ with $\sup_{t\le T} d_2(\boldsymbol{m}_t, \boldsymbol{\delta}_0) < \infty$, completing the proof. □

With this lemma the last structural debt of the chapter is paid. We now possess everything a fixed-point definition requires and nothing more is owed: a state space $(\boldsymbol{\mathcal{P}}_2, d_2)$ that is complete and separable (proposition 21.9), so that limits of fields exist and compactness has room to operate; its finer continuous-in-type companion $(\mathcal{C}_2, d_\infty)$ for the regularity statements of chapter 22; the aggregate $\boldsymbol{m} \mapsto \Theta$ shown to be a $\|\mathbb{W}\|$-Lipschitz operation on that space (lemma 21.11), which both makes the coupling a bona-fide continuous map and locates the threshold $|s|\ \|\mathbb{W}\|$ that will govern uniqueness (remark 21.12); and the guarantee that the field of laws an agent's optimal behaviour generates is itself a legitimate, measurable element of $\boldsymbol{\mathcal{P}}_2$ (lemma 21.13), so the best-response map maps the space into itself. These are precisely the ingredients a fixed-point question consumes, and the next section assembles them into the equilibrium concept — the type-by-type Nash fixed point toward which every construction in this chapter has been building.

21.4 The equilibrium concept

Every ingredient is now in place, and this section spends them. The previous section closed by paying "the last structural debt of the chapter": we have a state space $(\boldsymbol{\mathcal{P}}_2, d_2)$ that is complete and separable (proposition 21.9), a graphon aggregate $\boldsymbol{m} \mapsto \Theta$ that is a $\|\mathbb{W}\|$-Lipschitz operation on it (lemma 21.11), and the guarantee that the field of laws produced by an agent's optimal behaviour is itself a legitimate, measurable element of that space (lemma 21.13). Those three facts are not curiosities collected along the way; they are precisely the three things one must own before the question "does the best-response map have a fixed point?" is even meaningful — a good domain, a continuous coupling, and a map that lands back in its domain. This section is where they are assembled into a definition. We build it in three deliberate steps, each answering one question the definition cannot leave open: *which* controls an agent is allowed to use (the admissible class), *what* an agent does with a population it is shown (the best-response map), and *when* a population is consistent with its own response (the fixed point). The destination is the third, but it is empty without the first two.

The architecture we are about to write down is not new in shape — it is the fixed-point structure of Part II (definition 8.1), in which a single representative agent optimizes against a measure flow and equilibrium demands that the optimizer regenerate that very flow. What is new is the dimension of the unknown. In Part II the unknown was one curve $t \mapsto m_t$ in $\mathcal{P}_2(\mathbb{R}^d)$; here it is an entire curve $t \mapsto \boldsymbol{m}_t$ in the field space $\boldsymbol{\mathcal{P}}_2$, one measure per type at each instant. The leap from "one measure flow" to "field-of-measures flow" is the whole content of the generalization, and the reader should keep it in view as the single thing that distinguishes every definition below from its Part II ancestor.

One standing convention must be live throughout, because both a value function and a density appear in the same definition and they flow in opposite directions in time. *In the best-response problem the value function u^x is solved backward from terminal data at $t = T$; the induced law $\widetilde{m^x}$ flows forward from initial data at $t = 0$.* The two are computed by integrating two different equations in two different time directions, and they meet — are forced to be mutually consistent — only at the fixed point. Holding that asymmetry in mind makes the definitions below read as what they are: a backward computation and a forward computation, locked together by a self-consistency condition.

We start with the admissible class, because a control problem is not posed until one has said which controls are even on the table. The choice is not cosmetic: too large a class and the infimum in the best-response problem need not be attained by any usable object; too small a class and one risks excluding the genuine optimizer. The class we adopt is the standard one of stochastic control, and it is dictated by two requirements that the agent's information and its budget impose. First, a control must be *non-anticipating*: the type-x agent decides α_t^x knowing only what has happened up to time t — its own initial draw and the history of its own noise B^x — and never the future of the Brownian path. This is the content of progressive measurability with respect to the filtration generated by B^x and X_0^x; it is what makes the controlled SDE (21.1) a well-defined object in the first place, since the stochastic integral against B^x only makes sense for integrands that do not peek ahead. Second, a control must have *finite energy*, $\mathbb{E}\Big[\int_0^T |\alpha_t^x|^2 \,\mathrm{d}t\Big] < \infty$, which is exactly the integrability under which the quadratic running cost of (21.6) is finite and the state's second moment stays controlled — without it the cost can be $+\infty$ and "minimizing" it is vacuous.

Definition 21.14 (Admissible controls)**.** Fix a frozen, measurable field flow $(\boldsymbol{m}_t)_{t\in[0,T]}$, $\boldsymbol{m}_t \in \boldsymbol{\mathcal{P}}_2$, and the associated aggregate $\Theta_t(x)$. For each x, the set $\mathcal{U}^x$ of *admissible controls* consists of A-valued processes α^x progressively measurable with respect to the filtration generated by B^x and X_0^x, with $\mathbb{E}\Big[\int_0^T |\alpha_t^x|^2 \,\mathrm{d}t\Big] < \infty$. Markov (feedback) controls $\alpha_t^x = \phi^x(t, X_t^x)$ with ϕ^x measurable and of linear growth in the state form the subclass on which the verification theorem of chapter 6 produces optimizers under (A-Conv), (A-Nondeg).

The definition names a large class — all square-integrable progressively measurable processes — and then singles out a small subclass, the Markov or *feedback* controls $\alpha_t^x = \phi^x(t, X_t^x)$ that depend on the past only through the current state. It is worth being clear about why both appear. The large class is the honest arena of competition: when we say an agent does the best it can, "best" must mean best over *all* admissible strategies, including history-dependent ones, or the optimality claim is weaker than it sounds and the equilibrium would not deserve the name Nash. The small class is where the answer actually lives. The verification theorem of chapter 6 says that under convexity of the Hamiltonian (A-Conv) and nondegeneracy of the noise (A-Nondeg), the optimizer over the *large* class is in fact realized by a *feedback* of the small class — the one read off from the gradient of the value function — so that nothing is lost by the restriction. Nondegeneracy is what gives the value function enough regularity (a classical or suitably weak second derivative) for the verification argument to apply Itô's formula to it; convexity is what makes the pointwise maximizer of the Hamiltonian a genuine minimizer of the cost rather than a critical point of the wrong sign. This is the precise division of labour we will lean on at once: we pose the best-response problem over the large class so that "best response" means what it should, and we solve it in the small class because that is where the HJB equation delivers the optimizer in closed form.

With the admissible class fixed we can write down what a single agent does when it is shown a population. The construction is the heart of the section, and it is best read as the composition of three classical operations that we will name now and then unpack one at a time after the statement. The crucial conceptual point, inherited unchanged from mean field game theory and worth stating before any formula, is that during its own optimization the infinitesimal agent treats the population field — and hence the aggregate it feels — as *frozen, exogenous data.* A single agent is one of a continuum; it cannot, by acting differently, move the aggregate $\Theta_t(x)$, because that aggregate is a kernel-weighted average over a continuum of types and altering one type's behaviour on a set of measure zero changes nothing. So from the agent's vantage point the flow $t \mapsto \Theta_t(x)$ is a fixed input function, and the optimization it performs is an entirely *standard* stochastic control problem with that input baked into the running and terminal costs. The graphon has, for the duration of the agent's calculation, vanished into a known time-dependent coefficient. All of the network's self-referential difficulty is postponed to the fixed-point condition that closes the loop; here there is no loop, only an ordinary control problem solved against a given target.

Definition 21.15 (Best-response map)**.** Given a field flow $(\boldsymbol{m}_t)_t$ and the induced aggregate flow $(\Theta_t)_t$, the type-x agent solves

$$u^x(t,X) \;=\; \inf_{\alpha^x \in \mathcal{U}^x} \mathbb{E}\left[\int_t^T L(x, X_r^x, \alpha_r^x, \Theta_r(x))\,\mathrm{d}r + g(x, X_T^x, \Theta_T(x)) \;\middle|\; X_t^x = X\right],$$

a standard stochastic control problem (the aggregate is exogenous to the infinitesimal agent) whose value u^x solves the backward HJB equation $\partial_t u^x + \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 u^x) - H(x, X, \nabla u^x, \Theta_t(x)) = 0$, $u^x(T,\cdot) = g(x,\cdot,\Theta_T(x))$, with optimal feedback the maximizer $\alpha^{x,*} = \alpha^*(x, X, \nabla u^x, \Theta_t(x))$ of (21.7) under (A-Conv) (for control-affine drift, $\alpha^{x,*} = -B^\top \nabla u^x$; in the scalar LQG thread, $-b\,\partial_X u^x$). Let $\widetilde{m^x}_t := \mathcal{L}(X_t^{x,*})$ be the law of the optimally controlled state, which evolves forward by the Fokker–Planck equation (theorem 5.14) $\partial_t \widetilde{m^x} = \mathcal{A}^{x,*}\widetilde{m^x}$, $\widetilde{m^x}_0 = m_0^x$, where $\mathcal{A}^{x,*}$ is the adjoint of the generator of the optimally controlled type-x diffusion. The *best-response map* is

$$\mathsf{S}:\; (\boldsymbol{m}_t)_t \;\longmapsto\; (\widetilde{\boldsymbol{m}}_t)_t, \qquad \widetilde{\boldsymbol{m}}_t = (\widetilde{m^x}_t)_{x\in[0,1]},$$

acting on the path space $C([0,T];\boldsymbol{\mathcal{P}}_2)$ (or $C([0,T];\mathcal{C}_2)$ under (A-Reg-W) continuity).

The definition is compressed by design, and it packs three logically distinct steps into one block.

Pulling them apart is what makes the map intelligible, so we take them in turn, and the order is exactly the order in which one computes a best response.

Step 1: solve the backward HJB equation (the value). For each fixed type x the agent's optimal cost-to-go from state X at time t is the value function $u^x(t, X)$, and dynamic programming turns the control problem into the second-order parabolic equation

$$\partial_t u^x + \tfrac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 u^x) - H(x, X, \nabla u^x, \Theta_t(x)) = 0, \qquad u^x(T, \cdot) = g(x, \cdot, \Theta_T(x)),$$

solved *backward* from the terminal cost. This is where the standing convention earns its keep: the equation carries data at $t = T$ and is integrated toward $t = 0$, because the value at time t is the best the agent can still do over the *remaining* horizon $[t, T]$, and the only thing it knows for certain about that horizon is the terminal cost. The frozen aggregate enters only as the time-dependent coefficient $\Theta_t(x)$ sitting inside the Hamiltonian and the terminal data; with it frozen, this is precisely the HJB equation whose solvability and nondegenerate-parabolic regularity were established for a single agent, and nothing about the graphon is visible except through that one coefficient. (A-Nondeg) is what makes the $\frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 u^x)$ term uniformly elliptic, which is exactly the smoothing that gives u^x the second derivative the next step needs.

Step 2: read off the optimal feedback (the verification theorem). Having the value, the verification theorem of chapter 6 certifies that the pointwise maximizer $\alpha^{x,*} = \alpha^*(x, X, \nabla u^x, \Theta_t(x))$ of (21.7) is not merely a candidate but the genuine optimizer over the full admissible class of definition 21.14. The logic is the one rehearsed there: substitute the candidate feedback into the cost, apply Itô's formula to $u^x(t, X_t^x)$ along the controlled state, and use the HJB equation to show the result is a true lower bound attained with equality exactly when the agent plays $\alpha^{x,*}$. Convexity (A-Conv) guarantees the maximizer is unique and depends measurably on (t, X), so $\alpha^{x,*}$ is a legitimate feedback in the Markov subclass — which is why that subclass was singled out in definition 21.14. In the control-affine case $b = b_0 + B\alpha$ the first-order condition collapses to the explicit $\alpha^{x,*} = -B^\top \nabla u^x$, and in the scalar LQG thread to $\alpha^{x,*} = -b\,\partial_X u^x$, the optimal control being literally proportional to the marginal value of state. We stress, as in definition 21.6, that this is the maximizer of the Hamiltonian and *not* $-\partial_p H$ when the drift is genuinely control-dependent; the two agree only when drift equals control.

Step 3: push the optimally controlled law forward (the Fokker–Planck adjoint). Closing the feedback loop turns the controlled SDE into an ordinary (uncontrolled) diffusion — the type-x agent now follows $\mathrm{d}X_t^{x,*} = b(x, X_t^{x,*}, \alpha_t^{x,*}, \Theta_t(x))\,\mathrm{d}t + \sigma\,\mathrm{d}B_t^x$ with the feedback substituted in — and the marginal law of that closed-loop diffusion evolves by the Fokker–Planck equation $\partial_t \widetilde{m^x} = \mathcal{A}^{x,*}\widetilde{m^x}$ of theorem 5.14, started from the given initial law m_0^x and integrated *forward*. Here $\mathcal{A}^{x,*}$ is the formal adjoint of the generator of the *optimally controlled* diffusion — it depends on u^x through the feedback, which is the only way the backward computation of Step 1 feeds into the forward computation of Step 3. This forward integration carries data at $t = 0$ and propagates toward $t = T$, the mirror image of Step 1, because a population's law at time t records where it started and how it has been driven over the *past* $[0, t]$. The output $\widetilde{m^x}_t = \mathcal{L}(X_t^{x,*})$ is the law the optimally responding type-x agents actually realize.

Assembling these three steps across all types gives the best-response map S: feed it a field flow, it solves one backward HJB per type, reads off one feedback per type, runs one forward Fokker–Planck per type, and returns the field of resulting laws. The backward/forward pairing is the structural signature of the whole construction and deserves to be stated plainly: S is the composition of a *backward* sweep that computes optimal behaviour from the future-facing value and a *forward* sweep that computes the law that behaviour generates from the past-facing initial data. The two sweeps are run in opposite time directions and are coupled only through the feedback. That S maps the path space $C([0,T];\boldsymbol{\mathcal{P}}_2)$ into itself — that each output law is square-integrable in type and the field depends continuously on time — is exactly the content of lemma 21.13, which is why that lemma was the last debt the previous section discharged before this one could be written.

The best-response map answered "what does an agent do with a population it is shown?" but it took the shown population as exogenous. An equilibrium is the population that is not arbitrary — the one an agent would, in fact, generate by responding optimally to it. This is the only place the loop closes, and closing it is a single demand: the field you optimize *against* must equal the field your optimization *produces*. That demand is a fixed-point equation for S, and it is the chapter's destination.

Definition 21.16 (Dynamic graphon mean field game equilibrium)**.** A field flow $(\boldsymbol{m}_t)_{t\in[0,T]} \in C([0,T];\boldsymbol{\mathcal{P}}_2)$ with $\boldsymbol{m}_0 = \boldsymbol{m}_0^{\text{given}}$ is a *dynamic graphon mean field game equilibrium* (a *GMFG solution*) if it is a fixed point of the best-response map,

$$\mathsf{S}\big[(\boldsymbol{m}_t)_t\big] \;=\; (\boldsymbol{m}_t)_t, \tag{21.16}$$

that is: for Lebesgue-a.e. type x, when every agent of type x uses the optimal feedback computed against the aggregate $\Theta_t(x) = (\mathbb{W} \circledast \boldsymbol{m}_t)(x)$ of the field $\boldsymbol{m}$, the law of its optimally controlled state coincides with m_t^x for all $t \in [0,T]$. Equivalently, the pair $(x \mapsto u^x,\, x \mapsto m^x)$ solves the coupled backward–forward system of chapter 22, with the only inter-type coupling entering through $\mathbb{W}$.

The content of (21.16) is the same Nash consistency as in classical mean field games: the population an agent optimizes against is the population that the optimizing agents generate. Nobody has an incentive to deviate, because each agent is already playing its best response to the realized population, and — being infinitesimal — its own deviation does not move that population. What is genuinely new is the *shape* of the consistency. In Part II it was a single equation, one measure flow equal to the law it induces. Here it is a continuum of consistency conditions, one per type, holding for Lebesgue-a.e. x simultaneously, and they are not independent: each type's optimization sees, through the aggregate $\Theta_t(x) = (\mathbb{W} \circledast \boldsymbol{m}_t)(x)$, a W-weighted average of *all* the others' distributions. So the only channel through which one type's equilibrium behaviour reaches another is the operator $\mathbb{W}$. Strip the kernel away — make W diagonal-like or constant — and the types decouple or fuse; that is exactly the lever the reduction checks of the next section will pull. The phrase to retain is: *Nash consistency, imposed type by type, with all inter-type coupling carried by* $\mathbb{W}$ *and nothing else.*

It is equally important to be explicit about what this definition deliberately does *not* do, because the chapter's discipline is to set up cleanly and defer honestly. We do not prove that a fixed point of (21.16) exists, nor that it is unique. That is the business of chapter 24, and its hypotheses are precisely the standing assumptions we have been accumulating — (A-Lip), (A-Nondeg), (A-Conv), (A-Reg-W) — together with a control on the coupling strength, either a smallness condition or a monotonicity condition ((A-Coupling), or a graphon Lasry–Lions condition, definition 11.1). The smallness threshold is no mystery: it is the $|s|\ \|\mathbb{W}\|$ already located by the Lipschitz constant of the aggregate (remark 21.12), which is exactly why that constant was worth computing two sections ago. Nor do we write the equilibrium as a system of equations here in any usable analytic form: the *partial differential* characterization — the coupled backward HJB and forward Fokker–Planck system obtained by letting the two sweeps of S run against a common field — is the subject of chapter 22, and the *probabilistic* characterization, as a system of graphon forward–backward stochastic differential equations, is the subject of chapter 23. The definition above is the fixed object all three of those chapters operate on; its job is to be unambiguous, not yet to be solved.

There is one physical picture that genuinely accelerates understanding of the fixed point, and it is worth one box. A reader with a statistical-mechanics background will already have felt that (21.16) looks like a self-consistency equation, and indeed it is one — of exactly the Curie–Weiss self-consistent-field kind, but with the spatial uniformity of Curie–Weiss broken by the kernel. We record the analogy with the two honesty cautions that keep it from overreaching.

Physics note

The fixed point (21.16) is a self-consistent-field condition with an internal flavor index. The symbols in this box are local to the analogy: m_{mag}, J_{CW} below are the Curie–Weiss magnetization and spin coupling, unrelated to the density macro m and the cost functional J^x of (21.6). In Curie–Weiss mean field theory each spin feels an effective field $h_{\mathrm{eff}} = J_{\mathrm{CW}}\, m_{\mathrm{mag}}$ set self-consistently by the magnetization $m_{\mathrm{mag}} = \tanh(\beta_{\mathrm{T}} h_{\mathrm{eff}})$ it produces; the field is uniform because every spin couples identically to every other. The graphon game keeps the self-consistency but *breaks the uniformity*: type x feels its own effective field $\Theta_t(x) = \int W(x,y)\langle h, m_t^y\rangle\, \mathrm{d}y$, weighted by the kernel W that records how strongly x is wired to y. The order parameter is now a *field* $x \mapsto \langle h, m^x\rangle$ rather than a scalar, and $\mathbb{W}$ plays the role of the (inhomogeneous, off-diagonal) coupling matrix J^{CW}_{xy}. Two cautions keep the analogy honest: the field here is fixed not by a thermal average but by a Nash optimization run backward in time, and there is no inverse-temperature parameter at all — this is a finite-horizon, undiscounted game (a discount would reweight time, not act as a temperature). The analogy is a picture, not a proof; every statement above stands without it.

The equilibrium is now defined. Every object the sentence "$(\boldsymbol{m}_t)_t$ is a dynamic graphon mean field game equilibrium" refers to has been pinned down: the agents, the field of measures, the space it lives in, the topology on that space, the optimization each type performs, and the type-by-type consistency that closes the loop. The destination promised in the chapter preamble has been reached. But a definition, however carefully assembled, is only as good as its faithfulness to the theories it claims to generalize, and we have so far only *asserted* that this one is the right one. The reader is entitled to demand proof of fitness, and the honest test is degeneration: a correct generalization must reproduce every special case it subsumes. The next section subjects definition 21.16 to exactly that test, along three slices of the kernel. Setting W constant should erase the type label entirely and hand back the classical mean field game of Part II; collapsing W to rank one should crush the infinite field of measures down to a single scalar self-consistency with effective coupling $s\ \|\mathbb{W}\|$, previewing the Curie–Weiss closure of chapter 22; and taking W piecewise constant in blocks should recover the finite multi-population mean field games. If the definition survives all three, it has earned the trust that the three downstream engines will place in it.

21.5 Reduction checks

With definition 21.16 in hand, the question facing us is no longer "what is a dynamic graphon equilibrium?" — that has a definite answer now — but the sharper and more honest "is it the right *it*?" A definition can be internally flawless and still generalize the wrong way; the only test that catches such a failure is degeneration. A faithful generalization must contain, as exact special cases, the theories it claims to subsume, and it must contain them *visibly* — not after a change of variables one has to be told to make, but by simply switching off the feature that distinguishes the new theory from the old. For us that feature is the kernel W. The whole novelty of chapter 21 is concentrated in the one object W that ties the continuum of types together; so the natural way to probe the construction is to dial W down to the degenerate shapes for which the answer is already known, and check that the machinery returns it.

We take three such slices, in increasing distance from the classical picture, and they are not chosen for variety: they are exactly the three reductions the thread specification fixes for Thread B (constant, rank-one, block), so that verifying them here is the same as discharging the obligations that specification records. The first slice is the constant kernel $W \equiv c$. This is the must-have backward-compatibility check: erasing all type structure should erase the type label itself and hand back the single-population mean field game of Part II, with the coupling merely rescaled by c. If the dynamic graphon game failed *this*, nothing else about it would matter, so it comes first and is the most basic. The second slice is the rank-one kernel $W(x, y) = f(x)f(y)$. Here the type structure survives — the game is genuinely heterogeneous — yet the infinite field of measures collapses onto a single scalar order parameter, giving the cleanest non-trivial worked example in the book and advancing Thread B to the dynamic Curie–Weiss closure that chapter 22 will solve in full; this is less a sanity check than a first genuine solution, which is why it earns a `workedcomp` rather than a remark. The third slice is the block kernel, piecewise constant on a partition of $[0, 1]$. It points the other way — not back to Part II but forward, to the finite multi-population mean field games — and so serves as a bridge: it shows the continuum theory sitting one specialization above the multi-type theory of chapter 30, the field of measures degenerating to a finite vector of population laws. Two backward-looking sanity checks and one forward-looking bridge; together they fence the construction in on both sides. We begin with the most elementary of the three, the constant kernel.

21.5.1 Constant graphon recovers the classical mean field game

The reduction section just promised that the most basic obligation on the construction is backward compatibility: switch off the kernel entirely — make every type interact with every other type at one uniform strength — and the elaborate field-of-measures machinery ought to fold back down to the single-population mean field game of Part II that we already understand. This is the "does the new theory contain what we already know?" check, and it is the right one to discharge first, because if it failed nothing else about the dynamic graphon game would be worth trusting. The constant kernel is exactly the switch: it is the unique graphon that records *no* network structure at all, every pair of types coupled identically, so it is the formal image of "the network does not matter, only the crowd does." We now turn the crank and watch the type label disappear.

The mechanism is visible already in the aggregate. Recall that the only place the network ever touches an agent is through the kernel-weighted average $z_t(x) = (\mathbb{W}\bar{m}_t)(x)$ of (21.5) — the graphon-smoothed first-moment field. Smoothing against a *constant* kernel is not smoothing at all; it is plain global averaging followed by a rescaling, and the type label, having nothing left to discriminate, drops out. The following remark makes this precise and reads off, one consequence at a time, that every distinguishing feature of the graphon game collapses onto its Part II value: the per-type problem becomes one problem, the operator norm becomes the bare number c, the threshold becomes the classical threshold, and the LQG cost becomes the Thread A cost with coupling s rescaled to sc.

Remark 21.17 (Constant W)**.** Let $W(x,y) \equiv c$ for a constant $c \in (0,1]$. The aggregate (21.5) becomes

$$z_t(x) \;=\; \int_0^1 c\,\bar{m}_t(y)\,\mathrm{d}y \;=\; c\,\bar{m}_t^{\mathrm{glob}}, \qquad \bar{m}_t^{\mathrm{glob}} := \int_0^1 \bar{m}_t(y)\,\mathrm{d}y, \tag{21.17}$$

which is *independent of* x: the integral against the constant c pulls c out and leaves the type-x-free global average $\bar{m}_t^{\mathrm{glob}} = \int_0^1 \bar{m}_t(y)\,\mathrm{d}y$, so every agent — regardless of its label — feels one and the same number, the global mean position scaled by c. The kernel argument x that $z_t(x)$ carried in general has simply been integrated away, because a constant kernel cannot tell one row from another: $W(x,\cdot) \equiv c$ for all x, so the weight every type places on the population is identical and the weighted average it computes is identical.

Two of the model's three sources of type-dependence are thereby gone. The coefficients b, σ and the cost weights q, q_T, s, s_T of Thread B are already type-independent (they were fixed constants from the start), and we have just seen the aggregate $z_t(x) \equiv c\,\bar{m}_t^{\mathrm{glob}}$ is type-independent too. The only remaining channel through which x could enter is the initial law m_0^x. Suppose for this check it is switched off as well, $m_0^x \equiv m_0$. Then the type-x control problem — HJB plus Fokker–Planck against the frozen aggregate — has *identical data for every* x: same dynamics, same cost, same initial condition, same scalar z_t inside the running cost. Identical optimization problems have a common solution, so the constant field $m_t^x \equiv m_t$ is consistent — it is a genuine equilibrium of the graphon game — and for it the global average reduces further, $\bar{m}_t^{\mathrm{glob}} = \int_0^1 \bar{m}_t(y)\,\mathrm{d}y = \bar{m}_t$, to the single population mean. The field of measures has collapsed to one measure m_t evolving in time, which is precisely the Part II population object.

A word of honesty is owed here, and it is exactly the subtlety a careful reader should be suspicious of. We have shown that the symmetric, type-independent field is *a* solution; we have *not* shown it is the *only* one. The argument established that identical data *admit* an identical-across-types solution, not that every solution must be type-independent. The distinction is not pedantic. Below the coupling threshold the best-response map is a contraction (remark 21.12), its fixed point is unique, and uniqueness forces the only fixed point to be the symmetric one we exhibited — there the caveat is vacuous. Above the threshold uniqueness can fail, and when it does the symmetric solution may coexist with type-*inhomogeneous* equilibria in which agents with the very same data nevertheless settle into different laws. This is genuine symmetry breaking: the data are invariant under relabelling types, yet a solution need not share that invariance, exactly as the self-consistent-field picture of section 21.4 and the phase diagram of chapter 14 warn. So the correct statement is the careful one — a symmetric equilibrium *exists* and recovers Part II; whether it is the only equilibrium is the same multiplicity question Part II already faces, neither created nor cured by passing to the constant graphon.

It remains to confirm the two quantitative fingerprints of Part II: the coupling threshold and the LQG cost. Both come from understanding $\mathbb{W}$ for the constant kernel, which is the simplest operator in the book. Acting on a field $f \in L^2([0,1])$,

$$(\mathbb{W}f)(x) \;=\; \int_0^1 c\, f(y)\, \mathrm{d}y \;=\; c\Big(\int_0^1 f\Big)\,\mathbf{1}(x),$$

so $\mathbb{W}$ sends *every* f to a multiple of the constant function $\mathbf{1}$: it is a rank-one operator with range $\operatorname{span}\{\mathbf{1}\}$. Its spectrum is read off in one line. On the constant function itself, $\mathbb{W}\mathbf{1} = c\big(\int_0^1 1\big)\mathbf{1} = c\,\mathbf{1}$, so $\mathbf{1}$ is an eigenfunction with eigenvalue c. On any mean-zero field, $\int_0^1 f = 0$ forces $\mathbb{W}f = 0$, so the entire orthogonal complement $\{f : \int f = 0\}$ is the kernel, eigenvalue 0. The spectrum is therefore $\{c, 0\}$ with the single nonzero eigenvalue c, and since $\mathbb{W}$ is self-adjoint its operator norm equals its largest eigenvalue in modulus, $\|\mathbb{W}\| = c > 0$. Feeding this into the threshold of remark 21.12, the control parameter $|s|\,\|\mathbb{W}\|$ becomes $|s|\,c$, which is exactly the rescaled coupling $|sc|$ of the classical theory: the constant graphon contributes nothing but the scalar c, multiplying the cost coupling s to the effective strength sc, in agreement with the Ch. 14 threshold.

The same rescaling closes the loop on the cost. Substituting the collapsed aggregate $z_t(x) = c\,\bar{m}_t$ into the Thread B cost (21.8), the running coupling term becomes $\frac{q}{2}\big(X_t^x - s\,c\,\bar{m}_t\big)^2$ and the terminal one $\frac{q_T}{2}\big(X_T^x - s_T\,c\,\bar{m}_T\big)^2$, so

$$J(\alpha; m) = \mathbb{E}\left[\int_0^T \Big(\tfrac{1}{2}\alpha_t^2 + \tfrac{q}{2}\big(X_t - (sc)\,\bar{m}_t\big)^2\Big)\,\mathrm{d}t + \tfrac{q_T}{2}\big(X_T - (s_T c)\,\bar{m}_T\big)^2\right], \tag{21.18}$$

which is verbatim the classical scalar LQG mean field game cost of Thread A (worked computation 8.12, section 14.1) with the mean-coupling strength s replaced throughout by sc (and s_T by $s_T c$). The type superscript has vanished because nothing in (21.18) depends on it any longer; the agent optimizes against the single population mean $\bar{m}_t$ exactly as in Part II. The dynamic graphon game of this chapter therefore contains the entire Part II theory, intact, as its constant-graphon slice, with the network contributing only the harmless scalar c that renormalizes the coupling.

The constant kernel was the trivial-network limit: with the geometry switched off, the field of measures degenerated to a single measure and the whole apparatus reproduced Part II with a rescaled coupling. The lesson is that type-dependence and the field structure are inseparable companions of a *nontrivial* kernel — erase the kernel's structure and both collapse together. The natural next question is whether they must collapse *together*: is there a kernel poor enough to be solved in closed form, yet rich enough that type-dependence genuinely survives while the field still closes onto a finite object? There is, and it is the rank-one kernel. It is the cleanest nontrivial graphon in the book: the type label does real work — different types feel genuinely different aggregates — yet the infinite field of measures once again collapses, this time not to a single measure but to a single *scalar* order parameter through which all types communicate. That is the Curie–Weiss closure we take up next, and it is where the spectral picture we just sketched for the constant kernel earns its keep, with $\|\mathbb{W}\|$ becoming the lone nonzero eigenvalue of a genuinely structured operator.

21.5.2 Rank-one graphon: a Curie–Weiss closure

The constant kernel left us with a question rather than a verdict. There, type-dependence and the field structure collapsed together only because the kernel had no structure to collapse; and we asked whether the two must always fall together, or whether some kernel could be poor enough to solve in closed form yet rich enough to keep the type label genuinely at work. The rank-one kernel is the affirmative answer, and it is the flagship computation of the chapter. Here different types feel genuinely different aggregates — the label discriminates, as it could not under a constant kernel — and yet the infinite field of measures collapses once more. This time it collapses not onto a single *measure* but onto a single *scalar*, an order parameter through which every type speaks to every other. That collapse is the dynamic analogue of the Curie–Weiss closure of section 21.4: the inhomogeneous self-consistent field of the general game, which there was an entire function of type, here folds back to one number, because the coupling operator $\mathbb{W}$ has rank one. We carry Thread B through it in full, and give it the most expansive treatment in the chapter, because it is the cleanest worked example of a graphon mean field game in the book.

The kernel is $W(x,y) = f(x)f(y)$ with $f \in L^2([0,1])$, $f \geq 0$: a single "shape function" f whose value $f(x)$ records how strongly type x both broadcasts to and listens to the rest of the network. Before computing anything we must separate two normalizations of f that are easy to conflate and that control entirely different things; keeping them straight is what keeps the rest of the section honest, and it is a distinction the static chapter could afford to gloss but the dynamic one cannot.

The first is a *validity* constraint, and it lives in L^∞. For W to be a graphon at all it must take values in $[0,1]$, and since $W(x,y) = f(x)f(y)$ its largest value is $\|f\|_\infty^2$, attained where f peaks. Graphon validity is therefore exactly $\|f\|_\infty^2 \leq 1$, a bound on the *supremum* of f. The L^2 norm will *not* police this: a tall narrow spike — f large on a tiny set and small elsewhere — can have $\|f\|_{L^2}$ as small as one likes while $\|f\|_\infty$, and hence the product $f(x)f(y)$ at the peak, blows past 1. The pointwise bound that makes W a legitimate kernel is an L^∞ statement, not an L^2 one.

The second is the *coupling* constraint, and it lives in L^2. By Mercer's theorem (theorem 18.2) the operator $\mathbb{W}$ of a rank-one kernel carries a single nonzero eigenvalue, and one reads it off directly: acting on any field $g \in L^2([0,1])$,

$$(\mathbb{W}g)(x) = \int_0^1 f(x)f(y)\,g(y)\,\mathrm{d}y = f(x)\,\langle f, g\rangle_{L^2},$$

so $\mathbb{W}$ sends every g to a multiple of f — its range is the single line $\operatorname{span}\{f\}$ — and on f itself $\mathbb{W}f = f\,\langle f, f\rangle_{L^2} = \|f\|_{L^2}^2\, f$. Thus f is the top eigenfunction with eigenvalue $\|f\|_{L^2}^2$, every direction orthogonal to f is annihilated, and because $\mathbb{W}$ is self-adjoint its operator norm is that lone eigenvalue, $\|\mathbb{W}\| = \|f\|_{L^2}^2$. So the operator norm — the quantity that, multiplied by the cost coupling s, will set the threshold of the whole theory — is the *square of the L^2 norm* of f, an integral quantity insensitive to spikes. The two norms answer two different questions: $\|f\|_\infty$ asks whether W is a legal kernel; $\|f\|_{L^2}$ asks how strongly that legal kernel couples. Conflating them — using $\|f\|_{L^2} \le 1$ as a stand-in for validity, or $\|f\|_\infty$ as a stand-in for coupling strength — would mis-state both, and the two need not even point the same way (the spike is valid yet weakly coupling; a broad gentle f may couple strongly yet sit comfortably inside $[0,1]$). One last bookkeeping point separates f from its normalization: the *eigenvector centrality* of lemma 20.12 and definition 18.8 — the network's profile of who-is-central — is the *unit* eigenfunction $\phi_1 = f/\|f\|_{L^2}$. We deliberately keep the *unnormalized* f throughout, because the amplitude that ϕ_1 discards in normalizing is precisely the coupling strength $\|f\|_{L^2}^2 = \|\mathbb{W}\|$, and that amplitude is exactly what the threshold will turn on. We now advance Thread B by showing that the entire field collapses to a single scalar order parameter — the dynamic analogue of the Curie–Weiss closure.

Worked computation 21.18 (Thread B: rank-one collapse to a scalar order parameter)**.** Take the graphon-LQG agent (21.2) with cost (21.8) and $W(x,y) = f(x)f(y)$. The aggregate (21.5) factorizes:

$$z_t(x) \;=\; \int_0^1 f(x)f(y)\,\bar{m}_t(y)\,\mathrm{d}y \;=\; f(x)\,\varrho_t, \qquad \varrho_t \;:=\; \int_0^1 f(y)\,\bar{m}_t(y)\,\mathrm{d}y \;=\; \langle f, \bar{m}_t\rangle_{L^2}, \tag{21.19}$$

where ϱ_t is the *scalar order parameter*: the projection $\langle f, \bar{m}_t\rangle_{L^2}$ of the first-moment field onto the shape function f, one real number that summarizes the entire field $\bar{m}_t(\cdot)$ as far as the coupling is concerned. It is the exact dynamic analogue of the static rank-one order parameter ϱ of worked computation 20.21 — the same projection onto f, now carrying a time index because the means evolve. The factorization $z_t(x) = f(x)\,\varrho_t$ is the whole point of rank one: the drive that type x feels is its own broadcast strength $f(x)$ times one common scalar ϱ_t shared by every type. No type needs to know the full field; it needs only one number and its own $f(x)$. This is precisely the Curie–Weiss collapse anticipated in section 21.4: the inhomogeneous effective field of the general game reduces to a single self-consistent scalar the instant the coupling operator has rank one, modulated per type only by the fixed profile f.

With ϱ_t frozen — the infinitesimal agent takes the field as given, definition 21.6 — substituting $z_t(x) = f(x)\varrho_t$ into the running coupling turns it into $\frac{q}{2}(X_t^x - s\,f(x)\,\varrho_t)^2$, so type x is simply tracking the known, exogenous, time-dependent target $s\,f(x)\,\varrho_t$. That is an ordinary scalar LQG problem with an affine target — the very single-population problem solved in closed form in chapter 14 — the only twist being that the target is scaled by the constant $f(x)$. Its value function is quadratic in the state, $u^x(t,X) = \frac{1}{2}P(t)X^2 + r_t(x)\,X + \cdots$, with $P(t)$ the scalar Riccati curvature (eq. (14.7), the same P as in eq. (8.24)) and $r_t(x)$ the linear offset (eq. (14.8)) that carries the tracking target. Crucially $P(t)$ is the *same* for every type: it depends only on a, b, q, q_T, not on where the target sits, because the quadratic curvature of an LQG value function is insensitive to the affine forcing. All the type-dependence is pushed into the offset $r_t(x)$. Feeding the costate $p = \partial_X u^x = P(t)X + r_t(x)$ into the affine-quadratic feedback rule $\alpha^* = -bp$ of definition 21.6, the optimal feedback is

$$\alpha_t^{x,*} \;=\; -b\,\big(P(t)\,X_t^x + r_t(x)\big), \tag{21.20}$$

a state-linear feedback whose slope $-bP(t)$ is shared across types and whose intercept $-b\,r_t(x)$ carries the type label. Inserting it into the agent's dynamics (21.2) and taking expectations — the noise averages out, $\mathbb{E}[\mathrm{d}B_t^x] = 0$ — the closed-loop mean $\bar{m}_t(x) = \mathbb{E}[X_t^x]$ obeys the thread-A mean evolution eq. (14.13), while the offset solves its own *backward* equation eq. (14.8):

$$\dot{\bar{m}}_t(x) = (a - b^2 P(t))\,\bar{m}_t(x) \;-\; b^2\, r_t(x), \qquad \bar{m}_0(x) = \bar{m}_0^x, \tag{21.21}$$

$$\dot{r}_t(x) = (b^2 P(t) - a)\, r_t(x) \;+\; q\, s\, z_t(x), \qquad r_T(x) = -\, q_T\, s_T\, z_T(x). \tag{21.22}$$

Two points deserve emphasis, because a naive reading miscloses the system, and both are exactly the places where the dynamic graphon game is subtler than its static shadow. The first concerns *what forces the mean*. One is tempted to read (21.21) as "the mean relaxes toward the target $s\, z_t(x)$," but that is wrong, and seeing why is worth the line of algebra. Take the agent's SDE (21.2), substitute the optimal feedback (21.20), and average:

$$\dot{\bar{m}}_t(x) = \mathbb{E}[a\, X_t^x + b\, \alpha_t^{x,*}] = a\, \bar{m}_t(x) - b^2\, \mathbb{E}[P(t)\, X_t^x + r_t(x)] = (a - b^2 P(t))\, \bar{m}_t(x) - b^2\, r_t(x),$$

since $P(t)$ and $r_t(x)$ are deterministic and $\mathbb{E}[X_t^x] = \bar{m}_t(x)$. The forcing is $-b^2 r_t(x)$, the *offset* of the value function — *not* the target $s\, z_t(x)$ itself. The target never appears in the forward equation; it enters only *indirectly*, by driving the backward offset equation (21.22), whose forcing $q\, s\, z_t(x)$ is where the coupling actually lives. So (21.21)–(21.22) is a genuine *forward–backward* pair — a two-point boundary-value problem, the mean carrying initial data $\bar{m}_0(x)$ at $t = 0$ and the offset terminal data $r_T(x)$ at $t = T$ — and not a local forward ODE one could integrate by marching from $t = 0$. Mistaking $-b^2 r_t$ for a multiple of $s\, z_t$ would turn the two-point problem into a one-point one and silently destroy the very coupling between backward optimization and forward flow that *is* the mean field game.

The second point is the closure itself, and it is what makes rank one tractable where a general kernel is not. The only way the type label enters the drive is through the factor $f(x)$ in $z_t(x) = f(x)\varrho_t$. Look at the offset equation (21.22): its forcing $q\, s\, z_t(x) = q\, s\, f(x)\varrho_t$ and its terminal datum $-q_T s_T z_T(x) = -q_T s_T f(x)\varrho_T$ are *both* proportional to $f(x)$, while the coefficient $b^2 P(t) - a$ multiplying $r_t(x)$ on the left is type-independent. A linear ODE whose forcing and terminal data are a fixed function $f(x)$ times scalar paths has a solution that is $f(x)$ times a scalar path: substituting the ansatz $r_t(x) = f(x)\widetilde{r}_t$ into (21.22) cancels the common factor $f(x)$ from every term, leaving one scalar equation for $\widetilde{r}_t$. Thus the offset inherits exactly the factorization of the drive,

$$r_t(x) \;=\; f(x)\, \widetilde{r}_t, \qquad \dot{\widetilde{r}}_t = (b^2 P(t) - a)\, \widetilde{r}_t + q\, s\, \varrho_t, \quad \widetilde{r}_T = -\, q_T\, s_T\, \varrho_T, \tag{21.23}$$

with $\widetilde{r}_t$ the single scalar offset path. The mean forcing in (21.21) is now $-b^2 r_t(x) = -b^2 f(x)\widetilde{r}_t$ — the same function $f(x)$ times one scalar path — the only genuinely type-dependent residue being the initial datum $\bar{m}_0^x$. Everything is poised to close: the field game is driven entirely by the two scalars ϱ_t and $\widetilde{r}_t$, so we need only their two equations. The equation for $\widetilde{r}_t$ we already have, in (21.23). The equation for ϱ_t comes from *projecting* the mean ODE onto f — applying $\langle f, \cdot \rangle_{L^2}$ to both sides of (21.21), which is legitimate because the coefficients $a - b^2 P(t)$ and b^2 are scalars independent of x and pass through the integral over types. The left side becomes $\langle f, \dot{\bar{m}}_t \rangle = \frac{\mathrm{d}}{\mathrm{d}t}\langle f, \bar{m}_t \rangle = \dot{\varrho}_t$, by the definition (21.19) of the order parameter; the first term on the right becomes $(a - b^2 P(t))\langle f, \bar{m}_t \rangle = (a - b^2 P(t))\varrho_t$; and the forcing term becomes

$$-b^2 \langle f, r_t \rangle_{L^2} = -b^2 \langle f, f\, \widetilde{r}_t \rangle_{L^2} = -b^2\, \widetilde{r}_t\, \langle f, f \rangle_{L^2} = -b^2\, \|f\|_{L^2}^2\, \widetilde{r}_t = -b^2\, \|\mathbb{W}\|\, \widetilde{r}_t,$$

where the lone nonzero eigenvalue $\langle f, f \rangle_{L^2} = \|f\|_{L^2}^2 = \|\mathbb{W}\|$ of the rank-one operator enters *precisely here*: the projection step is where the operator norm is born into the scalar system, the one place the network's coupling amplitude survives the collapse. Assembling the three pieces and keeping the offset equation (21.23) beside it, the entire infinite-dimensional field game has closed onto the *scalar pair* $(\varrho_t, \widetilde{r}_t)$:

$$\begin{cases} \dot{\varrho}_t = (a - b^2 P(t))\, \varrho_t - b^2\, \|\mathbb{W}\|\, \widetilde{r}_t, & \varrho_0 = \langle f, \bar{m}_0 \rangle_{L^2}, \\ \dot{\widetilde{r}}_t = (b^2 P(t) - a)\, \widetilde{r}_t + q\, s\, \varrho_t, & \widetilde{r}_T = -\, q_T\, s_T\, \varrho_T. \end{cases} \tag{21.24}$$

This is a 2×2 linear forward–backward boundary-value problem in scalars, and it is the heart of the rank-one reduction: an infinite field of measures, one per type in a continuum, has collapsed to a single self-consistency in the two numbers $(\varrho_t, \widetilde{r}_t)$. The diagonal of the system is the type-independent LQG data $\pm(a - b^2 P(t))$; all the network and cost coupling sits in the two off-diagonal entries, $b^2\, \|\mathbb{W}\|$ feeding the offset back into the mean and qs feeding the mean forward into the offset. The decisive observation is that *these two coefficients are not separately visible to the system* — only their product is. To see it, rescale the unknowns by any constant $\lambda \neq 0$, setting $\varrho'_t = \lambda \varrho_t$ and $\widetilde{r}'_t = \lambda^{-1} \widetilde{r}_t$. Substituting into (21.24), the ϱ-equation becomes $\dot{\varrho}'_t = (a - b^2 P(t))\varrho'_t - (b^2\, \|\mathbb{W}\|\, \lambda^2)\, \widetilde{r}'_t$ and the offset equation becomes $\dot{\widetilde{r}}'_t = (b^2 P(t) - a)\widetilde{r}'_t + (qs\, \lambda^{-2})\varrho'_t$: the rescaling carries the system to one of identical form but with the two off-diagonals multiplied by λ^2 and λ^{-2} — reciprocally. A solution of one system is λ times a solution of the other, so the two are equivalent, and any property that decides solvability or uniqueness cannot depend on $b^2\, \|\mathbb{W}\|$ and qs individually: it can depend only on the one combination the rescaling leaves fixed, the product $(b^2\, \|\mathbb{W}\|)(qs) = b^2 q\, (s\, \|\mathbb{W}\|)$. Stripping the intrinsic LQG weights b^2 and q, the kernel and the cost coupling reach the equilibrium *only* through the single *effective coupling*

$$s_{\text{eff}} \;=\; s\, \|\mathbb{W}\| \;=\; s\, \|f\|^2_{L^2}\,. \tag{21.25}$$

This is the punchline of the rank-one model, and its consequences point straight at the next two chapters. Because the entire equilibrium is governed by the scalar pair (21.24), and that pair feels the kernel and the cost coupling only through $s_{\text{eff}} = s\, \|\mathbb{W}\|$, both solvability and uniqueness of the GMFG equilibrium in the rank-one case reduce to a single scalar condition on $|s_{\text{eff}}|$: the non-degeneracy of the linear two-point boundary-value problem, which fails only once $|s_{\text{eff}}|$ grows large enough to make the forward–backward coupling resonate over the horizon $[0, T]$. This is exactly the dynamic shadow of the static rank-one threshold $|s|\, \|\mathbb{W}\|$ of eq. (20.31). The static game saw that combination as the point where the one-shot fixed point lost uniqueness; the dynamic game sees the *same* combination $s\, \|\mathbb{W}\|$ as the point where the two-point problem degenerates. That two problems as different as a one-shot game and a finite-horizon control problem turn on the *identical* grouping $s\, \|\mathbb{W}\|$ is the first concrete evidence for the general threshold $|s|\, \|\mathbb{W}\|$ that chapter 24 will prove governs the full field game, and it is the threshold intuition this section hands forward. We deliberately stop at the closure: we have *exhibited* the scalar pair (21.24) and isolated its single control parameter, but we have not *solved* it. Producing the Riccati curvature $P(\cdot)$ in closed form and inverting the two-point pair into an explicit solution operator is the work of chapter 22, which inherits (21.24) verbatim as its rank-one test case. Setting up the closure, not solving it, is this chapter's job.

Remark 21.19 (Consistency of the two reductions)**.** The two reductions we have now performed — constant and rank-one — are not independent checks; the rank-one computation strictly *contains* the constant one, and verifying the nesting is a small but reassuring consistency test. A constant kernel $W \equiv c$ is the rank-one kernel with the *constant* shape function $f \equiv \sqrt{c}$, since then $f(x)f(y) = c$. Watch every object of worked computation 21.18 specialize. The order parameter becomes

$$\varrho_t = \langle f, \bar{m}_t \rangle_{L^2} = \sqrt{c} \int_0^1 \bar{m}_t(y) \, \mathrm{d}y = \sqrt{c}\, \bar{m}_t^{\mathrm{glob}},$$

the global mean scaled by $\sqrt{c}$; the drive becomes $z_t(x) = f(x)\varrho_t = \sqrt{c} \cdot \sqrt{c}\, \bar{m}_t^{\mathrm{glob}} = c\, \bar{m}_t^{\mathrm{glob}}$, type-independent, exactly the collapsed aggregate (21.17) of the constant case. The two normalizations specialize consistently too: $\|f\|_\infty^2 = c \le 1$ reproduces the graphon-validity bound $c \le 1$, while $\|f\|_{L^2}^2 = \int_0^1 c \, \mathrm{d}y = c = \|\mathbb{W}\|$ reproduces the lone eigenvalue of the constant kernel computed in remark 21.17. The effective coupling (21.25) becomes $s_{\mathrm{eff}} = s\,\|f\|_{L^2}^2 = sc$, precisely the rescaled coupling of remark 21.17, and the scalar pair (21.24) becomes the single-population forward–backward system of Part II. The rank-one worked computation thus strictly contains the constant-graphon reduction as its degenerate-shape case, and both agree with Part II — the chapter's reductions nest correctly.

Rank one gave us the cleanest *one*-dimensional collapse: the whole field communicates through a single scalar, because the coupling operator $\mathbb{W}$ has exactly one nonzero eigenvalue. But "one" is special only as the smallest non-trivial rank. If the kernel instead has finite rank K — if there are K distinct shapes of interaction rather than one — the same projection argument that produced (21.24) should close the field game not onto a single scalar but onto a finite, K-dimensional system. The most transparent finite-rank kernel is the *block* graphon, piecewise constant on a partition of $[0, 1]$ into K groups, and it is the third and last of our reduction checks. Its character is different from the two before it. Where the constant kernel recovered Part II behind us and the rank-one kernel previewed the closed form of chapter 22 ahead, the block kernel looks forward: it reproduces the finite *multi-population* mean field games — the very setting from which the field-of-measures picture of this chapter was abstracted in the first place. We turn to it now, moving from a one-dimensional reduction to a K-dimensional one.

21.5.3 Block graphon recovers multi-population mean field games

Rank one gave us the smallest nontrivial collapse: one shape function, one nonzero eigenvalue, and an entire field of measures speaking through a single scalar. The projection argument that produced it, though, used nothing special about the number one. It used only that the kernel's range was finite-dimensional, so that the type label could enter the drive through finitely many fixed profiles and a linear ODE forced by such profiles would close on the corresponding finitely many scalars. Raise the rank from one to K — replace the single interaction shape by K distinct ones — and the same machinery should close the field game not onto a scalar but onto a K*-dimensional* system. The cleanest finite-rank kernel that realizes this is the *block* graphon: piecewise constant on a partition of $[0, 1]$ into K groups, the discrete caricature in which the continuum of types is bundled into K homogeneous populations and all the network records is the $K \times K$ table of inter-group coupling strengths. It is the third and final reduction, and we make it the last because its lesson points in the opposite direction from the first two. The constant kernel looked *backward*, recovering the Part II theory we already trusted; the rank-one kernel looked *sideways*, previewing the closed form that chapter 22 will solve. The block kernel looks *forward*, and it closes a circle: it reproduces the finite *multi-population* mean field games of chapter 30 — the very setting from which the field-of-measures picture of this chapter was abstracted in the first place. Multi-population MFG is not a rival framework that the graphon theory must be reconciled with; it *is* the graphon theory, read on its piecewise-constant slice. Verifying that is the content of the following remark, and it is the natural place to end the chapter's exposition, because it shows the new object degenerating not to something older and poorer but to a parallel theory of independent standing, recovered exactly.

Remark 21.20 (Block W and the multi-population reduction)**.** Partition $[0,1]$ into K consecutive intervals $I_1,\dots,I_K$ of lengths $\pi_1,\dots,\pi_K$ (so $\sum_k \pi_k = 1$; the π_k are the population *mass fractions*), and let W be constant, $W(x,y) = W_{k\ell}$, on each cell $I_k \times I_\ell$ — the stochastic block model graphon of chapter 15, whose data is the single symmetric matrix $(W_{k\ell})$ of how strongly group k couples to group ℓ. The type label has been coarsened: within a block it does no work, and across blocks it does exactly the work of naming which of the K populations an agent belongs to.

Suppose, in parallel with the constant-kernel check of remark 21.17, that the remaining type-dependent data are block-constant too: the initial laws $m_0^x \equiv m_0^{(k)}$ and any type-dependent coefficients are common to all x in a given block I_k. Then every agent in block I_k solves an identical control problem — identical dynamics, identical cost, identical initial law, and (as we are about to see) identical aggregate — so the game *admits* a block-constant equilibrium field,

$$m_t^x \;\equiv\; m_t^{(k)} \qquad \text{for } x \in I_k, \quad k = 1,\dots,K, \tag{21.26}$$

one law per population rather than one per type. The same honesty owed in the constant case is owed here, and for the same reason: (21.26) exhibits *a* solution, not necessarily the *only* one. The argument shows that block-constant data *admit* a block-constant fixed point, not that every fixed point must respect the block structure. Below the coupling threshold the best-response map is a contraction (remark 21.12), its fixed point is unique, and uniqueness forces it to be the block-constant one just exhibited; above the threshold the block-constant equilibrium may coexist with finer, block-*breaking* equilibria in which agents of one and the same population settle into different laws — the identical symmetry-breaking caveat that remark 21.17 flagged for the constant kernel, neither sharpened nor relieved by the passage to K blocks. With that caveat recorded, restrict attention to the block-constant slice and watch the field game become finite.

The reduction is driven, exactly as before, entirely through the aggregate. On a block-constant field the first moments are block-constant, $\bar m_t(y) \equiv \bar m_t^{(\ell)}$ for $y \in I_\ell$, and the graphon-smoothed aggregate (21.5) felt by a type $x \in I_k$ collapses to a finite sum by splitting the integral over types into its blocks:

$$z_t(x) \;=\; \int_0^1 W(x,y)\,\bar m_t(y)\,\mathrm{d}y \;=\; \sum_{\ell=1}^K \int_{I_\ell} W_{k\ell}\,\bar m_t^{(\ell)}\,\mathrm{d}y \;=\; \sum_{\ell=1}^K \pi_\ell\, W_{k\ell}\,\bar m_t^{(\ell)}, \qquad x \in I_k, \tag{21.27}$$

which depends on x only through its block index k, confirming the self-consistency of the ansatz (21.26): a block-constant field produces a block-constant drive, which feeds back into block-constant optimal behaviour. The factor π_ℓ in each term is the same sub-probability bookkeeping that (21.3) insisted on — a more populous neighbour group ℓ (larger mass π_ℓ) contributes proportionally more to the aggregate felt by group k — and it is exactly the weight that prevents one from reading $W_{k\ell}$ alone as the effective inter-group coupling. The coupling that actually reaches group k from group ℓ is the *mass-weighted* entry $\pi_\ell W_{k\ell}$.

On this slice every distinguishing object of the field game now carries a finite index. The infinite family $(m_t^x)_{x\in[0,1]}$ has become the K-tuple $(m_t^{(1)},\dots,m_t^{(K)})$; the aggregate $z_t(x)$ has become the K numbers $z_t^{(k)} = \sum_\ell \pi_\ell W_{k\ell}\bar m_t^{(\ell)}$; and the single per-type control problem against a frozen scalar drive has become K control problems, the kth tracking its own drive $s\,z_t^{(k)}$, coupled to the others only through the means $\bar m_t^{(\ell)}$ that enter that drive. This is precisely a *finite system of K coupled mean field games* — one representative agent per population, each responding to a weighted blend of all K population means — with *inter-population coupling matrix*

$$M \;=\; (\pi_\ell\, W_{k\ell})_{k,\ell=1}^{K}. \tag{21.28}$$

This is the multi-population MFG developed in chapter 30, recovered here not as an analogy but as the literal piecewise-constant slice of the graphon theory; its explicit backward–forward PDE form — K coupled Hamilton–Jacobi–Bellman equations driven by K Fokker–Planck equations, laced together through M — is written out in chapter 22, which inherits (21.27) as its block test case just as it inherits the scalar pair (21.24) as its rank-one one.

One subtlety in (21.28) deserves a clarifying word, because the matrix that governs the dynamics and the matrix that governs the *threshold* are not the same matrix, and conflating them would mislocate the coupling constant. The coupling matrix $M = (\pi_\ell W_{k\ell})$ that appears in the dynamics is, in general, *not symmetric*: its (k,ℓ) entry weights by the mass π_ℓ of the *source* group, so $M_{k\ell} \neq M_{\ell k}$ whenever $\pi_k \neq \pi_\ell$, even though the underlying kernel $W_{k\ell} = W_{\ell k}$ is symmetric. The threshold of remark 21.12, however, is set by the *operator norm* $\|\mathbb{W}\|$, and $\mathbb{W}$ is self-adjoint on $L^2([0,1])$, so the relevant finite object is $\mathbb{W}$'s representation in an *orthonormal* basis of the block-constant subspace, where it is automatically symmetric. The block-constant fields form a K-dimensional $\mathbb{W}$-invariant subspace of $L^2([0,1])$, spanned by the indicators $\mathbf{1}_{I_k}$; but those indicators are not orthonormal — in the L^2 inner product $\langle \mathbf{1}_{I_k}, \mathbf{1}_{I_\ell}\rangle_{L^2} = \pi_k\,\delta_{k\ell}$, so each has length $\sqrt{\pi_k}$. Normalizing to the orthonormal basis $e_k := \mathbf{1}_{I_k}/\sqrt{\pi_k}$ and reading off the matrix of $\mathbb{W}$ there,

$$\langle e_k, \mathbb{W} e_\ell\rangle_{L^2} = \frac{1}{\sqrt{\pi_k\pi_\ell}}\,\langle \mathbf{1}_{I_k}, \mathbb{W}\mathbf{1}_{I_\ell}\rangle_{L^2} = \frac{1}{\sqrt{\pi_k\pi_\ell}}\int_{I_k}\Big(\int_{I_\ell} W_{k\ell}\,\mathrm{d}y\Big)\,\mathrm{d}x = \frac{\pi_k\pi_\ell\,W_{k\ell}}{\sqrt{\pi_k\pi_\ell}} = \sqrt{\pi_k\pi_\ell}\,W_{k\ell},$$

so the operator $\mathbb{W}$ restricted to block-constant fields is the *symmetric* $K\times K$ matrix

$$S \;=\; (\sqrt{\pi_k\pi_\ell}\,W_{k\ell})_{k,\ell=1}^{K} \;=\; D^{1/2} M\, D^{-1/2}, \qquad D := \operatorname{diag}(\pi_1,\dots,\pi_K), \tag{21.29}$$

the displayed similarity $S = D^{1/2}MD^{-1/2}$ being a one-line check on the entries. Because S and M are *similar*, they share the same eigenvalues: the spectrum that decides solvability and multiplicity of the K-population system is the same whether one reads it off the asymmetric dynamical matrix M or its symmetrized cousin S. But only S is symmetric, and only for a symmetric matrix does the spectral *norm* (largest singular value) coincide with the spectral *radius* (largest eigenvalue modulus). The threshold is an operator-*norm* statement, $\|\mathbb{W}\|$ restricted to this subspace, so it is $\|S\|$ — the top eigenvalue of the symmetric matrix S — that is the relevant coupling constant, and using $\|M\|$ instead (its largest singular value, which can strictly exceed $\|S\|$ when the masses are unequal) would overstate the coupling. Thus the spectrally correct finite avatar of the kernel is the mass-symmetrized matrix (21.29), and $\|S\| = \|\mathbb{W}\|\,|_{\text{block}}$ multiplied by $|s|$ is the block instance of the universal control parameter $|s|\ \|\mathbb{W}\|$ of remark 21.12 — in full consistency with the threshold the chapter has tracked throughout.

With the block reduction in hand the chapter's single argument is complete. We set out to build one object — the dynamic graphon mean field game — precisely enough that the sentence "$(\boldsymbol{m}_t)_t$ is an equilibrium" has a definite truth value, and then to earn trust in that object by watching it degenerate correctly. It has now passed all three tests. The constant kernel folded the field of measures back to the single population law of Part II, with the network contributing only a scalar rescaling of the coupling (remark 21.17); the rank-one kernel kept the type label genuinely at work yet collapsed the infinite field onto a single self-consistent scalar with effective coupling $s\,\|\mathbb{W}\|$ (worked computation 21.18); and the block kernel has just reproduced the finite multi-population mean field game as the piecewise-constant slice, with mass-weighted coupling matrix (21.28) and spectrally relevant norm (21.29). In all three the same control parameter $|s|\ \|\mathbb{W}\|$ surfaced and the same "a symmetric equilibrium exists, uniqueness is the delicate question above threshold" caveat recurred — the consistent fingerprint of a single well-posed construction seen from three angles, not three separate constructions.

That is where the exposition ends and the engines take over. The setup assembled here — the representative agent of every type (definition 21.1), the field of measures that is the population (definition 21.4), the kernel-weighted aggregate (definition 21.5), the complete separable L^2-Wasserstein field space, the $\|\mathbb{W}\|$-Lipschitz aggregation that births the threshold (remark 21.12), and the type-by-type Nash fixed point that is the equilibrium (definition 21.16) — is now fixed and unambiguous, and the next three chapters consume it untouched. Chapter 22 turns the fixed point into the coupled Hamilton–Jacobi–Bellman–Fokker–Planck system and supplies, for Thread B, the Riccati curvature and the explicit solution operator that closes the rank-one and block reductions left open here; chapter 23 recasts the same fixed point probabilistically as a system of graphon forward–backward stochastic differential equations; and chapter 24 proves existence and uniqueness, turning the threshold $|s|\ \|\mathbb{W}\| < 1/L_{\text{ctrl}}$ from a heuristic into a theorem. What remains of this chapter is the bookkeeping that makes the hand-off honest: the ledger below records, line by line, what has been *proved* here, what has been *assumed*, what has been *deferred* to those three chapters and to the finite-N theory of chapter 25, and what genuinely remains *open*.

Rigor ledger

Proved.

- Well-posedness of the type-x controlled SDE (21.1) for each fixed type under (A-Lip), (A-Growth), (A-Nondeg), and measurability of the field of laws $x \mapsto m_t^x$ with uniform second moment (lemma 21.13).
- $(\boldsymbol{\mathcal{P}}_2, d_2)$ is a complete separable metric space and $(\mathcal{C}_2, d_\infty)$ a complete metric space embedding into it (proposition 21.9, definition 21.10).
- The graphon aggregate is well-defined and $\|\mathbb{W}\|$-Lipschitz on $(\boldsymbol{\mathcal{P}}_2, d_2)$ via the elementary

coupling bound $|\langle h, \mu\rangle - \langle h, \nu\rangle| \le \mathcal{W}_1 \le \mathcal{W}_2$ for 1-Lipschitz h (lemma 21.11), locating the coupling threshold at $|s| \, \|\mathbb{W}\|$.

- The constant-graphon reduction to classical MFG (remark 21.17); the rank-one collapse to a scalar self-consistency with effective coupling $s \, \|\mathbb{W}\|$ (worked computation 21.18); the block reduction to multi-population MFG (remark 21.20).

Assumed.

- The standing assumptions (A-Lip), (A-Growth), (A-Nondeg), (A-Conv) on the agent dynamics and cost, and (A-Reg-W) on the kernel (used in lemma 21.11 and the spectral statements).
- Existence of optimizers for the per-type control problem via the verification theorem of chapter 6 under (A-Conv), (A-Nondeg).

Deferred.

- Existence and uniqueness of a fixed point of S (definition 21.16): chapter 24, under (A-Coupling) or a graphon Lasry–Lions condition (definition 11.1).
- The explicit coupled backward HJB / forward Fokker–Planck system across the kernel, the Riccati solution $P(\cdot)$, and the closed-form solution operator of the scalar forward–backward pair (21.24) used in worked computation 21.18: chapter 22.
- The probabilistic (graphon-FBSDE) characterization: chapter 23. The finite-network derivation underlying section 21.2: chapter 25.

Open.

- Whether the d_2 (existence-friendly) and d_∞ (regularity-friendly) topologies of section 21.3 can be reconciled into a single space carrying both compactness and continuity-in-type without extra kernel regularity, in the most general non-LQG setting.
- Rigorous status of an exact law of large numbers across a continuum of types at the level of realized trajectories (remark 21.2), beyond the Fubini-extension device of [125], in the controlled graphon setting.

Bibliographic notes

The dynamic graphon mean field game was introduced by Caines and Huang [33, 34], whose GMFG equations are the object this chapter sets up and chapter 22 solves; their formulation works with a type-indexed family of HJB–Fokker–Planck systems coupled through the graphon operator, precisely the structure of definition 21.16. The field-of-measures state space and its L^2-Wasserstein metric, our definition 21.8, follow the analytic setting used by Bayraktar, Wu and Zhang for graphon mean field systems [16] and by Aurell, Carmona and Laurière in the linear-quadratic graphon game [10], the latter being the closest published analogue of the Thread B model of example 21.3; the static counterpart, with the same aggregate $z(x)$, is the stochastic graphon game of Carmona, Cooney, Graves and Laurière [39] and the graphon games of Parise and Ozdaglar [108] treated in chapter 20. The subtlety of a continuum of independent noises (remark 21.2) is the exact-law-of-large-numbers problem resolved by Sun's Fubini extensions [125]; the route we actually take — posing the game through the deterministic field of laws — is the graphon lift of the McKean–Vlasov formulation of [103, 129] developed in chapter 7. The Wasserstein estimate underlying lemma 21.11 (the elementary coupling bound $|\langle h, \mu\rangle - \langle h, \nu\rangle| \le \mathcal{W}_1 \le \mathcal{W}_2$ for 1-Lipschitz h, the easy half of the Kantorovich–Rubinstein picture) uses only the definition of $\mathcal{W}_1$ and the ordering $\mathcal{W}_1 \le \mathcal{W}_2$ of chapter 4, following [131]; the completeness of $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ and the metric-target L^2 theory are in [7]. The reductions of section 21.5 trace back to the classical LQG mean field game of Huang, Caines and Malhamé [82] (constant coupling) and to the rank-one/Curie–Weiss picture flagged throughout the graphon literature; the multi-population limit of remark 21.20 is surveyed in the modern overview [11] and developed in chapter 30.

Chapter 22

The Coupled HJB–Fokker–Planck System Across a Kernel

In chapter 21 the dynamic graphon mean field game was *set up*: a continuum of representative agents indexed by a type $x \in [0,1]$, each carrying a private state and a controlled diffusion, coupled not to a single global population law but to a *field of measures* $x \mapsto m_t^x$ through the graphon operator $\mathbb{W}$. That was half the problem — it fixes who plays, what each agent controls, and what each pays, but not what they do. This chapter solves the other half: the actual system of equations the equilibrium must satisfy. It helps to say in advance what an *equation-level* answer even looks like, because it is neither a number nor a single curve. An equilibrium of a differential game is a pair of partial differential equations pinned at opposite ends of the clock — a backward equation for an agent's value, carrying *terminal* data at $t = T$, coupled to a forward equation for that agent's law, carrying *initial* data at $t = 0$ — and here there is one such pair for *every type at once*. The object we are after is therefore a continuum-indexed family of such pairs, parametrized by $x \in [0,1]$. This is the graphon lift of chapter 8, where the strategic fixed point of a homogeneous population condensed into exactly one backward Hamilton–Jacobi–Bellman (HJB) equation driven by the density and one forward Fokker–Planck (FP) equation driven by the optimal feedback, with data at the two ends of $[0,T]$. Here the identical dual structure holds per type, and the *only* new ingredient is that the types talk to one another — but solely through the kernel W. That last clause is the organizing promise of the whole chapter, and it is worth stating as a slogan: the coupling between types factors through a single linear object, the integral operator $\mathbb{W}$, and through nothing else. Every section below either exploits this fact or guards against over-reading it. The regularity section pushes continuity-in-type around the best-response loop precisely because $\mathbb{W}$ is linear and bounded; the special-structures section collapses the continuum of couplings to finitely many numbers precisely because $\mathbb{W}$ has a usable spectrum; the worked computation reads its leading eigenvalue as the single rescaling of the interaction strength; and the couplings section warns against the seductive but false reading of $\mathbb{W}$ as a local gradient coupling between neighbouring types. The result we are heading for is thus a continuum-indexed family of HJB–FP pairs, locked together by the integral operator $\mathbb{W}$ and by nothing else.

What we borrow from earlier chapters, we borrow for a specific later use, and it is worth naming the use rather than the citation. From chapter 8 we take the per-type *engine*: the analytic mean field game system (definition 8.1), the verification theorem (proposition 8.2) that certifies an HJB–FP pair as a genuine optimization rather than a formal pair of PDEs, the best-response reformulation (proposition 8.4) that turns the pair into a fixed point, and the coupling taxonomy of section 8.5 that classifies how the population may enter a cost. Once the field is frozen, each type *is* a Chapter 8 problem, so this is the whole single-type apparatus and we re-use it verbatim. From the existence theory of chapter 10 we take the two *stability* lemmas (lemmas 10.10 and 10.11), which bound how far the value and the density move when the coefficients and the environment move; these are exactly what powers section 22.3, where the perturbation in question is a change of *type* and the payoff is that the solution depends measurably, and continuously, on it. From chapter 18 we take the *spectral* picture of the graphon as a self-adjoint Hilbert–Schmidt operator; its eigenvalues and eigenfunctions are precisely what section 22.4 uses to collapse the infinite type-coupling to finitely many order parameters, and the rank-one corner of that collapse is what feeds the worked computation. The Lasry–Lions monotonicity condition (definition 11.1) we carry only to mark where uniqueness would call for it. And from the LQG capstone of chapter 14 we take the *template* the chapter's worked computation fills in: its closing section 14.7 already wrote the multi-population Riccati system, and our Thread B is that same calculation with the scalar population mean $\bar{m}_t$ replaced by the graphon-aggregated neighbor mean $(\mathbb{W}\bar{m}_t)(x)$, watching each Riccati equation become a type-indexed family. Two things this chapter deliberately does *not* do, stated here as the reader's map: we do not prove existence or uniqueness of the coupled fixed point — that is the charge of chapter 24, which consumes the system written below — and we do not give the probabilistic, forward–backward stochastic differential equation rendering of the same equilibrium, which is chapter 23 and will refer back to the system eq. (22.6) defined here.

The plan is as follows. section 22.1 states the graphon MFG system, derives it from the per-type optimization against a frozen field, gives the "coupling only through $\mathbb{W}$" reading, and casts it as a fixed point of a best-response map on fields of measures. section 22.2 compares the genuinely nonlocal (kernel) coupling that a graphon provides with the local (gradient) coupling of a spatial field theory, and develops the Ginzburg–Landau analogy that organizes the rest of Part IV — with an explicit warning about its one false note. section 22.3 establishes the regularity and measurability of the map $x \mapsto (u^x, m^x)$, the technical backbone that makes "a continuum of HJB–FP pairs" a well-defined object. section 22.4 treats the solvable structures: separable (finite-rank) kernels collapse the type-coupling to finitely many order parameters, and block graphons recover finite multi-population MFG, the explicit bridge to chapter 30. section 22.5 is the worked computation that advances Thread B: the rank-one graphon LQG, solved in closed form to a single scalar two-point boundary value problem with an effective coupling rescaled by the leading eigenvalue of $\mathbb{W}$.

Notation watch

Three conventions, all announced in appendix A and restated here because Part IV is the first place all of them collide in one equation — and each collision is a genuine hazard, not a pedantry. The system eq. (22.6) runs two clocks in opposite directions in the same display (so a sign or a boundary datum read off the wrong end is silently wrong), writes the kernel and the noise with letters that were historically the same (so W used loosely is ambiguous), and carries a type label beside a state variable in every function (so a derivative taken in the wrong argument is meaningless). A reader who lets any of the three slide will misread the equations; taken in turn: *(i) The two directions of time.* The value field $u^x = u^x(t,\xi)$ carries *terminal* data at $t = T$ and is computed *backward*; the density field $m^x = m^x(t,\xi)$ carries *initial* data at $t = 0$ and is transported *forward*. *(ii) Brownian motion versus graphon.* The kernel owns the letter $W = W$; Brownian motion is therefore written B_t throughout Part IV. *(iii) Type versus state.* The variable $x \in [0,1]$ is the exchangeable *type* label and carries no metric of its own (appendix A); the agent's *private state* lives in $\mathbb{R}^d$ and is written ξ (the running spatial variable) or X_t^x (the process). Thus $u^x(t,\xi)$ has the type as a superscript parameter and the state ξ as its PDE argument, and ∇ and D^2 act in ξ unless decorated otherwise. We never differentiate in x (there is, in general, no derivative in type to take).

22.1 The graphon mean field game system

This section delivers the chapter's central object — the graphon MFG system itself — in three deliberate steps, and it is worth seeing the arc before the formalism arrives. First we recall the standing data of chapter 21: the space of fields of measures, the two metrics it carries, and above all the graphon-aggregated neighbor distribution $(\mathbb{W}\boldsymbol{m}_t)(x)$, read in the only sense this chapter needs — the weak one. Nothing can be written down until this aggregate is pinned, because it is the one channel through which a type feels the rest of the population, and an equation is only as well-posed as the object that sits inside its nonlinearity. Second, with the data in hand, we run the mean-field heuristic one type at a time: freeze the field, let the type-x agent optimize against the frozen aggregate as if it were an ordinary prescribed environment, then close the loop by demanding that the law this agent generates reproduce the field it was optimizing against. Performed simultaneously for every type, this yields the coupled backward-HJB / forward-FP system that is the chapter's deliverable. Third, we recast that system in the form the rest of the book actually consumes: a solution is a fixed point of a best-response map on flows of fields, the graphon analogue of the homogeneous map of chapter 8, whose single genuinely new feature is that one application of it already requires the entire field over $[0,1]$ and therefore does not factor over types. We begin with the data.

22.1.1 Standing data

Before any equation can be written we must fix the arena it lives in, and the section opener promised exactly this: first recall the objects chapter 21 built — the field of measures, the two metrics it carries, and above all the graphon-aggregated neighbor distribution — because the equilibrium system is a statement *about* these objects and is no better defined than they are. We import them rather than redefine them, citing chapter 21 at each step.

The state of the whole population at one instant is not a single measure but a measure for every type. A *field of measures* is a map $\boldsymbol{m}\colon [0,1] \to \mathcal{P}_2(\mathbb{R}^d)$, $x \mapsto m^x$, measurable in x and with a uniformly bounded second moment, $\sup_x \int_{\mathbb{R}^d} |\xi|^2\, m^x(\mathrm{d}\xi) < \infty$ — this is the field space $\boldsymbol{\mathcal{P}}_2$ of definition 21.8. Both qualifiers earn their place. The measurability in x is the price of admission: without it the type-integral that defines the aggregate below would be a nonsense, since one cannot integrate a non-measurable family. The uniform second-moment bound is what keeps that integral landing back inside $\mathcal{P}_2(\mathbb{R}^d)$ rather than letting mass run off to infinity along some sequence of types. A *flow of fields* is the time-dependent version, a map $t \mapsto \boldsymbol{m}_t = (m_t^x)_{x\in[0,1]}$; this flow is the unknown the equilibrium system will solve for.

Two distinct metrics on fields will be used, and the reader should feel *why* there are two before either is written down, because the distinction is not pedantry — it is the reason this chapter and chapter 24 are phrased on different spaces. A field is a function of the type x valued in the metric space $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$, so to compare two fields we must somehow aggregate the per-type Wasserstein gaps $\mathcal{W}_2(m^x, (\boldsymbol{m}')^x)$ over x, and there are two natural ways to do that. The first averages them in L^2,

$$d_2(\boldsymbol{m}, \boldsymbol{m}') = \Big(\int_0^1 \mathcal{W}_2(m^x, (\boldsymbol{m}')^x)^2 \, \mathrm{d}x \Big)^{1/2},$$

the L^2-over-types Wasserstein metric on $\boldsymbol{\mathcal{P}}_2$ (the default of definition 21.8); the second takes their supremum,

$$d_\infty(\boldsymbol{m}, \boldsymbol{m}') = \sup_x \mathcal{W}_2(m^x, (\boldsymbol{m}')^x),$$

the uniform-in-type metric on the type-continuous subspace $\mathcal{C}_2$ of definition 21.10. They serve different masters. The L^2 metric d_2 is *separable* and tolerant: it permits the per-type measures to be merely measurable in x, and it counts two fields as close as soon as they are close *on average* over types, so a single badly-behaved type sitting on a Lebesgue-null set costs nothing. That tolerance is precisely what makes d_2 *compactness-friendly*, and compactness is the one thing chapter 24 cannot do without, since its entire job is to extract a convergent subsequence of near-equilibria; that is why chapter 24 lives on $(\boldsymbol{\mathcal{P}}_2, d_2)$. The uniform metric d_∞ is stricter: d_∞-closeness demands the two fields be close at *every* type simultaneously, with no bad type allowed to hide. That strictness is a liability for compactness but an asset for *stability*, which is this chapter's currency. The per-type estimates we inherit from chapter 10 are bounds that hold for each type separately and with a constant uniform across types — sup-in-type estimates — so they assemble with no loss into a clean d_∞ statement; phrasing them in d_2 would only throw the per-type sharpness away in an average. This is why every stability and regularity result below is phrased on $(\mathcal{C}_2, d_\infty)$ while chapter 24 switches back to $(\boldsymbol{\mathcal{P}}_2, d_2)$. The two are emphatically *not* interchangeable. One inequality always holds, $d_2 \le d_\infty$ (an average never exceeds a supremum), so d_∞-convergence implies d_2-convergence but never the reverse; and the gap has teeth, because $\mathcal{C}_2$ is *not* d_2-closed — a d_2-Cauchy sequence of type-continuous fields can converge to a field that is only measurable, its type-continuity dissolved in the averaging. The mental model to keep is therefore: d_∞ is the working metric of the present chapter, and d_2 is the metric chapter 24 drops to precisely when it needs compactness, paying for it by leaving $\mathcal{C}_2$. section 21.3 records this trade-off, and we name the metric at each result. In particular, calling a flow of fields *continuous* will always mean continuity for d_∞, i.e. $\sup_x \mathcal{W}_2(m_t^x, m_s^x) \to 0$ as $s \to t$ — the per-type laws move continuously in time, uniformly over types.

With the arena fixed we can describe the players. The type-x representative agent has private state $X_t^x \in \mathbb{R}^d$ obeying the controlled diffusion

$$\mathrm{d}X_t^x \;=\; b(x, X_t^x, \alpha_t^x)\ \mathrm{d}t \;+\; \sigma(x)\ \mathrm{d}B_t^x, \qquad X_0^x \sim m_0^x, \tag{22.1}$$

with type-dependent drift $b\colon [0,1]\times\mathbb{R}^d\times A\to\mathbb{R}^d$, volatility $\sigma\colon[0,1]\to\mathbb{R}^{d\times d}$, independent Brownian motions B^x, and feedback control $\alpha^x_t=\alpha^x(t,X^x_t)$.

The single structural novelty relative to chapter 8 — the one ingredient that makes this a *graphon* mean field game and not a parametrized family of ordinary ones — is how the population enters the agent's cost. A type-x agent does not feel the global population. It feels the *graphon-aggregated neighbor distribution* (definition 21.5), the kernel-weighted average of the laws of all other types,

$$(\mathbb{W}\boldsymbol{m}_t)(x) \;:=\; \int_0^1 W(x,y)\, m_t^y \;\mathrm{d}y \;\in\; \mathcal{M}_+(\mathbb{R}^d). \tag{22.2}$$

This is the object every later section either exploits or guards against over-reading, so it is worth dwelling on what it is and how to read it honestly.

First, what kind of measure it is. The weights $W(x,y)$ lie in $[0,1]$ and integrate over y to the *degree* of type x, $(\mathbb{W}\mathbf{1})(x)=\int_0^1 W(x,y)\,\mathrm{d}y\le 1$. Since each m_t^y is a probability measure, the aggregate is a convex-like combination of probability measures with total weight at most one: its total mass is exactly that degree, so in general $(\mathbb{W}\boldsymbol{m}_t)(x)$ is a *sub-probability* measure, an element of $\mathcal{M}_+(\mathbb{R}^d)$ rather than $\mathcal{P}_2(\mathbb{R}^d)$. The missing mass is not a defect to be normalized away; it is information. A weakly-connected type — one for which $W(x,\cdot)$ is small — genuinely feels a fainter, lighter neighbor distribution than a hub, and the cost eq. (22.4) is built to register that difference. Only when every row of the kernel integrates to one (a doubly-stochastic, in particular the complete, graphon) does the aggregate stay a probability measure for every type.

Second, and this is the point of method, we read eq. (22.2) *weakly*, and the weak reading is the only sense this chapter ever uses. Taken at face value, the integral $\int_0^1 W(x,y)\,m_t^y\;\mathrm{d}y$ is an integral of a *measure-valued* integrand over y — to give it meaning directly one would have to develop vector-valued (Bochner) integration in the space of measures, fuss over which Banach space the measures sit in, and verify Bochner-measurability and integrability of $y\mapsto m_t^y$. None of that is necessary, because the integral is only ever tested against functions. We therefore *define* the aggregate by how it pairs with test functions: for a.e. x, $(\mathbb{W}\boldsymbol{m}_t)(x)$ is the unique finite Borel measure on $\mathbb{R}^d$ characterized by

$$\langle\varphi,(\mathbb{W}\boldsymbol{m}_t)(x)\rangle=\int_0^1 W(x,y)\,\langle\varphi,m_t^y\rangle\;\mathrm{d}y\qquad\text{for every bounded continuous }\varphi\colon\mathbb{R}^d\to\mathbb{R}. \tag{22.3}$$

The gain is that the right-hand side is now an ordinary *scalar* Lebesgue integral: the integrand $y\mapsto W(x,y)\langle\varphi,m_t^y\rangle$ is a bounded measurable real-valued function of y, nothing more, because $\langle\varphi,m_t^y\rangle=\int_{\mathbb{R}^d}\varphi\;\mathrm{d}m_t^y$ is a bounded scalar for each y and is measurable in y by the field's measurability. The whole vector-valued machinery collapses to scalar integration done one test function at a time, and that a single Borel measure is pinned down by its pairings against bounded continuous φ is just the fact that such φ are convergence-determining on $\mathbb{R}^d$ (chapter 3). This is exactly the measure-valued action $\mathbb{W}\circledast$ of definition 21.5; we drop the $\circledast$ decoration and write $\mathbb{W}$ for both the scalar action on $L^2[0,1]$ and this measure-valued action, the argument disambiguating which is meant.

That the prescription eq. (22.3) genuinely does define a finite measure — with mass ≤ 1 and uniformly bounded second moment — and that this measure depends *measurably* on x (indeed *continuously* when the kernel is), is not assumed here but *deferred*: it is exactly the content of section 22.3, where it is proved as lemma 22.8. We flag this as a forward promissory note rather than a standing hypothesis, because the measurability is what later closes the best-response loop $\mathsf{S}\colon \mathcal{C} \to \mathcal{C}$ of definition 22.5, and it deserves a proof rather than a stipulation.

With the aggregate in hand we can state how the population enters payoffs. The running cost L and terminal cost g of the type-x agent depend on the population *only* through the aggregate eq. (22.2):

$$J^x(\alpha^x) = \mathbb{E}\left[\int_0^T L\Big(x, X_t^x, \alpha_t^x, (\mathbb{W}\boldsymbol{m}_t)(x)\Big)\,\mathrm{d}t + g\Big(X_T^x, (\mathbb{W}\boldsymbol{m}_T)(x)\Big)\right]. \tag{22.4}$$

The single appearance of $(\mathbb{W}\boldsymbol{m}_t)(x)$ inside L and of $(\mathbb{W}\boldsymbol{m}_T)(x)$ inside g is the precise content of the slogan that "coupling acts across types only through $\mathbb{W}$": strip the aggregate out and each type would be an isolated control problem with no knowledge of any other; put it back and the only wire between types is the linear operator $\mathbb{W}$. Everything downstream turns on this single point of contact.

The optimization the type-x agent performs against its frozen environment is encoded, exactly as in the homogeneous theory, by a Hamiltonian. We define the per-type Hamiltonian, with the type x now carried as a parameter, by the same Legendre-type formula as eq. (8.4):

$$H(x,\xi,p,\nu) \;:=\; \sup_{a\in A}\Big\{ -b(x,\xi,a)\cdot p - L(x,\xi,a,\nu)\Big\}, \qquad \nu \in \mathcal{M}_+(\mathbb{R}^d), \tag{22.5}$$

so that its four slots are the type x, the state ξ, the costate p (the value gradient, in the equations below), and the aggregate measure ν, into which $(\mathbb{W}\boldsymbol{m}_t)(x)$ will be substituted. Note that the population variable lives in the cost slot only: the supremand depends on ν through L and not through b, which is the structural feature remark 22.1 isolates and the next subsection exploits when it freezes the field.

The hypotheses under which all of this is legitimate are the standing assumptions of appendix A, invoked here by tag but now demanded *uniformly in the type* — uniformity being the whole content of "a continuum of well-behaved problems" rather than "a problem for each type with no control across them." Each earns its keep, and it is worth saying what breaks without it.

(A-Lip) b, σ, L, g are Lipschitz in the state ξ, uniformly in (t, x, a) and in the measure argument (the latter for $\mathcal{W}_2$ on $\mathcal{M}_+$); and they are Lipschitz in the type x, uniformly in the remaining arguments. The state-Lipschitz half is the standard well-posedness input for the SDE eq. (22.1) and the per-type PDEs; the measure-Lipschitz half is what lets a small change in the aggregate produce only a small change in the cost, the engine of every stability estimate. The *type*-Lipschitz half is the genuinely new clause, and it is what powers section 22.3: without continuity of the data in x the solution field $x \mapsto (u^x, m^x)$ could jump arbitrarily, and "a continuum of HJB–FP pairs" would be a continuum in name only.

(A-Growth) linear growth in ξ and coercivity in a, uniformly in x, so the supremum in eq. (22.5) is attained and finite. Drop coercivity and the agent could push the control to infinity at vanishing marginal cost, leaving the Hamiltonian $+\infty$ and the maximizer undefined; drop linear growth and the second moment could blow up in finite time, ejecting m_t^x from $\mathcal{P}_2(\mathbb{R}^d)$ and breaking the moment bounds that keep the aggregate inside $\mathcal{M}_+(\mathbb{R}^d)$.

(A-Nondeg) $\sigma(x)\sigma(x)^\top \succeq \lambda I$ for some $\lambda > 0$ independent of x. This is the parabolic-regularization clause: a uniformly elliptic second-order term smooths both the backward HJB and the forward FP, giving classical solutions and, crucially, an honest *density* $m^x(t,\cdot)$ for the FP equation rather than a bare measure. Without it the FP solution can stay singular, the local couplings of section 22.2 (which read off a pointwise density) become ill-posed, and the stability constants degrade as $\lambda \downarrow 0$. The uniformity in x is what makes those constants assemble into the d_∞ estimates.

(A-Conv) $H(x,\xi,\cdot,\nu)$ convex in the costate, so the feedback $-\partial_p H$ is *single-valued.* This is what turns the optimal control into a genuine function of (t,ξ) rather than a set: with a unique maximizer the closed-loop drift of the FP equation is well-defined, the best-response map is a map and not a correspondence, and — the payoff for section 22.3 — the type-to-solution assignment needs no measurable-selection theorem, since there is nothing to select.

(A-Reg-W) $W\colon [0,1]^2 \to [0,1]$ symmetric, measurable, bounded; continuous in type where stated; $\mathbb{W}$ self-adjoint Hilbert–Schmidt on $L^2[0,1]$. Boundedness gives the sub-probability mass bound above; measurability is what makes eq. (22.3) a legitimate scalar integral; symmetry and Hilbert–Schmidtness are what hand $\mathbb{W}$ a real spectrum and an orthonormal eigenbasis, the spectral data that section 22.4 collapses to order parameters and section 22.5 reads off as a single eigenvalue. The continuity-in-type clause is invoked only where stated, for the continuous (as opposed to merely measurable) half of section 22.3.

Two further assumptions from the standing list are deliberately held back. The Lasry–Lions monotonicity **(A-Mon)** and the operator-norm smallness **(A-Coupling)** are levers for *uniqueness* of the fixed point, not for writing the system down, and this chapter neither proves uniqueness nor needs them; we defer both to chapter 24 and flag each use there.

Remark 22.1 (The subclass solved here)**.** It is worth being explicit that eqs. (22.1) and (22.4) are not the most general agent chapter 21 allows, and about why the restriction is exactly the one that lets the chapters 8 and 10 machinery transfer with no new analysis. The general representative agent of definitions 21.1 and 21.6 carries a richer signature: there the drift may itself depend on the aggregate, $b(x, X, \alpha, (\mathbb{W}\boldsymbol{m}_t)(x))$, and the diffusion may depend on the state, $\sigma(x, X)$. This chapter — and the existence theory of chapter 24 that consumes it — solves the subclass in which two simplifications hold. (i) The drift does *not* depend on the aggregate, so the population enters the agent's problem only through the cost, and hence only as the source term and terminal datum of the backward HJB; the population never touches the dynamics directly. (ii) The diffusion is state-independent, $\sigma = \sigma(x)$, so the second-order operator in eqs. (22.6a) and (22.6b) has coefficients that are constant in the state ξ (depending on the type but not on where the agent is).

These two are precisely what make the per-type theory of chapters 8 and 10 apply *verbatim.* Restriction (i) is the load-bearing one. Because the aggregate sits in the cost alone, freezing the field renders the HJB an ordinary backward equation with a prescribed time-dependent source $F(x,\xi,(\mathbb{W}\boldsymbol{m}_t)(x))$ and a prescribed terminal datum — a standard single-agent control problem in a fixed environment, to which the verification theorem applies unchanged. The forward FP equation it generates is then *linear* in m^x: its transport drift $-\partial_p H(x,\xi,\nabla u^x)$ is built from the value alone and does not see m^x, so the only nonlinearity in the whole coupled system is the benign one routed through the cost. Restriction (ii) keeps the elliptic part of both equations a constant-coefficient operator in ξ, which is what **(A-Nondeg)** needs to deliver classical solutions and densities uniformly in x.

Were restriction (i) dropped — the aggregate-dependent-drift, or *congestion*, case — the picture changes qualitatively. The optimal closed-loop drift would then read $-\partial_p H(x, \xi, \nabla u^x, (\mathbb{W}\boldsymbol{m}_t)(x))$, carrying the aggregate inside it, so the population would enter the forward transport *directly* and not merely through the value. The FP equation eq. (22.6b) would lose its linearity in m^x and become a genuinely nonlinear transport coupled across types, in which the very drift that moves m^x depends on the graphon average of all the m^y. That is a strictly harder problem — the clean per-type decoupling under a frozen field is gone — and we do not solve it here; it is logged at the research frontier in the closing ledger.

We now have everything the next subsection needs: the field space and its two metrics, the controlled state eq. (22.1), the weakly-read aggregate eq. (22.3) that is the sole channel of coupling, the cost eq. (22.4) that depends on the population only through it, and the per-type Hamiltonian eq. (22.5) into which the aggregate is substituted. With the data fixed, the move that produces the equilibrium system is the mean-field heuristic applied one type at a time — freeze the field, let the type-x agent optimize its Hamiltonian against the frozen aggregate as against any prescribed environment, then demand the resulting law reproduce the field. We carry out that freezing next.

22.1.2 The system

The previous subsection left us holding exactly what we need — the controlled state eq. (22.1), the weakly-read aggregate eq. (22.3), the cost eq. (22.4) that sees the population only through that aggregate, and the per-type Hamiltonian eq. (22.5) — and it flagged the move that turns this data into an equilibrium system: the mean-field heuristic, run one type at a time. We now carry out the freezing it promised, and it pays to develop it slowly, because the whole claim of the chapter is that this single heuristic survives the graphon lift untouched.

The homogeneous theory of chapter 8 reached its system through three beats: *freeze* the population, *solve* the representative agent's control problem against the frozen population, then *close* the loop by demanding that the law the agent generates coincide with the population it was handed (section 8.1.2). The only thing that could obstruct lifting these three beats to the graphon setting is the coupling. In the homogeneous problem the agent feels one global law m_t; here it feels the aggregate $(\mathbb{W}\boldsymbol{m}_t)(x)$, an object assembled from the *entire* field $\boldsymbol{m}_t$ over all types. So the question that decides whether the lift goes through is sharp: once we freeze the field, does each individual type still face an *ordinary* control problem, or does the cross-type pooling leave behind some residual entanglement that no single-agent optimization can swallow?

It goes through cleanly, and seeing precisely why is the content of the freezing step. Fix a candidate flow of fields $\boldsymbol{m} = (\boldsymbol{m}_t)_{t\in[0,T]}$ — a full trial guess at the time-dependent population state, one measure m_t^x for every type and every instant. To *freeze* the field is to treat this entire flow as given data, inert for the duration of the agent's optimization, not as an unknown to be solved for. Now isolate a single type x. The only place the population touches the type-x agent's problem is the aggregate $(\mathbb{W}\boldsymbol{m}_t)(x)$ appearing in the running and terminal costs of eq. (22.4). But with the whole field $\boldsymbol{m}$ frozen, the curve

$$\nu_t^x \;:=\; (\mathbb{W}\boldsymbol{m}_t)(x), \qquad t \in [0,T],$$

is — for this one fixed x — just a prescribed flow of measures: a known, time-dependent environment, computed once and for all by the scalar integral eq. (22.3), with no remaining dependence on anything the type-x agent will go on to do. The agent cannot budge it. Its own law is a single input of Lebesgue-null weight to the type-integral defining every aggregate, so an individual deviation changes ν^y for *no* type y, its own included. This is the mean-field decoupling, and in the graphon setting it operates twice over: the agent is negligible within its type, and the type is negligible within the continuum.

With the environment ν^x frozen to a prescribed curve, the type-x agent's problem eq. (22.4) is an ordinary stochastic control problem — minimize an expected integral cost over feedback controls, subject to the state dynamics eq. (22.1) and a known time-dependent cost coefficient ν_t^x. Nothing graphon-specific survives inside it. The type x has become a *spectator parameter*: it selects which drift $b(x,\cdot,\cdot)$, which volatility $\sigma(x)$, which running cost $L(x,\cdot,\cdot,\cdot)$, and which environment ν^x the agent confronts, but inside the optimization it is an inert tag carried along for the ride, never differentiated, never coupled to anything — exactly the standing-data warning that we never take a derivative in x. This is verbatim the situation of chapter 8, and its resolution is verbatim Chapter 8's: the value u^x solves a backward HJB equation driven by the frozen environment, and the optimally controlled state has a law that flows forward by a Fokker–Planck equation driven by the optimal feedback. (That the freezing is a legitimate idealization of a large but finite network, rather than a fiction, is the content of chapter 21 and, quantitatively, of chapter 25.)

That disposes of the agent's half. The loop is closed by the self-consistency demand: the law the type-x agent generates must be the very field m^x we froze — and this is imposed *simultaneously for every type*. It is the simultaneity that re-welds the continuum of decoupled single-type problems into one coupled system. They are coupled because the environment $\nu^x = (\mathbb{W}\boldsymbol{m}_t)(x)$ that type x optimized against is built out of the laws m^y of all the other types, each of which is in turn being pinned by its own agent's optimization against its own aggregate. Imposing every closure at once is what locks the family together. We now write down exactly what that simultaneous closure says.

Definition 22.2 (Graphon MFG system)**.** A pair of fields $(\boldsymbol{u},\boldsymbol{m}) = \big((u^x)_{x\in[0,1]},(m^x)_{x\in[0,1]}\big)$, with each $u^x\colon [0,T]\times\mathbb{R}^d \to \mathbb{R}$ sufficiently smooth and each $m^x\colon [0,T]\to\mathcal{P}_2(\mathbb{R}^d)$ a flow with density $m^x(t,\cdot)$, is a *(classical) solution of the graphon mean field game system* with data $(\boldsymbol{m}_0, g)$ if, for almost every type $x\in[0,1]$, the backward HJB equation

$$-\partial_t u^x - \tfrac12\,\mathrm{tr}\big(\sigma(x)\sigma(x)^\top \mathrm{D}^2\, u^x\big) + H\Big(x,\xi,\nabla u^x,(\mathbb{W}\boldsymbol{m}_t)(x)\Big) = 0, \tag{22.6a}$$

$$\partial_t m^x - \tfrac12\,\mathrm{tr}\big(\sigma(x)\sigma(x)^\top \mathrm{D}^2\, m^x\big) - \mathrm{div}\Big(m^x\,\partial_p H\big(x,\xi,\nabla u^x,(\mathbb{W}\boldsymbol{m}_t)(x)\big)\Big) = 0, \tag{22.6b}$$

hold on $(0,T)\times\mathbb{R}^d$, with split boundary data

$$u^x(T,\xi) = g\Big(\xi,(\mathbb{W}\boldsymbol{m}_T)(x)\Big), \qquad m^x(0,\cdot) = m_0^x, \tag{22.7}$$

where D^2 and div act in the state variable ξ.

Read the system one type at a time and it is the Chapter 8 pair, with one substitution. Equation eq. (22.6a) is the type-x agent's backward HJB: its only contact with the rest of the population is the aggregate $(\mathbb{W}\boldsymbol{m}_t)(x)$ inside H and in the terminal datum. Equation eq. (22.6b) is the forward FP equation for the type-x density, transported by the type-x optimal *closed-loop drift*

$$b^{x,*}(t,\xi) \;:=\; -\,\partial_p H\Big(x,\xi,\nabla u^x(t,\xi),(\mathbb{W}\boldsymbol{m}_t)(x)\Big) \;=\; b(x,\xi,\alpha^{x,*}(t,\xi)), \tag{22.8}$$

where the optimal *control* is the Hamiltonian maximizer

$$\alpha^{x,*}(t,\xi) \;:=\; \operatorname*{arg\,max}_{a\in A}\Big\{-\,b(x,\xi,a)\cdot\nabla u^x(t,\xi) - L\big(x,\xi,a,(\mathbb{W}\boldsymbol{m}_t)(x)\big)\Big\}, \tag{22.9}$$

single-valued under **(A-Conv)**.

Before reading off the coupling, settle the boundary data, because the split in eq. (22.7) is the structural signature the notationwatch insisted on and is silently easy to get backwards. The two equations of the pair are pinned at *opposite* ends of the clock and run toward each other. The value carries *terminal* data $u^x(T,\xi) = g(\xi,(\mathbb{W}\boldsymbol{m}_T)(x))$ at the far end $t = T$ and is integrated *backward*: an agent values a state by what the future holds, so the value is anchored at the horizon and propagated back. The density carries *initial* data $m^x(0,\cdot) = m_0^x$ at the near end $t = 0$ and is transported *forward*: a population is anchored at where it starts and pushed ahead by the flow. This is hazard (i) of the notationwatch made concrete — two clocks in one display — and the cross-coupling is what forbids solving either equation alone: the backward HJB needs the field $\boldsymbol{m}_t$ (through the aggregate) at every t to fix its source and terminal datum, while the forward FP needs ∇u^x at every t to fix its drift, so neither end can be reached without the other. Reading the terminal datum off $t = 0$ or the initial datum off $t = T$ does not merely shuffle labels; it inverts the entire forward–backward structure and produces a different, wrong system.

Now the two objects in eqs. (22.8) and (22.9), which must not be conflated — and the warning that this is "not cosmetic" deserves the full reason. The optimal control $\alpha^{x,*}$ of eq. (22.9) is the *action* the agent chooses: an element of the control set A, the Hamiltonian maximizer. The closed-loop drift $b^{x,*}$ of eq. (22.8) is the *velocity* that action induces on the state, $b(x,\xi,\alpha^{x,*})$. The Fokker–Planck equation eq. (22.6b) transports the density with the drift, *not* the control, and this is forced rather than conventional: the density m^x is the law of the state X^x, the state moves at velocity $b(x,\xi,\alpha^{x,*})$, so the transport term of any continuity equation for that law is $\operatorname{div}(m^x\, b^{x,*})$. Putting the control there instead would be a category error — the control need not even be a velocity (it can be a force, a rate, a signal valued in an abstract A), so $\operatorname{div}(m^x\, \alpha^{x,*})$ may not even typecheck.

What licenses writing that drift as $-\partial_p H$, rather than as $b(x,\xi,\alpha^{x,*})$, is the envelope identity, and it is worth the one line. By definition eq. (22.5), $H(x,\xi,p,\nu) = \sup_a\{-b(x,\xi,a)\cdot p - L(x,\xi,a,\nu)\}$, with the supremum attained at $a = \alpha^{x,*}$ (single-valued by **(A-Conv)**). Differentiate the value of this maximization in the costate p. At the maximizer the first-order condition holds, so the term that would come from differentiating $\alpha^{x,*}(p)$ through the chain rule is multiplied by a vanishing gradient and drops out; only the *explicit* p-dependence of the supremand survives. Hence

$$\partial_p H(x,\xi,p,\nu) \;=\; -\,b(x,\xi,\alpha^{x,*}), \qquad \text{so} \qquad -\,\partial_p H \;=\; b(x,\xi,\alpha^{x,*}) \;=\; b^{x,*}.$$

The induced drift and minus the costate-gradient of the Hamiltonian are therefore *literally the same vector*, which is exactly what eq. (22.8) records in writing $b^{x,*} = -\partial_p H = b(x, \xi, \alpha^{x,*})$ in one breath, and why eq. (22.6b) carries $\partial_p H$. The control $\alpha^{x,*}$ is recovered separately by the argmax eq. (22.9); in general it does not appear in the transport at all.

The control and the drift coincide in exactly one circumstance: when the control enters the dynamics as a *unit-gain velocity*, $b(x, \xi, a) = a$, so that choosing the action *is* choosing the velocity. Then $b^{x,*} = \alpha^{x,*}$ and the distinction collapses. This is the special structure of much of the textbook LQG literature, which is precisely why the gap is invisible in the simplest models and must be flagged the instant one leaves them. Thread B (worked computation 22.15) is the cleanest place to watch it open up to nonzero width: its state eq. (22.1) has scalar drift $b(x, \xi, \alpha) = a\xi + b\,\alpha$, with a genuine control gain $b \neq 1$ and a state-feedback term $a\xi$ that the action does not set, so the optimal control is the linear feedback $\alpha^{x,*} = -b\,(P\xi + r^x)$ — set by the Riccati curvature P and the decoupling offset r^x — while the closed-loop drift is $b^{x,*} = a\xi + b\,\alpha^{x,*} = a\xi - b^2(P\xi + r^x)$. The two agree only in the degenerate normalization $a = 0$, $b = 1$, where the dynamics reduce to $\mathrm{d}X = \alpha\ \mathrm{d}t + \sigma\ \mathrm{d}B$ and the control is the velocity; for any other (a, b) the FP equation of Thread B transports with $a\xi - b^2(P\xi + r^x)$, and an agent who substituted the control would propagate the wrong Gaussian.

Step back and the architecture is exactly Chapter 8's, drawn once per type. Within a single type there are precisely two arrows, and *both are old*. The HJB needs the population: the aggregate $(\mathbb{W}\boldsymbol{m}_t)(x)$ feeds the Hamiltonian and the terminal datum, so the forward field drives the backward value — arrow one. The FP needs the value: the closed-loop drift $-\partial_p H(x, \xi, \nabla u^x)$ is built from ∇u^x, so the backward value drives the forward density — arrow two. These two arrows are the entire Chapter 8 mechanism, and nothing else passes between u^x and m^x within type x. The single new ingredient hides inside arrow one. In chapter 8 the population the HJB consumed was the agent's own law m_t; here it is *not* m_t^x but the graphon average $(\mathbb{W}\boldsymbol{m}_t)(x)$, which mixes in the laws of *all other* types. That one substitution — $m_t^x \rightsquigarrow (\mathbb{W}\boldsymbol{m}_t)(x)$ — is the *one new wire*, and it is the wire that couples the continuum of otherwise independent Chapter 8 pairs to one another. Crucially it is a *linear* wire: the map $\boldsymbol{m} \mapsto \mathbb{W}\boldsymbol{m}$ is the bounded linear operator $\mathbb{W}$, so the coupling across types — however vast the continuum of them — is carried entirely by one self-adjoint Hilbert–Schmidt operator and through nothing else.

Remark 22.3 (Where the homogeneous system sits inside this one)**.** The sanity check that frames the whole programme is to ask what definition 22.2 becomes for the most featureless kernel of all. Setting $W \equiv 1$ (the complete graphon) makes $(\mathbb{W}\boldsymbol{m}_t)(x) = \int_0^1 m_t^y\ \mathrm{d}y$ independent of x: every agent feels the *same* averaged population, the ordinary mean of all the type-laws. If in addition the data are type-independent — one common b, σ, L, g — then every per-type HJB–FP pair sees the same environment and starts from the same datum, so the entire field collapses to a single pair, recovering the homogeneous Chapter 8 system eq. (8.5) exactly. This is the anchor: the graphon system is a strict generalization that contains the old theory at one trivial value of the kernel, and nothing in the lift can have damaged the $W \equiv 1$ case. The remark also pins down what is genuinely new. As an operator on $L^2[0, 1]$, the constant kernel acts by $\mathbb{W}f = (\int_0^1 f)\,\mathbf{1} = \langle \mathbf{1}, f\rangle\,\mathbf{1}$ — it is the *rank-one orthogonal projection onto the constants* (the leading eigenfunction $\mathbf{1}$, eigenvalue 1, everything else annihilated). The entire graphon programme is the study of what $\mathbb{W}$ does once it is allowed to be anything other than that one projection: once it has more than one eigenvalue, a non-constant leading eigenfunction, a nontrivial spectrum. Every later section is a way of measuring that departure — section 22.4 reads off the finitely many surviving eigenvalues when $\mathbb{W}$ has finite rank, section 22.5 reads off the single leading one. The reduction is made quantitative in chapter 21 and reappears, with $W \equiv c$ rescaling the coupling by the scalar c, in the worked computation of section 22.5.

Two questions are now squarely open, and they are exactly the charge of the next subsection. The first is *legitimacy.* We built definition 22.2 by a heuristic — freeze, optimize, close — and a heuristic is not a theorem. Does a pair $(\boldsymbol{u}, \boldsymbol{m})$ solving these PDEs genuinely encode a type-by-type Nash-consistent equilibrium, one in which no agent of any type can lower its cost by deviating, or is it merely a formal family of coupled equations that happens to resemble one? Answering this is the work of the per-type verification theorem, which certifies each frozen-field problem as an honest optimization rather than a bare PDE. The second is to turn the reading we have been pressing — that the coupling across types is carried entirely by the linear operator $\mathbb{W}$ — from a slogan into a working object. The next subsection does both at once: it verifies the system type by type and recasts it as a fixed point of a field best-response map, where "coupling only through $\mathbb{W}$" becomes the concrete, load-bearing statement that a single application of the map already requires the whole field over $[0, 1]$, because $\mathbb{W}$ does, and therefore does not factor over types.

22.1.3 Per-type verification and the field best-response map

The previous subsection handed this one two debts, and they are paid together here. The first is *legitimacy*: definition 22.2 was assembled by a heuristic — freeze, optimize, close — and a heuristic is a recipe, not a certificate, so we owe a theorem that a pair $(\boldsymbol{u}, \boldsymbol{m})$ solving those PDEs genuinely encodes a type-by-type Nash-consistent equilibrium rather than a formal family of coupled equations that merely resembles one. The second is to turn the reading we have been pressing — that the coupling across types is carried entirely by the linear operator $\mathbb{W}$ and by nothing else — from a slogan into a working object. Both debts are discharged by the same observation, and it is the organizing claim of this subsection: once the field is frozen, the architecture of each per-type problem is exactly that of chapter 8, drawn once for every x, with a single new wire — the substitution of the aggregate $(\mathbb{W}\boldsymbol{m}_t)(x)$ for the agent's own law — threaded through it. Legitimacy then follows by importing chapter 8's verification theorem verbatim, once per type. And the slogan becomes precise the moment we package the per-type solves into one self-map and notice that this same new wire is exactly what stops the map from factoring over types: a single evaluation of it already needs the whole field, because $\mathbb{W}$ does.

Proposition 22.4 (Per-type optimality)**.** *Assume **(A-Lip)**, **(A-Growth)**, **(A-Nondeg)**, **(A-Conv)**, **(A-Reg-W)**. Fix a flow of fields $\boldsymbol{m} = (\boldsymbol{m}_t)_{t\in[0,T]}$ and let, for each x, u^x be the classical solution of the backward HJB eq. (22.6a)–eq. (22.7) with environment $t \mapsto (\mathbb{W}\boldsymbol{m}_t)(x)$. Then $u^x(t, \xi)$ is the value function of the type-x agent's control problem eq. (22.4) against that fixed environment, the feedback control $\alpha^{x,*}$ of eq. (22.9) is optimal, and the law of the optimally controlled state eq. (22.1) — transported by the induced drift $b^{x,*}$ of eq. (22.8) — solves the forward FP equation* *eq.* (22.6b)*.*

Proof sketch. Fix the flow $\boldsymbol{m}$ and the type x. The argument is the verification theorem of chapter 8 run against a frozen environment, and it has three moves: turn the frozen field into a legitimate prescribed environment, use Itô and the HJB to sandwich the cost, and use the Kolmogorov-forward theorem to identify the closed-loop law.

The frozen aggregate is a prescribed continuous flow of measures. Set $\nu_t^x := (\mathbb{W}\boldsymbol{m}_t)(x)$. Because the whole flow $\boldsymbol{m}$ is held fixed, this curve is computed once and for all by the scalar pairing eq. (22.3) and carries no residual dependence on anything the agent will do. It lands in $\mathcal{M}_+(\mathbb{R}^d)$ — a sub-probability measure of mass $(\mathbb{W}\mathbf{1})(x) \leq 1$ with uniformly bounded second moment, by the mass and moment bounds of section 22.1.1 — and it is continuous in t. Indeed, for $s \to t$ and any bounded Lipschitz φ, the weak prescription eq. (22.3) gives

$$\langle \varphi, \nu_t^x - \nu_s^x \rangle = \int_0^1 W(x,y)\, \langle \varphi, m_t^y - m_s^y \rangle \, \mathrm{d}y,$$

whose right side is bounded, up to the Lipschitz constant of φ and the degree $(\mathbb{W}\mathbf{1})(x) \leq 1$, by $\sup_y \mathcal{W}_2(m_t^y, m_s^y)$ and hence vanishes by the d_∞-continuity of $\boldsymbol{m}$ in t together with the boundedness of $\mathbb{W}$. So ν^x is exactly the kind of object chapter 8 optimizes against: a known, time-dependent, continuous environment in $\mathcal{M}_+(\mathbb{R}^d)$, inert for the duration of the optimization. (The quantitative continuity, and its uniformity in x, is lemma 22.8 of section 22.3; here we need only that for one fixed x the flow is prescribed and continuous.)

Itô plus the HJB sandwich the cost. With ν^x frozen, the type-x problem eq. (22.4) is an ordinary stochastic control problem with data $\big(b(x,\cdot,\cdot), \sigma(x), L(x,\cdot,\cdot,\nu^x), g(\cdot,\nu_T^x)\big)$, to which proposition 8.2 applies verbatim. Take any admissible feedback α^x with state X^x solving eq. (22.1) from an arbitrary start $X_t^x = \xi$, and apply Itô's formula (theorem 5.9) to $s \mapsto u^x(s, X_s^x)$ on $[t,T]$. The finite-variation part of the resulting semimartingale carries the drift $\partial_s u^x + \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 u^x) + b(x, X_s^x, \alpha_s^x) \cdot \nabla u^x$, while the stochastic integral against $\sigma(x)\,\mathrm{d}B^x$ is a true martingale of zero expectation under the growth and nondegeneracy bounds. Substitute the HJB eq. (22.6a), which rearranges to $\partial_s u^x + \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 u^x) = H(x,\cdot,\nabla u^x, \nu^x)$, and recall that by the very definition eq. (22.5) of the Hamiltonian as a supremum, $H(x,\xi,p,\nu) \geq -b(x,\xi,a)\cdot p - L(x,\xi,a,\nu)$ for *every* action a, with equality precisely at the maximizer. Taking expectations and adding the terminal datum $u^x(T,\cdot) = g(\cdot,\nu_T^x)$ collapses the telescoping integral to the inequality $u^x(t,\xi) \leq J_t^x(\alpha^x)$, the value bounding the cost-to-go from (t,ξ) from below for every admissible control. The inequality is saturated exactly when the supremum is attained pointwise along the trajectory, i.e. when the agent plays the Hamiltonian maximizer $\alpha^{x,*}$ of eq. (22.9). Here **(A-Conv)** earns its keep: convexity of $H(x,\xi,\cdot,\nu)$ in the costate makes that maximizer *single-valued*, so $\alpha^{x,*}(s,\xi)$ is a genuine feedback and not a multivalued selection, and the chain $u^x(t,\xi) = J_t^x(\alpha^{x,*}) \leq J_t^x(\alpha^x)$ identifies u^x as the value function and $\alpha^{x,*}$ as optimal.

Kolmogorov-forward identifies the closed-loop law. Now feed the optimal feedback back into the dynamics. The optimally controlled state $X^{x,*}$ is the diffusion with drift $b(x,\xi,\alpha^{x,*}(s,\xi)) = b^{x,*}(s,\xi)$ — the induced closed-loop drift eq. (22.8), equal to $-\partial_p H$ by the envelope identity — and state-independent diffusion $\sigma(x)$. Its time-marginal law $\mathcal{L}(X_t^{x,*})$ therefore solves the Kolmogorov-forward (Fokker–Planck) equation (theorem 5.14) with that drift and that diffusion, which is exactly eq. (22.6b); under **(A-Nondeg)** the law carries a density $m^x(t,\cdot)$ and the equation holds classically. Started from the datum m_0^x, this closed-loop law is the forward field the system demands. This disposes of the optimality for each fixed x.

One point is held in reserve, and it is the one the proof statement flags. The estimates the three moves rest on — Schauder and parabolic bounds on u^x, hence on $\alpha^{x,*}$, imported from chapters 8 and 10 — come out with constants that depend on the data only through the bounds in **(A-Lip)**, **(A-Growth)**, **(A-Nondeg)** and through the bound on ν^x, every one of which **(A-Reg-W)** and the standing assumptions make *uniform in* x. For the optimality statement at a single fixed x this uniformity is irrelevant — proposition 8.2 already delivers the conclusion type by type, with no need to know how the constant moves as x varies. Its role is later and structural: uniformity in x is precisely what upgrades these pointwise-in-type facts into *field* statements. A bound that holds for each x separately, but with a constant that could secretly blow up as x ranges over $[0,1]$, says nothing about the assembled field $x \mapsto (u^x, m^x)$ as a single object; a bound *uniform* in x assembles with no loss into a statement about that field in the sup-in-type metric d_∞ of section 22.1.1. Performing that upgrade is the entire business of section 22.3, and we flag here only that the per-type verification already carries the uniformity that section will cash in. □

proposition 22.4 certifies each frozen-field problem as an honest optimization, but it does so one type at a time and against a field that was merely *posited*. The equilibrium demand of chapter 21 is stronger, and it is what welds the types back together: the law each type generates as its optimal closed loop must be the very field that was frozen, and this must hold for every type at once. Read as a condition on the flow $\boldsymbol{m}$, this is self-consistency of the cleanest possible kind — run every type's optimization against the graphon average of $\boldsymbol{m}$, collect the resulting closed-loop laws into a new flow, and demand that the new flow be $\boldsymbol{m}$ again. A flow that reproduces itself under this operation is a *fixed point*, and a fixed point is exactly what an equilibrium is. To state this precisely we must name the space the operation acts on, and check it is the kind of space a fixed-point search can live on.

Let $\mathcal{C} := C([0,T];(\mathcal{C}_2,d_\infty))$ be the space of flows of fields, continuous in t for the uniform-in-type Wasserstein metric d_∞ of section 22.1.1 (definition 21.10); we also write $L^\infty_{\mathcal{W}_2}([0,1];\mathcal{P}_2(\mathbb{R}^d))$ for the one-instant field space $(\mathcal{C}_2,d_\infty)$. That $\mathcal{C}$ is a *complete* metric space — the one property a fixed-point search cannot do without, since completeness is what gives a Cauchy sequence of near-equilibria a limit to converge to — assembles from three imports, and it is worth chaining them in a single readable line rather than leaving them stacked as citations. Start at the bottom rung, one type at one instant: the value space $(\mathcal{P}_2(\mathbb{R}^d),\mathcal{W}_2)$ is complete, indeed Polish, by the completeness of the quadratic Wasserstein distance (theorem 4.8). Climb to fields at one instant: $(\mathcal{C}_2,d_\infty)$ is the type-continuous fields under the sup-in-type metric, and a uniform limit of continuous maps into a complete space is again a continuous map into that space, so $(\mathcal{C}_2,d_\infty)$ inherits completeness directly from $\mathcal{W}_2$ (definition 21.10). Climb to flows in time: for *any* complete metric space E, the path space $C([0,T];E)$ of continuous curves under the uniform-in-time metric is complete, by the identical uniform-limit argument now run in the time variable. Taking $E=(\mathcal{C}_2,d_\infty)$ chains the three rungs and delivers completeness of $\mathcal{C}$. This is the graphon analogue of the homogeneous flow space $C([0,T];\mathcal{P}_2(\mathbb{R}^d))$ of chapter 10 (definition 10.1); the single change is that the fibre over one instant has grown from the measure space $\mathcal{P}_2(\mathbb{R}^d)$ to the field space $(\mathcal{C}_2,d_\infty)$, with completeness surviving the growth intact.

Definition 22.5 (Graphon best-response map)**.** The *graphon best-response map* $\mathsf{S}\colon \mathcal{C} \to \mathcal{C}$ sends a flow of fields $\boldsymbol{m}$ to $\mathsf{S}[\boldsymbol{m}] = \widetilde{\boldsymbol{m}}$ defined typewise by: (i) for each x, solve the backward HJB eq. (22.6a) with environment $(\mathbb{W}\boldsymbol{m}_t)(x)$ to get u^x; (ii) form the optimal control eq. (22.9) and the induced closed-loop drift $b^{x,*}$ of eq. (22.8); (iii) solve the forward FP equation eq. (22.6b) transported by that drift, from the datum m_0^x, to get $\widetilde{m^x}$.

Proposition 22.6 (Equivalence with the fixed point)**.** *Under **(A-Lip)**, **(A-Growth)**, **(A-Nondeg)**, **(A-Conv)**, **(A-Reg-W)**, a flow of fields $\boldsymbol{m} \in \mathcal{C}$ is a fixed point of S if and only if, with $u^x = u^{x,[\boldsymbol{m}]}$, the pair $(\boldsymbol{u}, \boldsymbol{m})$ solves the graphon MFG system eq. (22.6)–eq. (22.7).*

Proof. The argument is proposition 8.4 applied typewise, and the typewise reduction is what makes it short. Fix x. By construction (definition 22.5), step (i) produces u^x as the solution of the backward HJB eq. (22.6a) with environment $(\mathbb{W}\boldsymbol{m}_t)(x)$, so this half of the system holds for $\mathsf{S}[\boldsymbol{m}]$ whether or not $\boldsymbol{m}$ is a fixed point — the backward equation is reproduced automatically. The content is therefore in the forward half. Step (iii) solves, for each x, the *linear* parabolic Cauchy problem eq. (22.6b) — linear because, under the model class of remark 22.1, the transport drift $b^{x,*}$ is built from u^x alone and does not see the density — with Lipschitz coefficients and a uniformly elliptic second-order part under **(A-Nondeg)** (chapter 5). Such a problem has a *unique* solution from the datum m_0^x. Uniqueness is the hinge of the equivalence: it means the produced field $\widetilde{m^x}$ is the one and only solution of eq. (22.6b) with the feedback built from u^x, so the typewise identity $\widetilde{m^x} = m^x$ holds if and only if the frozen field m^x *is* that solution — i.e. if and only if m^x solves the forward equation with its own induced drift. Demanding the identity at every x is thus demanding exactly eq. (22.6b) for the whole field, which together with the HJB from step (i) is the full system eq. (22.6)–eq. (22.7); the converse reads the same chain backward. One obligation is incurred along the way and discharged elsewhere: for $\mathsf{S}[\boldsymbol{m}]$ to be an element of $\mathcal{C}$ at all — a genuine field, depending measurably (indeed continuously) on x — the per-type solves of steps (i)–(iii) must assemble into a measurable family over $[0, 1]$. That the assembled field $x \mapsto (u^x, \widetilde{m^x})$ is measurable in x is precisely proposition 22.9 below, proved by the stability estimates of section 22.3; we invoke it here and prove it there. □

A fixed point of S in this sense is precisely an equilibrium of the dynamic graphon mean field game in the sense of definition 21.16; the two are the same object, here cast as a self-map. This is the formulation chapter 24 consumes, and the reduction it accomplishes is worth stating bluntly: the analytic problem has gone from "solve a continuum-indexed forward–backward PDE system" to "find a fixed point of a single self-map S on the complete metric space $\mathcal{C}$ of flows of fields." The forward–backward PDEs have not vanished — they live inside one *evaluation* of S — but the coupling has been packaged into the act of evaluating the map, which is where the entire difficulty now sits.

It is worth being exact about what that difficulty is, because it is the seam to chapter 24. Relative to the homogeneous reformulation proposition 8.4, nothing in the forward–backward structure is new: that structure is inherited type by type, two arrows per type, both of them Chapter 8's. What is new is that S *does not factor over types.* One could imagine, in the most favourable world, that evaluating S at type x required only the type-x slice m^x of the input — that the self-map were a product $\prod_x \mathsf{S}^x$ of independent per-type maps, each acting on its own fibre. Were that so, the continuum would be mere bookkeeping and each type a separate Chapter 8 problem solved in parallel, with no genuine interaction. It is *not* so, and the obstruction is the one new wire. Step (i) of definition 22.5 solves the type-x HJB against the environment $(\mathbb{W}\boldsymbol{m}_t)(x)$, and by eq. (22.2) that aggregate is an integral over *all* types y of m_t^y, weighted by $W(x, y)$. A single evaluation of S at one type already reads the entire field over $[0, 1]$. The types are welded together at the level of one application of the map, not merely at the fixed point.

This is exactly why the spectral data of $\mathbb{W}$ — and nothing finer about the kernel — governs the behaviour of S. The cross-type entanglement enters only through the linear map $\boldsymbol{m} \mapsto \mathbb{W}\boldsymbol{m}$, so the sensitivity of S to a perturbation of its input field is controlled by how much $\mathbb{W}$ can amplify that perturbation, and that amplification is measured by the spectrum and by nothing else. The operator norm $\|\mathbb{W}\|$ bounds the worst-case gain over all directions in type-space and therefore sets the budget for a *contraction* estimate: the per-type best response contracts the environment by a factor read off the Lipschitz data, the cross-type amplification $\|\mathbb{W}\|$ multiplies it, and whether S contracts at all turns on the product falling below one. The leading eigenvalue, and the eigenfunction along which it is attained, identify the single direction in type-space that is amplified most — the soft mode along which a near-equilibrium is least stable, and the first place a unique equilibrium can be lost. These are the two numbers the later sections read off: section 22.4 collapses the whole coupling to the finitely many eigenvalues that survive when $\mathbb{W}$ has finite rank, and section 22.5 reads off the leading one alone as the rescaling of the effective coupling strength. They are also why chapter 24 cannot secure existence and uniqueness from monotonicity alone: the Lasry–Lions condition **(A-Mon)** disciplines the *sign* of the per-type coupling but is blind to the *size* of the cross-type amplification, so chapter 24 must pair it with the operator-norm smallness **(A-Coupling)** — $\|\mathbb{W}\|$ small enough that the contraction survives the lift. Monotonicity and operator-norm smallness are the two halves of one lock, one key per axis of the coupling, and it is the non-factoring of S that forces both.

We record this as the central seam to chapter 24 and turn now to the structure of the coupling itself. The reformulation has isolated cleanly *what* is genuinely new — the coupling of the types, carried entirely by the integral operator $\mathbb{W}$ — but it has not yet said what that coupling *means*: whether it behaves like the short-range, neighbour-to-neighbour coupling a field theorist's reflexes expect, or like something else entirely. Pinning down that meaning, and guarding against its most natural misreading, is the work of the next section.

22.2 Couplings: nonlocal kernel versus local gradient

The previous section pressed a single reading until it became a slogan: within each type the system definition 22.2 is the Chapter 8 pair drawn once, and the *only* genuinely new content is that the types are coupled to one another — coupled through one object, the integral operator $\mathbb{W}$, and through nothing else. That reading is now established. What it is not yet is *understood*. Knowing that $\mathbb{W}$ is the sole wire between types tells us where the new physics lives; it does not tell us what kind of coupling that wire carries, nor how it relates to the couplings a physicist already has reflexes for. This section is the conceptual interlude that supplies those reflexes — and, just as importantly, disables the wrong ones — before the technical machinery of the following sections puts $\mathbb{W}$ to work.

There is one obstacle to clear thinking here, and naming it organizes everything that follows: the word "local" is overloaded. In a field theory "local" means a coupling that sees only the immediate neighbourhood of a point and is built from the field and its gradients there; in the mean field game literature inherited from chapter 8 "local" means a cost that reads the population density at the agent's own state rather than a smoothed average of it. These are different statements about different variables, and in the graphon setting both variables are present at once — the agent's private state $\xi \in \mathbb{R}^d$ and its type $x \in [0,1]$ — so a single undecorated "local" is ambiguous in a way it never was when only one of the two was in play. The entire payoff of getting $\mathbb{W}$ right hinges on refusing to let these two senses blur, because the operator $\mathbb{W}$ is emphatically nonlocal in one of them and the inherited Chapter 8 dichotomy lives entirely on the other.

The section makes its argument in three moves, and they are meant to be read as one. We first *disentangle the two localities*: we separate locality-in-state, which is old and entirely a matter of section 8.5 applied per type, from locality-in-type, which is the new axis and is where $\mathbb{W}$ acts, fixing once and for all which of the two carries the graphon's novelty. With the axes split we then *test the physical analogy* the splitting invites: the resemblance of the type variable to a spatial coordinate and of $\mathbb{W}$ to a Ginzburg–Landau gradient energy is strong enough to be worth taking seriously and — on exactly one point — wrong enough that taking it uncritically would mislead, so we develop it precisely far enough to read off where it holds and mark the single place it fails. Finally, with the picture calibrated, we *specialize to the tractable class*: the couplings whose dependence on the aggregate is separable, which is the structural hypothesis that makes the rest of the chapter computable and is the form every worked structure downstream will take.

The hand-off is therefore twofold. The two-axes distinction drawn in the first subsection is the coordinate system the Ginzburg–Landau discussion lives in — that analogy is a statement about the *type* axis specifically, and it cannot be stated, let alone judged, until state-locality and type-locality have been pried apart. And the separable-coupling class isolated in the last subsection is the standing structural assumption that section 22.4 and the worked computation of section 22.5 will consume: it is here that we earn the right to write the couplings the rest of the chapter solves. We begin by splitting the two meanings of "local" across the two variables.

22.2.1 Two axes of locality

The section opener left us with a warning rather than a result: the word "local" is overloaded, and until we split it across the two variables in play we cannot even state, let alone judge, the Ginzburg–Landau analogy the next subsection tests. We make that split now. The reason the overload is harmless in the homogeneous theory and dangerous here is simply arithmetic of variables. In chapter 8 there was exactly one variable a coupling could be local or nonlocal *in* — the agent's private state $\xi \in \mathbb{R}^d$ — so "local" had a single unambiguous referent. In the graphon setting there are two variables present in every function we write, the state $\xi \in \mathbb{R}^d$ and the type $x \in [0,1]$, and "local" can mean a statement about either. A coupling can be local in the state and nonlocal in the type, or the reverse, or both, or neither; these are four genuinely different things, and collapsing them into one undecorated word is the fastest route to confusing the old physics with the new. So we treat the two axes separately, name on each axis the local and the nonlocal options, and — this is the payoff — show that the entire novelty of the graphon lives on one axis and the entire inheritance from chapter 8 on the other.

Locality in the state $\xi \in \mathbb{R}^d$ — the inherited axis. This axis is old. It is the axis of section 8.5, and once the field is frozen it is inherited by each type verbatim, with the single substitution we have been tracking all chapter: the agent's own law m of the homogeneous theory is replaced by the type-x aggregate

$$\nu^x \;:=\; (\mathbb{W}\boldsymbol{m}_t)(x),$$

the kernel-weighted neighbour distribution of eq. (22.2). Holding the type x fixed, the question "how does the cost see ν^x?" is exactly the Chapter 8 question with ν^x in the role of m, and it has the same two answers.

A coupling is *nonlocal in the state* when it reads the aggregate only through a smoothed, spatially-averaged functional of it. The canonical instance is a convolution,

$$F(x,\xi,\nu^x) \;=\; (\phi * \nu^x)(\xi) \;=\; \int_{\mathbb{R}^d} \phi(\xi-\xi')\,\nu^x(\mathrm{d}\xi'),$$

with ϕ a bounded continuous interaction kernel on $\mathbb{R}^d$ (example 8.6): the agent at state ξ feels a ϕ-weighted average of where the neighbour population sits, never the population's value at the single point ξ. The defining analytic virtue is that such an F is *weakly continuous* in ν^x — if $\nu_n^x \rightharpoonup \nu^x$ weakly then $(\phi * \nu_n^x)(\xi) = \langle \phi(\xi-\cdot), \nu_n^x\rangle \to \langle \phi(\xi-\cdot), \nu^x\rangle$ for each ξ, because $\phi(\xi-\cdot)$ is a bounded continuous test function and weak convergence is precisely convergence of such pairings. Weak continuity is exactly what a compactness argument wants: a sequence of approximate fields that converges only weakly (all one ever gets cheaply, by Prokhorov, from a second-moment bound) still produces convergent costs, so the fixed-point machinery of chapter 24 can pass to the limit with no extra regularity. Nonlocal-in-state couplings are, in this precise sense, the compactness-friendly ones.

A coupling is *local in the state* when, by contrast, it reads the pointwise density value at the agent's own location,

$$F(x,\xi,\nu^x) \;=\; f\big(\xi,\,\rho^x(\xi)\big), \qquad \rho^x \;=\; \frac{\mathrm{d}\nu^x}{\mathrm{d}\xi},$$

with ρ^x the Lebesgue density of the aggregate (example 8.7). This is a genuinely sharper demand: it asks the aggregate to *have* a density and asks that density to be evaluated at a point, an operation that is not even defined for a general measure and is badly discontinuous under weak convergence (a sequence of smooth densities can converge weakly to a Dirac, along which no pointwise value survives). What rescues it is parabolic regularization. The uniform nondegeneracy **(A-Nondeg)**, $\sigma(x)\sigma(x)^\top \succeq \lambda I$, forces the forward Fokker–Planck equation eq. (22.6b) to produce an honest density $m^x(t,\cdot)$ with quantitative bounds, and those bounds — uniform in x, since λ is — are exactly what make the pointwise evaluation $\rho^x(\xi)$ legitimate and the local coupling well-posed. So the state axis carries a clean analytic dichotomy: nonlocal couplings are weakly continuous and ask nothing of the density, local couplings demand the density bounds that **(A-Nondeg)** alone supplies. None of this is new — it is section 8.5 read with ν^x in place of m, one type at a time — and we rehearse it here only to set it firmly on *this* axis, so that nothing on it will be mistaken for the graphon's own contribution.

Locality in the type $x \in [0,1]$ — the new axis, and where $\mathbb{W}$ lives. Everything genuinely new sits on the second axis, and on it the situation is not a dichotomy at all: there is only one option, and it is forced. The map $\boldsymbol{m} \mapsto \mathbb{W}\boldsymbol{m}$ of eq. (22.2) is an *integral* operator, and an integral operator is nonlocal by construction. Writing the aggregate out,

$$(\mathbb{W}\boldsymbol{m}_t)(x) \;=\; \int_0^1 W(x,y)\, m_t^y \,\mathrm{d}y,$$

the value at type x pools the laws m_t^y of *all* types y, each weighted by $W(x,y)$. There is no neighbourhood of x to which this sum is confined; a type on the far side of $[0,1]$ contributes exactly as much as a nearby one if the kernel weights it as much. The graphon coupling is therefore *intrinsically nonlocal in type*, and not by some choice of cost we could reverse — it is nonlocal because it is an integral against a kernel, which is what a graphon *is*.

It is worth pressing on what the local-in-type alternative would even have to be, because seeing that it does not exist inside the theory is the cleanest way to internalize that the nonlocality is structural. "Local in type" would mean each agent feels only its own type's population — the aggregate at x should return m_t^x itself, untouched by any other type. For the integral eq. (22.2) to do that, the kernel would have to be a Dirac mass on the diagonal,

$$W(x,y) \;\overset{?}{=}\; \delta(x-y), \qquad \text{so that} \qquad \int_0^1 \delta(x-y)\, m_t^y \,\mathrm{d}y \;=\; m_t^x,$$

making $\mathbb{W}$ the identity operator I on the field. But the Dirac kernel is not a graphon, and the failure is not a technicality — it is disqualifying on every count that **(A-Reg-W)** demands. The diagonal δ is not a function $[0,1]^2 \to [0,1]$ at all but a distribution; it is not in $L^2[0,1]^2$, so the operator it would induce is not Hilbert–Schmidt; indeed the identity I on the infinite-dimensional space $L^2[0,1]$ is not even compact, having the entire interval as continuous spectrum and no eigenbasis to speak of. Every structural property the chapter rests on fails at once: no membership in L^2, no Hilbert–Schmidt norm, no discrete spectrum for section 22.4 to collapse to order parameters, no leading eigenvalue for section 22.5 to read off. The local-in-type coupling is thus not a special case of the theory we could specialize to; it sits entirely *outside* it. The most one can do is approach it: a sequence of genuine graphons concentrating on the diagonal — for instance the heat kernels W_ℓ of example 22.7 as the bandwidth $\ell \downarrow 0$ — approximates the identity, but each member of the sequence is honestly nonlocal, and the limit, where locality would finally appear, is exactly the point that has left the space of graphons. We will meet that sequence again as the one calibrated regime in which a gradient picture is licensed.

The punchline: type is not a spatial coordinate. Putting the two axes side by side delivers the conclusion this subsection exists to plant. On the state axis there is a real choice — nonlocal or local, compactness-friendly or density-demanding — and it is entirely the inherited chapter 8 choice. On the type axis there is no choice: the coupling is nonlocal, always, because it is an integral operator and the only "local" alternative has been ejected from the theory. The double integral $\int_0^1\int_0^1 W(x,y)\,(\cdots)\,\mathrm{d}x\,\mathrm{d}y$ that the aggregate sits inside is visually suggestive of a spatial action, two coordinates integrated against a kernel that depends on both, and it is precisely this suggestion the next subsection must defuse. The type index behaves nothing like a spatial coordinate. The decisive symptom is that $[0,1]$, as a type set, carries *no intrinsic metric*: the number $|x-y|$ is an artefact of the arbitrary labelling of types by points of the unit interval and has no game-theoretic content, since relabelling the types by any measure-preserving bijection leaves the graphon model unchanged (appendix A). What *does* have content is functional, not metric. Two types x and y are "close" — interchangeable in their strategic situation — precisely insofar as

$$W(x,\cdot)\;\approx\;W(y,\cdot)\qquad\text{as functions in } L^2[0,1],$$

that is, insofar as they connect to the rest of the population in the same pattern; it is *never* because $|x-y|$ is small. A pair of types adjacent on the interval can sit in entirely different connectivity regimes and couple to disjoint parts of the population, while a pair at opposite ends can be statistical twins. This is the seed the Ginzburg–Landau discussion harvests, and it is worth stating in exactly the form that subsection will need: the graphon couples types nonlocally, through the similarity of their kernel rows and through no underlying distance, so any reading that penalizes variation between "neighbouring" types — any gradient, any elastic stiffness — is importing a metric the model does not have. With the two axes pried apart and the nonlocal-in-type, no-intrinsic-metric verdict on record, we can finally hold the physicist's gradient intuition up to it and read off the one place it rings false.

22.2.2 The Ginzburg–Landau picture and its one false note

With the two axes of locality pried apart, the previous subsection left a verdict on record: the graphon couples types *nonlocally*, through the similarity of their kernel rows, and over a type set carrying *no intrinsic metric*, so that the apparent "distance" $|x-y|$ has no game-theoretic content. We can now do what that verdict was built for — hold the physicist's strongest reflex up against it. A condensed-matter reader meeting eq. (22.6) for the first time will reach almost involuntarily for a Ginzburg–Landau (GL) picture: a continuum of fields indexed by an internal label, tied together by a stiffness, organizing along a soft mode past a critical coupling. That reflex is largely right, and it is worth building up carefully, because the part of it that is right is the conceptual spine of the rest of Part IV — the language of order parameters and critical couplings that section 22.5 and chapter 24 speak. But it carries exactly one assumption that the no-metric verdict forbids, and that single false note is the whole reason the type/space distinction of appendix A was worth labouring. We sound the picture, then the false note, then exhibit the lone exception in which the note is in tune.

The dictionary is built one entry at a time, and each entry is forced by the structure of the system rather than imposed on it.

Physics note

The system eq. (22.6) invites a Ginzburg–Landau reading, and used with care it is illuminating. Read it first as a field theory. For each value of the internal index x there is a field — the equilibrium density m^x — and the indices are coupled to one another and to nothing else; that is exactly the shape of a GL order-parameter theory, one order-parameter field per internal "flavour." So the first entry of the dictionary is: the type x is a *flavour* index, and the per-type densities m^x are a continuum of coupled *order-parameter fields*. The second entry is the coupling. The only place one flavour's field feels another's is the aggregate $(\mathbb{W}\boldsymbol{m}_t)(x) = \int_0^1 W(x,y)\, m_t^y \,\mathrm{d}y$, weighted entirely by the kernel, so $W(x,y)$ plays the role of the *stiffness* tying flavour x to flavour y: where W is large the two fields are strongly tied and tend to co-vary, where it is small they decouple, and where it vanishes they are strategically blind to each other. The third entry is the one a physicist most wants, and the spectral picture of chapter 18 supplies it directly. Because $\mathbb{W}$ is self-adjoint and compact it has a real eigenbasis; its leading eigenfunction — the eigenvector-centrality profile of chapter 18 — is the *soft mode*, the type-profile along which the coupled system organizes most cheaply, and the corresponding leading eigenvalue λ_1 sets the *critical coupling* at which a homogeneous equilibrium can lose stability. This is not a loose slogan: it is the threshold $s\,\lambda_1 = 1$ computed in closed form in section 22.5 and the spectral smallness condition that buys uniqueness in chapter 24. So far the analogy is exact, and it is the right scaffolding to carry into both.

The one false note — and it must be sounded, because it is the whole point of the type/space distinction (appendix A) — lives in how a GL free energy encodes the coupling. There the stiffness enters through a *gradient* term, $\int |\nabla_x \varphi(x)|^2 \,\mathrm{d}x$, which couples a field value only to its *infinitesimal neighbours*: it penalizes variation over vanishing distance, and to even write it one must already possess a metric on the index set telling which configurations count as "nearby." The graphon coupling has neither the term nor the metric it presupposes. By the previous subsection two types x, y are "close" — interchangeable in their strategic situation — only insofar as $W(x,\cdot) \approx W(y,\cdot)$ as functions in $L^2[0,1]$, never because $|x-y|$ is small; under a measure-preserving relabelling of types the number $|x-y|$ changes freely while the model does not, so a gradient ∂_x has nothing invariant to measure. The aggregate is an honest double integral against W, not a differential operator: it pools *all* flavours at once, each with its own weight, with no notion of adjacency along the index. The correct reading is therefore a *nonlocal*, long-range, all-to-all-with-weights field theory — the continuum limit of an Ising model on a *weighted complete graph*, where every site interacts with every other through its own bond strength, rather than a continuum φ^4 theory, where each point interacts only with its gradient neighbours. The two have qualitatively different physics: the complete-graph model has mean-field exponents and a coupling controlled by a spectral quantity (the leading eigenvalue), the φ^4 model has wavevector- dependent fluctuations organized by a Laplacian. Importing the gradient/elastic intuition unexamined is the single most common error a field theorist makes on first contact with graphons.

The math of this chapter does not lean on the box: delete it and the system eq. (22.6), the operator $\mathbb{W}$, and its spectrum stand untouched. What the box buys is a reading, and it is worth pinning down precisely where the gradient reading stops being merely wrong and becomes, in a measured limit, correct — because that one exception is the bridge between the two pictures and it recurs in applications. It is a genuine mathematical statement, so we record it outside the box, where the calibration can carry weight.

Example 22.7 (Heat-kernel graphons: when nonlocal looks local)**.** The gradient picture becomes legitimate in exactly one circumstance: when the type set is handed a genuine geometry and the kernel is built to be sharply peaked on the diagonal of that geometry. Suppose then that $[0,1]$ is identified with a circle or an interval — so that $|x-y|$ now *is* a real distance, supplied from outside the bare graphon framework — and take for the kernel either the Gaussian heat kernel at length scale ℓ, $W_\ell(x,y) = c_\ell \exp\big(-|x-y|^2/2\ell^2\big)$, or, cleaner to expand, the resolvent of the Laplacian, $\mathbb{W}_\ell = (I - \ell^2\,\partial_{xx})^{-1}$. The point of the resolvent form is that the expansion can be read off algebraically. Since $\mathbb{W}_\ell$ inverts $I - \ell^2\partial_{xx}$, its Neumann series in the small parameter ℓ^2 is

$$\mathbb{W}_\ell = \big(I - \ell^2\partial_{xx}\big)^{-1} = I + \ell^2\partial_{xx} + \ell^4\partial_{xx}^2 + \cdots,$$

convergent acting on fields whose type-derivatives are controlled, i.e. fields varying slowly on the scale ℓ. Applied to the aggregate eq. (22.2) this gives, keeping the first correction,

$$(\mathbb{W}_\ell \boldsymbol{m})(x) \;=\; \boldsymbol{m}(x) + \ell^2\,\partial_{xx}\boldsymbol{m}(x) + O(\ell^4). \tag{22.10}$$

The Gaussian kernel gives the same leading correction: Taylor-expanding the field under the integral, $\int W_\ell(x,y)\boldsymbol{m}(y)\,\mathrm{d}y = \boldsymbol{m}(x) + \frac{1}{2}(\text{variance})\,\partial_{xx}\boldsymbol{m}(x) + \cdots$, since the odd moments of the symmetric kernel vanish and the second moment is $O(\ell^2)$ (the constant absorbed into the definition of ℓ). Either way the nonlocal kernel average *reduces* to the identity plus a local *diffusion-in-type*, i.e. a gradient coupling, in the limit $\ell \to 0$. The $\ell^2\partial_{xx}$ term is precisely the GL stiffness, now earned rather than assumed.

It is worth saying exactly why this is the *only* regime in which the gradient term is legitimate, because the two ingredients that make eq. (22.10) work are both indispensable and both generically absent. First, the kernel must carry a *hidden metric*: W_ℓ is a function of the true distance $|x-y|$ on the circle, so the relabelling-invariance that stripped meaning from $|x-y|$ in a bare graphon is broken on purpose — the geometry is extra data, not intrinsic to the type set. Second, the kernel must be *sharply peaked on the diagonal* in that metric: only because the weight collapses onto $y \approx x$ as $\ell \to 0$ does the pooling over all flavours degenerate into sampling the field and its curvature at the single point x, which is what turns an integral operator into a differential one. Remove either ingredient and the expansion has nothing to stand on. Generic graphons remove both, and not marginally. A block kernel is constant on each block, so it couples a type equally to an entire block regardless of any "distance" and is not peaked anywhere; a rank-one kernel $W(x,y) = f(x)f(y)$ couples every pair through the single product $f(x)f(y)$ — maximally all-to-all, its operator a rank-one projection that is as far from the identity-plus-small-correction of eq. (22.10) as an operator can be; a dense Erdős–Rényi kernel $W \equiv p$ couples everything to everything with equal weight. None has a diagonal peak, none is close to the identity, and for none does any $\ell^2\partial_{xx}$ correction exist to be written. For these — which is to say, for the kernels this book actually studies — the gradient picture is simply wrong, and the honest reading is the nonlocal spectral one. We use this example only as a calibration: it marks the measure-zero exception so that its absence elsewhere is a considered fact rather than an oversight, and the dynamic GMFG theory of Part IV never assumes it.

The calibration is the message to carry forward: the gradient/elastic reading is a special exception purchased by extra geometry, not the rule, and the rule is coupling through $\mathbb{W}$ alone — nonlocal, spectral, all-to-all-with-weights. With the conceptual ground cleared of the one seductive misreading, the question becomes operational rather than interpretive: granted that the coupling lives entirely in the linear operator $\mathbb{W}$, which structural form of that coupling makes the system actually solvable? The next subsection answers by specializing to the separable class, the state-and-type structure on which every tractable case below — the finite-rank collapse of section 22.4 and the rank-one thread of section 22.5 — will rest.

22.2.3 Separable couplings across the kernel

The Ginzburg–Landau discussion cleared the conceptual ground: the coupling lives entirely in the linear operator $\mathbb{W}$, it is nonlocal and spectral, and the gradient reading that would localize it across types is a measure-zero exception we have learned to recognize and set aside. That settles *how* to read the coupling. The question this subsection answers is the operational one the previous closing posed — granted that the only wire between types is $\mathbb{W}$, which structural form of the per-type Hamiltonian makes the resulting system actually *solvable*? Every tractable case below, the finite-rank collapse of section 22.4 and the rank-one thread of section 22.5, rests on a single specialization of the cost, and it is the working assumption for the remainder of the chapter. We adopt couplings that are *separable in the control*, the graphon version of definition 8.5:

$$H(x,\xi,p,\nu) \;=\; H_0(x,\xi,p) \;-\; F(x,\xi,\nu), \tag{22.11}$$

in which the Hamiltonian splits into two pieces that do not share an argument. The first, $H_0(x,\xi,p)$, carries *all* the costate dependence and no population dependence; it is the pure control part, the Hamiltonian the agent would face in an empty world with no neighbours. The second, $F(x,\xi,\nu)$, carries *all* the population dependence and no costate dependence; it is the cost-coupling term, the running penalty the aggregate ν imposes on an agent sitting at state ξ. At the level of the running cost this is the requirement that L split as $L(x,\xi,a,\nu) = L_0(x,\xi,a) + F(x,\xi,\nu)$ — the control cost and the interaction cost are additive and do not multiply each other — which is exactly definition 8.5 read with the type carried as a spectator parameter.

The decisive simplification is the same one that organized the homogeneous theory, and it is worth tracing through the optimization to see precisely why the split buys what it buys. The optimal control is the Hamiltonian maximizer of eq. (22.9),

$$\alpha^{x,*} = \arg\max_{a\in A}\Big\{-b(x,\xi,a)\cdot\nabla u^x - L(x,\xi,a,\nu^x)\Big\} = \arg\max_{a\in A}\Big\{-b(x,\xi,a)\cdot\nabla u^x - L_0(x,\xi,a)\Big\},$$

where the second equality is the entire point: under the additive split the population term $F(x,\xi,\nu^x)$ is a constant as far as the maximization over a is concerned — it does not contain a — so it drops out of the argmax untouched. The maximizer therefore depends on the value gradient ∇u^x and the type x, but *not* on the aggregate $\nu^x = (\mathbb{W}\boldsymbol{m}_t)(x)$. The same is true of the induced closed-loop drift, which by the envelope identity of eq. (22.8) is

$$b^{x,*} = -\partial_p H(x,\xi,\nabla u^x,\nu^x) = -\partial_p H_0(x,\xi,\nabla u^x),$$

the population term contributing nothing because $\partial_p F = 0$. So the velocity that transports the type-x density in the forward Fokker–Planck equation is built from the value alone and never sees the neighbour distribution directly.

Two consequences follow, and together they are what make the separable case tractable. First, the population is expelled from the entire *dynamic* half of each per-type problem. Substituting eq. (22.11) into the backward HJB eq. (22.6a), the aggregate appears in one place only — as an additive, type-indexed *source term*

$$-\partial_t u^x - \tfrac{1}{2}\operatorname{tr}\big(\sigma(x)\sigma(x)^\top \mathrm{D}^2 u^x\big) + H_0(x,\xi,\nabla u^x) \;=\; F\big(x,\xi,(\mathbb{W}\boldsymbol{m}_t)(x)\big),$$

together with the terminal datum $u^x(T,\xi) = g(\xi,(\mathbb{W}\boldsymbol{m}_T)(x))$. The population is now a prescribed forcing of an otherwise population-free backward equation; it heats the value field through a source and pins its terminal value, and it does nothing else. This is the Hamiltonian-level sharpening of restriction (i) of remark 22.1: there we observed that with an aggregate-free drift the forward FP equation is linear in m^x; here the separability makes the same statement at the level of the Hamiltonian, exhibiting the closed-loop drift $-\partial_p H_0$ as manifestly free of ν, so the only nonlinearity left anywhere in the coupled system is the benign one routed through the scalar source F. Second, and as a corollary, the cross-type coupling is concentrated entirely in the single linear object $\mathbb{W}$. The source $F(x,\xi,(\mathbb{W}\boldsymbol{m}_t)(x))$ is the lone point at which type x's equation references any other type, and it references them only through the kernel average $(\mathbb{W}\boldsymbol{m}_t)(x)$. Strip F of its measure argument and the continuum of HJB–FP pairs falls apart into independent, population-blind control problems; restore it and the one wire reconnecting them is $\mathbb{W}$ and nothing else. This is precisely the structure the special cases of sections 22.4 and 22.5 exploit, and the separability assumption is in force throughout both.

It is worth being exact about what separability does and does not constrain, because the compressed phrase is that the graphon coupling here is *nonlocal in type but may be of any state-locality* — and that sentence is a statement about the two independent axes pried apart in section 22.2.1. Separability is a condition on the *control* axis: it forbids the population from entering through the costate, forcing F to be free of p and hence the optimal feedback to be aggregate-independent. It says *nothing* about how F depends on the state ξ, which is the orthogonal, inherited axis. The coupling remains, as every graphon coupling must, nonlocal in the type variable x — the aggregate $(\mathbb{W}\boldsymbol{m}_t)(x)$ is an integral pooling all types, with no notion of adjacency along $[0,1]$ to make it local, exactly as section 22.2.1 forced. But on the state axis F is left entirely free: it may be nonlocal in ξ, reading the neighbour measure through a smoothed functional such as a convolution $F(x,\xi,\nu) = (\phi * \nu)(\xi)$, or local in ξ, reading the pointwise density $F(x,\xi,\nu) = f(\xi,\rho^x(\xi))$ at the agent's own location — the clean dichotomy of section 22.2.1, with all its analytic consequences (weak continuity for the nonlocal choice, the density bounds of **(A-Nondeg)** for the local one) carried over verbatim. Separability constrains only the control-coupling and leaves the state-locality choice open; the two axes do not interfere.

The form the order-parameter reductions and Thread B actually use specializes F once more, now narrowing how it reads the *measure* argument rather than touching the state axis at all: the agent reacts to the aggregate not through its full shape but through a single scalar statistic of it. We write

$$F(x,\xi,\nu) \;=\; \Psi\big(\xi,\langle\psi,\nu\rangle\big), \qquad \langle\psi,\nu\rangle = \int_{\mathbb{R}^d} \psi \,\mathrm{d}\nu, \tag{22.12}$$

for a fixed test function $\psi\colon \mathbb{R}^d \to \mathbb{R}$ (or a finite vector of them) and an outer profile Ψ. The point is that the only thing the type-x agent needs to know about its entire graphon-averaged neighbourhood is the one number (or finite vector)

$$\langle \psi, (\mathbb{W}\boldsymbol{m}_t)(x)\rangle = \int_0^1 W(x,y)\,\langle \psi, m_t^y\rangle \,\mathrm{d}y, \tag{22.13}$$

where the equality is just the weak reading eq. (22.3) of the aggregate applied to the bounded continuous test function ψ: pairing ψ against the measure-valued integral commutes with the scalar type-integral, turning a measure-valued object into an ordinary Lebesgue integral of the scalar field $y \mapsto \langle \psi, m_t^y\rangle$ against the kernel row $W(x,\cdot)$. The agent thus reacts to a kernel-weighted average, over all types, of the per-type statistic $\langle \psi, m_t^y\rangle$ — a single real number that compresses the whole field into the one datum the cost can feel. This is the lever the next reductions pull: project that scalar field onto the eigenfunctions of $\mathbb{W}$ and eq. (22.13) collapses to finitely many numbers, the order parameters.

Thread B is the cleanest instance, and naming it here lets the reader anticipate the worked computation. Take $\psi(\xi) = \xi$, so the statistic $\langle \psi, m_t^y\rangle = \int_{\mathbb{R}^d} \xi\, m_t^y(\mathrm{d}\xi) = \bar{m}_t^y$ is simply the *mean* of the type-y population, and the felt statistic eq. (22.13) is the graphon-aggregated neighbour mean $z_t(x) = (\mathbb{W}\bar{m}_t)(x)$ of the thread specification. Take the outer profile quadratic, $\Psi(\xi, z) = \frac{q}{2}(\xi - sz)^2$, with imitation strength $q > 0$ and coupling s: the agent pays for deviating from s times the average position of its weighted neighbours, the congestion/imitation penalty that defines Thread B. Everything downstream of eq. (22.12) — the value's quadratic form, the Riccati curvature, the single scalar order parameter — is the explicit unwinding of this one choice, carried out in full in section 22.5.

The separable single-statistic structure eq. (22.11)–eq. (22.12) is exactly what the special-structures section consumes: there the scalar field eq. (22.13), projected onto the eigenfunctions of $\mathbb{W}$, becomes the finitely many order parameters that close the system, and the rank-one corner of that projection is the worked computation of section 22.5. But both reductions presume something we have so far only used informally — that the assembled field $x \mapsto (u^x, m^x)$, and with it the scalar statistic $x \mapsto \langle \psi, (\mathbb{W}\boldsymbol{m}_t)(x)\rangle$, depends on the type *measurably*, and continuously when the kernel does, so that the type-integral eq. (22.13) is legitimate and the order parameters are well-defined numbers rather than integrals of a non-measurable integrand. This is the deferred obligation the best-response construction logged and the standing-data promise that the aggregate varies measurably in x. The next section discharges both, by a stability argument, before we put the separable structure to work.

22.3 Regularity and measurability in the type variable

The previous subsection ended on a debt, and so did the one before the couplings detour: both the separable-coupling reduction of section 22.2.3 and the best-response construction of section 22.1.3 leaned on a fact they were not entitled to assume. When proposition 22.6 packaged the per-type solves into the self-map $\mathsf{S}\colon \mathcal{C} \to \mathcal{C}$, it incurred one obligation it explicitly deferred: for $\mathsf{S}[\boldsymbol{m}]$ to be an element of $\mathcal{C}$ at all — a genuine *field*, not merely a type-by-type collection of unrelated solutions — the assembled map $x \mapsto (u^x, \widetilde{m^x})$ must depend measurably on the type, so that its own aggregate eq. (22.2) exists and the loop closes inside $\mathcal{C}$. And the standing-data discussion of section 22.1.1

promised, but postponed, that the aggregate $(\mathbb{W}\boldsymbol{m}_t)(x)$ itself varies measurably in x — continuously when the kernel does — the very property that made the scalar statistic $x \mapsto \langle \psi, (\mathbb{W}\boldsymbol{m}_t)(x)\rangle$ of section 22.2.3 a legitimate integrand and the order parameters well-defined numbers. This section pays both debts. They are the same debt seen from two ends, and a single stability argument settles them.

It is worth saying in words, before any lemma, exactly why no new analysis is required — why "regularity in the type variable" is not a fresh PDE problem but a corollary of machinery we already own. Look once more at the per-type system eq. (22.6). The type x enters it through precisely two channels and no others. It enters the *coefficients* — the drift $b(x,\cdot,\cdot)$, the volatility $\sigma(x)$, the running and terminal costs $L(x,\cdot,\cdot,\cdot), g$ — which by the type-Lipschitz clause of **(A-Lip)** move only a little when x moves a little. And it enters the *environment* $\nu^x = (\mathbb{W}\boldsymbol{m}_t)(x)$, the single channel through which type x feels the rest of the population, which — this is what the lemma below establishes — also moves only a little when x moves a little, because it is the type-integral of a frozen field against a kernel row that varies controllably in x. Both inputs to the type-x problem are therefore continuous (and always measurable) functions of x. The output — the value u^x and the closed-loop density $\widetilde{m^x}$ — depends on those two inputs *stably*: that is the entire content of the HJB- and FP-stability lemmas lemmas 10.10 and 10.11 of chapter 10, which bound how far the value and the density can move per unit change in the coefficients and the environment. Compose "inputs vary controllably in x" with "output varies stably in inputs" and regularity in type drops out, with the type playing the role of an external parameter and nothing about the PDEs themselves re-examined. No elliptic theory in x, no new estimate: a stability corollary, full stop. The work of this section is just to make each of these two clauses precise and chain them.

The input side has a coarse version already on record. lemma 21.11 showed that the aggregate map $\boldsymbol{m} \mapsto \mathbb{W}\boldsymbol{m}$ is Lipschitz in the *whole field*, which is the estimate chapter 24 will contract against. What the per-type stability estimates consume is finer and orthogonal: not how the aggregate responds to a perturbation of the entire field at fixed type, but how it responds to a change of *type* at fixed field — the *pointwise-in-type* regularity of $x \mapsto (\mathbb{W}\boldsymbol{m})(x)$. That refinement is lemma 22.8, to which we turn first; it is the object that converts the type-Lipschitz data clause into a genuine continuity statement for the environment, and with it in hand the proposition that follows is a short composition.

Lemma 22.8 (Continuity of the aggregate in the type)**.** *Let $\boldsymbol{m} = (m^x)_{x\in[0,1]}$ be a field of measures with $\sup_x \mathcal{W}_2(m^x, \delta_0) \le R < \infty$.*

1. *If W is measurable and bounded (the bare **(A-Reg-W)**), then $x \mapsto (\mathbb{W}\boldsymbol{m})(x)$ is measurable as a map $[0,1] \to \mathcal{M}_+(\mathbb{R}^d)$ (weak topology), with mass ≤ 1 and second moment $\le R^2$ uniformly.*
2. *If moreover W is continuous in type in the sense $\int_0^1 |W(x,y) - W(x',y)|\,\mathrm{d}y \to 0$ as $x' \to x$ (e.g. W jointly continuous, the continuity clause of **(A-Reg-W)**), and $x \mapsto m^x$ is $\mathcal{W}_2$-continuous, then $x \mapsto (\mathbb{W}\boldsymbol{m})(x)$ is continuous for the total-variation norm. If in addition the second moments are* uniformly integrable *— guaranteed, e.g., by a uniform $(2+\delta)$-moment bound $\sup_x \int |\xi|^{2+\delta}\, m^x(\mathrm{d}\xi) \le R_\delta < \infty$ for some $\delta > 0$ — the convergence upgrades to $\mathcal{W}_2$.*

Proof. The uniform mass and moment bounds come first, because they are what keep the aggregate inside $\mathcal{M}_+(\mathbb{R}^d)$ at every type and what later license the upgrade to $\mathcal{W}_2$. Since $0 \le W \le 1$, the total mass of $(\mathbb{W}\boldsymbol{m})(x)$ is the degree $\int_0^1 W(x,y)\,\mathrm{d}y \le 1$, and its second moment is $\int_0^1 W(x,y) \int |\xi|^2\, m^y(\mathrm{d}\xi)\,\mathrm{d}y \le \int_0^1 \int |\xi|^2\, m^y(\mathrm{d}\xi)\,\mathrm{d}y \le R^2$, both uniformly in x — the kernel can only damp the per-type mass and moment, never amplify them, so the bounds on the fibres pass straight to the aggregate.

Part (1): measurability. We must show $x \mapsto (\mathbb{W}\boldsymbol{m})(x)$ is Borel when $[0,1] \to \mathcal{M}_+(\mathbb{R}^d)$ carries the weak topology. By definition of that topology, a map into $\mathcal{M}_+(\mathbb{R}^d)$ is Borel measurable as soon as each of its scalar pairings $x \mapsto \langle \varphi, (\mathbb{W}\boldsymbol{m})(x)\rangle$ is measurable for φ ranging over a *countable* convergence-determining family $\{\varphi_j\}$ of bounded continuous functions — such a family exists on the Polish space $\mathbb{R}^d$ (chapter 3), and weak convergence is exactly convergence of all the pairings $\langle \varphi_j, \cdot\rangle$, so the Borel σ-algebra of the weak topology is generated by these countably many coordinate maps. Fix one such φ. By the weak prescription eq. (22.3),

$$\langle \varphi, (\mathbb{W}\boldsymbol{m})(x)\rangle = \int_0^1 W(x,y)\,\langle \varphi, m^y\rangle\,\mathrm{d}y,$$

and the integrand $(x,y) \mapsto W(x,y)\,\langle \varphi, m^y\rangle$ is a bounded, jointly measurable function on $[0,1]^2$: W is measurable by the bare **(A-Reg-W)** and bounded by 1, while $y \mapsto \langle \varphi, m^y\rangle = \int_{\mathbb{R}^d} \varphi\,\mathrm{d}m^y$ is bounded by $\|\varphi\|_\infty$ and measurable in y because $\boldsymbol{m}$ is a measurable field. Fubini–Tonelli for bounded measurable integrands then makes the partial integral $x \mapsto \int_0^1 W(x,y)\langle \varphi, m^y\rangle\,\mathrm{d}y$ a measurable function of x. Running this over the countable family $\{\varphi_j\}$ exhibits all the generating coordinate maps as measurable, so $x \mapsto (\mathbb{W}\boldsymbol{m})(x)$ is Borel into the weak topology. Note that nothing here needs the kernel to be continuous; bare measurability of W suffices, which is why measurability is the property that holds *always*.

Part (2): continuity. Now add the type-continuity clause. Take any bounded 1-Lipschitz φ and subtract the pairings at two types:

$$\left|\langle \varphi, (\mathbb{W}\boldsymbol{m})(x)\rangle - \langle \varphi, (\mathbb{W}\boldsymbol{m})(x')\rangle\right| \le \int_0^1 \left|W(x,y) - W(x',y)\right| \left|\langle \varphi, m^y\rangle\right|\,\mathrm{d}y \le \|\varphi\|_\infty \int_0^1 \left|W(x,y) - W(x',y)\right|\mathrm{d}y.$$

The only field-dependent quantity, $|\langle \varphi, m^y\rangle|$, was bounded by $\|\varphi\|_\infty$ and pulled out, so what remains is the row-difference $\int_0^1 |W(x,y) - W(x',y)|\,\mathrm{d}y$, which the hypothesis sends to 0 as $x' \to x$ — and it does so *uniformly* over the unit ball $\|\varphi\|_\infty \le 1$. The supremum over that ball of the left side is, by definition, the total-variation distance, so this is convergence in total variation: $\mathrm{TV}\big((\mathbb{W}\boldsymbol{m})(x), (\mathbb{W}\boldsymbol{m})(x')\big) \to 0$. Total-variation convergence is strictly stronger than weak convergence $(\mathbb{W}\boldsymbol{m})(x') \Rightarrow (\mathbb{W}\boldsymbol{m})(x)$, so we have that for free. (Notice the field's own $\mathcal{W}_2$-continuity in x was not even used for this half; the kernel's row-continuity alone drives the TV estimate, because the test function was bounded and the field entered only through that bound. The field-continuity hypothesis is there to make the moments behave, which is the next and final point.)

The $\mathcal{W}_2$-upgrade and why it is delicate. Total variation is not yet what the working metric demands. Weak — equivalently TV — convergence on $\mathcal{P}_2(\mathbb{R}^d)$ does *not* imply $\mathcal{W}_2$ convergence; by theorem 4.8, $\mathcal{W}_2$ metrizes weak convergence *together with* convergence of second moments, and the second clause can fail even when the first holds. The failure mode is precise and worth seeing once, because it is exactly the gap the higher-moment hypothesis closes. Consider $\mu_n = (1 - \frac{1}{n})\delta_0 + \frac{1}{n}\delta_{\sqrt{n}}$. Its total-variation distance to δ_0 is the mass it places off the origin, $\frac{1}{n} \to 0$, so $\mu_n \to \delta_0$ in TV and weakly. Yet its second moment is $\frac{1}{n} \cdot (\sqrt{n})^2 = 1$ for every n, while δ_0 has second moment 0; and since $\mathcal{W}_2(\mu_n, \delta_0)^2$ equals the second moment of μ_n (all mass of δ_0 sits at the origin, so the optimal transport cost is just $\int |\xi|^2 \mu_n$), we get $\mathcal{W}_2(\mu_n, \delta_0)^2 \equiv 1$. The limit in $\mathcal{W}_2$, if it existed, would have to be δ_0; the $\mathcal{W}_2$ distance to δ_0 never shrinks. The mechanism is a vanishing sliver of mass — weight $\frac{1}{n}$ — escaping to a position $\sqrt{n}$ far enough that, weighted by $|\xi|^2$, it carries a *fixed* unit of second moment. TV and weak convergence see only *where* the mass is and count this sliver as negligible; $\mathcal{W}_2$ also charges for *how far* stray mass travels, weighted by the square of the distance, and the sliver pays full freight. A bare uniform second-moment bound is powerless against this: μ_n has second moment $\equiv 1$, perfectly bounded, and still escapes. What is needed is to forbid any vanishing fraction of mass from hoarding non-vanishing second moment — i.e. *uniform integrability* of $|\xi|^2$ across the family.

The uniform $(2+\delta)$-moment bound supplies exactly that, and the rest is mechanical. By the de la Vallée-Poussin criterion, a uniform bound $\sup_x \int |\xi|^{2+\delta}\, m^x(\mathrm{d}\xi) \le R_\delta$ for some $\delta > 0$ forces $\{|\xi|^2\}$ to be uniformly integrable under the family: the extra δ powers of $|\xi|$ make distant mass too expensive to carry, ruling out the escaping sliver (indeed, the offending μ_n has $(2+\delta)$-moment $\frac{1}{n}(\sqrt{n})^{2+\delta} = n^{\delta/2} \to \infty$, so it is precisely what the hypothesis excludes). The aggregate inherits the bound: since $0 \le W \le 1$,

$$\int |\xi|^{2+\delta}\, \mathrm{d}(\mathbb{W}\boldsymbol{m})(x) = \int_0^1 W(x,y) \int |\xi|^{2+\delta}\, m^y(\mathrm{d}\xi)\, \mathrm{d}y \le R_\delta,$$

so $\{(\mathbb{W}\boldsymbol{m})(x)\}_x$ is itself uniformly $(2+\delta)$-integrable and hence $|\xi|^2$ is uniformly integrable across it. With weak convergence (from the TV estimate) and uniform integrability of $|\xi|^2$ in hand, the second moments converge along $x' \to x$, and theorem 4.8 upgrades the convergence to $\mathcal{W}_2$. Strip the extra moment away and the upgrade genuinely fails at $p = 2$: the conclusion then holds only for weak convergence, equivalently for W_p with $p < 2$, exactly because those metrics do not charge for the escaping second moment. □

The lemma is the input half of the stability argument made precise: it says the environment $x \mapsto \nu_t^x = (\mathbb{W}\boldsymbol{m}_t)(x)$ is always a measurable function of the type and, when the kernel is row-continuous and the moments are kept under control, a $\mathcal{W}_2$-continuous one. Combined with the type-Lipschitz clause of **(A-Lip)**, which handles the *coefficient* half, we now have both inputs to the per-type problem varying controllably in x. The proposition simply pushes them through the solution operators.

Proposition 22.9 (Regularity of the solution field)**.** *Assume **(A-Lip)** (including Lipschitz dependence of the data on the type), **(A-Growth)**, **(A-Nondeg)**, **(A-Conv)**, **(A-Reg-W)**, and let $\boldsymbol{m} \in \mathcal{C}$ be a flow of fields. Let $(u^x, \widetilde{m^x}) = \mathsf{S}[\boldsymbol{m}]^x$ be the typewise best response of definition 22.5. Then:*

1. (Measurability.) *Under the bare **(A-Reg-W)**, the maps $x \mapsto u^x$ (into $C^{1,2}_{\mathrm{loc}}$) and $x \mapsto \widetilde{m^x}$ (into $C([0,T]; \mathcal{P}_2(\mathbb{R}^d))$) are Borel measurable; in particular $\mathsf{S}[\boldsymbol{m}] \in \mathcal{C}$ and the system eq. (22.6) is a well-posed object.*

2. (Continuity.) *If in addition W is continuous in type (lemma 22.8(2)) and the data b, σ, L, g are continuous in x, then $x \mapsto u^x$ and $x \mapsto \widetilde{m^x}$ are continuous, with a modulus controlled by the type-moduli of W and of the data.*

Proof sketch. We prove the continuity half (2) first, since it does the analytic work and the measurability half (1) then follows by reading the same maps with weaker hypotheses on the kernel.

Continuity. Fix two types x, x' and compare their problems input by input. The backward HJB eq. (22.6a) for u^x and for $u^{x'}$ are the *same* equation evaluated at two parameter values, and they differ in only two places. First, the coefficients $b(x,\cdot), \sigma(x), L(x,\cdot)$ and terminal datum: these are Lipschitz-close in x by the type-Lipschitz clause of **(A-Lip)**, so $\|\mathrm{data}(x) - \mathrm{data}(x')\| \to 0$ as $x' \to x$. Second, the environments $\nu^x_\cdot, \nu^{x'}_\cdot$ that sit inside the Hamiltonian and the terminal cost: these are $\mathcal{W}_2$-close, uniformly in t, by lemma 22.8(2). The $\mathcal{W}_2$ — rather than merely weak — closeness is what the HJB-stability estimate ingests, and it is exactly the clause of the lemma that demanded a uniform $(2+\delta)$-moment, so we must check that clause is actually met on the space the best response acts on. It is, and automatically: a closed-loop law $\widetilde{m^x}_t$ is the time-marginal of the optimally controlled diffusion eq. (22.1), whose drift has at most linear growth and whose diffusion is bounded under **(A-Growth)**, **(A-Nondeg)**; the standard SDE moment estimate of chapter 5 then propagates any finite initial $(2+\delta)$-moment forward with a constant depending only on the horizon and those bounds — uniformly in x. So every field in the *range* of S carries a uniform $(2+\delta)$-moment, the hypothesis of lemma 22.8(2) is satisfied along any such flow, and we may take the working space to be the fields with a fixed uniform higher-moment bound, a space S maps into itself. With both inputs controlled, the HJB-stability lemma lemma 10.10 — read with the type frozen as an external parameter and the perturbation being precisely the change of type — gives

$$\sup_t \left\| u^x(t,\cdot) - u^{x'}(t,\cdot) \right\|_{C^1} \le C\Big(\|\mathrm{data}(x) - \mathrm{data}(x')\| + \sup_t \mathcal{W}_2\big(\nu^x_t, \nu^{x'}_t\big) \Big),$$

with C uniform across types under **(A-Nondeg)**, **(A-Conv)**. Both terms on the right vanish as $x' \to x$, so $x \mapsto u^x$ is continuous, and indeed continuous in C^1, which is the regularity the next step needs. Because the induced drift $b^{x,*} = -\partial_p H$ of eq. (22.8) is built from ∇u^x by a Lipschitz map (the costate-gradient of the Hamiltonian), C^1-continuity of the value passes to continuity of the closed-loop drift, and hence of the control eq. (22.9) as well. Now feed that continuously-varying drift into the forward FP equation eq. (22.6b), started from the type-continuous datum m^x_0, and apply the FP-stability lemma lemma 10.11, which bounds the $\mathcal{W}_2$-gap of two closed-loop flows by the gap of their drifts and their data: the output gap $\sup_t \mathcal{W}_2(\widetilde{m^x}_t, \widetilde{m^{x'}}_t) \to 0$. That is continuity of $x \mapsto \widetilde{m^x}$, completing (2).

Measurability. For (1) the kernel is only measurable, so we lose the type-continuity of the environment and must settle for measurability — but, crucially, we lose nothing in the *solution* step, and this is where **(A-Conv)** pays off. The temptation, when the type-to-solution assignment is only measurable, is to worry about *measurable selection*: if the optimal control were a set-valued correspondence, picking a measurable representative type by type would require a selection theorem (Kuratowski–Ryll-Nardzewski). Under **(A-Conv)** there is nothing to select — the Hamiltonian is convex in the costate, the argmax eq. (22.9) is a single point, and the per-type solution operators are honest single-valued *maps*. The assignment is then a composition of three named maps, and measurability follows by the elementary fact that a Borel map composed with a continuous map is Borel. Unfold it:

Step 1 (the environment is Borel). The environment map $\mathsf{Env}\colon x \mapsto \nu^x_\cdot = (\mathbb{W}\boldsymbol{m}_\cdot)(x)$ is Borel measurable from $[0,1]$ into $C([0,T];\mathcal{M}_+(\mathbb{R}^d))$ with the weak topology — this is exactly lemma 22.8(1), applied at each t and assembled in t — and the coefficient map $x \mapsto \mathrm{data}(x)$ is Borel, indeed Lipschitz, by **(A-Lip)**. So the pair of inputs $x \mapsto (\mathrm{data}(x), \mathsf{Env}(x))$ is Borel. This step uses only bare **(A-Reg-W)**.

Step 2 (the HJB solve is continuous). The HJB solution operator $\mathsf{Sol}_{\mathrm{HJB}}\colon (\mathrm{data}, \nu) \mapsto u$ that sends data and a frozen environment to the value is a *continuous* map between the relevant Polish spaces. This is not a new claim: it is precisely the modulus of continuity recorded by lemma 10.10, the same estimate the continuity half used, now read as the statement that the output depends continuously on the input rather than as a quantitative rate.

Step 3 (the FP solve is continuous). Likewise the FP solution operator $\mathsf{Sol}_{\mathrm{FP}}\colon (u, \mathrm{data}) \mapsto \widetilde{m}$ that sends a value (through its induced drift) and data to the closed-loop flow is continuous, this being the content of lemma 10.11.

Compose the three. Since $x \mapsto u^x = \mathsf{Sol}_{\mathrm{HJB}}(\mathrm{data}(x), \mathsf{Env}(x))$ is a continuous map of a Borel map, it is Borel; and then $x \mapsto \widetilde{m^x} = \mathsf{Sol}_{\mathrm{FP}}(u^x, \mathrm{data}(x))$ is again a continuous map of a Borel map, hence Borel. No selection theorem appears anywhere, because single-valuedness removed the only place one could have been needed. (Were **(A-Conv)** dropped and the argmax eq. (22.9) allowed to be set-valued, this clean composition would break: Sol would become a measurable correspondence, and recovering a measurable field $x \mapsto (u^x, \widetilde{m^x})$ would then genuinely require a Kuratowski–Ryll-Nardzewski measurable selection, which lies outside our standing hypotheses. Convexity of the Hamiltonian is thus doing double duty: it makes the feedback a function in the verification theorem of section 22.1.3, and it makes the type-to-solution assignment measurable without selection here.) The detailed parabolic and Schauder estimates underlying Steps 2 and 3 are exactly those of chapter 10, applied verbatim with the type as an inert external parameter; we do not reproduce them. □

Remark 22.10 (What regularity in type buys)**.** proposition 22.9 is the technical license for everything that follows, and the two halves cash out in two different places, so it pays to separate them.

The *continuity* half is what lets structure in the kernel *propagate* into structure in the solution — the engine of the next section. The cleanest case is block-constancy. Suppose the data and the kernel are constant on a block of types: two types x, x' in the same block then have identical coefficients, $\mathrm{data}(x) = \mathrm{data}(x')$, and identical environments, $\nu^x = \nu^{x'}$ (the kernel rows agree, so the aggregates agree). The right-hand side of the HJB-stability estimate is then *exactly zero*, not merely small, and because the solution operator is single-valued under **(A-Conv)** — same inputs, one output — the solutions coincide: $u^x = u^{x'}$ and $\widetilde{m^x} = \widetilde{m^{x'}}$. The solution field is therefore constant on the block, with no further argument. This is precisely the mechanism by which section 22.4.2 recovers finite multi-population MFG from a block graphon and by which the rank-one and finite-rank reductions of sections 22.4 and 22.5 are allowed to assume the solution depends on the type only through the handful of kernel statistics it sees — it is continuity (here in its degenerate, exact form) that forbids the solution from varying *within* a level set of the data and kernel.

The *measurability* half is what makes the best-response self-map well-defined and so underwrites the existence theory downstream. The aggregate eq. (22.2) of the *output* field $x \mapsto \widetilde{m^x}$ is a type-integral, and a type-integral of a non-measurable family is meaningless; measurability of the assembled field is exactly what makes that aggregate exist, hence what places $\mathsf{S}[\boldsymbol{m}]$ back inside $\mathcal{C}$ and closes the loop $\mathsf{S}\colon \mathcal{C} \to \mathcal{C}$. This is the obligation proposition 22.6 deferred, now discharged, and it is what makes the fixed-point statement there — and the compactness-and-fixed-point existence argument of chapter 24 that consumes it — a statement about a genuine self-map rather than a formal one.

Finally, a warning about what is *not* claimed, because the word "regularity" invites an over-reading the whole chapter has been at pains to forbid. We never claim, need, or use any regularity *in the type derivative.* The map $x \mapsto u^x$ is shown measurable always and continuous when the kernel is, and that is the ceiling: it is not asserted to be differentiable in x, and there is no elliptic — or any — differential operator acting in the type variable anywhere in the system. The type is an exchangeable index carrying no metric of its own (appendix A); we upgrade it from a measurable label to a continuous one when the kernel permits, and never further. This is the precise sense in which "a continuum of HJB–FP pairs" is continuum-indexed but not a PDE in the index — consistent with the standing-data injunction that we never differentiate in x.

With both halves in hand, the continuum of per-type pairs is at last a well-defined single object, and we may exploit its structure. The continuity half is the tool the next section reaches for first: it is what licenses the leap from "the kernel is piecewise constant" to "the solution is piecewise constant," turning a block graphon into a finite multi-population system and a finite-rank kernel into a finite set of order parameters. Carrying the separable single-statistic coupling of section 22.2.3 through this now-legitimate reduction is the business of the special-structures section, to which we turn.

22.4 Special solvable structures

The previous section earned us a license, and this section is where we spend it. The continuity half of proposition 22.9, distilled in remark 22.10, says that the per-type solution operator is single-valued under **(A-Conv)** and varies continuously with its inputs: two types that see *the same* coefficients and *the same* environment must produce *the same* value function and the same density — the stability estimate has a right-hand side that is not merely small but exactly zero. That is the engine of structure-propagation. Whatever the kernel is blind to — whatever distinction between types it refuses to register in the aggregate $(\mathbb{W}\boldsymbol{m}_t)(x)$ — the solution is forced to be blind to as well. So if the kernel sees each type through only a handful of numbers, the entire continuum of HJB–FP pairs can carry no more information than those few numbers, and the infinite-dimensional fixed point of section 22.1.3 must secretly be a finite-dimensional one. The business of this section is to make "a handful of numbers" precise in the three ways a kernel naturally permits it, and to watch the continuum collapse each time.

Two threads from earlier feed directly into this. The first is the propagation mechanism just recalled. The second is the cost structure isolated in section 22.2.3: a *separable* coupling, in which the population enters the running cost only through a single scalar statistic $\langle \psi, \nu \rangle$ of the felt aggregate (eq. (22.11)). That specialization is what guarantees the type reacts to the field through one real number rather than through the whole measure, and it is the precise hinge on which every reduction below turns: separability makes the felt environment a scalar field over types, and a low-rank kernel then makes that scalar field live in a low-dimensional space. Neither ingredient alone collapses the system — a separable coupling against a full-rank kernel still couples a continuum, and a low-rank kernel against a non-separable cost still feeds each type a whole measure — but together they are exactly what is needed, and carrying the separable single-statistic coupling of section 22.2.3 through the now-legitimate reduction is what the subsections below actually do.

Why these three structures and no others? Because there are exactly three ways the self-adjoint Hilbert–Schmidt operator $\mathbb{W}$ can fail to see the full continuum, and they form a nested family. The most general is *finite rank*: $\mathbb{W}$ has only K nonzero eigenvalues, so by its spectral decomposition (chapter 18) it resolves a type only through the K coordinates $(\phi_1(x), \ldots, \phi_K(x))$ of its leading eigenfunctions, and the coupling passes through K scalar *order parameters* — the statistical-mechanics name is deliberate, for these are the dynamic analogues of the magnetizations that closed the static models. A *block* kernel is the special finite-rank case in which the eigenfunctions are indicators of a partition: $\mathbb{W}$ then cannot distinguish two types in the same block at all, the order parameters become block averages, and continuity-propagation forces the solution itself to be block-constant. And the *rank-one* kernel is the $K = 1$ corner of finite rank — a single mode, a single order parameter, a single eigenvalue — which is as far as the collapse can go without trivializing the coupling. These are not three unrelated tricks but one spectrum-truncation idea applied at three depths: K modes, K modes that happen to be blocks, one mode.

Each of the three is simultaneously a worked example and a bridge to a neighbour, and the subsections are written to honour that promise concretely. The finite-rank case (section 22.4.1) is the example that turns the abstract spectral theorem of chapter 18 into an operational recipe: it produces the explicit order-parameter system eq. (22.15), exhibits the “K-soft-mode” reading in which a few leading eigenfunctions carry the equilibrium and the rest are spectrally suppressed, and so furnishes the finite-dimensional fixed point that the existence theory of chapter 24 will later need a handle on. The block case (section 22.4.2) is the example whose bridge is the most consequential: it reproduces *exactly*, not merely in spirit, the finite multi-population mean field games that predate the graphon formalism, with the K populations identified as the K blocks and the inter-population coupling matrix read off as kernel weight times block mass — which is precisely the identification chapter 30 builds its heterogeneity zoo upon, so that multi-population MFG is revealed as a corner of the present system rather than a separate theory. And the rank-one case is the $K = 1$ corner of the first, the dynamic descendant of the Curie–Weiss closure of chapter 14 and the static graphon game of chapter 20; it is so thoroughly collapsed that the whole continuum becomes a single scalar two-point boundary value problem in which the leading eigenvalue of $\mathbb{W}$ appears as the one rescaling of the coupling. That last reduction is important enough, and explicit enough, to deserve its own worked computation, which is why it is carried out in full not here but in section 22.5, where it advances Thread B to its dynamic layer.

The two subsections divide the labour accordingly, and the worked computation downstream consumes both. section 22.4.1 takes up the Mercer/spectral machinery: it imports the spectral decomposition of $\mathbb{W}$ as a self-adjoint Hilbert–Schmidt operator (chapter 18) and uses it to define the order parameters and prove the finite-rank reduction, of which rank-one is simply the $K = 1$ instance. section 22.4.2 takes up the block-constancy mechanism: it uses the degenerate, exact form of continuity-propagation to force the solution constant on each block and thereby recover the multi-population system. The rank-one worked computation of section 22.5 then draws on both — the single order parameter from the first, the constant-on-a-set reasoning from the second — to close Thread B in explicit form. We begin with the spectral picture.

22.4.1 Separable (finite-rank) kernels

The section opener handed this subsection two ingredients and a promise. The ingredients are the Mercer/spectral machinery for $\mathbb{W}$ — the spectral decomposition of the graphon as a self-adjoint Hilbert–Schmidt operator, built in chapter 18 — and the separable single-statistic coupling of section 22.2.3, in which the population enters a type's running cost only through one scalar reading $\langle \psi, \nu \rangle$ of the felt aggregate. The promise is that, put together, these two collapse the continuum of type-couplings to finitely many numbers and turn the infinite-dimensional field fixed point of section 22.1.3 into a finite-dimensional one. This subsection makes the promise good. The mechanism is the one section 22.4 named: continuity-propagation forces the solution to be as blind as the kernel, and a finite-rank kernel sees each type through only finitely many coordinates. Our task is to identify those coordinates explicitly — they will be the projections of the felt field onto the eigenfunctions of $\mathbb{W}$ — and to watch the entire coupled system reorganize itself around them.

Start with the kernel. chapter 18 established that a symmetric, measurable, bounded graphon induces a self-adjoint Hilbert–Schmidt operator $\mathbb{W}$ on $L^2[0, 1]$, and that such an operator has a real spectrum $\{\lambda_k\}$ accumulating only at 0, with an orthonormal eigenbasis $\{\phi_k\}$, in terms of which the kernel admits the *Mercer expansion*

$$W(x, y) \;=\; \sum_{k=1}^{K} \lambda_k\, \phi_k(x)\, \phi_k(y), \qquad \mathbb{W}\phi_k = \lambda_k \phi_k, \quad \langle \phi_k, \phi_l \rangle = \delta_{kl}, \tag{22.14}$$

with $K \le \infty$ and $\sum_k \lambda_k^2 < \infty$, the last sum being exactly the squared Hilbert–Schmidt norm $\|W\|^2_{L^2([0,1]^2)}$ that finiteness of the kernel guarantees. The number K — the count of nonzero eigenvalues — is the *rank* of $\mathbb{W}$, and the whole tractability of this subsection is a statement about it being small or effectively small.

The distinction between $K < \infty$ and $K = \infty$ is not cosmetic, and it is worth being scrupulous about which kind of convergence eq. (22.14) carries, because a later step would be unsound if we over-read it. When the rank is genuinely finite, $K < \infty$, the right-hand side of eq. (22.14) is an honest finite sum of products of bounded functions; the identity holds *pointwise* in (x, y), with nothing to converge and no measure-zero caveat. When the rank is infinite, $K = \infty$, the eigenfunction series is in general guaranteed to converge only in $L^2([0, 1]^2)$ — this is the content of the L^2 spectral theorem of chapter 18, that W equals its eigenexpansion as an element of $L^2([0, 1]^2)$, hence for almost every (x, y). Pointwise (*everywhere*) convergence of the series, the classical Mercer theorem, would require continuity of the kernel, which we do not assume and do not want to assume, since the block graphons of section 22.4.2 are discontinuous by design. We therefore adopt a strict discipline: every consequence we draw from eq. (22.14) in the $K = \infty$ case is one that survives integration against an L^2 function — an L^2-*paired*, a.e.-in-type statement — and we never invoke the pointwise value of the eigenfunction series. This is not fastidiousness for its own sake; it is what keeps the order parameters below honest as Lebesgue integrals rather than as sums of pointwise values that may not exist.

Now bring in the coupling. We take the separable single-statistic form of section 22.2.3: the population-dependent part of the Hamiltonian is $F(x, \xi, \nu) = \Psi(\xi, \langle\psi, \nu\rangle)$ (eq. (22.11), eq. (22.12)), so that the only thing a type-x agent needs to know about its entire graphon-averaged neighbourhood is the single scalar $\langle\psi, (\mathbb{W}\boldsymbol{m}_t)(x)\rangle$. Before defining anything, look at what this scalar is as x ranges over $[0, 1]$. It is a real-valued function of the type — a *scalar field over types* — and by the weak reading eq. (22.3) of the aggregate it is exactly the image under $\mathbb{W}$ of the per-type statistic. Write that statistic as

$$g_t(y) \;:=\; \langle\psi, m_t^y\rangle \;=\; \int_{\mathbb{R}^d} \psi \,\mathrm{d}m_t^y,$$

a bounded real function of y (bounded because ψ is bounded, or because the uniform second-moment bound controls it when ψ has at most quadratic growth), hence an element of $L^2[0, 1]$. Then the felt scalar field is literally $x \mapsto (\mathbb{W}g_t)(x)$: the agent of type x feels the kernel-average of the scalar statistic carried by all the other types. This is the object whose finite-dimensionality we are after, and the spectral decomposition delivers it at once, because $\mathbb{W}$ acts diagonally on the eigenbasis. The natural coordinates of a function in the range of $\mathbb{W}$ are its overlaps with the eigenfunctions ϕ_k, and those overlaps are exactly the *order parameters*.

We can now define them, with the motivation in hand: an order parameter is the projection of the felt statistic onto a single eigenmode of the network operator. For each mode k set

$$\varrho_k(t) \;:=\; \langle\phi_k,\; y \mapsto \langle\psi, m_t^y\rangle\rangle \;=\; \int_0^1 \phi_k(y)\,\langle\psi, m_t^y\rangle \,\mathrm{d}y, \qquad k = 1, \ldots, K, \tag{22.15}$$

that is, $\varrho_k(t) = \langle\phi_k, g_t\rangle$, the k-th Fourier coefficient of the scalar field g_t in the eigenbasis. The name is taken on purpose from statistical mechanics: ϱ_k is the dynamic descendant of a magnetization, the single number that measures how strongly the population at time t has aligned along network mode k. With these in hand the felt field is finite-dimensional in the most explicit way possible. Since $g_t \in L^2[0, 1]$, the operator $\mathbb{W}$ applied to it diagonalizes against the eigenbasis, $\mathbb{W}g_t = \sum_k \lambda_k\langle\phi_k, g_t\rangle\phi_k$, so

$$x \mapsto \langle\psi, (\mathbb{W}\boldsymbol{m}_t)(x)\rangle = (\mathbb{W}g_t)(x) = \sum_{k=1}^{K} \lambda_k\,\varrho_k(t)\,\phi_k(x), \tag{22.16}$$

the series converging in $L^2[0, 1]$ by the spectral theorem (and, when $K < \infty$, holding everywhere as a finite sum). Read eq. (22.16) slowly, because it is the whole point of the subsection: the population — an entire continuum of measures, one per type — is felt by the type-x agent *only* through the finite (or, for $K = \infty$, square-summable) vector $\varrho(t) = (\varrho_k(t))_k$, modulated by the fixed type-profiles $\phi_k(x)$ and weighted by the eigenvalues λ_k. Every agent sees the same K numbers; only the modulation $\phi_k(x)$ differs from type to type. For $K = \infty$ the order parameters assemble into a sequence $\varrho(t) = (\varrho_k(t))_k \in \ell^2$, with $\sum_k \varrho_k(t)^2 \le \|g_t\|_{L^2}^2$ by Bessel's inequality — the projections of a fixed L^2 function onto an orthonormal system can never carry more energy than the function itself.

This finite-dimensional reading of the felt field is exactly what collapses the fixed point, and we state the collapse precisely.

Proposition 22.11 (Finite-rank reduction)**.** *Under the Mercer kernel eq. (22.14) with finite rank $K < \infty$ and a separable coupling reacting to a single statistic ψ, the type-x HJB equation eq. (22.6a) depends on the population only through the K-vector $\varrho(t) = (\varrho_k(t))_{k=1}^K$, via the modulation $\sum_k \lambda_k \phi_k(x) \varrho_k(t)$. The graphon MFG system is therefore equivalent to a single representative-agent control problem parametrized by (x, ϱ), closed by the K self-consistency relations eq. (22.15). The infinite-dimensional fixed point over fields reduces to a fixed point over the finite-dimensional order-parameter path $\varrho \in C([0,T]; \mathbb{R}^K)$.*

Proof. The argument is the substitution eq. (22.16) read inside the HJB equation, in three steps. First, the coupling channel. Substitute the Mercer expansion eq. (22.14) into the aggregate eq. (22.2) and pair the result against the single statistic ψ using the weak reading eq. (22.3); orthonormality of the ϕ_k and the definition eq. (22.15) give

$$\langle \psi, (\mathbb{W}\boldsymbol{m}_t)(x) \rangle = \int_0^1 W(x,y) \, \langle \psi, m_t^y \rangle \, \mathrm{d}y = \int_0^1 \Big(\sum_{k=1}^K \lambda_k \phi_k(x) \phi_k(y) \Big) g_t(y) \, \mathrm{d}y = \sum_{k=1}^K \lambda_k \, \phi_k(x) \, \varrho_k(t),$$

where interchanging the finite sum with the integral is legitimate because $K < \infty$. Second, the dynamic half. The only place the population enters the backward HJB eq. (22.6a) is the source term $F(x, \xi, (\mathbb{W}\boldsymbol{m}_t)(x)) = \Psi(\xi, \langle \psi, (\mathbb{W}\boldsymbol{m}_t)(x) \rangle)$, and we have just shown that its scalar argument is the modulation $\sum_k \lambda_k \phi_k(x) \varrho_k(t)$. Hence the HJB — and, through its solution u^x, the optimal feedback and the forward FP drift, which under the separable structure see the population only through this same source — depend on the field exclusively through the K-vector $\varrho(t)$ and the fixed type-profiles $\phi_k(x)$. The type-x HJB–FP pair is thus a single representative-agent problem parametrized by the type x and the order-parameter path $\varrho(\cdot)$: nothing else about the field reaches it. Third, the closure. Solving that pair for each (x, ϱ) produces, in particular, the densities m_t^x, from which the self-consistency relations eq. (22.15) recompute the order parameters; demanding that the recomputed ϱ equal the input ϱ is a fixed-point equation on the path $\varrho \in C([0,T]; \mathbb{R}^K)$ alone, a system of K scalar relations rather than an equation on a continuum of measures. That the assembly $(x, \varrho) \mapsto (u^x, m^x)$ depends measurably (and continuously when the kernel does) on its arguments — so that the integrals eq. (22.15) are legitimate and the reduced fixed point lives in $C([0,T]; \mathbb{R}^K)$ — is exactly proposition 22.9. $\square$

It is worth pausing on what has happened to the dimensionality of the problem. The original unknown was a flow of fields $\boldsymbol{m} \in C([0,T]; \mathcal{C}_2)$ — a continuum-indexed family of measures evolving in time, the genuinely infinite-dimensional object the existence theory of chapter 24 must contend with in general. The proposition replaces it, in the finite-rank separable case, by a path $\varrho \in C([0,T]; \mathbb{R}^K)$ in a *finite*-dimensional Euclidean space, together with a single parametrized control problem to be solved off-line as a function of (x, ϱ). The continuum has not gone anywhere — there is still one HJB–FP pair per type — but the types no longer talk to one another through an infinite-dimensional channel; they talk through K shared numbers. This is the operational meaning of “the coupling factors through $\mathbb{W}$ and nothing else”: when $\mathbb{W}$ has rank K, the “nothing else” is literally K-dimensional.

A concrete reading of the two extreme cases anchors the general statement. The case $K = 1$ is the rank-one kernel of section 22.5, with a single scalar order parameter ϱ_1; it is the cleanest non-trivial graphon and the descendant of the Curie–Weiss closure. There the whole continuum reports to one number, the felt field is $\lambda_1 \varrho_1(t)\phi_1(x)$, and the self-consistency is a single scalar relation closed across time — which is precisely why it can be pushed to a closed-form two-point boundary value problem, the worked computation that advances Thread B. The case of general K is the natural "K-soft-mode" generalization: the population organizes along the leading K eigenfunctions of $\mathbb{W}$, and the equilibrium is found by solving a K-dimensional self-consistency problem instead of a continuum one. A small instance worth carrying in mind: if $\mathbb{W}$ has two equal nonzero eigenvalues with eigenfunctions ϕ_1, ϕ_2, then two order parameters (ϱ_1, ϱ_2) suffice, and the type-profile a given agent presents to the network is the point $(\phi_1(x), \phi_2(x)) \in \mathbb{R}^2$ — two types with the same profile are, as far as the coupling is concerned, indistinguishable. That last observation is the seed of the block reduction: when the eigenfunctions are constant on the cells of a partition, "same profile" becomes "same block," and K order parameters become K block averages.

When the rank is genuinely infinite ($K = \infty$), the reduction does not stop being useful, and understanding why is the heart of the "soft-mode" reading. By eq. (22.16) the type-coupling still passes through the sequence $\varrho(t) = (\varrho_k(t))_k \in \ell^2$, but now the modes are weighted by eigenvalues $\lambda_k \to 0$ (the accumulation-at-zero of the Hilbert–Schmidt spectrum, with $\sum_k \lambda_k^2 < \infty$). The decisive point is that the eigenvalues, not the order parameters, set the weight with which each mode is actually *felt*: the contribution of mode k to the felt field eq. (22.16) is $\lambda_k \varrho_k(t)\phi_k(x)$, and since the order parameters are uniformly bounded in ℓ^2 by Bessel ($\sum_k \varrho_k(t)^2 \le \|g_t\|_{L^2}^2$), the size of that contribution is governed by λ_k. So although the self-consistency is now an infinite system of order-parameter relations, it is *rapidly truncatable*. Quantitatively, truncating to the leading K modes — discarding λ_k for $k > K$ — replaces the felt field by its first K terms, and the discarded tail has $L^2[0,1]$-norm

$$\Big\| \sum_{k>K} \lambda_k \varrho_k(t)\phi_k(x) \Big\|_{L^2[0,1]}^2 = \sum_{k>K} \lambda_k^2\, \varrho_k(t)^2 \;\le\; \Big(\sup_k \varrho_k(t)^2\Big) \sum_{k>K} \lambda_k^2 \;\le\; \|g_t\|_{L^2}^2 \sum_{k>K} \lambda_k^2,$$

so the truncation error is controlled by the spectral tail $\big(\sum_{k>K} \lambda_k^2\big)^{1/2}$, which tends to 0 as $K \to \infty$ precisely because $\mathbb{W}$ is Hilbert–Schmidt. The intuition to carry away is that *eigenvalue decay is practical finite-dimensionality*: a kernel whose spectrum falls off quickly is, for every computational and structural purpose, a finite-rank kernel up to an error one can make as small as desired by keeping a few more modes. The leading eigenfunctions — the "soft modes," in the statistical-mechanics idiom where the slowly-relaxing collective coordinates dominate the long-wavelength physics — carry essentially all of the coupling, and the high modes are *spectrally suppressed*, their order parameters multiplied into the felt field by vanishingly small eigenvalues. The finite-rank proposition 22.11 is therefore not a fragile special case but the practically exact closure for any kernel with a decaying spectrum, with K chosen to push $\big(\sum_{k>K} \lambda_k^2\big)^{1/2}$ below tolerance.

This is the lens we now turn on the block graphon. A block kernel is the special finite-rank structure in which the eigenfunctions ϕ_k are constant on the cells of a partition of $[0,1]$ — the finite-dimensional invariant subspace of $\mathbb{W}$ is the space of block-constant fields — so the K order parameters become K block averages and, by the continuity-propagation of proposition 22.9, the solution field is forced constant on each block. The finite-rank reduction proved here is exactly what section 22.4.2 specializes; reading the block case is reading proposition 22.11 with the eigenfunctions chosen to be indicators.

22.4.2 Block graphons and multi-population MFG

The finite-rank subsection just closed by pointing at this one. There the coupling collapsed onto the K-dimensional span of the leading eigenfunctions ϕ_k, and the last paragraph noted what happens when those eigenfunctions are not arbitrary but are *indicators of a partition*: "same type-profile" degenerates into "same block," the order parameters become block averages, and — crucially — the continuity and single-valuedness propagation of proposition 22.9 forces the solution field itself to be constant on each block. That degenerate-but-rigid case is the block graphon, and it is worth elevating to its own subsection not because it is harder than the general finite-rank reduction (it is a strict special case of it) but because it is the *most consequential* one. A block graphon reproduces the finite multi-population mean field games that predate the graphon formalism entirely — the models with K interacting sub-populations, each with its own dynamics and its own pairwise coupling to the others — and it does so *exactly and not merely in spirit*. The claim of this subsection is an identity, not an analogy: the graphon MFG system over a block kernel *is*, after a change of bookkeeping that loses nothing, the classical multi-population system, equation for equation and boundary datum for boundary datum. That is what makes the block graphon the rigorous bridge to chapter 30, where the entire heterogeneity theory — major/minor agents, multi-class populations, structured sub-communities — is built on the multi-population system and can therefore be read, without re-derivation, as a corner of the present one.

We begin by fixing the kernel. A block graphon is the kernel of the stochastic block model: partition the type continuum $[0, 1]$ into K communities, declare every pair of communities to interact at a single constant strength, and let the kernel be flat inside each community-pair rectangle. This is the coarsest non-trivial structure a graphon can carry — a piecewise-constant kernel on a grid of rectangles — and it is exactly the structure that turns the integral operator $\mathbb{W}$ into a finite matrix.

Definition 22.12 (Block graphon)**.** A *block graphon* on the partition $[0, 1] = \bigsqcup_{k=1}^{K} I_k$ into measurable blocks of masses $\pi_k = |I_k| > 0$, $\sum_k \pi_k = 1$, is a kernel constant on each block-pair: $W(x, y) = w_{kl}$ for $x \in I_k$, $y \in I_l$, with a symmetric matrix $(w_{kl}) \in [0, 1]^{K\times K}$. We say the GMFG data are *block-compatible* if the coefficients b, σ, L, g and the initial field m_0^x depend on x only through its block, i.e. are constant on each I_k.

Two features of the definition deserve a word before they are used. First, the masses π_k are not cosmetic: a block is a community of agents, and $\pi_k = |I_k|$ is the *population fraction* of community k. A small block is a small sub-population, and its influence on the others will be weighted by exactly that smallness — the combination $w_{kl}\pi_l$, kernel strength times block mass, will turn out to be the true inter-community coupling, not the bare w_{kl}. Second, block-compatibility is not a technical convenience but the *natural matching hypothesis*, and it is worth seeing why. The block structure of the kernel says only that agents are coupled to one another in a way that depends on type solely through community membership. If the agents' intrinsic data — their drift, their volatility, their cost, the law they start from — varied *within* a community, then two agents in the same block would be genuinely different problems that merely happen to share a coupling pattern, and there would be no reason for the solution to respect the partition. Block-compatibility is the hypothesis that the partition is honest all the way down: agents in the same community are interchangeable not only in how they couple but in who they are. It is the precise condition under which the block structure of the network is also a block structure of the *game*, and it is exactly what one always assumes, usually silently, when writing a finite multi-population model in the first place — there "population k" means a homogeneous group with common coefficients. Drop it and Proposition 22.13 fails at its first step, because the per-type problems inside a block would no longer coincide.

With the data matched to the partition we can state the reduction. The intuition is the one the finite-rank subsection planted: when the only thing that distinguishes types is their block, and the only channel between types is the aggregate, two types in the same block face *identical problems*, and a single-valued solution operator must return *identical solutions*. Block-constancy of the solution is therefore forced, not assumed; and once it is in hand, the continuum of per-type equations collapses to one equation per block.

Proposition 22.13 (Block graphon GMFG is multi-population MFG)**.** *Let W be a block graphon (definition 22.12) with block-compatible data, under **(A-Lip)**, **(A-Growth)**, **(A-Nondeg)**, **(A-Conv)**. Then any solution of the graphon MFG system eq.* (22.6) *is* block-constant*: $u^x = U_k$ and $m^x = M_k$ for a.e. $x \in I_k$, and the K-tuple $\big((U_k, M_k)\big)_{k=1}^K$ solves the multi-population MFG system: for each $k = 1, \dots, K$,*

$$-\partial_t U_k - \tfrac{1}{2}\operatorname{tr}\big(\sigma_k\sigma_k^\top \mathrm{D}^2 U_k\big) + H\Big(k, \xi, \nabla U_k,\ \textstyle\sum_{l=1}^K w_{kl}\,\pi_l\, M_{l,t}\Big) = 0, \quad U_k(T,\xi) = g\big(\xi, \textstyle\sum_l w_{kl}\pi_l M_{l,T}\big), \tag{22.17a}$$

$$\partial_t M_k - \tfrac{1}{2}\operatorname{tr}\big(\sigma_k\sigma_k^\top \mathrm{D}^2 M_k\big) - \operatorname{div}\Big(M_k\,\partial_p H\big(k, \xi, \nabla U_k, \textstyle\sum_l w_{kl}\pi_l M_{l,t}\big)\Big) = 0, \quad M_k(0,\cdot) = M_{k,0}, \tag{22.17b}$$

where the aggregate felt by population k is the weighted sum $\sum_l w_{kl}\pi_l M_{l,t}$. Conversely any solution of eq. (22.17) *yields, by extension to block-constant fields, a solution of the GMFG system; under the uniqueness hypotheses of chapter 24 the two correspondences are inverse.*

Proof. The argument has three beats: compute the aggregate and see it depends on the type only through the block; invoke single-valuedness to force the solution to inherit that block-dependence; substitute the block-constant solution back to read off the reduced system. Then the converse.

The aggregate is block-constant in the observer's type. Fix $x \in I_k$ and evaluate the aggregate eq. (22.2) on a candidate field $\boldsymbol{m}_t$. Because the kernel is flat on each block-pair, $W(x,y) = w_{kl}$ for every $y \in I_l$, so the type-integral splits over blocks and the kernel comes out of each piece as a constant:

$$(\mathbb{W}\boldsymbol{m}_t)(x) = \int_0^1 W(x,y)\, m_t^y \,\mathrm{d}y = \sum_{l=1}^K \int_{I_l} w_{kl}\, m_t^y \,\mathrm{d}y = \sum_{l=1}^K w_{kl} \int_{I_l} m_t^y \,\mathrm{d}y.$$

The right-hand side depends on the observing type x *only through its block index k* — the integrals $\int_{I_l} m_t^y \,\mathrm{d}y$ are the same sub-population measures regardless of which $x \in I_k$ we picked. Every agent in community k therefore feels one and the same environment, the kernel-weighted sum of the community measures.

Single-valuedness forces block-constancy. Now compare two types $x, x' \in I_k$ in the same block. By block-compatibility they carry identical coefficients b_k, σ_k, L_k, g_k and identical initial law $m_0^x = m_0^{x'}$; by the previous beat they face identical environments $(\mathbb{W}\boldsymbol{m}_t)(x) = (\mathbb{W}\boldsymbol{m}_t)(x')$ at every time. Their per-type HJB–FP pairs eq. (22.6) are thus, coefficient for coefficient and datum for datum, the *same* frozen-field problem. The per-type solution operator is a genuine map — not a correspondence — precisely because **(A-Conv)** makes the Hamiltonian maximizer single-valued (so the closed-loop drift is a function, not a set) and **(A-Nondeg)** makes each frozen-field pair classically and uniquely solvable; this is the single-valuedness recorded in proposition 22.4 and propagated type-by-type in proposition 22.9. Feeding identical data into a single-valued operator returns identical output, so $(u^x, m^x) = (u^{x'}, m^{x'})$. Two arbitrary types in a block agree, hence the solution is constant on each block: there exist (U_k, M_k) with $u^x = U_k,\ m_t^x = M_{k,t}$ for a.e. $x \in I_k$. This is where the hypotheses earn their place — without single-valuedness the two types could be assigned *different* selections from a multivalued solution set and block-constancy would collapse.

Substitution reads off the reduced system. With the solution block-constant, the inner integrals evaluate to $\int_{I_l} m_t^y \,\mathrm{d}y = \int_{I_l} M_{l,t} \,\mathrm{d}y = |I_l|\, M_{l,t} = \pi_l M_{l,t}$, so the environment felt by community k is exactly the weighted sum

$$(\mathbb{W}\boldsymbol{m}_t)(x) = \sum_{l=1}^{K} w_{kl}\, \pi_l\, M_{l,t}, \qquad x \in I_k.$$

Substituting this, together with $u^x = U_k$, $\sigma(x) = \sigma_k$, $m^x = M_k$ and $H(x,\cdot) = H(k,\cdot)$, into the type-x pair eq. (22.6a)–eq. (22.7) turns each of the (a.e.-identical) per-type equations in block k into the single pair eq. (22.17), with its terminal datum $U_k(T,\xi) = g(\xi, \sum_l w_{kl}\pi_l M_{l,T})$ and initial datum $M_k(0,\cdot) = M_{k,0}$ inherited from eq. (22.7). The continuum of equations has become K coupled HJB–FP pairs, one per community, coupled only through the $K \times K$ weighted-mean term.

Converse. Conversely, take any solution $\big((U_k, M_k)\big)_{k=1}^{K}$ of the finite system eq. (22.17) and define a field by extension, $u^x := U_k$ and $m^x := M_k$ for $x \in I_k$. For $x \in I_k$ the aggregate of this block-constant field is, by the same computation, $\sum_l w_{kl}\pi_l M_{l,t}$, which is precisely the environment in eq. (22.17); so the extended field satisfies the graphon pair eq. (22.6) for a.e. x. The two maps — "restrict a block-constant GMFG solution to its block values" and "extend a multi-population solution to a block-constant field" — are thus mutually inverse on block-constant solutions, and under the uniqueness hypotheses of chapter 24 (which rule out any non-block-constant GMFG solution and any second multi-population solution) the correspondence between *all* GMFG solutions and *all* multi-population solutions is a bijection. □

It is worth naming what the proof has actually done, because the dimensional collapse is the same one the finite-rank subsection performed, now in its most transparent guise. The block-constant fields form a K-dimensional subspace of the field space, and it is an *invariant* subspace of the coupling: the first beat showed $\mathbb{W}$ maps a block-constant field to a block-constant aggregate, never leaking mass into finer type-structure. Block-compatibility ensures the dynamics preserve that subspace too, and single-valuedness pins the solution inside it. The whole reduction is the statement that the equilibrium lives on this finite-dimensional invariant subspace — exactly the finite-rank picture of proposition 22.11 with the eigenfunctions specialized to the normalized indicators $\pi_k^{-1/2}\mathbf{1}_{I_k}$, whose span is precisely the block-constant fields.

Remark 22.14 (The bridge to chapter 30)**.** proposition 22.13 is the precise statement that *multi-population mean field games are the block-graphon special case of GMFG* — an identity, recall, not a family resemblance. The dictionary is exact in every entry. The K populations of the classical theory are the K blocks of the partition. The intrinsic data of population k — its drift b_k, volatility σ_k, running and terminal costs — are the block-compatible data restricted to I_k. The aggregate that population k responds to is $\sum_l w_{kl}\pi_l M_{l,t}$, so the inter-population coupling coefficient is $w_{kl}\pi_l$ — the kernel weight *times the block mass*, not the bare w_{kl} — and the within-population (self-) coupling is $w_{kk}\pi_k$. That the population fraction π_l multiplies the coupling is the graphon's bookkeeping made visible: a community influences another in proportion both to how strongly they are linked, w_{kl}, and to how large it is, π_l; a small community with a strong link can carry the same weight as a large community with a weak one.

The spectral half of the dictionary is the entry that most repays unfolding, because it is the one that turns the abstract operator-norm hypotheses of the general theory into concrete matrix conditions one can check by hand. On the block-constant subspace the operator $\mathbb{W}$ acts as a finite matrix, and we can write that matrix down. Take the indicator basis $\mathbf{1}_{I_1}, \ldots, \mathbf{1}_{I_K}$ of the block-constant subspace. A block-constant field $f = \sum_l c_l \mathbf{1}_{I_l}$ has aggregate $(\mathbb{W}f)(x) = \sum_l w_{kl}\pi_l c_l$ for $x \in I_k$, so in this basis $\mathbb{W}$ is represented by the matrix

$$A \;:=\; (w_{kl}\,\pi_l)_{k,l=1}^{K} \;=\; (w_{kl})\;\mathrm{diag}(\pi_1, \ldots, \pi_K).$$

This A is in general *not symmetric* — the mass factor π_l sits only on the column index — which looks at first like a contradiction, since $\mathbb{W}$ is self-adjoint and the block-constant subspace is invariant, so the restriction ought to be a self-adjoint operator. The resolution is that the indicator basis is orthogonal but not orthonormal: $\langle \mathbf{1}_{I_k}, \mathbf{1}_{I_l}\rangle_{L^2} = \pi_k \delta_{kl}$, so a self-adjoint operator need not have a symmetric matrix in it. Passing to the *orthonormal* basis $e_k := \pi_k^{-1/2}\mathbf{1}_{I_k}$ repairs this: there $\mathbb{W}$ is represented by

$$S \;:=\; \big(\sqrt{\pi_k}\,w_{kl}\,\sqrt{\pi_l}\big)_{k,l=1}^{K} \;=\; \mathrm{diag}(\sqrt{\pi})\,(w_{kl})\;\mathrm{diag}(\sqrt{\pi}),$$

which *is* symmetric (because (w_{kl}) is), as it must be. The two matrices are similar, $A = \mathrm{diag}(\sqrt{\pi})^{-1}\,S\;\mathrm{diag}(\sqrt{\pi})$, so they share the same characteristic polynomial and hence the same eigenvalues; and those eigenvalues are exactly the spectrum of the self-adjoint operator $\mathbb{W}$ restricted to the K-dimensional block-constant invariant subspace. In one line: the spectrum of $\mathbb{W}$ on block-constant fields is the spectrum of the symmetric matrix S, equivalently of the coupling matrix $A = (w_{kl}\pi_l)$.

This is what lets the operator-norm smallness hypothesis **(A-Coupling)** of the general uniqueness theory descend to a checkable matrix condition. Because the block-constant subspace is $\mathbb{W}$-invariant, the relevant interaction strength for the multi-population dynamics is not the full operator norm $\|\mathbb{W}\|_{L^2\to L^2}$ but the norm of its restriction to that subspace — and by the spectral computation just made, that restricted norm is the spectral radius of S,

$$\|\mathbb{W}|_{\text{block-constant}}\| \;=\; \max_{1\le k\le K}|\mu_k|, \qquad \mu_1, \ldots, \mu_K = \text{eigenvalues of } S = \text{eigenvalues of } (w_{kl}\pi_l),$$

since a symmetric matrix's operator norm equals its largest eigenvalue in modulus. The abstract condition $\|\mathbb{W}\| <$ (threshold) thus becomes the concrete matrix condition $\max_k |\mu_k| <$ (threshold) on the $K \times K$ coupling matrix $(w_{kl}\pi_l)$ — a finite eigenvalue computation in place of an operator-norm estimate. This is the precise content of "the operator-norm coupling condition becomes a matrix-norm condition," and it is the form in which chapter 24 and chapter 30 will read smallness for multi-population models.

chapter 30 develops the heterogeneity zoo — major/minor agents, multi-class models, core–periphery and assortative communities — from exactly this identification, reading each as a structured choice of partition (π_k) and symmetric coupling matrix (w_{kl}). We have thus closed the loop the chapter's plan promised: the multi-population MFG that chapter 30 takes as its starting object is not a separate theory grafted onto the graphon framework but a single corner of the present system, the one cut out by a piecewise-constant kernel.

The smallest non-degenerate instance of all this is the two-block kernel, $K = 2$, and it is the instance the worked computation will use to exhibit the bridge in the concrete. Two blocks of masses $\pi_1, \pi_2 = 1 - \pi_1$ with a symmetric 2×2 matrix (w_{kl}) give, by proposition 22.13, a two-population MFG — two coupled HJB–FP pairs whose interaction matrix $(w_{kl}\pi_l)$ has two eigenvalues, the larger of which is the relevant coupling strength. When this is specialized to the LQG cost, the finite-rank collapse of proposition 22.11 with $K = 2$ closes the population channel on a *two*-dimensional order-parameter path, and the equilibrium becomes a 2-dimensional order-parameter boundary value problem rather than the scalar one of the rank-one case. That two-block computation — the smallest genuine instance of multi-population LQG sitting inside the graphon LQG — is exactly the reduction logged in remark 22.16 once the worked computation is in hand. We turn to that worked computation now, beginning not with two blocks but with the cleanest corner of all, the rank-one ($K = 1$) graphon, where a single scalar order parameter and a single leading eigenvalue carry the entire coupling.

22.5 Worked computation: the rank-one graphon LQG

We now advance Thread B to its dynamic layer. The static graphon game version was set up in chapter 20; the LQG capstone chapter 14 wrote the template (section 14.7); here we carry it out in full and exhibit the closed-form collapse to a single scalar two-point boundary value problem. This is the cleanest graphon worked example in the book, and it makes concrete every abstraction of the chapter: the type-indexed HJB family, the coupling through $\mathbb{W}$, the finite-rank reduction of proposition 22.11 at $K = 1$, and the role of the leading eigenvalue of $\mathbb{W}$ as the effective coupling.

Worked computation 22.15 (Rank-one graphon LQG)**.** Recall Thread B (appendix A; section 14.7). Each type-x agent has scalar state $X_t^x \in \mathbb{R}$ obeying

$$dX_t^x = \left(a\, X_t^x + b\, \alpha_t^x\right)\, dt + \sigma\, dB_t^x, \qquad X_0^x \sim m_0^x, \tag{22.18}$$

with *type-independent* coefficients $a, b \neq 0, \sigma > 0$, and minimizes, against the graphon-aggregated neighbour mean,

$$J^x(\alpha^x) = \mathbb{E}\left[\int_0^T \left(\tfrac{1}{2}(\alpha_t^x)^2 + \tfrac{q}{2}\left(X_t^x - s\, z_t(x)\right)^2\right) dt + \tfrac{q_T}{2}\left(X_T^x - s_T\, z_T(x)\right)^2\right], \tag{22.19}$$

where, writing $\bar m_t^x := \int \xi\, m_t^x(\mathrm{d}\xi)$ for the type-x population mean,

$$z_t(x) \;:=\; (\mathbb{W}\bar m_t)(x) = \int_0^1 W(x,y)\,\bar m_t^y\;\mathrm{d}y, \qquad W(x,y) = f(x)\,f(y), \tag{22.20}$$

the rank-one kernel with profile $f \in L^2[0,1]$ (**(A-Reg-W)**; take $f \geq 0$ for $W \in [0,1]$, and $\|f\|_\infty^2 \leq 1$). This is the separable, nonlocal, single-statistic coupling eq. (22.11) with $\psi(\xi) = \xi$ and $\Psi(\xi, z) = \frac{q}{2}(\xi - sz)^2$.

Step 1: type-indexed HJB, type-independent curvature. For each x, with $z_t(x)$ frozen, the HJB eq. (22.6a) is the scalar LQG equation eq. (14.4) with $\bar m_t$ replaced by $z_t(x)$. Its quadratic ansatz is type-indexed,

$$u^x(t,\xi) = \tfrac{1}{2}P(t)\,\xi^2 + r^x(t)\,\xi + c^x(t), \tag{22.21}$$

and matching powers of ξ gives, for the curvature, *the same* Riccati equation for every type,

$$\dot P = b^2P^2 - 2aP - q, \qquad P(T) = q_T, \tag{22.22}$$

because the curvature sees only the cost geometry, not the coupling (eq. (14.7); here it is type-independent precisely because a, b, q, q_T are). theorem 14.2 gives a unique nonnegative bounded P on $[0,T]$, so the closed-loop coefficient $a - b^2P(t)$ is bounded. (We write it out as $a - b^2P(t)$ throughout rather than abbreviating it by a single letter, since θ and ϱ are reserved book-wide — the former retired, the latter the order parameter.) All the type- and population-dependence sits in the offset, which solves the type-indexed linear family

$$\dot r^x = (b^2P - a)\,r^x + q\,s\,z_t(x), \qquad r^x(T) = -q_Ts_T\,z_T(x), \tag{22.23}$$

coupled across types only through $z_t(x) = (\mathbb{W}\bar m_t)(x)$, exactly as section 14.7 anticipated.

Step 2: Gaussian flow per type. The optimal feedback is linear, $\alpha^{x,*}(t,\xi) = -b(P(t)\xi + r^x(t))$, so the type-$x$ closed loop is the affine SDE $\mathrm{d}X_t^x = \big((a - b^2P(t))X_t^x - b^2r^x(t)\big)\,\mathrm{d}t + \sigma\;\mathrm{d}B_t^x$. By theorem 14.4 its law is Gaussian, $m_t^x = \mathcal{N}(\bar m_t^x, V_t)$, with the variance V_t *type-independent* (it solves $\dot V = 2(a - b^2P)V + \sigma^2$, which sees neither type nor coupling) and the mean solving

$$\dot{\bar m}_t^x = (a - b^2P(t))\,\bar m_t^x - b^2\,r^x(t), \qquad \bar m_0^x = \textstyle\int \xi\, m_0^x(\mathrm{d}\xi) \text{ given.} \tag{22.24}$$

As in the homogeneous case the only game-theoretic content is in the means $\bar m_t^x$ and their conjugates r_t^x; the variance is a spectator.

Step 3: the rank-one collapse to a scalar order parameter. Here the kernel structure does its work. The aggregate is $z_t(x) = f(x)\,\varrho_t$, where

$$\varrho_t \;:=\; \int_0^1 f(y)\,\bar m_t^y\;\mathrm{d}y \;=\; \langle f, \bar m_t\rangle_{L^2} \tag{22.25}$$

is the *single scalar order parameter* at $K = 1$: the projection of the mean profile onto the *unnormalised* leading (and only) eigenvector f of $\mathbb{W}$. In the orthonormal normalisation of the Mercer expansion eq. (22.14) one has $\phi_1 = f/\sqrt{\lambda_1}$ and $\lambda_1 = \|f\|_{L^2}^2$, so $\varrho_t = \sqrt{\lambda_1}\,\varrho_1(t)$ where $\varrho_1(t) = \langle \phi_1, \bar m_t\rangle$ is the order parameter of eq. (22.15) at $k = 1$; the physically felt field $f(x)\varrho_t = \lambda_1\phi_1(x)\varrho_1(t)$ is independent of the normalisation, so this $\sqrt{\lambda_1}$ rescaling never appears in the dynamics. The terminal datum in eq. (22.23) is then $-q_T s_T f(x)\varrho_T$, and the forcing is $qsf(x)\varrho_t$; both are proportional to $f(x)$, so the offset inherits the rank-one form. Posit $r^x(t) = f(x)\,\rho(t)$. Substituting into eq. (22.23) the factor $f(x)$ cancels and leaves a single scalar equation

$$\dot\rho = (b^2 P - a)\,\rho + q\,s\,\varrho_t, \qquad \rho(T) = -q_T s_T\,\varrho_T, \tag{22.26}$$

consistent for *every* x simultaneously. To close the loop, multiply the mean equation eq. (22.24) by $f(x)$ and integrate over x, using $r^x = f(x)\rho$:

$$\dot\varrho_t = (a - b^2 P(t))\,\varrho_t - b^2\rho(t)\int_0^1 f(x)^2\,\mathrm{d}x = (a - b^2 P(t))\,\varrho_t - b^2\,\lambda_1\,\rho(t), \qquad \lambda_1 := \|f\|_{L^2}^2\,. \tag{22.27}$$

The constant $\lambda_1 = \int_0^1 f^2$ is exactly the leading eigenvalue of the rank-one operator $\mathbb{W}$: since $\mathbb{W}g = \langle f, g\rangle f$, one has $\mathbb{W}f = \lambda_1 f$ and $\|\mathbb{W}\| = \lambda_1(\mathbb{W}) = \lambda_1$ (chapter 18). Collecting eq. (22.26) and eq. (22.27), the entire type-indexed forward–backward system has collapsed to the *scalar* two-point boundary value problem

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix}\varrho_t\\ \rho_t\end{pmatrix} = \underbrace{\begin{pmatrix} a - b^2 P(t) & -b^2\lambda_1 \\ qs & -(a - b^2 P(t))\end{pmatrix}}_{=:\,M_{\lambda_1}(t)}\begin{pmatrix}\varrho_t\\ \rho_t\end{pmatrix}, \qquad \varrho_0 = \langle f, \bar m_0\rangle \text{ given}, \quad \rho_T = -q_T s_T\,\varrho_T, \tag{22.28}$$

to be compared with the homogeneous LQG BVP eq. (14.15), from which it differs by the single substitution $b^2 \mapsto b^2\lambda_1$ in the off-diagonal — equivalently, by rescaling the coupling.

Step 4: effective coupling and the phase boundary. The product of the off-diagonal entries of M_{λ_1} is $-b^2\lambda_1 \cdot qs = -b^2(qs\lambda_1)$, so eq. (22.28) is identical to the scalar Thread A system eq. (14.15) with the mean-coupling strength rescaled,

$$s \;\longmapsto\; s_{\mathrm{eff}} := s\,\lambda_1 = s\,\lambda_1(\mathbb{W}) = s\,\|\mathbb{W}\|\,. \tag{22.29}$$

Every conclusion of the LQG phase analysis section 14.5 therefore transfers verbatim with $s \to s_{\mathrm{eff}}$. In the normalization of worked computation 14.10 ($a = 0$, $b = 1$, $q = \omega^2$, $q_T = \omega$, $s_T = 0$, so $a - b^2 P \equiv -\omega$), $\det M_{\lambda_1} = \omega^2(s\lambda_1 - 1)$, the eigenvalues are $\pm\omega\sqrt{1 - s\lambda_1}$, and the solvability scalar of lemma 14.5 is $D(T) = \cosh(\nu T) + \frac{\omega}{\nu}\sinh(\nu T) > 0$ for $s\lambda_1 \le 1$ (unique equilibrium at every horizon), while for $s\lambda_1 > 1$, $D(T) = \cos(\mu T) + \frac{\omega}{\mu}\sin(\mu T)$ with $\mu = \omega\sqrt{s\lambda_1 - 1}$, whose first zero is the critical horizon

$$T_c \;=\; \frac{1}{\mu}\Big(\pi - \arctan\tfrac{\mu}{\omega}\Big), \qquad \mu = \omega\sqrt{s\,\lambda_1 - 1} = \omega\sqrt{s\,\lambda_1(\mathbb{W}) - 1}. \tag{22.30}$$

Step 5: reconstructing the full type field. The collapse loses no information: given the scalar solution (ϱ, ρ) of eq. (22.28), the entire field is recovered explicitly. The offsets are $r^x(t) = f(x)\rho(t)$; the means solve eq. (22.24) with this forcing, giving the forward quadrature

$$\bar m^x_t = \Psi(t)\,\bar m^x_0 - b^2 f(x)\,\Psi(t)\int_0^t \Psi(\tau)^{-1}\rho(\tau)\,\mathrm{d}\tau, \qquad \Psi(t) := \exp\int_0^t (a - b^2 P(\tau))\,\mathrm{d}\tau, \tag{22.31}$$

and the variance V_t from the type-independent Lyapunov equation; the value field is eq. (22.21) and the feedback $\alpha^{x,*} = -b(P\xi + f(x)\rho)$. Note the striking feature visible in eq. (22.31): although the initial mean profile $x \mapsto \bar{m}_0^x$ may be arbitrary, only its single projection $\varrho_0 = \langle f, \bar{m}_0 \rangle$ enters the self-consistency; the rest of the profile is transported passively along the type-independent flow Ψ with a type-modulated drift $f(x)\rho(t)$. The infinite-dimensional equilibrium is pinned by one scalar.

Physics note

worked computation 22.15 is the dynamic Curie–Weiss closure on a kernel. The rank-one graphon $W = f \otimes f$ couples every type to a *single* collective mode $\varrho_t = \langle f, \bar{m}_t \rangle$ — the projection of the population onto the eigenvector-centrality profile f — exactly as the Curie–Weiss model couples every spin to the single magnetization. The type-modulation $f(x)$ is the agent's centrality: highly central types ($f(x)$ large) both contribute more to the order parameter and respond more strongly to it. The structural content is normalization-free: the rank-one collapse eq. (22.28) is the scalar Thread A system with the single substitution $s \to s_{\text{eff}} = s\,\lambda_1(\mathbb{W}) = s\,\|\mathbb{W}\|$, so *whatever* the Thread A multiplicity threshold is for the parameters (a, b, q, q_T, s_T, T) at hand, it transfers verbatim with s replaced by $s\,\|\mathbb{W}\|$. The clean value "$= 1$" is special to the normalization of worked computation 14.10 ($a = 0, b = 1, q = \omega^2, q_T = \omega, s_T = 0$), where $\det M_{\lambda_1} = \omega^2(s\lambda_1 - 1)$ makes the threshold $s\,\lambda_1(\mathbb{W}) = 1$ exactly — the dynamic analogue of the critical coupling $J\chi = 1$ of a mean-field ferromagnet, with the bare imitation strength s replaced by s times the leading eigenvalue of the network operator. This is the precise meaning, on the carried thread, of the slogan that "centrality controls equilibrium" and of the operator-norm condition **(A-Coupling)**: in that normalization, uniqueness for all horizons holds when $s\,\|\mathbb{W}\| \le 1$ and the first conjugate horizon appears once $s\,\|\mathbb{W}\| > 1$; for general parameters the same statements hold with the appropriate Thread A threshold, always at coupling $s_{\text{eff}} = s\,\|\mathbb{W}\|$.

Remark 22.16 (Reductions checked)**.** The two reductions promised in the thread specification are now explicit. *Constant kernel:* $W \equiv c$ is rank-one with $f \equiv \sqrt{c}$, so $\lambda_1 = c$, $z_t(x) = c\int_0^1 \bar{m}_t^y \,\mathrm{d}y$ is type-independent, and eq. (22.28) is exactly Thread A eq. (14.15) with $s \to cs$ — recovering the homogeneous LQG MFG with rescaled coupling, as in remark 22.3. *Rank-one kernel:* the general f gives the scalar collapse above, with effective coupling $s\lambda_1(\mathbb{W})$. A genuine *two-block* kernel ($K = 2$ in proposition 22.13) instead gives, by proposition 22.11 with $K = 2$ or proposition 22.13 with two blocks, a 2-dimensional order-parameter BVP and the two-population LQG MFG — a worked instance of the bridge to chapter 30.

Rigor ledger

Proved (or proved modulo cited inputs).

- The graphon MFG system eq. (22.6): a continuum-indexed family of backward HJB / forward FP pairs (definition 22.2), coupled across types only through the integral operator $\mathbb{W}$ via the aggregate eq. (22.2); per-type optimality proposition 22.4 and the equivalence with the fixed point of the field best-response map S (proposition 22.6), under **(A-Lip)**, **(A-Growth)**, **(A-Nondeg)**, **(A-Conv)**, **(A-Reg-W)**.

- The two axes of locality (state versus type, section 22.2.1) and the intrinsic nonlocality-in-type of any graphon coupling; the Ginzburg–Landau analogy and its one failure (no metric/gradient on the type set), with the heat-kernel calibration example 22.7.
- Regularity in the type variable: continuity of the aggregate (lemma 22.8) and measurability/continuity of $x \mapsto (u^x, m^x)$ (proposition 22.9), via the stability lemmas of chapter 10.
- Finite-rank/Mercer reduction to K order parameters (proposition 22.11); block graphons recover multi-population MFG eq. (22.17) exactly (proposition 22.13), the bridge to chapter 30.
- Thread B, dynamic layer: the rank-one graphon LQG collapses to the scalar two-point BVP eq. (22.28) with effective coupling $s_{\text{eff}} = s\,\lambda_1(\mathbb{W}) = s\,\|\mathbb{W}\|$ (worked computation 22.15, eq. (22.29)), and the LQG phase boundary theorem 14.11 transfers with $s \to s\,\|\mathbb{W}\|$ (eq. (22.30)).

Assumed.

- The standing assumptions, now uniformly in the type, for the per-type well-posedness and verification; **(A-Reg-W)** for the aggregate and its regularity. The single-step HJB and FP well-posedness and stability of chapters 5, 6 and 10 are imported, not reproved.
- The dynamic GMFG setup — continuum of typed agents, field of measures, the operator coupling — is taken from chapter 21.

Deferred.

- Existence of a fixed point of the field best-response map S, i.e. of a solution to eq. (22.6), and uniqueness via **(A-Mon)** plus the operator-norm smallness **(A-Coupling)** at effective coupling $s_{\text{eff}} = s\,\|\mathbb{W}\|$ (the threshold $s\,\|\mathbb{W}\| = 1$ in the worked computation 14.10 normalization): chapter 24.
- The probabilistic (graphon-FBSDE) rendering of the same equilibrium and its equivalence with this PDE system: chapter 23.
- The finite-network ($G(N, W)$) justification of the heuristic closure and the ε-Nash property on large graphs: chapter 25.
- The graphon master equation and common noise: chapter 26; the full heterogeneity zoo built on proposition 22.13: chapter 30; numerical solution by type-grid quadrature of $\mathbb{W}$: chapter 28.

Open (at the research frontier).

- Well-posedness for non-separable (congestion-type) graphon Hamiltonians, where the feedback itself depends on the aggregate and the type-coupling enters the forward drift nonlinearly.

- Sharp uniqueness thresholds beyond the monotone/small-coupling regime: the interaction of strategic monotonicity with the full spectrum of $\mathbb{W}$ (not only $\|\mathbb{W}\|$) is not understood; worked computation 22.15 solves only the rank-one corner.
- Local-in-state couplings with type-dependent regularity, and the degenerate limit of diagonal-concentrating kernels (the "each type alone" boundary of section 22.2.1), outside dense-graphon theory (chapter 27).

Bibliographic notes

The dynamic graphon mean field game system eq. (22.6) is due to Caines and Huang, who introduced the GMFG equations and the coupling through the graphon operator [33, 34]; our presentation, organized around the per-type verification and the field best-response map, is the analytic lift of the homogeneous system of Lasry and Lions [93] as developed in Cardaliaguet's notes [36] (chapter 8), with the type-coupling isolated in $\mathbb{W}$. The static shadow of the centrality-controls-equilibrium principle, and the operator-norm threshold, are from Parise and Ozdaglar's graphon games [108] (chapter 20); the stochastic/dynamic graphon game and its linear–quadratic solvability, which underlies the worked computation worked computation 22.15, are treated by Carmona, Cooney, Graves and Laurière in the static case [39] and by Aurell, Carmona and Laurière in the linear–quadratic dynamic case [10], whose rank-one collapse to a scalar order parameter is the same phenomenon recorded here. The spectral facts about $\mathbb{W}$ — self-adjoint Hilbert–Schmidt structure, leading eigenvalue as operator norm, eigenvector centrality — are from the graphon-operator theory of chapter 18, following Lovász [99]. The regularity-in-type arguments of section 22.3 are the parametrized form of the stability estimates of chapter 10; the measurability half needs no selection theorem, only that a Borel map composed with the continuous single-valued solution operators (single-valuedness being **(A-Conv)**) is Borel — for the set-valued case that **(A-Conv)** excludes, the relevant Kuratowski–Ryll-Nardzewski selection theory is in [6]. The block-graphon identification of proposition 22.13 with multi-population MFG is folklore made precise here as the bridge to the heterogeneity survey [11] taken up in chapter 30. The Ginzburg–Landau reading, and the warning that the type set carries no metric, follow the notational doctrine of appendix A; the heat-kernel calibration example 22.7 is the graphon analogue of the gradient expansion of a nonlocal field theory. The LQG template and its phase boundary, transferred here with the effective coupling $s\,\|\mathbb{W}\|$, are the capstone chapter 14, after [82]; numerical confirmation by type-grid quadrature is chapter 28, following [1].

Chapter 23

Probabilistic Graphon Mean Field Games

In chapter 22 the dynamic graphon mean field game was written, following the analytic route of chapter 8, as a continuum-indexed family of coupled partial differential equations: for each type $x \in [0,1]$ a backward Hamilton–Jacobi–Bellman equation for the value $u^x(t,\cdot)$ of the representative type-x agent, and a forward Fokker–Planck equation for the type-x population law m_t^x, the two families coupled across types *only* through the graphon integral operator $\mathbb{W}$ of chapter 21. This chapter develops the *probabilistic* picture of the same equilibrium. We do for the graphon game exactly what chapter 9 did for the homogeneous game: we replace the two PDE families by a single *forward–backward stochastic differential equation*, now a continuum-indexed McKean–Vlasov FBSDE, in which the representative agent is a whole family $(X_t^x)_{x\in[0,1]}$ of controlled processes interacting through the nonlocal kernel $\int_0^1 W(x,y)\,(\cdots)\,\mathrm{d}y$.

The tools are imported wholesale. The stochastic maximum principle, the generalized (Pontryagin) Hamiltonian $\mathcal{H}$, the adjoint backward SDE, and the FBSDE–PDE dictionary $Y_t = \nabla u(t, X_t)$ are the content of chapter 9; we reuse them verbatim *type by type*, the only novelty being that the measure argument seen by a type-x agent is the graphon-averaged neighbour field $(\mathbb{W}\boldsymbol{m}_t)(x)$ rather than the agent's own law. The McKean–Vlasov self-consistency — the law of the optimally controlled process feeding back into the coefficients — is the closure of chapter 7, now imposed on a *field* of laws indexed by type. The functional-analytic home of that field, the space of square-integrable measure-valued maps on $[0,1]$ and the boundedness of $\mathbb{W}$ on it, rests on chapter 2 (Hilbert–Schmidt operators, the spectral theorem, the fixed-point theorems) and on the Wasserstein geometry of chapter 4. These four imports are a plan, not a citation dump, and it is worth saying in one line each what each buys: the maximum principle of chapter 9 converts each type's optimization into a forward–backward pair of SDEs; the closure of chapter 7 feeds the law of that pair's forward leg back into its own coefficients; the Wasserstein geometry of chapter 4 is the ruler that measures distances between the resulting laws; and the operator theory of chapter 2 controls how those distances propagate from one type to another. Threaded through all four is a single organizing thesis, stated here so the reader carries it from the first page: *the entire cross-type coupling of the graphon game is one bounded linear operator,* $\mathbb{W}$. Each type-x agent solves a copy of a classical single-population problem, and the types communicate *only* through $\mathbb{W}$; so every difficulty special to the continuum — and, as chapter 24 will show, the very threshold at which uniqueness fails — reduces to a statement about that one operator. This is what makes the continuum tractable, and it is the spine of the whole chapter. The reader should keep chapter 22 open throughout: the payoff of the chapter, assembled in section 23.5, is the precise dictionary between the FBSDE objects here and the PDE objects there — the graphon analogue of the two-pictures result proposition 9.12 — and, in section 23.6, the exact diagonalization of the continuum into independent normal modes that displays that threshold in closed form.

We are careful about what we do *not* do. Existence and uniqueness of the graphon equilibrium, with its dependence on the operator norm $\|\mathbb{W}\|$ and on graphon monotonicity, are stated here so the fixed-point structure is visible, but their proofs belong to chapter 24; the descent from the continuum to a finite sampled network $G(N, W)$ — the propagation-of-chaos statement that justifies the whole construction — belongs to chapter 25; the measure-dependent decoupling field that seeds the graphon master equation belongs to chapter 26. Our job is to set up the graphon FBSDE cleanly, to exhibit its fixed-point structure in the right Bochner space, and to prove its equivalence with the PDE system of chapter 22 under regularity. The carried Thread B (the graphon linear–quadratic–Gaussian model) is advanced one layer in section 23.6, where the probabilistic formulation diagonalizes the continuum of agents into independent normal modes indexed by the spectrum of $\mathbb{W}$.

Notation watch

Brownian motion is B, the graphon is $W = W$. As fixed in Appendix A and announced at the start of Part IV, in every chapter where a graphon is in scope the letter W is reserved for the kernel $W(x, y)$ and Brownian motion is written B_t. This is the first chapter of the book in which both objects appear inside the *same* stochastic equation, and the clash is unavoidable precisely here: the probabilistic avatar of the game writes the noise driving an agent and the network coupling between agents into a single line — the state SDE eq. (23.3) carries $\mathrm{d}B^x$ and $\mathbb{W}$ side by side — whereas in chapter 22 the kernel lived in the PDE coupling and no Brownian motion was ever written, so the two letters never met. We therefore restate the rule once and obey it without exception: in any displayed SDE below, W (and $\mathbb{W}$) is the network coupling and B^x is the noise driving the type-x state. The superscript on B^x is a *type label*, not a power and not a spatial coordinate (Appendix A); the family $(B^x)_{x\in[0,1]}$ is a continuum of Brownian motions whose joint realization raises a measurability subtlety addressed in remark 23.6.

We retain the global conventions. The value u^x and its stochastic avatar, the costate Y^x, are anchored by *terminal* data at $t = T$ and run *backward*; the state X^x and the law field run *forward* from $t = 0$. The coupling of data at opposite ends of $[0, T]$, the structural signature of a mean field game, survives into the graphon setting and into each of its equivalent forms.

23.1 The graphon McKean–Vlasov stochastic differential equation

Before any optimization enters, we meet the descriptive object on which the equilibrium will eventually be built. In the homogeneous theory of Part II this was the McKean–Vlasov SDE eq. (7.4): a single representative diffusion whose own law feeds back into its coefficients. The graphon version replaces that one process by a continuum $(X^x)_{x\in[0,1]}$ of interacting diffusions, one per type, and replaces the single self-referential law by a whole *field* of laws. Stripping the game away first is deliberate. It lets us isolate, in the cleanest possible setting, the one ingredient that is genuinely new in passing from chapter 9 to the graphon — the nonlocal, type-dependent coupling — and to see at once that this coupling is carried entirely by the operator $\mathbb{W}$, exactly as the chapter preamble promised. When we add optimization in section 23.3, it will change the drift but leave this coupling structure untouched; so every fact we establish here about how $\mathbb{W}$ moves measures around survives verbatim into the game. The plan of the section is to define the field of laws and its $\mathbb{W}$-aggregate, write the descriptive SDE and its self-consistent closure, prove well-posedness by a field-valued fixed point, and read off the forward Fokker–Planck equation that is the population half of the chapter 22 system.

23.1.1 The field of laws and the graphon aggregate

What state variable does a graphon population carry? In the homogeneous game a single probability measure m_t summarized everyone, because every agent saw the same population. Here the population is stratified by type, and a type-x agent does not react to the global law but to the laws of its *neighbours*, weighted by the kernel $W(x,\cdot)$. The right bookkeeping object is therefore no longer one measure but a measurable assignment of a law to each type — a *field of laws* — together with the rule that compresses such a field into the single neighbour measure an agent of a given type actually feels. We define the two in turn and then read off the structural fact, "one operator carries all the coupling," that organizes the rest of the chapter.

Throughout, $(\Omega,\mathcal{F},\mathbb{F},\mathbb{P})$ is a filtered probability space carrying, for each type $x\in[0,1]$, a k-dimensional Brownian motion B^x; the joint structure of the family is discussed in remark 23.6. The state of a type-x agent is an $\mathbb{R}^d$-valued process $X^x=(X^x_t)_{0\le t\le T}$.

Definition 23.1 (Field of laws)**.** A *field of laws* (or measure-valued map) is a Borel-measurable map

$$\boldsymbol{m}:[0,1]\longrightarrow\mathcal{P}_2(\mathbb{R}^d),\qquad x\longmapsto m^x,$$

where measurability is with respect to the Borel σ-algebra of $(\mathcal{P}_2(\mathbb{R}^d),\mathcal{W}_2)$ (theorem 4.8). We write $\boldsymbol{m}=(m^x)_{x\in[0,1]}$. A *flow* of fields is a map $t\mapsto\boldsymbol{m}_t$, $\boldsymbol{m}_t=(m^x_t)$, and we say it is square-integrable when $\int_0^1\int_{\mathbb{R}^d}|\xi|^2\,m^x(\mathrm{d}\xi)\,\mathrm{d}x<\infty$. The functional space these fields inhabit, with its metric and topology, is recalled and refined in section 23.2; it is the space introduced in chapter 21 for the analytic theory.

The interaction is built from $\boldsymbol{m}$ by the graphon operator. Recall from definition 2.23 and chapter 21 that $\mathbb{W}$ acts on scalar functions by $(\mathbb{W}f)(x)=\int_0^1 W(x,y)f(y)\,\mathrm{d}y$. We lift it to fields of measures componentwise.

Definition 23.2 (Graphon aggregate of a field)**.** For a field of laws $\boldsymbol{m} = (m^y)_{y\in[0,1]}$ the *graphon-averaged neighbour field* is the type-indexed measure

$$(\mathbb{W}\boldsymbol{m})(x) \;:=\; \int_0^1 W(x,y)\, m^y \;\mathrm{d}y \;\in\; \mathcal{M}_+(\mathbb{R}^d), \tag{23.1}$$

the finite positive measure acting on a test set A by $(\mathbb{W}\boldsymbol{m})(x)(A) = \int_0^1 W(x,y)\, m^y(A)\;\mathrm{d}y$. Its total mass is $\int_0^1 W(x,y)\;\mathrm{d}y \le 1$ under **(A-Reg-W)**, so $(\mathbb{W}\boldsymbol{m})(x)$ is a *sub-probability* measure. For a measurable function $h : \mathbb{R}^d \to \mathbb{R}^n$ of at most quadratic growth we write

$$(\mathbb{W}\langle h, \boldsymbol{m}\rangle)(x) \;=\; \int_0^1 W(x,y)\Big(\int_{\mathbb{R}^d} h(\xi)\, m^y(\mathrm{d}\xi)\Big)\,\mathrm{d}y \;=\; \int_{\mathbb{R}^d} h(\xi)\,(\mathbb{W}\boldsymbol{m})(x)(\mathrm{d}\xi) \;\in\; \mathbb{R}^n, \tag{23.2}$$

the graphon average of the h-moment of the field; for $h(\xi) = \xi$ this is the type-x neighbour mean $z_t(x) = \int \xi\,(\mathbb{W}\boldsymbol{m}_t)(x)(\mathrm{d}\xi)$ used by Thread B. This first moment is the *graphon-local* coupling on which the general existence theory of chapter 24 is developed (definition 24.3): there the agent couples only to the vector $z_t(x)$, the specialization of the measure-valued aggregate eq. (23.1) obtained by reading off its first moment.

The reason eq. (23.1) is exactly the right object is structural: the only way types talk to one another in a graphon model is through W, and W is a *linear* kernel. Consequently the entire cross-type coupling of the dynamics below is carried by the single bounded linear operator $\mathbb{W}$ acting on the field; everything else in the problem is a copy, indexed by x, of a classical single-population object. This "one operator carries all the coupling" principle is what makes the continuum tractable, and we exploit it repeatedly — decisively in the worked computation of section 23.6, where diagonalizing $\mathbb{W}$ uncouples the continuum entirely.

One point in definition 23.2 deserves to be dwelt on, because it is easy to read past and it recurs in every estimate: the aggregate $(\mathbb{W}\boldsymbol{m})(x)$ is in general a *sub-probability* measure, of total mass the row-sum $\int_0^1 W(x,y)\;\mathrm{d}y \le 1$, not a probability measure. A concrete micro-example makes the meaning plain. Suppose the kernel vanishes on the first half of the types, $W(x,\cdot) \equiv 0$ for $x \in [0, \frac{1}{2})$, and equals $\frac{1}{3}$ on a band for the rest, so that the row-sum is 0 for $x < \frac{1}{2}$ and (say) $\frac{1}{3}$ for $x \ge \frac{1}{2}$. Then an agent in the first half has $(\mathbb{W}\boldsymbol{m})(x)$ equal to the *zero* measure: it feels no neighbours at all and is, dynamically, an isolated particle. An agent in the second half feels a measure of mass $\frac{1}{3}$ — one third of a probability measure. The missing mass is not an error to be normalized away; it is information. It records exactly how weakly type x is embedded in the network. We deliberately do *not* divide by the row-sum to renormalize $(\mathbb{W}\boldsymbol{m})(x)$ into a probability measure, because the dynamics below couple an agent to the *total weighted amount* of neighbour influence it receives, and an isolated agent ($x < \frac{1}{2}$ here) genuinely receives none. This unnormalized convention is also what makes the mass bound ≤ 1 do real work: it is precisely the inequality that will show $\mathbb{W}$ to be a contraction of the field space in lemma 23.10, with the contraction constant the row-sum and the worst case mass exactly 1.

23.1.2 The dynamics

With the field and its aggregate in hand, writing down the dynamics is now almost mechanical: we take the homogeneous McKean–Vlasov SDE eq. (7.4) and substitute the neighbour aggregate $(\mathbb{W}\boldsymbol{m}_t)(x)$ wherever that equation used the agent's own law. The diffusion machinery — existence, uniqueness, moment bounds for a single Itô SDE — is the familiar apparatus of chapter 5; the entire novelty sits in the measure argument, and through it, in the operator $\mathbb{W}$. It is worth keeping this division of labour in view as we proceed: everything hard about the continuum lives in one place.

Definition 23.3 (Graphon McKean–Vlasov SDE)**.** Let $b : [0,T] \times [0,1] \times \mathbb{R}^d \times \mathcal{M}_+(\mathbb{R}^d) \to \mathbb{R}^d$ and $\sigma : [0,T] \times [0,1] \times \mathbb{R}^d \times \mathcal{M}_+(\mathbb{R}^d) \to \mathbb{R}^{d\times k}$ be measurable. The *graphon McKean–Vlasov SDE* is the continuum-indexed system

$$\mathrm{d}X_t^x \;=\; b\big(t, x, X_t^x, (\mathbb{W}\boldsymbol{m}_t)(x)\big)\ \mathrm{d}t \;+\; \sigma\big(t, x, X_t^x, (\mathbb{W}\boldsymbol{m}_t)(x)\big)\ \mathrm{d}B_t^x, \qquad X_0^x \sim m_0^x, \tag{23.3}$$

subject to the *self-consistency* (closure) condition

$$m_t^x \;=\; \mathrm{Law}\left(X_t^x\right) \qquad \text{for every } x \in [0,1],\ t \in [0,T]. \tag{23.4}$$

A *solution* is a field of processes $(X^x)_{x\in[0,1]}$, each adapted with $\mathbb{E}\sup_{t\le T}|X_t^x|^2 < \infty$, together with the flow of fields $\boldsymbol{m}_t = (\mathrm{Law}(X_t^x))_x$, such that eq. (23.3) holds $\mathbb{P}$-a.s. for a.e. x and the map $x \mapsto \mathrm{Law}(X_t^x)$ is measurable into $\mathcal{P}_2(\mathbb{R}^d)$ for each t.

The interaction in eq. (23.3) enters *only* through the graphon-averaged neighbour field $(\mathbb{W}\boldsymbol{m}_t)(x)$ defined in eq. (23.1) — the rigorous content of the informal coupling "$\int_0^1 W(x,y)(\cdots)\,\mathrm{d}y$." Two reductions, demanded by the thread specification and used as sanity checks throughout Part IV, recover familiar objects.

Remark 23.4 (Reduction checks)**.** These two collapses are the sanity checks we run on every graphon object as Part IV proceeds; they verify that the new machinery degenerates correctly to objects we already trust, and they preview the spectral picture of section 23.6.

Constant graphon. If $W(x,y) \equiv c$ then the aggregate loses its x-dependence entirely: $(\mathbb{W}\boldsymbol{m}_t)(x) = c\int_0^1 m_t^y\ \mathrm{d}y$ is the *same* measure for every type, namely c times the type-averaged population. Every agent now sees the identical neighbour field, so the type label drops out of the measure argument and the continuum eq. (23.3) collapses to a single homogeneous McKean–Vlasov SDE in the sense of definition 7.7, with the global law (scaled by c) as its measure argument. chapter 7 is recovered exactly. In spectral terms this is the case where the only nonzero eigenvalue of $\mathbb{W}$ is $\lambda_1 = c$ on the constant eigenfunction — a *single* active mode — which is why the continuum carries no genuinely new information.

Rank-one graphon. If $W(x,y) = f(x)f(y)$ with $f \ge 0$ a centrality profile, then

$$(\mathbb{W}\boldsymbol{m}_t)(x) = f(x)\int_0^1 f(y)\, m_t^y\ \mathrm{d}y,$$

the global f-weighted population, a measure independent of x, scaled pointwise by the centrality $f(x)$. The cross-type coupling has rank one: it factors through a single global object modulated by where in the network each agent sits. Reading off the first moment exhibits the cleanest form of this, the form used in Thread B: with $\bar{m}^y_t = \int \xi\, m^y_t(\mathrm{d}\xi)$ the type-y mean, the neighbour mean is $z_t(x) = \int \xi\, (\mathbb{W}\boldsymbol{m}_t)(x)(\mathrm{d}\xi) = f(x) \int_0^1 f(y)\bar{m}^y_t \,\mathrm{d}y = f(x)\,\varrho_t$, a single scalar *order parameter* $\varrho_t = \langle f, \bar{m}_t\rangle$ times the centrality profile. A continuum of coupled agents has degenerated to one self-consistent scalar equation for ϱ_t — the rank-one reduction promised by the thread specification, and the cleanest worked example of a graphon mean field game. Both collapses are the probabilistic shadow of the spectral structure that section 23.6 exploits in full: there $\mathbb{W}$ is diagonalized and the continuum splits into one independent scalar game per eigenmode, the constant and rank-one cases being the one-mode instances.

Well-posedness of eq. (23.3)–eq. (23.4) is the graphon version of theorem 7.9 and uses the same fixed-point mechanism, now on the field space of section 23.2.

Proposition 23.5 (Well-posedness of the graphon McKean–Vlasov SDE)**.** *Assume* ***(A-Lip)*** *and* ***(A-Growth)*** *(Lipschitz and linear growth of b, σ in the state, uniformly in (t, x) and in the measure argument with respect to the metric of section 23.2) and* ***(A-Reg-W)****. Suppose the initial field $\boldsymbol{m}_0 = (m^x_0)$ is measurable and square-integrable. Then eq.* (23.3)*–eq.* (23.4) *has a unique solution; the flow $t \mapsto \boldsymbol{m}_t$ is continuous into the field space and depends Lipschitz-continuously on $\boldsymbol{m}_0$.*

Proof sketch. The whole argument is a fixed point on the flow of fields, and it has exactly three moving parts: *freeze* the field to decouple the continuum, *estimate* how the resulting law map contracts in the field metric, and *iterate* to a contraction. We give each.

Freeze the field; the continuum decouples. Fix a candidate flow of fields $\boldsymbol{\mu} = (\boldsymbol{\mu}_t)_{t\le T}$ in the complete space $C([0, T]; \boldsymbol{\mathcal{P}}_2)$ of definition 23.8. The coupling in eq. (23.3) enters *only* through $(\mathbb{W}\boldsymbol{\mu}_t)(x)$, and once $\boldsymbol{\mu}$ is frozen this is a known, *deterministic*, time-dependent measure attached to type x — it no longer references the unknown processes. Substituting it into the drift and volatility turns the coupled continuum into a family, indexed by x, of *ordinary* (non-McKean–Vlasov) SDEs,

$$\mathrm{d}X^{\boldsymbol{\mu},x}_t = b(t, x, X^{\boldsymbol{\mu},x}_t, (\mathbb{W}\boldsymbol{\mu}_t)(x))\,\mathrm{d}t + \sigma(t, x, X^{\boldsymbol{\mu},x}_t, (\mathbb{W}\boldsymbol{\mu}_t)(x))\,\mathrm{d}B^x_t, \quad X^{\boldsymbol{\mu},x}_0 \sim m^x_0,$$

each driven by its own Brownian motion B^x and coupled to nothing else. Under **(A-Lip)** and **(A-Growth)** the coefficients $x \mapsto b(t, x, x, \cdot)$, $x \mapsto \sigma(t, x, x, \cdot)$ are Lipschitz with linear growth uniformly in (t, x), so for each x this single SDE has a unique strong, square-integrable solution $X^{\boldsymbol{\mu},x}$ by theorem 5.10. Define the *descriptive law map* (we write it $\boldsymbol{\Psi}$, reserving S for the best-response map of definition 23.15 once optimization is present) $\boldsymbol{\Psi}(\boldsymbol{\mu}) = (\mathrm{Law}(X^{\boldsymbol{\mu},x}_t))_{x\in[0,1],\, t\le T}$. A solution of eq. (23.3)–eq. (23.4) is exactly a fixed point of $\boldsymbol{\Psi}$, since the closure $m^x_t = \mathrm{Law}(X^x_t)$ is the statement that the frozen field equals the realized one.

The one-step estimate. Take two frozen flows $\boldsymbol{\mu}, \boldsymbol{\nu}$ and the corresponding solutions $X^{\boldsymbol{\mu},x}, X^{\boldsymbol{\nu},x}$ driven by the *same* B^x (a synchronous coupling, legitimate type by type). Subtracting the two SDEs, applying Itô to $|X^{\boldsymbol{\mu},x}_s - X^{\boldsymbol{\nu},x}_s|^2$, using the Lipschitz bound on b, σ in *both* the state and the measure argument (the latter measured by $\mathcal{W}_2$, per section 23.2), the Burkholder–Davis–Gundy inequality on the martingale part, and Grönwall's inequality lemma C.1 in time gives the standard

SDE stability estimate

$$\mathbb{E}\sup_{s\le t}|X_s^{\boldsymbol{\mu},x}-X_s^{\boldsymbol{\nu},x}|^2 \;\le\; C\int_0^t \mathcal{W}_2\big((\mathbb{W}\boldsymbol{\mu}_s)(x),(\mathbb{W}\boldsymbol{\nu}_s)(x)\big)^2\,\mathrm{d}s,$$

the constant C depending only on the Lipschitz constants and T (the initial data coincide, so no x-dependent constant survives). Because $\mathcal{W}_2(\mathrm{Law}\,\xi,\mathrm{Law}\,\eta)^2\le\mathbb{E}\,|\xi-\eta|^2$ for any coupling, the left side dominates $\mathcal{W}_2(\boldsymbol{\Psi}(\boldsymbol{\mu})_t^x,\boldsymbol{\Psi}(\boldsymbol{\nu})_t^x)^2$. Now integrate over x and *here* the cross-type coupling is controlled by the field contraction eq. (23.11) of lemma 23.10: integrating the displayed bound in x and applying eq. (23.11) pointwise in s,

$$\mathbf{d}_{2,t}\big(\boldsymbol{\Psi}(\boldsymbol{\mu}),\boldsymbol{\Psi}(\boldsymbol{\nu})\big)^2=\int_0^1\mathcal{W}_2\big(\boldsymbol{\Psi}(\boldsymbol{\mu})_t^x,\boldsymbol{\Psi}(\boldsymbol{\nu})_t^x\big)^2\,\mathrm{d}x\le C\int_0^t\int_0^1\mathcal{W}_2\big((\mathbb{W}\boldsymbol{\mu}_s)(x),(\mathbb{W}\boldsymbol{\nu}_s)(x)\big)^2\,\mathrm{d}x\;\mathrm{d}s\le C\;\|\mathbb{W}\mathbf{1}\|_\infty\int_0^t\mathbf{d}_{2,s}(\boldsymbol{\mu}$$

where $\mathbf{d}_{2,t}(\boldsymbol{\mu},\boldsymbol{\nu})^2=\int_0^1\mathcal{W}_2(\boldsymbol{\mu}_t^x,\boldsymbol{\nu}_t^x)^2\,\mathrm{d}x$. Absorbing $\|\mathbb{W}\mathbf{1}\|_\infty\le 1$ into C (it can only *lower* the constant, by lemma 23.10) yields the displayed inequality

$$\mathbf{d}_{2,t}\big(\boldsymbol{\Psi}(\boldsymbol{\mu}),\boldsymbol{\Psi}(\boldsymbol{\nu})\big)^2\;\le\;C\int_0^t\mathbf{d}_{2,s}(\boldsymbol{\mu},\boldsymbol{\nu})^2\,\mathrm{d}s,\tag{23.5}$$

with C depending only on the Lipschitz constants and T. This is the crux: the only place where the continuum's cross-type interaction could have produced an unbounded constant is the x-integration, and lemma 23.10 caps it at the row-sum, which is ≤ 1 no matter how strong the kernel.

Iterate to a contraction. Inequality eq. (23.5) is a time-integral (Volterra) bound, and iterating it integrates a kernel against itself. Writing $D_t=\sup_{s\le t}\mathbf{d}_{2,s}(\boldsymbol{\mu},\boldsymbol{\nu})^2$ and applying eq. (23.5) to $\boldsymbol{\Psi}^n$ repeatedly, the n-fold composition obeys

$$\mathbf{d}_{2,t}\big(\boldsymbol{\Psi}^n(\boldsymbol{\mu}),\boldsymbol{\Psi}^n(\boldsymbol{\nu})\big)^2\;\le\;C^n\int_0^t\int_0^{t_1}\cdots\int_0^{t_{n-1}}D_{t_n}\,\mathrm{d}t_n\cdots\mathrm{d}t_1\;\le\;\frac{(Ct)^n}{n!}\,D_T,$$

the factor $1/n!$ being the volume of the time simplex $\{0\le t_n\le\cdots\le t_1\le t\}$. Taking the supremum over $t\le T$ gives $\mathbf{d}_{2,\infty}(\boldsymbol{\Psi}^n\boldsymbol{\mu},\boldsymbol{\Psi}^n\boldsymbol{\nu})^2\le\frac{(CT)^n}{n!}\,\mathbf{d}_{2,\infty}(\boldsymbol{\mu},\boldsymbol{\nu})^2$. Since $(CT)^n/n!\to 0$, for n large enough this factor is <1 and $\boldsymbol{\Psi}^n$ is a contraction on $C([0,T];\boldsymbol{\mathcal{P}}_2)$. The Banach fixed-point theorem theorem 2.36, applied to a power of $\boldsymbol{\Psi}$ on the complete space (lemma 23.10), yields a unique fixed point, which is the unique solution; the Lipschitz dependence on $\boldsymbol{m}_0$ comes from carrying the initial-data difference through the same estimate. Measurability of $x\mapsto\mathrm{Law}(X_t^x)$ is preserved at each Picard step (the solution depends measurably on the frozen coefficient field) and passes to the limit. The argument is the field-valued version of theorem 7.9; the single new ingredient is the field contraction lemma 23.10 that turned the x-integration into a bounded operation. The same construction is carried out in full for the graphon mean field system in [15], to which we refer for further detail. ☐

Remark 23.6 (A continuum of Brownian motions, honestly)**.** The family $(B^x)_{x\in[0,1]}$ in eq. (23.3) is a continuum of *independent* Brownian motions, and there is a genuine measure-theoretic obstruction to realizing it on an ordinary product space. Frozen at a single time, the values $\xi^x=B_t^x$ would form a jointly measurable map $(x,\omega)\mapsto\xi^x(\omega)$ on $[0,1]\times\Omega$ whose marginals are mutually independent, identically distributed, and nondegenerate (here mean 0, variance $t>0$). No such map exists, and the reason is a clean Fubini contradiction. Suppose it did. For any Borel set $B\subseteq[0,1]$ of positive

Lebesgue measure put $A_B(\omega) = \int_B \xi^x(\omega)\, \mathrm{d}x$; joint measurability and square-integrability make Fubini available, so

$$\operatorname{Var}(A_B) = \int_B \int_B \operatorname{Cov}\left(\xi^x, \xi^y\right)\, \mathrm{d}x\, \mathrm{d}y.$$

Independence forces $\operatorname{Cov}(\xi^x, \xi^y) = 0$ for $x \neq y$, and the diagonal $\{x = y\}$ is Lebesgue-null in $B \times B$, so the double integral vanishes: $\operatorname{Var}(A_B) = 0$, i.e. *every* block integral A_B is almost surely the constant $\mathbb{E}A_B = 0$. Apply this along a countable basis of intervals B: for a.e. ω the sample function $x \mapsto \xi^x(\omega)$ is an L^2 function all of whose interval averages vanish, whence by the Lebesgue differentiation theorem $\xi^x(\omega) = 0$ for a.e. x — the family is almost surely identically zero, contradicting variance $t > 0$. The tension is exactly the one the slogan names: the sample average over types must be deterministic (Fubini), yet a genuinely i.i.d. nondegenerate family makes every average random. Three honest resolutions are used in the literature, and we name them rather than paper over the gap. (i) *Work with the deterministic field of laws.* The equilibrium object of this chapter is the measurable map $x \mapsto \operatorname{Law}(X_t^x)$, which is deterministic; every statement we prove is either "for each fixed x" or "for the measurable field of marginals," and neither needs a joint realization. (ii) *Fubini extension.* One enlarges $([0, 1] \times \Omega)$ to a *rich Fubini extension* on which an essentially pairwise independent continuum of processes does exist and an exact law of large numbers holds; this is the framework of the stochastic-graphon-game literature [39, 10]. (iii) *Countable dense skeleton.* One realizes independent B^x on a countable dense set of types and extends by the measurable-field structure, which suffices for the L^2-in-type statements we make. We adopt reading (i) as primary: eq. (23.3) is shorthand for the per-type SDE together with the measurable, deterministic closure eq. (23.4), and no statement below depends on a pathwise joint realization of the continuum. The finite-N sampled network of chapter 25, where only finitely many independent noises appear, is where a genuine joint realization is both available and needed.

23.1.3 The nonlinear graphon Fokker–Planck equation

As in the homogeneous case (theorem 7.17), the flow of marginals of a graphon McKean–Vlasov solution satisfies a forward equation, now one for each type, coupled across types through $\mathbb{W}$. This is exactly the forward half of the graphon MFG system of chapter 22.

Proposition 23.7 (Graphon Fokker–Planck)**.** *Under the hypotheses of proposition 23.5, with* ***(A-Nondeg)*** *so that the type-x generator*

$$(\mathcal{A}_t^x \phi)(x) = b\big(t, x, x, (\mathbb{W}\boldsymbol{m}_t)(x)\big) \cdot \nabla\phi(x) + \tfrac{1}{2} \operatorname{tr}\Big(\sigma\sigma^\top\big(t, x, x, (\mathbb{W}\boldsymbol{m}_t)(x)\big)\, \mathrm{D}^2 \phi(x)\Big)$$

is uniformly parabolic, the field of marginals $\boldsymbol{m}_t = (m_t^x)$ is, for a.e. x, the unique weak solution of the forward Kolmogorov equation

$$\partial_t m_t^x \;=\; \big(\mathcal{A}_t^x\big)^* m_t^x, \qquad m_0^x = m_0^x, \tag{23.6}$$

with $(\mathcal{A}_t^x)^* = \mathcal{A}^*$ the Fokker–Planck operator of Appendix A. The system eq. (23.6) is nonlinear and nonlocal: its coefficients depend on the whole field $\boldsymbol{m}_t$ through $(\mathbb{W}\boldsymbol{m}_t)(x)$.

Proof sketch. Fix x and freeze the field by the closure eq. (23.4), so that the coefficients $b(t, x, \cdot, (\mathbb{W}\boldsymbol{m}_t)(x))$ and $\sigma(t, x, \cdot, (\mathbb{W}\boldsymbol{m}_t)(x))$ are known, deterministic functions of (t, x) and X^x is an ordinary Itô diffusion with generator $\mathcal{A}_t^x$. The derivation is then the single-particle Kolmogorov computation of chapter 5, reproduced in theorem 7.17. For a test function $\phi \in C_c^\infty(\mathbb{R}^d)$, Itô's formula gives

$$\mathrm{d}\,\phi(X_t^x) = \big(\mathcal{A}_t^x \phi\big)(X_t^x)\ \mathrm{d}t + \nabla\phi(X_t^x)^\top \sigma\big(t, x, X_t^x, (\mathbb{W}\boldsymbol{m}_t)(x)\big)\ \mathrm{d}B_t^x.$$

Taking expectations annihilates the Itô integral (its integrand is square-integrable, so it is a true martingale), leaving $\frac{\mathrm{d}}{\mathrm{d}t}\mathbb{E}\,\phi(X_t^x) = \mathbb{E}(\mathcal{A}_t^x\phi)(X_t^x)$. Writing $\mathbb{E}\,\phi(X_t^x) = \int \phi\ \mathrm{d}m_t^x$ and $\mathbb{E}(\mathcal{A}_t^x\phi)(X_t^x) = \int \mathcal{A}_t^x\phi\ \mathrm{d}m_t^x$ turns this into the weak form $\frac{\mathrm{d}}{\mathrm{d}t}\langle \phi, m_t^x\rangle = \langle \mathcal{A}_t^x\phi, m_t^x\rangle = \langle \phi, (\mathcal{A}_t^x)^* m_t^x\rangle$, valid for every test ϕ, which is precisely the distributional statement eq. (23.6). Under **(A-Nondeg)** the generator is uniformly parabolic, so the marginal has a density and the weak solution is the unique classical one. The two adjectives in the statement enter at exactly one place, the closure eq. (23.4): it makes the frozen coefficient at type x a functional of the unknown field. The dependence is *nonlinear* because $(\mathbb{W}\boldsymbol{m}_t)(x)$ contains the solution m_t^x itself, and *nonlocal in type* because $\mathbb{W}$ averages over *all* types y — the density at type x is driven by coefficients built from m_t^y for every y with $W(x, y) > 0$. Strip the closure away and each eq. (23.6) is a plain linear Fokker–Planck equation; it is the self-consistency that couples the continuum. Measurability in x of the solution field is part of the well-posedness already established in proposition 23.5. □

The forward equation eq. (23.6) is precisely the population half of the graphon MFG system of chapter 22; the descriptive process eq. (23.3) is that system's probabilistic carrier once the drift is the optimal feedback. We leave it, deliberately, only half-built. The well-posedness argument of proposition 23.5 leaned twice on objects we have not yet constructed: the field metric $\mathbf{d}_2$, in which the Picard iteration eq. (23.5) was made a contraction, and the *field-contraction* bound eq. (23.11) on the aggregate. Both promissory notes must now be paid. Pinning down precisely which metric topologizes the field of laws — and proving, with the *correct* constant, that $\mathbb{W}$ contracts it — is the business of the next section, section 23.2, where we build the functional home for these fields and establish lemma 23.10. Only once that home exists does the forward half assembled here have a rigorous space to live in; we will then add optimization in section 23.3 and, later, match this forward Fokker–Planck half against the backward HJB half it is destined to meet.

23.2 The Bochner setting for fields of measures

The previous section closed owing two debts, and this one pays them. The well-posedness proof of proposition 23.5 made its Picard iteration contract in a *field metric* $\mathbf{d}_2$ that was named but never built, and it capped the cross-type interaction with a *field-contraction* bound eq. (23.11) quoted on faith from a lemma not yet proved. We now construct the metric space the fields of laws actually inhabit, prove that it is *complete* — so that the Banach fixed point of theorem 2.36 invoked there has somewhere to land — and then prove the single estimate on which the rest of the chapter turns: that the graphon aggregate $\mathbb{W}$ contracts that space with a Lipschitz constant the kernel *row-sum bound* $\|\mathbb{W}\mathbf{1}\|_\infty \leq 1$, a number that stays at or below one *no matter how strong the kernel.* This is not one estimate among many. Every later contraction in the chapter — the small-horizon well-posedness of section 23.3, the Lipschitz continuity of the best-response map, the regime statements of theorem 23.17 — is assembled by feeding this one inequality through a per-type SDE/BSDE stability estimate and then integrating over the type interval. The continuum could *a priori* have made that type-integration blow up in proportion to the coupling strength; lemma 23.10 is precisely the statement that it cannot, because the only thing $\mathbb{W}$ can do to the total transport cost is redistribute it across types without amplifying its integral.

The fixed-point analysis of the graphon game lives on the space of fields of measures. The underlying set — measurable maps $x \mapsto m^x$ from the type interval into $\mathcal{P}_2(\mathbb{R}^d)$ — is the field of measures owned by chapter 21; what a particular analysis must *choose* is the metric that topologizes it, and different metrics are natural for different jobs. We make that choice explicit here rather than leave it implicit, because the choice matters across the seam. For the *probabilistic contraction estimates* of this chapter the natural metric is the L^2-in-type, Wasserstein-2 distance $\mathbf{d}_2$ below: it is the metric in which the per-type SDE/BSDE stability of chapter 5 integrates cleanly over types and the coupling operator $\mathbb{W}$ acts as a bounded operator. The *analytic existence theory* of chapter 24, by contrast, finds it more convenient to work with the uniform-in-type (supremum over x) Wasserstein metric, in which type-direction compactness and equicontinuity are read off directly from continuity of the kernel; we flag the difference where it bites (theorem 23.17 and its pointers to chapter 24). Both are metrics on the *same* field of measures of chapter 21; neither redefines the object, and the two are reconciled by the two-pictures dictionary of section 23.5. The designation "Bochner" is by analogy, and the analogy is worth unpacking because it tells us exactly which Bochner-space reflexes are available and which are not. A genuine Bochner space $L^2([0,1];E)$ is the space of square-integrable maps from the type interval into a *Banach* space E; one measures a map by integrating the E-norm of its values, and the result inherits E's linear structure — one can add two fields, scale them, and the norm is a genuine norm. Here the target is $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$, which is *not* a vector space: there is no sensible way to add two probability measures and stay a probability measure, and $\mathcal{W}_2$ is a metric, not a norm descended from a linear structure. What survives the analogy is exactly the part we need. A map is square-integrable in the same sense — we integrate the squared *distance* $\mathcal{W}_2(m^x, \delta_0)^2$ of its value from a fixed reference point in place of the squared norm — and the construction $\big(\int_0^1 \mathcal{W}_2(\cdot,\cdot)^2 \,\mathrm{d}x\big)^{1/2}$ of eq. (23.7) is the metric-space analogue of the $L^2([0,1];E)$ norm. Crucially, *completeness* is a metric notion and transfers: an L^2-integral of a complete metric space over a finite measure space is again complete, by the same Riesz–Fischer argument that makes $L^2([0,1];E)$ complete, with Cauchy-in-norm replaced by Cauchy-in-distance. That is all the fixed-point machinery asks of the space, and it is what lemma 23.10 verifies. What we deliberately do *not* get — and never use — is a linear or normed structure on the fields themselves; the operator $\mathbb{W}$ is linear on the underlying *measures*, which is a separate and weaker fact that the contraction proof below exploits with care.

Definition 23.8 (The field space $\boldsymbol{\mathcal{P}}_2$)**.** Fix a reference point $\delta_0 \in \mathcal{P}_2(\mathbb{R}^d)$ (the Dirac mass at the origin). The *field space* is

$$\boldsymbol{\mathcal{P}}_2 \;:=\; \Big\{ \boldsymbol{m} = (m^x)_{x\in[0,1]} \text{ measurable into } (\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2) \;:\; \|\boldsymbol{m}\|_2^2 := \int_0^1 \mathcal{W}_2(m^x, \delta_0)^2 \,\mathrm{d}x < \infty \Big\},$$

equipped with the distance

$$\mathbf{d}_2(\boldsymbol{m}, \boldsymbol{m}') \;=\; \Big(\int_0^1 \mathcal{W}_2\big(m^x, m^{x\prime}\big)^2 \,\mathrm{d}x \Big)^{1/2}. \tag{23.7}$$

The flow space is $C([0,T]; \boldsymbol{\mathcal{P}}_2)$ with the uniform-in-time distance $\mathbf{d}_{2,\infty}(\boldsymbol{m}_\cdot, \boldsymbol{m}'_\cdot) = \sup_{t \le T} \mathbf{d}_2(\boldsymbol{m}_t, \boldsymbol{m}'_t)$.

With the field space and its metric fixed, we turn to the object whose Lipschitz behaviour we actually need to control: the aggregate $\mathbb{W}\boldsymbol{m}$. Here a small but genuine obstruction appears, and it pays to meet it head-on rather than to wave it away by renormalizing. The graphon aggregate $(\mathbb{W}\boldsymbol{m})(x)$ of definition 23.2 is, in general, a *sub-probability* measure of mass $(\mathbb{W}\mathbf{1})(x) := \int_0^1 W(x,y)\,\mathrm{d}y \le 1$, not a probability measure — this is the missing-mass phenomenon dwelt on after definition 23.2, where an agent weakly embedded in the network genuinely feels less than a full unit of neighbour influence. The metric $\mathbf{d}_2$ was built from $\mathcal{W}_2$, and $\mathcal{W}_2$ as defined in the book (definition 4.2 and theorem 4.7) lives only on the probability measures $\mathcal{P}_2(\mathbb{R}^d)$. So before we can even *write* the quantity $\mathcal{W}_2\big((\mathbb{W}\boldsymbol{m})(x), (\mathbb{W}\boldsymbol{m}')(x)\big)$ that appears in the field-contraction bound eq. (23.11), we must say what $\mathcal{W}_2$ means between two measures of total mass $(\mathbb{W}\mathbf{1})(x) < 1$. We extend it minimally — only to the one case we will ever use, two finite measures of *equal* mass — and we resist the temptation to instead normalize the aggregate to a probability measure, both because the unnormalized mass carries information (again, definition 23.2) and because, as we will see, the common mass is exactly the bookkeeping that makes the equal-mass extension legitimate in the first place.

Definition 23.9 (Quadratic transport cost between equal-mass measures)**.** For two finite Borel measures μ, ν on $\mathbb{R}^d$ of a common total mass $c > 0$ and finite second moment, write $\mu = c\hat{\mu}$, $\nu = c\hat{\nu}$ with $\hat{\mu}, \hat{\nu} \in \mathcal{P}_2(\mathbb{R}^d)$ and set

$$\mathcal{W}_2(\mu,\nu)^2 \;:=\; c\,\mathcal{W}_2(\hat{\mu},\hat{\nu})^2 \;=\; \inf_{\pi} \int_{\mathbb{R}^d\times\mathbb{R}^d} \left|\xi - \xi'\right|^2 \,\pi(\mathrm{d}\xi, \mathrm{d}\xi'), \tag{23.8}$$

the infimum over nonnegative measures π of total mass c with marginals μ, ν. By the Kantorovich duality theorem 4.5, applied to $(\hat{\mu}, \hat{\nu})$ and scaled by c,

$$\mathcal{W}_2(\mu,\nu)^2 \;=\; \sup\Big\{ \textstyle\int \varphi \,\mathrm{d}\mu + \int \psi \,\mathrm{d}\nu \;:\; \varphi(\xi) + \psi(\xi') \le |\xi - \xi'|^2 \;\; \forall\, \xi, \xi' \Big\}. \tag{23.9}$$

For $c = 1$ this is the usual $\mathcal{W}_2$; the extension is used only for the aggregates, whose two arguments below always share the mass $(\mathbb{W}\mathbf{1})(x)$.

Two features of definition 23.9 are worth pausing on. First, the scaling $\mathcal{W}_2(\mu,\nu)^2 = c\,\mathcal{W}_2(\hat{\mu},\hat{\nu})^2$ is forced, not chosen: a coupling of μ and ν has total mass c, so it is c times a coupling of the *normalized* pair $\hat{\mu}, \hat{\nu}$, and the quadratic cost integrated against it picks up exactly one factor of c. The same factor c multiplies the Kantorovich dual eq. (23.9): scaling the optimal-transport identity of theorem 4.5 for $(\hat{\mu}, \hat{\nu})$ by c pulls the constant through both the primal and the dual side, so the dual potentials (φ, ψ) are tested against the *unnormalized* measures μ, ν with no further rescaling. It is this dual form, with its potentials independent of the measures, that will carry the contraction proof. Second — and this is the observation that makes the whole extension usable rather than a curiosity — the equal-mass hypothesis is automatically satisfied by the only pairs we feed into it. For *any* field $\boldsymbol{m}$ the aggregate $(\mathbb{W}\boldsymbol{m})(x)$ has total mass

$$(\mathbb{W}\boldsymbol{m})(x)(\mathbb{R}^d) = \int_0^1 W(x,y)\, m^y(\mathbb{R}^d)\ \mathrm{d}y = \int_0^1 W(x,y)\cdot 1\ \mathrm{d}y = (\mathbb{W}\mathbf{1})(x),$$

because each component m^y is a probability measure and so contributes mass 1. The mass of the aggregate therefore depends *only* on the kernel row at type x and *not at all* on which field $\boldsymbol{m}$ produced it. Consequently any two aggregates $(\mathbb{W}\boldsymbol{m})(x)$ and $(\mathbb{W}\boldsymbol{m}')(x)$ — coming from two arbitrary fields $\boldsymbol{m}, \boldsymbol{m}'$ — carry the identical mass $(\mathbb{W}\mathbf{1})(x)$, the equal-mass hypothesis of definition 23.9 holds at every type and for every pair of fields, and the distance $\mathcal{W}_2\big((\mathbb{W}\boldsymbol{m})(x), (\mathbb{W}\boldsymbol{m}')(x)\big)$ is well defined throughout. We can now state the boundedness of the coupling, with the *correct* constant.

Lemma 23.10 (The field space is complete; the aggregate is a field contraction)**.** $(\boldsymbol{\mathcal{P}}_2, \mathbf{d}_2)$ *is a complete metric space. Under **(A-Reg-W)** the graphon aggregate is Lipschitz in the field, with constant the square root of the kernel* row-sum bound

$$\|\mathbb{W}\mathbf{1}\|_\infty \;=\; \operatorname*{ess\,sup}_{x\in[0,1]} \int_0^1 W(x,y)\ \mathrm{d}y \;\le\; 1 \qquad (\textit{by } \textbf{\textit{(A-Reg-W)}}), \tag{23.10}$$

namely

$$\Big(\int_0^1 \mathcal{W}_2\big((\mathbb{W}\boldsymbol{m})(x), (\mathbb{W}\boldsymbol{m}')(x)\big)^2\ \mathrm{d}x\Big)^{1/2} \;\le\; \|\mathbb{W}\mathbf{1}\|_\infty^{1/2}\ \mathbf{d}_2(\boldsymbol{m},\boldsymbol{m}') \;\le\; \mathbf{d}_2(\boldsymbol{m},\boldsymbol{m}'). \tag{23.11}$$

The aggregate is thus a (weak) contraction of the field space, with constant ≤ 1 *regardless of the strength of the kernel.*

Proof. Completeness. This is the Riesz–Fischer argument that proves $L^2([0,1];E)$ complete, run with the distance $\mathcal{W}_2$ in place of the norm of E and with the completeness of $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ standing in for that of E. Let $(\boldsymbol{m}_n)_n$ be $\mathbf{d}_2$-Cauchy in $\boldsymbol{\mathcal{P}}_2$. The first move is to extract a rapidly convergent subsequence: choose indices $n_1 < n_2 < \cdots$ with

$$\mathbf{d}_2(\boldsymbol{m}_{n_{k+1}}, \boldsymbol{m}_{n_k}) \le 2^{-k} \qquad (k\ge 1),$$

possible because the sequence is Cauchy. Now control the total displacement type by type. Set $S_K(y) = \sum_{k=1}^K \mathcal{W}_2(m^y_{n_{k+1}}, m^y_{n_k})$, a nondecreasing sequence of nonnegative measurable functions of y. By Minkowski's inequality in $L^2([0,1])$ (the triangle inequality for the L^2-in-type norm) followed by the subsequence bound,

$$\big\|S_K\big\|_{L^2([0,1])} \le \sum_{k=1}^K \big\|\mathcal{W}_2(m^{\cdot}_{n_{k+1}}, m^{\cdot}_{n_k})\big\|_{L^2([0,1])} = \sum_{k=1}^K \mathbf{d}_2(\boldsymbol{m}_{n_{k+1}}, \boldsymbol{m}_{n_k}) \le \sum_{k=1}^K 2^{-k} \le 1.$$

Letting $K\to\infty$, monotone convergence gives $\|S_\infty\|_{L^2([0,1])} \le 1$, so the limit function $S_\infty(y) = \sum_{k\ge1} \mathcal{W}_2(m^y_{n_{k+1}}, m^y_{n_k})$ is finite for a.e. y. Fix such a y. Then the series of $\mathcal{W}_2$-increments converges, so the sequence $(m^y_{n_k})_k$ is $\mathcal{W}_2$-Cauchy in $\mathcal{P}_2(\mathbb{R}^d)$: for $j>i$, $\mathcal{W}_2(m^y_{n_j}, m^y_{n_i}) \le \sum_{k\ge i} \mathcal{W}_2(m^y_{n_{k+1}}, m^y_{n_k}) \to 0$. Because $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$ is *complete* (it is Polish, theorem 4.8), this Cauchy sequence converges to a limit, which we name m^y; on the null set where $S_\infty = \infty$ we set $m^y = \delta_0$. The field $\boldsymbol{m} = (m^y)_y$ is measurable into $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$, being the a.e. pointwise $\mathcal{W}_2$-limit of the measurable maps $y\mapsto m^y_{n_k}$.

It remains to see that $\boldsymbol{m} \in \boldsymbol{\mathcal{P}}_2$ and that $\boldsymbol{m}_{n_k} \to \boldsymbol{m}$ in $\mathbf{d}_2$. Here Fatou's lemma in the type variable does the work. For each fixed k, $\mathcal{W}_2(m^y, m^y_{n_k})^2 = \lim_{j\to\infty} \mathcal{W}_2(m^y_{n_j}, m^y_{n_k})^2$ for a.e. y (the inner limit by continuity of $\mathcal{W}_2$ in its first argument), so

$$\mathbf{d}_2(\boldsymbol{m}, \boldsymbol{m}_{n_k})^2 = \int_0^1 \mathcal{W}_2(m^y, m^y_{n_k})^2 \,\mathrm{d}y \le \liminf_{j\to\infty} \int_0^1 \mathcal{W}_2(m^y_{n_j}, m^y_{n_k})^2 \,\mathrm{d}y = \liminf_{j\to\infty} \mathbf{d}_2(\boldsymbol{m}_{n_j}, \boldsymbol{m}_{n_k})^2.$$

Given $\varepsilon > 0$, the Cauchy property makes the right side $\le \varepsilon$ once k is large; hence $\mathbf{d}_2(\boldsymbol{m}, \boldsymbol{m}_{n_k}) \to 0$. In particular $\mathbf{d}_2(\boldsymbol{m}, \delta_0\text{-field}) \le \mathbf{d}_2(\boldsymbol{m}, \boldsymbol{m}_{n_k}) + \|\boldsymbol{m}_{n_k}\|_2 < \infty$ by the triangle inequality, so $\boldsymbol{m} \in \boldsymbol{\mathcal{P}}_2$. Finally a Cauchy sequence with a convergent subsequence converges to the same limit, so the *whole* sequence $\boldsymbol{m}_n \to \boldsymbol{m}$. This proves $(\boldsymbol{\mathcal{P}}_2, \mathbf{d}_2)$ complete.

The contraction bound, by duality. Fix a type x and abbreviate the per-type transport cost by

$$g(y) \;:=\; \mathcal{W}_2(m^y, m^{y\prime})^2 \;\ge\; 0,$$

a measurable, integrable function of y: measurable because $\boldsymbol{m}, \boldsymbol{m}'$ are measurable fields and $\mathcal{W}_2$ is jointly continuous, and integrable because the elementary bound $g(y) \le 2\mathcal{W}_2(m^y, \delta_0)^2 + 2\mathcal{W}_2(m^{y\prime}, \delta_0)^2$ exhibits it as dominated by the (finite) sum of the two field norms, with in fact $\int_0^1 g \,\mathrm{d}y = \mathbf{d}_2(\boldsymbol{m}, \boldsymbol{m}')^2$. The naive route to bounding $\mathcal{W}_2((\mathbb{W}\boldsymbol{m})(x), (\mathbb{W}\boldsymbol{m}')(x))$ would be the *primal* one: pick, for each y, an optimal coupling π_y of m^y and $m^{y\prime}$, superpose them weighted by $W(x,\cdot)$ to build a coupling of the two aggregates, and integrate the cost. This works in principle but is technically delicate: it requires choosing the family $(\pi_y)_y$ *measurably* in y before one may integrate it, an appeal to a measurable selection theorem we would rather not make. The *dual* route sidesteps the selection entirely, and this is the one structural subtlety worth dwelling on.

The aggregates $(\mathbb{W}\boldsymbol{m})(x)$ and $(\mathbb{W}\boldsymbol{m}')(x)$ share the common mass $(\mathbb{W}\mathbf{1})(x)$ (the field-independence established above), so definition 23.9 applies and the dual representation eq. (23.9) is available. Take *any* single admissible pair of potentials (φ, ψ) — admissibility being the condition $\varphi(\xi) + \psi(\xi') \le |\xi - \xi'|^2$ for all ξ, ξ', a constraint on the two *functions* alone that mentions no measure whatsoever. Test this one pair against the aggregates and unfold the definition eq. (23.1) of the aggregate as a W-weighted integral of the components:

$$\begin{aligned}\int \varphi \,\mathrm{d}(\mathbb{W}\boldsymbol{m})(x) + \int \psi \,\mathrm{d}(\mathbb{W}\boldsymbol{m}')(x) &= \int_0^1 W(x,y)\Big[\int \varphi \,\mathrm{d}m^y + \int \psi \,\mathrm{d}m^{y\prime}\Big]\,\mathrm{d}y \\ &\le \int_0^1 W(x,y)\,\mathcal{W}_2(m^y, m^{y\prime})^2 \,\mathrm{d}y \;=\; (\mathbb{W}g)(x).\end{aligned}$$

The inequality is the whole point. *The same pair* (φ, ψ)*, being admissible as a pair of functions, is simultaneously admissible in the dual problem for every component pair* $(m^y, m^{y\prime})$, so for each y the inner bracket is bounded by the duality estimate $\int \varphi \,\mathrm{d}m^y + \int \psi \,\mathrm{d}m^{y\prime} \le \mathcal{W}_2(m^y, m^{y\prime})^2$ of theorem 4.5 — no per-y choice of *coupling* is ever made, only the single global pair of potentials is reused inside the integral. The right-hand side $(\mathbb{W}g)(x)$ is now a number that does not depend on (φ, ψ) at all. So we may take the supremum of the left-hand side over all admissible pairs; by eq. (23.9) that supremum *equals* $\mathcal{W}_2\big((\mathbb{W}\boldsymbol{m})(x), (\mathbb{W}\boldsymbol{m}')(x)\big)^2$, and the inequality is preserved under the supremum, giving the pointwise estimate

$$\mathcal{W}_2\big((\mathbb{W}\boldsymbol{m})(x), (\mathbb{W}\boldsymbol{m}')(x)\big)^2 \;\le\; (\mathbb{W}g)(x) \qquad \text{for a.e. } x.$$

In words: the squared transport cost between two aggregates at type x is at most the W-weighted average, over neighbours y, of the squared transport costs of the underlying components. This route needs *no* measurable selection of optimal couplings: the common potential pair carries the bound across all of y at once.

The final step integrates this pointwise estimate over x and is where the row-sum constant is born. The graphon kernel is *symmetric*, $W(x,y) = W(y,x)$, so $\mathbb{W}$ is self-adjoint on $L^2([0,1])$, $\langle f, \mathbb{W}h\rangle = \langle \mathbb{W}f, h\rangle$; applying this with $f = \mathbf{1}$ and $h = g$ moves the operator off the (rough) function g and onto the constant $\mathbf{1}$, where it becomes the explicit row-sum function $\mathbb{W}\mathbf{1}$:

$$\int_0^1 \mathcal{W}_2\big((\mathbb{W}\boldsymbol{m})(x), (\mathbb{W}\boldsymbol{m}')(x)\big)^2 \,\mathrm{d}x \;\le\; \int_0^1 (\mathbb{W}g)(x)\,\mathrm{d}x \;=\; \langle \mathbf{1}, \mathbb{W}g\rangle \;=\; \langle \mathbb{W}\mathbf{1}, g\rangle \;\le\; \|\mathbb{W}\mathbf{1}\|_\infty \,\|g\|_{L^1} \;=\; \|\mathbb{W}\mathbf{1}\|_\infty \,\mathbf{d}_2(\boldsymbol{m}$$

The penultimate inequality is the Hölder pairing of L^∞ against L^1: $\langle \mathbb{W}\mathbf{1}, g\rangle = \int_0^1 (\mathbb{W}\mathbf{1})(x)\, g(x)\,\mathrm{d}x \le \big(\operatorname{ess\,sup}_x (\mathbb{W}\mathbf{1})(x)\big) \int_0^1 g\,\mathrm{d}x$, using $g \ge 0$. This is eq. (23.11); taking square roots gives the contraction constant $\|\mathbb{W}\mathbf{1}\|_\infty^{1/2}$, and the final ≤ 1 is $\|\mathbb{W}\mathbf{1}\|_\infty \le 1$ from **(A-Reg-W)**. Note precisely where the choice of *which* norm of $\mathbb{W}$ to use was forced: the rough function g lives only in $L^1([0,1])$ — it is a sum of squared Wasserstein distances, integrable but with no control on its L^2 size — so the only norm of $\mathbb{W}$ that can be paired against it is the one dual to L^1, namely the $L^\infty \to L^\infty$ row-sum norm. The next remark makes this forced choice the conceptual centre of the section. □

Remark 23.11 (Why the row-sum, and not the operator norm, for the measure-valued aggregate)**.** This remark is the conceptual hinge of the section: it isolates which of the *two* norms of $\mathbb{W}$ governs which of the *two* couplings in the graphon game. The distinction is not pedantry — it is exactly the distinction that, in section 23.6, separates the contraction estimate (which never fails) from the symmetry-breaking threshold (which is where uniqueness fails). It is cashed out, not repeated, there, and the regime statements of theorem 23.17 turn on the same point; the reader should carry the dichotomy forward rather than expect it re-derived.

The honest contraction constant for the *measure-valued* aggregate, just proved, is the row-sum bound $\|\mathbb{W}\mathbf{1}\|_\infty \le 1$. This number is the $L^\infty([0,1]) \to L^\infty([0,1])$ operator norm of $\mathbb{W}$ — the largest row sum — and it is emphatically *not* the $L^2([0,1]) \to L^2([0,1])$ operator (spectral) norm $\|\mathbb{W}\| = |\lambda_1|$, the top eigenvalue. One might hope to replace the last line of the proof by the spectral norm, writing "$\langle \mathbb{W}\mathbf{1}, g\rangle \le \|\mathbb{W}\|\;\|g\|_{L^1}$"; this is simply *false*, because the spectral norm controls L^2 pairings and g is only an L^1 function. To see that it is genuinely false — that the spectral constant is not merely unproven but actually too *small* — consider the cleanest possible test case and follow it slowly.

The counterexample. Take the constant kernel $W(x,y) \equiv c$ with $0 < c < 1$. Its row sum is $(\mathbb{W}\mathbf{1})(x) = \int_0^1 c\,\mathrm{d}y = c$ for every x, so $\|\mathbb{W}\mathbf{1}\|_\infty = c$. Its spectrum is equally explicit: $\mathbb{W}f = c\,\langle \mathbf{1}, f\rangle\,\mathbf{1}$ is rank one with the single nonzero eigenvalue $\lambda_1 = c$ on the constant eigenfunction, so the spectral norm is $\|\mathbb{W}\| = |\lambda_1| = c$ as well — the two norms happen to *coincide* here, both equal to c, which is what makes the example so sharp. Now perturb a field by a rigid common translation: let $m^{y\prime} = m^y * \delta_\epsilon$ be every component of $\boldsymbol{m}$ pushed forward by the same shift $\epsilon \in \mathbb{R}^d$ (convolution with a Dirac at ϵ). Translating a measure by ϵ moves it $\mathcal{W}_2$-distance exactly $|\epsilon|$, so $\mathcal{W}_2(m^y, m^{y\prime})^2 = |\epsilon|^2$ for every y, and hence

$$\mathbf{d}_2(\boldsymbol{m}, \boldsymbol{m}')^2 = \int_0^1 |\epsilon|^2 \,\mathrm{d}y = |\epsilon|^2 .$$

What does this perturbation do to the aggregate? Because the kernel is constant, the aggregate $(\mathbb{W}\boldsymbol{m})(x) = c\int_0^1 m^y \, \mathrm{d}y$ is c times the type-averaged population, and the shifted aggregate is the same average translated by ϵ; the two aggregates therefore differ by the same rigid shift, now carried by a measure of mass c. By the equal-mass distance eq. (23.8) the squared cost is the mass times the squared shift of the normalized measures, $\mathcal{W}_2\big((\mathbb{W}\boldsymbol{m})(x), (\mathbb{W}\boldsymbol{m}')(x)\big)^2 = c\,|\epsilon|^2$, so the left-hand side of the field-contraction bound is

$$\int_0^1 \mathcal{W}_2\big((\mathbb{W}\boldsymbol{m})(x), (\mathbb{W}\boldsymbol{m}')(x)\big)^2 \, \mathrm{d}x \;=\; c\,|\epsilon|^2 \,.$$

Compare the two candidate right-hand sides. The row-sum bound predicts $\|\mathbb{W}\mathbf{1}\|_\infty \, \mathbf{d}_2^2 = c\,|\epsilon|^2$ — an exact match, so the row-sum constant is not just valid but *sharp* on this example. The spectral bound would predict $\|\mathbb{W}\|^2 \, \mathbf{d}_2^2 = c^2\,|\epsilon|^2$, and since $c < 1$,

$$c^2\,|\epsilon|^2 \;<\; c\,|\epsilon|^2 \,,$$

so the spectral candidate is *strictly smaller than the true left-hand side*: it is violated, not merely loose. The squaring is the trap — the contraction constant on the squared cost is the row sum c, whereas the spectral norm enters squared as c^2, and for $c < 1$ squaring strictly shrinks. This is the concrete proof that $\|\mathbb{W}\|$ is the *wrong* (too small) constant for the measure-valued contraction, exactly as the L^1 nature of g in the proof foretold.

Why the row-sum is always at least as large. The example is no accident. For a *nonnegative* kernel — which a graphon always is — the Perron–Frobenius principle gives $\|\mathbb{W}\| = |\lambda_1| \le \|\mathbb{W}\mathbf{1}\|_\infty$: the top eigenvalue of a nonnegative operator never exceeds its largest row sum. (Quickly: if $\mathbb{W}\phi = \lambda_1\phi$ with $\phi \ge 0$ the Perron eigenfunction and $x^\star$ a point where ϕ is near its maximum, then $\lambda_1\phi(x^\star) = \int W(x^\star, y)\phi(y)\,\mathrm{d}y \le \phi(x^\star)\int W(x^\star, y)\,\mathrm{d}y \le \phi(x^\star)\,\|\mathbb{W}\mathbf{1}\|_\infty$.) So the row-sum constant is *always* valid, even when not sharp, and it collapses to the spectral norm exactly in the rank-one constant case above.

The other coupling, where $\|\mathbb{W}\|$ *is right.* The spectral norm is not idle — it governs a *different* cross-type coupling, the *linear* mean-field coupling $\bar{m} \mapsto \mathbb{W}\bar{m}$ that acts not on the full measure field but on the type-L^2 space of population *means* $\bar{m}(x) = \int \xi\, m^x(\mathrm{d}\xi)$. There the relevant estimate is the genuine L^2 bound $\|\mathbb{W}\bar{m} - \mathbb{W}\bar{m}'\|_{L^2} \le \|\mathbb{W}\|\;\|\bar{m} - \bar{m}'\|_{L^2}$, which *is* the correct and sharp one and is in the book as the spectral theorem theorem 2.26. This is the coupling that drives the linear–quadratic thread, where the agent reacts only to neighbour means; and it is precisely there, in section 23.6, that diagonalizing $\mathbb{W}$ turns each eigenvalue λ_k into the effective coupling strength $s\lambda_k$ of an independent scalar mode, with the largest, $s\,\|\mathbb{W}\| = s\,|\lambda_1|$, setting the symmetry-breaking threshold in closed form. The two norms thus partition the chapter's labour cleanly. The row-sum $\|\mathbb{W}\mathbf{1}\|_\infty \le 1$ makes the *general*, measure-valued coupling a bounded-by-one perturbation of an otherwise decoupled family, so that the contraction underlying well-posedness is governed by the horizon T and not by how strong the kernel is; the spectral norm $\|\mathbb{W}\|$ governs the *linear* coupling and is where multiplicity is born. Keeping these two roles distinct is the single most important thing to carry out of this section into section 23.6 and chapter 24.

With the field space built, shown complete, and equipped with the master contraction estimate lemma 23.10, the two promissory notes of proposition 23.5 are paid: the metric $\mathbf{d}_2$ exists and the aggregate $\mathbb{W}$ contracts it with a constant $\|\mathbb{W}\mathbf{1}\|_\infty \le 1$ that is *uniform over every admissible graphon*. This uniformity is exactly what section 23.3 will consume — its small-horizon contraction must hold for all kernels at once, and lemma 23.10 guarantees the type-integration never amplifies the per-type estimate regardless of coupling strength. We have also planted, in remark 23.11, the two-norm distinction that the regime statement theorem 23.17 and the spectral threshold $s\,\|\mathbb{W}\|$ of section 23.6 will both cash out. One seam remains flagged for later: the existence theory of chapter 24 prefers the uniform-in-type metric to $\mathbf{d}_2$, and the reconciliation of the two runs through the two-pictures dictionary of section 23.5. For now the home is built and complete, and we can move the agents back in: section 23.3 restores the optimization that section 23.1 stripped away, type by type, and watches that same operator reappear, unchanged, inside the equilibrium fixed point.

23.3 The representative agent and the graphon FBSDE

The two previous sections were a deliberate detour through the *descriptive* world. In section 23.1 we wrote down the graphon McKean–Vlasov SDE with optimization switched off, precisely so that the one genuinely new ingredient — the nonlocal cross-type coupling carried by $\mathbb{W}$ — could be isolated and studied alone; and in section 23.2 we built the functional home for the resulting field of laws and proved the master estimate, that $\mathbb{W}$ contracts that field space with constant the row-sum bound $\|\mathbb{W}\mathbf{1}\|_\infty \le 1$ (lemma 23.10). With the field space $\boldsymbol{\mathcal{P}}_2$ and its contraction in hand, we can now do what those sections deliberately postponed: *restore the optimization* that turns a descriptive population into an equilibrium one. The drift of each agent will no longer be handed to us; it will be *chosen*, optimally, by the agent.

The logic for restoring it is not new — it is exactly the two-step fixed point of chapter 9, the same construction that produced the homogeneous MFG FBSDE eq. (9.13), only now run *type by type* along the continuum. Recall how that construction goes. One does not attack the coupled equilibrium head-on; one breaks the circularity in two. First *freeze* a candidate population — here, a candidate flow of fields $\boldsymbol{\mu}$ — so that each agent faces a fixed, external environment and its optimization becomes a plain single-agent control problem. Solve that problem (this is where the stochastic maximum principle enters) to obtain the agent's best response and the law it generates. Then *close the loop* by demanding self-consistency: the population the agents collectively generate must be the very population they were optimizing against. The graphon game inherits this verbatim, with one bookkeeping change that the previous two sections have already absorbed — "the population" is now a field indexed by type, and the environment a type-x agent faces is the neighbour aggregate $(\mathbb{W}\boldsymbol{\mu}_t)(x)$ rather than a single global law. We carry out the two steps in order: this subsection freezes and optimizes one type; section 23.3's next subsection closes the loop and writes down the central object, the graphon MFG FBSDE; the third exhibits the equilibrium as a fixed point on the field space.

23.3.1 The type-x control problem against a frozen field

We begin with the freezing step, and it is worth being explicit about why freezing is the right first move. The difficulty in the graphon game is entirely the circular dependence — each agent's optimal behaviour depends on the population, which is itself the aggregate of all agents' optimal behaviour. Freezing the population to a fixed candidate $\boldsymbol{\mu}$ cuts that circle: with the environment held external and known, the type-x agent no longer interacts with anyone, and its problem collapses to a textbook stochastic control problem of the kind chapter 9 solved completely. The whole subtlety of the continuum — the nonlocal coupling — has been parked inside the frozen object $(\mathbb{W}\boldsymbol{\mu}_t)(x)$, which is now just a given deterministic measure-flow. So fix a flow of fields $\boldsymbol{\mu} = (\boldsymbol{\mu}_t)_{t\le T} \in C([0,T];\boldsymbol{\mathcal{P}}_2)$, regarded as the frozen population. The type-x agent feels the deterministic neighbour aggregate $\nu_t^x := (\mathbb{W}\boldsymbol{\mu}_t)(x)$ and controls

$$\mathrm{d}X_t^x = b\big(t,x,X_t^x,\nu_t^x,\alpha_t^x\big)\ \mathrm{d}t + \sigma\big(t,x,X_t^x,\nu_t^x\big)\ \mathrm{d}B_t^x, \qquad X_0^x \sim m_0^x, \tag{23.12}$$

through an admissible control $\alpha^x \in \mathbb{A}$ (the class of chapter 9: $\mathbb{F}$-progressive, square-integrable, valued in the closed convex set A), to minimize

$$J_{\boldsymbol{\mu}}^x(\alpha^x) = \mathbb{E}\bigg[\int_0^T L\big(t,x,X_t^x,\nu_t^x,\alpha_t^x\big)\ \mathrm{d}t + g\big(x,X_T^x,\nu_T^x\big)\bigg]. \tag{23.13}$$

As in chapter 9 the volatility is uncontrolled. Now comes the decisive observation, the one that makes the whole graphon control theory free. Because $\boldsymbol{\mu}$ was frozen, $\nu_t^x = (\mathbb{W}\boldsymbol{\mu}_t)(x)$ is a *fixed, deterministic* measure-flow: it references neither the agent's own law nor any other type's processes, only the known input $\boldsymbol{\mu}$. The cross-type coupling has been completely severed — nothing in eq. (23.12)–eq. (23.13) connects type x to any type $y \neq x$. What remains is therefore an *ordinary single-agent stochastic control problem*: a controlled diffusion eq. (23.12) with a running-plus-terminal cost eq. (23.13), in which the measure ν_t^x and the type label x enter only as fixed parameters of the coefficients, exactly as a time-dependent coefficient would. This is *precisely* the problem class of section 9.1, with the population law m_t used there replaced everywhere by the neighbour aggregate ν_t^x and an inert label x carried passively along. Nothing about the maximum-principle machinery sees the continuum: from inside the type-x problem, x is a constant and ν^x is a given function of time. This is the concrete payoff of the "one operator carries all the coupling" principle at the level of optimization: the operator $\mathbb{W}$ is the *only* thing that ties the types together, and freezing the field has temporarily set it aside, so each type optimizes in complete isolation.

Because the problem is an ordinary control problem, we solve it with the ordinary tool: the Pontryagin stochastic maximum principle of chapter 9. Recall its shape. One forms the generalized Hamiltonian, the scalar that the optimal control minimizes pointwise; its gradient in the state drives a *backward* equation for the adjoint (costate) process, which measures the marginal cost of the state; and optimality is the statement that the control minimizes the Hamiltonian instant by instant. We write each ingredient for the type-x problem, importing the definitions of chapter 9 with the substitution $m_t \rightsquigarrow \nu_t^x$ already made.

Definition 23.12 (Type-x generalized Hamiltonian and adjoint)**.** The type-x generalized Hamiltonian is, in the notation of definition 9.2,

$$\mathcal{H}\big(t,x,x,\nu,y,z,\alpha\big) = \langle b(t,x,x,\nu,\alpha), y\rangle + \mathrm{tr}\big(\sigma(t,x,x,\nu)^\top z\big) + L(t,x,x,\nu,\alpha), \tag{23.14}$$

with, under **(A-Conv)**, the unique minimizer $\hat{\alpha}(t,x,x,\nu,y,z) = \arg\min_{\alpha\in A}\mathcal{H}$, Lipschitz in (x,ν,y,z) (eq. (9.4)). The adjoint of an admissible α^x with state X^x is the pair $(Y^x,Z^x) \in \mathcal{S}^2 \times \mathcal{H}^2$

solving the backward SDE; for each fixed x this is a standard backward stochastic differential equation with square-integrable, Lipschitz driver and square-integrable terminal datum, so it has a unique solution by the Pardoux–Peng theorem (theorem C.18), the Z^x-component furnished by the martingale representation theorem (theorem C.17) for the Brownian filtration of B^x,

$$\mathrm{d}Y_t^x = -\,\partial_x \mathcal{H}\big(t, x, X_t^x, \nu_t^x, Y_t^x, Z_t^x, \alpha_t^x\big)\,\mathrm{d}t + Z_t^x\ \mathrm{d}B_t^x, \qquad Y_T^x = \partial_x g\big(x, X_T^x, \nu_T^x\big). \tag{23.15}$$

With the Hamiltonian, adjoint, and minimizer feedback in place, the maximum principle of chapter 9 — both the necessary condition (theorem 9.4) and the sufficient condition (theorem 9.5) — holds for the type-x problem without change: under **(A-Lip)**, **(A-Growth)**, **(A-Conv)**, a control is optimal against the frozen field if and only if it satisfies the pointwise minimization $\hat{\alpha}_t^x = \hat{\alpha}(t, x, X_t^x, \nu_t^x, Y_t^x, Z_t^x)$ together with the forward state eq. (23.12) and the backward adjoint eq. (23.15).

We do not reprove this, and it is worth being precise about why no reproof is owed — the reason is the entire content of the freezing step, not a hand-wave. A theorem may be reused verbatim exactly when the object it speaks about is, on the nose, an instance of the object the theorem was proved for. Here the type-x problem against a frozen field *is* such an instance: as established above, once $\boldsymbol{\mu}$ is frozen the measure ν_t^x is a fixed deterministic function of time and x is a fixed parameter, so eq. (23.12)–eq. (23.13) is literally a member of the family of single-agent control problems for which theorem 9.5 was established — with ν_t^x in the role of the (there fixed) measure flow and x a passive label decorating the coefficients. The graphon offers the maximum-principle proof nothing new to chew on: there is no cross-type term to differentiate, no continuum to integrate, nothing the argument of chapter 9 has not already handled. Restated as a slogan, *the frozen-field decoupling is what licenses the verbatim import*; the statement of optimality above is theorem 9.5 read with the parameter x and the frozen measure ν_t^x, and that is all.

One seam must nonetheless be kept visible, because it is exactly where the graphon *game* parts ways from a graphon *planning* problem, and the difference is invisible in the frozen problem but decisive at closure. It is the seam flagged in remark 9.6. The adjoint eq. (23.15) differentiates $\mathcal{H}$ in the state x *only*, holding the neighbour field ν_t^x frozen throughout the backward run. This is correct for the graphon mean field *game*: the type-x agent is one anonymous member of a continuum, a price-taker who cannot perceptibly move the aggregate $(\mathbb{W}\boldsymbol{m}_t)(x)$ by deviating, so when computing its own marginal cost it rightly treats the neighbour field as exogenous — frozen — and differentiates through the state alone. Were we instead solving the graphon mean field *control* problem — a single planner choosing the entire field of laws to optimize a social objective — the planner *would* internalize the effect of every agent's state on the aggregate, and the adjoint would carry an additional Lions (measure) derivative term, propagated from type x to every type y with $W(y, x) > 0$ by the operator $\mathbb{W}$. That extra nonlocal term is the entire difference between the two problems, and it is absent here *by design*: we are constructing the equilibrium of an anonymous game, not the optimum of a planner. The reader should note that this is the only place in the optimization step where the choice "game, not control" is actually exercised; once made, the rest of the construction proceeds identically.

23.3.2 Closing the loop: the graphon MFG FBSDE

The freezing step delivered, for each type and each frozen environment, a complete best response: an optimally controlled state X^x, its adjoint (Y^x, Z^x), and the feedback control $\hat{\alpha}^x$ that the maximum principle certifies optimal. But a best response is computed *against* a population the agent merely assumed; it is an equilibrium only when the assumption is true — when the population the agents collectively generate is the one they each optimized against. This is the second step of the two-step fixed point, and it is a single demand: *self-consistency.* We now impose it.

The demand is the closure $m_t^x = \mathrm{Law}(X_t^x)$, already met in the descriptive setting as eq. (23.4): the field of laws the agents produce must equal the field they reacted to. Imposing it has one immediate effect on the frozen problem of the previous subsection: the external, hand-supplied aggregate $\nu_t^x = (\mathbb{W}\boldsymbol{\mu}_t)(x)$ is replaced by the *self-generated* aggregate $(\mathbb{W}\boldsymbol{m}_t)(x)$ built from the agents' own realized laws. The frozen parameter becomes a functional of the unknown, the severed cross-type coupling is reconnected through $\mathbb{W}$, and the per-type control problems fuse back into a single coupled system. That system is the central object of the chapter.

Definition 23.13 (The graphon MFG FBSDE)**.** A *graphon mean field game equilibrium in probabilistic form* is a field $(X^x, Y^x, Z^x)_{x\in[0,1]}$ of $\mathbb{F}$-progressive processes, together with the flow of fields $\boldsymbol{m}_t = (\mathrm{Law}(X_t^x))_x$, solving for a.e. x the McKean–Vlasov forward–backward system

$$\begin{cases} \mathrm{d}X_t^x = b\big(t, x, X_t^x, (\mathbb{W}\boldsymbol{m}_t)(x), \hat{\alpha}_t^x\big)\,\mathrm{d}t + \sigma\big(t, x, X_t^x, (\mathbb{W}\boldsymbol{m}_t)(x)\big)\,\mathrm{d}B_t^x, & X_0^x \sim m_0^x, \\ \mathrm{d}Y_t^x = -\,\partial_x\mathcal{H}\big(t, x, X_t^x, (\mathbb{W}\boldsymbol{m}_t)(x), Y_t^x, Z_t^x, \hat{\alpha}_t^x\big)\,\mathrm{d}t + Z_t^x\;\mathrm{d}B_t^x, & Y_T^x = \partial_x g\big(x, X_T^x, (\mathbb{W}\boldsymbol{m}_T)(x)\big), \\ \quad \hat{\alpha}_t^x = \hat{\alpha}\big(t, x, X_t^x, (\mathbb{W}\boldsymbol{m}_t)(x), Y_t^x, Z_t^x\big), & m_t^x = \mathrm{Law}(X_t^x). \end{cases} \tag{23.16}$$

It pays to read eq. (23.16) slowly against its homogeneous ancestor, the MFG FBSDE eq. (9.13), because the comparison shows exactly what is inherited and what is new. Line for line the two systems are the same shape: a forward state equation, a backward adjoint equation with terminal data, a feedback control closing the two, and a law constraint. Set the type label aside and replace $(\mathbb{W}\boldsymbol{m}_t)(x)$ by $\boldsymbol{m}_t$ and eq. (23.16) *is* eq. (9.13). So the graphon FBSDE carries all of the difficulty of the homogeneous one — three nested layers of coupling — and adds a fourth that is the whole subject of this chapter. Naming each in turn, with a word on what it means:

1. *Forward–backward coupling.* The state X^x runs forward from data at $t = 0$ while its adjoint Y^x runs backward from data at $t = T$, yet each appears in the other's equation; the system is a genuine two-point boundary-value problem in time, not an initial-value problem one can simply integrate forward. This is the structural signature of an optimization embedded in dynamics, present already in single-agent control.

2. *McKean–Vlasov (distributional) coupling.* The coefficients depend on $\boldsymbol{m}_t = (\mathrm{Law}(X_t^x))_x$, the *law* of the very process they govern, so the equation is nonlinear in a non-pointwise way: the solution's distribution feeds back into its own dynamics. This is the mean-field closure, inherited from chapter 7.

3. *Implicit feedback.* The control $\hat{\alpha}_t^x$ is not given but is itself the argmin of the Hamiltonian, a function of (X_t^x, Y_t^x, Z_t^x) that must be solved for and substituted back, making the drift an implicit function of the unknowns. This is the maximum-principle closure, inherited from chapter 9.

4. *Nonlocal-in-type coupling (the new difficulty).* The distributional dependence is no longer on the agent's own law but on the aggregate $(\mathbb{W}\boldsymbol{m}_t)(x)$, which averages the laws of *all* types against the kernel row $W(x, \cdot)$. Equivalently, by symmetry of the bookkeeping, the law m_t^x at one type enters the dynamics at every type y for which $W(y, x) > 0$. The coupling is now spatial (in type) as well as distributional — a continuum of mean-field problems wired together across the network.

Everything technical in this chapter is the bookkeeping required to keep that fourth, nonlocal layer under control on top of the three classical ones, and the single fact that makes the bookkeeping close is the one established in section 23.2: the new coupling is the *bounded linear operator* $\mathbb{W}$, a field contraction with constant ≤ 1 (lemma 23.10). Because the novelty is one well-behaved operator, every estimate reduces to a classical per-type estimate followed by a single application of that contraction bound — which is exactly how the fixed-point analysis of section 23.4 will proceed.

Remark 23.14 (Per-type decoupling under a frozen field)**.** Here is the structural observation that organizes the entire analysis, and it is just the freezing step of this section read backwards. *Freeze the field* $\boldsymbol{m}_t \equiv \boldsymbol{\mu}_t$ in eq. (23.16) — that is, hold the distributional argument external rather than self-generated — and the continuum of coupled FBSDEs *falls apart into independent single-type FBSDEs*, one for each x. Each of these is a classical (non-McKean–Vlasov) FBSDE of exactly the kind solved in chapter 9, coupled to the others only through the frozen aggregate $(\mathbb{W}\boldsymbol{\mu}_t)(x)$, which is now an inert deterministic input. All four difficulties enumerated above survive individually — each per-type FBSDE is still forward–backward and still has implicit feedback — but two of them, the McKean–Vlasov coupling and the nonlocal-in-type coupling, go dormant: with the field frozen there is no self-reference and no live interaction across types. They re-enter *only* at the closure step, when the frozen field is required to equal the realized one. Closure, in other words, is where the entire continuum-wide difficulty lives; everything else is a parallel family of classical problems.

This is precisely why the natural fixed-point variable is the *field of laws*, not the processes. Were one to seek the equilibrium directly in the space of process-fields $(X^x)_x$, the McKean–Vlasov self-reference would be tangled into every component. Passing to the field of laws untangles it: in the law variable the problem is a fixed point of a single map $\boldsymbol{\mu} \mapsto (\mathrm{Law}(X^{\boldsymbol{\mu},x}))_x$ on $C([0,T]; \boldsymbol{\mathcal{P}}_2)$, and the per-type FBSDEs that *define* that map are individually classical and individually solvable. The unknown is demoted from a coupled continuum of processes to a single point in the field space, and the coupling is quarantined inside the map. This same decoupling-under-freezing is what section 23.5.2 will exploit at the level of the FBSDE–PDE dictionary: freezing the field exposes, type by type, a classical *decoupling field* u^x relating Y^x to X^x, and the family of these is what seeds the graphon master equation of chapter 26.

23.3.3 The fixed point in the field space

remark 23.14 told us where to look for the equilibrium: not among the process-fields, where the coupling is everywhere, but in the field of laws $\boldsymbol{m} \in C([0,T];\boldsymbol{\mathcal{P}}_2)$, where freezing decouples the continuum into classical per-type FBSDEs and the only residual constraint is self-consistency. We now make that observation into a clean fixed-point statement. The recipe is forced by the two-step structure of the whole section: take a candidate field, run the per-type optimizations against it (each classical, by the decoupling), collect the realized laws into a new field, and ask when input equals output. The map that sends candidate to realized field is the object that carries the equilibrium, and naming it is the last thing this section does before handing it to the well-posedness analysis.

Definition 23.15 (Graphon best-response map)**.** The *graphon best-response map* $\mathsf{S} : C([0,T];\boldsymbol{\mathcal{P}}_2) \to C([0,T];\boldsymbol{\mathcal{P}}_2)$ is defined as follows. Given an input flow of fields $\boldsymbol{\mu}$, solve for each x the decoupled FBSDE obtained by replacing $(\mathbb{W}\boldsymbol{m}_t)(x)$ in eq. (23.16) with the frozen aggregate $(\mathbb{W}\boldsymbol{\mu}_t)(x)$ — a classical FBSDE per type, by remark 23.14 — obtain its optimally controlled state $X^{\boldsymbol{\mu},x}$, and output the realized flow of fields

$$\mathsf{S}(\boldsymbol{\mu}) = \big(\operatorname{Law}(X_t^{\boldsymbol{\mu},x})\big)_{x\in[0,1],\,0\le t\le T}. \tag{23.17}$$

A flow $\boldsymbol{m}$ is a graphon MFG equilibrium if and only if it is a fixed point, $\mathsf{S}(\boldsymbol{m}) = \boldsymbol{m}$.

This is the same best-response map as the analytic one of chapter 22 (definition 22.5); it is merely *realized differently*. The analytic version takes the same input field $\boldsymbol{\mu}$, but processes each type through the PDE pair: it solves the type-x Hamilton–Jacobi–Bellman equation against the frozen aggregate $(\mathbb{W}\boldsymbol{\mu}_t)(x)$ to get the value and the optimal feedback, then pushes the initial law forward through the type-x Fokker–Planck equation to read off the realized law $\operatorname{Law}(X_t^{\boldsymbol{\mu},x})$. The probabilistic version above does the identical job through the type-x FBSDE. Same input field, same per-type best response, same output field — only the solver differs, PDE versus FBSDE. That the two realizations of S genuinely agree on every output is not a triviality to be assumed; it is a theorem, the two-pictures dictionary proposition 23.19, which section 23.5 proves by identifying $Y_t^x = \nabla u^x(t, X_t^x)$ type by type. We flag the agreement here so the reader carries it into that section as the thing to be shown.

There is in fact a third realization of the same map, and the shared symbol is deliberate. The existence theory of chapter 24 works not with the full measure-valued aggregate but with its first moment, the neighbour mean $z_t(x)$ of definition 23.2, on the uniform-in-type field space; the resulting graphon-local best-response map is definition 24.4. All three — the measure-valued probabilistic map here, the analytic PDE map of chapter 22, and the first-moment map of chapter 24 — are the same mathematical object viewed through different solvers and different couplings, and we write all three with the symbol S *by design*, so that “the equilibrium is a fixed point of S” reads the same in every chapter.

It remains to record what we mean by a solution, and the integrability conditions in the definition are not decoration — each is exactly what some later step needs, so we motivate them rather than merely list them. Three requirements appear, and each answers a question the construction will ask. *Per type, the processes must live in the standard spaces of chapter 9*: X^x, Y^x square-integrable with continuous paths ($\mathcal{S}^2$) and Z^x square-integrable ($\mathcal{H}^2$), because that is precisely the regularity in which the Pardoux–Peng theorem certifies the type-x BSDE well-posed and in which the per-type maximum principle was stated — without it the adjoint eq. (23.15) need not have a solution at all. *The field must be measurable in x into those spaces*, because the closure forms the field of laws $x \mapsto \mathrm{Law}(X_t^x)$ and integrates over x; an unmeasurable field could not be aggregated by $\mathbb{W}$ and the object $(\mathbb{W}\boldsymbol{m}_t)(x)$ would be meaningless. *Finally the field must be square-integrable in x*, $\int_0^1 \mathbb{E}[\sup_{t\le T}(|X_t^x|^2 + |Y_t^x|^2)]\,\mathrm{d}x < \infty$, because this is exactly the condition that places the flow of laws inside the Bochner field space $\boldsymbol{\mathcal{P}}_2$ of definition 23.8 — the complete metric space on which the contraction estimates run. The first condition is per-type and classical; the second and third are the genuinely field-level conditions, and they are precisely the hypotheses under which the row-sum contraction lemma 23.10 has a space to act on.

Definition 23.16 (Solution of the graphon MFG FBSDE)**.** A *solution* of eq. (23.16) is a measurable field $x \mapsto (X^x, Y^x, Z^x)$ with, for a.e. x, $X^x, Y^x \in \mathcal{S}^2(\mathbb{R}^d)$, $Z^x \in \mathcal{H}^2(\mathbb{R}^{d\times k})$, such that $x \mapsto (X^x, Y^x, Z^x)$ is measurable into those spaces, the integral forms hold $\mathbb{P}$-a.s. with $\hat{\alpha}^x$ as in eq. (23.16), and $\int_0^1 \mathbb{E}[\sup_{t\le T}(|X_t^x|^2 + |Y_t^x|^2)]\,\mathrm{d}x < \infty$. The flow $\boldsymbol{m}_t = (\mathrm{Law}(X_t^x))_x$ then lies in $C([0,T];\boldsymbol{\mathcal{P}}_2)$.

We have now assembled the central object and recast equilibrium in the cleanest possible terms: a graphon MFG equilibrium is a fixed point of the best-response map S on the field space $C([0,T];\boldsymbol{\mathcal{P}}_2)$, and nothing more. The construction has quarantined every continuum-wide difficulty inside that one map — the per-type problems that define it are classical, and the only operator wiring the types together is the bounded $\mathbb{W}$ of lemma 23.10. What we have *not* yet done is ask whether such a fixed point exists, and whether it is unique. That is the next question, and it is now a purely fixed-point-theoretic one: section 23.4 takes the map S and the characterization "equilibrium = fixed point of S" built here and asks, in three regimes, when S has a fixed point and when that fixed point is unique — each regime's answer flowing, as we will see, through the contraction constant $\|\mathbb{W}\mathbf{1}\|_\infty$ that section 23.2 handed forward. We carry the "same map, two realizations" observation along with it: it is the debt that section 23.5 will discharge, proving the probabilistic S here and the analytic S of chapter 22 produce the same output field.

23.4 Fixed-point analysis: three regimes

section 23.3 reduced the whole graphon equilibrium problem to a single demand: that the best-response map S of definition 23.15 have a fixed point on the field space $C([0,T];\boldsymbol{\mathcal{P}}_2)$, with every continuum-wide difficulty quarantined inside that one map and the types wired together only through the bounded operator $\mathbb{W}$. The question left open there is the one this section takes up: *when does* S *have a fixed point, and when is that fixed point unique?* It is now a purely fixed-point-theoretic question, and the shape of its answer is dictated by the spine of the chapter. Because the types communicate only through $\mathbb{W}$, every estimate that could decide existence or uniqueness inherits the kernel in exactly one way — through the field-contraction constant $\|\mathbb{W}\mathbf{1}\|_\infty \le 1$ that section 23.2 extracted in lemma 23.10. The analysis therefore mirrors the homogeneous theorem 9.10, with $\mathbb{W}$ entering every bound through that one constant in the general (measure-valued) estimates and — once the coupling is taken linear in the population mean — through the spectral norm $\|\mathbb{W}\|$, as section 23.6 will show. We state the result, develop the mechanism of each of three regimes, and make the role of the operator explicit; the full proofs are the content of chapter 24, which owns the existence and uniqueness theory for the graphon game exactly as chapters 10 and 11 own it for the homogeneous one.

We must be honest about the seam, because the division of labour between this section and chapter 24 is subtler than a plain deferral. chapter 24 carries out the existence/uniqueness analysis in the *uniform-in-type* field space $C([0,1]; C([0,T]; \mathcal{P}_1(\mathbb{R}^d)))$, metrized by the supremum over types of the Wasserstein distance (definition 24.1); that is the space in which type-direction compactness and equicontinuity are read off directly from continuity of the kernel. The FBSDE statement below, by contrast, is set in the L^2-in-type space $\boldsymbol{\mathcal{P}}_2$ of definition 23.8, the space in which the per-type stability estimates of chapters 5 and 9 integrate over types and $\mathbb{W}$ acts as the bounded operator of lemma 23.10. The two metrics are *not* equivalent — the supremum-in-type distance is strictly finer than the L^2-in-type distance, and no inequality runs the other way — so one cannot transport a fixed point from one space to the other by a topological comparison of the two field metrics. What reconciles them is therefore not a metric estimate but the two-pictures dictionary proposition 23.19: it characterizes the equilibrium as a single measurable field of laws through the relation $Y_t^x = \nabla u^x(t, X_t^x)$, a relation that mentions *no* field metric at all. Both the uniform-in-type analysis of chapter 24 and the L^2-in-type statement here are statements about fixed points of the *same* map S, in its analytic and probabilistic realizations; proposition 23.19 shows those realizations agree type by type, so an equilibrium certified to exist (or to be unique) in the uniform-in-type space is, as a measurable field, the very object this section's statement is about. The metric was only the scaffolding the fixed-point theorem stood on, never a property of the equilibrium it produced — which is exactly why a comparison of metrics is neither available nor needed, and the dictionary does the reconciling instead. The sharp L^2-in-type compactness criterion is genuinely more delicate than its uniform-in-type cousin and is discussed at remark 24.13. With the seam understood, we do not duplicate the chapter 24 proofs; we set up the FBSDE so that they have something to act on, and make the role of the coupling operator explicit.

Theorem 23.17 (Well-posedness of the graphon MFG FBSDE)**.** *Grant* ***(A-Lip)****,* ***(A-Growth)****,* ***(A-Nondeg)****,* ***(A-Conv)*** *(so the feedback $\hat{\alpha}$ is well defined and Lipschitz) and* ***(A-Reg-W)****. Then eq. (23.16) admits a solution in the sense of definition 23.16 in each of the following regimes:*

(i) (Small horizon or weak coupling.) *There is a constant $c_0 > 0$, depending only on the Lipschitz constants, such that if $T\, \|\mathbb{W}\mathbf{1}\|_\infty \le c_0$ then the solution exists and is unique, and the graphon best-response map S is a contraction on $C([0,T]; \boldsymbol{\mathcal{P}}_2)$ with factor at most $(c_0)^{1/2}$. Both a short horizon and a weak kernel (small row-sum) suffice. Because the field-contraction constant $\|\mathbb{W}\mathbf{1}\|_\infty \le 1$ (lemma 23.10) is bounded by one* independently of the kernel strength*, the small-horizon contraction holds uniformly over all admissible graphons, the coupling entering only to lower the factor. The* operator-norm smallness ***(A-Coupling)****, $\|\mathbb{W}\| < \kappa$, is the sharper, spectral form of weak coupling; it becomes the decisive condition in the complementary regime where the coupling is linear in the population mean and the relevant constant is the spectral norm $\|\mathbb{W}\|$ rather than the row-sum — the regime in which the symmetry-breaking threshold of section 23.6 lives.*

(ii) (Graphon monotonicity.) *If in addition the graphon Lasry–Lions monotonicity* ***(A-Mon)*** *holds for the type-aggregated couplings (chapter 24), the solution exists and is unique for* every *horizon T, by the continuation-in-parameter method.*

(iii) (Compactness, no monotonicity.) *Without monotonicity but with bounded, continuous couplings and **(A-Reg-W)**, a solution exists for every T (uniqueness may fail) via a Schauder fixed point for S on a convex compact subset of $C([0,T];\boldsymbol{\mathcal{P}}_2)$.*

Proof sketch and pointers. Regime (i): the small-horizon contraction, assembled one type at a time. The mechanism is the field-valued descendant of the homogeneous contraction, and it is worth tracing in full because every step but the last is classical and the last is exactly where $\mathbb{W}$ enters. Fix two input flows $\boldsymbol{\mu},\boldsymbol{\nu} \in C([0,T];\boldsymbol{\mathcal{P}}_2)$. By remark 23.14 the map S processes each separately by freezing the aggregate and solving, for each type, the decoupled classical FBSDE of eq. (23.16) with measure coefficient the *known* frozen field $\nu_t^{\boldsymbol{\mu},x} := (\mathbb{W}\boldsymbol{\mu}_t)(x)$ (and likewise $\nu^{\boldsymbol{\nu},x}$). The two per-type FBSDEs differ *only* in that frozen coefficient, so their optimally controlled marginals obey the standard FBSDE stability estimate of chapters 5 and 9: subtract the two equations, apply Itô to the squared difference of states, control the costate difference by the Pardoux–Peng a priori bound, use the Lipschitz dependence of the data on the measure argument (**(A-Lip)**, **(A-Conv)**), and close with Grönwall. The result, for each x, is

$$\sup_{t\le T} \mathcal{W}_2\big(\operatorname{Law}(X_t^{\boldsymbol{\mu},x}), \operatorname{Law}(X_t^{\boldsymbol{\nu},x})\big)^2 \le C\,T \sup_{t\le T} \mathcal{W}_2\big(\nu_t^{\boldsymbol{\mu},x}, \nu_t^{\boldsymbol{\nu},x}\big)^2, \quad \nu^{\boldsymbol{\mu},x} = (\mathbb{W}\boldsymbol{\mu})(x),$$

with C depending only on the Lipschitz constants of the data, *not* on x and *not* on the kernel. This is a per-type statement: it says each type's best response is stable in the neighbour field it is fed, and nothing has yet coupled the types. The coupling enters at the single step that turns this family of per-type bounds into a statement about the field map — integration over x. Integrating the display and using $\mathbf{d}_{2,\infty}(\mathsf{S}(\boldsymbol{\mu}),\mathsf{S}(\boldsymbol{\nu}))^2 = \sup_{t\le T}\int_0^1 \mathcal{W}_2(\operatorname{Law}(X_t^{\boldsymbol{\mu},x}), \operatorname{Law}(X_t^{\boldsymbol{\nu},x}))^2\,\mathrm{d}x \le \int_0^1 \sup_{t\le T} \mathcal{W}_2(\operatorname{Law}(X_t^{\boldsymbol{\mu},x}), \operatorname{Law}(X_t^{\boldsymbol{\nu},x}))^2\,\mathrm{d}x$,

$$\mathbf{d}_{2,\infty}\big(\mathsf{S}(\boldsymbol{\mu}),\mathsf{S}(\boldsymbol{\nu})\big)^2 \le C\,T \int_0^1 \sup_{t\le T} \mathcal{W}_2\big((\mathbb{W}\boldsymbol{\mu}_t)(x), (\mathbb{W}\boldsymbol{\nu}_t)(x)\big)^2\,\mathrm{d}x.$$

The right-hand integrand is the squared transport distance between the two aggregates, exactly the quantity the field-contraction bound eq. (23.11) controls. Its engine is the pointwise convexity estimate underlying lemma 23.10, $\mathcal{W}_2\big((\mathbb{W}\boldsymbol{m})(x), (\mathbb{W}\boldsymbol{m}')(x)\big)^2 \le \int_0^1 W(x,y)\mathcal{W}_2(m^y, m^{y\prime})^2\,\mathrm{d}y$ (the squared distance of a W-mixture is at most the mixture of squared distances); taking the supremum in time, integrating in x, and using the symmetry of W to recognize the inner mass as the row-sum $(\mathbb{W}\mathbf{1})(y) \le \|\mathbb{W}\mathbf{1}\|_\infty$ caps the whole integral by $\|\mathbb{W}\mathbf{1}\|_\infty\, \mathbf{d}_{2,\infty}(\boldsymbol{\mu},\boldsymbol{\nu})^2$. Hence

$$\mathbf{d}_{2,\infty}\big(\mathsf{S}(\boldsymbol{\mu}),\mathsf{S}(\boldsymbol{\nu})\big)^2 \le C\,T\, \|\mathbb{W}\mathbf{1}\|_\infty\, \mathbf{d}_{2,\infty}(\boldsymbol{\mu},\boldsymbol{\nu})^2,$$

so S has Lipschitz constant $\le (C\,T\,\|\mathbb{W}\mathbf{1}\|_\infty)^{1/2} \le (CT)^{1/2}$ on the flow space, the second inequality because $\|\mathbb{W}\mathbf{1}\|_\infty \le 1$ no matter how strong the kernel. It is therefore a contraction as soon as $C\,T\,\|\mathbb{W}\mathbf{1}\|_\infty < 1$ — the threshold c_0 of the statement, which absorbs the Lipschitz constant C — and theorem 2.36 delivers the unique fixed point. Read that threshold both ways. A *short horizon* forces $C\,T < 1$ and hence contraction for *every* admissible kernel, since the row-sum can only lower the product; this is the uniform-over-graphons claim of the theorem. A *weak kernel* (small row-sum) forces $CT\,\|\mathbb{W}\mathbf{1}\|_\infty < 1$ even at moderate horizons. The crucial structural point — the entire payoff of lemma 23.10 — is that the type-integration, the one place where the continuum's cross-type interaction could have injected a constant growing with coupling strength, instead contributes the bounded factor $\|\mathbb{W}\mathbf{1}\|_\infty \le 1$. The contrast with the *linear*-mean coupling, where the operative constant is not the row-sum but the spectral norm $\|\mathbb{W}\|$ and *its* size sets a genuine threshold, is the subject of remark 23.18 and is made explicit in section 23.6.

Regime (ii): monotonicity and continuation in a parameter. At large horizon the contraction of regime (i) is lost — the factor $(CT\,\|\mathbb{W}\mathbf{1}\|_\infty)^{1/2}$ exceeds one — and a different mechanism must furnish uniqueness. The classical substitute is the Lasry–Lions monotonicity of the coupling, **(A-Mon)**, and the device that turns it into well-posedness for *every* T is continuation in a parameter. One embeds eq. (23.16) in a one-parameter family indexed by $\lambda \in [0,1]$, interpolating from a trivially solvable endpoint at $\lambda = 0$ (the decoupled, or otherwise known, problem) to the target at $\lambda = 1$, and studies the set $S \subseteq [0,1]$ of parameters at which the family is uniquely solvable. The argument shows S is nonempty ($0 \in S$), *open*, and *closed*, whence $S = [0,1]$ by connectedness and in particular $1 \in S$. Openness is a perturbation step: near a solved λ_0 the linearized map is invertible, so a contraction on a small parameter ball relocates the fixed point and a whole neighbourhood of λ_0 lies in S. Closedness is where monotonicity does its work, and it rests on an *a priori bound uniform in λ* — the *monotone a priori estimate.* **(A-Mon)** supplies a bound on the solution, and on the difference of any two solutions, that does not degrade as λ varies, so a sequence of solutions along $\lambda_n \to \lambda_*$ cannot escape to infinity and its limit solves the problem at λ_*. That a priori bound is itself the graphon descendant of the Lasry–Lions pairing computation: one pairs the difference of two solutions' forward and backward components, the cross terms organize into the monotonicity functional of the coupling, and the entire identity is *integrated in x against* $\mathbb{W}$, so that it is the type-aggregated coupling, not the pointwise one, that must be monotone. That this x-integrated pairing closes is exactly the graphon form of the homogeneous Lasry–Lions uniqueness; it is stated and proved in full in chapter 24, and uniqueness for *every* horizon follows because the same monotone pairing controls the difference of two solutions directly, with no smallness of T required.

Regime (iii): existence by compactness, and the two compactness inputs. Drop monotonicity entirely and ask only for existence. The tool is the Schauder fixed-point theorem theorem 2.38: a continuous self-map of a convex compact subset of a Banach space has a fixed point. One builds such a set of fields, shows S maps it continuously into itself, and reads off a fixed point — an equilibrium, though Schauder says nothing about uniqueness, so multiplicity is allowed and, as remark 23.18 explains, genuinely occurs past a spectral threshold. The substance is the compactness, and here lies the one genuinely new feature of the graphon problem, easy to miss because two unrelated compactness requirements travel under the same word and must *not* be conflated.

The first is compactness in the *state* direction: for each fixed type x, the candidate marginals $\{m_t^x\}_{t\le T}$ must be precompact in $(\mathcal{P}_2(\mathbb{R}^d), \mathcal{W}_2)$. This is supplied exactly as in the homogeneous theory of chapters 9 and 10: x-uniform second-moment bounds from **(A-Growth)** give tightness of the marginals (chapter 3, Prokhorov), the nondegenerate, regularizing diffusion **(A-Nondeg)** controls their spatial regularity, and the SDE moment increments give $\mathcal{W}_2$-equicontinuity in time. Nothing about the graphon is new here; the diffusion does the work, type by type, precisely as a single population's diffusion does.

The second is compactness in the *type* direction: the field $x \mapsto m_t^x$ must itself be precompact, which on top of pointwise precompactness demands control of the field's oscillation in x. And here no dynamical mechanism helps. The dynamics treat each type as a *separate* diffusion driven by its own noise; nothing in the flow smooths across nearby types, because the only object linking types is $\mathbb{W}$, and $\mathbb{W}$ regularizes in x only to the extent that its kernel does. Type-direction compactness therefore cannot be earned from the diffusion; it must be *purchased* from the data — specifically from the uniform continuity of the kernel in its type variable, the continuity clause of **(A-Reg-W)**. When $x \mapsto W(x, \cdot)$ is uniformly continuous (say into L^1), the aggregate $x \mapsto (\mathbb{W}\boldsymbol{\mu}_t)(x)$ is equicontinuous in x uniformly over input fields, and the per-type stability of the FBSDE in its measure coefficient then transports that equicontinuity to the output field $x \mapsto \mathrm{Law}(X_t^{\boldsymbol{\mu},x})$. This type-direction equicontinuity is the genuinely new compactness input of the graphon problem — the price the continuum charges that neither the finite nor the homogeneous theory ever sees. It is established as lemma 24.9, and the fact that it must be bought from kernel continuity rather than produced by the dynamics is the first of the two senses, catalogued in remark 24.12, in which the graphon problem is strictly harder than the classical one. With both compactnesses in hand the convex set of fields is compact, S is continuous on it, and Schauder closes the argument.

The complete arguments — the continuation estimate of (ii), the precise compactness criterion of (iii), and the graphon monotonicity condition — are the business of chapter 24. One subtlety is worth flagging at the seam: the equicontinuity just described is cleanest in the uniform-in-type metric, and the sharp L^2-in-type compactness criterion appropriate to the space $\boldsymbol{\mathcal{P}}_2$ of this chapter is more delicate, since L^2-in-type control yields only measurable, not pointwise-equicontinuous, selections; this refinement is remark 24.13. Primary sources for all three regimes are [34, 10, 15]. ☐

Remark 23.18 (Two norms of $\mathbb{W}$, and which controls what)**.** This is the conceptual payoff of the section, and it deserves to be stated sharply, because two genuinely different norms of the one operator $\mathbb{W}$ are in play and conflating them is the central trap of the subject. The slogan "one operator carries all the coupling" is correct, but the operator carries it through *two* numbers, and they answer two different questions.

The row-sum governs the general contraction. The well-posedness of regime (i) — the measure-valued, fully nonlinear contraction — is controlled by the row-sum bound $\|\mathbb{W}\mathbf{1}\|_\infty = \operatorname{ess\,sup}_x \int_0^1 W(x,y)\,\mathrm{d}y$, which is the $L^\infty \to L^\infty$ operator norm of $\mathbb{W}$ and nothing finer. **(A-Reg-W)** makes the kernel sub-stochastic, so this number is ≤ 1 *no matter how strong the kernel*: it saturates at one and cannot be pushed past it by cranking up the coupling. Consequently coupling strength, by itself, never threatens small-horizon uniqueness — the worst a kernel can do to the contraction factor $(C\,T\,\|\mathbb{W}\mathbf{1}\|_\infty)^{1/2}$ is leave it at $(CT)^{1/2}$, and a short horizon defeats that for every admissible graphon at once. This is why regime (i) holds uniformly over all graphons.

The spectral norm governs the onset of multiplicity. Uniqueness is not the only question; whether the equilibrium is unique as opposed to one of several is a separate phenomenon, and it is governed by a different number. It surfaces when the coupling is *linear* in the population — the mean-field case, where an agent responds to the neighbour *mean* $z_t(x) = (\mathbb{W}\bar{m}_t)(x)$ rather than to the full measure. There the self-consistency closes through the linear operator $s\mathbb{W}$ acting on the field of means (s the coupling strength), and the fixed-point structure is the invertibility of $\mathrm{Id} - (\text{linear response})\, s\mathbb{W}$, governed not by the row-sum but by the *spectral operator norm* $\|\mathbb{W}\| = |\lambda_1|$ — the magnitude of the leading eigenvalue (theorem 2.26), whose eigenvector is the eigenvector-centrality mode of chapter 18. The boundary between a unique equilibrium and several is set by how $s\,\|\mathbb{W}\|$ compares with a critical coupling; crossing it is symmetry breaking, the appearance of new self-consistent solutions where the trivial one loses stability. This threshold is computed in closed form for the LQG thread in section 23.6 and in general in chapter 24.

Why the two need not agree, and when they do. For a nonnegative kernel one always has $\|\mathbb{W}\| \le \|\mathbb{W}\mathbf{1}\|_\infty$ — the spectral radius of a nonnegative operator is dominated by its maximal row-sum, the Perron–Frobenius bound — so the two numbers can differ, the spectral threshold being reached at *weaker* coupling than the row-sum ever signals. They coincide in exactly the degenerate case the reduction checks of remark 23.4 singled out: for a constant graphon $W \equiv c$ the only active mode is the constant eigenfunction, $\|\mathbb{W}\mathbf{1}\|_\infty = \|\mathbb{W}\| = c$, and the two questions collapse into one — which is precisely why the homogeneous theory, living on a single mode, never had to distinguish them. The continuum forces the distinction the moment $\mathbb{W}$ carries more than one eigenvalue.

It is always a norm of $\mathbb{W}$*, never the pointwise kernel.* In both regimes the controlling quantity is a *norm* of the operator, not the pointwise values $W(x, y)$. This is what makes the theory robust: two graphons close in cut metric but wildly different pointwise (chapter 17) induce operators close in norm, hence comparable contraction constants and comparable equilibria — the quantitative stability statement made precise in chapter 25. The pointwise kernel is not an observable of the equilibrium; the relevant norms of $\mathbb{W}$ are. Beyond the contraction regime one buys uniqueness with monotonicity (regime (ii)) or settles for existence without it (regime (iii)), but in every case it is through one of these two norms of the single operator $\mathbb{W}$ that the kernel speaks.

Two debts are now outstanding, and the next section discharges the structural one. The two-norms distinction just drawn is handed forward to section 23.6, where the spectral threshold $s\,\|\mathbb{W}\|$ is exhibited in closed form for Thread B — the continuum splitting into one scalar game per eigenmode, with the symmetry breaking visible mode by mode. The three regime statements, in turn, are entered in the chapter ledger as deferred to chapter 24. But that deferral rests on a bridge we have so far only invoked: that chapter 24's proofs, run in the uniform-in-type metric, certify the very object this section's L^2-in-type FBSDE statement is about. That bridge is the two-pictures dictionary, and building it is the task of section 23.5: there we prove that the probabilistic best-response map of this chapter and the analytic one of chapter 22 are the same map, by identifying $Y_t^x = \nabla u^x(t, X_t^x)$ type by type — the equivalence that lets a fixed point found in either metric be read as a solution of the other, and so transfers chapter 24's well-posedness to the FBSDE stated here.

23.5 Two pictures of one graphon equilibrium

Twice already this chapter has leaned on an equivalence it has not yet proved. In section 23.3 we observed that the probabilistic best-response map S built from the FBSDE eq. (23.16) and the analytic best-response map of chapter 22 built from the HJB/Fokker–Planck pair are not two maps that happen to agree but the *same* map in two realizations — the same population field, computed by a different solver. And in section 23.4 the three well-posedness regimes were proved on the probabilistic side, in the L^2-in-type field metric $\mathbf{d}_2$, yet the sharpest existence-and-uniqueness statements of chapter 24 are proved on the analytic side, in the uniform-in-type metric; the only thing that lets the one set of theorems discharge the other is precisely that the two formulations describe one equilibrium. Both debts come due here. This section pays them by writing down, and proving, the exact *dictionary* between the probabilistic objects (X^x, Y^x, Z^x) of this chapter and the analytic objects (u^x, m^x) of chapter 22 — the graphon analogue of the homogeneous two-pictures result proposition 9.12.

It is worth recalling exactly what chapter 22 built, because the dictionary is a statement about that object. There the dynamic graphon mean field game was written as a continuum-indexed system eq. (22.6): for each type x a *backward* Hamilton–Jacobi–Bellman equation eq. (22.6a) for the value $u^x(t,\cdot)$ of the representative type-x agent, run from terminal data at $t = T$, and a *forward* Fokker–Planck equation eq. (22.6b) for the type-x population law m_t^x, run from initial data at $t = 0$. The two families are coupled across types through one channel and one channel only: the graphon aggregate $(\mathbb{W}\boldsymbol{m}_t)(x)$ that each equation reads as its measure argument. The claim of this section is that the FBSDE eq. (23.16) assembled in section 23.3 and that PDE system are two representations of a single graphon equilibrium, and that the bridge between them is, type by type, the identification of the costate with the gradient of the value along the optimal trajectory — the measure argument being supplied by the *same* aggregate in both pictures. We state and prove the forward half of the dictionary in the first subsection and supply the converse machinery — a measurable family of decoupling fields — in the second.

23.5.1 The dictionary

Before stating the dictionary we must fix the regularity under which it even makes sense, and it pays to see why each clause is needed rather than to swallow a list of hypotheses. The dictionary will read $Y_t^x = \nabla u^x(t, X_t^x)$ and $Z_t^x = \mathrm{D}^2\, u^x(t, X_t^x)\,\sigma$; for the right-hand sides to exist pointwise and for Itô's formula to be applicable to ∇u^x we need u^x to be once continuously differentiable in time and *three* times in space. We therefore assume the regularity under which the analytic picture of chapter 22 is classical: for each x the type-x HJB value $u^x(t,x) = u^x(t,x)$ is $C^{1,2}$ on $[0,T) \times \mathbb{R}^d$ — in fact $C^{1,3}$ in the spatial variable. The reason we may demand the extra spatial derivative for free is interior parabolic regularity: **(A-Nondeg)** makes the generator uniformly elliptic, and a uniformly parabolic equation with smooth coefficients has a solution smoother in space than its data by the Schauder interior estimates, so $C^{1,2}$ is automatically upgraded to $C^{1,3}$ (indeed to $C^{1,\infty}$) away from the terminal time. We need exactly one notch of this upgrade and no more: $u^x \in C^{1,2}$ lets us write $Y^x = \nabla u^x$ and apply Itô, while the third spatial derivative is what makes *differentiating the HJB equation in x* a legitimate operation — the step in the proof that produces the adjoint driver. We record this as part of the standing hypothesis exactly as in chapter 22 rather than re-derive the Schauder theory here; the volatility is uncontrolled (so σ does not depend on the costate and the second-order term is a fixed linear operator on $\mathrm{D}^2\, u^x$); and — the one genuinely graphon-flavoured clause — the map $x \mapsto u^x$ is measurable with x-uniform parabolic bounds. This last clause is not decoration. The per-type problems are solved separately, one for each x, and what stitches the continuum of solutions back into a single measurable field is precisely that the coefficients depend on x only through bounded data and through the aggregate $\nu_t^x = (\mathbb{W}\boldsymbol{m}_t)(x)$, whose x-to-x variation the row-sum bound $\|\mathbb{W}\mathbf{1}\|_\infty \leq 1$ of lemma 23.10 controls; the Schauder constants therefore do not blow up as x varies, and the value field inherits a uniform-in-x modulus. We return to this measurability point inside the proof, where it is the only ingredient beyond the homogeneous result. Recall from chapter 22 (the system eq. (22.6), with halves eq. (22.6a) and eq. (22.6b)) that the equilibrium value field solves the type-x backward HJB equation

$$\partial_t u^x + \tfrac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2 u^x) - H(x, x, \nabla u^x, (\mathbb{W}\boldsymbol{m}_t)(x)) = 0, \qquad u^x(T, x) = g(x, x, (\mathbb{W}\boldsymbol{m}_T)(x)), \tag{23.18}$$

with $H = H$ the HJB Hamiltonian of Appendix A (convex in the costate variable p under **(A-Conv)**). The optimal feedback is the minimizer of the generalized Hamiltonian eq. (23.14); the compact convention $\alpha^* = -\partial_p H$ of Appendix A is the special case in which the control enters the drift additively with unit gain. For the Thread-A/B drift $b = ax + b\alpha$ the gain is b and the feedback is $\hat{\alpha}^x = -bY^x$, derived in worked computation 23.22; in general one minimizes eq. (23.14) directly. The population field evolves by the forward graphon Fokker–Planck eq. (23.6) carrying the optimal feedback drift. The measure argument in both eq. (23.18) and eq. (23.6) is the same aggregate $(\mathbb{W}\boldsymbol{m}_t)(x)$.

Proposition 23.19 (Graphon FBSDE–PDE dictionary)**.** *Under the regularity above, let $\boldsymbol{m} = (\boldsymbol{m}_t)$ be a graphon equilibrium flow and $(u^x)_x$ the corresponding HJB value field solving eq. (23.18). For each x let X^x solve the forward equation of eq. (23.16) with this $\boldsymbol{m}$, and set*

$$Y^x_t = \nabla u^x(t, X^x_t), \qquad Z^x_t = \mathrm{D}^2 u^x(t, X^x_t)\, \sigma(t, x, X^x_t, (\mathbb{W}\boldsymbol{m}_t)(x)). \tag{23.19}$$

(The order is fixed by dimensions: $\mathrm{D}^2 u^x$ is $d \times d$ and σ is $d \times k$, so $Z^x \in \mathbb{R}^{d\times k}$, the shape demanded by $Z^x \in \mathcal{H}^2(\mathbb{R}^{d\times k})$ in definition 23.16 and by the integrand of $Z^x_t \,\mathrm{d}B^x_t$.) Then for a.e. x the triple (X^x, Y^x, Z^x) solves the type-x FBSDE of eq. (23.16) with the same $m^x_t = \mathrm{Law}(X^x_t)$. Conversely, if $(X^x, Y^x, Z^x, \boldsymbol{m})$ solves eq. (23.16) and the per-type FBSDE admits a sufficiently regular decoupling field U^x (section 23.5.2), then ∇_x of the associated potential reconstructs ∇u^x and $(u^x)_x$ solves eq. (23.18). The two formulations are equivalent representations of the same graphon equilibrium.

Proof. The whole proof is the freezing trick run once more, now in the service of an *identity* rather than an existence statement: freeze the equilibrium aggregate to make the per-type problem classical, invoke the homogeneous two-pictures result for that classical problem, and then verify the four FBSDE requirements — the Z-identification, the driver, the terminal datum, and measurability in type — one at a time by an explicit Itô computation.

Freeze the aggregate. Fix x and set $\nu^x_t = (\mathbb{W}\boldsymbol{m}_t)(x)$. At a graphon equilibrium $\boldsymbol{m}$ is a fixed, deterministic flow of fields, so ν^x_t is a known deterministic measure flow — it no longer references the unknown processes. With ν^x frozen, the HJB equation eq. (23.18) is a *classical* backward parabolic equation in (t, x) alone, and the forward equation of eq. (23.16) is a classical optimally controlled SDE with a deterministic, time-dependent measure coefficient. The type-x problem is therefore, on the nose, an instance of the homogeneous control problem of chapter 9 with the measure flow m_t there replaced by ν^x_t and the label x a passive parameter; the assertion $Y^x = \nabla u^x$ is then exactly proposition 9.12 for that instance. We reproduce the computation to exhibit, in the graphon notation, where each piece of the FBSDE eq. (23.16) comes from.

Apply Itô to ∇u^x; identify Z^x. By the standing $C^{1,3}$ regularity the map $(t,x) \mapsto \nabla u^x(t,x)$ is $C^{1,2}$, so Itô's formula theorem 5.9 applies to each of its components $\partial_{x_i} u^x$ along the forward dynamics $\mathrm{d}X_t^x = b\ \mathrm{d}t + \sigma\ \mathrm{d}B_t^x$ (with b, σ evaluated at (t, x, X_t^x, ν_t^x) and the optimal feedback). Collecting the components into the vector $Y_t^x = \nabla u^x(t, X_t^x)$,

$$\mathrm{d}Y_t^x = \Big(\partial_t \nabla u^x + (b\cdot\nabla)\nabla u^x + \tfrac{1}{2}\operatorname{tr}\left(\sigma\sigma^\top \mathrm{D}^2\ \nabla u^x\right)\Big)(t, X_t^x)\ \mathrm{d}t + \mathrm{D}^2\, u^x(t, X_t^x)\,\sigma\ \mathrm{d}B_t^x, \tag{23.20}$$

where the bracketed drift is the generator $\partial_t + \mathcal{A}_t^x$ applied componentwise to ∇u^x. The martingale (Itô-integral) part is $\mathrm{D}^2\, u^x(t, X_t^x)\,\sigma\ \mathrm{d}B_t^x$, an $\mathbb{R}^{d\times k}$-valued integrand against $\mathrm{d}B_t^x$. Comparing with the backward equation of eq. (23.16), whose martingale part is by definition $Z_t^x\ \mathrm{d}B_t^x$, and using uniqueness of the martingale representation (theorem C.17) forces $Z_t^x = \mathrm{D}^2\, u^x(t, X_t^x)\,\sigma(t, x, X_t^x, \nu_t^x)$ — which is the second entry of eq. (23.19). The dimension bookkeeping is exactly the one flagged in the proposition: $\mathrm{D}^2\, u^x$ is the $d \times d$ Hessian and σ is $d \times k$, so their product is $d \times k$, the shape demanded both by $Z^x \in \mathcal{H}^2(\mathbb{R}^{d\times k})$ in definition 23.16 and by the very integrand $Z_t^x\ \mathrm{d}B_t^x$ we just matched.

Recover the adjoint driver by differentiating HJB. It remains to check that the drift in eq. (23.20) equals the adjoint driver $-\partial_x \mathcal{H}$ of eq. (23.15). Take the spatial gradient of the HJB equation eq. (23.18) — legitimate term by term precisely because u^x is $C^{1,3}$, so all the derivatives below exist and commute. Differentiating $\partial_t u^x + \frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2\, u^x) - H(x, x, \nabla u^x, \nu_t^x) = 0$ in x gives

$$\partial_t \nabla u^x + \tfrac{1}{2}\nabla \operatorname{tr}\left(\sigma\sigma^\top \mathrm{D}^2\, u^x\right) - \partial_x H - \partial_p H \cdot \mathrm{D}^2\, u^x = 0,$$

the last two terms coming from the chain rule applied to $H(x, x, \nabla u^x(t,x), \nu_t^x)$, whose x-dependence is both explicit and through $p = \nabla u^x$. Solving for $\partial_t \nabla u^x$ and substituting into the bracket of eq. (23.20), the second-order terms organize into $\frac{1}{2}\operatorname{tr}(\sigma\sigma^\top \mathrm{D}^2\ \nabla u^x)$ plus the $\partial_p H \cdot \mathrm{D}^2\, u^x$ piece, which together with the transport term $(b\cdot\nabla)\nabla u^x = \mathrm{D}^2\, u^x\, b$ from the Itô drift collapse once we use the envelope identity and the relation $H = -\widehat{\mathcal{H}}$ between the HJB Hamiltonian and the reduced generalized Hamiltonian (remark 9.11): at the optimal feedback $\hat\alpha_t^x$ the optimal drift b is exactly the Hamiltonian velocity $-\partial_p H$ (the envelope theorem, in the sign convention of Appendix A), so the transport contribution and the p-chain-rule contribution from differentiating HJB are equal and opposite and cancel. What survives is precisely $-\partial_x \mathcal{H}(t, x, X_t^x, \nu_t^x, Y_t^x, Z_t^x, \hat\alpha_t^x)$, the driver of eq. (23.15), with the optimal feedback $\hat\alpha_t^x = \alpha^*(t, x, X_t^x)$ given by the Hamiltonian minimizer. This is the calculation that the slogan "differentiate the value, get the costate; differentiate HJB, get the adjoint" compresses; the $C^{1,3}$ hypothesis is what licenses every differentiation in it.

Match the terminal data. At $t = T$ the value carries the terminal cost, $u^x(T, x) = g(x, x, \nu_T^x)$, so taking the gradient and evaluating along the trajectory, $Y_T^x = \nabla u^x(T, X_T^x) = \partial_x g(x, X_T^x, \nu_T^x)$, which is exactly the terminal datum of the backward equation in eq. (23.16). The three pieces — Z-identification, driver, and terminal datum — together say that (X^x, Y^x, Z^x) solves the type-x FBSDE with the *same* $m_t^x = \mathrm{Law}(X_t^x)$, since the forward law is untouched by the construction.

Measurability in type. This is the one ingredient with no homogeneous counterpart, and it is where the x-uniform regularity hypothesis earns its place, so we make it explicit rather than assert it. The triple is built from u^x by the three deterministic operations ∇, D^2, and "solve the forward SDE," each continuous in the coefficients; so measurability of $x \mapsto (X^x, Y^x, Z^x)$ reduces to measurability of $x \mapsto u^x$ into $C^{1,2}$. The latter holds because u^x is the unique classical solution of the HJB equation eq. (23.18) whose only x-dependence is through the bounded data and through the aggregate ν_t^x, and $x \mapsto \nu_t^x$ is measurable (it is $\mathbb{W}$ applied to the measurable equilibrium field, definition 23.2); the solution map of a uniformly parabolic equation is continuous in its coefficients with the x-uniform Schauder constants furnished above, so the composition $x \mapsto u^x$ is measurable into $C^{1,2}$ with a uniform modulus. This is the sense in which "$x \mapsto u^x$ measurable with x-uniform parabolic bounds" was the only extra hypothesis: it converts a continuum of separately-solved classical problems into one measurable field.

The converse. Conversely, suppose $(X^x, Y^x, Z^x, \boldsymbol{m})$ solves the FBSDE eq. (23.16). For a.e. x the per-type FBSDE is, with ν^x frozen, a classical decoupled FBSDE; if it admits a sufficiently regular decoupling field U^x — which the next subsection supplies as theorem 23.21 — then $Y_t^x = U^x(t, X_t^x)$, and integrating $U^x = \nabla u^x$ in x reconstructs a potential u^x that, by the same Itô-plus-HJB calculation read backward, solves eq. (23.18); uniqueness of the per-type BSDE solution (chapter 5) makes the forward map of this proposition and the converse exact inverses. The two formulations are thus equivalent representations of one graphon equilibrium. □

The entry to memorize is, again, the first equality in eq. (23.19):

$\boxed{Y_t^x = \nabla u^x(t, X_t^x)}$ the type-x costate is the gradient of the type-x value, along the type-x trajectory.

This is the single line the reader should carry out of the section, and it carries its own mnemonic: the backward process Y^x of the probabilistic picture is nothing but the analytic value's slope, sampled along the random path the agent actually follows. Everything else — the Z-identification, the matching of drivers and terminal data — is the bookkeeping that makes this one equality consistent with both equations at once.

It is worth saying carefully what each picture *stores*, because the two are not merely notational variants; they package the same equilibrium in genuinely different data structures, and which structure is convenient depends on the question. The PDE picture of chapter 22 stores the equilibrium as two *fields of fields*: a value $(t, x) \mapsto u^x(t, x)$ and a density $(t, x) \mapsto m_t^x(x)$, each itself indexed by the type x — functions of state and time, for every type. The FBSDE picture of this chapter stores the *same* equilibrium as a measurable family $x \mapsto (X^x, Y^x, Z^x)$ of coupled *processes* — random trajectories, one optimal path and its costate per type. Neither stores the cross-type coupling as a separate object: in both, the neighbour aggregate $(\mathbb{W}\boldsymbol{m}_t)(x)$ is computed once from the population field and read identically by the value equation and by the state dynamics, which is the concrete sense in which the population field is literally the same object in both pictures. The bridge between the two storage formats is, exactly as in chapter 9, "evaluate the field along the random trajectory": feed the random state X_t^x into the deterministic field $\nabla u^x(t, \cdot)$ and out comes the random costate Y_t^x. The only graphon novelty is that this evaluation is now done type by type, with the entire cross-type interaction held in the single aggregate — the chapter's organizing principle, "one operator carries all the coupling," visible once more at the level of the dictionary itself.

Remark 23.20 (What each picture sees better, in the graphon setting)**.** The division of labour of chapter 9 persists and sharpens. The PDE picture of chapter 22 exposes regularity in the *state* variable (parabolic estimates, maximum principle) and is what the type-grid finite-difference schemes of chapter 28 discretize. The FBSDE picture of this chapter exposes the *type* and *trajectory* structure: it is the formulation in which the descent to a finite sampled network $G(N, W)$ is a propagation-of-chaos statement about N coupled trajectories (chapter 25), in which the norms of the coupling operator $\mathbb{W}$ enter the estimates explicitly (the row-sum $\|\mathbb{W}\mathbf{1}\|_\infty$ for the general contraction, the spectral $\|\mathbb{W}\|$ for the multiplicity threshold; theorem 23.17), and in which the spectral decomposition of $\mathbb{W}$ literally diagonalizes the equilibrium in the solvable Thread B (section 23.6). It is also the natural home of the forward–backward Monte Carlo solvers of chapter 28 and of the common-noise extension of chapter 26, where the population field itself becomes random and only a measure-dependent (master) field tracks it.

23.5.2 Decoupling fields, type by type

The dictionary just proved runs in one direction with no extra machinery: given the analytic value field, Itô produces the probabilistic triple. The converse direction — reconstruct the value field from a solution of the FBSDE — was stated in proposition 23.19 but left conditional on "a sufficiently regular decoupling field U^x," a promissory note we now redeem. The obstruction the converse must overcome is structural and familiar from chapter 9: an FBSDE is a *two-point* boundary value problem in time, with X^x pinned at $t = 0$ and Y^x pinned at $t = T$, so neither leg can be integrated on its own. The device that resolves this two-point coupling is the decoupling field of section 9.4 — a deterministic function $U^x(t, x)$ that expresses the backward state as a function of the forward one, $Y^x_t = U^x(t, X^x_t)$, thereby reducing the coupled forward–backward pair to a single forward SDE with known feedback. In the homogeneous theory this function *is* ∇u^x, so the decoupling field is simultaneously the analytic gradient the converse needs and the algebraic device that closes the FBSDE; that double role is what makes it the right tool here. The only work specific to the graphon is to produce not one decoupling field but a whole *measurable family* of them, one per type, with constants that do not degrade as x ranges over the continuum.

Theorem 23.21 (Family of decoupling fields)**.** *Grant **(A-Lip)**, **(A-Growth)**, **(A-Nondeg)**, **(A-Conv)**, **(A-Reg-W)**, with the equilibrium field $\boldsymbol{m}$ fixed (so each per-type FBSDE is classical). Then there is a horizon $T_0 > 0$, depending only on the Lipschitz constants (and, through the aggregate, on the row-sum bound $\|\mathbb{W}\mathbf{1}\|_\infty \le 1$), such that for $T \le T_0$, for a.e. x the type-x decoupled FBSDE has a unique Lipschitz decoupling field $U^x : [0, T] \times \mathbb{R}^d \to \mathbb{R}^d$ with*

$$Y^x_t = U^x(t, X^x_t) = \nabla u^x(t, X^x_t), \qquad Z^x_t = \partial_x U^x(t, X^x_t)\,\sigma, \tag{23.21}$$

*the map $x \mapsto U^x$ measurable with x-uniform Lipschitz constant. Under **(A-Mon)** the family exists and is Lipschitz for every T.*

Proof sketch. We do *not* reprove the per-type result, which is owned by chapter 9, and we are explicit about the division of labour: for each fixed x, with the equilibrium field frozen, the type-x FBSDE is a classical decoupled FBSDE, and the existence of a unique Lipschitz decoupling field U^x for it — for short horizons in general, for all horizons under monotonicity — is exactly the decoupling-field theorem theorem 9.14, established there by the four-step scheme of Ma–Protter–Yong and the contraction scheme of Delarue. The nondegeneracy **(A-Nondeg)** is what supplies the parabolic smoothing that makes U^x Lipschitz rather than merely measurable, and the identification $U^x = \nabla u^x$ is the dictionary proposition 23.19 just proved. So the per-type content is imported wholesale. What is genuinely new in the graphon setting — and all that this sketch must establish — are two additions: that the horizon T_0 and the Lipschitz constant can be taken *uniform in x*, and that the assignment $x \mapsto U^x$ is *measurable.* We develop each.

x-uniformity of the horizon and the Lipschitz constant. The small-horizon threshold T_0 and the Lipschitz constant produced by theorem 9.14 are not abstract; they are explicit functions of the data entering the per-type FBSDE — the Lipschitz constants of b, σ, L, g, the nondegeneracy floor of **(A-Nondeg)**, and the modulus with which the coefficients respond to their measure argument. For the family to share a single T_0 and a single Lipschitz constant it suffices that these inputs be bounded uniformly over x. The state-coefficient constants are x-uniform by **(A-Lip)**–**(A-Growth)** outright. The only input that could in principle drift with x is the measure argument, which enters the type-x problem solely through the aggregate $\nu_t^x = (\mathbb{W}\boldsymbol{m}_t)(x)$; so x-uniformity comes down to controlling how much ν^x can vary as x moves — and this is precisely what the row-sum bound buys. By the field-contraction estimate eq. (23.11) of lemma 23.10, the aggregate's variation across the type interval is dominated by $\|\mathbb{W}\mathbf{1}\|_\infty \leq 1$ times the variation of the underlying field; the operator $\mathbb{W}$ cannot *amplify* type-to-type differences, it can only redistribute and average them, with total weight ≤ 1. Consequently the measure inputs to the per-type problems are bounded and equi-Lipschitz in x, the threshold T_0 of theorem 9.14 may be taken as its worst-case (smallest) value over x, which is still strictly positive because it depends only on the now-uniform data, and the same is true of the Lipschitz constant of U^x. The crucial point is the one the throughline keeps returning to: it is the bound ≤ 1 on the row-sum — independent of the kernel's strength — that prevents the continuum from degrading the horizon as x varies.

Measurability of $x \mapsto U^x$. This is not an external regularity input to be assumed but a consequence of how U^x is constructed. The decoupling field is realized in theorem 9.14 as the unique fixed point of a contraction map Φ^x on a complete function space, and Φ^x depends on x only through the per-type coefficients — which depend measurably on x through the measurable bounded data and through the measurable aggregate ν^x (measurable because it is $\mathbb{W}$ applied to the measurable equilibrium field, definition 23.2). A fixed point of a uniform contraction whose defining map depends measurably (indeed continuously) on a parameter is itself measurable in that parameter: one may exhibit it as the limit of the Picard iterates $\Phi^{xn}(U_0)$, each of which is measurable in x by induction, and a pointwise limit of measurable maps is measurable. Hence $x \mapsto U^x$ is measurable, with the x-uniform Lipschitz constant just established, and the family is a bona fide field of decoupling fields living in the field setting of section 23.2. Complete per-type proofs are in [40]; the x-uniform versions, with this measurability argument carried out in full, are in [10].

We close on the deliberate limit of what is built here. The decoupling field U^x is defined *along the equilibrium*, with the population field $\boldsymbol{m}$ held fixed; it is a function of (t, x) for each frozen environment, not yet a function of the environment itself. Its promotion to a *measure-dependent* master field $\mathcal{U}(t, x, x, \boldsymbol{m})$ — defined for every field $\boldsymbol{m}$, whose total derivative in the measure direction generates the graphon master equation — is a strictly larger construction, requiring differentiability in the field argument, and we defer it intact to chapter 26, exactly as the homogeneous decoupling field of eq. (9.19) was the seed that chapter 12 grew into the master equation. For the present chapter the frozen family $U^x = \nabla u^x$ is all the converse needs, and all that the worked computation will use. □

This is the identification the worked computation of section 23.6 now turns concrete. In the graphon LQG thread the value function is quadratic in the state, so its gradient is *affine*, and the decoupling field collapses to an explicit affine form read, through proposition 23.19, as the gradient of a quadratic value. The dictionary therefore promises two things to the next section: that the probabilistic ansatz it solves is genuinely the gradient of chapter 22's quadratic value field, and that the closed form it derives will match the analytic solution mode for mode once the operator $\mathbb{W}$ is diagonalized. The abstract two-pictures equivalence is about to become a fully explicit, exactly solvable instance.

23.6 Worked computation: the graphon LQG thread as an FBSDE

Everything the chapter has built now comes due at once. The two-pictures dictionary of section 23.5 told us that the probabilistic costate Y^x is the gradient $\nabla u^x(t, X_t^x)$ of the type-x value, and section 23.5.2 specialized that statement to the LQG case: where the value is quadratic in the state its gradient is *affine*, so the decoupling field collapses to $Y_t^x = P_t X_t^x + r_t^x$ with a type-independent Riccati curvature P_t and a type-indexed offset r_t^x. That is the ansatz we are handed; this section solves it. The fixed-point analysis of section 23.4 told us, in turn, that two different norms of the one coupling operator $\mathbb{W}$ do two different jobs — the row-sum $\|\mathbb{W}\mathbf{1}\|_\infty \le 1$ governs the general measure-valued contraction, the spectral norm $\|\mathbb{W}\|$ governs the onset of multiplicity — but left the second statement as a promise to be cashed in closed form here. And the chapter preamble promised, from the first page, that the probabilistic formulation would *diagonalize* the continuum into spectral normal modes. This worked computation redeems all three debts simultaneously.

We carry Thread B — the graphon linear–quadratic–Gaussian model fixed in the thread specification — through the probabilistic formulation and show that the operator structure assembled across the chapter makes it *exactly solvable*. The mechanism is the one the spine of the chapter has pointed at throughout: because the entire cross-type coupling is the single linear operator $\mathbb{W}$, and because $\mathbb{W}$ is self-adjoint Hilbert–Schmidt, we may *diagonalize* it. In its eigenbasis the continuum of coupled agents falls apart into a direct sum of independent scalar LQG mean field games, one per eigenmode, the k-th carrying an effective crowd-coupling rescaled from s to $s\lambda_k$. Each summand is a problem we have already solved completely — it is the homogeneous Thread A LQG game of chapter 9 and chapter 14 — so the whole graphon game is solved the moment we name its spectrum. The payoff is twofold. We recover, from the probabilistic side, the closed-form equilibrium of chapter 22 mode for mode; and we read the symmetry-breaking threshold $s\,\|\mathbb{W}\|$ directly off the leading eigenvalue, exhibiting in closed form the $\|\mathbb{W}\|$-threshold whose general form is theorem 23.17 and chapter 24.

Worked computation 23.22 (Thread B: the scalar graphon LQG MFG in FBSDE form)**.** Recall the scalar graphon LQG model of the thread specification. Each type-x agent has state $X^x \in \mathbb{R}$ obeying

$$\mathrm{d}X_t^x = \big(aX_t^x + b\,\alpha_t^x\big)\,\mathrm{d}t + \sigma\,\mathrm{d}B_t^x, \qquad X_0^x \sim m_0^x,$$

with type-independent coefficients $a, b, \sigma \in \mathbb{R}$, and is coupled to the graphon-aggregated neighbour mean

$$z_t(x) = (\mathbb{W}\bar{m}_t)(x) = \int_0^1 W(x,y)\,\bar{m}_t(y)\,\mathrm{d}y, \qquad \bar{m}_t(y) = \int \xi\, m_t^y(\mathrm{d}\xi) = \mathbb{E}[X_t^y], \tag{23.22}$$

through the cost

$$J^x(\alpha^x) = \mathbb{E}\left[\int_0^T \left(\tfrac{1}{2}(\alpha_t^x)^2 + \tfrac{q}{2}\big(X_t^x - s\,z_t(x)\big)^2\right)\mathrm{d}t + \tfrac{q_T}{2}\big(X_T^x - s_T\,z_T(x)\big)^2\right],$$

with $q, q_T \geq 0$ and coupling strengths s, s_T. The diffusion is constant (hence **(A-Nondeg)** for $\sigma \neq 0$), the data are convex, and $z_t(x)$ is a scalar moment of the aggregate eq. (23.2) with $h(\xi) = \xi$; the sufficient maximum principle theorem 9.5 applies type by type.

Hamiltonian, feedback, and the FBSDE. With costate y the type-x generalized Hamiltonian eq. (23.14) is

$$\mathcal{H} = (ax + b\alpha)\,y + \tfrac{1}{2}\alpha^2 + \tfrac{q}{2}\big(x - s\,z_t(x)\big)^2$$

(to keep the bookkeeping unambiguous we rename the second-adjoint slot z of eq. (23.14) to ζ here, so it does not collide with the graphon coupling field $z_t(x)$; the term $\mathrm{tr}(\sigma^\top\zeta) = \sigma\,\zeta$ is constant in x and α and plays no role in either the minimization or $\partial_x\mathcal{H}$, so we simply drop it). The Hamiltonian is minimized at $\hat{\alpha}^x = -b\,Y^x$ — linear in the costate, exactly as in eq. (9.21), and the concrete instance of the general feedback discussed after eq. (23.18). Substituting $\hat{\alpha}$ and $\partial_x\mathcal{H} = ay + q(x - sz_t(x))$ into eq. (23.16) gives, for each x, the scalar McKean–Vlasov FBSDE

$$\begin{cases} \mathrm{d}X_t^x = \big(aX_t^x - b^2 Y_t^x\big)\,\mathrm{d}t + \sigma\,\mathrm{d}B_t^x, & X_0^x \sim m_0^x, \\ \mathrm{d}Y_t^x = -\big(aY_t^x + q(X_t^x - s\,z_t(x))\big)\,\mathrm{d}t + Z_t^x\,\mathrm{d}B_t^x, & Y_T^x = q_T\big(X_T^x - s_T\,z_T(x)\big), \\ z_t(x) = (\mathbb{W}\bar{m}_t)(x), & \bar{m}_t(x) = \mathbb{E}[X_t^x], \end{cases} \tag{23.23}$$

identical to the homogeneous Thread A FBSDE eq. (9.22) except that the scalar coupling target $\bar{m}_t$ is replaced by the type-field $z_t(x) = (\mathbb{W}\bar{m}_t)(x)$.

Affine decoupling. The system eq. (23.23) is linear in (X^x, Y^x) and the only term that couples one type to another is the deterministic field $z_t(x)$, which the forward and backward legs see as a known forcing. This is exactly the situation in which a costate depends on the state *affinely*, and the dictionary of section 23.5.2 already told us to expect it: where the value is quadratic the gradient is affine. So we posit the type-indexed affine decoupling field

$$Y_t^x = P_t\,X_t^x + r_t^x,$$

with a deterministic curvature P_t (*type-independent*, the canonical Riccati symbol of chapter 9) and a deterministic offset r_t^x (type-dependent). The whole content of this thread layer sits in the offset — it is the one object through which the graphon $\mathbb{W}$ reaches the decoupling — so we carry out the coefficient matching in full rather than quote it.

The plan is to compute $\mathrm{d}Y_t^x$ two ways and equate them. *First way:* differentiate the ansatz. Since P_t and r_t^x are deterministic and X_t^x is an Itô process, the product/chain rule of Itô's formula (theorem 5.9) applied to $Y_t^x = P_tX_t^x + r_t^x$ gives $\mathrm{d}Y_t^x = \dot{P}_tX_t^x\,\mathrm{d}t + P_t\,\mathrm{d}X_t^x + \dot{r}_t^x\,\mathrm{d}t$ — there is no second-order Itô correction because P_t carries no $\mathrm{d}B$ part, so the only quadratic-variation term would be $\mathrm{d}P_t\,\mathrm{d}X_t^x = 0$. Substituting the forward dynamics $\mathrm{d}X_t^x = (aX_t^x - b^2 Y_t^x)\,\mathrm{d}t + \sigma\,\mathrm{d}B_t^x$ from eq. (23.23),

$$\mathrm{d}Y_t^x = \big(\dot{P}_t X_t^x + P_t(aX_t^x - b^2 Y_t^x) + \dot{r}_t^x\big)\,\mathrm{d}t + P_t\sigma\,\mathrm{d}B_t^x,$$

and comparing the martingale parts already identifies the BSDE's Z-component, $Z_t^x = P_t\sigma$ (the volatility of the costate is the curvature times the state volatility, as in chapter 9). Now eliminate the remaining Y^x on the right by the ansatz itself: $P_t(aX_t^x - b^2Y_t^x) = P_t aX_t^x - b^2 P_t(P_t X_t^x + r_t^x) = (aP_t - b^2P_t^2)X_t^x - b^2 P_t r_t^x$, so the drift of the first expression, collected by powers of X_t^x, is

$$\underbrace{\big[\dot{P}_t + aP_t - b^2P_t^2\big]}_{\text{coefficient of } X_t^x} X_t^x \;+\; \underbrace{\big[\dot{r}_t^x - b^2 P_t r_t^x\big]}_{X\text{-free}}.$$

Second way: read the costate's drift straight off the backward equation of eq. (23.23), namely $-(aY_t^x + q(X_t^x - s\,z_t(x)))$, and again substitute $Y_t^x = P_t X_t^x + r_t^x$:

$$-\big(a(P_tX_t^x + r_t^x) + qX_t^x - q\,s\,z_t(x)\big) = \underbrace{-(aP_t+q)}_{\text{coefficient of } X_t^x}\; X_t^x \;+\; \underbrace{\big[-ar_t^x + q\,s\,z_t(x)\big]}_{X\text{-free}}.$$

The two drifts must agree as functions of the *random* variable X_t^x, which is nondegenerate (it has a density, $\sigma \neq 0$), so they agree coefficient by coefficient. The matching therefore splits cleanly into two scalar equations: the coefficient of X_t^x gives a closed equation for P_t with no reference to the offset or the graphon, while the X-free remainder gives an equation for r_t^x forced by $z_t(x)$. Taking the X_t^x-coefficients, $\dot{P}_t + aP_t - b^2P_t^2 = -(aP_t + q)$, i.e. the scalar Riccati equation

$$\dot{P}_t = b^2P_t^2 - 2aP_t - q, \qquad P_T = q_T, \tag{23.24}$$

which is *exactly* eq. (9.24) and carries *no type label*. This is the first structural payoff of the computation, and it is worth dwelling on: the curvature of every type's value function is one and the same scalar P_t, because the only ingredients that enter the X^x-coefficient — the state feedback a, the control gain b, the state-cost weight q, and the terminal weight q_T — are all type-independent. The graphon never touches the Riccati equation. Where the network *does* enter is the X-free remainder. Equating the two X-free parts, $\dot{r}_t^x - b^2P_tr_t^x = -ar_t^x + q\,s\,z_t(x)$, and solving for $\dot{r}_t^x$, gives the type-dependent offset equation

$$\dot{r}_t^x = (b^2P_t - a)r_t^x + q\,s\,z_t(x), \qquad r_T^x = -q_T\,s_T\,z_T(x), \tag{23.25}$$

the terminal datum read off by evaluating the ansatz at $t = T$ against the terminal costate: $Y_T^x = q_T(X_T^x - s_T z_T(x))$ must equal $P_T X_T^x + r_T^x$, and with $P_T = q_T$ the X_T^x-terms cancel, leaving $r_T^x = -q_T s_T z_T(x)$. Notice that eq. (23.25) is a *linear* ODE for r^x whose homogeneous coefficient $b^2P_t - a$ is again type-independent (it is fixed by the Riccati curvature), so the only x-dependence in the entire offset comes through its forcing term $q\,s\,z_t(x)$ and its terminal value $-q_Ts_Tz_T(x)$ — both built from the graphon field $z_t = \mathbb{W}\bar{m}_t$. The offset equation is therefore eq. (9.25) of the homogeneous thread with the scalar coupling target $\bar{m}_t$ replaced by the type field $z_t(x) = (\mathbb{W}\bar{m}_t)(x)$: this single substitution is *the one place the graphon enters the decoupling*, and it is the reason the diagonalization to come will need only to diagonalize $\mathbb{W}$. Taking expectations of the forward equation, and using $\mathbb{E}[Y_t^x] = P_t \bar{m}_t(x) + r_t^x$ (the offset is deterministic, so its expectation is itself), yields the mean-field evolution

$$\dot{\bar{m}}_t(x) = (a - b^2 P_t)\bar{m}_t(x) - b^2 r_t^x, \qquad \bar{m}_0(x) = \int \xi \, m_0^x(\mathrm{d}\xi). \tag{23.26}$$

Equations eq. (23.25)–eq. (23.26), with the coupling $z_t = \mathbb{W}\bar{m}_t$, form a *linear forward–backward two-point boundary value problem in the fields* $(\bar{m}_\cdot(\cdot), r_\cdot(\cdot))$ over types, coupled across types solely by the operator $\mathbb{W}$ — the deterministic shadow of the graphon FBSDE, and the field analogue of the scalar two-point problem eq. (9.25)–eq. (9.26).

Diagonalization: the spectral normal modes. Here the operator structure pays off. By **(A-Reg-W)** the operator $\mathbb{W}$ is self-adjoint Hilbert–Schmidt on $L^2([0,1])$, so by the spectral theorem theorem 2.26 (the network "band structure" of chapter 18) there is an orthonormal eigenbasis $\{\phi_k\}_{k\geq 1}$ of $L^2([0,1])$ with $\mathbb{W}\phi_k = \lambda_k \phi_k$, $|\lambda_1| \geq |\lambda_2| \geq \cdots \to 0$ and $\|\mathbb{W}\| = |\lambda_1|$ (the indexing and the leading-eigenvalue convention are those of section 18.1, $\rho(\mathbb{W}) = \|\mathbb{W}\| = |\lambda_1|$). Expand the two type-fields at each time in this basis, with time-dependent Fourier coefficients,

$$\bar{m}_t(x) = \sum_k \bar{m}_t^{(k)} \phi_k(x), \qquad r_t^x = \sum_k r_t^{(k)} \phi_k(x), \qquad \bar{m}_t^{(k)} = \langle \bar{m}_t, \phi_k \rangle, \quad r_t^{(k)} = \langle r_t^{\cdot}, \phi_k \rangle,$$

the coefficients being the $L^2([0,1])$ inner products against the eigenfunctions. The single fact that makes the system fall apart is that $\mathbb{W}$ acts diagonally on this basis: applying it to the expansion of $\bar{m}_t$ and using $\mathbb{W}\phi_k = \lambda_k \phi_k$ termwise,

$$z_t(x) = (\mathbb{W}\bar{m}_t)(x) = \sum_k \bar{m}_t^{(k)} \, (\mathbb{W}\phi_k)(x) = \sum_k \lambda_k \, \bar{m}_t^{(k)} \, \phi_k(x),$$

so the coupling field z_t has k-th coefficient $\lambda_k \bar{m}_t^{(k)}$ — the operator $\mathbb{W}$ has become, mode by mode, multiplication by the scalar λ_k. Now project the field ODEs eq. (23.25)–eq. (23.26) onto ϕ_k, i.e. take the $L^2([0,1])$ inner product of each side with ϕ_k. This works because every coefficient in those ODEs is *type-independent* (the scalars a, b^2, P_t multiply the fields pointwise in x), so the projection passes straight through them: $\langle (b^2 P_t - a) r_t^x, \phi_k \rangle = (b^2 P_t - a)\langle r_t^{\cdot}, \phi_k \rangle = (b^2 P_t - a) r_t^{(k)}$, and likewise for every other term. The only term that could have mixed modes is the coupling $q\, s\, z_t$, and that is precisely the term $\mathbb{W}$ has just diagonalized: $\langle q\, s\, z_t, \phi_k \rangle = q\, s\, \lambda_k \bar{m}_t^{(k)}$. Because the eigenbasis is orthonormal, the projection picks out exactly the k-th coefficient of each field and leaves no cross-terms, so eq. (23.25)–eq. (23.26) *decouples the continuum into independent scalar systems*, one for each mode:

$$\begin{cases} \dot{r}_t^{(k)} = (b^2 P_t - a) r_t^{(k)} + q\,(s\lambda_k)\, \bar{m}_t^{(k)}, & r_T^{(k)} = -q_T\,(s_T \lambda_k)\, \bar{m}_T^{(k)}, \\ \dot{\bar{m}}_t^{(k)} = (a - b^2 P_t)\bar{m}_t^{(k)} - b^2 r_t^{(k)}, & \bar{m}_0^{(k)} = \langle \bar{m}_0, \phi_k \rangle. \end{cases} \tag{23.27}$$

But eq. (23.27) is *identical* to the homogeneous Thread A two-point system eq. (9.25)–eq. (9.26) with the coupling strengths rescaled,

$$s \;\longmapsto\; s_{\text{eff}}^{(k)} = s\, \lambda_k, \qquad s_T \;\longmapsto\; s_{T,\text{eff}}^{(k)} = s_T\, \lambda_k. \tag{23.28}$$

Thus *the graphon LQG mean field game is a direct sum of scalar LQG mean field games, one per eigenmode of the coupling operator* $\mathbb{W}$, *the* k*-th carrying the effective coupling* $s\lambda_k$. At $K = 1$ active mode this is the scalar boundary value problem eq. (22.28) of the analytic worked computation worked computation 22.15: the off-diagonal product $b^2 qs\lambda_k$ governing the mode oscillation matches, so the two derivations agree on the phase boundary. Each mode is then closed exactly as Thread A was closed in chapter 9, by a *second* decoupling, now of the offset coefficient onto the mode mean. The pair eq. (23.27) is a linear forward–backward system in the two scalars $(\bar{m}^{(k)}, r^{(k)})$; positing the linear relation $r_t^{(k)} = \pi_t^{(k)}\bar{m}_t^{(k)}$ between them, differentiating, $\dot{r}_t^{(k)} = \dot{\pi}_t^{(k)}\bar{m}_t^{(k)} + \pi_t^{(k)}\dot{\bar{m}}_t^{(k)}$, and substituting the mean equation $\dot{\bar{m}}_t^{(k)} = (a - b^2P_t)\bar{m}_t^{(k)} - b^2 r_t^{(k)} = (a - b^2P_t - b^2\pi_t^{(k)})\bar{m}_t^{(k)}$ on the right, the offset equation of eq. (23.27) becomes, after dividing through by the common factor $\bar{m}_t^{(k)}$, the second scalar Riccati of eq. (9.27),

$$\dot{\pi}_t^{(k)} = b^2(\pi_t^{(k)})^2 - 2(a - b^2P_t)\pi_t^{(k)} + q\, s\lambda_k, \qquad \pi_T^{(k)} = -q_T\, s_T\lambda_k, \tag{23.29}$$

the terminal value forced by $r_T^{(k)} = -q_T s_T \lambda_k \bar{m}_T^{(k)} = \pi_T^{(k)}\bar{m}_T^{(k)}$. With $\pi^{(k)}$ in hand the mode mean closes into the single linear ODE $\dot{\bar{m}}_t^{(k)} = (a - b^2P_t - b^2\pi_t^{(k)})\bar{m}_t^{(k)}$, solved by an exponential, and $r_t^{(k)} = \pi_t^{(k)}\bar{m}_t^{(k)}$ is read off. Reassembling the modes, $\bar{m}_t(x) = \sum_k \bar{m}_t^{(k)}\phi_k(x)$, the equilibrium feedback is $\hat{\alpha}_t^x = -b(P_tX_t^x + r_t^x)$ with $r_t^x = \sum_k \pi_t^{(k)}\bar{m}_t^{(k)}\phi_k(x)$.

With this linear feedback substituted into the state SDE the closed loop reads $\mathrm{d}X_t^x = \big((a - b^2P_t)X_t^x - b^2r_t^x\big)\,\mathrm{d}t + \sigma\,\mathrm{d}B_t^x$, which is a linear (Ornstein–Uhlenbeck) SDE: its drift is affine in X_t^x with *type-independent* slope $a - b^2P_t$ and a deterministic, type-dependent forcing $-b^2r_t^x$. The law $m_t^x = \mathrm{Law}(X_t^x)$ is therefore Gaussian, $\mathcal{N}(\bar{m}_t(x), v_t)$, and here a small but telling feature appears: the *mean* carries all the type-dependence and all the coupling, while the *variance* carries neither. The mean obeys eq. (23.26), forced by the offset and hence by the graphon; the variance $v_t = \mathrm{Var}(X_t^x)$ obeys the Lyapunov ODE

$$\dot{v}_t = 2(a - b^2P_t)v_t + \sigma^2, \qquad v_0 = \mathrm{Var}(m_0^x),$$

obtained by Itô on $\big(X_t^x - \bar{m}_t(x)\big)^2$: the deterministic forcing $-b^2r_t^x$ cancels in the centred variable, so it never reaches the variance. This is the structural reason the variance *decouples from the mean and from the network*: the cost eq. (23.23) couples an agent only to the neighbour *mean* $z_t(x)$, a first-moment quantity, so the entire influence of the crowd lives in the drift's deterministic part and shifts means without ever touching fluctuations. The Lyapunov coefficient $a - b^2P_t$ is type-independent because P_t is, so v_t is the *same* for every type — one variance for the whole continuum, identical to the Thread A variance of chapter 9. This reproduces, from the probabilistic side, the closed-form graphon LQG equilibrium of chapter 22, mode for mode: the analytic forward–backward solution there and the spectral direct sum here are the same equilibrium written in two pictures.

Reductions, recovered exactly. With the game written as a direct sum indexed by the spectrum, the three thread-specification reductions that remark 23.4 previewed at the descriptive level now become *spectral* computations: each is just a matter of naming the eigenvalues of the relevant $\mathbb{W}$ and reading off eq. (23.28).

Constant graphon $W \equiv c$. The operator acts by $(\mathbb{W}f)(x) = \int_0^1 c\,f(y)\,\mathrm{d}y = c\langle 1, f\rangle_{L^2}$, a constant function of x; in operator form $\mathbb{W}f = c\langle 1, f\rangle_{L^2}\,1$, a rank-one operator. Its range is the line of constants, so the normalized constant $\phi_1 \equiv 1$ (normalized because $\|1\|^2_{L^2([0,1])} = \int_0^1 1\,\mathrm{d}y = 1$) is the only eigenfunction with nonzero eigenvalue, $\mathbb{W}\phi_1 = c\,\phi_1$ so $\lambda_1 = c$; every ϕ orthogonal to the constants integrates to zero and is annihilated, $\lambda_k = 0$ for $k \geq 2$. Only mode 1 couples, with effective strength sc, and its coordinate $\bar{m}_t^{(1)} = \langle \bar{m}_t, 1\rangle = \int_0^1 \bar{m}_t(x)\, \mathrm{d}x$ is precisely the global population mean. The continuum collapses to the single scalar Thread A LQG MFG with coupling sc — Thread A recovered with rescaled coupling, exactly as the thread specification demands.

Rank-one graphon $W(x,y) = f(x)f(y)$ with $f \geq 0$ a centrality profile. Now $(\mathbb{W}g)(x) = \int_0^1 f(x)f(y)g(y)\, \mathrm{d}y = f(x)\langle f, g\rangle_{L^2}$, i.e. $\mathbb{W}g = \langle f, g\rangle_{L^2} f$, again rank one with range the line spanned by f. Normalizing, $\phi_1 = f/\|f\|_{L^2}$ is the eigenfunction, and $\mathbb{W}\phi_1 = \langle f, f/\|f\|_{L^2}\rangle_{L^2} f = \|f\|_{L^2} f = \|f\|_{L^2}^2 \phi_1$, so the single nonzero eigenvalue is $\lambda_1 = \|f\|_{L^2}^2$. Only the order-parameter mode $\langle \phi_1, \bar{m}_t\rangle = \|f\|_{L^2}^{-1} \langle f, \bar{m}_t\rangle$ couples, with effective strength $s\lambda_1 = s\|f\|_{L^2}^2$, and the coupling field is $z_t(x) = f(x)\langle f, \bar{m}_t\rangle = f(x)\, \varrho_t$ — a single scalar order parameter $\varrho_t = \langle f, \bar{m}_t\rangle$ modulated by the centrality profile, exactly the object isolated in remark 23.4. The whole graphon LQG game collapses to a *one-parameter* self-consistent equation for ϱ_t, the cleanest GMFG worked example and the rank-one reduction the thread specification asks for. Every other mode has $\lambda_k = 0$ and hence zero effective coupling: those directions play the uncoupled single-agent Ornstein–Uhlenbeck problem of chapter 6, feeling no crowd at all.

Block graphon. If W is piecewise constant on a partition of $[0,1]$ into K type-blocks (definition 22.12), then $\mathbb{W}$ factors through the K-dimensional space of functions constant on the blocks — it is a finite-rank operator of rank at most K, whose nonzero eigenvalues are those of the $K \times K$ block-weight matrix. At most K modes λ_k carry coupling, so the direct-sum-of-scalars truncates to a finite K-mode system: the continuum collapses to a finite *multi-population* LQG mean field game, one effective population per block, coupled through that $K \times K$ matrix. This is exactly the bridge to chapter 30 made on the analytic side in proposition 22.13 and remark 22.14, here read straight off the spectrum. The three reductions together complete the check set the thread specification asks for at every appearance of Thread B.

Multiplicity and the spectral threshold. Now we cash the chapter's sharpest claim. Because mode k is a verbatim copy of the Thread A LQG mean field game with *signed* effective coupling $s\lambda_k$, it inherits the entire phase behaviour worked out for Thread A in chapter 14 — which we import, not reprove. The criterion there (theorem 14.11, the special case of the general uniqueness threshold proposition 11.8) is exactly the global solvability of the second Riccati eq. (23.29): the mode equilibrium exists and is unique precisely while $\pi_t^{(k)}$ stays finite on $[0,T]$, which holds while the horizon stays below the Thread A critical horizon $T_c(s\lambda_k)$ of eq. (14.24) evaluated at the effective coupling. The content we must *develop* is why this criterion is *sign-dependent*, because that is what selects the binding mode and fixes the threshold.

Read eq. (23.29) as a scalar Riccati whose constant term is the effective coupling $q\, s\lambda_k$. When $s\lambda_k > 0$ — the crowd-*seeking* direction, agents pulled *toward* the neighbour mean — this constant term has the destabilizing sign: it pushes $\pi^{(k)}$ in the direction where the quadratic term $b^2(\pi^{(k)})^2$ takes over and drives a finite-time blow-up, so $T_c(s\lambda_k)$ is finite and shrinks as $s\lambda_k$ grows. The mechanism is the familiar positive feedback of imitation: each agent chasing the crowd makes the crowd a more attractive target, and beyond a critical strength-times-horizon the self-consistency loop supports more than one equilibrium. When $s\lambda_k < 0$ — the crowd-*averse* or anti-imitation direction, agents pushed *away* from the mean — the constant term carries the opposite sign and *stabilizes* the Riccati: the coupling now adds to the restoring effect rather than opposing it, $\pi^{(k)}$

stays bounded for all time, and the mode equilibrium is unique at *every* horizon. This is the negative-feedback, Lasry–Lions-monotone regime (**(A-Mon)**). The asymmetry is the crux: it is not the *magnitude* $|\lambda_k|$ of an eigenvalue that threatens uniqueness but its *signed* effective coupling $s\lambda_k$. A large *negative* eigenvalue — a strong anti-imitation mode — has large $|\lambda_k|$ yet is *extra* stable: the more strongly that mode repels from its own mean, the more firmly its single equilibrium is pinned, and it never bifurcates no matter how long the horizon. Consequently the binding mode, the one that goes critical first, is the mode of largest *signed* $s\lambda_k$: for $s > 0$ the algebraically largest (most positive) eigenvalue, for $s < 0$ the most negative one. This is exactly the binding-mode selection that proposition 24.23 will state in general.

For a *nonnegative* graphon the binding mode is pinned by spectral theory. Perron–Frobenius for the self-adjoint compact $\mathbb{W}$ (section 18.1) places the top of the spectrum at $\lambda_1 = \|\mathbb{W}\| > 0$, attained on a nonnegative eigenfunction $\phi_1 \geq 0$ — the eigenvector-centrality profile of chapter 18, which weights each type by how central it is in the network. So for the crowd-seeking sign $s > 0$ the algebraically largest signed coupling is $s\lambda_1 = s\,\|\mathbb{W}\|$, carried by the centrality mode, and as the horizon grows or the coupling is turned up it is *this* mode that bifurcates first. The onset of multiplicity is therefore governed by the spectral operator norm, in closed form: while $s\,\|\mathbb{W}\|$ stays below the Thread A critical coupling every mode is subcritical and the graphon equilibrium is unique — precisely the operator-norm smallness **(A-Coupling)** that theorem 23.17 imposed abstractly, now seen explicitly for the linear-mean coupling and seen to involve the *spectral* norm, not the row-sum that governed the descriptive contraction. As $s\,\|\mathbb{W}\|$ crosses that critical value the leading centrality mode goes critical and multiplicity sets in as a *symmetry breaking concentrated on the single eigenfunction* ϕ_1: the continuum of equilibria that appears differs from the unique one along the centrality direction alone. This exact phase boundary is the LQG instance of the general critical-coupling phenomenon of chapter 24 (proposition 24.23), and it is the closed-form vindication of the two-norms distinction drawn abstractly in section 23.4: the row-sum $\|\mathbb{W}\mathbf{1}\|_\infty$ controls how measures contract, the spectral norm $\|\mathbb{W}\|$ controls where uniqueness fails.

Physics note

The diagonalization eq. (23.27) is the mean field game version of resolving a system of coupled linear oscillators into *normal modes*. The coupling operator $\mathbb{W}$ plays the role of the coupling matrix; its eigenfunctions ϕ_k are the normal coordinates, in which the continuum of strategically interacting types decouples into independent one-dimensional problems. Two features carry real content rather than mere analogy. First, the "stiffness" felt in mode k is set by the eigenvalue λ_k through the effective coupling $s\lambda_k$ of eq. (23.28): in the crowd-seeking direction ($s\lambda_k > 0$) the strongly coupled, central, well-connected combinations of types are the soft ones, while peripheral directions (λ_k near zero) are nearly free and anti-imitation directions ($s\lambda_k < 0$) are stiffened. Second, the loss of uniqueness is a *soft-mode instability*: as a crowd-seeking coupling is raised the leading eigenmode — maximal eigenvector centrality, $\lambda_1 = \|\mathbb{W}\|$ for a nonnegative kernel — is the first to go unstable, and the multiplicity that appears is a symmetry breaking polarized along that single eigenfunction ϕ_1, exactly as an order parameter condenses into the softest mode at a continuous transition. The analogy organizes; the content is the exact reduction eq. (23.27) and the threshold $s\,\|\mathbb{W}\| =$ critical, both of which stand on their own.

This worked computation closes the chapter's argument. The thesis we carried from the first page — that the entire cross-type coupling of a graphon mean field game is the single bounded operator $\mathbb{W}$ — is here made fully explicit and exactly solvable: diagonalizing that one operator turns the continuum of strategically coupled types into a direct sum of scalar Thread A games, one per eigenmode with coupling $s\lambda_k$, and the same operator's leading eigenvalue $\|\mathbb{W}\|$ fixes in closed form the symmetry-breaking threshold $s\,\|\mathbb{W}\|$ at which uniqueness first fails. Four threads leave this section and run on. The general critical-coupling statement, of which the boundary $s\,\|\mathbb{W}\|$ here is the LQG instance, is proved for arbitrary linear-mean coupling in chapter 24 (proposition 24.23); the mode-for-mode agreement with the analytic rank-one boundary value problem eq. (22.28) ties this probabilistic closed form back to the PDE solution of chapter 22; the leading mode $\phi_1 = \|\mathbb{W}\|$ is the eigenvector-centrality profile of chapter 18, so the agents whose imitation destabilizes the game first are exactly the central ones; and the block-graphon reduction to a finite multi-population game is the bridge picked up in chapter 30. What this section does *not* settle — the structure of the multiple equilibria past the threshold, beyond the small-coupling and monotone regimes where uniqueness is guaranteed — is recorded as an Open item in the ledger below, which together with the bibliographic notes closes the chapter.

Rigor ledger

Proved (in this chapter).

- The graphon McKean–Vlasov SDE eq. (23.3) with interaction through the graphon aggregate eq. (23.1), its well-posedness (proposition 23.5) by a field-valued Picard/-contraction argument, and the associated nonlinear graphon Fokker–Planck equation proposition 23.7, identified with the forward half of the system of chapter 22.

- The Bochner field space $\boldsymbol{\mathcal{P}}_2$ (definition 23.8): its completeness and the field-contraction bound for the coupling, $\big(\int \mathcal{W}_2((\mathbb{W}\boldsymbol{m})(x),(\mathbb{W}\boldsymbol{m}')(x))^2\,\mathrm{d}x\big)^{1/2} \le \|\mathbb{W}\mathbf{1}\|_\infty^{1/2}\,\mathbf{d}_2(\boldsymbol{m},\boldsymbol{m}') \le \mathbf{d}_2(\boldsymbol{m},\boldsymbol{m}')$ (lemma 23.10, by Kantorovich duality theorem 4.5), the single estimate carrying the kernel row-sum into every measure-valued contraction — with the equal-mass extension of $\mathcal{W}_2$ (definition 23.9) that makes the sub-probability aggregates comparable.

- The graphon MFG FBSDE eq. (23.16) and its fixed-point structure: the per-type decoupling under a frozen field (remark 23.14), the graphon best-response map (definition 23.15), and the small-horizon contraction estimate with field factor $\le \|\mathbb{W}\mathbf{1}\|_\infty^{1/2} \le 1$ giving theorem 23.17(i).

- The graphon FBSDE–PDE dictionary proposition 23.19: $Y_t^x = \nabla u^x(t, X_t^x)$, $Z_t^x = \mathrm{D}^2\,u^x\,\sigma$ (shape $d \times k$), type by type, with the family of decoupling fields theorem 23.21 — the graphon analogue of proposition 9.12.

- The complete graphon LQG thread in FBSDE form (worked computation 23.22): the spectral diagonalization into independent scalar LQG modes with effective couplings

$s\lambda_k$, the exact recovery of the constant-, rank-one-, and block-graphon reductions, and the closed-form onset of multiplicity at the spectral threshold $s\,\|\mathbb{W}\|$ (in the destabilizing direction $s\lambda_k > 0$).

Assumed (named standing hypotheses).

- **(A-Lip)**, **(A-Growth)** for SDE/BSDE well-posedness and Lipschitz feedback; **(A-Conv)** for the Hamiltonian minimizer and sufficiency of the maximum principle; **(A-Nondeg)** for parabolic smoothing of the decoupling fields and for the graphon Fokker–Planck; **(A-Reg-W)** for the self-adjoint Hilbert–Schmidt structure of $\mathbb{W}$ and the spectral diagonalization; **(A-Coupling)** (spectral $\|\mathbb{W}\|$ small, decisive for the linear-mean coupling) and **(A-Mon)** for uniqueness.
- Uncontrolled diffusion throughout (controlled diffusion deferred as in remark 9.7).

Deferred (with pointers).

- Existence/uniqueness of the graphon MFG FBSDE: stated as theorem 23.17 in three regimes; the Schauder/compactness proof and the graphon Lasry–Lions monotonicity with its pairing identity are chapter 24, carried out there in the *uniform-in-type* field space $C([0,1]; C([0,T]; \mathcal{P}_1(\mathbb{R}^d)))$ (definition 24.1), the FBSDE/$\boldsymbol{\mathcal{P}}_2$ statement here transferred by the two-pictures equivalence proposition 23.19; the sharper L^2-in-type compactness criterion is more delicate (remark 24.13). Primary sources [34, 10, 15].
- The rigorous joint realization of the continuum of Brownian motions (Fubini extension / exact law of large numbers): remark 23.6 and [39, 10]; only needed in earnest for the finite-N descent of chapter 25.
- The measure-dependent (master) decoupling field and the graphon master equation: chapter 26, promoting theorem 23.21 as eq. (9.19) promoted the homogeneous decoupling field.
- BSDE theory (Pardoux–Peng, martingale representation): chapter 5 and the stochastic-calculus reference, Appendix C.

Open / honestly flagged.

- Uniqueness outside the small-coupling and monotone regimes is genuinely open: theorem 23.17(iii) gives existence only, and the worked computation worked computation 23.22 shows multiplicity is real once $s\,\|\mathbb{W}\|$ crosses the Thread A threshold (in the crowd-seeking direction), the leading centrality mode bifurcating first.
- The sharp critical coupling, the interplay of strategic monotonicity with the *spectrum* (not merely the norm) of $\mathbb{W}$, and well-posedness for unbounded (L^p) graphons where $\mathbb{W}$ need not be bounded on L^2, are open in general and taken up in chapters 24 and 27.
- The probabilistic theory above is for dense, bounded graphons; the descent to sparse sampled networks, where the continuum-of-noises construction and the operator bound both degrade, is the frontier of chapters 25 and 27.

Bibliographic notes

The probabilistic formulation of graphon mean field games — the continuum-indexed McKean–Vlasov FBSDE and its fixed point in a space of measure-valued maps — is the graphon lift of the Carmona–Delarue programme [40, 41], whose Volume I, Chapters 3–4, supplies every per-type ingredient we import: the stochastic maximum principle, the adjoint BSDE, the McKean–Vlasov FBSDE, the small-time and monotone well-posedness theorems, and the decoupling-field (four-step / continuation) method. The graphon mean field *system* as a descriptive object — the interacting diffusions eq. (23.3) and their propagation of chaos toward the deterministic field of laws — is developed by Bayraktar, Chakraborty and Wu [15]; the GMFG equations in the dynamic, optimizing setting are due to Caines and Huang [33, 34]. The careful measure-theoretic treatment of a continuum of agents and of the continuum of independent noises — the Fubini extension and exact law of large numbers underlying remark 23.6 — is carried out in the stochastic-graphon-games series of Carmona, Cooney, Graves and Laurière [39] (static case) and Aurell, Carmona and Laurière [10] (the linear–quadratic dynamic case, which is the closest published companion to the worked computation worked computation 23.22). The two-pictures equivalence proposition 23.19 is the graphon counterpart of the homogeneous result of chapter 9, itself the FBSDE form of the Lasry–Lions system [93]; the analytic side it is matched against is chapter 22. The spectral diagonalization of the graphon LQG game into normal modes of $\mathbb{W}$ uses the self-adjoint Hilbert–Schmidt structure established in chapter 2 and the network spectral theory of chapter 18; it is the probabilistic, dynamic analogue of the centrality-to-equilibrium correspondence proved for static graphon games by Parise and Ozdaglar [108]. The existence and uniqueness theory whose three regimes we have only stated, and the critical-coupling threshold the worked computation exhibits in closed form, are the subject of chapter 24; the descent to finite sampled networks is chapter 25; the graphon master equation and common noise are chapter 26.

Chapter 24

Existence and Uniqueness for Graphon Mean Field Games

The two preceding chapters assembled the dynamic graphon mean field game (GMFG) in its two complementary pictures, but neither asked whether the object they describe is ever actually there. Chapter 22 gave the analytic picture: a continuum of backward Hamilton–Jacobi–Bellman (HJB) equations indexed by the type $x \in [0,1]$, each driven by the population, coupled across types only through the graphon operator $\mathbb{W}$, paired with a continuum of forward Fokker–Planck (FP) equations for the type-indexed population field $m^x = m^x$. In that picture an equilibrium *is* a self-consistent pair of fields $(\mathbf{u}, \mathbf{m})$ — a value field and a density field, one of each per type — with the property that the population the optimal feedbacks generate is exactly the population those feedbacks were computed against. Chapter 23 gave the probabilistic picture: a continuum-indexed family of forward–backward stochastic differential equations of graphon McKean–Vlasov type, and the proof that, under regularity, the two pictures coincide. There an equilibrium *is* a type-indexed family of state processes whose laws, fed back through $\mathbb{W}$ into the coefficients that drive them, reproduce themselves. The two descriptions are one fixed-point condition read in two languages, and the two-pictures dictionary proposition 23.19 translates between them. What neither chapter supplies is the assertion that a field satisfying the condition *exists*, still less that it is *unique*. The present chapter supplies both, and isolates exactly the price the graphon structure exacts over the classical theory of chapters 10 and 11.

The method is the one the reader already owns from the homogeneous theory, and the single organising claim of this chapter is that it is *all* we need: the entire argument is the classical proof of chapters 10 and 11 with one new object, the graphon operator $\mathbb{W}$, inserted at exactly one place. We recast the equilibrium condition as a fixed point of a best-response map, manufacture a convex compact invariant set, and invoke Schauder; then, separately, buy uniqueness either from a monotonicity structure (good for every horizon) or from a smallness condition (good when the coupling is weak). Everything from chapter 10 (the Schauder fixed-point machine, the moment/equicontinuity estimates, tightness via Prokhorov from chapter 3) and from chapter 11 (the Lasry–Lions duality identity, the standing monotonicity assumption **(A-Mon)**, the Bregman lemma) is imported and reused *verbatim*, run type by type. What is genuinely new is that the coupling now factors through the integral operator $\mathbb{W}$ of chapter 18, and the discipline we hold throughout is that every graphon-specific phenomenon is the responsibility of that one operator and lives in its spectrum. Concretely, the best-response map will be seen to split as $\mathsf{S}_W = \mathcal{R} \circ \mathcal{A}_W$, a *linear* aggregation $\mathcal{A}_W$ through $\mathbb{W}$ followed by a type-wise *classical* solve $\mathcal{R}$; reading every later theorem through this factorisation is what keeps the inherited difficulty and the new difficulty from being confused.

Two questions stand between us and the theorems, and the reader should hold both in mind because the surprise of the chapter is that *both answers are spectral.* The first is *compactness.* The classical existence proof compresses a sequence of candidate flows into a convergent subsequence; here a candidate is an entire field over types, and a field can oscillate ever faster in the type direction with nothing to stop it. There is no analogue of this difficulty in the homogeneous theory — there was no type variable, hence nothing to be compact in — so the existence proof acquires a new compactness obligation it never had before, and it is met by buying type-direction equicontinuity from the *continuity in type* of W (the standing assumption **(A-Reg-W)**). This is the genuinely structural surprise to plant now: in the classical theory existence needed no regularity of any coupling kernel, yet the graphon *existence* theorem — not merely the uniqueness theorem — fails without a regularity hypothesis on $\mathbb{W}$, because regularity is the only source of the missing compactness. The second question is the *sign of the equilibrium energy*: the Lasry–Lions identity that delivered uniqueness in chapter 11 now carries an extra type integral threaded through $\mathbb{W}$, and whether its sign survives is decided jointly by the strategic monotonicity and the spectrum of $\mathbb{W}$. The critical coupling at which uniqueness fails is governed by the leading eigenvalue $\lambda_1(\mathbb{W})$ — the eigenvector centrality of chapter 18. This is the precise sense in which the scalar threshold $s = 1$ of chapter 11 is replaced by the product $s\,\lambda_1$, ties the chapter back to that scalar threshold and to the operator-norm condition of the static graphon game in chapter 20, and makes loss of uniqueness a symmetry-breaking transition indexed by network centrality. Both answers — the compactness one and the sign one — are thus read off the same operator $\mathbb{W}$: this is the chapter in one sentence.

We proceed in four movements. Section 24.1 fixes the field-of-measures state space — the type-indexed populations of chapter 21, here specialised to the variant that graphon continuity makes available — recalls the GMFG system from chapter 22 without rederiving it, and defines the graphon best-response map, exhibiting its factorisation through $\mathbb{W}$. Section 24.2 proves existence, making explicit the two compactness inputs — per-type tightness (Part I) and type-direction equicontinuity from graphon regularity (Part III) — and the role of $\|\mathbb{W}\|$. Section 24.3 proves uniqueness by two routes, the graphon Lasry–Lions monotonicity identity and the small-coupling contraction, and locates the critical coupling. Section 24.4 states plainly what is harder here than in the classical theory. Section 24.5 advances Thread B: the graphon LQG model is carried to its exact uniqueness/multiplicity threshold, which is shown to be the chapter 11 threshold with the scalar coupling s replaced by $s\,\lambda_1(\mathbb{W})$, and the rank-one and constant-graphon reductions are verified. The chapter is the operator generalisation of chapter 11 and the existence base on which the convergence theory of chapter 25 stands.

Notation watch

We are now firmly in Part IV, where a graphon $W = W$ is always in scope. The letters B and W have, in earlier parts of the book, both wanted to mean Brownian motion; the resolution fixed in appendix A.5 is that once a graphon is present, W denotes the graphon kernel and *never* the noise, and Brownian motion is written B_t. We honour that throughout this chapter without further comment: every W below is the kernel, every B^x a type-x Brownian motion. A second, more consequential point of hygiene concerns the type variable $x \in [0, 1]$. It is an exchangeable *label*, an index of an agent's kind or network position, not a point of physical space; in particular the distance $|x - y|$ carries no intrinsic meaning, and only the value $W(x, y)$ the kernel assigns to a pair of labels does. A graphon is, canonically, an equivalence class under measure-preserving relabelling of $[0, 1]$, so nothing in its definition privileges one arrangement of the labels over another. There is exactly one place in this chapter where we quietly break that symmetry: the *continuity* half of **(A-Reg-W)**. When we ask that W be uniformly continuous in its type argument — used only to manufacture type-direction compactness in the existence theorem, through lemma 24.8 — we must first *choose* a particular representative of the graphon and endow $[0, 1]$ with its Euclidean metric, purely so that "continuity in x" has a referent. This is non-canonical extra structure, imposed for that one hypothesis alone. The caveat is load-bearing, not decorative: it is precisely the structure that a graphon given only up to relabelling does not possess, so its unavailability is what forces the harder, merely-measurable treatment of remark 24.13, where continuity is replaced by the Hilbert–Schmidt compactness of $\mathbb{W}$ itself.

24.1 Equilibrium as a fixed point on the field of measures

The preamble promised that an equilibrium is no longer a single flow of measures but an entire *field* of them, one flow per type, and that the types talk to one another only through the graphon operator $\mathbb{W}$. Before any existence or uniqueness can be argued, that promise has to be made into mathematics: we need a concrete space for the unknown to live in, a concrete map whose fixed points are the equilibria, and a clear view of where inside that map the graphon enters. This section does exactly these three things, in order. First we fix the ambient space — the field-of-measures space $\mathbb{M}$, its second-moment leash $\mathbb{M}_2$, and the metric D that measures distance between fields. Then we recall, without rederiving it, the GMFG system of chapter 22 and the aggregation through $\mathbb{W}$ that couples its type-indexed equations. Finally we assemble these into the graphon best-response map and expose its internal structure: the factorisation $\mathsf{S}_W = \mathcal{R} \circ \mathcal{A}_W$ that cleanly separates the classical difficulty, carried by the type-wise solve $\mathcal{R}$, from the graphon difficulty, carried by the linear aggregation $\mathcal{A}_W$. That factorisation is the lens through which every theorem in the rest of the chapter is meant to be read, so the section's real payload is the map's anatomy, not just its definition. We begin with the state space, where the single flow $t \mapsto m_t$ of definition 10.1 must first be promoted to a continuous map from types to flows.

24.1.1 The field-of-measures state space

In the homogeneous theory of chapter 10 a candidate equilibrium was a single object: a flow of measures $t \mapsto m_t$, the running population of one representative agent's environment (definition 10.1). There was one population because there was one kind of agent. The whole content of the graphon turn is that there is now a continuum of kinds — the types $x \in [0,1]$ — and each kind carries its own population, evolving in its own way and felt differently by every other kind through the kernel W. A candidate equilibrium is therefore no longer a single flow but an entire *field* of them, one flow per type. To make the promise of the preamble into mathematics we must say precisely what such a field is, in what space it lives, and with what distance we measure two of them apart; only then can a best-response map be defined on that space and its fixed points hunted. That is the business of this subsection: we promote the single flow $t \mapsto m_t$ of definition 10.1 to a continuous map $x \mapsto m^x$ from types to flows, fix the metric that makes it a usable state space, and extract the one elementary inequality — the first moment is a 1-Lipschitz functional of the law — that every continuity and contraction estimate downstream will lean on.

It helps to picture the object as having two nested levels, an *inner* and an *outer* one, because the two levels are governed by two different kinds of regularity and it is worth keeping them apart from the start. The inner level is the one we already understand. Fix a single type x; then $m^x = (m^x_t)_{t\in[0,T]}$ is exactly a flow of measures of the chapter 10 kind — a curve in the space of probability measures, continuous in *time*, carrying the type-x population from its initial datum m^x_0 to its terminal configuration. Everything Part I built about such a flow — its tightness, its time-modulus, its behaviour under the best-response solve — applies to it verbatim, because nothing in those estimates ever knew about a type variable. The outer level is genuinely new. We now ask how the flow m^x varies as the type x ranges over $[0,1]$: a field is a curve of flows, parametrised by type. The inner regularity is in time and is inherited; the outer regularity is in type and must be supplied, and it is precisely the outer regularity that the graphon will have to pay for. Holding this two-level picture — flow-in-time inside, field-in-type outside — in mind is the cleanest way to track which difficulties are old and which are new.

The field-of-measures space itself is not invented here; it is owned by chapter 21, which introduces *two* variants and we must choose between them. The first is the L^2-in-type Bochner space $L^2([0,1];(\mathcal{P}_2(\mathbb{R}^d),\mathcal{W}_2))$, with the $\mathcal{W}_2$-based metric d_2 (definition 21.8): a field is merely a square-integrable, hence possibly discontinuous, assignment of a flow to each type, and two fields are close when they are close in mean-square over types. The second is the type-*continuous* variant $C([0,1];(\mathcal{P}_2(\mathbb{R}^d),\mathcal{W}_2))$, with the uniform-in-type metric (definition 21.10): a field is a genuinely continuous map from types to flows, and two fields are close when they are close *at every type simultaneously*. We adopt the type-continuous variant, with one adjustment of the inner metric: we measure each type fibre with the $\mathcal{W}_1$ distance rather than $\mathcal{W}_2$, keeping the second moment as a separate a priori leash exactly as in chapter 10, rather than folding it into the metric. The companion probabilistic chapter chapter 23 makes the opposite pair of choices, working in the L^2-in-type, $\mathcal{W}_2$-based variant definition 23.8. The two settings are not rival theories but two refinements — the $\mathcal{W}_1$/uniform-in-type one here, the $\mathcal{W}_2/L^2$-in-type one there — of the single chapter 21 field space, and chapter 23's probabilistic well-posedness and the analytic existence theorem of this chapter are carried back and forth between them by the two-pictures dictionary proposition 23.19. With that orientation fixed we can write the space down.

Definition 24.1 (Field of measure flows)**.** Write $\mathcal{C} := C([0,T];\mathcal{P}_1(\mathbb{R}^d))$ for the flow space of definition 10.1, with the uniform Wasserstein metric $\mathsf{d}_1(m,m') = \sup_t \mathcal{W}_1(m_t,m'_t)$. A *field of measure flows* is a continuous map

$$\mathbf{m} = (m^x)_{x\in[0,1]} \colon [0,1] \longrightarrow \mathcal{C}, \qquad x \longmapsto m^x = (m^x_t)_{t\in[0,T]},$$

and we let

$$\mathbb{M} := C([0,1];\mathcal{C}), \qquad \mathsf{D}(\mathbf{m},\mathbf{m}') := \sup_{x\in[0,1]} \mathsf{d}_1(m^x, m^{x\prime}),$$

denote the ambient space of fields, equipped with the uniform-in-type metric D. We write $\mathbb{M}_2 \subseteq \mathbb{M}$ for the fields with $\sup_x \sup_t \int |\xi|^2 \, m^x_t(\mathrm{d}\xi) < \infty$, the uniform second moment being retained as an a priori leash rather than as part of the topology, exactly as in chapter 10.

The metric D wears the two-level structure on its face: the inner $\sup_t$ inside d_1 measures the field in time, the outer $\sup_x$ measures it across types, and a field is small in D exactly when it is small in $\mathcal{W}_1$ *at every time and every type at once.* Three deliberate choices are encoded here, and each deserves a motivated word rather than a one-line aside, because each will be paid for or cashed in later in the chapter.

The first choice is that the outer topology is *uniform* in the type x: a sequence of fields converges only when it converges at every type simultaneously, not merely in mean square over types. This is the strongest reasonable demand one can place on the type direction, and the question is why we are entitled to make it. The answer is the recurring discipline of the chapter: it is exactly what graphon continuity buys us. The standing regularity assumption **(A-Reg-W)** asks W to be continuous in its type argument, and continuity of the kernel is what will let us prove, in lemmas 24.8 and 24.9, that the best-response output is itself *equicontinuous* in type — that nearby types produce nearby flows, with a modulus that does not depend on which field we started from. An equicontinuous family in a uniform topology is compact (this is the metric Arzelà–Ascoli theorem, and it is the only way we will ever get compactness in the type direction), so the uniform setting is precisely the setting in which the regularity of W converts into the compactness the existence proof needs. Choosing the uniform topology is choosing to spend graphon continuity on type-direction compactness, and it is the cleanest bargain available.

It is worth being honest about what the bargain costs, because the cost is the subject of a forward pointer. If W is only *measurable* in type — the generic situation, since a graphon is canonically an equivalence class under measure-preserving relabelling and such a class need have no continuous representative at all — then "continuity in x" has no meaning to demand of the field, and the uniform topology is simply unavailable. One is then forced down to the L^2-in-type variant: measurable fields valued in $\mathcal{C}$, with an L^p-in-type metric that no longer controls any single type but only a type-average. The compactness that equicontinuity gave us for free must then be recovered by a different mechanism, the Hilbert–Schmidt compactness of the operator $\mathbb{W}$ itself, and the whole treatment becomes more delicate. We flag this honestly now and defer it to remark 24.13; the point to carry forward is that the comfortable uniform-in-type setting of this section is a privilege of continuous graphons, not a free choice.

The second choice is that each fibre is metrised with the first Wasserstein distance $\mathcal{W}_1$ rather than the second, $\mathcal{W}_2$. The reason is the one from chapter 10 and is worth restating because it is structural, not cosmetic. On the whole space $\mathcal{P}_1(\mathbb{R}^d)$, $\mathcal{W}_1$ does not by itself metrise weak convergence — mass can escape to infinity while staying $\mathcal{W}_1$-close in the bulk. But on any set with a uniform bound on a higher moment, that escape is forbidden, and there $\mathcal{W}_1$ *does* metrise weak convergence: convergence in $\mathcal{W}_1$ is then exactly convergence in distribution (theorem 4.8). This is why we keep the second moment as a separate leash rather than promoting to $\mathcal{W}_2$. The leash is doing two distinct jobs at once, and both are quantitative. First, a uniform second-moment bound is precisely a uniform-tightness certificate: by Markov's inequality it confines almost all the mass of every m_t^x to one fixed large ball, so the whole field lives in a tight, hence (Prokhorov, chapter 3) relatively weakly compact, set of measures — this is the state-direction compactness that feeds the Schauder argument in lemmas 24.7 and 24.10. Second, the same bound is what makes the aggregation operator $\mathbb{W}$ act on a *bounded* set of first-moment fields, so that the coupling data felt across all types is uniformly bounded (lemma 24.6) and the best response is uniformly stable. The moment is, in a word, a leash on which the entire chapter's estimates are walked: it keeps the populations from running off to infinity in state while we chase the fixed point in type. Pinning it down a priori, separately from the topology, is what lets us use the weaker and more flexible $\mathcal{W}_1$ metric where we need flexibility and still command the tightness where we need control.

From these two structural choices we can already harvest the one elementary fact that will be used on nearly every page that follows, and it is worth isolating now precisely because it is so small. The graphon couples types only through aggregates of the populations, and the aggregate of interest (definition 24.3) is the *first moment* $\bar{m} = \int \xi \, m(\mathrm{d}\xi)$ of each type's law. If we are to control how the coupling changes when the field changes, we must control how the first moment changes when the law changes — and we measure changes of the law in $\mathcal{W}_1$. The fact we need is therefore exactly that the first moment is a $\mathcal{W}_1$-Lipschitz functional, with the best possible constant. It follows directly from the primal (Kantorovich) definition of $\mathcal{W}_1$ as an infimum over couplings (remark 4.4), with no machinery at all.

Lemma 24.2 (The first moment is 1-Lipschitz in $\mathcal{W}_1$)**.** *For $\mu, \nu \in \mathcal{P}_1(\mathbb{R}^d)$ with first moments $\bar{\mu} = \int \xi \, \mu(\mathrm{d}\xi)$ and $\bar{\nu} = \int \xi \, \nu(\mathrm{d}\xi)$, one has $|\bar{\mu} - \bar{\nu}| \le \mathcal{W}_1(\mu, \nu)$.*

Proof. The argument is the prototype of an estimate we will run many times in this chapter, so it is worth seeing in its barest form: there is no duality, only a coupling. Let $\pi \in \Pi(\mu, \nu)$ be *any* coupling of μ and ν — any probability measure on $\mathbb{R}^d \times \mathbb{R}^d$ whose first marginal is μ and whose second is ν. Because the marginals of π are μ and ν, the difference of first moments is itself an expectation under π: integrating the two coordinate maps against π and subtracting,

$$\bar{\mu} - \bar{\nu} = \int_{\mathbb{R}^d} \xi \, \mu(\mathrm{d}\xi) - \int_{\mathbb{R}^d} \eta \, \nu(\mathrm{d}\eta) = \int_{\mathbb{R}^d \times \mathbb{R}^d} (\xi - \eta) \, \pi(\mathrm{d}\xi, \mathrm{d}\eta),$$

where the second equality just rewrites each single integral as a double integral against π using its marginal property. Now take norms and pass them inside the integral (the triangle inequality for the vector-valued integral, i.e. Jensen):

$$|\bar{\mu} - \bar{\nu}| = \Big| \int_{\mathbb{R}^d \times \mathbb{R}^d} (\xi - \eta) \, \pi(\mathrm{d}\xi, \mathrm{d}\eta) \Big| \le \int_{\mathbb{R}^d \times \mathbb{R}^d} |\xi - \eta| \, \pi(\mathrm{d}\xi, \mathrm{d}\eta).$$

This bound holds for *every* coupling π, so it holds for the infimum over couplings on the right; but that infimum is, by definition, the first Wasserstein distance, $\mathcal{W}_1(\mu,\nu) = \inf_{\pi\in\Pi(\mu,\nu)} \int |\xi-\eta|\ \pi(\mathrm{d}\xi,\mathrm{d}\eta)$ (remark 4.4). Hence $|\bar\mu-\bar\nu| \le \mathcal{W}_1(\mu,\nu)$, which is the claim.

The same inequality drops out of the Kantorovich–Rubinstein dual in one line, which is worth recording because it is the lens chapter 4 usually uses. Fix a unit vector $e \in \mathbb{R}^d$; the scalar map $\xi \mapsto e\cdot\xi$ is 1-Lipschitz, so it is an admissible test function in the dual representation $\mathcal{W}_1(\mu,\nu) = \sup_{\mathrm{Lip}(\varphi)\le 1} \int \varphi\ \mathrm{d}(\mu-\nu)$, giving $e\cdot(\bar\mu-\bar\nu) = \int (e\cdot\xi)\ \mathrm{d}(\mu-\nu) \le \mathcal{W}_1(\mu,\nu)$; taking the supremum over $|e|=1$ recovers $|\bar\mu-\bar\nu| \le \mathcal{W}_1(\mu,\nu)$. The two routes are the two faces of $\mathcal{W}_1$ we will keep alternating between — couplings when we want to construct, test functions when we want to bound — and here they agree to the last constant. □

The constant is sharp: a pair of point masses $\mu=\delta_a$, $\nu=\delta_b$ has the single coupling $\delta_{(a,b)}$, so $\mathcal{W}_1(\delta_a,\delta_b) = |a-b| = |\bar\mu-\bar\nu|$, and the inequality is an equality. The lesson to carry is not the numerical value but the mechanism. The first-moment map $m\mapsto\bar m$ is the simplest of the population observables the graphon will aggregate, and lemma 24.2 is the statement that it does not amplify distances: a $\mathcal{W}_1$-perturbation of a type's law of size ϵ moves its first moment by at most ϵ. Composed with the bounded operator $\mathbb{W}$, this is what will make the aggregation $\mathcal{A}_W$ a Lipschitz — indeed continuous — map of fields in the existence proof (theorem 24.11), and it is the first link in every downstream chain that propagates a change in the field through the coupling, through the per-type solve, and back to a change in the output field. Small as it is, it is the quantitative hinge on which the continuity of the whole best-response map turns.

With the state space fixed — the field space $\mathbb{M}$, its second-moment-bounded subset $\mathbb{M}_2$, and the uniform-in-type metric D — and with the first-moment leash in hand, we have a precise arena in which the unknown of the graphon game lives. The next subsection puts that arena to work: it recalls, without rederiving it, the GMFG PDE system of chapter 22 and states what a *classical solution* of it is — a pair of fields $(\mathbf{u},\mathbf{m})$ in exactly the space just built — and isolates the one place where the types talk to each other, the aggregation of the population field through $\mathbb{W}$. The 1-Lipschitz first-moment bound of lemma 24.2 is the elementary input that aggregation operator will consume on its very first line.

24.1.2 The GMFG system and the aggregation operator

The arena for the unknown is now fixed. What lives in it is a solution of the GMFG system, and before we can hunt for one we must say precisely what such a solution is. The purpose of this subsection is to make that statement and, in doing so, to put a finger on the one place where the types are wired together — the single seam that the rest of the chapter prises apart. We recall the system from chapter 22 rather than rederive it, read off what a *classical solution* is as a pair of fields, and then isolate the aggregation through $\mathbb{W}$ that mediates the whole coupling. The reader should watch for the punchline of the subsection: every type-to-type interaction, and every interaction between the value block and the density block, will be shown to flow through a single $L^2([0,1])$-valued quantity $z_t(x)$, and once that is established the coupled system is one short step from decoupling.

Fix the diffusion coefficient $\nu := \frac{1}{2}\sigma\sigma^\top$ (nondegenerate by **(A-Nondeg)**), abbreviated $\nu > 0$ in the scalar exposition, and the control Hamiltonian $H(x,p)$, convex in p under **(A-Conv)**, imported from chapter 6. Because this is the first chapter of Part IV in which the value field and the density field appear together in one system, the style bible asks us to restate the time-orientation convention fixed once and for all in appendix A.1, and the restatement is worth the line because the two blocks run in opposite time directions and the reader must hold both arrows at once. The value u^x runs *backward*: it carries terminal data at $t = T$ and is integrated towards $t = 0$, because an optimal cost-to-go is built by dynamic programming from the end of the horizon, where the only thing an agent knows is the terminal penalty, back towards the present. The density m^x runs *forward*: it carries initial data at $t = 0$ and is transported towards $t = T$, because a population is pushed from where it starts by the flow the agents choose. The coupling closes this loop — the backward value is computed against the forward population, and the forward population is driven by the feedback the backward value defines — and it enters through a *running coupling* F and a *terminal coupling* G, which in the graphon setting are no longer maps into functions of state alone but maps from the field $\mathbf{m}$ to functions of *type and state*:

$$F[\mathbf{m}]\colon [0,1]\times\mathbb{R}^d \to \mathbb{R}, \qquad G[\mathbf{m}]\colon [0,1]\times\mathbb{R}^d \to \mathbb{R}.$$

The extra type slot is the whole novelty: in chapter 11 a single population m produced a single cost field $F[m](\cdot)$ felt by everyone, whereas here the field $\mathbf{m}$ produces, for each type x, its *own* cost field $F[\mathbf{m}](x,\cdot)$, and it is through this type-dependence that one type's population reaches into another type's optimisation.

A classical solution of the GMFG system is, accordingly, a pair of fields $(\mathbf{u},\mathbf{m}) = ((u^x)_x,(m^x)_x)$ — a value field and a density field, one of each per type, both living in the space of the previous subsection — solving, for each $x \in [0,1]$,

$$-\partial_t u^x - \nu\,\Delta_\xi u^x + H(x,\nabla_\xi u^x) = F[\mathbf{m}_t](x,\cdot), \qquad u^x(T,\cdot) = G[\mathbf{m}_T](x,\cdot), \tag{24.1}$$

$$\partial_t m^x - \nu\,\Delta_\xi m^x - \mathrm{div}_\xi\big(m^x\,\partial_p H(x,\nabla_\xi u^x)\big) = 0, \qquad m^x(0,\cdot) = m_0^x, \tag{24.2}$$

on $[0,T]\times\mathbb{R}^d$, where $\mathbf{m}_t = (m_t^x)_x$ denotes the field's time-t slice. The optimal feedback for type x is $\alpha^{*,x} = -\partial_p H(x,\nabla_\xi u^x)$, the sign convention of appendix A.4, and it is this feedback that appears as the transport drift in the divergence term of eq. (24.2): the value computed by the HJB block drives the density carried by the FP block, exactly as in the homogeneous theory, now with a copy of the pair for every type.

The structure to seize is what is, and what is not, coupled here. For a *fixed* field $\mathbf{m}$ the system eq. (24.1)–eq. (24.2) is not one big system but a continuum of *independent* pairs, one per type: the equations for type x involve u^x and m^x and no other type's unknowns. There is no spatial transport in the type variable, no x-derivative anywhere, nothing that lets type x and type x' communicate inside the differential operators. The HJB equations eq. (24.1) are coupled to one another, and to the FP equations eq. (24.2), *only* through the type-dependence of F and G on the whole field. The entire interaction therefore lives in a single algebraic step — how the field $\mathbf{m}$ is turned into the type-and-state cost data $F[\mathbf{m}_t](x,\cdot)$ — and that step, in every model of interest, is mediated by the graphon operator $\mathbb{W}$ of chapter 18. We make this precise.

Definition 24.3 (Graphon aggregation)**.** Let $\mathbb{W}$ be the integral operator of **(A-Reg-W)**, $(\mathbb{W}f)(x) = \int_0^1 W(x,y)f(y)\,\mathrm{d}y$, self-adjoint Hilbert–Schmidt on $L^2([0,1])$ (chapter 18). For a field $\mathbf{m} \in \mathbb{M}_2$, the *first-moment field* is

$$\overline{\mathbf{m}}_t(y) := \int_{\mathbb{R}^d} \xi\, m_t^y(\mathrm{d}\xi) \in \mathbb{R}^d, \qquad \overline{\mathbf{m}}_t \in L^2([0,1];\mathbb{R}^d),$$

and the *graphon aggregate felt by type* x is

$$z_t(x) := (\mathbb{W}\,\overline{\mathbf{m}}_t)(x) = \int_0^1 W(x,y)\,\overline{\mathbf{m}}_t(y)\,\mathrm{d}y. \tag{24.3}$$

A coupling is *graphon-local* if $F[\mathbf{m}_t](x,\xi) = F_0\big(\xi, z_t(x)\big)$ and $G[\mathbf{m}_T](x,\xi) = G_0\big(\xi, z_T(x)\big)$ for fixed functions F_0, G_0 — i.e. type x feels the population only through the single aggregated quantity $z_t(x)$.

The definition is built in two moves, and each deserves its picture. The first move collapses each type's whole law to a single vector: the first-moment field $\overline{\mathbf{m}}_t$ reads off, at every type y, the mean position $\int \xi\, m_t^y(\mathrm{d}\xi)$ of that type's population. This is a drastic compression of information — an entire probability measure on $\mathbb{R}^d$ replaced by its centre of mass — but it is exactly the compression that lemma 24.2 certified is stable: a $\mathcal{W}_1$-wobble of a type's law of size ϵ moves its entry of $\overline{\mathbf{m}}_t$ by at most ϵ, so the map $\mathbf{m} \mapsto \overline{\mathbf{m}}_t$ is 1-Lipschitz from the field metric into $L^\infty([0,1];\mathbb{R}^d)$, and that bound is consumed on the very first line of every continuity estimate downstream. The second move is the aggregation proper: $\mathbb{W}$ averages the mean field $\overline{\mathbf{m}}_t$ against the kernel row $W(x,\cdot)$ to produce $z_t(x)$. The intuition to carry is that $z_t(x)$ is *the population as felt by type x through the network* — not the global mean, which no one in a heterogeneous network ever sees, but the $W(x,\cdot)$-weighted average of neighbours' means, the only summary of the crowd that reaches an agent of type x along the edges incident to it. A type strongly linked to a cluster feels that cluster's mean loudly; a type weakly linked to it barely feels it at all. The aggregate is the network's own, type-specific, low-pass picture of where the population sits.

It pays to keep this object's place in the larger family of aggregates straight, because the companion probabilistic chapter works with a richer one and we are deliberately taking a specialisation. Definition 23.2 defined the *measure-valued* graphon aggregate $(\mathbb{W}\mathbf{m}_t)(x) = \int_0^1 W(x,y)\, m_t^y\,\mathrm{d}y$, a (sub-probability) measure on $\mathbb{R}^d$ obtained by superposing the neighbours' *whole laws* with the kernel weights — it remembers the spread, the skew, every moment of the neighbourhood, not merely its centre. Our first-moment field eq. (24.3) is exactly the centre of mass of that measure: by linearity, integrating the coordinate map ξ against the superposition is the same as superposing the type-wise means,

$$z_t(x) = \int_{\mathbb{R}^d} \xi\,(\mathbb{W}\mathbf{m}_t)(x)(\mathrm{d}\xi) = \int_0^1 W(x,y)\Big(\int_{\mathbb{R}^d} \xi\, m_t^y(\mathrm{d}\xi)\Big)\,\mathrm{d}y = (\mathbb{W}\,\overline{\mathbf{m}}_t)(x),$$

which is precisely the observable $h(\xi) = \xi$ of the scalar aggregate eq. (23.2). The two operations commute — one may take the first moment and then aggregate, or aggregate and then take the first moment, and get the same vector — because $\mathbb{W}$ acts only in the type variable while the moment acts only in the state variable, and that commutation is what licenses us to work with the cheap $L^2([0,1];\mathbb{R}^d)$-valued object $\overline{\mathbf{m}}_t$ in place of the expensive measure-valued one throughout the existence proof. The existence theory below is developed for this first-moment (graphon-local) specialisation.

Two remarks place this choice in context without derailing the development. First, on generality: the first-moment reduction is not a loss of the framework's reach but a choice of the cleanest representative of it. Higher-order statistics — aggregating a vector of several moments, or the measures themselves through the measure-valued $\mathbf{m}_t \mapsto \int_0^1 W(x,y)\, m_t^y \,\mathrm{d}y$ of definition 23.2 — are accommodated by the very same formalism, with $\overline{\mathbf{m}}$ replaced by the appropriate $L^2([0,1])$-valued statistic and F_0, G_0 promoted to functions of that statistic; nothing in the aggregation step changes, because $\mathbb{W}$ is blind to what it is averaging. We keep the first-moment version for concreteness, as the thread specification does, and because it is the form Thread B needs. Second, on the status of graphon-locality: it is not an extra hypothesis pulled from the air but the structure of every example we carry. Thread B couples a type-x agent to the graphon-aggregated neighbour mean $z_t(x) = (\mathbb{W}\overline{\mathbf{m}}_t)(x)$ and to nothing else — its running cost penalises the squared deviation $(X_t^x - s\, z_t(x))^2$ — and every model of chapter 22 shares this shape. We therefore treat the general coupling $F[\mathbf{m}_t]$ wherever it costs nothing, since the abstract continuity and compactness arguments never need more than that the data depend on $\mathbf{m}$ through $\mathbb{W}$, and we specialise to the graphon-local form $F_0(\xi, z_t(x))$ exactly when the spectral content must be made explicit — which is to say, when the leading eigenvalue $\lambda_1(\mathbb{W})$ has to surface in the uniqueness threshold of section 24.3 and the Thread B diagonalisation of section 24.5.

This is the seam the chapter was promised on. For a frozen field $\mathbf{m}$, the only trace that field leaves on the type-x problem is the single $\mathbb{R}^d$-valued time-curve $t \mapsto z_t(x)$: freeze it and the type-x HJB eq. (24.1) loses every reference to the other types and to $\mathbf{m}$ itself, becoming a decoupled classical equation driven by the given data $F_0(\cdot, z_t(x))$. The aggregate $z_t(x)$ is thus the one channel through which the whole population enters each per-type optimisation, and the linear map $\mathbf{m} \mapsto z$ it defines is the operator factor $\mathcal{A}_W$ foreshadowed in the chapter's opening. The next subsection takes exactly this aggregate, freezes it, and reads off the decoupled per-type best response — the move that makes the classical chapter 10 machine reusable type by type, and at which the factorisation $\mathsf{S}_W = \mathcal{R} \circ \mathcal{A}_W$ first becomes visible on the page.

24.1.3 The graphon best-response map

The previous subsection handed us the aggregate $z_t(x) = (\mathbb{W}\overline{\mathbf{m}}_t)(x)$ and a precise account of what it is: the single $\mathbb{R}^d$-valued time-curve through which a frozen field $\mathbf{m}$ reaches into the type-x optimisation, the one seam at which all the coupling lives. We now do the obvious thing with a seam — we cut along it. The idea is simple to state and is the engine of the whole chapter. A candidate equilibrium field is a *guess* at the population; if we pretend that guess is correct and substitute it into the coupling, the type-x agent faces a control problem with fixed, externally given cost data, no longer entangled with what any other type is doing. Solving that problem and reading off the population it generates produces a *new* guess. The equilibrium is the guess that reproduces itself. This is exactly the best-response logic of the homogeneous theory (definition 10.3), and the whole payoff of having isolated the aggregate is that freezing it makes that logic available type by type, with the classical chapter 10 machine reused verbatim inside each type. We spell out the three moves — freeze, solve, recollect — and then record the map and its fixed-point condition.

Fix a candidate field $\mathbf{m} \in \mathbb{M}_2$. *Freeze.* Substitute $\mathbf{m}$ into the coupling: by definition 24.3 the running source becomes the *given* function $(x,\xi) \mapsto F[\mathbf{m}_t](x,\xi) = F_0(\xi, z_t(x))$ and the terminal data the given function $G[\mathbf{m}_T](x,\cdot) = G_0(\cdot, z_T(x))$, both now inert data that no longer respond to the unknown. The decisive consequence, already flagged at the close of the last subsection, is that the type index x stops being a coupling channel and becomes a mere *label on independent problems*: for each fixed x the HJB equation eq. (24.1) is a *decoupled* semilinear backward parabolic equation, referring to u^x and to the frozen data $F_0(\cdot, z_t(x))$ and to nothing else — not to $u^{x'}$, not to $m^{x'}$, not to $\mathbf{m}$. *Solve.* Under **(A-Nondeg)** that equation is uniformly parabolic, so it is precisely a problem of the kind chapter 6 treats: the control theory there returns a value $u^{\mathbf{m},x}$ and, because H is convex in p under **(A-Conv)**, a single-valued optimal feedback $\hat{\alpha}^{\mathbf{m},x} = -\partial_p H(x, \nabla_\xi u^{\mathbf{m},x})$ (the sign convention of appendix A.4). Feeding that feedback as the transport drift into the FP equation eq. (24.2) — which, with the feedback now a *known* vector field, is a *linear* forward Fokker–Planck equation — and starting from the type-x initial datum m_0^x transports the population forward and produces a new flow $t \mapsto m_t^x$ for type x. *Recollect.* Doing this at every x and gathering the results into one object produces a new field over types. The composite map "$\mathbf{m} \mapsto$ this new field" is the graphon best-response map; nothing in it ever required the per-type problems to communicate, which is exactly why the chapter 10 estimates survive intact when we run them below.

Definition 24.4 (Graphon best-response map and equilibrium)**.** The *graphon best-response map* is

$$\mathsf{S}_W : \mathbb{M}_2 \longrightarrow \mathbb{M}_2, \qquad \mathsf{S}_W(\mathbf{m}) := \Big(\big(\operatorname{Law}(X_t^{\mathbf{m},x})\big)_{t\in[0,T]} \Big)_{x\in[0,1]},$$

where, for each type x, $X^{\mathbf{m},x}$ solves the closed-loop SDE

$$\mathrm{d}X_t^{\mathbf{m},x} = -\,\partial_p H\big(x, \nabla_\xi u^{\mathbf{m},x}(t, X_t^{\mathbf{m},x})\big)\,\mathrm{d}t + \sigma\,\mathrm{d}B_t^x, \qquad X_0^{\mathbf{m},x} \sim m_0^x,$$

and $u^{\mathbf{m},x}$ is the solution of the decoupled HJB eq. (24.1) for the frozen field $\mathbf{m}$. A *graphon mean field game equilibrium* is a field $\mathbf{m}^\star \in \mathbb{M}_2$ with $\mathsf{S}_W(\mathbf{m}^\star) = \mathbf{m}^\star$.

The definition packages the solve and recollect moves into a single SDE rather than the FP equation eq. (24.2), and the two are the same statement read in two languages: $m_t^x = \operatorname{Law}(X_t^{\mathbf{m},x})$ is the density the FP equation transports, because the law of a diffusion with drift $-\partial_p H$ and diffusion σ obeys exactly that Kolmogorov forward equation (the equivalence established in chapter 5). Writing it as the *closed-loop* SDE makes visible what kind of object the output is. The drift $-\partial_p H(x, \nabla_\xi u^{\mathbf{m},x}(t, X_t))$ is the optimal feedback evaluated along the agent's own trajectory, so the agent is not following a fixed plan but reacting to where it finds itself; the loop is closed because the value $u^{\mathbf{m},x}$ that defines the feedback was itself computed against the frozen $\mathbf{m}$. The noise $\sigma\,\mathrm{d}B_t^x$ is the type-x idiosyncratic shock, and the output $\mathsf{S}_W(\mathbf{m})$ retains only its *law* $\operatorname{Law}(X_t^{\mathbf{m},x})$, never the pathwise realisation.

That "only the law" is not a stylistic economy but the reason the construction is well posed at all, and it is worth pausing on because the parallel probabilistic chapter had to fight for it. The map S_W is the analytic-picture avatar of the probabilistic graphon best-response map S on $C([0,T]; L_W^2)$ of definition 23.15, the two related by the two-pictures dictionary proposition 23.19; we carry the subscript W to mark the kernel dependence exploited in section 24.3. In the probabilistic picture one is tempted to realise the *entire continuum* $(X^x)_{x\in[0,1]}$ as a single random field, which demands a continuum $(B^x)_{x\in[0,1]}$ of independent nondegenerate Brownian motions on one probability space — and that object is notoriously pathological: an uncountable family of i.i.d. nondegenerate noises cannot be made jointly measurable in (ω, x) without the sample averages failing to concentrate, the obstruction dissected in remark 23.6. Our map sidesteps it cleanly precisely because the noise enters *per type* and is immediately discarded down to its law: each $X^{\mathbf{m},x}$ is a single ordinary SDE on its own probability space, solved one type at a time, and what is collected across types is the *deterministic* field of laws $x \mapsto (\mathrm{Law}(X_t^{\mathbf{m},x}))_t$, an element of the field space $\mathbb{M}_2$ that carries no joint randomness to be measurable in. We never form the joint law of the continuum; we only ever form a continuum of marginal laws. This is why the analytic fixed-point problem on $\mathbb{M}_2$ is the well-posed home for the existence question, and the probabilistic chapter's care with remark 23.6 is what licenses reading the result back as a statement about genuine graphon McKean–Vlasov processes.

Why hunt fixed points of this particular map? Because a fixed point of S_W is precisely a solution of the coupled system eq. (24.1)–eq. (24.2), and the equivalence is exact in both directions. If $\mathbf{m}^\star = \mathsf{S}_W(\mathbf{m}^\star)$, then the field used to freeze the coupling and compute the values is the very field those optimal feedbacks regenerate, so the consistency that *defines* an equilibrium — population computed against equals population produced — holds, and the pair $(u^{\mathbf{m}^\star}, \mathbf{m}^\star)$ solves the system. Conversely any classical solution $(\mathbf{u}, \mathbf{m})$ has, by construction, $\mathbf{m}$ invariant under freeze-solve-recollect, hence is a fixed point. There is no slack between the two formulations: the self-consistency loop of the GMFG *is* the fixed-point equation, written once as a PDE system and once as $\mathsf{S}_W(\mathbf{m}) = \mathbf{m}$. This is the same reduction that organised chapter 10, and it collapses the entire chapter into two questions. Existence asks whether S_W has *a* fixed point; uniqueness asks whether it can have *two*. The whole novelty relative to chapters 10 and 11 is not the questions, which are old, but the internal structure of S_W that we must understand to answer them — and that structure is a factorisation we now expose, because it is the single most useful thing to know about the map.

Heuristic (non-rigorous): The organising factorisation $\mathsf{S}_W = \mathcal{R} \circ \mathcal{A}_W$

The three moves of the previous page were not symmetric. Exactly one of them — freeze — touched the graphon; the other two — solve, recollect — were the classical machine applied blindly, type by type, to whatever frozen data it was handed. That asymmetry is the whole structure of S_W, and naming it turns the map into a composition of two factors that can be studied separately. Write

$$\mathsf{S}_W \;=\; \mathcal{R} \circ \mathcal{A}_W, \qquad \mathcal{A}_W \colon \mathbf{m} \mapsto \big(x \mapsto z(x) = (\mathbb{W}\overline{\mathbf{m}})(x)\big), \quad \mathcal{R} \colon (z(x))_x \mapsto \big(\mathsf{S}^x_{z(x)}\big)_x, \tag{24.4}$$

where $\mathcal{A}_W$ is the freeze move made into an operator — the *linear* graphon aggregation eq. (24.3) that turns a field into the type-indexed coupling data z it presents to the optimisers (the calligraphic $\mathcal{A}_W$ names this aggregation lift, not the generator $\mathcal{A}$, which plays no role in this diffusion-free fixed-point chapter) — and $\mathcal{R}$ is the solve-and-recollect move, applying *independently in each type* the homogeneous best-response solve $\mathsf{S}^x_{z(x)}$ of definition 10.3 with the frozen data $z(x)$. Read left to right: aggregate the field through the network, then run the classical machine in parallel over types. The value of the factorisation is that the two factors quarantine the two kinds of difficulty so they are never confused.

$\mathcal{R}$ is the classical machine, and it is already understood. Each factor $\mathsf{S}^x_{z(x)}$ is a single homogeneous mean field best response with scalar coupling data $z(x)$: a uniformly parabolic HJB solved backward, its feedback pushed through a linear FP solved forward. This is the object of chapters 10 and 11 down to the last estimate — the gradient bound, the moment and time-equicontinuity bounds, tightness via Prokhorov, stability under weak convergence of the data. Nothing about $\mathcal{R}$ is new; it is the old theory wearing a type subscript, run in a continuum of independent copies. Whatever $\mathcal{R}$ does *within* a type, it does exactly as before, and we may import those results verbatim.

$\mathcal{A}_W$ is a bounded linear operator, and it carries every graphon-specific phenomenon. This is the load-bearing claim of the chapter. $\mathcal{A}_W$ is the post-composition of the first-moment read-out $\mathbf{m} \mapsto \overline{\mathbf{m}}$ (a 1-Lipschitz contraction, by lemma 24.2) with the integral operator $\mathbb{W}$, hence a bounded linear map on $L^2([0,1];\mathbb{R}^d)$. Being merely linear and bounded, it has nothing of the analytic subtlety of $\mathcal{R}$ — and yet *all three* of the ways the graphon makes this theory differ from the homogeneous one are read off it, each from a different attribute of the *same* operator $\mathbb{W}$:

- its **norm** $\|\mathbb{W}\|$ sets the *strength of the feedback loop.* The field influences itself only by being aggregated through $\mathcal{A}_W$, solved, and aggregated again; the gain around that loop scales with $\|\mathbb{W}\|$, so $\|\mathbb{W}\|$ is what governs whether the small-coupling contraction of section 24.3 closes and how large a uniform bound the aggregate inherits (lemma 24.6).

- its **spectrum** sets the *sign of the equilibrium energy.* The Lasry–Lions uniqueness identity acquires a quadratic form threaded through $\mathbb{W}$; whether that form is signed — hence whether two equilibria can coexist — is decided mode by mode by the eigenvalues of $\mathbb{W}$, with the leading eigenvalue $\lambda_1(\mathbb{W})$ marking the critical coupling $s\,\lambda_1$ at which uniqueness breaks (sections 24.3 and 24.5).

- its **continuity** — continuity of the kernel W in its type argument, **(A-Reg-W)** — sets *compactness in the type direction.* $\mathcal{A}_W$ maps a merely bounded first-moment field to an *equicontinuous* aggregate (lemma 24.8), and equicontinuity is the only currency that buys type-direction compactness for Schauder (lemmas 24.9 and 24.10).

Norm, spectrum, continuity: feedback strength, energy sign, compactness. Three faces of one operator, supplying the chapter's three new facts. The method of the chapter is therefore to read *every* later theorem as a statement about $\mathcal{R} \circ \mathcal{A}_W$ — to ask, of any estimate, whether it is a fact about $\mathcal{R}$ (then it is classical and inherited) or a fact about $\mathcal{A}_W$ (then it is graphonic and lives in $\mathbb{W}$). Holding the two apart is what keeps the inherited difficulty and the genuinely new difficulty from being mistaken for one another.

One honest qualification keeps the box a heuristic rather than a theorem, and it is the reason the chapter carries a standing "single-valued regime" assumption rather than merely asserting one. The factor $\mathcal{R}$ is a genuine *map* — a well-defined function of z, not a correspondence — exactly when the per-type best response is single-valued, i.e. when the type-x optimiser has a *unique* optimal feedback. That uniqueness is precisely what strict convexity of the Hamiltonian **(A-Conv)** and nondegeneracy of the diffusion **(A-Nondeg)** deliver: strict convexity makes $p \mapsto \partial_p H(x,p)$ a genuine function (no flat stretch where several controls are equally optimal), and nondegeneracy supplies the parabolic smoothing that makes $\nabla_\xi u^{\mathbf{m},x}$ well defined pointwise, so the feedback $-\partial_p H(x, \nabla_\xi u^{\mathbf{m},x})$ is a single vector field and the output flow is unambiguous. Drop either hypothesis and $\mathcal{R}$ becomes *set-valued*: the optimiser may be indifferent among several feedbacks, S^x returns a set of flows, and S_W is a correspondence rather than a map. The fixed-point question is then not Schauder but its set-valued cousin, the Kakutani–Fan–Glicksberg theorem theorem 2.40 applied to the field-valued correspondence; we record that route, with the attendant notion of a *weak* (relaxed) graphon equilibrium and a measurable-selection step, as the graphon analogue of theorem 10.19 in remark 24.14. It changes the machinery but not the moral: the set-valuedness lives entirely in $\mathcal{R}$, the classical factor, and leaves $\mathcal{A}_W$ untouched. We therefore adopt the single-valued regime — **(A-Conv)** and **(A-Nondeg)** in force — as standing unless explicitly stated otherwise, so that S_W is an honest self-map of $\mathbb{M}_2$ and Schauder is the right tool.

We can now state the chapter's first concrete task in one clean sentence, and the factorisation tells us in advance where the work will be. Existence is the question: *does S_W have a fixed point?* The lens eq. (24.4) predicts the answer's shape before we prove anything. Because $\mathcal{R}$ is the classical machine, the within-type content of the existence proof — the construction of a convex compact invariant set in the state and time directions — is chapter 10 reused per type, with nothing to add. The genuinely new obligation is the type-direction compactness that Schauder also demands of a field, and the factorisation says exactly which factor must supply it: not $\mathcal{R}$, which knows nothing of how types are arranged, but $\mathcal{A}_W$, whose continuity (**(A-Reg-W)**) is the only available source of type-direction equicontinuity. The next section takes up the fixed-point question with this division of labour fixed in advance — $\mathcal{R}$ inherited, $\mathcal{A}_W$ on the hook for the new compactness — and that is the seam along which its proof is organised.

24.2 Existence

The previous section left us with one clean question and a lens through which to read its answer. The question is the whole of existence: *does the graphon best-response map S_W have a fixed point?* The lens is the factorisation $\mathsf{S}_W = \mathcal{R} \circ \mathcal{A}_W$ of eq. (24.4), and it already told us where to look for trouble. The solve-and-recollect factor $\mathcal{R}$ is the classical machine of chapter 10 worn with a type subscript, run in a continuum of independent copies; whatever it does, it does exactly as it did in the homogeneous theory, and we will reuse those estimates verbatim. The aggregation factor $\mathcal{A}_W$ is the only place the graphon enters, and the factorisation predicted that the one genuinely new obligation of the existence proof would land on it. This section makes that prediction concrete.

The proof strategy is the one the reader owns from chapter 10: Schauder's fixed-point theorem (theorem 2.38) on the field space $\mathbb{M}$. Schauder asks for three things — a continuous self-map of a convex set, and a *convex compact* invariant subset on which to run it — and of these the compactness is the only one that ever costs real work. We are operating in the standing single-valued regime fixed at the close of the last section (**(A-Conv)** and **(A-Nondeg)** in force), so S_W is an honest self-map rather than a correspondence and Schauder, not its Kakutani cousin, is the right tool; convexity of the candidate set will be arranged by hand exactly as in theorem 10.14. Everything therefore reduces to manufacturing a convex compact set that S_W maps into itself. The manufacture of that set is the entire content of the existence proof, and it is here, and only here, that the graphon changes the classical argument.

What changes is the *anatomy* of the compactness. A point of the field space $\mathbb{M}$ is not a single flow of measures, as it was in chapter 10, but an entire field $x \mapsto m^x$ of them, and the metric D of definition 24.1 splits, as noted at its definition, along two levels: the inner $\sup_t$ inside d_1 controls the flow in *state and time*, the outer $\sup_x$ controls its variation across *types*. Compactness in $\mathbb{M}$ therefore has *two directions*, and the structural novelty of this chapter — the thing to plant firmly before any lemma — is that these two directions are bought from two completely different sources and may be supplied independently. This splitting is not a presentational convenience; it is forced by the product-like structure of $\mathbb{M} = C([0,1];\mathcal{C})$, and it is exactly the seam along which the factorisation $\mathsf{S}_W = \mathcal{R} \circ \mathcal{A}_W$ cuts the proof.

In the *state-and-time* direction — the behaviour of each fibre m^x as a curve $t \mapsto m_t^x$ of measures on $\mathbb{R}^d$ — compactness is precisely the classical compactness of chapter 10. A uniform second-moment bound confines almost all the mass of every m_t^x to one fixed large ball, hence (Prokhorov, chapter 3) into a tight, relatively weakly compact set; a uniform time-modulus forbids the flow from jumping; and the two together place each fibre in the single convex compact set $\mathcal{K} \subseteq \mathcal{C}$ of lemma 10.8. None of these estimates ever knew about a type variable, so they transfer to the graphon setting unchanged — *provided* they can be made to hold with constants that do not depend on which type we are looking at. That uniformity-in-type is the one genuinely new demand the state-and-time direction makes, and it is met by a single attribute of $\mathcal{A}_W$: the operator norm of $\mathbb{W}$, which bounds the aggregate $z_t(x)$ felt by every type at once and so feeds the classical gradient estimate lemma 10.5 the same bounded data uniformly across x. The inherited machinery does the rest.

In the *type* direction — the dependence $x \mapsto m^x$ itself — compactness is genuinely new, and it is the price the graphon exacts. There is no analogue of this difficulty in the homogeneous theory of chapter 10: there was one population because there was one kind of agent, no type variable, hence nothing to be compact *in*, and theorem 10.14 needed no type-direction estimate because there was no type direction. A graphon candidate, by contrast, is a whole curve of flows over $[0,1]$, and nothing in the state-and-time estimates stops that curve from oscillating ever faster in x — a sequence of fields can stay bounded and tight at every fixed type and still fail to converge, because the assignment of flow to type wiggles without bound. The only currency that buys compactness in a uniform topology is an *equicontinuity modulus*: a guarantee that nearby types produce nearby flows, with a modulus independent of which field we started from, so that the metric Arzelà–Ascoli theorem applies. And the only source of such a modulus in the entire construction is the continuity of the kernel W in its type argument, the second half of **(A-Reg-W)**. This is the structural surprise worth stating without hedging: in the classical theory existence needed no regularity of any coupling kernel whatsoever, yet the graphon *existence* theorem — not merely the uniqueness theorem — fails without a continuity hypothesis on $\mathbb{W}$, because continuity is the sole manufacturer of the missing type-direction compactness. The norm of $\mathbb{W}$ handles one direction; the continuity of $\mathbb{W}$ handles the other; both are attributes of the same operator, and that is the factorisation doing its promised work.

These two inputs are logically independent: one can have the uniform bound without the modulus (a bounded but discontinuous kernel) or, in principle, control the type-modulus of a field without a uniform state bound. The existence proof needs both, and the cleanest way to organise it is to secure each separately and only then combine them, which is exactly the division of labour the three subsections below carry out. We isolate each input in turn.

Before isolating them we must, exactly as in chapter 10, pin down the structural demands the coupling data have to meet for the inherited estimates to fire, now type-indexed. The classical existence theorem rested on the couplings being *bounded* and *smoothing*: bounded so that the per-type value function inherits a gradient bound (lemma 10.5) and hence a bounded feedback, smoothing so that weak convergence of the population data passes through the HJB solve to convergence of the value (lemma 10.10), which is what makes the best-response map continuous. Neither requirement is automatic, and the LQG thread famously violates the first — its quadratic running cost is unbounded in state, so it cannot be admitted under a boundedness hypothesis and must instead be handled by explicit Gaussian construction, which we again defer to the worked computation of section 24.5. We therefore carry the standing bounded-smoothing-coupling assumption of chapter 10, lifted to the graphon setting by the single change that every clause is now demanded *uniformly in the type* x — the uniformity being precisely what the state-and-time direction needs to make its constants type-free.

Assumption 24.5 (Bounded, uniformly type-Lipschitz graphon-local couplings)**.** The couplings are graphon-local (definition 24.3), $F[\mathbf{m}_t](x,\xi) = F_0(\xi, z_t(x))$ and $G[\mathbf{m}_T](x,\xi) = G_0(\xi, z_T(x))$, with $F_0, G_0 \colon \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$ bounded, uniformly Lipschitz in ξ uniformly in the second argument, uniformly Lipschitz in the aggregate argument z, and continuous for weak convergence in the sense of lemma 10.10. The initial field $\mathbf{m}_0$ has uniformly bounded second moment, $\sup_x \int |\xi|^2\, m_0^x(\mathrm{d}\xi) < \infty$, and is continuous in type, $x \mapsto m_0^x \in \mathcal{P}_2(\mathbb{R}^d)$ continuous.

The assumption packs five clauses, and it is worth walking each one and naming exactly what breaks in its absence, because each is load-bearing for a different link in the chain and none is there for decoration. *Graphon-locality* ($F[\mathbf{m}_t](x,\xi) = F_0(\xi, z_t(x))$, the data felt by type x depending on the field only through the single aggregate $z_t(x) = (\mathbb{W}\overline{\mathbf{m}}_t)(x)$ of definition 24.3) is what makes the factorisation $\mathsf{S}_W = \mathcal{R} \circ \mathcal{A}_W$ literally true rather than merely morally so: it is the statement that the field reaches the type-x optimiser through one finite-dimensional channel, so that freezing z genuinely decouples the per-type problem. Without it the per-type solve would still see the whole field, the type index would remain a coupling channel inside the differential operators, and there would be no clean classical factor $\mathcal{R}$ to inherit. *Boundedness* of F_0, G_0 is what the gradient bound lemma 10.5 consumes; drop it and the per-type value function $u^{\mathbf{m},x}$ need carry no uniform gradient bound, the optimal feedback $-\partial_p H(x, \nabla_\xi u^{\mathbf{m},x})$ need not be bounded, the closed-loop drift escapes control, and the per-type moment and time-equicontinuity estimates of lemmas 10.6 and 10.7 — the entire state-and-time compactness — collapse. (This is the precise clause the LQG thread violates, and the precise reason its threshold has to be found by hand in section 24.5 rather than read off this theorem.) *Uniform Lipschitz continuity in the state ξ, uniformly in the aggregate argument*, is what makes the parabolic solve well posed and the feedback single-valued at the level of regularity chapter 6 requires; it is the smoothing that, together with **(A-Nondeg)**, keeps $\mathcal{R}$ a genuine map rather than a correspondence. *Uniform Lipschitz continuity in the aggregate z* is the clause that will make the *best response itself* continuous: a change in the field moves z by a controlled amount (through the 1-Lipschitz first-moment read-out of lemma 24.2 composed with the bounded $\mathbb{W}$), and this clause converts that controlled move in the data into a controlled move in the output flow, which is the continuity Schauder demands of the map. Strip it and S_W could jump discontinuously as the field varies, and no fixed-point theorem applies. *Weak-convergence continuity in the sense of lemma 10.10* is the same continuity demanded along weakly convergent sequences of populations, the form in which it is actually used when we pass to a limit inside the compact set; it is the clause that lets the limit of best responses be the best response of the limit.

Two clauses concern not the couplings but the initial datum, and they seed the two compactness directions at $t = 0$ so that the dynamics can propagate them forward. The *uniform second-moment bound* $\sup_x \int |\xi|^2 \, m_0^x(\mathrm{d}\xi) < \infty$ is the initial tightness leash: it is the $t = 0$ end of the uniform moment bound that lemma 24.6 will carry across all times, and without it the populations could start already escaping to infinity in state, with no ball to confine them and no Prokhorov compactness to harvest. The *continuity in type of the initial field*, $x \mapsto m_0^x \in \mathcal{P}_2(\mathbb{R}^d)$ continuous, is the $t = 0$ seed of the type-direction equicontinuity: the existence proof will show the modulus in x is *produced* by the dynamics through the continuity of $\mathbb{W}$, but it can only be produced if the field is already continuous in type at the start, since a flow that begins with a discontinuous type-profile cannot be smoothed into a continuous one by a solve that acts type by type. The two initial-datum clauses are thus the boundary conditions for the two compactness arguments, one per direction. Every hypothesis in the box, then, is the in-force input to a specific later step; none is idle, and the reader can audit the proof by checking that each clause is spent exactly once.

With the standing data fixed and each direction of compactness identified with its source, the labour divides cleanly into three, and the three subsections below take them in order. First we secure the state-and-time direction made uniform in type: the next subsection turns the operator norm of $\mathbb{W}$ into a uniform bound on the aggregate, and through it a type-free bound on the per-type coupling data, so that the classical estimates of chapter 10 fire with constants independent of x and of the field — this is where $\|\mathbb{W}\|$ first does visible work. Second we secure the new type direction: the continuity of W is converted, through the aggregation operator, into a type-equicontinuity modulus for the output field that no oscillation can defeat. Third we assemble the two moduli into one convex compact invariant set in $\mathbb{M}$ and invoke Schauder to land the fixed point. We begin with the first, the operator-norm bound.

24.2.1 Uniform-in-type estimates from the operator norm

We take the first of the two compactness directions: the state-and-time direction, the behaviour of each fibre m^x as a curve of measures on $\mathbb{R}^d$, which the preceding section identified as classical compactness inherited from chapter 10 *provided* its constants can be made uniform in the type. That proviso is the whole job of this subsection, and it is the first place in the chapter where the operator $\mathbb{W}$ stops being a piece of notation and does visible quantitative work. The factorisation $\mathsf{S}_W = \mathcal{R} \circ \mathcal{A}_W$ tells us where to apply pressure. The classical machine $\mathcal{R}$ is a continuum of independent per-type solves, each a copy of the homogeneous problem of chapter 10; every estimate it produces — the gradient bound, the moment bound, the time-modulus — carries a constant that depends only on how large the coupling data handed to that solve is. So the entire question of type-uniformity reduces to a single quantitative question about the aggregation factor $\mathcal{A}_W$: can we bound the data $z_t(x)$ it presents to the type-x optimiser by a number that does not depend on x, and does not depend on *which* field $\mathbf{m}$ we froze? If we can, the per-type constants inherit that uniformity for free, and the state-and-time compactness of chapter 10 transfers wholesale. The answer is yes, and the number is supplied by a norm of $\mathbb{W}$ acting on the second-moment leash of definition 24.1. We state and prove it, then watch it feed the classical gradient estimate lemma 10.5 uniformly across types.

Lemma 24.6 (Uniform aggregate bound)**.** *Under **(A-Reg-W)** and assumption 24.5, there is a constant $Z < \infty$, depending only on the* row-sum norm $\|W\|_{L^\infty_x L^1_y} = \operatorname{ess\,sup}_x \int_0^1 |W(x,y)|\,\mathrm{d}y$ *(which dominates, but in general strictly exceeds, the $L^2 \to L^2$ operator norm $\|\mathbb{W}\| = \rho(\mathbb{W}) = \lambda_1$; see remark 24.19) and on the uniform second-moment bound of the field, such that for every $\mathbf{m} \in \mathbb{M}_2$ with* $\sup_x \sup_t \int |\xi|^2\, m_t^x(\mathrm{d}\xi) \le R^2$,

$$\sup_{x\in[0,1]} \sup_{t\in[0,T]} |z_t(x)| \;\le\; Z := \|W\|_{L^\infty_x L^1_y}\; R.$$

Consequently the frozen coupling data $F_0(\cdot, z_t(x))$, $G_0(\cdot, z_T(x))$ entering the type-x HJB are bounded and uniformly Lipschitz in ξ, with constants independent of x and of $\mathbf{m}$.

Proof. The estimate is a two-link chain, and the discipline of the chapter is visible in its shape: the first link lives entirely in the state variable and is the second-moment leash of definition 24.1 cashed in, while the second link lives entirely in the type variable and is the operator $\mathbb{W}$ cashed in. The two links never interfere because, as definition 24.3 recorded, the moment acts only in state and $\mathbb{W}$ acts only in type.

First link: the second moment controls each type's mean position. Fix a time t and a type y. The first-moment field reads off $\overline{\mathbf{m}}_t(y) = \int_{\mathbb{R}^d} \xi\, m_t^y(\mathrm{d}\xi)$, the centre of mass of that type's population. We bound its size by the square root of the second moment through Cauchy–Schwarz applied to the probability measure m_t^y: writing the coordinate map against the constant 1,

$$|\overline{\mathbf{m}}_t(y)| = \Big| \int_{\mathbb{R}^d} \xi\, m_t^y(\mathrm{d}\xi) \Big| \le \int_{\mathbb{R}^d} |\xi|\; m_t^y(\mathrm{d}\xi) \le \Big(\int_{\mathbb{R}^d} |\xi|^2\; m_t^y(\mathrm{d}\xi) \Big)^{1/2} \Big(\int_{\mathbb{R}^d} 1\, m_t^y(\mathrm{d}\xi) \Big)^{1/2} \le R \cdot 1 = R,$$

where the middle inequality is Jensen (the modulus moved inside the integral) and the last uses the hypothesised uniform bound $\int |\xi|^2\, m_t^y \le R^2$ together with m_t^y being a probability measure. The bound R is the *same* for every type y and every time t, because the second-moment leash of definition 24.1 was demanded uniformly in both. Hence the entire first-moment field is confined to a fixed ball: $\|\overline{\mathbf{m}}_t\|_{L^\infty([0,1];\mathbb{R}^d)} \le R$, uniformly in t. This is the only place the state direction enters, and the leash is the whole of what it contributes.

Second link: the operator spreads that bound across the network without amplifying it. The aggregate $z_t(x) = (\mathbb{W}\,\overline{\mathbf{m}}_t)(x) = \int_0^1 W(x,y)\, \overline{\mathbf{m}}_t(y)\,\mathrm{d}y$ is a kernel-weighted average of the bounded field $\overline{\mathbf{m}}_t$. Pulling the modulus inside the integral and using the just-proved L^∞ bound,

$$|z_t(x)| = \Big| \int_0^1 W(x,y)\, \overline{\mathbf{m}}_t(y)\; \mathrm{d}y \Big| \le \int_0^1 |W(x,y)|\; |\overline{\mathbf{m}}_t(y)|\; \mathrm{d}y \le \|\overline{\mathbf{m}}_t\|_{L^\infty} \int_0^1 |W(x,y)|\; \mathrm{d}y \le R \int_0^1 |W(x,y)|\; \mathrm{d}y.$$

The remaining integral $\int_0^1 |W(x,y)|\,\mathrm{d}y$ is the ℓ^1 mass of the x-th *row* of the kernel — the total weight type x assigns to the rest of the network. Taking the essential supremum over x replaces it by the row-sum norm $\|W\|_{L^\infty_x L^1_y} = \operatorname{ess\,sup}_x \int_0^1 |W(x,y)|\, \mathrm{d}y$, giving $|z_t(x)| \le R\, \|W\|_{L^\infty_x L^1_y} = Z$, and the bound is uniform in both x and t because we took a supremum over x and the first link was already uniform in t. Boundedness of W under **(A-Reg-W)** makes the row-sum norm finite, so $Z < \infty$.

It is worth saying out loud why Z is independent of the field $\mathbf{m}$ we started from, since that independence is exactly what the inherited estimates will need and it is easy to take for granted. Nothing in the chain saw $\mathbf{m}$ except through the single scalar R, the radius of the second-moment leash; the kernel contributes only its fixed row-sum norm, a property of W alone. So any two fields obeying the *same* leash R present coupling data confined to the *same* ball of radius Z in the aggregate variable, regardless of how different the two fields are as objects. That is the precise sense in which Z is a constant of the problem and not of the candidate. Likewise the independence from x is structural rather than accidental: we did not estimate one type's row and hope the others were no worse; we bounded *every* row at once by passing to the essential supremum, which is the operation the row-sum norm performs.

A word of caution to plant now and settle later. The norm that appeared here is the *row-sum* norm $\|W\|_{L^\infty_x L^1_y}$, which is the $L^\infty \to L^\infty$ operator norm of $\mathbb{W}$ — the natural one in the uniform-in-type metric D we are working in, because we are controlling a quantity at *every* type simultaneously. This is *not* the same as the $L^2 \to L^2$ operator norm $\|\mathbb{W}\| = \rho(\mathbb{W}) = \lambda_1$, the spectral radius that will govern the uniqueness threshold in section 24.3. The two are related by the Schur-test inequality $\lambda_1 \le \|W\|_{L^\infty_x L^1_y}$, with equality only for kernels of constant row sum and strict inequality in general, so the row-sum norm is the more conservative of the two. The distinction does not matter for existence — any finite norm of $\mathbb{W}$ suffices to bound the data — but it will matter when we count critical couplings, where the exact spectral quantity λ_1 is the one that decides. We register the gap here and reckon with it fully in remark 24.19. The final sentence of the lemma is now immediate: with the aggregate argument confined to the ball $|z| \le Z$, assumption 24.5 makes $F_0(\cdot, z)$ and $G_0(\cdot, z)$ bounded and uniformly Lipschitz in ξ across that ball, hence uniformly in x and $\mathbf{m}$. $\square$

Lemma 24.6 is where $\|\mathbb{W}\|$ first does visible work: it converts the uniform second-moment bound on the field into a uniform bound on the coupling data felt across all types, which is exactly the input the classical gradient estimate lemma 10.5 consumes. We now follow that input through the per-type solve and watch the uniformity propagate, link by link, to the output flow. The chain has three steps and each preserves type-independence for the same reason: at no point does any constant depend on the type except through the aggregate bound Z, which is itself type-free.

First, the coupling data. By the lemma, for every type x the frozen running source $F_0(\cdot, z_t(x))$ and terminal data $G_0(\cdot, z_T(x))$ are bounded by a constant fixed by Z and uniformly Lipschitz in ξ with a constant fixed by Z — the same two constants for every x, because the aggregate arguments $z_t(x)$ all lie in the single ball $|z| \le Z$ and F_0, G_0 are uniformly Lipschitz across it. Second, the value function. The per-type HJB eq. (24.1) is now a decoupled uniformly parabolic equation (**(A-Nondeg)** supplies the ellipticity) with bounded data, precisely the hypotheses of the classical gradient estimate lemma 10.5; that estimate returns a gradient bound L_u depending only on the data bounds, the horizon T, and the ellipticity constant — all type-free — hence *the same* L_u for every type. Third, the feedback and its drift. The optimal feedback $\hat{\alpha}^{\mathbf{m},x} = -\partial_p H(x, \nabla_\xi u^{\mathbf{m},x})$ is the Hamiltonian slope evaluated at a gradient bounded by L_u, so under **(A-Conv)** it is bounded by a constant M fixed by L_u and the local Lipschitz constant of $\partial_p H$ on the ball $|p| \le L_u$ — again type-free, hence one bound M for the whole continuum of feedbacks. The closed-loop drift of the SDE in definition 24.4 is thus bounded by M uniformly in x, and that single number is the only thing the state-and-time compactness will ask of the solve. With a type-free drift bound and a type-free diffusion in hand, the moment and equicontinuity lemmas of chapter 10 apply verbatim, type by type, with type-free constants.

Lemma 24.7 (Per-type compactness, uniform in type)**.** *Under **(A-Nondeg)**, assumption 24.5, and lemma 24.6, there are constants $R' < \infty$ and a modulus ω (the data of lemmas 10.6 and 10.7),* both independent of x and $\mathbf{m}$*, such that the output flow $\mathsf{S}_W(\mathbf{m})^x$ satisfies, for every x,*

$$\sup_t \int |\xi|^2 \, \mathsf{S}_W(\mathbf{m})^x_t(\mathrm{d}\xi) \le (R')^2, \qquad \mathcal{W}_1(\mathsf{S}_W(\mathbf{m})^x_s, \mathsf{S}_W(\mathbf{m})^x_t) \le \omega(|t-s|).$$

Hence each output flow lies in the single convex compact set $\mathcal{K} \subseteq \mathcal{C}$ of lemma 10.8, the same *$\mathcal{K}$ for all types.*

Proof. The output flow $\mathsf{S}_W(\mathbf{m})^x = (\mathrm{Law}(X_t^{\mathbf{m},x}))_t$ is the law of the closed-loop diffusion of definition 24.4, whose drift is bounded by the uniform constant M established in the paragraph above and whose diffusion coefficient σ has the type-independent bound Σ of **(A-Nondeg)**. These two numbers, M and Σ, are the *only* inputs the classical estimates consume. The moment estimate lemma 10.6 bounds $\sup_t \int |\xi|^2 \, \mathrm{Law}(X_t^{\mathbf{m},x})(\mathrm{d}\xi)$ by a constant $(R')^2$ built from M, Σ, the horizon T, and the uniform initial second moment of assumption 24.5 — quantities none of which carries a type, so R' is one number for the whole continuum. The time-equicontinuity estimate lemma 10.7 bounds the $\mathcal{W}_1$-increment of the flow over a time gap $|t-s|$ by a modulus ω built from the same M, Σ, T, again type-free. This is the point at which the work of lemma 24.6 pays off: had the drift bound M depended on x, the constants R' and ω would inherit that dependence and the output fibres would scatter across a x-dependent family of compact sets, with no single set to run Schauder in. Because M is type-free, R' and ω are too. Finally, lemma 10.8 assembles from the pair (R', ω) — a second-moment radius and a time-modulus — the convex compact set $\mathcal{K} \subseteq (\mathcal{C}, \mathsf{d}_1)$: the second-moment bound supplies tightness (Prokhorov, chapter 3) so that $\mathcal{K}$ is relatively weakly compact at each time, and the time-modulus rules out escape between times, the two together giving compactness of the whole flow in the uniform Wasserstein metric. Since R' and ω are the same for every x, the set $\mathcal{K}$ they build is one and the same set, and every output fibre $\mathsf{S}_W(\mathbf{m})^x$ lies in it. $\square$

The state-and-time direction is now closed, and it is worth being precise about what has been won and what remains. Lemma 24.7 delivers a *single* convex compact set $\mathcal{K} \subseteq \mathcal{C}$ — not one set per type, but one set for the whole continuum — into which S_W drops every fibre of every output field, no matter which field was fed in. In the language of the two-level picture of definition 24.1, the inner level is fully under control: each individual flow $x \mapsto m^x$, read as a curve in time, is trapped in a compact set, with a trap that does not move as the type or the input field varies. That is exactly the classical compactness of chapter 10, made type-uniform by the single mechanism of this subsection, the row-sum norm of $\mathbb{W}$ converting one second-moment leash into one bounded coupling ball into one drift bound into one compact $\mathcal{K}$. What is *not* yet controlled is the outer level: the assignment $x \mapsto m^x$ as a map from types to flows. Knowing that every fibre lives in $\mathcal{K}$ tells us each output field is a map $[0,1] \to \mathcal{K}$, but $C([0,1];\mathcal{K})$ is not compact — a sequence of such maps can oscillate ever faster in x, every fibre staying inside the compact $\mathcal{K}$ while the assignment of fibre to type refuses to settle. There is exactly one gap left in the existence argument, and it is this: compactness in the type direction itself. The next subsection closes it, and the structure of this subsection already names the only possible tool. Here the *magnitude* of the kernel rows — their ℓ^1 mass, the row-sum norm — did all the work; there the *variation* of the kernel rows with the type — the continuity of $x \mapsto W(x,\cdot)$, the second half of **(A-Reg-W)** — will be what buys the missing equicontinuity in x.

24.2.2 Type-direction equicontinuity from graphon continuity

The previous subsection closed the state-and-time direction and named, with some precision, the one gap it could not close. Lemma 24.7 traps every fibre of every output field in a single convex compact set $\mathcal{K} \subseteq \mathcal{C}$, so each output field is a map $x \mapsto m^x$ *into* that compact set — an element of $C([0,1];\mathcal{K})$. The inner, time level of the two-level picture is therefore fully under control. But knowing that a sequence of fields takes values in a compact set does not make the sequence itself relatively compact: $C([0,1];\mathcal{K})$, the continuous maps from types into $\mathcal{K}$, is *not* compact. A sequence of such maps can oscillate ever faster in x — every fibre obediently sitting inside $\mathcal{K}$ while the assignment of fibre to type refuses to settle, the curve $x \mapsto m^x$ wiggling on finer and finer type scales with no limit to extract. This is the outer-level pathology the field space was built to anticipate, and it is the exact obstruction that the homogeneous theory never had to face, because there was no type variable to wiggle in. To extract a convergent subsequence we need more than pointwise confinement: we need the maps to be *equicontinuous* in x, all sharing one modulus of continuity that forbids the oscillation. That single missing modulus is the whole content of this subsection.

The structure of the preceding subsection already told us where it must come from. There the *magnitude* of the kernel rows — their ℓ^1 mass, the row-sum norm of $\mathbb{W}$ — converted one second-moment leash into one bounded coupling ball into one drift bound into one compact $\mathcal{K}$. That bought confinement, but magnitude is blind to whether nearby types feel nearby populations: a kernel can have small, even constant, row sums and still jump wildly from one type's row to the next, and such a kernel would let $z_t(x)$ leap as x varies, dragging the output fibres apart and destroying any hope of a type-modulus. What we need instead is that the kernel rows *vary continuously* with the type — that $W(x,\cdot)$ and $W(x',\cdot)$ are close in L^1 when x and x' are close — and this is precisely the *continuity* half of the standing assumption **(A-Reg-W)**, the half that played no role at all in the magnitude estimate. Here it does all the work. The plan of the subsection is therefore a two-step transfer of regularity: first show that graphon continuity makes the aggregate $z_t(x)$ equicontinuous in x (lemma 24.8), then push that equicontinuity through the per-type solve — close data to close values to close feedbacks to close output flows — to obtain an equicontinuity modulus η for the output *field* itself (lemma 24.9). The first step is the linear aggregation factor $\mathcal{A}_W$ doing its job; the second is the classical solve $\mathcal{R}$ doing its, in the same type-by-type way it did everything else.

We begin with the aggregate. The intuition is the cleanest possible instance of the factorisation discipline: the aggregate $z_t(x) = (\mathbb{W}\overline{\mathbf{m}}_t)(x)$ is a linear read-out of the field through the kernel row

$W(x,\cdot)$, so the only way $z_t(x)$ can change as x moves is if that row changes, and how fast the row may change is exactly what graphon continuity controls. Nothing about the field's own complexity can enter, because the field is held fixed and merely weighted; only the kernel's type-regularity can be felt. The lemma makes this exact, converting the kernel's modulus ρ_W directly into a modulus for z, with the second-moment leash R as the only field-dependent constant — and even that enters only as a uniform bound, not through any finer feature of $\mathbf{m}$.

Lemma 24.8 (Continuity of the aggregation in type)**.** *Assume **(A-Reg-W)** with W continuous in its first argument, uniformly: there is a modulus ρ_W with $\int_0^1 |W(x,y) - W(x',y)|\,\mathrm{d}y \le \rho_W(|x-x'|)$, $\rho_W(0^+) = 0$. (Here $|x - x'|$ is the Euclidean distance on the chosen continuous representative of the graphon — the non-canonical labelling structure flagged in the opening notationwatch, whose absence in the measure-preserving-relabelling case forces the harder treatment of remark 24.13.) Then for every field with uniform second moment $\le R^2$,*

$$|z_t(x) - z_t(x')| \;\le\; R\,\rho_W(|x-x'|), \qquad t \in [0,T],$$

so $x \mapsto z_t(x)$ is equicontinuous, with a modulus $R\,\rho_W$ independent of t and of the field.

Proof. The argument is a single subtraction followed by the same two moves — pull the modulus inside the integral, then bound the integrand by a row of the kernel against the L^∞ leash — that ran the magnitude estimate of lemma 24.6, only now the kernel enters as a *difference of rows* rather than a single row. Fix a time t and two types x, x'. The aggregates differ only in which kernel row weights the common first-moment field, so subtracting the two integral representations eq. (24.3) collects the row difference under one integral:

$$z_t(x) - z_t(x') = \int_0^1 \left(W(x,y) - W(x',y)\right) \overline{\mathbf{m}}_t(y)\;\mathrm{d}y.$$

This is the crucial cancellation: the field $\overline{\mathbf{m}}_t$ is identical in both terms, so it survives as a common factor and never has to be differenced — the entire x-variation has been loaded onto the kernel, exactly as the linear-aggregation picture predicts. Take the modulus of both sides and pass it inside the integral (the triangle inequality for the vector-valued integral), then factor out the L^∞ size of the field:

$$|z_t(x) - z_t(x')| \le \int_0^1 |W(x,y) - W(x',y)|\;|\overline{\mathbf{m}}_t(y)|\;\mathrm{d}y \le \|\overline{\mathbf{m}}_t\|_{L^\infty} \int_0^1 |W(x,y) - W(x',y)|\;\mathrm{d}y.$$

The two factors are now exactly the two ingredients we have already secured. The first, $\|\overline{\mathbf{m}}_t\|_{L^\infty} \le R$, is the state-direction leash established in the proof of lemma 24.6: the second moment confines every type's centre of mass to the ball of radius R, uniformly in t and in x. The second is the kernel's own type-modulus: the L^1 distance between rows x and x' is, by the continuity hypothesis, at most $\rho_W(|x-x'|)$. Multiplying, $|z_t(x) - z_t(x')| \le R\,\rho_W(|x-x'|)$, which is the claim. The modulus $R\,\rho_W$ is independent of t because the leash R is uniform in time and ρ_W knows nothing of time, and independent of the field because the only trace the field left is the single scalar R bounding its second moment — precisely the field-independence the Schauder argument will require. ☐

It is worth dwelling on the hypothesis the lemma quietly leans on, because it is the one place in the whole existence proof where the chapter pays for a structure a graphon need not possess, and the preamble's `notationwatch` promised we would be honest about it. To write $\int_0^1 |W(x,y) - W(x',y)|\,\mathrm{d}y \le \rho_W(|x-x'|)$ is to assert that the row-map $x \mapsto W(x,\cdot)$ is uniformly continuous, and "continuous" presupposes a metric on the type set $[0,1]$ to measure $|x-x'|$. But a graphon is canonically an equivalence class under measure-preserving relabelling of $[0,1]$: nothing in its definition equips the labels with a distance, and a measurable relabelling can scramble any continuous representative into a wildly discontinuous one without changing the graphon as an analytic object at all. So before the hypothesis even has a referent we must *choose* a particular continuous representative of the class and endow $[0,1]$ with its Euclidean metric, purely so that "nearby types" means something. This is non-canonical extra structure, and it is imposed for this hypothesis alone — the magnitude estimates of the previous subsection, and every spectral statement of the uniqueness theory to come, are invariant under relabelling and ask for no such choice. The caveat is load-bearing, not decorative. When W is given only up to relabelling — the generic case — the choice is unavailable, the row-map has no continuity to invoke, and the modulus ρ_W simply does not exist; the equicontinuity bought here evaporates. That is exactly why the measurable case is genuinely harder and must be treated by a different mechanism, the Hilbert–Schmidt compactness of $\mathbb{W}$ itself replacing the lost row-continuity, which we defer to remark 24.13. The reader should carry forward that the comfortable type-modulus of this subsection is a privilege of continuous graphons, conjured by a non-canonical labelling we are borrowing for one lemma and will return.

With the aggregate equicontinuous in type we must now propagate that modulus through the per-type solve, and here the factorisation earns its keep once more: the solve $\mathcal{R}$ is the classical machine run independently in each type, so transferring closeness in the data to closeness in the output is exactly a pair of *stability* statements imported from chapter 10, applied to two neighbouring types rather than to two successive iterates. The logic is a chain of four links, and the discipline to hold throughout is that every constant produced is type-independent, because each is a classical constant that depends only on the data bounds, the horizon, and the ellipticity — never on the type label, which the per-type problem does not see. Trace the chain. Two nearby types x, x' present, after the freeze, coupling data $F_0(\cdot, z_t(x))$ and $F_0(\cdot, z_t(x'))$ whose aggregate arguments differ by at most $R\,\rho_W(|x-x'|)$; since F_0 is uniformly Lipschitz in that argument (assumption 24.5), the two data fields are correspondingly close in sup-norm — this is the aggregation modulus entering the solve. By the stability of the HJB solve in its frozen data (lemma 10.10) the two value functions, and crucially their gradients, are then close locally uniformly — a value problem with nearby sources and nearby terminal data has nearby solutions, with a constant inherited from the uniform parabolicity. Two nearby types, however, do not merely present nearby data to one common operator: the Hamiltonian $H(x,\cdot)$ carries the type slot explicitly (eq. (24.1)), so the two HJB operators are themselves different, and that direct difference enters the value comparison as a second forcing — one controlled, as the proof makes precise, by the type-modulus of H and not by the aggregate at all. Close gradients mean close optimal feedbacks, since the feedback is the Hamiltonian slope $-\partial_p H$ evaluated at the gradient and $\partial_p H$ is locally Lipschitz under **(A-Conv)** — to which the explicit type-dependence of $\partial_p H(x,\cdot)$ adds, again, its own direct term. Finally, close feedbacks mean close output flows: by the stability of the FP/SDE solve in its drift (lemma 10.11) two diffusions with the same initial law and nearby drifts have laws close in d_1. Composing the four Lipschitz links turns the input modulus $R\,\rho_W$ into an output modulus η for the field. We state the conclusion and then fill in each mechanism quantitatively.

Lemma 24.9 (Type-equicontinuity of the output field)**.** *Under **(A-Lip)**, **(A-Nondeg)**, assumption 24.5, and the uniform graphon continuity of lemma 24.8, there is a modulus η, with $\eta(0^+) = 0$, depending only on the data and on ρ_W but not on $\mathbf{m}$, such that*

$$\mathsf{d}_1(\mathsf{S}_W(\mathbf{m})^x, \mathsf{S}_W(\mathbf{m})^{x'}) \;\le\; \eta(\,|x - x'|\,), \qquad x, x' \in [0, 1].$$

Proof sketch and pointer. We follow the four-link chain just described, naming the mechanism behind each link and the type-independent constant it contributes, but we do not reproduce the underlying parabolic regularity estimate, which is established once and for all in chapter 6; this is the in-book-pointer rule of the style bible, honoured by pointing to where the estimate genuinely lives rather than asserting it. Write $\delta = |x - x'|$.

Link one: data. By lemma 24.8 the aggregates obey $|z_t(x) - z_t(x')| \le R\,\rho_W(\delta)$ uniformly in t, and by the uniform Lipschitz dependence of F_0, G_0 on their aggregate slot (assumption 24.5) this transfers to the frozen data,

$$\big\|F_0(\cdot, z_t(x)) - F_0(\cdot, z_t(x'))\big\|_\infty \;\le\; \mathrm{Lip}(F_0)\,R\,\rho_W(\delta) \qquad \text{uniformly in } t,$$

and the identical bound with $\mathrm{Lip}(G_0)$ for the terminal data. Call this common data-gap $\epsilon := \max(\mathrm{Lip}(F_0), \mathrm{Lip}(G_0))\,R\,\rho_W(\delta)$, an $O(\rho_W(\delta))$ quantity carrying no type dependence beyond δ.

Link two: value and gradient. Here the chain departs from a naive reading, and the departure is the one subtlety the type variable injects into an otherwise classical step: the two type problems are *not* one parabolic operator fed two data sets. The Hamiltonian $H(x, \cdot)$ in eq. (24.1) carries the type slot explicitly, so the operators $-\partial_t - \nu\Delta_\xi + H(x, \nabla_\xi\cdot)$ and $-\partial_t - \nu\Delta_\xi + H(x', \nabla_\xi\cdot)$ differ as operators even where the frozen data agree. Write $w := u^{\mathbf{m},x} - u^{\mathbf{m},x'}$ and subtract the two copies of eq. (24.1):

$$-\partial_t w - \nu\,\Delta_\xi w + \underbrace{\big[H(x, \nabla_\xi u^{\mathbf{m},x}) - H(x, \nabla_\xi u^{\mathbf{m},x'})\big]}_{= \mathbf{a}\cdot\nabla_\xi w} = \underbrace{\big[F_0(\cdot, z_t(x)) - F_0(\cdot, z_t(x'))\big]}_{\text{indirect: aggregate gap, } \le \epsilon} - \underbrace{\big[H(x, \nabla_\xi u^{\mathbf{m},x'}) - H(x', \nabla_\xi u^{\mathbf{m},x'})\big]}_{\text{direct: explicit type gap}}$$

with terminal data $w(T, \cdot) = G_0(\cdot, z_T(x)) - G_0(\cdot, z_T(x'))$ of sup-norm $\le \epsilon$. The left-hand bracket linearises into a transport term $\mathbf{a} \cdot \nabla_\xi w$ with bounded coefficient $\mathbf{a} = \int_0^1 \partial_p H\big(x, \nabla_\xi u^{\mathbf{m},x'} + s\,\nabla_\xi w\big)\,\mathrm{d}s$ (finite because both gradients lie in the ball $|p| \le L_u$ of lemma 10.5), so w solves a *linear* uniformly parabolic equation, with the uniform gradient bound L_u inherited by both $u^{\mathbf{m},x}$ and $u^{\mathbf{m},x'}$. Its forcing has exactly the two pieces that must be kept apart: the indirect aggregate gap, of size $\epsilon = O(\rho_W(\delta))$ from Link one, *and* the *direct* explicit type gap $H(x, p) - H(x', p)$ read at $p = \nabla_\xi u^{\mathbf{m},x'}$ — the contribution no aggregate can see, present even if the two types' coupling data coincided exactly. It is controlled by the type-modulus of the Hamiltonian on the gradient ball,

$$\sup_{|p| \le L_u} \big|H(x, p) - H(x', p)\big| \;\le\; \rho_H(\delta), \qquad \rho_H(0^+) = 0,$$

where ρ_H is furnished by the type-regularity of the coefficients (b, σ, L) under **(A-Lip)**: it is the data's *own* type-modulus, the cost-side companion of the kernel modulus ρ_W. Feeding both forcings through the quantitative perturbation estimate behind lemma 10.10 — two solutions of a linear uniformly parabolic equation whose forcing and terminal data are $O(\epsilon + \rho_H(\delta))$ in sup-norm differ by $O(\epsilon + \rho_H(\delta))$ in C^1_{loc} on the support-carrying region, gradients included, with a constant fixed by the horizon T, the ellipticity constant λ of **(A-Nondeg)**, and the Lipschitz data bounds, all of them type-free — gives

$$\left\| \nabla_\xi u^{\mathbf{m},x} - \nabla_\xi u^{\mathbf{m},x'} \right\|_{C_{\mathrm{loc}}} \lesssim \epsilon + \rho_H(\delta) \lesssim R\,\rho_W(\delta) + \rho_H(\delta).$$

Link three: feedback. The closed-loop drifts of the two types are $-\partial_p H(x, \nabla_\xi u^{\mathbf{m},x})$ and $-\partial_p H(x', \nabla_\xi u^{\mathbf{m},x'})$, and their gap carries the same two contributions, indirect and direct, for the same reason: the feedback map $-\partial_p H(x,\cdot)$ is itself type-dependent. Insert the cross term $\partial_p H(x, \nabla_\xi u^{\mathbf{m},x'})$:

$$\partial_p H(x, \nabla_\xi u^{\mathbf{m},x}) - \partial_p H(x', \nabla_\xi u^{\mathbf{m},x'}) = \underbrace{\left[\partial_p H(x, \nabla_\xi u^{\mathbf{m},x}) - \partial_p H(x, \nabla_\xi u^{\mathbf{m},x'})\right]}_{p\text{-Lipschitz}} + \underbrace{\left[\partial_p H(x, \nabla_\xi u^{\mathbf{m},x'}) - \partial_p H(x', \nabla_\xi u^{\mathbf{m},x'}\right.}_{\text{explicit type gap}}$$

The first term is the classical one: $\partial_p H$ is locally Lipschitz in p under **(A-Conv)** and both gradients lie in the fixed ball $|p| \le L_u$, so it is at most a type-free constant times the gradient gap of Link two, i.e. $O\big(R\,\rho_W(\delta) + \rho_H(\delta)\big)$. The second is the direct explicit-type term the gradient comparison cannot produce, bounded by the same Hamiltonian type-modulus now applied to $\partial_p H$ on the ball, $\sup_{|p|\le L_u} |\partial_p H(x,p) - \partial_p H(x',p)| \le \rho_H(\delta)$ (we read ρ_H as the joint type-modulus of H and $\partial_p H$ on that ball, both delivered by the coefficient regularity of **(A-Lip)**). The drift gap is therefore $O\big(R\,\rho_W(\delta) + \rho_H(\delta)\big)$ in sup-norm, every constant fixed by H on the ball and the horizon, and so type-free.

Link four: output flow. The two output flows $\mathsf{S}_W(\mathbf{m})^x$ and $\mathsf{S}_W(\mathbf{m})^{x'}$ are the laws of two diffusions started from their respective initial data with these nearby drifts. The SDE stability estimate behind lemma 10.11 is the synchronous-coupling estimate: drive the two diffusions by the *same* Brownian path and the same initial coupling, so the diffusion terms cancel exactly and only the drift difference accumulates; Grönwall control of the resulting pathwise discrepancy then bounds the d_1-distance of the laws by $C(T)$ times the sup-norm of the drift gap, where $C(T)$ is the Grönwall–Lipschitz constant $e^{\mathrm{Lip}\cdot T}$ built from the horizon and the drift's Lipschitz bound. Crucially $C(T)$ is the very constant that appears in the classical stability estimate of chapter 10; it is assembled from T, the ellipticity, and the data bounds and carries no type, which is what makes the resulting modulus uniform over the continuum of types. (To keep the initial slice from contributing, recall that all output flows share the type-continuous initial datum $x \mapsto m_0^x$ of assumption 24.5, whose own modulus is absorbed into η; the synchronous coupling starts the two diffusions from $\mathcal{W}_1$-close laws by exactly that initial modulus.)

Composing the four links — and carrying the direct explicit-type gap of Links two and three alongside the indirect aggregate gap throughout —,

$$\mathsf{d}_1\big(\mathsf{S}_W(\mathbf{m})^x, \mathsf{S}_W(\mathbf{m})^{x'}\big) \le C(T)\left[\max(\mathrm{Lip}(F_0), \mathrm{Lip}(G_0))\,R\,\rho_W(\delta) + \rho_H(\delta)\right] := \eta(\delta),$$

a modulus with $\eta(0^+) = 0$ since $\rho_W(0^+) = 0$ and $\rho_H(0^+) = 0$, built entirely from type-free constants and from the two type-moduli ρ_W (the kernel's) and ρ_H (the Hamiltonian's), hence independent of $\mathbf{m}$. The conclusion's stated dependence "only on the data and on ρ_W" survives intact: ρ_H is not a new kind of input but the data's own regularity in the type variable — the explicit-type modulus of H is part of "the data" exactly as the state-Lipschitz constants of **(A-Lip)** are — and it brings no dependence on the field $\mathbf{m}$ or on the bare type label. The full parabolic perturbation estimate underwriting links two and three is proved in chapter 6 and recorded in [36, Ch. 3]; we have named each mechanism and quantified its dependence without reproducing it here. □

This is the second and final compactness ingredient. The previous subsection handed the existence argument a single convex compact set $\mathcal{K}$ controlling each fibre in state and time; lemma 24.9 now hands it the type-direction modulus η controlling how the fibres vary from one type to the next — and, decisively, η is one modulus for *every* field $\mathsf{S}_W(\mathbf{m})$ in the range of the best-response map, because every constant in its construction was type- and field-independent. With confinement $\mathcal{K}$ in the inner direction and equicontinuity η in the outer direction, both wings of the two-level picture are pinned. The next subsection collects exactly these two ingredients and feeds them to the metric-space Arzelà–Ascoli theorem, which converts "every fibre in a compact set, plus a uniform type-modulus" into a single compact set of fields — the convex compact invariant domain on which Schauder finally produces the equilibrium.

24.2.3 The invariant set and the existence theorem

The two preceding subsections discharged, separately, the two compactness obligations the existence proof carries, one for each level of the field space's two-tier structure. Lemma 24.7 secured the inner, state-and-time level: it trapped every fibre m^x of every output field in a single convex compact set $\mathcal{K} \subseteq \mathcal{C}$, the trap not moving as the type or the input field varied, and bought that uniformity from the *magnitude* of the kernel rows through the row-sum norm of $\mathbb{W}$. Lemma 24.9 secured the outer, type level: it produced a single modulus of continuity η controlling how fast the fibre may change as the type moves, the modulus one and the same for every field in the range of S_W, and bought it from the *variation* of the kernel rows through the continuity half of **(A-Reg-W)**. We now hold both ingredients in raw form, and what remains is purely organisational: we must glue them into one set, check that S_W maps that set into itself, and verify the set has the three properties Schauder demands — nonempty, convex, compact. Of these the compactness is, as always, the only one that costs anything, and the tool that converts our two moduli into it is the metric-space form of the Arzelà–Ascoli theorem.

It is worth recalling exactly what that theorem says and why it is the right gluing device, because the entire force of the subsection is concentrated in its single application. The classical Arzelà–Ascoli theorem characterises the relatively compact subsets of $C(K;\mathbb{R})$, continuous real functions on a compact domain, as the bounded equicontinuous ones; its metric-space-valued generalisation (theorem B.24) replaces the scalar target $\mathbb{R}$ by an arbitrary complete metric space Y and the boundedness hypothesis by *pointwise relative compactness* — the requirement that, at each point of the domain, the set of values the family takes be relatively compact in Y. A family of maps $K \to Y$ is then relatively compact in $C(K;Y)$, under the uniform metric, if and only if it is equicontinuous and pointwise relatively compact. This is precisely the shape of our situation. Our domain is the compact type interval $[0,1]$; our target is the compact metric space $Y = (\mathcal{K}, \mathsf{d}_1)$ that lemma 24.7 delivered; the family is the set of fields in $\mathbb{K}_W$, each read as a map $x \mapsto m^x$ from types into $\mathcal{K}$. The η-modulus is exactly the equicontinuity hypothesis, and the values' membership in the compact $\mathcal{K}$ is exactly — more than exactly — the pointwise relative compactness hypothesis. The theorem then converts "every fibre in a compact set, plus a uniform type-modulus" into the one thing the construction has been driving at, a single compact set of *fields*. We assemble that set now.

Lemma 24.10 (A convex compact invariant set of fields)**.** *With $\mathcal{K} \subseteq \mathcal{C}$ from lemma 24.7 and η from lemma 24.9, define*

$$\mathbb{K}_W := \Big\{ \mathbf{m} \in \mathbb{M} : \ \mathbf{m}_0 \textit{ fixed}, \ m^x \in \mathcal{K} \ \forall x, \ \mathsf{d}_1(m^x, m^{x'}) \le \eta(|x - x'|) \ \forall x, x' \Big\}.$$

Then $\mathbb{K}_W$ is nonempty, convex, and compact in $(\mathbb{M}, \mathsf{D})$, and $\mathsf{S}_W(\mathbb{K}_W) \subseteq \mathbb{K}_W$.

The set $\mathbb{K}_W$ is cut out by exactly the three constraints the two compactness lemmas certify: its members start from the prescribed initial field $\mathbf{m}_0$, run each fibre inside the inner compact set $\mathcal{K}$, and obey the outer type-modulus η. The fixed initial slice is the third, quiet, constraint — not a compactness device but the boundary condition that pins the whole problem, and it is harmless to all four verifications because it is an *affine* condition (it survives convex combinations) that is *closed* (it survives uniform limits) and is *respected* by S_W (the best response never moves a population's time-zero law). We verify the four claims in turn, and the reader should watch each one consume precisely one of the inputs already in hand.

Proof. Nonempty. We must exhibit at least one field obeying all three constraints, and the cheapest candidate is the one that does nothing: the *frozen* field $\mathbf{m}^{\text{stat}}$ whose every fibre is constant in time, $m^x_t \equiv m^x_0$. Each such constant flow lies in $\mathcal{K}$, for $\mathcal{K}$ was built in lemma 10.8 from a second-moment radius R' and a time-modulus ω, and a flow that never moves trivially meets the time-modulus (its $\mathcal{W}_1$-increment over any time gap is zero, hence below ω) while its second moment is the initial one $\int |\xi|^2 \, m^x_0(\mathrm{d}\xi)$, bounded by the uniform initial bound of assumption 24.5 and hence inside the radius R' that dominates it. The type-modulus is met because $x \mapsto m^x_0$ is continuous in type by assumption 24.5; its own modulus of continuity need not literally be $\le \eta$, but this is the one place where we are free to *enlarge* η by the initial modulus once and for all, which costs nothing downstream because every later use of η only needs $\eta(0^+) = 0$, a property the enlargement preserves. With η so enlarged, the static field sits in $\mathbb{K}_W$, which is therefore nonempty.

Self-map. This is where the two compactness lemmas are spent. Take any $\mathbf{m} \in \mathbb{K}_W$ and apply S_W. By lemma 24.7 every output fibre $\mathsf{S}_W(\mathbf{m})^x$ lies in the same $\mathcal{K}$, so the inner constraint holds; by lemma 24.9 the output field obeys the η-modulus $\mathsf{d}_1(\mathsf{S}_W(\mathbf{m})^x, \mathsf{S}_W(\mathbf{m})^{x'}) \le \eta(|x - x'|)$, so the outer constraint holds; and the initial-slice constraint holds because the best response leaves time-zero laws untouched — by definition 24.4 the closed-loop diffusion starts from $X^{\mathbf{m},x}_0 \sim m^x_0$, so $\mathsf{S}_W(\mathbf{m})^x_0 = \mathrm{Law}(X^{\mathbf{m},x}_0) = m^x_0$, the prescribed datum, for every x. All three defining constraints survive the map, so $\mathsf{S}_W(\mathbf{m}) \in \mathbb{K}_W$, which is the self-map property.

Convex. We must check that $\mathbb{K}_W$ is closed under convex combinations, constraint by constraint. Fix $\mathbf{m}, \mathbf{m}' \in \mathbb{K}_W$ and $\lambda \in [0, 1]$, and form the fieldwise combination $\mathbf{n} := \lambda \mathbf{m} + (1 - \lambda)\mathbf{m}'$, i.e. $n^x_t := \lambda m^x_t + (1 - \lambda) m'^x_t$. First, each fibre n^x lies in $\mathcal{K}$ because $\mathcal{K}$ is convex (lemma 10.8) and n^x is the convex combination of the two fibres $m^x, m'^x \in \mathcal{K}$. Second, the type-modulus survives because $\mathcal{W}_1$ is jointly convex in its two arguments — a standard consequence of the linearity of the coupling constraints in the Kantorovich problem (theorem 4.8): superposing optimal couplings of the two pairs gives an admissible, generally suboptimal, coupling of the combinations, so

$$\mathcal{W}_1(\lambda\mu_1+(1-\lambda)\mu_2,\ \lambda\nu_1+(1-\lambda)\nu_2)\ \le\ \lambda\,\mathcal{W}_1(\mu_1,\nu_1)+(1-\lambda)\,\mathcal{W}_1(\mu_2,\nu_2).$$

Taking the supremum over time turns this into the same convexity for d_1, whence at any two types

$$\mathsf{d}_1(n^x,n^{x'})\le\lambda\,\mathsf{d}_1(m^x,m^{x'})+(1-\lambda)\,\mathsf{d}_1(m'^x,m'^{x'})\le\lambda\,\eta(|x-x'|)+(1-\lambda)\,\eta(|x-x'|)=\eta(|x-x'|),$$

so the η-bound passes to $\mathbf{n}$. Third, the fixed initial slice survives because it is an affine condition: $n^x_0=\lambda m^x_0+(1-\lambda)m^x_0=m^x_0$, both fields carrying the same prescribed $\mathbf{m}_0$. All three constraints are convex, so $\mathbb{K}_W$ is convex. (The convexity is genuine and not a formality: Schauder, unlike Banach, asks nothing of contractivity but it does demand a convex domain on which to run the topological degree argument, and this is where that demand is met.)

Compact. Here the Arzelà–Ascoli machinery does its work, and we run it in two stages: relative compactness from the theorem, then closedness by hand, the two combining to compactness. For relative compactness apply theorem B.24 to the family of maps $x\mapsto m^x$ as $\mathbf{m}$ ranges over $\mathbb{K}_W$, with compact domain $K=[0,1]$ and complete target $Y=(\mathcal{K},\mathsf{d}_1)$. The theorem's two hypotheses are exactly our two ingredients. Pointwise relative compactness holds because, at every fixed type x, the set of values $\{m^x:\mathbf{m}\in\mathbb{K}_W\}$ lies in $\mathcal{K}$, which is compact (lemma 10.8) — indeed the family is not merely pointwise but *uniformly* valued in one compact set, which is stronger than required. Uniform equicontinuity holds because every $\mathbf{m}\in\mathbb{K}_W$ satisfies the same η-bound $\mathsf{d}_1(m^x,m^{x'})\le\eta(|x-x'|)$ with $\eta(0^+)=0$, a modulus that does not depend on which field we look at — this is the field-independence we laboured to secure in lemma 24.9, now cashed as the equicontinuity Arzelà–Ascoli needs. The theorem therefore returns relative compactness of $\mathbb{K}_W$ in $C([0,1];\mathcal{K})$ under the uniform metric, which is exactly the restriction of D.

It remains to show $\mathbb{K}_W$ is *closed* in $(\mathbb{M},\mathsf{D})$, for a relatively compact set is compact precisely when it is closed. Let $\mathbf{m}^{(n)}\to\mathbf{m}$ in D with every $\mathbf{m}^{(n)}\in\mathbb{K}_W$; we check that the limit inherits all three constraints. Convergence in D is uniform in type, so in particular at each fixed x the fibres converge, $\mathsf{d}_1(m^{(n),x},m^x)\to0$. The inner constraint passes because $\mathcal{K}$ is closed (being compact): each $m^{(n),x}\in\mathcal{K}$ and $m^{(n),x}\to m^x$ in d_1 force $m^x\in\mathcal{K}$. (Implicit here is that the second-moment radius defining $\mathcal{K}$ is itself closed under $\mathcal{W}_1$-limits, which is the lower semicontinuity of the second moment along $\mathcal{W}_1$-convergent sequences, theorem 4.8: mass cannot appear from infinity in the limit, so the moment cannot jump up, and the radius bound survives.) The outer constraint passes because d_1 is continuous in each argument, so $\mathsf{d}_1(m^x,m^{x'})=\lim_n\mathsf{d}_1(m^{(n),x},m^{(n),x'})\le\eta(|x-x'|)$, the bound holding for every n and hence in the limit. The initial slice passes because $m^x_0=\lim_n m^{(n),x}_0=m^x_0$ is the common prescribed datum. So $\mathbf{m}\in\mathbb{K}_W$, the set is closed, and being closed and relatively compact it is compact in $(\mathbb{M},\mathsf{D})$. $\square$

The lemma has manufactured the arena: a nonempty convex compact set on which S_W acts as a self-map. Schauder's fixed-point theorem (theorem 2.38) asks for exactly this geometry plus one analytic fact — that the self-map be *continuous* — and then guarantees a fixed point. The continuity is the last thing to check, and it is here that the factorisation $\mathsf{S}_W=\mathcal{R}\circ\mathcal{A}_W$ pays its final dividend in the existence proof: continuity of a composition follows from continuity of each factor, and we have arranged the two factors so that one is a bounded linear operator (trivially continuous, once we know in which topology) and the other is the classical solve whose continuity is an imported chapter 10 fact. We state the theorem and then run the continuity through the two factors.

Theorem 24.11 (Existence of GMFG equilibria)**.** *Assume **(A-Lip)**, **(A-Growth)**, **(A-Nondeg)**, **(A-Conv)** with $H(x,\cdot)$ strictly convex and C^1 and $\partial_p H$ of at most linear growth in p; assume **(A-Reg-W)** with W uniformly continuous in its type argument (lemma 24.8); and assume the coupling and initial-data hypotheses of assumption 24.5. Then the graphon best-response map S_W has a fixed point $\mathbf{m}^\star \in \mathbb{K}_W$. Equivalently, the GMFG system eq.* (24.1)*–eq.* (24.2) *admits a solution $(\mathbf{u}^\star, \mathbf{m}^\star)$ with $x \mapsto m^{\star,x} \in C([0,1]; C([0,T]; \mathcal{P}_2(\mathbb{R}^d)))$, each $u^{\star,x}$ Lipschitz in ξ uniformly in (t,x), and the field uniformly $\frac{1}{2}$-Hölder in time and ρ_W-continuous in type.*

Proof. By lemma 24.10, $\mathbb{K}_W$ is a nonempty convex compact subset of $(\mathbb{M}, \mathsf{D})$ mapped into itself by S_W. It remains to verify that $\mathsf{S}_W|_{\mathbb{K}_W}$ is continuous; then Schauder's theorem (theorem 2.38; viewed inside the locally convex space $C([0,1];\text{signed measures})$ as in the proof of theorem 10.14, the ambient linear structure in which $\mathbb{K}_W$ sits as a compact convex set) yields a fixed point. We obtain the continuity from the factorisation eq. (24.4), $\mathsf{S}_W = \mathcal{R} \circ \mathcal{A}_W$, showing each factor continuous on the relevant space and composing.

The aggregation factor $\mathcal{A}_W$ is continuous from $(\mathbb{K}_W, \mathsf{D})$ to $(C([0,1];\mathbb{R}^d), \|\cdot\|_\infty)$, and the argument is a two-link chain in the now-familiar pattern: the first-moment read-out is continuous in the field, the operator $\mathbb{W}$ is continuous on its output. Take $\mathbf{m}^{(n)} \to \mathbf{m}$ in D. For the first link, the first-moment field converges, $\overline{\mathbf{m}}_t^{(n)} \to \overline{\mathbf{m}}_t$ in $L^2([0,1];\mathbb{R}^d)$ uniformly in t. This is the 1-Lipschitz bound lemma 24.2 doing exactly its advertised job: at each type the first moment is a $\mathcal{W}_1$-Lipschitz functional of the law, and on the second-moment-bounded set $\mathcal{K}$ the metric $\mathcal{W}_1$ genuinely metrises weak convergence (theorem 4.8), so a D-convergent sequence of fields has fibrewise-, indeed uniformly-, convergent first moments, $\sup_t \left\|\overline{\mathbf{m}}_t^{(n)} - \overline{\mathbf{m}}_t\right\|_{L^\infty} \le \mathsf{D}(\mathbf{m}^{(n)}, \mathbf{m}) \to 0$. For the second link, $\mathbb{W}$ is a bounded operator, so post-composing it with the evaluation $z_t(x) = (\mathbb{W}\overline{\mathbf{m}}_t)(x)$ turns that convergence of first moments into convergence of aggregates; and because the aggregates carry the *uniform* type-modulus $R\,\rho_W$ of lemma 24.8 — a modulus the limit aggregate shares, since it is field-independent — the convergence is not merely in L^2 but uniform in x, i.e. $z^{(n)} \to z$ in $C([0,1] \times [0,T])$. (Equicontinuity in type plus pointwise convergence upgrades to uniform convergence, the same Arzelà–Ascoli mechanism, used now to control a limit rather than to extract a subsequence.)

The solve factor $\mathcal{R}$ is continuous, and this is the classical statement proposition 10.13 applied uniformly across the continuum of types. The input to $\mathcal{R}$ is the aggregate data $z = (z(x))_x$, just shown to converge $z^{(n)}(x) \to z(x)$ locally uniformly in x. In each type this is precisely the data-convergence that the homogeneous stability chain consumes: convergence of the frozen running source and terminal data gives convergence of the value functions and, crucially, of their gradients (lemma 10.10), hence of the optimal feedbacks $-\partial_p H(x, \nabla_\xi u^{\mathbf{m},x})$ (the Hamiltonian slope being locally Lipschitz under **(A-Conv)**), hence of the output flows, by the stability of the Fokker–Planck/SDE solve in its drift (lemma 10.11). The one new word is *uniformly*: all the constants in this chain are the type-free constants secured in lemmas 24.6 and 24.9 — the gradient bound L_u, the drift bound M, the Grönwall constant $C(T)$ — none of which carries a type label, so the per-type convergences are uniform in x and assemble into convergence of the output *field* in D. Thus $\mathcal{R}$ is continuous on the convergent aggregates produced by $\mathcal{A}_W$.

Composition of continuous maps is continuous, so $\mathsf{S}_W = \mathcal{R} \circ \mathcal{A}_W$ is continuous on $\mathbb{K}_W$, and Schauder delivers the fixed point $\mathbf{m}^\star \in \mathbb{K}_W$. That $\mathbf{m}^\star$ is an equilibrium, and equivalently that the pair $(\mathbf{u}^{\mathbf{m}^\star}, \mathbf{m}^\star)$ solves the GMFG system, is the exact reduction recorded after definition 24.4. The asserted regularity of the fixed point is read off the set it lives in and the solve that produced it: membership in $\mathbb{K}_W$ gives, by lemma 24.10, that $x \mapsto m^{\star,x}$ is continuous in type with modulus η (hence ρ_W-continuous, η being $O(\rho_W)$ by lemma 24.9) and that each fibre lies in $\mathcal{K}$, whose time-modulus is the uniform $\frac{1}{2}$-Hölder bound of lemma 10.8; and the per-type value $u^{\star,x}$ inherits the gradient bound L_u of lemma 10.5, uniform in (t, x). These are precisely the regularity facts the later sections will draw on. □

The proof is complete, and before moving on it is worth standing back to name what powered it, because the two compactness inputs came from genuinely different parts of the book and the distinction is the throughline made audible. The next remark does this naming; the two that follow it open the doors the standing hypotheses kept shut — merely measurable kernels, and set-valued or block-structured couplings — and each is a deliberate signpost to a later chapter rather than a parenthetical aside.
