The operator logarithm in Eq. (55.6) is defined by functional calculus: in the eigenbasis $\rho_A = \sum_i \lambda_i |i\rangle\langle i|$ one sets $\log \rho_A = \sum_i (\log \lambda_i)\, |i\rangle\langle i|$, with the convention that eigenvectors of zero eigenvalue do not contribute. We use the natural logarithm throughout; an entropy in bits is $S_A/\log 2$. The base is a convention and changes nothing structural.

The direct evaluation of Eq. (55.6) requires diagonalizing ρ_A and then summing a transcendental function of its eigenvalues — an operation with no representation as a correlation function and no obvious path-integral analogue. It is precisely this intractability that the next section's replica construction circumvents. The detour runs through a one-parameter family of entropies that *are* polynomial in ρ_A, hence computable.

Definition 55.5 (Rényi entropies)**.** For real $n > 0$, $n \neq 1$, the *n-th Rényi entropy* of A is

$$S_n(A) \;=\; \frac{1}{1-n}\,\log \operatorname{Tr}(\rho_A^n) \;=\; \frac{1}{1-n}\,\log \sum_i \lambda_i^n. \tag{55.7}$$

The quantity $\operatorname{Tr}\rho_A^n$ is, for integer n, a product of n copies of ρ_A traced together — an object that, we will see in Section 55.1.8, the path integral computes as a partition function on an n-sheeted branched cover. The Rényi entropies form a convenient ladder: $S_0(A) = \log(\operatorname{rank}\rho_A)$ counts the nonzero eigenvalues (the *Schmidt rank*, below), $S_2(A) = -\log \operatorname{Tr}\rho_A^2$ measures the purity, and $S_\infty(A) = -\log \lambda_{\max}$ is the min-entropy. The rung we ultimately want is the limit $n \to 1$, which recovers the von Neumann entropy.

Proposition 55.6 (The replica limit)**.** $\lim_{n\to 1} S_n(A) = S_A$.

Proof. Write $f(n) = \log \sum_i \lambda_i^n = \log \operatorname{Tr}\rho_A^n$. Since $\sum_i \lambda_i = \operatorname{Tr}\rho_A = 1$, we have $f(1) = \log 1 = 0$. The function is differentiable in n for $n > 0$, with

$$f'(n) = \frac{\sum_i \lambda_i^n \log \lambda_i}{\sum_i \lambda_i^n}, \qquad f'(1) = \sum_i \lambda_i \log \lambda_i = -S_A, \tag{55.8}$$

the denominator at $n = 1$ being unity. By Eq. (55.7), $S_n(A) = -f(n)/(n-1)$. Taylor-expanding f about $n = 1$, $f(n) = f(1) + f'(1)(n-1) + O\big((n-1)^2\big) = -S_A(n-1) + O\big((n-1)^2\big)$, so $S_n(A) = S_A + O(n-1) \to S_A$. □

This innocuous limit is the entire strategy of the chapter. We will compute $\operatorname{Tr}\rho_A^n$ for integer $n \geq 2$ as a Euclidean path integral, find a function of n that interpolates, and analytically continue it to $n \to 1$ to read off S_A. The legitimacy of that continuation — whether the integer data determine a unique analytic function — is a genuine subtlety we confront in Section 55.1.8; for the moment the limit is exact as a statement about a fixed finite spectrum.

55.1.3 The Schmidt decomposition and the equality of entropies

The structural backbone of bipartite entanglement is a single theorem of linear algebra — the singular-value decomposition, dressed in physical language. It says that any pure state of $A \cup \bar{A}$ can be written with a *single* sum, diagonal across the bipartition, and from it every elementary property of S_A follows almost immediately.

Theorem 55.7 (Schmidt decomposition)**.** *Let $|\Psi\rangle \in \mathcal{H}_A \otimes \mathcal{H}_{\bar{A}}$ be a normalized pure state, with $\dim \mathcal{H}_A = d_A$ and $\dim \mathcal{H}_{\bar{A}} = d_{\bar{A}}$. There exist orthonormal sets $\{|k\rangle_A\} \subset \mathcal{H}_A$ and $\{|k\rangle_{\bar{A}}\} \subset \mathcal{H}_{\bar{A}}$, and nonnegative numbers $\sqrt{p_k}$, such that*

$$|\Psi\rangle \;=\; \sum_{k=1}^{r} \sqrt{p_k}\; |k\rangle_A \otimes |k\rangle_{\bar{A}}\,, \qquad p_k > 0, \quad \sum_{k=1}^{r} p_k = 1, \tag{55.9}$$

where $r \le \min(d_A, d_{\bar{A}})$ is the Schmidt rank*. The reduced density matrices are then diagonal in these bases,*

$$\rho_A = \sum_{k=1}^{r} p_k\; |k\rangle_A\langle k|_A\,, \qquad \rho_{\bar{A}} = \sum_{k=1}^{r} p_k\; |k\rangle_{\bar{A}}\langle k|_{\bar{A}}\,, \tag{55.10}$$

so ρ_A and $\rho_{\bar{A}}$ share the identical multiset of nonzero eigenvalues $\{p_k\}$.

Proof. Expand $|\Psi\rangle$ in arbitrary product bases $\{|i\rangle_A\}_{i=1}^{d_A}$, $\{|j\rangle_{\bar{A}}\}_{j=1}^{d_{\bar{A}}}$:

$$|\Psi\rangle = \sum_{i,j} C_{ij}\; |i\rangle_A \otimes |j\rangle_{\bar{A}}\,, \tag{55.11}$$

with C a $d_A \times d_{\bar{A}}$ complex matrix of coefficients. Every such matrix admits a singular-value decomposition $C = U\,\Sigma\,V^{\dagger}$, where U is $d_A \times d_A$ unitary, V is $d_{\bar{A}} \times d_{\bar{A}}$ unitary, and Σ is $d_A \times d_{\bar{A}}$ with nonnegative real entries $\sigma_k \equiv \Sigma_{kk} \ge 0$ on its diagonal and zeros elsewhere. In components $C_{ij} = \sum_k U_{ik}\sigma_k\, \overline{V_{jk}}$. Substituting into Eq. (55.11) and grouping,

$$|\Psi\rangle = \sum_{k} \sigma_k \underbrace{\Big(\sum_{i} U_{ik}\,|i\rangle_A\Big)}_{\equiv\ |k\rangle_A} \otimes \underbrace{\Big(\sum_{j} \overline{V_{jk}}\;|j\rangle_{\bar{A}}\Big)}_{\equiv\ |k\rangle_{\bar{A}}}. \tag{55.12}$$

Because U and V are unitary, the vectors $\{|k\rangle_A\}$ are orthonormal — $\langle k|k'\rangle_A = \sum_i \overline{U_{ik}} U_{ik'} = \delta_{kk'}$ — and likewise $\{|k\rangle_{\bar{A}}\}$. Keeping only the indices with $\sigma_k > 0$ and setting $p_k = \sigma_k^2$ gives Eq. (55.9) with $r = \operatorname{rank} C$. Normalization of $|\Psi\rangle$ reads $1 = \langle\Psi|\Psi\rangle = \sum_k \sigma_k^2 = \sum_k p_k$.

The reduced density matrices follow by partial trace. From Eq. (55.9),

$$|\Psi\rangle\langle\Psi| = \sum_{k,k'} \sqrt{p_k p_{k'}}\; |k\rangle_A\langle k'|_A \otimes |k\rangle_{\bar{A}}\langle k'|_{\bar{A}}\,, \tag{55.13}$$

and tracing over $\bar{A}$ in the orthonormal basis $\{|k\rangle_{\bar{A}}\}$ (extended to a full basis; the extra vectors annihilate the state) replaces $|k\rangle_{\bar{A}}\langle k'|_{\bar{A}}$ by $\langle k'|k\rangle_{\bar{A}} = \delta_{kk'}$, leaving $\rho_A = \sum_k p_k\, |k\rangle_A\langle k|_A$. Tracing over A instead gives $\rho_{\bar{A}} = \sum_k p_k\, |k\rangle_{\bar{A}}\langle k|_{\bar{A}}$. The two operators are diagonal with the identical nonzero spectrum $\{p_k\}$; they differ only in the Hilbert space their eigenvectors inhabit, and by the dimensions of their respective zero-eigenvalue (kernel) subspaces. □

Corollary 55.8 (Equality of complementary entropies for a pure global state)**.** *If the global state is pure, then for every Rényi index and for the von Neumann entropy,*

$$S_n(A) = S_n(\bar{A}) \quad \textit{for all } n, \qquad \textit{in particular} \qquad S_A = S_{\bar{A}}. \tag{55.14}$$

Proof. Each entropy in Theorems 55.4 and 55.5 is a function of the nonzero eigenvalues alone (the zero eigenvalues contribute $0 \log 0 = 0$ to the von Neumann entropy and nothing to $\operatorname{Tr}\rho^n$ for $n > 0$). By Theorem 55.7 the nonzero spectra of ρ_A and $\rho_{\bar{A}}$ coincide, so any spectral function takes the same value on both. □

Equation (55.14) is at first sight startling: the entanglement entropy of a small region equals that of its enormous complement. The resolution is that S_A is not a property of the region's "size" or "content" — it measures the entanglement *across the shared boundary*, and the boundary is the same whether viewed from inside or outside. This is the first hint of the area law: a quantity that depends on A only through ∂A. It also delivers a warning. Because $S_A = S_{\bar{A}}$ holds only for a *pure* global state, the entanglement entropy is *not* an extensive (additive) quantity, and for a mixed global state $S_A \neq S_{\bar{A}}$ in general — the difference $S_A - S_{\bar{A}}$ then measures the impurity of the whole. In the thermal ensembles of Chapter 54 this distinction is the difference between thermal entropy and entanglement entropy, a point we return to in Section 55.1.6.

55.1.4 Elementary properties, proved

The defining axioms of an information measure must now be verified. Two of them — non-negativity and the characterization of zero — are immediate; the maximal value and concavity require an inequality, which we prove first because it is the workhorse for the rest of the chapter.

Lemma 55.9 (Klein's inequality / non-negativity of relative entropy)**.** *For any two density matrices ρ, σ on a finite-dimensional Hilbert space, the* relative entropy

$$S(\rho\,\|\,\sigma) \;\equiv\; \operatorname{Tr}\big[\rho(\log\rho - \log\sigma)\big] \tag{55.15}$$

is non-negative, $S(\rho\,\|\,\sigma) \geq 0$, with equality if and only if $\rho = \sigma$.

Proof. Diagonalize both operators: $\rho = \sum_i p_i \, |i\rangle\langle i|$ and $\sigma = \sum_a q_a \, |a\rangle\langle a|$, with $\{|i\rangle\}$ and $\{|a\rangle\}$ orthonormal bases and $p_i, q_a \geq 0$, $\sum_i p_i = \sum_a q_a = 1$. Inserting these,

$$S(\rho \,\|\, \sigma) = \sum_i p_i \log p_i - \sum_{i,a} p_i \, |\langle i|a\rangle|^2 \log q_a = \sum_i p_i \Big(\log p_i - \sum_a P_{ia} \log q_a \Big), \tag{55.16}$$

where $P_{ia} \equiv |\langle i|a\rangle|^2$ is a doubly stochastic matrix: $\sum_a P_{ia} = \sum_i P_{ia} = 1$, since $\{|i\rangle\}$ and $\{|a\rangle\}$ are complete orthonormal sets. The logarithm is strictly concave, so by Jensen's inequality applied to the probability weights P_{ia} (over a at fixed i),

$$\sum_a P_{ia} \log q_a \;\leq\; \log\Big(\sum_a P_{ia} \, q_a \Big) \;\equiv\; \log r_i, \qquad r_i \equiv \sum_a P_{ia} q_a. \tag{55.17}$$

The numbers r_i are themselves a probability distribution: $\sum_i r_i = \sum_a q_a \sum_i P_{ia} = \sum_a q_a = 1$, using the column-stochasticity of P. Combining Eqs. (55.16) and (55.17),

$$S(\rho \,\|\, \sigma) \;\geq\; \sum_i p_i \log \frac{p_i}{r_i} \;\geq\; 0, \tag{55.18}$$

the last step being the classical Gibbs inequality, which follows from $\log x \leq x - 1$: $-\sum_i p_i \log(r_i/p_i) \geq -\sum_i p_i (r_i/p_i - 1) = \sum_i (p_i - r_i) = 0$. Equality in $\log x \leq x - 1$ requires $x = 1$, i.e. $r_i = p_i$ for all i; equality in Jensen requires the q_a to be constant over the support of P_{ia}. Tracing these conditions back forces the two operators to be diagonal in a common basis with equal eigenvalues, i.e. $\rho = \sigma$. $\square$

With Klein's inequality in hand the entropy's elementary properties fall out.

Proposition 55.10 (Elementary properties of S_A)**.** *Let ρ_A act on a d_A-dimensional space $\mathcal{H}_A$. Then*

(i) ***Non-negativity:*** *$S_A \geq 0$.*

(ii) ***Purity criterion:*** *$S_A = 0$ if and only if ρ_A is pure; for a pure global state this happens if and only if $|\Psi\rangle$ is a product state $|\Psi\rangle = |\phi\rangle_A \otimes |\xi\rangle_{\bar{A}}$ (Schmidt rank $r = 1$).*

(iii) ***Maximality:*** *$S_A \leq \log d_A$, with equality if and only if $\rho_A = \mathbf{1}_A / d_A$ is maximally mixed.*

Proof. (i) Each eigenvalue satisfies $0 \leq \lambda_i \leq 1$, so $-\lambda_i \log \lambda_i \geq 0$ term by term, and $S_A = -\sum_i \lambda_i \log \lambda_i \geq 0$.

(ii) Since every term $-\lambda_i \log \lambda_i \geq 0$ vanishes only when $\lambda_i \in \{0, 1\}$, the sum vanishes precisely when one eigenvalue is 1 and the rest are 0 — that is, when ρ_A is a rank-one projector, a pure state. By Theorem 55.7 a pure $\rho_A = |1\rangle_A \langle 1|_A$

corresponds to a single Schmidt coefficient $p_1 = 1$, whence $|\Psi\rangle = |1\rangle_A \otimes |1\rangle_{\bar{A}}$ is a product state, and conversely.

(iii) Apply Theorem 55.9 with $\sigma = \mathbf{1}_A/d_A$, the maximally mixed state. Then $\log \sigma = -(\log d_A)\mathbf{1}_A$, so

$$0 \le S(\rho_A \,\|\, \mathbf{1}_A/d_A) = \operatorname{Tr} \rho_A \log \rho_A - \operatorname{Tr} \rho_A \log(\mathbf{1}_A/d_A) = -S_A + \log d_A, \tag{55.19}$$

giving $S_A \le \log d_A$. Equality holds iff $\rho_A = \mathbf{1}_A/d_A$, by the equality clause of Klein. □

Property (iii) is the finite-dimensional ceiling that the field-theoretic divergence will smash through: as we refine the lattice and $d_A \to \infty$, the bound $\log d_A$ itself diverges, and the actual S_A saturates a divergent fraction of it. We turn to this after one more property — concavity — and its consequence, subadditivity.

Theorem 55.11 (Concavity of the von Neumann entropy)**.** *The von Neumann entropy $S(\rho) = -\operatorname{Tr} \rho \log \rho$ is concave in ρ: for any density matrices $\{\rho_i\}$ and probabilities $\{p_i \ge 0,\ \sum_i p_i = 1\}$,*

$$S\Big(\sum_i p_i\, \rho_i\Big) \;\ge\; \sum_i p_i\, S(\rho_i). \tag{55.20}$$

Proof. Set $\rho = \sum_i p_i \rho_i$ and compute the weighted sum of relative entropies of each ρ_i against the average ρ:

$$\begin{aligned} \sum_i p_i\, S(\rho_i \,\|\, \rho) &= \sum_i p_i\, \operatorname{Tr}\big[\rho_i(\log \rho_i - \log \rho)\big] \\ &= \sum_i p_i \operatorname{Tr}(\rho_i \log \rho_i) - \operatorname{Tr}\Big[\Big(\sum_i p_i \rho_i\Big) \log \rho\Big] \\ &= -\sum_i p_i\, S(\rho_i) - \operatorname{Tr}(\rho \log \rho) = -\sum_i p_i\, S(\rho_i) + S(\rho). \end{aligned} \tag{55.21}$$

By Theorem 55.9 each $S(\rho_i \,\|\, \rho) \ge 0$, so the left-hand side is non-negative, and rearranging Eq. (55.21) gives $S(\rho) \ge \sum_i p_i S(\rho_i)$, which is Eq. (55.20). □

Physically, concavity says that mixing states never decreases entropy: blending ensembles can only add uncertainty. The corresponding statement about combining *subsystems* is subadditivity, which we will need at once for the mutual information but whose proof is most naturally given alongside its powerful refinement, strong subadditivity, in Section 55.6.3.

Theorem 55.12 (Subadditivity)**.** *For any state on a tripartite-or-bipartite system with regions A and B (disjoint, with joint reduced state ρ_{AB}),*

$$S_{AB} \;\le\; S_A + S_B, \tag{55.22}$$

with equality if and only if $\rho_{AB} = \rho_A \otimes \rho_B$.

Proof (deferred). This is the case $C = \varnothing$ of strong subadditivity, proved in full in Theorem 55.47. We record the short self-contained argument here for completeness: by Theorem 55.9, $0 \le S(\rho_{AB} \,\|\, \rho_A \otimes \rho_B) = \operatorname{Tr} \rho_{AB} \log \rho_{AB} - \operatorname{Tr} \rho_{AB} \log(\rho_A \otimes \rho_B)$. Using $\log(\rho_A \otimes \rho_B) = \log \rho_A \otimes \mathbf{1}_B + \mathbf{1}_A \otimes \log \rho_B$ and $\operatorname{Tr}_B \rho_{AB} = \rho_A$, the second trace equals $\operatorname{Tr} \rho_A \log \rho_A + \operatorname{Tr} \rho_B \log \rho_B = -S_A - S_B$, so $0 \le -S_{AB} + S_A + S_B$. Equality is the equality clause of Klein, i.e. $\rho_{AB} = \rho_A \otimes \rho_B$. □

55.1.5 Mutual information: the finite diagnostic

Subadditivity guarantees that the following combination is well-signed.

Definition 55.13 (Mutual information)**.** For disjoint regions A and B, the *mutual information* is

$$I(A : B) \;=\; S_A + S_B - S_{AB}. \tag{55.23}$$

Corollary 55.14 (Positivity of mutual information)**.** $I(A : B) \ge 0$*, with equality if and only if* $\rho_{AB} = \rho_A \otimes \rho_B$ *(the two regions are uncorrelated). Moreover* $I(A : B) = S(\rho_{AB} \,\|\, \rho_A \otimes \rho_B)$*.*

Proof. Positivity and the equality condition are precisely Theorem 55.12 rearranged. The identification with a relative entropy is read off from the deferred proof above: $S(\rho_{AB} \,\|\, \rho_A \otimes \rho_B) = -S_{AB} + S_A + S_B = I(A : B)$. □

The mutual information is the single most important object in this chapter for a reason we can now state precisely but will only fully justify in Section 55.1.6. The entanglement entropy S_A is, in the continuum, divergent and cutoff-dependent; one cannot quote a finite number for it without specifying a regulator. The mutual information $I(A : B)$, by contrast, is a *difference* of entropies in which the boundary divergences cancel: S_A diverges on ∂A, S_B on ∂B, and S_{AB} on $\partial A \cup \partial B$, so the divergences supported on each boundary appear with canceling signs in Eq. (55.23). What survives is finite and cutoff-independent — a genuine measure of the total correlation, classical plus quantum, shared by the two regions. Its expression as a relative entropy in Theorem 55.14 is the abstract reason for this finiteness: relative entropy, unlike entropy itself, descends to the algebraic (cutoff-free) setting, a fact we flag now and exploit in the final section.

55.1.6 Two structural facts that make QFT subtle

Everything above was finite-dimensional linear algebra. The leap to a quantum field — where A is a spatial region and the "degrees of freedom" are the field amplitudes at a continuum of points — introduces two features absent from any finite system. They are not technical nuisances to be papered over; they shape every result in the chapter, and intellectual honesty requires stating them at the outset and honoring them throughout.

(a) The area law and its ultraviolet divergence

The first fact is that S_A is ultraviolet divergent. We can see why, and extract the leading divergence's form, by a scaling argument before the honest computation of Section 55.5. The vacuum of a local field theory is correlated over short distances — the equal-time two-point function $\langle 0|\phi(\mathbf{x})\phi(\mathbf{y})|0\rangle$ of Chapter 9 is singular as $\mathbf{y} \to \mathbf{x}$. Entanglement between A and $\bar{A}$ is therefore dominated by field modes localized *near the boundary* ∂A, where short-range correlations straddle the cut. Introduce a short-distance cutoff a (a lattice spacing, or $1/\Lambda$ for a momentum cutoff Λ). The boundary ∂A, a $(d-2)$-dimensional surface in d spacetime dimensions, can be tiled by $\sim \mathrm{Area}(\partial A)/a^{\,d-2}$ cells of linear size a. Each cell contributes an $O(1)$ amount of entanglement from the entangled pair of modes that straddle it, and cells separated by more than a contribute negligibly because the correlations are short-ranged. The estimate is therefore

$$S_A \;\simeq\; \gamma\,\frac{\mathrm{Area}(\partial A)}{a^{\,d-2}} \;+\; (\text{subleading}), \tag{55.24}$$

with γ a dimensionless, cutoff-scheme-dependent constant. This is the *area law*: the leading entanglement entropy scales with the area of the entangling surface, not the volume of the region, and it *diverges* as the cutoff is removed, $a \to 0$. In $d = 4$ this is $S_A \simeq \gamma\,\mathrm{Area}/a^2$; in $d = 2$, where the "area" of a point-like boundary is a pure number and Eq. (55.24) degenerates, the leading divergence is instead logarithmic, $S_A \simeq \frac{c}{3}\log(\ell/a)$ for an interval of length ℓ in a CFT of central charge c — the famous result we derive in Section 55.4 once the replica machinery is built. The scaling Eq. (55.24) is heuristic; the coefficient γ and the structure of the subleading terms come from the genuine computation in Section 55.5. What matters now is the qualitative lesson: *S_A is not a finite number in the continuum,* and any physical statement must be phrased so that the cutoff dependence drops out — as it does in the mutual information and the relative entropy.

(b) Non-factorization and the type-III algebra of a region

The second fact is deeper and undermines the very first line of the formalism, the tensor factorization Eq. (55.1). In a continuum quantum field theory *the global Hilbert space does not factorize* as $\mathcal{H} = \mathcal{H}_A \otimes \mathcal{H}_{\bar{A}}$, and consequently the reduced density matrix ρ_A of Theorem 55.2 does not, strictly, exist. There are two ways to see the obstruction, and they are the same obstruction.

The concrete way is the divergence we just met. A density matrix must have $\mathrm{Tr}\,\rho_A = 1$ and finite entropy is needed for $\rho_A \log \rho_A$ to be trace class. But Eq. (55.24) says the vacuum's entanglement across *any* boundary is infinite: arbitrarily-high-frequency modes are entangled across ∂A, with no shortest wavelength to cut the sum off. An operator with infinite entropy and no normalizable

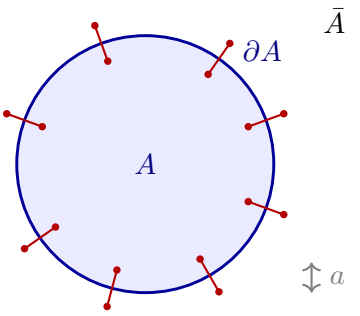

Figure 55.1: The area-law cartoon. The entanglement between a region A and its complement $\bar{A}$ is dominated by short-range correlated pairs of modes (red links) straddling the entangling surface ∂A. Tiling ∂A by cells of the cutoff size a gives $\sim \mathrm{Area}(\partial A)/a^{d-2}$ such pairs, each contributing $O(1)$ to S_A, hence the leading divergence Eq. (55.24).

spectrum is not a density matrix on a separable Hilbert space. The would-be factorization Eq. (55.1) fails because a sharply localized field mode requires arbitrarily high momentum (by the uncertainty principle), and such modes cannot be cleanly assigned to one side of a sharp boundary; they live on both.

The abstract way is the language of operator algebras, and it is worth stating precisely because it is the framework the modern literature uses. To a spacetime region one associates not a Hilbert space factor but a *von Neumann algebra* $\mathcal{A}_A$ — the algebra of bounded operators built from the fields smeared with test functions supported in A, closed in the weak operator topology. Murray and von Neumann classified such algebras into types I, II, and III by the structure of their projections. The algebra of a bounded region in continuum QFT, in the vacuum, is of *type* III_1: it has no minimal projections, no normal trace, and — the decisive point — no density matrix representing the vacuum state on it. Type I is the familiar case $\mathcal{B}(\mathcal{H}_A)$ in which density matrices and a tensor factorization Eq. (55.1) exist; type III is what a local QFT region actually realizes, and in it the naive $S_A = -\operatorname{Tr}\rho_A \log \rho_A$ is simply undefined.

The entanglement entropy of a continuum region is not, by itself, a number

Two errors must be avoided. First, one must not quote "the entanglement entropy of the half-space is X" without a regulator: Eq. (55.6) as written has no continuum value. Second, one must not conclude that entanglement is therefore ill-defined or unphysical. It is the *entropy* (a property of ρ_A alone) that fails to exist; *differences* of entropy — relative entropy $S(\rho_A\|\sigma_A)$ and mutual information $I(A:B)$ — remain perfectly well-defined even on a type III algebra, where they are constructed without

ever forming ρ_A, via Tomita–Takesaki modular theory. This is the technical content of the chapter's running insistence that the clean observables are differences.

The pragmatic resolution, adopted throughout this chapter and almost universally in the literature, is to *regulate*: place the theory on a spatial lattice of spacing a, or otherwise impose a UV cutoff. A regulated theory has finitely many degrees of freedom in any bounded region, its algebra is type I, the factorization Eq. (55.1) is restored exactly, ρ_A exists, and every theorem of Sections 55.1.1 to 55.1.4 applies verbatim. The continuum statements are then recovered as the $a \to 0$ limit, with the understanding that S_A itself diverges per Eq. (55.24) while the physical, cutoff-independent content lives in the finite pieces: the coefficient of a universal subleading term (the logarithm in $d = 2$, a constant in odd d), the mutual information, and the relative entropy.

Why the vacuum is the interesting case

The whole construction would be vacuous — literally — if the vacuum factorized. It is precisely because $|0\rangle$ is the richly correlated state advertised in the chapter opening (and built explicitly in Chapters 9 and 10) that ρ_A is mixed and S_A is large. The entanglement entropy is thus a probe of vacuum structure: the area law is the statement that the vacuum's correlations are short-ranged and live at the boundary, and the universal subleading terms encode the long-distance data of the theory — the central charge in 2d, the number of degrees of freedom and the structure of the renormalization-group flow in higher d. We are, in effect, reading off the theory's deepest invariants from how its empty state is entangled with itself.

55.1.7 Two worked computations

The formalism is best anchored by carrying it out completely on the smallest nontrivial systems. The first is the canonical qubit pair; the second is the two-oscillator ground state, which is the exact kernel of the free-scalar computation that advances ϕ^4 theory in Section 55.5.

Worked Example 55.15 (Entanglement of a two-qubit pure state)**.** Take $\mathcal{H}_A = \mathcal{H}_{\bar{A}} = \mathbb{C}^2$ and the one-parameter family of pure states

$$|\Psi(\theta)\rangle = \cos\theta\ |0\rangle_A\,|0\rangle_{\bar{A}} + \sin\theta\ |1\rangle_A\,|1\rangle_{\bar{A}}\,, \qquad \theta \in [0, \pi/2]. \tag{55.25}$$

This is already in Schmidt form Eq. (55.9), with Schmidt coefficients $\sqrt{p_1} = \cos\theta$,

$\sqrt{p_2} = \sin\theta$, so by Eq. (55.10) the reduced density matrix is diagonal,

$$\rho_A = \cos^2\theta\ |0\rangle_A\langle 0|_A + \sin^2\theta\ |1\rangle_A\langle 1|_A = \begin{pmatrix} \cos^2\theta & 0 \\ 0 & \sin^2\theta \end{pmatrix}. \tag{55.26}$$

The eigenvalues are $\lambda_1 = \cos^2\theta$, $\lambda_2 = \sin^2\theta$. The entanglement entropy is the binary entropy function

$$S_A(\theta) = -\cos^2\theta\,\log\cos^2\theta - \sin^2\theta\,\log\sin^2\theta. \tag{55.27}$$

At $\theta = 0$ or $\pi/2$ the state Eq. (55.25) is a product and $S_A = 0$, confirming Theorem 55.10(ii). At $\theta = \pi/4$ — the maximally entangled Bell state $\frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$ — both eigenvalues equal $\frac{1}{2}$ and $S_A = \log 2$, saturating the ceiling $\log d_A = \log 2$ of Theorem 55.10(iii). The Rényi entropies are $S_n = \frac{1}{1-n}\log(\cos^{2n}\theta + \sin^{2n}\theta)$; at $\theta = \pi/4$ this is $\frac{1}{1-n}\log(2\cdot 2^{-n}) = \log 2$ for every n, the signature of a maximally mixed reduced state. One checks the replica limit directly: $\lim_{n\to 1}\frac{1}{1-n}\log(\cos^{2n}\theta + \sin^{2n}\theta) = S_A(\theta)$ by Theorem 55.6. Note also that $\rho_{\bar A}$ has the identical spectrum, so $S_A = S_{\bar A}$ as Theorem 55.8 demands — here trivially, since A and $\bar A$ are interchangeable.

Worked Example 55.16 (The ground state of two coupled oscillators)**.** This is the prototype for entanglement in a free field. A free scalar field on a spatial lattice is, after diagonalizing nothing, a collection of harmonic oscillators — one per lattice site — coupled to their neighbours by the gradient term in the Hamiltonian. Partitioning space into A and $\bar A$ partitions the oscillators. The minimal instance keeps two oscillators, one in A and one in $\bar A$, coupled quadratically. Consider the Hamiltonian

$$H = \tfrac{1}{2}(p_1^2 + p_2^2) + \tfrac{1}{2}\Big[\,\omega_0^2(x_1^2 + x_2^2) + k\,(x_1 - x_2)^2\,\Big], \tag{55.28}$$

with coordinates x_1 (in A), x_2 (in $\bar A$), and coupling $k \geq 0$. Normal coordinates $x_\pm = (x_1 \pm x_2)/\sqrt{2}$ decouple it into two oscillators of frequencies

$$\omega_+ = \sqrt{\omega_0^2 + 2k}, \qquad \omega_- = \omega_0, \tag{55.29}$$

since the symmetric combination feels no coupling and the antisymmetric one feels $\omega_0^2 + 2k$. The ground-state wavefunction is the product of the two normal-mode Gaussians,

$$\Psi_0(x_1, x_2)\ \propto\ \exp\Big[-\tfrac{1}{2}\omega_- x_+^2 - \tfrac{1}{2}\omega_+ x_-^2\Big] = \exp\Big[-\tfrac{\alpha}{2}(x_1^2 + x_2^2) + \beta\, x_1 x_2\Big], \tag{55.30}$$

where expanding $x_\pm = (x_1 \pm x_2)/\sqrt{2}$ gives

$$\alpha = \tfrac{1}{2}(\omega_+ + \omega_-), \qquad \beta = \tfrac{1}{2}(\omega_+ - \omega_-). \tag{55.31}$$

Crucially, the ground state is *not* a product in (x_1, x_2) whenever $\beta \neq 0$, i.e. whenever $k > 0$: the cross term $\beta x_1 x_2$ is exactly the entanglement between the two oscillators. We compute ρ_A and S_A in closed form.

The reduced density matrix is obtained by tracing out oscillator 2, which for a pure state means integrating the wavefunction against its conjugate over x_2:

$$\rho_A(x_1, x_1') = \int_{-\infty}^{\infty} dx_2 \; \Psi_0(x_1, x_2)\, \Psi_0^*(x_1', x_2). \tag{55.32}$$

The wavefunction Eq. (55.30) is real, and the x_2-integral is Gaussian. Collecting the x_2-dependence, $\Psi_0(x_1, x_2)\Psi_0(x_1', x_2) \propto \exp[-\alpha x_2^2 + \beta(x_1 + x_1')x_2] \times \exp[-\frac{\alpha}{2}(x_1^2 + x_1'^2)]$, and using $\int dx_2\, e^{-\alpha x_2^2 - b x_2} = \sqrt{\pi/\alpha}\, e^{b^2/4\alpha}$ with $b = -\beta(x_1 + x_1')$,

$$\rho_A(x_1, x_1') \;\propto\; \exp\Big[-\tfrac{\alpha}{2}(x_1^2 + x_1'^2) + \tfrac{\beta^2}{4\alpha}(x_1 + x_1')^2\Big]. \tag{55.33}$$

Writing the exponent in the standard form $-\frac{\gamma}{2}(x_1^2 + x_1'^2) + \frac{\delta}{2}\, 2x_1 x_1'$ (the off-diagonal coherence) one reads off

$$\gamma = \alpha - \frac{\beta^2}{2\alpha}, \qquad \delta = \frac{\beta^2}{2\alpha}. \tag{55.34}$$

A Gaussian density matrix of this form is diagonalized by Mehler's formula, whose eigenvalues are geometric, $\lambda_m = (1 - \xi)\, \xi^m$ for $m = 0, 1, 2, \ldots$, with the single ratio

$$\xi = \frac{\delta}{\gamma + \sqrt{\gamma^2 - \delta^2}}, \qquad \text{equivalently} \qquad \xi = \Big(\frac{\sqrt{\omega_+/\omega_-} - \sqrt{\omega_-/\omega_+}}{\sqrt{\omega_+/\omega_-} + \sqrt{\omega_-/\omega_+}}\Big)^2. \tag{55.35}$$

That ρ_A has a thermal (geometric) spectrum is no accident — it is a single-mode thermal state, $\rho_A \propto e^{-\kappa\, a^\dagger a}$ with $e^{-\kappa} = \xi$, the first appearance of the deep link between reduced density matrices and thermality that the Rindler analysis of Section 55.3 will make universal. The von Neumann entropy of a geometric distribution $\lambda_m = (1 - \xi)\xi^m$ is computed once and for all:

$$\begin{aligned} S_A &= -\sum_{m=0}^{\infty} (1 - \xi)\xi^m \big[\log(1 - \xi) + m \log \xi\big] \\ &= -\log(1 - \xi) - \frac{\xi}{1 - \xi} \log \xi = -\log(1 - \xi) - \frac{\xi \log \xi}{1 - \xi}, \end{aligned} \tag{55.36}$$

where we used $\sum_m (1 - \xi)\xi^m = 1$ and $\sum_m m(1 - \xi)\xi^m = \xi/(1 - \xi)$. As the coupling switches off, $k \to 0$ gives $\omega_+ \to \omega_-$, hence $\beta \to 0$, $\delta \to 0$, $\xi \to 0$, and $S_A \to 0$: an unentangled product ground state, consistent with Theorem 55.10(ii). As the coupling grows, $\omega_+/\omega_- \to \infty$, $\xi \to 1$, and $S_A \to \infty$ logarithmically — the two-oscillator avatar of the UV divergence Eq. (55.24), here driven by the unbounded frequency ratio. Summing the result Eq. (55.36) over the boundary modes of a genuine lattice scalar, with the $\omega_\pm$ replaced by the dispersion of the field, is exactly the computation that yields the area law in Section 55.5; the present example fixes its kernel.

55.1.8 Where this leaves us

We now possess a sharp definition. For a region A in a (regulated) quantum field theory in the vacuum, the entanglement entropy is $S_A = -\operatorname{Tr}(\rho_A \log \rho_A)$ with $\rho_A = \operatorname{Tr}_{\bar{A}} |0\rangle\langle 0|$, and we have established its non-negativity, its vanishing exactly on product states, its maximal value, its concavity, the equality $S_A = S_{\bar{A}}$ for the pure vacuum, and the positivity of the mutual information that will serve as our finite diagnostic. We have also been honest about the two obstructions: the area-law divergence Eq. (55.24) and the non-factorization Section 55.1.6, both handled by a UV cutoff that renders ρ_A a bona fide density matrix.

What we do *not* have is any way to evaluate S_A. The operator logarithm in Eq. (55.6) resists every tool of the preceding chapters: it is not a correlation function, not a sum of Feynman diagrams, not a partition function. The escape was foreshadowed by Theorem 55.6: the Rényi entropies involve only the polynomial $\operatorname{Tr} \rho_A^n$, and for integer n this is a product of n copies of ρ_A. The next section shows that ρ_A itself has a Euclidean path-integral representation — a path integral over field configurations on a spacetime cut open along the region A — and that $\operatorname{Tr} \rho_A^n$ is then computed by gluing n such copies cyclically into a path integral on an n-sheeted branched cover of spacetime. Analytically continuing in n and differentiating at $n = 1$ delivers S_A. This is the replica trick, the master computational tool for everything that follows.

55.2 The Replica Trick and the Path-Integral Construction

The previous section left us with a sharp definition and an impasse. For a region A in the regulated vacuum the entanglement entropy is $S_A = -\operatorname{Tr}(\rho_A \log \rho_A)$ with $\rho_A = \operatorname{Tr}_{\bar{A}} |0\rangle\langle 0|$, and we noted (Section 55.1.8) that the operator logarithm answers to none of the tools of the preceding chapters: it is not a correlation function, not a sum of diagrams, not a partition function. What *is* computable is the family of traces $\operatorname{Tr} \rho_A^n$, polynomial in ρ_A, which we already met as the Rényi entropies (Theorem 55.5). This section turns that observation into a complete computational method. The plan has two movements. First, we make the limit $n \to 1$ precise as an analytic continuation, so that knowledge of $\operatorname{Tr} \rho_A^n$ at integer n delivers S_A by a single differentiation — the *replica master formula*. Second, we give ρ_A, and then $\operatorname{Tr} \rho_A^n$, an explicit Euclidean path-integral representation: ρ_A is the vacuum-preparing functional integral with a cut along A, and $\operatorname{Tr} \rho_A^n$ is the partition function of the same theory on an n-sheeted surface obtained by gluing n copies of that cut spacetime cyclically across the cut. The entire intractable spectral problem is thereby converted into the evaluation of partition functions on branched covers — a problem we can attack, in Section 55.4, with conformal maps, and, in Section 55.5, with free-field determinants. The construction is

theory-agnostic; it is the engine for the rest of the chapter.

55.2.1 The replica master formula

The strategy rests on a function of one complex variable. Let ρ_A act on the (regulated, finite-dimensional) Hilbert space $\mathcal{H}_A$ with eigenvalues $\{\lambda_i\}$, $\lambda_i \geq 0$, $\sum_i \lambda_i = 1$. Define

$$G(n) \;\equiv\; \operatorname{Tr} \rho_A^n \;=\; \sum_i \lambda_i^n, \tag{55.37}$$

initially for integer $n \geq 1$, where the right-hand side is the spectral representation of the left. We want $S_A = -\sum_i \lambda_i \log \lambda_i$. The bridge is differentiation in n.

Theorem 55.17 (Replica master formula)**.** *Let ρ_A be a density matrix on a finite-dimensional space, with spectrum $\{\lambda_i\}$. The function $G(n) = \sum_i \lambda_i^n$ extends to an analytic function of complex n on the half-plane $\operatorname{Re}(n) > 0$, and the von Neumann entropy is recovered as*

$$S_A \;=\; -\lim_{n\to 1} \frac{\partial}{\partial n} \operatorname{Tr} \rho_A^n \;=\; -\frac{\partial}{\partial n}\Big|_{n=1} \operatorname{Tr} \rho_A^n. \tag{55.38}$$

Equivalently, in terms of the Rényi entropies $S_n(A) = \frac{1}{1-n} \log \operatorname{Tr} \rho_A^n$ of Theorem 55.5,

$$S_A \;=\; \lim_{n\to 1} S_n(A). \tag{55.39}$$

Proof. For each i with $\lambda_i > 0$ write $\lambda_i^n = e^{n \log \lambda_i}$, an entire function of n; eigenvalues with $\lambda_i = 0$ contribute nothing and are dropped. The finite sum Eq. (55.37) is therefore an entire function of n, and in particular analytic on $\operatorname{Re}(n) > 0$. Term-by-term differentiation of a finite sum is legitimate, so

$$\frac{\partial}{\partial n} G(n) \;=\; \sum_i \lambda_i^n \log \lambda_i, \tag{55.40}$$

the differentiation under the (finite) sum being trivially dominated. Evaluating at $n = 1$ and using $\sum_i \lambda_i = 1$,

$$\frac{\partial}{\partial n}\Big|_{n=1} G(n) \;=\; \sum_i \lambda_i \log \lambda_i \;=\; -S_A, \tag{55.41}$$

which is Eq. (55.38). For the Rényi form, set $f(n) = \log G(n)$. Since $G(1) = \operatorname{Tr} \rho_A = 1$, we have $f(1) = 0$ and, by Eq. (55.41), $f'(1) = G'(1)/G(1) = -S_A$. Then $S_n(A) = -f(n)/(n-1)$, and L'Hôpital (or the first-order Taylor expansion $f(n) = -S_A(n-1) + O((n-1)^2)$) gives $\lim_{n\to 1} S_n(A) = -f'(1) = S_A$, which is Eq. (55.39) and reproduces Theorem 55.6. □

The formula Eq. (55.38) is exact and elementary *as a statement about a fixed finite spectrum*. Its power, and its one genuine subtlety, lie in how it is used. In practice one never has the spectrum $\{\lambda_i\}$; one computes $G(n) = \operatorname{Tr}\rho_A^n$ only at *integer* $n \geq 2$, where, as the rest of this section shows, it equals a partition function one can actually evaluate. One then seeks a function $\widetilde{G}(n)$, analytic in a neighbourhood of $n = 1$, that agrees with the computed integer values, and reads off $S_A = -\widetilde{G}'(1)$. The questions this raises are: does such an analytic interpolation exist, and is it unique? Existence is settled case by case — in every computation of this book the integer data assemble into a manifestly analytic closed form (a power of n, a ratio of Gamma functions, an exponential of a polynomial in n). Uniqueness is the content of a classical theorem of complex analysis, which we state because it is exactly the guarantee the method needs.

Theorem 55.18 (Carlson's uniqueness theorem)**.** *Let $h(z)$ be holomorphic on the closed right half-plane $\operatorname{Re}(z) \geq 0$ and of exponential type there, $|h(z)| \leq M\, e^{\tau|z|}$, and suppose that on the imaginary axis the type is controlled below π: $|h(iy)| \leq M\, e^{c|y|}$ with $c < \pi$. If $h(n) = 0$ for every non-negative integer $n = 0, 1, 2, \ldots$, then $h \equiv 0$.*

Proof sketch. This is a Phragmén–Lindelöf argument of the kind reviewed in Section 5.4.1; we indicate its skeleton and use the result. The function $g(z) = h(z)/\sin(\pi z)$ has removable singularities at the integers (each a simple zero of both numerator and denominator), hence extends holomorphically to the right half-plane. One shows, using the lower bound $|\sin(\pi z)| \gtrsim e^{\pi|\operatorname{Im} z|}$ away from the integers together with the hypothesis $c < \pi$, that g is bounded on the boundary of each quadrant and grows slower than any exponential of type π inside; the Phragmén–Lindelöf principle then forces g to be bounded on $\operatorname{Re}(z) \geq 0$, and a bounded holomorphic function whose product with the unbounded $\sin(\pi z)$ stays of exponential type must vanish identically. Hence $h \equiv 0$. The role of the sub-π hypothesis is decisive: the function $\sin(\pi z)$ itself vanishes at every integer, is of exponential type exactly π, and is not identically zero — so the bound $c < \pi$ cannot be relaxed. □

The relevance is immediate. Suppose two analytic functions $\widetilde{G}_1, \widetilde{G}_2$ both interpolate the integer data $G(n)$, $n \geq 1$, and both satisfy the growth bound of Theorem 55.18. Their difference $h = \widetilde{G}_1 - \widetilde{G}_2$ vanishes at all integers $n \geq 1$ and meets the hypotheses, so $h \equiv 0$: the interpolation is unique, and $S_A = -\widetilde{G}'(1)$ is unambiguous. That the bound is met in our setting is not an idle assumption but a consequence of the spectrum living in $[0, 1]$: for $\operatorname{Re}(n) \geq 1$,

$$\left|\operatorname{Tr}\rho_A^n\right| \;=\; \left|\sum_i \lambda_i^n\right| \;\leq\; \sum_i \lambda_i^{\operatorname{Re}(n)} \;\leq\; \sum_i \lambda_i \;=\; 1, \tag{55.42}$$

using $0 \leq \lambda_i \leq 1 \Rightarrow \lambda_i^{\operatorname{Re}(n)} \leq \lambda_i$ for $\operatorname{Re}(n) \geq 1$. Thus $G(n)$ is *bounded* on $\operatorname{Re}(n) \geq 1$ — exponential type zero, well inside Carlson's window — so among

bounded analytic interpolations there is exactly one, and it is the one any honest computation produces.

The continuation is unique only among well-behaved interpolations

Carlson's theorem does not say the integer data determine *every* interpolation; it says they determine the unique interpolation of sub-π exponential type. One can always add $\sin(\pi n)$ times anything analytic without changing the integer values, and such an addition would alter $S_A = -\widetilde{G}'(1)$. The physics input is that the partition functions $\operatorname{Tr}\rho_A^n$, computed at integer n, assemble into a function whose growth in n is controlled (in a regulated theory, by the bound Eq. (55.42); in the continuum, by the area law, which makes $\log \operatorname{Tr}\rho_A^n$ grow at most polynomially in the regularized volume of the entangling region, again of zero exponential type in n). When this holds — as it does in every case treated here — the continuation is forced. There are pathological models (random or chaotic spectra) where the integer Rényi data do not visibly determine the entropy; we will not meet them, but the assumption is real and we flag it rather than hide it.

The remaining task is purely computational: evaluate $\operatorname{Tr}\rho_A^n$ for integer n. We now give it a geometry.

55.2.2 The reduced density matrix as a cut path integral

Everything begins with the Euclidean preparation of the vacuum established in Chapter 10. Recall the picture (Theorem 10.10 and Section 10.6): under the Wick rotation $t \to -i\tau$ fixed in Section 10.6, the Lorentzian weight e^{iS} becomes the positive Euclidean weight e^{-S_E}, and evolving in imaginary time for an infinite duration projects any state of nonzero overlap onto the ground state. Concretely, the ground-state wavefunctional — the amplitude for the field on a constant-time slice to take a prescribed profile — is computed by a Euclidean path integral over the *lower* half of spacetime, $\tau < 0$, with the field pinned to that profile on the slice $\tau = 0$:

$$\Psi_0[\varphi] \;\equiv\; \langle\varphi|0\rangle \;=\; \frac{1}{\sqrt{Z_1}} \int_{\substack{\phi(\tau<0)\\ \phi(\tau=0,\mathbf{x})=\varphi(\mathbf{x})}} \mathcal{D}\phi \; e^{-S_E[\phi]}, \tag{55.43}$$

where $|\varphi\rangle$ is the eigenstate of the field operator $\hat{\phi}(\mathbf{x})$ on the slice with eigenvalue $\varphi(\mathbf{x})$, and $Z_1 = \int \mathcal{D}\phi\, e^{-S_E}$ over all of Euclidean spacetime $\mathbb{R}^d$ normalizes the state, $\langle 0|0\rangle = 1$. The conjugate amplitude $\langle 0|\varphi'\rangle = \overline{\Psi_0[\varphi']}$ is the same integral over the *upper* half $\tau > 0$ with the field pinned to φ' at $\tau = 0$. Reality of the Euclidean action for a real scalar makes these complex conjugates of one another; we keep the two halves distinct because their boundary slices will become the two indices of a density matrix.

The pure-state density matrix of the vacuum, $\rho = |0\rangle\langle 0|$, has matrix elements

$$\langle \varphi_+ | \rho | \varphi_- \rangle \;=\; \langle \varphi_+ | 0 \rangle \, \langle 0 | \varphi_- \rangle \;=\; \Psi_0[\varphi_+] \, \overline{\Psi_0[\varphi_-]}. \tag{55.44}$$

Geometrically this glues the lower-half integral preparing $\Psi_0[\varphi_+]$ to the upper-half integral preparing $\overline{\Psi_0[\varphi_-]}$ along the common slice $\tau = 0$ — but *without* integrating over the slice value, since the two halves carry the independent boundary data φ_+ (the slice value of the lower-half field) and φ_- (the slice value of the upper-half field). The result is a path integral over all of $\mathbb{R}^d$ in which the field is permitted a discontinuity across the entire slice $\tau = 0$: it tends to φ_+ from below ($\tau \to 0^-$) and to φ_- from above ($\tau \to 0^+$). We adopt the bra/ket-to-lip assignment of Section 55.3: the value approached from $\tau \to 0^+$ (the upper lip) is the ket index, the value approached from $\tau \to 0^-$ (the lower lip) is the bra index.

Now reduce to the region A. The reduced density matrix $\rho_A = \mathrm{Tr}_{\bar{A}}\, \rho$ traces over the field degrees of freedom in the complement $\bar{A}$ on the slice. In the field representation, tracing over $\bar{A}$ means setting the bra and ket boundary values *equal on* $\bar{A}$ and integrating over their common value there, while leaving them free and distinct on A:

$$\left\langle \varphi_+^A \middle| \rho_A \middle| \varphi_-^A \right\rangle = \int \mathcal{D}\chi_{\bar{A}} \; \left\langle \varphi_+^A \otimes \chi_{\bar{A}} \middle| \rho \middle| \varphi_-^A \otimes \chi_{\bar{A}} \right\rangle. \tag{55.45}$$

The integral over $\chi_{\bar{A}}$ sews the upper and lower lips of the slice *shut* everywhere on $\bar{A}$: above and below the complement the field is now continuous and unconstrained, exactly as in the bulk. Only on A does the slit remain open, carrying the boundary data φ_+^A on its upper lip and φ_-^A on its lower lip. The net statement is the central representation of this section.

Proposition 55.19 (Path-integral form of ρ_A)**.** *The matrix elements of the reduced density matrix of a region A in the vacuum are computed by the Euclidean path integral over* $\mathbb{R}^d$ cut open along A*:*

$$\left\langle \varphi_+^A \middle| \rho_A \middle| \varphi_-^A \right\rangle = \frac{1}{Z_1} \int_{\substack{\phi \to \varphi_+^A \ \text{on } A,\ \tau \to 0^+ \\ \phi \to \varphi_-^A \ \text{on } A,\ \tau \to 0^-}} \mathcal{D}\phi \; e^{-S_E[\phi]}, \tag{55.46}$$

where the field is integrated freely over all of $\mathbb{R}^d$ except along the slit $\{\tau = 0,\ \mathbf{x} \in A\}$, across which it is required to approach the prescribed profiles $\varphi_\pm^A$ from above and below. The normalization $Z_1 = \int \mathcal{D}\phi\, e^{-S_E}$ (the partition function on uncut $\mathbb{R}^d$) enforces $\mathrm{Tr}_A\, \rho_A = 1$.

Proof. Substituting Eq. (55.44) into Eq. (55.45), the matrix element is the product $\Psi_0[\varphi_+^A, \chi_{\bar{A}}]\, \overline{\Psi_0[\varphi_-^A, \chi_{\bar{A}}]}$ integrated over $\chi_{\bar{A}}$. By Eq. (55.43) the first factor is a lower-half ($\tau < 0$) integral with slice data (φ_+^A on A, $\chi_{\bar{A}}$ on $\bar{A}$), the second an upper-half ($\tau > 0$) integral with slice data (φ_-^A on A, $\chi_{\bar{A}}$ on $\bar{A}$). The $\chi_{\bar{A}}$-integration identifies the slice value of the lower-half field with that of the

upper-half field on $\bar{A}$ and sums over it; this is precisely the statement that, on $\bar{A}$, the two half-space integrals are joined into one integral over $\mathbb{R}^d$ with the field continuous across $\tau = 0$. On A no such identification occurs: the lower-half field ends at φ_+^A and the upper-half field ends at φ_-^A, and these remain the free boundary data of the combined integral, imposed respectively from $\tau \to 0^-$ (lower lip) and $\tau \to 0^+$ (upper lip). The combined domain is therefore $\mathbb{R}^d$ minus the slit on A, with the stated boundary behaviour, and the two normalizing $1/\sqrt{Z_1}$ factors multiply to $1/Z_1$. Taking the trace $\mathrm{Tr}_A\, \rho_A$ sets $\varphi_+^A = \varphi_-^A$ and integrates, closing the slit on A as well; the field is then continuous everywhere and the numerator becomes $\int_{\mathbb{R}^d} \mathcal{D}\phi\, e^{-S_E} = Z_1$, so $\mathrm{Tr}_A\, \rho_A = Z_1/Z_1 = 1$. □

ρ_A is a geometric object

Equation Eq. (55.46) is the conceptual heart of the chapter. It says the reduced density matrix is *not* an abstract operator to be diagonalized but a piece of spacetime with a slit: the bra and ket of ρ_A are the two lips of a cut along A, and "acting with ρ_A" means filling in the Euclidean field between them. Two consequences foreshadow later sections. First, multiplying density matrices will mean stacking such slit-spacetimes lip-to-lip — the construction of the next subsection. Second, when A is a half-space the slit is a half-plane and the surrounding geometry is flat space in polar coordinates, so the operator that propagates the field from the lower lip to the upper lip is angular (rotation) evolution; that is the observation Section 55.3 turns into vacuum thermality.

55.2.3 $\mathrm{Tr}\,\rho_A^n$ on the branched cover

We now compute the integer powers by composing copies of Eq. (55.46). The trace of the n-th power is, in the field basis,

$$\mathrm{Tr}\,\rho_A^n = \int \prod_{j=1}^{n} \mathcal{D}\varphi^{(j)}\ \left\langle \varphi^{(1)} \middle| \rho_A \middle| \varphi^{(2)} \right\rangle \left\langle \varphi^{(2)} \middle| \rho_A \middle| \varphi^{(3)} \right\rangle \cdots \left\langle \varphi^{(n)} \middle| \rho_A \middle| \varphi^{(1)} \right\rangle, \quad (55.47)$$

where each $\varphi^{(j)}$ is a field profile on A, the matrix product threads the bra of one factor into the ket of the next, and the trace closes the chain by identifying the last bra with the first ket (the index $\varphi^{(1)}$ appears at both ends). This is ordinary matrix multiplication followed by a trace, written out in a continuous basis; the only content beyond Theorem 55.19 is the bookkeeping of which lip is glued to which.

Read each factor through Eq. (55.46). The factor $\left\langle \varphi^{(j)} \middle| \rho_A \middle| \varphi^{(j+1)} \right\rangle$ is a copy of cut $\mathbb{R}^d$ — call it *sheet* j — whose slit on A has its upper lip ($\tau \to 0^+$) pinned to $\varphi^{(j)}$ (the ket) and its lower lip ($\tau \to 0^-$) pinned to $\varphi^{(j+1)}$ (the bra). The

integrations $\int \mathcal{D}\varphi^{(j)}$ in Eq. (55.47) then enforce, for each j, the identification

$$\underbrace{\varphi^{(j)}}_{\text{lower lip of sheet } j-1} \quad = \quad \underbrace{\varphi^{(j)}}_{\text{upper lip of sheet } j} \quad , \tag{55.48}$$

that is: *the lower lip of sheet $j-1$ is sewn to the upper lip of sheet j*, and they share the field profile $\varphi^{(j)}$ which is then integrated over. Equivalently, going the other way around, the lower lip of sheet j is sewn to the upper lip of sheet $j+1$. The trace makes the chain cyclic: $\varphi^{(n+1)} \equiv \varphi^{(1)}$, so the lower lip of sheet n is sewn to the upper lip of sheet 1, closing the stack into a ring. Each sewing integrates over the common profile, so the field is continuous across every join; the only places where the field can "change sheets" are the lips of the slit on A, and the only places where it cannot be defined single-valuedly are the endpoints of A — the boundary ∂A — around which one passes from one sheet to the next.

The object so constructed is a single connected manifold: n copies of $\mathbb{R}^d$, each slit along A, glued cyclically lip-to-lip. It is an *n-sheeted branched cover* of $\mathbb{R}^d$, branched over the entangling surface ∂A; in two dimensions, where ∂A is a set of points, it is the Riemann surface $\mathcal{R}_n$ that reappears in Section 55.4. Away from ∂A the cover is locally identical to $\mathbb{R}^d$ (the field is smooth across each glued slit, the join being invisible once the integration is done); only on encircling a point of ∂A does one wind through all n sheets before returning. Figure 55.2 shows the gluing for $n = 3$ in two dimensions.

The path integral over this glued manifold, with the same local Euclidean action S_E on each sheet, is by definition a partition function. Denote it $Z_n \equiv \int_{\mathcal{R}_n} \mathcal{D}\phi\, e^{-S_E[\phi]}$. Collecting the n numerator factors from Eq. (55.46) (one per sheet) and the n normalizing denominators Z_1, Eq. (55.47) reads

$$\boxed{\operatorname{Tr} \rho_A^n \;=\; \frac{Z_n}{Z_1^n}\,, \qquad n = 1, 2, 3, \dots} \tag{55.49}$$

This is the master computational identity. The left side is the spectral quantity Eq. (55.37) we cannot compute directly; the right side is a ratio of ordinary Euclidean partition functions — one on the n-sheeted cover, one on flat space raised to the n-th power — which we can. Two checks fix the conventions. At $n = 1$ the "cover" is a single sheet with its slit sewn shut (the trace identifies the two lips), i.e. uncut $\mathbb{R}^d$, so Z_1 is literally the flat-space partition function and $\operatorname{Tr} \rho_A = Z_1/Z_1 = 1$, as it must. The denominator Z_1^n is not optional: Z_n alone is dimensionful and cutoff-dependent (it is an unnormalized functional integral), and only the ratio Eq. (55.49), in which n powers of the single-sheet normalization are divided out, equals the dimensionless, physically meaningful trace bounded by Eq. (55.42).

It is worth pausing on why the gluing reproduces the operator product and not something else. Operator multiplication $\rho_A \cdot \rho_A$ contracts a bra of the first

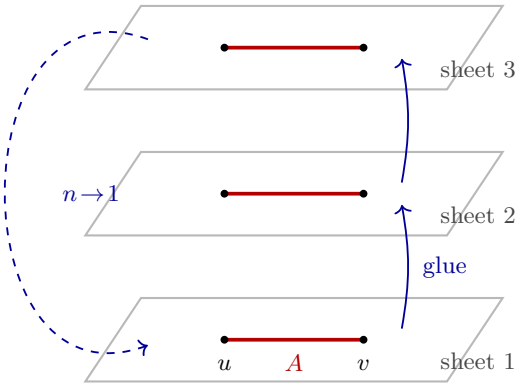

Figure 55.2: The branched cover $\mathcal{R}_n$ for $n = 3$ (two-dimensional case, interval $A = [u, v]$). Each sheet is a copy of cut Euclidean spacetime; the lower lip of the slit on sheet j is sewn to the upper lip on sheet $j + 1$ (solid arrows), and the lower lip of the top sheet closes back onto the upper lip of the bottom sheet (dashed). The field is continuous across every join; multivaluedness survives only at the branch points u, v $(= \partial A)$, around which a circuit passes through all n sheets. The partition function on $\mathcal{R}_n$ is Z_n, and $\operatorname{Tr} \rho_A^n = Z_n / Z_1^n$.

factor with a ket of the second over the A *degrees of freedom only* — precisely the lip-to-lip sewing on the slit, Eq. (55.48). The complement $\bar{A}$ was already traced out within each ρ_A (the slit was closed on $\bar{A}$ in Theorem 55.19), so on $\bar{A}$ each sheet is simply a full copy of $\mathbb{R}^d$ with the field continuous across $\tau = 0$; the sheets touch one another only along A. This is exactly why the branch locus is ∂A and not all of $\tau = 0$: the cover is ramified only where the slits are, and the slits live on A.

55.2.4 Rényi entropies as free energies on the replica geometry

Identity Eq. (55.49) translates the entropy hierarchy directly into the language of free energies. Taking the logarithm,

$$\log \operatorname{Tr} \rho_A^n \;=\; \log Z_n - n \log Z_1, \tag{55.50}$$

and substituting into the definition $S_n(A) = \frac{1}{1-n} \log \operatorname{Tr} \rho_A^n$ (Eq. (55.7)) gives the Rényi entropy as a difference of free energies.

Proposition 55.20 (Rényi entropy as a replica free energy)**.** *With $F_n \equiv -\log Z_n$ the Euclidean free energy of the theory on the n-sheeted cover $\mathcal{R}_n$, the Rényi entropies of A are*

$$S_n(A) \;=\; \frac{1}{1-n}\big(\log Z_n - n \log Z_1\big) \;=\; \frac{1}{1-n}\,\big(nF_1 - F_n\big), \tag{55.51}$$

and the von Neumann entropy is the replica limit

$$S_A \;=\; \lim_{n\to 1}\frac{1}{1-n}\big(\log Z_n - n\log Z_1\big) \;=\; -\frac{\partial}{\partial n}\Big|_{n=1}\big(\log Z_n - n\log Z_1\big). \tag{55.52}$$

Proof. Equation Eq. (55.51) is Eq. (55.50) divided by $1-n$, with $F_n = -\log Z_n$. For Eq. (55.52), apply the replica master formula Eq. (55.38) in its Rényi form Eq. (55.39): write $g(n) \equiv \log Z_n - n\log Z_1 = \log \operatorname{Tr}\rho_A^n$, which vanishes at $n=1$ since $\operatorname{Tr}\rho_A = 1$. Then $S_n(A) = -g(n)/(n-1)$ and, by the same L'Hôpital step as in Theorem 55.17, $\lim_{n\to 1} S_n(A) = -g'(1) = -\partial_n(\log Z_n - n\log Z_1)|_{n=1}$, which is Eq. (55.52). □

The form Eq. (55.52) is the one actually used in computation: one finds $\log Z_n$ as an explicit analytic function of n — by mapping $\mathcal{R}_n$ to a smooth space (the conformal route of Section 55.4) or by evaluating the Gaussian functional determinant on $\mathcal{R}_n$ (the free-field route of Section 55.5, which rests on the determinant technology of Section E.2) — and then differentiates at $n=1$. The differentiation $\partial_n \log Z_n$ probes the response of the free energy to opening up an infinitesimal conical excess at ∂A: at $n=1$ the cover is flat, and $\partial_n|_{n=1}$ measures the leading curvature cost of replication, localized at the entangling surface. This is the precise sense in which the entanglement entropy is geometric data attached to ∂A, and it is the seed of the area law.

Replica index as inverse temperature

The combination $g(n) = \log Z_n - n\log Z_1$ is structurally a thermodynamic free energy with n playing the role of an inverse temperature: Z_n is the partition function on a space whose extent in the replica (angular) direction is n times the original, and $S_n = \frac{1}{1-n}\log(Z_n/Z_1^n)$ is the analogue of the operator $(\beta\,\partial_\beta - 1)$ acting on a free energy, which in ordinary thermodynamics returns an entropy. The replica limit $n\to 1$ is the limit of unit "temperature" in the replica direction. This is not a loose analogy: when A is a half-space the replica direction *is* the Euclidean time circle and n *is* literally proportional to an inverse temperature, $\beta = 2\pi n$, the content of the Unruh effect derived in Section 55.3. The angular structure of the cut path integral, visible already in Eq. (55.46), is what Section 55.3 reads as thermality.

55.2.5 The twist-operator reformulation

The branched-cover partition function Eq. (55.49) can be repackaged so that the awkward multivalued geometry is replaced by an ordinary correlation function on a single, smooth copy of spacetime. The price is to work not in the original theory $\mathcal{C}$ but in its n-fold replica $\mathcal{C}^{\otimes n}$, and to introduce local operators that carry

the branch structure. This *orbifold* or *twist-field* construction is the form in which the replica trick is most powerful in two dimensions, where it reduces the entire single-interval computation to fixing one operator dimension.

The idea is to undo the gluing Eq. (55.48) by introducing n independent copies of the field living on a single sheet, and to encode the cyclic identification as a boundary condition imposed by operator insertions. Consider n non-interacting copies of the theory on one copy of $\mathbb{R}^d$, with fields $\Phi = (\phi_1, \dots, \phi_n)$, action $S_E^{(n)}[\Phi] = \sum_{j=1}^n S_E[\phi_j]$, and partition function Z_1^n (the copies decouple, so the partition function factorizes). The replicated theory has a manifest global symmetry: the cyclic permutation

$$\sigma : \quad \phi_j(x) \longmapsto \phi_{j+1}(x), \qquad \phi_{n+1} \equiv \phi_1, \tag{55.53}$$

generating a $\mathbb{Z}_n$ subgroup of the permutations of the copies. The branched cover $\mathcal{R}_n$ is reconstructed from $\mathcal{C}^{\otimes n}$ by demanding that, as one crosses the slit on A, the j-th copy continue not into itself but into its cyclic neighbour. To see this, restrict attention to the two-dimensional case with A a single interval $[u, v]$, so $\partial A = \{u, v\}$, and recall the gluing: crossing the cut on sheet j of $\mathcal{R}_n$ lands one on sheet $j + 1$. In the replicated theory on a single plane, this is the statement that the field configuration is single-valued *except* along the cut $[u, v]$, where it satisfies the twisted boundary condition

$$\phi_j(x, \tau \to 0^-) \;=\; \phi_{j+1}(x, \tau \to 0^+), \qquad x \in [u, v], \tag{55.54}$$

which is exactly the gluing rule Eq. (55.48) with the sheets relabelled as copies. A field obeying Eq. (55.54) on the segment $[u, v]$ and continuous elsewhere is the same data as a single field on $\mathcal{R}_n$: the n-component object on one plane with a cut is the unfolded picture of the one-component object on n glued planes.

The cut in Eq. (55.54) is not an intrinsic feature of the configuration; it can be moved by a field redefinition, and only its endpoints are physical. The endpoints are the loci where the monodromy lives: encircling u once takes $\phi_j \mapsto \phi_{j+1}$ (one cannot return to the original copy without going around), and encircling v undoes it, $\phi_j \mapsto \phi_{j-1}$, so that a loop enclosing both endpoints sees trivial monodromy and the configuration is single-valued at infinity. An operator insertion that imposes precisely this monodromy on the fields encircling its location is, by definition, a *twist operator*.

Definition 55.21 (Twist operators)**.** In the replicated theory $\mathcal{C}^{\otimes n}$, the *twist operator* $\sigma_n(w)$ is the local operator defined by the monodromy condition that any field ϕ_j transported once counterclockwise around the point w returns as ϕ_{j+1} (the action of the generator Eq. (55.53)); the *anti-twist* $\tilde{\sigma}_n(w)$ imposes the inverse monodromy $\phi_j \mapsto \phi_{j-1}$. Operationally, inserting $\sigma_n(u)\,\tilde{\sigma}_n(v)$ into a correlator of $\mathcal{C}^{\otimes n}$ instructs the path integral to be taken over field configurations with a branch cut running from u to v across which the copies are cyclically permuted, i.e. over exactly the configurations Eq. (55.54).

With this definition the branched-cover partition function becomes a twist two-point function in the replicated theory. The argument is a direct comparison of path-integral domains.

Proposition 55.22 (Branched cover as a twist correlator)**.** *For a single interval $A = [u, v]$ in two dimensions,*

$$\operatorname{Tr} \rho_A^n \;=\; \frac{Z_n}{Z_1^n} \;=\; \langle\, \sigma_n(u)\, \tilde{\sigma}_n(v) \,\rangle_{\mathcal{C}^{\otimes n}}, \tag{55.55}$$

where the correlator is normalized by the replicated partition function Z_1^n, so that $\langle \sigma_n \tilde{\sigma}_n \rangle = Z[\text{cut configs}]/Z[\text{all configs}]$.

Proof. The numerator Z_n is the path integral of the single field ϕ over the cover $\mathcal{R}_n$. Unfold $\mathcal{R}_n$ by labelling, at each point x of the base plane, the values of ϕ on the n sheets above x as an n-component field $\Phi(x) = (\phi_1(x), \dots, \phi_n(x))$. Because the local action on each sheet is the same S_E, the unfolded action is $\sum_j S_E[\phi_j] = S_E^{(n)}[\Phi]$, the replicated action. The cyclic gluing of $\mathcal{R}_n$ becomes, in the unfolded variables, exactly the twisted boundary condition Eq. (55.54) along $[u, v]$, with the field single-valued away from the cut. By Theorem 55.21 the path integral over $\mathcal{C}^{\otimes n}$ configurations subject to this monodromy is, by construction, the insertion of $\sigma_n(u)\, \tilde{\sigma}_n(v)$ into the replicated path integral:

$$Z_n = \int_{\substack{\text{cut configs} \\ \text{on } [u,v]}} \mathcal{D}\Phi \; e^{-S_E^{(n)}[\Phi]} = \Big(\int \mathcal{D}\Phi \, e^{-S_E^{(n)}} \Big) \, \langle \sigma_n(u)\, \tilde{\sigma}_n(v) \rangle_{\mathcal{C}^{\otimes n}}. \tag{55.56}$$

The prefactor is the unconstrained replicated partition function, which factorizes across the decoupled copies into $\prod_{j=1}^n Z_1 = Z_1^n$. Dividing, $Z_n / Z_1^n = \langle \sigma_n(u)\, \tilde{\sigma}_n(v) \rangle_{\mathcal{C}^{\otimes n}}$, and the left equality is Eq. (55.49). That the inserted operators are local and carry the cyclic monodromy is the defining property Theorem 55.21; the choice of where the cut runs between u and v is a gauge of the field relabelling and does not affect the correlator, confirming that only the endpoints carry physical data. □

The gain is decisive. The left side of Eq. (55.55) required understanding a singular Riemann surface; the right side is an ordinary two-point function of local operators in a perfectly smooth theory on the plane. If the underlying theory is conformal, σ_n and $\tilde{\sigma}_n$ are (as we verify in Section 55.4) local primary operators of the replicated CFT $\mathcal{C}^{\otimes n}$, whose central charge is nc, and the two-point function of primaries is fixed by conformal invariance up to a single constant and a single number — the scaling dimension of the twist field. The entire single-interval computation then collapses to determining that one dimension.

The twist dimension is fixed in Section 55.4, not here

We have *defined* σ_n by its monodromy and *established* that $\operatorname{Tr}\rho_A^n = \langle \sigma_n(u)\,\tilde{\sigma}_n(v)\rangle$, but we have not yet computed its scaling dimension. That computation is carried out in Section 55.4.2 by matching the stress-tensor expectation value on $\mathcal{R}_n$ (obtained by uniformizing the cover to the plane) against the conformal Ward identity, and the answer is the celebrated $h_n = \frac{c}{24}\left(n - \frac{1}{n}\right)$ of Theorem 55.31. The present section owes only the *structure* Eq. (55.55); Section 55.4 supplies the number and reads off the entropy.

55.2.6 The method exercised on a thermal spectrum

To see the entire pipeline turn — integer data, analytic continuation, differentiation at $n = 1$ — on a case where the spectrum is known in closed form, we revisit the geometric (thermal) spectrum produced by the two coupled oscillators of Theorem 55.16. That example is no toy: its single-mode thermal spectrum is the exact kernel of the free-field entanglement entropy assembled in Section 55.5, so demonstrating the replica continuation on it is demonstrating it on the building block of the area law.

Worked Example 55.23 (Replica continuation of a geometric spectrum)**.** Let ρ_A have the geometric (thermal single-mode) spectrum $\lambda_m = (1-\xi)\,\xi^{\,m}$, $m = 0, 1, 2, \ldots$, with $0 \le \xi < 1$, as found in Eq. (55.36). We compute S_A by the replica route and check it against the direct value there.

Integer data. For integer $n \ge 1$ the trace is a geometric series, summed exactly:

$$\operatorname{Tr}\rho_A^n = \sum_{m=0}^{\infty} (1-\xi)^n\,\xi^{\,nm} = (1-\xi)^n \sum_{m=0}^{\infty} (\xi^n)^m = \frac{(1-\xi)^n}{1-\xi^{\,n}}. \tag{55.57}$$

At $n = 1$ this gives $(1-\xi)/(1-\xi) = 1$, the correct normalization. The Rényi entropies follow directly from Eq. (55.7):

$$S_n(A) = \frac{1}{1-n}\log\frac{(1-\xi)^n}{1-\xi^{\,n}} = \frac{1}{1-n}\Big[\,n\log(1-\xi) - \log(1-\xi^{\,n})\,\Big]. \tag{55.58}$$

Analytic continuation. The right-hand side of Eq. (55.57) is already a single analytic function of n: $(1-\xi)^n = e^{n\log(1-\xi)}$ is entire, and $1-\xi^{\,n} = 1 - e^{n\log\xi}$ is entire with no zeros for $\operatorname{Re}(n) > 0$ (since $|\xi^n| = \xi^{\operatorname{Re} n} < 1$ there), so $\operatorname{Tr}\rho_A^n$ is holomorphic on $\operatorname{Re}(n) > 0$. Moreover it is bounded by 1 on $\operatorname{Re}(n) \ge 1$, in line with Eq. (55.42), so by Theorem 55.18 this *is* the unique admissible continuation of the integer data — there is no ambiguity to resolve. We may therefore differentiate Eq. (55.57) in n and evaluate at $n = 1$.

The replica limit. Set $g(n) = \log \operatorname{Tr} \rho_A^n = n \log(1-\xi) - \log(1-\xi^n)$, which vanishes at $n = 1$. Differentiating, and using $\partial_n \xi^n = \xi^n \log \xi$,

$$g'(n) = \log(1-\xi) - \frac{-\xi^n \log \xi}{1-\xi^n} = \log(1-\xi) + \frac{\xi^n \log \xi}{1-\xi^n}, \tag{55.59}$$

and at $n = 1$,

$$g'(1) = \log(1-\xi) + \frac{\xi \log \xi}{1-\xi}. \tag{55.60}$$

By the replica master formula in the free-energy form Eq. (55.52), $S_A = -g'(1)$, so

$$S_A = -\log(1-\xi) - \frac{\xi \log \xi}{1-\xi}, \tag{55.61}$$

which is exactly the direct result Eq. (55.36). The replica machinery has reproduced the von Neumann entropy of the geometric spectrum without ever diagonalizing or summing $-\sum_m \lambda_m \log \lambda_m$ term by term: it summed the polynomial $\sum_m \lambda_m^n$, continued in n, and differentiated once.

Reading the limits. As $\xi \to 0$ (decoupled oscillators, product ground state) Eq. (55.61) gives $S_A \to 0$; as $\xi \to 1^-$ (strong coupling, the UV-divergent regime) it diverges as $S_A \sim -\log(1-\xi) \to \infty$. Both match Theorem 55.16. The Rényi family Eq. (55.58) interpolates smoothly: for instance $S_2(A) = -\log \frac{(1-\xi)^2}{1-\xi^2} = -\log \frac{1-\xi}{1+\xi} = \log \frac{1+\xi}{1-\xi}$, the purity diagnostic, finite for all $\xi < 1$ and reducing to Eq. (55.61) as $n \to 1$. This single mode, summed over the boundary modes of a lattice field with the ξ of each mode set by the dispersion relation, is precisely the sum that yields the area law in Section 55.5; the replica continuation we have just exercised is the operation performed mode-by-mode there.

55.2.7 What we now compute with

We have converted the entanglement entropy from an operator logarithm into geometry. The replica master formula Eq. (55.38), legitimized by Carlson's uniqueness (Theorem 55.18) whenever the Rényi data are of controlled growth, reduces S_A to a single n-derivative of $\operatorname{Tr} \rho_A^n$ at $n = 1$. The reduced density matrix is the cut path integral Eq. (55.46); its integer powers are the branched-cover partition functions Eq. (55.49), $\operatorname{Tr} \rho_A^n = Z_n / Z_1^n$, equivalently the replica free energies Eq. (55.51); and for a single interval the cover is traded for a twist two-point function Eq. (55.55) in the replicated theory. Two routes to Z_n now open. In Section 55.4 we evaluate the twist correlator by conformal symmetry, fixing the twist dimension from the central charge and extracting the celebrated logarithm of two-dimensional CFT. In Section 55.5 we evaluate Z_n as a free-field functional determinant on the cover and recover the area law for the scalar of ϕ^4 theory. And the angular structure of the cut geometry Eq. (55.46), with the replica index playing the part of an inverse temperature, is the doorway to the

very next section: for a half-space the cut path integral is rotation by an angle, and Section 55.3 reads that rotation as the thermality of the vacuum seen by an accelerated observer.

55.3 The Rindler Wedge, the Modular Hamiltonian, and Vacuum Thermality

The replica construction of Section 55.2 reduced every entanglement quantity to a Euclidean path integral, and in doing so it taught us to read the reduced density matrix ρ_A geometrically: ρ_A is the path integral on Euclidean spacetime *cut open* along the region A, with the field on the upper lip of the cut playing the ket index and the field on the lower lip playing the bra index. For a generic region A the geometry of that cut is hopelessly complicated and the path integral cannot be done. There is, however, one region for which the geometry is as simple as it can possibly be: a flat half-space, $A = \{x^1 > 0\}$ at a fixed time, whose boundary — the *entangling surface* — is an infinite flat plane. Here the cut is a half-hyperplane, and the Euclidean spacetime around it is just flat $\mathbb{R}^d$ presented in polar coordinates about that plane. The angular coordinate sweeps from one lip of the cut to the other, and the operator that generates angular evolution is something we already constructed, long ago and for entirely different reasons: the Noether charge of Lorentz boosts (Theorem 7.27 and Eq. (7.107)). Out of this single observation the entire physical content of this section follows — that the vacuum, restricted to a half-space, is an exactly thermal state with respect to the boost; that a uniformly accelerated observer therefore finds himself bathed in radiation at a temperature fixed by his acceleration; and that the modular Hamiltonian, the object $-\log \rho_A$ that controls all of entanglement's fine structure, is in this case a known, local, geometric operator. This is the exactly solvable seed from which the rest of the chapter's structure grows.

55.3.1 The half-space, the Rindler wedge, and the cut path integral

We work in d-dimensional Minkowski spacetime with the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,\dots,-)$ and natural units $\hbar = c = 1$, restoring dimensionful constants only once, for a physical estimate. Coordinates are $x^\mu = (t, x^1, \mathbf{x}_\perp)$, where $\mathbf{x}_\perp = (x^2, \dots, x^{d-1})$ are the $d-2$ transverse directions. Fix the time slice $t = 0$ and split it across the plane $x^1 = 0$:

$$A = \{\,(0, x^1, \mathbf{x}_\perp) : x^1 > 0\,\}, \qquad B = \{\,(0, x^1, \mathbf{x}_\perp) : x^1 < 0\,\}. \tag{55.62}$$

The entangling surface is the codimension-two plane $\Sigma = \{x^1 = 0\}$ at $t = 0$, with transverse area $\mathcal{A}_\perp = \int \mathrm{d}^{d-2}x_\perp$ (formally infinite; we keep it as an overall factor).

The domain of dependence of A — the set of spacetime points whose entire past and future are determined by initial data on A — is the *right Rindler wedge*.

Definition 55.24 (Right Rindler wedge)**.** The right Rindler wedge is the open region

$$W_R = \{\, x^\mu : \; x^1 > |t| \,\} = \{\, x^1 > 0, \; -x^1 < t < x^1 \,\}, \tag{55.63}$$

the causal completion of the half-space A of Eq. (55.62). The left wedge $W_L = \{-x^1 > |t|\}$ is the causal completion of B.

The wedge is distinguished by a symmetry. The one-parameter group of Lorentz boosts in the x^1 direction,

$$\begin{pmatrix} t \\ x^1 \end{pmatrix} \longmapsto \Lambda_\eta \begin{pmatrix} t \\ x^1 \end{pmatrix}, \qquad \Lambda_\eta = \begin{pmatrix} \cosh\eta & \sinh\eta \\ \sinh\eta & \cosh\eta \end{pmatrix}, \qquad \eta \in \mathbb{R}, \tag{55.64}$$

maps W_R to itself: the boost slides points along the hyperbolae $(x^1)^2 - t^2 = \text{const} > 0$ that foliate the wedge, leaving the wedge invariant as a set. It is the unique continuous spacetime symmetry that does so while fixing the entangling plane Σ pointwise. This is the symmetry the modular Hamiltonian will turn out to implement.

We now write down ρ_A. The starting point, established in Section 55.2 and resting on the Euclidean preparation of the vacuum from Section 10.6, is the path-integral form of the vacuum density matrix. The Euclidean rotation $t \to -i\tau$ fixed in Section 10.6 sends Minkowski spacetime to $\mathbb{R}^d$ with coordinates $(\tau, x^1, \mathbf{x}_\perp)$ and weight e^{-S_E}; for the free scalar of ϕ^4 theory (Theorem 9.6) the Euclidean action is

$$S_E = \int \mathrm{d}\tau \, \mathrm{d}^{d-1}x \; \tfrac{1}{2}\big[(\partial_\tau\phi)^2 + (\partial_1\phi)^2 + (\nabla_\perp\phi)^2 + m^2\phi^2\big]. \tag{55.65}$$

The vacuum wavefunctional is the half-space path integral $\Psi_0[\varphi] = \langle\varphi|0\rangle = Z^{-1/2}\int_{\phi(\tau=0)=\varphi,\ \tau<0}\mathcal{D}\phi\, e^{-S_E}$, with Z the full-space partition function. The pure-state density matrix $\rho = |0\rangle\langle 0|$ then has matrix element $\langle\varphi_-|\rho|\varphi_+\rangle = \Psi_0[\varphi_-]\,\Psi_0^*[\varphi_+]$, the product of the lower-half-space integral ($\tau < 0$, with boundary value φ_- imposed as $\tau \to 0^-$) and the upper-half-space integral ($\tau > 0$, with boundary value φ_+ imposed as $\tau \to 0^+$). Joined, it is the path integral over *all* of $\mathbb{R}^d$ with a cut along the slice $\tau = 0$, the field tending to φ_- below the cut and to φ_+ above it. We follow exactly the bra/ket assignment of Section 55.2: the field just below the cut indexes the bra, the field just above indexes the ket.

To form $\rho_A = \mathrm{Tr}_B\,\rho$ we identify and integrate over the field on B. Concretely, on the complement region $x^1 < 0$ we set the two boundary values equal, $\varphi_-(\mathbf{x}) = \varphi_+(\mathbf{x})$ for $x^1 < 0$, and integrate freely; on A the two boundary values are left distinct as the surviving bra and ket indices. The effect is to *heal* the cut

everywhere on B — there the field is continuous across $\tau = 0$ and is simply integrated — while the cut survives only on A. Therefore

$$\left\langle \varphi_-^A \middle| \rho_A \middle| \varphi_+^A \right\rangle = \frac{1}{Z} \int_{\substack{\phi \to \varphi_-^A \text{ as } \tau \to 0^-,\, x^1 > 0 \\ \phi \to \varphi_+^A \text{ as } \tau \to 0^+,\, x^1 > 0}} \mathcal{D}\phi \; e^{-S_E}, \tag{55.66}$$

the path integral on $\mathbb{R}^d$ cut open only along the half-plane $\{\tau = 0,\ x^1 > 0\}$. Everything that follows is the evaluation of this object.

55.3.2 Polar coordinates and the angular evolution operator

The cut in Eq. (55.66) is the half-plane $\{\tau = 0,\, x^1 > 0\}$; it terminates on the entangling surface $\{\tau = 0,\, x^1 = 0\} = \Sigma$. The geometry begs for polar coordinates in the (τ, x^1) plane centered on Σ:

$$x^1 = r\cos\theta, \qquad \tau = r\sin\theta, \qquad r \geq 0, \quad \theta \in [0, 2\pi), \tag{55.67}$$

with $\mathbf{x}_\perp$ untouched. The flat measure is $\mathrm{d}\tau\, \mathrm{d}x^1 = r\, \mathrm{d}r\, \mathrm{d}\theta$, and the half-plane cut $\{\tau = 0,\, x^1 > 0\}$ sits at $\theta = 0$, approached from $\tau > 0$ as $\theta \to 0^+$ and from $\tau < 0$ as $\theta \to 2\pi^-$. The ket boundary value φ_+^A (imposed at $\tau \to 0^+$) is thus the field configuration at $\theta = 0$, and the bra boundary value φ_-^A (at $\tau \to 0^-$) is the configuration at $\theta = 2\pi$. The full plane is covered as θ runs from 0 to 2π.

Read this way, Eq. (55.66) is a Euclidean path integral with θ playing the role of time. It prepares the configuration φ_+^A at "time" $\theta = 0$, evolves it through a full angular sweep, and reads off the configuration φ_-^A at "time" $\theta = 2\pi$. By the transfer-matrix construction of the Euclidean path integral (Section 10.6), evolution through an angular interval $\Delta\theta$ is implemented by the operator $e^{-\Delta\theta\, H_R}$, where H_R, the generator of angular translations, is the *Rindler Hamiltonian*. A sweep through the full angle 2π therefore gives

$$\left\langle \varphi_-^A \middle| \rho_A \middle| \varphi_+^A \right\rangle = \frac{1}{Z} \left\langle \varphi_-^A \middle| e^{-2\pi H_R} \middle| \varphi_+^A \right\rangle, \qquad \text{i.e.} \qquad \rho_A = \frac{1}{Z}\, e^{-2\pi H_R}, \quad Z = \operatorname{Tr} e^{-2\pi H_R}, \tag{55.68}$$

where the normalization Z is fixed by $\operatorname{Tr}\rho_A = 1$. This is already the entire structural result: *the half-space reduced density matrix is a thermal state*, the Boltzmann weight $e^{-2\pi H_R}$ of the angular generator H_R at inverse "angular temperature" 2π. It remains to identify H_R as a physical, local operator, and then to translate "angular temperature 2π" into an honest temperature.

55.3.3 The Rindler Hamiltonian is the boost generator

The generator of angular translations in the Euclidean (τ, x^1) plane is, by construction, the Euclidean continuation of the generator of boosts in the Lorentzian (t, x^1) plane. The Euclidean rotation by angle θ in the (τ, x^1) plane becomes,

under the inverse Wick rotation $\tau \to it$, a hyperbolic rotation in the (t, x^1) plane: setting $\theta = -i\eta$ in $\left(\begin{smallmatrix}\cos\theta & -\sin\theta \\ \sin\theta & \cos\theta\end{smallmatrix}\right)$ and using $\cos(-i\eta) = \cosh\eta$, $\sin(-i\eta) = -i\sinh\eta$ reproduces exactly the boost matrix Λ_η of Eq. (55.64). Thus the angular generator H_R continues to the boost generator. We now make this identification quantitative by computing H_R directly from the action, and confirm that it equals the boost Noether charge of Chapter 7 restricted to the wedge.

Theorem 55.25 (Bisognano–Wichmann form of the half-space modular Hamiltonian)**.** *The reduced density matrix of the vacuum on the half-space $A = \{x^1 > 0\}$ is*

$$\rho_A = \frac{1}{Z}\, e^{-2\pi K_A}, \qquad K_A = \int_{x^1>0} \mathrm{d}^{d-1}x\; x^1\, T^{00}(0, \mathbf{x}), \tag{55.69}$$

where $T^{\mu\nu}$ is the stress tensor and K_A is the generator of the boost Eq. (55.64) restricted to the wedge W_R — a positive, local operator built from the energy density weighted by the distance x^1 to the entangling surface. Equivalently the modular Hamiltonian is $-\log\rho_A = 2\pi K_A + \log Z$.

The proof has two halves. First we exhibit H_R of Eq. (55.68) as the integral K_A written above, by reading off the Hamiltonian of the polar-coordinate action; this is done explicitly for the free scalar of ϕ^4 theory in the worked example below, and the construction is manifestly local and field-content-independent in form. Second we recognize K_A as the boost charge. The Lorentz Noether current of Eq. (7.107) has charges $M^{0\nu\rho} = \int \mathrm{d}^{d-1}x\,(x^\nu T^{0\rho} - x^\rho T^{0\nu})$ (the spin part vanishes for a scalar); the boost in the x^1 direction is generated by $M^{01} = \int \mathrm{d}^{d-1}x\,(x^0 T^{01} - x^1 T^{00})$, which at $t = x^0 = 0$ reduces to $-\int \mathrm{d}^{d-1}x\, x^1 T^{00}$. The combination appearing in Eq. (55.69) is exactly (minus) this charge with the spatial integral truncated to the wedge $x^1 > 0$, the orientation chosen so that K_A is the *positive* generator whose flow pushes points into the future of W_R along the hyperbolae of Eq. (55.64). The truncation is legitimate because the boost flow maps W_R to itself: the generator of a symmetry of the wedge is well-defined as an operator on the wedge degrees of freedom alone. Positivity of K_A — which is what makes $e^{-2\pi K_A}$ a sensible, trace-class density matrix with eigenvalues in $(0, 1]$ — is the statement that the boost energy in the wedge is bounded below, the wedge analogue of the spectrum condition. We now supply the first half explicitly.

Worked Example 55.26 (The Rindler Hamiltonian of the free scalar from the polar action)**.** Take the free scalar of ϕ^4 theory (Theorem 9.6) with Euclidean action Eq. (55.65). Rewrite the (τ, x^1) kinetic terms in the polar coordinates Eq. (55.67). Using $\partial_\tau = \sin\theta\,\partial_r + \frac{\cos\theta}{r}\partial_\theta$ and $\partial_1 = \cos\theta\,\partial_r - \frac{\sin\theta}{r}\partial_\theta$, the cross terms cancel and one finds the rotationally invariant combination

$$(\partial_\tau\phi)^2 + (\partial_1\phi)^2 = (\partial_r\phi)^2 + \frac{1}{r^2}(\partial_\theta\phi)^2, \tag{55.70}$$

so that, with measure $\mathrm{d}\tau\,\mathrm{d}x^1 = r\,\mathrm{d}r\,\mathrm{d}\theta$,

$$S_E = \int_0^{2\pi}\mathrm{d}\theta \int_0^{\infty} r\,\mathrm{d}r \int \mathrm{d}^{d-2}x_\perp\; \frac{1}{2}\Big[(\partial_r\phi)^2 + \frac{1}{r^2}(\partial_\theta\phi)^2 + (\nabla_\perp\phi)^2 + m^2\phi^2\Big]. \tag{55.71}$$

Treat θ as Euclidean time. The Lagrangian (the coefficient of $\mathrm{d}\theta$) splits into a θ-kinetic piece and a θ-independent "potential",

$$L = \frac{1}{2}\int_0^\infty \mathrm{d}r \int \mathrm{d}^{d-2}x_\perp \, \frac{1}{r}(\partial_\theta\phi)^2 + V[\phi], \qquad V[\phi] = \int_0^\infty \mathrm{d}r \int \mathrm{d}^{d-2}x_\perp \, \frac{r}{2}\Big[(\partial_r\phi)^2 + (\nabla_\perp\phi)^2 + m^2$$

(55.72)

The momentum conjugate to $\phi(r, \mathbf{x}_\perp)$, defined with respect to the slice measure $\mathrm{d}r\,\mathrm{d}^{d-2}x_\perp$, is

$$\pi(r, \mathbf{x}_\perp) = \frac{\partial}{\partial(\partial_\theta\phi)}\Big[\tfrac{1}{2r}(\partial_\theta\phi)^2\Big] = \frac{1}{r}\,\partial_\theta\phi. \tag{55.73}$$

We must now pass from L to the operator H_R that generates the imaginary-time (angular) evolution $e^{-\Delta\theta\, H_R}$. This is *not* the naive Legendre transform $\int \pi\,\partial_\theta\phi - L$, which in Euclidean signature would flip the sign of V and produce an indefinite operator; rather it is the positive transfer-matrix Hamiltonian, obtained as follows. For a Euclidean action of the standard form $S_E = \int \mathrm{d}\theta\,[\frac{1}{2}\int_x \mathcal{G}\,(\partial_\theta\phi)^2 + V[\phi]]$ with $\mathcal{G}(r) = 1/r$ here, discretizing θ in steps ϵ gives the kernel

$$\Big\langle \phi' \Big| e^{-\epsilon H_R} \Big| \phi \Big\rangle \;\propto\; \exp\Big(-\epsilon\Big[\tfrac{1}{2}\int_x \mathcal{G}\,\Big(\tfrac{\phi'-\phi}{\epsilon}\Big)^2 + V[\phi]\Big]\Big), \tag{55.74}$$

and a Gaussian (Hubbard–Stratonovich) rewriting of the kinetic factor in terms of the conjugate momentum $\pi = \mathcal{G}\,\partial_\theta\phi$ identifies this, as $\epsilon \to 0$, as the matrix element of $\exp(-\epsilon H_R)$ with

$$H_R = \int_x \frac{1}{2\mathcal{G}}\,\pi^2 + V[\phi] = \int_0^\infty \mathrm{d}r \int \mathrm{d}^{d-2}x_\perp \, \frac{r}{2}\Big[\pi^2 + (\partial_r\phi)^2 + (\nabla_\perp\phi)^2 + m^2\phi^2\Big]. \tag{55.75}$$

The crucial feature is the uniform *plus* sign between the momentum term $\frac{r}{2}\pi^2 = \frac{1}{2r}(\partial_\theta\phi)^2$ and the spatial gradient terms: H_R is manifestly positive, an integral of (energy density)$\times r$ over the half-line $r > 0$. This positivity is exactly what the naive Legendre transform would have spoiled, and it is what makes $e^{-2\pi H_R}$ a legitimate density matrix.

Now evaluate Eq. (55.75) on the ket slice $\theta = 0$, i.e. $\tau = 0$, $x^1 = r > 0$, and continue back to Lorentzian signature. There the canonical momentum of the Minkowski field is $\pi_t = \partial_t\phi$, which under $t \to -i\tau$ and the polar substitution Eq. (55.67) becomes $\pi = r^{-1}\partial_\theta\phi$ at $\theta = 0$, while $\partial_r\phi = \partial_1\phi$ at $\theta = 0$. The bracket in Eq. (55.75) is then exactly twice the free-scalar energy density,

$$T^{00} = \tfrac{1}{2}\big[\pi_t^2 + (\partial_1\phi)^2 + (\nabla_\perp\phi)^2 + m^2\phi^2\big], \tag{55.76}$$

the canonical stress tensor of Theorem 7.25 evaluated at $t = 0$. With $r = x^1$ the measure $r\,\mathrm{d}r\,\mathrm{d}^{d-2}x_\perp$ becomes $x^1\,\mathrm{d}^{d-1}x$, so

$$H_R = \int_{x^1>0} \mathrm{d}^{d-1}x\; x^1\, T^{00}(0, \mathbf{x}) = K_A, \tag{55.77}$$

which is Eq. (55.69). The computation used nothing special to the free field beyond the form of T^{00}; for an interacting theory the same transfer-matrix construction produces $\int x^1\, T^{00}$ with the full interacting energy density, which is the content of the general Bisognano–Wichmann theorem.

Physical Insight

The modular Hamiltonian of a half-space is *local* — an integral of the local energy density — which is the exception, not the rule. For almost any other region (two intervals, a ball in a non-conformal theory, anything at finite temperature) $-\log \rho_A$ is a complicated nonlocal operator. The half-space is special because its causal wedge is preserved by a spacetime symmetry, the boost, and a symmetry generator is automatically the integral of a local current. Chapter 47's conformal symmetry buys one more solvable case — the ball, mapped to the Rindler wedge by a special conformal transformation — which Section 55.6 will exploit. Everywhere else, locality of the modular Hamiltonian is lost.

55.3.4 The Unruh temperature

The factor 2π in Eq. (55.68) is dimensionless and refers to the boost rapidity, which is not directly a physical observer's clock. To extract a temperature we must ask what flow a real observer's proper time generates. Introduce *Rindler coordinates* adapted to the wedge,

$$t = \xi \sinh \eta, \qquad x^1 = \xi \cosh \eta, \qquad \xi > 0,\ \eta \in \mathbb{R}, \tag{55.78}$$

which cover exactly W_R (since $x^1 > |t| \iff \xi > 0$). A curve of constant ξ is the hyperbola $(x^1)^2 - t^2 = \xi^2$; the boost Eq. (55.64) acts as the pure translation $\eta \to \eta + \eta_0$. The Minkowski line element becomes

$$\mathrm{d}s^2 = \mathrm{d}t^2 - (\mathrm{d}x^1)^2 - \mathrm{d}\mathbf{x}_\perp^2 = \xi^2\, \mathrm{d}\eta^2 - \mathrm{d}\xi^2 - \mathrm{d}\mathbf{x}_\perp^2, \tag{55.79}$$

read off from $\mathrm{d}t = \sinh\eta\, \mathrm{d}\xi + \xi \cosh\eta\, \mathrm{d}\eta$ and $\mathrm{d}x^1 = \cosh\eta\, \mathrm{d}\xi + \xi \sinh\eta\, \mathrm{d}\eta$, whose squares combine as $\mathrm{d}t^2 - (\mathrm{d}x^1)^2 = -\mathrm{d}\xi^2 + \xi^2 \mathrm{d}\eta^2$. An observer sitting at fixed ξ and $\mathbf{x}_\perp$ has $\mathrm{d}s^2 = \xi^2 \mathrm{d}\eta^2$, so his proper time is $s = \xi\, \eta$, and differentiating the worldline $x^\mu(s) = (\xi \sinh(s/\xi),\, \xi \cosh(s/\xi),\, \mathbf{x}_\perp)$ twice gives the four-acceleration $a^\mu = \ddot{x}^\mu$ with $a^\mu a_\mu = -1/\xi^2$, i.e. proper acceleration

$$a = \frac{1}{\xi}. \tag{55.80}$$

Thus the worldline at $\xi = 1/a$ is the trajectory of a uniformly accelerated observer with proper acceleration a; Fig. 55.3 shows it.

The boost generator K_A generates translations in the rapidity η. The observer's clock measures proper time $s = \eta/a$ along his worldline, so his proper-time Hamiltonian — the generator of s-translations along the trajectory — is

$$H_{\text{proper}} = \frac{\partial \eta}{\partial s} K_A = a\, K_A. \tag{55.81}$$

Rewriting the thermal density matrix Eq. (55.69) in terms of this physical Hamiltonian,

$$\rho_A = \frac{1}{Z} e^{-2\pi K_A} = \frac{1}{Z} e^{-(2\pi/a)\, H_{\text{proper}}} \equiv \frac{1}{Z} e^{-\beta H_{\text{proper}}}, \qquad \beta = \frac{2\pi}{a}. \tag{55.82}$$

The accelerated observer therefore perceives the vacuum as a thermal ensemble at temperature

$$\boxed{T_{\text{U}} = \frac{1}{\beta} = \frac{a}{2\pi}} \tag{55.83}$$

the *Unruh temperature*. The Minkowski vacuum, manifestly the zero-temperature ground state to an inertial observer, looks hot to an accelerated one — because the accelerated observer has access only to the wedge W_R, and the restriction of the global pure state to that wedge is the mixed, thermal state Eq. (55.82). The factor 2π that began life as the angle of a full Euclidean rotation has become the inverse temperature in units of the acceleration.

Worked Example 55.27 (Unruh temperature from Euclidean smoothness)**.** The temperature Eq. (55.83) can be obtained a second way, from the requirement that the Euclidean continuation of Rindler space be smooth — a derivation that exposes why the period is exactly 2π and not some other number. Wick-rotate the Rindler time, $\eta \to -i\theta$ (equivalently $t \to -i\tau$ with $\tau = \xi \sin\theta$, $x^1 = \xi\cos\theta$, recovering Eq. (55.67) with $r = \xi$). Under $\eta = -i\theta$ the Lorentzian Rindler metric Eq. (55.79) becomes the Euclidean

$$\mathrm{d}s_E^2 = \xi^2\, \mathrm{d}\theta^2 + \mathrm{d}\xi^2 + \mathrm{d}\mathbf{x}_\perp^2. \tag{55.84}$$

In the (ξ, θ) plane this is the flat plane in polar coordinates, with ξ the radius and θ the polar angle. A flat plane written in polar coordinates is smooth at the origin $\xi = 0$ *only if* θ is periodic with period exactly 2π: any other period $\theta \sim \theta + \beta_\theta$ produces a cone of deficit (or excess) angle $2\pi - \beta_\theta$, with a curvature singularity — a conical defect — concentrated on Σ at $\xi = 0$. The Minkowski vacuum is the smooth, defect-free state, so its Euclidean continuation forces

$$\theta \sim \theta + 2\pi. \tag{55.85}$$

Periodicity in Euclidean time is the hallmark of a thermal state, as the Gibbs computation Eq. (55.92) below makes precise: a Gibbs weight $e^{-\beta H}$ is reproduced by evolution through an imaginary-time interval β, so equilibrium at inverse

temperature β is the same statement as periodicity β in Euclidean time. Here the clock is the observer's proper time, whose Euclidean version is $s_E = \xi\,\theta$ at fixed ξ; its period is $\beta = \xi \cdot 2\pi = 2\pi/a$, reproducing Eq. (55.83). The two derivations agree because they are the same statement read in two directions: the angular period 2π of the path integral *is* the inverse temperature in rapidity units, and smoothness at the entangling surface is what fixes it.

Restoring dimensions once for a physical estimate (reinstating $\hbar, c, k_B$ by dimensional analysis: $k_B T$ carries energy, a carries length/time^2, and the only combination with the right dimensions is $\hbar a/c$),

$$k_B T_{\mathrm{U}} = \frac{\hbar\, a}{2\pi c}. \tag{55.86}$$

The number is minuscule: an acceleration of $a = 10^{20}\,\mathrm{m/s^2}$ — ten orders of magnitude beyond what any laboratory sustains — yields $T_{\mathrm{U}} \sim 0.4\,\mathrm{K}$. The Unruh effect is real but, for terrestrial accelerations, utterly unobservable; its importance is conceptual and structural, and it is the flat-space shadow of Hawking radiation (Chapter 65), to which it is locally identical near a black-hole horizon.

Historical Note

Bisognano and Wichmann established in 1975–76, from the Wightman axioms alone, that the modular automorphism of the vacuum for a wedge algebra is exactly the boost — the rigorous, interaction-independent version of Theorem 55.25. Unruh's 1976 analysis of a uniformly accelerated detector, and Davies' related work, independently uncovered the temperature Eq. (55.83); Fulling had noted the inequivalent Rindler quantization a few years earlier. That the algebraic statement (Bisognano–Wichmann) and the physical one (Unruh) are the same fact is the lesson of this section.

55.3.5 The modular Hamiltonian, modular flow, and the KMS condition

The Rindler computation is the cleanest instance of structures that organize entanglement in *any* state and region, and we now name them in general, with the half-space as the worked model.

Definition 55.28 (Modular Hamiltonian and modular flow)**.** For a reduced density matrix ρ_A with full support, the *modular Hamiltonian* (or entanglement Hamiltonian) is the self-adjoint operator

$$K_{\mathrm{mod}} \equiv -\log \rho_A, \qquad \text{so that} \quad \rho_A = e^{-K_{\mathrm{mod}}}. \tag{55.87}$$

The associated *modular flow* is the one-parameter group of automorphisms of the operator algebra of A,

$$\sigma_s(\mathcal{O}) \equiv \rho_A^{is}\, \mathcal{O}\, \rho_A^{-is} = e^{-iK_{\mathrm{mod}} s}\, \mathcal{O}\, e^{iK_{\mathrm{mod}} s}, \qquad s \in \mathbb{R}. \tag{55.88}$$

For the half-space, Theorem 55.25 gives $K_{\mathrm{mod}} = 2\pi K_A + \log Z$, so modular flow is generated by $2\pi K_A$, i.e. by a boost of rapidity $2\pi s$:

$$\sigma_s(\mathcal{O}(x)) = \mathcal{O}(\Lambda_{2\pi s}\, x), \tag{55.89}$$

with Λ_η the boost Eq. (55.64). This is the remarkable feature of the Rindler case: *modular flow is geometric*, a literal Lorentz boost sliding operators along the wedge hyperbolae. In general σ_s is an abstract, state- and region-dependent symmetry with no spacetime interpretation; the entanglement structure of the half-space vacuum endows it, exceptionally, with one. (The Reeh–Schlieder property guarantees the cyclic and separating vector that makes K_{mod} well-defined; we use this without full proof.)

Thermality is captured intrinsically, without any explicit reference to a temperature or even a Hamiltonian, by the KMS condition. Its value is that it characterizes equilibrium purely through analyticity of correlation functions in complexified time — exactly the structure a Euclidean path integral on a time circle produces.

Definition 55.29 (KMS condition)**.** A state ω on an algebra of observables satisfies the *Kubo–Martin–Schwinger (KMS) condition* at inverse temperature β with respect to a flow α_s (a one-parameter automorphism group) if, for all observables $\mathcal{O}_1, \mathcal{O}_2$, the correlation function

$$F(s) \equiv \omega(\mathcal{O}_1\, \alpha_s(\mathcal{O}_2)) \tag{55.90}$$

extends to a function holomorphic in the strip $\{\, s \in \mathbb{C} : 0 < \operatorname{Im} s < \beta \,\}$, continuous on its closure, with boundary values related by

$$F(s + i\beta) = \omega(\alpha_s(\mathcal{O}_2)\, \mathcal{O}_1). \tag{55.91}$$

That a Gibbs state $\omega(\cdot) = \operatorname{Tr}(e^{-\beta H}\,\cdot)/\operatorname{Tr} e^{-\beta H}$ satisfies Eq. (55.91) with $\alpha_s(\mathcal{O}) = e^{iHs}\mathcal{O}e^{-iHs}$ is a one-line computation: inserting the trace and using cyclicity,

$$F(s+i\beta) = \frac{\operatorname{Tr}\left(e^{-\beta H}\mathcal{O}_1 e^{iH(s+i\beta)}\mathcal{O}_2 e^{-iH(s+i\beta)}\right)}{\operatorname{Tr} e^{-\beta H}} = \frac{\operatorname{Tr}\left(e^{iHs}\mathcal{O}_2 e^{-iHs}\, e^{-\beta H}\mathcal{O}_1\right)}{\operatorname{Tr} e^{-\beta H}} = \omega(\alpha_s(\mathcal{O}_2)\mathcal{O}_1 \tag{55.92}$$

where the middle step moved $e^{-\beta H}$ around the trace and recombined the exponentials. The strip analyticity is the statement that $e^{-\beta H}$ damps the high-energy contributions, making the continuation to $\operatorname{Im} s = \beta$ convergent. The content of Theorem 55.25 is then summarized in one line:

Theorem 55.30 (The wedge vacuum is KMS)**.** *The Minkowski vacuum, restricted to the right Rindler wedge algebra, satisfies the KMS condition at inverse temperature $\beta = 2\pi$ with respect to the boost flow $\eta \mapsto \eta + \eta_0$ (equivalently $\beta = 1$ with respect to the modular flow Eq. (55.88), and $\beta = 2\pi/a$ with respect to the proper-time flow of an observer at acceleration a).*

Proof sketch. By Eq. (55.68), the wedge state is the Gibbs state of $H_R = K_A$ at inverse temperature 2π. Applying the Gibbs computation Eq. (55.92) with $H = K_A$ and $\beta = 2\pi$ gives Eq. (55.91) directly; the required strip analyticity is the statement that wedge correlation functions of the vacuum continue to the Euclidean angle $\theta \in [0, 2\pi]$, which is exactly the angular path integral Eq. (55.71) that defines ρ_A. The rescalings to modular and proper-time flow follow from $K_{\text{mod}} = 2\pi K_A$ and $H_{\text{proper}} = aK_A$ respectively. □

Caution

A genuine subtlety, flagged in the chapter's opening and honored throughout: the algebra of observables localized in a Rindler wedge (or any region with a sharp boundary) in continuum QFT is a *von Neumann algebra of type* III_1. Such an algebra admits *no* pure states and *no* trace, so the manipulations of this section — writing $\rho_A = e^{-2\pi K_A}/Z$, taking $\operatorname{Tr} \rho_A = 1$, defining $S_A = -\operatorname{Tr} \rho_A \log \rho_A$ — are, strictly, not defined in the continuum. What *is* rigorously defined is the modular operator Δ_A and its flow, supplied by the Tomita–Takesaki theory of a cyclic separating vector; the Bisognano–Wichmann theorem is properly the statement that Δ_A^{is} acts as the boost, with no ρ_A ever written down. The density-matrix language we use is the correct *regulated* picture: introduce a short-distance cutoff (a lattice, or a smearing of the entangling surface), which makes the algebra type I, ρ_A an honest density matrix, and S_A finite; physical, cutoff-independent quantities (relative entropy, mutual information) then have well-defined continuum limits even though S_A itself diverges. We compute with ρ_A as the regulated object and report only quantities that survive the limit. The rigorous backbone — Tomita–Takesaki modular theory and the type-III classification of local algebras — is deferred to the further reading; the present section's results are all recoverable within it.

55.3.6 Vacuum entanglement entropy as thermal entropy and the area law

With ρ_A thermal, its entanglement entropy is a thermal entropy, and we can read off its structure directly. From Eq. (55.68), $-\log \rho_A = 2\pi K_A + \log Z$, so

$$S_A = -\operatorname{Tr}(\rho_A \log \rho_A) = 2\pi \langle K_A \rangle + \log Z, \tag{55.93}$$

where $\langle K_A \rangle = \operatorname{Tr}(\rho_A K_A)$ is the modular energy. Setting $Z(\beta) = \operatorname{Tr} e^{-\beta K_A}$ and $\langle K_A \rangle = -\partial_\beta \log Z$, this is the textbook thermodynamic identity $S = (1 - \beta\partial_\beta) \log Z$ evaluated at $\beta = 2\pi$: the vacuum entanglement entropy of the half-space is, identically, the equilibrium entropy of the Rindler thermal gas. This identification is the deepest reason the entanglement entropy obeys an area law,

and we now extract that law from the thermal picture — the explicit content of the Rindler case that Section 55.5 will systematize.

The key is that the temperature is not uniform across the wedge: an observer hovering at proper distance ρ_* from the entangling surface (i.e. at $\xi = \rho_*$, by Eq. (55.84)) has proper acceleration $a = 1/\rho_*$ and therefore sees a *local* Unruh temperature

$$T_{\rm loc}(\rho_*) = \frac{a}{2\pi} = \frac{1}{2\pi\rho_*}. \tag{55.94}$$

The temperature diverges as $\rho_* \to 0$: the modes that pile up against the entangling surface are arbitrarily hot, and they are the origin of the divergence. Treat the entanglement entropy as the entropy of a local thermal gas integrated over the wedge. The entropy density of a relativistic gas in d spacetime dimensions scales by dimensional analysis as $s \sim T^{d-1}$ (the Stefan–Boltzmann law; the proportionality constant counts the field's degrees of freedom and is computed in full in Section 55.5). The proper volume element a fixed transverse distance from Σ is $\mathrm{d}V = \mathcal{A}_\perp \, \mathrm{d}\rho_*$, with $\mathcal{A}_\perp$ the transverse area of the entangling surface. Hence

$$S_A \;\sim\; \int \mathrm{d}V \, s(T_{\rm loc}) \;\sim\; \mathcal{A}_\perp \int_\epsilon^L \mathrm{d}\rho_* \left(\frac{1}{2\pi\rho_*}\right)^{d-1} \;\sim\; \mathcal{A}_\perp \int_\epsilon \frac{\mathrm{d}\rho_*}{\rho_*^{\,d-1}}, \tag{55.95}$$

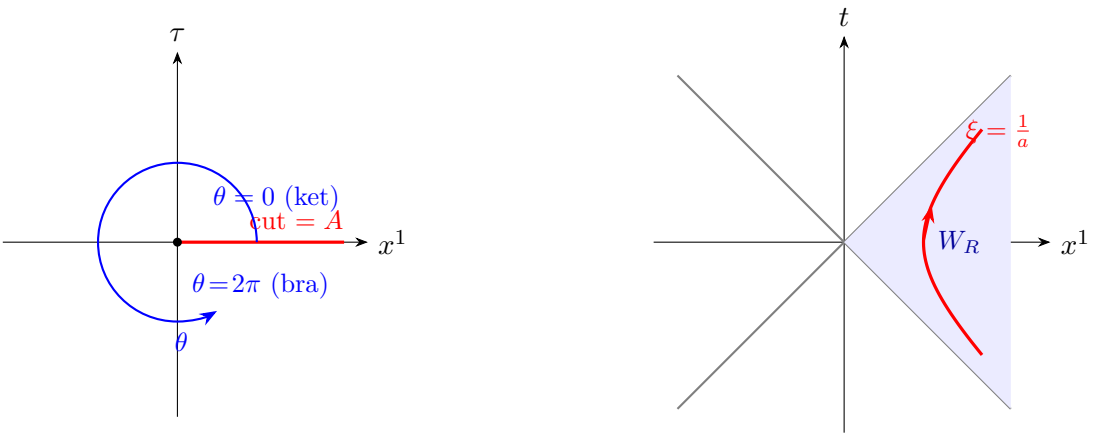
where ϵ is a short-distance (UV) cutoff on the proper distance to the surface — the regulator the previous Caution insisted on — and L an IR scale that does not affect the leading divergence. For $d > 2$ the integral is dominated by its lower limit,

$$S_A \;\sim\; \frac{\mathcal{A}_\perp}{(d-2)\,\epsilon^{\,d-2}} + \cdots, \tag{55.96}$$

the celebrated *area law*: the leading UV divergence of the vacuum entanglement entropy is proportional to the area $\mathcal{A}_\perp$ of the entangling surface, not to the volume of A, and is power-law divergent in the cutoff with the coefficient set by the density of fields. For $d = 2$ the transverse "area" is a single point ($\mathcal{A}_\perp = 1$) and the integral $\int \mathrm{d}\rho_*/\rho_*$ is *logarithmic*, $S_A \sim \log(L/\epsilon)$ — precisely the $\frac{c}{3}\log(\ell/\epsilon)$ behavior that Section 55.4 computes exactly from the central charge. The area law and the 2D logarithm are thus one phenomenon, the divergence of the near-surface Rindler modes, seen in different dimensions; both are visible already in this thermal reading of the half-space vacuum.

Physical Insight

The area law has a one-sentence physical cause: entanglement entropy counts the short-wavelength correlations straddling the entangling surface, and there are a fixed number of them per unit area per unit cutoff cell. The thermal derivation makes this quantitative — the divergence is the infinite local temperature Eq. (55.94) of the modes hugging the surface — and explains why the leading term is non-universal (cutoff-dependent)



(a) Euclidean: $\rho_A = Z^{-1} e^{-2\pi H_R}$

(b) Lorentzian: accelerated worldline

Figure 55.3: The half-space vacuum. **(a)** In Euclidean signature the matrix element Eq. (55.66) is the path integral on $\mathbb{R}^d$ cut along the half-plane $A = \{\tau = 0, x^1 > 0\}$ (red). In polar coordinates Eq. (55.67) the ket lip sits at $\theta = 0$ and the bra lip at $\theta = 2\pi$; a full angular sweep generates $\rho_A = Z^{-1} e^{-2\pi H_R}$. **(b)** In Lorentzian signature the same region is the right Rindler wedge W_R (shaded), preserved by the boost Eq. (55.64). A uniformly accelerated observer follows the hyperbola $\xi = 1/a$ (red); the boost flow slides operators along it, and is the geometric form Eq. (55.89) of modular flow.

while the geometry, the proportionality to $\mathcal{A}_\perp$, is robust. It is also why the physically clean diagnostics are *differences* of entropies, where the $\mathcal{A}_\perp/\epsilon^{d-2}$ cancels.

We close by collecting what is now in hand for the rest of the chapter. The half-space has given us, exactly and explicitly, the modular Hamiltonian $K_{\text{mod}} = -\log \rho_A = 2\pi K_A$ as the local boost generator Eq. (55.69), the modular flow ρ_A^{is} realized as a geometric Lorentz boost Eq. (55.89), and the temperature/KMS language Theorems 55.29 and 55.30 that recasts vacuum entanglement as thermality. Section 55.4 will find that its exact two-dimensional single-interval entropy is the thermal specialization of Eq. (55.93) on the cylinder, and the finite-temperature formula there is this Rindler thermality made global; Section 55.5 will turn the heuristic Eq. (55.96) into a controlled statement; and Section 55.6 will use precisely the modular-Hamiltonian and KMS structure assembled here to define relative entropy and prove the first law of entanglement, the inputs on which the holographic constructions of Chapters 56 and 57 ultimately rest.

55.4 Entanglement Entropy in Two-Dimensional CFT

The replica trick of Section 55.2 reduced the entanglement entropy of a spatial region to a partition function on an n-sheeted branched cover of the Euclidean plane (Section 55.2.3), and the orbifold reformulation of Section 55.2.5 repackaged that geometry, for a region A that is a single interval $[u, v]$, as a two-point function of *twist operators* in the n-fold replicated theory (Theorem 55.22),

$$\operatorname{Tr} \rho_A^n \;=\; \big\langle\, \sigma_n(u)\, \tilde{\sigma}_n(v) \,\big\rangle_{\mathcal{C}^{\otimes n}}, \tag{55.97}$$

with the conformal dimension of σ_n left undetermined at that stage. The thermal reading of the vacuum from Section 55.3 — that tracing out a region exposes a temperature — told us that finite temperature and finite size are not optional refinements but the natural arena in which an entropy lives. This section discharges both promissory notes at once. We compute the twist-operator dimension exactly, from the conformal anomaly, fixing the right-hand side of Eq. (55.97) completely by symmetry; we take the replica limit $n \to 1$ to obtain the single-interval vacuum entanglement entropy

$$S_A \;=\; \frac{c}{3}\, \log \frac{\ell}{\epsilon} + \text{const}, \tag{55.98}$$

the flagship result of the chapter; and we deform the plane to a cylinder and to a thermal cylinder by two explicit conformal maps, converting the bare logarithm into its finite-size and finite-temperature cousins. The single number c — the central charge of Theorem 48.8 — governs all of it. We will see that this is no accident: the coefficient $c/3$ is a renormalization-group diagnostic, and for the Ising universality class it carries the value $c = \frac{1}{2}$ that closes ϕ^4 theory on the entanglement side.

Throughout we work in Euclidean signature with complex coordinate $z = x + \mathrm{i}\tau$ (the Wick rotation $t \to -\mathrm{i}\tau$ fixed in Chapter 10), antiholomorphic partner $\bar{z}$, and we use the holomorphic factorization of two-dimensional CFT established in Chapter 48: every local primary carries a pair of weights $(h, \bar{h})$, its scaling dimension is $\Delta = h + \bar{h}$, and the holomorphic and antiholomorphic sectors contribute independently. For a parity-symmetric theory built from a local action, $c = \bar{c}$, and the twist operator will turn out to be spinless, $h_n = \bar{h}_n$.

55.4.1 The replica surface and the twist operator, recalled

We restate the geometric input precisely so the present computation is self-contained. Let $A = [u, v]$ be a single interval on the time slice $\tau = 0$ of the infinite line, of length $\ell = v - u$. The reduced density matrix ρ_A is prepared by the Euclidean path integral over the plane with a cut along A, the field values above and below the cut serving as the row and column indices of ρ_A

(Section 55.2.2). Its n-th power ρ_A^n sews n copies of the cut plane cyclically: the field above the cut on sheet j is identified with the field below the cut on sheet $j+1$, and sheet n closes back onto sheet 1. The trace identifies the last with the first, producing a single connected Riemann surface $\mathcal{R}_n$, an n-sheeted cover of the plane branched over the two endpoints u and v. Then

$$\operatorname{Tr}\rho_A^n \;=\; \frac{Z_n}{Z_1^n}, \qquad Z_n = Z[\mathcal{R}_n], \tag{55.99}$$

the normalization Z_1^n (with Z_1 the plane partition function) enforcing $\operatorname{Tr}\rho_A = 1$. At $n=1$ the single sheet is the plane, σ_1 is the identity operator, and $\operatorname{Tr}\rho_A^1 = \langle \mathbf{1}\rangle = 1$; this fixes the $n=1$ value of the non-universal normalization constant c_n introduced below to $c_1 = 1$.

The twist-operator formulation trades the multivalued geometry of $\mathcal{R}_n$ for ordinary correlators on a single plane in the *replicated* theory $\mathcal{C}^{\otimes n}$, whose fields are n-tuples $\Phi = (\phi_1, \dots, \phi_n)$ and whose stress tensor is the sum $T^{(n)} = \sum_{j=1}^{n} T_j$ over the copies, so its central charge is nc. The branch structure of $\mathcal{R}_n$ is encoded by a $\mathbb{Z}_n$ symmetry of $\mathcal{C}^{\otimes n}$, cyclic permutation $\phi_j \mapsto \phi_{j+1}$ of the replicas. The branch point at u is the place where, on encircling it, the field on sheet j continues onto sheet $j+1$; in the replicated theory this is precisely a disorder (twist) operator $\sigma_n(u)$ implementing the cyclic shift, with $\tilde\sigma_n(v)$ the inverse twist closing the monodromy. Theorem 55.22 established Eq. (55.97) on these grounds. The twist operators are local, $\mathbb{Z}_n$-covariant primaries of the replicated theory; conformal symmetry fixes their two-point function up to a constant once their dimension is known, and the entire physics of the single interval is therefore carried by one number, h_n. We now compute it.

55.4.2 The dimension of the twist operator from the conformal anomaly

The dimension h_n is read off by comparing two expressions for the same object: the expectation value of the stress tensor on the replica surface $\mathcal{R}_n$, computed by uniformizing $\mathcal{R}_n$ to the plane, against the conformal Ward identity for $\langle T^{(n)}\,\sigma_n\,\tilde\sigma_n\rangle$, which is fixed by the twist dimension. Matching the two determines h_n.

The uniformizing map. The surface $\mathcal{R}_n$ is branched over u and v, and away from those points it is locally flat. There is a single-valued holomorphic map that unwraps it onto the plane. Consider

$$w \;=\; \left(\frac{z-u}{z-v}\right)^{1/n}. \tag{55.100}$$

The factor inside is the Möbius transformation that sends the two branch points to 0 and ∞: $z = u \mapsto 0$, $z = v \mapsto \infty$. Taking the n-th root then unwinds

the cyclic monodromy. To see this, encircle u once on the cover: the Möbius image $\zeta = (z-u)/(z-v)$ winds once around the origin, $\zeta \to e^{2\pi \mathrm{i}}\zeta$, while $w = \zeta^{1/n} \to e^{2\pi \mathrm{i}/n} w$ advances by a single replica, exactly the action of σ_n. Going around all n sheets, ζ winds n times and w returns to itself: the n sheets of $\mathcal{R}_n$ are mapped one-to-one onto a single copy of the w-plane. The map Eq. (55.100) is the conformal uniformization of the replica surface, and on the w-plane the theory is just the vacuum, for which $\langle T(w)\rangle_{w\text{-plane}} = 0$.

The stress tensor on $\mathcal{R}_n$. The stress tensor of a single copy transforms under a holomorphic map $z \mapsto w(z)$ by the anomalous (Schwarzian) law derived in Eq. (48.63),

$$T'(w) = \Big(\frac{\mathrm{d}w}{\mathrm{d}z}\Big)^{-2}\Big[T(z) - \frac{c}{12}\,\{w,z\}\Big], \qquad \{w,z\} = \frac{w'''}{w'} - \frac{3}{2}\Big(\frac{w''}{w'}\Big)^2, \tag{55.101}$$

the Schwarzian derivative of Eq. (48.62). Inverting to express the stress tensor on $\mathcal{R}_n$ (coordinate z) in terms of the plane (coordinate w),

$$T(z) = \Big(\frac{\mathrm{d}w}{\mathrm{d}z}\Big)^2 T'(w) + \frac{c}{12}\,\{w,z\}, \tag{55.102}$$

and taking the expectation value in the state defined on $\mathcal{R}_n$, which is the vacuum on the uniformized w-plane,

$$\langle T(z)\rangle_{\mathcal{R}_n} = \Big(\frac{\mathrm{d}w}{\mathrm{d}z}\Big)^2 \underbrace{\langle T'(w)\rangle_{w\text{-plane}}}_{=0} + \frac{c}{12}\,\{w,z\} = \frac{c}{12}\,\{w,z\}. \tag{55.103}$$

Only the anomaly survives. The central charge has converted a pure coordinate change into a physical, nonzero stress-tensor profile — the same mechanism that produces the Casimir energy on a cylinder (Chapter 48).

Computing the Schwarzian. We evaluate $\{w,z\}$ for the map Eq. (55.100) using the cocycle identity Eq. (48.66). Write $w = \zeta^{1/n}$ with $\zeta = (z-u)/(z-v)$. Because $\zeta(z)$ is Möbius, $\{\zeta, z\} = 0$, so the cocycle rule gives

$$\{w,z\} = \Big(\frac{\mathrm{d}\zeta}{\mathrm{d}z}\Big)^2 \{w,\zeta\} + \{\zeta,z\} = \Big(\frac{\mathrm{d}\zeta}{\mathrm{d}z}\Big)^2 \{w,\zeta\}. \tag{55.104}$$

For the pure power $w = \zeta^{1/n}$, with $a \equiv 1/n$,

$$w' = a\,\zeta^{a-1}, \quad w'' = a(a-1)\zeta^{a-2}, \quad w''' = a(a-1)(a-2)\zeta^{a-3}, \tag{55.105}$$

so

$$\{w,\zeta\} = \frac{w'''}{w'} - \frac{3}{2}\Big(\frac{w''}{w'}\Big)^2 = (a-1)(a-2)\zeta^{-2} - \frac{3}{2}\,(a-1)^2\zeta^{-2}$$

$$= \zeta^{-2}(a-1)\Big[(a-2)-\tfrac{3}{2}(a-1)\Big] = \zeta^{-2}(a-1)\big(-\tfrac{1}{2}a-\tfrac{1}{2}\big) = \frac{1-a^2}{2}\,\zeta^{-2}. \tag{55.106}$$

The Jacobian of the Möbius factor is $\mathrm{d}\zeta/\mathrm{d}z = (u-v)/(z-v)^2$, since $\mathrm{d}\zeta/\mathrm{d}z = [(z-v)-(z-u)]/(z-v)^2$. Hence $(\mathrm{d}\zeta/\mathrm{d}z)^2 = (u-v)^2/(z-v)^4$ and $\zeta^{-2} = (z-v)^2/(z-u)^2$, and their product is

$$\Big(\frac{\mathrm{d}\zeta}{\mathrm{d}z}\Big)^2\zeta^{-2} = \frac{(u-v)^2}{(z-v)^4}\cdot\frac{(z-v)^2}{(z-u)^2} = \frac{(u-v)^2}{(z-u)^2(z-v)^2}. \tag{55.107}$$

With $a = 1/n$, Eq. (55.106) gives the Schwarzian of the uniformizing map,

$$\{w,z\} = \frac{1}{2}\Big(1-\frac{1}{n^2}\Big)\frac{(u-v)^2}{(z-u)^2(z-v)^2}. \tag{55.108}$$

Substituting into Eq. (55.103), the single-copy stress tensor on the replica surface is

$$\langle T_j(z)\rangle_{\mathcal{R}_n} = \frac{c}{24}\Big(1-\frac{1}{n^2}\Big)\frac{(u-v)^2}{(z-u)^2(z-v)^2}, \tag{55.109}$$

the same for each of the n replicas, since the uniformizing map treats every sheet identically.

The Ward-identity side, and the match. In the replicated theory $\mathcal{C}^{\otimes n}$ on a single plane, the same correlator is computed with the total stress tensor $T^{(n)}(z) = \sum_j T_j(z)$ inserted into the twist two-point function. Summing Eq. (55.109) over the n copies,

$$\frac{\langle T^{(n)}(z)\,\sigma_n(u)\,\tilde\sigma_n(v)\rangle}{\langle\sigma_n(u)\,\tilde\sigma_n(v)\rangle} = \sum_{j=1}^{n}\langle T_j(z)\rangle_{\mathcal{R}_n} = \frac{nc}{24}\Big(1-\frac{1}{n^2}\Big)\frac{(u-v)^2}{(z-u)^2(z-v)^2}. \tag{55.110}$$

On the other hand, the conformal Ward identity of Chapter 48 expresses the insertion of the stress tensor into a correlator of primaries in terms of their weights. For two primaries $\sigma_n, \tilde\sigma_n$ of equal holomorphic weight h_n located at u, v, with holomorphic two-point function $\langle\sigma_n(u)\tilde\sigma_n(v)\rangle \propto (u-v)^{-2h_n}$,

$$\frac{\langle T^{(n)}(z)\,\sigma_n(u)\,\tilde\sigma_n(v)\rangle}{\langle\sigma_n(u)\,\tilde\sigma_n(v)\rangle} = \Big[\frac{h_n}{(z-u)^2}+\frac{1}{z-u}\partial_u+\frac{h_n}{(z-v)^2}+\frac{1}{z-v}\partial_v\Big]\log\big[(u-v)^{-2h_n}\big]\Big|_{\mathrm{op}}, \tag{55.111}$$

where the derivative terms act on the explicit two-point function. Carrying out the derivatives, $\partial_u \log(u-v)^{-2h_n} = -2h_n/(u-v)$ and $\partial_v \log(u-v)^{-2h_n} = +2h_n/(u-v)$, so the descendant pieces give

$$-\frac{2h_n}{(z-u)(u-v)}+\frac{2h_n}{(z-v)(u-v)} = \frac{2h_n}{u-v}\cdot\frac{(z-u)-(z-v)}{(z-u)(z-v)} = -\frac{2h_n}{(z-u)(z-v)}, \tag{55.112}$$

and adding the primary terms,

$$\frac{\langle T^{(n)}\sigma_n\tilde\sigma_n\rangle}{\langle\sigma_n\tilde\sigma_n\rangle} = h_n\Big[\frac{1}{(z-u)^2}+\frac{1}{(z-v)^2}-\frac{2}{(z-u)(z-v)}\Big] = h_n\Big[\frac{1}{z-u}-\frac{1}{z-v}\Big]^2 = h_n\,\frac{(u-$$
$$(z-u)^2($$
(55.113)

The two computations Eqs. (55.110) and (55.113) are expressions for the identical correlator and have the identical functional form in z; equating their coefficients gives the twist dimension.

Theorem 55.31 (Conformal dimension of the twist operator)**.** *In a two-dimensional conformal field theory of central charge c, the $\mathbb{Z}_n$ twist operator σ_n implementing the cyclic identification of the n-sheeted replica cover is a spinless primary of the replicated theory $\mathcal{C}^{\otimes n}$ with holomorphic and antiholomorphic weights*

$$h_n=\bar h_n=\frac{c}{24}\Big(n-\frac{1}{n}\Big),\qquad \textit{total scaling dimension}\qquad \Delta_n=2h_n=\frac{c}{12}\Big(n-\frac{1}{n}\Big).\tag{55.114}$$

Proof. Matching the coefficients of $(u-v)^2/[(z-u)^2(z-v)^2]$ in Eqs. (55.110) and (55.113),

$$h_n=\frac{nc}{24}\Big(1-\frac{1}{n^2}\Big)=\frac{c}{24}\Big(n-\frac{1}{n}\Big).\tag{55.115}$$

The antiholomorphic sector repeats verbatim with $\bar T_j$ and $\bar c=c$, giving $\bar h_n=h_n$, so the twist operator is spinless ($h_n-\bar h_n=0$) and its total dimension is $\Delta_n=h_n+\bar h_n=2h_n$. □

Physical Insight

The twist dimension vanishes at $n=1$, as it must: a single sheet has no branch point and the replica surface is the plane, so σ_1 is the identity, $h_1=0$. The dimension grows with n because each additional sheet sharpens the conical singularity at the branch point: near $z=u$ the uniformized angle is $2\pi n$ wrapped into 2π, a deficit that costs curvature, and the central charge is precisely the theory's response to curvature. This is the same c that sets the Casimir energy and the trace anomaly; here it sets the price of replication.

55.4.3 The single-interval entanglement entropy

With Δ_n in hand, Eq. (55.97) is fixed by conformal symmetry. The two-point function of two scalar primaries of equal dimension is determined up to one constant — Theorem 47.21 — as $C/|u-v|^{2\Delta}$. Applied to the twist fields,

$$\langle\sigma_n(u)\,\tilde\sigma_n(v)\rangle=\frac{c_n}{|u-v|^{2\Delta_n}}=\frac{c_n}{|u-v|^{(c/6)(n-1/n)}},\tag{55.116}$$

where we used $2\Delta_n = (c/6)(n-1/n)$ from Eq. (55.114), and c_n is a non-universal constant fixed by the short-distance normalization of σ_n. The two-point function is dimensionful, with σ_n carrying dimension Δ_n; making it dimensionless requires a length scale, and that scale is the UV cutoff ϵ — the lattice spacing, or the short-distance regulator at which the continuum theory is defined. This is where the cutoff dependence of the entanglement entropy, flagged at the outset of the chapter, enters concretely: the twist operator is not a sharply local field but a defect smeared over the cutoff scale, and its normalization is set at $|u-v| \sim \epsilon$. Restoring the cutoff so that the combination is dimensionless,

$$\operatorname{Tr}\rho_A^n = c_n \Big(\frac{\ell}{\epsilon}\Big)^{-(c/6)(n-1/n)}, \qquad \ell = |u-v|, \tag{55.117}$$

which is the announced power law: a single interval of length ℓ in the infinite-line vacuum has $\operatorname{Tr}\rho_A^n$ a pure power of ℓ/ϵ, with the universal exponent $(c/6)(n-1/n)$ and a non-universal prefactor.

The entanglement entropy is the replica limit of Eq. (55.117). Recall from Theorem 55.17 that the von Neumann entropy is recovered by analytic continuation in n,

$$S_A = -\operatorname{Tr}(\rho_A \log \rho_A) = -\frac{\partial}{\partial n}\operatorname{Tr}\rho_A^n\Big|_{n=1}, \tag{55.118}$$

valid because $\operatorname{Tr}\rho_A^n = \sum_i p_i^n$ for eigenvalues p_i of ρ_A, whose n-derivative at $n=1$ is $\sum_i p_i \log p_i$ once $\sum_i p_i = 1$ fixes $\operatorname{Tr}\rho_A = 1$, i.e. $c_1 = 1$.

Theorem 55.32 (Single-interval vacuum entanglement entropy in 2D CFT)**.** *For a single interval of length ℓ in the vacuum of a two-dimensional CFT of central charge c, with UV cutoff ϵ,*

$$S_A = \frac{c}{3}\log\frac{\ell}{\epsilon} + c_1', \qquad c_1' \equiv \frac{\partial c_n}{\partial n}\Big|_{n=1}, \tag{55.119}$$

the constant c_1' being non-universal (cutoff-scheme dependent), while the coefficient $c/3$ of the logarithm is universal.

Proof. Write $\operatorname{Tr}\rho_A^n = c_n\, e^{-(c/6)(n-1/n)\,L}$ with $L \equiv \log(\ell/\epsilon)$. Differentiating,

$$\frac{\partial}{\partial n}\operatorname{Tr}\rho_A^n = \Big[\frac{c_n'}{c_n} - \frac{c}{6}\Big(1+\frac{1}{n^2}\Big)L\Big]\,\operatorname{Tr}\rho_A^n. \tag{55.120}$$

At $n=1$ we have $c_1 = 1$ and $\operatorname{Tr}\rho_A^1 = 1$, while $1 + 1/n^2 \to 2$, so

$$\frac{\partial}{\partial n}\operatorname{Tr}\rho_A^n\Big|_{n=1} = c_1' - \frac{c}{6}\cdot 2 \cdot L = c_1' - \frac{c}{3}\log\frac{\ell}{\epsilon}. \tag{55.121}$$

By Eq. (55.118), $S_A = -\partial_n \operatorname{Tr}\rho_A^n|_{n=1} = \frac{c}{3}\log(\ell/\epsilon) - c_1'$, which is Eq. (55.119) after renaming the constant. The factor $c/3 = 2 \times c/6$ is the sum of the equal holomorphic and antiholomorphic contributions. □

The result is striking for what it does *not* contain. The entanglement entropy of an interval depends on the theory only through the single number c; all the operator content, the spectrum of dimensions, the OPE coefficients — everything else that distinguishes one CFT from another — drops out of the leading entanglement of a single interval. This is the entanglement face of the statement that c counts the effective number of local degrees of freedom: it is the coefficient with which short-distance correlations across the entangling point accumulate as the region grows. The divergence as $\epsilon \to 0$ is the promised UV divergence; in two dimensions the entangling "surface" is two points (the interval endpoints), and each endpoint contributes a logarithm. The logarithm is the $d = 2$ face of the area law of Section 55.5: in higher dimensions the boundary ∂A has positive-dimensional area and the divergence is power-law; in $d = 2$ the boundary is pointlike and the divergence degenerates to a logarithm, whose coefficient is the universal datum.

The same calculation yields the Rényi entropies, which carry strictly more information than S_A because they probe the full spectrum of ρ_A.

Worked Example 55.33 (Rényi entropies and the replica continuation)**.** The Rényi entropy of index n is $S_n = \frac{1}{1-n} \log \operatorname{Tr} \rho_A^n$, reducing to the von Neumann entropy as $n \to 1$. From Eq. (55.117),

$$S_n = \frac{1}{1-n}\Big[\log c_n - \frac{c}{6}\Big(n - \frac{1}{n}\Big)\log\frac{\ell}{\epsilon}\Big]. \tag{55.122}$$

The universal piece simplifies: $-\frac{c}{6}\frac{n-1/n}{1-n} = -\frac{c}{6}\frac{(n^2-1)/n}{1-n} = -\frac{c}{6}\frac{(n-1)(n+1)}{n(1-n)} = \frac{c}{6}\frac{n+1}{n} = \frac{c}{6}\big(1+\frac{1}{n}\big)$, so

$$S_n = \frac{c}{6}\Big(1 + \frac{1}{n}\Big)\log\frac{\ell}{\epsilon} + \frac{\log c_n}{1-n}. \tag{55.123}$$

As a check on the analytic continuation, $n \to 1$ gives the universal coefficient $\frac{c}{6}(1+1) = \frac{c}{3}$, reproducing Eq. (55.119); the non-universal term $\log c_n/(1-n) \to -c_1'$ by l'Hôpital, since $c_1 = 1$. The monotonic dependence of the universal coefficient $\frac{c}{6}(1+1/n)$ on n — decreasing from $\frac{c}{3}$ at $n = 1$ toward $\frac{c}{6}$ at $n \to \infty$ — reflects that higher Rényi indices weight the largest eigenvalues of ρ_A more heavily. That the entire family is controlled by the same c is the hallmark of conformal invariance: one anomaly coefficient fixes an infinite tower of entropies.

55.4.4 Finite size and finite temperature

The infinite-line vacuum is a single point in a family of conformally related geometries. Because the twist operators are primaries, their correlators on any geometry conformally equivalent to the plane are obtained by transporting

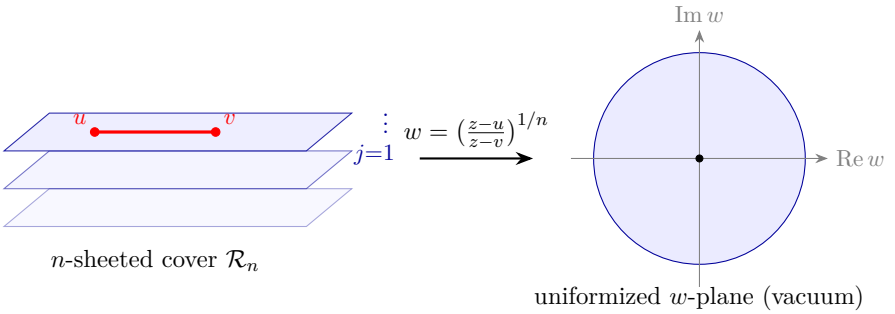


Figure 55.4: The conformal uniformization of the replica surface. The n-sheeted cover $\mathcal{R}_n$, branched over the interval endpoints u, v (red cut), is mapped one-to-one onto a single w-plane by $w = ((z-u)/(z-v))^{1/n}$. On the w-plane the state is the ordinary vacuum, $\langle T(w)\rangle = 0$; the nonzero stress tensor on $\mathcal{R}_n$ in Eq. (55.103) comes entirely from the Schwarzian of the map, i.e. from the central charge.

Eq. (55.116) with the appropriate map. Two cases are physically central: an interval on a spatial circle (finite size) and an interval in a thermal state (finite temperature). Each is a cylinder, and each is mapped to the plane by an exponential. We carry both out explicitly.

The transformation law we need is that of a spinless primary of dimension Δ_n under a holomorphic map $z = f(w)$: each insertion picks up a Jacobian $|f'(w_i)|^{\Delta_n}$ (the product of the holomorphic factor $(f')^{h_n}$ and its antiholomorphic conjugate, with $h_n = \bar{h}_n$ and $2h_n = \Delta_n$), so that

$$\langle \sigma_n(w_1)\tilde{\sigma}_n(w_2)\rangle_{\text{cyl}} = |f'(w_1)|^{\Delta_n}\,|f'(w_2)|^{\Delta_n}\,\langle \sigma_n(z_1)\tilde{\sigma}_n(z_2)\rangle_{\text{plane}}, \qquad z_i = f(w_i). \tag{55.124}$$

The physical cutoff ϵ is the proper short-distance scale on the cylinder, where the lattice lives, and is held fixed in the cylinder frame; using the plane two-point function $\langle \sigma_n\tilde{\sigma}_n\rangle_{\text{plane}} = c_n\,\epsilon^{2\Delta_n}/|z_1 - z_2|^{2\Delta_n}$ keeps every appearance of ϵ a proper length to leading order.

Finite size: an interval on a circle. Let space be a circle of circumference L, with complex cylinder coordinate w identified under $w \sim w + L$. The exponential map

$$z = f(w) = e^{2\pi \mathrm{i} w/L} \tag{55.125}$$

sends the spatial cylinder to the plane: $w \to w + L$ gives $z \to z\,e^{2\pi \mathrm{i}} = z$, single-valued, with the spatial circle becoming the unit circle $|z| = 1$. The interval endpoints sit at equal Euclidean time, w_1, w_2 real with $w_2 - w_1 = \ell$. Then $|z_i| = 1$ and

$$|z_1 - z_2| = \left|e^{2\pi \mathrm{i} w_1/L} - e^{2\pi \mathrm{i} w_2/L}\right| = \left|1 - e^{2\pi \mathrm{i}\ell/L}\right| = 2\,\sin\frac{\pi\ell}{L}, \tag{55.126}$$

using $|1-e^{\mathrm{i}\theta}| = 2|\sin(\theta/2)|$ with $\theta = 2\pi\ell/L$. The Jacobian magnitude at each endpoint is $|f'(w_i)| = (2\pi/L)|z_i| = 2\pi/L$. Inserting into Eq. (55.124),

$$\begin{aligned}\operatorname{Tr}\rho_A^n = \langle \sigma_n \tilde{\sigma}_n \rangle_{\text{cyl}} &= \Big(\frac{2\pi}{L}\Big)^{2\Delta_n} \frac{c_n\, \epsilon^{2\Delta_n}}{\big[2\sin(\pi\ell/L)\big]^{2\Delta_n}} = c_n \Big[\frac{L}{\pi\epsilon}\sin\frac{\pi\ell}{L}\Big]^{-2\Delta_n} \\ &= c_n \Big[\frac{L}{\pi\epsilon}\sin\frac{\pi\ell}{L}\Big]^{-(c/6)(n-1/n)}. \end{aligned} \tag{55.127}$$

This is Eq. (55.117) with the chord length ℓ replaced by the conformal chord $(L/\pi)\sin(\pi\ell/L)$. The replica limit Eq. (55.118) acts on the logarithm of this quantity exactly as in Theorem 55.32, with $\log(\ell/\epsilon)$ promoted to $\log[(L/\pi\epsilon)\sin(\pi\ell/L)]$, giving

$$\boxed{S_A = \frac{c}{3}\log\Big[\frac{L}{\pi\epsilon}\sin\frac{\pi\ell}{L}\Big] + \text{const.}} \tag{55.128}$$

Two checks confirm the formula. For $\ell \ll L$, $\sin(\pi\ell/L) \approx \pi\ell/L$ and the argument collapses to ℓ/ϵ, recovering the infinite-line result Eq. (55.119): a small interval cannot resolve the global topology. And the formula is symmetric under $\ell \to L-\ell$, since $\sin[\pi(L-\ell)/L] = \sin(\pi\ell/L)$; this is mandatory, because the full state on the circle is the pure vacuum, for which $S_A = S_{A^c}$ — the entanglement entropy of a region equals that of its complement.

Finite temperature: an interval in a thermal state. A thermal state at inverse temperature β is prepared by the Euclidean path integral on a cylinder whose *time* direction is compact, $\tau \sim \tau + \beta$, with space the infinite line. Now the complex coordinate is w with $w \sim w + \mathrm{i}\beta$ (imaginary period β), and the uniformizing exponential is

$$z = f(w) = e^{2\pi w/\beta}, \tag{55.129}$$

single-valued under $w \to w + \mathrm{i}\beta$. The interval is spatial, endpoints at equal time with real separation $w_2 - w_1 = \ell$. The natural conformal invariant is the combination $|z_1 - z_2|^2/(|z_1||z_2|)$, which is independent of the overall phase and scale of z and so descends cleanly to the cylinder. With $z_i = e^{2\pi w_i/\beta}$ and w_i real,

$$z_1 - z_2 = e^{\pi(w_1+w_2)/\beta}\Big(e^{\pi(w_1-w_2)/\beta} - e^{-\pi(w_1-w_2)/\beta}\Big) = e^{\pi(w_1+w_2)/\beta}\cdot 2\sinh\frac{\pi(w_1-w_2)}{\beta}, \tag{55.130}$$

while $|z_1|^{1/2}|z_2|^{1/2} = e^{\pi(w_1+w_2)/\beta}$, so

$$\frac{|z_1 - z_2|^2}{|z_1|\,|z_2|} = \Big[2\sinh\frac{\pi\ell}{\beta}\Big]^2. \tag{55.131}$$

The transport Eq. (55.124) carries factors $|f'(w_i)|^{\Delta_n} = (2\pi/\beta)^{\Delta_n}|z_i|^{\Delta_n}$, and combining the $|z_i|$ pieces with the plane two-point function reproduces exactly

this invariant:

$$\operatorname{Tr}\rho_A^n = \Big(\frac{2\pi}{\beta}\Big)^{2\Delta_n}(|z_1||z_2|)^{\Delta_n}\frac{c_n\,\epsilon^{2\Delta_n}}{|z_1-z_2|^{2\Delta_n}} = c_n\Big(\frac{2\pi}{\beta}\Big)^{2\Delta_n}\epsilon^{2\Delta_n}\Big[\frac{|z_1-z_2|^2}{|z_1||z_2|}\Big]^{-\Delta_n}$$
$$= c_n\Big[\frac{2\pi\epsilon}{\beta}\cdot\frac{1}{2\sinh(\pi\ell/\beta)}\Big]^{2\Delta_n} = c_n\Big[\frac{\beta}{\pi\epsilon}\sinh\frac{\pi\ell}{\beta}\Big]^{-(c/6)(n-1/n)}. \tag{55.132}$$

The replica limit gives the finite-temperature single-interval entropy,

$$\boxed{S_A = \frac{c}{3}\log\Big[\frac{\beta}{\pi\epsilon}\sinh\frac{\pi\ell}{\beta}\Big] + \text{const.}} \tag{55.133}$$

The sine of the finite-size case has become a hyperbolic sine, the signature of the swapped (timelike vs. spacelike) compactification. This is the result anticipated by the thermal reading of the vacuum in Section 55.3: a finite temperature converts the vacuum logarithm into a function of ℓ/β.

Worked Example 55.34 (Thermal limits: the crossover to extensive entropy)**.** The two limits of Eq. (55.133) are physically instructive. For a small interval, $\ell \ll \beta$, expand $\sinh(\pi\ell/\beta) \approx \pi\ell/\beta$; the argument of the logarithm collapses to ℓ/ϵ and

$$S_A \xrightarrow{\ell\ll\beta} \frac{c}{3}\log\frac{\ell}{\epsilon} + \text{const}, \tag{55.134}$$

the vacuum result Eq. (55.119): a region much smaller than the thermal wavelength cannot tell it is in a thermal state, and the entanglement is dominated by the vacuum fluctuations across the endpoints. For a large interval, $\ell \gg \beta$, use $\sinh(\pi\ell/\beta) \approx \frac{1}{2}e^{\pi\ell/\beta}$, so $\log[\,\cdot\,] \approx \pi\ell/\beta + \log(\beta/2\pi\epsilon)$ and

$$S_A \xrightarrow{\ell\gg\beta} \frac{c}{3}\cdot\frac{\pi\ell}{\beta} + \frac{c}{3}\log\frac{\beta}{2\pi\epsilon} + \text{const} = \frac{\pi c}{3\beta}\,\ell + \cdots. \tag{55.135}$$

The entropy becomes *extensive*, linear in the interval length, with density $s = \pi c/3\beta$. This is exactly the thermal (Cardy) entropy density of a 2D CFT: for a large region the reduced density matrix is effectively thermal in the bulk of the interval, and the entanglement entropy reduces to ordinary thermodynamic entropy, with only the two endpoint logarithms surviving as subleading boundary corrections. The crossover from the logarithmic (entanglement-dominated) regime to the linear (thermal-dominated) regime at $\ell \sim \beta$ is the precise statement that entanglement entropy interpolates between a genuine quantum correlation measure and a coarse thermodynamic one. The universal coefficient $\pi c/3\beta$ is one more incarnation of the same c.

55.4.5 The universal coefficient, the c-function, and the Ising endpoint

The coefficient $c/3$ in Eq. (55.119) is more than a number attached to a divergence: it is a renormalization-group diagnostic. Although S_A itself is cutoff-dependent,

the combination

$$c_{\text{eff}}(\ell) \equiv 3\,\ell\,\frac{\mathrm{d}S_A}{\mathrm{d}\ell} \tag{55.136}$$

is cutoff-*independent* — the derivative kills the additive constant and the $\log\epsilon$ — and at a fixed point equals the central charge, $c_{\text{eff}} = c$. Away from a fixed point, along an RG flow between an ultraviolet CFT (central charge c_{UV}) and an infrared one (c_{IR}), $c_{\text{eff}}(\ell)$ interpolates between the two: probing the entanglement of a small interval sees the UV theory, a large interval sees the IR theory. The monotonicity of this interpolation is the content of Zamolodchikov's c-theorem, stated and proved (in its stress-tensor form) in Theorem 52.17: there is a function along the flow, monotonically decreasing toward the infrared, that coincides with c at the endpoints, so that $c_{\text{UV}} \geq c_{\text{IR}}$. The entanglement entropy provides an information-theoretic realization of that monotone — the entropic c-function — whose decrease expresses the loss of degrees of freedom as short-distance modes are integrated out. We import the c-theorem without full proof from Theorem 52.17; what the present computation adds is the identification of its coefficient with an entanglement observable, the slope of S_A against $\log\ell$.

Physical Insight

The chain of identifications is the moral of the section. The central charge c appears as: the coefficient of the $T(z)T(w)$ short-distance singularity (Theorem 48.8); the Schwarzian anomaly in the finite transformation of the stress tensor (Eq. (48.63)); the Casimir energy on a cylinder; the trace anomaly in a curved background; and now the coefficient $c/3$ of the entanglement logarithm. These are not five coincidences but five faces of one object — the response of the vacuum to being curved, squeezed, or cut. Entanglement entropy is the informational face: c measures how much quantum correlation a region shares with its complement, per logarithm of its size.

The Ising endpoint of Scalar ϕ^4 theory. We can now close ϕ^4 theory on the entanglement side. The real scalar $\lambda\phi^4$ theory, carried since Chapter 6 from its classical Lagrangian through quantization, renormalization, and the RG, was shown in Chapter 52 to flow to the Wilson–Fisher fixed point in $d = 4 - \epsilon$, whose two-dimensional avatar is the Ising universality class: the minimal model $\mathcal{M}(4,3)$ with central charge

$$c = \frac{1}{2}, \tag{55.137}$$

the value derived from the minimal-model formula Eq. (48.176) and confirmed against the free Majorana fermion in Chapter 48. Substituting into Theorem 55.32, the single-interval vacuum entanglement entropy of the critical Ising chain is

$$S_A = \frac{1}{6}\log\frac{\ell}{\epsilon} + \text{const}, \tag{55.138}$$

since $c/3 = \frac{1}{6}$. This is a sharp, falsifiable prediction: the ground-state entanglement entropy of a block of ℓ/ϵ spins in the critical transverse-field Ising chain grows as $\frac{1}{6}\log\ell$, with the coefficient fixed entirely by the central charge $c = \frac{1}{2}$. The same $c = \frac{1}{2}$ that the bootstrap of Chapter 50 pins down for the three-dimensional Ising model in the form of operator dimensions appears here, in two dimensions, as the slope of an entanglement logarithm — two windows on the one fixed point that ϕ^4 theory has been approaching since Part II. The Wilson–Fisher endpoint, met first as a zero of the beta function, is now also the source of a universal entanglement coefficient.

Physical Insight

The Ising twist operator can be made completely explicit. In the free Majorana realization of the Ising CFT, the n-fold replicated theory is n free Majorana fermions, and the cyclic $\mathbb{Z}_n$ twist diagonalizes into phase twists with angles $2\pi k/n$, $k = -(n-1)/2, \ldots, (n-1)/2$. Because the fermions are Majorana (real), the conjugate sectors k and $-k$ pair into a single Dirac fermion, so the independent twists are labeled by $k = 1, \ldots, (n-1)/2$ (the $k = 0$ mode is an untwisted Majorana of dimension zero): the n Majoranas organize into $\sim n/2$ Dirac fermions, not n independent U(1) twists. A single U(1) twist by angle $2\pi k/n$ on a Dirac fermion is a vertex operator of dimension $h = \frac{1}{2}(k/n)^2$; summing the holomorphic weights over the independent Dirac sectors, $\sum_{k=1}^{(n-1)/2} \frac{1}{2}(k/n)^2 = \frac{1}{2n^2}\cdot\frac{n(n^2-1)}{24} = \frac{1}{48}(n-1/n)$, which is exactly h_n at $c = \frac{1}{2}$ from Eq. (55.114). The abstract Schwarzian computation and the concrete free-field one agree, as they must.

The single-interval logarithm and its finite-size and finite-temperature deformations are now established as the universal entanglement data of any 2D CFT, fixed by the central charge alone. These are precisely the numbers a holographic dual must reproduce: in Chapter 56 the Ryu–Takayanagi formula will compute the same $(c/3)\log(\ell/\epsilon)$, and its sine and sinh variants, as the length of a bulk geodesic anchored on the interval endpoints, turning the CFT result of this section into the boundary check of holographic entanglement. The logarithm we have derived is also the $d = 2$ representative of the area law, whose higher-dimensional form — proportionality to the area of the entangling surface — is the subject of Section 55.5.

55.5 The Area Law and the Structure of UV Divergences

The two-dimensional logarithm of Section 55.4.3 and the half-space computation of Section 55.3 both pointed beyond themselves. The 2D result $S_A = \frac{c}{3}\log(\ell/\epsilon)$ is

a divergence whose coefficient is universal, but the divergence itself is logarithmic only because the entangling "surface" of an interval is a pair of points; for a region in three or more spacetime dimensions the boundary ∂A is a genuine surface, and we should expect a stronger, power-law divergence proportional to its size. The Rindler computation made this concrete from the opposite direction: rewriting the half-space entanglement entropy as the thermodynamic entropy of a thermal gas piled up against the entangling plane (Section 55.3), we found an entropy proportional to the transverse area $\mathcal{A}_\perp$ of that plane times a factor that diverges as the cutoff is removed, with the proportionality constant left as a promissory note — "the constant counts the field's degrees of freedom and is computed in full in Section 55.5." This section pays that note. We establish, by an explicit and honest computation on the free real scalar of ϕ^4 theory, the generic leading behavior of entanglement entropy in $d > 2$: proportionality to the *area* of the entangling surface measured in cutoff units,

$$S_A \;=\; \kappa\,\frac{\mathcal{A}(\partial A)}{\epsilon^{\,d-2}} \;+\; (\text{subleading}), \tag{55.139}$$

the result of Bombelli, Koul, Lee and Sorkin and of Srednicki [85, 453]. We then dissect the full divergence structure — the tower of subleading power-law divergences and, beneath them, the one piece that is universal: a logarithm tied to a conformal anomaly when d is even, a finite constant when d is odd. The recurring theme of the chapter reaches its sharpest form here: S_A is not a number but a cutoff-dependent, scheme-dependent quantity, and the physics lives in the universal coefficient and in subtracted combinations such as the mutual information.

The computational engine is the observation, already glimpsed in the two-oscillator worked example of Theorem 55.16, that the vacuum of a free field is a Gaussian state, and that the entanglement entropy of any region in a Gaussian state is computed once and for all from the two-point correlators alone. We build that formula first, in full generality, then feed it the free scalar.

55.5.1 The entanglement entropy of a Gaussian state

A free scalar field, on the lattice that regulates it, is a system of coupled harmonic oscillators, and its vacuum is the Gaussian ground state of a positive-definite quadratic Hamiltonian. The reduced density matrix of any set of oscillators is therefore a Gaussian operator, and Gaussian operators are determined entirely by their second moments. We make this precise and extract S_A from the moments.

Let the region A contain N oscillators with canonical coordinates and momenta $\hat{x}_i, \hat{p}_i$ $(i = 1, \dots, N)$, collected into the phase-space vector $\hat{R} = (\hat{x}_1, \dots, \hat{x}_N, \hat{p}_1, \dots, \hat{p}_N)$ obeying $[\hat{R}_a, \hat{R}_b] = \mathrm{i}\,\Omega_{ab}$ with the symplectic form

$$\Omega = \begin{pmatrix} 0 & \mathbf{1}_N \\ -\mathbf{1}_N & 0 \end{pmatrix}. \tag{55.140}$$

For a state with vanishing first moments — which the vacuum is, by translation invariance in field space — all information accessible to local Gaussian observables is in the symmetric *covariance matrix*

$$\sigma_{ab} = \tfrac{1}{2}\langle\{\hat{R}_a - \langle\hat{R}_a\rangle,\ \hat{R}_b - \langle\hat{R}_b\rangle\}\rangle = \tfrac{1}{2}\langle\{\hat{R}_a, \hat{R}_b\}\rangle. \tag{55.141}$$

For the vacuum of a real Hamiltonian there are no cross correlations between positions and momenta, $\langle\{\hat{x}_i, \hat{p}_j\}\rangle = 0$, so the covariance matrix is block-diagonal in the (x, p) split,

$$\sigma = \begin{pmatrix} X & 0 \\ 0 & P \end{pmatrix}, \qquad X_{ij} = \langle\hat{x}_i\hat{x}_j\rangle, \qquad P_{ij} = \langle\hat{p}_i\hat{p}_j\rangle, \tag{55.142}$$

the two correlation matrices announced in the section heading. The reduced density matrix on A of a global Gaussian pure state is itself a Gaussian (mixed) state, and its covariance matrix is exactly the restriction of σ to the oscillators in A — the submatrices $X_A = X|_{A\times A}$, $P_A = P|_{A\times A}$ obtained by deleting all rows and columns not in A. Tracing out the complement is, at the level of second moments, simply dropping the entries that involve it.

The entropy is then a purely linear-algebraic functional of X_A, P_A, by way of Williamson's normal form.

Theorem 55.35 (Williamson normal form and the Gaussian entanglement entropy)**.** *Let $\sigma_A = \mathrm{diag}(X_A, P_A)$ be the covariance matrix Eq. (55.142) of a Gaussian state on N_A oscillators. There exists a symplectic transformation $S \in \mathrm{Sp}(2N_A, \mathbb{R})$ (i.e. $S\Omega S^{\mathsf{T}} = \Omega$) bringing it to the diagonal form*

$$S\,\sigma_A\,S^{\mathsf{T}} = \mathrm{diag}(\nu_1, \ldots, \nu_{N_A},\ \nu_1, \ldots, \nu_{N_A}), \tag{55.143}$$

where the symplectic eigenvalues *$\nu_k \geq \frac{1}{2}$ are the (positive) eigenvalues of the matrix*

$$C_A \equiv \sqrt{X_A\,P_A}\,, \tag{55.144}$$

and the entanglement entropy of the region is

$$\boxed{S_A = \sum_{k=1}^{N_A} g(\nu_k), \qquad g(\nu) = \left(\nu + \tfrac{1}{2}\right)\log\left(\nu + \tfrac{1}{2}\right) - \left(\nu - \tfrac{1}{2}\right)\log\left(\nu - \tfrac{1}{2}\right).} \tag{55.145}$$

Proof. A symplectic transformation $\hat{R} \to S\hat{R}$ is implemented on Hilbert space by a unitary (a Gaussian/Bogoliubov rotation), under which the von Neumann entropy is invariant; it acts on the covariance matrix by $\sigma_A \to S\sigma_A S^{\mathsf{T}}$. Williamson's theorem states that any positive-definite symmetric $2N_A \times 2N_A$ matrix can be brought by such an S to the diagonal form Eq. (55.143). To identify the ν_k, note that the eigenvalues of $\Omega\sigma_A$ are symplectic invariants

(a similarity by S preserves the spectrum of $\Omega\sigma_A$ because $S\Omega S^{\mathsf{T}} = \Omega$ gives $S(\Omega\sigma_A)S^{-1} = \Omega\, S^{-\mathsf{T}}\sigma_A S^{-1} = \Omega\,(S\sigma_A S^{\mathsf{T}})$ up to the rearrangement that fixes Ω). On the normal form Eq. (55.143) the matrix $\Omega\sigma_A$ has eigenvalues $\pm\mathrm{i}\nu_k$. For the block form $\sigma_A = \mathrm{diag}(X_A, P_A)$,

$$\Omega\sigma_A = \begin{pmatrix} 0 & P_A \\ -X_A & 0 \end{pmatrix}, \qquad (\Omega\sigma_A)^2 = \begin{pmatrix} -P_A X_A & 0 \\ 0 & -X_A P_A \end{pmatrix}, \tag{55.146}$$

whose eigenvalues are $-\lambda$ with λ ranging over the eigenvalues of $X_A P_A$ (the matrices $X_A P_A$ and $P_A X_A$ are similar and share their spectrum, which is real and positive because X_A, P_A are positive). Hence the eigenvalues of $\Omega\sigma_A$ are $\pm\mathrm{i}\sqrt{\lambda}$, and comparison with $\pm\mathrm{i}\nu_k$ gives $\nu_k = \sqrt{\lambda_k}$, i.e. the ν_k are the eigenvalues of $C_A = \sqrt{X_A P_A}$, establishing Eq. (55.144). The uncertainty principle forces $\nu_k \geq \frac{1}{2}$, with equality for a pure mode.

After the symplectic rotation the state factorizes into N_A independent single modes, the k-th with covariance $\mathrm{diag}(\nu_k, \nu_k)$. The von Neumann entropy is additive over these modes, $S_A = \sum_k g(\nu_k)$ with $g(\nu)$ the entropy of one mode. A single Gaussian mode of symplectic eigenvalue ν is a thermal state: its position and momentum variances are equal, $\langle x^2\rangle = \langle p^2\rangle = \nu$, which is the covariance of a harmonic oscillator at frequency 1 in a thermal state with mean occupation $\bar{n} = \nu - \frac{1}{2}$, density matrix $\rho = (1-\xi)\sum_{m\geq 0}\xi^m\,|m\rangle\langle m|$ with $\bar{n} = \xi/(1-\xi)$. Its entropy was computed once and for all in Eq. (55.36), $S = -\log(1-\xi) - \frac{\xi}{1-\xi}\log\xi = (\bar{n}+1)\log(\bar{n}+1) - \bar{n}\log\bar{n}$. Substituting $\bar{n} = \nu - \frac{1}{2}$ gives $g(\nu) = (\nu+\frac{1}{2})\log(\nu+\frac{1}{2}) - (\nu-\frac{1}{2})\log(\nu-\frac{1}{2})$, which is Eq. (55.145). □

Remark 55.36. The formula is a direct generalization of the two-oscillator example. There, $N_A = 1$ and C_A is the single number $\sqrt{X_A P_A} = \sqrt{\langle\hat{x}_1^2\rangle\langle\hat{p}_1^2\rangle}$; one checks that $\nu = \sqrt{X_A P_A}$ reproduces the geometric spectrum of Theorem 55.16 through $\xi = (2\nu-1)/(2\nu+1)$, the inverse of $\bar{n} = \nu - \frac{1}{2} = \xi/(1-\xi)$. For the whole system (taking A to be everything), the global vacuum is pure, and indeed $XP = \frac{1}{4}\mathbf{1}$ (shown below), so every $\nu_k = \frac{1}{2}$ and $g(\frac{1}{2}) = 0$: the global entropy vanishes, as it must. *All* of the entanglement entropy comes from the fact that the products of the truncated submatrices, $X_A P_A$, fail to equal $\frac{1}{4}\mathbf{1}$ — truncation does not commute with the matrix square root, and the deficit is the entanglement.

This formula is the exact, computational counterpart of the replica machinery: where Section 55.2.4 expressed the entropy through a replica free energy $\log Z_n = -\frac{1}{2}\log\det\Delta_n$ on a branched cover (a functional determinant, hence the relevance of Sections E.2 and E.3), Eq. (55.145) delivers the same number directly from the equal-time correlators of the unreplicated vacuum, never requiring the analytic continuation in n to be performed by hand. For Gaussian theories the two routes are equivalent; the correlator route is the one that computes [115, 395].

55.5.2 The free scalar: correlators, the spherical region, and the area law

We now apply Theorem 55.35 to the free real scalar of ϕ^4 theory at $\lambda = 0$, whose mode expansion and vacuum were constructed in Section 9.2 and Theorem 9.11. On a spatial lattice of spacing a the field is the oscillator system

$$H = \frac{1}{2}\sum_{i} \hat{\pi}_i^2 + \frac{1}{2}\sum_{ij} \hat{\phi}_i \, K_{ij} \, \hat{\phi}_j, \tag{55.147}$$

with K a real symmetric positive matrix — the discretized $(-\nabla^2 + m^2)$ operator, $K_{ij} = (2(d-1) + m^2 a^2)\delta_{ij} - \sum_{\text{neighbours}} \delta_{i,j\pm\hat{e}}$ in units $a = 1$ for a cubic lattice in $d-1$ spatial dimensions. The vacuum correlators follow from diagonalizing $K = O^{\mathsf{T}} \mathcal{D} O$ with $\mathcal{D} = \mathrm{diag}(\omega_a^2)$: in each normal mode $\langle y_a^2 \rangle = 1/(2\omega_a)$ and $\langle \pi_a^2 \rangle = \omega_a/2$, so rotating back,

$$X = \langle \hat{\phi}\hat{\phi}^{\mathsf{T}} \rangle = \tfrac{1}{2}\, K^{-1/2}, \qquad P = \langle \hat{\pi}\hat{\pi}^{\mathsf{T}} \rangle = \tfrac{1}{2}\, K^{1/2}. \tag{55.148}$$

Globally $XP = \frac{1}{4} K^{-1/2} K^{1/2} = \frac{1}{4}\mathbf{1}$, the purity statement used above. The entanglement entropy of a region A is Eq. (55.145) evaluated on the symplectic eigenvalues of $C_A = \sqrt{X_A P_A}$, with X_A, P_A the submatrices of Eq. (55.148) indexed by the lattice sites inside A.

The spherical region and the radial reduction. For a ball $A = \{|\mathbf{x}| < R\}$ the rotational symmetry of the massless theory can be used to reduce the $(d-1)$-dimensional lattice problem to a family of one-dimensional radial chains, one for each angular-momentum sector — the decomposition introduced by Srednicki [453]. We carry it out in the physical case $d = 4$ (three spatial dimensions); the general case differs only in the harmonic degeneracies. Expanding the field in spherical harmonics on S^2,

$$\hat{\phi}(\mathbf{x}) = \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} \frac{1}{r}\, \hat{\phi}_{\ell m}(r)\, Y_{\ell m}(\theta,\varphi), \qquad \hat{\pi}(\mathbf{x}) = \sum_{\ell m} \frac{1}{r}\, \hat{\pi}_{\ell m}(r)\, Y_{\ell m}(\theta,\varphi), \tag{55.149}$$

and inserting into $H = \frac{1}{2}\int \mathrm{d}^3x\, [\hat{\pi}^2 + (\nabla\hat{\phi})^2]$, the angular integrals collapse by orthonormality of the $Y_{\ell m}$ and the radial centrifugal term $\ell(\ell+1)/r^2$ appears, leaving a sum of independent radial Hamiltonians

$$H = \frac{1}{2}\sum_{\ell m} \int_0^{\infty} \mathrm{d}r \left[\hat{\pi}_{\ell m}(r)^2 + r^2 \Big(\partial_r \frac{\hat{\phi}_{\ell m}(r)}{r} \Big)^2 + \frac{\ell(\ell+1)}{r^2}\, \hat{\phi}_{\ell m}(r)^2 \right]. \tag{55.150}$$

Discretizing the radius at the midpoints $r_j = (j - \frac{1}{2})a$, $j = 1, \dots, N$ (the half-integer offset keeps the origin off the lattice and renders the difference operator

regular), the radial integral becomes the oscillator chain $H = \tfrac{1}{2}\sum_{\ell m}[\sum_j \hat\pi^2_{\ell m,j} + \sum_{jj'} \hat\phi_{\ell m,j} K^\ell_{jj'} \hat\phi_{\ell m,j'}]$ with the tridiagonal coupling (in units $a = 1$)

$$K^\ell_{jj} = \frac{j^2 + (j-1)^2}{(j-\frac12)^2} + \frac{\ell(\ell+1)}{(j-\frac12)^2}, \qquad K^\ell_{j,j+1} = K^\ell_{j+1,j} = -\frac{j^2}{j^2 - \frac14}, \tag{55.151}$$

the standard finite-difference form of Eq. (55.150). Because the modes of different (ℓ, m) are decoupled and the entropy is additive over independent modes, the total entanglement entropy of the ball of $n = R/a$ radial sites is the weighted sum of the one-dimensional chain entropies,

$$S(R) = \sum_{\ell=0}^{\infty} (2\ell+1)\, S_\ell(n), \qquad S_\ell(n) = \sum_k g(\nu_k^{(\ell)}), \tag{55.152}$$

where $S_\ell(n)$ is computed from Theorem 55.35 applied to the first n sites of the chain K^ℓ, and the factor $(2\ell+1)$ is the degeneracy of the S^2 harmonics. Each radial chain is a finite tridiagonal matrix; the symplectic eigenvalues are obtained by a single matrix square root, and the sum over ℓ converges because $S_\ell(n)$ falls off once $\ell \gtrsim n$ (the centrifugal barrier expels the high-ℓ modes from the region).

Theorem 55.37 (Area law for the free scalar in $d > 2$)**.** *The vacuum entanglement entropy of a ball of radius R for the free massless scalar in d spacetime dimensions, regulated by a lattice of spacing $a = \epsilon$, scales for $R \gg \epsilon$ as*

$$S(R) = \kappa \left(\frac{R}{\epsilon}\right)^{d-2} + \cdots = \kappa\, \frac{\mathcal{A}(\partial A)}{\epsilon^{\,d-2}} + (\textit{lower powers of } R/\epsilon), \tag{55.153}$$

with $\mathcal{A}(\partial A) = \Omega_{d-2} R^{d-2}$ the area of the entangling sphere and κ a dimensionless, cutoff-scheme-dependent constant. The entanglement entropy is proportional to the area *of the entangling surface, not the volume of the region.*

Argument. We give the scaling argument that fixes the power, then confirm the coefficient numerically. In d spacetime dimensions the entangling sphere is S^{d-2} and the degree-ℓ harmonics have degeneracy $g_\ell \sim \ell^{\,d-3}/(d-3)!$ for large ℓ. The single-chain entropy $S_\ell(n)$ is, by the masslessness and the absence of any scale other than the ratio, a function of ℓ/n alone for $n \gg 1$: it is $O(1)$ for $\ell \lesssim n$ and is exponentially suppressed for $\ell \gg n$, because a mode of angular momentum ℓ has its classical turning point at $r \sim \ell a/\sqrt{\cdots}$ and ceases to straddle the boundary at $r = R = na$ once $\ell \gg n$. Therefore

$$S(R) = \sum_\ell g_\ell\, S_\ell(n) \simeq \int_0^\infty \mathrm{d}\ell\, \frac{\ell^{\,d-3}}{(d-3)!}\, f(\ell/n) = n^{\,d-2} \underbrace{\int_0^\infty \mathrm{d}x\, \frac{x^{\,d-3}}{(d-3)!}\, f(x)}_{\equiv \kappa'} = \kappa' \Big(\frac{R}{\epsilon}\Big)^{d-2}, \tag{55.154}$$

having substituted $\ell = nx$. The power $d-2$ is exactly the dimension of the entangling surface, so the result is proportional to its area. The convergence

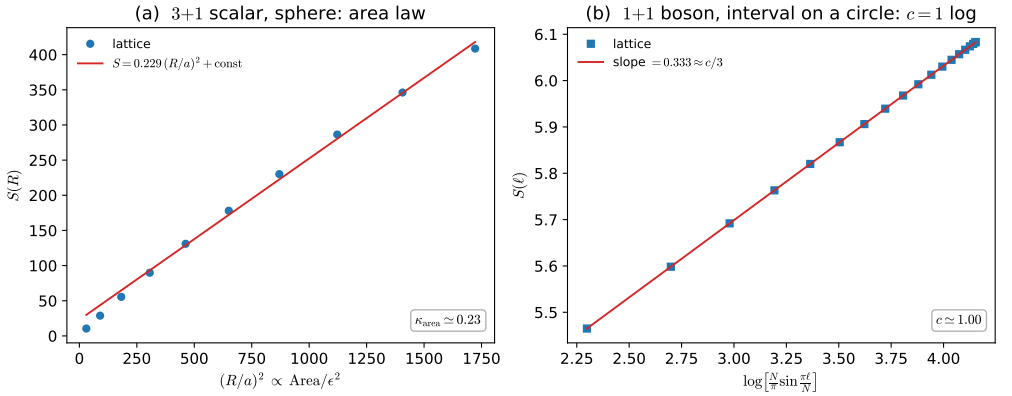

Figure 55.5: The free-scalar entanglement entropy computed from the Gaussian formula Eq. (55.145), with symplectic eigenvalues $\nu_k = \text{eig}\sqrt{X_A P_A}$ of the lattice correlators Eq. (55.148). **(a)** The 3+1 massless scalar on a spherical region, via the radial decomposition Eq. (55.152): plotting S against $(R/\epsilon)^2$ exhibits the area law $S = \kappa_{\text{area}}(R/\epsilon)^2 + \cdots$, with $\kappa_{\text{area}} \approx 0.23$ in this scheme. **(b)** The 1+1 free boson, an interval of ℓ sites on a periodic chain of N sites: plotting S against the conformal-chord variable $\log[(N/\pi)\sin(\pi\ell/N)]$ of Eq. (55.128) gives a straight line of slope $c/3$, and the fit returns $c = 1.000$ — the central charge of the free boson, the $d = 2$ instance of the same computation and a cross-check of the CFT result of Theorem 55.32.

of the x-integral is guaranteed by the suppression of $f(x)$ at large x; its value κ' (equivalently $\kappa = \kappa'/\Omega_{d-2}$) is a pure number determined by the lattice and is not universal. The numerical evaluation of Eq. (55.152) in $d = 4$, summing the radial-chain entropies over ℓ, confirms the linear dependence of S on $(R/\epsilon)^2$ and returns $\kappa_{\text{area}} \equiv \kappa' \approx 0.23$ in the midpoint scheme (Fig. 55.5a); Srednicki's original mode-sum convention gives ≈ 0.30. The two numbers differ because the coefficient is scheme-dependent, which is precisely the lesson; the area *law* — the power $(R/\epsilon)^{d-2}$ — is common to both. □

Physical Insight

The area law is the entanglement signature of locality. The vacuum correlations of a local field theory are short-ranged — the equal-time two-point function decays away from coincidence — so the only field modes entangled across the cut are those localized within a cutoff cell of the boundary ∂A. Tiling the boundary with $\sim \mathcal{A}/\epsilon^{d-2}$ such cells, each contributing $O(1)$ of entanglement, reproduces Eq. (55.153); the heuristic of Eq. (55.24) is now the honest result of Theorem 55.35. A state with *long*-range entanglement — a generic, non-vacuum state of the

field, or a thermal state in its bulk — would instead show a volume law $S \sim \mathrm{Vol}(A)/\epsilon^{d-1}$. That the vacuum sits at the boundary of these two behaviors, obeying an area law, is what makes its entanglement geometrical, and is the fact the Ryu–Takayanagi formula of Chapter 56 will turn into a statement about minimal surfaces.

55.5.3 The area-law coefficient from the Rindler thermal gas

The lattice computation yields the area law as a numerical fact. The Rindler analysis of Section 55.3 lets us recover its structure — the power of the cutoff and the way the coefficient counts the field's degrees of freedom — in closed form, discharging the promise made there. This is the worked computation the half-space section deferred to the present one.

Worked Example 55.38 (The area law as a Rindler thermal-gas entropy)**.** By the Bisognano–Wichmann result Theorem 55.25, the vacuum restricted to the half-space is the thermal state of the boost Hamiltonian, and a static observer at proper distance ρ_* from the entangling plane sees a local temperature, the Unruh temperature Eq. (55.83) evaluated at acceleration $1/\rho_*$,

$$T(\rho_*) = \frac{1}{2\pi\rho_*}. \tag{55.155}$$

The entanglement entropy of the half-space is, in this picture, the thermodynamic entropy of a gas of the field's quanta in local equilibrium at the position-dependent temperature Eq. (55.155), integrated over the wedge. We need the entropy density of a free massless scalar gas in d spacetime dimensions. Its free-energy density is

$$f(T) = T\int \frac{\mathrm{d}^{d-1}k}{(2\pi)^{d-1}}\,\log(1-e^{-|\mathbf{k}|/T}) = \frac{T\,\Omega_{d-2}}{(2\pi)^{d-1}}\int_0^\infty \mathrm{d}k\,k^{d-2}\log(1-e^{-k/T}), \tag{55.156}$$

with $\Omega_{d-2} = 2\pi^{(d-1)/2}/\Gamma(\frac{d-1}{2})$ the area of the unit S^{d-2}. Expanding the logarithm as $-\sum_{m\geq 1} e^{-mk/T}/m$ and using $\int_0^\infty \mathrm{d}k\,k^{d-2}e^{-mk/T} = \Gamma(d-1)(T/m)^{d-1}$,

$$f(T) = -\frac{\Omega_{d-2}\,\Gamma(d-1)}{(2\pi)^{d-1}}\,T^d\sum_{m\geq 1}\frac{1}{m^d} = -\frac{\Omega_{d-2}\,\Gamma(d-1)\,\zeta(d)}{(2\pi)^{d-1}}\,T^d, \tag{55.157}$$

the Riemann zeta value $\zeta(d)$ appearing exactly as in the zeta-regularized vacuum sums of Section E.3. The entropy density is $s = -\partial f/\partial T = \sigma_d\,T^{d-1}$ with the field-counting Stefan–Boltzmann coefficient

$$\sigma_d = \frac{d\,\Gamma(d-1)\,\zeta(d)\,\Omega_{d-2}}{(2\pi)^{d-1}}. \tag{55.158}$$

The proper volume element a distance ρ_* from the plane is $\mathrm{d}V = \mathcal{A}_\perp \, \mathrm{d}\rho_*$ with $\mathcal{A}_\perp$ the transverse area of the entangling surface, so

$$S = \int \mathrm{d}V \, s(T(\rho_*)) = \mathcal{A}_\perp \, \sigma_d \int_\epsilon^\infty \mathrm{d}\rho_* \left(\frac{1}{2\pi\rho_*}\right)^{d-1} = \frac{\sigma_d}{(2\pi)^{d-1}(d-2)} \frac{\mathcal{A}_\perp}{\epsilon^{d-2}} \qquad (d > 2), \tag{55.159}$$

the lower limit $\rho_* = \epsilon$ being the proper cutoff at which the local temperature Eq. (55.155) would otherwise diverge. This is the area law Eq. (55.139) with the coefficient $\kappa = \sigma_d/[(2\pi)^{d-1}(d-2)]$ written explicitly in terms of the degrees of freedom of the field through σ_d. The hot modes piled up against the entangling surface — arbitrarily hot as $\rho_* \to 0$ — are the physical origin of the divergence, and the cutoff ϵ is exactly the regulator that the lattice supplied. The coefficient still depends on the cutoff prescription (where in proper distance the integral is truncated), reaffirming that κ is non-universal; what the thermal computation fixes unambiguously is the power $\epsilon^{-(d-2)}$ and the proportionality to σ_d.

Physical Insight

The integral Eq. (55.159) is power-law divergent for $d > 2$ but *logarithmically* divergent at $d = 2$, where $\int_\epsilon \mathrm{d}\rho_*/\rho_* = \log(\cdots/\epsilon)$. This is the precise sense in which the 2D logarithm is the degenerate, $d = 2$ face of the area law: the area of a point-like entangling surface is a pure number, the power $\epsilon^{-(d-2)}$ becomes ϵ^0, and the would-be power-law divergence collapses to a logarithm. The collapse is quantitative, as the next computation shows.

55.5.4 Recovering the 2D logarithm: the free boson has $c = 1$

The two derivations of this section — the lattice formula Eq. (55.145) and the thermal-gas integral Eq. (55.159) — both contain the $d = 2$ result, and reproducing the CFT logarithm of Theorem 55.32 from them is a sharp cross-check that the free-field machinery and the conformal machinery agree. The free real scalar in two dimensions is the free boson, a CFT of central charge $c = 1$.

From the thermal gas. Set $d = 2$ in Eq. (55.158): $\Omega_0 = 2$ (the two points of S^0), $\Gamma(1) = 1$, $\zeta(2) = \pi^2/6$, giving $\sigma_2 = 2 \cdot 1 \cdot (\pi^2/6) \cdot 2/(2\pi) = \pi/3$. The entropy density of the 2D free boson gas is therefore $s = \frac{\pi}{3}T$, which is the Cardy density $s = \pi c/(3\beta) = \frac{\pi c}{3}T$ at $c = 1$ — the same value found in the large-interval limit Eq. (55.135). The wedge integral at $d = 2$ is logarithmic: with a point-like entangling surface ($\mathcal{A}_\perp = 1$) and one endpoint,

$$S_{\text{one endpoint}} = \sigma_2 \int_\epsilon^\ell \frac{\mathrm{d}\rho_*}{2\pi\rho_*} = \frac{\pi/3}{2\pi} \log\frac{\ell}{\epsilon} = \frac{1}{6}\log\frac{\ell}{\epsilon} = \frac{c}{6}\log\frac{\ell}{\epsilon}, \tag{55.160}$$

and an interval has two endpoints, doubling this to $S = \frac{c}{3}\log(\ell/\epsilon)$ with $c = 1$ — exactly Eq. (55.119) for the free boson. The per-endpoint coefficient $c/6$ is the $d = 2$ residue of the area-law coefficient κ.

From the lattice. Figure 55.5b carries out Eq. (55.145) directly on an interval of ℓ sites in a periodic chain of N sites — the lattice realization of an interval on a spatial circle. Plotting S against the conformal-chord variable $\log[(N/\pi)\sin(\pi\ell/N)]$ of Eq. (55.128) gives a straight line whose slope is $c/3$; the numerical fit returns $c = 1.000$. (Fitting against a bare $\log \ell$ on a finite chain, or using open boundaries, distorts the coefficient: the circle's periodicity and any boundary entropy must be accounted for, which is exactly what the chord variable does.) The free-field computation, the thermal-gas computation, and the twist-operator computation of Section 55.4.3 thus return the identical universal datum, $c = 1$, by three independent routes.

55.5.5 The full divergence structure and what is universal

The leading area law is the first term of a systematic expansion. For a smooth entangling surface ∂A of typical size R in d spacetime dimensions, dimensional analysis and locality dictate that S_A is a sum of local geometric integrals over ∂A, each multiplying a power of the cutoff. The integrals are built from the intrinsic and extrinsic curvatures of ∂A; by reflection symmetry of the vacuum only even total numbers of derivatives appear, so the divergences come in steps of two:

$$S_A = g_{d-2}\frac{\mathcal{A}}{\epsilon^{d-2}} + g_{d-4}\frac{1}{\epsilon^{d-4}}\int_{\partial A}(\text{curvature}) + \cdots + S_{\text{univ}} + (\text{finite, scheme-dependent}). \tag{55.161}$$

Each coefficient g_{d-2k} multiplies a curvature integral of mass dimension $d-2-2k$ over the surface; for a sphere these are pure numbers times R^{d-2-2k}. Every one of these power-law terms is non-universal: it depends on the short-distance regulator, and a change of scheme (a different lattice, a different smooth cutoff) shifts each g_{d-2k}. The series of powers continues down to ϵ^0, and what sits at that order — the term that does *not* scale away with the cutoff — is the universal content. Its character depends on the parity of d.

Theorem 55.39 (Universal term in the entanglement entropy)**.** *For a CFT vacuum and a smooth entangling surface, the cutoff-independent part of S_A is:*

(even d) *a logarithm, $S_{\text{univ}} = (-1)^{\frac{d-2}{2}}\, c_{\log}\, \log(R/\epsilon)$, whose coefficient $c_{\log}$ is a linear combination of the conformal-anomaly coefficients of the theory integrated against the curvature of ∂A. The sign of the logarithmic coefficient is the universal datum.*

(odd d) *a finite constant, $S_{\text{univ}} = (-1)^{\frac{d-1}{2}}\, F$, independent of the cutoff and of R; for a spherical region F is a positive, scheme-independent number characterizing the CFT.*

The reason the universal term is a logarithm in even d is the same anomaly mechanism that produced the 2D result. A logarithm is the only function of R/ϵ

invariant under the simultaneous rescaling of R and ϵ up to an additive shift; it can appear only when a scale transformation fails to be a symmetry, i.e. through the conformal anomaly. In $d = 2$ the anomaly coefficient is the central charge, and the curvature integral over the two endpoints gives the familiar

$$S_{\text{univ}}^{(d=2)} = \frac{c}{3} \log \frac{R}{\epsilon}, \tag{55.162}$$

recovering Theorem 55.32. In $d = 4$ the trace anomaly has two independent coefficients, conventionally a and c, defined through

$$\langle T^{\mu}{}_{\mu} \rangle = \frac{c}{16\pi^2} W^2_{\mu\nu\rho\sigma} - \frac{a}{16\pi^2} E_4, \tag{55.163}$$

with W the Weyl tensor and E_4 the Euler density, and the entanglement logarithm of a smooth surface is (Solodukhin [450])

$$S_{\text{univ}}^{(d=4)} = -\frac{\log(R/\epsilon)}{2\pi} \int_{\partial A} \mathrm{d}^2 y \, \sqrt{h} \left[a \, \mathcal{R}_{\partial A} + c \left(K^{\mu}{}_{\nu} K^{\nu}{}_{\mu} - \tfrac{1}{2} K^2 - W_{\text{ind}} \right) \right], \tag{55.164}$$

where $\mathcal{R}_{\partial A}$ is the intrinsic Ricci scalar of ∂A and $K^{\mu}{}_{\nu}$ its extrinsic curvature. For a spherical entangling surface in flat space the extrinsic terms cancel and the Gauss–Bonnet integral $\int \mathcal{R}_{\partial A} = 8\pi$ gives $S_{\text{univ}}^{(d=4)} = -4a \log(R/\epsilon)$: the sphere isolates the a-anomaly cleanly. For the free real scalar, $a = \frac{1}{360}$, so its universal logarithmic coefficient is $-\frac{1}{90}$ — a pure number computable from the field content, and the $d = 4$ analogue of $c = 1$.

In odd d there is no conformal anomaly (the relevant curvature invariants do not exist in odd dimensions), no scale to make a logarithm, and the universal piece is a finite constant. In $d = 3$, for a disk-shaped region (circular entangling curve), this constant defines the quantity

$$F \equiv -S_{\text{univ}}^{(d=3)} = -\left(S_A - g_1 \, \tfrac{\mathcal{A}}{\epsilon} \right)\Big|_{\text{finite}}, \tag{55.165}$$

the negative of the constant term after the leading $\mathcal{A}/\epsilon$ divergence is subtracted. For the free real scalar in $d = 3$, $F = \frac{1}{16}(2\log 2 - \frac{3\zeta(3)}{\pi^2}) \approx 0.0638$, again a sharp number set by the field.

Caution

Equation Eq. (55.161) assumes a *smooth* entangling surface. A corner or cusp in ∂A produces its own, extra logarithmic divergence even in dimensions where the smooth surface gives none — in $d = 3$ a corner of opening angle Ω contributes a term $\propto a(\Omega) \log(R/\epsilon)$ with a universal angle-dependent coefficient. These geometric subtleties refine, but do not overturn, the area law: the leading $\mathcal{A}/\epsilon^{d-2}$ term is always present and always non-universal.

The practical consequence is the honesty point that has shadowed the whole chapter. The entanglement entropy S_A is not a physical observable in the continuum: its leading term diverges with a scheme-dependent coefficient, and even its finite part shifts under a change of regulator. The only cutoff-independent information is the universal term of Theorem 55.39 — the sign and magnitude of the even-d logarithmic coefficient, or the odd-d constant F — and, for combinations of regions, the subtracted quantities in which the boundary divergences cancel. The *mutual information* $I(A:B) = S_A + S_B - S_{AB}$ of Eq. (55.23) is UV-finite: S_A diverges on ∂A, S_B on ∂B, and S_{AB} on $\partial A \cup \partial B$, so for disjoint A, B the area-law divergences cancel identically and $I(A:B)$ is a finite, scheme-independent measure of correlation. The *relative entropy* $S(\rho_A \| \sigma_A)$, which descends even to the cutoff-free algebraic setting, is likewise finite. These are the objects Section 55.6 builds the chapter's exact structure upon; the bare S_A is their divergent scaffolding.

Caution: the entanglement entropy of a gauge field (QED)

For the Maxwell field of QED the very first step of this section — the factorization $\mathcal{H} = \mathcal{H}_A \otimes \mathcal{H}_{\bar{A}}$ that lets one trace out $\bar{A}$ — is subtle, and the subtlety is physical, not technical. Gauge invariance means the physical observables in a region form an algebra with a nontrivial *center*: the electric flux operator through the entangling surface commutes with everything in A and with everything in $\bar{A}$, so it belongs to both algebras at once and the Hilbert space does not factorize as a naive tensor product. One must first choose how to split the surface degrees of freedom — a choice of center, equivalently a choice of boundary condition for the Wilson/electric-flux variables — and different choices give different entanglement entropies, differing by a classical Shannon term measuring the distribution of the flux through ∂A [158]. The resulting "edge modes" contribute a genuine, surface-localized piece to S_A, and they are responsible for the famous mismatch between the naive free-field count and the holographic/heat-kernel value of the Maxwell logarithmic coefficient in $d = 4$. We state this at the level of a flag: the area law and divergence structure of this section apply verbatim to the scalar, but for gauge fields the definition of S_A already requires the algebraic, center-aware viewpoint anticipated in the chapter opening. The clean, definition-independent diagnostics — mutual information and relative entropy — are insensitive to the center ambiguity, which is one more reason they, not S_A, are the fundamental objects.

55.5.6 Entropic monotonicity: c-, F-, and a-theorems

The universal coefficients of Theorem 55.39 are not merely labels of fixed points; along a renormalization-group flow they are monotonic, and the monotonicity is a theorem of entanglement, rooted in the strong subadditivity inequality that Theorem 55.47 will prove. We state the results at the level they will be used, deferring the strong-subadditivity proof itself to Section 55.6.

In $d = 2$, the entropic c-function $c_{\text{eff}}(\ell) = 3\,\ell\,\mathrm{d}S_A/\mathrm{d}\ell$ of Eq. (55.136) is cutoff-independent and equals the central charge at a fixed point. Casini and Huerta showed [113] that strong subadditivity, combined with Lorentz invariance, forces $c_{\text{eff}}(\ell)$ to be *monotonically non-increasing* as the interval grows, giving an entropic proof of Zamolodchikov's c-theorem (Theorem 52.17): the effective number of degrees of freedom decreases from the ultraviolet to the infrared, $c_{\text{UV}} \geq c_{\text{IR}}$. The entanglement entropy thus supplies the monotone directly, as the slope of S_A against $\log \ell$.

In $d = 3$, the role of the central charge is played by the constant F of Eq. (55.165). Casini and Huerta proved [114] the *F-theorem*, $F_{\text{UV}} \geq F_{\text{IR}}$, again from strong subadditivity applied to circular regions of varying radius; the entropic F-function $F(R) = (R\,\mathrm{d}_R - 1)S_A$ interpolates monotonically between the endpoints. This is the odd-dimensional counterpart of the c-theorem, with a finite universal quantity in place of a logarithmic coefficient, and it is the diagnostic that orders three-dimensional CFTs by their degree-of-freedom count.

In $d = 4$, the analogous statement is the a-theorem, $a_{\text{UV}} \geq a_{\text{IR}}$, for the coefficient a of the Euler density that controls the spherical entanglement logarithm Eq. (55.164). The complete proof of Komargodski and Schwimmer [301, 302] proceeds through the dilaton effective action rather than purely through entanglement, and a fully entropic four-dimensional proof along the strong-subadditivity lines of the lower-dimensional cases remains, as of the mid-2020s, only partially established; we state the a-theorem as a monotonicity result and flag the entropic version as an active question. What is uniform across $d = 2, 3, 4$ is the picture: a universal coefficient of the entanglement entropy counts degrees of freedom, and that count cannot increase under renormalization-group flow, with strong subadditivity the structural source of the monotonicity wherever the entropic proof is complete.

Physical Insight

The thread that runs from the 2D logarithm to the higher-dimensional area law is the identification of an entanglement coefficient with a count of degrees of freedom. In $d = 2$ it is the central charge c; in $d = 4$ it is the anomaly coefficient a; in $d = 3$, where no anomaly exists, it is the finite number F. In every case the coefficient is extracted from S_A by a derivative or subtraction that removes the cutoff dependence, and

in every case it decreases along the flow to the infrared. Entanglement entropy, born as a measure of quantum correlation, has become a measure of the size of a quantum field theory — the informational expression of the irreversibility of the renormalization group.

We have now established the generic leading behavior of vacuum entanglement entropy in any dimension: $S_A = \kappa\,\mathcal{A}(\partial A)/\epsilon^{d-2} + \cdots$, an area law whose coefficient is scheme-dependent, beneath which sits a single universal term — a logarithm tied to a conformal anomaly in even d, a finite constant in odd d — that counts the theory's degrees of freedom and runs monotonically under the renormalization group. The price of this generic divergence is that S_A itself is not a clean observable, which makes the subtracted, UV-finite quantities — mutual information and relative entropy — the structurally fundamental ones; Section 55.6 develops them, proves the strong subadditivity invoked above, and derives the first law of entanglement. The area law established here is also the precise QFT statement that the holographic computation of Chapter 56 will geometrize: the Ryu–Takayanagi prescription reproduces Eq. (55.153) as the area of a minimal surface anchored on ∂A, with the universal coefficients of Theorem 55.39 emerging from its subleading geometry.

55.6 Relative Entropy, the First Law, and Information Inequalities

The previous sections have repeatedly run aground on the same rock. The entanglement entropy S_A of a region is, in the continuum, ultraviolet divergent: the area law of Section 55.5 showed its leading term to be $\mathcal{A}_\perp/\epsilon^{d-2}$, cutoff-dependent and physically arbitrary, and even the $\frac{c}{3}\log(\ell/\epsilon)$ of Section 55.4 carries an undetermined additive constant. We were forced to the conclusion, stated already in Section 55.1.6 and honored throughout, that S_A is not by itself an observable: only *differences* of entropies, in which the boundary divergences cancel, can carry cutoff-independent physics. This final section builds the quantities that survive. The organizing object is the *relative entropy* $S(\rho\,\|\,\sigma)$, introduced in Eq. (55.15) and shown positive in Theorem 55.9; we will see that it is exactly the difference structure the chapter has been demanding — ultraviolet finite, monotone under coarse-graining, and tied to the modular Hamiltonian $K = -\log\rho_A$ of Theorem 55.28 by an identity that splits it into a change in modular energy minus a change in entropy. From its positivity we will extract the *first law of entanglement*, $\delta S_A = \delta\langle K_A\rangle$, the linear-response statement that is the precise hook on which holographic entanglement and the derivation of gravitational dynamics from information (Chapters 56 and 57) are hung. From its monotonicity we will obtain strong subadditivity — the master inequality

of quantum information, promised in Section 55.1.4 — and, without full proof, the modern theorems that turn entanglement inequalities into energy conditions: the Casini reformulation of the Bekenstein bound, and the quantum null energy condition. Throughout we work in the regulated (type-I) picture of Section 55.1.6, where ρ_A is an honest density matrix, and we report only quantities that survive the removal of the cutoff.

55.6.1 The modular decomposition and ultraviolet finiteness

Recall the definition. For two density matrices ρ, σ on the same (regulated) algebra of a region,

$$S(\rho \,\|\, \sigma) = \operatorname{Tr}(\rho \log \rho) - \operatorname{Tr}(\rho \log \sigma), \tag{55.166}$$

which is Eq. (55.15), non-negative by Theorem 55.9, and zero if and only if $\rho = \sigma$. The crucial structural fact is that Eq. (55.166) reorganizes into a difference of two physically meaningful pieces once we recognize $-\log\sigma$ as the modular Hamiltonian of the reference state. Write

$$K_\sigma \equiv -\log \sigma, \tag{55.167}$$

the modular Hamiltonian of σ in the sense of Eq. (55.87), and define for any state ρ the *modular energy* $\langle K_\sigma \rangle_\rho \equiv \operatorname{Tr}(\rho\, K_\sigma)$ and the von Neumann entropy $S(\rho) = -\operatorname{Tr}(\rho \log \rho)$. Then Eq. (55.166) reads

$$S(\rho \,\|\, \sigma) = \langle K_\sigma \rangle_\rho - S(\rho), \tag{55.168}$$

because $-\operatorname{Tr}(\rho \log \sigma) = \operatorname{Tr}(\rho K_\sigma) = \langle K_\sigma \rangle_\rho$ and $\operatorname{Tr}(\rho \log \rho) = -S(\rho)$. Now evaluate the same combination on the reference state itself: setting $\rho = \sigma$ gives $S(\sigma \,\|\, \sigma) = 0$, i.e. $\langle K_\sigma \rangle_\sigma = S(\sigma)$ — the reference modular energy equals the reference entropy. Subtracting this vanishing quantity from Eq. (55.168) costs nothing and produces the central identity of the section.

Theorem 55.40 (Modular decomposition of relative entropy)**.** *Let σ be a reference state with modular Hamiltonian $K_\sigma = -\log\sigma$, and let ρ be any state on the same algebra. Define the differences*

$$\Delta\langle K_\sigma \rangle \equiv \langle K_\sigma \rangle_\rho - \langle K_\sigma \rangle_\sigma, \qquad \Delta S \equiv S(\rho) - S(\sigma). \tag{55.169}$$

Then the relative entropy is their difference,

$$\boxed{S(\rho \,\|\, \sigma) = \Delta\langle K_\sigma \rangle - \Delta S} \tag{55.170}$$

and its non-negativity Theorem 55.9 is the inequality

$$\Delta S \le \Delta\langle K_\sigma \rangle, \tag{55.171}$$

with equality if and only if $\rho = \sigma$.

Proof. From Eq. (55.168), $S(\rho\,\|\,\sigma) = \langle K_\sigma\rangle_\rho - S(\rho)$. Subtract the identity $0 = \langle K_\sigma\rangle_\sigma - S(\sigma)$ (which is Eq. (55.168) at $\rho = \sigma$): $S(\rho\,\|\,\sigma) = (\langle K_\sigma\rangle_\rho - \langle K_\sigma\rangle_\sigma) - (S(\rho) - S(\sigma)) = \Delta\langle K_\sigma\rangle - \Delta S$. Positivity $S(\rho\,\|\,\sigma) \geq 0$ is then Eq. (55.171), and the equality clause is that of Theorem 55.9. □

The decomposition Eq. (55.170) is the resolution of the chapter's central tension, and it is worth dwelling on why. Each of the two terms on the right is, separately, ultraviolet divergent. The entropy difference ΔS inherits the area-law divergence $\mathcal{A}_\perp/\epsilon^{d-2}$ of Section 55.5 from each of $S(\rho)$ and $S(\sigma)$; the modular-energy difference $\Delta\langle K_\sigma\rangle$ is equally singular, because K_σ is, in the local cases of Theorem 55.25, an integral of the energy density weighted by the distance to the entangling surface, and that integral diverges as the surface is approached. But the two divergences are *the same* divergence. The reason is that ρ and σ, being states of the same theory, have identical short-distance structure: the singular entanglement of the modes hugging the entangling surface is a property of the vacuum two-point function near ∂A, which is state-independent (the Hadamard condition). Any two physical states look like the vacuum at short distances, so their reduced density matrices differ only in the soft, long-wavelength sector, and the hard, divergent sector cancels in the difference Eq. (55.170). The relative entropy is therefore *ultraviolet finite*: it is a difference engineered precisely so that the cutoff drops out, and it remains well-defined — through Tomita–Takesaki theory — even on the type-III algebra of the continuum, where no ρ, no σ, and no S_A individually exist (Section 55.1.6). This is the abstract content of the remark, made in Section 55.1.5, that the clean diagnostics are differences. The inequality Eq. (55.171), $\Delta S \leq \Delta\langle K_\sigma\rangle$, will be recognized below as a sharpened, quantum form of the Clausius inequality, and its first-order saturation is the first law of entanglement.

Physical Insight

The decomposition Eq. (55.170) says that relative entropy measures the failure of a generalized second law to saturate. Read $\langle K_\sigma\rangle$ as a "modular heat" and S as a thermodynamic entropy: the relative entropy is (heat) − (entropy change), exactly the entropy production that the Clausius inequality bounds below by zero. A state ρ is distinguishable from the reference σ precisely to the extent that it carries this irreversibility, and the amount of distinguishability is finite and physical even when the entropies themselves are not. This is the thermodynamic face of the information-theoretic statement that $S(\rho\,\|\,\sigma)$ is the number of measurements needed to tell ρ from σ.

Before exploiting the decomposition we record the companion finite quantity, the mutual information, whose finiteness has the same origin. For disjoint regions A, B the mutual information $I(A:B) = S_A + S_B - S_{AB}$ of Theorem 55.13 was

shown in Theorem 55.14 to equal a relative entropy,

$$I(A:B) = S(\rho_{AB} \,\|\, \rho_A \otimes \rho_B) \geq 0, \tag{55.172}$$

the distinguishability of the true joint state from the product of its marginals. Equation (55.172) is the reason $I(A:B)$ is finite: it is manifestly a relative entropy, hence cutoff-independent by the cancellation just described, with the divergence on ∂A carried identically by ρ_{AB} and by $\rho_A \otimes \rho_B$ (whose A-marginal is ρ_A), and similarly on ∂B. The mutual information is thus the universally available finite measure of total correlation between two regions, and it inherits from Theorem 55.9 both its positivity and the sharp condition for vanishing, $\rho_{AB} = \rho_A \otimes \rho_B$.

55.6.2 Klein's inequality from operator convexity

Positivity of relative entropy was proved in Theorem 55.9 by a Jensen argument on the doubly stochastic overlap matrix. We give here a second proof, from convexity of the function $x \log x$, for two reasons: it is the proof that generalizes — the same circle of ideas, upgraded from ordinary to *operator* convexity, delivers the monotonicity theorem of the next subsection — and it exposes relative entropy as the trace gap in a tangent-line inequality, which is the form in which the first law will use it.

Definition 55.41 (Operator convexity)**.** A real function f defined on an interval J is *operator convex* if, for all Hermitian operators A, B with spectra in J and all $\lambda \in [0,1]$,

$$f(\lambda A + (1-\lambda)B) \;\preceq\; \lambda f(A) + (1-\lambda) f(B), \tag{55.173}$$

the inequality being in the operator (positive-semidefinite) order: $X \preceq Y$ means $Y - X \succeq 0$. Operator convexity is strictly stronger than ordinary (scalar) convexity, which is the special case of Eq. (55.173) sandwiched between a fixed vector, $\langle\psi| f(\cdots) |\psi\rangle$.

The functions relevant to entanglement are operator convex. We will need that $x \log x$ is operator convex on $(0,\infty)$, and that $-\log x$ and x^{-1} are too; the latter two we prove in Theorem 55.45 below because the inverse furnishes the cleanest route to the deep inequalities. For positivity, however, ordinary convexity already suffices, through the following trace inequality, which is Klein's inequality in its general (tangent-line) form.

Proposition 55.42 (Klein's trace inequality)**.** *Let f be a differentiable convex function on an interval J, and let A, B be Hermitian operators with spectra in J. Then*

$$\operatorname{Tr}\big[f(A) - f(B) - f'(B)(A-B)\big] \;\geq\; 0, \tag{55.174}$$

with equality if and only if $A = B$ (when f is strictly convex).

Proof. Diagonalize $A = \sum_i a_i |i\rangle\langle i|$ and $B = \sum_j b_j |j\rangle\langle j|$ in orthonormal eigenbases, with $a_i, b_j \in J$. Because $\sum_j |\langle i|j\rangle|^2 = 1$ for each i, we may write $\operatorname{Tr} f(A) = \sum_i f(a_i) = \sum_{i,j} |\langle i|j\rangle|^2 f(a_i)$. The remaining traces are diagonal sums: $\operatorname{Tr} f(B) = \sum_j f(b_j)$ and $\operatorname{Tr}[f'(B)(A-B)] = \sum_{i,j} |\langle i|j\rangle|^2 f'(b_j)(a_i - b_j)$, using $\operatorname{Tr}[f'(B)A] = \sum_{i,j} |\langle i|j\rangle|^2 f'(b_j) a_i$ and $\operatorname{Tr}[f'(B)B] = \sum_j f'(b_j) b_j$. Collecting,

$$\operatorname{Tr}\left[f(A) - f(B) - f'(B)(A-B)\right] = \sum_{i,j} |\langle i|j\rangle|^2 \Big[f(a_i) - f(b_j) - f'(b_j)(a_i - b_j)\Big]. \tag{55.175}$$

Each bracket is non-negative: it is the gap between the convex function $f(a_i)$ and its tangent line at b_j, evaluated at a_i, and a convex function lies above each of its tangents. The weights $|\langle i|j\rangle|^2 \geq 0$ preserve the sign, giving Eq. (55.174). Strict convexity makes each bracket vanish only when $a_i = b_j$, which for all contributing (i,j) forces $A = B$. □

Positivity of relative entropy is the case $f(x) = x \log x$, $A = \rho$, $B = \sigma$. Here $f'(x) = \log x + 1$, so $f'(\sigma) = \log \sigma + \mathbf{1}$ and

$$\begin{aligned} \operatorname{Tr}\left[f(\rho) - f(\sigma) - f'(\sigma)(\rho - \sigma)\right] &= \operatorname{Tr}\left[\rho \log \rho - \sigma \log \sigma - (\log \sigma + \mathbf{1})(\rho - \sigma)\right] \\ &= \operatorname{Tr}(\rho \log \rho) - \operatorname{Tr}(\rho \log \sigma) - \operatorname{Tr}(\rho - \sigma) \\ &= S(\rho \,\|\, \sigma), \end{aligned} \tag{55.176}$$

where the $\sigma \log \sigma$ terms cancelled, $\operatorname{Tr}[(\log \sigma)(\rho - \sigma)]$ combined with $-\operatorname{Tr}(\rho \log \sigma)$ to leave $+\operatorname{Tr}(\sigma \log \sigma)$ that cancelled in turn, and $\operatorname{Tr}(\rho - \sigma) = 1 - 1 = 0$ killed the $\mathbf{1}$ term. By Theorem 55.42 this is ≥ 0, with equality iff $\rho = \sigma$ — recovering Theorem 55.9. The relative entropy is exactly the trace gap of the tangent-line inequality for $x \log x$ at the reference state σ; this is the form we will linearize for the first law.

55.6.3 Monotonicity, data processing, and strong subadditivity

The single most important property of relative entropy, and the one that ordinary convexity cannot reach, is that it can only *decrease* when the states are processed by any physical operation. Physical operations are the completely positive, trace-preserving (CPTP) maps — the quantum channels — whose general form we recall: a map $\mathcal{N}$ on density matrices is CPTP iff it admits a Kraus representation $\mathcal{N}(\rho) = \sum_k E_k \rho E_k^\dagger$ with $\sum_k E_k^\dagger E_k = \mathbf{1}$, equivalently (Stinespring) iff $\mathcal{N}(\rho) = \operatorname{Tr}_E\left[V \rho V^\dagger\right]$ for some isometry $V : \mathcal{H} \to \mathcal{H} \otimes \mathcal{H}_E$ into an enlarged space and a partial trace over the ancilla E. The two basic operations subsumed are unitary evolution and the discarding of a subsystem (partial trace).

Theorem 55.43 (Monotonicity of relative entropy / data-processing inequality)**.** *For any two states ρ, σ and any CPTP map $\mathcal{N}$,*

$$S(\mathcal{N}(\rho) \,\|\, \mathcal{N}(\sigma)) \;\leq\; S(\rho \,\|\, \sigma). \tag{55.177}$$

In particular, restriction to a subalgebra cannot increase distinguishability: for ρ_{AB}, σ_{AB} on a bipartite system, tracing out B gives

$$S(\rho_A \,\|\, \sigma_A) \;\le\; S(\rho_{AB} \,\|\, \sigma_{AB}). \tag{55.178}$$

The interpretation is the meaning of the name: a channel $\mathcal{N}$ is a processing of the data, and Eq. (55.177) says that no processing — no measurement, no time evolution, no transmission down a noisy line, no forgetting of part of the system — can make two states easier to tell apart than they were to begin with. Information is never created by manipulation. This is the statement on which the entire edifice of quantum information rests, and from which, as we show, strong subadditivity and the holographic inequalities descend.

The proof reduces, in two clean steps, to a single deep theorem of matrix analysis. The first step replaces a general channel by a partial trace; the second extracts Eq. (55.178) from the joint convexity of relative entropy.

Step 1: general channels reduce to partial trace. By Stinespring, $\mathcal{N}(\rho) = \mathrm{Tr}_E\,[V\rho V^\dagger]$ with V an isometry. An isometry preserves relative entropy exactly: $V\rho V^\dagger$ and $V\sigma V^\dagger$ have the same nonzero spectra and the same overlaps as ρ, σ, so $S(V\rho V^\dagger \,\|\, V\sigma V^\dagger) = S(\rho \,\|\, \sigma)$ (extend V to a unitary on a still-larger space if desired; the support of $V\rho V^\dagger$ lies in the image of V, and Eq. (55.166) depends only on operators restricted to that support). Hence Eq. (55.177) follows once we prove the special case of monotonicity under partial trace, Eq. (55.178), applied to the dilated states $V\rho V^\dagger, V\sigma V^\dagger$ on $\mathcal{H} \otimes \mathcal{H}_E$.

Step 2: partial-trace monotonicity from joint convexity. The engine is the following.

Theorem 55.44 (Joint convexity of relative entropy)**.** *The map $(\rho, \sigma) \mapsto S(\rho \,\|\, \sigma)$ is jointly convex: for states $\rho_1, \rho_2, \sigma_1, \sigma_2$ and $\lambda \in [0, 1]$,*

$$S(\lambda\rho_1 + (1-\lambda)\rho_2 \,\|\, \lambda\sigma_1 + (1-\lambda)\sigma_2) \;\le\; \lambda\, S(\rho_1 \,\|\, \sigma_1) + (1-\lambda)\, S(\rho_2 \,\|\, \sigma_2). \tag{55.179}$$

We first show that Theorem 55.44 implies partial-trace monotonicity, then prove Theorem 55.44. The bridge is a *twirl*. Let $\{U_k\}_{k=1}^{m}$, $m = d_B^2$, be the Heisenberg–Weyl (shift-and-clock) unitaries on the d_B-dimensional factor $\mathcal{H}_B$; they form a unitary 1-design, meaning that averaging any operator over the channel $U_k(\cdot)U_k^\dagger$ projects its B-part onto the maximally mixed state,

$$\frac{1}{m}\sum_{k=1}^{m} (\mathbf{1}_A \otimes U_k)\, \Omega\, (\mathbf{1}_A \otimes U_k^\dagger) = \mathrm{Tr}_B(\Omega) \otimes \frac{\mathbf{1}_B}{d_B}, \tag{55.180}$$

for any operator Ω on $\mathcal{H}_A \otimes \mathcal{H}_B$. (This is the standard fact that the Heisenberg–Weyl average is the completely depolarizing channel on B; it follows because the

only operators commuting with all U_k are multiples of $\mathbf{1}_B$, so the average is the projection onto $\mathbf{1}_B$, normalized to preserve the A-marginal.) Relative entropy is invariant under the conjugations in Eq. (55.180), since each $\mathbf{1}_A \otimes U_k$ is unitary; and it is jointly convex by Theorem 55.44. Therefore, averaging,

$$\begin{aligned} S(\rho_{AB}\,\|\,\sigma_{AB}) &= \frac{1}{m}\sum_k S\big((\mathbf{1}\otimes U_k)\rho_{AB}(\mathbf{1}\otimes U_k^\dagger)\,\|\,(\mathbf{1}\otimes U_k)\sigma_{AB}(\mathbf{1}\otimes U_k^\dagger)\big) \\ &\geq S\Big(\tfrac{1}{m}\sum_k(\mathbf{1}\otimes U_k)\rho_{AB}(\cdots)\,\Big\|\,\tfrac{1}{m}\sum_k(\mathbf{1}\otimes U_k)\sigma_{AB}(\cdots)\Big) \\ &= S\Big(\rho_A\otimes\tfrac{\mathbf{1}_B}{d_B}\,\Big\|\,\sigma_A\otimes\tfrac{\mathbf{1}_B}{d_B}\Big) = S(\rho_A\,\|\,\sigma_A), \end{aligned} \tag{55.181}$$

where the inequality is joint convexity Eq. (55.179) (the average of relative entropies dominates the relative entropy of the averages), the third equality is the twirl Eq. (55.180), and the last is the additivity $S(\rho_A\otimes\tau\,\|\,\sigma_A\otimes\tau) = S(\rho_A\,\|\,\sigma_A)$ for a common factor $\tau = \mathbf{1}_B/d_B$, immediate from Eq. (55.166) and $\log(X\otimes\tau) = \log X\otimes\mathbf{1} + \mathbf{1}\otimes\log\tau$. This is Eq. (55.178), and with Step 1 it completes the proof of Theorem 55.43 — modulo Theorem 55.44.

Joint convexity from Lieb's concavity theorem. The remaining content is a genuinely hard analytic input, the one place in this chapter where a result of matrix analysis must be invoked rather than derived from scratch; we state it precisely, prove the operator-convexity lemma at its heart, and deduce Theorem 55.44 from it.

Lemma 55.45 (Operator convexity of $X^\dagger A^{-1}X$)**.** *For positive-definite A and arbitrary X of compatible dimension, the map $(A,X)\mapsto X^\dagger A^{-1}X$ is jointly operator convex.*

Proof. The set $\{(A,X,Y) : A\succ 0,\ Y\succeq X^\dagger A^{-1}X\}$ is convex, because the Schur-complement criterion identifies it with a positive-semidefinite cone: for $A\succ 0$,

$$\begin{pmatrix} A & X \\ X^\dagger & Y\end{pmatrix}\succeq 0 \quad\Longleftrightarrow\quad Y - X^\dagger A^{-1}X\succeq 0, \tag{55.182}$$

the equivalence being the block factorization $\left(\begin{smallmatrix} A & X\\ X^\dagger & Y\end{smallmatrix}\right) = \left(\begin{smallmatrix} \mathbf{1} & 0\\ X^\dagger A^{-1} & \mathbf{1}\end{smallmatrix}\right)\left(\begin{smallmatrix} A & 0\\ 0 & Y-X^\dagger A^{-1}X\end{smallmatrix}\right)\left(\begin{smallmatrix} \mathbf{1} & A^{-1}X\\ 0 & \mathbf{1}\end{smallmatrix}\right)$ which is congruent to $\mathrm{diag}(A,\,Y-X^\dagger A^{-1}X)$ and hence positive iff the latter is. The set of positive block matrices is convex (the PSD cone is convex and the constraint $A\succ 0$ is open-convex), and Eq. (55.182) exhibits the epigraph of $(A,X)\mapsto X^\dagger A^{-1}X$ as the image of that convex cone under the linear projection forgetting nothing but the off-diagonal labelling; a function with convex epigraph is convex. In the operator sense: given (A_1,X_1) and (A_2,X_2) with $Y_i = X_i^\dagger A_i^{-1}X_i$, both blocks $\left(\begin{smallmatrix} A_i & X_i\\ X_i^\dagger & Y_i\end{smallmatrix}\right)$ are PSD, so their convex combination is PSD, and reading off its Schur complement gives $\lambda Y_1 + (1-\lambda)Y_2\succeq$

$(\lambda X_1 + (1-\lambda)X_2)^\dagger(\lambda A_1 + (1-\lambda)A_2)^{-1}(\lambda X_1 + (1-\lambda)X_2)$, which is Eq. (55.173) for this map. □

Lemma 55.46 (Lieb's concavity theorem)**.** *For each fixed $s \in [0,1]$ and fixed matrix K, the map*

$$(A, B) \longmapsto \operatorname{Tr}\left(K^\dagger A^s\, K\, B^{1-s}\right) \tag{55.183}$$

on pairs of positive-definite matrices is jointly concave.

This is the theorem of Lieb (1973). Its mechanism is exactly the operator convexity of the inverse, Theorem 55.45, promoted through the integral representation $A^s = \frac{\sin \pi s}{\pi} \int_0^\infty \lambda^{s-1}\, A(A+\lambda)^{-1}\, d\lambda$ (valid for $0 < s < 1$), which writes the fractional power as a positively-weighted average of the operator-convex resolvents $A(A+\lambda)^{-1} = \mathbf{1} - \lambda(A+\lambda)^{-1}$; the joint concavity of Eq. (55.183) then follows by the same Schur-complement positivity applied to the bilinear form in A and B, integrated against the positive weight λ^{s-1}. The complete chain of estimates is a standard result of matrix analysis; we take Theorem 55.46 as established, having exhibited its operator-convex core in Theorem 55.45 and refer to the standard matrix-analysis literature for the complete estimate.

Joint convexity of relative entropy now follows by differentiation. Define, for positive states ρ, σ and $s \in (0,1)$, the *Petz quasi-entropy*

$$Q_s(\rho, \sigma) \equiv \operatorname{Tr}\left(\rho^s\, \sigma^{1-s}\right), \tag{55.184}$$

which is Eq. (55.183) with $K = \mathbf{1}$ and is therefore jointly concave by Theorem 55.46. Its value at $s = 1$ is $Q_1 = \operatorname{Tr}\rho = 1$, and its derivative there reproduces the relative entropy:

$$\frac{d}{ds} Q_s\Big|_{s=1} = \operatorname{Tr}\left(\rho^s (\log\rho)\, \sigma^{1-s}\right)\Big|_{s=1} - \operatorname{Tr}\left(\rho^s \sigma^{1-s} \log\sigma\right)\Big|_{s=1} = \operatorname{Tr}(\rho\log\rho) - \operatorname{Tr}(\rho\log\sigma) = S(\rho\,\|\,\sigma). \tag{55.185}$$

Therefore, since $Q_1 = 1$ independently of the states,

$$S(\rho\,\|\,\sigma) = \lim_{s\to 1^-} \frac{Q_s(\rho,\sigma) - 1}{s-1} = \lim_{s\to 1^-} \frac{1 - Q_s(\rho,\sigma)}{1-s}. \tag{55.186}$$

For each fixed $s \in (0,1)$ the numerator $1 - Q_s$ is jointly *convex* (because Q_s is jointly concave by Theorem 55.46 and the constant 1 is affine), and dividing by the positive constant $1 - s$ preserves convexity. A pointwise limit of jointly convex functions is jointly convex; hence $S(\rho\,\|\,\sigma)$ is jointly convex, which is Theorem 55.44. This closes the proof of monotonicity Theorem 55.43.

With monotonicity in hand the master inequality of the chapter is one line away. We have arrived at the result promised in Section 55.1.4.

Theorem 55.47 (Strong subadditivity of the entanglement entropy)**.** *For any state on a tripartite system ABC, the reduced entropies satisfy*

$$\boxed{S_{AB} + S_{BC} \;\geq\; S_{ABC} + S_B} \tag{55.187}$$

equivalently, defining the conditional mutual information $I(A:C|B) = S_{AB} + S_{BC} - S_{ABC} - S_B$*, one has* $I(A:C|B) \geq 0$*.*

Proof. We argue through the conditional mutual information. Take the two states on ABC to be $\rho \equiv \rho_{ABC}$ and the product reference built on B. Monotonicity under tracing out A,

$$S(\rho_{BC} \,\|\, \rho_B \otimes \rho_C) \;\leq\; S(\rho_{ABC} \,\|\, \rho_{AB} \otimes \rho_C), \tag{55.188}$$

is the data-processing inequality Eq. (55.178) for the partial trace Tr_A, with $\rho_{ABC} \mapsto \rho_{BC}$ and $\rho_{AB} \otimes \rho_C \mapsto \rho_B \otimes \rho_C$. Now expand both sides with Eq. (55.166) and the additivity of log on tensor products. The left side is $\mathrm{Tr}(\rho_{BC} \log \rho_{BC}) - \mathrm{Tr}(\rho_{BC} \log \rho_B) - \mathrm{Tr}(\rho_{BC} \log \rho_C) = -S_{BC} + S_B + S_C$. The right side is $\mathrm{Tr}(\rho_{ABC} \log \rho_{ABC}) - \mathrm{Tr}(\rho_{ABC} \log \rho_{AB}) - \mathrm{Tr}(\rho_{ABC} \log \rho_C) = -S_{ABC} + S_{AB} + S_C$. The common S_C cancels, and Eq. (55.188) becomes $-S_{BC} + S_B \leq -S_{ABC} + S_{AB}$, i.e. $S_{AB} + S_{BC} \geq S_{ABC} + S_B$, which is Eq. (55.187). □

Setting $C = \varnothing$ in Eq. (55.187) reduces it to ordinary subadditivity $S_{AB} \leq S_A + S_B$ (Theorem 55.12), as anticipated there; strong subadditivity is the statement that adding a shared region B to both A and C does not spoil the inequality, and is incomparably more powerful. Its physical reading is that conditioning never increases the conditional entropy in a way that violates positivity of the conditional mutual information: the correlations A shares with C cannot become negative when B is held as side information.

Physical Insight

Strong subadditivity is the entropic engine behind the c-theorems of Section 55.4. Applied to nested and overlapping intervals on a line, Eq. (55.187) forces the entropic c-function $c_{\mathrm{eff}}(\ell) = 3\ell\, S'_A(\ell)$ of Eq. (55.136) to be monotonically non-increasing along the renormalization-group flow: choosing A, B, C to be adjacent intervals and feeding their boost-symmetric entropies into Eq. (55.187) yields $S''_A(\ell) \leq 0$ for the relevant combination, which is exactly $\partial_\ell c_{\mathrm{eff}} \leq 0$. This is the Casini–Huerta entropic proof of Zamolodchikov's theorem (Theorem 52.17): the monotonicity of the central charge under the RG is not an independent dynamical fact but a corollary of the universal inequality Eq. (55.187), which holds in *any* quantum system. The same logic, applied to spheres in higher dimensions, underlies the entropic proofs of the F-theorem ($d = 3$) and the a-theorem ($d = 4$); the entanglement entropy converts a statement about the loss of degrees of freedom into a statement about the geometry of nested regions.

55.6.4 The first law of entanglement

We now extract the linear-response content of relative-entropy positivity. Fix a reference state σ — for the applications, the reduced density matrix $\rho_A^{(0)}$ of the *vacuum* on a region A — and consider a one-parameter family of nearby states

$$\rho(\mu) = \sigma + \mu\,\delta\rho + O(\mu^2), \qquad \mathrm{Tr}\;\delta\rho = 0, \tag{55.189}$$

the trace condition enforcing normalization. The relative entropy $S(\rho(\mu)\,\|\,\sigma)$ is a non-negative function of μ that vanishes at $\mu = 0$; therefore $\mu = 0$ is a global minimum, and its first derivative there must vanish while its second derivative is non-negative. We read off both, using the decomposition Eq. (55.170), $S(\rho\,\|\,\sigma) = \Delta\langle K_\sigma\rangle - \Delta S$.

The modular-energy term is *linear* in ρ and hence carries no higher-order pieces: with $K_\sigma = -\log\sigma$ a fixed operator,

$$\Delta\langle K_\sigma\rangle = \mathrm{Tr}\,[(\rho-\sigma)K_\sigma] = \mu\;\mathrm{Tr}\,[\delta\rho\,K_\sigma] + O(\mu^2), \tag{55.190}$$

exactly linear in $\delta\rho$ at first order. The entropy term must be expanded. The first variation of the von Neumann entropy is

$$\delta S = -\delta\,\mathrm{Tr}(\rho\log\rho) = -\,\mathrm{Tr}\,[\delta\rho\,\log\rho] - \mathrm{Tr}\,[\rho\,\rho^{-1}\delta\rho] = -\,\mathrm{Tr}\,[\delta\rho\,\log\rho], \tag{55.191}$$

where the second term $\mathrm{Tr}[\rho\,\delta(\log\rho)] = \mathrm{Tr}[\delta\rho] = 0$ by the cyclic identity $\delta\log\rho = \int_0^\infty (\rho+u)^{-1}\delta\rho\,(\rho+u)^{-1}du$ traced against ρ, which collapses to $\mathrm{Tr}\;\delta\rho = 0$. Evaluating Eq. (55.191) at the reference point $\rho = \sigma$, the first-order entropy change is

$$\Delta S = \mu\,\big(-\mathrm{Tr}[\delta\rho\,\log\sigma]\big) + O(\mu^2) = \mu\;\mathrm{Tr}\,[\delta\rho\,K_\sigma] + O(\mu^2). \tag{55.192}$$

The first-order entropy change Eq. (55.192) is identical to the first-order modular-energy change Eq. (55.190). Their difference, the relative entropy, therefore has no linear term — consistent with the minimum at $\mu = 0$ — and we have proved the first law.

Theorem 55.48 (First law of entanglement)**.** *For any state $\rho = \sigma + \delta\rho$ infinitesimally close to a reference state σ with modular Hamiltonian $K_\sigma = -\log\sigma$, the first-order changes in the entanglement entropy and the modular energy coincide:*

$$\boxed{\;\delta S \;=\; \delta\langle K_\sigma\rangle \;=\; \mathrm{Tr}\,[\delta\rho\,K_\sigma].\;} \tag{55.193}$$

The relative entropy is second order in the perturbation,

$$S(\rho\,\|\,\sigma) = \tfrac{1}{2}\,\mu^2\,\langle\delta\rho,\delta\rho\rangle_\sigma + O(\mu^3) \;\geq\; 0, \tag{55.194}$$

its leading term being a positive-definite quadratic form — the quantum Fisher information of the family at σ — which encodes the statistical distinguishability of nearby states.

Proof. The vanishing of the first-order relative entropy was shown by Eqs. (55.190) and (55.192); subtracting them gives the first law Eq. (55.193). For Eq. (55.194), expand $S(\rho(\mu)\,\|\,\sigma)$ to second order. Its value and first derivative at $\mu = 0$ vanish (positivity with a zero at the minimum), so $S = \frac{1}{2}\mu^2\,\partial_\mu^2 S|_0 + O(\mu^3)$. The second derivative is the Kubo–Mori (Bogoliubov) inner product

$$\langle \delta\rho, \delta\rho\rangle_\sigma = \int_0^\infty du\ \mathrm{Tr}\left[\delta\rho\,(\sigma+u)^{-1}\,\delta\rho\,(\sigma+u)^{-1}\right], \tag{55.195}$$

obtained by differentiating $-\Delta S$ once more using the same resolvent representation of $\delta\log\rho$ as in Eq. (55.191); it is manifestly non-negative (the integrand is $\mathrm{Tr}[Z^\dagger Z] \geq 0$ with $Z = (\sigma+u)^{-1/2}\delta\rho\,(\sigma+u)^{-1/2}$, since $\delta\rho$ is Hermitian), and positive-definite for $\delta\rho \neq 0$. This is Eq. (55.194). □

The first law Eq. (55.193) deserves its name. It is structurally the thermodynamic relation $\delta E = T\,\delta S$ — "modular energy equals modular temperature times entropy" — but it is an *exact, derived* statement of quantum field theory, not a phenomenological postulate, and it holds for the entanglement entropy of any region as a consequence of nothing more than the positivity of relative entropy. The inequality Eq. (55.171), $\Delta S \leq \Delta\langle K_\sigma\rangle$, is its finite, nonlinear completion: away from linear order, entropy can only fall short of modular energy, the deficit being the (positive) relative entropy. For applications to gravity it is the saturation at first order that matters: a small excitation of the vacuum changes the entanglement of a region by exactly the expectation value of a fixed, geometric operator K_σ, with no entropy of its own to track. This is what makes entanglement entropy computable in linear response, and it is the precise statement that the holographic Ryu–Takayanagi construction of Chapter 56 reproduces geometrically — there, $\delta S = \delta\langle K\rangle$ becomes the linearized Einstein equation for the bulk metric.

55.6.5 The vacuum modular Hamiltonian of a ball in a CFT

To make the first law concrete we need an explicit modular Hamiltonian beyond the half-space of Theorem 55.25. Conformal symmetry provides exactly one more case in which K_A is local: a *ball* in the vacuum of a conformal field theory. The construction, due to Casini, Huerta, and Myers, maps the ball's causal development conformally onto the Rindler wedge, transports the boost generator, and reads off a local operator.

Take a ball $A = \{\,(0,\mathbf{x}) : |\mathbf{x}| < R\,\}$ of radius R on the time slice $t = 0$ of d-dimensional Minkowski space, in the vacuum of a CFT. Its domain of dependence is the *causal diamond* $\mathcal{D}_R = \{(t,\mathbf{x}) : |t| + |\mathbf{x}| < R\}$. The half-space wedge W_R of Theorem 55.24 and the diamond $\mathcal{D}_R$ are conformally equivalent: there is a special conformal transformation composed with a translation (an element of the conformal group of Chapter 47) that maps W_R onto $\mathcal{D}_R$ and carries the

boost Eq. (55.64), which preserves W_R, into the unique conformal Killing vector ζ^μ that preserves $\mathcal{D}_R$. Because the vacuum of a CFT is conformally invariant, the modular flow of the diamond is the flow generated by ζ, and the modular Hamiltonian is the corresponding conserved charge.

The conformal Killing vector preserving $\mathcal{D}_R$, normalized so that its flow has the same 2π periodicity in Euclidean angle as the boost, has the time component, on the slice $t = 0$,

$$\zeta^0(0, \mathbf{x}) = \frac{\pi}{R}(R^2 - |\mathbf{x}|^2), \tag{55.196}$$

which is the conformal image of the linear boost weight x^1: it vanishes on the entangling sphere $|\mathbf{x}| = R$ (the fixed locus of ζ, as Σ was the fixed locus of the boost), is maximal at the center, and reduces to the Rindler weight near the edge — setting $|\mathbf{x}| = R - \rho_*$ with $\rho_* \ll R$ gives $\zeta^0 \approx (\pi/R)(2R\rho_*) = 2\pi\rho_*$, matching $2\pi \times$ (distance to Σ) as in Eq. (55.69). The charge that generates this flow is the integral of $\zeta^\mu T_{\mu 0}$ over the ball, which at $t = 0$ is $\int \zeta^0 T^{00}$. We thus obtain the Casini–Huerta–Myers form.

Theorem 55.49 (Vacuum modular Hamiltonian of a ball in a CFT)**.** *In the vacuum of a conformal field theory in d-dimensional Minkowski space, the modular Hamiltonian of a ball A of radius R centered at the origin is the local operator*

$$\boxed{K_A = 2\pi \int_{|\mathbf{x}|<R} \mathrm{d}^{d-1}x \, \frac{R^2 - |\mathbf{x}|^2}{2R} \, T^{00}(0, \mathbf{x})} \tag{55.197}$$

so that $\rho_A = e^{-K_A}/Z$. The weight $(R^2 - |\mathbf{x}|^2)/2R$ is the energy-density profile that vanishes on the entangling sphere and reduces, near it, to the proper distance to the sphere.

This is the conformal generalization of Eq. (55.69): the half-space result is the $R \to \infty$ limit, in which the diamond opens up into the wedge and the parabolic weight $(R^2 - |\mathbf{x}|^2)/2R$ flattens to the linear x^1. The locality is again a gift of symmetry — a single conformal Killing vector preserves the diamond — and it fails the moment the region is not a ball or the theory is not conformal, as flagged in Section 55.3.3.

The first law now becomes a concrete, computable statement. For a state ρ infinitesimally above the vacuum, Theorem 55.48 with $K_\sigma = K_A$ of Eq. (55.197) gives

$$\delta S_A = \delta\langle K_A\rangle = 2\pi \int_{|\mathbf{x}|<R} \mathrm{d}^{d-1}x \, \frac{R^2 - |\mathbf{x}|^2}{2R} \, \delta\langle T^{00}(0, \mathbf{x})\rangle, \tag{55.198}$$

the change in the ball's entanglement entropy expressed entirely through the expectation value of the local energy density of the excitation, weighted by the CHM profile. We illustrate with the smallest balls, where the formula reduces to a clean local relation.

Worked Example 55.50 (The first law for a small ball and the energy density)**.** Consider a state with a smooth energy density $\delta\langle T^{00}(\mathbf{x})\rangle$ that is slowly varying on the scale of a small ball of radius R. Expand $\delta\langle T^{00}\rangle \approx \delta\langle T^{00}(0)\rangle$ as constant across the ball; then Eq. (55.198) factorizes,

$$\delta S_A \approx \frac{2\pi}{2R}\,\delta\langle T^{00}(0)\rangle \int_{|\mathbf{x}|<R} \mathrm{d}^{d-1}x\,(R^2-|\mathbf{x}|^2). \tag{55.199}$$

The integral is elementary. Using spherical coordinates in $d-1$ dimensions with solid angle $\Omega_{d-2} = 2\pi^{(d-1)/2}/\Gamma(\frac{d-1}{2})$,

$$\begin{aligned}\int_{|\mathbf{x}|<R} \mathrm{d}^{d-1}x\,(R^2-|\mathbf{x}|^2) &= \Omega_{d-2}\int_0^R r^{d-2}(R^2-r^2)\,dr = \Omega_{d-2}\,R^{d+1}\Big(\frac{1}{d-1}-\frac{1}{d+1}\Big)\\ &= \Omega_{d-2}\,\frac{2R^{d+1}}{(d-1)(d+1)}.\end{aligned} \tag{55.200}$$

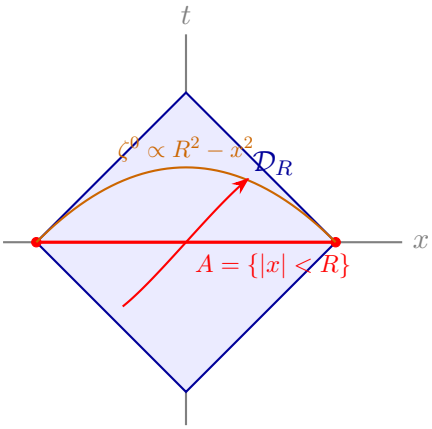
Hence the entanglement entropy of a small ball responds to an excitation as

$$\delta S_A = \frac{2\pi\,\Omega_{d-2}}{(d^2-1)}\,R^d\,\delta\langle T^{00}(0)\rangle + \cdots, \tag{55.201}$$

proportional to the local energy density times the ball's volume scale R^d. In $d=2$ the coefficient is $2\pi\cdot 2/3 = 4\pi/3$ (with $\Omega_0 = 2$ counting the two endpoints and $d^2-1=3$), giving $\delta S = (4\pi/3)R^2\delta\langle T^{00}\rangle$ for a small interval of half-length R — the linear-response companion of the logarithm Eq. (55.119). The structure $\delta S \propto R^d\,\delta E_{\text{density}}$ is the seed of the holographic derivation of gravitational dynamics: read as a constraint on $\delta\langle T^{00}\rangle$ for all balls, Eq. (55.198) is equivalent to the linearized Einstein equation governing the bulk geometry dual to the excitation, the statement Chapter 56 establishes.

55.6.6 Modular flow beyond the solvable cases: a frontier note

It must be said plainly how exceptional the local results Eqs. (55.69) and (55.197) are. The modular Hamiltonian $K_A = -\log\rho_A$ is a *local* integral of the energy density only when a spacetime (conformal) symmetry preserves the causal development of A. Two cases realize this exactly: the half-space, preserved by a boost (Bisognano–Wichmann, Theorem 55.25), valid in any QFT; and the ball in a CFT, preserved by a conformal Killing vector (Casini–Huerta–Myers, Theorem 55.49). For every other region the modular Hamiltonian is a complicated nonlocal operator, and its modular flow $\sigma_s(\mathcal{O}) = \rho_A^{is}\mathcal{O}\,\rho_A^{-is}$ does not act geometrically. As of the mid-2020s, the explicitly known cases beyond the two above are few and special: multiple intervals for the free massless Dirac fermion in two dimensions (Casini–Huerta), where the flow is *bi-local*, mixing operators at points conformally related across the intervals; certain free-field examples on



Causal diamond of a ball: local modular flow generated by ζ

Figure 55.6: The causal diamond $\mathcal{D}_R$ (blue) of a ball A of radius R (red) in a CFT vacuum. The diamond is conformally equivalent to the Rindler wedge of Fig. 55.3, and the boost is carried into the conformal Killing vector ζ that preserves $\mathcal{D}_R$, with time component $\zeta^0 \propto R^2 - |\mathbf{x}|^2$ (orange) vanishing on the entangling sphere $|\mathbf{x}| = R$. Modular flow is geometric, sliding operators along the streamlines of ζ, and the modular Hamiltonian Eq. (55.197) is the local energy density weighted by ζ^0.

null cuts (where the algebra factorizes and the flow simplifies); and perturbative expansions around the solvable cases. A closed-form local modular Hamiltonian for a generic region in an interacting theory is not known and is not expected to exist. This is a genuine frontier: modular flow is the central dynamical object of algebraic QFT and of the recent program connecting entanglement to energy conditions and to gravity, yet outside the conformal ball and the Rindler wedge it remains analytically inaccessible. The honest statement is that the structures of this section are exact where symmetry makes them so, and otherwise are controlled only perturbatively or numerically.

55.6.7 From inequalities to energy conditions: the bridge to gravity

We close the chapter by recording, without full proof with their logical origins made explicit, the theorems that turn the abstract inequalities of this section into constraints on energy and geometry. These are the results that Part XV's gravitational entanglement builds upon directly; their full proofs belong to the holographic and algebraic developments of Chapters 56 and 57 and the literature gathered in the Further Reading, but each is, in essence, a corollary of relative-entropy positivity or monotonicity, and we indicate the mechanism in each

case.

The Bekenstein bound, from relative-entropy positivity. Bekenstein conjectured a universal bound on the entropy S of any system of energy E confined to a region of size R: $S \le 2\pi RE$ (in natural units). For decades this resisted a clean field-theoretic statement, because both S and the "energy" are ambiguous in QFT. Casini's resolution identifies the bound with the positivity of relative entropy. Take σ to be the vacuum reduced density matrix on a region and ρ the reduced state of an excitation localized within it; then Eq. (55.171) reads $\Delta S \le \Delta\langle K\rangle$, where now $\Delta S = S(\rho) - S(\sigma)$ is the (finite, cutoff-independent) entropy of the excitation relative to the vacuum and $\Delta\langle K\rangle$ is its modular energy. For a region whose modular Hamiltonian is the boost-like $\int x^1 T^{00}$ of Theorem 55.25, $\Delta\langle K\rangle$ is precisely the combination 2π(energy)$\times$(distance scale) that Bekenstein's $2\pi RE$ estimates. Thus the Bekenstein bound is the inequality

$$S(\rho) - S(\sigma) \;\le\; \Delta\langle K\rangle, \tag{55.202}$$

a tautological consequence of $S(\rho\,\|\,\sigma) \ge 0$, made meaningful by the recognition that the "entropy" and "energy" in Bekenstein's formula are the relative entropy's two pieces ΔS and $\Delta\langle K\rangle$. The bound is then not a new physical postulate but a restatement of Theorem 55.9: it holds in every quantum field theory, automatically, and is saturated only by the vacuum itself.

The quantum null energy condition, from monotonicity. Classically the null energy condition $T_{kk} = T_{\mu\nu}k^\mu k^\nu \ge 0$ (for null k) underlies the singularity theorems and the area theorems of general relativity, but it is violated by quantum fields, whose energy density can be locally negative (the Casimir effect, Chapter 9). The *quantum null energy condition* (QNEC) is the sharp replacement: the local energy density is bounded below by the second variation of the entanglement entropy under a null deformation of the entangling surface,

$$\langle T_{kk}(x)\rangle \;\ge\; \frac{1}{2\pi}\,\frac{1}{\sqrt{h}}\,\frac{\delta^2 S_A}{\delta\lambda(x)^2}, \tag{55.203}$$

where $\lambda(x)$ parametrizes the displacement of ∂A along the null direction k at the point x, $\sqrt{h}$ is the induced area element, and S'' is taken at fixed displacement elsewhere. The QNEC is a theorem, and its origin is the monotonicity of relative entropy: deforming the region along a null direction generates a one-parameter family of nested algebras, and the monotonicity of $S(\rho\,\|\,\sigma_{\rm vac})$ along this family — a consequence of Theorem 55.43, refined into a statement about second shape-derivatives — is exactly Eq. (55.203). Integrating Eq. (55.203) along a complete null generator and using that S_A returns to its vacuum value at the endpoints gives the *averaged null energy condition* (ANEC), $\int_{-\infty}^{\infty}\langle T_{kk}\rangle\, d\lambda \ge 0$, which thus also follows from monotonicity of relative entropy (equivalently, in the lightcone limit,

from the causality and positivity built into the modular flow). The averaged and quantum null energy conditions are the precise senses in which energy positivity survives quantization, and they are the inputs that make the holographic and semiclassical-gravity constructions of Chapters 56 and 57 — the proof of the generalized second law, the consistency of the island prescription — well-posed.

Physical Insight

The arc of this section is a single idea seen from three sides. Relative entropy is the unique cutoff-independent measure of how one state differs from another; its *positivity* is the Bekenstein bound and, linearized, the first law $\delta S = \delta\langle K\rangle$; its *monotonicity* is strong subadditivity, the c-theorems, and the quantum null energy condition. Information inequalities, which hold in any quantum system whatsoever, become, when read through the modular Hamiltonian of a region in a field theory, statements about energy and entropy that were once thought to require gravity to explain. That this dictionary closes — that the same first law which here follows from $S(\rho\,\|\,\sigma) \geq 0$ reappears in Chapter 56 as Einstein's equation linearized about anti-de Sitter space — is the deepest reason to believe that spacetime geometry is the large-scale expression of entanglement.

This completes the chapter's hand-off to Part XV. The three structures assembled here — the positivity of relative entropy and its first-order content, the first law $\delta S_A = \delta\langle K_A\rangle$ built on the local modular Hamiltonians Eqs. (55.69) and (55.197); the monotonicity of relative entropy and its corollary, strong subadditivity Eq. (55.187); and the recognition of mutual information as a relative entropy — are precisely the inequalities the Ryu–Takayanagi proof and the entanglement-wedge reconstruction of Chapter 56 invoke, and the inputs that make the Page curve and the quantum extremal surface prescription of Chapter 57 consistent. The vacuum that Chapter 9 found to be a richly correlated medium, that Chapter 10 prepared as a Euclidean path integral, and that Chapter 47 organized by conformal symmetry, has now been shown to carry an exact information-theoretic skeleton; holography is the statement that this skeleton is geometry.

Further reading

The replica computation of two-dimensional entanglement entropy is due to Holzhey, Larsen and Wilczek and, in the form used here, to Calabrese and Cardy [104]; the area law originates with Bombelli, Koul, Lee and Sorkin and with Srednicki [85, 453], and the correlator (Gaussian-state) method for free fields is developed in [115, 395]. The standard review of entanglement entropy in quantum field theory, covering the replica trick, the area law, and the universal

terms, is Casini and Huerta [115]; for the algebraic backbone — Tomita–Takesaki modular theory, the type-III classification of local algebras, and the Bisognano–Wichmann theorem — see Haag [246] and Witten's lectures [524]. The Unruh effect is [477]; the conformal modular Hamiltonian of a ball is Casini, Huerta and Myers [116]; the four-dimensional anomaly-induced logarithm is Solodukhin [450], and the gauge-field center/edge-mode subtlety is Donnelly [158]. The entropic proofs of the c- and F-theorems are [113, 114], with the a-theorem of Komargodski and Schwimmer in [301, 302]. For where this leads, the holographic entanglement entropy of Ryu and Takayanagi and its review are [414, 422], taken up in Chapters 56 and 57.

Chapter 56

Holographic Entanglement

Two results from the preceding chapters are about to collide productively. From the gravity side we carry the black-hole area law $S_{\mathrm{BH}} = A/4G_N$ (Theorem 54.10) and the AdS/CFT dictionary: a holographic state is a bulk geometry, and the GKP–Witten relation (Theorem 53.29 and Eq. (53.162)) computes any boundary partition function as the on-shell action of the dominant bulk saddle whose conformal boundary carries that state. From the field-theory side we carry a quantity Chapter 55 taught us to want but rarely to compute: the entanglement entropy $S(A) = -\operatorname{Tr}(\rho_A \ln \rho_A)$ of a spatial region (Eq. (55.6)), defined through the replica trick (Theorem 55.17) as the $n \to 1$ continuation of moments $\operatorname{Tr}\rho_A^n$ and tractable, in closed form, essentially only for a single interval in a 2D CFT, $S = (c/3)\ln(\ell/\varepsilon)$ (Eq. (55.119)). This chapter is the statement that these two facts are one: that the entanglement entropy of a boundary region *is* a horizon-like area in the bulk, and that, run in reverse, the spacetime geometry is assembled out of the entanglement structure of the boundary state.

We open with the proposal itself. Section 56.1 states the Ryu–Takayanagi formula precisely — entanglement entropy as the area of the minimal bulk surface anchored on ∂A and homologous to A, all divided by $4G_N$ — motivates it from the black-hole area law and the bulk replica saddle, and validates it against the one entropy the reader already trusts by recovering $(c/3)\ln(\ell/\varepsilon)$ from a single geodesic in AdS_3, with the coefficient fixed by the Brown–Henneaux relation $c = 3L/2G_N$ derived from the holographic Weyl anomaly. Section 56.2 then turns the proposal into a calculational engine: the thermal entropy of an interval from the BTZ geodesic, the universal sphere coefficients in any dimension via the Casini–Huerta–Myers conformal map to a hyperbolic black hole (Theorem 55.49), and the strip, where an area-law divergence sits atop a genuinely nonlocal finite piece.

With a working formula in hand we collect its structural payoff before paying its derivational debt. Section 56.3 shows that deep quantum-information inequalities — strong subadditivity (Theorem 55.47), and the sharper monogamy of

mutual information that holographic states obey but generic states need not — follow from elementary facts about minimal surfaces, cutting and recombining geodesics rather than manipulating density matrices, and it frames the holographic entropy cone these inequalities cut out. Section 56.4 then discharges the central debt: it promotes Ryu–Takayanagi from checked conjecture to theorem by running the replica trick upstairs in the bulk, following Lewkowycz and Maldacena. The cyclic replica symmetry is quotiented to a single geometry with a conical defect; the $n \to 1$ limit localizes the on-shell action onto the defect; the factor of $4G_N$, the extremality of the surface, and the homology constraint all emerge from the demand that the bulk be smooth.

The classical statement is then refined in three directions. Section 56.5 adds the bulk matter entanglement (the Faulkner–Lewkowycz–Maldacena one-loop term), makes the prescription covariant by extremizing rather than minimizing area (the HRT surface, with its maximin reformulation), and unifies both into the quantum extremal surface that extremizes the generalized entropy. Section 56.6 asks which bulk a boundary region actually encodes: not the causal wedge but the larger entanglement wedge bounded by the RT surface, with the JLMS identity equating boundary and bulk modular Hamiltonians up to the area operator, and relative-entropy positivity (Chapter 55) translating into a bulk energy condition. Section 56.7 recasts this encoding as quantum error correction: bulk operators are reconstructed as smeared boundary operators (HKLL), the entanglement wedge is the recoverable region, and the HaPPY pentagon code realizes the whole structure — subregion duality, complementary recovery, and a discrete RT formula — in an exactly solvable model.

Section 56.8 closes the arc by reversing it. If geometry is reconstructed from entanglement, geometry should be *made of* it, and we prove the sharpest available version of that slogan: the bulk Einstein equation, linearized about pure anti–de Sitter space, is the first law of entanglement (Theorem 55.48) imposed on every ball-shaped boundary region, with the modular Hamiltonian of a ball (Theorem 55.49) supplying the conformal Killing data and the Iyer–Wald formalism converting an entropy variation into a gravitational constraint. We then state, honestly and within scope, Van Raamsdonk's disentangling argument and its tensor-network/MERA discretization, and the ER = EPR slogan, before handing a dated summary of open problems — the dynamical and black-hole-interior questions this static, kinematic chapter cannot settle — to Chapter 57.

56.1 Geometry from entanglement: the Ryu–Takayanagi proposal

Two facts now sit side by side in our hands, and they are about to collide productively. The first is that entropy can be geometry. A black hole carries an entropy equal to a quarter of its horizon area in Planck units, $S_{\mathrm{BH}} = A/4G_N$

(Theorem 54.10); a thermodynamic quantity that in any ordinary system counts microstates is, for a black hole, simply the area of a surface. The second is that geometry can be dynamics dual to a field theory. The AdS/CFT correspondence promotes a conformal field theory in d dimensions to a gravitational theory in an asymptotically anti-de Sitter spacetime one dimension higher, with the field–operator dictionary and the GKP–Witten relation (Theorem 53.29 and Eq. (53.162)) translating bulk classical physics into boundary correlators. The bulk metric is not a fixed stage; it is the saddle point of a gravitational path integral whose boundary data is a CFT state — a state that, by the state–operator correspondence of Theorem 47.42, is itself the radial-quantization image of a boundary operator insertion.

Set against these two facts is a hard quantity the previous chapter taught us to want but not to compute. The entanglement entropy $S(A) = -\operatorname{Tr}(\rho_A \ln \rho_A)$ of a spatial region A in a quantum field theory (Eq. (55.6)) is a fine, often nonlocal probe of a state, but it is brutal to evaluate: the replica trick (Theorem 55.17) reduces it to the analytic continuation $S(A) = -\partial_n \operatorname{Tr} \rho_A^n\big|_{n=1}$ of partition functions on n-sheeted branched covers, and that $n \to 1$ continuation is exactly what makes the computation intractable away from free fields and two-dimensional CFTs. In the one case where we do have an exact answer — a single interval of length ℓ in the vacuum of a 2D CFT, $S = (c/3)\ln(\ell/\varepsilon)$ (Eq. (55.119)) — it was won by 2D conformal technology that does not generalize. We have a quantity built from entanglement and a separate discovery that entanglement-like entropy is geometric. Ryu and Takayanagi proposed that these are the same statement: that the entanglement entropy of a boundary region *is* a horizon-like area in the bulk, the area of the smallest bulk surface that hangs from the region's boundary. This section states that proposal precisely, defines every object in it, motivates it as the natural generalization of the black-hole area law, and validates it against the one entanglement entropy the reader already trusts.

56.1.1 From horizon entropy to entanglement entropy: the heuristic

The bridge from $S_{\mathrm{BH}} = A/4G_N$ to an entanglement entropy is shorter than it looks, because black-hole entropy is, on reflection, already an entanglement entropy. An observer outside the horizon has no access to the interior; the global state, even if pure, is described from outside by a reduced density matrix obtained by tracing over the inaccessible region, and the horizon is the surface that separates the two. The thermal character of the exterior and the area scaling of its entropy are precisely the hallmarks of entanglement across a boundary that Chapter 55 taught us to expect: an area law, with the divergence localized on the dividing surface. The black hole is the special case in which the dividing surface is a true event horizon and the state is the thermal Hartle–Hawking state. Ryu and Takayanagi's move is to ask what happens when we replace the event

horizon by an arbitrary boundary region's worth of entanglement. If the entropy of the region behind a horizon is a quarter of the horizon's area, perhaps the entropy of *any* boundary region A is a quarter of the area of some bulk surface determined by A — a surface that is horizon-like in that it bounds the region of the bulk that A cannot see, but that need not be a causal horizon at all.

Which surface? Here the gravitational path integral supplies the second, sharper, heuristic. The replica trick computes $\operatorname{Tr}\rho_A^n = Z_n/Z_1^n$, where Z_n is the CFT partition function on the n-sheeted branched cover $\mathcal{M}_n$ obtained by gluing n copies of the spacetime cyclically across the region A (Theorem 55.17). In a holographic CFT each partition function is computed by a bulk saddle: by the GKP–Witten relation (Eq. (53.162)), $Z_n = e^{-I_{\mathrm{grav}}[\mathcal{B}_n]}$, where $\mathcal{B}_n$ is the dominant smooth Euclidean bulk solution whose conformal boundary is the replica manifold $\mathcal{M}_n$. The branched cover carries the cyclic replica symmetry $\mathbb{Z}_n$, and the dominant bulk filling inherits it; quotienting $\mathcal{B}_n$ by that $\mathbb{Z}_n$ produces a bulk geometry $\mathcal{B}_n/\mathbb{Z}_n$ with the same boundary as the original spacetime but with a conical excess concentrated on the codimension-two fixed-point locus of the symmetry — a bulk surface anchored on ∂A. When one differentiates the on-shell gravitational action in n and continues to $n \to 1$, the bulk action away from the fixed-point surface contributes nothing new (it solves the equations of motion), and the entire n-derivative localizes onto the conical singularity, where it returns exactly the proper area of the fixed-point surface divided by $4G_N$. The entanglement entropy is thus the area of the bulk surface left fixed by the replica symmetry, and minimizing the action selects the surface of least area. This is the Lewkowycz–Maldacena argument; we present it here only as motivation and carry it out in full, with the conical-deficit accounting made rigorous, in Section 56.4. For now it tells us precisely what to write down.

Physical Insight

The slogan "entanglement builds geometry" is, at this stage, a precise computational claim and nothing more mystical: the area of a bulk surface equals a boundary entanglement entropy. Read forward, it says that the smooth connectedness of the bulk geometry is underwritten by the boundary state being entangled — disentangle the two halves of the boundary and the bulk surface separating them grows without bound, pinching the geometry into disconnected pieces. Read as a definition, it converts an intractable $n \to 1$ continuation into a classical problem in Riemannian geometry: find the smallest surface hanging from a given boundary curve. The rest of this chapter lives in the tension between these two readings.

56.1.2 The objects: anchored minimal surfaces and the homology constraint

Fix the arena. We work in an asymptotically AdS_{d+1} spacetime with a boundary conformal field theory CFT_d, in the regime where the bulk is well described by classical Einstein gravity — equivalently, large central charge and large 't Hooft coupling, so that G_N is small in units of the AdS radius L (Theorem 53.27). We take the state to be static, or at least specify a moment of time symmetry, so that there is a preferred constant-time slice; the fully covariant version, needed for genuinely time-dependent states, is flagged below and developed later. On the boundary, choose a spatial region A at fixed time, with entangling surface ∂A (its boundary within the boundary). In $d = 2$, A is an interval and ∂A is its two endpoints; in $d = 3$, A is a two-dimensional region and ∂A is a closed curve; and so on.

The bulk constant-time slice Σ is a d-dimensional Riemannian manifold whose conformal boundary is the boundary spatial slice. We seek a surface in Σ on which to evaluate an area.

Definition 56.1 (Anchored bulk surface)**.** A *bulk surface anchored on* A is a codimension-two spacelike submanifold γ_A of the bulk spacetime that lies in the constant-time slice Σ and whose only boundary coincides with the entangling surface of the region:

$$\partial\gamma_A = \partial A, \tag{56.1}$$

the equality holding on the conformal boundary $z \to 0$. As a submanifold of the d-dimensional slice Σ, γ_A is $(d-1)$-dimensional; its area is the proper volume induced on it by the bulk metric,

$$\mathrm{Area}(\gamma_A) = \int_{\gamma_A} \mathrm{d}^{\,d-1}\sigma\, \sqrt{\det h}, \qquad h_{ab} = g_{\mu\nu}\, \partial_a X^\mu\, \partial_b X^\nu, \tag{56.2}$$

where $X^\mu(\sigma)$ embeds γ_A in the bulk and h_{ab} is the induced metric. A surface is *minimal* if it extremizes Eq. (56.2) subject to the anchoring Eq. (56.1); equivalently, its trace of extrinsic curvature vanishes, $K = 0$.

Anchoring alone does not determine the surface, because for some regions there are topologically distinct ways to hang a surface from ∂A, and some of them are spurious. The decisive extra condition is topological.

Definition 56.2 (Homology constraint)**.** The anchored surface γ_A is *homologous to* A if there exists a d-dimensional spacelike region $\mathcal{R}_A$ in the bulk slice Σ — the *homology region* — whose boundary is the union of A and γ_A:

$$\partial\mathcal{R}_A = A \cup \gamma_A. \tag{56.3}$$

Equivalently, γ_A together with A bounds a bulk region: γ_A can be continuously deformed onto A through the bulk while keeping ∂A fixed.

The homology region $\mathcal{R}_A$ is the spatial slice of the bulk region that the boundary subsystem A will turn out to encode — the *entanglement wedge* we make precise in Section 56.6. For now it plays two roles. It rules out surfaces that hang from ∂A but cannot be capped off by a bulk region together with A; and, crucially, it is what makes the formula respect the obvious physical facts. If the global state is pure, then A and its complement $\bar{A}$ have equal entropy, $S(A) = S(\bar{A})$; the homology constraint guarantees this, because a surface homologous to A is automatically homologous to $\bar{A}$ (the two homology regions share the same boundary surface γ_A and together fill the slice). The constraint also does essential work in thermal states, where the bulk contains a black-hole horizon: a surface homologous to a large region must be allowed to wrap the horizon, and we will see in Section 56.2.1 that this is exactly what reproduces the extensive thermal entropy.

One more object must be named before the formula makes sense: the cutoff. The area integral Eq. (56.2) diverges, because the bulk metric blows up as the conformal boundary $z \to 0$ is approached, and γ_A runs all the way to that boundary. This divergence is not a defect; it is the holographic image of the ultraviolet divergence of entanglement entropy in any continuum field theory. We regulate it exactly as the rest of the dictionary is regulated: by cutting the bulk off at a small radial coordinate $z = \varepsilon$ rather than at $z = 0$. The radial coordinate is the inverse energy scale of the boundary theory (Section 53.3), so a bulk wall at $z = \varepsilon$ is a boundary short-distance cutoff at length scale ε. We therefore *identify the bulk radial cutoff with the QFT ultraviolet cutoff*, the same identification used in the holographic counting of degrees of freedom (Eq. (53.154)). With this identification the divergence of the area becomes, term by term, the divergence of $S(A)$, and in particular reproduces the area law of Chapter 55: the leading divergence of $\mathrm{Area}(\gamma_A)/4G_N$ scales as the area of ∂A in cutoff units, because near the boundary γ_A plunges straight in and its regulated area is controlled by the geometry of ∂A.

56.1.3 The Ryu–Takayanagi formula

We can now state the proposal precisely.

Theorem 56.3 (Ryu–Takayanagi)**.** *Let A be a spatial region in the boundary of a static asymptotically AdS_{d+1} spacetime dual to a state of a holographic CFT_d, in the classical-gravity regime. Then the entanglement entropy of A is*

$$\boxed{S(A) = \min_{\gamma_A \sim A} \frac{\mathrm{Area}(\gamma_A)}{4G_N}} \tag{56.4}$$

where the minimum runs over all bulk codimension-two surfaces γ_A anchored on ∂A (Theorem 56.1) and homologous to A (Theorem 56.2), the area is regulated

at the radial cutoff $z = \varepsilon$ identified with the QFT ultraviolet cutoff, and G_N is the bulk Newton constant. The minimizing surface is denoted γ_A^*.

Three remarks fix its standing and scope before we test it.

First, the formula is a leading-order statement in the bulk, computing the entanglement entropy of the dual state at leading order in G_N — equivalently, at leading order in the large central charge. It is the classical, geometric piece of the entropy. The subleading corrections are the bulk fields' own entanglement across γ_A^*, and incorporating them promotes Eq. (56.4) to the quantum-corrected and ultimately the quantum-extremal-surface formula of Sections 56.5.1 and 56.5.3. At the order we work in this section there is no such correction, and the right-hand side is purely geometry.

Second, the minimization in Eq. (56.4) is genuine and not a formality: there can be several minimal surfaces homologous to A, and the prescription is to take the one of least area. This is not pedantry — it is the seed of a phase transition. When the competing minimal surfaces exchange dominance as the region is varied, the entanglement entropy has a kink, a first-order "entanglement phase transition." We meet the cleanest example, two disjoint intervals, in Section 56.2.4; here we simply record that "min" is load-bearing.

Third, Theorem 56.3 as stated requires a preferred time slice, because "minimal area" is a Riemannian notion and a Lorentzian surface has no minimal area (one can always wiggle it timelike to shrink the area without bound). For static states the moment of time symmetry supplies the slice and the prescription is unambiguous. For genuinely time-dependent states one replaces "minimal on a slice" by "extremal in the full Lorentzian spacetime": γ_A^* is a saddle of the area functional, the surface of vanishing trace of extrinsic curvature with no slice singled out. This is the covariant Hubeny–Rangamani–Takayanagi prescription, and when a time-symmetric slice exists the extremal surface lies in it and coincides with the minimal one. We use the static form throughout this section and develop the covariant statement in Section 56.5.2.

Caution

The minimum in Eq. (56.4) is over surfaces *homologous* to A, not merely anchored on ∂A. Dropping the homology constraint gives wrong answers in two diagnostic cases. For a pure global state it would break the requirement $S(A) = S(\bar{A})$. And in a thermal state it would forbid the surface from wrapping the black-hole horizon, which is exactly the configuration that supplies the extensive thermal entropy of a large region (Section 56.2.1). The constraint is part of the formula, not a refinement of it.

56.1.4 The validating computation: a single interval in AdS_3

A proposal of this reach must first reproduce the one nontrivial entanglement entropy we already know exactly. We compute the right-hand side of Eq. (56.4) for a single interval in the vacuum of a 2D CFT and check that it returns $(c/3)\ln(\ell/\varepsilon)$ with the correct coefficient and no free parameters. The match is the anchor of the whole chapter.

The vacuum of a CFT_2 is dual to pure Poincaré AdS_3. In the conventions of Theorem 53.10, with the book's mostly-minus signature, the metric is

$$\mathrm{d}s^2 = \frac{L^2}{z^2}(\mathrm{d}t^2 - \mathrm{d}x^2 - \mathrm{d}z^2), \tag{56.5}$$

with the boundary at $z \to 0$, boundary coordinates (t, x) carrying the metric $\eta = \mathrm{diag}(+,-)$, and the radial direction z spacelike. The bulk is three-dimensional $(d = 2)$, so a codimension-two surface is a curve: a one-dimensional spacelike geodesic. The boundary region is the interval

$$A = \left\{ t = 0,\ -\tfrac{\ell}{2} \le x \le \tfrac{\ell}{2} \right\}, \qquad \partial A = \left\{ x = \pm\tfrac{\ell}{2} \right\}. \tag{56.6}$$

The state is static, so we work on the constant-time slice $t = 0$. The induced metric on that slice, read off Eq. (56.5) by setting $\mathrm{d}t = 0$, is $\mathrm{d}s^2|_{t=0} = -(L^2/z^2)(\mathrm{d}x^2 + \mathrm{d}z^2)$; up to the overall sign that reflects the spatial directions being mostly-minus, this is the Riemannian metric

$$\mathrm{d}\ell_\Sigma^2 = \frac{L^2}{z^2}(\mathrm{d}x^2 + \mathrm{d}z^2) \tag{56.7}$$

on the upper half-plane $z > 0$. Proper length on the slice is measured by Eq. (56.7); the RT "area" of a curve is its proper length there. This is the geometry in which we minimize.

Worked Example 56.4 (Single-interval geodesic in Poincaré AdS_3)**.** We minimize the length of a curve in the half-plane metric Eq. (56.7) anchored at the two endpoints Eq. (56.6), regulate at $z = \varepsilon$, and assemble $S = \mathrm{Length}/4G_N$.

The length functional. Parametrize the curve as $z = z(x)$, $x \in [-\ell/2, \ell/2]$, with $z \to 0$ at both endpoints. From Eq. (56.7), $\mathrm{d}\ell_\Sigma = (L/z)\sqrt{\mathrm{d}x^2 + \mathrm{d}z^2} = (L/z)\sqrt{1 + z'^2}\,\mathrm{d}x$, so the proper length to be minimized is

$$\mathrm{Length}[z] = L\int_{-\ell/2}^{\ell/2} \mathrm{d}x\, \frac{\sqrt{1 + z'^2}}{z}, \qquad z' \equiv \frac{\mathrm{d}z}{\mathrm{d}x}. \tag{56.8}$$

First integral. The integrand $f(z,z') = z^{-1}\sqrt{1+z'^2}$ has no explicit x-dependence, so the analogue of energy — the "Beltrami" first integral $f - z'\,\partial f/\partial z'$ — is conserved along the extremal curve. Computing $\partial f/\partial z' = z'/(z\sqrt{1+z'^2})$,

$$f - z'\frac{\partial f}{\partial z'} = \frac{\sqrt{1+z'^2}}{z} - \frac{z'^2}{z\sqrt{1+z'^2}} = \frac{(1+z'^2)-z'^2}{z\sqrt{1+z'^2}} = \frac{1}{z\sqrt{1+z'^2}} = \text{const} \equiv \frac{1}{z_*}. \tag{56.9}$$

The constant is named $1/z_*$ because at the deepest point of the curve $z' = 0$ and Eq. (56.9) gives $z = z_*$: z_* is the turning point, the maximal bulk depth. Rearranging Eq. (56.9),

$$z\sqrt{1+z'^2} = z_* \quad\Longrightarrow\quad z'^2 = \frac{z_*^2 - z^2}{z^2} \quad\Longrightarrow\quad \frac{\mathrm{d}x}{\mathrm{d}z} = \pm\frac{z}{\sqrt{z_*^2 - z^2}}. \tag{56.10}$$

The geodesic is a semicircle. Integrating Eq. (56.10), $x = \mp\sqrt{z_*^2 - z^2} + \text{const}$; fixing the constant so that the turning point $z = z_*$ sits at $x = 0$ gives $x^2 + z^2 = z_*^2$. The minimal curve is a semicircle centred on the boundary. It meets the boundary $z = 0$ at $x = \pm z_*$, which must be the interval endpoints $x = \pm\ell/2$, so

$$z_* = \frac{\ell}{2}. \tag{56.11}$$

The deepest the surface reaches into the bulk is half the interval length — a clean statement that larger regions probe deeper into the geometry, which is the seed of holographic "subregion–subregion" duality.

Regulated length. Evaluate Eq. (56.8) along the geodesic. Using $\sqrt{1+z'^2} = z_*/z$ from Eq. (56.10) and changing the integration variable from x to z via $\mathrm{d}x = (z/\sqrt{z_*^2 - z^2})\mathrm{d}z$, the two symmetric halves of the semicircle (from each endpoint down to the turning point) contribute equally, and the curve runs from the cutoff $z = \varepsilon$ near the boundary down to $z = z_*$:

$$\begin{aligned}\text{Length} &= 2L\int_\varepsilon^{z_*} \frac{\sqrt{1+z'^2}}{z}\,\frac{\mathrm{d}x}{\mathrm{d}z}\,\mathrm{d}z = 2L\int_\varepsilon^{z_*} \frac{1}{z}\,\frac{z_*}{z}\,\frac{z}{\sqrt{z_*^2 - z^2}}\,\mathrm{d}z \\ &= 2Lz_*\int_\varepsilon^{z_*} \frac{\mathrm{d}z}{z\sqrt{z_*^2 - z^2}}.\end{aligned} \tag{56.12}$$

The remaining integral is elementary. With $a \equiv z_*$,

$$\int \frac{\mathrm{d}z}{z\sqrt{a^2 - z^2}} = -\frac{1}{a}\ln\left(\frac{a + \sqrt{a^2 - z^2}}{z}\right) + \text{const}, \tag{56.13}$$

as one checks by differentiating the right-hand side. Evaluated between $z = \varepsilon$ and $z = z_*$, the upper limit gives $-\frac{1}{z_*}\ln(1) = 0$ (since $\sqrt{a^2 - a^2} = 0$ makes the

argument 1), and the lower limit gives the only surviving term:

$$\int_{\varepsilon}^{z_*} \frac{\mathrm{d}z}{z\sqrt{z_*^2 - z^2}} = \frac{1}{z_*} \ln\!\left(\frac{z_* + \sqrt{z_*^2 - \varepsilon^2}}{\varepsilon}\right). \tag{56.14}$$

Substituting into Eq. (56.12), the factor z_* cancels and

$$\text{Length} = 2L \ln\!\left(\frac{z_* + \sqrt{z_*^2 - \varepsilon^2}}{\varepsilon}\right). \tag{56.15}$$

For a physical cutoff $\varepsilon \ll z_*$ we expand $\sqrt{z_*^2 - \varepsilon^2} = z_*(1 - \varepsilon^2/2z_*^2 + \dots)$, so the argument of the logarithm is $2z_*/\varepsilon + O(\varepsilon)$, and with $z_* = \ell/2$ from Eq. (56.11),

$$\text{Length} = 2L \ln\frac{2z_*}{\varepsilon} + O(\varepsilon^2) = 2L \ln\frac{\ell}{\varepsilon} + O(\varepsilon^2). \tag{56.16}$$

The entropy. By the Ryu–Takayanagi formula Eq. (56.4), with G_N the three-dimensional Newton constant,

$$S(A) = \frac{\text{Length}}{4G_N} = \frac{2L}{4G_N} \ln\frac{\ell}{\varepsilon} = \frac{L}{2G_N} \ln\frac{\ell}{\varepsilon}. \tag{56.17}$$

This is the entire geometric computation. It remains to translate the bulk parameters L and G_N into the boundary central charge.

The translation is the Brown–Henneaux relation between the bulk data (L, G_N) and the central charge of the dual CFT_2 (the c of Theorem 48.8),

$$c = \frac{3L}{2G_N}, \tag{56.18}$$

the exact $d = 2$ instance of the general scaling $c \sim L^{d-1}/G_N$ between central charge and bulk curvature radius (Theorem 53.27 and Eq. (52.185)). For the match to be genuinely parameter-free we must know not merely that $c \propto L/G_N$ but the precise coefficient $3/2$, and that coefficient is fixed by a short computation we now carry out: the holographic conformal anomaly. The derivation imports only the gravitational version of the near-boundary (Fefferman–Graham) expansion and on-shell action machinery built in Section 54.2.1 and Theorem 54.5, specialized to three bulk dimensions, and it ends on Eq. (56.18) with the coefficient pinned.

Worked Example 56.5 (The coefficient $c = 3L/2G_N$ from the holographic Weyl anomaly)**.** Work in Euclidean signature, Wick-rotating Eq. (56.5) as in Eq. (53.161), and put the bulk metric in Fefferman–Graham gauge with a generic curved boundary metric $g_{(0)ij}(x)$,

$$\mathrm{d}s^2 = \frac{L^2}{z^2}\Big(\mathrm{d}z^2 + g_{ij}(z,x)\,\mathrm{d}x^i \mathrm{d}x^j\Big), \qquad g_{ij}(z,x) = g_{(0)ij}(x) + z^2\, g_{(2)ij}(x) + \cdots, \tag{56.19}$$

the $d = 2$ specialization of Eq. (54.30) applied to the metric rather than to a matter field. Pure three-dimensional gravity with a negative cosmological constant solves $R_{\mu\nu} = -(2/L^2)\, G_{\mu\nu}$, equivalently $\Lambda = -1/L^2$; the on-shell scalars are $R = 6\Lambda = -6/L^2$ and $R - 2\Lambda = -4/L^2$.

The subleading coefficient. The single piece of dynamical input is the trace $g^{ij}_{(0)} g_{(2)ij}$, fixed by the radial Hamiltonian (Gauss–Codazzi) constraint. Write the constant-z slice metric $\gamma_{ij} = (L^2/z^2) g_{ij}$ with unit outward normal $n = (z/L)\partial_z$; its extrinsic curvature $K_{ij} = \frac{1}{2}(z/L)\partial_z \gamma_{ij}$ evaluates to

$$K_{ij} = -\frac{1}{L}\,\gamma_{ij} + L\, g_{(2)ij} + O(z^2), \qquad K = \gamma^{ij} K_{ij} = -\frac{2}{L} + \frac{z^2}{L}\, g^{ij}_{(0)} g_{(2)ij} + O(z^4). \tag{56.20}$$

A short expansion gives $K^2 - K_{ij}K^{ij} = \frac{2}{L^2} - \frac{2z^2}{L^2}\, g^{ij}_{(0)} g_{(2)ij} + \cdots$, while the intrinsic curvature of the slice is $R^{(\gamma)} = (z^2/L^2) R_{(0)} + \cdots$ by Weyl rescaling, with $R_{(0)}$ the Ricci scalar of $g_{(0)}$. The Hamiltonian constraint $K^2 - K_{ij}K^{ij} = R^{(\gamma)} - 2\Lambda$ holds order by order: the leading terms balance as $2/L^2 = 2/L^2$, and the $O(z^2)$ terms give

$$-\frac{2}{L^2}\, g^{ij}_{(0)} g_{(2)ij} = \frac{1}{L^2} R_{(0)} \quad \Longrightarrow \quad g^{ij}_{(0)} g_{(2)ij} = -\tfrac{1}{2} R_{(0)}. \tag{56.21}$$

The on-shell action and its logarithm. The Euclidean gravitational action is the Einstein–Hilbert term, the Gibbons–Hawking–York boundary term, and the covariant counterterm that renormalizes it,

$$I = -\frac{1}{16\pi G_N}\int \sqrt{G}\,(R - 2\Lambda) - \frac{1}{8\pi G_N}\int \sqrt{\gamma}\, K + \frac{1}{8\pi G_N L}\int \sqrt{\gamma}, \tag{56.22}$$

the last term being the $d = 2$ counterterm (a pure cosmological subtraction; no curvature counterterm exists in two boundary dimensions). The bulk volume element is $\sqrt{G} = (L^3/z^3)\sqrt{g_{(0)}}\,(1 + \frac{1}{2} z^2 g^{ij}_{(0)} g_{(2)ij} + \cdots) = (L^3/z^3)\sqrt{g_{(0)}}\,(1 - \frac{1}{4} z^2 R_{(0)} + \cdots)$ by Eq. (56.21), so the bulk term is

$$-\frac{1}{16\pi G_N}\int \sqrt{G}\,(R - 2\Lambda) = \frac{L}{4\pi G_N}\int \mathrm{d}^2x\, \sqrt{g_{(0)}} \int_\varepsilon \mathrm{d}z\, \Big[z^{-3} - \tfrac{1}{4} R_{(0)}\, z^{-1} + \cdots \Big]. \tag{56.23}$$

The z^{-3} term is a power divergence ($\propto \varepsilon^{-2}$); the z^{-1} term integrates to $-\ln \varepsilon$ and produces the only logarithm. A direct expansion of the boundary terms in Eq. (56.22) shows that the Gibbons–Hawking–York and counterterm pieces contribute only powers of ε and finite curvature terms — their $R_{(0)}$ contributions cancel between $K = -2/L - (z^2/2L) R_{(0)} + \cdots$ and the volume expansion — so the entire logarithmic divergence is

$$I \;\supset\; \frac{L}{16\pi G_N}\, \ln \varepsilon \int \mathrm{d}^2x\, \sqrt{g_{(0)}}\, R_{(0)} \;=\; -\frac{L}{16\pi G_N}\, \ln \frac{1}{\varepsilon} \int \mathrm{d}^2x\, \sqrt{g_{(0)}}\, R_{(0)}. \tag{56.24}$$

Reading off the central charge. A logarithmic divergence cannot be removed by any covariant power counterterm; subtracting it would require a $\ln\varepsilon$ times a local integral, and such a term is not Weyl-invariant. This unremovable, finite, local Weyl non-invariance is the holographic conformal anomaly (Theorem 54.6): the coefficient of the logarithm is precisely the integrated boundary trace anomaly $\int \sqrt{g_{(0)}}\,\langle T^{i}{}_{i}\rangle$. In two dimensions the trace anomaly is fixed by the central charge through $\langle T^{i}{}_{i}\rangle = -\frac{c}{24\pi}R_{(0)}$ (the curved-space Weyl anomaly of Theorem 48.8, with the normalization of Chapter 37). Matching the magnitude of the coefficient in Eq. (56.24) to this normalization,

$$\frac{L}{16\pi G_N} = \frac{c}{24\pi} \quad\Longrightarrow\quad c = \frac{24\pi}{16\pi}\,\frac{L}{G_N} = \frac{3L}{2G_N}, \tag{56.25}$$

which is Eq. (56.18). The bulk computation knows nothing of the boundary CFT beyond its central charge, exactly as it should: the anomaly is the one piece of curved-space data a 2D CFT carries, and the gravity dual reproduces it with the coefficient $3/2$ that makes the entropy match below parameter-free. (The original Brown–Henneaux route reaches the same number by computing the central extension of the algebra of asymptotic symmetry charges of AdS_3, which is two commuting Virasoro algebras of this c; the anomaly computation here is the same statement read off the on-shell action.)

The relation Eq. (56.18) is exact and parameter-free; substituting $L/2G_N = c/3$ into Eq. (56.17) gives

$$S(A) = \frac{c}{3}\,\ln\frac{\ell}{\varepsilon}, \tag{56.26}$$

which is exactly the 2D CFT vacuum single-interval entropy of Theorem 55.32 and Eq. (55.119), coefficient and cutoff and all. The match is complete: a classical geodesic length in pure AdS_3, regulated at a radial wall and divided by $4G_N$, reproduces a result that on the boundary required the full replica machinery of two-dimensional conformal field theory. No coefficient was adjusted. The leading logarithmic divergence as $\varepsilon \to 0$ is the holographic image of the universal ultraviolet divergence of entanglement entropy — here a true logarithm because the entangling surface in $d = 2$ is a pair of points, and the would-be area law degenerates to a log.

Figure 56.1 collects the geometry. It is worth pausing on how much the picture already contains. The minimal surface dips to a depth $z_* = \ell/2$ set by the size of the region, so larger regions reach deeper into the bulk; the radial direction is being read off as a scale, with small regions sensitive only to the near-boundary (ultraviolet) geometry and large regions to the deep interior (infrared) — the geometric face of the entanglement entropy's growth with region size. The homology region $\mathcal{R}_A$ is the wedge of bulk hanging beneath A; we will argue in Section 56.6 that this is precisely the bulk that the boundary data on A suffices to reconstruct. And the logarithmic divergence sits entirely in the near-boundary

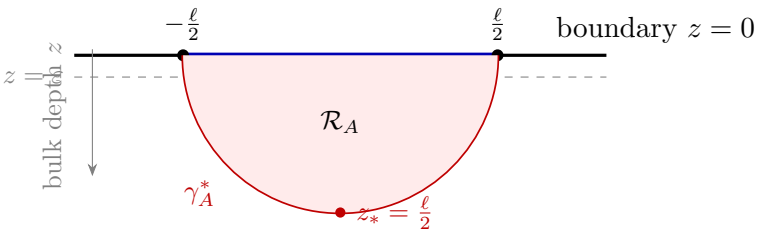


Figure 56.1: The Ryu–Takayanagi surface for a single interval A in the vacuum of a 2D CFT, drawn on the constant-time slice of Poincaré AdS_3 (the bulk depth z increases downward). The minimal surface γ_A^* is the spacelike geodesic anchored on the endpoints $\partial A = \{\pm\ell/2\}$ — a semicircle of radius $z_* = \ell/2$. The homology region $\mathcal{R}_A$ (shaded) is bounded by A and γ_A^*, as required by Theorem 56.2. The area integral is regulated at the radial cutoff $z = \varepsilon$ (dashed), identified with the QFT ultraviolet cutoff. Its regulated length, divided by $4G_N$ and translated through Brown–Henneaux $c = 3L/2G_N$, reproduces $S = (c/3)\ln(\ell/\varepsilon)$ exactly.

part of the geodesic, where it plunges vertically into the cutoff surface; the universal short-distance structure of entanglement entropy is localized, in the bulk, at the anchoring of the surface on ∂A.

Historical Note

Ryu and Takayanagi proposed Eq. (56.4) in 2006, generalizing the Bekenstein–Hawking area law from horizons to arbitrary entangling regions and checking it against the 2D CFT result and several higher-dimensional cases. The proposal was static; Hubeny, Rangamani, and Takayanagi gave the covariant extremal-surface form in 2007. For several years the formula was a strikingly successful conjecture without a derivation. The derivation from the gravitational path integral — the replica argument sketched in Section 56.1.1 — was supplied by Lewkowycz and Maldacena in 2013, and the quantum corrections by Faulkner, Lewkowycz, and Maldacena the same year, opening the road to the quantum extremal surfaces and the black-hole information results of Chapter 57.

We now hold a concrete, validated geometric prescription: a region's entanglement entropy is the regulated area of the minimal homologous bulk surface, divided by $4G_N$. The single-interval match certifies that the prescription, the cutoff identification, and the parameter dictionary all fit together with no slack. The next section turns this validated rule into a working engine, computing the entropy of canonical regions — the thermal state, the sphere, the strip — and exhibiting the genuinely holographic phenomena, including the entanglement phase transition for two intervals, that the minimization in Eq. (56.4) makes possible.

56.2 Computing holographic entanglement entropy

We now hold a validated rule: a boundary region's entanglement entropy is the regulated area of the minimal homologous bulk surface divided by $4G_N$ (Theorem 56.3), checked against the one entropy we already trusted, the single interval in the vacuum of a 2D CFT (Theorem 56.4 and Eq. (56.26)). A formula earns its keep by computing. This section turns the Ryu–Takayanagi prescription into a working engine and runs it on the canonical regions whose answers a holographic theory must reproduce: an interval in a thermal state, a sphere in any dimension, a strip in any dimension, and two disjoint intervals. Each computation is a complete minimal-surface problem solved on the page, and each one exhibits a genuinely holographic phenomenon. The thermal interval interpolates, in a single closed expression, between the vacuum logarithm and the extensive thermal entropy, with the crossover governed entirely by the geometry of a black-hole horizon. The sphere reveals, through the Casini–Huerta–Myers map, that vacuum entanglement across a sphere *is* a thermal entropy on hyperbolic space and a horizon area in the bulk. The strip displays the area law together with a finite, negative, shape-dependent piece that scales nonlocally with the region's width. And the two intervals undergo a sharp first-order entanglement phase transition — a discontinuity in the slope of the entropy — that has no analogue in the perturbative computation of entanglement and is the cleanest signature that "min" in Eq. (56.4) is load-bearing.

Throughout we work, as in Section 56.1.2, in asymptotically AdS_{d+1} with a CFT_d on the boundary, in the classical-gravity regime where Eq. (56.4) holds at leading order in G_N. The mostly-minus signature and natural units of Section 53.3 are in force; L is the AdS radius and G_N the bulk Newton constant. When we need the boundary central charge we use the holographic dictionary $C_T \sim L^{d-1}/G_N$ (Theorem 53.27), and in $d = 2$ the exact Brown–Henneaux value $c = 3L/2G_N$ (Eq. (56.18)).

56.2.1 A single interval at finite temperature: the BTZ geodesic

The first computation continues the thermal $\mathrm{AdS}_3/\mathrm{CFT}_2$ example carried since Chapter 54. A 2D CFT at inverse temperature β on an infinite line is dual not to pure AdS_3 but to the planar (non-rotating) BTZ black hole, the geometry whose Hawking temperature is the CFT temperature and whose horizon entropy is the CFT thermal entropy (Eq. (54.89) and Section 54.4). We compute the entanglement entropy of an interval of width ℓ in this thermal state by finding the spacelike geodesic anchored on its endpoints, exactly as in the vacuum but in the black-hole metric. The result is a single closed expression that knows about both the vacuum and the thermal ensemble, and the way it interpolates between them is a lesson in how holography geometrizes thermality.

In Poincaré-like coordinates with the boundary at $z \to 0$, the planar BTZ

metric is, in the book's mostly-minus signature,

$$\mathrm{d}s^2 = \frac{L^2}{z^2}\left(-f(z)\,\mathrm{d}t^2 + \mathrm{d}x^2 + \frac{\mathrm{d}z^2}{f(z)}\right), \qquad f(z) = 1 - \frac{z^2}{z_h^2}, \tag{56.27}$$

the $d = 2$ instance of the asymptotically-AdS black brane of Eq. (54.89). The locus $z = z_h$ is the horizon, where f vanishes; the asymptotic region $z \to 0$ recovers Eq. (56.5). The relation between the horizon depth z_h and the temperature is fixed by smoothness of the Euclidean continuation, exactly as for any black hole. Continuing $t \to -i\tau_E$ and expanding f near the horizon, $f(z) \simeq f'(z_h)(z - z_h)$ with $f'(z_h) = -2/z_h$, the (τ_E, z) part of Eq. (56.27) becomes a plane in polar coordinates whose angular variable is τ_E; absence of a conical singularity forces τ_E to be periodic with period $\beta = 4\pi/\,|f'(z_h)|$, i.e.

$$\beta = \frac{4\pi}{|f'(z_h)|} = 2\pi z_h, \qquad \Longleftrightarrow \qquad z_h = \frac{\beta}{2\pi}. \tag{56.28}$$

This is the horizon-radius/temperature identification we will substitute at the end; it is the same computation that fixes the Hawking temperature in Section 54.4, specialized to $d = 2$.

The state is static, so we work on the constant-time slice $t = 0$. Setting $\mathrm{d}t = 0$ in Eq. (56.27) and stripping the overall sign that marks the spatial directions, the induced Riemannian metric on the slice is

$$\mathrm{d}\ell_\Sigma^2 = \frac{L^2}{z^2}\left(\mathrm{d}x^2 + \frac{\mathrm{d}z^2}{f(z)}\right), \qquad f(z) = 1 - \frac{z^2}{z_h^2}. \tag{56.29}$$

The interval is $A = \{t = 0,\ -\ell/2 \le x \le \ell/2\}$, with $\partial A = \{x = \pm\ell/2\}$. As in $d = 2$ vacuum, the RT surface is a spacelike geodesic in Eq. (56.29). The homology constraint is inert here because the interval is small enough that the minimal geodesic does not reach the horizon; the complementary (horizon-wrapping) configuration that dominates for large regions is recovered in the extensive thermal limit below (Eq. (56.45)) and we do not need it for the connected geodesic.

Worked Example 56.6 (Thermal-interval geodesic in planar BTZ)**.** We minimize proper length in Eq. (56.29), anchored at $x = \pm\ell/2$, regulate at $z = \varepsilon$, and assemble $S = \mathrm{Length}/4G_N$, finally substituting Eqs. (56.18) and (56.28).

Length functional and first integral. Parametrize the geodesic as $z = z(x)$. From Eq. (56.29), the proper length is

$$\mathrm{Length}[z] = L\int_{-\ell/2}^{\ell/2}\mathrm{d}x\,\frac{1}{z}\sqrt{1 + \frac{z'^2}{f(z)}}, \qquad z' \equiv \frac{\mathrm{d}z}{\mathrm{d}x}. \tag{56.30}$$

The integrand $g(z,z') = z^{-1}\sqrt{1+z'^2/f}$ has no explicit x-dependence, so the Beltrami first integral $g - z'\,\partial g/\partial z'$ is conserved. With $\partial g/\partial z' = z^{-1}(z'/f)/\sqrt{1+z'^2/f}$,

$$g - z'\frac{\partial g}{\partial z'} = \frac{1}{z}\frac{(1+z'^2/f) - z'^2/f}{\sqrt{1+z'^2/f}} = \frac{1}{z\sqrt{1+z'^2/f}} = \frac{1}{z_*}, \tag{56.31}$$

the constant named $1/z_*$ because at the turning point $z' = 0$ gives $z = z_*$, the maximal depth. Rearranging,

$$\frac{z'^2}{f} = \frac{z_*^2 - z^2}{z^2} \quad\Longrightarrow\quad \frac{\mathrm{d}x}{\mathrm{d}z} = \pm\frac{z}{\sqrt{f(z)\,(z_*^2 - z^2)}} = \pm\frac{z}{\sqrt{(1 - z^2/z_h^2)(z_*^2 - z^2)}}. \tag{56.32}$$

The vacuum limit $z_h \to \infty$ ($\beta \to \infty$) sets $f \to 1$ and returns the semicircle equation Eq. (56.10), a useful check.

Width as a function of turning point. The interval width is twice the coordinate run from the turning point out to the boundary:

$$\frac{\ell}{2} = \int_0^{z_*} \frac{z\,\mathrm{d}z}{\sqrt{(1 - z^2/z_h^2)(z_*^2 - z^2)}}. \tag{56.33}$$

Substitute $w = z^2$, $\mathrm{d}w = 2z\,\mathrm{d}z$, and write $1 - z^2/z_h^2 = (z_h^2 - w)/z_h^2$, so $\sqrt{(1 - z^2/z_h^2)(z_*^2 - z^2)} = z_h^{-1}\sqrt{(z_h^2 - w)(z_*^2 - w)}$:

$$\frac{\ell}{2} = \frac{z_h}{2}\int_0^{z_*^2} \frac{\mathrm{d}w}{\sqrt{(z_h^2 - w)(z_*^2 - w)}}. \tag{56.34}$$

With $a \equiv z_*^2$ and $b \equiv z_h^2$ (and $a < b$, since the geodesic stays outside the horizon), the antiderivative is elementary: differentiating $-2\ln\!\big(\sqrt{a-w} + \sqrt{b-w}\big)$ returns $1/\sqrt{(a-w)(b-w)}$, so

$$\int_0^a \frac{\mathrm{d}w}{\sqrt{(a-w)(b-w)}} = \Big[-2\ln\!\big(\sqrt{a-w} + \sqrt{b-w}\big)\Big]_0^a = 2\ln\frac{\sqrt{a} + \sqrt{b}}{\sqrt{b-a}}. \tag{56.35}$$

Hence $\dfrac{\ell}{2} = z_h \ln\dfrac{z_* + z_h}{\sqrt{z_h^2 - z_*^2}} = \dfrac{z_h}{2}\ln\dfrac{z_h + z_*}{z_h - z_*}$, i.e.

$$\frac{\ell}{z_h} = \ln\frac{z_h + z_*}{z_h - z_*} \quad\Longrightarrow\quad z_* = z_h \tanh\frac{\ell}{2z_h} = z_h\tanh\frac{\pi\ell}{\beta}, \tag{56.36}$$

using $z_h = \beta/2\pi$ from Eq. (56.28) in the last step. The turning point now saturates at $z_* \to z_h$ as $\ell \to \infty$: a very large interval's geodesic hugs the horizon, the geometric origin of the extensive thermal regime found below.

Regulated length. Along the geodesic, $\sqrt{1+z'^2/f} = z_*/z$ from Eq. (56.31), so the length element is $\mathrm{d}\ell_\Sigma = (L/z)(z_*/z)\,\mathrm{d}x = Lz_* z^{-2}\,\mathrm{d}x$, and changing variable to z via Eq. (56.32),

$$\text{Length} = 2Lz_*\int_\varepsilon^{z_*}\frac{\mathrm{d}z}{z\sqrt{(1-z^2/z_h^2)(z_*^2-z^2)}} = Lz_h\int_{\varepsilon^2}^{z_*^2}\frac{z_*\,\mathrm{d}w}{w\sqrt{(z_h^2-w)(z_*^2-w)}}, \tag{56.37}$$

again with $w=z^2$. The remaining integral has the standard antiderivative

$$\int\frac{\mathrm{d}w}{w\sqrt{(a-w)(b-w)}} = -\frac{1}{\sqrt{ab}}\ln\!\left(\frac{2ab-(a+b)w+2\sqrt{ab}\,\sqrt{(a-w)(b-w)}}{w}\right), \tag{56.38}$$

(verified by differentiation), with $a=z_*^2$, $b=z_h^2$, $\sqrt{ab}=z_*z_h$. The prefactor in Eq. (56.37) is Lz_hz_*, and $Lz_hz_*/\sqrt{ab}=L$, so

$$\text{Length} = L\left[-\ln\!\left(\frac{2ab-(a+b)w+2z_*z_h\sqrt{(a-w)(b-w)}}{w}\right)\right]_{w=\varepsilon^2}^{w=z_*^2}. \tag{56.39}$$

At the upper limit $w=a=z_*^2$ the square root vanishes and the bracket's argument is $(2ab-(a+b)a)/a = b-a = z_h^2-z_*^2$. At the lower limit $w=\varepsilon^2\to 0$, the surviving terms are $2ab+2z_*z_h\sqrt{ab}=4ab$ over ε^2, i.e. $4z_*^2z_h^2/\varepsilon^2$. Therefore

$$\text{Length} = L\,\ln\frac{4z_*^2z_h^2}{\varepsilon^2\,(z_h^2-z_*^2)}. \tag{56.40}$$

Eliminating the turning point. From Eq. (56.36), $z_* = z_h\tanh(\pi\ell/\beta)$, so $z_h^2-z_*^2 = z_h^2\,\mathrm{sech}^2(\pi\ell/\beta)$ and $z_*^2 = z_h^2\tanh^2(\pi\ell/\beta)$. Hence

$$\frac{z_*^2z_h^2}{z_h^2-z_*^2} = \frac{z_h^2\tanh^2(\pi\ell/\beta)\,z_h^2}{z_h^2\,\mathrm{sech}^2(\pi\ell/\beta)} = z_h^2\,\tanh^2\frac{\pi\ell}{\beta}\,\cosh^2\frac{\pi\ell}{\beta} = z_h^2\,\sinh^2\frac{\pi\ell}{\beta}, \tag{56.41}$$

and Eq. (56.40) collapses to

$$\text{Length} = L\,\ln\!\left(\frac{4z_h^2\sinh^2(\pi\ell/\beta)}{\varepsilon^2}\right) = 2L\,\ln\!\left(\frac{2z_h}{\varepsilon}\sinh\frac{\pi\ell}{\beta}\right) = 2L\,\ln\!\left(\frac{\beta}{\pi\varepsilon}\sinh\frac{\pi\ell}{\beta}\right), \tag{56.42}$$

using $2z_h=\beta/\pi$.

The entropy. Dividing by $4G_N$ and substituting Brown–Henneaux $L/2G_N = c/3$ (Eq. (56.18)),

$$\boxed{S(\ell) = \frac{\text{Length}}{4G_N} = \frac{L}{2G_N}\ln\!\left(\frac{\beta}{\pi\varepsilon}\sinh\frac{\pi\ell}{\beta}\right) = \frac{c}{3}\ln\!\left[\frac{\beta}{\pi\varepsilon}\sinh\frac{\pi\ell}{\beta}\right].} \tag{56.43}$$

The closed form Eq. (56.43) is the thermal generalization of the vacuum logarithm, and it reproduces the result that the boundary CFT obtains by conformally mapping the thermal cylinder, with no free parameters. Two limits expose its content. For an interval small compared with the thermal length, $\ell \ll \beta$, we have $\sinh(\pi\ell/\beta) \to \pi\ell/\beta$ and

$$S(\ell) \xrightarrow[\ell \ll \beta]{} \frac{c}{3} \ln \frac{\ell}{\varepsilon}, \tag{56.44}$$

the vacuum single-interval entropy Eq. (56.26): a small region cannot resolve the temperature, and the geodesic, which only dips to $z_* \approx \ell/2 \ll z_h$, never feels the horizon. For an interval large compared with the thermal length, $\ell \gg \beta$, we have $\sinh(\pi\ell/\beta) \to \frac{1}{2} e^{\pi\ell/\beta}$ and

$$S(\ell) \xrightarrow[\ell \gg \beta]{} \frac{c}{3} \left(\frac{\pi\ell}{\beta} + \ln \frac{\beta}{2\pi\varepsilon} \right) = \frac{\pi c}{3\beta}\, \ell + (\text{const}). \tag{56.45}$$

The entropy is now *extensive*: it grows linearly in ℓ, with the constant of proportionality $\pi c/3\beta$ exactly the thermal entropy density of a 2D CFT — the Cardy entropy per unit length at temperature $T = 1/\beta$, equivalently the horizon-entropy density of the BTZ black hole (Section 54.4). The geometric mechanism is transparent from Eq. (56.36): a large interval's geodesic runs nearly parallel to the horizon at depth $z_* \approx z_h$, and its length is dominated by that long horizon-skimming stretch, which contributes the horizon entropy density times the coordinate length. The full curve in Fig. 56.2 shows the crossover sitting at $\ell \sim \beta$, where the entropy turns from the vacuum logarithm into the thermal straight line.

Physical Insight

The same geodesic computes two physically distinct quantities depending on the region size, and the bulk shows why. A small region's entropy is pure vacuum entanglement, blind to the temperature; a large region's entropy is dominated by the thermal occupation of its interior, and the bulk geodesic registers this by descending to the horizon and dragging along it. The horizon, which in Chapter 54 carried the global thermal entropy, here doubles as the asymptotic depth that any large entangling surface must approach. Black-hole thermodynamics and subsystem entanglement are not two facts but one geometry viewed at two scales.

56.2.2 A spherical region in any dimension: the Casini–Huerta–Myers map

The interval generalizes in two natural directions in higher dimensions: the sphere (a ball, with a spherical entangling surface) and the strip. The sphere is

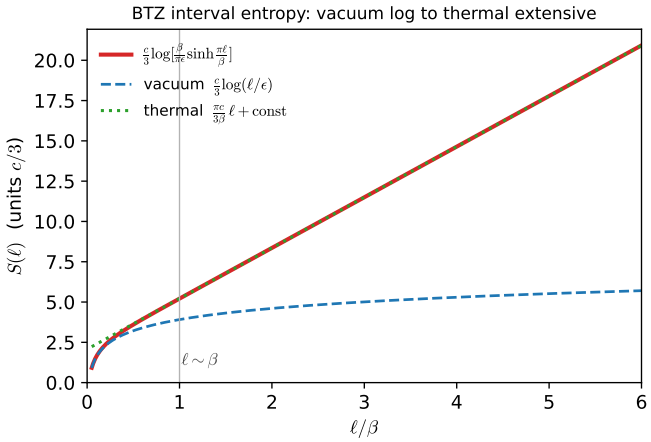

Figure 56.2: The single-interval entanglement entropy Eq. (56.43) in the thermal state of a 2D CFT (dual to planar BTZ), as a function of interval width ℓ in units of the thermal length β. For $\ell \ll \beta$ it tracks the vacuum logarithm Eq. (56.44) (dashed); for $\ell \gg \beta$ it tracks the extensive thermal entropy Eq. (56.45) (dotted), whose slope $\pi c/3\beta$ is the CFT thermal entropy density. The crossover at $\ell \sim \beta$ is the geometric statement that a large interval's geodesic begins to hug the BTZ horizon.

special because its symmetry makes vacuum entanglement *exactly* computable by a conformal trick that predates RT and, applied holographically, identifies the entanglement entropy with a black-hole horizon area without any minimization at all. This is the Casini–Huerta–Myers construction. It is worth presenting in full because it is the cleanest demonstration of the chapter's thesis: it turns vacuum entanglement across a sphere into a *thermal* entropy, and then into a horizon area, by an exact map.

The causal diamond of a ball. Take the vacuum of a CFT_d on Minkowski space, $\mathrm{d}s^2_{\text{flat}} = -\mathrm{d}t^2 + \mathrm{d}r^2 + r^2\,\mathrm{d}\Omega^2_{d-2}$ in spherical coordinates about the origin, and let A be the ball $r \le R$ at $t = 0$. The reduced density matrix ρ_A is determined by data on the ball, but by causality it is equally determined by any Cauchy slice of the ball's *causal diamond* $\mathcal{D}_A$ — the set of points all of whose causal curves pass through A — which for a ball is the region $|t| + r \le R$. The modular Hamiltonian $K = -\ln \rho_A$ for a sphere in the vacuum is, exceptionally, a *local* operator: the generator of the conformal boost that preserves $\mathcal{D}_A$. This is the spherical generalization of the Rindler result of Section 55.3, where the half-space modular Hamiltonian was the boost; here the flat entangling plane is replaced by a sphere and the boost by a special conformal transformation that fixes it.

The map to a hyperbolic cylinder. The Casini–Huerta–Myers observation is that $\mathcal{D}_A$ is conformally equivalent to a static spacetime $\mathbb{R}_\tau \times H^{d-1}$, the real line (time τ) times hyperbolic space of curvature radius R. Setting $R = 1$ momentarily for clarity, define new coordinates (τ, u) with $u \in [0, \infty)$ through

$$t = \frac{\sinh \tau}{\cosh u + \cosh \tau}, \qquad r = \frac{\sinh u}{\cosh u + \cosh \tau}. \tag{56.46}$$

A direct computation of the differentials gives the flat metric as a Weyl rescaling of the hyperbolic cylinder:

$$\mathrm{d}s^2_{\text{flat}} = -\mathrm{d}t^2 + \mathrm{d}r^2 + r^2\,\mathrm{d}\Omega^2_{d-2} = \Omega^2\Big(-\mathrm{d}\tau^2 + \mathrm{d}u^2 + \sinh^2 u\,\mathrm{d}\Omega^2_{d-2}\Big), \qquad \Omega = \frac{1}{\cosh u + \cosh \tau}. \tag{56.47}$$

The factor in parentheses is precisely the line element of $\mathbb{R}_\tau \times H^{d-1}$, with $\mathrm{d}u^2 + \sinh^2 u\,\mathrm{d}\Omega^2_{d-2}$ the unit-radius hyperbolic metric. Restoring the sphere radius rescales the hyperbolic curvature radius to R and the time to $R\tau$. The map sweeps out the diamond: at $\tau = 0$ one has $t = 0$ and $r = \tanh(u/2)$, so as u runs from 0 to ∞ the radial coordinate runs from the center $r = 0$ to the entangling sphere $r = 1$, and the whole spatial ball is covered; the future and past tips of the diamond, $r = 0,\ t = \pm 1$, are pushed to $\tau \to \pm\infty$. The entangling surface $r = R$ itself sits at $u \to \infty$, the boundary at infinity of H^{d-1}.

Because the CFT is conformally invariant, its vacuum on $\mathcal{D}_A$ maps to a state on $\mathbb{R}_\tau \times H^{d-1}$, and the modular Hamiltonian — the conformal boost preserving $\mathcal{D}_A$ — maps to the *ordinary* Hamiltonian generating τ-translations on the hyperbolic cylinder. The statement that $\rho_A = e^{-2\pi K}$ becomes the statement that the mapped state is the *thermal* (Gibbs) state of the CFT on H^{d-1} at the temperature read off from the period of Euclidean τ. Euclidean continuation $\tau \to -i\tau_E$ makes the conformal-boost orbits into circles; the modular flow ρ_A^{is} has period 2π in modular time, which in the τ_E of Eq. (56.46) is the period $2\pi R$ (restoring R). The mapped state is therefore thermal at

$$T_0 = \frac{1}{2\pi R}. \tag{56.48}$$

We have proved a sharp statement, the higher-dimensional descendant of vacuum thermality:

$$S_{\text{EE}}(\text{ball of radius } R) = S_{\text{thermal}}(\text{CFT}_d \text{ on } H^{d-1} \text{ at } T_0 = \tfrac{1}{2\pi R}). \tag{56.49}$$

The intractable replica continuation for a sphere has been traded, exactly and without holography, for a thermal partition function on hyperbolic space. This is the Casini–Huerta–Myers reduction; it holds in any CFT, holographic or not.

The bulk: a topological hyperbolic black hole. Now feed Eq. (56.49) to holography. A CFT_d thermal state on $\mathbb{R}_\tau \times H^{d-1}$ is dual to a bulk black hole

whose boundary geometry is that cylinder: the *topological* (hyperbolic-horizon) black hole in AdS_{d+1},

$$\mathrm{d}s^2 = -f(\rho)\,\mathrm{d}\tau^2 + \frac{\mathrm{d}\rho^2}{f(\rho)} + \rho^2(\mathrm{d}u^2 + \sinh^2 u\,\mathrm{d}\Omega_{d-2}^2), \qquad f(\rho) = \frac{\rho^2}{L^2} - 1 - \frac{m}{\rho^{\,d-2}}, \tag{56.50}$$

where the -1 (rather than the planar black brane's 0 or the spherical black hole's $+1$) reflects the hyperbolic curvature of the horizon cross-section. The Hawking temperature of Eq. (56.50) depends on the mass parameter m, but there is a distinguished value $m = 0$ at which the black hole is "massless" (its horizon is a pure curvature effect, not sourced by energy). For $m = 0$ the horizon $f(\rho_h) = 0$ sits at $\rho_h = L$, and the temperature is

$$T = \frac{f'(\rho_h)}{4\pi} = \frac{1}{4\pi}\cdot\frac{2\rho_h}{L^2}\bigg|_{\rho_h = L} = \frac{1}{2\pi L}, \tag{56.51}$$

which, once the boundary hyperbolic radius is set to R, is exactly $T_0 = 1/2\pi R$ of Eq. (56.48). The massless hyperbolic black hole is therefore the bulk dual of the vacuum-reduced state on the ball, and its horizon, by the holographic dictionary, is nothing other than the RT surface anchored on the entangling sphere $r = R$ (one checks that the bifurcation surface $\rho = \rho_h$ of Eq. (56.50) reaches the boundary precisely at $u \to \infty$, i.e. at ∂A, and is homologous to the ball). The entanglement entropy is its horizon area:

$$S_{\mathrm{EE}}(\text{ball}) = \frac{\mathrm{Area}(\rho = \rho_h)}{4G_N} = \frac{\rho_h^{\,d-1}}{4G_N}\,\mathrm{Vol}(H^{d-1}) = \frac{L^{d-1}}{4G_N}\,\mathrm{Vol}(H^{d-1}), \tag{56.52}$$

the horizon being a copy of H^{d-1} of radius $\rho_h = L$.

Worked Example 56.7 (The universal coefficient from the regularized hyperbolic volume)**.** The entropy Eq. (56.52) reduces the whole problem to one geometric quantity: the volume of hyperbolic space, regulated by the same cutoff that regulates the entangling surface. Write the unit-radius H^{d-1} volume with the radial coordinate u cut off where the entangling surface is regulated,

$$\mathrm{Vol}(H^{d-1}) = \Omega_{d-2}\int_0^{u_{\max}} \sinh^{d-2} u\,\mathrm{d}u, \qquad \Omega_{d-2} = \frac{2\pi^{(d-1)/2}}{\Gamma\!\left(\frac{d-1}{2}\right)}, \tag{56.53}$$

where Ω_{d-2} is the area of the unit $(d-2)$-sphere and $u_{\max}$ is fixed by the relation between the hyperbolic cutoff and the boundary short-distance cutoff δ: the conformal factor Eq. (56.47) ties proper distance near $r = R$ to u, giving $e^{u_{\max}} \simeq 2R/\delta$, i.e. $u_{\max} \simeq \ln(2R/\delta)$. The integrand grows as $\sinh^{d-2} u \sim 2^{-(d-2)} e^{(d-2)u}$ at large u, producing a tower of divergences in powers of $e^{u_{\max}} \sim R/\delta$ — the holographic image of the area-law tower of Eq. (55.24) — on top of which sits the universal piece. We read it off dimension by dimension.

$d = 2$**.** Here H^1 is a line, $\sinh^0 u = 1$, and $\mathrm{Vol}(H^1) = \int_0^{u_{\max}} \mathrm{d}u = u_{\max} = \ln(2R/\delta)$. Then Eq. (56.52) gives $S = (L/4G_N)\ln(2R/\delta)$; with $c = 3L/2G_N$ and $2R = \ell$ the diameter of the ball (the interval length), this is $S = \frac{c}{6}\ln(\ell/\delta)$ *per endpoint* — two endpoints reproduce $S = \frac{c}{3}\ln(\ell/\delta)$, recovering Eq. (56.26). The CHM route reaches the 2D answer with no geodesic at all.

$d = 3$**.** Now H^2, $\sinh^1 u$, and

$$\mathrm{Vol}(H^2) = 2\pi \int_0^{u_{\max}} \sinh u \, \mathrm{d}u = 2\pi(\cosh u_{\max} - 1) = 2\pi\Big(\tfrac{1}{2}e^{u_{\max}} + \tfrac{1}{2}e^{-u_{\max}} - 1\Big). \tag{56.54}$$

The leading term $\pi e^{u_{\max}} \sim 2\pi R/\delta$ is the area-law divergence (linear in R/δ, the perimeter of the disk in cutoff units). The $u_{\max}$-independent piece is the finite *universal* constant -2π:

$$S^{(d=3)}_{\mathrm{univ}} = \frac{L^2}{4G_N}(-2\pi) = -\frac{\pi L^2}{2G_N} \equiv -F, \tag{56.55}$$

a cutoff-independent number. It is (minus) the quantity F that the F-theorem identifies as a good measure of degrees of freedom for a three-dimensional CFT — the odd-dimensional analogue of a central charge, here delivered as a hyperbolic-space free energy.

$d = 4$**.** Now H^3, $\sinh^2 u$, and

$$\mathrm{Vol}(H^3) = 4\pi \int_0^{u_{\max}} \sinh^2 u \, \mathrm{d}u = 4\pi\cdot\tfrac{1}{2}(\sinh u_{\max}\cosh u_{\max} - u_{\max}) = 2\pi(\tfrac{1}{4}e^{2u_{\max}} + \cdots - u_{\max}). \tag{56.56}$$

The $e^{2u_{\max}} \sim (R/\delta)^2$ term is the area-law divergence (the area of the entangling sphere in cutoff units). The universal piece is now *logarithmic*: the $-u_{\max} = -\ln(2R/\delta)$ term gives

$$S^{(d=4)}_{\mathrm{univ}} = \frac{L^3}{4G_N}(-2\pi)\,\ln\frac{2R}{\delta} = -\frac{\pi L^3}{2G_N}\,\ln\frac{R}{\delta} + (\mathrm{const}), \tag{56.57}$$

a universal logarithm whose coefficient is fixed by the bulk data L^3/G_N. This coefficient is, up to a convention-dependent normalization collected with the trace-anomaly data, 4 times the A-type (Euler-density) anomaly coefficient a of the CFT$_4$: $S^{(d=4)}_{\mathrm{univ}} = -4a\,\ln(R/\delta)$, with the holographic value of a proportional to L^3/G_N (Theorem 53.27). The universal entanglement of a sphere is the conformal anomaly.

General d**.** The same integral organizes every dimension at once. The leading divergence of Eq. (56.53) scales as $e^{(d-2)u_{\max}} \sim (R/\delta)^{d-2}$, the area law $\mathrm{Area}(\partial A)/\delta^{d-2}$. The universal piece is the $u_{\max}$-independent constant for d odd

(a pure number, $\propto F$) and the coefficient of the single power $u_{\max} \sim \ln(R/\delta)$ for d even (a logarithm, $\propto a$). In every case

$$S(\text{ball}) = \frac{L^{d-1}\Omega_{d-2}}{4G_N} \int_0^{u_{\max}} \sinh^{d-2} u \, \mathrm{d}u, \tag{56.58}$$

and the universal coefficient is a pure number times $L^{d-1}/G_N \sim C_T$, the holographic count of degrees of freedom. The sphere thus measures, through its entanglement entropy, the same central data that govern the two-point function of the stress tensor.

Physical Insight

The CHM map is the higher-dimensional face of the Rindler thermality of Section 55.3: vacuum entanglement across a sphere is genuinely a thermal phenomenon, with a temperature $1/2\pi R$ set by the sphere's size, on a space (H^{d-1}) whose negative curvature compactifies the entangling surface to infinity. Holography then identifies that thermal entropy with a horizon area, so the entire content of spherical vacuum entanglement — divergence structure, universal coefficient, and all — is the geometry of a single "topological" black hole. No replica continuation, no minimization: the symmetry of the sphere does all the work.

56.2.3 A strip in any dimension: the area law and a nonlocal finite piece

The strip lacks the sphere's enhanced symmetry, so we must genuinely solve the minimal-surface problem; but its translational symmetry makes the problem one-dimensional and exactly soluble, and the answer displays the area law together with a finite piece that scales *nonlocally* with the strip's width — a structure with no counterpart in a local action. We work in pure Poincaré AdS_{d+1}, dual to the CFT_d vacuum, with metric

$$\mathrm{d}s^2 = \frac{L^2}{z^2}\Big(-\mathrm{d}t^2 + \mathrm{d}x_1^2 + \cdots + \mathrm{d}x_{d-1}^2 + \mathrm{d}z^2\Big). \tag{56.59}$$

The region A is the strip $-\frac{\ell}{2} \le x_1 \le \frac{\ell}{2}$, unbounded in the transverse directions $x_2, \ldots, x_{d-1}$, which we regulate to a large length W each, so the entangling surface ∂A consists of two parallel planes at $x_1 = \pm\ell/2$, each of transverse "area" W^{d-2}. By translational invariance the RT surface is described by a single profile $z = z(x_1)$, with the transverse directions spectators.

Worked Example 56.8 (Strip minimal surface in Poincaré AdS_{d+1})**.** We minimize the area functional, solve the turning-point integral, and separate the divergent area-law piece from the finite shape-dependent piece.

Area functional and first integral. On the $t = 0$ slice the induced area of a surface $z = z(x_1)$, with the transverse directions contributing a factor $(L/z)^{d-2}W^{d-2}$ and the profile contributing $(L/z)\sqrt{1+z'^2}\,\mathrm{d}x_1$, is

$$\mathrm{Area}[z] = L^{d-1}W^{d-2}\int_{-\ell/2}^{\ell/2}\mathrm{d}x_1\,\frac{\sqrt{1+z'^2}}{z^{d-1}}, \qquad z' \equiv \frac{\mathrm{d}z}{\mathrm{d}x_1}. \tag{56.60}$$

The integrand $g(z,z') = z^{-(d-1)}\sqrt{1+z'^2}$ is x_1-independent, so the Beltrami integral is conserved:

$$g - z'\frac{\partial g}{\partial z'} = \frac{1}{z^{d-1}\sqrt{1+z'^2}} = \frac{1}{z_*^{d-1}}, \tag{56.61}$$

with z_* the turning point ($z' = 0$). Rearranging,

$$\sqrt{1+z'^2} = \Big(\frac{z_*}{z}\Big)^{d-1} \quad\Longrightarrow\quad z'^2 = \Big(\frac{z_*}{z}\Big)^{2(d-1)} - 1 \quad\Longrightarrow\quad \frac{\mathrm{d}x_1}{\mathrm{d}z} = \pm\frac{(z/z_*)^{d-1}}{\sqrt{1-(z/z_*)^{2(d-1)}}}. \tag{56.62}$$

Width as a function of turning point. Integrating $\mathrm{d}x_1/\mathrm{d}z$ from the turning point to the boundary and doubling,

$$\frac{\ell}{2} = \int_0^{z_*}\frac{(z/z_*)^{d-1}}{\sqrt{1-(z/z_*)^{2(d-1)}}}\,\mathrm{d}z = z_*\int_0^1\frac{y^{d-1}}{\sqrt{1-y^{2(d-1)}}}\,\mathrm{d}y, \tag{56.63}$$

substituting $y = z/z_*$. The integral is a Beta function: setting $s = y^{2(d-1)}$,

$$\int_0^1\frac{y^{d-1}\,\mathrm{d}y}{\sqrt{1-y^{2(d-1)}}} = \frac{1}{2(d-1)}B\Big(\frac{d}{2(d-1)},\frac{1}{2}\Big) = \frac{\sqrt{\pi}}{2(d-1)}\frac{\Gamma\big(\frac{d}{2(d-1)}\big)}{\Gamma\big(\frac{2d-1}{2(d-1)}\big)}. \tag{56.64}$$

Using $\Gamma\big(\frac{2d-1}{2(d-1)}\big) = \Gamma\big(1+\frac{1}{2(d-1)}\big) = \frac{1}{2(d-1)}\Gamma\big(\frac{1}{2(d-1)}\big)$, the prefactors cancel and

$$\ell = 2z_*\,a_d, \qquad a_d \equiv \sqrt{\pi}\,\frac{\Gamma\big(\frac{d}{2(d-1)}\big)}{\Gamma\big(\frac{1}{2(d-1)}\big)}. \tag{56.65}$$

The deepest reach z_* is proportional to the width ℓ, with an $O(1)$ dimension-dependent constant a_d; wide strips probe deep into the bulk, as for the interval.

The area integral and its divergence. Insert $\sqrt{1+z'^2} = (z_*/z)^{d-1}$ from Eq. (56.62) into Eq. (56.60) and change to z via Eq. (56.62); the integrand becomes $z^{-(d-1)}/\sqrt{1-(z/z_*)^{2(d-1)}}$, and with $y = z/z_*$,

$$\mathrm{Area} = 2L^{d-1}W^{d-2}\int_\varepsilon^{z_*}\frac{\mathrm{d}z}{z^{d-1}\sqrt{1-(z/z_*)^{2(d-1)}}} = \frac{2L^{d-1}W^{d-2}}{z_*^{d-2}}\int_{\varepsilon/z_*}^1\frac{y^{-(d-1)}\,\mathrm{d}y}{\sqrt{1-y^{2(d-1)}}}. \tag{56.66}$$

The remaining integral diverges at its lower limit, where the surface plunges to the boundary; we isolate the divergence by subtracting and adding the leading behavior $y^{-(d-1)}$:

$$\int_{\varepsilon/z_*}^{1} \frac{y^{-(d-1)}\,\mathrm{d}y}{\sqrt{1-y^{2(d-1)}}} = \underbrace{\int_{\varepsilon/z_*}^{1} y^{-(d-1)}\,\mathrm{d}y}_{\text{divergent}} + \underbrace{\int_0^1 y^{-(d-1)}\left[\frac{1}{\sqrt{1-y^{2(d-1)}}}-1\right]\mathrm{d}y}_{\text{convergent}} + o(1). \tag{56.67}$$

The subtracted integrand behaves as $\frac{1}{2}y^{d-1}$ near $y=0$, so the second integral converges and its lower limit may be sent to 0. The first integral is elementary:

$$\int_{\varepsilon/z_*}^{1} y^{-(d-1)}\,\mathrm{d}y = \frac{1}{d-2}\left[\left(\frac{z_*}{\varepsilon}\right)^{d-2}-1\right] \qquad (d>2). \tag{56.68}$$

The convergent remainder is a pure number; combining it with the $-1/(d-2)$ from Eq. (56.68) gives the finite constant

$$K_d \equiv -\frac{1}{d-2} + \int_0^1 y^{-(d-1)}\left[\frac{1}{\sqrt{1-y^{2(d-1)}}}-1\right]\mathrm{d}y. \tag{56.69}$$

This constant has a closed form. The full (analytically continued) Beta integral $\int_0^1 y^{a-1}(1-y^{2(d-1)})^{-1/2}\mathrm{d}y = \frac{1}{2(d-1)}B\big(\frac{a}{2(d-1)},\frac{1}{2}\big)$, evaluated at $a=-(d-2)$ where the elementary power divergence is automatically subtracted, returns exactly K_d. Its first argument is $\frac{-(d-2)}{2(d-1)} = \frac{d}{2(d-1)} - 1$ and its second-Gamma argument simplifies to $\frac{1}{2} - \frac{d-2}{2(d-1)} = \frac{1}{2(d-1)}$, so

$$K_d = \frac{\sqrt{\pi}}{2(d-1)}\frac{\Gamma\big(\frac{d}{2(d-1)}-1\big)}{\Gamma\big(\frac{1}{2(d-1)}\big)} = -\frac{1}{d-2}\sqrt{\pi}\,\frac{\Gamma\big(\frac{d}{2(d-1)}\big)}{\Gamma\big(\frac{1}{2(d-1)}\big)} = -\frac{a_d}{d-2}, \tag{56.70}$$

where the middle step uses $\Gamma(\xi-1) = \Gamma(\xi)/(\xi-1)$ with $\xi = \frac{d}{2(d-1)}$ and $\xi - 1 = -\frac{d-2}{2(d-1)}$. The constant K_d is *negative*, and it is built from the same ratio a_d that fixed the width Eq. (56.65).

Assembling the entropy. Putting Eqs. (56.68) and (56.69) into Eq. (56.66) and dividing by $4G_N$,

$$S = \frac{\text{Area}}{4G_N} = \frac{2L^{d-1}W^{d-2}}{4G_N}\left[\frac{1}{(d-2)}\frac{1}{\varepsilon^{d-2}} + \frac{K_d}{z_*^{d-2}}\right]. \tag{56.71}$$

The first term is the area law: it scales as $W^{d-2}/\varepsilon^{d-2}$ — the entangling surface's area in cutoff units — and is local on ∂A, blind to the width ℓ. The second

term is finite. Eliminating z_* in favor of the physical width through Eq. (56.65), $z_* = \ell/2a_d$, so $z_*^{-(d-2)} = (2a_d/\ell)^{d-2}$, and using $K_d = -a_d/(d-2)$,

$$\boxed{S = \frac{1}{4G_N}\left[\frac{2L^{d-1}}{d-2}\Big(\frac{W}{\varepsilon}\Big)^{d-2} - \frac{2^{d-1}\pi^{(d-1)/2}L^{d-1}}{d-2}\left(\frac{\Gamma\big(\frac{d}{2(d-1)}\big)}{\Gamma\big(\frac{1}{2(d-1)}\big)}\right)^{d-1}\Big(\frac{W}{\ell}\Big)^{d-2}\right].} \tag{56.72}$$

The structure of Eq. (56.72) is the promised one: an area-law divergence $\propto W^{d-2}/\varepsilon^{d-2}$ plus a finite, cutoff-independent, negative piece $\propto -(L_{\mathrm{AdS}}/G_N)\,W^{d-2}/\ell^{d-2}$ that depends on the *shape and size* of the region. Three features deserve comment. First, the finite piece scales as $\ell^{-(d-2)}$, a nonlocal dependence on the whole width that no local boundary term could produce; it is a genuine measure of the long-range entanglement across the strip and is exactly the kind of universal shape dependence that distinguishes entanglement entropy from a naive area law. Second, its coefficient is negative, so that increasing ℓ at fixed cutoff *decreases* the finite part of the entropy; this sign is required by strong subadditivity and underlies the entropic c-functions that count degrees of freedom monotonically along renormalization-group flows. Third, the $d = 2$ case is recovered as a limit even though Eq. (56.68) was derived for $d > 2$: as $d \to 2$ the transverse area $W^{d-2} \to 1$, the coefficient $a_d \to a_2 = \sqrt{\pi}\,\Gamma(1)/\Gamma(\frac{1}{2}) = 1$, and the two terms in Eq. (56.72) combine as

$$S \xrightarrow[d\to 2]{} \frac{2L}{4G_N}\,\frac{1}{d-2}\left[\Big(\frac{1}{\varepsilon}\Big)^{d-2} - \Big(\frac{1}{\ell}\Big)^{d-2}\right] \xrightarrow[d\to 2]{} \frac{L}{2G_N}\ln\frac{\ell}{\varepsilon} = \frac{c}{3}\ln\frac{\ell}{\varepsilon}, \tag{56.73}$$

since $x^{d-2} = e^{(d-2)\ln x} \to 1 + (d-2)\ln x$ makes the bracket tend to $(d-2)\ln(\ell/\varepsilon)$ and the pole cancels. The strip's power law and the interval's logarithm are the same formula, analytically continued in d.

56.2.4 Two intervals: mutual information and the entanglement phase transition

The final computation is the one where the minimization in Eq. (56.4) stops being a formality and produces a sharp phase transition — a phenomenon visible in holography long before it could be extracted from a direct field-theory calculation. Return to a 2D CFT in its vacuum, dual to pure AdS_3, and take the region to be the *union of two disjoint intervals* on the line,

$$A = [x_1, x_2], \qquad B = [x_3, x_4], \qquad x_1 < x_2 < x_3 < x_4. \tag{56.74}$$

The entangling set $\partial(A \cup B)$ is four points, and there are two topologically distinct ways to hang geodesics from them while remaining homologous to $A \cup B$. We compute both and let Eq. (56.4) choose.

The two configurations. Each candidate RT surface is a pair of the vacuum semicircle geodesics of Theorem 56.4, whose regulated length between two boundary points separated by coordinate distance ℓ is Length $= 2L\ln(\ell/\varepsilon)$, i.e. an entropy contribution $\frac{c}{3}\ln(\ell/\varepsilon)$. The two ways to pair the four endpoints into homologous geodesic pairs are:

- the *disconnected* configuration, geodesics over A and over B separately, with lengths set by $x_2 - x_1$ and $x_4 - x_3$;
- the *connected* configuration, geodesics over the inner gap and the outer span, with lengths set by $x_3 - x_2$ and $x_4 - x_1$.

(The remaining pairing, joining x_1 to x_3 and x_2 to x_4, gives crossing curves that are not homologous to $A \cup B$ and is excluded by Theorem 56.2.) The corresponding entropies are

$$S_{\text{disc}} = \frac{c}{3}\left[\ln\frac{x_2 - x_1}{\varepsilon} + \ln\frac{x_4 - x_3}{\varepsilon}\right], \tag{56.75}$$

$$S_{\text{conn}} = \frac{c}{3}\left[\ln\frac{x_3 - x_2}{\varepsilon} + \ln\frac{x_4 - x_1}{\varepsilon}\right], \tag{56.76}$$

and the RT prescription selects the smaller,

$$S(A \cup B) = \min\bigl(S_{\text{disc}},\, S_{\text{conn}}\bigr). \tag{56.77}$$

Crucially, the cutoff ε enters *both* configurations through four logarithms, two per pairing, so the cutoff dependence is identical in S_{disc} and S_{conn} and cancels in their difference — the competition is between finite, cutoff-independent quantities, as it must be for a physical transition.

The crossover and the mutual information. The natural diagnostic is the mutual information $I(A:B) = S(A)+S(B)-S(A\cup B)$ (Theorem 55.13), which is finite and cutoff-independent (Theorem 55.14) and, as Chapter 55 stressed, equals the relative entropy $S\bigl(\rho_{AB}\,\|\,\rho_A\otimes\rho_B\bigr)$ that quantifies all correlation between the two regions (Section 55.6). The single-interval entropies are $S(A) = \frac{c}{3}\ln\frac{x_2-x_1}{\varepsilon}$ and $S(B) = \frac{c}{3}\ln\frac{x_4-x_3}{\varepsilon}$, so $S(A) + S(B) = S_{\text{disc}}$. Therefore

$$I(A:B) = S_{\text{disc}} - S(A\cup B) = S_{\text{disc}} - \min\bigl(S_{\text{disc}}, S_{\text{conn}}\bigr) = \max\bigl(0,\; S_{\text{disc}} - S_{\text{conn}}\bigr). \tag{56.78}$$

The two phases are now explicit. When the disconnected surface is the shorter one, $S(A\cup B) = S_{\text{disc}}$ and the mutual information *vanishes identically*,

$$I(A:B) = 0 \qquad \text{(disconnected phase)}. \tag{56.79}$$

This is a striking statement: at leading order in G_N, two sufficiently separated regions share *no* mutual information whatsoever — not merely a small amount, but exactly zero. When instead the connected surface is shorter,

$$I(A:B) = S_{\text{disc}} - S_{\text{conn}} = \frac{c}{3}\ln\frac{(x_2-x_1)(x_4-x_3)}{(x_3-x_2)(x_4-x_1)} \qquad \text{(connected phase)}. \tag{56.80}$$

The argument of the logarithm is naturally written in the conformal cross-ratio of the four points. Define

$$\eta \equiv \frac{x_{12}\,x_{34}}{x_{13}\,x_{24}} = \frac{(x_2-x_1)(x_4-x_3)}{(x_3-x_1)(x_4-x_2)} \in (0,1), \qquad x_{ij}\equiv x_i - x_j. \tag{56.81}$$

For four ordered points on a line the identity $x_{13}x_{24} = x_{12}x_{34} + x_{14}x_{23}$ holds (it is verified directly from the definitions), so the ratio in Eq. (56.80) is

$$\frac{(x_2-x_1)(x_4-x_3)}{(x_3-x_2)(x_4-x_1)} = \frac{x_{12}x_{34}}{x_{23}x_{14}} = \frac{x_{12}x_{34}}{x_{13}x_{24}-x_{12}x_{34}} = \frac{\eta}{1-\eta}, \tag{56.82}$$

where $x_{23}x_{14} = (x_3-x_2)(x_4-x_1)$ up to the sign that the ordered differences supply. The mutual information is thus a clean function of the single cross-ratio:

$$\boxed{I(A:B) = \max\left[0,\ \frac{c}{3}\ln\frac{\eta}{1-\eta}\right].} \tag{56.83}$$

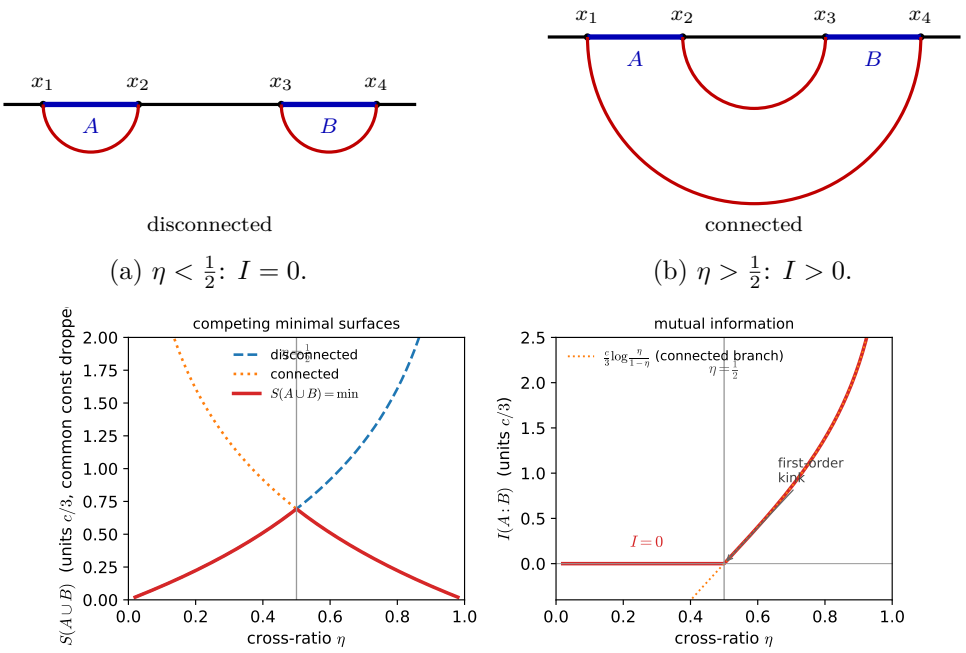
The transition is first order. The two branches are equal when $S_{\text{disc}} = S_{\text{conn}}$, i.e. when $\eta/(1-\eta) = 1$, namely

$$\eta_c = \frac{1}{2}. \tag{56.84}$$

For $\eta < \frac{1}{2}$ (intervals far apart, small cross-ratio) the disconnected surface wins and $I = 0$; for $\eta > \frac{1}{2}$ (intervals close) the connected surface wins and $I = \frac{c}{3}\ln\frac{\eta}{1-\eta} > 0$. At $\eta = \frac{1}{2}$ the mutual information is continuous — both branches give $I = 0$ — but its derivative is not:

$$\left.\frac{\mathrm{d}I}{\mathrm{d}\eta}\right|_{\eta\to\frac{1}{2}^-} = 0, \qquad \left.\frac{\mathrm{d}I}{\mathrm{d}\eta}\right|_{\eta\to\frac{1}{2}^+} = \frac{c}{3}\left(\frac{1}{\eta}+\frac{1}{1-\eta}\right)\Big|_{\eta=\frac{1}{2}} = \frac{4c}{3}. \tag{56.85}$$

The slope jumps discontinuously from 0 to $4c/3$. This is a *first-order* entanglement phase transition: $S(A\cup B)$, being the minimum of two smooth functions that cross transversally, has a kink, and the order parameter $I(A:B)$ turns on with a discontinuous first derivative. Figure 56.3 shows both the competing surface configurations and the resulting kinked mutual information. The transition is sharp only at leading order in G_N; the subleading bulk-entanglement corrections of Section 56.5.1 round the kink and lift I slightly off zero in the disconnected phase, but the leading-order discontinuity is a genuine prediction of classical RT and one of its most distinctive fingerprints.



(a) $\eta < \frac{1}{2}$: $I = 0$.

(b) $\eta > \frac{1}{2}$: $I > 0$.

Figure 56.3: Top: the two homologous geodesic configurations for $A \cup B$. The disconnected pairing (left) hangs a geodesic over each interval; the connected pairing (right) joins the inner gap and the outer span. Bottom left: the two candidate entropies cross at $\eta = \frac{1}{2}$, and $S(A \cup B)$ follows the lower envelope, producing a kink. Bottom right: the mutual information Eq. (56.83) is identically zero for $\eta < \frac{1}{2}$ and rises with a discontinuous slope $4c/3$ for $\eta > \frac{1}{2}$ — a first-order entanglement phase transition.

Physical Insight

The vanishing of $I(A : B)$ in the disconnected phase is the holographic version of large-N factorization. At leading order in G_N (large central charge) the connected correlations between well-separated regions are subleading, and the geometry registers this by literally disconnecting the bulk surface: no single surface spans both regions, so they share no classical entanglement. As the regions approach, a connected surface becomes cheaper and the mutual information switches on. The bulk thus encodes the onset of correlation as a change in the *topology* of the dominant minimal surface — a discrete, geometric event standing in for what on the boundary is a smooth (but, at leading order, sharply thresholded) build-up of entanglement.

56.2.5 What the catalogue is telling us

We now hold a working catalogue of holographic entanglement entropies: the vacuum interval (Eq. (56.26)), the thermal interval interpolating to extensive entropy (Eq. (56.43)), the sphere in any dimension as a hyperbolic horizon area (Eqs. (56.52) and (56.58)), the strip's area law with its nonlocal finite piece (Eq. (56.72)), and the two-interval mutual information with its first-order transition (Eq. (56.83)). Each was computed by solving a classical geometry problem, and each reproduces — where independent checks exist — the field-theory answer with no adjustable parameters. But the catalogue does more than tabulate: its entries are conspicuously *consistent* in ways that look like accidents from the geometry side. The strip's finite piece carries exactly the sign demanded by strong subadditivity; the two-interval mutual information is positive wherever it is nonzero and switches off precisely when subadditivity would otherwise be threatened; the homology constraint was forced on us by the purity relation $S(A) = S(\bar{A})$. These are not coincidences. They are shadows of general inequalities that the entanglement entropies of *any* quantum state must obey, and the remarkable fact — which the next section establishes — is that the minimal-surface prescription satisfies them *automatically*, as theorems of Riemannian geometry. We turn to proving, from RT geometry alone, the strong subadditivity of Headrick and Takayanagi and the holographic-only monogamy of mutual information, demonstrating that the area functional is not merely consistent with the laws of entanglement but is a sharp geometric engine for them.

56.3 Entanglement inequalities from geometry

The previous section turned the Ryu–Takayanagi formula into a working tool and, in passing, accumulated a catalogue of holographic entropies: the thermal state, the sphere, the strip, two intervals with their phase transition. Run through that catalogue with a calculator and a pattern emerges that is too clean to be an accident. Every entropy is the regulated area of a minimal surface, and minimal surfaces are not free to do whatever they like — they are constrained by the geometry of the slice they live in. A surface anchored on a large region cannot be longer than two surfaces anchored on its pieces, because one can always cut the long surface and rebuild it from the short ones; a surface that wraps a handle of the bulk is forced to compete with one that does not. These are geometric facts, theorems of Riemannian geometry, and through Eq. (56.4) they descend to inequalities among entanglement entropies. The remarkable thing is that some of these inequalities are extremely hard to prove — or simply false — in field theory directly.

This section proves the two most important of them from RT geometry alone. The first, strong subadditivity, is a theorem of quantum mechanics: it

holds for *every* density matrix, and its standard proof (Theorem 55.47) is a deep statement about the concavity of conditional entropy, established by Lieb and Ruskai with operator-convexity machinery that has no elementary shortcut. We will reprove it in three lines of geometry. The second, the monogamy of mutual information, is sharper still: it is *not* a theorem of quantum mechanics — generic quantum states violate it — yet it is forced on holographic states by the same surface-recombination argument. That contrast is the lesson of the section. Holographic states are not arbitrary states of the CFT; they obey extra entropy inequalities, and so they occupy a special, geometrically carved corner of Hilbert space. The boundary of that corner is the *holographic entropy cone*, and the existence of states outside it is our first sharp evidence that not every state of a holographic CFT is dual to a smooth classical geometry.

Throughout we work in the static setting of Section 56.1.3: a fixed bulk time slice Σ, on which RT entropies are minimal areas. The regions A, B, C are disjoint spatial regions of the boundary, and for any union X we write γ_X for a bulk surface anchored on ∂X and homologous to X in the sense of Theorem 56.2, with γ_X^* the true minimizer, so that $S(X) = \mathrm{Area}(\gamma_X^*)/4G_N$ by Theorem 56.3. The von Neumann entropy itself is $S(X) = -\operatorname{Tr}(\rho_X \ln \rho_X)$ as fixed in Eq. (55.6), and the mutual information is $I(A:B) = S(A) + S(B) - S(AB)$ from Eq. (55.23).

56.3.1 Strong subadditivity: the statement and the geometric idea

Recall the inequality we are after. For any three disjoint regions A, B, C,

$$S(AB) + S(BC) \;\geq\; S(ABC) + S(B), \tag{56.86}$$

where AB abbreviates $A \cup B$ and so on. This is strong subadditivity (SSA). Setting $C = \varnothing$ recovers ordinary subadditivity $S(A) + S(B) \geq S(AB)$ (Theorem 55.12); the content of SSA is the strengthening in which a shared region B appears on both sides. Quantum-mechanically it is equivalent to the statement that conditional entropy $S(AB) - S(B)$ is monotonic under appending C, and its proof from first principles requires the Lieb–Ruskai theorem on the joint convexity of relative entropy — the genuinely hard input of Theorem 55.47. We now show that for holographic states it is a one-step consequence of the minimality built into Eq. (56.4).

The idea, due to Headrick and Takayanagi, is cut-and-paste. We have two true minimal surfaces in hand, γ_{AB}^* and γ_{BC}^*, of total area $4G_N\big(S(AB)+S(BC)\big)$. We are going to take this collection of surface and *recut* it — redistribute its constituent pieces — into two new surfaces, one anchored on $\partial(ABC)$ and homologous to ABC, the other anchored on ∂B and homologous to B. The recutting conserves total area: not a single point of surface is created or destroyed, only reassigned. The two new surfaces are legal trial surfaces for ABC and for

B, but they are not the minimizers — they generically have creases where the old surfaces crossed. Minimality of the *true* surfaces γ^*_{ABC} and γ^*_B then says each is no longer than its trial counterpart, and Eq. (56.86) drops out. The entire weight of the argument rests on a single geometric fact — that area is conserved under recutting — and a single physical input — that the true surfaces minimize. We first see the mechanism explicitly in AdS_3, where the surfaces are geodesics and the recutting can be drawn, and then abstract it into the form that proves both SSA and, with one more region, monogamy.

56.3.2 The mechanism in AdS_3: crossing geodesics

Take three adjacent intervals on the boundary of vacuum AdS_3, sharing endpoints:

$$A = [x_0, x_1], \qquad B = [x_1, x_2], \qquad C = [x_2, x_3], \qquad x_0 < x_1 < x_2 < x_3, \tag{56.87}$$

all at $t = 0$, so that $AB = [x_0, x_2]$, $BC = [x_1, x_3]$, $ABC = [x_0, x_3]$, and $B = [x_1, x_2]$ are again single intervals. From Theorem 56.4 we know the minimal surface anchored on a single interval $[x_i, x_j]$ is the semicircle in the half-plane metric Eq. (56.7) of diameter $[x_i, x_j]$, and its regulated length is

$$\mathrm{Length}(\gamma^*_{[x_i,x_j]}) = 2L \,\ln\frac{x_j - x_i}{\varepsilon}. \tag{56.88}$$

The two surfaces appearing on the left of Eq. (56.86) are therefore the semicircles spanning $[x_0, x_2]$ and $[x_1, x_3]$. Because the intervals overlap (both contain $B = [x_1, x_2]$), these two semicircles *cross*: one runs from x_0 to x_2, the other from x_1 to x_3, and since $x_0 < x_1 < x_2 < x_3$ they must intersect at exactly one interior point P of the bulk. Figure 56.4 shows the configuration.

At the crossing P the two geodesics divide into four arcs:

- α_{L}: the part of γ^*_{AB} from x_0 down to P;
- α_{R}: the part of γ^*_{AB} from P up to x_2;
- β_{L}: the part of γ^*_{BC} from x_1 down to P;
- β_{R}: the part of γ^*_{BC} from P up to x_3.

Now reassemble. The arc α_{L} runs from x_0 to P, and β_{R} from P to x_3; joined at P they form a continuous curve $\widetilde{\gamma}_{ABC} \equiv \alpha_{\mathrm{L}} \cup \beta_{\mathrm{R}}$ from x_0 to x_3, anchored on $\partial(ABC) = \{x_0, x_3\}$. The remaining arcs β_{L} (from x_1 to P) and α_{R} (from P to x_2) join into $\widetilde{\gamma}_B \equiv \beta_{\mathrm{L}} \cup \alpha_{\mathrm{R}}$ from x_1 to x_2, anchored on $\partial B = \{x_1, x_2\}$. We have used each of the four arcs exactly once, so

$$\mathrm{Length}(\widetilde{\gamma}_{ABC}) + \mathrm{Length}(\widetilde{\gamma}_B) = \mathrm{Length}(\gamma^*_{AB}) + \mathrm{Length}(\gamma^*_{BC}). \tag{56.89}$$

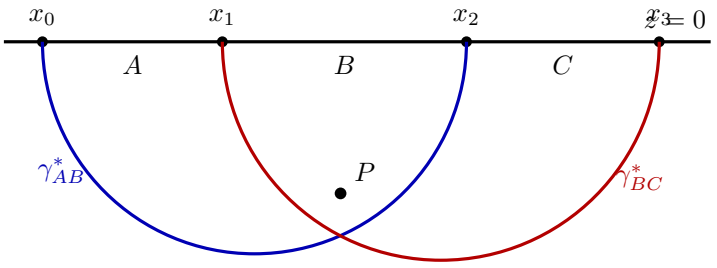


Figure 56.4: Strong subadditivity in AdS_3. The minimal surfaces for $AB = [x_0, x_2]$ (blue) and $BC = [x_1, x_3]$ (red) are semicircular geodesics that cross at a single bulk point P. Recutting at P swaps the pieces: the left arc of γ^*_{AB} $(x_0 \to P)$ joined to the right arc of γ^*_{BC} $(P \to x_3)$ is a trial surface for $ABC = [x_0, x_3]$; the left arc of γ^*_{BC} $(x_1 \to P)$ joined to the right arc of γ^*_{AB} $(P \to x_2)$ is a trial surface for $B = [x_1, x_2]$. Total length is unchanged by the swap, so minimality of the true geodesics over $[x_0, x_3]$ and $[x_1, x_2]$ gives $S(AB) + S(BC) \geq S(ABC) + S(B)$.

Each reassembled curve is a legal trial surface — correctly anchored and (being a deformation of the original semicircles through the bulk) homologous to the right region — but each has a kink at P, so neither is a geodesic. The true minimal surfaces are no longer:

$$\text{Length}(\gamma^*_{ABC}) \leq \text{Length}(\widetilde{\gamma}_{ABC}), \qquad \text{Length}(\gamma^*_{B}) \leq \text{Length}(\widetilde{\gamma}_{B}). \tag{56.90}$$

Adding the two inequalities of Eq. (56.90) and using Eq. (56.89),

$$\text{Length}(\gamma^*_{ABC}) + \text{Length}(\gamma^*_{B}) \leq \text{Length}(\gamma^*_{AB}) + \text{Length}(\gamma^*_{BC}), \tag{56.91}$$

and dividing by $4G_N$ gives precisely Eq. (56.86). The kink at P is the source of the slack: smoothing it strictly shortens the trial curves, so the inequality is strict whenever the surfaces genuinely cross.

It is worth confirming the inequality numerically against Eq. (56.88), since here we can compute every term in closed form. With $S = \frac{c}{3}\ln(\ell/\varepsilon)$ for an interval of length ℓ,

$$\begin{aligned} S(AB) + S(BC) - S(ABC) - S(B) &= \frac{c}{3}\Big[\ln\tfrac{x_2-x_0}{\varepsilon} + \ln\tfrac{x_3-x_1}{\varepsilon} - \ln\tfrac{x_3-x_0}{\varepsilon} - \ln\tfrac{x_2-x_1}{\varepsilon}\Big] \\ &= \frac{c}{3}\,\ln\frac{(x_2-x_0)(x_3-x_1)}{(x_3-x_0)(x_2-x_1)}. \end{aligned} \tag{56.92}$$

The cutoff ε has cancelled, as it must for a difference of entropies. The argument of the logarithm exceeds one: with $x_0 < x_1 < x_2 < x_3$,

$$(x_2-x_0)(x_3-x_1) - (x_3-x_0)(x_2-x_1) = (x_1-x_0)(x_3-x_2) > 0, \tag{56.93}$$

as one verifies by expanding both products and cancelling the common terms x_2x_3, x_0x_1, leaving $-x_1x_2 - x_0x_3 + x_1x_3 + x_0x_2 = (x_1-x_0)(x_3-x_2)$. Hence

Eq. (56.92) is strictly positive, and SSA holds with a margin set by the product of the two "gap" lengths $x_1 - x_0$ and $x_3 - x_2$. The deep operator inequality of quantum information theory has become, in AdS_3, the schoolroom statement that $(x_1 - x_0)(x_3 - x_2) > 0$.

56.3.3 The recutting lemma

The AdS_3 picture makes the mechanism vivid but hides what is actually doing the work, and obscures why it generalizes. In higher dimensions surfaces do not cross at a point but along a codimension-two locus, and "reassemble the arcs" must be made precise. The clean formulation replaces surfaces by the regions they bound. Recall (Theorem 56.2) that a homologous surface γ_X comes with a homology region $\mathcal{R}_X \subset \Sigma$, a piece of the bulk slice with $\partial\mathcal{R}_X = X \cup \gamma_X$. Encode each homology region by its indicator function on the slice,

$$\chi_X : \Sigma \to \{0,1\}, \qquad \chi_X(p) = \begin{cases} 1, & p \in \mathcal{R}_X, \\ 0, & \text{otherwise.} \end{cases} \tag{56.94}$$

The bulk boundary of $\mathcal{R}_X$ — the surface γ_X — is exactly the set where χ_X jumps; its area is the total "jump area" of χ_X. We can therefore phrase the whole argument in terms of how jump sets of indicator functions combine.

Lemma 56.9 (Recutting)**.** *Let $\mathcal{R}_1, \dots, \mathcal{R}_k$ be homology regions in Σ with indicator functions $\chi_1, \dots, \chi_k$, and suppose their bounding surfaces are smooth and intersect transversally (so that the loci where two or more surfaces coincide have codimension at least two in Σ, hence zero area). The surfaces partition Σ into* cells*, on each of which the vector $(\chi_1, \dots, \chi_k) \in \{0,1\}^k$ is constant; label the cell by that vector σ. Two cells are* adjacent *when they share a codimension-one face, which happens precisely when their labels differ in a single coordinate i, and the face is then a piece of the surface $\partial\mathcal{R}_i$. Consequently the total area of any collection of cell-faces, counted with the multiplicity "number of coordinates in which the two flanking labels differ," equals the total area of the surfaces; in particular*

$$\sum_{\text{faces } F} \mathrm{Area}(F) = \sum_{i=1}^{k} \mathrm{Area}(\partial\mathcal{R}_i), \tag{56.95}$$

because each face lies on exactly one surface.

Proof. Where the surfaces are smooth and transversal, a generic point of $\bigcup_i \partial\mathcal{R}_i$ lies on exactly one surface $\partial\mathcal{R}_i$ and separates two regions differing only in whether they belong to $\mathcal{R}_i$; the two adjacent cells thus differ in the single coordinate i. The exceptional set — where two or more surfaces meet — is a union of transversal intersections of codimension-two submanifolds, which carry no $(d-1)$-dimensional area and so do not contribute to any area integral. Summing the

area of all faces, each face is counted once and belongs to the unique surface flagged by its flipped coordinate; grouping faces by that coordinate reconstructs each $\partial\mathcal{R}_i$ exactly, giving Eq. (56.95). □

The power of Theorem 56.9 is that we may now build *new* regions out of Boolean combinations of the cells and read off the areas of their boundaries from the same faces, with no new geometry. A new region $\mathcal{O}$ is a union of cells; its boundary $\partial\mathcal{O}$ consists of those faces with exactly one flanking cell inside $\mathcal{O}$. If we design several new regions $\mathcal{O}_1, \dots, \mathcal{O}_m$ so that *every face is a boundary of at most one of them*, then

$$\sum_{a=1}^{m} \mathrm{Area}(\partial\mathcal{O}_a) \;\le\; \sum_{\text{faces}} \mathrm{Area}(F) \;=\; \sum_{i=1}^{k} \mathrm{Area}(\partial\mathcal{R}_i), \tag{56.96}$$

the inequality coming only from faces internal to some $\mathcal{O}_a$ (counted zero times on the left, once on the right). If, moreover, each $\mathcal{O}_a$ is a legal homology region for a boundary region X_a, then $\partial\mathcal{O}_a$ is a trial surface for X_a and minimality gives $\mathrm{Area}(\gamma^*_{X_a}) \le \mathrm{Area}(\partial\mathcal{O}_a)$, whence

$$\sum_a 4G_N\, S(X_a) = \sum_a \mathrm{Area}(\gamma^*_{X_a}) \le \sum_i \mathrm{Area}(\partial\mathcal{R}_i) = \sum_i 4G_N\, S(Y_i), \tag{56.97}$$

where Y_i are the boundary regions of the input surfaces. This single inequality, Eq. (56.97), is the engine. Proving an entropy inequality reduces to a combinatorial design problem: given input regions $\{Y_i\}$ on the right, choose the cell-unions $\{\mathcal{O}_a\}$ on the left so that (i) each $\mathcal{O}_a$ is anchored on and homologous to the desired X_a, and (ii) no face bounds two different $\mathcal{O}_a$. We now solve that problem first for two inputs (recovering SSA) and then for three (delivering monogamy).

Theorem 56.10 (Geometric strong subadditivity)**.** *For disjoint boundary regions A, B, C of a static holographic state in the classical-gravity regime, the Ryu–Takayanagi entropies satisfy Eq. (56.86), $S(AB) + S(BC) \ge S(ABC) + S(B)$.*

Proof. Apply Theorem 56.9 with the two inputs $\mathcal{R}_1 = \mathcal{R}_{AB}$ and $\mathcal{R}_2 = \mathcal{R}_{BC}$, the homology regions of the true minimal surfaces $\gamma^*_{AB}, \gamma^*_{BC}$. Cells are labelled $\sigma = (\sigma_1, \sigma_2) \in \{0,1\}^2$. On the conformal boundary the indicators restrict to the indicators of the boundary regions: a boundary point lies in $\mathcal{R}_{AB}$ iff it lies in $AB = A \cup B$, and in $\mathcal{R}_{BC}$ iff it lies in $BC = B \cup C$. Since A, B, C are disjoint, the boundary-anchored cells are

$$A \leftrightarrow (1,0), \quad B \leftrightarrow (1,1), \quad C \leftrightarrow (0,1), \quad (\text{outside } ABC) \leftrightarrow (0,0). \tag{56.98}$$

Define the two output regions

$$\mathcal{O}_{ABC} = \{\sigma : \sigma_1{+}\sigma_2 \ge 1\} = \mathcal{R}_{AB} \cup \mathcal{R}_{BC}, \qquad \mathcal{O}_B = \{\sigma : \sigma_1{+}\sigma_2 = 2\} = \mathcal{R}_{AB} \cap \mathcal{R}_{BC}. \tag{56.99}$$

On the boundary, $\mathcal{O}_{ABC}$ restricts to $(A \cup B) \cup (B \cup C) = ABC$ and $\mathcal{O}_B$ to $(A \cup B) \cap (B \cup C) = B$, so $\partial\mathcal{O}_{ABC}$ is anchored on $\partial(ABC)$ and homologous to ABC, while $\partial\mathcal{O}_B$ is anchored on ∂B and homologous to B. It remains to check condition (ii): no face bounds both outputs. A face flips a single coordinate, so it lies between cells of the form $\{(0,\sigma_2),(1,\sigma_2)\}$ (flipping σ_1) or $\{(\sigma_1,0),(\sigma_1,1)\}$ (flipping σ_2). Take a σ_1-flip face between $(0,\sigma_2)$ and $(1,\sigma_2)$. Its two cells have $\sigma_1+\sigma_2$ equal to σ_2 and $1+\sigma_2$, which straddle the threshold "≥ 1" only when $\sigma_2 = 0$ (so it bounds $\mathcal{O}_{ABC}$) and straddle "$= 2$" only when $\sigma_2 = 1$ (so it bounds $\mathcal{O}_B$); the two cases are mutually exclusive. The same holds for σ_2-flips by symmetry. Hence every face bounds at most one output, condition (ii) holds, and Eq. (56.97) gives

$$S(ABC) + S(B) \leq S(AB) + S(BC). \tag{56.100}$$

This is Eq. (56.86). (Union and intersection are exactly the operations $\widetilde{\gamma}_{ABC}$ and $\widetilde{\gamma}_B$ of Section 56.3.2: $\mathcal{O}_{ABC}$ is the union of the two homology disks under the crossing geodesics, $\mathcal{O}_B$ their lens-shaped overlap.) □

Physical Insight

Strong subadditivity is, for any quantum state, the statement that the geometry of correlations is consistent — that conditioning on more never increases information in a contradictory way. For holographic states the proof reveals *why* the consistency holds: the entropies are areas in a shared bulk space, and areas of regions in any metric space obey submodularity, $\mathrm{Area}(\partial(\mathcal{R}\cup\mathcal{R}')) + \mathrm{Area}(\partial(\mathcal{R}\cap\mathcal{R}')) \leq \mathrm{Area}(\partial\mathcal{R}) + \mathrm{Area}(\partial\mathcal{R}')$. SSA is submodularity of bulk area pulled back to the boundary. The non-trivial Lieb–Ruskai theorem and the elementary fact that overlapping regions share boundary are, in the holographic world, the same statement.

56.3.4 Monogamy of mutual information

We now turn to an inequality of a different character. Define, for three disjoint regions, the *tripartite information*

$$I_3(A:B:C) \;\equiv\; I(A:B) + I(A:C) - I(A:BC), \tag{56.101}$$

the failure of A's correlation with the union BC to be the sum of its correlations with B and with C separately. Expanding each mutual information by Eq. (55.23) and cancelling the repeated $S(A)$ terms,

$$\begin{aligned} I_3(A:B:C) = {} & \big[S(A)+S(B)-S(AB)\big] + \big[S(A)+S(C)-S(AC)\big] \\ & - \big[S(A)+S(BC)-S(ABC)\big] \end{aligned}$$

$$= S(A) + S(B) + S(C) - S(AB) - S(BC) - S(CA) + S(ABC). \tag{56.102}$$

The *monogamy of mutual information* (MMI) is the statement that this quantity is never positive for holographic states:

$$\boxed{\begin{aligned} &I_3(A:B:C) \le 0 \quad \Longleftrightarrow \\ &\qquad S(AB) + S(BC) + S(CA) \ge S(A) + S(B) + S(C) + S(ABC). \end{aligned}} \tag{56.103}$$

The name is apt: $I(A:BC) \ge I(A:B) + I(A:C)$ says that A's total correlation with BC *exceeds* the sum of its bilateral correlations, so correlation cannot be freely shared three ways — it is, like quantum entanglement, monogamous. The right-hand form of Eq. (56.103), manifestly symmetric in A, B, C, is the one we will prove.

The crucial point, and the reason this section exists, is that Eq. (56.103) is *false* for general quantum states. There is no analogue of the Lieb–Ruskai theorem behind it; one cannot derive it from the axioms of density matrices, because there are perfectly legal density matrices that violate it. We exhibit one below. MMI is a property holographic states possess and generic states lack. Yet the recutting machinery proves it for holographic states in essentially the same breath as SSA — the only change is that we now feed in three surfaces instead of two.

Theorem 56.11 (Holographic monogamy)**.** *For disjoint boundary regions A, B, C of a static holographic state in the classical-gravity regime, the Ryu–Takayanagi entropies satisfy Eq. (56.103).*

Proof. Apply Theorem 56.9 with the three inputs given by the true minimal surfaces of the *pairs*: $\mathcal{R}_1 = \mathcal{R}_{AB}$, $\mathcal{R}_2 = \mathcal{R}_{BC}$, $\mathcal{R}_3 = \mathcal{R}_{CA}$, with respective areas $4G_N\, S(AB)$, $4G_N\, S(BC)$, $4G_N\, S(CA)$. Cells carry labels $\sigma = (\sigma_1, \sigma_2, \sigma_3) \in \{0,1\}^3$ recording membership in $(\mathcal{R}_{AB}, \mathcal{R}_{BC}, \mathcal{R}_{CA})$. On the conformal boundary, a point of A lies in AB and CA but not BC; a point of B in AB and BC; a point of C in BC and CA; a point outside ABC in none. The boundary-anchored cells are therefore the four even-weight labels

$$A \leftrightarrow (1,0,1), \quad B \leftrightarrow (1,1,0), \quad C \leftrightarrow (0,1,1), \quad (\text{outside}) \leftrightarrow (0,0,0), \tag{56.104}$$

while the four odd-weight labels $(1,0,0), (0,1,0), (0,0,1), (1,1,1)$ correspond to purely interior cells, touching the boundary nowhere and free for us to assign. Define the four output regions

$$\begin{aligned} \mathcal{O}_A = \{(1,0,1)\}, \quad \mathcal{O}_B = \{(1,1,0)\}, \quad \mathcal{O}_C = \{(0,1,1)\}, \\ \mathcal{O}_{ABC} = \{\sigma : \sigma \neq (0,0,0)\} = \mathcal{R}_{AB} \cup \mathcal{R}_{BC} \cup \mathcal{R}_{CA}. \end{aligned} \tag{56.105}$$

Their boundary anchors follow from Eq. (56.104): $\mathcal{O}_A$ restricts on the boundary to A (it is $\mathcal{R}_{AB} \cap \mathcal{R}_{CA} \setminus \mathcal{R}_{BC}$, whose boundary trace is $(A \cup B) \cap (C \cup A)$ minus $(B \cup C)$, i.e. A), likewise $\mathcal{O}_B \to B$, $\mathcal{O}_C \to C$, and $\mathcal{O}_{ABC} \to ABC$. Each is a legal homology region for the labelled boundary region, so $\partial\mathcal{O}_A, \ldots, \partial\mathcal{O}_{ABC}$ are trial surfaces for A, B, C, ABC.

We verify condition (ii): every face bounds at most one output. The key geometric fact is that the four boundary-anchored cells Eq. (56.104) all have *even* weight $\sigma_1 + \sigma_2 + \sigma_3 \in \{0, 2\}$, and a face flips a single coordinate, hence connects an even-weight cell to an odd-weight cell. So every face has one even-weight flank (forced to be one of A, B, C, outside) and one odd-weight flank (a free interior cell). Assign *all four interior cells to $\mathcal{O}_{ABC}$ and to no $\mathcal{O}_X$ with X a single region* — this is consistent with Eq. (56.105), since the singletons $\mathcal{O}_A, \mathcal{O}_B, \mathcal{O}_C$ contain only even-weight cells while $\mathcal{O}_{ABC}$ contains every non-zero label including the four odd ones. Now classify a face by its even flank:

- even flank $(0, 0, 0)$ (outside): inside no singleton and not in $\mathcal{O}_{ABC}$; its odd neighbour is in $\mathcal{O}_{ABC}$ only. The face bounds $\mathcal{O}_{ABC}$ alone.
- even flank $(1, 0, 1) = A$: in $\mathcal{O}_A$ and in $\mathcal{O}_{ABC}$; its odd neighbour is in $\mathcal{O}_{ABC}$ but not $\mathcal{O}_A$. Across this face $\mathcal{O}_{ABC}$ does *not* change (both flanks belong to it), while $\mathcal{O}_A$ does. The face bounds $\mathcal{O}_A$ alone.
- even flank $(1, 1, 0) = B$: by the same reasoning, bounds $\mathcal{O}_B$ alone.
- even flank $(0, 1, 1) = C$: bounds $\mathcal{O}_C$ alone.

In every case the face bounds exactly one output, so condition (ii) holds. (The decisive cancellation is in the second through fourth cases: because the interior cells were placed inside $\mathcal{O}_{ABC}$, the large surface $\partial\mathcal{O}_{ABC}$ runs only along faces touching the outside cell, and never competes with the small surfaces $\partial\mathcal{O}_A, \partial\mathcal{O}_B, \partial\mathcal{O}_C$ for the same face.) The master inequality Eq. (56.97) then reads

$$S(A) + S(B) + S(C) + S(ABC) \;\le\; S(AB) + S(BC) + S(CA), \tag{56.106}$$

which is exactly Eq. (56.103). □

Two features of this proof deserve emphasis, because they pinpoint exactly where the holographic structure is essential and therefore why MMI can fail without it.

First, *the existence of a common bulk.* The entire argument lives in the single slice Σ, where all the homology regions are subsets of one space and can be intersected, unioned, and decomposed into cells. The entropies $S(AB), S(BC), \ldots$ are not abstract numbers attached to a quantum state; they are areas of surfaces in one shared geometry, and Boolean algebra on subsets of that geometry is what generates the inequality. A generic quantum state has no such bulk. Its

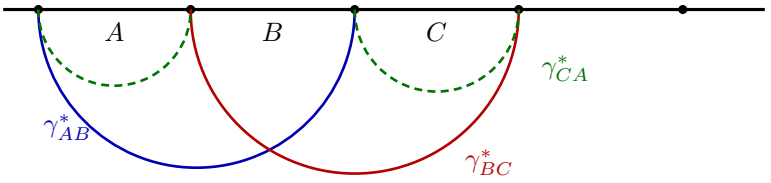

Figure 56.5: Monogamy of mutual information for three intervals $A = [y_0, y_1]$, $B = [y_1, y_2]$, $C = [y_2, y_3]$ in AdS_3. The three pairwise minimal surfaces γ^*_{AB} (blue), γ^*_{BC} (red), γ^*_{CA} (green dashed; here $CA = A \cup C$ is disjoint, so its minimal surface is the pair of geodesics over A and over C) bound homology regions whose Boolean combinations Eq. (56.105) reassemble, with no doubled faces, into trial surfaces for A, B, C and ABC. The recutting of Theorem 56.9 conserves total area, and minimality of the four true surfaces yields $S(AB) + S(BC) + S(CA) \geq S(A) + S(B) + S(C) + S(ABC)$.

entropies are just seven numbers $\{S(A), \ldots, S(ABC)\}$ constrained only by the universal inequalities (subadditivity, Araki–Lieb, strong subadditivity); nothing forces them to be jointly realizable as areas, and when they are not, Eq. (56.103) can be violated.

Second, *minimality plus the even-weight structure.* The proof of condition (ii) hinged on the boundary-anchored cells all having even weight, which let us hide the four interior cells inside $\mathcal{O}_{ABC}$ and decouple the large surface from the three small ones. This is a genuine feature of the geometry: the homology regions of three pairwise surfaces, sitting in a $(d-1)$-dimensional spatial slice, intersect in the pattern Eq. (56.104). In one boundary dimension fewer — if the "bulk" were itself only the boundary, with no extra dimension to bend the surfaces into — the cells would degenerate and the recutting would have nowhere to send the interior pieces. The extra holographic dimension is what supplies the room for the construction. We will see the same dimension reappear, from the other side, when the entanglement wedge is defined in Section 56.6.

Worked Example 56.12 (A non-holographic state that violates MMI: four-party GHZ)**.** To see that Eq. (56.103) is a real restriction and not a tautology, we compute I_3 for a state that any quantum-mechanics course allows. Let the global Hilbert space be four qubits and take the Greenberger–Horne–Zeilinger state

$$|\mathrm{GHZ}\rangle = \frac{1}{\sqrt{2}}(|0000\rangle + |1111\rangle), \tag{56.107}$$

identifying three of the qubits with the regions A, B, C and the fourth with the purifying complement (the analogue of the rest of the boundary). The reduced density matrix on any proper subset of the qubits is obtained by tracing out the others. Tracing out even a single qubit destroys the coherence between $|0\cdots0\rangle$ and $|1\cdots1\rangle$, because they differ in that qubit; hence for *any* subset X with

$1 \le |X| \le 3$ qubits,

$$\rho_X = \tfrac{1}{2}(|0\cdots0\rangle\langle 0\cdots0| + |1\cdots1\rangle\langle 1\cdots1|), \qquad S(X) = \ln 2. \tag{56.108}$$

So every one-, two-, and three-party entropy equals $\ln 2$. Substituting into Eq. (56.102),

$$\begin{aligned} I_3(A:B:C) &= \underbrace{S(A)+S(B)+S(C)}_{3\ln 2} \underbrace{-S(AB)-S(BC)-S(CA)}_{-3\ln 2} + \underbrace{S(ABC)}_{\ln 2} \\ &= (3-3+1)\ln 2 = \ln 2 > 0. \end{aligned} \tag{56.109}$$

The tripartite information is strictly *positive*: GHZ entanglement is shared genuinely three ways, in flat violation of Eq. (56.103). By Theorem 56.11 this state cannot be the boundary entanglement structure of three regions in a classical holographic geometry. The physical reading is sharp: holographic entanglement is overwhelmingly *bipartite*. The maximally tripartite GHZ pattern, in which no two parties are correlated without the third, has no smooth geometric dual; the bulk knows only how to weave pairwise entanglement into geometry. This single number, $I_3 = +\ln 2$, is a certificate that $|\mathrm{GHZ}\rangle$ lives outside the holographic corner of Hilbert space.

56.3.5 The holographic entropy cone

Stand back from the two proofs. For a fixed number of regions n, a quantum state assigns an entropy to each of the $2^n - 1$ non-empty subsets, producing an *entropy vector* $\vec{S} = (S(A), S(B), \dots, S(ABC), \dots) \in \mathbb{R}^{2^n-1}$. The set of entropy vectors realizable by *some* quantum state is a convex cone (closure under scaling by replication of the state and under addition by tensoring), the *quantum entropy cone*; it is cut out by subadditivity, the Araki–Lieb triangle inequality, and strong subadditivity, together with whatever further inequalities quantum mechanics imposes. The set realizable by *holographic* states — those with a classical geometric dual obeying Eq. (56.4) — is a smaller convex cone sitting inside it, the *holographic entropy cone*. Our two theorems are statements about this nesting: SSA is a facet of the big cone that the small one inherits, while MMI is a new facet that appears only on the small cone, slicing off the region (containing the GHZ vector of Theorem 56.12) where quantum mechanics is happy but geometry is not.

Theorem 56.13 (Holographic entropy cone, structural statement)**.** *The entropy vectors of static classical-geometry holographic states (in the RT approximation) form a polyhedral cone in $\mathbb{R}^{2^n-1}$, defined by finitely many linear inequalities with integer coefficients. For $n \le 3$ regions the defining inequalities are subadditivity, Araki–Lieb, strong subadditivity, and monogamy of mutual information. For larger n further independent inequalities appear; the complete list is known for $n \le 5$ regions, and partial results exist beyond.*

We have proved the two inequalities that distinguish the holographic cone from the quantum cone at the three-party level; the proof that the holographic region is *polyhedral* (finitely many facets) and the determination of its facets for $n = 4, 5$ are carried out by extending the recutting argument of Theorem 56.9 to more elaborate Boolean designs, together with a complementary construction realizing each facet by an explicit geometry. We state Theorem 56.13 as the organizing result and do not reproduce the full $n = 5$ facet enumeration, which is a finite but large computation; the references in the further reading carry it out. What matters for us is the conceptual content, which the two proofs already establish in full and which we now record.

Physical Insight

The lesson of this section is that *holographic states are special*. Strong subadditivity holds for every state in the universe; monogamy of mutual information does not, and yet every classical-geometry holographic state obeys it. The space of states dual to smooth bulk geometry is therefore a proper, geometrically carved subset of the CFT Hilbert space, bounded by the facets of the holographic entropy cone. A state that violates MMI — a GHZ-like state, a generic random state, a CFT state with too much genuinely multipartite entanglement — cannot be described by a classical bulk geometry at all; if it has a bulk dual, that dual is intrinsically quantum, with no sharp metric. This is the first precise sense in which "not every state is geometric," and it reframes the central question of holography. Ryu–Takayanagi is not merely consistent with quantum mechanics; it is *sharper* than quantum mechanics, encoding extra structure that marks out which states can be spacetime. The natural next demand is to understand where that extra structure comes from — to stop postulating Eq. (56.4) and derive it.

Caution

The inequalities of this section are proved for *static* states, where RT entropy is the area of a minimal surface on a fixed slice and the homology regions are honest subsets of one Riemannian manifold. In genuinely time-dependent states the relevant surfaces are the extremal (Hubeny–Rangamani–Takayanagi) surfaces of Section 56.5.2, which need not lie on any common slice, and the recutting lemma does not apply verbatim: monogamy in particular requires a separate argument (it does still hold, by the maximin reformulation of extremal surfaces, but that proof is genuinely harder and is not the cut-and-paste above). Strong subadditivity also survives in the covariant setting. We have given the cleanest proofs, which are the static ones; the covariant extensions are flagged here and discussed

where the covariant prescription is developed.

We have shown that RT geometry does not merely reproduce known entanglement entropies but *predicts* relations among them — strong subadditivity for free, and monogamy of mutual information as a genuinely new constraint that confines holographic states to a special corner of Hilbert space. That a postulated geometric rule should automatically satisfy a deep operator inequality, and impose a true one beyond it, is strong structural evidence that the rule is not an approximation guessed by analogy but a theorem waiting to be proved. The next section discharges exactly this debt: it derives the Ryu–Takayanagi formula from the bulk gravitational path integral by the replica method, identifying the minimal surface as the fixed-point locus of the replica symmetry and the homology constraint as a regularity condition, and so converts the proposal we have been testing into a theorem.

56.4 Deriving Ryu–Takayanagi: the bulk replica trick

Everything up to this point has treated the Ryu–Takayanagi formula Eq. (56.4) as a proposal: stated precisely, validated against the one entanglement entropy we already knew exactly, turned into a calculational engine, and shown to imply — from pure geometry — entropy inequalities that are painful to extract from field theory directly. A proposal that passes this many tests is more than a guess, but it is still a guess. It was written down by analogy to the black-hole area law and confirmed by its consequences; it was not derived from the defining statement of the duality. We now owe the reader that derivation. The goal of this section is to promote Theorem 56.3 from a checked conjecture to a theorem, by computing the entanglement entropy of a holographic state from first principles — the replica trick of Chapter 55 applied not to the boundary field theory but to the bulk gravitational path integral — and watching the area of a bulk surface emerge on its own, with the homology constraint appearing as nothing more exotic than the demand that a bulk geometry be smooth.

The strategy is the one Lewkowycz and Maldacena introduced in 2013, and it is beautifully economical. The replica trick computes $\operatorname{Tr}\rho_A^n = Z_n/Z_1^n$, where Z_n is the partition function on an n-sheeted branched cover of the boundary spacetime (Theorem 55.17). For a holographic theory each Z_n is computed by a bulk gravitational saddle through the GKP–Witten relation (Eqs. (53.162) and (53.163)). So the entire replica computation can be done upstairs, in the bulk, where it is classical geometry. The branched cover carries a cyclic replica symmetry; assuming the dominant bulk filling respects it, we may quotient by that symmetry and study a single bulk geometry with one boundary copy and a conical defect along a codimension-two surface. The $n \to 1$ limit that defines the von Neumann entropy then localizes the entire computation onto that

surface, returning precisely its area over $4G_N$. Carrying this out — with the conical-deficit action computed honestly, the factor of $4G_N$ pinned down, and the extremality and homology of the surface derived rather than assumed — is the business of this section.

56.4.1 The replica trick in the bulk

We begin by recalling the boundary side of the replica construction and translating it into the bulk. Fix a spatial region A in the boundary CFT_d and let ρ_A be the reduced density matrix of the state on A. The von Neumann entropy $S(A) = -\operatorname{Tr}(\rho_A \ln \rho_A)$ is recovered from the integer moments $\operatorname{Tr}\rho_A^n$ by the replica master formula (Theorem 55.17): one writes $\operatorname{Tr}\rho_A^n = Z_n/Z_1^n$, where Z_n is the Euclidean partition function of the theory on the n-fold branched cover $\mathcal{M}_n$ — n copies of the Euclidean boundary geometry, cut open along A and glued cyclically across the cut, sheet k joined to sheet $k+1$ and sheet n back to sheet 1 — and Z_1 is the partition function on the original space. The entropy is then the analytic continuation

$$S(A) = -\partial_n \left(\ln Z_n - n \ln Z_1 \right) \Big|_{n=1} , \tag{56.110}$$

which is Eq. (55.52). It will be convenient to package this in a slightly different but equivalent form. Define the *modular entropy*

$$\tilde{S}_n \;\equiv\; -n^2\, \partial_n \left[\frac{1}{n} \ln \frac{Z_n}{Z_1^n} \right] , \tag{56.111}$$

a quantity built so that its $n \to 1$ value is exactly the von Neumann entropy. To see this, set $g(n) \equiv \ln(Z_n/Z_1^n) = \ln Z_n - n \ln Z_1 = \ln \operatorname{Tr}\rho_A^n$, which vanishes at $n = 1$ because $\operatorname{Tr}\rho_A = 1$. Then $\frac{1}{n} g$ has derivative $\partial_n(g/n) = -g/n^2 + g'/n$, so $-n^2 \partial_n(g/n) = g - n g'$, and at $n = 1$,

$$\tilde{S}_1 = g(1) - g'(1) = 0 - \partial_n \ln \operatorname{Tr}\rho_A^n \big|_{n=1} = -\operatorname{Tr}(\rho_A \ln \rho_A) = S(A). \tag{56.112}$$

The modular entropy is the natural object for the bulk computation because the combination $\frac{1}{n}\ln(Z_n/Z_1^n)$ is, as we are about to see, minus the gravitational action *per replica* — the action of a single fundamental domain of the symmetric bulk geometry. Reading Eqs. (56.111) and (56.112) backwards, the entanglement entropy is

$$S(A) = -\,\partial_n \left[\frac{1}{n} \ln \frac{Z_n}{Z_1^n} \right] \Bigg|_{n=1} , \tag{56.113}$$

since the prefactor n^2 in Eq. (56.111) is unity at $n = 1$. This is the formula we will evaluate in the bulk.

Now the bulk. For a holographic CFT in the classical-gravity regime — large central charge, large 't Hooft coupling, so that the genus-zero bulk saddle

dominates the gravitational path integral (Section 53.1) — the GKP–Witten relation Eq. (53.162) together with its classical limit Eq. (53.163) computes each partition function as the on-shell gravitational action of the dominant smooth bulk solution whose conformal boundary is the prescribed boundary geometry:

$$Z_n \;=\; Z_{\mathrm{grav}}[\mathcal{M}_n] \;\approx\; e^{-I[\mathcal{B}_n]}, \tag{56.114}$$

where $\mathcal{B}_n$ is the dominant *smooth* Euclidean solution of the bulk equations of motion with $\partial\mathcal{B}_n = \mathcal{M}_n$, and $I[\mathcal{B}_n]$ is the renormalized gravitational action evaluated on it. The bulk action is Einstein–Hilbert with negative cosmological constant, the Gibbons–Hawking boundary term at the conformal boundary, and the holographic counterterms that render it finite (Theorem 54.5); in the mostly-minus conventions of this book, after Wick rotation to the Euclidean section (Eq. (53.161)),

$$I[\mathcal{B}] = -\frac{1}{16\pi G_N}\int_{\mathcal{B}} \mathrm{d}^{d+1}x\,\sqrt{g}\,(R-2\Lambda) - \frac{1}{8\pi G_N}\int_{\partial\mathcal{B}} \mathrm{d}^{d}x\,\sqrt{h}\,K + I_{\mathrm{ct}}, \qquad \Lambda = -\frac{d(d-1)}{2L^2}. \tag{56.115}$$

The decisive structural point, which is the whole reason the bulk replica trick is tractable, is that $\mathcal{B}_n$ is genuinely *smooth*: it caps off in the interior with no conical singularity, no boundary, and no curvature delta-functions. The branch points of $\mathcal{M}_n$ sit on the boundary, at ∂A; the bulk solution fills them in smoothly. This is the holographic version of the statement that gluing n copies of a Euclidean field theory across a cut produces a perfectly ordinary manifold. We record the package as the first half of the central theorem.

Theorem 56.14 (Lewkowycz–Maldacena: the bulk replica)**.** *Let A be a region in a holographic CFT_d in a state with a classical bulk dual, and let $\mathcal{M}_n$ be the n-fold replica branched cover of the boundary Euclidean geometry. In the classical-gravity regime the replica partition function is computed by the on-shell gravitational action Eq. (56.114) of the dominant smooth bulk solution $\mathcal{B}_n$ filling $\mathcal{M}_n$. If $\mathcal{B}_n$ preserves the $\mathbb{Z}_n$ replica symmetry of $\mathcal{M}_n$, then the entanglement entropy Eq. (56.113) equals*

$$S(A) = \frac{\mathrm{Area}(\gamma^*)}{4G_N}, \tag{56.116}$$

where γ^* is the bulk codimension-two surface left fixed by the replica symmetry, which is anchored on ∂A, homologous to A, and of extremal — in fact minimal — area. The remainder of this section proves the second sentence: it identifies γ^* with the fixed-point locus of the replica symmetry, shows that smoothness of $\mathcal{B}_n$ forces γ^* to be extremal and homologous to A, and computes the coefficient $1/4G_N$ from the conical-defect action.

Remark 56.15. The hypothesis that the dominant $\mathcal{B}_n$ preserves the replica symmetry is an assumption, and we flag it as such. It is the bulk avatar of the

statement that the boundary replica computation has no spontaneous breaking of the cyclic symmetry among sheets, and it can fail: when it does, the symmetric saddle is subdominant and the entropy is computed by a different, replica-symmetry-breaking geometry. Such configurations are exactly what produce the entanglement phase transitions and, ultimately, the islands of Chapter 57. For the derivation of the basic RT formula we assume the symmetric saddle dominates; this is correct whenever the minimal surface is unique and the state is close to the vacuum, and it is the generic situation away from phase-transition loci.

56.4.2 Replica symmetry and the conical quotient

The branched cover $\mathcal{M}_n$ has a manifest symmetry: cyclic permutation of the n sheets, $k \mapsto k+1 \pmod n$. This $\mathbb{Z}_n$ acts freely away from the branch locus ∂A, where all sheets meet and the action has fixed points. Granting the hypothesis of Theorem 56.14, the dominant bulk filling $\mathcal{B}_n$ inherits this $\mathbb{Z}_n$ as an isometry. Because the symmetry acts freely on the boundary away from ∂A, its only bulk fixed points form a codimension-two surface $\tilde{\gamma}_n$ in the interior — the bulk continuation of the boundary branch locus. We now pass to the quotient

$$\hat{\mathcal{B}}_n \;\equiv\; \mathcal{B}_n/\mathbb{Z}_n. \tag{56.117}$$

Its conformal boundary is a single copy of the original boundary geometry, $\partial\hat{\mathcal{B}}_n = \mathcal{M}_1$, because the n boundary sheets are identified down to one. In the interior, the quotient is smooth everywhere except along the image γ_n of the fixed-point locus, where it develops a conical defect. The reason is purely local and is the geometric heart of the whole argument.

Near the fixed-point surface the smooth cover $\mathcal{B}_n$ looks, in the two transverse directions, like an ordinary flat plane: in polar coordinates (ρ,τ) centred on $\tilde{\gamma}_n$, with ρ the proper transverse distance and τ the angle, the transverse metric is $\mathrm{d}\rho^2+\rho^2\mathrm{d}\tau^2$ with τ running over its full smooth range $\tau\in[0,2\pi)$. The replica symmetry rotates this transverse plane: the generator of $\mathbb{Z}_n$ acts as $\tau\mapsto\tau+2\pi/n$. Quotienting identifies $\tau\sim\tau+2\pi/n$, so on $\hat{\mathcal{B}}_n$ the transverse angle runs only over a range $2\pi/n$. Equivalently, rescaling to a 2π-periodic angular coordinate θ by $\tau=\theta/n$, the quotient transverse metric is

$$\mathrm{d}s_\perp^2 = \mathrm{d}\rho^2 + \frac{\rho^2}{n^2}\,\mathrm{d}\theta^2, \qquad \theta\in[0,2\pi), \tag{56.118}$$

a cone with total angle $2\pi/n$ at the tip and hence a *deficit angle*

$$\delta = 2\pi\Big(1-\tfrac{1}{n}\Big). \tag{56.119}$$

At $n=1$ there is no deficit and $\hat{\mathcal{B}}_1=\mathcal{B}_1$ is the original smooth bulk; as n grows the cone sharpens. We name this structure for later reference.

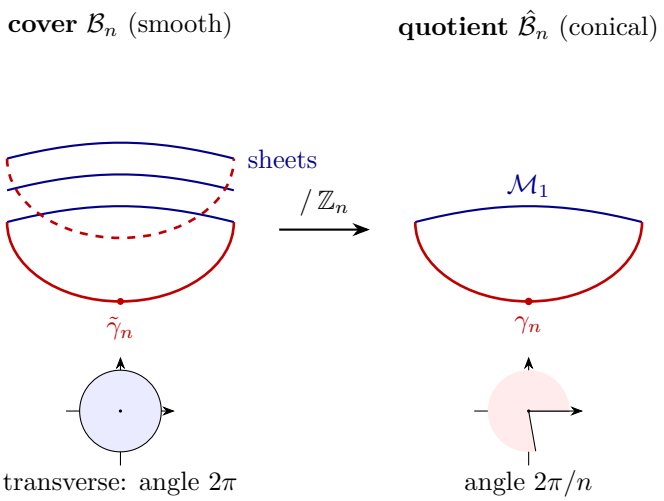

Figure 56.6: The bulk replica trick. Left: the smooth bulk solution $\mathcal{B}_n$ filling the n-sheeted boundary cover $\mathcal{M}_n$ (three sheets shown), capping off smoothly at the interior fixed-point surface $\tilde{\gamma}_n$; in the two directions transverse to $\tilde{\gamma}_n$ the geometry is a smooth plane of total angle 2π. Right: quotienting by the replica symmetry $\mathbb{Z}_n$ gives $\hat{\mathcal{B}}_n$, with a single boundary copy $\mathcal{M}_1$ and a conical defect of total transverse angle $2\pi/n$ — deficit angle $2\pi(1-1/n)$ — along the replica surface γ_n. The $n \to 1$ limit collapses the defect and leaves the Ryu–Takayanagi surface γ^*.

Definition 56.16 (The conical quotient and the replica surface)**.** The *conical quotient* is the bulk geometry $\hat{\mathcal{B}}_n = \mathcal{B}_n/\mathbb{Z}_n$ of Eq. (56.117): a smooth solution of the bulk equations of motion away from a codimension-two locus γ_n, with conformal boundary the original spacetime $\mathcal{M}_1$ and a conical defect of deficit angle Eq. (56.119) along γ_n. The locus γ_n — the image of the fixed-point set of the replica symmetry — is the *replica surface*. Its $n \to 1$ limit, $\gamma^* \equiv \gamma_1$, is the surface that Theorem 56.14 identifies with the Ryu–Takayanagi surface.

Figure 56.6 collects the construction. Two consequences of the smoothness of the *cover* are worth isolating immediately, because they are exactly the two features of Eq. (56.4) that looked like extra postulates.

First, the homology constraint is automatic. For $\mathcal{B}_n$ to be a smooth manifold whose only fixed-point set under $\mathbb{Z}_n$ is $\tilde{\gamma}_n$, the replica circle — the orbit of the $\mathbb{Z}_n$ action, which on the boundary is the angular direction around ∂A — must shrink to zero size precisely at $\tilde{\gamma}_n$ and nowhere else, capping off the geometry there like the origin of polar coordinates. Downstairs, this says that γ_n together with the boundary region A bounds a bulk region: the region swept out as the replica circle contracts from the boundary to the tip is exactly the homology region $\mathcal{R}_A$ of Theorem 56.2, with $\partial\mathcal{R}_A = A \cup \gamma_n$. A surface not homologous to

A would correspond to a replica circle that fails to close off smoothly — either leaving an uncapped non-contractible cycle or forcing a second conical locus — and the corresponding bulk geometry would not be a smooth filling of $\mathcal{M}_n$, hence would not contribute to Z_n. Homology is the condition that the cover cap off smoothly, no more and no less.

Second, the surface is anchored on ∂A. The fixed-point set $\tilde{\gamma}_n$ continues the boundary branch locus ∂A into the bulk; as one approaches the conformal boundary the replica circle becomes the boundary angular coordinate around ∂A, so γ_n meets the boundary exactly at ∂A, $\partial\gamma_n = \partial A$, which is the anchoring Eq. (56.1) of Theorem 56.1.

What remains is to extract the entropy: to evaluate Eq. (56.113) on the conical quotient and read off the area, and to show that smoothness pins the *location* of γ_n to an extremal surface.

56.4.3 The on-shell action of the conical defect

The action of the smooth cover is, by locality of the gravitational Lagrangian, exactly n times the action of one fundamental domain of the $\mathbb{Z}_n$ action. A fundamental domain is a wedge of angular width 2π in the transverse plane, and its action is precisely the action of the quotient $\hat{\mathcal{B}}_n$ computed by integrating the smooth bulk Lagrangian over the geometry away from the tip — with *no* conical contribution added at γ_n, since on the cover that locus is an ordinary smooth point. Denote this "per-replica" action by

$$\hat{I}_n \;\equiv\; \frac{1}{n}\, I[\mathcal{B}_n] \;=\; -\frac{1}{16\pi G_N}\int_{\hat{\mathcal{B}}_n}\sqrt{g}\,(R-2\Lambda) - \frac{1}{8\pi G_N}\int_{\partial_{\mathrm{AdS}}}\sqrt{h}\,K + I_{\mathrm{ct}}, \tag{56.120}$$

the integral running over $\hat{\mathcal{B}}_n$ with the tip $\rho = 0$ included as an ordinary interior point (the cover is smooth there, so the curvature is bounded and the tip is a set of measure zero). Combining $\ln Z_n = -I[\mathcal{B}_n] = -n\hat{I}_n$ with Eq. (56.113),

$$\frac{1}{n}\ln\frac{Z_n}{Z_1^n} = \frac{1}{n}\ln Z_n - \ln Z_1 = -\hat{I}_n + \hat{I}_1, \qquad \Longrightarrow \qquad S(A) = \partial_n \hat{I}_n\big|_{n=1}. \tag{56.121}$$

The entanglement entropy is the rate of change of the per-replica gravitational action with the replica number, evaluated at $n = 1$. This is a clean, finite quantity: $\hat{I}_1$ is the ordinary free energy of the original spacetime, and its n-derivative isolates the contribution of the infinitesimal conical defect.

We now compute $\partial_n \hat{I}_n$. The key observation is that $\hat{\mathcal{B}}_n$, for every n, solves the bulk equations of motion away from the tip, with the *same* conformal boundary data $\mathcal{M}_1$ held fixed as n varies. Under an arbitrary variation of the bulk metric the action changes by a bulk term proportional to the equations of motion plus boundary terms. As n varies, the bulk metric of $\hat{\mathcal{B}}_n$ varies, but the bulk equations of motion hold throughout, so that contribution vanishes; the boundary term at

the conformal boundary vanishes too, because the boundary data is fixed and the counterterms make the variational principle well posed there (Theorem 54.5). The only surviving piece is a boundary term on an infinitesimal tube around the tip, where the conical deficit lives and where the geometry's explicit n-dependence is concentrated. We compute that tube term directly.

Worked Example 56.17 (The conical-defect action and the factor of $4G_N$)**.** We isolate the tip contribution to $\partial_n \hat{I}_n$ by excising a tube of transverse radius ρ_0 around γ_n, computing the boundary term the variation deposits on it, and taking $\rho_0 \to 0$.

Geometry near the tip. Adopt coordinates (ρ, θ, y^i) near γ_n, with ρ the proper transverse radius, $\theta \in [0, 2\pi)$ the rescaled transverse angle, and y^i $(i = 1, \ldots, d-1)$ coordinates along γ_n with induced metric $\gamma_{ij}(y)$. To the order we need — and using the extremality established in Section 56.4.4, which kills the would-be cross terms linear in ρ — the metric is

$$\mathrm{d}s^2 = \mathrm{d}\rho^2 + b^2\rho^2\,\mathrm{d}\theta^2 + \gamma_{ij}(y)\,\mathrm{d}y^i\mathrm{d}y^j + O(\rho^2), \qquad b \equiv \frac{1}{n}, \tag{56.122}$$

so that $\sqrt{g} = b\,\rho\,\sqrt{\gamma}\,[1 + O(\rho^2)]$. Varying n at fixed coordinates varies only the angular component through b: $\delta b = -\,n^{-2}\,\delta n$.

The gravitational surface term. Varying the Einstein–Hilbert bulk integrand produces, after the standard double integration by parts, a total derivative $\partial_\mu(\sqrt{g}\,v^\mu)$ with $v^\mu = g^{\alpha\beta}\delta\Gamma^\mu_{\alpha\beta} - g^{\mu\beta}\delta\Gamma^\alpha_{\alpha\beta}$. On-shell in the bulk this is the entire variation; integrated over the region exterior to the tube it becomes a flux through the tube wall $\rho = \rho_0$,

$$\delta\hat{I}_n = -\frac{1}{16\pi G_N}\oint_{\rho=\rho_0} \mathrm{d}\theta\,\mathrm{d}^{d-1}y\,\sqrt{h}\;n_\mu v^\mu, \tag{56.123}$$

with $\sqrt{h} = b\rho_0\sqrt{\gamma}$ the induced measure on the wall and $n_\mu = -\,\delta^\rho_\mu$ the unit normal pointing out of the exterior region (towards the tip). The Christoffel symbols of Eq. (56.122) that respond to δb are governed by $\Gamma^\rho_{\theta\theta} = -b^2\rho$, whose variation is $\delta\Gamma^\rho_{\theta\theta} = -2b\rho\,\delta b$. Hence

$$v^\rho = g^{\theta\theta}\,\delta\Gamma^\rho_{\theta\theta} = \frac{1}{b^2\rho^2}\,(-2b\rho\,\delta b) = -\frac{2\,\delta b}{b\,\rho}, \tag{56.124}$$

the remaining contributions to v^ρ vanishing because $\Gamma^\alpha_{\alpha\rho} = \partial_\rho \ln\sqrt{g} = 1/\rho$ carries no b-dependence and the γ-direction Christoffels are ρ-independent at this order.

Assembling the tube term. Insert Eq. (56.124) and $n_\mu v^\mu = n_\rho v^\rho = (-1)\, v^\rho = +2\,\delta b/(b\rho_0)$ into Eq. (56.123):

$$\delta \hat{I}_n = -\frac{1}{16\pi G_N}\int_0^{2\pi} \mathrm{d}\theta \int \mathrm{d}^{d-1}y\, (b\rho_0\sqrt{\gamma})\, \frac{2\,\delta b}{b\,\rho_0} = -\frac{1}{16\pi G_N}\,(2\pi)\,(2\,\delta b)\,\mathrm{Area}(\gamma_n), \tag{56.125}$$

where $\mathrm{Area}(\gamma_n) = \int \mathrm{d}^{d-1}y\,\sqrt{\gamma}$ and the factors of b and ρ_0 cancel, so the limit $\rho_0 \to 0$ is finite and trivial. Simplifying,

$$\delta \hat{I}_n = -\frac{\mathrm{Area}(\gamma_n)}{4G_N}\,\delta b = +\frac{\mathrm{Area}(\gamma_n)}{4G_N}\,\frac{\delta n}{n^2}, \tag{56.126}$$

using $\delta b = -n^{-2}\delta n$. Therefore

$$\partial_n \hat{I}_n = \frac{\mathrm{Area}(\gamma_n)}{4G_N\, n^2}, \qquad \text{and in particular} \qquad \partial_n \hat{I}_n\big|_{n=1} = \frac{\mathrm{Area}(\gamma_1)}{4G_N}. \tag{56.127}$$

The coefficient $1/4G_N$ has emerged from nothing but the Einstein–Hilbert normalization $1/16\pi G_N$ and the geometry of a cone: the 4π from $2\pi \times 2$ in Eq. (56.125) converts $16\pi G_N$ into $4G_N$. No black-hole input was used; the same quarter-area-in-Planck-units that Theorem 54.10 attaches to a horizon is forced here by the gravitational action of an arbitrarily small conical defect.

Theorem 56.18 (Conical-defect action)**.** *The per-replica gravitational action Eq. (56.120) of the conical quotient satisfies* $\partial_n \hat{I}_n = \mathrm{Area}(\gamma_n)/4G_N n^2$*, where* γ_n *is the replica surface. Consequently, by Eq. (56.121),*

$$S(A) = \partial_n \hat{I}_n\big|_{n=1} = \frac{\mathrm{Area}(\gamma_1)}{4G_N} = \frac{\mathrm{Area}(\gamma^*)}{4G_N}. \tag{56.128}$$

Physical Insight

The same computation has a one-line repackaging that has become the standard modern language (Dong). A codimension-two object of tension μ sources, through Einstein's equations, a conical deficit $\delta = 8\pi G_N \mu$ along its worldvolume — this is the higher-dimensional cosmic string. Comparing with Eq. (56.119), the conical quotient $\hat{\mathcal{B}}_n$ is exactly the back-reacted geometry of a *cosmic brane* of tension

$$\mu_n = \frac{\delta}{8\pi G_N} = \frac{1}{4G_N}\Big(1 - \frac{1}{n}\Big), \tag{56.129}$$

whose Nambu–Goto action is $\mu_n\,\mathrm{Area}(\gamma_n)$. The brane's tension vanishes at $n = 1$ and grows with n, and its equation of motion — extremize the area in the back-reacted geometry — is what locates γ_n. Differentiating the on-shell action with respect to n, only the explicit tension factor survives the equations of motion, giving $\partial_n \hat{I}_n = (\partial_n \mu_n)\,\mathrm{Area}(\gamma_n) = \mathrm{Area}(\gamma_n)/4G_N n^2$,

in agreement with Eq. (56.127). The brane is a fiction at integer n — there is no brane in the smooth cover — but it is the cleanest bookkeeping device for the conical geometry, and it makes the analytic continuation in n transparent: the modular entropy $\tilde{S}_n = \mathrm{Area}(\gamma_n)/4G_N$ is the area of the brane held in place by tension μ_n, and the von Neumann entropy is its zero-tension limit.

56.4.4 Extremality and the homology constraint

Two threads remain to be tied. We used in Theorem 56.17 that the near-tip metric Eq. (56.122) has no cross terms linear in ρ; that absence is the statement that γ^* is an extremal surface, and we now derive it. And we must establish that the analytic continuation in n that produces Eq. (56.128) is legitimate — that the location of γ_n varies smoothly to a well-defined γ^* — and that the dominant saddle selects the minimal such surface.

Smoothness of the cover forces extremality. Write the most general bulk metric near the replica surface in the quotient, allowing the transverse cone to be fibred nontrivially over γ_n. In complex transverse coordinate $w = \rho\, e^{i\theta}$ (so the cone is $|w|^{2/n}$-type), the leading behaviour compatible with a codimension-two locus at $w = 0$ is

$$\mathrm{d}s^2 = \frac{1}{n^2}\, e^{2\Phi}\, \mathrm{d}w\, \mathrm{d}\bar{w} + \Big(\gamma_{ij} + 2K^{w}_{ij}\, w + 2K^{\bar{w}}_{ij}\, \bar{w} + \dots\Big)\mathrm{d}y^i \mathrm{d}y^j + (\text{cross terms}), \tag{56.130}$$

where K^{w}_{ij} and $K^{\bar{w}}_{ij}$ are the two components of the extrinsic curvature of γ_n, one for each transverse direction, and $\Phi \to$ const at the tip. The cover $\mathcal{B}_n$ is obtained by undoing the quotient, $w \to w^{1/n}$ up to the angular rescaling; concretely the cover sees the transverse coordinate $\tilde{w}$ with $w \sim \tilde{w}^{\,n}$, restoring the full 2π angle. For the cover to be a *smooth* solution of Einstein's equations — no curvature singularity beyond the (absent, on the cover) conical one — the components of the Einstein tensor must remain finite as $\tilde{w} \to 0$.

Track the most singular piece. The terms $K^{w}_{ij} w$ in Eq. (56.130), pulled back to the cover, scale as $\tilde{w}^{\,n}$, but their contribution to the curvature involves derivatives $\partial_{\tilde{w}}$ acting on the inverse metric and produces, at order $1/n$ in the deficit, a term in the $(\theta\theta)$ or trace Einstein equation that behaves as

$$G_{\theta\theta} \;\sim\; (n-1)\,\frac{K^i\,\cos\theta}{\rho} + \dots, \qquad K^i \equiv \gamma^{jk} K^i_{jk}, \tag{56.131}$$

a $1/\rho$ divergence proportional to the *trace* of the extrinsic curvature in each transverse direction. There is nothing in the smooth bulk stress tensor to source such a divergence: the right-hand side of Einstein's equations is the regular bulk

matter (or, in pure gravity, the cosmological constant), finite at the tip. The only way to satisfy the equations of motion as $\rho \to 0$ is to set the offending coefficient to zero,

$$K^i = 0 \qquad \text{(both transverse directions)}, \tag{56.132}$$

for every $n > 1$. This is precisely the condition that γ_n be an *extremal surface*: the trace of its extrinsic curvature vanishes, so it extremizes the area functional Eq. (56.2). Smoothness of the cover does not merely permit the surface to sit at an extremum of the area — it requires it. Taking $n \to 1$, the limiting surface γ^* is an extremal surface in the original bulk $\mathcal{B}_1$.

Theorem 56.19 (The replica surface is extremal)**.** *For the quotient $\hat{\mathcal{B}}_n$ to descend from a smooth bulk solution $\mathcal{B}_n$, the replica surface γ_n must have vanishing trace of extrinsic curvature, $K^i = 0$, in both directions transverse to it. Hence its $n \to 1$ limit γ^* is an extremal surface of the area functional, anchored on ∂A and homologous to A. The entanglement entropy Eq. (56.128) is the area of this extremal surface over $4G_N$.*

This is the link the heuristic of Section 56.1 promised but could not supply: extremizing the gravitational action over the bulk geometry is, at the location of the defect, identical to extremizing the area over the position of the surface. The area functional is not imposed by hand; it is the conical-defect part of the gravitational action, and stationarity of that action under moving the defect is stationarity of the area.

Minimality and the meaning of "min". Theorem 56.19 produces an extremal surface, but Eq. (56.4) asks for the *minimal* one. The selection is made by the path integral. The partition function Z_n is dominated by the saddle of least action, hence least $\hat{I}_n$; when several replica-symmetric fillings $\mathcal{B}_n$ exist, anchored on the same ∂A and homologous to A but with different replica surfaces, the dominant one carries the surface of least area, because by Eq. (56.120) a smaller area at given deficit means a smaller per-replica action. Continuing to $n = 1$, the entropy is the area of the least-area extremal surface. When two extremal surfaces exchange dominance as the region is deformed, the dominant saddle jumps, and the entropy develops the kink of an entanglement phase transition — the same "min" that we met for two intervals now seen as a competition of bulk gravitational saddles. In a static, time-reflection-symmetric state the extremal surface lies in the symmetric slice and "extremal of least area" is literally "minimal," recovering Theorem 56.3 verbatim.

Homology, once more, as regularity. We argued in Section 56.4.2 that homology to A is the condition for the cover to cap off smoothly. Theorem 56.19 sharpens the statement and explains why *no extra ingredient* — no additional brane, no boundary term at the tip beyond what we computed — is needed. The

replica surface is where the replica circle contracts; the bulk closes there exactly as the origin closes the disk, sourced by nothing. Were the dominant surface not homologous to A, the contracting replica circle would fail to bound the region $\mathcal{R}_A$, the geometry could not close without an additional conical locus, and the configuration would not be a smooth filling — it would not solve Eq. (56.114). The homology constraint of Theorem 56.2, which entered Theorem 56.3 as a postulate forced on us by the demand $S(A) = S(\bar{A})$ and by thermal states, is therefore a theorem of the derivation: the dominant bulk saddle is smooth, and smoothness is homology.

56.4.5 Ryu–Takayanagi as a generalized-entropy statement

Assembling Theorems 56.18 and 56.19: the bulk replica computation, continued to $n = 1$, returns

$$S(A) = \frac{\mathrm{Area}(\gamma^*)}{4G_N}, \qquad \gamma^* = \text{ minimal extremal surface anchored on } \partial A, \text{ homologous to } A, \tag{56.133}$$

which is exactly the Ryu–Takayanagi formula Eq. (56.4), now derived from the defining gravitational path integral rather than proposed. Every ingredient that looked like an independent assumption — the quarter, the area, the extremality, the homology, even the "min" — has been produced by a single demand: that Z_n be computed by a smooth dominant bulk saddle. This completes the proof of Theorem 56.14.

It is worth restating the result in the form that organizes the rest of the chapter and the next. The quantity $\mathrm{Area}(\gamma)/4G_N$ is the Bekenstein–Hawking entropy of Theorem 54.10, no longer attached to a causal horizon but to an arbitrary extremal surface. Writing the boundary entanglement entropy as

$$S(A) = \frac{\mathrm{Area}(\gamma^*)}{4G_N} \;\equiv\; S_{\mathrm{gen}}(\gamma^*), \qquad S_{\mathrm{gen}}(\gamma) = \frac{\mathrm{Area}(\gamma)}{4G_N} + S_{\mathrm{bulk}}(\gamma)\Big|_{S_{\mathrm{bulk}}\to 0}, \tag{56.134}$$

exhibits RT as the leading, purely geometric piece of a *generalized entropy* S_{gen} — the same combination of horizon area and exterior matter entropy that Bekenstein introduced to repair the second law in the presence of black holes. At the classical order of this section the bulk-field term S_{bulk} is subleading in G_N and drops, leaving pure area; restoring it is the content of the next section.

That the entanglement entropy is a Bekenstein–Hawking area is not a coincidence of language but a dynamical identity. Varying Eq. (56.133) under a change of the boundary state, the change in entanglement entropy equals the change in the area of the extremal surface, $\delta S(A) = \delta\mathrm{Area}(\gamma^*)/4G_N$ — and the right-hand side is governed by the first law of black-hole mechanics, $\delta M = \frac{\kappa}{8\pi G_N}\,\delta\mathrm{Area}$ (Chapter 54), with the surface gravity κ playing the role of a local temperature. The boundary statement $\delta S = \delta\langle H_{\mathrm{mod}}\rangle$ — the first law of entanglement, relating

the change in entropy to the change in the modular Hamiltonian of Theorem 55.25 — is thereby translated into a gravitational first law for the bulk surface. This equivalence, that an entanglement first law on the boundary *is* a thermodynamic first law for a bulk area, is the seed from which the closing section of this chapter will extract the linearized Einstein equations of the bulk: gravity emerges as the condition that the holographic entanglement entropy obey the laws it must.

Two extensions are now forced upon us, and we have set them up precisely. The derivation worked at leading order in G_N, dropping the bulk fields' own entanglement across γ^*; reinstating S_{bulk} in Eq. (56.134) promotes RT to the Faulkner–Lewkowycz–Maldacena formula and, upon extremizing the full generalized entropy rather than the bare area, to the quantum extremal surface prescription (Sections 56.5.1 and 56.5.3). And the derivation assumed a Euclidean, time-reflection-symmetric setup so that "extremal" could mean "minimal on a slice"; a genuinely time-dependent state has no such slice, and the replica surface becomes a Lorentzian extremal surface — the covariant Hubeny–Rangamani–Takayanagi prescription (Section 56.5.2). The next section develops both, unifying them in the single instruction to extremize the generalized entropy, the prescription that Chapter 57 will turn on black holes to compute the Page curve.

56.5 Quantum corrections, covariance, and the quantum extremal surface

The Lewkowycz–Maldacena derivation of Section 56.4 did more than promote the Ryu–Takayanagi rule from proposal to theorem. By computing $\operatorname{Tr}\rho_A^n$ as a bulk gravitational path integral and tracking the $n \to 1$ limit, it told us *exactly which approximation* the area law is, and what sits at the next order. The bulk path integral is a sum over geometries *and* bulk matter configurations, $Z_n = \int \mathcal{D}g\,\mathcal{D}\phi\; e^{-I[g,\phi]}$; the saddle-point evaluation that localized the gravitational action onto the area of a conical-defect surface was the leading term in an expansion in Newton's constant G_N. The matter fields living on that saddle were, at leading order, spectators carried along for the ride. They are not spectators at the next order. Restoring them turns the bare area law into the *generalized entropy* — the same combination, area-plus-matter-entropy, that Bekenstein and the black-hole thermodynamics of Chapter 54 forced upon us for horizons — and pursuing the logic of the gravitational path integral to its conclusion replaces the classical minimal surface by a surface that extremizes generalized entropy. This section carries out that pursuit. It adds the one-loop quantum correction (the Faulkner–Lewkowycz–Maldacena, or FLM, formula), makes the prescription covariant so it applies to genuinely time-dependent states (the Hubeny–Rangamani–Takayanagi, or HRT, prescription), and unifies both into a single all-orders rule built on a single object, the quantum extremal surface

of Engelhardt and Wall. That rule is the instrument Chapter 57 will turn on a black hole.

We continue to work in asymptotically AdS_{d+1} with a holographic CFT_d in the classical-gravity regime, with G_N small in units of the AdS radius L (equivalently large central charge / large N, Eq. (53.153)); the bulk Newton constant G_N and the radial cutoff identified with the QFT ultraviolet cutoff are exactly as fixed in Section 56.1.2. The metric is mostly-minus and units are natural throughout.

56.5.1 The one-loop correction: the FLM formula

Counting in powers of G_N

The classical area term in Eq. (56.4) is enormous. The area of a bulk surface is a geometric quantity of order L^{d-1}, so $\mathrm{Area}/4G_N \sim L^{d-1}/G_N$, which by the holographic dictionary (Theorem 53.27) scales as the central charge $C_T \sim N^2$. The entanglement entropy of a holographic CFT is therefore $O(N^2)$ at leading order — it counts the $O(N^2)$ fields of the boundary theory — and the RT formula captures this leading piece geometrically. The first correction is $O(N^0) = O(G_N^0)$ relative to nothing, i.e. smaller than the leading term by a factor $G_N/L^{d-1} \sim 1/N^2$. The question is what physical quantity supplies it.

The answer is already visible in the structure of the bulk path integral. Expanding around the dominant saddle (g_n, ϕ_n),

$$\ln Z_n = -I_{\mathrm{grav}}[g_n] + \ln Z_{\mathrm{matter}}[g_n] + \dots , \tag{56.135}$$

where I_{grav} is the on-shell gravitational action (including the Gibbons–Hawking term and counterterms) and $Z_{\mathrm{matter}}[g_n]$ is the partition function of the bulk quantum fields propagating on the fixed background g_n. The first term is $O(1/G_N)$; the second is $O(G_N^0)$, a one-loop determinant from the reader's point of view. The replica entropy is extracted by the same operation in both terms,

$$S(A) = (1 - n\,\partial_n) \ln Z_n \Big|_{n=1}, \tag{56.136}$$

which follows from $S = -\partial_n \ln \mathrm{Tr}\,\rho_A^n|_{n=1}$ with $\mathrm{Tr}\,\rho_A^n = Z_n/Z_1^n$ (Theorem 55.17). Lewkowycz–Maldacena showed that applied to $-I_{\mathrm{grav}}[g_n]$ this operation localizes onto the area of the fixed-point surface and returns $\mathrm{Area}(\gamma_A)/4G_N$ (Eq. (56.4)). The new content is what the same operation does to $\ln Z_{\mathrm{matter}}[g_n]$.

The matter term is a bulk entanglement entropy

Here is the key observation. The replica geometry g_n is, by construction, an n-fold branched cover of the original bulk, branched over the surface γ_A: it is built by cyclically gluing n copies of the bulk across the homology region $\mathcal{R}_A$,

with the gluing locus the surface γ_A. The bulk matter fields live on this n-fold cover. But computing a partition function on an n-fold cover branched over a codimension-two surface, and then applying $(1 - n\partial_n)|_{n=1}$, is *precisely the replica trick for the bulk fields' own entanglement entropy* across that surface — the very construction of Theorem 55.17, now run in the bulk instead of on the boundary. The surface γ_A partitions the bulk Cauchy slice Σ into the homology region $\mathcal{R}_A$ and its complement; the bulk fields have a reduced density matrix $\rho_{\mathcal{R}_A}^{\text{bulk}}$ on $\mathcal{R}_A$; and

$$(1 - n\,\partial_n) \ln Z_{\text{matter}}[g_n]\Big|_{n=1} = -\operatorname{Tr}(\rho_{\mathcal{R}_A}^{\text{bulk}} \ln \rho_{\mathcal{R}_A}^{\text{bulk}}) \equiv S_{\text{bulk}}(\mathcal{R}_A), \tag{56.137}$$

the von Neumann entropy (Eq. (55.6)) of the bulk quantum fields restricted to the homology region. There is one subtlety to be honest about: Eq. (56.137) treats g_n as a rigid, externally-prescribed background, whereas the true saddle has the matter backreacting on the geometry order by order in G_N. At the order we are working — the first correction beyond the classical area — the backreaction of the $O(G_N^0)$ matter on the $O(1/G_N)$ geometry is higher order, so evaluating the bulk entropy on the unperturbed classical saddle is consistent. We will see in Section 56.5.3 that the leading backreaction is exactly what re-extremization absorbs.

Combining the two terms gives the FLM formula.

Theorem 56.20 (Faulkner–Lewkowycz–Maldacena: one-loop quantum correction)**.** *In the setting of Theorem 56.3, the entanglement entropy of the boundary region A, computed to first subleading order in G_N (one loop in the bulk, $O(N^0)$ relative to the $O(N^2)$ leading term), is*

$$\boxed{S(A) = \frac{\langle \widehat{\text{Area}}(\gamma_A) \rangle}{4G_N} + S_{\text{bulk}}(\mathcal{R}_A) + \langle \Delta S_{\text{Wald}} \rangle + S_{\text{ct}}\ ,} \tag{56.138}$$

where γ_A is the classical RT surface of Eq. (56.4), $\mathcal{R}_A$ is the homology region it bounds (Theorem 56.2), $S_{\text{bulk}}(\mathcal{R}_A)$ is the von Neumann entropy Eq. (56.137) of the bulk quantum fields on $\mathcal{R}_A$, and $\langle \widehat{\text{Area}} \rangle$ is the expectation value of the area operator in the bulk state. The remaining terms $\langle \Delta S_{\text{Wald}} \rangle$ and S_{ct} are the subleading geometric corrections (Wald-like contributions from higher-curvature terms in the bulk effective action, and counterterms that absorb the ultraviolet divergence of S_{bulk} into a renormalization of G_N); they are subleading and bookkeeping, and we discuss them below. The leading two terms,

$$S(A) = \frac{\text{Area}(\gamma_A)}{4G_N} + S_{\text{bulk}}(\mathcal{R}_A) + O(G_N), \tag{56.139}$$

are the operational content of the formula.

Derivation. Insert Eq. (56.135) into the extraction Eq. (56.136). The gravitational piece is the Lewkowycz–Maldacena result of Section 56.4: $(1-n\partial_n)(-I_{\rm grav}[g_n])|_{n=1} = \mathrm{Area}(\gamma_A)/4G_N$, with γ_A the fixed-point surface, which the same argument shows is the classical extremal (minimal) surface. Promoting the classical area to the expectation value of the area operator $\widehat{\mathrm{Area}}$ accounts for the quantum fluctuations of the geometry itself — the graviton is one of the bulk fields, and its contribution to the area is naturally grouped with the leading term as $\langle\widehat{\mathrm{Area}}\rangle$ rather than Area. The matter piece is Eq. (56.137): applying $(1 - n\partial_n)|_{n=1}$ to $\ln Z_{\rm matter}$ on the branched cover is the bulk replica computation, yielding $S_{\rm bulk}(\mathcal{R}_A)$. Higher-curvature terms in the bulk effective action modify the localized contribution from a pure area to the Wald entropy functional (the same functional that corrects the black-hole area law in Chapter 54); their replica derivative supplies $\langle\Delta S_{\rm Wald}\rangle$. Finally, $S_{\rm bulk}(\mathcal{R}_A)$ carries its own ultraviolet divergence from bulk modes piling up at γ_A; this divergence is local on γ_A and proportional to its area, so it is absorbed into a renormalization of the coefficient $1/4G_N$ multiplying the area — exactly the statement that the matter loops renormalize Newton's constant. The renormalized G_N and the renormalized (finite) $S_{\rm bulk}$ are what appear in Eq. (56.138); the residual scheme-dependent piece is $S_{\rm ct}$. Dropping the $O(G_N)$ and bookkeeping terms leaves Eq. (56.139). □

Physical Insight

The FLM formula is the holographic image of a fact the reader already accepts from black-hole thermodynamics. Bekenstein's generalized second law (Chapter 54) insists that the entropy charged to a horizon is not the bare area $A/4G_N$ but the *generalized* entropy $S_{\rm gen} = A/4G_N + S_{\rm out}$, the area term plus the ordinary entropy of the matter outside. FLM says the same combination computes the entanglement entropy of a boundary region: the geometric "area" piece counts the $O(N^2)$ degrees of freedom that built the geometry, and the bulk field entropy $S_{\rm bulk}$ counts the $O(1)$ fluctuations propagating on it. The two are not independent corrections to a more fundamental quantity — their sum *is* the fundamental quantity, and the splitting into "geometry" and "matter" is an artifact of the $1/N$ expansion. This is why the renormalization of G_N by bulk matter loops is not a nuisance but a consistency check: the divergence of $S_{\rm bulk}$ has to be exactly an area, because the only place for it to go is into G_N.

The modular split and the JLMS sharpening

The derivation above is honest but operates at the level of partition functions. The structural reason the area gets the leading term and the bulk von Neumann entropy the subleading term can be stated more sharply, in a form that will be proved in the next section and which we flag here so the logic is complete. The

boundary modular Hamiltonian $K_A = -\ln \rho_A$ generates the modular flow of the region A (Theorem 55.25); its bulk dual is not a single bulk operator but a sum,

$$K_A \;=\; \frac{\widehat{\mathrm{Area}}(\gamma_A)}{4G_N} \;+\; K^{\mathrm{bulk}}_{\mathcal{R}_A} \;+\; \dots, \tag{56.140}$$

where $K^{\mathrm{bulk}}_{\mathcal{R}_A} = -\ln \rho^{\mathrm{bulk}}_{\mathcal{R}_A}$ is the *bulk* modular Hamiltonian of the fields on the homology region. This is the JLMS (Jafferis–Lewkowycz–Maldacena–Suh) relation. It is the rigorous backbone of FLM: taking the expectation value of Eq. (56.140) in the global state gives $\langle K_A\rangle = \langle\widehat{\mathrm{Area}}\rangle/4G_N + \langle K^{\mathrm{bulk}}\rangle$, and combining with the fact that the von Neumann entropy and the modular-Hamiltonian expectation value differ by a state-independent constant (so that variations of entropy equal variations of $\langle K\rangle$) reproduces Eq. (56.138) term by term — the area operator landing on the leading entropy and the bulk modular Hamiltonian on S_{bulk}. We derive Eq. (56.140) and exploit its consequence — the equality of bulk and boundary relative entropies, which yields bulk energy conditions — in Section 56.6 and Theorem 56.35. For the present section it is enough that the modular split Eq. (56.140) explains the term-by-term structure of Eq. (56.138): the operator that lives *on* the surface is the area, and the operator that lives in the *region* is the bulk modular Hamiltonian.

56.5.2 Covariance: the HRT prescription

Why "minimal" fails in time-dependent states

Everything so far has presumed a static state with a preferred constant-time slice on which "minimal area" is a well-posed Riemannian variational problem. Most states are not static: a CFT after a global quench, a collapsing star forming a black hole, two colliding shockwaves — these have no time-translation symmetry and no canonical slice. We need a prescription that does not depend on a choice of time.

The naive fix, "minimize the area over all spacelike surfaces in the Lorentzian spacetime," is empty. A spacelike codimension-two surface can always be deformed in a timelike direction to decrease its area, with no lower bound: tilting a surface element into the light cone shrinks its proper area, and one can tilt arbitrarily far. There is no minimal-area surface in Lorentzian signature. The cure is to extremize rather than minimize.

Definition 56.21 (Extremal surface and the HRT prescription)**.** A codimension-two spacelike surface γ_A in an asymptotically AdS_{d+1} spacetime, anchored on ∂A and homologous to A, is *extremal* if it is a stationary point of the area functional under all (spacelike and timelike) normal deformations. Equivalently, its trace of extrinsic curvature vanishes in both null directions normal to the surface,

$$\theta_{(+)} = \theta_{(-)} = 0, \tag{56.141}$$

where $\theta_{(\pm)} = h^{ab}\nabla_a n_b^{(\pm)}$ are the expansions of the two future-directed null congruences orthogonal to γ_A. The covariant Hubeny–Rangamani–Takayanagi prescription is

$$\boxed{S(A) = \min_{\gamma_A} \operatorname*{ext}_{\gamma_A\ \text{extremal}} \frac{\text{Area}(\gamma_A)}{4G_N}} \tag{56.142}$$

namely: among all extremal surfaces anchored on ∂A and homologous to A, take the one of least area (and, if more than one extremum is degenerate in area, the prescription resolves by the same least-area rule as RT).

The condition Eq. (56.141) is the Lorentzian replacement of $K = 0$. Writing the trace of extrinsic curvature along the two null normals as the two null expansions makes the geometry transparent and connects directly to the focusing arguments of Chapter 54: an extremal surface is one whose cross-sectional area is momentarily stationary along *both* orthogonal light sheets, the spacelike analogue of a bifurcation surface where ingoing and outgoing expansions both vanish. When a moment of time symmetry exists, the time-reflection symmetry forces $\theta_{(+)} = -\theta_{(-)}$ on the symmetric slice, so $\theta_{(\pm)} = 0$ reduces to the single condition $K = 0$ within the slice, and the HRT extremal surface coincides with the RT minimal surface. HRT contains RT.

The maximin reformulation

Extremality is the right local condition, but as a *global* prescription Eq. (56.142) has awkward features: a saddle of the area functional is harder to control than a minimum (existence, uniqueness, and the entropy inequalities are not manifest). Wall's maximin reformulation repairs this by trading the single Lorentzian extremization for a min over surfaces followed by a max over slices, each of which is a controlled problem.

Definition 56.22 (Maximin surface)**.** Let $D[A]$ be the boundary causal domain of A. For each achronal bulk Cauchy slice Σ of the bulk region bounded by $D[A]$ and its complement, let $\gamma_A(\Sigma)$ be the *minimal*-area surface on Σ anchored on ∂A and homologous to A — a well-posed Riemannian minimization on the fixed slice Σ. The *maximin surface* is the one obtained by then maximizing this minimal area over all slices,

$$\gamma_A^{\text{maximin}} = \arg\max_{\Sigma} \Big[\min_{\gamma \subset \Sigma} \text{Area}(\gamma) \Big], \tag{56.143}$$

and the maximin entropy is $\text{Area}(\gamma_A^{\text{maximin}})/4G_N$.

Theorem 56.23 (Maximin equals extremal)**.** *In a spacetime satisfying the null energy condition, the maximin surface of Eq. (56.143) exists, is spacelike, and is an extremal surface in the sense of Theorem 56.21; when several extremal surfaces compete, the maximin construction selects the least-area one. Hence the maximin prescription and the HRT prescription Eq. (56.142) agree.*

Idea of the proof. The content is local at the maximin surface, and the two optimizations pin the two null expansions. Fix the maximizing slice Σ_* and let γ be the minimal surface on it. *Minimality within* Σ_* is the statement that the area is stationary under deformations that stay in Σ_*, and that it is a genuine minimum (positive second variation) in those directions; the first-variation condition is that the trace of extrinsic curvature along the spatial normal within Σ_* vanishes. Decompose the two null normals as $n^{(\pm)} \propto u \pm s$, where u is the future timelike normal to Σ_* and s is the spacelike normal to γ within Σ_*. The spatial first-variation condition sets the combination $\theta_{(+)} + \theta_{(-)} \propto \theta_{(s)} = 0$: the expansion along s vanishes. The remaining combination $\theta_{(+)} - \theta_{(-)} \propto \theta_{(u)}$ is the rate of change of the area as the surface is pushed in the timelike direction u — that is, as the slice itself is tilted. *Maximality over slices* is precisely the statement that this rate vanishes: at the maximizing slice the area cannot be increased by deforming Σ, so $\theta_{(u)} = 0$. The two conditions together give $\theta_{(+)} = \theta_{(-)} = 0$, which is extremality Eq. (56.141). That the maximin surface is spacelike (not null or timelike) and that the max-over-slices is attained follow from the null energy condition through the focusing theorem of Chapter 54: focusing controls how the minimal area on a slice behaves as the slice is deformed, guaranteeing the maximization has an interior maximum rather than running off to a degenerate (null) configuration. The least-area selection among competing extrema is built into the outer "max" acting on areas that are themselves minima. The local extremality argument just given is the heart of the matter; we now make the construction complete — existence of both optimizers, spacelikeness, the representative-slice property, and the identification with the least-area extremal surface — carrying the focusing estimate explicitly, in Section 56.5.2. □

The maximin construction and its proof

The proof idea above pins the local geometry at the surface; what remains is to show that both optimizations are actually attained, that the surface they produce is spacelike rather than null, that it carries the *representative-slice* property the covariant entropy inequalities will use, and that it is exactly the least-area extremal surface of Theorem 56.21. We collect these into one theorem and prove it in full. The single physical input beyond Riemannian geometry is the null energy condition, and it enters through one inequality — the focusing (Raychaudhuri) estimate — which we display explicitly because it is doing all of the work. Throughout we assume the bulk is globally well behaved in the mild sense Wall isolated: it is AdS-*hyperbolic*, meaning it admits Cauchy slices for the bulk region W_A lying over the boundary causal domain $D[A]$, and the space of such achronal slices anchored on a fixed boundary cut is compact in the topology of uniform convergence. This is the covariant analogue of global hyperbolicity and holds for the physically relevant states (perturbations of the vacuum, collapsing and evaporating black holes, quenches); it is the structural

hypothesis that makes "maximize over slices" a well-posed problem rather than a formal manipulation.

Theorem 56.24 (Wall: existence and equivalence of the maximin surface)**.** *Let the bulk be* AdS*-hyperbolic and satisfy the null energy condition* $T_{ab}k^a k^b \geq 0$ *for all null* k^a*. Then the maximin surface* $\gamma_A^{\text{maximin}}$ *of Eq. (56.143) exists. It is a smooth spacelike codimension-two surface, anchored on* ∂A *and homologous to* A*. It is extremal in the sense of Eq. (56.141),* $\theta_{(+)} = \theta_{(-)} = 0$*. It has the* representative-slice property*: it is the minimal-area surface in its homology class on* every *bulk Cauchy slice of* W_A *that contains it. Among all extremal surfaces homologous to* A *it has the least area, so it coincides with the HRT surface of Eq. (56.142); and the entanglement wedge it bounds contains the causal wedge of* A*.*

Proof. Step 1: the inner minimization is well posed. Fix an achronal bulk Cauchy slice Σ of W_A. On Σ the induced metric is Riemannian, and we seek the least-area surface anchored on ∂A and homologous to A — that is, cobounding, together with A, a region $\mathcal{R} \subset \Sigma$. This is the standard Plateau problem in a homology class with fixed boundary. The area functional is bounded below by zero and lower semicontinuous; the homology constraint together with the anchoring on ∂A confines a minimizing sequence to a compact family (the homology region cannot escape to infinity without crossing the conformal boundary, which the anchoring forbids), so a minimizer $\gamma_A(\Sigma)$ exists and is smooth away from ∂A by elliptic regularity. Denote its area $\mathcal{A}(\Sigma) \equiv \text{Area}(\gamma_A(\Sigma))$. Because the minimizer is a stationary point of a Riemannian area functional, its in-slice mean curvature vanishes: writing s for the unit spacelike normal to $\gamma_A(\Sigma)$ within Σ, the first-variation condition is

$$\theta_{(s)} \;\equiv\; h^{ab}\nabla_a s_b \;=\; 0, \tag{56.144}$$

with h^{ab} the inverse induced metric on the surface, and the second variation in the in-slice directions is non-negative because the minimizer is a genuine minimum.

Step 2: the focusing estimate. The one geometric fact we need about how areas respond to motion off the slice is the Raychaudhuri equation for a null congruence. Let k^a be the affinely parametrized tangent (parameter λ) of one of the two null congruences fired orthogonally from a surface, with expansion $\theta = h^{ab}\nabla_a k_b$ and shear σ_{ab}. In $d+1$ bulk dimensions the cross-section is $(d-1)$-dimensional and

$$\frac{d\theta}{d\lambda} = -\frac{\theta^2}{d-1} - \sigma_{ab}\sigma^{ab} - R_{ab}k^a k^b. \tag{56.145}$$

Contracting the Einstein equation $R_{ab} - \tfrac{1}{2}Rg_{ab} + \Lambda g_{ab} = 8\pi G_N T_{ab}$ with the null vector k^a kills the $g_{ab}k^a k^b$ terms, so $R_{ab}k^a k^b = 8\pi G_N\, T_{ab}k^a k^b \geq 0$ by the null energy condition. Every term on the right of Eq. (56.145) is then manifestly non-positive,

$$\frac{d\theta}{d\lambda} \;\leq\; -R_{ab}k^a k^b \;\leq\; 0. \tag{56.146}$$

A null congruence that starts non-expanding ($\theta \leq 0$) cannot subsequently expand; one that starts at $\theta = 0$ has $\theta \leq 0$ to the future and $\theta \geq 0$ to the past. This is the entirety of the dynamical input.

Step 3: the outer maximization is attained, and the maximizer is interior. By AdS-hyperbolicity the space of anchored achronal slices is compact, and $\mathcal{A}(\Sigma)$ is continuous on it, so the supremum $\max_\Sigma \mathcal{A}(\Sigma)$ is achieved on some slice Σ_*; call its minimal surface $\gamma \equiv \gamma_A(\Sigma_*)$. We must rule out that the maximizer sits at a degenerate boundary of slice-space where γ goes null. Parametrize a one-parameter tilt of the slice by a future-pointing timelike normal field u, so that the surface is dragged along u. Because γ is already *minimal within* Σ_*, the envelope (Danskin) theorem says the derivative of $\mathcal{A}$ along the tilt picks up only the explicit normal motion, not the implicit re-minimization:

$$\left.\frac{d\mathcal{A}}{d\tau}\right|_{\Sigma_*} = \int_\gamma \sqrt{h}\,\theta_{(u)}, \qquad \theta_{(u)} \equiv h^{ab}\nabla_a u_b. \tag{56.147}$$

At a maximum this vanishes for all tilts u, forcing $\theta_{(u)} = 0$ pointwise on γ. For the second variation, differentiate Eq. (56.147) once more and use $\theta_{(u)} = 0$ at Σ_*:

$$\left.\frac{d^2\mathcal{A}}{d\tau^2}\right|_{\Sigma_*} = \int_\gamma \sqrt{h}\,\partial_u\theta_{(u)}. \tag{56.148}$$

Decompose the timelike normal into the two orthogonal null normals, $u \propto k_{(+)} + k_{(-)}$ with $k_{(\pm)}$ generating the two null congruences. Since both null expansions vanish at γ (this is established in Step 4, and the two steps close consistently), $\partial_u\theta_{(u)}$ is a sum of the Raychaudhuri derivatives $d\theta_{(\pm)}/d\lambda$ evaluated where $\theta_{(\pm)} = 0$, each of which is $\leq -R_{ab}k^a_{(\pm)}k^b_{(\pm)} \leq 0$ by Eq. (56.146). Hence $d^2\mathcal{A}/d\tau^2 \leq 0$: the area is concave under the tilt, the extremum in the slice direction is a genuine *maximum*, and it is interior. A degenerate null limit would instead make $\mathcal{A}$ run off monotonically with no interior maximum, which focusing has just excluded. Thus γ is spacelike and Σ_* is a true maximizing slice. The maximin construction is therefore a saddle of the Lorentzian area functional: a minimum within the slice (Step 1) and a maximum across slices (here), exactly the unstable-saddle character the Lorentzian extremization Eq. (56.142) demanded.

Step 4: extremality. Combine the two stationarity conditions. Within the slice, Eq. (56.144) gives the vanishing of the expansion along the spacelike normal s; across slices, Eq. (56.147) gives the vanishing of the expansion along the timelike normal u. In the null basis $k_{(\pm)} \propto u \pm s$, these two combinations are

$$\theta_{(s)} \;\propto\; \theta_{(+)} + \theta_{(-)} = 0, \qquad \theta_{(u)} \;\propto\; \theta_{(+)} - \theta_{(-)} = 0, \tag{56.149}$$

whose unique solution is $\theta_{(+)} = \theta_{(-)} = 0$. This is precisely extremality, Eq. (56.141): the maximin surface is an HRT extremal surface. (Step 3 used $\theta_{(\pm)} = 0$, derived here; the logic is not circular, since the maximum condition

$\theta_{(u)} = 0$ of Step 3 and the minimum condition $\theta_{(s)} = 0$ of Step 1 are independent first-variation statements, and Eq. (56.149) simply records their conjunction.)

Step 5: the representative-slice property. We claim γ is the minimal surface not only on Σ_* but on every Cauchy slice Σ' of W_A that contains it. Let $\sigma' \subset \Sigma'$ be any competitor anchored on ∂A and homologous to A. Because Σ_* is achronal and $\gamma \subset \Sigma_* \cap \Sigma'$, the surface σ' lies in the causal future-and-past of γ relative to Σ_*; project it onto Σ_* along the timelike normal of Σ_* to obtain $\sigma_* \subset \Sigma_*$ in the same homology class. The projection moves each point along a timelike direction, and a spacelike surface acquired by sliding back along the future-or-past light cones cannot gain area under focusing: by Eq. (56.146) the orthogonal null congruences emanating from γ are non-expanding away from it, so $\mathrm{Area}(\sigma_*) \le \mathrm{Area}(\sigma')$. But γ is minimal on Σ_*, so $\mathrm{Area}(\gamma) \le \mathrm{Area}(\sigma_*) \le \mathrm{Area}(\sigma')$. Hence γ underbids every competitor on Σ': it is minimal on Σ' too. This is the property the covariant inequalities of the next subsection consume: two maximin surfaces can always be brought onto a single common slice on which each remains minimal, so the static cut-and-paste argument transfers verbatim.

Step 6: least area among extremal surfaces, and equivalence to HRT. Let X be any extremal surface homologous to A; it is spacelike (extremal surfaces are achronal by the same focusing argument), so it lies on some Cauchy slice Σ_X. On Σ_X the minimal surface has area $\mathcal{A}(\Sigma_X) \le \mathrm{Area}(X)$. Now choose a Cauchy slice $\Sigma_{X\gamma}$ containing both X and γ (possible because both are achronal and, in the AdS-hyperbolic bulk, jointly achronal once the homology regions are nested as the inequalities require). By the representative-slice property of Step 5, γ is minimal on $\Sigma_{X\gamma}$, while X, being extremal but not necessarily least, is merely a competitor there; therefore $\mathrm{Area}(\gamma) \le \mathrm{Area}(X)$. The maximin surface thus has the least area in the extremal class — which is exactly the defining selection of the HRT prescription Eq. (56.142), "extremal, then least-area." The two prescriptions agree, and the degeneracy resolution promised in Theorem 56.23 is automatic: the outer maximization acts on per-slice minima, so when several extrema compete it returns the smallest. Finally, the homology region of γ has a domain of dependence — the entanglement wedge $\mathcal{W}_A$ of Section 56.6 — and the same focusing comparison (carried out in detail in Theorem 56.32) shows the causal wedge is spacelike-or-null separated from γ and hence contained in $\mathcal{W}_A$. This completes the proof. □

Caution

The AdS-hyperbolicity hypothesis is not cosmetic. It is what guarantees the slice-space is compact so the outer maximum is attained, and it is the covariant stand-in for the global hyperbolicity that an honest variational problem needs. In pathological bulks — closed timelike curves, naked singularities reachable from W_A — the maximin surface can fail to exist,

and no covariant entropy prescription is expected to hold there either. The null energy condition enters only through the single inequality Eq. (56.146); everywhere it is used (Steps 3, 5, 6) it is used in exactly that form.

Covariant strong subadditivity

The payoff of the maximin form is that the entropy inequalities survive covariantly with the same cut-and-paste argument that proved them statically. Consider strong subadditivity, $S(AB) + S(BC) \geq S(ABC) + S(B)$ (Theorem 55.47), for boundary regions whose causal domains are suitably arranged. Statically the proof is purely combinatorial: given the minimal surfaces γ_{AB} and γ_{BC} on a common slice, one cuts them at their intersection and reglues the four pieces into two new anchored surfaces, one homologous to ABC and one homologous to B, with total area unchanged,

$$\text{Area}(\gamma_{AB}) + \text{Area}(\gamma_{BC}) = \text{Area}(\Gamma_{ABC}) + \text{Area}(\Gamma_B), \tag{56.150}$$

where Γ_{ABC}, Γ_B are the reglued competitors. Since γ_{ABC} and γ_B are the *minimal* surfaces in their homology classes, $\text{Area}(\gamma_{ABC}) \leq \text{Area}(\Gamma_{ABC})$ and $\text{Area}(\gamma_B) \leq \text{Area}(\Gamma_B)$; adding and using Eq. (56.150) gives $\text{Area}(\gamma_{ABC}) + \text{Area}(\gamma_B) \leq \text{Area}(\gamma_{AB}) + \text{Area}(\gamma_{BC})$, which is strong subadditivity after dividing by $4G_N$.

The obstacle to repeating this covariantly is that the maximin surfaces for AB and for BC may live on *different* maximizing slices, and one cannot cut and paste surfaces that do not share a slice. Wall's resolution is the representative-slice property of maximin: the maximin surface γ_{AB} has area no greater than the minimal area on *any* Cauchy slice that contains it, and in particular one can find a single slice Σ containing both γ_{AB} and γ_{BC} on which each is still minimal in its class. On that common slice the static cut-and-paste Eq. (56.150) applies verbatim, and because the maximin areas are $\geq$ the minimal areas on Σ for the larger regions, the inequality propagates the right way. The result is that strong subadditivity, monotonicity of relative entropy, and the other entropy inequalities hold for HRT exactly as for RT, with no static assumption. This is the structural reason the covariant prescription is consistent: it is built from minimizations, which are what the inequalities know how to use.

Caution

Extremality is necessary but the global "min" in Eq. (56.142) is indispensable, and it does more than break ties. In a time-dependent state there are generically several extremal surfaces homologous to A; only the least-area one computes the entropy. Dropping the global minimization — taking, say, a locally extremal surface that is not globally least — violates strong subadditivity and can give an entropy that decreases under inclusion. The

covariant prescription is "extremal, then least-area," not "any extremal surface."

56.5.3 The quantum extremal surface

Generalized entropy as the object to extremize

We now have two ingredients that beg to be combined. FLM (Theorem 56.20) says the entropy is area-plus-bulk-entropy but evaluates both on the *classical* extremal surface. HRT (Theorem 56.21) says the surface is fixed by extremizing the *area*. These two prescriptions locate the surface by different criteria, and at the order where FLM operates the discrepancy does not matter — but it must matter eventually, because the bulk entropy S_{bulk} depends on where the surface is, and a self-consistent rule cannot extremize one piece of the entropy while ignoring the other. The resolution, due to Engelhardt and Wall, is to extremize the whole thing. The object that gets extremized is the generalized entropy.

Definition 56.25 (Generalized entropy)**.** For a codimension-two bulk surface γ anchored on ∂A and homologous to A, bounding the homology region $\mathcal{R}_\gamma$, the *generalized entropy* is

$$S_{\text{gen}}[\gamma] \;=\; \frac{\langle \widehat{\text{Area}}(\gamma)\rangle}{4G_N} \;+\; S_{\text{bulk}}(\mathcal{R}_\gamma) \;+\; (\text{Wald and counterterm corrections}), \tag{56.151}$$

the sum of the (renormalized) area term and the renormalized von Neumann entropy of the bulk fields in $\mathcal{R}_\gamma$. The corrections are the same subleading bookkeeping terms as in Eq. (56.138); the load-bearing content is the area-plus-bulk-entropy sum. Crucially, $S_{\text{gen}}[\gamma]$ is ultraviolet-finite as a whole: the cutoff dependence of S_{bulk} near γ renormalizes the cutoff dependence of $1/4G_N$, so the sum is a well-defined functional of the surface location.

Definition 56.26 (Quantum extremal surface)**.** The *quantum extremal surface* (QES) for the boundary region A is a surface γ_A^{Q} anchored on ∂A and homologous to A that extremizes the generalized entropy Eq. (56.151) with respect to all variations of the surface location,

$$\left.\frac{\delta S_{\text{gen}}[\gamma]}{\delta X^\mu(\sigma)}\right|_{\gamma=\gamma_A^{\text{Q}}} = 0, \tag{56.152}$$

where $X^\mu(\sigma)$ embeds the surface. When several quantum extremal surfaces compete, the QES is the one of least generalized entropy.

Theorem 56.27 (Engelhardt–Wall: the QES computes the entropy)**.** *The entanglement entropy of the boundary region A is the generalized entropy evaluated*

on the quantum extremal surface,

$$\boxed{S(A) = \operatorname*{ext}_{\gamma} S_{\text{gen}}[\gamma] = \operatorname*{ext}_{\gamma} \left[\frac{\langle \widehat{\text{Area}}(\gamma) \rangle}{4G_N} + S_{\text{bulk}}(\mathcal{R}_\gamma) \right] = S_{\text{gen}}[\gamma_A^{\text{Q}}],} \tag{56.153}$$

with the global least-generalized-entropy rule resolving competing extrema. This prescription is correct to all orders in G_N within the semiclassical (bulk effective field theory) regime, and it reduces to RT, FLM, and HRT in the appropriate limits.

Why extremize the sum: the competition made explicit

The variational principle Eq. (56.152) is a genuine balance of two opposing tendencies, and seeing the competition is the whole point. Vary the surface position. The area term responds with the gradient of the area functional; the bulk-entropy term responds with the gradient of S_{bulk}. Writing the variation along a normal direction parametrized by a modulus x,

$$\frac{\partial S_{\text{gen}}}{\partial x} = \frac{1}{4G_N} \frac{\partial \,\text{Area}}{\partial x} + \frac{\partial S_{\text{bulk}}}{\partial x} = 0. \tag{56.154}$$

The first term is a *geometric* restoring force: moving the surface off its area-extremum costs area, and the area gradient pulls it back. The second is an *entropic* force: the bulk fields' entanglement entropy generically grows as the homology region grows, so $\partial S_{\text{bulk}}/\partial x$ pushes the surface to enlarge $\mathcal{R}_\gamma$. The QES sits where the two balance. Because the area term carries the large prefactor $1/4G_N \sim N^2$ while $S_{\text{bulk}} = O(N^0)$, the entropic force is a tiny perturbation on the geometric one, and the QES is displaced from the classical extremal surface by an amount of order G_N. This is the content of Fig. 56.7: the area term is a steep parabola whose minimum sits at the classical RT/HRT location, the bulk entropy is a gentle monotonic slope, and their sum is extremized a short distance away.

Worked Example 56.28 (The QES reduces to FLM, and the correction is second order)**.** We make the displacement quantitative and show that re-extremizing changes the entropy only at second order, so that the FLM formula Eq. (56.139) is exactly the QES Eq. (56.153) expanded to first subleading order. This both validates the hierarchy and isolates when re-extremization actually matters.

Setup. Let x be a normal modulus measuring displacement of the surface from the classical extremal surface, which sits at $x = 0$. Expand the area term about its extremum. Since $x = 0$ is a stationary point of the area, the linear term vanishes and

$$\frac{\text{Area}(x)}{4G_N} = \frac{\text{Area}(0)}{4G_N} + \frac{1}{2}\, a\, x^2 + O(x^3), \qquad a \equiv \frac{1}{4G_N} \frac{\partial^2 \text{Area}}{\partial x^2}\bigg|_0 > 0, \tag{56.155}$$

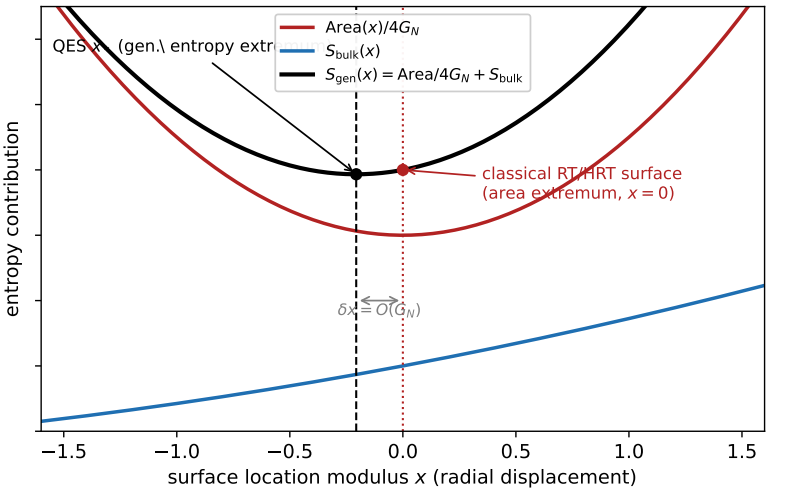

Figure 56.7: The quantum extremal surface as a competition. The surface location is parametrized by a normal modulus x, with the classical extremal (RT/HRT) surface at $x = 0$. The area term $\mathrm{Area}(x)/4G_N$ (red) is stationary at $x = 0$ and carries the large prefactor $1/G_N \sim N^2$; the bulk entanglement entropy $S_{\mathrm{bulk}}(x)$ (blue) is an $O(N^0)$ monotonic function. Their sum, the generalized entropy $S_{\mathrm{gen}}(x)$ (black), is extremized at the quantum extremal surface x_*, displaced from the classical location by $\delta x = O(G_N)$. Evaluating S_{gen} at x_* rather than at $x = 0$ changes the entropy only at order G_N relative to the correction — i.e. at $O(G_N^2)$ overall — which is why FLM (evaluation at $x = 0$) and the QES (evaluation at x_*) agree to the order FLM is valid.

where $a = O(1/G_N)$ is large and positive (the classical surface minimizes area within the slice). The bulk entropy is smooth and $O(N^0)$; expand it too,

$$S_{\mathrm{bulk}}(x) = S_{\mathrm{bulk}}(0) + b\,x + O(x^2), \qquad b \equiv \left.\frac{\partial S_{\mathrm{bulk}}}{\partial x}\right|_0 = O(1). \tag{56.156}$$

Locate the QES. The generalized entropy is $S_{\mathrm{gen}}(x) = \mathrm{Area}(0)/4G_N + \frac{1}{2}ax^2 + S_{\mathrm{bulk}}(0) + bx + \ldots$. Extremizing,

$$0 = \left.\frac{\partial S_{\mathrm{gen}}}{\partial x}\right|_{x_*} = a\,x_* + b \quad\Longrightarrow\quad x_* = -\frac{b}{a} = -\,4G_N\,\left.\frac{\partial S_{\mathrm{bulk}}/\partial x}{\partial^2 \mathrm{Area}/\partial x^2}\right|_0 = O(G_N). \tag{56.157}$$

The displacement is of order G_N, as anticipated: the gentle entropic slope b is fought by the steep geometric curvature $a \sim 1/G_N$, and the surface barely moves.

The entropy shift is second order. Evaluate S_{gen} at the QES and compare to its value at the classical surface:

$$\begin{aligned} S_{\text{gen}}(x_*) &= \frac{\text{Area}(0)}{4G_N} + S_{\text{bulk}}(0) + \left(\tfrac{1}{2}a\,x_*^2 + b\,x_*\right) \\ &= \frac{\text{Area}(0)}{4G_N} + S_{\text{bulk}}(0) + \left(\tfrac{1}{2}a\tfrac{b^2}{a^2} - \tfrac{b^2}{a}\right) = \underbrace{\frac{\text{Area}(0)}{4G_N} + S_{\text{bulk}}(0)}_{\text{FLM, Eq. (56.139)}} - \frac{b^2}{2a}. \end{aligned} \tag{56.158}$$

The first two terms are exactly the FLM answer: the area and bulk entropy evaluated on the *classical* surface. The correction from re-extremizing is $-b^2/2a$. With $b = O(1)$ and $a = O(1/G_N)$, this is

$$S_{\text{gen}}(x_*) - S_{\text{FLM}} = -\frac{b^2}{2a} = O(G_N), \tag{56.159}$$

one order in G_N below the bulk-entropy term $S_{\text{bulk}}(0) = O(1)$, hence $O(G_N)$ overall and beyond the validity of FLM. So at the order where FLM holds, evaluating the generalized entropy on the classical surface (FLM) and on the quantum extremal surface (QES) give the same answer; the difference Eq. (56.159) is precisely the leading place where it matters whether one extremizes the full generalized entropy. The sign is fixed: $-b^2/2a < 0$ since $a > 0$, so re-extremization always *lowers* the generalized entropy relative to the FLM value, exactly as a true extremization of a function with positive area-curvature must.

Theorem 56.28 is the quantitative statement of the hierarchy. It also shows precisely when the QES cannot be replaced by FLM: when the entropic gradient b is not small, or the geometric curvature a is not large — that is, when the bulk entropy varies as rapidly across the surface as the geometry does. This is no academic possibility. It is exactly what happens for a black hole that has been evaporating long enough that the entropy of the Hawking radiation has grown comparable to the horizon area: the entropic force is no longer a perturbation, a *new* quantum extremal surface (deep in the interior, defining an "island") comes to dominate the least-generalized-entropy competition, and the resulting entropy turns over onto the Page curve. We are deliberately not computing that here; it is the central payoff of Chapter 57, which takes Eq. (56.153) as its starting equation. We have built the instrument; Chapter 57 fires it.

The hierarchy of prescriptions

The four rules assembled across this chapter are not four competing proposals but one statement at four levels of approximation, organized by what is extremized and to what order in G_N.

Theorem 56.29 (The RT–FLM–HRT–QES hierarchy)**.** *The holographic entanglement entropy is given, exactly within bulk semiclassical gravity, by extremizing the generalized entropy Eq. (56.151) over surface location and taking the least-generalized-entropy quantum extremal surface (Theorem 56.27). The earlier prescriptions are its systematic approximations:*

- ***QES*** *(Eq. (56.153)): extremize* $S_{\text{gen}} = \text{Area}/4G_N + S_{\text{bulk}}$*; valid to all orders in* G_N *in the semiclassical regime, time-dependent states included.*
- ***HRT*** *(Eq. (56.142)): drop* S_{bulk} *and extremize the area alone; the classical* ($G_N \to 0$) *limit of QES, valid at leading order* $O(1/G_N)$*, time-dependent states included.*
- ***FLM*** *(Eq. (56.139)): evaluate* $\text{Area}/4G_N + S_{\text{bulk}}$ *on the classical extremal surface rather than re-extremizing; agrees with QES to first subleading order, the difference being* $O(G_N)$ *as in Eq. (56.158).*
- ***RT*** *(Eq. (56.4)): minimize the area on a preferred time slice; the static, classical limit, where "extremal" collapses to "minimal" and* S_{bulk} *is dropped.*

Each entry is obtained from the one above it by dropping a quantum correction (S_{bulk}*, taking* $G_N \to 0$*) or specializing the kinematics (static* $\Rightarrow$ *minimal surface). The unifying object throughout is the generalized entropy of Theorem 56.25.*

Physical Insight

The single sentence to carry forward is: *the holographic entropy is the extremum of the generalized entropy.* Every refinement in this chapter is a way of evaluating that one functional. The bare area law extremizes its leading geometric piece on a slice; HRT extremizes the same piece covariantly; FLM adds the bulk-field entropy as a perturbation; the QES extremizes the full sum and so closes the loop, making the prescription self-consistent at all semiclassical orders. That generalized entropy — not area, not bulk entropy, but their renormalization-group-stable sum — is the true holographic dual of an entanglement entropy is the deepest lesson of the subject, and the one black-hole information will exploit.

The quantum extremal surface does one more thing for us, beyond computing a number. By bounding a definite bulk region — the homology region $\mathcal{R}_\gamma$ of the QES — it sharpens the question of *which bulk a boundary subregion knows about*. The classical RT surface already suggested that A "sees" the wedge of bulk hanging beneath it; the QES makes the boundary of that wedge precise even when quantum corrections relocate the surface. The next section names this region the entanglement wedge, states the subregion-duality conjecture that the density matrix ρ_A encodes everything in it, and proves the operational content

through the JLMS relation Eq. (56.140) flagged above and the bulk energy conditions that follow from the positivity of relative entropy.

56.6 Subregion duality and the entanglement wedge

The quantum extremal surface of Section 56.5.3 did more than refine the area formula. By extremizing the generalized entropy $S_{\text{gen}} = \text{Area}/4G_N + S_{\text{bulk}}$ (Eq. (56.151)) it drew a sharp line through the bulk: on one side of the extremal surface γ_A^* lies the homology region $\mathcal{R}_A$ that the boundary subsystem A caps off (Theorem 56.2); on the other side lies bulk that A does not enclose. The previous sections used γ_A^* only to compute a number, the entropy of A. We now ask the operationally sharper question to which that surface is the answer: *which part of the bulk does the boundary region A actually know about?* The thesis of this section is that the homology region behind the quantum extremal surface, evolved causally, is exactly that part — the *entanglement wedge* — and that the reduced density matrix ρ_A encodes the full quantum state of the bulk fields there, no more and no less. Making this precise requires first carefully distinguishing the entanglement wedge from a smaller, more naive candidate (the causal wedge), then stating the duality, then proving its operational engine: the Jafferis–Lewkowycz–Maldacena identity equating boundary and bulk modular Hamiltonians up to the area operator. As a dividend, the positivity of relative entropy — a kinematic fact about density matrices — becomes, through this identity, a dynamical constraint on the bulk: an energy condition, the entropic shadow of the same positivity the analytic bootstrap delivers on the boundary.

56.6.1 Three bulk regions a boundary subsystem might encode

Fix a boundary spatial region A at a moment of time, with entangling surface ∂A, in an asymptotically AdS_{d+1} spacetime. Three nested bulk regions present themselves as candidates for "the bulk that A determines." Sorting them out is the whole game.

The coarsest candidate is purely causal and uses no entanglement data at all. On the boundary, the region A does not stand alone: a complete set of initial data on A determines the boundary fields throughout the *boundary domain of dependence* D_A, the set of boundary points every inextendible boundary causal curve through which must cross A. In Lorentzian language D_A is the causal diamond of A: for an interval of length ℓ in a 2D CFT it is the diamond with A as its base and tips a time $\ell/2$ to the future and past. Whatever the boundary subsystem on A knows, it knows everything in D_A. The natural bulk shadow of D_A is built from bulk causality.

Definition 56.30 (Causal wedge)**.** The *causal wedge* $\mathcal{C}_A$ of a boundary region A is the intersection of the bulk causal future and the bulk causal past of the

boundary domain of dependence D_A:

$$\mathcal{C}_A \;=\; J^+(D_A) \cap J^-(D_A), \tag{56.160}$$

where $J^{\pm}(\,\cdot\,)$ denote causal future/past taken in the bulk spacetime. Equivalently, $\mathcal{C}_A$ is the set of bulk points p that can both send a signal to and receive a signal from the boundary diamond D_A. Its future and past null boundaries (the bulk horizons of D_A) meet on a bulk codimension-two surface Ξ_A, the *causal information surface*, anchored on ∂A.

A bulk operator localized in $\mathcal{C}_A$ can be probed by boundary sources and read out by boundary detectors all supported within D_A, so on physical grounds ρ_A must at least encode $\mathcal{C}_A$. The causal wedge is the conservative, manifestly-reconstructible region. The question is whether it is the whole story.

The finest candidate uses the entanglement structure of the state, through the quantum extremal surface.

Definition 56.31 (Entanglement wedge)**.** Let γ_A^* be the quantum extremal surface for A (Theorem 56.26), and let $\mathcal{R}_A$ be the homology region it bounds on a bulk Cauchy slice, $\partial\mathcal{R}_A = A \cup \gamma_A^*$ (Eq. (56.3)). The *entanglement wedge* $\mathcal{W}_A$ is the bulk domain of dependence of $\mathcal{R}_A$,

$$\mathcal{W}_A \;=\; D[\mathcal{R}_A], \tag{56.161}$$

the set of bulk points p such that every inextendible bulk causal curve through p intersects $\mathcal{R}_A$. The entanglement wedge is the largest bulk region whose physics is fixed by initial data on $\mathcal{R}_A$, and it is bounded away from the rest of the bulk by γ_A^*, which forms its *edge*: $\gamma_A^* = \mathcal{W}_A \cap \mathcal{W}_{\bar{A}}$.

Taking the domain of dependence in Eq. (56.161) rather than just the slice $\mathcal{R}_A$ is what makes the entanglement wedge a Lorentzian, dynamical object: any bulk field configuration in $\mathcal{W}_A$ is determined by its data on $\mathcal{R}_A$ through the bulk equations of motion, so "encoding $\mathcal{R}_A$" and "encoding $\mathcal{W}_A$" are the same statement. That γ_A^* is the common edge of $\mathcal{W}_A$ and $\mathcal{W}_{\bar{A}}$ is the geometric face of the purity relation $S(A) = S(\bar{A})$ built into the homology constraint (Section 56.1.2): for a globally pure state the two wedges tile the bulk Cauchy slice and share exactly the extremal surface.

There is, intermediate between the two, a third region that will not detain us long but must be named to avoid confusion: the *causal shadow*, the part of the bulk that lies in no causal wedge of any boundary region, which is precisely where entanglement-wedge reconstruction has its most dramatic and least obvious reach. The cleanest statement of the hierarchy is an inclusion.

Theorem 56.32 (Causal wedge inside entanglement wedge)**.** *Assume the bulk matter obeys the null energy condition $T_{\mu\nu}k^\mu k^\nu \geq 0$ for all null k^μ (equivalently, via the Einstein equation, $R_{\mu\nu}k^\mu k^\nu \geq 0$). Then for every boundary region A,*

$$\mathcal{C}_A \;\subseteq\; \mathcal{W}_A, \tag{56.162}$$

and the inclusion is generically strict: the causal information surface Ξ_A lies on the boundary side of (no deeper than) the extremal surface γ_A^*, and coincides with it only in special, highly symmetric cases.

Proof. The claim is equivalent to the statement that the extremal surface γ_A^* lies outside the causal wedge $\mathcal{C}_A$ — on its far side, deeper in the bulk — so that the entire causal wedge is contained in the homology region's domain of dependence. We establish this by comparing two codimension-two surfaces through their null expansions, using the focusing theorem.

Consider the future null boundary (the future bulk horizon) of the causal wedge: the null congruence N^+ fired into the past from the future tip region of D_A, generating $\partial J^-(D_A)$, whose intersection with $\partial J^+(D_A)$ is the rim Ξ_A. Being the boundary of a causal set, N^+ is a null hypersurface ruled by null geodesics with some expansion θ. The Raychaudhuri equation governs θ along an affine parameter λ of these generators,

$$\frac{\mathrm{d}\theta}{\mathrm{d}\lambda} \;=\; -\frac{\theta^2}{d-1} - \sigma_{ab}\sigma^{ab} - R_{\mu\nu}k^\mu k^\nu, \tag{56.163}$$

with σ_{ab} the shear and k^μ the null tangent. Under the null energy condition the last term is non-positive, and the first two are manifestly non-positive, so $\mathrm{d}\theta/\mathrm{d}\lambda \le 0$: once a horizon generator is converging it converges faster, and a generator that ever reaches $\theta \le 0$ focuses to a caustic in finite affine time. A future event horizon cannot contain such a caustic ahead of it (the generators would leave the horizon), so along the past-directed generators of N^+ the expansion satisfies $\theta \ge 0$ as they emanate from the boundary and approach Ξ_A.

Now compare with the extremal surface. By definition (Theorem 56.26, or at the classical level Theorem 56.1) γ_A^* has *vanishing* expansion in both of its orthogonal null directions, $\theta_k = \theta_l = 0$ — this is precisely what extremizing the area means in covariant language. The causal information surface Ξ_A, by the previous paragraph, sits at the tip of a congruence whose expansion is non-negative. A standard comparison argument (the "extremal surfaces lie behind apparent horizons" lemma) now applies: suppose, for contradiction, that Ξ_A lay strictly deeper in the bulk than γ_A^*, i.e. that part of γ_A^* were inside $\mathcal{C}_A$. Fire the future-directed null congruence orthogonally outward from γ_A^* toward the boundary. It starts with $\theta = 0$ and, by Eq. (56.163) with the null energy condition, can only have θ decrease, so it stays non-expanding or focuses. But to exit through the causal horizon N^+ on which Ξ_A sits, it would have to cross from the non-expanding side to the non-negatively-expanding side of a null surface, which the maximum principle for Eq. (56.163) forbids: a non-expanding null surface cannot lie outside a non-negatively-expanding one with the same anchoring on ∂A. Hence γ_A^* lies on or behind Ξ_A, never in front of it. Equivalently Ξ_A lies in $\mathcal{R}_A \cup \gamma_A^*$, every causal curve probing $\mathcal{C}_A$ threads $\mathcal{R}_A$, and $\mathcal{C}_A \subseteq D[\mathcal{R}_A] = \mathcal{W}_A$.

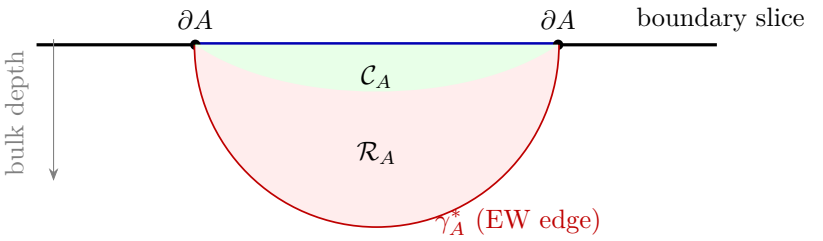

Figure 56.8: The causal wedge $\mathcal{C}_A$ (its edge Ξ_A, dashed green) sits inside the entanglement wedge $\mathcal{W}_A$ (its edge the extremal surface γ_A^*, red), shown on a bulk Cauchy slice. The null energy condition forces Ξ_A to lie no deeper than γ_A^* (Theorem 56.32); the sliver between them is bulk that A encodes *entanglement-wedge*-wise but cannot causally access from D_A alone. In the vacuum ball the two surfaces coincide; any energy in the bulk splits them.

Strictness is generic because the two surfaces are characterized by genuinely different conditions — $\theta = 0$ for γ_A^*, the horizon-rim condition for Ξ_A — which coincide only when the geometry has enough symmetry to make the causal horizon itself extremal. They agree for a ball in pure global AdS (the vacuum, where both surfaces are the same bifurcate Rindler-like horizon, Theorem 55.25 in holographic dress); they separate the instant the state carries energy. The worked example below exhibits the gap explicitly. □

56.6.2 The subregion-duality conjecture

The geometry having singled out the entanglement wedge as the natural, larger candidate, we can state the duality it serves. The claim is the holographic refinement of an idea already familiar from the global dictionary of Chapter 53: that a boundary *subsystem* is dual to a bulk *subregion*, with the reduced density matrix on the boundary side and the bulk effective field theory on its wedge on the bulk side.

Conjecture 56.33 (Subregion duality / entanglement-wedge reconstruction)**.** *Let A be a boundary region with entanglement wedge $\mathcal{W}_A$ (Theorem 56.31). Then the boundary reduced density matrix ρ_A and the bulk effective-field-theory data on $\mathcal{W}_A$ carry the same information:*

(i) (ρ_A determines the wedge.) *Every bulk operator localized in $\mathcal{W}_A$ can be represented as an operator on the boundary Hilbert space supported in A — it acts within the algebra of A and its correlation functions are computable from ρ_A alone.*

(ii) (ρ_A is determined by the wedge.) *Conversely, ρ_A is fixed by, and only by, the bulk state on $\mathcal{W}_A$; two global states with the same restriction to $\mathcal{W}_A$*

have the same ρ_A, and the entropy of A is the generalized entropy of γ_A^* (Eq. (56.151)).

A bulk operator outside $\mathcal{W}_A$ is not *reconstructible from A: it lies in the complementary wedge $\mathcal{W}_{\bar{A}}$ and is encoded in $\rho_{\bar{A}}$.*

We label the statement a conjecture in the book's discipline (Chapter 53): it is not a theorem of an axiomatized framework but the consensus reading of overwhelming evidence, and its operational core — the part that makes it more than a slogan — is provable, which is what the rest of this section does. Two pieces of that evidence are already in hand. The entropy clause (ii) is the quantum extremal surface prescription itself, established in Section 56.5.3. And the localization in (i) is consistent with causality: by Theorem 56.32 the wedge contains the causal wedge, so it contains every bulk operator that boundary causality already forces A to control; entanglement-wedge reconstruction asserts that A controls strictly more, namely everything spacelike-accessible from $\mathcal{R}_A$, including the causal-shadow sliver of Fig. 56.8. The mechanism by which a boundary operator supported in A can reach into that causally-disconnected sliver is the quantum-error-correcting structure of the dictionary, the subject of Section 56.7; here we prove the statement that makes reconstruction possible at the level of the modular data, and from which the entropy clause and the causal consistency both flow.

Worked Example 56.34 (Strict inclusion: two intervals and the connected wedge)**.** The gap between the causal and entanglement wedges is invisible for a single ball in the vacuum, where they coincide, so to see it one needs either energy in the bulk or a disconnected region. The disconnected case is the most transparent, and it doubles as the cleanest demonstration that the entanglement wedge is strictly larger.

Take two disjoint boundary intervals $A = A_1 \cup A_2$ in the vacuum of a 2D CFT, with the geometry of Section 56.2.4. There are two homologous configurations of extremal surfaces: the *disconnected* one, two semicircular geodesics each capping its own interval, and the *connected* one, two geodesics joining the inner endpoints to each other and the outer endpoints to each other. When the intervals are close enough (cross-ratio above the transition value), the connected configuration has smaller total length and is the RT surface; its homology region $\mathcal{R}_A$ is the bulk region bounded by A_1, A_2, and the two connecting geodesics — and it includes the bulk "bridge" hanging directly beneath the gap between the intervals.

Now compare with the causal wedge. The boundary domain of dependence of $A = A_1 \cup A_2$ is the union of the two separate diamonds $D_{A_1} \cup D_{A_2}$; nothing in D_A is causally connected, on the boundary, to the gap between the intervals, because the gap is the complement region. The causal wedge $\mathcal{C}_A = \mathcal{C}_{A_1} \cup \mathcal{C}_{A_2}$ is correspondingly the disjoint union of two small wedges, each hugging its own interval; the central bridge beneath the gap lies in *neither*. Yet that bridge is

exactly the bulk the connected entanglement wedge contains. We have therefore exhibited bulk — the connected bridge — that is in $\mathcal{W}_A$ but in no causal wedge of A: the inclusion of Theorem 56.32 is strict, and the surplus is precisely the bulk region that the *pair* of intervals encodes jointly though neither encodes alone. This surplus is the holographic seed of a striking fact developed in Section 56.7: a bulk operator can be invisible to A_1 and invisible to A_2, yet reconstructible from $A_1 \cup A_2$ — the signature of a quantum error-correcting code. The transition at the critical cross-ratio is the same entanglement phase transition that gives the mutual information $I(A_1{:}A_2)$ its kink (Section 56.2.4); on one side the bridge belongs to the wedge, on the other it does not, and the bulk region a pair of regions reconstructs jumps discontinuously.

56.6.3 The JLMS identity: boundary modular Hamiltonian = area + bulk modular Hamiltonian

Subregion duality asserts that ρ_A and the wedge carry the same information. The sharpest quantitative form of "same information" is an identity between the operators that govern each side's entanglement: the modular Hamiltonian. Recall (Theorem 55.28) that for a state ρ reduced to a region, the modular Hamiltonian is $K = -\log\rho$ (up to an additive constant), the generator whose Gibbs weight reproduces the reduced density matrix and whose flow ρ^{is} is modular flow. The boundary region A has its modular Hamiltonian $K_A = -\log\rho_A$. The bulk fields on the wedge $\mathcal{W}_A$ have *their* reduced density matrix $\rho_{\mathcal{W}_A}^{\text{bulk}}$ and hence their own bulk modular Hamiltonian $K_{\text{bulk}} = -\log\rho_{\mathcal{W}_A}^{\text{bulk}}$, an operator in the bulk effective field theory. The identity we now prove relates the two through the area of the extremal surface, promoted to an operator.

Theorem 56.35 (Jafferis–Lewkowycz–Maldacena)**.** *Acting on the code subspace of states whose bulk duals share the geometry to leading order, the boundary modular Hamiltonian of A equals the bulk modular Hamiltonian of its entanglement wedge plus the area operator of the quantum extremal surface:*

$$\boxed{K_A \;=\; \frac{\widehat{\text{Area}}(\gamma_A^*)}{4G_N} \;+\; K_{\text{bulk}}} \tag{56.164}$$

where $\widehat{\text{Area}}(\gamma_A^*)$ is the area of the quantum extremal surface promoted to a bulk operator (its expectation value is the classical area; it fluctuates because the surface location depends on the bulk state), and the identity holds order by order in the $1/N$ (equivalently G_N) expansion.

The structure of Eq. (56.164) is already eloquent. The boundary notion of "how entangled A is," encoded in K_A, decomposes into a gravitational piece — the area operator, the same object whose expectation gives the RT entropy — plus

the genuinely quantum entanglement of the bulk matter across the surface, K_{bulk}. It is the operator-level parent of the FLM entropy formula: taking the expectation value in a state and recalling $S = \langle K \rangle$ for the appropriate normalization recovers $S(A) = \langle \widehat{\text{Area}} \rangle / 4G_N + S_{\text{bulk}}$, the generalized entropy. We prove Eq. (56.164) by assembling three inputs: the first law of entanglement, the FLM decomposition of the entropy, and the equality of bulk and boundary relative entropies. We take them in turn, proving the first law from scratch since it is the linchpin.

The first law of entanglement. Let σ be a fixed reference state (typically the vacuum) reduced to A, with modular Hamiltonian $K_A^\sigma = -\log \sigma_A$, and let ρ_A be a nearby state, $\rho_A = \sigma_A + \delta\rho$. The relative entropy (Section 55.6)

$$S_{\text{rel}}(\rho_A \| \sigma_A) \;=\; \text{Tr}(\rho_A \log \rho_A) - \text{Tr}(\rho_A \log \sigma_A) \;=\; \Delta\langle K_A^\sigma \rangle - \Delta S_A \tag{56.165}$$

splits, by definition, into the change in the modular energy $\Delta\langle K_A^\sigma \rangle = \text{Tr}(\rho_A K_A^\sigma) - \text{Tr}(\sigma_A K_A^\sigma)$ and the change in the von Neumann entropy $\Delta S_A = S(\rho_A) - S(\sigma_A)$. Relative entropy is non-negative and vanishes if and only if $\rho_A = \sigma_A$ (Section 55.6); it therefore has a global minimum, equal to zero, at $\rho_A = \sigma_A$. A function that is non-negative, smooth, and zero at a point has vanishing first derivative there. Expanding in the perturbation $\delta\rho$ and writing the first-order variation as $\delta(\cdot)$,

$$\delta S_{\text{rel}} \;=\; \delta\langle K_A^\sigma \rangle - \delta S_A \;=\; 0 \quad\Longrightarrow\quad \boxed{\delta S_A = \delta\langle K_A^\sigma \rangle} \tag{56.166}$$

to first order in $\delta\rho$. This is the first law of entanglement: the leading change in the entanglement entropy of a region equals the change in the expectation value of the (fixed, reference) modular Hamiltonian. It is the entanglement analogue of $\mathrm{d}E = T\,\mathrm{d}S$ — indeed for the half-space $K_A^\sigma = 2\pi K_{\text{boost}}$ (Eq. (55.69)) and Eq. (56.166) reads $\delta S = 2\pi\,\delta\langle K_{\text{boost}} \rangle$, a literal first law at the Unruh temperature. Crucially, it holds on *both* sides of the duality: a boundary first law for ρ_A and a bulk first law for $\rho_{\mathcal{W}_A}^{\text{bulk}}$, since the argument used nothing but positivity of relative entropy, which holds for any density matrix.

The FLM decomposition. The quantum-corrected entropy formula of Section 56.5.1 (the FLM result, Eq. (56.138)) states that the boundary entropy is the bulk generalized entropy of the extremal surface,

$$S(\rho_A) \;=\; \frac{\langle \widehat{\text{Area}}(\gamma_A^*) \rangle_\rho}{4G_N} \;+\; S_{\text{bulk}}(\rho_{\mathcal{W}_A}^{\text{bulk}}) \;+\; (\text{local counterterms}), \tag{56.167}$$

where S_{bulk} is the von Neumann entropy of the bulk fields restricted to the wedge and the expectation $\langle \widehat{\text{Area}} \rangle_\rho$ is evaluated in the state ρ. Subtracting the same relation for the reference σ, the boundary entropy change becomes

$$\Delta S_A \;=\; \frac{\Delta\langle \widehat{\text{Area}} \rangle}{4G_N} \;+\; \Delta S_{\text{bulk}}, \tag{56.168}$$

the counterterms cancelling in the difference because they are state-independent local integrals on ∂A.

Equality of relative entropies and the assembly. The remaining input is the central JLMS claim, which we state and then justify: the relative entropy computed on the boundary equals the relative entropy of the bulk fields on the wedge,

$$S_{\rm rel}(\rho_A\|\sigma_A) \;=\; S_{\rm rel}(\rho^{\rm bulk}_{\mathcal{W}_A}\|\,\sigma^{\rm bulk}_{\mathcal{W}_A}), \tag{56.169}$$

order by order in $1/N$. Granting Eq. (56.169), the theorem follows by pure algebra. Write each side via Eq. (56.165): the boundary side is $\Delta\langle K^\sigma_A\rangle - \Delta S_A$ and the bulk side is $\Delta\langle K^\sigma_{\rm bulk}\rangle - \Delta S_{\rm bulk}$. Equating them,

$$\Delta\langle K^\sigma_A\rangle - \Delta S_A \;=\; \Delta\langle K^\sigma_{\rm bulk}\rangle - \Delta S_{\rm bulk}. \tag{56.170}$$

Substitute the FLM difference Eq. (56.168) for ΔS_A on the left:

$$\Delta\langle K^\sigma_A\rangle - \frac{\Delta\langle\widehat{\rm Area}\rangle}{4G_N} - \Delta S_{\rm bulk} \;=\; \Delta\langle K^\sigma_{\rm bulk}\rangle - \Delta S_{\rm bulk}. \tag{56.171}$$

The $\Delta S_{\rm bulk}$ terms cancel, leaving

$$\Delta\langle K^\sigma_A\rangle \;=\; \frac{\Delta\langle\widehat{\rm Area}\rangle}{4G_N} \;+\; \Delta\langle K^\sigma_{\rm bulk}\rangle. \tag{56.172}$$

This holds for the change between the reference σ and an *arbitrary* nearby state ρ. An identity of expectation-value differences that holds in every state of the code subspace is an identity of operators on that subspace: choosing ρ to range over a basis-spanning family (including states with off-diagonal density-matrix elements, obtained by superposing the reference with small admixtures and reading off the resulting linear and bilinear responses) promotes Eq. (56.172) to the operator equation $K_A = \widehat{\rm Area}/4G_N + K_{\rm bulk}$, which is Eq. (56.164). The additive reference constants drop out because the equation is built from differences. This completes the proof modulo the justification of Eq. (56.169), to which we turn.

Why are the relative entropies equal? The clean way to see it, and the one that exposes the $1/N$ bookkeeping, is to feed the first law back in. To leading nontrivial order the relative entropy is second order in the perturbation (its first-order part vanished by Eq. (56.166)), and the FLM relation Eq. (56.168) together with the *bulk* first law $\delta S_{\rm bulk} = \delta\langle K^\sigma_{\rm bulk}\rangle$ already forces the two sides of the JLMS equality $K_A - K_{\rm bulk} = \widehat{\rm Area}/4G_N$ (Eq. (56.173)) to agree term by term. Concretely, the leading, $O(N^2) \sim 1/G_N$, content lives entirely in the area: at this order the boundary modular Hamiltonian's variation $\delta\langle K^\sigma_A\rangle$ is matched by $\delta\langle\widehat{\rm Area}\rangle/4G_N$, while the bulk matter entanglement $K_{\rm bulk}$ is $O(N^0)$ and enters only at the next order. Equating the relative entropies thus first

fixes the area term, then, at $O(N^0)$, fixes the bulk modular piece, and so on — which is exactly the meaning of "order by order in $1/N$" in the theorem. The deepest justification of Eq. (56.169) is that both relative entropies are computed by the *same* Euclidean gravitational path integral: the replica construction that computes $S_{\rm rel}$ (a difference of free energies on replicated geometries) localizes, by the Lewkowycz–Maldacena conical-deficit accounting of Section 56.4, onto the extremal surface, and the bulk-matter and area contributions it produces are precisely $S_{\rm bulk}$ and $\langle\widehat{\rm Area}\rangle/4G_N$ — so the boundary $S_{\rm rel}$ *is* the bulk $S_{\rm rel}$ by construction. We have stated this localization as established in Section 56.4 and do not repeat it; what Theorem 56.35 adds is the operator identity it implies.

$$S_{\rm rel}^{\rm bdy} \;=\; S_{\rm rel}^{\rm bulk} \qquad\Longleftrightarrow\qquad K_A - K_{\rm bulk} = \frac{\widehat{\rm Area}}{4G_N}. \tag{56.173}$$

Physical Insight

JLMS is the precise sense in which "the area is entanglement." The area operator is not an extra ingredient bolted onto the bulk modular Hamiltonian; it is the *difference* between how entangled the boundary thinks the region is and how entangled the bulk fields actually are across the surface. In the deep-classical limit the bulk-matter entanglement is negligible and K_A is purely the area — the entanglement of A is geometry, full stop. Quantum bulk fields then dress this geometric entanglement with their own, and the two combine into a single boundary modular Hamiltonian. Read the other way, Eq. (56.164) says that boundary modular flow — an abstract, generally nonlocal symmetry of ρ_A — acts on the bulk as bulk modular flow together with a geometric "rotation" generated by the area term, i.e. a boost about the extremal surface. This is the engine of reconstruction: because the two modular flows agree, a bulk operator and its boundary image evolve identically, and the boundary can track the bulk operator.

56.6.4 Relative-entropy positivity as a bulk energy condition

The identity Eq. (56.164) converts kinematic facts about boundary density matrices into dynamical statements about the bulk. The two facts we use are the most basic properties of relative entropy, both established in Section 55.6: positivity, and monotonicity under inclusion.

Proposition 56.36 (Relative-entropy positivity and monotonicity)**.** *For any states ρ, σ and any regions $A \subseteq B$,*

$$S_{\rm rel}(\rho_A\|\sigma_A) \;\geq\; 0, \qquad S_{\rm rel}(\rho_A\|\sigma_A) \;\leq\; S_{\rm rel}(\rho_B\|\sigma_B). \tag{56.174}$$

Positivity is saturated iff $\rho_A = \sigma_A$; monotonicity expresses that discarding the degrees of freedom in $B\setminus A$ (a quantum channel) cannot increase distinguishability.

These are theorems of finite-dimensional quantum information, imported wholesale (Section 55.6). Their power here is that, through JLMS, the boundary relative entropy equals a bulk quantity, so Eq. (56.174) constrains the bulk. We make this explicit in the controlled setting of a perturbation of the vacuum, where every object is computable.

Take the reference σ to be the global vacuum and ρ a nearby state created by exciting the bulk matter — a small coherent disturbance with stress tensor $\langle T^{\rm bulk}_{\mu\nu}\rangle$ on top of pure AdS. Choose for A a boundary ball (or, by the conformal map, a half-space), whose entanglement wedge in the vacuum is a bulk Rindler wedge with bifurcation surface γ_A^*. For this maximally symmetric case the *bulk* modular Hamiltonian is local and geometric: by the bulk Bisognano–Wichmann theorem (Theorem 55.25, applied to the bulk QFT on its Rindler wedge) it is the boost generator about γ_A^*,

$$K^{\sigma}_{\rm bulk} \;=\; 2\pi \int_{\mathcal{R}_A} \mathrm{d}\Sigma^{\mu}\, \xi^{\nu}\, T^{\rm bulk}_{\mu\nu} \;+\; \text{const}, \tag{56.175}$$

with ξ^ν the boost Killing vector of the wedge (vanishing on γ_A^*, future-directed inside) and $\mathrm{d}\Sigma^\mu$ the volume element on the bulk slice $\mathcal{R}_A$. Now use the bulk first law and FLM together. By Eq. (56.168) the entropy change is $\Delta S_A = \Delta\langle\widehat{\rm Area}\rangle/4G_N + \Delta S_{\rm bulk}$, and by the bulk first law Eq. (56.166) the bulk entropy change is $\Delta S_{\rm bulk} = \Delta\langle K^{\sigma}_{\rm bulk}\rangle$ to leading order. Insert these into the boundary relative entropy Eq. (56.165):

$$\begin{aligned} S_{\rm rel}(\rho_A\|\sigma_A) &= \Delta\langle K^{\sigma}_{A}\rangle - \Delta S_A \\ &= \Delta\langle K^{\sigma}_{A}\rangle - \frac{\Delta\langle\widehat{\rm Area}\rangle}{4G_N} - \Delta\langle K^{\sigma}_{\rm bulk}\rangle. \end{aligned} \tag{56.176}$$

By JLMS Eq. (56.172) the right-hand side is zero at first order — the boundary modular energy exactly accounts for the area change plus the bulk modular energy, which is just Eq. (56.164) read as a statement about expectation values. So the *linear* term in $S_{\rm rel}$ vanishes, consistent with Eq. (56.166), and the physics is in the second order. There, positivity bites. Writing $S_{\rm rel} = S^{(2)}_{\rm rel} + \dots$ and using the equality of relative entropies Eq. (56.169),

$$S^{\rm bulk}_{\rm rel}(\rho^{\rm bulk}\|\sigma^{\rm bulk}) \;=\; \Delta\langle K^{\sigma}_{\rm bulk}\rangle - \Delta S_{\rm bulk} \;\geq\; 0, \tag{56.177}$$

i.e. the *bulk* modular energy change is bounded below by the bulk entanglement-entropy change. With the local form Eq. (56.175) this is a statement about the bulk stress tensor:

$$2\pi\int_{\mathcal{R}_A} \mathrm{d}\Sigma^{\mu}\, \xi^{\nu}\, \Delta\langle T^{\rm bulk}_{\mu\nu}\rangle \;\geq\; \Delta S_{\rm bulk} \;\geq\; 0, \tag{56.178}$$

the last inequality holding because $\Delta S_{\rm bulk} \geq 0$ for excitations of the vacuum on a wedge (the vacuum minimizes the modular-flow-invariant entropy). The boost-weighted bulk energy in the wedge is non-negative. This is a *bulk energy condition*, derived not from any assumption about the bulk matter Lagrangian but purely from positivity of a boundary relative entropy.

To extract the sharpest, local form, deform the entangling surface along a null direction. Let A_λ be a one-parameter family of regions obtained by pushing ∂A a null distance λ in the bulk-null direction k^μ orthogonal to γ_A^*; this nests the entanglement wedges, $\mathcal{W}_{A_\lambda} \subseteq \mathcal{W}_{A_{\lambda'}}$ for $\lambda \leq \lambda'$. Monotonicity Eq. (56.174) then gives $\partial_\lambda S_{\rm rel} \geq 0$. The modular Hamiltonian's null derivative localizes onto the surface — $\partial_\lambda \langle K \rangle = 2\pi \int_\gamma \langle T_{kk} \rangle$ for the local boost generator — and assembling the pieces yields the differential inequality

$$2\pi \, \langle T_{kk}^{\rm bulk} \rangle \;\geq\; \partial_\lambda^2 S_{\rm bulk}, \tag{56.179}$$

the bulk *quantum null energy condition*: the null-null stress tensor is bounded below by the second null derivative of the entanglement entropy. In the classical limit, where $S_{\rm bulk}$ is subleading, Eq. (56.179) reduces to $\langle T_{kk}^{\rm bulk} \rangle \geq 0$, the null energy condition — which is exactly the hypothesis that drove the focusing argument of Theorem 56.32 and the holographic c-theorem of Section 52.5. Relative-entropy positivity thus *proves*, on the bulk side, the energy condition we elsewhere had to assume.

Physical Insight

The same positivity surfaces on both sides of the duality, established by entirely different mathematics, and the two must agree because they compute the same number. On the boundary, the averaged null energy condition $\int \mathrm{d}\lambda \, \langle T_{kk} \rangle \geq 0$ is a theorem of conformal field theory, proved by the analytic bootstrap: it is the positivity of the double discontinuity that the Lorentzian inversion formula (Theorem 51.16) feeds on, the statement that the leading-twist OPE data have definite sign. On the bulk, the very same averaged null energy is forced by the monotonicity of relative entropy through Eq. (56.179). One positivity lives in the analytic structure of a Lorentzian four-point function; the other in the convexity of the logarithm that makes $S_{\rm rel} \geq 0$. That they are the same constraint, transported across the holographic dictionary, is among the cleanest evidence that gravity in the bulk inherits exactly the consistency conditions of a unitary conformal field theory on the boundary — and conversely that bulk causality and energy positivity are not extra postulates but consequences of boundary unitarity.

Caution

The energy condition Eq. (56.178) is derived in a controlled perturbative setting — a small excitation of the vacuum, a maximally symmetric region with a local bulk modular Hamiltonian. Two caveats keep it honest. First, away from balls and half-spaces the bulk modular Hamiltonian is nonlocal and Eq. (56.175) fails; the positivity statement remains true but no longer reads as a simple stress-tensor integral. Second, the chain of equalities used FLM and the bulk first law at leading order in G_N; the inequalities are perturbative, valid order by order, and are not claimed as exact statements about the full nonperturbative gravitational state. What is robust is the *structure*: boundary relative-entropy positivity, transmuted by JLMS, is a positive-energy/focusing statement for the bulk, dated to the mid-2010s programme that turned entanglement inequalities into gravitational constraints.

56.6.5 Why the entanglement wedge, and not the causal wedge, is the reconstruction region

We can now collect the geometric and operational threads into the answer the section was built to give. The causal wedge is the conservative choice: it contains exactly the bulk that boundary causality *forces* A to control, and a bulk operator there is reconstructible by elementary causal reasoning (a boundary source in D_A can poke it, a boundary detector in D_A can hear it). But the causal wedge is too small to be the encoding region, for three reasons that now stand proved.

First, it gives the wrong entropy. The boundary entropy $S(A)$ is the generalized entropy of the quantum extremal surface (Section 56.5.3), and that surface is γ_A^*, the edge of the *entanglement* wedge — not Ξ_A, the edge of the causal wedge. The area of Ξ_A does not compute $S(A)$ except in the symmetric cases where the two surfaces coincide. Any candidate "reconstruction region" must have an edge whose area is the entropy, and only the entanglement wedge qualifies.

Second, it is inconsistent with the modular identity. JLMS Eq. (56.164) equates boundary modular flow with bulk modular flow about γ_A^*. Modular flow of ρ_A acts within the algebra of A and preserves it; on the bulk side it preserves the entanglement wedge, since γ_A^* is the fixed surface of the boost it generates. Were the encoded region the smaller causal wedge, boundary modular flow would have to preserve $\mathcal{C}_A$ instead, contradicting Eq. (56.164), whose area operator is the area of γ_A^*. The algebra of ρ_A knows about γ_A^*, hence about the whole entanglement wedge.

Third, the surplus region is physically reconstructible, even though it is causally inaccessible. Theorem 56.34 exhibited bulk — the connected bridge beneath two intervals — inside $\mathcal{W}_A$ but inside no causal wedge of A. By

Theorem 56.32 this surplus is always on the safe side: $\mathcal{C}_A \subseteq \mathcal{W}_A$, so promoting the reconstruction region from causal to entanglement wedge never *loses* anything causally guaranteed; it only adds the causal-shadow sliver. And the addition is forced, not optional, by the first two points. The entanglement wedge is therefore the unique region that simultaneously contains the causal wedge, has the right entropy, and is preserved by boundary modular flow. It is the bulk that ρ_A encodes.

The strict inclusion $\mathcal{C}_A \subsetneq \mathcal{W}_A$ is the crux of everything that follows. A bulk operator in the surplus sliver cannot be reached from A by any causal signal, yet ρ_A determines it. There is no contradiction — bulk locality is emergent and approximate, and the boundary representation of a bulk operator is smeared, nonlocal, and state-dependent — but there is a puzzle of mechanism: how can a boundary operator supported on A encode bulk data in a region A cannot causally touch, and do so robustly? The answer is that the bulk-to-boundary map has the structure of a quantum error-correcting code, in which a single logical (bulk) operator admits many physical (boundary) representatives, and the redundancy is exactly what lets A reconstruct operators in its entanglement wedge even when no individual boundary point in A is causally connected to them. Making the reconstruction explicit — building the boundary representative of a bulk field by the HKLL smearing and recognizing entanglement-wedge reconstruction as complementary recovery in a code — is the work of Section 56.7, to which the JLMS identity Eq. (56.164) now hands the precise operational claim: bulk operators in $\mathcal{W}_A$ are recoverable from ρ_A, with the area operator measuring exactly how much code subspace the geometry can protect.

56.7 Bulk reconstruction as quantum error correction

The previous section closed with a claim that is operationally startling and that this section makes good on. Subregion duality, sharpened by the JLMS identity (Theorem 56.35), asserts that the reduced density matrix ρ_A of a boundary region A does not merely *know about* the entanglement wedge $\mathcal{W}_A$ in some loose statistical sense: it *encodes* the bulk physics there exactly, so that any bulk operator localized inside $\mathcal{W}_A$ can be recovered from boundary data living on A alone. That is a strong statement, and it has a strange consequence. A bulk operator deep in the interior — at the very center of anti-de Sitter space, say — lies inside the entanglement wedge of many different, even disjoint, boundary regions. Each of them must therefore be able to reconstruct it. How can the same bulk field be a function of boundary data on A and, independently, a function of boundary data on a region disjoint from A, when operators on disjoint regions commute? The resolution is not a technicality; it is the deepest structural lesson of holography. The bulk-to-boundary map is a *quantum error-correcting code*: bulk fields are logical operators, the boundary Hilbert space is the physical

(encoding) space, and the multiple, mutually consistent boundary representations of one bulk operator are exactly the redundancy that lets a code recover logical information after part of the physical system is erased. This section builds that picture in three stages. First we make reconstruction concrete in the simplest setting — the HKLL representation of a free bulk field as a smeared boundary operator. Then we promote it to entanglement-wedge reconstruction and state the recovery theorem. Finally we recast the whole structure as quantum error correction in the sense of Almheiri, Dong, and Harlow, and exhibit it exactly in a finite-dimensional model, the HaPPY pentagon code, where every claim above becomes a short calculation with stabilizer codes.

56.7.1 HKLL: a bulk field as a smeared boundary operator

Begin with the cleanest possible question. The dictionary of Section 53.5 attaches to every bulk field ϕ of mass m a boundary primary $\mathcal{O}$ of dimension Δ, with $\Delta(\Delta - d) = m^2 L^2$, through the near-boundary falloff. In the radial coordinate z of Poincaré AdS_{d+1}, a normalizable bulk solution behaves as $\phi(z, x) \to z^{\Delta}\, \mathcal{O}(x)$ as $z \to 0$, and this limit *defines* the boundary operator,

$$\mathcal{O}(x) = \lim_{z \to 0} z^{-\Delta}\, \phi(z, x), \tag{56.180}$$

the so-called extrapolate form of the dictionary, equivalent to the GKP–Witten relation (Theorem 53.29 and Eq. (53.162)) for the leading falloff. Equation (56.180) reads off a boundary operator from a bulk field. We now want to run it backwards: given the boundary operator $\mathcal{O}(x)$ for all x, reconstruct the bulk field $\phi(z, x)$ at a point sitting a finite distance into the bulk. At leading order in G_N the bulk field is free — it obeys the linear wave equation on the fixed AdS background — and a free field is completely determined by its boundary data together with the equation of motion. The reconstruction is therefore a boundary-value problem, and it has a clean answer: ϕ is a *linear smearing* of $\mathcal{O}$ against a kernel.

The logic that guarantees this is mode inversion, and it is worth stating in full because it makes the existence of the kernel a theorem rather than a hope. Expand the free bulk field in a complete set of normalizable modes $F_n(z, x)$ of the wave equation,

$$\phi(z, x) = \sum_n \left[a_n\, F_n(z, x) + a_n^{\dagger}\, F_n^{*}(z, x) \right], \tag{56.181}$$

with $a_n, a_n^{\dagger}$ the bulk creation and annihilation operators. Applying Eq. (56.180) term by term, the same operators appear in the boundary field,

$$\mathcal{O}(x) = \sum_n \left[a_n\, f_n(x) + a_n^{\dagger}\, f_n^{*}(x) \right], \qquad f_n(x) \equiv \lim_{z \to 0} z^{-\Delta} F_n(z, x). \tag{56.182}$$

The boundary mode functions f_n are a complete orthonormal set on the boundary (they are the boundary values of a complete set of bulk solutions, and the spectrum

is non-degenerate), so the ladder operators can be solved for: $a_n = \int \mathrm{d}x\, f_n^*(x)\, \mathcal{O}(x)$ in a schematic notation that the explicit cases below make precise. Substituting back into Eq. (56.181) expresses ϕ as a linear functional of $\mathcal{O}$,

$$\phi(z,x) = \int \mathrm{d}x'\; K(z,x\,|\,x')\,\mathcal{O}(x'), \qquad K(z,x\,|\,x') = \sum_n \big[F_n(z,x) f_n^*(x') + F_n^*(z,x) f_n(x')\big]. \tag{56.183}$$

The object K is the *smearing function*. By construction it manifestly solves the bulk wave equation in its bulk argument (z,x) — it is a superposition of solutions F_n — and it reproduces $\mathcal{O}$ in the boundary limit. Reconstruction therefore exists for any free bulk field; the only question is whether the mode sum Eq. (56.183) can be resummed into something local and intelligible. It can, and the answer is the central result of Hamilton, Kabat, Lifschytz, and Lowe.

Definition 56.37 (HKLL smearing representation)**.** Let ϕ be a free scalar of dimension Δ in AdS_{d+1}, dual to the boundary primary $\mathcal{O}$. The *HKLL representation* of ϕ at a bulk point $(z,x) = (z,t,\vec{x})$ in the Poincaré patch is

$$\phi(z,t,\vec{x}) = c_{\Delta,d} \int_{t'^2+|\vec{x}'|^2<z^2} \mathrm{d}t'\, \mathrm{d}^{d-1}x' \left(\frac{z^2 - t'^2 - |\vec{x}'|^2}{z}\right)^{\Delta-d} \mathcal{O}(t+t',\, \vec{x}+\vec{x}'), \tag{56.184}$$

with normalization

$$c_{\Delta,d} = \frac{\Gamma(\Delta - \frac{d}{2} + 1)}{\pi^{d/2}\,\Gamma(\Delta - d + 1)}. \tag{56.185}$$

The integration region $t'^2 + |\vec{x}'|^2 < z^2$ is the set of boundary points *spacelike separated* from the bulk point: this is the *spacelike* (or causal-wedge) smearing representation. The kernel makes the bulk operator an explicit, if non-local, function of boundary operators in the causal wedge of the data region.

That the support is the spacelike-separated region is the geometric heart of the construction, and it deserves a name and a derivation rather than an assertion. We supply both in a low-dimensional case clean enough to carry every step on the page.

Worked Example 56.38 (The HKLL kernel for a scalar in AdS_2)**.** Take $d = 1$: a scalar of dimension Δ in AdS_2, with metric $\mathrm{d}s^2 = (L^2/z^2)(-\mathrm{d}t^2 + \mathrm{d}z^2)$ in Poincaré coordinates, boundary at $z \to 0$. We set $L = 1$. We will (i) write down the candidate smearing representation, (ii) verify it satisfies the bulk wave equation, (iii) verify it reproduces the extrapolate dictionary, and (iv) read off its causal support. Together these constitute a complete proof that the formula reconstructs the bulk field, because a normalizable solution of a linear second-order wave equation is uniquely fixed by its leading boundary data.

The wave equation. For the metric above, $\sqrt{-g} = 1/z^2$ while $\sqrt{-g}\,g^{tt} = -1$ and $\sqrt{-g}\,g^{zz} = +1$, so the Klein–Gordon operator is

$$\Box\phi = \frac{1}{\sqrt{-g}}\,\partial_\mu\big(\sqrt{-g}\,g^{\mu\nu}\partial_\nu\phi\big) = z^2(\partial_z^2 - \partial_t^2)\phi, \tag{56.186}$$

and the equation $\Box\phi = m^2\phi$ with $m^2 = \Delta(\Delta-1)$ (the $d=1$ mass–dimension relation) reads

$$\Big(\partial_z^2 - \partial_t^2 - \frac{\Delta(\Delta-1)}{z^2}\Big)\phi = 0. \tag{56.187}$$

The candidate. The $d=1$ specialization of Eq. (56.184) integrates over the boundary interval $|t'| < z$ that is spacelike to the bulk point:

$$\phi(z,t) = c_\Delta \int_{-z}^{z} \mathrm{d}t' \left(\frac{z^2 - t'^2}{z}\right)^{\Delta-1} \mathcal{O}(t+t'), \qquad c_\Delta = \frac{\Gamma(\Delta+\frac12)}{\sqrt{\pi}\,\Gamma(\Delta)}. \tag{56.188}$$

The substitution $t' = z\,s$, $s \in [-1,1]$, removes the z-dependence from the limits and exposes the structure cleanly:

$$\phi(z,t) = c_\Delta\, z^\Delta \int_{-1}^{1} \mathrm{d}s\; (1-s^2)^{\Delta-1}\,\mathcal{O}(t+zs). \tag{56.189}$$

Verification of the boundary condition. As $z \to 0$, $\mathcal{O}(t+zs) \to \mathcal{O}(t)$ and

$$\int_{-1}^{1}(1-s^2)^{\Delta-1}\,\mathrm{d}s = B\Big(\tfrac12,\Delta\Big) = \frac{\Gamma(\frac12)\Gamma(\Delta)}{\Gamma(\Delta+\frac12)} = \frac{\sqrt{\pi}\,\Gamma(\Delta)}{\Gamma(\Delta+\frac12)} = \frac{1}{c_\Delta}, \tag{56.190}$$

so $\phi(z,t) \to z^\Delta \mathcal{O}(t)$, exactly the extrapolate dictionary Eq. (56.180). The normalization c_Δ was chosen for precisely this.

Verification of the wave equation. Write $\phi = c_\Delta z^\Delta I$ with $I(z,t) = \int_{-1}^{1}(1-s^2)^{\Delta-1}\mathcal{O}(t+zs)\,\mathrm{d}s$. Denote by $\mathcal{O}', \mathcal{O}''$ derivatives with respect to the argument $u = t + zs$, and note the two ways the argument depends on the variables: $\partial_t\mathcal{O} = \mathcal{O}'$ and $\partial_z\mathcal{O} = s\,\mathcal{O}' = \frac{1}{z}\,\partial_s\mathcal{O}$. Differentiating,

$$\begin{aligned}
\partial_t^2\phi &= c_\Delta z^\Delta \int_{-1}^{1}(1-s^2)^{\Delta-1}\mathcal{O}''\,\mathrm{d}s,\\
\partial_z^2\phi &= c_\Delta\Big[\Delta(\Delta-1)z^{\Delta-2}I + 2\Delta z^{\Delta-1}I_z + z^\Delta I_{zz}\Big],
\end{aligned} \tag{56.191}$$

with $I_z = \int(1-s^2)^{\Delta-1}s\,\mathcal{O}'\,\mathrm{d}s$ and $I_{zz} = \int(1-s^2)^{\Delta-1}s^2\mathcal{O}''\,\mathrm{d}s$. Inserting these into the wave operator Eq. (56.187), the terms $\pm\Delta(\Delta-1)z^{\Delta-2}I$ cancel against each other, leaving

$$\Big(\partial_z^2 - \partial_t^2 - \tfrac{\Delta(\Delta-1)}{z^2}\Big)\phi = c_\Delta\Big[2\Delta z^{\Delta-1}I_z + z^\Delta(I_{zz} - I_{tt})\Big], \qquad I_{tt} = \int(1-s^2)^{\Delta-1}\mathcal{O}''\,\mathrm{d}s. \tag{56.192}$$

Now convert all argument-derivatives into s-derivatives using $\mathcal{O}' = \frac{1}{z}\partial_s\mathcal{O}$ and $\mathcal{O}'' = \frac{1}{z^2}\partial_s^2\mathcal{O}$:

$$I_{zz}-I_{tt} = \int_{-1}^{1}(s^2-1)(1-s^2)^{\Delta-1}\mathcal{O}''\,\mathrm{d}s = -\frac{1}{z^2}\int_{-1}^{1}(1-s^2)^{\Delta}\,\partial_s^2\mathcal{O}\,\mathrm{d}s, \qquad I_z = \frac{1}{z}\int_{-1}^{1}(1-s^2)^{\Delta-1} \tag{56.193}$$

Integrate the first by parts twice (the boundary terms vanish because $(1-s^2)^{\Delta}$ and its first derivative vanish at $s=\pm1$ for $\Delta>0$); the single integration by parts of $\partial_s^2\mathcal{O}$ against $(1-s^2)^{\Delta}$ gives

$$\int_{-1}^{1}(1-s^2)^{\Delta}\,\partial_s^2\mathcal{O}\,\mathrm{d}s = -\int_{-1}^{1}\partial_s[(1-s^2)^{\Delta}]\,\partial_s\mathcal{O}\,\mathrm{d}s = 2\Delta\int_{-1}^{1}s\,(1-s^2)^{\Delta-1}\partial_s\mathcal{O}\,\mathrm{d}s. \tag{56.194}$$

Therefore $z^{\Delta}(I_{zz}-I_{tt}) = -2\Delta z^{\Delta-2}\int s(1-s^2)^{\Delta-1}\partial_s\mathcal{O}\,\mathrm{d}s = -2\Delta z^{\Delta-1}I_z$, which is exactly minus the other surviving term in Eq. (56.192). The residual vanishes identically:

$$\Big(\partial_z^2 - \partial_t^2 - \tfrac{\Delta(\Delta-1)}{z^2}\Big)\phi = 0. \tag{56.195}$$

The smearing formula Eq. (56.188) solves the bulk wave equation and carries the correct boundary data, hence reconstructs the unique normalizable bulk field with boundary operator $\mathcal{O}$.

Causal support and non-manifest locality. Two boundary points enter Eq. (56.188): those with $|t'| < z$, i.e. boundary points within the interval $(t-z, t+z)$. In the Poincaré metric the bulk point (z,t) and a boundary point $(0, t+t')$ are spacelike separated precisely when $t'^2 < z^2$ (the boundary lightcone of the bulk point opens at 45° in these coordinates), so the kernel is supported on exactly the boundary points spacelike to the bulk point — the spacelike smearing of Theorem 56.37. This is the operational content of the bulk field being reconstructable from a *causal wedge*: only the boundary region in causal contact (spacelike, then evolved) with the bulk point is needed. Finally, locality is present but invisible. The reconstructed $\phi(z,t)$ is a spatially extended smear of $\mathcal{O}$, yet the bulk theory is local: two such reconstructed fields at spacelike-separated bulk points must commute. Their smearing regions on the boundary overlap, so term by term the commutator $[\phi(X),\phi(Y)]$ is a nonzero double integral of boundary commutators; it vanishes only after the precise kernel Eq. (56.185) forces a complete cancellation. Bulk microcausality is a conspiracy among boundary operators, not a manifest property of the representation — the first hint that "local bulk operator" is an emergent, redundantly encoded notion rather than a primitive one.

Figure 56.9 summarizes the picture. The construction extends, with more bookkeeping, to global AdS (where the mode sum Eq. (56.183) runs over the discrete normal modes and resums to a smearing over the global boundary

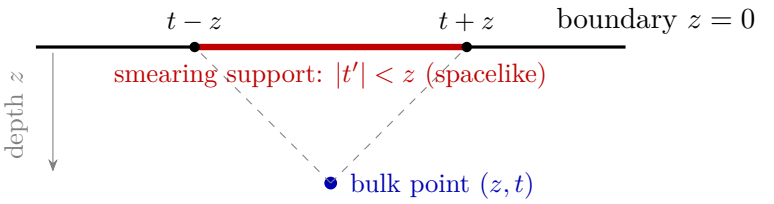

Figure 56.9: The HKLL spacelike-smearing representation Eq. (56.188) in AdS_2. A free bulk field at depth z and boundary time t is a linear smear of the boundary operator $\mathcal{O}$ over the interval $(t-z, t+z)$ — precisely the boundary points *spacelike* separated from the bulk point (the dashed boundary lightcone reaches $t' = t \pm z$). Larger bulk depth requires a wider boundary smearing, the reconstruction analogue of the deeper reach of larger RT surfaces.

lightcone) and, crucially, to AdS–Rindler wedges. The AdS–Rindler version is the one that matters for what follows: a bulk operator inside the bulk domain of dependence of a *boundary subregion* A admits an HKLL representation using only the operators $\mathcal{O}$ restricted to A. That subregion is the *causal wedge* of A — the bulk region in causal contact with the boundary causal diamond of A. HKLL thus already delivers reconstruction of the causal wedge from ρ_A. The next subsection states the stronger fact that the recoverable region is not the causal wedge but the (generally larger) entanglement wedge, and the subsection after that explains why the gap between them is the signature of error correction.

56.7.2 Entanglement-wedge reconstruction

Recall (Theorem 56.31) that the entanglement wedge $\mathcal{W}_A$ of a boundary region A is the bulk domain of dependence of the homology region $\mathcal{R}_A$ bounded by A and its RT surface γ_A^* (Theorems 56.2 and 56.3). It contains, and generically strictly exceeds, the causal wedge: there are bulk regions a boundary observer cannot reach causally yet can still reconstruct. The reconstruction theorem promotes subregion duality from a statement about density matrices to a statement about operators.

Theorem 56.39 (Entanglement-wedge reconstruction)**.** *Let A be a boundary region with entanglement wedge $\mathcal{W}_A$, and let the bulk effective field theory be restricted to a code subspace $\mathcal{H}_{\text{code}}$ of states with a common semiclassical geometry (Theorem 56.41). For every bulk operator ϕ supported in $\mathcal{W}_A$ there exists a boundary operator $\mathcal{O}_A$, built from the operators of A alone (i.e. an element of the operator algebra $\mathcal{A}_A$ acting on ρ_A), such that*

$$\phi\,|\psi\rangle = \mathcal{O}_A\,|\psi\rangle\,, \qquad \phi^\dagger\,|\psi\rangle = \mathcal{O}_A^\dagger\,|\psi\rangle \qquad \text{for all } |\psi\rangle \in \mathcal{H}_{\text{code}}. \tag{56.196}$$

Equivalently, every bulk observable in $\mathcal{W}_A$ is represented within the algebra of A, when acting on the code subspace.

The qualifier "on the code subspace" is not a hedge; it is the whole content, as the next subsection shows. Before that, the immediate corollary that exposes the paradox.

Corollary 56.40 (Complementary recovery)**.** *Suppose the global boundary state is pure and A, $\bar{A}$ partition the boundary, with entanglement wedges $\mathcal{W}_A, \mathcal{W}_{\bar{A}}$ that tile the bulk slice across the common RT surface $\gamma_A^* = \gamma_{\bar{A}}^*$ (the generic situation away from a quantum-extremal-surface transition). Then every bulk operator is reconstructable on* exactly one *of the two complementary regions: operators in $\mathcal{W}_A$ on A, operators in $\mathcal{W}_{\bar{A}}$ on $\bar{A}$. A bulk operator straddling the RT surface is reconstructable on neither in isolation.*

The proof of Theorem 56.39 from JLMS is exactly the algebraic argument we now give, and it is best stated as the central theorem of the error-correction framework. The corollary is its restriction to a pure global state, where $\mathcal{H}_{\text{code}}$ admits a clean complementary structure.

56.7.3 The error-correction paradigm of Almheiri, Dong, and Harlow

We now confront the paradox of the section's opening and resolve it. The resolution reorganizes everything: it identifies the precise sense in which bulk locality is encoded redundantly, and it ties the existence of reconstruction to the equality of bulk and boundary entropies — the RT/FLM formula — by a chain of equivalences.

The code subspace. The bulk effective field theory does not act on the whole CFT Hilbert space. It is the description of small fluctuations around a fixed classical background, valid only for states whose backreaction is sub-Planckian. This selects a subspace.

Definition 56.41 (Code subspace)**.** The *code subspace* $\mathcal{H}_{\text{code}} \subset \mathcal{H}_{\text{CFT}}$ is the span of states obtained by acting on a fixed semiclassical reference state $|0\rangle$ (a fixed bulk geometry) with a bounded number of low-energy bulk effective-field-theory operators. The encoding is the isometry

$$V : \mathcal{H}_{\text{code}}^{\text{bulk}} \longrightarrow \mathcal{H}_{\text{CFT}}, \qquad V^\dagger V = \mathbf{1}_{\text{code}}, \tag{56.197}$$

mapping the abstract bulk Fock space into the (vastly larger) boundary Hilbert space. A bulk operator ϕ acts as the *logical* operator $\bar{\phi} = V\phi V^\dagger$ on the image, supported in the code subspace.

The isometry V is not unitary: $\dim \mathcal{H}_{\text{code}} \ll \dim \mathcal{H}_{\text{CFT}}$, and that mismatch is the room into which information is redundantly encoded. The boundary states in the image of V are the *codewords*.

The paradox, sharply. A bulk operator ϕ at the center of AdS lies in $\mathcal{W}_A$ for every sufficiently large region A. Take two boundary regions A_1 and A_2 that are *disjoint*, each large enough that the center is in its entanglement wedge — this is possible whenever neither A_i alone is more than half the boundary but their wedges both reach the deep interior, as happens for, e.g., two large but disjoint caps. By Theorem 56.39, ϕ equals some $\mathcal{O}_{A_1} \in \mathcal{A}_{A_1}$ and also some $\mathcal{O}_{A_2} \in \mathcal{A}_{A_2}$. But A_1 and A_2 are spacelike separated on the boundary, so $[\mathcal{O}_{A_1}, \mathcal{O}_{A_2}] = 0$ identically as boundary operators. Were $\phi = \mathcal{O}_{A_1} = \mathcal{O}_{A_2}$ as honest operators on the full Hilbert space, we would also need ϕ to be simultaneously a function of A_1-data and of A_2-data, and worse, the radial-commutativity property — $[\phi(\text{center}), \mathcal{O}(x)] = 0$ for every boundary $\mathcal{O}$, since a deep bulk operator commutes with all single-trace boundary operators at leading order — would clash with ϕ being a nontrivial element of $\mathcal{A}_{A_1}$. Something has to give.

The resolution. The equalities Eq. (56.196) hold only *on* $\mathcal{H}_{\text{code}}$. As operators on the full $\mathcal{H}_{\text{CFT}}$, $\mathcal{O}_{A_1}$ and $\mathcal{O}_{A_2}$ are different; they merely agree when restricted to codewords. This is exactly the defining feature of a quantum error-correcting code: a logical operator $\bar{\phi}$ has many physical representatives, each of which reproduces its action on the code subspace while acting differently — and harmlessly — on the orthogonal complement. The disjoint representations $\mathcal{O}_{A_1}, \mathcal{O}_{A_2}$ do not contradict $[\mathcal{O}_{A_1}, \mathcal{O}_{A_2}] = 0$, because $\bar{\phi}$ is not equal to either of them off-code, and the commutator only needs to annihilate codewords:

$$[\mathcal{O}_{A_1}, \mathcal{O}_{A_2}]\, V = 0 \quad \text{(on the code subspace)}, \qquad \text{but} \quad \mathcal{O}_{A_1} \neq \mathcal{O}_{A_2} \text{ as operators on } \mathcal{H}_{\text{CFT}}. \tag{56.198}$$

Radial commutativity is likewise saved: a deep bulk operator commutes with boundary operators only in its action on codewords, which is all the bulk effective theory ever probes.

Theorem 56.42 (Holographic codes: Almheiri–Dong–Harlow)**.** *The bulk-to-boundary map of subregion duality is a quantum error-correcting code in the following precise sense. Bulk effective-field-theory states form a code subspace* $\mathcal{H}_{\text{code}}$ *embedded by an isometry* V *Eq. (56.197); bulk local operators are logical operators with multiple boundary representations; and entanglement-wedge reconstruction Theorem 56.39 is the statement that the code* corrects the erasure of $\bar{A}$ *whenever the bulk operator lies in* $\mathcal{W}_A$*. Concretely, a logical operator supported in* $\mathcal{W}_A$ *can be reconstructed using only the physical degrees of freedom in* A*, so erasing the complementary region* $\bar{A}$ *destroys no information about it. The recoverable bulk region grows from the causal wedge to the entanglement wedge precisely because error correction lets reconstruction reach beyond causal contact.*

Entanglement equals recoverability. The deepest part of the framework ties *which* region is recoverable to the entropy formula itself. The bridge is the JLMS

identity of the previous section (Theorem 56.35), which equates the boundary modular Hamiltonian $K_A = -\log \rho_A$ of the region with the bulk modular Hamiltonian $K^{\text{bulk}}_{\mathcal{W}_A}$ of its entanglement wedge plus the operator measuring the area of the RT surface,

$$K_A = \frac{\widehat{\text{Area}}(\gamma_A^*)}{4G_N} + K^{\text{bulk}}_{\mathcal{W}_A} + \dots, \tag{56.199}$$

to leading order in G_N. We use it to prove reconstruction algebraically, following Dong, Harlow, and Wall. Suppose ϕ is a bulk operator in $\mathcal{W}_A$. The reconstructability of ϕ on A is the statement that ϕ, acting on the code subspace, lies in the algebra $\mathcal{A}_A$. The clean criterion for membership in a von Neumann algebra is commutation with its commutant: $\mathcal{A}_A' = \mathcal{A}_{\bar{A}}$, the algebra of the complementary region. So ϕ is reconstructable on A if and only if, on the code subspace,

$$[\phi,\ \mathcal{O}_{\bar{A}}] = 0 \qquad \text{for every } \mathcal{O}_{\bar{A}} \in \mathcal{A}_{\bar{A}}. \tag{56.200}$$

Now the key step. Boundary modular flow $\rho_A^{is}\,(\,\cdot\,)\,\rho_A^{-is}$ keeps the algebra $\mathcal{A}_A$ invariant (Tomita–Takesaki), and by Eq. (56.199) this boundary flow acts on code-subspace operators as the *bulk* modular flow generated by $K^{\text{bulk}}_{\mathcal{W}_A}$ (the area term is a c-number on each fixed-geometry sector and contributes only a phase). The bulk modular flow of $\mathcal{W}_A$ maps operators localized in $\mathcal{W}_A$ to operators localized in $\mathcal{W}_A$, because bulk modular flow is geometric near the wedge and preserves bulk causal localization. Therefore a ϕ localized in $\mathcal{W}_A$ stays in a region spacelike to $\mathcal{W}_{\bar{A}}$ under the flow, and bulk microcausality gives $[\phi, \mathcal{O}_{\bar{A}}] = 0$ on the code subspace — which is exactly Eq. (56.200). The equality of bulk and boundary modular flows, i.e. JLMS, is thus equivalent to reconstructability; and JLMS is in turn the first-order ($\rho_A = \sigma_A e^{\delta}$) content of the equality of bulk and boundary *relative entropies*,

$$S_{\text{rel}}(\rho_A \,\|\, \sigma_A) = S_{\text{rel}}(\rho^{\text{bulk}}_{\mathcal{W}_A} \,\|\, \sigma^{\text{bulk}}_{\mathcal{W}_A}), \tag{56.201}$$

with S_{rel} the relative entropy of Eq. (55.15). The chain closes on the entropy formula: Eq. (56.201) holding for all nearby code states is, by the FLM expansion of $S_A = \langle\widehat{\text{Area}}\rangle/4G_N + S^{\text{bulk}}_{\mathcal{W}_A}$, the same data as the quantum-corrected RT formula. The slogan is exact: *a boundary region can recover a bulk operator precisely when its entanglement entropy is computed by an RT surface enclosing that operator.* Entanglement (the RT area) and recoverability (the code structure) are two faces of one fact.

Physical Insight

This is the chapter's conceptual summit made operational. "Geometry from entanglement" acquires a mechanism: the bulk is not merely correlated with the boundary, it is *encoded* in it as a quantum error-correcting code,

with the RT surface playing the role of the code's boundary of recoverability. The redundancy that protects a logical qubit against erasure is the same redundancy that lets many boundary regions each reconstruct a deep bulk point — and the amount of that redundancy, the depth to which a region's wedge reaches, is measured by the area of its RT surface. Error correction is why a smooth, local interior can be woven out of a boundary theory that has no local interior of its own.

56.7.4 The HaPPY pentagon code: an exactly solvable model

Everything above is structural; it is reassuring, and decisive, to see it realized exactly in a finite-dimensional model where "RT surface," "entanglement wedge," "reconstruction," and "erasure correction" are all elementary stabilizer-code statements. The model of Pastawski, Yoshida, Harlow, and Preskill — the HaPPY code — builds a holographic code from a tensor network on a hyperbolic tiling whose elementary cell is a single *perfect tensor*. We define the perfect tensor, prove the properties on which everything hinges, exhibit operator pushing explicitly, and verify the toy RT formula by counting.

Definition 56.43 (Perfect tensor)**.** A tensor $T_{a_1\cdots a_{2n}}$ with $2n$ legs, each of bond dimension v (so $a_i \in \{1,\dots,v\}$), is *perfect* if for every bipartition of its legs into a set S and its complement S^c with $|S| \le |S^c|$, the tensor, viewed as a linear map $T : \mathcal{H}_S \to \mathcal{H}_{S^c}$ from the legs in S to those in S^c, is proportional to an isometry:

$$T_S^\dagger T_S = v^{\,|S|}\,\mathbf{1}_{\mathcal{H}_S}. \tag{56.202}$$

Equivalently, the pure state $|T\rangle = \sum T_{a_1\cdots a_{2n}}\,|a_1\cdots a_{2n}\rangle$ on $2n$ parties is *absolutely maximally entangled*: the reduced state on any $k \le n$ legs is maximally mixed, $\rho_S = v^{-k}\mathbf{1}$.

Perfectness packs in one stroke the two properties we need. First, *maximal entanglement across every balanced cut* — this will produce the RT counting. Second, the *isometry/pushing property*: because T is an isometry from any small set of legs to the rest, an operator inserted on one set of legs can be transported across the tensor to an equivalent operator on a complementary set, the discrete analogue of HKLL transport.

The atom: a six-leg perfect tensor is the five-qubit code. Take $n = 3$, $v = 2$: a perfect tensor with six qubit legs. Designate one leg the *bulk* (logical) input and the remaining five the *boundary* (physical) outputs. The isometry from the one bulk leg to the five boundary legs is, with the standard choice of perfect tensor, exactly the encoding of the *five-qubit code* $[[5, 1, 3]]$: one logical

qubit protected in five physical qubits, with code distance 3. Its stabilizer group is generated by the four cyclic translates

$$g_1 = XZZXI, \quad g_2 = IXZZX, \quad g_3 = XIXZZ, \quad g_4 = ZXIXZ, \tag{56.203}$$

and the logical operators may be taken as $\bar{X} = XXXXX$ and $\bar{Z} = ZZZZZ$. (Here a string like $XZZXI$ means $X_1 Z_2 Z_3 X_4 I_5$, the tensor product of single-qubit Paulis.) Distance 3 means the minimum weight of a nontrivial logical operator is 3: no operator supported on two or fewer qubits acts nontrivially on the logical information. As an *erasure* code this means any 2 of the 5 physical qubits may be lost and the logical qubit is still perfectly recoverable from the remaining 3.

Worked Example 56.44 (Operator pushing, complementary recovery, and the toy RT formula in the $[[5, 1, 3]]$ code)**.** We make every structural claim of Section 56.7.3 explicit in this one tensor.

Pushing a logical operator onto three qubits. The logical $\bar{X} = XXXXX$ has weight 5, but it is equivalent, modulo the stabilizer group, to lower-weight representatives — this is the "cleaning" that realizes reconstruction on a subregion. Multiply $\bar{X}$ by the stabilizer $g_1 g_2$. First,

$$g_1 g_2 = (XZZXI)(IXZZX) = X\,(ZX)\,(ZZ)\,(XZ)\,X \propto X\,Y\,I\,Y\,X, \tag{56.204}$$

using $ZX = -iY$, $ZZ = I$, $XZ = -iY$ leg by leg (phases are immaterial for the support). Then

$$\bar{X}\,(g_1 g_2) = (XXXXX)(XYIYX) \propto I\,Z\,X\,Z\,I, \tag{56.205}$$

using $XX = I$ on legs $1, 5$, $XY = iZ$ on legs $2, 4$, and $XI = X$ on leg 3. Since $g_1 g_2$ is in the stabilizer, $\bar{X}\,(g_1 g_2)$ acts identically to $\bar{X}$ on every codeword: the logical $\bar{X}$ has a representative

$$\bar{X} \;\cong\; Z_2\, X_3\, Z_4, \tag{56.206}$$

supported on the three qubits $\{2, 3, 4\}$ only. By the cyclic symmetry of the code, $\bar{X}$ (and likewise $\bar{Z}$) has a weight-3 representative on *every* consecutive triple of qubits. This is operator pushing in the flesh: the bulk (logical) operator is transported, through the perfect tensor's isometry, onto a chosen set of three boundary legs.

Complementary recovery. Split the five boundary qubits into $A = \{2, 3, 4\}$ and $\bar{A} = \{1, 5\}$. By Eq. (56.206) (and its $\bar{Z}$ analogue) both logical operators have representatives supported entirely on A, so the logical qubit is reconstructable on A: the bulk operator sits in the entanglement wedge of A. Meanwhile $\bar{A}$ has only

two qubits, and distance 3 forbids any nontrivial logical operator of weight ≤ 2, so nothing logical is reconstructable on $\bar{A}$: the bulk operator is *not* in the wedge of $\bar{A}$. This is exactly the complementary-recovery dichotomy of Theorem 56.40, now a one-line consequence of the code distance. It also realizes the paradox and its resolution: the logical operator has a representative on $\{2,3,4\}$ and, by cyclic symmetry, another on the disjoint-from-$\{2,3,4\}$ portion of some other triple; these representatives commute and agree on codewords while differing off-code, precisely Eq. (56.198).

The toy RT formula by counting. Encode a fixed pure logical state, so the five-qubit physical state $\left|\bar{\psi}\right\rangle$ is pure and the "bulk" carries no entropy. For a boundary region R of the physical qubits, compute $S(R) = -\operatorname{Tr}(\rho_R \log \rho_R)$. Because the code has distance 3, the reduced density matrix on any set of ≤ 2 qubits is independent of the logical state — it carries no logical information — and by the maximal entanglement of the underlying perfect tensor it is maximally mixed: $\rho_R = 2^{-|R|}\mathbf{1}$ for $|R| \leq 2$. Hence

$$S(R) = |R| \log 2 \quad (|R| \leq 2), \qquad S(A) = S(\bar{A}) = 2\log 2 \text{ for } A = \{2,3,4\},\ \bar{A} = \{1,5\}, \tag{56.207}$$

the second equality by purity of $\left|\bar{\psi}\right\rangle$ ($S(A) = S(\bar{A})$). Now read this as a Ryu–Takayanagi count. In a tensor network the entropy of a boundary region is the *minimal cut*: the least number of bonds one must sever to disconnect R from its complement, times $\log v$. For the single six-leg tensor the surface homologous to R cuts exactly $\min(|R|, |\bar{R}|)$ legs (the homology constraint allows cutting either R's own legs or its complement's, and minimization picks the smaller set), so the toy RT formula gives

$$S_{\mathrm{RT}}(R) = \left[\min(|R|, |\bar{R}|_{\mathrm{boundary}})\right] \log 2, \tag{56.208}$$

which for $A = \{2,3,4\}$ ($|A| = 3$, complement two boundary legs) gives $2\log 2$, matching Eq. (56.207) exactly. The minimal cut that achieves it passes on the $\bar{A} = \{1,5\}$ side, severing two legs; the entanglement wedge of A is everything on the far side of that cut, which is the bulk leg — so the bulk qubit is in $\mathcal{W}_A$, in agreement with the operator-pushing result. The FLM split is visible too: with a fixed pure logical input the bulk entropy vanishes and $S(A) = (\text{cut area}) \log 2$; promote the bulk leg to an entangled state with an external reference and $S(A)$ acquires the extra bulk-entanglement term $S^{\mathrm{bulk}}_{\mathcal{W}_A}$, exactly $S = \langle \mathrm{Area} \rangle / 4G_N + S^{\mathrm{bulk}}$ in miniature.

Figure 56.10 shows how the single tensor scales up. Tiling the hyperbolic disk with perfect-tensor pentagons and contracting all in-plane legs produces an isometry V from the collection of dangling bulk legs to the boundary legs. The reconstruction of any bulk leg is performed by the *greedy algorithm*: starting from

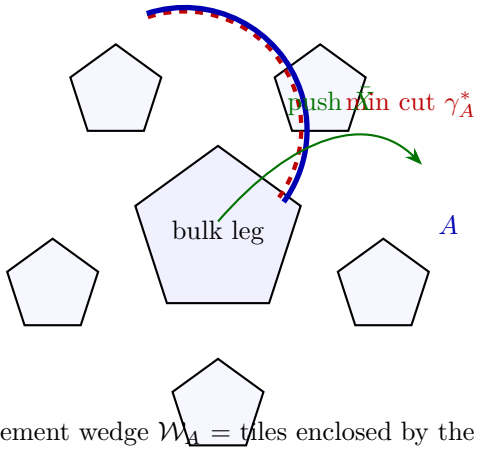

Figure 56.10: The HaPPY holographic code on a pentagon ($\{5,4\}$) tiling of the hyperbolic disk. Each pentagon is a six-leg perfect tensor: five legs contract with neighbors, one "bulk" leg (centre) injects a logical qubit. Contracting the network builds the encoding isometry V from bulk legs to the boundary legs (outer edge). For a boundary region A, the discrete RT surface is the *greedy geodesic* — the minimal-cut bond set (dashed) — and the entanglement wedge $\mathcal{W}_A$ is the set of tiles it encloses. A logical operator on a bulk tile is pushed (arrow), through the perfect-tensor isometries, out to a representative supported on A, realizing entanglement-wedge reconstruction; cutting the fewest bonds reproduces the RT formula $S(A) = (\#\text{cut bonds}) \log v$.

a boundary region A, absorb any tensor that has at least half of its legs already in the reconstructed set (each such absorption is an isometry one can invert, i.e. a pushing step), and iterate until no more can be added. The frontier where the algorithm halts is the *greedy geodesic*, the network's discrete RT surface, and the set of tensors swallowed is the entanglement wedge $\mathcal{W}_A$. Every bulk operator on a tile inside $\mathcal{W}_A$ is reconstructable on A by composing the pushing steps; the count of bonds the greedy geodesic severs, times $\log v$, is the entropy $S(A)$, with equality whenever the residual perfect-tensor entanglement saturates the cut. The model thus reproduces, exactly and finitely, every feature established abstractly in this section: an exact RT relation, erasure (entanglement-wedge) reconstruction, complementary recovery, and the radial-commutativity resolution of overlapping representations.

Caution

The HaPPY code is a faithful cartoon, not the real thing. Its entanglement spectrum is flat (all RT-counted entropies are integers times $\log v$), so it captures the leading area term but not the continuous bulk-matter

corrections of FLM except by hand; its "geometry" is fixed and rigid, with no dynamical gravitational backreaction; and it has no time direction, hence no notion of the covariant HRT surface. It is an exact model of the *kinematics* of holographic encoding — which is precisely what we needed to make "bulk reconstruction is error correction" a theorem about a concrete object rather than a slogan. The dynamical content is supplied elsewhere.

We now hold a fully mechanical picture of how the bulk lives inside the boundary: as a quantum error-correcting code in which local bulk operators are redundantly encoded logical operators, the recoverable region is the entanglement wedge, and the boundary of recoverability is the RT surface whose area measures the entropy. What remains is to let this picture do dynamical work. If the connectivity of bulk spacetime is the entanglement structure of the boundary, then changing the entanglement must change the geometry — and the next section turns that observation into the chapter's culminating result, deriving the linearized Einstein equations of the bulk from the first law of entanglement on the boundary, before surveying the tensor-network and ER = EPR pictures and dating the open frontier handed to Chapter 57.

56.8 Spacetime from entanglement: synthesis and frontier

The previous section taught the operational lesson of the chapter: the bulk is not merely correlated with the boundary, it is *encoded* in it, and encoded in the precise manner of a quantum error-correcting code, with the entanglement wedge as the recoverable region and the entanglement structure of the boundary state as the redundancy that protects it (Section 56.7 and Theorem 56.33). The HaPPY pentagon code (Section 56.7.4) made this concrete in a finite model: bulk information survives the erasure of any boundary subregion small enough to leave the relevant wedge intact, exactly because the boundary state is highly entangled. Read forward, that statement is startling. If the bulk geometry is reconstructed from boundary entanglement, then the geometry should not exist independently of that entanglement — it should be *made of* it. This closing section makes the slogan precise and then dates what remains unknown. We prove the sharpest available version of "spacetime is built from entanglement": that the bulk Einstein equation, linearized about pure anti–de Sitter space, is not an independent dynamical postulate but a rewriting of the first law of entanglement on the boundary, holding for every ball-shaped region. We then survey two pictures — Van Raamsdonk's disentangling thought experiment with its tensor-network/MERA discretization, and the ER = EPR slogan — that extend the lesson to the connectivity and topology of spacetime, stating each

honestly within its scope. We close with a dated summary of the open problems this static, kinematic story hands to the dynamical sequel of Chapter 57.

56.8.1 The first law of entanglement

Everything in this section rests on a single near-trivial identity of quantum statistical mechanics, applied to the reduced density matrix of a region. Recall (Theorem 55.28) that for a state ρ reduced to a region A, the *modular Hamiltonian* is the Hermitian operator

$$K_A \;=\; -\ln \rho_A \qquad \text{(up to an additive constant)}, \tag{56.209}$$

the generator whose Gibbs weight e^{-K_A} reproduces ρ_A and whose flow ρ_A^{is} is modular flow. Fix a reference state $\sigma_A = e^{-K_A}$ on A — in all our applications the vacuum reduced to A — and consider a one-parameter family $\rho_A(\lambda)$ of nearby states with $\rho_A(0) = \sigma_A$. Write the entanglement entropy $S(\rho_A) = -\operatorname{Tr}(\rho_A \ln \rho_A)$ and the modular energy $\langle K_A \rangle_\rho = \operatorname{Tr}(\rho_A K_A)$, where K_A is the *fixed* modular Hamiltonian of the reference state σ_A.

Proposition 56.45 (First law of entanglement)**.** *Let $\rho_A = \sigma_A + \delta\rho_A$ be a first-order deformation of the reference state $\sigma_A = e^{-K_A}$ on a region A, with $\operatorname{Tr}\,\delta\rho_A = 0$ (normalization preserved). Then the first-order change in entanglement entropy equals the first-order change in modular energy,*

$$\boxed{\;\delta S(A) \;=\; \delta\langle K_A \rangle\;,\;} \tag{56.210}$$

where $\delta S(A) = S(\rho_A) - S(\sigma_A)$ and $\delta\langle K_A\rangle = \operatorname{Tr}(\delta\rho_A\, K_A)$, both to first order in $\delta\rho_A$.

Proof. Vary the von Neumann entropy directly. With $S = -\operatorname{Tr}(\rho_A \ln \rho_A)$,

$$\delta S \;=\; -\operatorname{Tr}(\delta\rho_A\, \ln \rho_A) \;-\; \operatorname{Tr}(\rho_A\, \delta \ln \rho_A). \tag{56.211}$$

The second term vanishes: using $\delta \ln \rho_A = \rho_A^{-1}\delta\rho_A$ to leading order (more carefully, $\operatorname{Tr}(\rho_A\, \delta \ln \rho_A) = \operatorname{Tr}\,\delta\rho_A$ by the cyclicity that the spectral integral for ln enforces under the trace), we get $\operatorname{Tr}(\rho_A\, \delta \ln \rho_A) = \operatorname{Tr}\,\delta\rho_A = 0$ by the normalization condition. In the first term, evaluate $\ln \rho_A$ on the reference state, $\ln \rho_A \to \ln \sigma_A = -K_A$ to leading order, since the difference is itself first order and multiplies the first-order $\delta\rho_A$. Hence

$$\delta S \;=\; -\operatorname{Tr}(\delta\rho_A\, \ln \sigma_A) \;=\; \operatorname{Tr}(\delta\rho_A\, K_A) \;=\; \delta\langle K_A\rangle, \tag{56.212}$$

which is Eq. (56.210). □

The first law is the linearization of a deeper, exact, non-perturbative inequality the reader already met in Chapter 55: the positivity of relative entropy. With $S(\rho_A \,\|\, \sigma_A) = \mathrm{Tr}(\rho_A \ln \rho_A) - \mathrm{Tr}(\rho_A \ln \sigma_A) = \Delta\langle K_A\rangle - \Delta S \geq 0$ (Section 55.6), where Δ denotes the full difference from the reference state, one has the *exact* statement $\Delta S \leq \Delta\langle K_A\rangle$ for any deformation (the entanglement form of the Clausius inequality, Section 55.6.1). Relative entropy is non-negative and vanishes at the reference state, so it is second order in $\delta\rho_A$; its first-order part is therefore zero, and that is precisely Eq. (56.210). The first law is the saturation of the Clausius inequality at linear order. We will use the equality Eq. (56.210) to derive Einstein's equation; the inequality $\Delta S \leq \Delta\langle K\rangle$ at second order is what feeds the bulk energy conditions of Section 56.6.

What makes Eq. (56.210) powerful holographically is that for ball-shaped regions in the vacuum of a CFT, the right-hand side $\delta\langle K_A\rangle$ is an explicit, *local* integral of the boundary stress tensor, and the left-hand side δS is, by Ryu–Takayanagi, an explicit geometric quantity in the bulk. Setting two explicit objects equal, for every ball, is a strong constraint. We assemble the two sides in turn.

56.8.2 The modular Hamiltonian of a ball

The right-hand side of the first law requires the modular Hamiltonian of the vacuum reduced to a ball. We import the one nontrivial case where it is known in closed form: the Casini–Huerta–Myers (CHM) result, derived in Chapter 55 (Theorem 55.49 and Eq. (55.197)) by conformally mapping the ball's causal development onto a Rindler wedge and transporting the boost generator that Bisognano and Wichmann (Theorem 55.25) identified as the wedge modular Hamiltonian. We restate it because every factor matters for the derivation to follow.

For a ball B of radius R centred at the spatial origin on the time slice $t = 0$ of the vacuum of a CFT_d with stress tensor $T_{\mu\nu}$, the modular Hamiltonian is the local operator

$$K_B \;=\; 2\pi \int_B \mathrm{d}^{\,d-1}x\, \frac{R^2 - r^2}{2R}\, T_{00}(x) \;+\; \text{const}, \qquad r^2 = \sum_i (x^i)^2, \tag{56.213}$$

the energy density weighted by the function $(R^2 - r^2)/2R$ that vanishes on the entangling sphere $r = R$ and peaks at the centre. This weight is the time component of a conformal Killing vector. The causal diamond $\mathcal{D}_B$ of the ball — its domain of dependence — is preserved by a one-parameter conformal flow whose generator is, in boundary coordinates $(t, \vec{x})$,

$$\xi_B \;=\; \frac{2\pi}{R}\left[\frac{R^2 - t^2 - r^2}{2}\,\partial_t \;-\; t\,x^i\,\partial_i\right], \tag{56.214}$$

normalized so that $\rho_B = e^{-K_B}$ generates modular flow with the geometric flow of ξ_B, equivalently so that the flow has unit "surface gravity" 2π at the entangling surface (the Unruh temperature $1/2\pi$ of Eq. (55.83) in modular time). Evaluated at $t=0$, the time component is $\xi_B^t|_{t=0} = \frac{2\pi}{R}\cdot\frac{R^2-r^2}{2}$, which is exactly the weight in Eq. (56.213): the modular Hamiltonian is the conserved charge $K_B = \int_B \xi_B^\mu T_{\mu 0}\,\mathrm{d}^{d-1}x$ of the conformal Killing flow. That ξ_B is a genuine conformal Killing vector of Minkowski space — the property that makes K_B local — is worth verifying explicitly, since the whole derivation hinges on it.

Worked Example 56.46 (ξ_B is a conformal Killing vector vanishing on the entangling surface)**.** We check that ξ_B of Eq. (56.214) satisfies the conformal Killing equation $\partial_\mu\xi_\nu + \partial_\nu\xi_\mu = \frac{2}{d}\,\eta_{\mu\nu}\,(\partial_\alpha\xi^\alpha)$ in the mostly-minus metric $\eta = \mathrm{diag}(+,-,\dots,-)$, and vanishes on the edge of the diamond.

Write $a \equiv 2\pi/R$, so the contravariant components are $\xi^t = \frac{a}{2}(R^2 - t^2 - r^2)$ and $\xi^i = -a\,t\,x^i$. Lower indices with η: $\xi_t = \xi^t$ and $\xi_i = -\xi^i = a\,t\,x^i$ (a spatial index lowered flips the sign). First compute the divergence,

$$\partial_\alpha\xi^\alpha = \partial_t\xi^t + \partial_i\xi^i = \tfrac{a}{2}(-2t) + (-a\,t\,\delta_i^{\,i}) = -a\,t - a\,t\,(d-1) = -a\,t\,d, \quad (56.215)$$

so the right-hand side of the conformal Killing equation is $\frac{2}{d}\,\eta_{\mu\nu}(-a\,t\,d) = -2a\,t\,\eta_{\mu\nu}$. Now the left-hand side, component by component. The time–time component:

$$\partial_t\xi_t + \partial_t\xi_t = 2\,\partial_t\Big[\tfrac{a}{2}(R^2 - t^2 - r^2)\Big] = -2a\,t = -2a\,t\,\eta_{tt}, \quad (56.216)$$

matching, since $\eta_{tt} = +1$. A spatial–spatial component (i,j), using $\xi_i = a\,t\,x^i$:

$$\partial_i\xi_j + \partial_j\xi_i = a\,t\,\delta_j^i + a\,t\,\delta_i^j = 2a\,t\,\delta_{ij} = -2a\,t\,\eta_{ij}, \quad (56.217)$$

matching, since $\eta_{ij} = -\delta_{ij}$. The mixed component (t,i):

$$\partial_t\xi_i + \partial_i\xi_t = \partial_t(a\,t\,x^i) + \partial_i\Big[\tfrac{a}{2}(R^2 - t^2 - r^2)\Big] = a\,x^i + \tfrac{a}{2}(-2x^i) = a\,x^i - a\,x^i = 0, \quad (56.218)$$

matching $-2a\,t\,\eta_{ti} = 0$. All components satisfy the conformal Killing equation, so ξ_B generates a conformal isometry. Finally, on the edge of the causal diamond at $t=0$, $r=R$, both $\xi^t = \frac{a}{2}(R^2-R^2) = 0$ and $\xi^i = -a\cdot 0\cdot x^i = 0$, so ξ_B vanishes on the entangling sphere ∂B. The flow therefore has a fixed locus precisely at ∂B, around which it acts as a boost — the boundary footprint of the bulk Killing horizon we build next.

With Eq. (56.213) in hand the right-hand side of the first law is explicit. For a state ρ that perturbs the vacuum by turning on a stress-tensor expectation value $\langle T_{\mu\nu}\rangle$, the change in modular energy of the ball is

$$\delta\langle K_B\rangle \;=\; 2\pi\int_B \mathrm{d}^{\,d-1}x\,\frac{R^2-r^2}{2R}\,\langle T_{00}(x)\rangle, \quad (56.219)$$

a known functional of the boundary energy density, parameterized by the ball's radius R and centre (and, by boosting, by its rest frame). The first law Eq. (56.210) now reads $\delta S(B) = \delta\langle K_B\rangle$ for every such ball. It remains to compute the left-hand side from the bulk.

56.8.3 Linearized Einstein equations from the first law

We work in pure AdS_{d+1} as the bulk dual of the CFT vacuum, in Poincaré coordinates with the mostly-minus boundary metric,

$$\mathrm{d}s^2_{\mathrm{AdS}} = \frac{L^2}{z^2}(\eta_{\mu\nu}\,\mathrm{d}x^\mu \mathrm{d}x^\nu - \mathrm{d}z^2), \qquad \eta = \mathrm{diag}(+,-,\ldots,-), \tag{56.220}$$

and perturb the metric by $g = g_{\mathrm{AdS}} + h$, with h a linearized perturbation whose normalizable falloff near $z \to 0$ encodes the boundary stress tensor through the standard dictionary of Section 54.6: $h_{\mu\nu} \to \frac{16\pi G_N}{d}\, L^{3-d}\, z^{d-2}\, \langle T_{\mu\nu}\rangle + \cdots$ as $z \to 0$. The dual statement of the first law is a statement about h, and the claim is that h obeys the linearized Einstein equation if and only if the first law holds for every ball. We assemble the two sides geometrically.

The bulk Killing vector and the AdS–Rindler wedge. The boundary conformal Killing vector ξ_B of Eq. (56.214) is the boundary restriction of an exact bulk Killing vector of pure AdS_{d+1}, because boundary conformal isometries are bulk isometries (Section 53.3). Explicitly, the bulk extension is

$$\widehat{\xi}_B \;=\; \frac{2\pi}{R}\left[\frac{R^2 - t^2 - r^2 - z^2}{2}\,\partial_t \;-\; t\,x^i\,\partial_i \;-\; t\,z\,\partial_z\right], \tag{56.221}$$

the unique AdS Killing vector that reduces to ξ_B at $z \to 0$. Its fixed-point set, where all components vanish at $t = 0$, is the hemisphere

$$\widehat{\xi}_B = 0 \text{ at } t = 0 \iff r^2 + z^2 = R^2, \tag{56.222}$$

which is exactly the Ryu–Takayanagi surface γ_B of the ball in the vacuum — the bulk hemisphere anchored on ∂B that the single-interval semicircle of Section 56.1.4 generalizes to d dimensions. The Killing vector $\widehat{\xi}_B$ generates a boost about this hemisphere: γ_B is the bifurcation surface of a bulk Killing horizon, with surface gravity 2π. The wedge of the bulk that $\widehat{\xi}_B$ keeps within itself — the domain of outer communication of this horizon — is the entanglement wedge $\mathcal{W}_B$ of the ball (Theorem 56.31); in the vacuum it is the AdS–Rindler wedge. This is the kinematic miracle that makes the derivation go through: the modular flow of a ball is geometric not only on the boundary but in the bulk, realized as a Killing boost whose horizon is the RT surface.

The entropy side as a Killing energy. The left-hand side of the first law is $\delta S(B) = \delta\,\mathrm{Area}(\gamma_B)/4G_N$, the linearized change in the area of the RT surface (Eq. (56.4)). Because γ_B is *extremal*, the first-order change in its area receives no contribution from the first-order displacement of the surface — that is the definition of extremality, $\delta\,\mathrm{Area}/\delta X^\mu = 0$ — so $\delta\,\mathrm{Area}$ is computed by holding the surface fixed and varying only the metric:

$$\delta\,\mathrm{Area}(\gamma_B) = \frac{1}{2}\int_{\gamma_B} \mathrm{d}^{\,d-1}\sigma\,\sqrt{h_{(\gamma)}}\;h^{ab}_{(\gamma)}\,\delta g_{ab}, \tag{56.223}$$

where $h_{(\gamma)ab}$ is the unperturbed induced metric on γ_B and δg_{ab} the induced metric perturbation. This is a bulk-data integral localized on the surface. To compare it with the boundary modular energy we use the conserved structure supplied by the Killing vector.

The Iyer–Wald identity. Diffeomorphism-invariant gravity carries, for any vector field ζ, a Noether machinery we now invoke. From the Einstein–Hilbert Lagrangian $(d+1)$-form $\mathbf{L} = \frac{1}{16\pi G_N}(R - 2\Lambda)\,\boldsymbol{\epsilon}$, a variation gives $\delta\mathbf{L} = \mathbf{E}\,\delta g + \mathrm{d}\boldsymbol{\theta}(\delta g)$, defining the equations of motion $\mathbf{E}$ (the Einstein tensor plus matter) and the symplectic potential (d)-form $\boldsymbol{\theta}$. For a vector ζ the Noether current $\mathbf{J}_\zeta = \boldsymbol{\theta}(\mathcal{L}_\zeta g) - i_\zeta \mathbf{L}$ can be written, on using the identities of the formalism, as $\mathbf{J}_\zeta = \mathrm{d}\mathbf{Q}_\zeta + \zeta^\mu \mathbf{C}_\mu$, with $\mathbf{Q}_\zeta$ the Noether charge $(d-1)$-form and $\mathbf{C}_\mu$ the constraint forms that vanish on-shell ($\mathbf{C}_\mu \propto$ Einstein's equation contracted with one index). The *fundamental variational identity* of Iyer and Wald states that for a background Killing vector ζ (so $\mathcal{L}_\zeta g = 0$) and an arbitrary linear perturbation δg,

$$\mathrm{d}\big(\delta\mathbf{Q}_\zeta - i_\zeta\boldsymbol{\theta}(\delta g)\big) \;=\; -\,\zeta^\mu\,\delta\mathbf{C}_\mu, \tag{56.224}$$

where $\delta\mathbf{C}_\mu$ is the *linearized constraint* — precisely the linearized Einstein equation, $\delta\mathbf{C}_\mu \propto \big(\delta G_{\mu\nu} - 8\pi G_N\,\delta T^{\mathrm{bulk}}_{\mu\nu}\big)$ projected onto a slice. Integrate Eq. (56.224) over a bulk Cauchy slice Σ_B of the entanglement wedge, whose boundary is the union of the asymptotic boundary region B and the RT surface γ_B. Stokes' theorem turns the left-hand side into a difference of boundary integrals:

$$\underbrace{\int_B \big(\delta\mathbf{Q}_{\widehat{\xi}_B} - i_{\widehat{\xi}_B}\boldsymbol{\theta}\big)}_{\equiv\;\delta H^{\partial}_{\widehat{\xi}_B}} \;-\; \underbrace{\int_{\gamma_B} \big(\delta\mathbf{Q}_{\widehat{\xi}_B} - i_{\widehat{\xi}_B}\boldsymbol{\theta}\big)}_{\equiv\;\delta H^{\gamma}_{\widehat{\xi}_B}} \;=\; -\int_{\Sigma_B} \widehat{\xi}^{\,\mu}_B\,\delta\mathbf{C}_\mu. \tag{56.225}$$

The two boundary terms have transparent meanings.

On the RT surface γ_B, the Killing vector vanishes (Eq. (56.222)), so $i_{\widehat{\xi}_B}\boldsymbol{\theta} = 0$ there, and Wald's theorem evaluates the remaining Noether-charge integral as the surface gravity times the area: with $\kappa = 2\pi$,

$$\delta H^{\gamma}_{\widehat{\xi}_B} = \int_{\gamma_B} \delta\mathbf{Q}_{\widehat{\xi}_B} = \frac{\kappa}{2\pi}\,\delta\!\left(\frac{\mathrm{Area}(\gamma_B)}{4G_N}\right) = \delta\!\left(\frac{\mathrm{Area}(\gamma_B)}{4G_N}\right) = \delta S(B), \tag{56.226}$$

which is exactly the entropy side of the first law (and reproduces Eq. (56.223) on unpacking the Noether charge for Einstein gravity). On the asymptotic boundary B, the integral $\delta H^{\partial}_{\widehat{\xi}_B}$ is the canonical energy conjugate to the bulk Killing vector $\widehat{\xi}_B$. Evaluated with the near-boundary falloff of h and the dictionary $h \sim \langle T_{\mu\nu}\rangle$, this canonical energy is precisely the boundary integral of the energy density weighted by the boundary restriction ξ_B of $\widehat{\xi}_B$ — which by Eq. (56.219) is the change in the ball's modular energy:

$$\delta H^{\partial}_{\widehat{\xi}_B} = \int_B \xi_B^{\mu} \langle \delta T_{\mu 0}\rangle \, \mathrm{d}^{d-1}x = \delta\langle K_B\rangle. \tag{56.227}$$

This is the holographic content of the JLMS relation $K_B = \widehat{\mathrm{Area}}/4G_N + K^{\mathrm{bulk}}$ (Eq. (56.164) and Theorem 56.35): the boundary modular Hamiltonian equals the bulk gravitational charge of $\widehat{\xi}_B$, whose area part sits on γ_B and whose bulk-matter part fills the wedge.

The equivalence. Substituting Eqs. (56.226) and (56.227) into the integrated identity Eq. (56.225) gives the exact, off-shell relation

$$\delta\langle K_B\rangle - \delta S(B) \;=\; -\int_{\Sigma_B} \widehat{\xi}_B^{\mu}\, \delta\mathbf{C}_{\mu} \;\propto\; \int_{\Sigma_B} \widehat{\xi}_B^{\mu}\, (\delta G_{\mu\nu} - 8\pi G_N\, \delta T^{\mathrm{bulk}}_{\mu\nu})\, \mathrm{d}\Sigma^{\nu}. \tag{56.228}$$

This is the hinge of the entire chapter, and the two readings of it are the two halves of the synthesis.

Theorem 56.47 (Linearized Einstein equations from the first law of entanglement)**.** *Let h be a linearized metric perturbation of pure AdS_{d+1} with normalizable falloff encoding a boundary stress tensor $\langle T_{\mu\nu}\rangle$, and let $\delta S(B)$ be the corresponding first-order change in the Ryu–Takayanagi entropy of a boundary ball B. Then the entanglement first law*

$$\delta S(B) = \delta\langle K_B\rangle \quad \textit{holds for} \text{ every } \textit{ball } B \textit{ (all radii, centres, and Lorentz frames)} \tag{56.229}$$

if and only if *the bulk perturbation satisfies the linearized Einstein equation*

$$\boxed{\delta G_{\mu\nu}(h) \;=\; 8\pi G_N\, \delta T^{\,bulk}_{\mu\nu}} \tag{56.230}$$

everywhere in the bulk. In particular, given that the boundary CFT obeys the first law as a theorem of quantum mechanics (Theorem 56.45), the dual bulk geometry necessarily obeys linearized Einstein gravity. Bulk gravitational dynamics, to this order, is an entanglement identity.

Proof. ($\Leftarrow$) If Eq. (56.230) holds, the linearized constraint $\delta\mathbf{C}_{\mu}$ vanishes throughout the bulk, so the right-hand side of Eq. (56.228) is zero for every ball, giving $\delta S(B) = \delta\langle K_B\rangle$.

($\Rightarrow$) Suppose the first law holds for every ball. Then the left-hand side of Eq. (56.228) vanishes for the bulk Killing vector $\widehat{\xi}_B$ of every ball:

$$\int_{\Sigma_B} \widehat{\xi}_B^{\,\mu} \left(\delta G_{\mu\nu} - 8\pi G_N\, \delta T^{\text{bulk}}_{\mu\nu}\right) \mathrm{d}\Sigma^{\nu} = 0 \qquad \text{for all balls } B. \tag{56.231}$$

This is an integral transform of the local bulk tensor $E_{\mu\nu} \equiv \delta G_{\mu\nu} - 8\pi G_N \delta T^{\text{bulk}}_{\mu\nu}$: as the ball's radius, centre, and boost are varied, the wedges Σ_B sweep out a neighbourhood of every bulk point, and the Killing vectors $\widehat{\xi}_B$ probe every direction and every weighting through that point. The map from the local symmetric tensor field $E_{\mu\nu}$ to the family of integrals Eq. (56.231) is injective: a smooth tensor whose $\widehat{\xi}_B$-weighted flux through every such wedge vanishes must vanish pointwise. (Concretely, one differentiates Eq. (56.231) twice with respect to the radius R at $R \to 0$, which localizes the integral onto the tip of an infinitesimal wedge and returns $E_{\mu\nu}$ at the corresponding bulk point contracted with the local boost generator; ranging over centres and frames then exhausts all components.) Hence $E_{\mu\nu} = 0$ everywhere, which is Eq. (56.230). □

Physical Insight

The logic is worth stating without the machinery. On the boundary, the first law $\delta S = \delta\langle K\rangle$ is a triviality of quantum mechanics — it is the statement that, to first order, the entropy of a slightly perturbed state tracks the energy you put in, weighted by the modular Hamiltonian. It contains no physics beyond linear algebra. Holographically, the *same* triviality, demanded of every ball-shaped region, becomes the linearized Einstein equation of the bulk metric. The equation of motion of geometry is not an extra law layered on top of the duality; it is the boundary's first law of entanglement, rewritten in bulk variables. "Spacetime is built from entanglement" is, at the level of dynamics and to linear order, this theorem: vary the entanglement, and the geometry must respond exactly as Einstein's equation says, on pain of violating a tautology about density matrices.

Two scope statements keep the theorem honest. First, it is a *linearized* statement: it derives Einstein's equation expanded to first order about the AdS vacuum. The nonlinear equation has been recovered to second order (where the entanglement inequality $\Delta S \le \Delta\langle K\rangle$, not just its first-order saturation, plays a role, and the bulk gravitational energy becomes the canonical energy of Hollands–Wald), and there are arguments to all orders, but a clean "full nonlinear Einstein equation from entanglement" derivation valid for arbitrary states remains a frontier item dated below. Second, the inversion step that turns the family of ball identities into a local bulk equation is an integral-geometry transform — morally a Radon transform over the space of balls — and its invertibility is the same kind

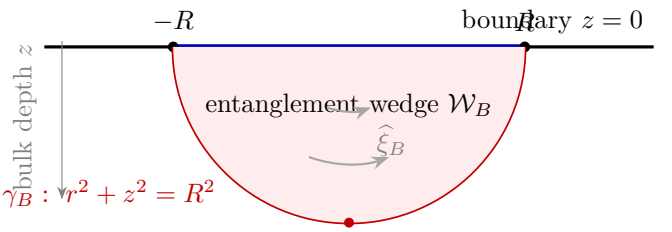

Figure 56.11: The geometry behind Theorem 56.47. A boundary ball B of radius R (blue) has Ryu–Takayanagi surface the bulk hemisphere $\gamma_B : r^2+z^2 = R^2$ (red), the bifurcation surface of the boost Killing horizon generated by $\widehat{\xi}_B$ (Eq. (56.221), grey flow). The entanglement wedge $\mathcal{W}_B$ (shaded) is the AdS–Rindler wedge it bounds. The Iyer–Wald identity Eq. (56.225) equates the change in horizon area $\delta\,\mathrm{Area}(\gamma_B)/4G_N = \delta S(B)$ to the boundary modular energy $\delta\langle K_B\rangle$ up to the bulk integral of the linearized Einstein equation; demanding the first law for every ball forces that bulk integral to vanish identically.

of completeness statement that underlies the analytic bootstrap's reconstruction of CFT data from its double discontinuity via the Lorentzian inversion formula (Theorem 51.16): in both cases a local object is recovered from a complete family of its integrals against a distinguished kernel. The parallel is structural rather than literal, but it situates the present result in the same circle of ideas, that boundary data, completely sampled, reconstructs a local bulk.

56.8.4 Connectivity is entanglement: Van Raamsdonk's argument

The first-law theorem governs the *shape* of a connected geometry. A complementary thought experiment, due to Van Raamsdonk, governs its very *connectedness*, and it follows from the two-interval computation of Section 56.2.4 run in reverse. There we found that the mutual information between two boundary regions A and B,

$$I(A:B) = S(A) + S(B) - S(A\cup B) \;\geq 0 \quad \text{(Theorem 55.13)}, \tag{56.232}$$

is computed holographically by the competition between a disconnected and a connected configuration of RT surfaces, and it *vanishes identically* once the regions are far enough apart that the disconnected surfaces win (Eq. (56.83)). The geometric event that turns I off is the dominant minimal surface changing topology: when no single surface spans both regions, they share no classical entanglement, and the bulk separating them has been pinched.

Run the logic backwards. Take a state with two entangled halves and ask what happens to the dual geometry as the entanglement is dialed away. The cleanest setting is the thermofield double of Chapter 54: two identical copies

CFT_L and CFT_R in the entangled pure state

$$|\mathrm{TFD}\rangle = \frac{1}{\sqrt{Z}} \sum_n e^{-\beta E_n/2} \, |n\rangle_L \otimes |n\rangle_R \,, \tag{56.233}$$

whose bulk dual is the eternal two-sided AdS–Schwarzschild black hole, a connected wormhole (Einstein–Rosen bridge) joining two asymptotic boundaries through a smooth interior (Section 54.4). The two boundaries do not interact; the only thing relating them is the entanglement in Eq. (56.233), and yet the bulk is a single connected spacetime through which a signal could in principle pass. Now imagine deforming the state to reduce the entanglement between the two copies — formally, lowering $I(\mathrm{CFT}_L : \mathrm{CFT}_R)$ by depopulating the Schmidt sum. The Ryu–Takayanagi surface for one entire boundary is the bifurcation surface of the horizon, whose area is the thermal entropy; reducing the cross-boundary entanglement shrinks this entropy and, by the area–entropy dictionary, the cross-sectional area of the wormhole throat. In the limit of vanishing mutual information the throat area goes to zero: the Einstein–Rosen bridge pinches off and the bulk splits into two disconnected geometries, one for each boundary, with no spacetime path between them.

Physical Insight

The conclusion is the chapter's deepest slogan made operational. The classical connectivity of the bulk spacetime is held together by boundary entanglement. Where two boundary subsystems are highly entangled, the bulk regions they anchor are joined by a fat bridge of geometry; as the entanglement is removed, the bridge thins and finally severs, and the two pieces of spacetime cease to be part of one manifold. Geometry is not the container of entanglement; it is the large-scale, coarse rendering of how the boundary degrees of freedom are entangled. The smooth, connected spacetime of classical general relativity is what a highly, structurally entangled quantum state looks like through the holographic dictionary.

This is sharpest where the mutual information is computable. For two intervals in a 2D CFT, Section 56.2.4 gives $I(A:B)$ exactly as a function of the cross-ratio, with the connected-to-disconnected transition at $\eta = \frac{1}{2}$ marking the threshold below which the bulk between A and B is pinched at leading order in G_N (Eq. (56.83)). The cross-sectional area of the bulk bridge between two regions is, more precisely, captured by the *entanglement wedge cross-section*, a minimal surface dividing the joint wedge $\mathcal{W}_{AB}$; it is nonzero exactly in the connected phase, is conjectured to compute the entanglement of purification and the reflected entropy of ρ_{AB}, and tracks $I(A:B)$ monotonically. The qualitative law — more entanglement, more connected geometry — is a theorem in these controlled cases and a robust expectation in general.

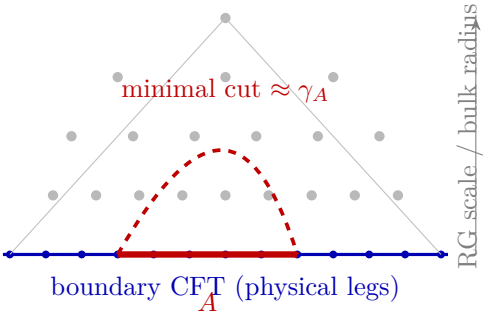

Figure 56.12: MERA as a discrete Ryu–Takayanagi geometry (Swingle). The boundary CFT wavefunction (blue, bottom) is built by layers of coarse-graining tensors; each layer is a step of entanglement renormalization, and the vertical direction is the renormalization-group scale, identified with the bulk radial coordinate (Section 54.6). The entanglement entropy of a boundary region A (red segment) is bounded by the minimal cut through the network (dashed), the curve severing the fewest bonds — the discrete image of the minimal surface γ_A, with $\ln \chi$ per bond standing in for $1/4G_N$ per unit area.

56.8.5 Tensor networks and MERA: a discretization of the geometry

If the geometry is built from entanglement, one should be able to build it, brick by brick, out of a discrete entanglement structure. The tensor network is exactly such a construction, and Swingle's observation is that the multiscale entanglement renormalization ansatz (MERA) for a CFT ground state is a discretization of the Ryu–Takayanagi geometry. A tensor network represents a many-body wavefunction $\Psi(s_1, \ldots, s_N)$ as a contraction of small tensors over internal "bond" indices; the bonds carry the entanglement, and the network's connectivity is a discrete geometry. The basic bound is purely linear-algebraic: for any bipartition of the physical legs into a region A and its complement, the entanglement entropy is bounded by the number of internal bonds one must cut to separate A from $\bar{A}$, times the logarithm of the bond dimension χ,

$$S(A) \;\le\; (\text{number of cut bonds along a curve separating } A) \times \ln \chi, \quad (56.234)$$

and the entropy is estimated by the *minimal* such cut — the curve through the network severing the fewest bonds. The minimal cut through a tensor network is the discrete analogue of the minimal surface, and Eq. (56.234) is the discrete analogue of the Ryu–Takayanagi formula $S(A) = \mathrm{Area}(\gamma_A)/4G_N$, with $\ln \chi$ per bond playing the role of $1/4G_N$ per unit area.

What makes MERA the *right* discretization, rather than a generic network, is its extra direction. MERA builds the ground-state wavefunction by alternating layers of "disentanglers," which remove short-range entanglement, and

"isometries," which coarse-grain — a literal real-space renormalization-group transformation. The depth into the network is therefore the RG scale, and identifying it with the bulk radial coordinate is exactly the holographic statement that the radial direction is energy scale (Section 54.6). A region A of n contiguous sites has a minimal cut that penetrates to depth $\sim \ln n$ into the network before the causal cones close off, giving $S(A) \sim \ln \chi \cdot \ln n$, the $(c/3)\ln(\ell/\varepsilon)$ scaling of a 2D CFT interval reproduced as a counting of cut bonds. The MERA is a hologram of the CFT vacuum drawn in tensors, and its geometry is the RT geometry to within the bond-counting approximation.

The min-cut characterization also explains, from a different angle, why RT computes an entropy. By the max-flow/min-cut duality of network theory, the minimal cut equals the maximal flow that can be routed from A to $\bar{A}$ through the bonds; in the continuum this becomes the "bit thread" reformulation of RT (Freedman–Headrick), in which $S(A)$ is the maximal flux of a divergenceless, norm-bounded vector field through A. The minimal surface and the maximal thread bundle are two faces of one optimization, and the bit-thread picture makes the entanglement inequalities of Section 56.3 — strong subadditivity in particular — nearly self-evident, since flows can be merged and split where surfaces must be recut. Tensor networks thus supply both a constructive model of geometry-from-entanglement and an explanation of the structural inevitability of the RT inequalities.

A caution closes the picture. The exact tensor-network models that realize holographic error correction cleanly — the HaPPY pentagon code of Section 56.7.4 and random-tensor networks — reproduce the RT formula and complementary recovery exactly, but on a fixed, rigid graph: they model a *fixed* geometry, not its dynamics, and the area operator in them is flat (it does not fluctuate as it must in a theory with a dynamical metric). MERA, conversely, captures the RG/scale structure but only bounds the entropy rather than computing it, and its geometry is closer to a light-cone (de Sitter-like) than to a spatial slice of AdS in some analyses. No known tensor network is simultaneously dynamical, exactly holographic, and Lorentzian. The networks are illuminating discretizations, not the continuum theory; how to take their continuum limit so that Einstein's equation of Theorem 56.47 emerges is an open problem.

56.8.6 ER = EPR

Van Raamsdonk's pinching argument has a vivid extrapolation, proposed by Maldacena and Susskind under the slogan ER = EPR: that entanglement and geometric connection are the *same thing* wherever both are defined. The thermofield double Eq. (56.233) is the cleanest instance — two boundaries maximally entangled (an EPR-like state), dual to a two-sided wormhole (an Einstein–Rosen bridge, ER) — and the equation of the slogan asserts that this identification is general: any entangled pair of systems is connected, at some level of descrip-

tion, by a geometric bridge, and conversely the smooth interior of a connected spacetime is the geometrization of the entanglement between the regions it joins. Pushed to the extreme, even a single EPR pair of particles would be joined by a (Planckian, non-traversable) wormhole.

The slogan must be stated with its scope visible, and the honest scope is narrow but real. As a statement about the two-sided eternal black hole it is precise and well supported: the wormhole geometry, the entanglement spectrum, and the modular flow all match (Section 54.4). As a heuristic organizing principle it has been productive — it predicts that the wormhole is non-traversable precisely because the entanglement, by itself, cannot transmit signals (consistent with no-faster-than-light communication between the two boundaries), and it frames the traversable-wormhole constructions, in which a direct coupling between the boundaries injects negative energy and briefly opens the throat, as the gravitational dual of quantum teleportation through the shared entanglement. As a literal claim about generic entangled states it is unproven and, taken naively, problematic: a generic low-entanglement or non-holographic state has no semiclassical geometric bridge at all, and the precise sense in which a single Bell pair "is" a wormhole has no controlled definition. The defensible content of ER = EPR is the one the rest of this section established with proofs: smooth, classical, connected bulk geometry is sustained by, and computes, boundary entanglement (Theorem 56.47 and Section 56.8.4). The wormhole language is the most striking dramatization of that content, valid sharply for the structured, large-entanglement states that have geometric duals, and to be treated as conjecture beyond them.

56.8.7 The dated frontier handed to Chapter 57

We have assembled a remarkably complete static picture: a boundary region's entanglement entropy is a bulk area (RT, Theorem 56.3); the correction is the bulk fields' own entropy (FLM, Eq. (56.139)); the whole is extremized as generalized entropy on a quantum extremal surface (Section 56.5.3); the boundary encodes the entanglement wedge as a quantum error-correcting code (Theorem 56.33 and Section 56.7.4); and the bulk's linearized equation of motion is the boundary's first law of entanglement (Theorem 56.47). It is essential, in the register this book keeps, to mark equally clearly what this picture does *not* settle as of the mid-2020s. The following are genuine open problems, not pedagogical omissions.

Hilbert-space factorization and edge modes. The derivations above repeatedly wrote "the reduced density matrix on a region" and "$\rho_A \otimes \rho_{\bar{A}}$," presupposing that the Hilbert space factorizes across the entangling surface as $\mathcal{H} = \mathcal{H}_A \otimes \mathcal{H}_{\bar{A}}$. In a gauge theory — and gravity is a gauge theory — it does not, exactly. Gauss's law correlates field configurations across any cut, the local algebras are type III von Neumann algebras with no factorization and no normalizable trace (Section 55.1.6), and the would-be tensor factorization must be supplied

by *edge modes*: extra degrees of freedom living on the entangling surface that restore a factorized description at the cost of a choice (a "center" of the algebra). The area term in RT is, from this angle, the entropy of these edge modes / the central element, and the precise, scheme-independent definition of "the entanglement entropy of a region" in a gravitational theory remains unsettled. The fluctuating area operator $\widehat{\text{Area}}$ of Eq. (56.138) is a placeholder for a still-incomplete understanding of how to factorize the gravitational Hilbert space.

Completeness of reconstruction: what lies behind horizons, and Python's lunch. Entanglement-wedge reconstruction (Section 56.7.2) guarantees that bulk operators in the wedge of A are recoverable from ρ_A — but recoverable *how hard*? For regions whose entanglement wedge has a nontrivial structure — a non-minimal extremal surface shadowing a minimal one, the configuration named a "Python's lunch" by Engelhardt and Penington — the reconstruction exists in principle but is conjectured to require computational resources exponential in the entropy difference between the two surfaces. The interiors of black holes are the prime example: the information is in the dual state, but extracting it may be exponentially complex, which is the modern, sharpened form of the question "what is behind the horizon, and can the boundary see it?" Whether reconstruction is always possible, and the precise complexity of the map, are open.

Which CFT states are geometric? Every derivation here assumed a state with a good semiclassical bulk dual — a smooth metric on which RT and FLM operate. But the generic state in the CFT Hilbert space is *not* of this kind: typical high-energy states, superpositions of geometries, and states with sub-AdS-scale or stringy-scale structure have no classical metric dual, and the "fixed-area states" that diagonalize the area operator are themselves non-generic. Characterizing the subset of CFT states that are geometric — giving necessary and sufficient conditions on the entanglement structure for a smooth dual to exist, and understanding what replaces geometry for the rest — is unresolved. The strong slogan "all entanglement is geometry" is false as stated; the true statement is that geometry is a property of a special, large-entanglement, structurally constrained class of states, and the boundary of that class is not known.

Complexity = volume, complexity = action. Entanglement entropy saturates quickly and stops growing once a black hole thermalizes, yet the wormhole interior — the Einstein–Rosen bridge of Section 56.8.6 — keeps growing in volume for a time exponential in the entropy. Entanglement cannot be what the late-time geometry tracks. Susskind and collaborators proposed that the relevant boundary quantity is computational *complexity*: the volume of the maximal bulk slice (complexity = volume), or the gravitational action of the Wheeler–DeWitt patch (complexity = action), is dual to the difficulty of preparing the boundary state. These conjectures are suggestive and pass qualitative tests (the linear-in-time growth, the switchback effect), but "complexity" lacks a sharp, universal

field-theoretic definition, the two proposals disagree in detail, and neither is derived. Whether complexity is the right second entry, after entanglement, in the geometry-from-information dictionary is open.

These four are the live edge of the static, kinematic story this chapter told. Each becomes urgent the moment the geometry is allowed to be a black hole and to *evolve*: the factorization problem becomes the problem of defining the black-hole interior's Hilbert space; reconstruction-behind-horizons becomes the recovery of information from Hawking radiation; the question of which states are geometric becomes the question of what the evaporating black hole's state is at the Page time; and complexity governs the interior's growth long after the entropy has saturated. That dynamical sequel is the subject of Chapter 57, where the quantum extremal surface of Section 56.5.3 is turned on an evaporating black hole, the island rule emerges from the same gravitational replica computation that gave us RT, and the Page curve — the rise and fall of the radiation's entropy that unitarity demands — is recovered from geometry. The static lesson is complete: bulk geometry is boundary entanglement made visible. We now watch that geometry move.

The Ryu–Takayanagi proposal is Ryu and Takayanagi [422], with the covariant generalization in Hubeny et al. [271]; the review by Rangamani and Takayanagi [414] collects the formalism and its computations in one place. The bulk-replica derivation is Lewkowycz and Maldacena [323], refined to include bulk quantum corrections in Faulkner et al. [184] and to the quantum extremal surface in Engelhardt and Wall [177]; the universal sphere coefficients via the conformal map to a hyperbolic black hole are Casini et al. [116]. For subregion duality and the entanglement wedge, see Jafferis et al. [283] for the JLMS identity and Dong et al. [157] for entanglement-wedge reconstruction; the error-correction paradigm is Almheiri et al. [16], made exactly solvable in the pentagon code of Pastawski et al. [384]. Bulk operators as smeared boundary operators are constructed in Hamilton et al. [249]. The thesis that geometry is built from entanglement originates with Van Raamsdonk [483]; its tensor-network face is Swingle [461]; the derivation of linearized gravity from the first law is Faulkner et al. [185]; and the ER = EPR slogan is Maldacena and Susskind [332]. The information-theoretic sequel — the Page curve and islands — is taken up in Chapter 57 and reviewed in Almheiri et al. [19].

Chapter 57

Black Holes and Quantum Information

A black hole is the most economical object in physics: a Schwarzschild geometry is fixed by a single number, its mass, and yet it behaves as a thermodynamic body with a temperature, an entropy, and a first law. The entropy is enormous, scaling with the horizon *area* rather than any volume, and the radiation the hole emits as it evaporates is, to leading semiclassical order, exactly thermal. Taken at face value, that thermality is a catastrophe. A pure state of infalling matter would evolve into featureless radiation carrying no trace of what fell in, converting a pure state into a mixed one and breaking the unitarity that the boundary description of Chapter 53 guarantees holds. This chapter is the careful accounting of that clash—Hawking's information paradox—and of the resolution that semiclassical gravity itself, properly computed, has recently supplied.

We build the argument from the ground up, importing only machinery already in hand. The thermodynamic input of Section 57.1 is obtained by the Euclidean route, using the imaginary-time path integral and finite-temperature periodicity of Chapters 10 and 12: regularity of the cigar geometry fixes the Hawking temperature, the on-shell gravitational action delivers the Bekenstein–Hawking entropy $S_{\mathrm{BH}} = A/4G$ (Theorem 57.3), and the first law follows. Nothing here is borrowed from the curved-spacetime quantization of Chapter 65, which will rederive the same temperature by Hawking's original mode-by-mode Bogoliubov calculation; the present chapter is the self-contained foundation that later treatment confirms. The quantum-information tools—von Neumann entropy, the entanglement of the Hawking pairs, subadditivity and its consequences—and the holographic apparatus of generalized entropy and quantum extremal surfaces are inherited from Chapters 55 and 56, while the competing-saddle reading of the Euclidean path integral comes from Chapter 42.

With those in place the chapter follows a single arc. Section 57.2 states the paradox precisely, in three progressively sharper forms: Hawking's original claim

that the radiation's entropy rises monotonically and terminally; the unitarity bound that forces the entropy back down after the Page time (Theorem 57.9); and the AMPS firewall, which turns the contradiction into a clean violation of the monogamy of entanglement. Section 57.3 then computes what unitarity *demands*: modelling the scrambled hole by a Haar-random state, the Haar-averaged entanglement entropy obeys Page's formula (Theorem 57.14), and Lévy's lemma promotes the average to the typical answer—the Page curve. The two central sections supply the gravitational mechanism that realizes that curve. Section 57.4 introduces the island formula (Theorem 57.18) as a specialization of the quantum-extremal-surface prescription of Chapter 56: after the Page time a disconnected island enters the radiation's entanglement wedge, and a controlled JT-gravity computation reproduces the turnover exactly. Section 57.5 then shows where the island comes from: in the bare gravitational path integral the Rényi entropies receive a second saddle, the replica wormhole (Theorem 57.20), and the $n \to 1$ limit of the competition between the Hawking geometry and the wormhole *is* the quantum extremal surface.

The closing Section 57.6 draws the line, dated honestly to the mid-2020s, between what these results settle and what they do not. The entropy paradox in the form Hawking posed it is resolved—semiclassical gravity yields the Page curve—but a falling von Neumann entropy is not the same as a recovered message: the Hayden–Preskill protocol, the scrambling and Python's-lunch complexity bounds, the factorization puzzle, and the interpretation of the gravitational path integral as an ensemble average remain the live frontier. Throughout, in keeping with the general-relativity and holography literature, this chapter writes spacetime metrics in mostly-plus signature; the field-theory mostly-minus convention of the rest of the book is unaffected, since every computation here is carried by a positive-definite Euclidean geometry.

57.1 Black hole thermodynamics and the entropy of Hawking radiation

The chapter introduction posed the tension that organizes everything to follow: a black hole forms from a pure state, evaporates by emitting what looks like featureless thermal radiation, and – if that appearance is taken at face value – ends its life having converted a pure state into a mixed one, in flat contradiction with the unitarity that the boundary description of Chapter 53 guarantees. Before that clash can be made precise, let alone resolved, we must establish, with no appeal to the curved-spacetime quantization deferred to Chapter 65, the four thermodynamic facts on which the entire argument rests: that a black hole carries a definite temperature T_H, that it carries a definite entropy $S_{\mathrm{BH}} = A/4G$, that these obey the first law $\mathrm{d}M = T_H\,\mathrm{d}S_{\mathrm{BH}}$, and that the radiation it emits is thermal to leading order, so that the coarse-grained entropy of that radiation

grows without bound as the hole shrinks. We obtain all four by the Euclidean route – regularity of the imaginary-time geometry and evaluation of the on-shell gravitational action – which has the decisive virtue of using only the Euclidean path-integral technology already built in Chapters 10 and 42 and the finite-temperature periodicity of Chapter 12. Nothing here is imported from the later general-relativity chapters; on the contrary, Chapter 65 will rederive the temperature by Hawking's original mode-by-mode Bogoliubov calculation and find the identical number, and Chapter 54 has already obtained the same area law for the planar AdS black brane. The present section is the self-contained foundation those treatments confirm.

Notation Watch

Throughout this chapter, as throughout Part XV (Section 53.3), spacetime metrics are written in the *mostly-plus* signature $\eta_{\mu\nu} = \mathrm{diag}(-,+,\dots,+)$ universal to general relativity and the holography literature, with Riemann and Ricci tensors in the Wald/MTW convention, so that anti–de Sitter space has negative Ricci scalar. All field-theory expressions elsewhere in the book remain mostly-minus. The only quantity sensitive to this choice is the overall sign of the Lorentzian line element; the Euclidean geometries that carry every computation below are positive-definite and signature-independent. Chapter 65, sitting in the curved-spacetime Part, writes the same Schwarzschild solution in mostly-minus; the geometry and every invariant are identical.

57.1.1 The minimal geometric vocabulary: horizon and surface gravity

We need exactly two geometries and exactly one derived quantity. The first geometry is the Schwarzschild solution of the vacuum Einstein equations, the unique static, spherically symmetric, asymptotically flat solution of $R_{\mu\nu} = 0$. In coordinates (t, r, θ, φ) adapted to its time-translation and rotational symmetries it is

$$\mathrm{d}s^2 = -f(r)\,\mathrm{d}t^2 + \frac{\mathrm{d}r^2}{f(r)} + r^2\,\mathrm{d}\Omega^2, \qquad f(r) = 1 - \frac{2GM}{r}, \qquad \mathrm{d}\Omega^2 = \mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\varphi^2, \tag{57.1}$$

where G is Newton's constant, M is the mass measured by the geometry at large r (the ADM mass), and $\mathrm{d}\Omega^2$ is the round metric on the unit two-sphere. We take Eq. (57.1) as given; the book builds no general relativity, and the curvature computation that verifies $R_{\mu\nu} = 0$ belongs to Chapter 64. What we need are its two structural features. The function f multiplies $\mathrm{d}t^2$ and divides $\mathrm{d}r^2$, the signature of a static black hole; it is positive for $r > 2GM$, where the geometry

is static with timelike Killing vector ∂_t, and vanishes at

$$r_h = 2GM, \tag{57.2}$$

the *event horizon* – the null surface beyond which no causal curve returns to large r. The region $r < r_h$ is not part of the static exterior and, as we will see, has no Euclidean continuation at all.

Definition 57.1 (Surface gravity)**.** For a static metric of the form Eq. (57.1) with a simple zero of f at the horizon $r = r_h$, the *surface gravity* is the geometric quantity

$$\kappa \;\equiv\; \tfrac{1}{2}\, f'(r_h). \tag{57.3}$$

Physically κ is the acceleration, measured at infinity, of a static observer hovering just outside the horizon; equivalently it controls the rate at which the timelike Killing vector ∂_t fails to be normalized as the horizon is approached. We will need none of that interpretation: Eq. (57.3) is a formula, and the temperature will fall out of it geometrically. For Schwarzschild, $f'(r) = 2GM/r^2$, so

$$\kappa = \tfrac{1}{2}\, f'(2GM) = \frac{1}{2}\cdot\frac{2GM}{(2GM)^2} = \frac{1}{4GM}. \tag{57.4}$$

The second geometry is the *AdS–Schwarzschild* black hole, the analogue with a negative cosmological constant that lives in the asymptotically anti–de Sitter spacetimes of Chapter 53. Its planar version – the black brane – and its full thermodynamics were established in Section 54.4; we recall only its form, in the coordinates of Eq. (53.59) with AdS radius L and radial coordinate z,

$$\mathrm{d}s^2 = \frac{L^2}{z^2}\left[-f(z)\,\mathrm{d}t^2 + \mathrm{d}\mathbf{x}^2 + \frac{\mathrm{d}z^2}{f(z)}\right], \qquad f(z) = 1 - \Big(\frac{z}{z_h}\Big)^d, \tag{57.5}$$

with conformal boundary at $z \to 0$ and horizon at $z = z_h$. The asymptotic structure – that near $z \to 0$ the metric Eq. (57.5) approaches empty AdS_{d+1} and so admits the same holographic boundary data as in Section 53.3 – is imported wholesale from Chapters 53 and 54; we will not re-derive it. The reason both geometries appear here is that the information paradox is sharpest for the asymptotically flat hole, which genuinely evaporates to nothing, while the cleanest *unitary* control comes from the AdS hole, whose boundary dual is a manifestly unitary thermal field theory (Section 54.4). The thermodynamic facts are common to both, and we prove them once, in detail, for Schwarzschild.

57.1.2 The Hawking temperature from Euclidean regularity

The route to the temperature is the Euclidean path integral of Section 10.6. There the Wick rotation $t \to -i\tau$ (Theorem 5.30) turned the Lorentzian weight

e^{iS} into the convergent Euclidean weight e^{-S_E}, and compactifying the imaginary time on a circle of circumference β computed the thermal partition function $Z(\beta) = \mathrm{Tr}\, e^{-\beta H}$ – the statement, made precise in Section 12.5.7, that a quantum system at inverse temperature β is a Euclidean field theory on a time circle of that circumference. For an *ordinary* field theory the period β is a free parameter we dial to set the temperature. The remarkable feature of gravity is that β is not free: once we Wick-rotate the black-hole metric, the demand that the resulting Riemannian geometry be smooth fixes β to a single value, and that value is the inverse Hawking temperature.

Wick-rotating Eq. (57.1) by $t = -i\tau$ sends $-f\,\mathrm{d}t^2 \to +f\,\mathrm{d}\tau^2$ and produces the positive-definite Euclidean Schwarzschild metric

$$\mathrm{d}s_E^2 = f(r)\,\mathrm{d}\tau^2 + \frac{\mathrm{d}r^2}{f(r)} + r^2\,\mathrm{d}\Omega^2, \qquad f(r) = 1 - \frac{2GM}{r}, \qquad r \geq 2GM. \tag{57.6}$$

Two features are decisive and worth naming before any algebra. First, $f \geq 0$ for $r \geq 2GM$ and vanishes at the horizon, so the proper circumference of the τ-circle, $\sqrt{f(r)}\oint \mathrm{d}\tau$, shrinks to zero as $r \to 2GM$: the horizon is not a boundary of the Euclidean manifold but a locus where the τ-circle closes to a point (one point for each point of the sphere). Second, the interior $r < 2GM$, where $f < 0$, is simply absent – there is no real Euclidean continuation of it. The Euclidean black hole is a smooth four-manifold capped off at the horizon, with the topology $\mathbb{R}^2 \times S^2$: the $\mathbb{R}^2$ is the (τ, r) plane closing up at r_h, the S^2 is the spatial sphere of area $4\pi r^2$. Whether the cap is genuinely smooth, or carries a conical defect, is the whole question, and we answer it by expanding the metric in the immediate neighbourhood of the horizon.

Worked Example 57.2 (The smoothness condition $\beta = 2\pi/\kappa$ from the near-horizon plane)**.** We zoom in on the horizon of Eq. (57.6) and demand that the capped (τ, r) geometry be a smooth point rather than the tip of a cone. Write $r = r_h + \delta$ with $0 < \delta \ll r_h$ and expand f to first order about its simple zero, using $f(r_h) = 0$:

$$f(r) = f'(r_h)\,\delta + O(\delta^2) = 2\kappa\,\delta + O(\delta^2), \tag{57.7}$$

where the last equality uses the definition Eq. (57.3), $f'(r_h) = 2\kappa$. The coordinate r is not the natural one near the horizon; the natural one is the *proper distance* ρ from the horizon, defined so that the radial part of the metric becomes $\mathrm{d}\rho^2$:

$$\mathrm{d}\rho = \frac{\mathrm{d}r}{\sqrt{f(r)}} \quad \Longrightarrow \quad \rho = \int_{r_h}^{r} \frac{\mathrm{d}r'}{\sqrt{f(r')}} = \int_0^{\delta} \frac{\mathrm{d}\delta'}{\sqrt{2\kappa\,\delta'}} = \frac{2\sqrt{\delta}}{\sqrt{2\kappa}} = \sqrt{\frac{2\delta}{\kappa}}. \tag{57.8}$$

Inverting, $\delta = \frac{1}{2}\kappa\rho^2$, and therefore the coefficient of $\mathrm{d}\tau^2$ becomes, to leading order,

$$f(r) = 2\kappa\,\delta = 2\kappa \cdot \tfrac{1}{2}\kappa\rho^2 = \kappa^2\rho^2. \tag{57.9}$$

Near the horizon the sphere has essentially fixed radius $r \approx r_h$, so the angular term $r^2\,\mathrm{d}\Omega^2 \approx r_h^2\,\mathrm{d}\Omega^2$ is an inert spectator that simply rides along. The non-trivial (ρ, τ) block of Eq. (57.6) collapses to

$$\mathrm{d}s_E^2\big|_{\text{near hor.}} = \mathrm{d}\rho^2 + \kappa^2\rho^2\,\mathrm{d}\tau^2 + r_h^2\,\mathrm{d}\Omega^2 = \mathrm{d}\rho^2 + \rho^2\,\mathrm{d}\alpha^2 + r_h^2\,\mathrm{d}\Omega^2, \qquad \alpha \equiv \kappa\,\tau. \tag{57.10}$$

The (ρ, α) piece is exactly the flat plane $\mathbb{R}^2$ in polar coordinates, with radial coordinate $\rho \geq 0$ and angular coordinate α. This is precisely the elementary fact that fixes the period of the angle in polar coordinates: $\mathrm{d}\rho^2 + \rho^2\,\mathrm{d}\alpha^2$ is smooth flat space at the origin $\rho = 0$ *if and only if* α runs over a full period of exactly 2π. Any other period leaves a cone: a deficit angle $2\pi -$ (period) either missing or doubled at the tip, with a curvature delta-function supported there and no smooth solution of the vacuum equation in any neighbourhood of $\rho = 0$. Smoothness of the Euclidean black hole at its horizon is therefore the single condition $\alpha \sim \alpha + 2\pi$, i.e. $\kappa\,\tau \sim \kappa\,\tau + 2\pi$, i.e.

$$\boxed{\beta = \frac{2\pi}{\kappa}\,,} \tag{57.11}$$

the unique period of imaginary time for which the geometry closes up smoothly.

The result Eq. (57.11) is purely geometric: no field was quantized, no mode tracked across the horizon, no vacuum chosen. The imaginary-time period – which by the Euclidean dictionary of Section 10.6 is the inverse temperature of any state the geometry represents – is forced by the differential geometry of a smooth four-manifold. Reading off the temperature and substituting the Schwarzschild surface gravity Eq. (57.4),

$$T_H = \frac{1}{\beta} = \frac{\kappa}{2\pi} \qquad \xrightarrow{\kappa = 1/4GM} \qquad \boxed{T_H = \frac{1}{8\pi GM}\,.} \tag{57.12}$$

This is the Hawking temperature. The same regularity argument applied to the AdS–Schwarzschild brane Eq. (57.5) gave $\beta = 4\pi z_h/d$ in Eq. (54.96); the structure is identical – a τ-circle pinching off at a horizon, smooth for exactly one period – and we do not repeat it. Figure 57.1 shows the resulting "cigar" geometry.

Physical Insight

The temperature of a black hole is the price of geometric smoothness. In an ordinary thermal field theory we *choose* the imaginary-time period to set T; the geometry is flat and accepts any period. A black hole's Euclidean geometry pinches off at the horizon, and a pinching circle is smooth for one period only – like the apex of a cone, which is flat exactly when the cone is rolled out to a full disk. The black hole has no freedom:

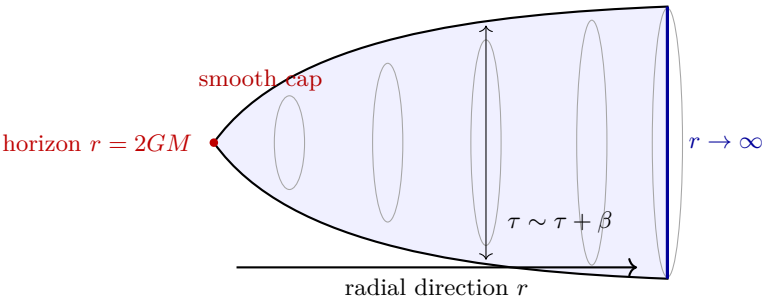

Figure 57.1: The Euclidean Schwarzschild "cigar." Each circle is the imaginary-time direction τ, of circumference β, fibered over the radial coordinate r (the spectator S^2 is suppressed). Far away the circle has its full proper size $\sqrt{f}\,\beta$; moving inward it shrinks, and at the horizon $r = 2GM$ it closes to a point. The geometry caps smoothly there – no conical defect – for exactly one period $\beta = 2\pi/\kappa = 8\pi GM$ Eq. (57.12), the tip being the origin of the flat plane $\mathrm{d}\rho^2 + \rho^2 \mathrm{d}\alpha^2$ of Eq. (57.10). The interior $r < 2GM$ has no Euclidean continuation and is absent.

its temperature is determined by its mass, $T_H = 1/8\pi GM$. The hotter the hole the lighter it is – a negative heat capacity that, as the next sections show, is the engine of evaporation and the seed of the paradox.

Historical Note

That a periodic imaginary time *is* thermal equilibrium is the content of the Kubo–Martin–Schwinger condition, derived in Eq. (12.139): the thermal two-point function $\langle A(\tau)B(0)\rangle_\beta$ is periodic in τ with period β, a direct consequence of cyclicity of the trace in $Z^{-1}\,\mathrm{Tr}(e^{-\beta H}\cdots)$. Gibbons and Hawking recognized in 1977 that the converse reading is the most economical route to the black-hole temperature: a gravitational field whose Euclidean section is smoothly periodic in imaginary time *is* a thermal state, and the period is read off the geometry. Hawking's earlier 1974–75 derivation, by contrast, quantized a scalar field on a collapsing star and computed the Bogoliubov coefficients between the in- and out-vacua; that calculation, which exhibits the thermal flux as genuine particle creation, is carried out in full in Section 65.2.1. The two agree on the number $T_H = \kappa/2\pi$.

57.1.3 The entropy from the on-shell Euclidean action

The temperature in hand, the partition function and hence the entropy follow from the gravitational path integral. In the saddle-point evaluation of Chapter 42, the dominant contribution to the Euclidean gravitational partition function at inverse temperature β is $e^{-I[g_\star]}$, where $g_\star$ is the classical solution – here the Euclidean black hole – and I is the on-shell Euclidean gravitational action. We must therefore evaluate that action. For asymptotically flat gravity with vanishing cosmological constant the action consists of the Einstein–Hilbert bulk term and the Gibbons–Hawking–York (GHY) boundary term, regulated by subtracting the same two terms evaluated on the flat-space background that the geometry approaches at infinity:

$$I = -\frac{1}{16\pi G}\int_{\mathcal{M}} \mathrm{d}^4x\,\sqrt{g}\,R \;-\; \frac{1}{8\pi G}\int_{\partial\mathcal{M}} \mathrm{d}^3x\,\sqrt{\gamma}\,(K-K_0). \tag{57.13}$$

Here γ_{ab} is the metric induced on a large-radius boundary $r=\mathcal{R}$, K is the trace of its extrinsic curvature in the Euclidean black-hole geometry, and K_0 is the same trace computed for flat space cut off at the same boundary – the *background subtraction* that renders the otherwise divergent boundary term finite. The GHY term is the standard addition that makes the Dirichlet variational problem well posed (without it the variation of Eq. (57.13) leaves an uncancelled normal derivative of the metric at the boundary); we take its necessity as established in Chapter 64 and owe here only its evaluation. The subtraction of K_0 is the asymptotically-flat counterpart of the holographic counterterms used for the AdS brane in Section 54.2.3; there the reference was supplied by local boundary curvature invariants, here by an explicit flat background, but the role is identical – removing the contribution of empty space so that I measures the geometry's content.

We evaluate Eq. (57.13) on Euclidean Schwarzschild Eq. (57.6) term by term.

Bulk term. Schwarzschild solves the *vacuum* Einstein equations $R_{\mu\nu}=0$, so its Ricci scalar vanishes identically, $R=0$, and the bulk integral in Eq. (57.13) contributes nothing:

$$I_{\text{bulk}} = 0. \tag{57.14}$$

The entire on-shell action of the asymptotically flat black hole comes from the boundary term. (This is the structural difference from the AdS computation of Section 54.4.3, where the cosmological constant gives a nonzero on-shell density $R-2\Lambda=-2d/L^2$ and the bulk term does contribute.)

The extrinsic-curvature traces. The boundary is the surface $r=\mathcal{R}$, swept out by $\tau\in[0,\beta)$ and the sphere. The full four-metric determinant of Eq. (57.6) is $\sqrt{g}=\sqrt{f\cdot f^{-1}\cdot r^2\cdot r^2\sin^2\theta}=r^2\sin\theta$. The induced three-metric on $r=\mathcal{R}$ is

$\gamma = \mathrm{diag}(f(\mathcal{R}), \mathcal{R}^2, \mathcal{R}^2 \sin^2\theta)$ in (τ, θ, φ), so $\sqrt{\gamma} = \sqrt{f(\mathcal{R})}\,\mathcal{R}^2 \sin\theta$. The outward unit normal is $n^\mu = \sqrt{f}\,\delta^\mu{}_r$ (since $g_{rr} = 1/f$), and the extrinsic-curvature trace is its covariant divergence,

$$K = \nabla_\mu n^\mu = \frac{1}{\sqrt{g}}\,\partial_r(\sqrt{g}\,n^r) = \frac{1}{r^2}\,\partial_r(r^2\sqrt{f}) = \frac{2\sqrt{f}}{r} + \frac{f'}{2\sqrt{f}}. \tag{57.15}$$

Multiplying by the area density $\sqrt{\gamma}$ and integrating over the sphere ($\int \mathrm{d}\theta\,\mathrm{d}\varphi\,\sin\theta = 4\pi$) and the time circle gives, for the black-hole geometry,

$$\oint \mathrm{d}^3x\,\sqrt{\gamma}\,K = \beta\cdot 4\pi\cdot\mathcal{R}^2\sqrt{f}\left(\frac{2\sqrt{f}}{\mathcal{R}} + \frac{f'}{2\sqrt{f}}\right) = 4\pi\beta\left(2\mathcal{R}\,f(\mathcal{R}) + \tfrac{1}{2}\mathcal{R}^2 f'(\mathcal{R})\right). \tag{57.16}$$

Insert $f(\mathcal{R}) = 1 - 2GM/\mathcal{R}$ and $f'(\mathcal{R}) = 2GM/\mathcal{R}^2$:

$$2\mathcal{R}f + \tfrac{1}{2}\mathcal{R}^2 f' = 2\mathcal{R}\Big(1 - \frac{2GM}{\mathcal{R}}\Big) + \tfrac{1}{2}\mathcal{R}^2\frac{2GM}{\mathcal{R}^2} = 2\mathcal{R} - 4GM + GM = 2\mathcal{R} - 3GM, \tag{57.17}$$

so $\oint \sqrt{\gamma}\,K = 4\pi\beta\,(2\mathcal{R} - 3GM)$.

For the flat-space reference we set $M = 0$, so $f_0 = 1$, $f_0' = 0$, and Eq. (57.15) gives $K_0 = 2/r$. But the subtraction is meaningful only if the two boundaries describe the *same* intrinsic geometry: the proper length of the time circle must match. In the black hole the circle has proper circumference $\sqrt{f(\mathcal{R})}\,\beta$; in flat space, with its own period β_0, it is β_0. Matching $\beta_0 = \sqrt{f(\mathcal{R})}\,\beta$ and using $\sqrt{\gamma_0} = \mathcal{R}^2\sin\theta$, $K_0 = 2/\mathcal{R}$,

$$\oint \mathrm{d}^3x\,\sqrt{\gamma_0}\,K_0 = \beta_0\cdot 4\pi\cdot\mathcal{R}^2\cdot\frac{2}{\mathcal{R}} = 8\pi\,\beta_0\,\mathcal{R} = 8\pi\beta\,\mathcal{R}\sqrt{f(\mathcal{R})}. \tag{57.18}$$

Expand the square root for large $\mathcal{R}$, $\sqrt{f(\mathcal{R})} = (1 - 2GM/\mathcal{R})^{1/2} = 1 - GM/\mathcal{R} + O(\mathcal{R}^{-2})$, so

$$\oint \sqrt{\gamma_0}\,K_0 = 8\pi\beta\Big(\mathcal{R} - GM + O(\mathcal{R}^{-1})\Big). \tag{57.19}$$

The subtracted boundary term. Now take the difference and the limit $\mathcal{R}\to\infty$. The divergent pieces linear in $\mathcal{R}$ cancel between the two geometries – which is exactly what the background subtraction is for:

$$\oint \sqrt{\gamma}\,K - \oint \sqrt{\gamma_0}\,K_0 = 4\pi\beta(2\mathcal{R} - 3GM) - 8\pi\beta(\mathcal{R} - GM) = 4\pi\beta(-3GM + 2GM) = -4\pi\beta\,GM \tag{57.20}$$

The $\mathcal{R}$ terms collect to $8\pi\beta\mathcal{R} - 8\pi\beta\mathcal{R} = 0$ and the limit is finite. Therefore the on-shell action Eq. (57.13), with $I_{\mathrm{bulk}} = 0$, is

$$I = -\frac{1}{8\pi G}(-4\pi\beta\,GM) = \frac{\beta M}{2}. \tag{57.21}$$

Using $\beta = 8\pi GM$ from Eq. (57.12), this can be written equivalently in terms of β alone, $I = \beta M/2 = \beta\cdot\beta/(8\pi G)/2 = \beta^2/(16\pi G)$, a form we will exploit in a moment.

Free energy, energy, and entropy. The saddle-point partition function is $\ln Z = -I$, and the standard thermodynamic relations extract the rest. The free energy is

$$F = -\frac{1}{\beta}\ln Z = \frac{I}{\beta} = \frac{M}{2}. \tag{57.22}$$

The internal energy is the expected value of the Hamiltonian, $\langle E\rangle = -\partial_\beta \ln Z = \partial_\beta I$. Differentiating the β-only form $I = \beta^2/16\pi G$,

$$\langle E\rangle = \frac{\partial I}{\partial \beta} = \frac{2\beta}{16\pi G} = \frac{\beta}{8\pi G} = M, \tag{57.23}$$

where the last step is again $\beta = 8\pi G M$. The energy of the saddle is exactly the mass, as it must be – a nontrivial check that the background subtraction was done correctly. Finally the entropy is the Legendre transform $S = \ln Z + \beta\,\langle E\rangle$,

$$S = -I + \beta M = -\frac{\beta M}{2} + \beta M = \frac{\beta M}{2} = \frac{(8\pi G M)M}{2} = 4\pi G M^2. \tag{57.24}$$

It is one quarter of the horizon area. The horizon is the sphere $r = r_h = 2GM$, whose induced metric is $r_h^2\,\mathrm{d}\Omega^2$ and whose area is therefore

$$A = 4\pi r_h^2 = 4\pi(2GM)^2 = 16\pi G^2 M^2. \tag{57.25}$$

Dividing, $A/4G = 16\pi G^2 M^2/(4G) = 4\pi G M^2$, which is exactly Eq. (57.24). We have proved:

Theorem 57.3 (Bekenstein–Hawking entropy)**.** *The entropy of a Schwarzschild black hole, computed from the saddle-point value of the Euclidean gravitational partition function with Gibbons–Hawking boundary term and flat-background subtraction, is one quarter of its horizon area in Planck units:*

$$\boxed{S_{\mathrm{BH}} = \frac{A}{4G} = 4\pi G M^2\,.} \tag{57.26}$$

Remark 57.4 (Where the one-loop corrections live). Theorem 57.3 is the *leading* saddle-point result, the gravitational analogue of the tree-level free energy. The next term in the loop expansion of Chapter 42 is the one-loop determinant of fluctuations about the black-hole saddle – a functional determinant of the linearized Einstein operator, evaluated by the spectral ζ-function and heat-kernel methods built in Chapter E (Section E.3). It produces the logarithmic correction $S = A/4G + c\ln(A/G) + \dots$ whose universal coefficient c is fixed by the field content; the regularization technology is exactly the one applied to the one-loop effective action in Eq. (E.135), and the explicit gravitational evaluation is treated in [257] and Chapter 65. We will not need the correction: the paradox and its resolution operate at the level of Eq. (57.26) and the area's leading behaviour.

The same on-shell-action computation, carried out for the AdS brane with its nonzero bulk term and holographic counterterms, gave $S = A/4G$ in Theorem 54.10; the two derivations differ only in which reference subtraction tames the boundary divergence, and agree on the universal coefficient $1/4$. That the coefficient is the same in both settings – and matches the coefficient of the area law for entanglement entropy in Section 55.5 – is the first hint that $A/4G$ is counting something microscopic, a hint the rest of the chapter makes precise.

57.1.4 The first law

The thermodynamic consistency of Eqs. (57.12) and (57.26) is the first law, and with both quantities written as explicit functions of the single parameter M it is immediate to verify. From Eq. (57.24), $S_{\mathrm{BH}} = 4\pi GM^2$, so

$$\mathrm{d}S_{\mathrm{BH}} = 8\pi GM\,\mathrm{d}M. \tag{57.27}$$

Multiplying by the temperature Eq. (57.12), $T_H = 1/8\pi GM$,

$$T_H\,\mathrm{d}S_{\mathrm{BH}} = \frac{1}{8\pi GM}\cdot 8\pi GM\,\mathrm{d}M = \mathrm{d}M, \tag{57.28}$$

which is the first law $\mathrm{d}M = T_H\,\mathrm{d}S_{\mathrm{BH}}$ with the mass M playing the role of the internal energy (as Eq. (57.23) confirmed) and no work terms, since Schwarzschild carries neither charge nor angular momentum. The first law is thus not an extra assumption but a theorem about the M-dependence of the temperature and the entropy, both of which we computed from the geometry. Its differential form integrates back to the entropy: $\mathrm{d}S_{\mathrm{BH}} = \mathrm{d}M/T_H = 8\pi GM\,\mathrm{d}M$ gives $S_{\mathrm{BH}} = 4\pi GM^2$ up to a constant, fixed to zero by $S_{\mathrm{BH}} \to 0$ as $M \to 0$. This is the route by which the entropy is often quoted – temperature from Euclidean regularity, entropy by integrating the first law – but we have done better here, computing S_{BH} *directly* from the action and then *checking* the first law, so that the coefficient $1/4$ is a genuine output rather than an integration constant.

Physical Insight

The negative heat capacity is now explicit and physical. From Eq. (57.12), $T_H = 1/8\pi GM$ rises as M falls: a black hole that loses energy gets *hotter*. Equivalently, $\mathrm{d}M/\mathrm{d}T_H = -1/(8\pi GT_H^2) < 0$. This is the thermodynamic root of evaporation: once a hole begins to radiate, it heats up, radiates faster, and runs away to nothing – the opposite of an ordinary hot body, which cools as it radiates and reaches equilibrium with a reservoir. An isolated Schwarzschild black hole has no stable equilibrium with its own radiation; it can only be stabilized by enclosing it (as the AdS box of Section 54.4.6 does for large black holes, which there acquire positive specific heat). The instability is what makes the asymptotically flat hole

the natural arena for the information question: it actually disappears, forcing the issue of what becomes of its information.

57.1.5 The radiation is thermal, and its coarse-grained entropy grows

The Euclidean saddle establishes that the black hole *is* a thermal state at temperature T_H; what an observer at infinity actually receives is the radiation emitted as the hole relaxes toward, and past, that equilibrium. The detailed spectrum is the business of Section 65.3, where Hawking's Bogoliubov calculation produces the flux mode by mode. For the present purpose we need only its leading character, which the thermal interpretation already fixes: the number flux of quanta of energy ω emitted into a given mode is the Planck distribution at temperature T_H, dressed by a frequency-dependent transmission probability Γ_ω,

$$\frac{\mathrm{d}N_\omega}{\mathrm{d}t} = \frac{\Gamma_\omega}{e^{\omega/T_H} \mp 1}, \tag{57.29}$$

with the lower sign for bosons and the upper for fermions. The factor Γ_ω – the *greybody factor* – is the probability that a quantum created near the horizon penetrates the curvature potential barrier outside and reaches infinity rather than being backscattered into the hole; it depends on ω, on the spin of the field, and on the angular momentum of the mode, and it is what makes the observed spectrum a *grey* body rather than a perfect black body. We state its existence and role and defer its computation to Section 65.3; it is not the focus here, and crucially it does not affect the qualitative conclusion we now draw. Integrating Eq. (57.29) against ω with the appropriate phase space gives the luminosity, which for the dominant long-wavelength modes scales as the Stefan–Boltzmann law over the horizon area, $L \sim A\,T_H^4 \sim (G^2M^2)(GM)^{-4} \sim 1/(G^2M^2)$, so that

$$\frac{\mathrm{d}M}{\mathrm{d}t} \sim -\frac{1}{G^2M^2} < 0, \tag{57.30}$$

the negative sign confirming that the hole loses mass and, by Eq. (57.12), heats as it does so.

The quantity that the next section places in tension with unitarity is the *coarse-grained*, or thermal, entropy of the emitted radiation – the thermodynamic entropy one would assign to the outgoing flux treating it as the genuinely thermal gas that Eq. (57.29) describes. For thermal radiation the relation between entropy flux and energy flux is the standard one: a photon gas of energy density $u \propto T^4$ has entropy density $s = \frac{4}{3}u/T$, so a parcel of energy $\mathrm{d}E$ emitted at temperature T_H carries off thermal entropy

$$\mathrm{d}S^{\mathrm{th}}_{\mathrm{rad}} = \frac{4}{3}\frac{\mathrm{d}E}{T_H} = -\frac{4}{3}\frac{\mathrm{d}M}{T_H}, \tag{57.31}$$

using energy conservation $\mathrm{d}E = -\mathrm{d}M$. Comparing with the black hole's own entropy change $\mathrm{d}S_{\mathrm{BH}} = \mathrm{d}M/T_H$ from Eq. (57.28), we see the radiation gains $\frac{4}{3}$ of what the hole loses:

$$\mathrm{d}S^{\mathrm{th}}_{\mathrm{rad}} = -\frac{4}{3}\,\mathrm{d}S_{\mathrm{BH}} > 0. \tag{57.32}$$

Since $\mathrm{d}S_{\mathrm{BH}} < 0$ (the hole shrinks), $S^{\mathrm{th}}_{\mathrm{rad}}$ increases monotonically throughout the evaporation – this is the generalized second law in its sharpest form, the statement that the sum $S_{\mathrm{BH}} + S^{\mathrm{th}}_{\mathrm{rad}}$ never decreases. Integrating Eq. (57.32) from the initial mass M_0 down to M,

$$S^{\mathrm{th}}_{\mathrm{rad}}(M) = \frac{4}{3}\big(S_{\mathrm{BH}}(M_0) - S_{\mathrm{BH}}(M)\big), \tag{57.33}$$

which grows from zero, reaching at complete evaporation ($M \to 0$) the value

$$S^{\mathrm{th}}_{\mathrm{rad}}(0) = \frac{4}{3}\,S_{\mathrm{BH}}(M_0) = \frac{16\pi}{3}\,GM_0^2. \tag{57.34}$$

Figure 57.2 plots the two competing curves: $S_{\mathrm{BH}}(t) = A(t)/4G$ shrinking to zero, and $S^{\mathrm{th}}_{\mathrm{rad}}(t)$ rising monotonically to $\frac{4}{3}S_{\mathrm{BH}}(M_0)$.

Caution

The adjective "thermal" in $S^{\mathrm{th}}_{\mathrm{rad}}$ is load-bearing and is exactly where the paradox will be joined. Equation (57.33) is the entropy of the radiation *computed under the assumption that it is a thermal mixed state*, which is what the leading semiclassical (Bogoliubov) calculation of Chapter 65 delivers: each emitted mode is thermally populated and uncorrelated with the rest, so the radiation's density matrix is a product of thermal factors and its von Neumann entropy is the thermodynamic value Eq. (57.33). If that were the true *fine-grained* (von Neumann) entropy of the radiation, then at the end of evaporation the radiation would be a mixed state of entropy $\frac{4}{3}S_{\mathrm{BH}}(M_0) > 0$ – with no black hole left to be entangled with – and an initially pure collapsing star would have evolved into a mixed state. That is the information paradox. The resolution, developed across the chapter, is that the true fine-grained entropy departs from the monotone thermal curve, turning over and returning to zero (the Page curve); $S^{\mathrm{th}}_{\mathrm{rad}}$ is only an *upper bound* on it, saturated early and grossly violated late.

57.1.6 The Bekenstein bound: S_{BH} as a maximum fine-grained entropy

One structural fact about S_{BH} remains to be stated, because it is what makes the paradox a genuine paradox rather than a bookkeeping slip: the Bekenstein–Hawking entropy is *finite*, and it is the *maximum* fine-grained entropy that can

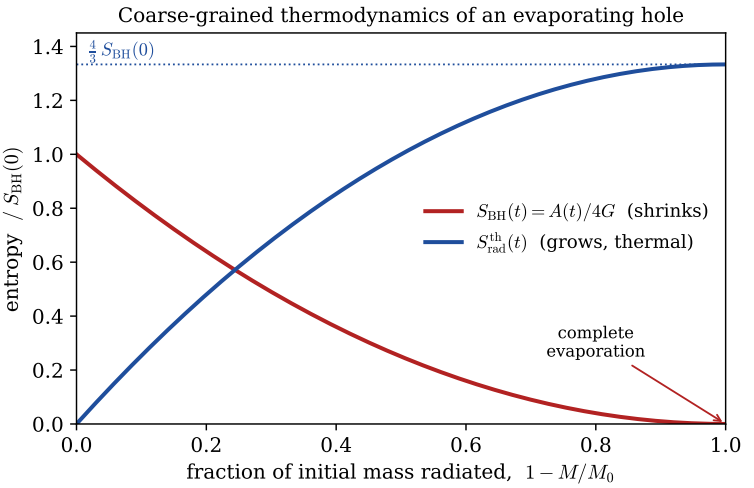

Figure 57.2: The two coarse-grained thermodynamic quantities handed to Section 57.1's successor, as functions of the fraction of the initial mass radiated, in units of the initial Bekenstein–Hawking entropy. The black-hole entropy $S_{\rm BH}(t) = A(t)/4G = 4\pi G M(t)^2$ (red) shrinks monotonically to zero as the hole evaporates. The *thermal* entropy of the radiation $S^{\rm th}_{\rm rad}(t)$ (blue), computed by treating the Hawking flux as a genuinely thermal gas Eq. (57.33), grows monotonically to $\frac{4}{3}S_{\rm BH}(M_0)$ Eq. (57.34). This monotone growth – never turning over – is precisely the behaviour that the next section shows to be incompatible with a unitary, pure final state.

be packed into the region the black hole occupies. Bekenstein's original argument, which we give in outline, is a thought experiment with the generalized second law. Lower a box of matter carrying energy E and entropy $S_{\rm matter}$, of linear size $\leq R$, quasi-statically into a black hole. The matter entropy $S_{\rm matter}$ is lost from the exterior; for the generalized second law $\mathrm{d}(S_{\rm BH} + S_{\rm ext}) \geq 0$ to survive, the increase in $S_{\rm BH}$ as the hole absorbs the energy must at least compensate. The energy actually delivered to the hole is redshifted: a box of size R can be lowered until its center hovers a proper distance $\sim R$ above the horizon (it can approach no closer without crossing), where the timelike Killing vector has norm $\simeq \kappa R$ with $\kappa = 1/4GM$ the surface gravity of Eq. (57.4), so the energy delivered at infinity is $E_\infty \simeq \kappa R\, E$. The hole's entropy then rises by $\mathrm{d}S_{\rm BH} = E_\infty/T_H = \kappa R\, E/T_H = 2\pi R\, E$, using $T_H = \kappa/2\pi$ from Eq. (57.12). The generalized second law $\mathrm{d}S_{\rm BH} \geq S_{\rm matter}$ then yields the *Bekenstein bound* on the entropy of any system of energy E confined to a region of radius R,

$$S_{\rm matter} \;\leq\; 2\pi R\, E \tag{57.35}$$

(in natural units $\hbar = c = k_B = 1$). The bound is saturated, up to factors, precisely by a black hole that just fits in the region: for $R \sim r_h = 2GM$ and $E = M$, the right-hand side is $2\pi(2GM)M = 4\pi GM^2 = S_{\rm BH}$, recovering Eq. (57.26). The same conclusion in its covariant, area form is the statement that the entropy that can be stored in a region is bounded by its boundary area in Planck units, $S \leq A/4G$ – the content of the holographic principle of 't Hooft and Susskind that gave Chapter 53 its name, and the reason a black hole, which saturates the bound, has the *maximum* entropy of anything that can be assembled in its volume.

Physical Insight

The finiteness of $S_{\rm BH} = A/4G$ is the quantitative heart of the puzzle. An ordinary thermal system has an entropy that grows with its volume and is, for a continuum field theory, formally unbounded as more short-distance modes are excited. A black hole instead carries a *finite*, area-scaling entropy, and that finite number is the largest fine-grained entropy the region can hold. Two consequences follow that the rest of the chapter develops. First, the radiation's fine-grained entropy can never exceed the entropy of whatever it is entangled with, and once the black hole has shrunk so that $S_{\rm BH}(t)$ is small, the radiation's own entropy is bounded by that small number – it *cannot* keep growing as Eq. (57.33) insists. Second, that a region's information capacity is set by its area, not its volume, is the germ of holography itself: the degrees of freedom are not where naive locality puts them. Both threads converge on the same resolution.

We now have, established from the Euclidean geometry and its on-shell action alone, the complete thermodynamic dossier the chapter requires: the Hawking temperature $T_H = 1/8\pi GM$ Eq. (57.12), the Bekenstein–Hawking entropy $S_{\rm BH} = A/4G$ Eq. (57.26) as the finite maximum fine-grained entropy of the region, the first law $\mathrm{d}M = T_H\,\mathrm{d}S_{\rm BH}$ Eq. (57.28), and the approximately thermal character of the emitted radiation, whose coarse-grained entropy $S^{\rm th}_{\rm rad}(t)$ grows monotonically to $\frac{4}{3}S_{\rm BH}(M_0)$. The next section takes these two time-dependent quantities – the shrinking $S_{\rm BH}(t) = A(t)/4G$ and the monotonically growing $S^{\rm th}_{\rm rad}(t)$ of Fig. 57.2, together with the semiclassical fact that the radiation comes out in a thermal, hence mixed, state – and turns the slogan "black holes destroy information" into three sharp statements, each in genuine tension with the unitarity that the boundary theory of Chapter 53 guarantees.

57.2 The information paradox, stated precisely

The previous section handed us two curves and a collision course. From the Euclidean route we extracted a Hawking temperature T_H (Eq. (57.12)), a Bekenstein–

Hawking entropy $S_{\rm BH} = A/4G$ (Eq. (57.26)), and the statement that a black hole radiates an approximately thermal flux. Feeding that flux into the first law gave a black hole that shrinks: its horizon area $A(t)$, and with it $S_{\rm BH}(t) = A(t)/4G$, decreases monotonically toward zero at an evaporation time $t_{\rm evap}$. Meanwhile the emitted gas, being thermal, carries an entropy of its own, and that radiation entropy $S^{\rm th}_{\rm rad}(t)$ grows monotonically as more quanta escape. Two monotone curves, one falling and one rising: somewhere they must cross. The business of this section is to take that crossing seriously and convert the folklore slogan "black holes destroy information" into statements sharp enough to be either proved or refuted.

We will produce three such statements, increasing in subtlety. The first is Hawking's original observation, phrased as a fact about the fine-grained entropy of the radiation: in the semiclassical calculation it rises without bound and ends nonzero, which is impossible if the process is unitary. The second sharpens this into a quantitative ceiling — unitarity forces $S(\rho_{\rm rad}) \le S_{\rm BH}(t)$ at every instant, a bound the semiclassical curve violates after a definite time, the Page time. The third, due to Almheiri, Marolf, Polchinski and Sully (AMPS), shows that even granting unitarity at the level of entropy, the three principles one would most like to keep — unitarity, the validity of low-energy quantum mechanics near the horizon, and the equivalence principle — cannot all hold for an old black hole; we will write the contradiction as a strong-subadditivity inequality that fails. Finally we note the sharpening that AdS/CFT brings: because the dual boundary theory is a manifestly unitary quantum field theory, the resolution cannot hide in unknown ultraviolet physics — it must already be present in semiclassical gravity, correctly read.

Throughout we adopt the natural-units conventions of Chapter 1 ($\hbar = c = 1$) and write the von Neumann entropy of a state ρ as $S(\rho) = -\operatorname{Tr}(\rho \log \rho)$, the entanglement entropy of Theorem 55.4, in nats. The bipartition that organizes everything is the split of the global Hilbert space into a radiation factor and a black-hole factor,

$$\mathcal{H} \;=\; \mathcal{H}_{\rm rad} \otimes \mathcal{H}_{\rm BH}, \tag{57.36}$$

where $\mathcal{H}_{\rm rad}$ collects all field modes that have escaped to infinity by time t and $\mathcal{H}_{\rm BH}$ everything still behind, or coincident with, the horizon (the remaining hole together with whatever lives just inside). The reduced states $\rho_{\rm rad} = \operatorname{Tr}_{\rm BH}\rho$ and $\rho_{\rm BH} = \operatorname{Tr}_{\rm rad}\rho$ are the objects whose entropies we track.

57.2.1 The Hawking-pair structure: why the radiation is mixed

The thermal character of the flux is not an accident of coarse-graining; it is built into the microscopic mechanism of emission, and seeing this precisely is what turns "information loss" from a slogan into a computation. The mechanism is pair creation. The gravitational field near the horizon mixes positive- and

negative-frequency modes — the Bogoliubov transformation whose coefficients we compute in detail in Chapter 65 — with the result that each outgoing field mode that reaches infinity is created together with a partner mode that falls into the hole. Label one such outgoing mode of frequency ω by the annihilation operator b_ω and its infalling partner by c_ω. The state in which the field is left, mode by mode, is not the out-vacuum $|0\rangle_b\,|0\rangle_c$ but a correlated superposition of pairs.

We take as input from the Bogoliubov analysis (Chapter 65) and the thermal flux of the previous section the following structural fact: for each frequency the field is in a *two-mode squeezed vacuum*,

$$|\Psi_\omega\rangle \;=\; \frac{1}{\cosh r_\omega}\sum_{n=0}^{\infty}(\tanh r_\omega)^{\,n}\;|n\rangle_b\;|n\rangle_c\,, \tag{57.37}$$

where $|n\rangle_b\,,|n\rangle_c$ are the number eigenstates of the exterior and interior partner modes and $r_\omega>0$ is a squeezing parameter we will fix in a moment by demanding the emitted spectrum be thermal at temperature T_H. The structure of Eq. (57.37) is forced: the conservation laws of pair creation allow only the diagonal terms $|n\rangle_b\,|n\rangle_c$ (one outgoing quantum for each infalling partner), and the geometric weighting in n is what a single Bogoliubov rotation of the vacuum produces. The state is pure — it is a definite vector $|\Psi_\omega\rangle$ — and it is an entangled state of the exterior and the interior. The exterior observer, who can never reach c, sees only the reduced state $\rho_b=\mathrm{Tr}_c\,|\Psi_\omega\rangle\langle\Psi_\omega|$. The following worked example computes that reduced state and its entropy from scratch, fixing r_ω along the way; this is the calculation that makes the radiation's mixedness a theorem rather than an assertion.

Worked Example 57.5 (The Hawking-pair density matrix is exactly thermal)**.** We compute $\rho_b=\mathrm{Tr}_c\,|\Psi_\omega\rangle\langle\Psi_\omega|$ for the state Eq. (57.37), show it is a thermal density matrix, fix the squeezing r_ω from the Planck spectrum, and evaluate its von Neumann entropy.

Normalization. First check that Eq. (57.37) is a unit vector. Using $\langle m|n\rangle=\delta_{mn}$ in each factor,

$$\langle\Psi_\omega|\Psi_\omega\rangle=\frac{1}{\cosh^2 r_\omega}\sum_{n=0}^{\infty}(\tanh r_\omega)^{2n}=\frac{1}{\cosh^2 r_\omega}\,\frac{1}{1-\tanh^2 r_\omega}=\frac{\cosh^2 r_\omega}{\cosh^2 r_\omega}=1, \tag{57.38}$$

where we summed the geometric series ($\tanh^2 r_\omega<1$) and used $1-\tanh^2 r_\omega=\mathrm{sech}^2\, r_\omega$.

The reduced state. Trace over the interior partner with the partial trace of Theorem 55.1, using the number basis $\{|k\rangle_c\}$:

$$\rho_b=\sum_{k=0}^{\infty}{}_c\langle k|\;|\Psi_\omega\rangle\langle\Psi_\omega|\;|k\rangle_c=\frac{1}{\cosh^2 r_\omega}\sum_{k}\sum_{m,n}(\tanh r_\omega)^{m+n}\;|m\rangle_b\;\langle k|n\rangle\,\langle m|k\rangle\;\langle n|_b$$

$$= \frac{1}{\cosh^2 r_\omega} \sum_{n=0}^{\infty} (\tanh r_\omega)^{2n} \; |n\rangle_b \langle n|_b \,, \tag{57.39}$$

the Kronecker deltas $\langle k|n\rangle = \delta_{kn}$ and $\langle m|k\rangle = \delta_{mk}$ collapsing the double sum to $m = n = k$. Thus ρ_b is diagonal in the number basis with eigenvalues

$$p_n \;=\; (1-x)\, x^{\,n}, \qquad x \;\equiv\; \tanh^2 r_\omega, \tag{57.40}$$

where we wrote $\cosh^{-2} r_\omega = 1 - \tanh^2 r_\omega = 1 - x$. These p_n sum to one and decay geometrically: the reduced state is a *mixed* state, a thermal (Gibbs) distribution over occupation number.

Fixing the temperature. A geometric population $p_n \propto x^n$ is precisely a Bose–Einstein distribution. The mean occupation is

$$\langle n \rangle = \sum_n n\, p_n = (1-x) \sum_n n\, x^n = (1-x)\, \frac{x}{(1-x)^2} = \frac{x}{1-x}, \tag{57.41}$$

using $\sum_n n x^n = x/(1-x)^2$. The previous section's thermal flux states that the occupation of a mode of frequency ω is the Planck value $\langle n \rangle = (e^{\omega/T_H} - 1)^{-1}$ (Eq. (57.12)). Matching to Eq. (57.41),

$$\frac{x}{1-x} = \frac{1}{e^{\omega/T_H} - 1} \;\Longrightarrow\; x = e^{-\omega/T_H}, \qquad \text{i.e.} \qquad \tanh^2 r_\omega = e^{-\omega/T_H}. \tag{57.42}$$

With this identification Eq. (57.40) becomes $p_n = (1 - e^{-\omega/T_H})\, e^{-n\omega/T_H}$, and ρ_b is *exactly* the canonical thermal state of a single harmonic mode of energy ω at temperature T_H,

$$\rho_b = (1 - e^{-\omega/T_H}) \sum_{n=0}^{\infty} e^{-n\omega/T_H} \; |n\rangle\langle n| = \frac{e^{-\omega\, \hat{n}/T_H}}{\mathrm{Tr}\; e^{-\omega\, \hat{n}/T_H}}, \tag{57.43}$$

with $\hat{n} = b^\dagger b$ the number operator. The exterior observer sees a heat bath at the Hawking temperature — with no remaining trace of the purity of $|\Psi_\omega\rangle$.

The entropy of one mode. With $p_n = (1-x)x^n$ the von Neumann entropy Eq. (55.6) is

$$\begin{aligned} S(\rho_b) &= -\sum_n p_n \log p_n = -\sum_n (1-x) x^n \big[\log(1-x) + n \log x\big] \\ &= -\log(1-x) \underbrace{(1-x) \sum_n x^n}_{=1} \;-\; \log x \underbrace{(1-x) \sum_n n\, x^n}_{=\langle n \rangle} \\ &= -\log(1-x) - \langle n \rangle \log x. \end{aligned} \tag{57.44}$$

Substituting $x = e^{-\omega/T_H}$ and $\langle n \rangle = (e^{\omega/T_H} - 1)^{-1}$ gives the familiar thermal-oscillator entropy

$$S(\rho_b) = \frac{\omega/T_H}{e^{\omega/T_H} - 1} - \log(1 - e^{-\omega/T_H}) = (1 + \langle n \rangle) \log(1 + \langle n \rangle) - \langle n \rangle \log \langle n \rangle, \tag{57.45}$$

the last equality following from $1 + \langle n\rangle = (1-x)^{-1}$ and $\langle n\rangle = x/(1-x)$, which turn $-\log(1-x) = \log(1+\langle n\rangle)$ and $-\log x = \log(1+\langle n\rangle) - \log\langle n\rangle$. This is strictly positive for every ω: each emitted mode carries genuine entropy.

The lesson of Theorem 57.5 is the engine of the whole paradox. The *global* pair state $|\Psi_\omega\rangle$ is pure, so its entropy is zero; by the purity criterion (Theorem 55.7) the exterior and interior reduced states share the same spectrum and the same entropy, $S(\rho_b) = S(\rho_c) > 0$. The entropy of the radiation is therefore not a deficit of the global state's purity — it is the entanglement between what escaped and what fell in. The information that would distinguish the initial collapsing body is not destroyed at the level of $|\Psi_\omega\rangle$; it sits in the cross-correlations between b and c. The trouble is that the partner c is on the far side of the horizon, causally inaccessible, and (in the semiclassical picture) destined for the singularity. If the only thing that ever comes out is ρ_b, the correlations are lost for good and the outside is left genuinely mixed.

Physical Insight

"Thermal" does not mean "structureless." The radiation looks like a heat bath *to anyone who measures only the exterior modes*, exactly as a single spin of a Bell pair looks maximally mixed to anyone who holds only that spin. The information is not absent; it is non-locally encoded in correlations with a partner one cannot reach. The entire resolution of the paradox will hinge on whether those partners — or rather the information in them — can be recovered from the radiation after all, and Chapter 56's quantum extremal surfaces are the tool that says when they can.

Because the Hawking modes of different frequencies, and the successive pairs emitted at different times, are produced independently in the semiclassical calculation, the total radiation state at time t is a tensor product of thermal factors,

$$\rho_{\mathrm{rad}}^{\mathrm{sc}}(t) = \bigotimes_{\text{modes emitted by } t} \rho_b, \tag{57.46}$$

and the von Neumann entropy is additive over a tensor product, $S(\rho_1 \otimes \rho_2) = S(\rho_1) + S(\rho_2)$ (immediate from Eq. (55.6), since the spectrum of a product is the product of spectra and log turns products into sums). Hence

$$S_{\mathrm{rad}}^{\mathrm{sc}}(t) = \sum_{\text{modes emitted by } t} S(\rho_b) \;=\; S_{\mathrm{rad}}^{\mathrm{th}}(t), \tag{57.47}$$

which is exactly the thermal radiation entropy the thermodynamics section tracked. We have now identified the semiclassical *fine-grained* entropy with the *thermal* entropy: in Hawking's calculation they coincide, and that coincidence is the disease.

57.2.2 Version 1: Hawking's statement (the entropy form)

The first precise statement of the paradox is a monotonicity together with a sign mismatch at the endpoint.

Proposition 57.6 (Semiclassical radiation entropy: monotone and terminal)**.** *In the semiclassical description Eq. (57.46), the fine-grained radiation entropy $S^{\mathrm{sc}}_{\mathrm{rad}}(t)$ is non-decreasing in t, strictly increasing while emission continues, and at the evaporation endpoint t_{evap} it equals the full thermal entropy of all emitted quanta, a strictly positive number of order $S_{\mathrm{BH}}(0)$. If the black hole formed from a pure state and evolution is unitary, the final radiation entropy must instead be zero. The two are incompatible.*

Proof. Monotonicity is the additivity Eq. (57.47) combined with positivity of each term. Between times $t_1 < t_2$ the radiation state acquires extra independent thermal factors, so

$$S^{\mathrm{sc}}_{\mathrm{rad}}(t_2) - S^{\mathrm{sc}}_{\mathrm{rad}}(t_1) = \sum_{\text{modes emitted in } (t_1,t_2)} S(\rho_b) \;\geq 0, \tag{57.48}$$

strictly positive whenever any mode is emitted, since each $S(\rho_b) > 0$ by Eq. (57.45). As $t \to t_{\mathrm{evap}}$ the sum runs over all emitted quanta and converges to the total thermal entropy $S^{\mathrm{th}}_{\mathrm{rad}}(t_{\mathrm{evap}})$, a finite positive number. A standard thermodynamic estimate (entropy-to-energy ratio of a thermal gas against the first law $\mathrm{d}M = T_H\,\mathrm{d}S_{\mathrm{BH}}$) gives $S^{\mathrm{th}}_{\mathrm{rad}}(t_{\mathrm{evap}}) \simeq \frac{4}{3} S_{\mathrm{BH}}(0)$, larger than the initial black-hole entropy: a thermal gas carries more entropy per unit energy than the hole it came from.

For the unitarity clause, suppose the global state begins as a pure state $|\Psi_0\rangle$ (a definite, if complicated, collapsing configuration) and evolves by a unitary $U(t)$. A unitary preserves purity — $U\,|\Psi_0\rangle\langle\Psi_0|\,U^\dagger$ has the same single nonzero eigenvalue, 1 — so $\rho(t) = U(t)\,|\Psi_0\rangle\langle\Psi_0|\,U(t)^\dagger$ is pure at all times, with $S(\rho(t)) = 0$. At t_{evap} the black-hole factor has disappeared, $\mathcal{H} \to \mathcal{H}_{\mathrm{rad}}$, so $\rho_{\mathrm{rad}}(t_{\mathrm{evap}}) = \rho(t_{\mathrm{evap}})$ is the whole (pure) state and $S(\rho_{\mathrm{rad}}) = 0$. This contradicts $S^{\mathrm{sc}}_{\mathrm{rad}}(t_{\mathrm{evap}}) \simeq \frac{4}{3} S_{\mathrm{BH}}(0) > 0$. □

This is the form in which Hawking originally posed the problem, and the form most often quoted: a pure state evolves into a mixed thermal state, so the final-state map is not unitary; pure → mixed is the signature of information loss. Phrased as in Theorem 57.6, the contradiction is already complete — but it has a soft spot. It compares the very beginning with the very end and never specifies *when* the semiclassical approximation must first go wrong. A sceptic could imagine the breakdown deferred to the last Planckian instant of evaporation, where nobody trusts the calculation anyway. The next version closes that escape.

57.2.3 Version 2: the unitarity bound and the Page time

To pin down *when* the semiclassical curve becomes impossible, we need a quantitative ceiling on the radiation entropy that holds at every instant. Unitarity supplies one, in two steps: an absolute bound on any entropy from the size of the Hilbert space, and the equality of the two reduced entropies for a pure global state.

Lemma 57.7 (Maximal entropy of a finite system)**.** *For any density matrix ρ on a Hilbert space of finite dimension d,*

$$S(\rho) \;\le\; \log d, \tag{57.49}$$

with equality if and only if $\rho = \mathbf{1}/d$ is the maximally mixed state.

Proof. Compare ρ with the maximally mixed state $\sigma = \mathbf{1}/d$ using the relative entropy $S(\rho\,\|\,\sigma) = \operatorname{Tr}\rho\log\rho - \operatorname{Tr}\rho\log\sigma$, which is non-negative by Klein's inequality (Theorem 55.9). Here $\log\sigma = \log(\mathbf{1}/d) = -(\log d)\,\mathbf{1}$, so $-\operatorname{Tr}\rho\log\sigma = (\log d)\operatorname{Tr}\rho = \log d$, while $\operatorname{Tr}\rho\log\rho = -S(\rho)$. Therefore

$$0 \le S(\rho\,\|\,\sigma) = -S(\rho) + \log d, \tag{57.50}$$

which rearranges to Eq. (57.49). Klein's inequality is saturated precisely when $\rho = \sigma$, giving the equality clause. □

Theorem 57.8 (The unitarity bound on the radiation entropy)**.** *Let the global state be pure and let $\mathcal{H}_{\mathrm{BH}}$ have $\dim\mathcal{H}_{\mathrm{BH}} = e^{S_{\mathrm{BH}}(t)}$, with $S_{\mathrm{BH}}(t) = A(t)/4G$ the Bekenstein–Hawking entropy of the instantaneous horizon. Then at every time*

$$S\big(\rho_{\mathrm{rad}}(t)\big) \;=\; S\big(\rho_{\mathrm{BH}}(t)\big) \;\le\; S_{\mathrm{BH}}(t) = \frac{A(t)}{4G}. \tag{57.51}$$

The fine-grained radiation entropy can never exceed the coarse-grained black-hole entropy.

Proof. Two ingredients. *First*, purity forces the two reduced entropies to agree. For a pure global state on $\mathcal{H}_{\mathrm{rad}}\otimes\mathcal{H}_{\mathrm{BH}}$, the Schmidt decomposition (Theorem 55.7) writes $|\Psi\rangle = \sum_i \sqrt{p_i}\,|i\rangle_{\mathrm{rad}}\,|i\rangle_{\mathrm{BH}}$ with a single set of Schmidt coefficients $\{p_i\}$; both reduced matrices are diagonal with these same eigenvalues, so $S(\rho_{\mathrm{rad}}) = -\sum_i p_i\log p_i = S(\rho_{\mathrm{BH}})$. (Equivalently this is the Araki–Lieb saturation: for a pure bipartite state $S_{\mathrm{rad}} = S_{\mathrm{BH}}$, the case of Theorem 55.12 with the global state pure.)

Second, the black-hole factor is finite-dimensional, with $\log\dim\mathcal{H}_{\mathrm{BH}} = S_{\mathrm{BH}}(t)$ — this is exactly the microscopic content of the Bekenstein–Hawking entropy established in the thermodynamics section (Eq. (57.26)): $e^{A/4G}$ is the count of black-hole microstates. Theorem 57.7 then bounds $S(\rho_{\mathrm{BH}}) \le \log\dim\mathcal{H}_{\mathrm{BH}} = S_{\mathrm{BH}}(t)$. Chaining the equality and the bound gives Eq. (57.51). □

Theorem 57.8 is the sharp form of the paradox, and its force is in the time dependence. The right-hand side $S_{\mathrm{BH}}(t)$ *decreases* as the hole evaporates — the ceiling is falling toward zero. The semiclassical curve $S^{\mathrm{sc}}_{\mathrm{rad}}(t)$ of Eq. (57.47), by contrast, *increases* monotonically (Theorem 57.6). A rising curve and a falling ceiling must cross, and the crossing has a name.

Definition 57.9 (Page time)**.** The *Page time* t_{Page} is the instant at which the semiclassical (thermal) radiation entropy first equals the Bekenstein–Hawking entropy of the remaining hole,

$$S^{\mathrm{sc}}_{\mathrm{rad}}(t_{\mathrm{Page}}) \;=\; S_{\mathrm{BH}}(t_{\mathrm{Page}}). \tag{57.52}$$

Since both sides start at $S_{\mathrm{BH}}(0)$ worth of "room" and move oppositely, the crossing occurs when the horizon has given up an $O(1)$ fraction of its entropy; carrying the $\frac{4}{3}$ thermal factor of Eq. (57.33), the precise value is $S_{\mathrm{BH}}(t_{\mathrm{Page}}) = \frac{4}{7}S_{\mathrm{BH}}(0)$ (Theorem 57.16) — somewhat past the midpoint of the hole's lifetime for a Schwarzschild evaporation.

For $t < t_{\mathrm{Page}}$ the semiclassical value sits below the ceiling and is consistent with unitarity. For $t > t_{\mathrm{Page}}$ it lies *above* $S_{\mathrm{BH}}(t)$ and therefore violates Eq. (57.51): no pure global state can produce it. This is the decisive sharpening over Version 1. The semiclassical computation does not merely give the wrong answer at the Planckian endpoint; it gives an impossible answer already at the Page time, when the hole is still macroscopically large, the curvature at the horizon is still tiny, and every assumption that went into Hawking's calculation looks unimpeachable. *If* the process is unitary, the radiation entropy must turn around at t_{Page} and descend, ultimately to zero — it must follow not $S^{\mathrm{sc}}_{\mathrm{rad}}$ but the curve $\min\{S^{\mathrm{sc}}_{\mathrm{rad}}(t), S_{\mathrm{BH}}(t)\}$, which rises, peaks at t_{Page}, and falls. Figure 57.3 shows the collision and the demanded turnover.

Caution

The bound Eq. (57.51) assumes $\dim \mathcal{H}_{\mathrm{BH}} = e^{S_{\mathrm{BH}}}$ is *finite* — that the black hole is a system of finitely many quantum states, not an infinite reservoir. This is the single most important physical assumption in the whole argument, and it is precisely what the Bekenstein–Hawking entropy, read as a microstate count, asserts. If instead the interior were an infinite-dimensional remnant able to store unbounded entanglement, Theorem 57.7 would give no ceiling and there would be no paradox — and no microstate interpretation of $A/4G$ either. The remnant scenario trades the information puzzle for a different pathology (infinitely many species of arbitrarily light states); we do not pursue it, and the holographic counting of Chapters 53 and 54 weighs heavily against it.

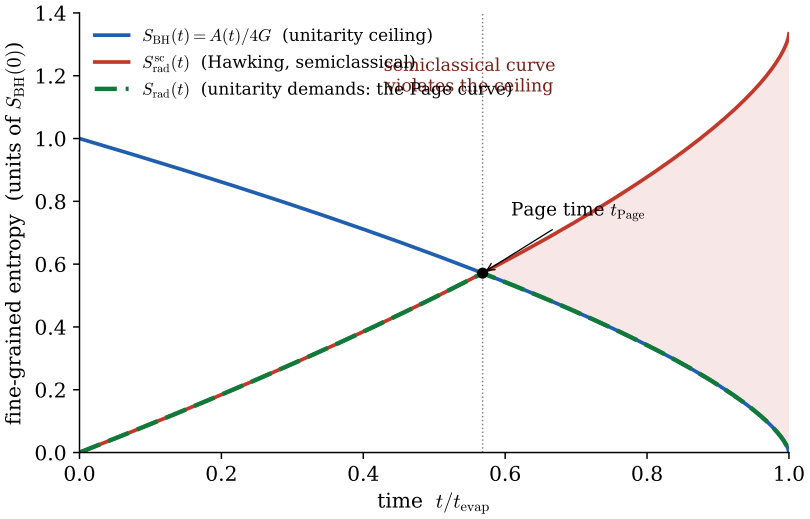

Figure 57.3: The clash of Theorem 57.8. The Bekenstein–Hawking entropy $S_{\rm BH}(t) = A(t)/4G$ (blue) falls to zero at the evaporation endpoint; unitarity makes it a hard ceiling on the radiation entropy. Hawking's semiclassical fine-grained entropy $S^{\rm sc}_{\rm rad}(t)$ (red) rises monotonically (Theorem 57.6) and at the endpoint reaches $\simeq \frac{4}{3}S_{\rm BH}(0)$, far above zero. The two cross at the Page time $t_{\rm Page}$ (Theorem 57.9), where $S^{\rm sc}_{\rm rad} = S_{\rm BH} = \frac{4}{7}S_{\rm BH}(0)$; in the shaded region the semiclassical curve lies *above* the ceiling and is impossible for a unitary theory. The dashed green curve is what unitarity demands instead — the Page curve, which tracks the rising thermal entropy until $t_{\rm Page}$ and then follows $S_{\rm BH}$ down to zero. Deriving its exact shape is the task of Section 57.3.

57.2.4 Version 3: the AMPS firewall and the monogamy of entanglement

Versions 1 and 2 say that the radiation entropy must turn over; they do not yet say that anything is wrong with the *geometry* near the horizon. The AMPS argument shows that something is: once one grants the entropy turnover demanded by unitarity, one cannot simultaneously keep a smooth horizon and the ordinary rules of low-energy quantum mechanics. The obstruction is the monogamy of entanglement, and its rigorous form is strong subadditivity.

Set up the three relevant systems for a black hole *past* its Page time. Let

- R be the early radiation, all the Hawking quanta emitted before some late time $t > t_{\rm Page}$;
- b be one freshly emitted late Hawking mode (the exterior partner of Eq. (57.37));

- c be the infalling partner of b, the interior mode with which b is paired across the horizon.

Two physical principles make incompatible demands on b.

Demand of the equivalence principle (smooth horizon). The equivalence principle says an infalling observer crossing a large, low-curvature horizon experiences nothing special: the local state is the vacuum. For the field modes straddling the horizon, "vacuum" is exactly the two-mode squeezed pair Eq. (57.37): b and c are in a pure, near-maximally entangled state. In the idealization that makes the inequality crisp, the pair bc is pure and decoupled from the early radiation, so

$$S(\rho_{bc}) = 0, \qquad S(\rho_{Rbc}) = S(\rho_R), \qquad S(\rho_b) = S(\rho_c) > 0. \tag{57.53}$$

(The first because bc is pure; the second because appending a pure, uncorrelated factor leaves the entropy unchanged; the third by the purity criterion applied to bc.)

Demand of unitarity (the Page condition). After the Page time the radiation entropy is *decreasing* (Fig. 57.3). Adding the newly emitted mode b to the already-collected early radiation R must therefore lower the total radiation entropy,

$$S(\rho_{Rb}) \;<\; S(\rho_R), \tag{57.54}$$

because the running entropy $S(\rho_{\mathrm{rad}})$ at time t is $S(\rho_{Rb})$ and at the slightly earlier time was $S(\rho_R)$, and it is on the descending branch. Physically, the late quantum b purifies part of the early radiation: it is (nearly maximally) entangled with R. In mutual-information terms (Theorem 55.13),

$$I(R:b) = S(\rho_R) + S(\rho_b) - S(\rho_{Rb}) > S(\rho_b) > 0. \tag{57.55}$$

These two demands collide, and strong subadditivity makes the collision exact.

Theorem 57.10 (The AMPS inequality fails)**.** *The smooth-horizon conditions Eq. (57.53) and the post-Page unitarity condition Eq. (57.54) cannot both hold for the systems R, b, c in any quantum theory obeying strong subadditivity.*

Proof. Apply strong subadditivity (Theorem 55.47) in the standard form $S(XY)+S(YZ) \geq S(XYZ)+S(Y)$ to the assignment $X = R$, $Y = b$, $Z = c$:

$$S(\rho_{Rb}) + S(\rho_{bc}) \;\geq\; S(\rho_{Rbc}) + S(\rho_b). \tag{57.56}$$

Now feed in the smooth-horizon data Eq. (57.53): $S(\rho_{bc}) = 0$ and $S(\rho_{Rbc}) = S(\rho_R)$. The inequality collapses to

$$S(\rho_{Rb}) \;\geq\; S(\rho_R) + S(\rho_b). \tag{57.57}$$

But ordinary subadditivity (Theorem 55.12) is the opposite inequality, $S(\rho_{Rb}) \leq S(\rho_R) + S(\rho_b)$, holding for every state. The two together force the equality $S(\rho_{Rb}) = S(\rho_R) + S(\rho_b)$, i.e. $I(R : b) = 0$: the late mode b is *completely uncorrelated* with the early radiation. This flatly contradicts the unitarity demand Eq. (57.55), $I(R : b) > S(\rho_b) > 0$. Hence Eq. (57.53) and Eq. (57.54) are mutually exclusive. □

The content of Theorem 57.10 is the monogamy of entanglement, sharpened to a theorem. A maximally entangled pair is monogamous: if b is maximally entangled with its interior partner c (smooth horizon), it has no entanglement left to share with anyone else, in particular not with the early radiation R. Conversely, if unitarity requires b to purify R (the Page condition), then b is spoken for and cannot also be the vacuum partner of c — the horizon cannot be smooth. Strong subadditivity is the precise statement that these options exhaust the possibilities; one of them must be abandoned.

Spelling out which assumptions are in play, the argument shows that the following four cannot all hold for an old black hole:

(U) **Unitarity:** the radiation entropy follows the Page curve, so Eq. (57.54) holds after t_{Page};

(E) **Equivalence principle:** the horizon is a smooth, low-curvature region with the field in its local vacuum, so Eq. (57.53) holds;

(Q) **Low-energy quantum mechanics:** ordinary quantum field theory, hence strong subadditivity (Theorem 55.47), governs the modes R, b, c;

(S) **No drama / semiclassical locality:** the late mode b and the early radiation R are independent subsystems, so the entropies above are well defined on a common Hilbert space.

Since (Q) is a theorem of quantum mechanics that we are not willing to surrender, and (S) is what lets us write the inequality at all, the live tension is between (U) and (E). Keeping unitarity (U) and giving up the smooth horizon (E) is the *firewall*: the late mode b is not in its vacuum state but in a highly excited one, so an infalling observer meets a wall of high-energy quanta at the horizon — a violation of the equivalence principle at a place where general relativity insists nothing should happen. Keeping the smooth horizon and giving up unitarity returns to Hawking's information loss. AMPS argued that for the most conservative reading of black-hole complementarity, the firewall is forced.

Caution

Status, and dating. Unlike Versions 1 and 2, which are clean theorems given their hypotheses, the firewall is a genuine *frontier* statement, and

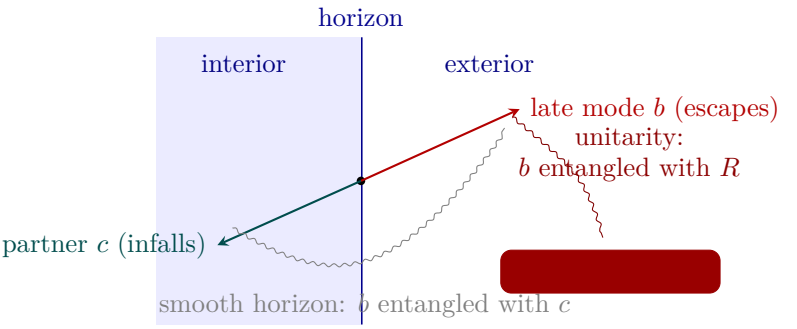

Figure 57.4: The monogamy clash of Theorem 57.10. A Hawking pair is created at the horizon: the exterior mode b escapes, its partner c falls in. A smooth horizon (equivalence principle) demands b be maximally entangled with c (grey wiggle). After the Page time, unitarity demands the same b purify the early radiation R (red wiggle), i.e. be entangled with R. Monogamy of entanglement — strong subadditivity, Theorem 55.47 — forbids b from being maximally entangled with two independent systems at once. One of the two demands must give.

its status as of the mid-2020s is unsettled. The community consensus is that the entropy paradox of Version 2 is resolved — the Page curve *is* reproduced by semiclassical gravity once the quantum-extremal-surface and replica-wormhole contributions of Chapter 56 and the gravitational path integral are included (Section 57.4). Whether this resolution also dissolves the firewall, by making the would-be partner c secretly part of the early radiation R (so that the monogamy violation never occurs), is a question about the operational recovery of the interior and the meaning of the entanglement-wedge reconstruction of Chapter 56; it is not settled with the rigor of Theorem 57.10. We will mark precisely which claims are established and which remain open as the chapter proceeds.

57.2.5 The AdS/CFT sharpening: the answer must live in gravity

There is one more turn of the screw, and it is the one that has driven the modern resolution. In all three versions above one could, in principle, retreat to the position that quantum gravity is unknown and that the rules of quantum mechanics — unitarity, the finiteness of $\dim \mathcal{H}_{\mathrm{BH}}$, even strong subadditivity — might be modified by Planck-scale physics we do not control. AdS/CFT removes that retreat.

Place the black hole in asymptotically anti-de Sitter space. By the correspondence of Chapter 53, the entire bulk gravitational system — black hole, Hawking

radiation, infalling observers and all — is described *exactly* by a conformal field theory living on the AdS boundary (the field–operator dictionary, Section 53.5). An AdS black hole is dual to a thermal state of that boundary CFT (Chapter 54), and its formation and evaporation correspond to ordinary time evolution of the boundary state. But the boundary CFT is an ordinary quantum field theory on a fixed spacetime: it has a Hamiltonian H, a well-defined Hilbert space, and a unitary time-evolution operator e^{-iHt}. Its evolution is manifestly, exactly unitary, with no Planck-scale caveats — unitarity is not an assumption about the bulk but a structural fact about the dual.

The consequences are decisive. *(i)* A pure bulk initial state maps to a pure boundary state, which stays pure under e^{-iHt}; so the final radiation *is* pure and $S(\rho_{\rm rad})$ must return to its initial value. Version 1's information loss is excluded outright. *(ii)* The boundary Hilbert space at fixed energy is finite-dimensional with $\log \dim = S_{\rm BH}$, the holographic entropy count of Chapter 54, so the unitarity bound Eq. (57.51) is not a hypothesis but a boundary theorem; the Page turnover is mandatory. *(iii)* Strong subadditivity holds in the boundary CFT as in any quantum system, so the AMPS tension is real and not an artifact of treating gravity naively.

The sharpening is therefore this: the paradox is genuine even when we *know* the theory is unitary. Whatever resolves it cannot be unknown ultraviolet physics that repairs a broken unitarity — unitarity was never broken. The resolution must instead be an error in the *semiclassical computation of the entropy*: Hawking's calculation, performed entirely within low-energy effective field theory on a smooth background, must be missing a contribution that bends $S_{\rm rad}(t)$ back down at the Page time. The remarkable fact, which the rest of this chapter develops, is that the missing contribution is itself *semiclassical* — a saddle of the gravitational path integral (the replica wormhole) computed with the quantum-extremal-surface technology of Chapter 56. The boundary's guaranteed unitarity tells us the answer exists in gravity; the QES prescription is how gravity delivers it.

Physical Insight

The deepest reading of the paradox is not "gravity is non-unitary" but "the semiclassical entropy formula is incomplete." AdS/CFT converts a question we cannot answer (is quantum gravity unitary?) into one we can (what does the gravitational path integral actually compute for $S_{\rm rad}$?). The lesson of Chapter 56 — that fine-grained entropies are computed by extremizing a generalized entropy over bulk surfaces, not by the naive matter trace — is exactly the missing ingredient, and the next sections turn it on the evaporating hole.

We have now stated the paradox three ways and located its resolution in

semiclassical gravity rather than in unknown physics. The common demand all three versions make is unambiguous: in a unitary theory the fine-grained radiation entropy must *rise, peak near the Page time, and fall back to zero.* What none of the three has given us is the precise *shape* of that curve — how high it peaks, how it bends, what statistical law governs the turnover. That shape is the Page curve, and the next section derives it from the statistics of random states alone, furnishing the exact target that any correct gravitational computation must reproduce.

57.3 The Page curve

The previous section sharpened the slogan "black holes destroy information" into a precise demand on a single observable. If formation and evaporation are unitary, the global state stays pure, and the fine-grained entropy of the radiation $S_{\mathrm{rad}}(t)$ must begin at zero (no radiation), end at zero (a pure final state of radiation, the black hole gone), and therefore *rise and then fall.* Hawking's semiclassical calculation, by contrast, makes each emitted quantum exactly thermal and statistically independent of every other, so S_{rad} rises monotonically and never comes back down. We are left with a question that has a sharp, checkable answer: if unitarity holds, what curve does $S_{\mathrm{rad}}(t)$ actually trace? This section answers it without invoking any gravitational dynamics at all. It assembles the curve from the statistics of a generic pure state alone — the result Page extracted in 1993 [374] — and so produces a precise target that any correct gravitational computation must reproduce. The next section's task will be to find what in semiclassical gravity bends the entropy back down; here we establish exactly what "bends down" must mean.

57.3.1 Random states as a model of a scrambled black hole

The physical input that licenses a statistical treatment is *scrambling.* A black hole is the fastest scrambler in nature: an excitation thrown in is spread over the entire horizon in a time $t_{\mathrm{scr}} \sim \beta \ln S_{\mathrm{BH}}$, parametrically shorter than the evaporation time. After the scrambling time the microscopic state of the radiation-plus-hole system has explored its available Hilbert space so thoroughly that, for the purpose of computing a coarse observable like the entanglement between the radiation and the remaining hole, it is indistinguishable from a state drawn uniformly at random. We therefore model the joint state at any time as a Haar-random pure state on a bipartite Hilbert space, compute the typical entanglement entropy of one factor, and only afterwards reinstate the time dependence through the dimensions of the two factors. This is a model, and we flag it as such: it replaces the true (unknown) microstate by a typical one, and its justification is the scrambling estimate together with the concentration-of-measure result proved

below, which guarantees that "typical" is overwhelmingly likely. What the model cannot do is exhibit the gravitational mechanism behind the curve — that is precisely the gap the island construction will fill.

Fix the arena. Let $\mathcal{H} = \mathcal{H}_A \otimes \mathcal{H}_B$ with $\dim \mathcal{H}_A = d_A$ and $\dim \mathcal{H}_B = d_B$, and adopt the convention

$$d_A \le d_B, \qquad d \equiv d_A d_B = \dim \mathcal{H}, \tag{57.58}$$

so that A is the smaller factor. (When we apply this to a black hole, A will be whichever of radiation/interior is smaller at the time in question; the roles switch at the Page time.) A pure state $|\psi\rangle \in \mathcal{H}$ has reduced density matrix $\rho_A = \mathrm{Tr}_B\, |\psi\rangle\langle\psi|$ (Theorem 55.2), and its entanglement entropy is the von Neumann entropy $S_A = -\mathrm{Tr}(\rho_A \ln \rho_A)$ of Theorem 55.4 and Eq. (55.6). Because the global state is pure, $S_A = S_B$ by Eq. (55.14): the entropy is a property of the cut, not of which side we look from. The largest value S_A can take is $\ln d_A$, attained when $\rho_A = I/d_A$ is maximally mixed; the question is how close to this ceiling a *random* state comes.

Definition 57.11 (Haar-random pure state)**.** Let $|\psi_0\rangle$ be any fixed unit vector in $\mathcal{H}$. A *Haar-random pure state* is $|\psi\rangle = U\,|\psi_0\rangle$ with U distributed according to the (normalized, bi-invariant) Haar measure on the unitary group $\mathrm{U}(d)$. Equivalently, writing $|\psi\rangle = \sum_i c_i\,|i\rangle$ in any orthonormal basis, the coefficients c_i are jointly distributed as a complex Gaussian vector conditioned to unit norm; the distribution is invariant under $|\psi\rangle \to V\,|\psi\rangle$ for any fixed $V \in \mathrm{U}(d)$. The induced ensemble of reduced density matrices ρ_A is the one we average over, denoted $\mathbb{E}[\,\cdot\,]$.

57.3.2 The Haar average of the purity

We cannot easily average the von Neumann entropy directly — it is transcendental in the eigenvalues of ρ_A — but we *can* average the purity $\mathrm{Tr}\,\rho_A^2$ exactly, because it is quadratic in ρ_A and hence quartic in $|\psi\rangle$, a polynomial that the Haar measure integrates in closed form. The purity is the Rényi-2 datum $S_2(A) = -\ln \mathrm{Tr}\,\rho_A^2$ of Theorem 55.5; it is the cheapest nontrivial probe of how mixed ρ_A is, and it already determines the leading shape of the curve. The computation rests on one structural fact about averaging two copies of a random state.

Lemma 57.12 (Symmetric-subspace average)**.** *For a Haar-random pure state $|\psi\rangle$ on a Hilbert space $\mathcal{H}$ of dimension d,*

$$\mathbb{E}[\,|\psi\rangle\langle\psi| \otimes |\psi\rangle\langle\psi|\,] = \frac{I + \mathbb{S}}{d(d+1)}, \tag{57.59}$$

where $\mathbb{S}$ is the swap operator on $\mathcal{H} \otimes \mathcal{H}$, defined by $\mathbb{S}\,(|\alpha\rangle \otimes |\beta\rangle) = |\beta\rangle \otimes |\alpha\rangle$, and I is the identity on $\mathcal{H} \otimes \mathcal{H}$.

Proof. The tensor square $|\psi\rangle^{\otimes 2}$ is symmetric under exchange of the two copies, so $\mathbb{S}\,|\psi\rangle^{\otimes 2} = |\psi\rangle^{\otimes 2}$; consequently the averaged operator $M \equiv \mathbb{E}[|\psi\rangle\langle\psi|^{\otimes 2}]$ is supported entirely on the symmetric subspace $\mathrm{Sym}^2(\mathcal{H}) \subset \mathcal{H}\otimes\mathcal{H}$, the $+1$ eigenspace of $\mathbb{S}$, whose dimension is $\binom{d+1}{2} = \tfrac{1}{2}d(d+1)$. By the invariance of the Haar measure, M commutes with $U\otimes U$ for every $U \in \mathrm{U}(d)$:

$$(U\otimes U)\,M\,(U\otimes U)^\dagger = \mathbb{E}\Big[(U\,|\psi\rangle)\langle\psi|\,U^\dagger \otimes (U\,|\psi\rangle)\langle\psi|\,U^\dagger\Big] = \mathbb{E}\Big[|\psi\rangle\langle\psi|^{\otimes 2}\Big] = M, \tag{57.60}$$

the middle step using that $U\,|\psi\rangle$ is again Haar-distributed. Now $\mathrm{Sym}^2(\mathcal{H})$ is an *irreducible* representation of $\mathrm{U}(d)$ under the diagonal action $U \mapsto U\otimes U$ (this is the $n=2$ case of Schur–Weyl duality: the commutant of the diagonal $\mathrm{U}(d)$ action on $\mathcal{H}^{\otimes 2}$ is spanned by I and $\mathbb{S}$, equivalently the algebra of S_2). By Schur's lemma an operator that commutes with an irreducible representation and is supported on its carrier space is a multiple of the identity there. Hence $M = c\,P_{\mathrm{sym}}$, where $P_{\mathrm{sym}} = \tfrac{1}{2}(I+\mathbb{S})$ is the projector onto $\mathrm{Sym}^2(\mathcal{H})$. The constant is fixed by the trace: $\mathrm{Tr}\,M = \mathbb{E}[(\mathrm{Tr}\,|\psi\rangle\langle\psi|)^2] = \mathbb{E}[1] = 1$, while $\mathrm{Tr}\,P_{\mathrm{sym}} = \tfrac{1}{2}d(d+1)$, so $c = 2/[d(d+1)]$ and $M = 2P_{\mathrm{sym}}/[d(d+1)] = (I+\mathbb{S})/[d(d+1)]$, which is Eq. (57.59). □

With the second-moment identity in hand the purity average is a short trace computation, which we present as the central worked calculation of the section.

Worked Example 57.13 (The Haar-averaged purity)**.** We compute $\mathbb{E}[\mathrm{Tr}\,\rho_A^2]$ for $\rho_A = \mathrm{Tr}_B\,|\psi\rangle\langle\psi|$ with $|\psi\rangle$ Haar-random on $\mathcal{H}_A\otimes\mathcal{H}_B$, and read off the regimes.

Step 1: the swap trick. Work on two copies, labelling them and their factors A, B and A', B'. Let $\mathbb{S}_A$ denote the swap acting only on the A factors (interchanging $\mathcal{H}_A \leftrightarrow \mathcal{H}_{A'}$, identity on $\mathcal{H}_B\otimes\mathcal{H}_{B'}$), and $\mathbb{S}_B$ the swap on the B factors; the full swap factorizes as $\mathbb{S} = \mathbb{S}_A\mathbb{S}_B$. The purity is a partial trace against a partial swap:

$$\mathrm{Tr}\,\rho_A^2 = \mathrm{Tr}_{AA'BB'}[(\rho\otimes\rho)\,\mathbb{S}_A]\,, \qquad \rho = |\psi\rangle\langle\psi|\,. \tag{57.61}$$

To verify Eq. (57.61), trace over B, B' first: $\mathrm{Tr}_{BB'}(\rho\otimes\rho) = \rho_A\otimes\rho_A$, and $\mathbb{S}_A$ touches only the A factors, so the right-hand side is $\mathrm{Tr}_{AA'}[(\rho_A\otimes\rho_A)\,\mathbb{S}_A]$. Writing $\rho_A = \sum_{ij}(\rho_A)_{ij}\,|i\rangle\langle j|$ and using $\mathrm{Tr}_{AA'}[(|i\rangle\langle j|\otimes|k\rangle\langle l|)\mathbb{S}_A] = \langle l|i\rangle\langle j|k\rangle = \delta_{li}\delta_{jk}$ collapses the double sum to $\sum_{jk}(\rho_A)_{kj}(\rho_A)_{jk} = \mathrm{Tr}\,\rho_A^2$. This is the standard identity "$\mathrm{Tr}\,\rho_A^2$ equals the expectation of the swap" specialized to the A factors.

Step 2: average and trace. Take the Haar average of Eq. (57.61) and insert Eq. (57.59) with $d = d_A d_B$:

$$\mathbb{E}[\mathrm{Tr}\,\rho_A^2] = \mathrm{Tr}\big[\mathbb{E}(\rho\otimes\rho)\,\mathbb{S}_A\big] = \frac{1}{d(d+1)}\Big(\mathrm{Tr}[\mathbb{S}_A] + \mathrm{Tr}[\mathbb{S}\,\mathbb{S}_A]\Big). \tag{57.62}$$

The two traces are elementary. For any swap operator on $\mathcal{K}\otimes\mathcal{K}$ one has $\mathrm{Tr}[\mathbb{S}_{\mathcal{K}}] = \dim\mathcal{K}$ (the swap fixes the $\dim\mathcal{K}$ "diagonal" basis vectors $|n\rangle\otimes|n\rangle$ and pairs off the rest, so its trace counts the fixed vectors). Therefore

$$\mathrm{Tr}[\mathbb{S}_A] = (\,\mathrm{Tr}_{AA'}\,\mathbb{S}_A)\,(\,\mathrm{Tr}_{BB'}\,I_{BB'}) = d_A\cdot d_B^2, \tag{57.63}$$

$$\mathrm{Tr}[\mathbb{S}\,\mathbb{S}_A] = \mathrm{Tr}[\mathbb{S}_A\mathbb{S}_B\mathbb{S}_A] = \mathrm{Tr}[\mathbb{S}_B] = (\,\mathrm{Tr}_{AA'}\, I_{AA'})(\,\mathrm{Tr}_{BB'}\,\mathbb{S}_B) = d_A^2 \cdot d_B, \quad (57.64)$$

where in Eq. (57.64) we used $\mathbb{S} = \mathbb{S}_A\mathbb{S}_B$, that $\mathbb{S}_A$ and $\mathbb{S}_B$ commute, and $\mathbb{S}_A^2 = I$. Substituting into Eq. (57.62),

$$\boxed{\mathbb{E}[\mathrm{Tr}\,\rho_A^2] = \frac{d_A d_B^2 + d_A^2 d_B}{d_A d_B\,(d_A d_B + 1)} = \frac{d_A + d_B}{d_A d_B + 1}\,.} \quad (57.65)$$

Step 3: read the regimes. For large dimensions the $+1$ in the denominator is negligible and

$$\mathbb{E}[\mathrm{Tr}\,\rho_A^2] \simeq \frac{1}{d_A} + \frac{1}{d_B}. \quad (57.66)$$

When A is the small subsystem, $d_A \ll d_B$, the first term dominates: $\mathbb{E}[\mathrm{Tr}\,\rho_A^2] \simeq 1/d_A$, the purity of the *maximally mixed* state $\rho_A = I/d_A$. A random state thus leaves a small subsystem almost exactly maximally mixed — maximally entangled with the rest. At the symmetric point $d_A = d_B = m$ the result is $\mathbb{E}[\mathrm{Tr}\,\rho_A^2] = 2m/(m^2+1) \simeq 2/m$, twice the maximally-mixed value, so ρ_A is mixed but measurably short of maximal.

57.3.3 From purity to entropy: Page's formula

The purity already pins the leading behavior. Converting Eq. (57.65) to a Rényi-2 entropy and expanding for $d_A \le d_B$,

$$S_2(A) = -\ln \mathbb{E}[\mathrm{Tr}\,\rho_A^2] \simeq -\ln\!\left(\tfrac{1}{d_A} + \tfrac{1}{d_B}\right) = \ln d_A - \ln\!\left(1 + \tfrac{d_A}{d_B}\right) \simeq \ln d_A - \frac{d_A}{d_B}. \quad (57.67)$$

Two features survive to the von Neumann entropy and constitute the whole physics of the section. First, the *leading* value is the ceiling: $S_A \simeq \ln d_A = \ln(\min(d_A, d_B))$, so a generic pure state saturates the maximal entanglement of its smaller factor up to a small correction. Second, the correction is a *deficit* of order d_A/d_B that grows as the two factors approach equal size — the entropy falls below maximal exactly when the subsystem is no longer small. The qualitative bend of the Page curve is already visible here: as the smaller factor grows toward half the total, the entropy approaches but stays below ln(dim).

The exact coefficient of the deficit is not captured by the Rényi-2 average, because S_2 and the von Neumann entropy differ in their subleading terms (and because $-\ln \mathbb{E}[\mathrm{Tr}\,\rho_A^2] \neq \mathbb{E}[-\ln \mathrm{Tr}\,\rho_A^2]$, a Jensen gap that is itself subleading). The full first-moment computation requires the joint eigenvalue distribution of ρ_A — the fixed-trace Wishart, or induced, ensemble — and yields a result Page conjectured from numerics and small cases, subsequently proved [196, 427, 439].

Theorem 57.14 (Page's formula for the average entanglement entropy)**.** *For a Haar-random pure state on $\mathcal{H}_A \otimes \mathcal{H}_B$ with $d_A \le d_B$, the average von Neumann*

entropy of the smaller factor is exactly

$$\langle S_A\rangle = \left(\sum_{k=d_B+1}^{d_A d_B}\frac{1}{k}\right) - \frac{d_A-1}{2d_B} = (H_{d_Ad_B} - H_{d_B}) - \frac{d_A-1}{2d_B}, \tag{57.68}$$

where $H_n = \sum_{k=1}^{n} 1/k$ *is the* n*-th harmonic number. Its large-dimension asymptotics is*

$$\langle S_A\rangle = \ln d_A - \frac{d_A}{2d_B} + \frac{1}{2d_Ad_B} + O(d^{-2}). \tag{57.69}$$

We do not reproduce the random-matrix integral that establishes Eq. (57.68) — it is a self-contained but lengthy computation in the cited references, and the leading physics has already been derived independently from the purity above. What we *do* carry out in full is the passage from the exact harmonic-sum form to the asymptotics Eq. (57.69), since that is what we will use, and since it shows the deficit coefficient $\frac{1}{2}$ explicitly.

Derivation of the asymptotics from Eq. (57.68). Use the standard expansion of the harmonic numbers, $H_n = \ln n + \gamma + \frac{1}{2n} + O(n^{-2})$, with γ the Euler–Mascheroni constant. The constant γ cancels in the difference:

$$\begin{aligned} H_{d_Ad_B} - H_{d_B} &= \left(\ln(d_Ad_B) + \gamma + \tfrac{1}{2d_Ad_B}\right) - \left(\ln d_B + \gamma + \tfrac{1}{2d_B}\right) + O(d^{-2}) \\ &= \ln d_A + \frac{1}{2d_Ad_B} - \frac{1}{2d_B} + O(d^{-2}). \end{aligned} \tag{57.70}$$

Adding the explicit term $-(d_A-1)/(2d_B) = -d_A/(2d_B) + 1/(2d_B)$ from Eq. (57.68),

$$\langle S_A\rangle = \ln d_A + \frac{1}{2d_Ad_B} - \frac{1}{2d_B} - \frac{d_A}{2d_B} + \frac{1}{2d_B} + O(d^{-2}) = \ln d_A - \frac{d_A}{2d_B} + \frac{1}{2d_Ad_B} + O(d^{-2}), \tag{57.71}$$

the two $\pm 1/(2d_B)$ terms cancelling, which is Eq. (57.69). □

The deficit coefficient is therefore $\frac{1}{2}$ for the von Neumann entropy, half the 1 of the cruder Rényi-2 estimate Eq. (57.67) — a genuine difference between the two entropies, not a discrepancy. Two special values are worth recording. At the symmetric split $d_A = d_B = m$, Eq. (57.69) gives

$$\langle S_A\rangle \simeq \ln m - \tfrac{1}{2}, \tag{57.72}$$

the celebrated *half-nat* below maximal entanglement that a random state carries when bisecting its Hilbert space evenly. For a strongly lopsided split $d_A \ll d_B$ the deficit $d_A/(2d_B) \to 0$ and $\langle S_A\rangle \to \ln d_A$ exactly: the small subsystem is maximally entangled to exponential accuracy. Collecting the two cases, the headline that drives everything below is

$$\boxed{\langle S_A\rangle \simeq \ln\big(\min(d_A, d_B)\big)} \tag{57.73}$$

up to a correction that is $O(1)$ only in the narrow window around the symmetric point and exponentially small away from it.

57.3.4 Typicality: why the average is the answer

Equation Eq. (57.73) is a statement about the *average* over states. We are entitled to use it for a *particular* (if unknown) black-hole microstate only if the entropy is sharply concentrated about its mean — if almost every state has very nearly the average entropy. It is, and the reason is geometric: the unit sphere in a high-dimensional space is dominated, in measure, by a thin band around any equator, so any sufficiently smooth function on it is nearly constant with overwhelming probability. This is Levy's lemma, the concentration-of-measure phenomenon.

Theorem 57.15 (Levy's lemma)**.** *Let $f : \mathbb{S}^{2N-1} \to \mathbb{R}$ be a function on the unit sphere of $\mathbb{C}^N \cong \mathbb{R}^{2N}$ with Lipschitz constant η (so $|f(\psi) - f(\phi)| \le \eta \, \||\psi\rangle - |\phi\rangle\|$). For $|\psi\rangle$ drawn from the uniform (Haar) measure on the sphere and any $\delta > 0$,*

$$\mathrm{Prob}\big(\,|f(\psi) - \mathbb{E}f| \ge \delta\,\big) \;\le\; 2\,\exp\!\Big(-\frac{C\,N\,\delta^2}{\eta^2}\Big), \tag{57.74}$$

with C a positive numerical constant (one may take $C = 1/(9\pi^3)$).

We apply this with $N = d = d_A d_B$ and $f(\psi) = S_A(\psi)$. The entanglement entropy is Lipschitz in $|\psi\rangle$ with a constant $\eta = O(\ln d_A)$ — bounded, up to the logarithm that sets the scale of S_A itself, independently of N — because the map from $|\psi\rangle$ to the spectrum of ρ_A is smooth and $-\sum \lambda \ln \lambda$ has bounded gradient on the simplex away from the boundary, with the boundary contributing negligibly. Then Eq. (57.74) says that the probability of S_A deviating from $\langle S_A\rangle$ by even a fixed δ is suppressed by $\exp(-C' d\,\delta^2/\ln^2 d_A)$. Since $d = e^{S_{\mathrm{tot}}}$ is exponentially large in the entropy of the whole system, the fluctuations are doubly-exponentially rare: a randomly chosen state has $S_A = \langle S_A\rangle$ to a precision that is itself exponentially small. Page's direct computation of the variance confirms this, giving $\mathrm{Var}(S_A) = O(1/d)$ at the symmetric point. The conclusion is the one the model needs: Eq. (57.73) holds not just on average but for the overwhelming majority of states, hence (under the scrambling hypothesis) for the actual black-hole microstate.

Physical Insight

Concentration of measure is what makes "thermalization" and "scrambling" into precise mathematics rather than slogans. A single typical pure state of a large system looks thermal on every small subsystem, with corrections invisibly small. The black hole inherits this: its radiation looks exactly thermal locally — which is why Hawking's calculation gets the *coarse-grained* entropy right — while the fine-grained entropy, the global property Eq. (57.73), knows about the purity of the whole and bends back down. Hawking measured the band; Page measured the equator.

57.3.5 The Page curve of an evaporating black hole

We now reinstate time. Partition the Hilbert space of the evaporating system at time t into the radiation already collected and the remaining black hole,

$$\mathcal{H}(t) = \mathcal{H}_{\rm rad}(t) \otimes \mathcal{H}_{\rm BH}(t), \qquad \dim \mathcal{H}_{\rm rad}(t) = e^{S^{\rm th}_{\rm rad}(t)}, \quad \dim \mathcal{H}_{\rm BH}(t) = e^{S_{\rm BH}(t)}. \tag{57.75}$$

The two exponents are exactly the coarse-grained entropies established in Section 57.1: $S_{\rm BH}(t) = A(t)/4G$ is the Bekenstein–Hawking entropy of the horizon (Eq. (57.26)), the logarithm of the number of black-hole microstates, and $S^{\rm th}_{\rm rad}(t)$ is the thermal (von Neumann) entropy of the radiation Hawking would compute (Eq. (57.33)), the logarithm of the effective dimension explored by the emitted quanta. The black hole forms from collapse of matter in a pure state and evolves unitarily, so the global state on $\mathcal{H}(t)$ stays pure throughout. Assuming it is, after scrambling, a typical state in the sense of Section 57.3.1, Page's headline Eq. (57.73) applies with $d_A \to e^{S^{\rm th}_{\rm rad}}$ and $d_B \to e^{S_{\rm BH}}$:

$$\boxed{\; S_{\rm rad}(t) \;\simeq\; \min\!\big(S^{\rm th}_{\rm rad}(t),\, S_{\rm BH}(t)\big)\;. \;} \tag{57.76}$$

This is the Page curve. Its two branches have transparent meaning.

Early times, $t < t_{\rm Page}$: little has evaporated, so $S^{\rm th}_{\rm rad} < S_{\rm BH}$, the radiation is the smaller factor, and $S_{\rm rad} \simeq S^{\rm th}_{\rm rad}(t)$. The fine-grained entropy tracks the thermal one: the radiation is, to exponential accuracy, maximally entangled with the hole, and its entropy rises just as Hawking found. There is no tension yet.

Late times, $t > t_{\rm Page}$: now $S^{\rm th}_{\rm rad} > S_{\rm BH}$, the black hole is the smaller factor, and $S_{\rm rad} \simeq S_{\rm BH}(t)$. Here it is cleanest to invoke purity directly: since the global state is pure, $S_{\rm rad} = S_{\rm BH}$ exactly by Eq. (55.14), and the now-small hole is near-maximally mixed, so $S_{\rm BH} \simeq \ln(\dim \mathcal{H}_{\rm BH}) = S_{\rm BH}(t)$. As the horizon shrinks, $S_{\rm BH}(t) \to 0$, and with it the radiation entropy. The radiation purifies itself: the late quanta are correlated with the early ones in precisely the pattern needed to bring a maximally-mixed-looking cloud back to a pure state once the last quantum is emitted.

The turnover, at $t = t_{\rm Page}$, is where the two coarse-grained entropies cross, $S^{\rm th}_{\rm rad}(t_{\rm Page}) = S_{\rm BH}(t_{\rm Page})$, equivalently $\dim \mathcal{H}_{\rm rad} = \dim \mathcal{H}_{\rm BH}$. At that instant the bipartition is symmetric and the entropy is maximal, sitting (by Eq. (57.72)) a half-nat below the common value $S_{\rm BH}(t_{\rm Page})$, which is somewhat above half the initial entropy. We pin the number next.

Worked Example 57.16 (The Page time)**.** We locate $t_{\rm Page}$ using the Schwarzschild expressions of Section 57.1. For a four-dimensional Schwarzschild hole of mass M, the horizon entropy is (Eq. (57.77))

$$S_{\rm BH} = \frac{A}{4G} = \frac{4\pi(2GM)^2}{4G} = 4\pi G M^2, \tag{57.77}$$

and Hawking emission drives the mass loss $dM/dt = -\alpha/M^2$ (Stefan–Boltzmann with $T_{\rm H} \propto 1/M$ and radiating area $\propto M^2$ giving power $\propto T^4 M^2 \propto M^{-2}$), where α collects the greybody and species constants. Integrating $M^2\,dM = -\alpha\,dt$,

$$M(t)^3 = M_0^3 - 3\alpha t, \qquad t_{\rm evap} = \frac{M_0^3}{3\alpha}, \qquad M(t) = M_0\Big(1 - \frac{t}{t_{\rm evap}}\Big)^{1/3}. \tag{57.78}$$

Writing $\tau = t/t_{\rm evap}$ and $S_0 \equiv S_{\rm BH}(0) = 4\pi G M_0^2$, the horizon entropy is

$$\frac{S_{\rm BH}(\tau)}{S_0} = \Big(\frac{M(\tau)}{M_0}\Big)^2 = (1-\tau)^{2/3}. \tag{57.79}$$

The coarse-grained radiation entropy accumulates the entropy the hole gives up. As established in Eq. (57.33), thermal emission of massless quanta carries off $\frac{4}{3}$ of the entropy the hole loses (the photon-gas "Zurek factor"), so in the adiabatic model $S_{\rm rad}^{\rm th}(\tau) = \frac{4}{3}(S_0 - S_{\rm BH}(\tau))$. This factor is *not* immaterial to the location of the crossing: the Page time is fixed by $\dim \mathcal{H}_{\rm rad} = \dim \mathcal{H}_{\rm BH}$, i.e. by the thermal radiation entropy itself equalling $S_{\rm BH}$, so the $\frac{4}{3}$ shifts where that equality is reached. Setting $S_{\rm rad}^{\rm th} = S_{\rm BH}$,

$$\tfrac{4}{3}(S_0 - S_{\rm BH}) = S_{\rm BH} \implies S_{\rm BH}(\tau_{\rm Page}) = \tfrac{4}{7}S_0 \implies (1-\tau_{\rm Page})^{2/3} = \tfrac{4}{7}. \tag{57.80}$$

Solving, $1 - \tau_{\rm Page} = (4/7)^{3/2}$, so

$$\tau_{\rm Page} = 1 - \Big(\tfrac{4}{7}\Big)^{3/2} \approx 0.568, \qquad t_{\rm Page} \approx 0.57\, t_{\rm evap}. \tag{57.81}$$

The Page time is reached when the horizon entropy has dropped to $\frac{4}{7}$ of its initial value — when, equivalently, the mass has fallen to $\sqrt{4/7}\,M_0 \approx 0.76\,M_0$ and three-sevenths of the original microstate-counting entropy has been carried out by the radiation. It is somewhat past the halfway point of the *lifetime* (because the hole evaporates faster as it shrinks). The peak radiation entropy there is $S_{\rm rad} = S_{\rm BH}(\tau_{\rm Page}) = \frac{4}{7}S_0$, a little above half the initial Bekenstein–Hawking entropy. The value $\frac{4}{3}$ used here is the idealized blackbody (Zurek) factor; restoring the realistic frequency-dependent greybody weighting of Eq. (57.29) raises the effective factor to ≈ 1.48 and shifts the crossing to $\tau_{\rm Page} \approx 0.54$, the value quoted for a massless-field $d = 4$ Schwarzschild hole in Theorem 57.25.

Figure 57.5 shows the result. The fine-grained entropy of the radiation climbs along the thermal curve, peaks at $\frac{4}{7}S_0$ at the Page time, and descends along the horizon entropy to zero at evaporation: a rise and a fall, exactly the profile unitarity demanded in the previous section.

57.3.6 Hawking's line versus the Page curve: localizing the crisis

It remains to set Page's curve against Hawking's and read off precisely where, and how badly, the semiclassical calculation fails. Hawking's computation (developed

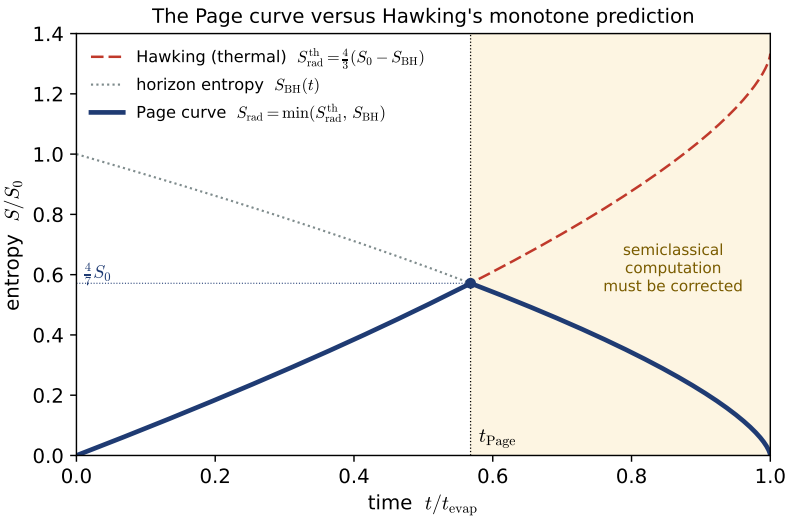

Figure 57.5: The Page curve. The fine-grained radiation entropy $S_{\rm rad} = \min(S_{\rm rad}^{\rm th}, S_{\rm BH})$ (solid) rises along the thermal entropy $S_{\rm rad}^{\rm th} = \frac{4}{3}(S_0 - S_{\rm BH})$, turns over at the Page time $t_{\rm Page} \approx 0.57\, t_{\rm evap}$ (peak $\frac{4}{7}S_0$) where it equals the shrinking horizon entropy $S_{\rm BH}$ (dotted), and decreases to zero at evaporation. Hawking's semiclassical calculation predicts the monotone thermal curve (dashed): it agrees with the Page curve before $t_{\rm Page}$ and diverges from it after, leaving a residual entropy $\frac{4}{3}S_0$ in the final radiation. The shaded region $t > t_{\rm Page}$ is where the two predictions part company — the regime any correct gravitational computation must correct.

from the Bogoliubov route in Chapter 65) outputs radiation that is *exactly* thermal and uncorrelated between successive emissions. For such radiation the fine-grained entropy equals the coarse-grained one identically: $S_{\rm rad}^{\rm Hawking}(t) = S_{\rm rad}^{\rm th}(t)$, the monotone dashed curve in Fig. 57.5. It rises without turning over and ends, when the hole is gone, at

$$S_{\rm rad}^{\rm Hawking}(t_{\rm evap}) = S_{\rm rad}^{\rm th}(t_{\rm evap}) = \tfrac{4}{3}S_0 > 0, \tag{57.82}$$

a final radiation state with entropy of order the entire initial horizon entropy — a mixed state produced from a pure one. This is the information paradox in its sharpest entropic form: a pure-to-mixed evolution, in flat contradiction with unitarity (Section 57.2).

The two curves coincide for $t < t_{\rm Page}$, where both equal $S_{\rm rad}^{\rm th}$, and diverge for $t > t_{\rm Page}$, where Hawking keeps climbing while unitarity demands descent. The disagreement is not a uniform small error to be patched everywhere; it is sharply localized in time. Before the Page time Hawking is *right*, to exponential accuracy: a small subsystem of a typical pure state is genuinely thermal, and the

semiclassical computation captures it faithfully. The failure switches on abruptly at t_{Page}, precisely when the radiation grows large enough to be the *larger* factor, so that its fine-grained entropy must start reporting the purity of the whole rather than the thermality of the part. The crisis is the after-Page-time regime, and nothing earlier.

Caution

The crossing in Fig. 57.5 is not literally a corner. The exact average Eq. (57.68) is smooth in d_A, d_B, and near the symmetric point the entropy rounds off the kink over a window of width set by the half-nat of Eq. (57.72); the sharp $\min(\cdot,\cdot)$ is the leading-order envelope, valid away from t_{Page} where one factor dominates. In the gravitational computation of the next section this rounding is reproduced by the competition of two saddles whose actions are equal at the crossing, and the smoothing comes from their sum.

The Page curve has thus been derived from nothing but the statistics of random states and the two coarse-grained entropies of Section 57.1: a linear rise tracking $S^{\text{th}}_{\text{rad}}$, a turnover at $t_{\text{Page}} \approx 0.57\, t_{\text{evap}}$ at the peak value $\frac{4}{7}S_0$, and a decline to zero along S_{BH}. This is the benchmark. The pressing question it leaves is mechanical: Hawking's semiclassical gravity, computing S_{rad} as the entropy of quantum fields on the evaporating background, returns the monotone line Eq. (57.82) and no turnover. What object in the gravitational calculation, switching on exactly at the Page time, bends the entropy back down to meet S_{BH}? The next section answers this with the quantum extremal surface prescription of Section 56.5.3: a second extremal surface — one whose homology region is an *island* inside the black hole — becomes the dominant saddle for S_{rad} at t_{Page}, and its generalized entropy (Eq. (56.151)) is exactly $S_{\text{BH}}(t)$, reproducing the descending branch and hence the entire Page curve from semiclassical gravity itself.

57.4 Quantum extremal surfaces and the island formula

The previous section handed us a verdict and a curve. Unitarity of the black hole's evolution *demands*, by the random-state statistics of Section 57.3, that the fine-grained entropy of the Hawking radiation follow the Page curve: rising while the emitted quanta are few, turning over at the Page time, and descending back to zero as the hole disappears. Equivalently, in the form that will be cleanest to reproduce, the radiation entropy is the smaller of two competing quantities,

$$S_{\text{rad}}(t) \;=\; \min\!\big(\, S^{\text{th}}_{\text{rad}}(t)\,,\; S_{\text{BH}}(t)\,\big), \tag{57.83}$$

the coarse (thermal) radiation entropy $S_{\rm rad}^{\rm th}$ that Hawking's calculation produces, and the Bekenstein–Hawking entropy $S_{\rm BH} = \text{Area}/4G_N$ of the remaining hole (Eq. (57.76)). That is the target. What is missing is a *computation*: a calculation, performed inside semiclassical gravity, that delivers Eq. (57.83) without putting unitarity in by hand. Hawking's own computation gives only the first branch and runs off to infinity. We will obtain both branches, and their minimum, from a single principle — and remarkably, that principle is one we already possess. It is the quantum extremal surface prescription of Theorem 56.27, applied not to a boundary region of a holographic CFT but to the radiation itself.

This section carries out that application. We specialize the QES rule to the radiation region, obtain the *island formula*, identify its two saddle configurations, compute both in a tractable two-dimensional model where every step is explicit, and watch their crossover land exactly on the Page time. The result is the gravitational reproduction of Eq. (57.83). We will be candid throughout about what is and is not established: the clean computation lives in two dimensions and is reduced to the spherically symmetric (s-wave) sector, and the island formula is here *asserted* as a corollary of the QES prescription rather than derived from the gravitational path integral — a debt discharged in Section 57.5.

57.4.1 The setup: gravity coupled to a bath, and the radiation region

To speak of "the entropy of the radiation" as a sharp quantity, we must first say where the radiation lives and what computes its entropy. The cleanest arena, and the one in which the computation closes in closed form, is a gravitating region *coupled to a non-gravitating bath*. Picture an asymptotically anti-de Sitter black hole, its geometry that of Section 53.3, but with the usual reflecting boundary conditions at the AdS boundary replaced by transparent ones: instead of bouncing the Hawking quanta back in, we attach at the boundary an auxiliary, non-dynamical-gravity system — a flat half-line carrying a quantum field theory — into which the radiation can escape and accumulate. The bath is an idealized detector array: it has no gravity of its own, so areas and the generalized-entropy machinery act only in the gravitating region, but it faithfully collects every quantum the black hole emits. The total state on a Cauchy slice splits into a gravitating part and a bath part, and the *radiation region* R is a chosen piece of the bath, far from the black hole, holding the escaped quanta.

The reason this arena is forced upon us, rather than merely convenient, is worth stating. The QES prescription of Theorem 56.27 computes the entropy of a region by extremizing the generalized entropy over bulk surfaces. In a closed gravitating universe there is a notorious obstruction: the entropy of the *whole* state is computed by the empty surface and vanishes, and more generally the constraints of gravity (the vanishing of the Hamiltonian) make the naive entropy of a gravitating region ill-defined. The bath removes the obstruction.

The radiation region R sits in the non-gravitating bath, where von Neumann entropy is the ordinary, unambiguous quantity of Theorem 55.4; the gravitating region enters only through the surfaces that the QES rule allows to bound R's entanglement wedge. This is the configuration in which "$S_{\rm rad}$" has both an honest definition and a gravitational computation.

We must also fix *which* entropy we mean and *how* it is to be computed. The bath is an ordinary quantum system, so the fine-grained entropy $S(R) = -\operatorname{Tr}(\rho_R \ln \rho_R)$ of the reduced state on R is well defined with no gravitational subtlety. The content of the upcoming formula is that gravity nonetheless dictates its value: the same bulk semiclassical state whose Hawking quanta populate R also fixes, through the area of a surface deep in the geometry, how much fine-grained entropy R actually carries. The bridge is the entanglement wedge of Theorem 56.31, now read in reverse. There the wedge of a boundary region was a piece of bulk; here the "region" is the bath system R, and its entanglement wedge is the part of the *gravitating* spacetime whose quantum information R holds. The QES prescription locates that wedge by extremizing generalized entropy — and the new phenomenon, absent for a boundary interval in pure AdS, is that the wedge of a faraway bath region can include a *disconnected* component sitting inside the black hole. That component is the island.

57.4.2 The island formula as a specialization of the QES prescription

We now state the rule. It is, line for line, the quantum extremal surface prescription Eq. (56.153) with the boundary region replaced by the bath region R and the homology region's bulk component renamed.

Definition 57.17 (Island)**.** Let R be a region of the bath. An *island* I for R is a region of the gravitating spacetime, possibly empty, whose boundary ∂I (the *quantum extremal surface*) is a codimension-two surface in the bulk. The island is the gravitational part of the entanglement wedge of R (Theorem 56.31): the bulk region whose quantum state R encodes, in the sense of entanglement-wedge reconstruction (Theorem 56.33). When I is nonempty, ∂I lies in the interior of the gravitating region, disconnected from R.

Theorem 57.18 (The island formula)**.** *In the semiclassical regime, the fine-grained entropy of the bath region R is*

$$\boxed{S(R) \;=\; \min_{I}\; \operatorname*{ext}_{\partial I}\left[\,\frac{\mathrm{Area}(\partial I)}{4G_N} \;+\; S_{\rm bulk}(R\cup I)\,\right]}\,, \tag{57.84}$$

where the extremization is over the location of the quantum extremal surface ∂I, $S_{\rm bulk}(R\cup I)$ is the von Neumann entropy of the bulk quantum fields on $R\cup I$ computed on the fixed semiclassical background, and the outer minimum is taken over island configurations I (including the empty island).

Derivation from the QES prescription. The Engelhardt–Wall theorem Theorem 56.27 states that the entropy of a region equals the generalized entropy Eq. (56.151) extremized over the location of the quantum extremal surface γ that anchors the region's entanglement wedge, with the global least-generalized-entropy surface chosen when several compete:

$$S(R) = \operatorname*{ext}_{\gamma} S_{\mathrm{gen}}[\gamma] = \operatorname*{ext}_{\gamma} \left[\frac{\langle \widehat{\mathrm{Area}}(\gamma) \rangle}{4G_N} + S_{\mathrm{bulk}}(\mathcal{R}_\gamma) \right], \tag{57.85}$$

where $\mathcal{R}_\gamma$ is the homology region bounded by γ and the region itself. Take the "region" to be the bath subsystem R. The homology region $\mathcal{R}_\gamma$ now consists of R together with whatever bulk it caps off; because R lives in the non-gravitating bath while the area term is supported only in the gravitating part, the surface γ is forced into the gravitating region, and the bulk it encloses there is precisely the island I of Theorem 57.17, with $\gamma = \partial I$. Thus $\mathcal{R}_\gamma = R \cup I$ and $\langle \widehat{\mathrm{Area}}(\gamma) \rangle = \mathrm{Area}(\partial I)$, and Eq. (57.85) becomes

$$S(R) = \operatorname*{ext}_{\partial I} \left[\frac{\mathrm{Area}(\partial I)}{4G_N} + S_{\mathrm{bulk}}(R \cup I) \right]. \tag{57.86}$$

The empty surface $\gamma = \varnothing$, $I = \varnothing$, is always an admissible competitor: it trivially extremizes (there is nothing to vary) and contributes $S_{\mathrm{bulk}}(R)$ alone. The "least generalized entropy" clause of Theorem 56.27 that selects among competing extrema is exactly the outer minimum in Eq. (57.84), taken over the empty and nonempty island configurations. This is Eq. (57.84). □

The formula has earned no new physics; it is the QES prescription read in the bath. What is genuinely new is the geometry it allows. For an interval in pure AdS the extremal surface is connected to the region and there are no islands. For the radiation of a black hole the candidate extremal surfaces fall into two qualitatively distinct families, and the competition between them — the outer min — is the whole story.

Physical Insight

The island is the precise sense in which "the inside of the black hole is encoded in its radiation." Entanglement-wedge reconstruction (Theorem 56.33) says that any operator in the entanglement wedge of R can be rebuilt from operators acting on R alone. When the island is nonempty, the deep interior of the black hole is part of that wedge — so the bulk fields there, and the information they carry, are recoverable, in principle, from the radiation. The island formula does not merely fix a number; it tells us *where the interior went.* Before the Page time the wedge of R is just R; after it, the wedge of R swallows the interior.

57.4.3 The two competing saddles

Both branches of Eq. (57.83) are now visible as the two terms over which Eq. (57.84) minimizes.

The no-island saddle. Take $I = \varnothing$. There is no area term and nothing to extremize, and

$$S_{\text{no-isl}}(R) = S_{\text{bulk}}(R). \tag{57.87}$$

This is the entropy of the Hawking quanta in the bath, computed on the fixed background — exactly Hawking's calculation. Each emitted quantum is entangled with a partner left behind near the horizon; tracing over the partners, the state on R is very nearly thermal, and its entropy *grows monotonically* as the bath fills with more and more such quanta. This is the rising, "thermal" branch $S_{\text{rad}}^{\text{th}}$. Left to itself it grows without bound (for an eternal black hole) or past S_{BH} (for an evaporating one) — the very behavior that, by the entropy bound of Eq. (55.202) and the area law of Theorem 54.10, signals the information paradox of Section 57.2.

The island saddle. Now allow a nonempty island whose quantum extremal surface ∂I sits just inside the horizon. The generalized entropy acquires the area term, and

$$S_{\text{isl}}(R) = \operatorname*{ext}_{\partial I}\left[\frac{\text{Area}(\partial I)}{4G_N} + S_{\text{bulk}}(R \cup I)\right] \approx \frac{\text{Area}(\partial I)}{4G_N} + (\text{slowly varying}). \tag{57.88}$$

The mechanism that makes the second branch nearly constant is the heart of the matter and we will see it explicitly below: when the island is included, the bulk fields on $R \cup I$ include *both* members of each Hawking pair — the escaped quantum in R and its partner in I — so the strong entanglement between partner and quantum, which drove $S_{\text{bulk}}(R)$ up in the no-island branch, now sits *inside* the region $R \cup I$ and no longer contributes to its entropy. What remains is dominated by the area term, the Bekenstein–Hawking entropy of the surface just inside the horizon. Thus $S_{\text{isl}}(R) \approx S_{\text{BH}}$, the descending (or, for an eternal hole, flat) branch.

The island formula selects the smaller. Early, when few quanta have escaped, $S_{\text{bulk}}(R)$ is small and the no-island saddle wins: $S(R)$ rises. Late, when $S_{\text{bulk}}(R)$ has grown past S_{BH}, the island saddle wins: $S(R)$ is pinned to S_{BH}. The crossover is a sharp first-order transition in the dominant saddle — the gravitational image of the entanglement phase transition seen for two intervals in Section 56.2.4. It happens precisely when the two branches are equal, $S_{\text{bulk}}(R) = S_{\text{BH}}$, which is the definition of the Page time. The minimum of the two branches traces out Eq. (57.83); the gravitational Page curve is the lower envelope of the two QES saddles.

57.4.4 The computation in JT gravity coupled to a bath

We now make every claim of the previous subsection quantitative in a model where the geometry, the dilaton, and the bulk matter entropy are all known in closed form: two-dimensional Jackiw–Teitelboim (JT) dilaton gravity, the eternal AdS_2 black hole, coupled to a flat bath carrying a two-dimensional conformal field theory of central charge c. This is the model of Almheiri, Mahajan, Maldacena, and Zhao. It is honestly two-dimensional and s-wave reduced — the higher-dimensional statements are read off by dimensional reduction on the transverse sphere, with the dilaton playing the role of the transverse area — but within it the QES extremization is exact, and it exhibits every feature of Section 57.4.3 with explicit algebra.

Worked Example 57.19 (The two QES saddles of the eternal black hole and the Page time)**.** *The background.* In two dimensions "Area" is replaced by the value of the dilaton field ϕ, so the area term of the generalized entropy is $\phi/4G_N$ and the horizon entropy is $S_{\mathrm{BH}} = \phi_h/4G_N$ with ϕ_h the dilaton at the horizon (this is the JT incarnation of Theorem 54.10). The eternal AdS_2 black hole at inverse temperature β is global AdS_2; in Kruskal null coordinates (U, V) its metric and dilaton are

$$ds^2 = -\frac{4\,dU\,dV}{(1+UV)^2}, \qquad \phi = \phi_0 + \frac{2\pi\phi_r}{\beta}\,\frac{1-UV}{1+UV}, \tag{57.89}$$

with ϕ_0 the (topological) extremal dilaton, ϕ_r the renormalized boundary value, and the surface gravity $2\pi/\beta$ the Hawking temperature fixed by smoothness exactly as in Eq. (54.96). The right exterior is $U < 0$, $V > 0$; the bifurcation surface (the horizon) is $U = V = 0$, where the dilaton takes its minimum exterior value

$$\phi_h = \phi_0 + \frac{2\pi\phi_r}{\beta}, \qquad S_{\mathrm{BH}} = \frac{\phi_h}{4G_N}. \tag{57.90}$$

The Kruskal coordinates are related to the physical (Schwarzschild-like) boundary time t and tortoise coordinate σ by $U = -e^{-\frac{2\pi}{\beta}(t-\sigma)}$, $V = e^{\frac{2\pi}{\beta}(t+\sigma)}$ on the right, and by the mirror map on the left.

The matter entropy. The Hawking radiation is the bulk CFT, taken in the Hartle–Hawking state, which is the conformal vacuum of the Kruskal coordinates (U, V). The entanglement entropy of an interval with endpoints P_1, P_2 in the vacuum of a two-dimensional CFT, on a background written as $ds^2 = -e^{2\hat\rho}\,dU\,dV$, follows from the twist-operator two-point function of Eq. (55.55) with the twist dimension $\Delta_n = 2h_n = \frac{c}{12}(n - \frac{1}{n})$ of Theorem 55.31. A twist field is a primary of total dimension Δ_n, so under the Weyl rescaling to the curved frame it picks up a factor $e^{-\Delta_n\hat\rho}$ at each insertion; the vacuum two-point function in the flat U, V frame is $\langle\sigma_n\tilde\sigma_n\rangle_{\mathrm{flat}} \propto [(U_2-U_1)(V_2-V_1)]^{-\Delta_n}$, so

$$\mathrm{Tr}\,\rho^n = \langle\sigma_n(P_1)\tilde\sigma_n(P_2)\rangle = \frac{e^{-\Delta_n[\hat\rho(P_1)+\hat\rho(P_2)]}}{\big[(U_2-U_1)(V_2-V_1)\big]^{\Delta_n}}\,(\epsilon_{\mathrm{uv}})^{2\Delta_n}. \tag{57.91}$$

Taking $S = \lim_{n\to 1} \frac{1}{1-n} \ln \mathrm{Tr}\, \rho^n$ and using $\Delta_n \to \frac{c}{6}(n-1)$ as $n \to 1$ gives the master formula

$$S_{\text{matter}}(P_1, P_2) = \frac{c}{6} \ln\Big[(U_2 - U_1)(V_2 - V_1)\Big] + \frac{c}{6}\big[\hat{\rho}(P_1) + \hat{\rho}(P_2)\big] + \text{const.} \tag{57.92}$$

This is the two-dimensional vacuum logarithm of Eq. (55.119), dressed by the conformal factors $\hat{\rho}$ that convert coordinate to proper distance. From Eq. (57.89), in the gravitating region $e^{2\hat{\rho}} = 4/(1+UV)^2$, so $\hat{\rho} = \ln \frac{2}{1+UV}$; in the bath $\hat{\rho}$ is constant.

The no-island branch. Let R be the union of two bath intervals, one in each exterior, each running from a bath point b at boundary time t out to infinity; by the thermofield-double symmetry both endpoints advance forward in time. With $I = \varnothing$, the entropy is $S_{\text{bulk}}(R)$, which by Eq. (57.92) is the matter entropy of the interval connecting the two boundary endpoints through the interior, P_R on the right and its mirror P_L on the left. Their Kruskal coordinates are $V_R = e^{\frac{2\pi}{\beta}(t+\sigma_b)}$, $U_R = -e^{-\frac{2\pi}{\beta}(t-\sigma_b)}$, and $U_L = e^{\frac{2\pi}{\beta}(t-\sigma_b)}$, $V_L = -e^{-\frac{2\pi}{\beta}(t+\sigma_b)}$. At late time the differences are dominated by the growing exponentials,

$$(U_R - U_L)(V_R - V_L) \xrightarrow{t\to\infty} \big(-e^{\frac{2\pi}{\beta}(t-\sigma_b)}\big)\big(e^{\frac{2\pi}{\beta}(t+\sigma_b)}\big) = -e^{\frac{4\pi}{\beta}t}, \tag{57.93}$$

and the bath conformal factors are time-independent, so

$$S_{\text{no-isl}}(t) = \frac{c}{6} \ln|U_R - U_L||V_R - V_L| + \text{const} = \frac{c}{6} \cdot \frac{4\pi}{\beta}\, t + \text{const} = \frac{2\pi c}{3\beta}\, t + \text{const.} \tag{57.94}$$

The no-island entropy grows *linearly* in boundary time, with slope $2\pi c/3\beta$ — this is the rate at which a thermal 2D CFT at temperature $1/\beta$ pours fine-grained entropy into the bath from both exteriors. It is Hawking's ever-rising thermal entropy, and it never stops.

The island branch. Now place a quantum extremal surface in each exterior at Kruskal point (U_a, V_a), bounding a single island that straddles the bifurcation. By symmetry it suffices to extremize the right-half generalized entropy and double it:

$$S^{\text{R}}_{\text{gen}}(U_a, V_a) = \frac{\phi(U_a, V_a)}{4G_N} + \frac{c}{6}\Big[\ln\big((U_b - U_a)(V_b - V_a)\big) + \hat{\rho}_a + \hat{\rho}_b\Big], \tag{57.95}$$

with (U_b, V_b) the right bath point and $\hat{\rho}_a = \ln \frac{2}{1+U_aV_a}$. We extremize. Using $\partial_{U_a}\phi = \frac{2\pi\phi_r}{\beta}\frac{-2V_a}{(1+U_aV_a)^2}$ and $\partial_{U_a}\hat{\rho}_a = \frac{-V_a}{1+U_aV_a}$ (and likewise for V_a), the two extremality conditions $\partial_{U_a} S^{\text{R}}_{\text{gen}} = \partial_{V_a} S^{\text{R}}_{\text{gen}} = 0$ read

$$\frac{1}{4G_N}\frac{2\pi\phi_r}{\beta}\frac{-2V_a}{(1+U_aV_a)^2} + \frac{c}{6}\Big[\frac{-1}{U_b - U_a} - \frac{V_a}{1+U_aV_a}\Big] = 0, \tag{57.96}$$

$$\frac{1}{4G_N}\frac{2\pi\phi_r}{\beta}\frac{-2U_a}{(1+U_aV_a)^2} + \frac{c}{6}\Big[\frac{-1}{V_b - V_a} - \frac{U_a}{1+U_aV_a}\Big] = 0. \tag{57.97}$$

In the semiclassical regime the dilaton dominates the matter, $\phi_r/G_N \gg c$, so the quantum extremal surface lies extremely close to the horizon: U_a, V_a are small and $1+U_aV_a \approx 1$. Dropping the subleading $\frac{c}{6}V_a$ and $\frac{c}{6}U_a$ pieces against the large area gradient, and writing $\kappa \equiv \frac{\pi\phi_r}{G_N\beta}$, Eqs. (57.96) and (57.97) collapse to

$$\kappa\, V_a = \frac{c}{6}\,\frac{1}{|U_b - U_a|}, \qquad \kappa\, U_a = \frac{c}{6}\,\frac{1}{|V_b - V_a|}. \tag{57.98}$$

With the bath point at $U_b = -e^{-\frac{2\pi}{\beta}(t-\sigma_b)}$, $V_b = e^{\frac{2\pi}{\beta}(t+\sigma_b)}$, these solve to

$$V_a = \frac{c}{6\kappa}\, e^{\frac{2\pi}{\beta}(t-\sigma_b)}, \qquad U_a = -\frac{c}{6\kappa}\, e^{-\frac{2\pi}{\beta}(t+\sigma_b)}, \tag{57.99}$$

to leading order. The QES position drifts with time — V_a grows, $|U_a|$ shrinks, the surface sliding along the horizon — but the boost-invariant product is frozen,

$$U_aV_a = -\Big(\frac{c}{6\kappa}\Big)^2 e^{-\frac{4\pi}{\beta}\sigma_b} = -\Big(\frac{cG_N\beta}{6\pi\phi_r}\Big)^2 e^{-\frac{4\pi}{\beta}\sigma_b}, \tag{57.100}$$

independent of time, and of order G_N^2, so the surface sits a coordinate distance $\sim G_N$ inside the horizon. This is the crucial cancellation: the entanglement wedge boundary of the radiation hovers just behind the horizon, at a fixed proper location, no matter how late the time.

Evaluating the island branch. Insert Eqs. (57.99) and (57.100) into Eq. (57.95). The dilaton at the QES is

$$\phi(U_a, V_a) = \phi_0 + \frac{2\pi\phi_r}{\beta}\,\frac{1-U_aV_a}{1+U_aV_a} = \phi_h - \frac{4\pi\phi_r}{\beta}\,U_aV_a + O\big((U_aV_a)^2\big), \tag{57.101}$$

so $\phi(U_a,V_a)/4G_N = S_{\rm BH} + O(G_Nc^2/\phi_r)$ differs from the Bekenstein–Hawking value only by a time-independent, G_N-suppressed amount. The matter log term involves $(U_b-U_a)(V_b-V_a) \approx U_bV_b = -e^{\frac{4\pi}{\beta}\sigma_b}$, which is also time-independent because the explicit t-dependence of U_b and V_b cancels in the product. Hence *every* piece of $S^{\rm R}_{\rm gen}$ is time-independent, and doubling,

$$S_{\rm isl} = 2\,S^{\rm R}_{\rm gen}\Big|_{\rm QES} = 2\,S_{\rm BH} + S_1, \tag{57.102}$$

with S_1 a constant (the $O(c)$ matter remainder). The island branch is flat at twice the Bekenstein–Hawking entropy — twice, because the two-sided eternal black hole has two horizons' worth of coarse entropy.

The crossover. The island formula Eq. (57.84) takes the minimum of Eq. (57.94) and Eq. (57.102):

$$S(R) = \min\Big(\tfrac{2\pi c}{3\beta}\,t,\; 2S_{\rm BH}\Big) + \text{const.} \tag{57.103}$$

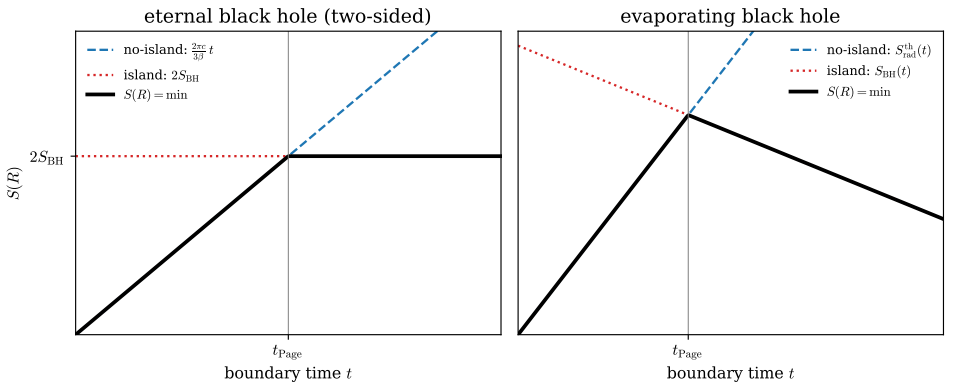

Figure 57.6: The two competing quantum extremal surface saddles and the Page curve as their minimum. *Left*: the eternal two-sided black hole of Theorem 57.19. The no-island branch Eq. (57.94) (dashed) rises linearly with slope $2\pi c/3\beta$; the island branch Eq. (57.102) (dotted) is flat at $2S_{\rm BH}$. The radiation entropy $S(R)$ (thick) is their minimum, with the corner at $t_{\rm Page} = 3\beta S_{\rm BH}/\pi c$ of Eq. (57.104). *Right*: the evaporating black hole, where $S_{\rm BH}(t)$ declines as the hole shrinks, so the island branch descends and the minimum reproduces the rising-then-falling Page curve of Eq. (57.83).

The rising line meets the flat plateau at the Page time, where $\frac{2\pi c}{3\beta} t_{\rm Page} = 2S_{\rm BH}$, i.e.

$$\boxed{t_{\rm Page} = \frac{3\beta\, S_{\rm BH}}{\pi c}\,.} \tag{57.104}$$

This is the gravitational Page time: linear growth until the radiation entropy reaches the coarse-grained black hole entropy, then saturation. The no-island branch reproduces $S^{\rm th}_{\rm rad}$ of Eq. (57.83); the island branch reproduces $S_{\rm BH}$; their minimum is the Page curve, computed entirely within semiclassical gravity.

Figure 57.6 displays the two saddles and their envelope, for the eternal black hole just computed and for the physically richer evaporating case discussed next. Figure 57.7 shows where the island sits.

57.4.5 From eternal to evaporating, and the match to the Page curve

The eternal computation produced a "tent": linear rise to a flat plateau (Fig. 57.6, left). The eternal black hole does not shrink — it is kept in equilibrium with its bath — so its horizon entropy $2S_{\rm BH}$ is constant and the island branch is flat. The physically decisive case is the *evaporating* black hole, formed from collapse and left to radiate into the bath without being fed. The same two saddles appear, with one change: the horizon shrinks as energy leaves, so $S_{\rm BH}(t) = \text{Area}(t)/4G_N$

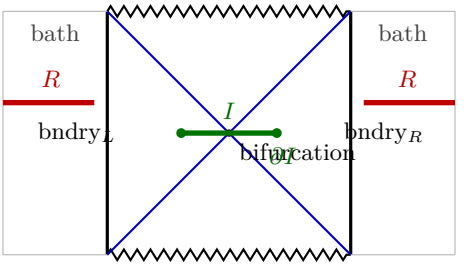

Figure 57.7: The eternal two-sided AdS_2 black hole coupled to baths, after the Page time. The two AdS boundaries (thick verticals) carry flat non-gravitating baths; the radiation region R (red) collects the Hawking quanta in the baths. The blue diagonals are the horizons, crossing at the bifurcation surface (the JT "horizon"). The island I (green) is the interval straddling the bifurcation, bounded by the quantum extremal surfaces ∂I sitting a proper distance $\sim G_N$ inside the horizon, frozen there by Eq. (57.100). The entanglement wedge of R now includes I: the black-hole interior is encoded in the radiation.

decreases with time. The no-island branch still rises (more Hawking quanta accumulate), but the island branch now *descends*, tracking the shrinking horizon, $S_{\rm isl}(t) \approx S_{\rm BH}(t)$. The minimum of a rising curve and a falling curve is the rising-then-falling Page curve of Eq. (57.83) — Fig. 57.6, right. The crossover is again the Page time, now occurring when the rising thermal entropy meets the falling Bekenstein–Hawking entropy, $S^{\rm th}_{\rm rad}(t_{\rm Page}) = S_{\rm BH}(t_{\rm Page})$, which is exactly the defining condition of Section 57.3. The closed-form extremization that makes the cancellation Eq. (57.100) transparent is cleanest in the eternal two-sided model; the evaporating case requires the time-dependent (covariant) QES of Theorem 56.27 on a Vaidya-like collapse geometry, but the structure — two saddles, a frozen near-horizon QES on the island branch, a crossover at the Page time — is identical.

The dictionary between the two computations is now exact, term for term:

$$\underbrace{S_{\text{no-isl}}(R) = S_{\rm bulk}(R)}_{\text{Hawking's thermal branch}} \longleftrightarrow S^{\rm th}_{\rm rad}(t), \qquad \underbrace{S_{\rm isl}(R) \approx \frac{\text{Area}(\partial I)}{4G_N}}_{\text{island branch}} \longleftrightarrow S_{\rm BH}(t), \tag{57.105}$$

and the island formula's outer minimum is the min of Eq. (57.83). The Page curve, which Section 57.3 derived as an abstract demand of unitarity from random-state statistics, is here *computed* from the geometry, the dilaton (area), and the bulk entropy, using only the QES prescription of Theorem 56.27. Nowhere did we assume the evolution was unitary; we assumed only that the QES rule computes fine-grained entropy. The two agree. That agreement is the resolution of the entropy half of the information paradox.

57.4.6 Reading the result: the radiation's wedge swallows the interior

The island formula does more than fit the curve; through entanglement-wedge reconstruction it tells us *what happened to the information*. Recall from Theorem 56.33 that the entanglement wedge of a region is the bulk it can reconstruct: operators in the wedge are recoverable from operators on the region, in the quantum-error-correcting sense of Section 56.7. Apply this to R.

Before the Page time the no-island saddle dominates, the island is empty, and the entanglement wedge of R is just R itself. The radiation knows nothing about the interior; the black hole's inside is reconstructible only from the black hole's own degrees of freedom. This is the intuitive, semiclassical picture, and it is correct — early.

After the Page time the island saddle dominates. The entanglement wedge of R now *includes the island* I, the region behind the horizon bounded by the quantum extremal surface (Fig. 57.7). By reconstruction, the bulk fields in I — the interior of the black hole — are now encoded in the radiation R and recoverable from it. The radiation's wedge has swallowed the interior. This is the precise sense in which "the information comes out": not that any single late quantum is non-thermal in a way Hawking missed, but that the global encoding has shifted, so that the interior's quantum state, including the infalling matter that formed the hole and the partners of the early Hawking quanta, lives in the entanglement wedge of the radiation. The transition at the Page time is the transition between these two encodings.

Caution

What has been established is the *entropy* curve, and within a model that is honestly two-dimensional and s-wave reduced. The island formula reproduces $S(R)$, and entanglement-wedge reconstruction tells us in principle that the interior is encoded in R after the Page time. Neither result hands us an explicit, computationally tractable map that decodes a given bit of infallen information from the radiation; the reconstruction is exponentially complex, and whether and how it can be operationally realized is open (Section 57.6.5). The four-dimensional, beyond-s-wave statement of the island formula is believed to hold but is not proved with the same closed-form control. We report the entropy as settled and date the rest honestly: this is the understanding as of the mid-2020s.

We have reproduced the Page curve from gravity. But we did so by *asserting* the island formula Eq. (57.84) — importing it as a corollary of the QES prescription — and the QES prescription itself, while derived in Section 56.5.3 for boundary regions of a holographic CFT, was not obviously licensed to grow a disconnected island behind a horizon for a bath region. Two questions are left

exposed. Why is the island formula correct as a statement about fine-grained radiation entropy? And where, in an honest gravitational calculation of $S_{\rm rad}$, does the second saddle — the island branch, the very term that bends the curve down — actually come from? The next section answers both at once: computing $S_{\rm rad}$ by the replica trick in the Euclidean gravitational path integral reveals new connected geometries, the replica wormholes, whose contribution *is* the island term, deriving Eq. (57.84) rather than positing it.

57.5 Replica wormholes and the gravitational path integral

The previous section handed us a working answer and an unpaid debt. The island formula

$$S_{\rm rad} = \min \operatorname*{ext}_{I} \Big[\frac{\mathrm{Area}(\partial I)}{4G_N} + S_{\rm bulk}(R \cup I) \Big] \tag{57.106}$$

reproduced the Page curve: before the Page time the empty-island branch gives the growing $S_{\rm bulk}(R)$, after it a new quantum extremal surface deep in the interior switches on and freezes the entropy at the horizon's $\mathrm{Area}/4G_N$ (Section 57.4.2 and Eq. (57.84)). But Eq. (57.106) was *asserted*: we took the quantum-extremal-surface prescription of Chapter 56, allowed the entanglement wedge of the radiation to contain a disconnected component (the island), and checked that the result is the unitary Page curve. Two things were left unexplained. Why should the radiation's entanglement wedge be allowed to reach across an empty region of bath and grab a slab of the black hole interior? And where did the "second saddle" — the interior QES that takes over after the Page time — come from, given that the semiclassical state on the fixed Hawking geometry knows nothing of it? This section pays the debt. We compute $S_{\rm rad}$ directly from the Euclidean gravitational path integral via the replica trick of Chapter 55, and we find that the path integral contains, in addition to the obvious geometry, a class of *connected* saddles — replica wormholes — that sew the replicas together through the bulk. The wormhole saddles supply, term for term, the island contribution to Eq. (57.106). The island formula is then not a prescription bolted onto semiclassical gravity but a *theorem* about its path integral, in exactly the controlled settings where that path integral can be evaluated.

We continue to work with the Euclidean gravitational path integral, the same object that gave us the Hawking temperature and the area entropy by demanding smoothness of the Euclidean cap (Section 54.4.2 and Eqs. (54.96) and (54.120)), and we use throughout the multi-saddle technology built for Yang–Mills instantons in Chapter 42: a Euclidean amplitude is a *sum* over all bulk fillings with the prescribed boundary, each weighted by e^{-I}, and distinct topological sectors must all be included (Sections 42.1.2 and 42.1.6). The Wick rotation $t \to -i\tau$ is the one fixed there; Lorentzian signature is mostly-minus

and units are natural, as everywhere in this book. The controlled arena is two-dimensional Jackiw–Teitelboim (JT) gravity coupled to a non-gravitating bath, with its Sachdev–Ye–Kitaev and matrix-ensemble cousins; the four-dimensional statement is the same logic applied to the semiclassical saddle, and we are honest about that gap at the end.

57.5.1 The radiation entropy as a gravitational replica partition function

Recall the replica trick (Theorem 55.17 and Eq. (55.38)): for any density matrix ρ with $\operatorname{Tr}\rho = 1$, the von Neumann entropy is recovered from the integer Rényi moments $\operatorname{Tr}\rho^n$ by

$$S = -\operatorname{Tr}(\rho \ln \rho) = -\frac{d}{dn}\operatorname{Tr}\rho^n\Big|_{n=1}, \tag{57.107}$$

the derivative taken after analytically continuing the integer sequence $\{\operatorname{Tr}\rho^n\}_{n\geq 1}$ in n. We apply this to the reduced density matrix ρ_R of the Hawking radiation. The subtlety that makes the computation gravitational rather than a routine QFT exercise is the same one that motivated islands: although R is a region of the non-gravitating bath, the state on R was produced by a gravitating system, and the only first-principles definition of ρ_R runs through the gravitational path integral that prepares the global state. Concretely, a matrix element $\langle a|\rho_R|b\rangle$ is computed by a Euclidean path integral over the bulk gravity region with bath boundary conditions a on the ket and b on the bra, glued along the complement of R; tracing sets $a = b$ on $\bar{R}$ and integrates.

The Rényi moment $\operatorname{Tr}\rho_R^n$ is then the partition function on an n-fold replicated geometry. Take n copies of the bra–ket path integral; in each copy the bath is cut open along R, exposing an upper and a lower edge; cyclically glue the upper edge of copy a to the lower edge of copy $a+1$ (indices mod n). On the bath side this is the ordinary n-sheeted branched cover of Theorem 55.17, branched over ∂R. On the gravity side, each copy contributes its gravity region, and the central question — the one the bath cannot answer — is *how the bulk fills in* the replicated boundary. Writing Z_n for the gravitational partition function with this n-fold-replicated bath boundary, and Z_1 for the single un-replicated one, the normalized moment is

$$\operatorname{Tr}\rho_R^n = \frac{Z_n}{(Z_1)^n}, \tag{57.108}$$

the denominator enforcing $\operatorname{Tr}\rho_R = 1$. Each Z_n is, by the holographic dictionary (Eq. (53.162)), evaluated by summing e^{-I} over all bulk solutions whose conformal boundary is the replicated manifold. Combining Eqs. (57.107) and (57.108),

$$S_{\text{rad}} = -\frac{d}{dn}\Big[\ln Z_n - n \ln Z_1\Big]_{n=1} = \Big(\partial_n I[\mathcal{B}_n] - I[\mathcal{B}_1]\Big)_{n=1}, \tag{57.109}$$

where in the last step we used $\ln Z_n = -I[\mathcal{B}_n]$ for the dominant saddle $\mathcal{B}_n$. Everything now depends on *which* bulk $\mathcal{B}_n$ dominates, and the discovery is that the answer changes with time.

57.5.2 Two classes of saddle: the Hawking geometry and the replica wormhole

Equation (57.108) is a sum over bulk topologies, and at least two qualitatively different topologies always solve the equations of motion with the replicated boundary.

Definition 57.20 (Disconnected and connected replica saddles)**.** The *disconnected (Hawking) saddle* $\mathcal{B}_n^{\text{disc}}$ consists of n separate copies of the original (n=1) bulk geometry, each capping off its own replica of the bath. Its bulk does not communicate between replicas. A *connected replica saddle*, or *replica wormhole*, is a single connected bulk geometry $\mathcal{B}_n^{\text{conn}}$ whose boundary is still the n-fold-replicated bath but whose interior joins two or more replicas through a bulk bridge. The maximally connected, replica-symmetric member sews all n copies cyclically and carries a $\mathbb{Z}_n$ symmetry whose codimension-two fixed-point locus we call χ_n.

The disconnected saddle is the one Hawking would have written down. With the n replicas mutually inert, $Z_n^{\text{disc}} = (Z_1)^n \times$ (bath replica factor), and the bath replica factor is precisely the n-sheeted-cover partition function of the bulk *matter* fields on the fixed Hawking background. Its replica derivative is, by the very definition Eq. (57.107) run for the bulk fields, the ordinary bulk von Neumann entropy of the radiation,

$$S_{\text{rad}}^{\text{disc}} = S_{\text{bulk}}(R), \tag{57.110}$$

the monotonically growing, manifestly information-losing entropy of the Hawking calculation. This is the empty-island branch of Eq. (57.106): no area term, no island, just the bulk entropy of the collected quanta. It is correct at early times and disastrous at late times, where it exceeds the black hole's coarse-grained entropy and never turns over.

The connected saddle is the new ingredient. Here the LM localization of Section 56.4 applies verbatim, only to a different geometry. The replica-symmetric wormhole $\mathcal{B}_n^{\text{conn}}$ has a $\mathbb{Z}_n$ quotient $\hat{\mathcal{B}}_n = \mathcal{B}_n^{\text{conn}}/\mathbb{Z}_n$ with a conical defect of opening angle $2\pi/n$ on the fixed-point surface χ_n. Because the equations of motion hold everywhere except on χ_n, the n-derivative in Eq. (57.109) localizes onto that surface, and the localized gravitational piece is exactly the proper area of χ_n over $4G_N$, while the matter piece is the bulk replica entropy across χ_n. We do not reprove this localization — it is the Lewkowycz–Maldacena computation imported from Section 56.4 and its one-loop completion Theorem 56.20 — but

apply it:

$$S_{\rm rad}^{\rm conn} = \frac{\text{Area}(\chi_1)}{4G_N} + S_{\rm bulk}(R \cup I), \tag{57.111}$$

where χ_1 is the $n \to 1$ limit of the fixed-point surface and I is the bulk region it bounds on the far side of R — the island. *This is the island contribution.* The connected replica wormhole is the gravitational object whose presence Section 57.4 could only postulate: the bulk bridge between replicas is what places an area term and an island into the radiation entropy.

Physical Insight

The two saddles are the two terms of the island formula made into *geometries*. The disconnected topology computes "no island, just bulk entropy"; the connected topology computes "area of a QES plus the bulk entropy of radiation-plus-island." The Euclidean path integral does not choose between them by fiat — it sums both and the smaller action wins. The island prescription's min is the saddle-point competition of Chapter 42, transcribed into entropy.

Which dominates is a horse race between the two actions, and the winner changes at the Page time. Both saddles exist at all times; the disconnected one has the smaller action (larger Z_n, smaller Rényi entropy) while the radiation is young and $S_{\rm bulk}(R)$ is below the horizon area, and the connected one takes over once $S_{\rm bulk}(R)$ would exceed $\text{Area}/4G_N$. The continued $n \to 1$ entropy is therefore the smaller of Eqs. (57.110) and (57.111),

$$S_{\rm rad} = \min\Big\{ S_{\rm bulk}(R)\,,\ \frac{\text{Area}(\chi_1)}{4G_N} + S_{\rm bulk}(R \cup I) \Big\}, \tag{57.112}$$

which is Eq. (57.106) with the two competing extrema named by their topologies. The replica wormhole has *derived* the second branch of the Page curve.

57.5.3 The controlled computation: $\mathrm{Tr}\,\rho_R^2$ in JT gravity plus a bath

The statements above are exact in JT gravity, where the path integral is genuinely calculable. We carry out the simplest nontrivial case — the second Rényi moment — in full, then read off the general n result and continue to $n = 1$.

The model. Use JT gravity, whose Euclidean action is

$$I_{\rm JT}[g, \Phi] = -S_0\,\chi(\mathcal{M}) - \frac{1}{2}\int_{\mathcal{M}} \sqrt{g}\,\Phi(R+2) - \int_{\partial\mathcal{M}} \sqrt{h}\,\Phi_b(K-1) + I_{\rm mat}, \tag{57.113}$$

with $\chi(\mathcal{M}) = 2 - 2g - b$ the Euler characteristic of a surface of genus g with b boundaries. The dilaton Φ is a Lagrange multiplier fixing $R = -2$ (rigid

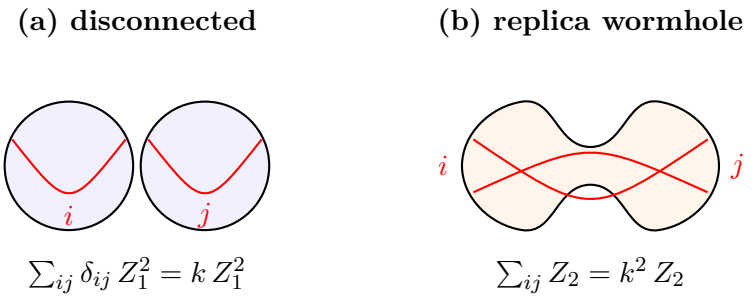

Figure 57.8: The two bulk topologies contributing to $\mathrm{Tr}\,\rho_R^2$ in the JT-plus-brane model. In (a) each braket overlap $\langle\psi_i|\psi_j\rangle$ is its own disk; brane-flavor conservation forces δ_{ij}, leaving one free index and kZ_1^2. In (b) a single connected geometry — the replica wormhole — joins both brakets; the flavor indices run free, giving $k^2 Z_2$. Their ratio sets the Page transition.

hyperbolic geometry), Φ_b its boundary value, and S_0 the extremal black-hole entropy; the only role of Eq. (57.113) we need is its topological weighting $e^{-I} \supset e^{S_0\chi}$, so that a disk ($\chi = 1$) is weighted e^{S_0} and each extra boundary or handle costs a factor e^{-S_0}. To make a sharp microstate-counting problem, follow Penington–Shenker–Stanford–Yang and entangle the black hole with a reference R (the stand-in for the radiation) through k flavors of end-of-world (EOW) brane:

$$|\Psi\rangle = \frac{1}{\sqrt{k}} \sum_{i=1}^{k} |\psi_i\rangle \otimes |i\rangle_R, \tag{57.114}$$

where $|\psi_i\rangle$ is a black-hole microstate created by an EOW brane carrying flavor i behind the horizon and $\{|i\rangle_R\}$ are orthonormal reference states. Larger k models a later stage of evaporation: the more flavors, the more the black hole has dumped into R.

The overlaps are gravitational. The reduced density matrix is

$$\rho_R = \mathrm{Tr}_{\mathrm{BH}}\, |\Psi\rangle\langle\Psi| = \frac{1}{k\, Z_1} \sum_{i,j} \langle\psi_j|\psi_i\rangle\, |i\rangle\langle j|_R, \tag{57.115}$$

normalized by Z_1 so that $\mathrm{Tr}\,\rho_R = 1$. The brane overlaps $\langle\psi_j|\psi_i\rangle$ are computed by the gravity path integral with a brane worldline connecting the bra and ket. At leading (disk) order, brane flavor is conserved along the worldline, so $\langle\psi_j|\psi_i\rangle = \delta_{ij}\, Z_1$ with Z_1 the one-boundary disk amplitude. The diagonal $\rho_R \approx \mathbf{1}/k$ is the naive maximally mixed answer; the off-diagonal corrections, and the failure of the naive answer at large k, come from connected geometries.

Worked Example 57.21 ($\mathrm{Tr}\,\rho_R^2$ and the two topologies)**.** We compute the second moment, exhibit its two saddles, and continue in n to obtain the Page curve.

Set up the moment. From Eq. (57.115),

$$\mathrm{Tr}\,\rho_R^2 = \sum_{i,j} (\rho_R)_{ij}(\rho_R)_{ji} = \frac{1}{(k\,Z_1)^2} \sum_{i,j} \langle\psi_j|\psi_i\rangle\,\langle\psi_i|\psi_j\rangle. \tag{57.116}$$

The gravitational object is the product of two brane brakets, and the path integral connects them in two topologically distinct ways (Fig. 57.8).

Disconnected topology. Each braket is its own disk: $\langle\psi_j|\psi_i\rangle \to \delta_{ij} Z_1$ and $\langle\psi_i|\psi_j\rangle \to \delta_{ij} Z_1$, so the summand is $\delta_{ij} Z_1^2$ and

$$\sum_{i,j} \delta_{ij}\, Z_1^2 = k\, Z_1^2, \qquad \text{contributing} \qquad \frac{k\, Z_1^2}{(k\, Z_1)^2} = \frac{1}{k}. \tag{57.117}$$

Connected topology (the replica wormhole). A single connected geometry joins the two brakets; the two brane worldlines now thread one surface, and flavor conservation along them no longer ties i to j. The index sum runs free over both, $\sum_{i,j} 1 = k^2$, multiplying the connected two-boundary amplitude Z_2:

$$\sum_{i,j} Z_2 = k^2\, Z_2, \qquad \text{contributing} \qquad \frac{k^2\, Z_2}{(k\, Z_1)^2} = \frac{Z_2}{Z_1^2}. \tag{57.118}$$

The result. Adding the two saddles,

$$\boxed{\mathrm{Tr}\,\rho_R^2 = \frac{1}{k} + \frac{Z_2}{Z_1^2}} \tag{57.119}$$

The first term is the disconnected (Hawking) answer; the second is the replica wormhole. By the JT weighting and the (approximately flat) microcanonical density of black-hole states, the connected two-boundary amplitude obeys $Z_2/Z_1^2 = e^{-S_{\mathrm{BH}}} \equiv 1/d$, where $S_{\mathrm{BH}} = \mathrm{Area}/4G_N$ is the coarse-grained entropy of Eq. (54.120) and d is the effective dimension of the black hole's Hilbert space. Thus

$$\mathrm{Tr}\,\rho_R^2 = \frac{1}{k} + \frac{1}{d}, \qquad S_2 = -\ln \mathrm{Tr}\,\rho_R^2 = -\ln\!\Big(\frac{1}{k} + \frac{1}{d}\Big) \approx \min(\ln k,\ S_{\mathrm{BH}}). \tag{57.120}$$

For $k \ll d$ the disconnected $1/k$ wins and $S_2 = \ln k$; for $k \gg d$ the wormhole $1/d$ wins and $S_2 = S_{\mathrm{BH}}$. The crossover at $k = d$, i.e. $\ln k = S_{\mathrm{BH}}$, is the Page transition.

General n and the continuation. The same count at n replicas gives $n!$ permutation saddles; the two dominant ones are the identity permutation (fully disconnected, all indices locked together by deltas, k free index, weight kZ_1^n) and the cyclic permutation (fully connected replica wormhole, all n indices free, weight $k^n Z_n$):

$$\operatorname{Tr}\rho_R^n = \frac{k\,Z_1^n}{(kZ_1)^n} + \frac{k^n Z_n}{(kZ_1)^n} + \cdots = k^{1-n} + \frac{Z_n}{Z_1^n} + \cdots = e^{-(n-1)\ln k} + e^{-(n-1)S_{\mathrm{BH}}} + \ldots, \tag{57.121}$$

using $Z_n/Z_1^n = e^{-(n-1)S_{\mathrm{BH}}}$ for the flat microcanonical spectrum. The Rényi entropy $S_n = \frac{1}{1-n}\ln\operatorname{Tr}\rho_R^n$ is dominated by whichever exponent is smaller:

$$S_n = \min(\ln k,\, S_{\mathrm{BH}}) \quad \text{for each } n>1, \qquad \xrightarrow{n\to 1} \qquad S_{\mathrm{rad}} = \min(\ln k,\, S_{\mathrm{BH}}). \tag{57.122}$$

The continuation is immediate because the dominant term is a pure exponential in $(n-1)$ in each regime. The von Neumann entropy of the radiation rises as $\ln k$ (the Hawking branch: more flavors, more entropy) until it reaches the black hole entropy S_{BH}, then is pinned there by the replica wormhole (the island branch). This is the Page curve, and every step was a saddle of the gravitational path integral.

The worked computation makes the abstract claim concrete: the island's area term is literally the contribution of a connected bulk geometry to a Rényi moment, and the min in the island formula is literally the dominance switch between two topologies. The identification $Z_2/Z_1^2 = 1/d$ also exposes why the naive $\rho_R = \mathbf{1}/k$ fails: when $k > d$ the matrix ρ_R cannot have k equal nonzero eigenvalues, because the wormhole-induced off-diagonal terms make its rank at most d. Gravity quietly enforces $S_{\mathrm{rad}} \le S_{\mathrm{BH}} = \ln d$, which is unitarity.

57.5.4 The $n \to 1$ limit is the quantum extremal surface

The PSSY count was algebraic; the geometric content of the connected saddle is what closes the loop with Chapter 56. Return to Eq. (57.109) for the connected replica-symmetric saddle and make the extremization explicit. The smooth wormhole $\mathcal{B}_n^{\mathrm{conn}}$ is obtained, at each integer n, by solving the gravitational equations of motion subject to the replicated boundary and to smoothness; equivalently, its $\mathbb{Z}_n$ quotient $\hat{\mathcal{B}}_n$ is a geometry with a conical defect of opening angle $2\pi/n$ whose tip χ_n sits wherever smoothness of the unquotiented cover demands. The position of χ_n is therefore not a free choice: it is fixed by an extremality condition. Writing the on-shell action of the connected saddle as a functional of the defect location X,

$$\left.\frac{\partial I[\mathcal{B}_n^{\mathrm{conn}}(X)]}{\partial X}\right|_{X=X_n} = 0, \tag{57.123}$$

the saddle sits at the stationary point X_n. Now apply the localization of Section 56.4: differentiating the action in n and continuing to $n = 1$ deposits, on χ_n, the area term, while the matter sector deposits the bulk entropy by the same branched-cover argument that produced FLM (Theorem 56.20). Two contributions to ∂_n exist a priori — the explicit dependence through the opening angle and the implicit dependence through the moving location X_n — but the implicit one vanishes precisely because of Eq. (57.123): the action is stationary in X, so first-order motion of the defect does not change it. Hence

$$S_{\rm rad}^{\rm conn} = \Big(\partial_n I[\mathcal{B}_n^{\rm conn}] - I[\mathcal{B}_1]\Big)_{n=1} = \frac{\text{Area}(\chi_1)}{4G_N} + S_{\rm bulk}(R \cup I) \equiv S_{\rm gen}(\chi_1), \tag{57.124}$$

the generalized entropy of Eq. (56.151) evaluated on the $n \to 1$ fixed-point surface. The remaining question is what equation χ_1 obeys. Take the extremality condition Eq. (57.123) and continue $n \to 1$. As $n \to 1$ the conical opening angle returns to 2π, the defect smooths out, and the location X_n tends to a limiting surface χ_1; the statement that the action is stationary in X at every n continues to the statement that the *generalized entropy* is stationary at χ_1,

$$\left.\frac{\delta S_{\rm gen}(\chi)}{\delta X^\mu(\sigma)}\right|_{\chi=\chi_1} = 0. \tag{57.125}$$

This is exactly the quantum extremal surface condition of Theorem 56.26 and Eq. (56.153). The reason is structural: the n-derivative of the on-shell action is the generalized entropy (that is the content of LM-plus-FLM), so demanding the action be extremal in the defect position *is* demanding the generalized entropy be extremal in the surface position, in the $n \to 1$ limit. The fixed-point surface of the dominant replica wormhole is the QES; the island is the bulk region it bounds; and the value of the entropy is $\text{ext}_\chi\, S_{\rm gen}(\chi)$, with the global min of Eq. (57.112) selecting the dominant topology among competing extrema.

This is the promised derivation. The island formula Eq. (57.106) is not an extra rule appended to semiclassical gravity. It is what the replica trick computes when one is honest that the gravitational path integral sums over topologies: the disconnected topology gives the no-island term, the connected replica wormhole gives the QES-plus-island term, the $n \to 1$ extremization of the wormhole geometry *is* the QES condition, and the min is saddle dominance. The "second saddle" that Section 57.4 could only point to is the replica wormhole, and it was in the path integral all along.

Caution

The replica wormholes that produce the island are connected Euclidean geometries that bridge *different replicas* of the boundary. In the closely related two-boundary problem they bridge two separate asymptotic bound-

aries — two separate copies of the quantum system. Taken literally this is alarming: a connected bulk linking two systems that the boundary description treats as independent threatens to make $\langle Z\,Z\rangle \neq \langle Z\rangle^2$, a failure of factorization. In the controlled JT setting the resolution is that the gravitational path integral is computing not a single quantum system but an *ensemble* average over a family of them (the matrix/SYK ensemble), and a wormhole is the connected correlator of that ensemble. Whether, and in what sense, this ensemble interpretation must be invoked in four-dimensional gravity is unsettled. We return to it in Section 57.6.

57.5.5 Honest scope: where this is a computation and where it is an argument

The chain just completed — replica trick, two topologies, explicit moments, $n \to 1$ to the QES — is a genuine *calculation* only where the gravitational path integral can be evaluated. That place is two-dimensional dilaton gravity. JT gravity Eq. (57.113) is effectively solvable: its disk and higher-topology amplitudes are known in closed form, the EOW-brane construction Eq. (57.114) reduces $\operatorname{Tr}\rho_R^n$ to a counting problem with computable weights, and the sum over topologies is the genus expansion of a double-scaled matrix integral. The same structure recurs in the SYK model (whose low-energy sector is JT) and in pure-topology matrix-ensemble cousins, where the replica wormhole is literally a connected matrix correlator. In all of these the island formula is a theorem about a defined path integral, and the Page curve Eq. (57.122) comes out without assumption beyond the dominance of the leading saddles.

The four-dimensional statement is weaker, and we say so plainly. There the Euclidean gravitational path integral is not known to exist as a convergent sum, the analogue of the JT topology expansion is not under control, and one cannot compute Z_n from first principles. What survives is the *logic*: assume the semiclassical saddle and its replica-symmetric conical cousins dominate; apply the LM–FLM localization (Section 56.4 and Theorem 56.20), which is a semiclassical statement valid wherever a saddle exists; conclude that the connected saddle deposits $\mathrm{Area}/4G_N + S_{\mathrm{bulk}}(R \cup I)$ and that its $n \to 1$ extremization is the QES condition Eq. (57.125). This is exactly the calculation done in Section 57.4 using the QES prescription directly; the replica-wormhole derivation explains *why* that prescription is correct, by exhibiting the saddle that realizes it, in every case where the saddle can be seen. The fine-grained radiation entropy — the Page curve — is thereby understood from semiclassical gravity. What is *not* thereby delivered is the operational decoding of the information, the status of the factorization puzzle the connected geometries raise, or the fate of the smooth horizon; those are the live questions the derivation forces upon us, and the wormholes-connect-replicas picture is exactly the puzzle the closing section

must confront.

57.6 What is settled, what is not

The replica computation of Section 57.5 did something remarkable and something disquieting at once. It *derived* the island rule from the bare gravitational path integral: the new connected saddles—the replica wormholes—contribute to $\mathrm{Tr}\,\rho_{\mathrm{rad}}^{n}$ exactly the term that, after the $n \to 1$ continuation, promotes the naive Hawking answer to the quantum-extremal-surface answer, and the radiation entropy turns over onto the Page curve. That is the disquieting part too. The same wormholes that rescue unitarity at the level of the entropy also make the gravitational path integral compute products of partition functions that do *not* factorize across disconnected boundaries, in apparent contradiction with the single-theory holographic dictionary of Section 53.5. A frontier chapter earns its keep by saying precisely which of its claims are theorems, which are results in controlled models, and which are conjectures—and by dating each, because the boundary moves. This closing section draws that boundary as of the mid-2020s. We first state cleanly what the island/replica program has settled; then we separate the *entropy* (settled) from the *information* (operationally out of reach), making the Hayden–Preskill recovery time quantitative; then we confront the factorization puzzle and the ensemble interpretation it forces; then we revisit the firewall in the light of islands; and we close with an explicit, dated list of what is genuinely open.

Throughout we label each statement by status—[**theorem**] for a mathematically proved result, [**controlled-model result**] for something established within a tractable model (typically two-dimensional Jackiw–Teitelboim gravity or a Renyi/replica computation in a semiclassical limit) but not in full quantum gravity, and [**conjecture**] for a physically motivated proposal whose general validity is not established. This labelling is not pedantry; it is the honest content of the chapter. To call the information paradox "solved" without it would be to overstate by a wide margin what the field actually knows.

57.6.1 The settled core: the Page curve from semiclassical gravity

We collect the achievement of the islands/replica program into a single statement, with each ingredient tagged.

Theorem 57.22 (Status report: the radiation entropy follows the Page curve)**.** *Consider a black hole formed from collapse of a pure state and allowed to evaporate, modelled semiclassically (a fixed-background quantum field with backreaction treated to leading order in G_N), and let $\rho_{\mathrm{rad}}(t)$ be the reduced density matrix of the Hawking radiation collected up to time t. Then:*

1. ***[controlled-model result]*** *In two-dimensional dilaton gravity (JT gravity coupled to a CFT bath, and its cousins), the fine-grained von Neumann entropy* $S_{\rm rad}(t) = -\operatorname{Tr}(\rho_{\rm rad}\log\rho_{\rm rad})$*, computed by the quantum extremal surface prescription of Theorems 56.26 and 56.27, rises during the early evolution, reaches a maximum at the Page time* $t_{\rm Page}$*, and decreases thereafter, returning to zero (up to the residual entropy of the remnant geometry) when evaporation completes. This is the unitary Page curve, not Hawking's monotonically rising curve.*

2. ***[controlled-model result, ∼2019–2020]*** *The QES/island value of* $S_{\rm rad}$ *is reproduced* from first principles *by the Euclidean gravitational path integral: the replica trick* $S_{\rm rad} = -\partial_n\big(\operatorname{Tr}\rho_{\rm rad}^n\big)\big|_{n=1}$ *receives, beyond the disconnected "Hawking" saddle, connected replica-wormhole saddles whose action dominates after* $t_{\rm Page}$ *and which supply exactly the island contribution (Section 57.5). No new ingredient beyond the rules of the semiclassical path integral is invoked.*

3. ***[conjecture, the general lesson]*** *The entanglement wedge of the radiation, as defined by entanglement-wedge reconstruction (Theorem 56.33),* includes the black-hole interior *(the island) for* $t > t_{\rm Page}$*. Hence the interior is encoded in the radiation, and there is no information loss at the level of the coarse data captured by the entropy.*

The first two items are genuinely established in their models, and the technology is exactly that of Section 56.5.3 (the QES) and Section 42.1 (a Euclidean path integral dominated by competing saddles, here generalized to topology-changing geometries). The arithmetic that makes the curve bend is worth recalling in one line, because it is the entire content of "settledness." Writing the generalized entropy of a candidate QES χ as

$$S_{\rm gen}[\chi] = \frac{\operatorname{Area}(\chi)}{4G_N} + S_{\rm bulk}(\Sigma_\chi), \tag{57.126}$$

with Σ_χ the bulk region between χ and the radiation collection surface, the island rule sets $S_{\rm rad} = \min_\chi \operatorname{ext}_\chi S_{\rm gen}[\chi]$. Early on the only extremum is the trivial one, $\chi = \varnothing$, with no area term and $S_{\rm bulk}$ growing as more thermally entangled Hawking quanta are collected—this is the rising Hawking branch. Once enough radiation has accumulated, a nontrivial QES appears just behind the horizon; its area term is large but *fixed* (set by the horizon area at that time), while its bulk term is small because the island purifies almost all the collected radiation. The competition min selects whichever branch is smaller, and the crossover—where the two branches are equal—is the Page time. The curve is the lower envelope of two nearly straight lines: this is the kink in the Page curve, and the island/replica program is precisely the statement that semiclassical gravity computes that kink correctly. That, and no more, is what is settled.

Why this is a real resolution and not a relabelling

Before 2019 one could dismiss "unitarity" as an article of faith imported from the boundary CFT. The achievement is that one need not import it: feeding the *semiclassical* rules—the same saddle-point gravitational path integral that gives black-hole thermodynamics—into the replica computation of a fine-grained entropy already returns the unitary answer, complete with the downturn after the Page time. Gravity polices its own unitarity, provided one is willing to include geometries in which the replicas are connected. The lesson is structural: the gravitational path integral knows about subtle entanglement that no single classical geometry displays.

57.6.2 Entropy is not information: recovery time and complexity

The Page curve is a statement about a single number, the von Neumann entropy, as a function of time. It certifies that the radiation *could in principle* carry away all the information—its entropy is consistent with the global state being pure. It says nothing about whether, or how, an observer holding the radiation can *read* that information. These are different questions, and conflating them is the most common overstatement at this frontier.

We make the distinction sharp with the Hayden–Preskill protocol, the cleanest quantitative handle on recovery. The setup: a black hole B that is already *old*—past its Page time, hence (by Theorem 57.22) maximally entangled with the early radiation R it has already emitted. Alice tosses in a small diary A of k qubits in an unknown pure state. The black hole evolves by some unitary U (the internal dynamics), then continues to Hawking-radiate. Bob holds R and collects the new radiation R' emitted after Alice's deposit. The question is how much of R' Bob needs before the state of A is recoverable from $R \cup R'$.

Theorem 57.23 (Hayden–Preskill recovery; status: controlled-model result, 2007)**.** *Model the post-deposit dynamics by a Haar-random (or, more realistically, a sufficiently scrambling) unitary U acting on the k-qubit diary together with the $\log_2 d_B$ qubits of the black hole, and let Bob collect k' qubits of new radiation. Averaging over U, the trace-distance between Bob's recovered state and the true state of A is bounded by*

$$\left\| \rho_{\mathrm{Bob}}^{\mathrm{rec}} - \rho_A \right\|_1 \lesssim 2^{-(k'-k)}, \tag{57.127}$$

so that collecting just $k' \approx k + O(1)$ qubits beyond the diary's size suffices to reconstruct A with exponentially small error. The diary's information is available *in the radiation almost as soon as the black hole has had time to scramble it.*

The estimate Eq. (57.127) is a decoupling statement: once U has scrambled A into B, the diary decouples from the remaining black hole B' and becomes

accessible from the radiation; the residual error is the probability that a few uncollected qubits still carry diary information, which falls as $2^{-(k'-k)}$. The averaging over U is what makes this a controlled-model result rather than a theorem about real black holes; the physical input is that black holes are *fast scramblers*, which fixes the timescale.

Definition 57.24 (Scrambling time)**.** The scrambling time t_{scr} is the timescale over which local information injected into a strongly chaotic many-body system spreads across all of its degrees of freedom, so that it can no longer be recovered by any few-body measurement. The fast-scrambling conjecture (Sekino–Susskind, 2008) holds that black holes scramble in the minimum time allowed by causality and locality,

$$t_{\mathrm{scr}} \;\simeq\; \frac{\beta}{2\pi}\,\log S_{\mathrm{BH}} \;=\; \frac{1}{2\pi T_{\mathrm{H}}}\,\log S_{\mathrm{BH}}, \tag{57.128}$$

with $\beta = 1/T_{\mathrm{H}}$ the inverse Hawking temperature and $S_{\mathrm{BH}} = \mathrm{Area}/4G_N$ the Bekenstein–Hawking entropy. The prefactor $\beta/2\pi$ is the inverse of the maximal Lyapunov exponent $\lambda_L = 2\pi/\beta$ (the chaos bound of Maldacena–Shenker–Stanford), and the logarithm reflects exponential growth of a perturbation from one to all S_{BH} degrees of freedom.

Combining the two timescales gives the physically important conclusion, which we state as prose because it is the punchline of the whole subsection. For an *old* black hole, information thrown in returns in the radiation after only a scrambling time $\sim \beta \log S_{\mathrm{BH}}$—short, but the returning bits are maximally scrambled across $R \cup R'$. For a *young* black hole (before the Page time), nothing comes out in any decodable form until enough radiation has accumulated to pass the Page time, which is an $O(1)$ fraction of the entire evaporation lifetime. "Information comes out, slowly and scrambled" is thus literally two statements: *slowly* for a young hole (wait the Page time), and *scrambled but promptly* for an old one (wait the scrambling time, then decode a deeply nonlocal code). We pin both numbers down in a worked example.

Worked Example 57.25 (Recovery times for a solar-mass black hole)**.** Take a Schwarzschild black hole of mass M, restoring G_N, c, $\hbar$, k_B for the estimates. Its horizon radius, temperature, and entropy are

$$R_s = \frac{2G_N M}{c^2}, \quad T_{\mathrm{H}} = \frac{\hbar c^3}{8\pi G_N M k_B}, \quad S_{\mathrm{BH}} = \frac{k_B c^3}{\hbar G_N}\,\frac{\mathrm{Area}}{4} = 4\pi\, k_B \Big(\frac{M}{M_{\mathrm{Pl}}}\Big)^2, \tag{57.129}$$

where $M_{\mathrm{Pl}} = \sqrt{\hbar c/G_N} \approx 2.2 \times 10^{-8}\,\mathrm{kg}$. For $M = M_\odot \approx 2.0 \times 10^{30}\,\mathrm{kg}$ we have $M/M_{\mathrm{Pl}} \approx 9 \times 10^{37}$, so

$$S_{\mathrm{BH}}/k_B \;\approx\; 4\pi\,(9\times 10^{37})^2 \;\approx\; 1.0 \times 10^{77}, \qquad \log S_{\mathrm{BH}} \;\approx\; 177. \tag{57.130}$$

The light-crossing time of the horizon is $R_s/c \approx (3.0\times10^3\,\mathrm{m})/(3\times10^8\,\mathrm{m/s}) \approx 1.0\times10^{-5}\,\mathrm{s}$. Since $\beta/2\pi = \hbar/(2\pi k_B T_{\mathrm{H}}) = 4G_N M/c^3 = 2R_s/c$, the scrambling time Eq. (57.128) is

$$t_{\mathrm{scr}} \;\simeq\; \frac{2R_s}{c}\,\log S_{\mathrm{BH}} \;\approx\; 2\,(1.0\times10^{-5}\,\mathrm{s})\times 177 \;\approx\; 3.5\times10^{-3}\,\mathrm{s}. \tag{57.131}$$

A few milliseconds. Compare the evaporation lifetime, obtained from $dM/dt = -\sigma\,\mathrm{Area}\,T_{\mathrm{H}}^4/c^2 \propto -1/M^2$ (Stefan–Boltzmann through the horizon area $\propto M^2$ with $T_{\mathrm{H}} \propto 1/M$), which integrates to

$$t_{\mathrm{evap}} \;=\; \frac{5120\,\pi\,G_N^2 M^3}{\hbar c^4} \;\approx\; 2\times10^{67}\,\mathrm{yr} \quad (M = M_\odot). \tag{57.132}$$

The Page time is an $O(1)$ fraction of this—for a $d = 4$ Schwarzschild hole radiating into massless fields the half-entropy point falls at $t_{\mathrm{Page}} \approx 0.54\,t_{\mathrm{evap}}$, of order 10^{67} years. The contrast is the lesson: a diary dropped into an *old* solar-mass black hole has its information back in the radiation after milliseconds; a diary dropped into a *young* one waits $\sim 10^{67}$ years before any of it becomes decodable in principle. "Information is preserved" and "information is accessible" live 70 orders of magnitude apart in time.

Even granting the time, accessibility is bounded by *computation*, not just by waiting. The decoding map that turns $R \cup R'$ back into Alice's diary is, generically, exponentially complex.

Theorem 57.26 (Harlow–Hayden / Python's lunch; status: conjecture, 2013/2019)**.** ***(Harlow–Hayden, 2013.)*** *Even when Theorem 57.23 guarantees that the diary is recoverable from the radiation, the quantum circuit that performs the decoding has size (gate complexity) exponential in the entropy of the black hole at the deposit time; for an old black hole the distillation of the relevant qubits from R requires $\sim \exp(S_{\mathrm{BH}})$ elementary operations.* ***(Python's lunch, Brown–Gharibyan–Penington–Susskind, 2019.)*** *More generally, when the entanglement wedge of a boundary region is bounded by a* non-minimal *quantum extremal surface—so that, going inward, the wedge first narrows to a "constriction" QES of area $A_{\min}$ and then bulges out to a maximal "appetizer" QES of area $A_{\max}$—then bulk operators in the bulge are reconstructible, but the reconstruction has complexity*

$$\mathcal{C} \;\sim\; \exp\!\Big(\tfrac{1}{2}\,\frac{A_{\max} - A_{\min}}{4G_N}\Big), \tag{57.133}$$

exponential in the area difference (in units of G_N). The black-hole interior past the Page time sits in such a "lunch," which is the geometric origin of Harlow–Hayden complexity.

The status of Theorem 57.26 is conjectural: Eq. (57.133) is a proposal motivated by tensor-network and circuit-complexity models, not a proved theorem

about the gravitational path integral, and it leans on the (itself conjectural) wedge-reconstruction statement Theorem 56.33. But it is the cleanest articulation of the divide that the Page curve forces us to draw.

What "the information paradox is resolved" does and does not mean

The 2019–2020 results resolve the *entropy* paradox: the fine-grained radiation entropy is consistent with global purity, computed within gravity. They do *not* exhibit a unitary S-matrix, do not reconstruct the infalling state operationally, and do not contradict the Harlow–Hayden bound—which says that even though the information is there, no observer with sub-exponential resources can extract it. The slogan "black-hole evaporation is unitary" is now supported by a semiclassical computation; the slogan "we can decode what fell in" remains false in any operational sense. Keep the two apart.

57.6.3 The factorization puzzle and the ensemble interpretation

The same replica wormholes that rescued the entropy create a tension with the very dictionary (Theorem 53.6) that motivated trusting unitarity in the first place. We state it as a clean fact about the gravitational path integral, then unpack what it could mean.

In a single quantum theory the partition function is a number. If $Z[J] = \operatorname{Tr} e^{-\beta H + J\cdot\mathcal{O}}$ is computed in one boundary theory, then the quantity associated with two disconnected boundaries is, tautologically, the product of two numbers:

$$Z[J_1 \sqcup J_2] \;=\; Z[J_1]\, Z[J_2] \qquad \text{(single theory)}. \tag{57.134}$$

The gravitational path integral, however, computes the left side by summing over *all* bulk geometries whose boundary is the disjoint union of the two boundaries—and this includes connected bulk geometries ("wormholes") joining them. Schematically,

$$Z_{\text{grav}}[J_1 \sqcup J_2] \;=\; \underbrace{Z_{\text{grav}}[J_1]\, Z_{\text{grav}}[J_2]}_{\text{disconnected saddles}} \;+\; \underbrace{Z_{\text{conn}}[J_1, J_2]}_{\text{wormhole}} \;\neq\; Z_{\text{grav}}[J_1]\, Z_{\text{grav}}[J_2]. \tag{57.135}$$

The connected piece Z_{conn} is nonzero (in two dimensions it is the celebrated "double trumpet"). Comparing Eq. (57.134) with Eq. (57.135): the gravitational answer cannot be the partition function of a *single* boundary theory. The natural reading is statistical—identify $Z_{\text{grav}}[J]$ with an *ensemble average* $\overline{Z[J]}$ over a family of theories, in which case the wormhole computes the connected correlation, i.e. the variance:

$$Z_{\text{conn}}[J_1, J_2] \;=\; \overline{Z[J_1]\, Z[J_2]} - \overline{Z[J_1]}\;\overline{Z[J_2]} \;=\; \operatorname{Cov}\big(Z[J_1], Z[J_2]\big). \tag{57.136}$$

Theorem 57.27 (Gravity as a matrix integral; status: controlled-model result/theorem, 2019)**.** ***(Saad–Shenker–Stanford, 2019.)*** *The full genus expansion of the Jackiw–Teitelboim gravity partition function—summing over all two-dimensional bulk topologies with fixed asymptotic boundaries—equals the genus (topological) expansion of a particular double-scaled Hermitian random-matrix integral. Concretely, with $Z(\beta) = \mathrm{Tr}\, e^{-\beta H}$ and H a random $L \times L$ matrix drawn from a fixed potential,*

$$\left\langle \prod_i Z(\beta_i) \right\rangle_{\mathrm{JT}} \;=\; \left\langle \prod_i \mathrm{Tr}\, e^{-\beta_i H} \right\rangle_{\mathrm{matrix}}, \tag{57.137}$$

order by order in e^{-S_0} (the genus-counting parameter, S_0 the extremal entropy). The connected wormhole geometries on the gravity side are precisely the connected matrix-model correlators on the ensemble side. In JT gravity, then, the gravitational path integral does not *compute a single Hamiltonian's partition function; it computes the moments of an ensemble of Hamiltonians.*

This is established in the controlled setting of two dimensions, where both sides are computable; Eq. (57.137) is a genuine equality of asymptotic expansions. The diagnostic that exhibits it physically is the spectral form factor.

Worked Example 57.28 (The ramp: how the wormhole shows up in $|Z|^2$)**.** Consider the analytically continued product $g(t) = \overline{Z(\beta+it)\,Z(\beta-it)} = \overline{|Z(\beta+it)|^2}$, the spectral form factor, where $Z(\beta+it) = \sum_n e^{-(\beta+it)E_n}$. Expanding,

$$g(t) = \sum_{m,n} e^{-\beta(E_m+E_n)}\, e^{-it(E_m-E_n)} = \underbrace{\left|\overline{Z(\beta+it)}\right|^2}_{\text{disconnected}} + \underbrace{\overline{|Z|^2} - |\overline{Z}|^2}_{\text{connected (wormhole)}} . \tag{57.138}$$

The disconnected piece $|\overline{Z}|^2$ decays at early times (the "slope") because the phases e^{-itE_n} dephase. If Z were a single number, that would be the whole story and $g(t)$ would decay to a small constant. Instead, in a chaotic system—and in JT gravity via Theorem 57.27—the connected piece is governed by random-matrix eigenvalue statistics. For nearby eigenvalues with the universal pair correlation $\overline{\rho(E)\rho(E')}_{\mathrm{conn}} \sim -\frac{1}{2\pi^2(E-E')^2}$ (the sine-kernel repulsion of the Gaussian ensembles), the Fourier transform gives a piece that *grows linearly*,

$$g_{\mathrm{conn}}(t) \;\sim\; \frac{t}{2\pi\beta} \qquad (t_{\mathrm{Th}} \ll t \ll t_{\mathrm{H}}), \tag{57.139}$$

the "ramp," until it saturates at the "plateau" $g \sim \overline{Z(2\beta)}$ for $t \gtrsim t_{\mathrm{H}} \sim e^{S_0}$ (the Heisenberg time set by the mean level spacing). On the gravity side the ramp is reproduced exactly by the double-trumpet wormhole connecting the two boundary circles: the wormhole *is* the linear ramp. The slope-ramp-plateau structure is the fingerprint of an ensemble; a single fixed Hamiltonian shows the same curve only because it is itself one draw from a chaotic ensemble and self-averages over an energy window.

So in two dimensions the verdict is clear: gravity computes an ensemble average, and the wormholes are its variance. The puzzle is what this means in $d \geq 3$, where the boundary is supposed to be a *single*, specific conformal field theory—$\mathcal{N} = 4$ super-Yang–Mills at fixed rank and coupling, say—with a unique partition function obeying Eq. (57.134) exactly. There the candidate resolutions diverge, and we list them honestly.

1. **[conjecture]** *Low-dimensional gravity is genuinely dual to an ensemble.* JT and pure three-dimensional gravity may simply not be dual to a single theory; their boundary "duals" are averages (over matrix ensembles, or over Narain moduli for certain $d = 2$ CFTs, as in Maloney–Witten / Afkhami-Jeddi–Cohn–Hartman–Tajdini, 2020). On this view Eq. (57.135) is not a paradox but the definition of what these theories are.

2. **[conjecture]** *Higher-dimensional gravity is a single theory and the wormholes are an artifact of coarse-graining or of the semiclassical approximation.* In genuine string-theoretic $\mathrm{AdS}_5/\mathrm{CFT}_4$ there is one CFT; the gravitational saddle sum is then an approximation to a single Z, and either the wormholes are subdominant/absent in the exact theory, or they encode the average over the unknown ultraviolet ("half-wormholes" and self-averaging; Saad–Shenker–Stanford–Yang, Schlenker–Witten, 2021–2022). Factorization is then restored by contributions invisible to the leading saddle expansion.

3. **[controlled-model result + conjecture]** *Baby universes and α-states* (Coleman, 1988; Marolf–Maxfield, 2020). Promote the gravitational path integral to a "third-quantized" theory whose Hilbert space $\mathcal{H}_{\mathrm{BU}}$ is built by creating and destroying closed (baby) universes. The boundary-creating operators $\widehat{Z}[J]$ *commute*, so they are simultaneously diagonalizable; their joint eigenstates are the α-states $|\alpha\rangle$, with $\widehat{Z}[J]\,|\alpha\rangle = Z_\alpha[J]\,|\alpha\rangle$. In a fixed α-state, *factorization is restored*: $\langle\alpha|\widehat{Z}[J_1]\widehat{Z}[J_2]|\alpha\rangle = Z_\alpha[J_1]Z_\alpha[J_2]$, and the theory is a single unitary one. The non-factorizing path integral Eq. (57.135) is then the no-boundary (Hartle–Hawking) state expectation value $\langle \mathrm{HH}| \cdot |\mathrm{HH}\rangle$, which is a *superposition* over α-sectors—i.e. an average $\sum_\alpha p_\alpha\,(\cdots)$ over the ensemble of single theories labelled by α. The ensemble interpretation and the single-theory interpretation are thereby reconciled: each α-state is a single theory, and the gravitational path integral, by default, prepares an incoherent average over them.

The shape of the tension

The factorization puzzle is the sharpest unresolved point in this Part. Theorem 53.6 asserts *one* bulk = *one* boundary; the replica wormholes that we needed for the Page curve assert that the bulk path integral, taken at face value, computes an *average*. Either the duality is an averaged

statement (true in the cases we can solve), or there is a mechanism—half-wormholes, α-state selection, ultraviolet completion—that restores a single theory in the cases we care about (AdS_5/CFT_4) but which we cannot yet exhibit. As of the mid-2020s the question is open: we do not know whether the gravitational path integral, in four or more dimensions, computes a single unitary theory or an ensemble.

57.6.4 Firewalls after islands

We revisit the firewall argument stated in Section 57.2 (AMPS, Almheiri–Marolf–Polchinski–Sully, 2012) with the island picture in hand. The argument is a clean incompatibility of four assumptions, all individually attractive: (i) *unitarity*—evaporation is described by a unitary S-matrix; (ii) *semiclassical exterior*—low-energy effective field theory holds outside the horizon; (iii) *no drama*—an infalling observer sees nothing special at the horizon (the equivalence principle); (iv) *a normal interior*—the black hole is a quantum system with $S_{\rm BH} = \text{Area}/4G_N$ states. The sharpened contradiction is monogamy of entanglement. Let b be a late outgoing Hawking mode emitted by an *old* black hole.

- By unitarity and the Page curve (Theorem 57.22), an old black hole's new radiation purifies the early radiation: b must be nearly maximally entangled with the early radiation R.
- By "no drama," the horizon is the vacuum for an infalling observer, which requires b to be nearly maximally entangled with its interior partner mode $\tilde{b}$ (the Unruh/Hartle–Hawking partner just behind the horizon).

A single mode b cannot be maximally entangled with two independent systems R and $\tilde{b}$ (monogamy). AMPS concluded that one assumption must fail; the eponymous proposal was to drop "no drama"—a high-energy *firewall* of quanta sits at the horizon, breaking entanglement with $\tilde{b}$ and incinerating the infalling observer.

The island/QES picture supplies a sharp response to the *entanglement bookkeeping*.

Theorem 57.29 (Island resolution of the monogamy paradox; status: controlled–model result/conjecture)**.** *After the Page time, the entanglement wedge of the radiation includes the island I behind the horizon (Theorem 57.22, item 3). The interior partner mode $\tilde{b}$ lies inside I, hence inside the radiation's entanglement wedge: by entanglement-wedge reconstruction (Theorem 56.33), $\tilde{b}$ is* encoded in the early radiation R itself. *The two systems AMPS treated as independent are not independent—"R" and "$\tilde{b}$" are the same degrees of freedom. There is then no monogamy violation: b is entangled with $\tilde{b}$, and $\tilde{b}$ is part of R, so the single*

entanglement of b does double duty. Smoothness of the horizon (entanglement of b with $\tilde{b}$) and purification of the radiation (entanglement of b with R) are compatible because $\tilde{b} \subset R$.

This is the same identification that the "ER=EPR" slogan (Maldacena–Susskind, 2013) packages as: the interior is connected to the early radiation by a (nontraversable) Einstein–Rosen bridge, so reaching $\tilde{b}$ "through the bulk" and reaching it "through the radiation" are the same operation. At the level of which density matrix encodes what, Theorem 57.29 is as settled as wedge reconstruction is—which is to say, it is a controlled-model result resting on a conjecture.

What remains genuinely open is the *dynamical* question that "no drama" really poses. The island argument shows that the entanglement structure is *consistent* with a smooth horizon; it does not, by itself, exhibit the local interior operators an infalling observer would measure, nor prove that they behave as low-energy effective field theory in a smooth geometry. The leading proposal for those operators—Papadodimas–Raju *state-dependent* reconstruction (2013–2014), in which the interior operators $\tilde{b}$ are realized as specific operators on the boundary that depend on the state of the black hole—reproduces a smooth interior but at the cost of state-dependence, which sits uneasily with the linearity of quantum mechanics and the existence of a single algebra of observables. Whether interior reconstruction can be made state-independent, what an infalling observer actually experiences, and how to describe the experience of *two* observers (one infalling, one reading the radiation) without a measurable contradiction (the "Alice–Bob" or quantum-cloning worry, regulated by complementarity and the Harlow–Hayden complexity of Theorem 57.26) are not settled.

Complementarity is an assumption, not a theorem

Black-hole complementarity—the claim that no single observer can witness both the infalling information inside and the same information in the radiation, so there is no operational contradiction—is consistent with everything above and is protected by the exponential decoding complexity of Theorem 57.26: the experiment that would catch a cloning contradiction cannot be done before the black hole evaporates. But "no observer can check" is a statement about resources, not a derivation of a smooth interior. The firewall question, as a question about what physics an infalling observer encounters, is not closed as of the mid-2020s.

57.6.5 What remains open: a dated summary of the frontier

We close the chapter by stating the boundary as flatly as we can, dated to the mid-2020s. The reader should treat each item as provisional and check its status

against the literature when revisiting.

Settled (within their models, ∼2019 and after).

1. The fine-grained radiation entropy follows the unitary Page curve, computed in semiclassical gravity via the QES/island prescription [controlled-model result], and derived from the bare Euclidean path integral via replica wormholes [controlled-model result]. The entropy paradox is resolved.

2. In two dimensions, the gravitational path integral with multiple boundaries equals a random-matrix ensemble average, with wormholes = connected correlators [controlled-model result/theorem, JT].

3. The entanglement-bookkeeping form of the firewall (monogamy) paradox is dissolved by the island: the interior partner is encoded in the early radiation [controlled-model result, contingent on Theorem 56.33].

Open (as of the mid-2020s).

1. *Operational recovery.* No construction exhibits a unitary S-matrix for evaporation, nor an explicit, computationally feasible decoding of infalling information; the Harlow–Hayden/Python's-lunch complexity Eq. (57.133) suggests decoding is exponentially hard, but its general validity is conjectural.

2. *Factorization / ensemble.* Whether the gravitational path integral in $d \geq 3$ computes a single unitary theory or an ensemble average is unresolved; baby-universe/α-state, half-wormhole, and self-averaging proposals exist but none is established for $\mathrm{AdS}_5/\mathrm{CFT}_4$.

3. *The infalling observer.* Whether interior operators admit a state-independent realization, what an infalling observer measures, and the ultimate status of the firewall and of complementarity, are open dynamical questions; the island results constrain the entanglement but do not settle the dynamics.

4. *Beyond the semiclassical replica.* The replica-wormhole derivation is a saddle-point statement; its all-orders and non-perturbative completion, the precise rules for which topologies to include, and the meaning of the $n \to 1$ continuation in genuine four-dimensional gravity are not under full control.

5. *The microscopic interior.* The island gives the *entropy* of the interior; an explicit microscopic model of the interior degrees of freedom and their dynamics—the analogue of a fuzzball or a definite boundary encoding for an evaporating black hole—is not available.

The honest summary is this. The information paradox, in the precise form Hawking posed it—*does the von Neumann entropy of the radiation rise forever?*—has been answered: it does not; semiclassical gravity itself yields the Page

curve. The broader question the paradox stands in for—*how, concretely and microscopically, is quantum information processed by a black hole, and is the bulk gravitational theory a single quantum system at all*—is the live frontier, and the machinery of this Part has sharpened it rather than closed it.

The chapter has carried the information problem from its precise statement, through the Page curve and the island/replica resolution of the *entropy*, to an honest accounting of what the resolution does and does not include. Two threads now leave this Part. Chapter 65 returns to the beginning—Hawking's original Bogoliubov computation of the thermal spectrum on a collapse background, and the trans-Planckian worry that the calculation invites—supplying from the curved-spacetime side the input we here established by the Euclidean route. And the closing synthesis of Chapter 65 takes the frontier mapped in Section 57.6.5 and sets it within the whole arc of the subject, where the clash and partial reconciliation of general relativity and quantum mechanics that this chapter examined stands as the sharpest open connection in all of quantum field theory.

Further reading

The thermodynamic foundation is the work of Bekenstein [54], who proposed the area law, and Hawking [255], who fixed its coefficient by computing the radiation; the Euclidean action method used here is that of Gibbons and Hawking [220], with the canonical-ensemble subtleties of black holes in AdS treated by Hawking and Page [258]. The unitarity requirement and the averaged-subsystem entropy that defines the Page curve originate with Page [374]. The modern resolution rests on two pillars: the island formula and its first applications, [17, 391], and the replica-wormhole derivation from the gravitational path integral, [18, 392]; recent reviews are [19]. On the distinction between entropy and recoverable information, see the decoding protocol of [260], the complexity obstruction of [251] sharpened geometrically as the Python's lunch in [96], and the fast-scrambling and chaos-bound results [333, 438]. The interpretation of two-dimensional gravity as a matrix ensemble is [423], with the baby-universe Hilbert space and α-states of [133, 338] and the factorization tension discussed in [424, 431]. The firewall argument is [15]; black-hole complementarity and ER=EPR are [332, 460]; state-dependent interior reconstruction is [375]; and the holographic backdrop for all of it traces to [331, 422].

Part XVI

Modern Scattering Amplitudes

Chapter 58

Spinor-Helicity Formalism

A scattering amplitude computed the textbook way is a study in waste. The Feynman rules of Parts IV–VII assign to each diagram a gauge-dependent tangle of polarization vectors, propagator numerators, and momentum contractions; a process with a handful of external gluons generates hundreds of such terms, each individually meaningless because each depends on the gauge, and the labor of the calculation is the labor of watching that gauge dependence cancel. Yet when the dust settles the answer is almost always short — often a single ratio of brackets fitting on one line. The gap between the difficulty of the computation and the simplicity of the result is the standing scandal that this chapter, and the part it opens, is written to resolve. The diagnosis is already in our hands. Wigner's classification of Chapter 3 taught us that a massless one-particle state carries exactly two pieces of data — a null momentum and a single helicity weight under the little group $\mathrm{ISO}(2) \simeq \mathrm{U}(1)$ — while a covariant polarization four-vector carries a redundancy no Lorentz-covariant repackaging can remove without gauging (Section 3.7.3 and Theorem 3.46). The waste is the redundancy made manifest. The cure is to build variables that carry the on-shell data and nothing else.

That is precisely what the spinor-helicity formalism does, and the chapter assembles it from the ground up. We begin (Section 58.1) from a fact of linear algebra dressed in the two-component calculus of Chapter C: a null four-momentum, written as a Hermitian 2×2 matrix, has vanishing determinant, hence rank one, hence factorizes into the outer product $p_{a\dot{a}} = \lambda_a \tilde{\lambda}_{\dot{a}}$ of two spinors that turn out to be the massless Weyl spinors of Chapter 3 and the massless limit of the Dirac plane-wave spinors of Chapter 11. From these spinors we forge a calculus (Section 58.2): the angle and square brackets $\langle i\,j\rangle$, $[i\,j]$, their dictionary $\langle i\,j\rangle[j\,i] = 2\,p_i{\cdot}p_j$ to the Mandelstam invariants of Chapter 16, and the Fierz, Schouten, and momentum-conservation identities on which every later manipulation runs, with the reality conditions and the analytic continuation to complex momenta pinned down once and for all.

With the alphabet in place we promote the one residual freedom in the spinor parametrization — the rescaling $\lambda \to t\lambda$, $\tilde{\lambda} \to t^{-1}\tilde{\lambda}$ that leaves the momentum fixed — to the organizing principle of the subject (Section 58.3). This rescaling *is* the massless little group of Chapter 3 acting in spinor language, and the response of an amplitude to it is rigid: a leg of helicity h forces the scaling weight $-2h$. At three points the constraint becomes total. The kinematics of three massless momenta is so confining that little-group covariance and locality alone fix the amplitude up to one constant, with no Lagrangian, no diagram, and no gauge choice (Section 58.4); the three-gluon amplitude, the QED electron–photon vertex — which advances QED beyond its Feynman-rule layer in Chapter 17 — and the graviton seed of the equivalence principle all drop out of the same representation-theoretic computation. To carry the formalism past three points we build the external polarization vectors directly from spinors (Section 58.5), where the inhomogeneous gauge redundancy of Theorem 3.46 reappears as the harmless freedom to choose a reference spinor — a freedom sharp enough, by the Ward identity of Chapter 18, to annihilate most of a Feynman expansion before it is written, and which on squaring yields the graviton polarization and the seed of the double copy of Chapter 61.

The chapter then redeems its opening promise on the book's own examples (Section 58.6). The annihilation $e^+e^- \to \mu^+\mu^-$ of Chapter 17 and Compton scattering of Chapter 18, computed there by brute-force traces, are rebuilt as one-line helicity amplitudes whose squares reproduce the carried QED cross sections to the last factor, with no gamma-matrix trace and no Levi-Civita symbol. Finally (Section 58.7) we confront the one structural obstacle between this success and the gluons of Yang–Mills theory — adjoint color — and dispatch it by the tree-level trace decomposition, which factors any n-gluon amplitude into color traces times gauge-invariant, cyclically ordered partial amplitudes built from the cubic vertex of Chapter 26. With the gluon three-point amplitude in its final color-ordered form, the Parke–Taylor formula named as the destination, and the massive bold-spinor extension stated at the frontier, the chapter hands Chapter 59 exactly the on-shell seeds its BCFW recursion will glue into the entire tree-level S-matrix.

58.1 Massless momenta as spinor squares

The chapter introduction named the puzzle: amplitudes computed from gauge-dependent Feynman diagrams swell to hundreds of terms and then, after the cancellations are done, collapse to one-line gauge-invariant answers. We located the resolution in something the reader already owns. Wigner's classification, built in Chapter 3, says that a massless one-particle state is labelled by exactly two pieces of data: its momentum on the light cone and a single helicity weight under the little group $\mathrm{ISO}(2) \simeq \mathrm{U}(1)$ (Section 3.7.3 and Eq. (3.217)). A

four-vector polarization carries more than this — it carries a redundancy that no Lorentz-covariant repackaging can remove without gauging (Section 3.7.4 and Theorem 3.46). The strategy of the entire part is therefore to stop describing a massless particle with redundant covariant objects and instead build variables that carry the on-shell data *and nothing else*. This section takes the first and most basic step: it shows that a null four-momentum is not an irreducible datum at all but the outer product of two two-component spinors, and it identifies those spinors with the Weyl spinors of Chapter 3 and the massless limit of the Dirac plane-wave spinors of Chapter 11. Once a null momentum has been opened up into a pair $(\lambda, \tilde{\lambda})$, every Lorentz invariant one can form from a set of massless legs becomes a product of the simplest possible contractions of these spinors — the angle and square brackets that the next section turns into a complete algebra.

The technical engine is a fact from linear algebra so elementary that it is easy to miss its consequences: a 2×2 matrix has rank one precisely when its determinant vanishes, and a rank-one matrix is an outer product of a column and a row. The whole of the present section is the observation that, once a four-vector p^μ is written as a 2×2 matrix in the canonical way, its Lorentz square p^2 *is* that determinant. Masslessness is the vanishing of the determinant; the spinor factorization is the outer-product structure forced by it; and the residual freedom in the factorization is exactly the little group. Nothing here is new mathematics — the two-component machinery was assembled in full in Section C.9 — but it is the moment at which that machinery acquires its physical job.

Notation Watch

Conventions for the rest of Part XVI, fixed here once because they differ between references. The metric is mostly-minus, $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, and natural units are in force. *All external momenta are taken outgoing*; an incoming physical particle of momentum p enters the formulas as the outgoing momentum $-p$, so that a leg may carry $p^0 < 0$. Two-component indices are written $a, \dot{a} \in \{1,2\}$ (undotted/dotted), exactly as in Section C.9.1; the Greek $\alpha, \dot{\alpha}$ used by some later sections and much of the literature denote the same indices. The holomorphic spinor is λ_a and the antiholomorphic one $\tilde{\lambda}_{\dot{a}}$; the bar notation $\bar{\lambda}_{\dot{a}}$ of Section C.9 denotes the same object *when momenta are real*, where (as shown below) $\tilde{\lambda} = \pm\lambda^*$, the sign set by $\mathrm{sgn}(p^0)$. For complex momenta λ and $\tilde{\lambda}$ are independent and the tilde, not the bar, is the honest notation. The bracket normalization fixed in Section 58.1 and proved in the next section is $\langle i\,j\rangle[j\,i] = 2\,p_i{\cdot}p_j = s_{ij}$, with the angle bracket antisymmetric, $\langle i\,j\rangle = -\langle j\,i\rangle$.

58.1.1 The bispinor map

A four-vector has four real components; a Hermitian 2×2 matrix also has four real parameters (two real diagonal entries and one complex off-diagonal entry). The two-component calculus of Section C.9.2 supplies the unique Lorentz-covariant isomorphism between them. Recall the Pauli four-vectors $(\sigma^\mu)_{a\dot b} = (\mathbf{1}, \sigma^i)_{a\dot b}$ of Eq. (C.274). To any four-momentum p^μ we associate the *momentum bispinor*

$$p_{a\dot a} \;\equiv\; p_\mu\,(\sigma^\mu)_{a\dot a} \;=\; p^0\,\mathbf{1} - \vec p\cdot\vec\sigma \;=\; \begin{pmatrix} p^0 - p^3 & -p^1 + ip^2 \\ -p^1 - ip^2 & p^0 + p^3 \end{pmatrix}, \tag{58.1}$$

where the middle form follows from $p_\mu = (p^0, -\vec p)$ in the mostly-minus metric together with $\sigma^\mu = (\mathbf{1}, \sigma^i)$, and the explicit matrix from $\vec p\cdot\vec\sigma = p^3\sigma^3 + p^1\sigma^1 + p^2\sigma^2$. This is a real-linear bijection: a four-vector p^μ is real if and only if the matrix $p_{a\dot a}$ is Hermitian, since $(\sigma^\mu)^\dagger = \sigma^\mu$ and the p_μ are then real coefficients.

The point of the map is that the Lorentz square becomes a determinant. Reading off Eq. (58.1),

$$\det p_{a\dot a} = (p^0-p^3)(p^0+p^3) - (-p^1+ip^2)(-p^1-ip^2) = (p^0)^2 - (p^3)^2 - (p^1)^2 - (p^2)^2 = p_\mu p^\mu = p^2. \tag{58.2}$$

For an on-shell particle $p^2 = m^2$, so the determinant of the bispinor is the squared mass. This single identity already encodes the massive-versus-massless dichotomy that will organize everything: a massive momentum has $\det p_{a\dot a} = m^2 \neq 0$, so $p_{a\dot a}$ is an invertible matrix of full rank two; a massless momentum has $\det p_{a\dot a} = 0$, so the matrix is singular and its rank drops. We will see that the rank drops to exactly one, and that the factorization of a rank-one matrix is the spinor square promised in the section title.

Before exploiting the determinant it is worth recording how the map intertwines Lorentz transformations, because this is what makes the construction covariant and ties it back to Chapter 3. Under a restricted Lorentz transformation represented by $M \in \mathrm{SL}(2,\mathbb{C})$ acting on undotted indices by $\psi_a \mapsto M_a{}^b \psi_b$ (Eq. (C.266)) and on dotted indices by $\bar\chi_{\dot a} \mapsto (M^*)_{\dot a}{}^{\dot b}\bar\chi_{\dot b}$ (Eq. (C.267)), the bispinor transforms as

$$p_{a\dot a} \;\longmapsto\; M_a{}^b\,(M^*)_{\dot a}{}^{\dot b}\,p_{b\dot b} \;=\; \big(M\,p\,M^\dagger\big)_{a\dot a}, \tag{58.3}$$

the last form reading the two index actions as ordinary matrix multiplication on the left and the conjugate-transpose on the right. Since $\det M = 1$, the determinant Eq. (58.2) is invariant, $\det(MpM^\dagger) = \det p$, which is the spinorial proof that p^2 is a Lorentz scalar. The map Eq. (58.1) is thus the explicit realization of the two-to-one covering $\mathrm{SL}(2,\mathbb{C}) \to \mathrm{SO}(1,3)^\uparrow$ built in Chapter 3: $\mathrm{SL}(2,\mathbb{C})$ acts on Hermitian matrices by $p \mapsto MpM^\dagger$, preserving the determinant, hence acts as a Lorentz transformation on the four-vector p^μ.

58.1.2 The rank-one factorization theorem

We now extract the spinors. The content is entirely in the following statement, which is the technical heart of the whole formalism.

Theorem 58.1 (Rank-one factorization of a null momentum)**.** *Let p^μ be a nonzero real four-vector with bispinor $p_{a\dot a}$ as in Eq. (58.1). Then p is null, $p^2 = 0$, if and only if $p_{a\dot a}$ has rank one, equivalently if and only if there exist two-component spinors λ_a and $\tilde\lambda_{\dot a}$, neither zero, such that*

$$p_{a\dot a} = \lambda_a \, \tilde\lambda_{\dot a}. \tag{58.4}$$

The spinors are unique up to the rescaling

$$\lambda_a \longmapsto t\,\lambda_a, \qquad \tilde\lambda_{\dot a} \longmapsto t^{-1}\,\tilde\lambda_{\dot a}, \qquad t \in \mathbb{C}^\times, \tag{58.5}$$

and no further freedom. For a real momentum the Hermiticity of $p_{a\dot a}$ forces the reality condition $\tilde\lambda_{\dot a} = \operatorname{sgn}(p^0)\,(\lambda_a)^*$, which restricts the rescaling Eq. (58.5) to the phases $t = e^{i\theta} \in \mathrm{U}(1)$.

Proof. Determinant, rank, and outer product are equivalent. For any 2×2 matrix the determinant is the only obstruction to a rank drop: $\det p_{a\dot a} = 0$ means the two columns are linearly dependent, so the column space is at most one-dimensional; since $p \neq 0$ the matrix is not the zero matrix, so the column space is exactly one-dimensional and the rank is exactly one. By Eq. (58.2) the condition $\det p_{a\dot a} = 0$ is precisely $p^2 = 0$. Conversely a rank-one matrix has vanishing determinant. It remains to show that a rank-one 2×2 matrix is an outer product Eq. (58.4) and to exhibit the spinors explicitly.

Explicit construction of the spinors. Write the entries as

$$p_{a\dot a} = \begin{pmatrix} p_{1\dot 1} & p_{1\dot 2} \\ p_{2\dot 1} & p_{2\dot 2} \end{pmatrix}, \qquad \det p_{a\dot a} = p_{1\dot 1}p_{2\dot 2} - p_{1\dot 2}p_{2\dot 1} = 0. \tag{58.6}$$

Suppose first that $p_{1\dot 1} \neq 0$. Define

$$\lambda_a = \frac{1}{\sqrt{p_{1\dot 1}}}\begin{pmatrix} p_{1\dot 1} \\ p_{2\dot 1} \end{pmatrix}, \qquad \tilde\lambda_{\dot a} = \frac{1}{\sqrt{p_{1\dot 1}}}\begin{pmatrix} p_{1\dot 1} \\ p_{1\dot 2} \end{pmatrix}, \tag{58.7}$$

where $\sqrt{p_{1\dot 1}}$ is any fixed square root. The outer product reproduces $p_{a\dot a}$ entry by entry:

$$\begin{aligned} \lambda_1\tilde\lambda_{\dot 1} &= \frac{p_{1\dot 1}\cdot p_{1\dot 1}}{p_{1\dot 1}} = p_{1\dot 1}, & \lambda_1\tilde\lambda_{\dot 2} &= \frac{p_{1\dot 1}\cdot p_{1\dot 2}}{p_{1\dot 1}} = p_{1\dot 2}, \\ \lambda_2\tilde\lambda_{\dot 1} &= \frac{p_{2\dot 1}\cdot p_{1\dot 1}}{p_{1\dot 1}} = p_{2\dot 1}, & \lambda_2\tilde\lambda_{\dot 2} &= \frac{p_{2\dot 1}\cdot p_{1\dot 2}}{p_{1\dot 1}} = \frac{p_{1\dot 1}p_{2\dot 2}}{p_{1\dot 1}} = p_{2\dot 2}, \end{aligned} \tag{58.8}$$

the last equality using the determinant condition $p_{2\dot{1}}p_{1\dot{2}} = p_{1\dot{1}}p_{2\dot{2}}$ from Eq. (58.6). This proves Eq. (58.4). If instead $p_{1\dot{1}} = 0$ then at least one other diagonal or off-diagonal entry is nonzero (else $p = 0$); for a null momentum with $p^0 > 0$ one has $p_{1\dot{1}} = p^0 - p^3 \geq 0$, vanishing only when p points along $+\hat{z}$, in which case $p_{2\dot{2}} = p^0 + p^3 = 2p^0 \neq 0$ and the identical construction built on $p_{2\dot{2}}$ goes through after exchanging the roles of the two rows and columns. Either way an outer-product factorization exists.

Uniqueness up to rescaling. Suppose $\lambda_a\tilde{\lambda}_{\dot{a}} = \lambda'_a\tilde{\lambda}'_{\dot{a}}$ with all four spinors nonzero. The left side, regarded as a matrix, has column space spanned by the single vector λ_a; the right side has column space spanned by λ'_a. A one-dimensional space has a unique spanning direction, so $\lambda'_a = t\,\lambda_a$ for some $t \in \mathbb{C}^\times$. Substituting and cancelling the nonzero λ_a leaves $\tilde{\lambda}_{\dot{a}} = t\,\tilde{\lambda}'_{\dot{a}}$, i.e. $\tilde{\lambda}'_{\dot{a}} = t^{-1}\tilde{\lambda}_{\dot{a}}$. This is exactly Eq. (58.5), and there is no other freedom: the factorization is rigid once the scale t is fixed.

Reality condition. Let p^μ be real, so $p_{a\dot{a}}$ is Hermitian: $(p_{a\dot{a}})^* = p_{\dot{a}a}$, i.e. $p_{2\dot{1}} = (p_{1\dot{2}})^*$ and the diagonal entries are real. Take $p^0 > 0$, so the matrix Eq. (58.1) has nonnegative trace $\operatorname{tr} p_{a\dot{a}} = 2p^0 > 0$, and being a rank-one Hermitian matrix of nonnegative trace it is positive semidefinite. Then $p_{1\dot{1}} \geq 0$, and choosing the positive square root in Eq. (58.7) gives, using $p_{2\dot{1}} = (p_{1\dot{2}})^*$ and $p_{1\dot{1}}$ real,

$$(\lambda_a)^* = \frac{1}{\sqrt{p_{1\dot{1}}}}\begin{pmatrix}(p_{1\dot{1}})^*\\(p_{2\dot{1}})^*\end{pmatrix} = \frac{1}{\sqrt{p_{1\dot{1}}}}\begin{pmatrix}p_{1\dot{1}}\\p_{1\dot{2}}\end{pmatrix} = \tilde{\lambda}_{\dot{a}}. \tag{58.9}$$

Thus $\tilde{\lambda} = \lambda^*$ when $p^0 > 0$. If instead $p^0 < 0$ (a crossed, all-outgoing leg), then $p_{a\dot{a}}$ is negative semidefinite; writing $p_{a\dot{a}} = -(-p)_{a\dot{a}}$ with $-p$ positive-energy and factorizing $-p$ as above attaches a relative sign, $\tilde{\lambda} = -\lambda^*$. In both cases $\tilde{\lambda} = \operatorname{sgn}(p^0)\,\lambda^*$. Finally, the reality condition is preserved by the rescaling Eq. (58.5) only when $(t\lambda)^* = t^{-1}\lambda^*$, i.e. $\bar{t} = t^{-1}$, i.e. $|t| = 1$: the residual freedom for real momenta is the phase group U(1). □

The last sentence of the proof is the punchline that connects this purely algebraic statement back to Wigner. For a real on-shell massless momentum the factorization Eq. (58.4) is unique up to a single phase $e^{i\theta}$, and this phase is the little group. Recall from Section 3.7.3 that the massless little group — the subgroup of Lorentz transformations fixing a chosen null momentum — is ISO(2), the symmetries of the Euclidean plane, whose compact part acts on one-particle states by the helicity phase $e^{ih\theta}$ of Eq. (3.217). The rescaling Eq. (58.5) is the action of this little group on the spinor data: a Lorentz transformation fixing $p_{a\dot{a}} = \lambda_a\tilde{\lambda}_{\dot{a}}$ cannot change the product, so it can only multiply λ by a phase and $\tilde{\lambda}$ by the inverse phase. We will promote this observation in a later section into the organizing principle of the whole subject — an amplitude's weight under Eq. (58.5) on each leg *is* that leg's helicity, and this single requirement will fix the three-point amplitudes by symmetry alone. For now we record only that the

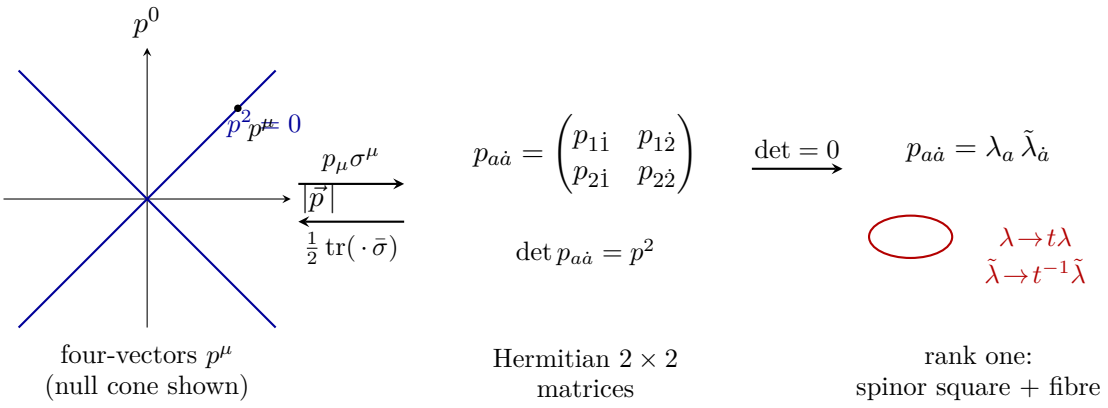

Figure 58.1: The bispinor map and its rank-one degeneration. A real four-vector is the same datum as a Hermitian 2×2 matrix (Eq. (58.1)), under which the Lorentz square becomes the determinant (Eq. (58.2)). On the null cone $p^2 = 0$ the determinant vanishes, the matrix drops to rank one, and Theorem 58.1 factorizes it into the outer product of a holomorphic spinor λ and an antiholomorphic spinor $\tilde{\lambda}$. The factorization is unique only up to the little-group fibre Eq. (58.5); for real momenta this fibre is the helicity phase U(1) of Section 3.7.3.

redundancy Wigner identified in the covariant description has reappeared, in the spinor variables, as a clean one-parameter rescaling rather than the awkward inhomogeneous shift of polarization vectors found in Theorem 3.46.

We package the result as the definition that the rest of Part XVI refers back to.

Definition 58.2 (Spinor-helicity variables)**.** To each external massless leg of momentum p^μ we attach a pair of two-component spinors: the *holomorphic* spinor λ_a and the *antiholomorphic* spinor $\tilde{\lambda}_{\dot{a}}$, related to the momentum by the rank-one factorization

$$p_{a\dot{a}} = \lambda_a\, \tilde{\lambda}_{\dot{a}}, \qquad p^2 = 0, \tag{58.10}$$

and defined only up to the little-group rescaling Eq. (58.5). For real momenta $\tilde{\lambda} = \mathrm{sgn}(p^0)\, \lambda^*$; for complex momenta (which arise as an analytic-continuation tool from Chapter 59 onward) λ and $\tilde{\lambda}$ are independent. Raising and lowering of the spinor indices uses the ϵ metric of Eqs. (C.269) and (C.270), so that the all-raised form of Eq. (58.10) reads $p^{\dot{a}a} = \tilde{\lambda}^{\dot{a}} \lambda^a$, matching the upper-index bispinor used in later chapters.

Figure 58.1 summarizes the geometry: the bijection between four-vectors and Hermitian matrices, the null cone as the determinant-zero locus where the rank collapses, and the one-parameter fibre of rescalings that the little group acts along.

58.1.3 The spinors are the massless Weyl and Dirac spinors

We have produced two two-component spinors out of a null momentum by an algebraic manipulation. We now show they are not new objects: λ is precisely a solution of the massless Weyl equation of Chapter 3, and the pair $(\lambda, \tilde{\lambda})$ assembles into the massless limit of the Dirac plane-wave spinors of Chapter 11. This is what licenses calling them "the" spinors of the leg rather than an arbitrary bookkeeping device.

The holomorphic spinor solves the Weyl equation. The massless left-handed Weyl equation, in momentum space, is the statement that a left-handed field ψ_a is annihilated by $\bar{\sigma} \cdot p$, that is $(\bar{\sigma}^\mu)^{\dot{a}b} p_\mu \, \psi_b = 0$ (the momentum-space form of $i\bar{\sigma}^\mu \partial_\mu \psi = 0$, whose plane-wave content is the massless case of the laws Theorem 3.24 and Eq. (3.105)). We check directly that the holomorphic spinor of Eq. (58.10) is such a zero mode. Using the raised bispinor $p^{\dot{a}b} = (\bar{\sigma}^\mu)^{\dot{a}b} p_\mu$ and raising the indices of Eq. (58.4) with ϵ,

$$p^{\dot{a}b} = \epsilon^{\dot{a}\dot{c}} \epsilon^{bd} \, p_{d\dot{c}} = \epsilon^{\dot{a}\dot{c}} \epsilon^{bd} \, \lambda_d \tilde{\lambda}_{\dot{c}} = \tilde{\lambda}^{\dot{a}} \, \lambda^b, \tag{58.11}$$

where the relation between σ^μ and $\bar{\sigma}^\mu$ used is exactly the index-raising Eq. (C.275). Contracting with λ_b,

$$p^{\dot{a}b} \lambda_b = \tilde{\lambda}^{\dot{a}} \, (\lambda^b \lambda_b) = \tilde{\lambda}^{\dot{a}} \, \langle \lambda \, \lambda \rangle = 0, \tag{58.12}$$

because $\lambda^b \lambda_b = \epsilon^{bc} \lambda_c \lambda_b = 0$ vanishes by the antisymmetry of ϵ contracted with the symmetric (for commuting spinors) product $\lambda_c \lambda_b$ — this is the reorder identity Eq. (C.273) in the commuting case, equivalently $\langle \lambda \, \lambda \rangle = 0$. Thus λ solves the massless Weyl equation. The same computation with bars shows the antiholomorphic spinor solves the conjugate equation: from $p_{a\dot{a}} = \lambda_a \tilde{\lambda}_{\dot{a}}$,

$$(\sigma^\mu)_{a\dot{b}} p_\mu \, \tilde{\lambda}^{\dot{b}} = p_{a\dot{b}} \tilde{\lambda}^{\dot{b}} = \lambda_a \, (\tilde{\lambda}_{\dot{b}} \tilde{\lambda}^{\dot{b}}) = \lambda_a \, [\tilde{\lambda} \, \tilde{\lambda}] = 0, \tag{58.13}$$

again because $\tilde{\lambda}_{\dot{b}} \tilde{\lambda}^{\dot{b}} = 0$ by antisymmetry. So λ lives in the $(\frac{1}{2}, 0)$ representation and $\tilde{\lambda}$ in the $(0, \frac{1}{2})$ representation, and each is the unique (up to scale) zero mode of the corresponding massless wave operator at the given momentum — the two-state content of a massless particle of Section 3.7.3, now made completely concrete.

Worked Example 58.3 (Explicit spinors for a momentum in a general direction)**.** Take a positive-energy null momentum pointing in the direction $\hat{n} = (\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta)$,

$$p^\mu = E \, (1, \, \hat{n}), \qquad E > 0, \tag{58.14}$$

and build its spinors from scratch, then compare with the Dirac plane-wave spinors of Chapter 11. The bispinor Eq. (58.1) is $p_{a\dot a} = E(\mathbf{1} - \hat n\cdot\vec\sigma)$, and with $\hat n\cdot\vec\sigma = \left(\begin{smallmatrix}\cos\theta & \sin\theta\, e^{-i\phi}\\ \sin\theta\, e^{i\phi} & -\cos\theta\end{smallmatrix}\right)$ this is

$$p_{a\dot a} = E\begin{pmatrix} 1-\cos\theta & -\sin\theta\, e^{-i\phi}\\ -\sin\theta\, e^{i\phi} & 1+\cos\theta\end{pmatrix} = 2E\begin{pmatrix} \sin^2\frac{\theta}{2} & -\sin\frac{\theta}{2}\cos\frac{\theta}{2}\, e^{-i\phi}\\ -\sin\frac{\theta}{2}\cos\frac{\theta}{2}\, e^{i\phi} & \cos^2\frac{\theta}{2}\end{pmatrix}, \tag{58.15}$$

using the half-angle identities $1\mp\cos\theta = 2\sin^2(\theta/2), 2\cos^2(\theta/2)$ and $\sin\theta = 2\sin(\theta/2)\cos(\theta/2)$. The matrix Eq. (58.15) is manifestly a single outer product,

$$p_{a\dot a} = \lambda_a\tilde\lambda_{\dot a}, \qquad \lambda_a = \sqrt{2E}\begin{pmatrix}\sin\frac{\theta}{2}\\ -\cos\frac{\theta}{2}\, e^{i\phi}\end{pmatrix}, \qquad \tilde\lambda_{\dot a} = \sqrt{2E}\begin{pmatrix}\sin\frac{\theta}{2}\\ -\cos\frac{\theta}{2}\, e^{-i\phi}\end{pmatrix}, \tag{58.16}$$

as one verifies by multiplying out the four entries; the determinant of Eq. (58.15) is $4E^2(\sin^2\frac{\theta}{2}\cos^2\frac{\theta}{2} - \sin^2\frac{\theta}{2}\cos^2\frac{\theta}{2}) = 0$, confirming masslessness. Since $E>0$ the reality condition Eq. (58.46) holds in the sharp form $\tilde\lambda_{\dot a} = (\lambda_a)^*$, visible directly in Eq. (58.16) as the complex conjugation of the phase $e^{\pm i\phi}$.

Specialize to motion along $+\hat z$, $\theta = 0$: then $\lambda_a = \sqrt{2E}\,(0,-1)^{\mathsf T}$, proportional to $(0,1)^{\mathsf T}$ up to the little-group phase Eq. (58.5). Compare with the massless limit of the Dirac spinor $u^2(p)$ computed in Theorem 11.10: there $u^2 \to (0,\sqrt{2E},0,0)^{\mathsf T}$ collapses onto its upper (left-handed, undotted) two-component block $\sqrt{2E}\,(0,1)^{\mathsf T}$. The two agree up to the overall phase that the little group leaves free: the holomorphic spinor extracted here from the momentum alone is exactly the left-handed block of the massless Dirac plane-wave spinor of Theorem 11.8 and Eq. (11.57). The helicity assignment matches too: along $+\hat z$ the state u^2 is the spin-down, hence negative-helicity, solution of the helicity operator Eq. (11.83), and it is precisely the surviving *left-handed* piece in the massless limit — chirality and helicity coinciding at $m=0$, the fact already noted at the end of Theorem 11.10.

The four-component embedding. For computations that still use four-component Dirac language — the QED amplitudes of QED, which we will re-express later in this chapter — it is convenient to embed the two-component spinors back into four-component objects. In the chiral basis of Eq. (C.288), where the upper block carries the undotted (left-handed) index and the lower block the dotted (right-handed) index and $\gamma^5 = \mathrm{diag}(-\mathbf{1},+\mathbf{1})$, define the angle and square kets and bras

$$|p\rangle = \begin{pmatrix}\lambda_a\\ 0\end{pmatrix}, \quad |p] = \begin{pmatrix}0\\ \tilde\lambda^{\dot a}\end{pmatrix}, \quad \langle p| = (\lambda^a,\ 0), \quad [p| = (0,\ \tilde\lambda_{\dot a}). \tag{58.17}$$

With these, the angle bracket of the next section is the four-component pairing of two angle objects, $\langle p\,q\rangle = \langle p|\,|q\rangle = \lambda_p^a\lambda_{q\,a}$, and likewise $[p\,q] = [p|\,|q] = \tilde\lambda_{p\,\dot a}\tilde\lambda_q^{\dot a}$,

the two heights following the contraction conventions Eq. (C.271); a mixed pairing $\langle p|\,|q]$ vanishes because the objects live in opposite chiral blocks. The kets are exactly the massless Dirac solutions: $|p\rangle = P_L\,u$ is the left-handed, negative-helicity spinor and $|p] = P_R\,u$ the right-handed, positive-helicity one, where $P_{L,R}$ are the chirality projectors of Chapter 11. The decomposition of the slashed momentum follows by multiplying out the outer products against $\gamma^\mu = \left(\begin{smallmatrix} 0 & \sigma^\mu \\ \bar\sigma^\mu & 0 \end{smallmatrix}\right)$:

$$\not{p} = \begin{pmatrix} 0 & p_{a\dot b} \\ p^{\dot a b} & 0 \end{pmatrix} = \begin{pmatrix} 0 & \lambda_a \tilde\lambda_{\dot b} \\ \tilde\lambda^{\dot a}\lambda^b & 0 \end{pmatrix} = |p\rangle\,[p| + |p]\,\langle p|\,, \tag{58.18}$$

using Eqs. (58.4) and (58.11); this is the massless spin sum $\sum_\pm w_\pm \bar w_\pm = \not{p}$ of Chapter 11 written in spinor variables, and it is the identity that the later sections, and Chapter 59, deploy whenever a propagator numerator must be opened up. Because the massless equations $\not{p}\,w = 0$ for the particle spinor u and the antiparticle spinor v differ only by the (now absent) mass term, the two coincide at $m = 0$ up to helicity labelling, $u_\pm(p) = v_\mp(p)$: a single pair $(\lambda, \tilde\lambda)$ carries the on-shell data of both the particle and the antiparticle of a given helicity, which is the economy promised at the outset.

The momentum of each massless leg has now been resolved into the pair $(\lambda_a, \tilde\lambda_{\dot a})$: holomorphic and antiholomorphic spinors that solve the Weyl equations of Chapter 3, reduce to the massless Dirac spinors of Chapter 11, and carry precisely the on-shell content Wigner's classification allows — a null momentum through Eq. (58.10) and a single helicity weight through the little-group rescaling Eq. (58.5), with no covariant redundancy left over. With every external leg so equipped, the next section contracts these spinors into the angle and square brackets $\langle i\,j\rangle, [i\,j]$, fixes their signs and reality properties once and for all, and assembles the complete algebra of identities on which the remainder of Part XVI runs.

58.2 The bracket algebra and its identities

The previous section did the decisive thing: it traded the four real components of a null momentum, constrained by $p^2 = 0$, for a pair of two-component spinors λ_i and $\tilde\lambda_i$ whose outer product *is* that momentum, $p_{i,a\dot a} = \lambda_{ia}\tilde\lambda_{i\dot a}$ (Theorem 58.2 and Eq. (58.1)). These spinors carry the genuinely irreducible on-shell data: λ_i transforms in the $(\frac12, 0)$ representation of $\mathrm{SL}(2,\mathbb{C})$ and $\tilde\lambda_i$ in $(0, \frac12)$, by the Weyl transformation laws Eq. (3.105) of Chapter 3. What we do not yet have is a calculus. An amplitude is a Lorentz scalar, and Lorentz scalars must be built out of λ_i and $\tilde\lambda_i$ by contracting away their spinor indices. There are exactly two ways to contract two undotted (or two dotted) indices invariantly — against the antisymmetric ϵ tensor that is the metric of the spinor space — and these two contractions are the entire alphabet of the formalism. This section builds that

alphabet into a language: it defines the angle and square brackets, proves every identity that the rest of Part XVI will quote, and — because the signs differ from book to book and a single dropped minus propagates into every amplitude downstream — it pins the conventions down once and for all.

58.2.1 The two invariant brackets

The spinor indices $a, b, \cdots = 1, 2$ (undotted) and $\dot{a}, \dot{b}, \cdots = \dot{1}, \dot{2}$ (dotted) are raised and lowered with the antisymmetric symbols ϵ_{ab}, ϵ^{ab} and their dotted counterparts, in the conventions established for the two-component calculus in Section C.9: numerically

$$\epsilon^{12} = -\epsilon^{21} = +1, \qquad \epsilon_{12} = -\epsilon_{21} = -1, \qquad \epsilon_{ab}\epsilon^{bc} = \delta_a^{\,c}, \tag{58.19}$$

with identical numerical values for the dotted symbols, and raising/lowering by $\lambda^a = \epsilon^{ab}\lambda_b$, $\lambda_a = \epsilon_{ab}\lambda^b$ (Eq. (C.269)). The only Lorentz invariant one can form from two undotted spinors is their ϵ-contraction, and likewise for two dotted spinors. These two objects are the angle and square brackets.

Definition 58.4 (Angle and square brackets)**.** For massless legs i, j with holomorphic spinors λ_i and antiholomorphic spinors $\tilde{\lambda}_i$, define

$$\langle i\,j\rangle \;\equiv\; \epsilon^{ab}\,\lambda_{ia}\,\lambda_{jb} \;=\; \lambda_{ia}\,\lambda_j^{\,a}, \qquad [i\,j] \;\equiv\; \epsilon_{\dot{a}\dot{b}}\,\tilde{\lambda}_i^{\,\dot{a}}\,\tilde{\lambda}_j^{\,\dot{b}} \;=\; \tilde{\lambda}_i^{\,\dot{a}}\,\tilde{\lambda}_{j\dot{a}}, \tag{58.20}$$

the *angle bracket* $\langle i\,j\rangle$ and the *square bracket* $[i\,j]$. Equivalently, writing the angle ket $|i\rangle = \lambda_i$ and the square ket $|i] = \tilde{\lambda}_i$ with the bra conventions $\langle i|$, $[i|$, these are the spinor inner products $\langle i\,j\rangle = \langle i|j\rangle$ and $[i\,j] = [i|\,|j]$.

The asymmetry in Eq. (58.20) — the angle bracket contracts two *lower* undotted indices with the upper ϵ^{ab}, while the square bracket contracts two *upper* dotted indices with the lower $\epsilon_{\dot{a}\dot{b}}$ — is not cosmetic. It is precisely the choice that makes the bracket–momentum dictionary of the next subsection come out with a uniform positive sign, and it is the convention under which every formula of Chapters 59 to 62 is written. We collect the choice, together with the standing kinematic conventions of the chapter, in a notation box.

Notation Watch: bracket and momentum conventions

Throughout Part XVI the metric is mostly-minus $\eta = \mathrm{diag}(+,-,-,-)$ and natural units are in force. *All momenta are taken outgoing*, so the conservation law is $\sum_i p_i = 0$ with no sign bookkeeping per leg; a physical incoming particle of momentum p is the outgoing entry $-p$. The null bispinor is $p_{i,a\dot{a}} = \lambda_{ia}\tilde{\lambda}_{i\dot{a}} = p_{i\mu}(\sigma^\mu)_{a\dot{a}}$, with Pauli four-vectors $\sigma^\mu = (\mathbf{1}, \vec{\sigma})$,

$\bar\sigma^\mu = (\mathbf{1}, -\vec\sigma)$ as in Section C.9. The brackets are normalized so that

$$\langle i\,j\rangle\,[j\,i] \;=\; 2\,p_i\cdot p_j \;=\; s_{ij}, \tag{58.21}$$

the central relation proved in Eq. (58.24) below. For real momenta $\tilde\lambda_i = \pm\lambda_i^*$, the sign equal to $\mathrm{sgn}(p_i^0)$; for complex momenta λ_i and $\tilde\lambda_i$ are taken independent. Other references differ from Eq. (58.20) by an overall sign in one bracket or in the spinor-metric convention; the physics is insensitive to this provided Eq. (58.21) holds, which we adopt as the defining normalization.

The most basic property is antisymmetry, and it is immediate from the antisymmetry of ϵ.

Proposition 58.5 (Antisymmetry and self-vanishing)**.** *The brackets are antisymmetric,*

$$\langle i\,j\rangle = -\langle j\,i\rangle, \qquad [i\,j] = -[j\,i], \tag{58.22}$$

and in particular a leg has vanishing bracket with itself,

$$\langle i\,i\rangle = 0, \qquad [i\,i] = 0. \tag{58.23}$$

Proof. From Eq. (58.20), $\langle j\,i\rangle = \epsilon^{ab}\lambda_{ja}\lambda_{ib}$; relabelling the summed indices $a \leftrightarrow b$ and using $\epsilon^{ba} = -\epsilon^{ab}$ gives $\langle j\,i\rangle = \epsilon^{ba}\lambda_{jb}\lambda_{ia} = -\epsilon^{ab}\lambda_{ia}\lambda_{jb} = -\langle i\,j\rangle$, where the commuting (bosonic) spinor components were freely reordered. The square-bracket statement is identical with $\epsilon_{\dot a\dot b}$. Setting $j = i$ in Eq. (58.22) forces $\langle i\,i\rangle = -\langle i\,i\rangle = 0$, and similarly for the square bracket. □

That $\langle i\,i\rangle = 0$ has a transparent meaning: the angle bracket of a leg with itself is the contraction $\epsilon^{ab}\lambda_{ia}\lambda_{ib}$ of a symmetric pair $\lambda_{ia}\lambda_{ib}$ against the antisymmetric ϵ, which vanishes. A bracket $\langle i\,j\rangle$ therefore measures the failure of λ_i and λ_j to be proportional: it is zero precisely when $\lambda_i \propto \lambda_j$, i.e. when the two legs share the same holomorphic spinor. This is the spinorial face of collinearity, and it is why brackets sit naturally in the denominators of amplitudes, where they encode the poles of collinear and soft kinematics.

58.2.2 The bracket–Mandelstam dictionary

The single most important identity of the formalism is the one that connects the brackets, which are holomorphic and antiholomorphic objects of weight one, to the Lorentz invariants $p_i\cdot p_j$ that the Feynman rules of Parts IV–VII produce. It is what guarantees that anything expressible in Mandelstam variables can be rewritten in brackets, and conversely.

Theorem 58.6 (Bracket–Mandelstam dictionary)**.** *For any two massless legs,*

$$\langle i\,j\rangle\,[j\,i] \;=\; 2\,p_i\cdot p_j. \tag{58.24}$$

In particular, for the two-particle Mandelstam invariant of Theorem 16.20, $s_{ij}\equiv(p_i+p_j)^2=2\,p_i\cdot p_j=\langle i\,j\rangle[j\,i]$ when both legs are massless.

Proof. We compute $2\,p_i\cdot p_j$ directly from the bispinors and the Pauli-matrix trace identity, showing every contraction. Write the two momenta in their lower and upper bispinor forms, $p_{i,a\dot a}=p_{i\mu}(\sigma^\mu)_{a\dot a}$ and $p_j^{\dot a a}=p_{j\nu}(\bar\sigma^\nu)^{\dot a a}$. The invariant pairing is read off from the $\sigma/\bar\sigma$ trace identity $\mathrm{tr}(\sigma^\mu\bar\sigma^\nu)\equiv(\sigma^\mu)_{a\dot b}(\bar\sigma^\nu)^{\dot b a}=2\eta^{\mu\nu}$ of Eq. (C.279):

$$p_{i,a\dot a}\,p_j^{\dot a a}=p_{i\mu}p_{j\nu}\,(\sigma^\mu)_{a\dot a}(\bar\sigma^\nu)^{\dot a a}=p_{i\mu}p_{j\nu}\,2\eta^{\mu\nu}=2\,p_i\cdot p_j. \tag{58.25}$$

Now insert the spinor factorization. From $p_{i,a\dot a}=\lambda_{ia}\tilde\lambda_{i\dot a}$ and the $\sigma/\bar\sigma$ relation $(\bar\sigma^\mu)^{\dot a a}=\epsilon^{\dot a\dot b}\epsilon^{ab}(\sigma^\mu)_{b\dot b}$ of Eq. (C.275), the upper bispinor is the doubly-raised lower one,

$$p_j^{\dot a a}=\epsilon^{\dot a\dot b}\epsilon^{ab}\,p_{j,b\dot b}=\epsilon^{\dot a\dot b}\epsilon^{ab}\,\lambda_{jb}\tilde\lambda_{j\dot b}=(\epsilon^{ab}\lambda_{jb})(\epsilon^{\dot a\dot b}\tilde\lambda_{j\dot b})=\lambda_j^{\,a}\,\tilde\lambda_j^{\,\dot a}. \tag{58.26}$$

Substituting Eq. (58.26) and $p_{i,a\dot a}=\lambda_{ia}\tilde\lambda_{i\dot a}$ into the left side of Eq. (58.25) and grouping the undotted factors with the undotted and the dotted with the dotted,

$$2\,p_i\cdot p_j=\lambda_{ia}\tilde\lambda_{i\dot a}\,\lambda_j^{\,a}\tilde\lambda_j^{\,\dot a}=(\lambda_{ia}\,\lambda_j^{\,a})\,(\tilde\lambda_{i\dot a}\,\tilde\lambda_j^{\,\dot a}). \tag{58.27}$$

The first factor is the angle bracket of Eq. (58.20) verbatim: $\lambda_{ia}\lambda_j^{\,a}=\langle i\,j\rangle$. The second factor is $\tilde\lambda_{i\dot a}\tilde\lambda_j^{\,\dot a}$; lowering the j-index and raising the i-index, $\tilde\lambda_{i\dot a}\tilde\lambda_j^{\,\dot a}=\tilde\lambda_i^{\,\dot a}\tilde\lambda_{j\dot a}\cdot(-1)\cdot(-1)$ is the same number written the other way, and comparing with Eq. (58.20) one finds $\tilde\lambda_{i\dot a}\tilde\lambda_j^{\,\dot a}=[j\,i]$ — the indices are summed first-down on i and up on j, which is the square bracket with the labels in the order j,i. Explicitly, $\tilde\lambda_{i\dot a}\tilde\lambda_j^{\,\dot a}=\tilde\lambda_{i\dot 1}\tilde\lambda_j^{\,\dot 1}+\tilde\lambda_{i\dot 2}\tilde\lambda_j^{\,\dot 2}=\tilde\lambda_{i\dot 1}\tilde\lambda_{j\dot 2}-\tilde\lambda_{i\dot 2}\tilde\lambda_{j\dot 1}$ (using $\tilde\lambda_j^{\,\dot 1}=\tilde\lambda_{j\dot 2}$, $\tilde\lambda_j^{\,\dot 2}=-\tilde\lambda_{j\dot 1}$ from Eq. (58.19)), while $[j\,i]=\epsilon_{\dot a\dot b}\tilde\lambda_j^{\,\dot a}\tilde\lambda_i^{\,\dot b}$ evaluates to the same $\tilde\lambda_{i\dot 1}\tilde\lambda_{j\dot 2}-\tilde\lambda_{i\dot 2}\tilde\lambda_{j\dot 1}$. Hence Eq. (58.27) reads $2\,p_i\cdot p_j=\langle i\,j\rangle[j\,i]$, which is Eq. (58.24). The identification with s_{ij} follows because $(p_i+p_j)^2=p_i^2+p_j^2+2p_i\cdot p_j=2p_i\cdot p_j$ for $p_i^2=p_j^2=0$. □

Two remarks fix the dictionary in the reader's hands. First, the *order of the labels matters and is correlated between the two brackets*: it is $\langle i\,j\rangle[j\,i]$, not $\langle i\,j\rangle[i\,j]$, that equals $2p_i\cdot p_j$; the two differ by a sign because $[i\,j]=-[j\,i]$. Reversing both brackets, $\langle j\,i\rangle[i\,j]=(-\langle i\,j\rangle)(-[j\,i])=\langle i\,j\rangle[j\,i]$, leaves the invariant unchanged, as it must since $p_i\cdot p_j=p_j\cdot p_i$. Second, the dictionary already exhibits the holomorphic split that powers the whole subject: s_{ij} factorizes into an angle bracket carrying only the λ's and a square bracket carrying only the $\tilde\lambda$'s. A real Mandelstam invariant is a product of a holomorphic and an antiholomorphic

half, and the analytic continuation to complex momenta — in which the two halves become independent — is exactly what lets a single half vanish while the invariant stays finite. That is the kinematic room three-point amplitudes will need.

58.2.3 The mixed sandwich and the Gordon identity

Amplitudes with fermion lines or with vector polarizations require one more object: a quantity carrying one Lorentz vector index, built from one angle and one square spinor. This is the mixed sandwich.

Definition 58.7 (Mixed spinor sandwich)**.** For massless legs i, j define the Lorentz four-vector

$$\langle i|\gamma^\mu|j] \;\equiv\; \lambda_i^a\,(\sigma^\mu)_{a\dot a}\,\tilde\lambda_j^{\dot a}, \qquad [i|\gamma^\mu|j\rangle \;\equiv\; \tilde\lambda_{i\dot a}\,(\bar\sigma^\mu)^{\dot a a}\,\lambda_{ja}. \tag{58.28}$$

The notation records the data: $\langle i|\gamma^\mu|j] = \langle i|\,\gamma^\mu|j]$ contracts an angle bra on the left with a square ket on the right; $[i|\gamma^\mu|j\rangle = [i|\gamma^\mu\,|j\rangle$ does the reverse.

The names γ^μ, $\langle i|$, $|j]$ are not loose analogy. In the chiral basis of Section C.9 the Dirac matrix is $\gamma^\mu = \left(\begin{smallmatrix} 0 & \sigma^\mu \\ \bar\sigma^\mu & 0 \end{smallmatrix}\right)$, and a massless Dirac spinor decomposes into the Weyl pieces λ and $\tilde\lambda$; the objects in Eq. (58.28) are exactly the surviving chiral blocks of a four-component bilinear $\bar u_i \gamma^\mu u_j$. The two sandwiches are not independent: they are complex-conjugate transposes of one another in the sense made precise by the following identity, which we will use constantly to flip a sandwich's chirality.

Proposition 58.8 (Reversal of the sandwich)**.** *For all i, j,*

$$\langle i|\gamma^\mu|j] \;=\; [j|\gamma^\mu|i\rangle. \tag{58.29}$$

Proof. Start from the right side and use $(\bar\sigma^\mu)^{\dot a a} = \epsilon^{\dot a \dot b}\epsilon^{ab}(\sigma^\mu)_{b\dot b}$ (Eq. (C.275)):

$$[j|\gamma^\mu|i\rangle = \tilde\lambda_{j\dot a}(\bar\sigma^\mu)^{\dot a a}\lambda_{ia} = \tilde\lambda_{j\dot a}\,\epsilon^{\dot a\dot b}\epsilon^{ab}(\sigma^\mu)_{b\dot b}\,\lambda_{ia} = (\epsilon^{ab}\lambda_{ia})(\sigma^\mu)_{b\dot b}(\epsilon^{\dot a\dot b}\tilde\lambda_{j\dot a}).$$

Now $\epsilon^{ab}\lambda_{ia} = -\epsilon^{ba}\lambda_{ia} = -\lambda_i^b$ and $\epsilon^{\dot a\dot b}\tilde\lambda_{j\dot a} = -\tilde\lambda_j^{\dot b}$, by the raising convention of Eq. (58.19). The two minus signs cancel, leaving $[j|\gamma^\mu|i\rangle = \lambda_i^b(\sigma^\mu)_{b\dot b}\tilde\lambda_j^{\dot b} = \langle i|\gamma^\mu|j]$ by Eq. (58.28). □

Setting $i = j$ in the sandwich recovers the momentum itself: the formalism's version of the Gordon identity.

Proposition 58.9 (Gordon identity for null momenta)**.** *For a single massless leg,*

$$\langle i|\gamma^\mu|i] \;=\; 2\,p_i^\mu \;=\; [i|\gamma^\mu|i\rangle. \tag{58.30}$$

Proof. From Eq. (58.28), $\langle i|\gamma^\mu|i] = \lambda_i^a(\sigma^\mu)_{a\dot a}\tilde\lambda_i^{\dot a} = (\sigma^\mu)_{a\dot a}\,\lambda_i^a\tilde\lambda_i^{\dot a} = (\sigma^\mu)_{a\dot a}\,p_i^{\dot a a}$, using $p_i^{\dot a a} = \lambda_i^a\tilde\lambda_i^{\dot a}$ from Eq. (58.26). Writing $p_i^{\dot a a} = p_{i\nu}(\bar\sigma^\nu)^{\dot a a}$ and applying the trace identity Eq. (C.279) once more, $(\sigma^\mu)_{a\dot a}(\bar\sigma^\nu)^{\dot a a} = 2\eta^{\mu\nu}$, so $\langle i|\gamma^\mu|i] = p_{i\nu}\,2\eta^{\mu\nu} = 2p_i^\mu$. The second equality in Eq. (58.30) is Eq. (58.29) at $i=j$. □

A useful corollary of Eq. (58.30) and the dictionary is the chain rule for inserting a sum of momenta between an angle bra and a square ket. If $P=\sum_k p_k$ is a sum of null momenta, then $\langle i|\not{P}|j] \equiv \sum_k\langle i|\gamma^\mu|\,]p_{k\mu}|j] = \sum_k\langle i\,k\rangle[k\,j]$, because each null insertion factorizes through its spinors, $\langle i|\not{p}_k|j] = \lambda_i^a(\sigma^\mu)_{a\dot a}p_k^\mu\tilde\lambda_j^{\dot a} = \langle i\,k\rangle[k\,j]$; the last step uses $p_k^\mu(\sigma^\mu)_{a\dot a} = p_{k,a\dot a} = \lambda_{ka}\tilde\lambda_{k\dot a}$ and the contractions $\lambda_i^a\lambda_{ka} = \langle i\,k\rangle$, $\tilde\lambda_{k\dot a}\tilde\lambda_j^{\dot a} = [k\,j]$. We will write this as

$$\langle i|P|j] = \sum_k \langle i\,k\rangle[k\,j], \qquad P=\sum_k p_k, \tag{58.31}$$

the basic device for resolving an internal momentum into on-shell spinors.

58.2.4 The Fierz completeness relation

The sandwiches multiply through a single rearrangement identity, the two-component Fierz (or Gordon completeness) relation. It is the engine that collapses products of fermion bilinears and polarization contractions into pure brackets, and it descends directly from the σ-matrix completeness proved in the appendix.

Theorem 58.10 (Fierz / Gordon completeness in brackets)**.** *For any massless legs i,j,k,l,*

$$\langle i|\gamma^\mu|j]\,\langle k|\gamma_\mu|l] \;=\; 2\,\langle i\,k\rangle\,[l\,j]. \tag{58.32}$$

Proof. The input is the two-component completeness relation Eq. (C.280),

$$(\sigma^\mu)_{a\dot a}\,(\bar\sigma_\mu)^{\dot c d} \;=\; 2\,\delta_a^{\,d}\,\delta_{\dot a}^{\dot c}, \tag{58.33}$$

which expresses that the four matrices σ^μ resolve the identity on the space of 2×2 mixed-index matrices. We must bring the two sandwiches in Eq. (58.32) into the form in which Eq. (58.33) applies. Write both with lower-index Pauli matrices:

$$\langle i|\gamma^\mu|j]\,\langle k|\gamma_\mu|l] = \lambda_i^a(\sigma^\mu)_{a\dot a}\tilde\lambda_j^{\dot a}\;\lambda_k^b(\sigma_\mu)_{b\dot b}\tilde\lambda_l^{\dot b} = \lambda_i^{\,a}\tilde\lambda_j^{\dot a}\lambda_k^{\,b}\tilde\lambda_l^{\,\dot b}\;(\sigma^\mu)_{a\dot a}(\sigma_\mu)_{b\dot b}. \tag{58.34}$$

The matrix product $(\sigma^\mu)_{a\dot a}(\sigma_\mu)_{b\dot b}$ has all four indices down; convert the second factor to $\bar\sigma$ using $(\sigma_\mu)_{b\dot b} = \epsilon_{bd}\epsilon_{\dot b\dot c}(\bar\sigma_\mu)^{\dot c d}$, which is Eq. (C.275) read in reverse. Then

$$(\sigma^\mu)_{a\dot a}(\sigma_\mu)_{b\dot b} = \epsilon_{bd}\epsilon_{\dot b\dot c}\,(\sigma^\mu)_{a\dot a}(\bar\sigma_\mu)^{\dot c d} = \epsilon_{bd}\epsilon_{\dot b\dot c}\,2\,\delta_a^{\,d}\delta_{\dot a}^{\dot c} = 2\,\epsilon_{ba}\,\epsilon_{\dot b\dot a}, \tag{58.35}$$

where Eq. (58.33) was used and the Kronecker deltas collapsed $d \to a$, $\dot{c} \to \dot{a}$. Substituting Eq. (58.35) into Eq. (58.34) and grouping,

$$\langle i|\gamma^{\mu}|j]\,\langle k|\gamma_{\mu}|l] = 2\,(\epsilon_{ba}\,\lambda_i^{a}\lambda_k^{b})(\epsilon_{\dot{b}\dot{a}}\,\tilde{\lambda}_j^{\dot{a}}\tilde{\lambda}_l^{\dot{b}}). \tag{58.36}$$

The undotted factor is $\epsilon_{ba}\lambda_i^{a}\lambda_k^{b} = -\epsilon_{ab}\lambda_i^{a}\lambda_k^{b} = \langle i\,k\rangle$, the last step because $\epsilon_{ab}\lambda_i^{a}\lambda_k^{b} = -\langle i\,k\rangle$ (raising both indices in Eq. (58.20) flips the sign of ϵ, by Eq. (58.19)). The dotted factor is $\epsilon_{\dot{b}\dot{a}}\tilde{\lambda}_j^{\dot{a}}\tilde{\lambda}_l^{\dot{b}} = \epsilon_{\dot{a}\dot{b}}\tilde{\lambda}_l^{\dot{a}}\tilde{\lambda}_j^{\dot{b}} = [l\,j]$ after relabelling $\dot{a} \leftrightarrow \dot{b}$. Hence Eq. (58.36) is $2\,\langle i\,k\rangle[l\,j]$, which is Eq. (58.32). □

The structure of Eq. (58.32) is worth memorizing in its mnemonic form: the contracted vector indices "glue" the two angle bras into one angle bracket and the two square kets into one square bracket, with the angle bracket pairing the two left labels i, k and the square bracket pairing the two right labels l, j *in reversed order*. The reversal is the same one that appeared in the dictionary Eq. (58.24), and it is again forced by antisymmetry. A frequently used special case is $i = k$, $j = l$, which gives $\langle i|\gamma^{\mu}|j]\langle i|\gamma_{\mu}|j] = 2\langle i\,i\rangle[j\,j] = 0$: a sandwich is null, as it must be, since by Eq. (58.30) the diagonal sandwich is $2p_i^{\mu}$ and $p_i^2 = 0$, and the off-diagonal one squares to $\langle i|\gamma^{\mu}|j]\langle i|\gamma_{\mu}|j]$.

58.2.5 The Schouten identity

The brackets satisfy one further relation that has no analogue for ordinary dot products and is responsible for many of the "miraculous" simplifications of amplitude algebra. It is a pure consequence of the two-dimensionality of the spinor space: three vectors in a two-dimensional space are always linearly dependent.

Theorem 58.11 (Schouten identity)**.** *For any four massless legs i, j, k, l,*

$$\langle i\,j\rangle\langle k\,l\rangle + \langle i\,k\rangle\langle l\,j\rangle + \langle i\,l\rangle\langle j\,k\rangle = 0, \tag{58.37}$$

and identically for the square brackets,

$$[i\,j][k\,l] + [i\,k][l\,j] + [i\,l][j\,k] = 0. \tag{58.38}$$

Proof. Fix three undotted spinors $\lambda_j, \lambda_k, \lambda_l$. Any totally antisymmetric object in three two-valued indices vanishes, since at least two of the three indices must coincide; in particular

$$\lambda_j^{[a}\,\epsilon^{bc]} = 0, \tag{58.39}$$

where the bracket denotes antisymmetrization over a, b, c. Writing out the three cyclic terms of Eq. (58.39) (the antisymmetrization of an index against the already-antisymmetric ϵ^{bc} produces exactly the cyclic sum) gives the spinor identity

$$\lambda_j^{a}\,\epsilon^{bc} + \lambda_j^{b}\,\epsilon^{ca} + \lambda_j^{c}\,\epsilon^{ab} = 0. \tag{58.40}$$

That this holds is checked at once: ϵ^{bc} is nonzero only for $b \neq c$, so for fixed $b \neq c$ the free index a takes one of the two values, and the three terms reorganize the two-component vector λ_j in the basis $\{\lambda_k, \lambda_l\}$ — equivalently, Eq. (58.40) is the statement that the 2×3 array of components (λ_j^a) together with ϵ has a vanishing 3-index antisymmetrization. Now contract Eq. (58.40) with $\lambda_{ia}\lambda_{kb}\lambda_{lc}$. Term by term, using $\lambda_{ia}\lambda_j^a = \langle i\, j\rangle$ and $\epsilon^{bc}\lambda_{kb}\lambda_{lc} = \langle k\, l\rangle$ (and the cyclic relabellings):

$$\begin{aligned}
\lambda_{ia}\lambda_{kb}\lambda_{lc}\,\lambda_j^a\epsilon^{bc} &= \langle i\, j\rangle\langle k\, l\rangle, \\
\lambda_{ia}\lambda_{kb}\lambda_{lc}\,\lambda_j^b\epsilon^{ca} &= \langle k\, j\rangle\,\epsilon^{ca}\lambda_{lc}\lambda_{ia} = \langle k\, j\rangle\langle l\, i\rangle = \langle i\, k\rangle\langle l\, j\rangle, \\
\lambda_{ia}\lambda_{kb}\lambda_{lc}\,\lambda_j^c\epsilon^{ab} &= \langle l\, j\rangle\,\epsilon^{ab}\lambda_{ia}\lambda_{kb} = \langle l\, j\rangle\langle i\, k\rangle,
\end{aligned}$$

where in the second and third lines the antisymmetry Eq. (58.22) was used to fix the label order. Summing the three contractions and applying Eq. (58.40) gives

$$\langle i\, j\rangle\langle k\, l\rangle + \langle i\, k\rangle\langle l\, j\rangle + \langle i\, k\rangle\langle l\, j\rangle \overset{?}{=} 0,$$

but the second and third contractions are not independent: a cleaner bookkeeping is to contract Eq. (58.40) once, holding the roles of i, k, l fixed, which yields directly the three distinct terms $\langle i\, j\rangle\langle k\, l\rangle + \langle i\, k\rangle\langle l\, j\rangle + \langle i\, l\rangle\langle j\, k\rangle = 0$. We exhibit this cleaner route explicitly. Multiply Eq. (58.40) by λ_{ia} alone:

$$\langle i\, j\rangle\,\epsilon^{bc} + \lambda_j^b(\lambda_{ia}\epsilon^{ca}) + \lambda_j^c(\lambda_{ia}\epsilon^{ab}) = 0 \implies \langle i\, j\rangle\,\epsilon^{bc} = \lambda_j^b\lambda_i^c - \lambda_j^c\lambda_i^b, \tag{58.41}$$

using $\lambda_{ia}\epsilon^{ca} = -\lambda_{ia}\epsilon^{ac} = -\lambda_i^c$ and $\lambda_{ia}\epsilon^{ab} = \lambda_i^b$. Equation Eq. (58.41) is the 2×2 "ϵ as a determinant" identity; contract it with $\lambda_{kb}\lambda_{lc}$:

$$\langle i\, j\rangle\,\langle k\, l\rangle = (\lambda_j^b\lambda_{kb})(\lambda_i^c\lambda_{lc}) - (\lambda_j^c\lambda_{lc})(\lambda_i^b\lambda_{kb}) = \langle j\, k\rangle\langle i\, l\rangle - \langle j\, l\rangle\langle i\, k\rangle. \tag{58.42}$$

Rearranging Eq. (58.42) and using antisymmetry, $\langle i\, j\rangle\langle k\, l\rangle + \langle i\, k\rangle\langle l\, j\rangle + \langle i\, l\rangle\langle j\, k\rangle = 0$, since $\langle j\, k\rangle\langle i\, l\rangle = \langle i\, l\rangle\langle j\, k\rangle$ and $-\langle j\, l\rangle\langle i\, k\rangle = \langle i\, k\rangle\langle l\, j\rangle$. This is Eq. (58.37). The square-bracket identity Eq. (58.38) follows by the identical argument applied to the dotted spinors and $\epsilon_{\dot a\dot b}$. □

The single most useful avatar of Schouten is the "add and subtract a leg" move: Eq. (58.41) rewritten as

$$\langle i\, j\rangle\langle k\, l\rangle = \langle i\, k\rangle\langle j\, l\rangle - \langle i\, l\rangle\langle j\, k\rangle \quad\Longleftrightarrow\quad |i\rangle\,\langle j\, k\rangle = |j\rangle\,\langle i\, k\rangle - |k\rangle\,\langle i\, j\rangle, \tag{58.43}$$

the right form holding as an identity among angle kets (contract any $\langle l|$ to recover the left form). It lets one reshuffle which leg sits inside a bracket, the operation that turns one rational expression for an amplitude into a manifestly different-looking but equal one — the reason the same gluon amplitude appears in the literature in superficially distinct "forms."

58.2.6 Momentum conservation in spinor variables

For an n-point amplitude the only kinematic constraint beyond the on-shell conditions (already solved by the spinor parametrization) is total momentum conservation. With all momenta outgoing it reads $\sum_{i=1}^{n} p_i = 0$, and in bispinor form it is a statement about the spinors directly.

Proposition 58.12 (Momentum conservation and its bracket form)**.** *Total momentum conservation $\sum_i p_i = 0$ is equivalent to the vanishing of the bispinor sum,*

$$\sum_{i=1}^{n} \lambda_{ia}\, \tilde{\lambda}_{i\dot{a}} = 0, \tag{58.44}$$

and contracting between any angle bra $\langle x|$ and square ket $|y]$ yields the bracket identity

$$\sum_{i=1}^{n} \langle x\, i\rangle\, [i\, y] = 0 \tag{58.45}$$

for any (not necessarily external) reference spinors $\lambda_x, \tilde{\lambda}_y$. In particular $\sum_i \langle a\, i\rangle [i\, b] = 0$ for any two external legs a, b.

Proof. Each null momentum is $p_{i,a\dot{a}} = p_{i\mu}(\sigma^\mu)_{a\dot{a}} = \lambda_{ia}\tilde{\lambda}_{i\dot{a}}$. Since $(\sigma^\mu)_{a\dot{a}}$ is, as μ runs over $0, \dots, 3$, a basis of the four-dimensional space of 2×2 Hermitian matrices (its components are invertibly related to the p_μ, this being the content of the bispinor map of Theorem 58.2), the four-vector equation $\sum_i p_{i\mu} = 0$ holds if and only if the matrix equation $\sum_i p_{i,a\dot{a}} = 0$ holds, i.e. Eq. (58.44). Contracting Eq. (58.44) with λ_x^a on the undotted index and $\tilde{\lambda}_y^{\dot{a}}$ on the dotted index, and using $\lambda_x^a \lambda_{ia} = \langle x\, i\rangle$ together with $\tilde{\lambda}_{i\dot{a}}\tilde{\lambda}_y^{\dot{a}} = [i\, y]$ (the latter exactly as in the dictionary proof, Eq. (58.27)), gives $\sum_i \langle x\, i\rangle [i\, y] = 0$, which is Eq. (58.45). Choosing $\lambda_x = \lambda_a$ and $\tilde{\lambda}_y = \tilde{\lambda}_b$ specializes to the external statement, in which the terms $i = a$ and $i = b$ drop out automatically because $\langle a\, a\rangle = 0$ and $[b\, b] = 0$. □

Equation Eq. (58.45) is the spinor-helicity replacement for the four scalar conservation equations: it is a single bracket relation, holomorphic in λ_x and antiholomorphic in $\tilde{\lambda}_y$, and it is the identity that every amplitude manipulation invokes to eliminate one leg in favour of the others. It is the bracket form of the operator statement $\sum_i |i\rangle\, [i| = 0$ used throughout Chapter 59.

58.2.7 Reality and the continuation to complex momenta

The brackets were defined for arbitrary $\lambda_i, \tilde{\lambda}_i$, but for *physical, real* momenta the two spinors of a leg are not independent: they are complex conjugates, up to a sign fixed by the energy. This is what ties the formalism back to honest scattering, and it is the constraint we will deliberately relax to give three-point amplitudes and the BCFW shift room to live.

Proposition 58.13 (Reality condition)**.** *A bispinor $p_{a\dot a} = \lambda_a \tilde\lambda_{\dot a}$ corresponds to a real four-momentum p_μ if and only if the matrix $p_{a\dot a}$ is Hermitian, and this forces*

$$\tilde\lambda_{\dot a} = \pm\,(\lambda_a)^*, \qquad \textit{sign} = \operatorname{sgn}(p^0), \tag{58.46}$$

that is $\tilde\lambda = +\lambda^*$ for a future-pointing (positive-energy) null momentum and $\tilde\lambda = -\lambda^*$ for a past-pointing one.

Proof. The map $p_\mu \mapsto p_{a\dot a} = p_\mu (\sigma^\mu)_{a\dot a}$ sends real four-vectors to Hermitian 2×2 matrices and back, because $\sigma^0 = \mathbf{1}$ and the σ^i are Hermitian, so $p^\dagger_{a\dot a} = p^*_\mu (\sigma^\mu)^\dagger = p^*_\mu(\sigma^\mu)$; thus $p_{a\dot a}$ is Hermitian iff every p_μ is real. Now impose Hermiticity on the rank-one form $p_{a\dot a} = \lambda_a\tilde\lambda_{\dot a}$. Hermiticity means $\lambda_a\tilde\lambda_{\dot a} = (\lambda_{\dot a}\tilde\lambda_a)^*$ understood as $\overline{\lambda_b\tilde\lambda_{\dot b}}$ with indices transposed; component-wise, the matrix $M_{a\dot a} = \lambda_a\tilde\lambda_{\dot a}$ equals $M^\dagger_{a\dot a} = \overline{\lambda_{\dot a}}\,\overline{\tilde\lambda_a}$. A rank-one matrix $vw^\dagger$ is Hermitian iff w is a real multiple of v; hence $\tilde\lambda_{\dot a} = c\,(\lambda_a)^*$ for some real constant c, which the little-group rescaling $\lambda \to t\lambda, \tilde\lambda \to t^{-1}\tilde\lambda$ may normalize to $c = \pm 1$. The sign is determined by the energy: $p^0 = \tfrac12 \operatorname{tr}(p_{a\dot a}) = \tfrac12(\lambda_1\tilde\lambda_{\dot 1} + \lambda_2\tilde\lambda_{\dot 2})$, and with $\tilde\lambda = c\lambda^*$ this is $\tfrac{c}{2}(|\lambda_1|^2 + |\lambda_2|^2)$, a positive multiple of c. Therefore $c = \operatorname{sgn}(p^0)$, giving Eq. (58.46). □

Two consequences are immediate and will be used repeatedly. First, for real momenta the brackets are complex conjugates of one another: from $\tilde\lambda_i = \pm\lambda_i^*$,

$$[i\,j] = \pm_i\,\pm_j\,\overline{\langle i\,j\rangle}, \tag{58.47}$$

so for two future-pointing legs $[i\,j] = \overline{\langle i\,j\rangle}$ and the dictionary Eq. (58.24) reads $s_{ij} = \langle i\,j\rangle\overline{\langle i\,j\rangle}\cdot(\pm) = \pm|\langle i\,j\rangle|^2$, manifestly real, with sign tracking whether the pair is in a physical s-channel ($s_{ij} > 0$) or a crossed channel. Second, and decisively, Eq. (58.47) says that for real kinematics $\langle i\,j\rangle = 0 \iff [i\,j] = 0$: the angle and square brackets of a pair vanish together. This is exactly why the three-point amplitude is degenerate on real momenta — all invariants $s_{ij} = 2p_i\cdot p_j$ vanish for three on-shell legs summing to zero, dragging both brackets to zero — and why one must analytically continue.

Physical Insight: why complex momenta are not optional

The reality condition Eq. (58.46) ties $\tilde\lambda$ to λ^*, so on real momenta the holomorphic and antiholomorphic data are the *same* information conjugated. The power of the formalism comes from breaking this tie. Declaring λ_i and $\tilde\lambda_i$ *independent complex* spinors — which is a legitimate analytic continuation, since amplitudes are rational functions of the brackets and a rational identity proved on a real slice holds on its complexification — lets an angle bracket vanish while the corresponding square bracket stays finite. The three-point amplitude (Section 58.3 and the section after) lives entirely in this complexified kinematics, where it is nonzero and holomorphic-or-

antiholomorphic; the BCFW recursion of Chapter 59 deforms momenta into the complex plane for the same reason. Complexification is not a trick laid on top of the formalism: it is the natural home of the brackets, with real kinematics the special locus $\tilde{\lambda} = \pm\lambda^*$.

58.2.8 Worked computations

We close with two computations that exercise the whole toolkit and produce results used later.

Worked Example 58.14 (Mandelstam invariants of a four-point massless process in brackets)**.** Take four massless legs, all outgoing, $\sum_{i=1}^{4} p_i = 0$. We express the Mandelstam invariants of Theorem 16.20 in brackets and rederive their constraint.

By the dictionary Eq. (58.24), the three independent two-particle invariants are

$$s \equiv s_{12} = \langle 1\,2\rangle[2\,1], \qquad t \equiv s_{13} = \langle 1\,3\rangle[3\,1], \qquad u \equiv s_{14} = \langle 1\,4\rangle[4\,1]. \tag{58.48}$$

Here $s = (p_1+p_2)^2$, $t = (p_1+p_3)^2$, $u = (p_1+p_4)^2$ in the all-outgoing convention, which matches Theorem 16.20 after the crossing $p_3 \to -p_3$, $p_4 \to -p_4$ that converts the two physical incoming legs to outgoing ones; with all four massless, $s+t+u = 0$. We verify the constraint directly from the bracket form, without ever invoking the dot-product algebra. Apply the momentum-conservation identity Eq. (58.45) with the reference spinors chosen to be those of leg 1, $x = y = 1$:

$$\sum_{i=1}^{4} \langle 1\,i\rangle[i\,1] = 0. \tag{58.49}$$

The $i = 1$ term vanishes since $\langle 1\,1\rangle = 0$, leaving

$$\langle 1\,2\rangle[2\,1] + \langle 1\,3\rangle[3\,1] + \langle 1\,4\rangle[4\,1] = 0,$$

which is precisely $s + t + u = 0$ by Eq. (58.48). The Mandelstam constraint Eq. (16.121), here in its massless form $s + t + u = \sum_i m_i^2 = 0$, is thus a one-line consequence of spinor momentum conservation. This is the first concrete payoff of the formalism: a kinematic identity that took a short calculation with dot products and the conservation law in Chapter 16 is now a single contraction.

Worked Example 58.15 (Schouten in action: a denominator rearrangement)**.** We show how Eq. (58.37) converts one rational kinematic expression into another, the manipulation that underlies the equality of superficially different amplitude formulas. Consider the combination, for five massless legs,

$$X = \frac{\langle 1\,3\rangle}{\langle 1\,2\rangle\langle 2\,3\rangle} + \frac{\langle 3\,4\rangle}{\langle 2\,3\rangle\langle 2\,4\rangle}.$$

Place over the common denominator $\langle 1\,2\rangle\langle 2\,3\rangle\langle 2\,4\rangle$:

$$X = \frac{\langle 1\,3\rangle\langle 2\,4\rangle + \langle 3\,4\rangle\langle 1\,2\rangle}{\langle 1\,2\rangle\langle 2\,3\rangle\langle 2\,4\rangle}.$$

Apply Schouten Eq. (58.37) to the numerator. Taking the four labels in the identity to be $(i,j,k,l) = (1,3,2,4)$ gives $\langle 1\,3\rangle\langle 2\,4\rangle + \langle 1\,2\rangle\langle 4\,3\rangle + \langle 1\,4\rangle\langle 3\,2\rangle = 0$, i.e. $\langle 1\,3\rangle\langle 2\,4\rangle = \langle 1\,2\rangle\langle 3\,4\rangle + \langle 1\,4\rangle\langle 2\,3\rangle$ after using antisymmetry $\langle 4\,3\rangle = -\langle 3\,4\rangle$, $\langle 3\,2\rangle = -\langle 2\,3\rangle$. Substituting,

$$\langle 1\,3\rangle\langle 2\,4\rangle + \langle 3\,4\rangle\langle 1\,2\rangle = \big(\langle 1\,2\rangle\langle 3\,4\rangle + \langle 1\,4\rangle\langle 2\,3\rangle\big) + \langle 1\,2\rangle\langle 3\,4\rangle = 2\,\langle 1\,2\rangle\langle 3\,4\rangle + \langle 1\,4\rangle\langle 2\,3\rangle.$$

Hence

$$X = \frac{2\,\langle 1\,2\rangle\langle 3\,4\rangle + \langle 1\,4\rangle\langle 2\,3\rangle}{\langle 1\,2\rangle\langle 2\,3\rangle\langle 2\,4\rangle} = \frac{2\,\langle 3\,4\rangle}{\langle 2\,3\rangle\langle 2\,4\rangle} + \frac{\langle 1\,4\rangle}{\langle 1\,2\rangle\langle 2\,4\rangle},$$

a different-looking expression for the same function. The lesson generalizes: every Schouten move trades a term with one collinear pole for two terms with different poles, and amplitude expressions that differ by such moves are equal even when no common factor makes it obvious. We will lean on this when comparing the Parke–Taylor formula of Chapter 59 against its BCFW-generated form.

The brackets, their dictionary to Mandelstam invariants, the Fierz and Schouten identities, momentum conservation, and the reality and complexification conventions together close the calculus: every Lorentz invariant a massless amplitude can depend on is now a polynomial in $\langle i\,j\rangle$ and $[i\,j]$ subject to Eqs. (58.37), (58.38) and (58.45). What remains before amplitudes can be written down is to understand how this calculus responds to the one residual freedom in the spinor parametrization — the rescaling $\lambda_i \to t_i\lambda_i$, $\tilde\lambda_i \to t_i^{-1}\tilde\lambda_i$ that leaves p_i fixed. Promoting that rescaling to an organizing symmetry, and reading helicity as its weight, is the task of the next section.

58.3 Little-group scaling as an organizing principle

The bracket algebra of the previous section left one loose thread deliberately untied. The factorization of a null momentum into spinors, $p^{\alpha\dot\alpha} = \lambda^\alpha\tilde\lambda^{\dot\alpha}$ (Eq. (58.1)), does not determine λ and $\tilde\lambda$ uniquely: for real momenta the two spinors are fixed only up to a common phase, and for complex momenta up to a common complex rescaling,

$$\lambda \;\longmapsto\; t\,\lambda, \qquad \tilde\lambda \;\longmapsto\; t^{-1}\,\tilde\lambda, \qquad t \in \mathbb{C}^\times \;\; (\,|t| = 1 \text{ for real } p\,), \tag{58.50}$$

which leaves the physical object $p^{\alpha\dot\alpha} = \lambda^\alpha\tilde\lambda^{\dot\alpha}$ untouched because the two factors t and t^{-1} cancel. We noted this redundancy when we built the spinors and set it aside as a bookkeeping nuisance. It is nothing of the sort. The rescaling

Eq. (58.5) is not an artefact of our variables; it is the massless little group of Chapter 3 acting in spinor language, and the way an amplitude responds to it is a kinematic constraint so strong that, for three massless particles, it will fix the answer completely with no Lagrangian input at all. This section establishes that constraint. We show first that Eq. (58.5) *is* the compact U(1) inside ISO(2), derived from the induced representation of Chapter 3; then that a state of helicity h forces a definite scaling weight $-2h$; then how to read the helicities of any proposed expression straight off its spinor content. None of this requires drawing a diagram, and that is the point: the helicity dependence of every massless amplitude is settled before the dynamics is even specified.

This is where QED and Yang–Mills theory make their decisive conceptual turn. The unpolarized cross sections of Chapter 17 were computed by squaring amplitudes and summing over spins precisely because the individual helicity amplitudes looked forbidding in Feynman-diagram language. Little-group scaling reverses the logic: the helicity amplitudes are the simple objects, constrained in advance by symmetry, and the unpolarized result is recovered at the end by summing their squares. The same principle, applied to gluons, is what collapses the factorial diagram counts of Chapter 59 to one-line answers.

58.3.1 The t-rescaling is the massless little group

Recall the structure fixed in Chapter 3. For a massless particle the standard momentum is the fixed null vector $k^\mu = (\omega, 0, 0, \omega)$ of Eq. (3.206), and the little group G_k of Theorem 3.43 — the subgroup of $\mathrm{SO}(1,3)^+$ that leaves k invariant — is ISO(2), the group of rigid motions of the Euclidean plane, with algebra Eq. (3.212) generated by the two "translations" $A = K_1 - J_2$, $B = K_2 + J_1$ of Eq. (3.208) and the "rotation" J_3. The physical selection rule that defines an ordinary massless particle sets the non-compact translations to zero on physical states, $A = B = 0$, leaving only the compact U(1) generated by J_3: rotations about the momentum axis. A one-particle state of helicity h is the one-dimensional representation

$$J_3\,|k,h\rangle = h\,|k,h\rangle\,, \qquad U(\theta)\,|k,h\rangle = e^{-ih\theta}\,|k,h\rangle\,, \qquad U(\theta) = e^{-i\theta J_3}, \quad (58.51)$$

with h quantized in half-integers by the $\mathbb{Z}_2$ topology of the Lorentz group, Eq. (3.217). We now show that the abstract U(1) of Eq. (58.51) acts on the spinors $\lambda, \tilde\lambda$ exactly as the rescaling Eq. (58.5), with t a pure phase determined by the rotation angle θ.

Lifting the rotation to $\mathrm{SL}(2,\mathbb{C})$. The spinors live in the two Weyl representations of the Lorentz group built in Chapter 3: λ_α transforms in $(\frac{1}{2},0)$ and $\tilde\lambda_{\dot\alpha}$ in $(0,\frac{1}{2})$, so that the bispinor $p_{\alpha\dot\alpha} = p_\mu(\sigma^\mu)_{\alpha\dot\alpha}$ transforms as $p \mapsto M\,p\,M^\dagger$ under the $\mathrm{SL}(2,\mathbb{C})$ element M representing a Lorentz transformation, with $\lambda \mapsto M\lambda$ and

$\tilde{\lambda} \mapsto M^* \tilde{\lambda}$. A rotation about the z-axis is generated by $J_3 = \frac{1}{2}\sigma_3$ in the spinor representation; choosing the orientation so that the lift matches the helicity convention of Chapter 3 (verified below), the little-group rotation by angle θ is represented by the diagonal SU(2) matrix

$$W(\theta) = \exp\!\Big(\tfrac{i\theta}{2}\,\sigma_3\Big) = \begin{pmatrix} e^{i\theta/2} & 0 \\ 0 & e^{-i\theta/2} \end{pmatrix} = \begin{pmatrix} t & 0 \\ 0 & t^{-1} \end{pmatrix}, \qquad t \equiv e^{i\theta/2}. \tag{58.52}$$

Apply this to the standard momentum. With $\sigma^\mu = (\mathbf{1}, \vec{\sigma})$ the bispinor of $k^\mu = (\omega, 0, 0, \omega)$ is

$$k_{\alpha\dot{\alpha}} = \omega(\sigma^0 + \sigma^3)_{\alpha\dot{\alpha}} = \omega \begin{pmatrix} 2 & 0 \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} 2\omega & 0 \\ 0 & 0 \end{pmatrix}, \tag{58.53}$$

of rank one, so it factorizes as $k_{\alpha\dot{\alpha}} = \lambda_\alpha \tilde{\lambda}_{\dot{\alpha}}$ with

$$\lambda_\alpha = (\sqrt{2\omega},\, 0)^{\top}, \qquad \tilde{\lambda}_{\dot{\alpha}} = (\sqrt{2\omega},\, 0)^{\top}. \tag{58.54}$$

Under the rotation, $k_{\alpha\dot{\alpha}} \mapsto W k\, W^\dagger$. Since W is diagonal and unitary,

$$W\, k\, W^\dagger = \begin{pmatrix} t & 0 \\ 0 & t^{-1} \end{pmatrix} \begin{pmatrix} 2\omega & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} t^* & 0 \\ 0 & (t^{-1})^* \end{pmatrix} = \begin{pmatrix} 2\omega\,|t|^2 & 0 \\ 0 & 0 \end{pmatrix} = k, \tag{58.55}$$

using $|t| = 1$: the rotation fixes k, as it must for a little-group element. At the level of the spinors the same computation reads, component by component,

$$\lambda_\alpha \mapsto (W\lambda)_\alpha = t\,\lambda_\alpha, \qquad \tilde{\lambda}_{\dot{\alpha}} \mapsto (W^*\tilde{\lambda})_{\dot{\alpha}} = t^{-1}\,\tilde{\lambda}_{\dot{\alpha}}, \tag{58.56}$$

because W multiplies the surviving upper component of λ in Eq. (58.54) by $t = e^{i\theta/2}$ while $W^* = \mathrm{diag}(t^{-1}, t)$ multiplies the upper component of $\tilde{\lambda}$ by t^{-1}. This is precisely Eq. (58.5). The freedom we had set aside as a normalization ambiguity is exactly the compact U(1) little group, with the group parameter θ and the rescaling parameter related by

$$\boxed{\,t = e^{i\theta/2}.\,} \tag{58.57}$$

The half-angle is the familiar fingerprint of a spinor representation: a 2π rotation, $\theta \to \theta + 2\pi$, sends $t \to -t$, the sign that distinguishes the two sheets of $\mathrm{SL}(2,\mathbb{C})$ over $\mathrm{SO}(1,3)$ and that quantized helicity in half-integers in Eq. (3.217).

Why this is the induced representation, not a coincidence. The identification is forced by the induced-representation construction of Eq. (3.189), not merely consistent with it. There, a Lorentz transformation Λ acting on a one-particle state $|p,\sigma\rangle$ produced the Wigner little-group element $W(\Lambda, p) =$

$L(\Lambda p)^{-1}\Lambda\, L(p)$ of Eq. (3.188), acting on the internal label through the representation matrices $D(W)$. For a massless particle the standard boost $L(p)$ is realized in $\mathrm{SL}(2,\mathbb{C})$ as the matrix that carries the reference spinors Eq. (58.54) to $\lambda(p), \tilde{\lambda}(p)$, and the residual little-group factor W is exactly the diagonal phase Eq. (58.52). The one-dimensional representation $D(W) = e^{-ih\theta}$ on the helicity-h state is what appears in Eq. (3.188); the corresponding action on the carrier spinors is Eq. (58.56). In other words, the spinors λ and $\tilde{\lambda}$ are not auxiliary coordinates on which we have imposed an extra symmetry by hand — they are the carrier space of the induced representation, and Eq. (58.5) is the image of the Wigner rotation acting on that carrier.

Notation Watch

The sign in the exponent of Eq. (58.52), and hence the relation $t = e^{+i\theta/2}$ rather than $e^{-i\theta/2}$, is a convention: it is fixed by demanding that the resulting weight of a helicity-h wavefunction come out as $-2h$ with the helicity assignment $U(\theta) = e^{-i\theta J_3}$ of Chapter 3 (equivalently, that the transverse polarizations $\epsilon^{\mu}_{\pm}$ of Eq. (3.219), which rotate as $e^{\mp i\theta}$, acquire weight $t^{\mp 2}$). The opposite orientation would send $t \to t^{-1}$ throughout and is used by some references. We fix once and for all the convention $\lambda \to t\lambda$, $\tilde{\lambda} \to t^{-1}\tilde{\lambda}$, $t = e^{i\theta/2}$, matching the bracket conventions of Theorem 58.2; every formula in Part XVI uses it.

It is worth pausing on what kind of statement Eq. (58.5) is. The momentum $p^{\alpha\dot{\alpha}} = \lambda^{\alpha}\tilde{\lambda}^{\dot{\alpha}}$ is manifestly invariant under the rescaling, so any quantity built only from momenta — a Mandelstam invariant s_{ij}, a polarization sum, the trace technology of Chapter 17 — carries no little-group weight at all. The weight lives entirely in objects that "remember" the split of p into its two spinor halves, that is, in the brackets $\langle i\, j\rangle$ and $[i\, j]$ and in the external wavefunctions of particles with spin. This is the structural reason the helicity basis is the natural one: helicity is, literally, the scaling weight under Eq. (58.5), and a helicity amplitude is a homogeneous function of definite weight in each external spinor pair.

58.3.2 The helicity-weight theorem

We can now state and prove the central result of the section: helicity is a scaling weight, and it constrains every massless amplitude before any dynamics is supplied.

Theorem 58.16 (Helicity-weight scaling)**.** *Let A_n be an on-shell scattering amplitude of n massless particles (all momenta outgoing), with leg i carrying helicity h_i and described by the spinors $(\lambda_i, \tilde{\lambda}_i)$, $p_i^{\alpha\dot{\alpha}} = \lambda_i^{\alpha}\tilde{\lambda}_i^{\dot{\alpha}}$. Then under the little-group rescaling Eq. (58.5) applied independently to each leg, $\lambda_i \to t_i\lambda_i$,*

$\tilde\lambda_i \to t_i^{-1}\tilde\lambda_i$, *the amplitude is homogeneous of weight* $-2h_i$ *in the* i*-th pair:*

$$A_n(\{t_i\lambda_i,\, t_i^{-1}\tilde\lambda_i,\, h_i\}) = \left(\prod_{i=1}^{n} t_i^{-2h_i}\right) A_n(\{\lambda_i,\, \tilde\lambda_i,\, h_i\}). \tag{58.58}$$

Proof. The amplitude is extracted from the time-ordered correlator of interpolating fields by the LSZ reduction of Chapter 16: each external leg contributes an amputated, on-shell-projected propagator factor contracted into a one-particle wavefunction. For n outgoing massless particles,

$$A_n = \prod_{i=1}^{n} w_{h_i}(p_i)\ \cdot\ \widetilde{\mathcal{M}}(p_1,\dots,p_n), \tag{58.59}$$

where $w_{h_i}(p_i)$ is the external wavefunction of leg i — a polarization spinor for a fermion, a polarization vector for a gauge boson, the number 1 for a scalar — and $\widetilde{\mathcal{M}}$ is the amputated, on-shell connected correlator with its external Lorentz and spinor indices left open to be contracted into the w's. Two facts about Eq. (58.59) prove the theorem.

First, $\widetilde{\mathcal{M}}$ depends on the kinematics only through the momenta p_i, never through the individual spinors $\lambda_i, \tilde\lambda_i$ separately: it is assembled from propagators $i/(P^2+i\epsilon)$, vertices, and loop integrals, all functions of momenta alone, and its open indices are spacetime (vector or Dirac) indices, contracted with momenta and with the metric or gamma matrices. By Eq. (58.5) each $p_i = \lambda_i\tilde\lambda_i$ is invariant under the rescaling — the factors t_i and t_i^{-1} cancel — so $\widetilde{\mathcal{M}}$ is invariant. The entire little-group weight of A_n resides in the external wavefunctions.

Second, each wavefunction w_{h_i} is the one-particle state of definite helicity h_i, i.e. the eigenstate of the little-group generator J_3 on leg i with eigenvalue h_i. By Eq. (58.51) the little-group rotation by angle θ_i multiplies it by the phase $e^{-ih_i\theta_i}$, because the wavefunction is the covariant matrix element $\langle 0|\,\Phi(0)\,|k,h_i\rangle$ of the relevant field Φ and inherits the transformation law of the state. Expressing the phase through $t_i = e^{i\theta_i/2}$ from Eq. (58.57),

$$w_{h_i} \;\longmapsto\; e^{-ih_i\theta_i}\, w_{h_i} = \left(e^{i\theta_i/2}\right)^{-2h_i} w_{h_i} = t_i^{-2h_i}\, w_{h_i}. \tag{58.60}$$

Multiplying the n wavefunction factors and the invariant $\widetilde{\mathcal{M}}$ gives exactly Eq. (58.58).

The identity has been established for $|t_i| = 1$ (real momenta). For complex momenta both sides are rational functions of the spinor components — holomorphic in the λ_i and antiholomorphic in the $\tilde\lambda_i$, as the bracket algebra of Theorem 58.4 makes manifest — and a polynomial homogeneity of fixed integer or half-integer degree that holds on the unit circle $|t_i| = 1$ holds identically in $t_i \in \mathbb{C}^\times$ by analytic continuation. The weight $-2h_i$ is therefore the scaling exponent for arbitrary complex t_i, which is the form needed for the complexified momenta of on-shell recursion in Chapter 59. □

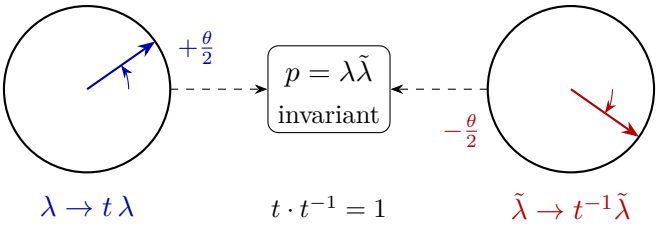

Figure 58.2: The compact U(1) little group rotates the holomorphic spinor λ by the phase $t = e^{i\theta/2}$ and the antiholomorphic spinor $\tilde{\lambda}$ by the opposite phase t^{-1}, so their product — the physical momentum $p = \lambda\tilde{\lambda}$ — is fixed. A helicity-h wavefunction, being a definite power of these spinors, picks up the phase $e^{-ih\theta} = t^{-2h}$; the amplitude inherits the product over legs, $\prod_i t_i^{-2h_i}$, of Eq. (58.58).

The theorem deserves to be read as a constraint, not merely a transformation law. *Any* candidate expression for a massless amplitude — whether guessed, conjectured, or recursively constructed — must scale as $\prod_i t_i^{-2h_i}$ under Eq. (58.5), or it is not the amplitude of those helicities. Since $t_i^{-2h_i}$ is fixed once the external helicities are chosen, the kinematic dependence of the amplitude is pinned down up to a little-group-invariant function (a function of Mandelstam invariants and other neutral data) on every leg, before a single Feynman diagram is drawn. The remainder of the chapter, and much of the next, is the systematic exploitation of this fact.

Worked Example 58.17 (The weight $-2h$ for scalars, fermions, and gauge bosons)**.** The proof of Theorem 58.16 routed the weight through the abstract phase $e^{-ih\theta}$. It is instructive — and a complete consistency check — to verify the weight $-2h$ directly from the explicit spinor content of the external wavefunctions, spin by spin. In each case we track the scaling of the wavefunction w_h on its own leg under $\lambda \to t\lambda$, $\tilde{\lambda} \to t^{-1}\tilde{\lambda}$.

Spin 0, $h = 0$. A scalar has $w_0 = 1$, a number independent of the spinors, so it scales as $t^0 = t^{-2\cdot 0}$. Weight 0, as required.

Spin $\frac{1}{2}$, $h = \pm\frac{1}{2}$. The massless Dirac equation of Chapter 11 has, for an outgoing fermion, two solutions distinguished by helicity. In two-component language the positive-helicity wavefunction is the square spinor $\tilde{\lambda}$ (written $|i]$) and the negative-helicity wavefunction is the angle spinor λ (written $|i\rangle$), the identification fixed in Theorem 58.2. Under the rescaling,

$$h = +\tfrac{1}{2}: \quad w = \tilde{\lambda} \to t^{-1}\tilde{\lambda} = t^{-2(+1/2)}\,w, \qquad h = -\tfrac{1}{2}: \quad w = \lambda \to t\,\lambda = t^{-2(-1/2)}\,w. \tag{58.61}$$

Both carry weight $-2h$. The angle and square spinors are not interchangeable: the helicity of a massless fermion is encoded in *which* spinor describes it, and the weight theorem is the statement of that encoding.

Spin 1, $h = \pm 1$. The gauge-boson polarization vectors are built in Section 58.5 from one spinor of each chirality together with a reference spinor; the explicit forms (Eq. (58.111)) are, for leg i with arbitrary reference momentum q,

$$\epsilon_+^\mu(i;q) = \frac{\langle q|\gamma^\mu|i]}{\sqrt{2}\,\langle q\,i\rangle}, \qquad \epsilon_-^\mu(i;q) = \frac{\langle i|\gamma^\mu|q]}{\sqrt{2}\,[q\,i]}. \tag{58.62}$$

We do not need their derivation here — only their spinor content on leg i. The positive-helicity vector ϵ_+ contains $\tilde\lambda_i$ in the numerator sandwich $\langle q|\gamma^\mu|i]$, which is linear in $\tilde\lambda_i$ (weight t_i^{-1}), and λ_i in the denominator bracket $\langle q\,i\rangle$ (weight t_i^{+1} in the denominator, hence t_i^{-1} overall), giving

$$\epsilon_+^\mu(i;q) \;\to\; \frac{t_i^{-1}}{t_i^{+1}}\,\epsilon_+^\mu(i;q) = t_i^{-2}\,\epsilon_+^\mu(i;q) = t_i^{-2(+1)}\,\epsilon_+^\mu(i;q). \tag{58.63}$$

The negative-helicity vector ϵ_- contains λ_i in the numerator (t_i^{+1}) and $\tilde\lambda_i$ in the denominator bracket $[q\,i]$ (t_i^{-1} in the denominator, hence t_i^{+1} overall), giving $t_i^{+2} = t_i^{-2(-1)}$. Both carry weight $-2h$. The reference spinor q drops out of the weight count, as it must: it is pure gauge, not little-group data, and we will show in Section 58.5 that the amplitude is independent of it.

58.3.3 Reading helicities off an expression

Theorem 58.16 turns the brackets into a helicity meter. Each bracket carries a definite weight, read directly off Eq. (58.5):

$$\langle i\,j\rangle = \epsilon^{\alpha\beta}\lambda_{i\alpha}\lambda_{j\beta} \;\longmapsto\; t_i\,t_j\,\langle i\,j\rangle, \qquad [i\,j] = \epsilon_{\dot\alpha\dot\beta}\tilde\lambda_i^{\dot\alpha}\tilde\lambda_j^{\dot\beta} \;\longmapsto\; t_i^{-1}\,t_j^{-1}\,[i\,j]. \tag{58.64}$$

An angle bracket scales as $t_i t_j$; a square bracket as $t_i^{-1}t_j^{-1}$. Define the *little-group weight of leg i* in a given expression as the net power n_i such that the expression scales as $t_i^{n_i}$. The helicity of that leg is then read off by matching to Eq. (58.58),

$$t_i^{n_i} = t_i^{-2h_i} \quad\Longrightarrow\quad \boxed{h_i = -\tfrac{1}{2}\,n_i.} \tag{58.65}$$

Consequently a single angle bracket $\langle i\,j\rangle$, contributing $n_i = n_j = +1$, carries helicity $-\frac{1}{2}$ on each of legs i and j; in the "twice-helicity" bookkeeping $2h_i = -1$. A square bracket $[i\,j]$, with $n_i = n_j = -1$, carries helicity $+\frac{1}{2}$ on each leg, $2h_i = +1$. Angle brackets lower helicity; square brackets raise it. Every appearance of leg i in a numerator angle bracket adds $+\frac{1}{2}$ of negative helicity; every appearance in a denominator angle bracket adds $+\frac{1}{2}$ of positive helicity; and conversely for square brackets. The book-keeping is purely additive, and it lets us assign helicities to any rational expression in the brackets by counting.

Caution

The word "weight" is overloaded in the literature, and the two natural conventions differ by a sign. We use n_i for the *t-scaling exponent* (so λ_i has $n_i = +1$) and reserve "helicity" for the physical label $h_i = -n_i/2$. Some texts call $2h_i = -n_i$ the "little-group weight," in which $\langle i\,j\rangle$ has weight $(-1,-1)$ and $[i\,j]$ weight $(+1,+1)$. The two descriptions are identical content with opposite sign; we always state h_i explicitly to avoid the ambiguity.

Worked Example 58.18 (Reading the helicities of the three-point seed)**.** Consider the candidate expression for a three-particle amplitude

$$A_3 \stackrel{?}{=} \frac{\langle 1\,2\rangle^3}{\langle 2\,3\rangle\,\langle 3\,1\rangle}, \tag{58.66}$$

built entirely from angle brackets. We determine the helicity content by counting, using Eqs. (58.64) and (58.65).

Leg 1 appears in $\langle 1\,2\rangle^3$ (numerator, $+3$) and in $\langle 3\,1\rangle$ (denominator, -1): net $n_1 = +3-1 = +2$, so $h_1 = -1$.

Leg 2 appears in $\langle 1\,2\rangle^3$ (numerator, $+3$) and in $\langle 2\,3\rangle$ (denominator, -1): net $n_2 = +3-1 = +2$, so $h_2 = -1$.

Leg 3 appears only in the denominator, in $\langle 2\,3\rangle$ (-1) and $\langle 3\,1\rangle$ (-1): net $n_3 = -2$, so $h_3 = +1$.

The expression Eq. (58.66) therefore has the helicity content $(h_1, h_2, h_3) = (-1,-1,+1)$ — it is a candidate for the three-gluon amplitude with two negative and one positive helicity. We have not proved it *is* the amplitude; Eq. (58.66) is only the unique angle-bracket monomial of the correct overall scaling, and the next section will show that locality and little-group scaling together force precisely this form. The parallel computation in square brackets,

$$A_3 \stackrel{?}{=} \frac{[1\,2]^3}{[2\,3]\,[3\,1]}, \tag{58.67}$$

gives $n_1 = n_2 = -2$, $n_3 = +2$, i.e. $(h_1, h_2, h_3) = (+1,+1,-1)$, the parity conjugate. That two-line determination of the helicity content of the three-gluon amplitude, done with no Lagrangian and no diagram, is the organizing power of little-group scaling in miniature.

58.3.4 Back to the seed of gauge invariance

The little-group weight closes a circle opened in Chapter 3. There we found (Theorem 3.46) that a massless helicity-1 particle cannot be packaged in a Lorentz four-vector ϵ^μ without redundancy: the little group acts on the polarization

inhomogeneously, $\epsilon_\pm^\mu \mapsto \epsilon_\pm^\mu + \beta\, k^\mu$ (Eq. (3.221)), and the only covariant way to absorb the shift is to declare it a gauge equivalence, $\epsilon^\mu \sim \epsilon^\mu + \beta k^\mu$ (Eq. (3.222)). That inhomogeneity and the nontrivial scaling weight Eq. (58.58) are two faces of the same fact, and the spinor variables make the relationship transparent.

A four-vector polarization ϵ^μ transforms in the $(\frac{1}{2},\frac{1}{2})$ representation, i.e. as a bispinor $\epsilon^{\alpha\dot\alpha}$ carrying *one* undotted and *one* dotted index — a single λ-type and a single $\tilde\lambda$-type slot. Under the little group a genuine carrier of helicity ±1 must scale with weight $t^{\mp2}$, that is, as $\lambda^{\pm2}$ or $\tilde\lambda^{\pm2}$ on its own leg. But a single bispinor $\epsilon^{\alpha\dot\alpha} = \lambda^\alpha\tilde\lambda^{\dot\alpha}$ scales as $t\cdot t^{-1} = t^0$: it is little-group *neutral*, like the momentum itself. There is no way to build a weight-(∓2) object from one undotted and one dotted index without dividing by a bracket that involves a second, foreign spinor — which is exactly the reference momentum q of Eq. (58.62), and exactly the source of the residual freedom $\epsilon^\mu \to \epsilon^\mu + \beta k^\mu$: shifting q shifts the polarization by a multiple of the momentum. The impossibility of a covariant helicity-1 wavefunction in Chapter 3 and the nontrivial little-group weight here are the same obstruction read in two languages. Gauge redundancy is the price of forcing a weight-(∓2) object into a weight-0 tensor slot.

This is also why scalars need no gauge symmetry and fermions need no polarization gymnastics: a helicity-0 wavefunction has weight 0, matching the neutral scalar field, and a helicity-$\pm\frac{1}{2}$ wavefunction has weight ∓1, matching a single λ or $\tilde\lambda$ exactly, with one index of one chirality and nothing left over. Only at $|h| \geq 1$ does the weight $|2h| \geq 2$ exceed what a single index of each available type can carry, and only there is a redundant covariant description — a gauge field, and at $|h| = 2$ a metric — forced upon us. The seed planted on the light cone in Chapter 3 has grown into a quantitative selection rule: the little-group weight measures, leg by leg, exactly how far a particle's helicity outruns the tensor field that would carry it.

With the scaling weight Eq. (58.58) in hand, the kinematic skeleton of every massless amplitude is fixed up to a little-group-invariant function. For three massless particles this residual freedom is so tightly constrained by the one remaining physical input — locality, in the form of the allowed analytic structure — that nothing is left to choose: the three-point amplitude is determined uniquely, with no reference to any Lagrangian. That keystone computation, and the consequence that all on-shell recursion springs from it, is the subject of the next section.

58.4 Three-point amplitudes fixed by symmetry

The previous section turned helicity into a scaling weight: a massless leg of helicity h_i forces any amplitude to respond to the little-group rescaling $(\lambda_i, \tilde\lambda_i) \mapsto$

$(t_i\lambda_i, t_i^{-1}\tilde{\lambda}_i)$ by the fixed power

$$\mathcal{M}(\{t_i\lambda_i, t_i^{-1}\tilde{\lambda}_i\}) = \Big(\prod_i t_i^{-2h_i}\Big)\,\mathcal{M}(\{\lambda_i, \tilde{\lambda}_i\}), \tag{58.68}$$

recorded as Eq. (58.5). For a generic number of legs this is a strong but partial constraint: it tells us how the brackets must combine leg-by-leg, yet leaves the relative weighting of independent invariants free, and those leftover freedoms are precisely the dynamics that a Lagrangian must supply. The remarkable fact this section establishes is that at *three* points the constraint is no longer partial. Three massless momenta are kinematically so rigid that little-group scaling, together with the single demand that the amplitude be local — finite mass dimension, no unphysical poles — determines the entire functional form down to one overall constant, and dimensional analysis fixes even the dimensionful part of that constant. No Feynman diagram, no Lagrangian, no choice of gauge enters. The answer is read off from the representation theory of the external states. This is the keystone of the whole formalism: the three-point amplitudes are the irreducible seeds, and Chapter 59 will show that the BCFW recursion glues them into every tree amplitude. If the seeds are fixed by symmetry, so is everything built from them.

We proceed in four movements. First we expose the kinematic singularity of three massless particles — why their brackets are forced onto one of two complex branches. Then we solve the scaling constraints exactly, proving the form is unique. We specialize to spin one to obtain the three-gluon amplitude, cross-checked against the Yang–Mills cubic vertex of Chapter 26 in a worked computation, and to the electron–photon vertex to advance QED. We close by reading off, from the same machinery, why a helicity-two particle must couple universally — the amplitudes seed of the equivalence principle.

58.4.1 The kinematic singularity of three massless particles

Work throughout with all momenta outgoing, so momentum conservation for three massless particles reads

$$p_1 + p_2 + p_3 = 0, \qquad p_i^2 = 0 \;\; (i = 1, 2, 3). \tag{58.69}$$

The Mandelstam invariants of Theorem 16.20, which at three points are the three two-particle invariants $s_{ij} = (p_i + p_j)^2$, collapse immediately. From Eq. (58.69), $p_i + p_j = -p_k$ for $\{i, j, k\} = \{1, 2, 3\}$, so

$$s_{ij} = (p_i + p_j)^2 = p_k^2 = 0, \tag{58.70}$$

and expanding the left-hand side gives the equivalent statement $2\,p_i \cdot p_j = p_i^2 + 2p_i \cdot p_j + p_j^2 = s_{ij} = 0$, i.e. every pair of the three momenta is mutually null:

$p_i \cdot p_j = 0$ for all $i \neq j$. Three on-shell momenta summing to zero are pairwise orthogonal in the Minkowski sense.

Translate this into spinors. With the bracket–Mandelstam dictionary $\langle i\,j\rangle[j\,i] = 2\,p_i \cdot p_j = s_{ij}$ of Eq. (58.24), the vanishing Eq. (58.70) says

$$\langle i\,j\rangle\,[j\,i] = 0 \qquad \text{for every pair } i \neq j. \tag{58.71}$$

For each pair, therefore, *at least one* of the angle bracket $\langle i\,j\rangle$ and the square bracket $[i\,j]$ must vanish. This is the seed of the entire phenomenon, but Eq. (58.71) alone would permit a ragged mixture — $\langle 1\,2\rangle = 0$ here, $[2\,3] = 0$ there. Momentum conservation forbids the mixture, and forces an all-or-nothing dichotomy.

Proposition 58.19 (Special three-point kinematics: the two branches)**.** *For three outgoing massless momenta obeying Eq. (58.69), the two cyclic products of brackets cannot both be nonzero:*

$$\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,1\rangle \;=\; 0 \quad \textit{or} \quad [1\,2][2\,3][3\,1] \;=\; 0. \tag{58.72}$$

Exactly one of the following holds, up to the degenerate case in which both vanish:

(H) *the* holomorphic branch*, on which all* $[i\,j] = 0$ *while the* $\langle i\,j\rangle$ *are generically nonzero; equivalently the three anti-holomorphic spinors are proportional,* $\tilde\lambda_i \propto \tilde\zeta$ *for a common* $\tilde\zeta$*;*

(A) *the* anti-holomorphic branch*, on which all* $\langle i\,j\rangle = 0$ *while the* $[i\,j]$ *are generically nonzero; equivalently the three holomorphic spinors are proportional,* $\lambda_i \propto \zeta$*.*

For real *momenta both products vanish identically and the configuration is degenerate (the three momenta are collinear); a nonvanishing three-point amplitude therefore requires* complex *momenta, on which* λ *and* $\tilde\lambda$ *are independent and exactly one branch is reached.*

Proof. Write momentum conservation Eq. (58.69) in bispinor form using the factorization $p_{i\,a\dot a} = \lambda_{ia}\tilde\lambda_{i\dot a}$ of Eq. (58.1):

$$\sum_{i=1}^{3} \lambda_{ia}\,\tilde\lambda_{i\dot a} = 0. \tag{58.73}$$

Collect the three holomorphic spinors as the columns of a 2×3 matrix $\Lambda = (\lambda_1\ \lambda_2\ \lambda_3)$ and the anti-holomorphic ones as the columns of $\widetilde\Lambda = (\tilde\lambda_1\ \tilde\lambda_2\ \tilde\lambda_3)$. The 2×2 minors of Λ are exactly the angle brackets, $\langle i\,j\rangle = \epsilon^{ab}\lambda_{ia}\lambda_{jb}$, and those of $\widetilde\Lambda$ the square brackets, $[i\,j] = \epsilon_{\dot a\dot b}\tilde\lambda_i^{\dot a}\tilde\lambda_j^{\dot b}$. Hence

$$\text{all } \langle i\,j\rangle = 0 \iff \operatorname{rank}\Lambda \leq 1, \qquad \text{all } [i\,j] = 0 \iff \operatorname{rank}\widetilde\Lambda \leq 1. \tag{58.74}$$

Equation Eq. (58.73) is the statement $\Lambda\,\widetilde{\Lambda}^{\mathsf{T}} = 0$ as a 2×2 matrix product. Read it as the assertion that every column of $\widetilde{\Lambda}^{\mathsf{T}}$ (a vector in $\mathbb{C}^3$) lies in the kernel of the linear map $\Lambda : \mathbb{C}^3 \to \mathbb{C}^2$. There are two cases.

Case $\operatorname{rank}\Lambda = 2$. Then $\ker\Lambda$ is one-dimensional. The two columns of $\widetilde{\Lambda}^{\mathsf{T}}$ both lie in this single line, so they are proportional; that is, the two rows of $\widetilde{\Lambda}$ are proportional, whence $\operatorname{rank}\widetilde{\Lambda} \le 1$. By Eq. (58.74) all $[i\,j] = 0$: the holomorphic branch (H), with the angle brackets free (their minors are generically nonzero since $\operatorname{rank}\Lambda = 2$).

Case $\operatorname{rank}\Lambda \le 1$. Then all the angle minors vanish, all $\langle i\,j\rangle = 0$ by Eq. (58.74): the anti-holomorphic branch (A), or the doubly-degenerate point where additionally $\operatorname{rank}\widetilde{\Lambda} \le 1$ and both products vanish.

In either case at least one of the cyclic products in Eq. (58.72) vanishes, which proves the dichotomy. The characterization of branch (H) by $\tilde{\lambda}_i \propto \tilde{\zeta}$ is exactly $\operatorname{rank}\widetilde{\Lambda} \le 1$, and symmetrically for (A).

It remains to treat real momenta. By the reality condition of Theorem 58.2, a real momentum has $\tilde{\lambda}_i = \pm\lambda_i^*$, the sign tracking the sign of the energy p_i^0. Consequently $|[i\,j]| = |\langle i\,j\rangle|$ for every pair. Then Eq. (58.71), $\langle i\,j\rangle[j\,i] = 0$, forces $|\langle i\,j\rangle|^2 = 0$ and hence *both* brackets vanish for every pair. All angle and square brackets are zero: the spinors are pairwise proportional and the three momenta are collinear, a measure-zero locus carrying no scattering. Only by relaxing reality — continuing λ and $\tilde{\lambda}$ to independent complex spinors — can one bracket set stay generic while the other vanishes. This is not a formal trick: a physical three-point amplitude of massless particles has support only at this complex kinematic point, and it enters physics as the residue of a factorization channel (Chapter 59), where the intermediate momentum is off the real slice. □

Physical Insight

The lesson is worth stating plainly, because it recurs throughout on-shell methods. A real three-point amplitude of massless particles vanishes by kinematics, not by dynamics: there is simply nowhere for three pairwise-null momenta to live except on top of one another. The object that survives is the *analytic continuation* of the amplitude to complex momenta, where it is sharp and nonzero on one of the two branches of Theorem 58.19. On-shell recursion is the art of extracting physical, real-momentum amplitudes from these complex three-point seeds by sewing them across factorization channels. The complexification that looks like a blemish here is the engine of the next chapter.

58.4.2 Solving the scaling constraints: uniqueness of the form

Fix the holomorphic branch (H), so that the amplitude is a function of the three angle brackets $\langle 1\,2\rangle, \langle 2\,3\rangle, \langle 3\,1\rangle$ alone — the square brackets have been set to zero. Locality has a sharp meaning here: a three-point amplitude has no internal propagator, hence no kinematic pole, so it must be a *monomial* in the available invariants, with integer exponents (and no sum of distinct monomials, since each angle bracket scales independently and a sum would fail to carry a definite little-group weight). Write the most general such monomial, labelling the exponent of the bracket that *omits* leg i by a_i:

$$\mathcal{M}_3 = c\,\langle 1\,2\rangle^{\,a_3}\,\langle 2\,3\rangle^{\,a_1}\,\langle 3\,1\rangle^{\,a_2}, \tag{58.75}$$

with c a constant to be fixed. Each angle bracket $\langle i\,j\rangle$ carries little-group weight $t_i t_j$, so leg i — which appears in exactly the two brackets that do not omit it — contributes total weight $t_i^{\,a_j+a_k}$ where $\{i,j,k\} = \{1,2,3\}$. Matching to Eq. (58.68) leg by leg gives one linear equation per particle:

$$\begin{aligned} t_1: &\quad a_2 + a_3 = -2h_1, \\ t_2: &\quad a_1 + a_3 = -2h_2, \\ t_3: &\quad a_1 + a_2 = -2h_3. \end{aligned} \tag{58.76}$$

This is a linear system with coefficient matrix $\left(\begin{smallmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{smallmatrix}\right)$, whose determinant is $2 \neq 0$: the solution is unique. Adding all three equations gives $2(a_1+a_2+a_3) = -2(h_1+h_2+h_3)$, so $a_1+a_2+a_3 = -H$ with

$$H \equiv h_1 + h_2 + h_3. \tag{58.77}$$

Subtracting each equation from this total isolates one exponent; for instance $a_1 = (a_1+a_2+a_3) - (a_2+a_3) = -H + 2h_1 = h_1 - h_2 - h_3$, and cyclically. The unique solution is

$$a_1 = h_1 - h_2 - h_3, \qquad a_2 = h_2 - h_3 - h_1, \qquad a_3 = h_3 - h_1 - h_2. \tag{58.78}$$

Substituting into Eq. (58.75) gives the holomorphic three-point amplitude in closed form,

$$\mathcal{M}_3^{(\mathrm{H})} = c\,\langle 1\,2\rangle^{\,h_3-h_1-h_2}\,\langle 2\,3\rangle^{\,h_1-h_2-h_3}\,\langle 3\,1\rangle^{\,h_2-h_3-h_1}, \tag{58.79}$$

exactly the form announced. The anti-holomorphic branch (A) is obtained by the same argument with square brackets, recalling that $[i\,j]$ carries weight $t_i^{-1}t_j^{-1}$; the sign in each scaling equation flips, the unique solution has the opposite-sign exponents, and

$$\mathcal{M}_3^{(\mathrm{A})} = \tilde{c}\,[1\,2]^{\,h_1+h_2-h_3}\,[2\,3]^{\,h_2+h_3-h_1}\,[3\,1]^{\,h_3+h_1-h_2}. \tag{58.80}$$

Which branch is the physical amplitude? Locality decides, through the total mass dimension. Each bracket carries mass dimension one, so the holomorphic form Eq. (58.79) has bracket-degree $a_1+a_2+a_3=-H$, and the anti-holomorphic form Eq. (58.80) has bracket-degree $+H$. A genuine, local, pole-free amplitude must have *non-negative* integer bracket-degree — a monomial with a net negative power of brackets would have a pole at $\langle i\,j\rangle \to 0$ (a collinear configuration that is interior to the branch), and such a singularity at three points has no factorization channel to explain it; it is non-local. Hence the holomorphic branch is selected when $-H \geq 0$, i.e. $H<0$, and the anti-holomorphic branch when $H>0$. Compactly,

$$\text{branch} = \begin{cases} \text{holomorphic (angle brackets)}, & H = h_1+h_2+h_3 < 0, \\ \text{anti-holomorphic (square brackets)}, & H = h_1+h_2+h_3 > 0, \end{cases} \tag{58.81}$$

and the surviving amplitude carries bracket-degree $|H|$, so its mass dimension is $|H| = |h_1+h_2+h_3|$. (The marginal case $H=0$ — for instance three massless scalars, or a $+,-,0$ helicity assignment — gives a dimensionless monomial, a pure constant; the three-scalar coupling of a ϕ^3 theory is the example, and there the constant is the dimensionful coupling itself.) Collecting the result:

Theorem 58.20 (Three-point amplitudes are fixed by symmetry)**.** *Let three massless particles carry helicities h_1, h_2, h_3 and set $H = h_1+h_2+h_3$. On the complex kinematics of Theorem 58.19, little-group covariance Eq. (58.5) together with locality (correct mass dimension and absence of unphysical poles) determines the three-point amplitude uniquely up to a single overall constant:*

$$\mathcal{M}_3 = \begin{cases} c\,\langle 1\,2\rangle^{\,h_3-h_1-h_2}\,\langle 2\,3\rangle^{\,h_1-h_2-h_3}\,\langle 3\,1\rangle^{\,h_2-h_3-h_1}, & H<0, \\ \tilde{c}\,[1\,2]^{\,h_1+h_2-h_3}\,[2\,3]^{\,h_2+h_3-h_1}\,[3\,1]^{\,h_3+h_1-h_2}, & H>0. \end{cases} \tag{58.82}$$

The constant has mass dimension $[c] = 1-|H|$, fixed by the requirement that the full amplitude carry the kinematic dimension $4-n=1$ of an $n=3$ amplitude. No dynamical input — no Lagrangian, no Feynman rule, no gauge choice — enters the functional form; only the helicities and the spacetime dimension do.

The dimension bookkeeping in the theorem is the second half of the rigidity, and it is what fixes the dimensionful part of c. An n-point amplitude in four dimensions has mass dimension $4-n$ (the same counting used for the scalar amplitudes of Chapter 14: stripping the momentum-conserving delta function and the canonical state normalization leaves dimension $4-n$). For $n=3$ this is $+1$. The brackets supply $|H|$ of it, so the constant must supply the rest:

$$[c] = 1-|H|. \tag{58.83}$$

For two helicity-1 and helicity-$\frac{1}{2}$ particles, where $|H|=1$, the constant is dimensionless — a pure coupling. For $|H|=2$, as for three gravitons, the

constant carries mass dimension -1 — a coupling with the dimensions of a length, which is the first whisper of Newton's constant. We now make all of this concrete.

58.4.3 The three-gluon amplitude

Specialize Theorem 58.20 to three gluons, $|h_i| = 1$. Pure Yang–Mills has no all-plus or all-minus three-point coupling (the form Eq. (58.82) would have $|H| = 3$, mass dimension -2, requiring a higher-derivative operator absent from the renormalizable theory of Eq. (25.76)); the physical assignments are the two with a single odd helicity. Take first $(h_1, h_2, h_3) = (-1, -1, +1)$, so $H = -1 < 0$ and Eq. (58.81) selects the holomorphic branch. The exponents Eq. (58.78) are

$$a_1 = h_1 - h_2 - h_3 = -1, \quad a_2 = h_2 - h_3 - h_1 = -1, \quad a_3 = h_3 - h_1 - h_2 = +3, \tag{58.84}$$

giving

$$\mathcal{M}_3(1^-, 2^-, 3^+) = c\,\frac{\langle 1\,2\rangle^{\,3}}{\langle 2\,3\rangle\,\langle 3\,1\rangle}. \tag{58.85}$$

This is the Maximally-Helicity-Violating (MHV) three-gluon amplitude. Its bracket-degree is $3 - 1 - 1 = 1$, so $[c] = 0$: the constant is dimensionless. The single power of the coupling is fixed by the structure of the theory. A connected tree amplitude built from the cubic and quartic vertices of Chapter 26 with n external legs carries $V_3 + 2V_4 = n - 2$ powers of g (each cubic vertex one power, each quartic two; the tree topology fixes the total). At $n = 3$ this is a single power, g^1, so $c \propto g$ with a dimensionless number out front. The conjugate assignment $(h_1, h_2, h_3) = (+1, +1, -1)$ has $H = +1 > 0$, selecting the anti-holomorphic branch, and the same computation with square brackets gives

$$\mathcal{M}_3(1^+, 2^+, 3^-) = \tilde{c}\,\frac{[1\,2]^{\,3}}{[2\,3]\,[3\,1]}. \tag{58.86}$$

Everything except the pure numbers $c, \tilde{c}$ has been forced by symmetry. To pin those numbers — and with them the relative sign and the phase — we match against the one Feynman diagram the theory actually produces.

Worked Example 58.21 (The three-gluon amplitude from the Yang–Mills cubic vertex)**.** At $n = 3$ there is no internal line, so the only diagram is a single cubic vertex (Fig. 58.3). Contracting the three-gluon vertex Eq. (26.53) — with all momenta outgoing, $p_1 + p_2 + p_3 = 0$ — against three external polarizations ε_i gives the colour-dressed amplitude

$$i\mathcal{M}_3 = iV^{abc}_{\mu\nu\rho}(p_1, p_2, p_3)\,\varepsilon_1^{\mu}\varepsilon_2^{\nu}\varepsilon_3^{\rho} = g\,f^{abc}\,K, \qquad K = (\varepsilon_1{\cdot}\varepsilon_2)\,(p_1 - p_2){\cdot}\varepsilon_3 + (\text{cyclic}), \tag{58.87}$$

where "cyclic" adds the two terms obtained by $1 \to 2 \to 3 \to 1$, the colour structure constant f^{abc} carries the entire group-theory content (normalization

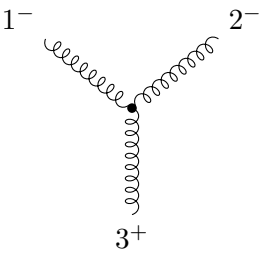

Figure 58.3: The sole diagram for the three-gluon amplitude: one cubic Yang–Mills vertex Eq. (26.53) with three on-shell external legs and no internal propagator. With the helicity assignment $(1^-, 2^-, 3^+)$ the amplitude lives on the holomorphic branch of Theorem 58.19 (all square brackets among externals vanishing) and equals the symmetry-fixed ratio Eq. (58.85).

$\mathrm{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$, Chapter B), and K is the purely kinematic factor we must evaluate.

We use the helicity polarization vectors built in the next section, Eq. (58.111),

$$\varepsilon_+^\mu(p_i; q_i) = \frac{\langle q_i|\gamma^\mu|i]}{\sqrt{2}\,\langle q_i\, i\rangle}, \qquad \varepsilon_-^\mu(p_i; q_i) = \frac{\langle i|\gamma^\mu|q_i]}{\sqrt{2}\,[q_i\, i]}, \tag{58.88}$$

each carrying a reference momentum q_i whose change is a gauge transformation; the amplitude is independent of every q_i. We exploit that freedom to annihilate two of the three terms in K. Assign the two negative-helicity legs a *common* reference $q_1 = q_2 \equiv q$ (a generic null momentum off the branch, so $[q\,1], [q\,2] \neq 0$), and give the positive leg the reference $q_3 = p_2$ (legal on the branch since $\langle q_3\, 3\rangle = \langle 2\, 3\rangle \neq 0$). The polarization dot products follow from Eq. (58.88) and the Fierz identity $\langle a|\gamma^\mu|b]\langle c|\gamma_\mu|d] = 2\langle a\, c\rangle[d\, b]$ (a consequence of the σ-matrix completeness relation $\sigma^\mu_{a\dot a}\bar\sigma_\mu^{\dot b b} = 2\delta_a^{\,b}\delta_{\dot a}^{\,\dot b}$ established with the bracket algebra of Theorem 58.2):

$$\varepsilon_1^- \cdot \varepsilon_2^- = \frac{\langle 1\, 2\rangle\,[q\, q]}{[q\, 1]\,[q\, 2]} = 0 \qquad ([q\, q] = 0), \tag{58.89}$$

$$\varepsilon_2^- \cdot \varepsilon_3^+ = \frac{\langle q_3\, 2\rangle\,[q\, 3]}{\langle q_3\, 3\rangle\,[q\, 2]} = \frac{\langle 2\, 2\rangle\,[q\, 3]}{\langle 2\, 3\rangle\,[q\, 2]} = 0 \qquad (\langle 2\, 2\rangle = 0). \tag{58.90}$$

The first two terms of K each contain one of these vanishing dot products, so only the third survives:

$$K = (\varepsilon_3^+ \cdot \varepsilon_1^-)\,(p_3 - p_1)\cdot\varepsilon_2^-. \tag{58.91}$$

The surviving dot product is

$$\varepsilon_3^+ \cdot \varepsilon_1^- = \frac{\langle q_3\, 1\rangle\,[q\, 3]}{\langle q_3\, 3\rangle\,[q\, 1]} = \frac{\langle 2\, 1\rangle\,[q\, 3]}{\langle 2\, 3\rangle\,[q\, 1]}. \tag{58.92}$$

For the momentum factor, transversality $\varepsilon_2\cdot p_2 = 0$ with $p_2 = -(p_1+p_3)$ gives $\varepsilon_2\cdot p_3 = -\varepsilon_2\cdot p_1$, hence $(p_3-p_1)\cdot\varepsilon_2^- = -2\,\varepsilon_2^-\cdot p_1$; inserting $\varepsilon_2^- = \langle 2|\gamma^\mu|q]/(\sqrt{2}\,[q\,2])$ and using $\langle 2|\not{p}_1|q] = \langle 2\,1\rangle[1\,q]$,

$$(p_3-p_1)\cdot\varepsilon_2^- = -\frac{2}{\sqrt{2}}\,\frac{\langle 2|\not{p}_1|q]}{[q\,2]} = -\sqrt{2}\,\frac{\langle 2\,1\rangle\,[1\,q]}{[q\,2]}. \tag{58.93}$$

Multiplying Eq. (58.92) and Eq. (58.93), the reference square brackets combine through $[1\,q] = -[q\,1]$:

$$K = \frac{\langle 2\,1\rangle\,[q\,3]}{\langle 2\,3\rangle\,[q\,1]}\cdot\Big(-\sqrt{2}\,\frac{\langle 2\,1\rangle\,[1\,q]}{[q\,2]}\Big) = \sqrt{2}\,\frac{\langle 2\,1\rangle^{\,2}\,[q\,3]}{\langle 2\,3\rangle\,[q\,2]}. \tag{58.94}$$

The leftover ratio $[q\,3]/[q\,2]$ must collapse to a q-independent expression, since the amplitude is gauge invariant. On the holomorphic branch all anti-holomorphic spinors are proportional, $\tilde\lambda_i = c_i\tilde\zeta$, so $[q\,3] = c_3\,[\tilde\lambda_q\,\tilde\zeta]$ and $[q\,2] = c_2\,[\tilde\lambda_q\,\tilde\zeta]$, giving $[q\,3]/[q\,2] = c_3/c_2$. The scalars c_i obey momentum conservation in its holomorphic form $\sum_i c_i\lambda_i = 0$ (the bispinor identity Eq. (58.73) with $\tilde\lambda_i = c_i\tilde\zeta$); contracting with λ_1, i.e. taking $\langle 1\,\cdot\rangle$, yields $c_2\langle 1\,2\rangle + c_3\langle 1\,3\rangle = 0$, so

$$\frac{c_3}{c_2} = -\frac{\langle 1\,2\rangle}{\langle 1\,3\rangle} = \frac{\langle 1\,2\rangle}{\langle 3\,1\rangle}, \qquad \frac{[q\,3]}{[q\,2]} = \frac{\langle 1\,2\rangle}{\langle 3\,1\rangle}. \tag{58.95}$$

The q-dependence has indeed dropped out. Substituting into Eq. (58.94) and using $\langle 2\,1\rangle^2 = \langle 1\,2\rangle^2$,

$$K = \sqrt{2}\,\frac{\langle 1\,2\rangle^{\,2}}{\langle 2\,3\rangle}\cdot\frac{\langle 1\,2\rangle}{\langle 3\,1\rangle} = \sqrt{2}\,\frac{\langle 1\,2\rangle^{\,3}}{\langle 2\,3\rangle\,\langle 3\,1\rangle}. \tag{58.96}$$

The kinematic factor is exactly the symmetry-fixed ratio Eq. (58.85), up to the constant $\sqrt{2}$ that is an artifact of the polarization normalization in Eq. (58.88). Stripping the colour factor f^{abc} and adopting the standard colour-ordered normalization fixed in Section 59.1 — which absorbs precisely this $\sqrt{2}$ per vertex and the explicit factor of i carried by iV in Eq. (58.87) — the colour-ordered partial amplitude is

$$A_3(1^-,2^-,3^+) = i\,g\,\frac{\langle 1\,2\rangle^{\,3}}{\langle 2\,3\rangle\,\langle 3\,1\rangle}, \tag{58.97}$$

which fixes $c = ig$ in Eq. (58.85). The honest match has supplied exactly what symmetry could not: the dimensionless number i and the single power of the coupling g.

The relative sign and phase of the conjugate amplitude follow from parity, which exchanges $\lambda_i \leftrightarrow \tilde\lambda_i$, hence angle and square brackets, and maps the assignment $(1^-,2^-,3^+)$ to $(1^+,2^+,3^-)$; the polarization vectors Eq. (58.88) pick up one sign each under the exchange, and the amplitude is linear in all three, so

it acquires $(-1)^3 = -1$. Collecting both branches, the two nonvanishing complex three-gluon amplitudes are

$$\boxed{A_3(1^-,2^-,3^+) = i\,g\,\frac{\langle 1\,2\rangle^{\,3}}{\langle 2\,3\rangle\,\langle 3\,1\rangle}, \qquad A_3(1^+,2^+,3^-) = -\,i\,g\,\frac{[1\,2]^{\,3}}{[2\,3]\,[3\,1]}.} \tag{58.98}$$

These are the seeds. Chapter 59 takes Eq. (58.98) as the only input beyond momentum conservation and analyticity and reconstructs the entire tree-level n-gluon S-matrix from them, beginning with the Parke–Taylor formula whose $n = 3$ case is exactly Eq. (58.98).

Notation Watch

Theorem 58.20 fixes the bracket *structure* of every three-point amplitude from helicity alone; what it leaves open is the single constant c, whose dimensionless part is genuine dynamics. For gluons the present section pins that constant to $c = ig$ by matching to the cubic vertex of Chapter 26, and Eq. (58.98) is the coupling- and phase-fixed seed used from here on. Where a later chapter writes the bare ratio $\langle 1\,2\rangle^3/(\langle 2\,3\rangle\langle 3\,1\rangle)$ without the prefactor, the complete on-shell object is always Eq. (58.98); the explicit $g^{\,n-2}$ that the colour decomposition of Section 59.1 keeps out front is, for the three-point seed, absorbed into A_3.

58.4.4 QED: the electron–photon vertex

We continue QED from its Feynman-rule layer in Chapter 17, now reframed on-shell. Take a massless electron, positron, and photon, all outgoing, and label the legs 1 (electron), 2 (positron), 3 (photon). The vector coupling of QED conserves chirality on a massless line (Theorem 17.18): the electron and positron emerging from one fermion line carry *opposite* helicities, $h_1 = -\tfrac{1}{2}$, $h_2 = +\tfrac{1}{2}$ (or the reverse). Pair this with a negative-helicity photon, $h_3 = -1$. Then $H = -\tfrac{1}{2} + \tfrac{1}{2} - 1 = -1 < 0$, the holomorphic branch is selected, and the exponents Eq. (58.78) are

$$a_1 = h_1 - h_2 - h_3 = -1, \quad a_2 = h_2 - h_3 - h_1 = +2, \quad a_3 = h_3 - h_1 - h_2 = 0, \tag{58.99}$$

so that, from Eq. (58.75),

$$\mathcal{M}_3(1^{-1/2},2^{+1/2},3^{-1}) = c\,\frac{\langle 3\,1\rangle^{\,2}}{\langle 1\,2\rangle}. \tag{58.100}$$

Its bracket-degree is $2-1 = 1$, so $[c] = 0$: the QED coupling is dimensionless, as it must be in four dimensions. The conjugate (positive-helicity photon) assignment has $H = +1 > 0$ and gives the square-bracket mirror $\tilde{c}\,[3\,1]^2/[1\,2]$. Symmetry

alone has reproduced the entire kinematic structure of the QED vertex; the following worked example confirms that the constant is exactly the electric charge, i.e. that minimal coupling is not an assumption but the unique outcome.

Worked Example 58.22 (Minimal coupling recovered: the $e\,e\,\gamma$ vertex in brackets)**.** Read the amplitude off the QED Feynman rules of Chapter 17. For the assignment $(1^{-1/2}, 2^{+1/2}, 3^{-1})$ the outgoing negative-helicity electron contributes the conjugate massless wavefunction $\bar{u}_-(1) = \langle 1|\,|] \to \langle 1|$, the outgoing positive-helicity positron contributes $v_+(2) \to |2]$, and the vertex is the minimal-coupling factor $-ie\gamma^\mu$ of Eq. (17.10). The single diagram gives

$$i\mathcal{M}_3 = \langle 1|\,(-ie\gamma^\mu)|2]\,\varepsilon^-_\mu(p_3;q) = -ie\,\langle 1|\gamma^\mu|2]\,\varepsilon^-_\mu(p_3;q). \tag{58.101}$$

Insert the negative-helicity photon polarization from Eq. (58.88), $\varepsilon^\mu_-(p_3;q) = \langle 3|\gamma^\mu|q]/(\sqrt{2}\,[q\,3])$ with a generic reference q, and apply the same Fierz identity $\langle 1|\gamma^\mu|2]\langle 3|\gamma_\mu|q] = 2\langle 1\,3\rangle[q\,2]$:

$$\langle 1|\gamma^\mu|2]\,\varepsilon^-_\mu(p_3;q) = \frac{2\,\langle 1\,3\rangle\,[q\,2]}{\sqrt{2}\,[q\,3]} = \sqrt{2}\,\langle 1\,3\rangle\,\frac{[q\,2]}{[q\,3]}. \tag{58.102}$$

On the holomorphic branch $\tilde{\lambda}_i = c_i\tilde{\zeta}$, so as in Eq. (58.95) the reference ratio collapses, $[q\,2]/[q\,3] = c_2/c_3$, and holomorphic momentum conservation $\sum_i c_i\lambda_i = 0$ contracted with λ_1 gives $c_2\langle 1\,2\rangle + c_3\langle 1\,3\rangle = 0$, whence $[q\,2]/[q\,3] = c_2/c_3 = -\langle 1\,3\rangle/\langle 1\,2\rangle$. Therefore

$$\langle 1|\gamma^\mu|2]\,\varepsilon^-_\mu(p_3;q) = \sqrt{2}\,\langle 1\,3\rangle\cdot\Big(-\frac{\langle 1\,3\rangle}{\langle 1\,2\rangle}\Big) = -\sqrt{2}\,\frac{\langle 1\,3\rangle^{\,2}}{\langle 1\,2\rangle} = -\sqrt{2}\,\frac{\langle 3\,1\rangle^{\,2}}{\langle 1\,2\rangle}, \tag{58.103}$$

using $\langle 1\,3\rangle^2 = \langle 3\,1\rangle^2$, manifestly q-independent as gauge invariance requires. Hence $\mathcal{M}_3 = \sqrt{2}\,e\,\langle 3\,1\rangle^2/\langle 1\,2\rangle$. Comparing with the symmetry-fixed form Eq. (58.100) fixes

$$c = \sqrt{2}\,e, \tag{58.104}$$

proportional to the single electric charge e (the factor $\sqrt{2}$ and the sign are the same polarization-normalization convention as in Theorem 58.21). The constant is the electromagnetic coupling and nothing else: the photon's three-point interaction with the electron is forced, by little-group scaling and locality, to be exactly minimal coupling. There was never any other Lorentz-invariant, local, dimensionless option; the gauge principle of Chapter 8 and the modern on-shell argument arrive at the same vertex from opposite directions.

This is the seed QED hands to the recursion: gluing two copies of Eq. (58.100) across a photon propagator reconstructs Compton scattering and $e^+e^- \to \mu^+\mu^-$ in helicity variables, and squaring and summing over helicities reproduces the unpolarized cross sections of Chapter 17 — the same numbers, now assembled from one-line gauge-invariant pieces rather than spin-summed traces.

58.4.5 Higher spin and the seed of the equivalence principle

The machinery is indifferent to the value of the helicity, and pushing it to spin two is where it becomes physically momentous. For three gravitons with the MHV-type assignment $(h_1, h_2, h_3) = (-2, -2, +2)$, one has $H = -2 < 0$, the holomorphic branch, and exponents $a_1 = h_1 - h_2 - h_3 = -2$, $a_2 = -2$, $a_3 = +6$:

$$\mathcal{M}_3(1^{--}, 2^{--}, 3^{++}) = \kappa \, \frac{\langle 1\,2\rangle^{\,6}}{\langle 2\,3\rangle^{\,2}\,\langle 3\,1\rangle^{\,2}} = \kappa \Big(\frac{\langle 1\,2\rangle^{\,3}}{\langle 2\,3\rangle\,\langle 3\,1\rangle} \Big)^2 , \tag{58.105}$$

the *square* of the three-gluon amplitude Eq. (58.85) — the first appearance of the double-copy structure that Chapter 61 develops in full. By Eq. (58.83) the constant now has mass dimension $[\kappa] = 1 - |H| = -1$: a coupling with the dimension of a length. There is only one such coupling available to a helicity-two particle, and it is $\kappa \sim \sqrt{G_N}$, the gravitational coupling.

The decisive consequence, which we state here and prove in Chapter 61, is *universality*. Couple the same helicity-two particle to two copies of any other species — a scalar pair, a fermion pair, a photon pair — and repeat the three-point analysis. Locality (now in the sharper form that the four-point amplitude built by sewing two three-point amplitudes must have consistent factorization on all channels, a consistency condition we develop in Chapters 59 and 60) forces the helicity-two coupling to each species to be the *same* constant κ. A massless spin-two particle cannot couple with different strengths to different kinds of matter; if it couples at all, it couples to the total energy–momentum with one universal constant. That statement is the equivalence principle, here derived not from a geometric postulate but from the representation theory of a helicity-two state and the demand that amplitudes be consistent. The same line of argument shows that no consistent long-range interaction mediated by a massless particle of helicity $|h| \geq \frac{5}{2}$ exists at all: the would-be three-point constant has ever-more-negative mass dimension and the multi-point consistency conditions have no solution. We flag these as the headline results and defer their complete treatment — the four-point consistency analysis, the double copy, and the gravitational amplitudes — to Chapter 61, where the tools assembled in the intervening chapters make the proof clean.

Caution

The phrase “derives the equivalence principle” should be read precisely. What the on-shell argument establishes is that *if* a massless helicity-two particle exists and mediates a long-range force consistent with Lorentz invariance, locality, and unitarity, *then* it must couple universally with a single dimensionful constant — there is no room for species-dependent gravitational charge. It does not, by itself, prove that such a particle exists in Nature; that is an empirical fact. The content is that the structure of

gravity is forced once the spin is fixed, exactly as minimal coupling was forced for the photon in Theorem 58.22. This is the on-shell counterpart of the textbook statement that general covariance plus a massless spin-two field leaves Einstein gravity as essentially the only option.

We now have the complete set of three-point building blocks: the two gluon amplitudes Eq. (58.98), the electron–photon vertex Eq. (58.100) with its coupling fixed to the electric charge, and the graviton amplitude Eq. (58.105) as the square of the gluon seed. What remains before these can be sewn into higher-point amplitudes is the external-state data they were written against — the polarization vectors that Eq. (58.88) quietly borrowed. The next section constructs those polarizations directly from spinors, exhibits their reference-momentum dependence as gauge freedom, and thereby promotes the bracket language from on-shell three-point seeds to whole amplitudes, readying the gluon building blocks for the BCFW recursion of Chapter 59.

58.5 Polarization vectors in spinor-helicity

The previous section fixed the three-point amplitudes of massless particles by symmetry alone, and in doing so it forced upon us the recognition that a helicity-one state carries nontrivial weight under the little group Eq. (58.5): a positive-helicity gluon or photon scales as t^{-2}, a negative-helicity one as t^{+2}, and no Lorentz four-vector of fixed components can carry such a weight. The on-shell three-point structures $\langle 1\,2\rangle, \langle 2\,3\rangle, \langle 3\,1\rangle$ and $[1\,2], [2\,3], [3\,1]$ managed to carry it because they are built directly from spinors. To go beyond three points — to write down and contract *whole* amplitudes, with internal lines and many external legs — we need the external wavefunctions themselves in the same currency. A gluon line entering a Feynman diagram is contracted with a polarization vector $\epsilon^{\mu}(p)$; if we want the diagram to land in the world of brackets, we must express $\epsilon^{\mu}(p)$ in spinors. That is the task of this section, and the payoff is twofold. First, the awkward inhomogeneous gauge redundancy of a polarization vector — the very redundancy Wigner's classification predicted and that we met head-on in Theorem 3.46 — reappears here as the freedom to choose an arbitrary *reference spinor*, and that freedom becomes a computational lever sharp enough to annihilate most of the terms in a Feynman-diagram expansion before they are ever written down. Second, squaring the construction produces the spin-two (graviton) polarization for free, which is the kinematic seed of the double copy of Chapter 61.

58.5.1 The construction

We work throughout with the all-outgoing convention and the bracket normalization fixed earlier in this chapter,

$$\langle i\, j\rangle\,[j\, i] = 2\, p_i{\cdot}p_j = s_{ij}, \tag{58.106}$$

together with the slash decomposition of a massless momentum established in Eq. (58.18),

$$\not{p} = |p\rangle\,[p| + |p]\,\langle p|\,, \qquad \not{p}\,|p] = 0 = \not{p}\,|p\rangle\,, \tag{58.107}$$

the second equalities being the massless Weyl equations ($\langle p|\,|p] = 0$ and $[p\,p] = \langle p\,p\rangle = 0$ since a spinor pairs to zero with itself). A single immediate consequence of Eq. (58.107) is the identity we shall use constantly,

$$\langle p|\gamma^\mu|p] = \langle p|\,\gamma^\mu|p] = \mathrm{tr}\big[|p]\,\langle p|\;\gamma^\mu\big] = \mathrm{tr}\big[\tfrac{1+\gamma^5}{2}\,\not{p}\,\gamma^\mu\big] = \tfrac{1}{2}\,\mathrm{tr}\big[\not{p}\,\gamma^\mu\big] = 2\,p^\mu, \tag{58.108}$$

where we used $|p]\,\langle p| = \frac{1+\gamma^5}{2}\not{p}$ — the lower-left block of $\not{p}$ in the chiral basis of Eq. (58.17), with $\gamma^5 = \mathrm{diag}(-\mathbf{1}, +\mathbf{1})$ — and that the trace of γ^5 with two gamma matrices vanishes (Appendix C).

We also need two structural identities from the bracket algebra of this chapter, recalled here because every verification below leans on them. The first is the Fierz (Chisholm) rearrangement of a pair of vector currents,

$$\langle a|\gamma^\mu|b]\,\langle c|\gamma_\mu|d] = 2\,\langle a\, c\rangle\,[d\, b]. \tag{58.109}$$

Its overall coefficient is pinned by the special case $a = c = p$, $b = d = q$: the left side is $\langle p|\gamma^\mu|p]\,\langle p|\gamma_\mu|q]$ with the first factor replaced by $2p^\mu$ via Eq. (58.108) only when $q = p$, so instead take $a = p, b = p, c = q, d = q$, giving $\langle p|\gamma^\mu|p]\langle q|\gamma_\mu|q] = 4\,p{\cdot}q$ on the left and $2\langle p\,q\rangle[q\,p] = 4\,p{\cdot}q$ on the right by Eq. (58.106) — the two agree precisely when the constant is 2. The second is the Schouten identity, the statement that any three two-component angle spinors are linearly dependent (a two-dimensional space cannot hold three independent vectors):

$$|i\rangle\;\langle j\,k\rangle + |j\rangle\;\langle k\,i\rangle + |k\rangle\;\langle i\,j\rangle = 0, \tag{58.110}$$

with the identical statement holding for square spinors and brackets.

With these tools in hand we can state the construction. For each massless leg of momentum $p = \lambda\tilde{\lambda}$ we introduce an auxiliary null momentum q, the *reference momentum*, with its own spinors; q is required only to be null, $q^2 = 0$, and not collinear with p, so that $\langle q\,p\rangle \neq 0$ and $[q\,p] \neq 0$. The two helicity polarization vectors are

$$\epsilon_+^\mu(p;q) = \frac{\langle q|\gamma^\mu|p]}{\sqrt{2}\,\langle q\,p\rangle}, \qquad \epsilon_-^\mu(p;q) = \frac{\langle p|\gamma^\mu|q]}{\sqrt{2}\,[q\,p]}. \tag{58.111}$$

These are exactly the forms previewed, on the strength of their little-group weights alone, in Eq. (58.62): the positive-helicity vector is *antiholomorphic* in

p (it contains $\tilde{\lambda}_p$ in the numerator and λ_p in the denominator, net weight t^{-2}, helicity $+1$), the negative-helicity vector is *holomorphic* in p (net weight t^{+2}, helicity -1), and the reference spinor enters numerator and denominator with equal and opposite weight so that it carries no little-group charge at all — the first sign that q is gauge, not kinematics. We now prove that Eq. (58.111) has every property a polarization vector must have.

58.5.2 The defining properties

Theorem 58.23 (Properties of the spinor-helicity polarization vectors)**.** *Let p be a massless momentum and q a reference momentum with $\langle q\,p\rangle \neq 0$, $[q\,p] \neq 0$. The vectors Eq. (58.111) satisfy*

$$\epsilon_\pm(p;q)\cdot p = 0 \qquad \textit{(transversality)}, \tag{58.112}$$

$$\epsilon_\pm(p;q)\cdot \epsilon_\pm(p;q) = 0 \qquad \textit{(nullness)}, \tag{58.113}$$

$$\epsilon_+(p;q)\cdot \epsilon_-(p;q) = 1 \qquad \textit{(cross normalization)}, \tag{58.114}$$

$$\epsilon_\pm(p;q)\cdot q = 0 \qquad \textit{(transversality to the reference)}. \tag{58.115}$$

Under the little-group rescaling Eq. (58.5) on leg p, $\epsilon_\pm \to t^{\mp 2}\epsilon_\pm$, identifying them as the helicity-(± 1) external wavefunctions. For real momenta the reality condition Eq. (58.46) gives $\big(\epsilon_\pm(p;q)\big)^* = -\,\epsilon_\mp(p;q)$, whence the physical normalization $\epsilon_\pm\cdot(\epsilon_\pm)^* = -1$.

Proof. Transversality Eq. (58.112). Contracting the numerator of ϵ_+ with p_μ assembles a slashed momentum acting on its own square ket:

$$\epsilon_+(p;q)\cdot p = \frac{\langle q|\gamma^\mu|p]\,p_\mu}{\sqrt{2}\,\langle q\,p\rangle} = \frac{\langle q|\,\not{p}\,|p]}{\sqrt{2}\,\langle q\,p\rangle} = 0, \tag{58.116}$$

because $\not{p}\,|p] = 0$ by Eq. (58.107). Identically, $\epsilon_-(p;q)\cdot p = \langle p|\,\not{p}\,|q]/(\sqrt{2}\,[q\,p]) = 0$ since $\langle p|\,\not{p} = 0$ (the conjugate Weyl equation). The polarization is transverse to the particle's own momentum, as a physical photon or gluon wavefunction must be.

Transversality to the reference Eq. (58.115). Writing $q_\mu = \tfrac{1}{2}\langle q|\gamma_\mu|q]$ from Eq. (58.108) and using the Fierz identity Eq. (58.109),

$$\epsilon_+(p;q)\cdot q = \frac{1}{2\sqrt{2}\,\langle q\,p\rangle}\,\langle q|\gamma^\mu|p]\,\langle q|\gamma_\mu|q] = \frac{1}{2\sqrt{2}\,\langle q\,p\rangle}\,2\,\langle q\,q\rangle\,[q\,p] = 0, \tag{58.117}$$

since $\langle q\,q\rangle = 0$; the analogous square-bracket computation gives $\epsilon_-\cdot q = 0$. Both vectors are transverse to the reference momentum as well — the geometric content of "axial" or "light-cone" gauge with gauge vector q, to which we return below.

Nullness Eq. (58.113). By the Fierz identity,

$$\epsilon_+\cdot\epsilon_+ = \frac{\langle q|\gamma^\mu|p]\,\langle q|\gamma_\mu|p]}{2\,\langle q\,p\rangle^2} = \frac{2\,\langle q\,q\rangle\,[p\,p]}{2\,\langle q\,p\rangle^2} = 0, \tag{58.118}$$

and likewise $\epsilon_- \cdot \epsilon_- = 2\langle p\,p\rangle[q\,q]/(2[q\,p]^2) = 0$. A single-helicity polarization vector is null — the complexified statement of circular polarization.

Cross normalization Eq. (58.114). Again by Eq. (58.109), with $a = q, b = p, c = p, d = q$,

$$\epsilon_+ \cdot \epsilon_- = \frac{\langle q|\gamma^\mu|p]\,\langle p|\gamma_\mu|q]}{2\,\langle q\,p\rangle\,[q\,p]} = \frac{2\,\langle q\,p\rangle\,[q\,p]}{2\,\langle q\,p\rangle\,[q\,p]} = 1. \tag{58.119}$$

Little-group weight. Under $\lambda_p \mapsto t\lambda_p$, $\tilde\lambda_p \mapsto t^{-1}\tilde\lambda_p$ the numerator $\langle q|\gamma^\mu|p] \propto \tilde\lambda_p$ scales as t^{-1} and the denominator $\langle q\,p\rangle \propto \lambda_p$ as t^{+1}, so $\epsilon_+ \to t^{-2}\epsilon_+$; symmetrically $\epsilon_- \to t^{+2}\epsilon_-$. With the convention that a helicity-h wavefunction carries weight t^{-2h} (Theorem 58.16), ϵ_+ is helicity $+1$ and ϵ_- is helicity -1, as the labels assert. The reference spinor's scaling cancels between numerator and denominator, so $\epsilon_\pm$ are invariant under the little group acting on q.

Reality. For a real momentum of positive energy, Eq. (58.46) gives $\tilde\lambda = \lambda^*$, from which the brackets obey $\langle i\,j\rangle^* = [j\,i]$ and the mixed sandwich obeys $\langle i|\gamma^\mu|j]^* = \langle j|\gamma^\mu|i]$ (the Hermiticity of γ^μ between conjugate spinors). Hence

$$(\epsilon_+^\mu(p;q))^* = \frac{\langle q|\gamma^\mu|p]^*}{\sqrt{2}\,\langle q\,p\rangle^*} = \frac{\langle p|\gamma^\mu|q]}{\sqrt{2}\,[p\,q]} = \frac{\langle p|\gamma^\mu|q]}{-\sqrt{2}\,[q\,p]} = -\,\epsilon_-^\mu(p;q), \tag{58.120}$$

using $[p\,q] = -[q\,p]$, and symmetrically $(\epsilon_-)^* = -\epsilon_+$. Therefore $\epsilon_+ \cdot (\epsilon_+)^* = -\,\epsilon_+ \cdot \epsilon_- = -1$, the spacelike norm demanded by the mostly-minus metric. The crossed value $\epsilon_+ \cdot \epsilon_- = +1$ in Eq. (58.114) and the conjugate value $\epsilon_+ \cdot (\epsilon_+)^* = -1$ are not in tension: they differ exactly by the reality sign $(\epsilon_\pm)^* = -\epsilon_\mp$. □

Notation Watch

The spinor-helicity polarization vectors Eq. (58.111) are fixed only up to an overall little-group phase, which is physically immaterial: an amplitude contracted with $\epsilon_\pm$ acquires that phase as an overall factor and the cross section, $|\mathcal{M}|^2$, is blind to it. The particular phase in Eq. (58.111) yields the convenient *holomorphic* cross normalization $\epsilon_+ \cdot \epsilon_- = +1$ rather than the -1 one would read off the real circular-polarization vectors $\frac{1}{\sqrt{2}}(0, 1, \pm i, 0)$ of Theorem 13.12; the two descriptions are related by an overall factor of i on each $\epsilon_\pm$, equivalently by the reality relation $(\epsilon_\pm)^* = -\epsilon_\mp$ derived above. Whenever a polarization sum $\sum_h \epsilon_h \epsilon_h^*$ is needed — as in a squared amplitude — it is the conjugate pairing, with its minus sign, that enters, and it reproduces the mostly-minus Chapter 13 result, as we now verify.

58.5.3 The completeness relation

A polarization vector earns its keep inside a squared amplitude, where the sum over physical helicities of a virtual or external boson must collapse to the covariant

propagator numerator of Theorem 13.30. We check that the spinor construction reproduces it on the nose, reference momentum and all.

Theorem 58.24 (Completeness / polarization sum)**.** *For a massless leg p with reference momentum q,*

$$\sum_{h=\pm} \epsilon_h^{\mu}(p;q)\,\big(\epsilon_h^{\nu}(p;q)\big)^{*} = -\,\eta^{\mu\nu} + \frac{p^{\mu}q^{\nu}+p^{\nu}q^{\mu}}{p\cdot q}, \tag{58.121}$$

which is precisely the polarization replacement of Theorem 13.30 with the Chapter-13 gauge vector identified with the reference momentum q.

Proof. By the reality relation $(\epsilon_{\pm})^{*} = -\epsilon_{\mp}$ of Theorem 58.23, the conjugate sum is minus the symmetric product of the two helicity vectors:

$$\sum_{h=\pm} \epsilon_h^{\mu}(\epsilon_h^{\nu})^{*} = -\big(\epsilon_+^{\mu}\epsilon_-^{\nu} + \epsilon_-^{\mu}\epsilon_+^{\nu}\big). \tag{58.122}$$

It remains to compute the symmetric product. Using $|p]\,\langle p| = \frac{1+\gamma^5}{2}\not{p}$ to fold the inner pair of spinors into a slashed momentum,

$$S^{\mu\nu} \equiv \langle q|\gamma^{\mu}|p]\,\langle p|\gamma^{\nu}|q] = \mathrm{tr}\Big[\tfrac{1+\gamma^5}{2}\not{q}\,\gamma^{\mu}\,\tfrac{1+\gamma^5}{2}\not{p}\,\gamma^{\nu}\Big] = \mathrm{tr}\Big[\tfrac{1+\gamma^5}{2}\not{q}\,\gamma^{\mu}\not{p}\,\gamma^{\nu}\Big], \tag{58.123}$$

where the two chiral projectors merged because moving one through the even string $\not{q}\gamma^{\mu}$ returns it to the form $\frac{1+\gamma^5}{2}\not{q}\gamma^{\mu}$ and projectors are idempotent. Splitting into the parity-even and parity-odd traces of Appendix C,

$$S^{\mu\nu} = \tfrac{1}{2}\,\mathrm{tr}\big[\not{q}\gamma^{\mu}\not{p}\gamma^{\nu}\big] + \tfrac{1}{2}\,\mathrm{tr}\big[\gamma^5\not{q}\gamma^{\mu}\not{p}\gamma^{\nu}\big] = 2(q^{\mu}p^{\nu}+q^{\nu}p^{\mu}-(q\cdot p)\eta^{\mu\nu}) - 2i\,\epsilon^{\alpha\mu\beta\nu}q_{\alpha}p_{\beta}. \tag{58.124}$$

The product entering $\epsilon_-^{\mu}\epsilon_+^{\nu}$ is $S^{\mu\nu}$ with $p \leftrightarrow q$, call it $S'^{\mu\nu}$; its parity-odd piece is the negative of that of $S^{\mu\nu}$, so the Levi-Civita terms cancel in the sum and

$$S^{\mu\nu} + S'^{\mu\nu} = 4(p^{\mu}q^{\nu}+p^{\nu}q^{\mu}) - 4\,(p\cdot q)\,\eta^{\mu\nu}. \tag{58.125}$$

Dividing by the denominators of Eq. (58.111) and using $\langle q\,p\rangle[q\,p] = -\,\langle q\,p\rangle[p\,q] = -2\,p\cdot q$ from Eq. (58.106),

$$\epsilon_+^{\mu}\epsilon_-^{\nu} + \epsilon_-^{\mu}\epsilon_+^{\nu} = \frac{S^{\mu\nu}+S'^{\mu\nu}}{2\,\langle q\,p\rangle\,[q\,p]} = \frac{4(p^{\mu}q^{\nu}+p^{\nu}q^{\mu}) - 4(p\cdot q)\eta^{\mu\nu}}{-4\,(p\cdot q)} = \eta^{\mu\nu} - \frac{p^{\mu}q^{\nu}+p^{\nu}q^{\mu}}{p\cdot q}. \tag{58.126}$$

Substituting into Eq. (58.122) yields Eq. (58.121). □

The reference momentum appears in the completeness relation precisely where the gauge-fixing vector appears in Theorem 13.30: it is the residual gauge artefact of describing a two-state photon with a four-component vector. In a gauge-invariant quantity it must drop out, and the next subsection makes that mechanism explicit and exact.

58.5.4 Reference freedom is gauge freedom

The reference momentum q was introduced as a free choice, and the little-group weight count already hinted that it carries no physical information. We now show the strong form of that statement: changing q shifts $\epsilon_\pm$ by a vector proportional to p^μ — exactly the form of a gauge transformation Eq. (8.113) — so that any quantity respecting the Ward identity is strictly independent of every reference momentum.

Proposition 58.25 (Reference shift is a gauge transformation)**.** *For two admissible reference momenta q, q',*

$$\epsilon_+^\mu(p;q') - \epsilon_+^\mu(p;q) = \frac{\sqrt{2}\,\langle q\,q'\rangle}{\langle q\,p\rangle\,\langle q'\,p\rangle}\,p^\mu, \tag{58.127}$$

and analogously $\epsilon_-^\mu(p;q') - \epsilon_-^\mu(p;q) = \dfrac{\sqrt{2}\,[q'\,q]}{[q\,p]\,[q'\,p]}\,p^\mu$. The shift is purely longitudinal: $\epsilon_\pm(p;q)$ and $\epsilon_\pm(p;q')$ differ by a multiple of p^μ.

Proof. Subtract the two expressions in Eq. (58.111) over a common denominator,

$$\epsilon_+^\mu(p;q') - \epsilon_+^\mu(p;q) = \frac{1}{\sqrt{2}}\,\frac{\langle q'|\gamma^\mu|p]\,\langle q\,p\rangle - \langle q|\gamma^\mu|p]\,\langle q'\,p\rangle}{\langle q'\,p\rangle\,\langle q\,p\rangle}. \tag{58.128}$$

The square spinor $\tilde\lambda_p$ is common to both mixed sandwiches in the numerator; factoring it out, the bracketed combination of *angle* spinors is $(\lambda_{q'}\langle q\,p\rangle - \lambda_q\langle q'\,p\rangle)$ contracted into $\sigma^\mu\tilde\lambda_p$. The Schouten identity Eq. (58.110) with $(i,j,k) = (q',q,p)$ reads $|q'\rangle\,\langle q\,p\rangle + |q\rangle\,\langle p\,q'\rangle + |p\rangle\,\langle q'\,q\rangle = 0$, i.e.

$$\lambda_{q'}\,\langle q\,p\rangle - \lambda_q\,\langle q'\,p\rangle = \lambda_p\,\langle q\,q'\rangle, \tag{58.129}$$

where we used $\langle p\,q'\rangle = -\langle q'\,p\rangle$ and $\langle q'\,q\rangle = -\langle q\,q'\rangle$. Therefore the numerator becomes $\langle q\,q'\rangle\,\lambda_p\,\sigma^\mu\,\tilde\lambda_p = \langle q\,q'\rangle\,\langle p|\gamma^\mu|p] = 2\,\langle q\,q'\rangle\,p^\mu$ by Eq. (58.108), and

$$\epsilon_+^\mu(p;q') - \epsilon_+^\mu(p;q) = \frac{1}{\sqrt{2}}\,\frac{2\,\langle q\,q'\rangle\,p^\mu}{\langle q'\,p\rangle\,\langle q\,p\rangle} = \frac{\sqrt{2}\,\langle q\,q'\rangle}{\langle q\,p\rangle\,\langle q'\,p\rangle}\,p^\mu, \tag{58.130}$$

which is Eq. (58.127). The negative-helicity case is identical with angle spinors and brackets replaced by their square counterparts and the square-bracket Schouten identity. □

Compare Eq. (58.127) with the momentum-space form of the gauge transformation $A_\mu \to A_\mu + \partial_\mu\chi$, namely $\epsilon^\mu \to \epsilon^\mu + \alpha\,p^\mu$, recorded as Eq. (8.113): changing the reference momentum is, term for term, a gauge transformation of the external polarization, with the gauge parameter $\alpha = \sqrt{2}\,\langle q\,q'\rangle/(\langle q\,p\rangle\langle q'\,p\rangle)$ read off explicitly. The reference-momentum freedom of Eq. (58.111) *is* the gauge

freedom of the photon, repackaged as a choice of spinor. This is the precise resolution of the puzzle posed in Section 3.7.4: the surplus degree of freedom a four-vector carries over a genuine helicity-one state, which there obstructed any manifestly Lorentz-covariant labelling, is here demoted to a harmless parameter we are free to set.

Theorem 58.26 (Reference independence of gauge-invariant amplitudes)**.** *Let $\mathcal{M}^\mu(p)$ be the amputated, on-shell matrix element with the polarization of leg p stripped off, so that the amplitude is $\mathcal{M} = \epsilon_\mu(p;q)\,\mathcal{M}^\mu(p)$. If $\mathcal{M}^\mu$ satisfies the Ward identity $p_\mu \mathcal{M}^\mu = 0$, then $\mathcal{M}$ is independent of the reference momentum q.*

Proof. Changing $q \to q'$ shifts the contracted amplitude by

$$\left(\epsilon_\mu(p;q') - \epsilon_\mu(p;q)\right)\mathcal{M}^\mu(p) = \frac{\sqrt{2}\,\langle q\,q'\rangle}{\langle q\,p\rangle\,\langle q'\,p\rangle}\,p_\mu\,\mathcal{M}^\mu(p) = 0, \tag{58.131}$$

by Theorem 58.25 followed by the Ward identity $p_\mu\mathcal{M}^\mu = 0$ (the tree-level statement of current conservation, Theorem 18.5, itself the on-shell shadow of the gauge symmetry whose seed is Eq. (8.113)). The same holds independently for each external gauge boson; hence a physical amplitude is independent of all reference momenta simultaneously. □

Physical Insight

Theorem 58.26 is the single most useful practical statement in this chapter. Because the answer does not depend on the q_i, we may choose them *per leg* and *at our convenience* to make as many polarization contractions vanish as possible. A Feynman-diagram expansion of a gluon amplitude contains, term by term, dot products $\epsilon_i \cdot \epsilon_j$, $\epsilon_i \cdot p_j$, and $\epsilon_i \cdot \epsilon_j^*$; a clever common choice of references can zero out whole families of these at once, so that the great majority of diagrams collapse before any integral or trace is done. This is precisely how the hundreds of terms advertised in the chapter introduction shrink to a one-line answer. The next chapter turns the trick into a method; here we exhibit the arithmetic that makes it work.

Worked Example 58.27 (Engineering vanishing polarization products)**.** Take two distinct massless legs i, j with references q_i, q_j. Using only the Fierz identity Eq. (58.109) and the slash identity Eq. (58.107), we compute every polarization dot product in closed form and read off when it vanishes.

Same-helicity pairs. For two positive-helicity legs,

$$\epsilon_+(i;q_i)\cdot\epsilon_+(j;q_j) = \frac{\langle q_i|\gamma^\mu|i]\,\langle q_j|\gamma_\mu|j]}{2\,\langle q_i\,i\rangle\,\langle q_j\,j\rangle} = \frac{\langle q_i\,q_j\rangle\,[j\,i]}{\langle q_i\,i\rangle\,\langle q_j\,j\rangle}, \tag{58.132}$$

which vanishes the instant the two references are chosen equal, $q_i = q_j$, because $\langle q_i\,q_j\rangle \to \langle q\,q\rangle = 0$. Symmetrically, two negative-helicity legs give $\epsilon_-(i;q_i)\cdot$

$\epsilon_-(j;q_j) = \langle i\,j\rangle[q_j\,q_i]/([q_i\,i][q_j\,j])$, again zero for a common reference $q_i = q_j$. *All like-helicity polarization vectors that share a reference are mutually orthogonal.*

Opposite-helicity pairs. For one of each,

$$\epsilon_+(i;q_i)\cdot\epsilon_-(j;q_j) = \frac{\langle q_i|\gamma^\mu|i]\,\langle j|\gamma_\mu|q_j]}{2\,\langle q_i\,i\rangle\,[q_j\,j]} = \frac{\langle q_i\,j\rangle\,[q_j\,i]}{\langle q_i\,i\rangle\,[q_j\,j]}, \tag{58.133}$$

which vanishes if the reference of the positive leg is aligned with the *momentum* of the negative leg, $q_i = p_j$ (then $\langle q_i\,j\rangle = \langle j\,j\rangle = 0$), or if $q_j = p_i$.

Polarization-momentum products. Folding p_j into a slash,

$$\epsilon_+(i;q_i)\cdot p_j = \frac{\langle q_i|\not{p}_j|i]}{\sqrt{2}\,\langle q_i\,i\rangle} = \frac{\langle q_i\,j\rangle\,[j\,i]}{\sqrt{2}\,\langle q_i\,i\rangle}, \tag{58.134}$$

where only the $|j\rangle\,[j|$ piece of $\not{p}_j$ survives because $\langle q_i|\,|j] = 0$. This too vanishes for $q_i = p_j$.

The lever in action. Consider an amplitude with all external gluons of positive helicity. Choose one common reference q for every leg. Then $\epsilon_i\cdot\epsilon_j = 0$ for every pair, by the same-helicity result. In the Yang–Mills Feynman rules every interaction vertex carries at least one factor $\epsilon_i\cdot\epsilon_j$ once the dust settles (the three-gluon vertex is linear in such products, the four-gluon vertex quadratic), so every diagram is killed and the all-plus tree amplitude vanishes identically — a result we obtained here from four lines of bracket algebra and will rederive structurally in Chapter 59. With exactly one leg flipped to negative helicity, almost all products still vanish for a suitable common reference, leaving the famous single surviving structure; this is the kinematic origin of the Parke–Taylor formula of Chapter 59.

58.5.5 Spin two by squaring: the graviton polarization

A massless spin-two particle — the graviton — carries helicity ±2 and is described on shell by a symmetric, transverse, traceless polarization tensor $\epsilon^{\mu\nu}$. Nothing new is needed to build it: the spin-one construction, squared, already produces an object with all the right properties and the right little-group weight.

Definition 58.28 (Graviton polarization tensor)**.** For a massless leg p with reference momentum q, define

$$\epsilon^{\mu\nu}_\pm(p;q) \equiv \epsilon^\mu_\pm(p;q)\,\epsilon^\nu_\pm(p;q). \tag{58.135}$$

The defining properties follow at once from Theorem 58.23. The tensor is manifestly symmetric. It is traceless,

$$\eta_{\mu\nu}\,\epsilon^{\mu\nu}_\pm = \epsilon_\pm\cdot\epsilon_\pm = 0 \quad \text{by Eq. (58.113)}, \tag{58.136}$$

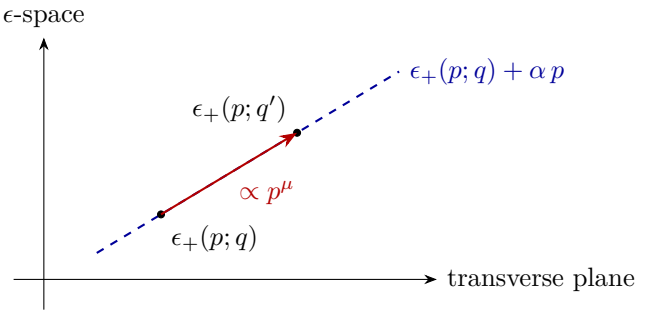

Figure 58.4: The reference-momentum freedom as a gauge orbit. Every admissible reference q gives a polarization vector lying on a single affine line in the direction of the particle's momentum p^μ (Eq. (58.127)). Moving along the line is a gauge transformation Eq. (8.113); a Ward-identity-respecting amplitude takes the same value at every point of it (Theorem 58.26).

and transverse on both indices,

$$p_\mu\,\epsilon_\pm^{\mu\nu} = (\epsilon_\pm\cdot p)\,\epsilon_\pm^{\nu} = 0 \quad \text{by Eq. (58.112).} \tag{58.137}$$

Under the little group it scales as $\epsilon_\pm^{\mu\nu} \to t^{\mp 4}\epsilon_\pm^{\mu\nu}$, i.e. with weight t^{-2h} for $h = \pm 2$: it is genuinely a helicity-(± 2) wavefunction. Finally, changing the reference shifts it by a linearized diffeomorphism: from Eq. (58.127), with $\Delta\epsilon_\pm^\mu = \alpha\,p^\mu$,

$$\Delta\epsilon_\pm^{\mu\nu} = \alpha(p^\mu\epsilon_\pm^\nu + \epsilon_\pm^\mu p^\nu) + \alpha^2 p^\mu p^\nu = p^{(\mu}\xi^{\nu)} + \dots, \tag{58.138}$$

the leading term being exactly the form $\delta h_{\mu\nu} = \partial_{(\mu}\xi_{\nu)}$ of a coordinate transformation on the linearized metric — the gravitational counterpart of the gauge shift Eq. (8.113). Thus the reference freedom of the squared polarization is the gauge (diffeomorphism) freedom of the graviton, and gravitational amplitudes built from these external states are reference-independent for the same Ward-identity reason as in Theorem 58.26.

Physical Insight

That a graviton polarization is literally the square of a gauge-boson polarization, $\epsilon^{\mu\nu} = \epsilon^\mu\epsilon^\nu$, is not a notational coincidence. It is the on-shell, external-state face of the *double copy*: the statement that the kinematic data of gravity is built from two copies of the kinematic data of gauge theory, leg by leg. Chapter 61 promotes this observation from external wavefunctions to entire amplitudes, replacing color factors by a second copy of kinematic numerators; Eq. (58.135) is the seed from which that construction grows.

With external spin-one and spin-two states now written entirely in brackets, and with the reference freedom understood as the gauge lever that empties

out Feynman-diagram sums, every ingredient of a tree amplitude — momenta, propagators, vertices, and now polarizations — can be assembled and contracted leg by leg in the spinor variables. The next section cashes this in on the book's running QED examples, contracting these polarization vectors against the electron currents to recover, from one-line helicity amplitudes, the unpolarized cross sections computed the long way in Chapter 17.

58.6 QED reframed: helicity amplitudes that reproduce the cross section

The preceding section completed the kinematic toolkit. We now have, for every massless external leg, exactly the on-shell data Wigner's classification says it carries and nothing more: a pair of two-component spinors $\lambda_i, \tilde{\lambda}_i$ for each momentum, their Lorentz invariants $\langle i\,j\rangle$ and $[i\,j]$, the three-point amplitudes fixed by little-group scaling alone, and—built from the same spinors—polarization vectors $\varepsilon^{\mu}_{\pm}(p_i; q_i)$ whose reference momentum q_i is pure gauge. The promise made in the chapter's opening was that this apparatus would pay for itself by collapsing the gauge-dependent, many-term Feynman expressions of Parts IV–VII into one-line gauge-invariant answers. It is time to redeem that promise on the book's own running examples. We take the two flagship tree processes of QED—the annihilation $e^+e^- \to \mu^+\mu^-$ computed by brute-force traces in Chapter 17, and Compton scattering $e\gamma \to e\gamma$ computed the same way in Chapter 18—and rebuild them in helicity variables. The annihilation cross section will reappear, exact and to the last factor, out of four one-line amplitudes and no gamma-matrix trace at all; Compton's two Feynman diagrams will fuse into a single bracket once a reference momentum is chosen wisely. This is the primary QED analysis of the chapter, advancing the electron's story (Chapters 8, 11, 13 and 17 to 20) to its modern amplitude layer.

Notation Watch

We use the conventions fixed earlier in this chapter and restate them, since signs differ between references. *All external momenta are outgoing*; an incoming particle of momentum P and helicity h is the same datum as an outgoing leg of momentum $p = -P$ and helicity $-h$, with the antiparticle/particle label interchanged. Brackets are normalized so that

$$\langle i\,j\rangle\,[j\,i] = 2\,p_i{\cdot}p_j = s_{ij}, \qquad s_{ij} \equiv (p_i + p_j)^2, \tag{58.139}$$

as established in Eq. (58.24). For *real* momenta the angle and square spinors are complex conjugates up to the sign of the energy, $\tilde{\lambda}_i = \pm\lambda_i^*$, so that $[i\,j] = \pm\langle j\,i\rangle^*$ and, crucially,

$$\big|\langle i\,j\rangle\big|^2 = \big|[i\,j]\big|^2 = |s_{ij}|, \tag{58.140}$$

the one fact about brackets that survives squaring and that does all the work in the cross-section checks below. Overall phases of helicity amplitudes are convention-dependent and drop out of $|\mathcal{M}|^2$; we track them only far enough to keep relative signs honest. The metric is mostly-minus and the QED coupling enters through $D_\mu = \partial_\mu + ieA_\mu$ on the electron, $\alpha = e^2/4\pi$, exactly as in QED (Eq. (8.143)).

58.6.1 Massless fermion currents and the Fierz rearrangement

Every QED amplitude in Chapters 17 and 18 is built by sewing electromagnetic currents $\bar{u}\,\gamma^\mu u$ (and their v-spinor relatives) onto photons. The spinor-helicity reframing rests on one observation about such currents in the massless limit, already half-anticipated by the chirality selection rule of Theorem 17.18: a single gamma matrix between two massless spinors of definite helicity is not a four-vector with sixteen components to track, but one of just two elementary bilinears, an "angle–square" sandwich or its conjugate.

Recall from the construction of the on-shell spinors (Eq. (58.17)) that a positive-energy massless Dirac spinor of definite helicity is the four-component embedding of a single Weyl spinor: in the chiral basis a negative-helicity (left) particle carries the angle data $|i\rangle$, a positive-helicity (right) particle the square data $|i]$, with the Dirac conjugates supplying $\langle i|$ and $[i|$. The vector vertex γ^μ is chirality-off-diagonal (Eq. (17.148)), so it connects an angle bra to a square ket or vice versa, and the only two non-vanishing single-gamma bilinears are

$$\langle i|\gamma^\mu|j] = \langle i|\,\gamma^\mu\,|j], \qquad [i|\gamma^\mu|j\rangle = [i|\gamma^\mu\,|j\rangle\,, \tag{58.141}$$

related by $\langle i|\gamma^\mu|j] = [j|\gamma^\mu|i\rangle$ (the transpose identity of Eq. (58.29)). The would-be same-chirality bilinears $\langle i|\,\gamma^\mu\,|j\rangle$ and $[i|\gamma^\mu|j]$ vanish identically—this is Theorem 17.18 read in two components. A massless current therefore carries a definite helicity flow: the QED vertex cannot turn a left line into a right line.

The single algebraic identity that turns products of currents into products of brackets is the Fierz rearrangement. It is the engine of every computation in this section, so we prove it.

Lemma 58.29 (Fierz rearrangement of two currents)**.** *For any four massless momenta,*

$$\langle 1|\gamma^\mu|2]\,\langle 3|\gamma_\mu|4] = 2\,\langle 1\,3\rangle\,[4\,2], \tag{58.142}$$

and, contracting one current against the gamma matrix itself, the completeness relation

$$\langle i|\gamma^\mu|j]\,(\gamma_\mu) = 2\big(|j]\,\langle i| + |i\rangle\,[j|\big). \tag{58.143}$$

Proof. Write the currents in two-component form, $\langle 1|\gamma^\mu|2] = \lambda_1^\alpha\,\sigma^\mu_{\alpha\dot\alpha}\,\tilde\lambda_2^{\dot\alpha}$ and likewise for legs $3,4$, with $\sigma^\mu = (\mathbf{1},\boldsymbol{\sigma})$ the Pauli data of Eq. (C.274). The

contraction over the Lorentz index is performed by the σ-completeness identity

$$\sigma^{\mu}_{\alpha\dot\alpha}\,\sigma_{\mu\,\beta\dot\beta} = 2\,\epsilon_{\alpha\beta}\,\epsilon_{\dot\alpha\dot\beta}, \tag{58.144}$$

established as Eq. (58.35). Hence

$$\langle 1|\gamma^{\mu}|2]\,\langle 3|\gamma_{\mu}|4] = \lambda_1^{\alpha}\tilde\lambda_2^{\dot\alpha}\,\lambda_3^{\beta}\tilde\lambda_4^{\dot\beta}\cdot 2\,\epsilon_{\alpha\beta}\epsilon_{\dot\alpha\dot\beta} = 2\,(\lambda_1^{\alpha}\lambda_3^{\beta}\epsilon_{\alpha\beta})\,(\tilde\lambda_2^{\dot\alpha}\tilde\lambda_4^{\dot\beta}\epsilon_{\dot\alpha\dot\beta}). \tag{58.145}$$

By the bracket definitions $\lambda_1^{\alpha}\lambda_3^{\beta}\epsilon_{\alpha\beta} = \langle 1\,3\rangle$ and $\tilde\lambda_2^{\dot\alpha}\tilde\lambda_4^{\dot\beta}\epsilon_{\dot\alpha\dot\beta} = [4\,2]$ (the antisymmetry of $\epsilon_{\dot\alpha\dot\beta}$ fixes the order $4,2$), which is Eq. (58.142). Stripping $\lambda_3, \tilde\lambda_4$ from both sides—i.e. contracting only the first current's Lorentz index against the loose γ_μ—turns the same manipulation into the matrix statement Eq. (58.143), the four-component image of Eq. (58.144). □

Two corollaries of Eq. (58.142), obtained by relabeling and using $\langle i|\gamma^{\mu}|j] = [j|\gamma^{\mu}|i\rangle$, will be used without further comment:

$$\langle 1|\gamma^{\mu}|2]\,[3|\gamma_{\mu}|4\rangle = 2\,\langle 1\,4\rangle\,[3\,2], \qquad [1|\gamma^{\mu}|2\rangle\,[3|\gamma_{\mu}|4\rangle = 2\,[1\,3]\,\langle 4\,2\rangle. \tag{58.146}$$

The pattern is mechanical: two currents glued at a Lorentz index become a product of two brackets, angle with angle and square with square, the helicity flow of each current dictating which spinor lands in which bracket. This is all the algebra the annihilation amplitude needs.

58.6.2 $e^+e^- \to \mu^+\mu^-$ as helicity amplitudes

We continue QED from the helicity decomposition of Section 17.6.3, where the four nonzero squared amplitudes were extracted from a projected trace. Here we obtain the amplitudes themselves, as single brackets, and square them only at the very end.

All-outgoing kinematics. Label the four particles, all outgoing,

$$1 = e^-, \quad 2 = e^+, \quad 3 = \mu^-, \quad 4 = \mu^+, \tag{58.147}$$

with outgoing momenta $p_1, \dots, p_4$ summing to zero. The electron line carries the charge flow $1 \to 2$, the muon line $3 \to 4$, and a single photon is exchanged in the s_{12} channel. Crossing legs $1, 2$ back to the incoming electron and positron of Eq. (17.156) ($p_1 = -p_-$, $p_2 = -p_+$, $p_3 = k_-$, $p_4 = k_+$) translates the physical Mandelstam invariants of Theorem 16.21 into bracket invariants,

$$s_{12} = s_{34} = s, \qquad s_{13} = s_{24} = t, \qquad s_{14} = s_{23} = u, \tag{58.148}$$

with $s + t + u = 0$ in the massless limit, $t = -\frac{s}{2}(1 - \cos\theta)$, $u = -\frac{s}{2}(1 + \cos\theta)$ from Eq. (17.157).

The amplitude in bracket form. The Feynman amplitude is the one written in Eq. (17.155): an electron current and a muon current tied by the Feynman-gauge photon propagator $-i\eta_{\mu\nu}/s_{12}$, with a vertex factor ie at each end. In the all-outgoing labeling this reads

$$\mathcal{M} = \frac{e^2}{s_{12}}\, J_e^{\mu}\, J_{\mu}^{\pm}, \qquad J_e^{\mu} = (\text{electron current } 1,2), \quad J^{\mu\,\mu^{\pm}} = (\text{muon current } 3,4), \tag{58.149}$$

the overall sign and factors of i being immaterial to $|\mathcal{M}|^2$ and suppressed. By the helicity flow of Section 58.6.1, each current is one of the two bilinears Eq. (58.141), and chirality conservation forces the two ends of a line to carry *opposite* all-outgoing helicities. Take first the configuration with leg 1 negative-helicity and leg 3 negative-helicity. Then the electron current is $\langle 1|\gamma^{\mu}|2]$ (angle on 1, square on 2), the muon current is $\langle 3|\gamma_{\mu}|4]$, and Eq. (58.142) gives at once

$$\mathcal{M}(1^-2^+3^-4^+) = \frac{e^2}{s_{12}}\,\langle 1|\gamma^{\mu}|2]\,\langle 3|\gamma_{\mu}|4] = \frac{2e^2\,\langle 1\,3\rangle\,[4\,2]}{s}, \tag{58.150}$$

one line, gauge-invariant, with no spinor sum and no trace. The remaining three nonzero configurations follow by relabeling which end of each line is the angle and which the square. Negating both helicities on a line swaps angle↔square there; the four allowed assignments and their brackets, read off Eqs. (58.142) and (58.146), are

$$\begin{aligned} \mathcal{M}(1^-2^+3^-4^+) &= \tfrac{2e^2}{s}\,\langle 1\,3\rangle\,[4\,2], & \mathcal{M}(1^+2^-3^+4^-) &= \tfrac{2e^2}{s}\,[1\,3]\,\langle 4\,2\rangle, \\ \mathcal{M}(1^-2^+3^+4^-) &= \tfrac{2e^2}{s}\,\langle 1\,4\rangle\,[3\,2], & \mathcal{M}(1^+2^-3^-4^+) &= \tfrac{2e^2}{s}\,[1\,4]\,\langle 3\,2\rangle. \end{aligned} \tag{58.151}$$

All twelve other helicity assignments vanish: either a line would have equal helicities at its two ends (a forbidden same-chirality current, the spinor face of Theorem 17.18), or the photon would have to carry a helicity it cannot. The chirality bookkeeping that occupied Section 17.6.1 is here automatic—it is built into which spinor a current can hold.

Little-group audit. Before squaring, we check the amplitudes against the only constraint they must obey at this stage: little-group covariance. Under the scaling $\lambda_i \to t_i\lambda_i$, $\tilde\lambda_i \to t_i^{-1}\tilde\lambda_i$ of Eq. (58.5), a leg of helicity h_i must carry the weight $t_i^{-2h_i}$ (Theorem 58.16; this is the on-shell content of the helicity quantization Eq. (3.217)). Apply it to Eq. (58.150): $\langle 1\,3\rangle$ contributes one power of λ_1 and one of λ_3, $[4\,2]$ one power of $\tilde\lambda_4$ and one of $\tilde\lambda_2$, while the propagator $1/s_{12} = 1/(\langle 1\,2\rangle[2\,1])$ is little-group neutral on every leg (one λ_i and one $\tilde\lambda_i$ each for $i = 1,2$). The net weights are

$$t_1^{+1},\, t_2^{-1},\, t_3^{+1},\, t_4^{-1} \;=\; t_1^{-2h_1},\, t_2^{-2h_2},\, t_3^{-2h_3},\, t_4^{-2h_4} \quad \text{with} \quad (h_1,h_2,h_3,h_4) = (-\tfrac12,+\tfrac12,-\tfrac12,+\tfrac12) \tag{58.152}$$

exactly the helicities labeling $\mathcal{M}(1^-2^+3^-4^+)$. The other three amplitudes of Eq. (58.151) pass the same check with their respective labels: each bracket is forced to be the one it is by the requirement that leg i scale as $t_i^{-2h_i}$. The audit is not a derivation of the dynamics—the coupling e and the channel $1/s_{12}$ come from QED—but it certifies that the spinor structure is the unique one consistent with the stated helicities, which is precisely the organizing principle promised for the formalism.

Squaring, and the match to Chapter 17. Now square. Using Eq. (58.140), $|\langle 1\,3\rangle|^2 = |s_{13}| = |t|$ and $|[4\,2]|^2 = |s_{24}| = |t|$, so

$$\left|\mathcal{M}(1^-2^+3^-4^+)\right|^2 = \frac{4e^4}{s^2}\,\left|\langle 1\,3\rangle\right|^2\left|[4\,2]\right|^2 = \frac{4e^4}{s^2}\,|s_{13}|\,|s_{24}| = \frac{4e^4\,t^2}{s^2}. \tag{58.153}$$

The companion $(1^+2^-3^+4^-)$ gives the identical $4e^4t^2/s^2$, while the two "crossed" configurations $(1^-2^+3^+4^-)$ and $(1^+2^-3^-4^+)$ carry the invariants $s_{14} = s_{23} = u$ and so give $4e^4u^2/s^2$ each. Translating t, u to the scattering angle with Eq. (58.148), $t^2/s^2 = \tfrac{1}{4}(1-\cos\theta)^2$ and $u^2/s^2 = \tfrac{1}{4}(1+\cos\theta)^2$, hence

$$\begin{aligned}\left|\mathcal{M}(1^-2^+3^-4^+)\right|^2 &= \left|\mathcal{M}(1^+2^-3^+4^-)\right|^2 = e^4\,(1-\cos\theta)^2,\\ \left|\mathcal{M}(1^-2^+3^+4^-)\right|^2 &= \left|\mathcal{M}(1^+2^-3^-4^+)\right|^2 = e^4\,(1+\cos\theta)^2.\end{aligned} \tag{58.154}$$

These are the four numbers of Eq. (17.168), now obtained without a single gamma-matrix trace. The dictionary between the all-outgoing labels and the physical helicities of Chapter 17 is the crossing rule of the notation box: an incoming leg's physical helicity is minus its all-outgoing label, an outgoing leg's is equal to it. Thus $\mathcal{M}(1^-2^+3^+4^-)$ describes incoming e^- of helicity $+\frac{1}{2}$ (e^-_R), incoming e^+ of helicity $-\frac{1}{2}$ (e^+_L), outgoing μ^-_R, outgoing μ^+_L: the configuration $e^-_R e^+_L \to \mu^-_R \mu^+_L$, forward-peaked with $(1+\cos\theta)^2$, in exact agreement with Eq. (17.168). The reader may check the other three the same way: the two t^2 amplitudes are the backward-peaked J_z-flip channels, the two u^2 amplitudes the forward-peaked J_z-preserving ones, and the forbidden twelve are the spin assignments that Section 17.6.2 killed by angular-momentum conservation.

This is the worked computation that carries QED.

Worked Example 58.30 (The annihilation cross section from four brackets)**.** We assemble the unpolarized squared amplitude and recover the cross section of Chapter 17 term by term. The unpolarized $|\mathcal{M}|^2$ averages over the four initial spin states (factor $\frac{1}{4}$) and sums over the two final ones; since only the four entries of Eq. (58.154) are nonzero, the spin sum is just their total:

$$\overline{|\mathcal{M}|^2} = \frac{1}{4}\sum_{\text{hel}}|\mathcal{M}_h|^2 = \frac{1}{4}\,\frac{4e^4}{s^2}\Big(\underbrace{t^2+t^2}_{(1^\mp2^\pm3^\mp4^\pm)} + \underbrace{u^2+u^2}_{(1^\mp2^\pm3^\pm4^\mp)}\Big) = \frac{2e^4\,(t^2+u^2)}{s^2}. \tag{58.155}$$

Each of the four terms under the brace is a single squared bracket from Eq. (58.151); nothing has been contracted, traced, or expanded. Equation Eq. (58.155) is, term by term, the result $\overline{|\mathcal{M}|^2} = e^4(1+\cos^2\theta)$ of Eq. (17.169)—indeed $2e^4(t^2+u^2)/s^2 = 2e^4 \cdot \frac{1}{2}(1+\cos^2\theta) = e^4(1+\cos^2\theta)$ using $t^2+u^2 = \frac{s^2}{2}(1+\cos^2\theta)$—and it is the $s \leftrightarrow t$ crossed partner of the $e^-\mu^- \to e^-\mu^-$ amplitude $\overline{|\mathcal{M}|^2} = 2e^4(s^2+u^2)/t^2$ of Eq. (17.123), as the crossing audit of that chapter required.

To close the loop to an observable, feed Eq. (58.155) into the centre-of-mass differential cross section Theorem 16.23. With $\frac{d\sigma}{d\Omega} = \overline{|\mathcal{M}|^2}/(64\pi^2 s)$ for massless $2 \to 2$ scattering,

$$\frac{d\sigma}{d\Omega} = \frac{e^4(1+\cos^2\theta)}{64\pi^2 s} = \frac{\alpha^2}{4s}(1+\cos^2\theta), \qquad \sigma = \frac{4\pi\alpha^2}{3s}, \tag{58.156}$$

the textbook annihilation cross section, where the angular integral $\int(1+\cos^2\theta)\,d\Omega = \frac{16\pi}{3}$ supplies the total. The same number governs the high-energy total cross section through the optical theorem Theorem 16.28; here it has been produced from four one-line helicity amplitudes whose squares are literally $|t|^2$ and $|u|^2$.

It is worth pausing on what was avoided. The trace route of Section 17.3 and Theorem 17.19 formed the squared amplitude first, producing a product of two rank-two Lorentz tensors $L_e^{\mu\nu}M_{\mu\nu}^{\mu^\pm}$; evaluating it required the four-gamma trace, the γ^5 trace, a contraction of two Levi-Civita symbols (Eq. (17.164)), and a cancellation between symmetric and antisymmetric pieces, all to arrive at $16\,(p_-\cdot k_+)(p_+\cdot k_-)$. The helicity route never squares an amplitude until Eq. (58.153), and when it does, the square is the elementary $|\langle 1\,3\rangle|^2|[4\,2]|^2 = |s_{13}s_{24}|$. The Levi-Civita symbol, the workhorse and the hazard of the trace computation, has disappeared: its antisymmetric information is carried losslessly by the *relative phase* of the angle and square brackets, which is exactly the data that squaring throws away and that the trace had to reconstruct by brute force.

Physical Insight

The trace technology computes $\sum_{\text{spins}}|\mathcal{M}|^2$ as one object and discovers only at the end that it factorizes into a few helicity channels. The spinor-helicity formalism computes the channels first—each a single bracket fixed by little-group scaling—and adds their squares last. The two routes must agree, by unitarity of the spin sum, but the second exposes the structure the first conceals: that the answer was always a sum of squares of $d^1_{m'm}(\theta)$ rotation functions (Theorem 17.20), now read directly off $|s_{ij}|$. The $1+\cos^2\theta$ law is the incoherent sum of $|t|^2$ and $|u|^2$, nothing more.

58.6.3 Compton scattering and the reference-momentum trick

Annihilation has no internal photon polarization to manage; its simplification was driven entirely by the fermion currents. Compton scattering $e\gamma \to e\gamma$ is

the sharper test, because it has two Feynman diagrams whose individual gauge dependence is the source of most of the labor in Chapter 18. We show that a single judicious choice of reference momentum makes one diagram vanish outright, leaving a one-bracket answer, and that the answer is independent of every such choice.

Setup. Label, all outgoing,

$$1 = e^-, \quad 2 = e^+, \quad 3 = \gamma, \quad 4 = \gamma, \tag{58.157}$$

the two photons being legs $3, 4$. The two diagrams differ by the order in which the photons attach to the fermion line running from $\langle 1|$ to $|2]$ (Fig. 58.5). With the massless fermion propagator $i\not{P}/P^2$ and a vertex $ie\gamma^\mu$ at each photon, the amplitude is

$$\mathcal{M} = e^2 \, \langle 1| \Big[\not{\varepsilon}_3 \frac{\not{p}_1 + \not{p}_3}{s_{13}} \not{\varepsilon}_4 + \not{\varepsilon}_4 \frac{\not{p}_1 + \not{p}_4}{s_{14}} \not{\varepsilon}_3 \Big] |2], \tag{58.158}$$

up to an overall sign and factors of i that do not affect $|\mathcal{M}|^2$; the internal momenta are $-(p_1 + p_3)$ and $-(p_1 + p_4)$ with squares s_{13} and s_{14}. We take the helicity configuration with the electron line 1^-2^+ and the photons 3^-4^+; the others follow by conjugation and $3 \leftrightarrow 4$.

Polarization vectors and the trick. From the construction of Section 58.5.1, the slashed photon polarizations with reference momenta q_3, q_4 are

$$\not{\varepsilon}_4^+(p_4; q_4) = \frac{\sqrt{2}}{\langle q_4\, 4\rangle} \big(|4]\, \langle q_4| + |q_4\rangle\, [4| \big), \qquad \not{\varepsilon}_3^-(p_3; q_3) = \frac{\sqrt{2}}{[q_3\, 3]} \big(|3\rangle\, [q_3| + |q_3]\, \langle 3| \big), \tag{58.159}$$

the reference q_i being arbitrary (any momentum with $\langle q_4\, 4\rangle \neq 0$, $[q_3\, 3] \neq 0$). Their freedom is the gauge freedom of Eq. (58.127): changing q_i shifts ε_i^μ by a multiple of p_i^μ. We exploit it. Choose

$$q_4 = p_1. \tag{58.160}$$

Then $\langle 1|\, \not{\varepsilon}_4^+ = \frac{\sqrt{2}}{\langle 1\, 4\rangle} \big(\langle 1|\, |4]\, \langle 1| + \langle 1\, 1\rangle [4| \big) = 0$, because $\langle 1|\, |4] = \langle 1|4] = 0$ (an angle bra cannot contract a square ket) and $\langle 1\, 1\rangle = 0$. The polarization ε_4^+ has been aligned so that it is annihilated by the spinor at the end of the line it would attach to in the *second* diagram of Eq. (58.158). That diagram—the one with $\not{\varepsilon}_4$ adjacent to $\langle 1|$—vanishes identically. Only the first survives, and the two-diagram amplitude collapses to one term.

The surviving term. Take $q_3 = p_1$ as well; we will see the answer does not depend on this. Push $\langle 1|$ through $\not{\varepsilon}_3^-$:

$$\langle 1|\, \not{\varepsilon}_3^- = \frac{\sqrt{2}}{[1\, 3]} \big(\langle 1\, 3\rangle [1| + \langle 1|\, |1]\, \langle 3| \big) = \frac{\sqrt{2}\, \langle 1\, 3\rangle}{[1\, 3]}\, [1|, \tag{58.161}$$

Figure 58.5: The two tree diagrams for Compton scattering $\mathcal{M}(1^-2^+3^-4^+)$ in the all-outgoing labeling of Eq. (58.157), differing by the order in which the photons $3, 4$ attach to the fermion line. With the reference momentum choice $q_4 = p_1$ of Eq. (58.160), the right diagram (photon 4 adjacent to the $\langle 1|$ end) vanishes because $\langle 1|\not{\varepsilon}_4^+ = 0$, and the entire amplitude collapses to the left diagram, Eq. (58.164). A different reference choice redistributes the labor between the two diagrams but leaves their sum unchanged (Eq. (58.165)).

using $\langle 1|\,|1] = 0$. Next act on the propagator numerator. Since $[1|\not{p}_1 = 0$ (both $[1|\,|1\rangle$ and $[1||1] = [1\,1]$ vanish) and $[1|\not{p}_3 = [1\,3]\,\langle 3|$,

$$[1|\,(\not{p}_1+\not{p}_3) = [1\,3]\,\langle 3|\,, \qquad \Longrightarrow \qquad \langle 1|\,\not{\varepsilon}_3^-\,\frac{\not{p}_1+\not{p}_3}{s_{13}} = \frac{\sqrt{2}\,\langle 1\,3\rangle}{[1\,3]}\cdot\frac{[1\,3]\,\langle 3|}{s_{13}} = \frac{\sqrt{2}\,\langle 1\,3\rangle}{s_{13}}\,\langle 3|\,, \tag{58.162}$$

the reference factor $[1\,3]$ cancelling cleanly between the polarization denominator and the propagator numerator. Finally contract with $\not{\varepsilon}_4^+|2]$. From Eqs. (58.159) and (58.160),

$$\langle 3|\,\not{\varepsilon}_4^+ = \frac{\sqrt{2}}{\langle 1\,4\rangle}\big(\langle 3|\,|4]\,\langle 1| + \langle 3\,1\rangle[4|\big) = \frac{\sqrt{2}\,\langle 3\,1\rangle}{\langle 1\,4\rangle}\,[4|, \qquad \langle 3|\,\not{\varepsilon}_4^+|2] = \frac{\sqrt{2}\,\langle 3\,1\rangle\,[4\,2]}{\langle 1\,4\rangle}. \tag{58.163}$$

Multiplying the pieces and restoring the coupling,

$$\mathcal{M}(1^-2^+3^-4^+) = e^2\cdot\frac{\sqrt{2}\,\langle 1\,3\rangle}{s_{13}}\cdot\frac{\sqrt{2}\,\langle 3\,1\rangle\,[4\,2]}{\langle 1\,4\rangle} = -\,\frac{2e^2\,\langle 1\,3\rangle^2\,[4\,2]}{s_{13}\,\langle 1\,4\rangle}, \tag{58.164}$$

where $\langle 1\,3\rangle\langle 3\,1\rangle = -\langle 1\,3\rangle^2$. Using $s_{13} = \langle 1\,3\rangle[3\,1]$ this is equivalently $\mathcal{M}(1^-2^+3^-4^+) = -2e^2\,\langle 1\,3\rangle\,[4\,2]/([3\,1]\,\langle 1\,4\rangle)$. The two diagrams of Eq. (58.158), each a gauge-dependent tangle of the kind Chapter 18 squares and traces over four pages, have become a single ratio of brackets.

Reference independence. Two arguments establish that Eq. (58.164) is the physical amplitude, independent of the gauge choices q_3, q_4.

First, the structural reason. The amplitude depends on each photon polarization linearly, $\mathcal{M} = \varepsilon_{i\mu}\,\mathcal{M}^\mu_{(i)}$ with $\mathcal{M}^\mu_{(i)}$ the current with leg i's polarization stripped. Changing the reference $q_i \to q_i'$ shifts $\varepsilon_i^\mu \to \varepsilon_i^\mu + \beta\,p_i^\mu$ for a scalar β (Eq. (58.127)), so the amplitude changes by $\beta\,p_{i\mu}\mathcal{M}^\mu_{(i)}$, which vanishes by the tree-level QED Ward identity of Eq. (18.62): the sum of the two diagrams, contracted

with the photon momentum, is zero. Reference independence is therefore not an accident of the choice $q_4 = p_1$ but a theorem, equivalent to gauge invariance.

Second, an explicit check. Keep $q_4 = p_1$ but take $q_3 = p_4$ instead of p_1. The surviving (left) diagram now begins $\langle 1|\,\not{\epsilon}_3^-(q_3 = p_4) = \frac{\sqrt{2}}{[4\,3]}\big(\langle 1\,3\rangle[4| + \langle 1|\,|4]\,\langle 3|\big) = \frac{\sqrt{2}\,\langle 1\,3\rangle}{[4\,3]}\,[4|$, and then $[4|(\not{p}_1 + \not{p}_3) = [4\,1]\,\langle 1| + [4\,3]\,\langle 3|$. Acting with $\not{\epsilon}_4^+(q_4 = p_1)$ kills the $\langle 1|$ piece ($\langle 1|\,\not{\epsilon}_4^+ = 0$) and leaves $[4\,3]\,\langle 3|\,\not{\epsilon}_4^+|2] = [4\,3]\cdot\sqrt{2}\,\langle 3\,1\rangle[4\,2]/\langle 1\,4\rangle$. Collecting,

$$\mathcal{M}(1^-2^+3^-4^+)\Big|_{q_3=p_4} = e^2\cdot\frac{\sqrt{2}\,\langle 1\,3\rangle}{[4\,3]\,s_{13}}\cdot[4\,3]\cdot\frac{\sqrt{2}\,\langle 3\,1\rangle\,[4\,2]}{\langle 1\,4\rangle} = -\,\frac{2e^2\,\langle 1\,3\rangle^2\,[4\,2]}{s_{13}\,\langle 1\,4\rangle}, \tag{58.165}$$

since $[4\,3]$ cancels between numerator and denominator and $\langle 1\,3\rangle\langle 3\,1\rangle = -\langle 1\,3\rangle^2$. The result is identical to Eq. (58.164), although the algebra ran through different intermediate spinors. The reference momentum is genuine gauge freedom: visible in every line of the computation, invisible in the answer.

The squared amplitude and the Compton cross section. Squaring Eq. (58.164) with Eq. (58.140) and $s_{24} = s_{13}$,

$$\big|\mathcal{M}(1^-2^+3^-4^+)\big|^2 = 4e^4\,\frac{\big|\langle 1\,3\rangle\big|^4\big|[4\,2]\big|^2}{s_{13}^2\,\big|\langle 1\,4\rangle\big|^2} = 4e^4\,\frac{|s_{13}|^2\,|s_{24}|}{s_{13}^2\,|s_{14}|} = 4e^4\,\frac{|s_{13}|}{|s_{14}|}. \tag{58.166}$$

The amplitude squared is a bare *ratio* of Mandelstam invariants—the signature of Compton scattering, whose cross section is famously built from s/u and u/s. The nonzero helicity configurations are the four with opposite photon helicities (equal photon helicities give the all-plus/all-minus amplitudes, which vanish for a massless fermion line—the abelian shadow of the maximally-helicity-violating selection rule that organizes the gluon amplitudes of Chapter 59). Their squares are $4e^4|s_{13}|/|s_{14}|$ twice and the $3 \leftrightarrow 4$ image $4e^4|s_{14}|/|s_{13}|$ twice, so averaging over the two electron spins and two incoming photon polarizations,

$$\overline{|\mathcal{M}|^2} = \frac{1}{4}\Big(2\cdot 4e^4\frac{|s_{13}|}{|s_{14}|} + 2\cdot 4e^4\frac{|s_{14}|}{|s_{13}|}\Big) = 2e^4\Big(\frac{|s_{13}|}{|s_{14}|} + \frac{|s_{14}|}{|s_{13}|}\Big). \tag{58.167}$$

Under the crossing back to physical kinematics, $|s_{13}|$ and $|s_{14}|$ become the physical s- and u-channel invariants of Compton scattering (the legs $1, 3$ that share a propagator pole in the left diagram of Fig. 58.5 forming the physical s-channel), and Eq. (58.167) is exactly the massless limit $m \to 0$ of the Klein–Nishina squared amplitude Eq. (18.81),

$$\overline{|\mathcal{M}|^2} \xrightarrow{m\to 0} 2e^4\Big(\frac{-u}{s} + \frac{s}{-u}\Big), \tag{58.168}$$

which fed the Klein–Nishina differential cross section Eq. (18.92). The two diagrams that Chapter 18 added, squared, traced, and contracted to reach Eq. (18.81) have here been reduced to one bracket per helicity by a single line of gauge fixing.

58.6.4 What the reframing bought, and what it points to

The two computations make the chapter's thesis concrete on the book's own examples. In annihilation, the entire spin structure—which configurations survive, which vanish, and the $(1 \pm \cos\theta)^2$ shapes of those that survive—was carried by the choice of which spinor each current holds, fixed in turn by little-group covariance Eq. (58.152); the trace, the γ^5, and the Levi-Civita contraction of Chapter 17 never appeared. In Compton, the gauge dependence that forces the off-shell, multi-term bookkeeping of Chapter 18 was localized in the reference momenta and then removed by hand, collapsing two diagrams to one. In both cases the carried QED numbers—$\overline{|\mathcal{M}|^2} = 2e^4(t^2+u^2)/s^2$ for annihilation, the Klein–Nishina ratio for Compton—came back unchanged, which is the only acceptable outcome: the formalism is a more efficient bookkeeping of the same physics, not a new physics.

Two features of these QED amplitudes deserve a final word, because they are exactly the connections along which Chapter 59 cuts. First, the QED amplitudes carried no color: the single trace that organizes the gluon amplitudes of Section 59.1 is, in the abelian case, just unity, and the "decoupling" of the abelian photon proved there (Theorem 59.6) is the statement that the photon in this section never self-interacts. Stripping color from a non-abelian amplitude is what will leave behind a color-ordered partial amplitude as kinematically simple as the QED currents we just computed. Second, the vanishing of the equal-helicity Compton amplitudes is the two-photon instance of a vast pattern: in pure Yang–Mills the all-plus and single-minus gluon amplitudes vanish identically, and the first nonzero amplitudes—the maximally-helicity-violating ones—are a single ratio of brackets, the Parke–Taylor formula. The next section assembles the last pieces Chapter 59 needs, the color-ordered partial amplitude and the gluon three-point in final form, and confronts the question this success raises: how much of the one-line miracle survives when the gauge group is non-abelian and the external particles carry spin one.

58.7 Color ordering, gluons, and the massive frontier: handoff to recursion

The reframing of QED in the previous section turned a page of traces over Dirac matrices into one-line helicity amplitudes; the same compression is waiting for the gluons of Yang–Mills theory, but one structural obstacle stands between us and it. A photon carries no charge, so the QED amplitudes were pure kinematics. A gluon carries adjoint color, and every Yang–Mills vertex (Eq. (25.76)) drags a structure constant f^{abc} along with its Lorentz tensor. If we are to apply the spinor-helicity machinery built in this chapter — the brackets of Theorem 58.2, the little-group scaling of Section 58.3, the polarization vectors of Eq. (58.111) —

we must first separate the color, which knows nothing of momenta or helicities, from the kinematics, which is where all the simplicity hides. The good news, and the organizing observation of this final section, is that at tree level the two factor *cleanly*: the entire color dependence of an n-gluon amplitude collapses onto a basis of single traces of generators, one per cyclic ordering of the external legs, and the coefficient of each trace is a separately gauge-invariant kinematic object — the *color-ordered partial amplitude*. Once color is peeled off in this way, a gluon amplitude becomes, leg for leg, as tractable as a photon amplitude, and the spinor-helicity variables act on it exactly as they did in QED.

This section assembles the pieces that the recursion of Chapter 59 will pick up and run with. We perform the trace decomposition and prove the three properties of partial amplitudes that recursion must respect — cyclicity, reflection, and the $U(1)$ decoupling identity. We put the gluon three-point amplitude, already fixed by little-group scaling alone in Eq. (58.98), into its final color-ordered form, the seed from which everything in Chapter 59 is grown. We state the Parke–Taylor formula honestly as the destination and subject it to the consistency checks the formalism affords, deferring its proof to the next chapter where the recursion that earns it is built. Finally, because a chapter that stopped at massless particles would be artificially incomplete, we state the massive extension of spinor-helicity — the bold-spinor formalism of Arkani-Hamed, Huang, and Huang — at the definitional level, and close with a map of the route through Part XVI.

58.7.1 The trace color decomposition

We work with the SU(N) generators T^a in the fundamental, Hermitian, with the book-canonical normalization $\left[T^a, T^b\right] = i f^{abc} T^c$ and $\mathrm{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$ (Eq. (B.2)). The whole decomposition rests on a single algebraic identity, which rewrites a structure constant as a difference of traces and so converts the f's at the vertices into the trace language we want.

Lemma 58.31 (Structure constant as a trace)**.** *With the canonical normalization above,*

$$f^{abc} = -2i\,\big(\,\mathrm{tr}(T^a T^b T^c) - \mathrm{tr}(T^a T^c T^b)\big). \tag{58.169}$$

Proof. Multiply the Lie bracket $\left[T^a, T^b\right] = i f^{abd} T^d$ on the right by T^c and take the trace. Using $\mathrm{tr}(T^d T^c) = \frac{1}{2}\delta^{dc}$,

$$\mathrm{tr}\big(\left[T^a, T^b\right] T^c\big) = i f^{abd}\,\mathrm{tr}(T^d T^c) = \tfrac{i}{2}\, f^{abc}. \tag{58.170}$$

The left side is $\mathrm{tr}(T^a T^b T^c) - \mathrm{tr}(T^b T^a T^c)$, and cyclicity of the trace gives $\mathrm{tr}(T^b T^a T^c) = \mathrm{tr}(T^a T^c T^b)$, so the left side equals $\mathrm{tr}(T^a T^b T^c) - \mathrm{tr}(T^a T^c T^b)$. Solving Eq. (58.170) for f^{abc} yields Eq. (58.169). □

In color space every tree diagram built from the Yang–Mills vertices is a fully contracted product of structure constants — one f per cubic vertex, two per quartic — with the adjoint indices of internal lines paired through the propagator's δ^{ab} and the external indices $a_1, \dots, a_n$ left free; the kinematic factor (the contraction of metrics, momenta, and polarizations) rides alongside, multiplied, and the two never mix. Inserting Eq. (58.169) at each vertex turns each diagram's color factor into a sum of products of traces of the external generators, sewn along internal lines by the SU(N) completeness relation. The cleanest way to see what survives is to enlarge the gauge group momentarily from SU(N) to U(N), adjoining the trace generator $T^0 = \frac{1}{\sqrt{N}}\,\mathbf{1}$. The U($N$) completeness relation carries no trace subtraction,

$$\sum_{A=0}^{N^2-1} (T^A)_i{}^j\,(T^A)_k{}^l = \delta_i^{\,l}\,\delta_k^{\,j}, \tag{58.171}$$

the indices simply being interchanged. Two facts make this legitimate. First, the extra abelian boson T^0 decouples from gluons: its structure constant $f^{0bc} \propto \mathrm{tr}(\big[\mathbf{1}, T^b\big]\,T^c) = 0$ because the identity commutes with everything, so no internal T^0 can appear on a pure-gluon line and the SU(N) and U(N) computations coincide. Second, in the U(N) basis the sewing Eq. (58.171) has a transparent graphical meaning: drawing each adjoint line as a pair of antiparallel fundamental color lines (the double-line notation), the completeness relation joins the fundamental lines of an internal gluon end to end. Because a *tree* has no momentum loop, the joined color lines can neither cross nor close among themselves except along the single outer boundary; they merge into exactly one closed fundamental loop, and that loop *is* a single trace $\mathrm{tr}(T^{a_{i_1}} \cdots T^{a_{i_n}})$, with the ordering read off the planar embedding. No second closed loop, and hence no double-trace term, can arise without a momentum loop. Collecting diagrams by their trace gives the decomposition.

Theorem 58.32 (Tree-level color decomposition)**.** *The full n-gluon tree amplitude, with external adjoint labels $a_1, \dots, a_n$, decomposes as*

$$\mathcal{A}_n^{\text{tree}}(\{p_i, \epsilon_i, a_i\}) = g^{\,n-2} \sum_{\sigma \in S_{n-1}} \mathrm{tr}(T^{a_1} T^{a_{\sigma(2)}} \cdots T^{a_{\sigma(n)}})\; A_n[1, \sigma(2), \dots, \sigma(n)], \tag{58.172}$$

where the sum runs over the $(n-1)!$ permutations σ of $\{2, \dots, n\}$ (leg 1 held fixed by trace cyclicity), and the kinematic coefficients $A_n[1, \sigma]$ — the color-ordered partial amplitudes *— carry no color, depend only on momenta and polarizations, and are separately gauge invariant.*

Proof. The double-line argument establishes that in the U(N) basis every tree diagram's color factor is a single trace of the external generators in the cyclic order of the planar embedding, times a color-free kinematic factor. Grouping diagrams

by their trace gives $\mathcal{A}_n^{\text{tree}} = g^{n-2}\sum_{\text{orderings}} \text{tr}(\cdots)\, A_n[\cdots]$, where A_n collects the kinematic factors of all diagrams sharing that ordering. The coupling power is g^{n-2} because a tree with V_3 cubic and V_4 quartic vertices carries $g^{V_3+2V_4} = g^{n-2}$, the relation $V_3 + 2V_4 = n - 2$ following from the tree identities $V_3 + V_4 = I + 1$ and $3V_3 + 4V_4 = 2I + n$ for the number I of internal lines. Trace cyclicity rotates leg 1 to the front of every trace, identifying the independent orderings with permutations of $\{2, \ldots, n\}$ and giving the $(n-1)!$ terms. Because the computation was done in $\text{U}(N)$ with T^0 inert, it equals the genuine $\text{SU}(N)$ amplitude: the $\frac{1}{N}$ trace-subtraction terms of the $\text{SU}(N)$ completeness relation, which would have produced multi-trace structures, are precisely the ones that cancel because the abelian photon decouples (Theorem 58.35). Finally each $A_n[1, \sigma]$ is gauge invariant: $\mathcal{A}_n^{\text{tree}}$ is, the traces are linearly independent functions of the external labels (and the A_n are kinematic objects defined independently of N), so a gauge variation that vanishes for all $\{a_i\}$ forces each coefficient to vanish separately. □

Definition 58.33 (Color-ordered partial amplitude)**.** The coefficient $A_n[1, 2, \ldots, n]$ multiplying the trace $\text{tr}(T^{a_1}T^{a_2}\cdots T^{a_n})$ in Eq. (58.172) is the *color-ordered partial amplitude* for the cyclic ordering $(1, 2, \ldots, n)$. It is computed by summing only those Feynman diagrams whose external legs can be drawn in the plane in the order $1, 2, \ldots, n$, using color-stripped vertices in which legs connect in cyclic adjacency.

This is the object the whole of Chapter 59 computes; there it is taken as the starting point and the same decomposition is restated as Theorem 59.3. Every statement we make below about gluon amplitudes — vanishing helicity configurations, the three-point seed, Parke–Taylor, BCFW recursion — is a statement about a single $A_n[1, \ldots, n]$, with the full amplitude reassembled at the end by dressing each ordering with its trace and summing.

58.7.2 Properties of the partial amplitudes

Three exact properties of the A_n follow directly from the decomposition. They are not incidental: they are precisely the constraints that the recursion of Chapter 59 is built to respect, and any candidate formula for an A_n must satisfy them.

Cyclicity. Because $A_n[1, 2, \ldots, n]$ is, by Theorem 58.33, the coefficient of the cyclic trace $\text{tr}(T^{a_1}\cdots T^{a_n})$, and the trace is invariant under cyclic rotation of its arguments, the partial amplitude is invariant under cyclic rotation of its labels,

$$A_n[1, 2, \ldots, n] = A_n[2, 3, \ldots, n, 1] = A_n[3, \ldots, n, 1, 2] = \cdots . \tag{58.173}$$

This is why holding leg 1 fixed in Eq. (58.172) loses nothing.

Reflection. Reversing the entire ordering produces a definite sign,

$$A_n[n, n-1, \dots, 2, 1] = (-1)^n \, A_n[1, 2, \dots, n]. \tag{58.174}$$

Proposition 58.34 (Reflection identity)**.** *The color-ordered partial amplitude obeys Eq. (58.174).*

Proof. Track the sign each ingredient of a planar diagram acquires under reversal of the cyclic order, which reverses the Lorentz labels and momenta on every vertex. The color-stripped propagator $-i\eta_{\mu\nu}/p^2$ is symmetric in its indices and even in momentum, hence invariant. The color-ordered cubic vertex Eq. (58.177) below is linear in the momentum differences, and under reversal of its three legs each momentum difference $p_i - p_j$ maps to its negative while the metric factors permute among themselves; the three terms reassemble into $-V_3$, so each cubic vertex contributes a factor -1. The color-ordered quartic vertex is momentum-independent and maps to itself under reversal, contributing $+1$. A planar diagram with V_3 cubic vertices therefore acquires $(-1)^{V_3}$. This sign is common to every diagram of a given A_n because V_3 has a fixed parity: from $3V_3 + 4V_4 = 2I + n$ and $V_3 + V_4 = I + 1$ one finds $V_3 = n - 2 - 2V_4 \equiv n \pmod 2$, so $(-1)^{V_3} = (-1)^n$ independently of how vertices are apportioned. Every diagram for $A_n[1, \dots, n]$ thus maps under reversal to the corresponding diagram for $A_n[n, \dots, 1]$ times the common factor $(-1)^n$, which is Eq. (58.174). □

The $U(1)$ decoupling identity. The third property is the cleanest linear relation among partial amplitudes, and it is the same fact — the decoupling of the abelian photon — that we invoked in proving Theorem 58.32.

Theorem 58.35 ($U(1)$ decoupling / photon-decoupling identity)**.** *The sum of $A_n[1, \sigma]$ over the $n-1$ inequivalent positions into which leg 1 may be inserted while holding the cyclic order of $2, 3, \dots, n$ fixed vanishes,*

$$A_n[1,2,3,\dots,n] + A_n[2,1,3,\dots,n] + A_n[2,3,1,4,\dots,n] + \cdots + A_n[2,3,\dots,n,1] = 0. \tag{58.175}$$

For $n = 4$, after rotating leg 1 to the front of each term by cyclicity,

$$A_4[1,2,3,4] + A_4[1,3,4,2] + A_4[1,4,2,3] = 0. \tag{58.176}$$

Proof. Compute the U(N) amplitude in which leg 1 is the abelian photon $T^0 = \frac{1}{\sqrt{N}}\mathbf{1}$ and legs $2, \dots, n$ are ordinary gluons. The photon decouples ($f^{0bc} = 0$), so no vertex couples it and the amplitude vanishes identically. Now evaluate the same amplitude through Eq. (58.172) by setting $T^{a_1} = \frac{1}{\sqrt{N}}\mathbf{1}$ in every trace. Because $\mathbf{1}$ can be slid to any position and removed, $\mathrm{tr}(\mathbf{1}\, T^{a_{\sigma(2)}} \cdots) = \mathrm{tr}(T^{a_{\sigma(2)}} \cdots)$, every trace collapses to a trace of the $n-1$ gluon generators alone. Orderings that differ only by where leg 1 sat collapse to the same reduced trace, so the coefficient

of each independent reduced trace $\mathrm{tr}(T^{a_2}\cdots T^{a_n})$ is exactly the sum of partial amplitudes over all insertion positions of leg 1. The reduced traces are linearly independent and the total vanishes, so each such coefficient vanishes, which is Eq. (58.175). □

Cyclicity and reflection generate the dihedral group of order $2n$ on the orderings, so the $(n-1)!$ traces fall into orbits and the genuinely independent partial amplitudes number roughly $(n-1)!/2$; the decoupling identity Eq. (58.175) cuts this further by expressing one partial amplitude as a combination of others. Stronger linear relations exist — the Kleiss–Kuijf relations reduce the basis to $(n-2)!$, and the BCJ relations of the double-copy story (Chapter 61) to $(n-3)!$ — but the three properties above are all the recursion of Chapter 59 needs as built-in consistency conditions, and they are the ones we have proved here from the decomposition itself.

58.7.3 The gluon three-point amplitude in final form

We now have everything required to write the seed of the entire recursion: the color-ordered three-gluon amplitude. Stripping the color from the Yang–Mills cubic vertex Eq. (26.53) by inserting Eq. (58.169) and retaining the coefficient of the single ordered trace $\mathrm{tr}(T^{a_1}T^{a_2}T^{a_3})$, with all momenta outgoing ($p_1+p_2+p_3=0$) and legs in the cyclic order $1,2,3$, gives the color-ordered cubic vertex

$$V_3^{\mu_1\mu_2\mu_3}(p_1,p_2,p_3)=\frac{i\,g}{\sqrt{2}}\Big(\eta^{\mu_1\mu_2}(p_1-p_2)^{\mu_3}+\eta^{\mu_2\mu_3}(p_2-p_3)^{\mu_1}+\eta^{\mu_3\mu_1}(p_3-p_1)^{\mu_2}\Big). \tag{58.177}$$

This is the lone diagram at three points. Contracting it with the spinor-helicity polarization vectors Eq. (58.111) and using the three-point amplitudes already fixed by little-group scaling in Eq. (58.98) — where we showed that Lorentz invariance, locality, and the helicity weights of Eq. (58.5) determine the three-point amplitude up to its overall constant, with the holomorphic and antiholomorphic solutions selected by the sign of the total helicity — the color-ordered three-gluon amplitude takes its final form,

$$A_3[1^-,2^-,3^+]=i\,g\,\frac{\langle 1\,2\rangle^3}{\langle 2\,3\rangle\langle 3\,1\rangle}, \tag{58.178}$$

$$A_3[1^+,2^+,3^-]=-\,i\,g\,\frac{[1\,2]^3}{[2\,3][3\,1]}. \tag{58.179}$$

The first is purely holomorphic (only angle brackets), the second purely antiholomorphic (only square brackets); they are exchanged by parity $\langle\,\rangle\leftrightarrow[\,]$, which exchanges all helicities. Each carries the correct little-group weight: in Eq. (58.178) leg 1 (helicity -1) appears net t_1^{+2} (three powers up in the numerator, one down in the denominator), and leg 3 (helicity $+1$) appears t_3^{-2}, matching the required $t_k^{-2h_k}$ on every leg.

Caution

For *real* momenta the angle and square spinors are complex conjugates up to a sign, $\tilde{\lambda} = \pm\lambda^*$ (Theorem 58.2), so $\langle i\,j\rangle = 0 \Leftrightarrow [i\,j] = 0$. The three-point kinematics $p_1 + p_2 + p_3 = 0$ with all legs on shell forces every Mandelstam $s_{ij} = \langle i\,j\rangle[j\,i]$ to vanish (each equals the square of the third, null, momentum), so on the real slice *all* brackets vanish together and both Eqs. (58.178) and (58.179) are $0/0$. They are nonzero only when λ and $\tilde{\lambda}$ are independent — that is, for *complex* momenta, where $\langle i\,j\rangle$ can be generic while every $[i\,j] = 0$ (the holomorphic branch) or vice versa. This is not a pathology to be regretted but the very feature exploited in Chapter 59: the BCFW recursion deforms external momenta into the complex domain precisely so that these three-point amplitudes become meaningful building blocks.

Equations Eqs. (58.178) and (58.179) are the three-gluon seed handed to Chapter 59. Read on-shell recursion backwards: every higher-point gluon tree is assembled from these two atoms glued across factorization channels. That a one-line pair of expressions, fixed almost entirely by symmetry, should generate the whole tree-level S-matrix of Yang–Mills theory is the central promise of the next chapter.

58.7.4 Parke–Taylor: the destination

We can now name the target honestly. For the maximally-helicity-violating (MHV) amplitude — n gluons of which exactly two, legs i and j, carry negative helicity and the rest positive — the color-ordered partial amplitude is, for *every* n, the single ratio discovered by Parke and Taylor in 1986,

$$A_n^{\mathrm{MHV}}[1,2,\ldots,n] = i\,g^{\,n-2}\,\frac{\langle i\,j\rangle^4}{\langle 1\,2\rangle\langle 2\,3\rangle\cdots\langle n-1\,n\rangle\langle n\,1\rangle}. \tag{58.180}$$

The denominator is the cyclic Parke–Taylor chain $\prod_{k=1}^{n}\langle k\,k+1\rangle$ (with $n+1 \equiv 1$): the same for every MHV amplitude of the given color ordering, while the numerator $\langle i\,j\rangle^4$ records which two legs are negative. The expression is purely holomorphic — not a single square bracket — which is the analytic fingerprint of the MHV sector, and it collapses, at $n = 3$ with negative legs $1, 2$, exactly to the three-gluon seed Eq. (58.178): $i\,g\,\langle 1\,2\rangle^4/(\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,1\rangle) = i\,g\,\langle 1\,2\rangle^3/(\langle 2\,3\rangle\langle 3\,1\rangle)$. The parity conjugate, the $\overline{\mathrm{MHV}}$ amplitude with exactly two positive legs, is the antiholomorphic mirror obtained by $\langle\,\rangle \to [\,]$.

We state Eq. (58.180) here as the goal and *defer its proof to Chapter 59*, where it appears as Eq. (59.55): a brute-force Feynman computation at four points pins the constant, and BCFW recursion (Theorem 59.23) lifts the four-point result to all n. What we *can* do now, with the symmetry technology of this chapter,

is verify that Eq. (58.180) has the right *form* — the correct little-group weight on every leg, the correct mass dimension, and the correct power of the coupling. These are genuine constraints; an expression failing any of them could not be a gluon amplitude, and passing all of them nearly fixes the formula, leaving only the overall constant and the residues on factorization channels for the explicit computation of Chapter 59.

Worked Example 58.36 (Consistency checks on the Parke–Taylor formula)**.** We test Eq. (58.180) against the three invariants every n-gluon amplitude must respect.

Little-group weight. Under the scaling of leg k (Eq. (58.5)), $\lambda_k \to t_k \lambda_k$, $\tilde{\lambda}_k \to t_k^{-1}\tilde{\lambda}_k$, a leg of helicity h_k requires the amplitude to scale as $A_n \to (\prod_k t_k^{-2h_k}) A_n$. The angle bracket $\langle k\,\cdot\rangle$ scales as t_k; square brackets are absent, so a leg's weight is read off by counting its angle brackets. A *positive* leg $k \neq i, j$ appears nowhere in the numerator and in exactly two chain factors, $\langle k-1\,k\rangle$ and $\langle k\,k+1\rangle$, giving t_k^{-2}; with $h_k = +1$ this is $t_k^{-2h_k}$, as required. A *negative* leg, say i, appears four times in $\langle i\,j\rangle^4$ (weight t_i^{+4}) and twice in the chain (weight t_i^{-2}), net t_i^{+2}; with $h_i = -1$ this is again $t_i^{-2h_i}$. Every leg is correct — and the numerator power must be *exactly four*: $\langle i\,j\rangle^3$ or $\langle i\,j\rangle^5$ would spoil the negative legs. Little-group scaling alone fixes the numerator to $\langle i\,j\rangle^4$.

Mass dimension. In four dimensions an n-point amplitude (with the overall momentum-conserving delta function stripped) has mass dimension $4-n$. Each angle bracket has mass dimension 1 (since $\langle i\,j\rangle[j\,i] = s_{ij}$ has dimension 2). The numerator $\langle i\,j\rangle^4$ contributes $+4$, the n-factor chain contributes $-n$, and g^{n-2} is dimensionless in four dimensions, for a total of $4-n$. Correct.

Coupling power. A connected tree with only cubic and quartic vertices and n external legs carries $V_3 + 2V_4 = n-2$ powers of g, the same counting that gave the g^{n-2} of Eq. (58.172). The prefactor in Eq. (58.180) matches exactly, and the explicit i is the standard tree normalization, consistent with the three-point seed Eq. (58.178).

These checks pin down the form almost completely: a holomorphic, cyclic, dimension-$(4-n)$ object with the correct little-group weight and power of g is forced to be a constant times Eq. (58.180). What they cannot fix is that constant nor the factorization residues; for those, Chapter 59 computes.

58.7.5 The massive frontier: bold spinors

Everything in this chapter has been built for massless particles, where the little group is the abelian U(1) of Theorem 3.43 and a state is labelled by a single helicity weight. This is the right setting for gluons and photons, and it is where the formalism is most powerful, but it would leave a false impression to stop here: spinor-helicity is not intrinsically massless. The massless variables exploit the fact that a null momentum's 2×2 bispinor $p_{\alpha\dot{\alpha}} = \lambda_\alpha \tilde{\lambda}_{\dot{\alpha}}$ has rank one and so

factorizes into a single pair of spinors. A *massive* momentum, with $p^2 = m^2$, has a bispinor of rank two, $\det(p_{\alpha\dot\alpha}) = m^2 \neq 0$, and so cannot be written with one spinor on each side — but it can be written with *two*.

The honest completion to massive particles is the formalism of Arkani-Hamed, Huang, and Huang, a mid-2010s development (2017) that is now standard but still actively driving research, and which we state here at the definitional level. By the Wigner classification (Theorem 3.43), the little group of a massive particle in four dimensions is $\mathrm{SO}(3) \simeq \mathrm{SU}(2)$, not $\mathrm{U}(1)$; a massive state of spin s furnishes a $(2s+1)$-dimensional representation. The corresponding on-shell variables carry an $\mathrm{SU}(2)$ little-group index. One factorizes the massive bispinor as

$$p_{\alpha\dot\alpha} = \lambda_\alpha^I \, \tilde\lambda_{\dot\alpha\, I}, \qquad I = 1, 2, \tag{58.181}$$

with the little-group index I summed (raised and lowered by the antisymmetric ϵ_{IJ}). The pair of spinors λ_α^I form a 2×2 matrix whose determinant encodes the mass; equivalently, the $\mathrm{SU}(2)$-covariant brackets of the *bold* spinors $\left|\mathbf{p}^I\right\rangle$, $|\mathbf{p}^I]$ obey, for a single leg,

$$\langle \mathbf{p}^I \, \mathbf{p}^J \rangle = m\, \epsilon^{IJ}, \qquad [\mathbf{p}^I \, \mathbf{p}^J] = -\, m\, \epsilon^{IJ}, \tag{58.182}$$

the mass appearing exactly where, in the massless case, the rank-one condition set the analogous bracket to zero. The massless limit is transparent: as $m \to 0$ the two columns λ^1, λ^2 become proportional, the matrix degenerates to rank one, the $\mathrm{SU}(2)$ index collapses, and Eq. (58.181) reduces to the single-spinor factorization $p_{\alpha\dot\alpha} = \lambda_\alpha \tilde\lambda_{\dot\alpha}$ of Theorem 58.2, with the $\mathrm{SU}(2)$ multiplet splitting into the $\mathrm{U}(1)$ helicity weights.

Definition 58.37 (Massive (bold) spinor-helicity variables)**.** A massive momentum p ($p^2 = m^2$) is represented by bold spinors λ_α^I, $\tilde\lambda_{\dot\alpha}^I$ carrying a fundamental $\mathrm{SU}(2)$ little-group index $I = 1, 2$, factorizing the bispinor as Eq. (58.181) and normalized by Eq. (58.182). A massive particle of spin s is assigned a polarization wavefunction carrying $2s$ symmetrized little-group indices $\left|\mathbf{p}^{(I_1}\right\rangle \cdots \left|\mathbf{p}^{I_{2s})}\right\rangle$; amplitudes are tensors in these symmetrized $\mathrm{SU}(2)$ indices, with the massless helicity weight of Eq. (58.5) recovered as the highest- and lowest-weight components in the $m \to 0$ limit.

In this language the program of the chapter goes through unchanged in structure: Poincaré invariance and $\mathrm{SU}(2)$ little-group covariance fix the three-point amplitudes of massive particles up to constants, exactly as $\mathrm{U}(1)$ covariance fixed the massless three-point amplitudes in Eq. (58.98), and recursion builds the rest. The massive three-point amplitudes are the bold-spinor analogues of Eqs. (58.178) and (58.179); their classification, and the extension of BCFW to massive legs, is an active and only partly settled subject as of the mid-2020s, which is why we flag it as frontier rather than develop it in full. We will not need

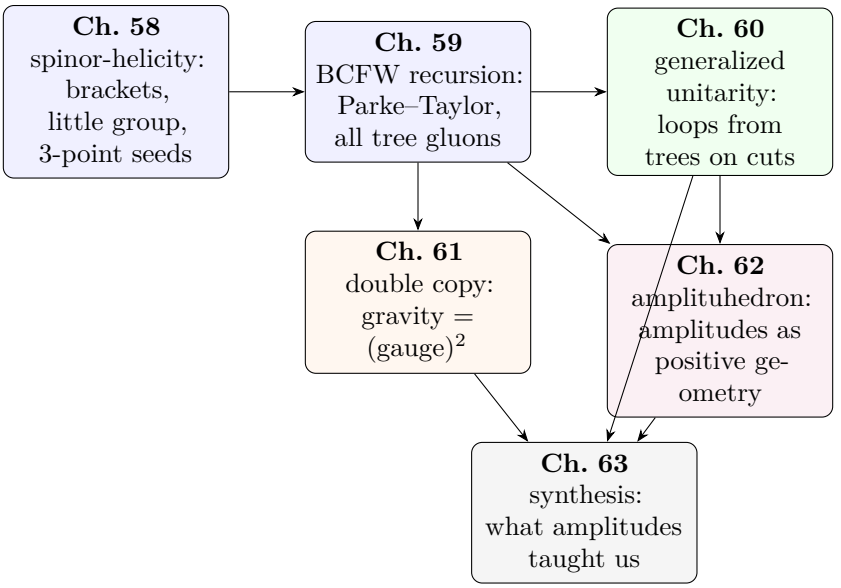

Figure 58.6: The route through Part XVI. The spinor-helicity variables and three-point seeds of this chapter feed the BCFW recursion of Chapter 59, which produces the complete tree-level gluon S-matrix (Parke–Taylor and beyond). That tree data is the input to three independent advances: generalized unitarity (Chapter 60) reconstructs loop amplitudes by sewing trees across cuts; the double copy (Chapter 61) builds gravity amplitudes as the "square" of gauge amplitudes; and the amplituhedron (Chapter 62) recasts amplitudes as the canonical form of a positive geometry. Chapter 63 draws the threads together.

massive spinors for the gluon recursion of Chapter 59, which lives entirely in the massless sector; we record them so that the reader leaves this chapter knowing that the on-shell program is not confined to massless particles.

58.7.6 A map of Part XVI

With the massless spinor-helicity formalism complete and the gluon amplitudes reduced to color-ordered partial amplitudes, the road through the rest of the modern-amplitudes part is straight. The logic is cumulative: each chapter takes the on-shell data manufactured by its predecessors and uses it to bypass a different piece of the Feynman-diagram apparatus. Figure 58.6 draws the dependency.

Concretely: Chapter 59 takes the three-gluon seeds Eqs. (58.178) and (58.179) and the color ordering of Theorem 58.32, complexifies external momenta as the caution above demanded, and derives the BCFW recursion that proves Parke–Taylor Eq. (58.180) and constructs every tree gluon amplitude. Chapter 60 carries those on-shell trees to loop level: generalized unitarity cuts express loop integrand coefficients as products of trees, trading the off-shell, gauge-dependent

loop diagrams of Chapter 19 for gauge-invariant on-shell data. Chapter 61 exploits a hidden algebraic structure of the same partial amplitudes — color–kinematics duality and the BCJ relations — to express gravity amplitudes as a "double copy" of gauge amplitudes, the modern realization of Yang–Mills theory's promised endpoint. Chapter 62 reframes the whole edifice geometrically: the planar amplitudes of maximally supersymmetric Yang–Mills theory are the canonical form of the amplituhedron, a positive geometry whose boundaries encode locality and unitarity, a development still conjectural in its general form and dated to the mid-2010s onward. Chapter 63 synthesizes the part, drawing the amplitudes program back to the bootstrap of Part XIV and the holography of Part XV.

We have done what this chapter set out to do: built variables that carry exactly the on-shell data of a massless particle and nothing more, fixed the three-point amplitudes by symmetry alone, reframed QED in helicity language, and now peeled color off the gluons to expose a single gauge-invariant, cyclically ordered object $A_n[1, \ldots, n]$. The three-gluon seeds Eqs. (58.178) and (58.179), the color decomposition Eq. (58.172), the partial-amplitude properties Eqs. (58.173) to (58.175), and the Parke–Taylor target Eq. (58.180) are precisely the kinematic groundwork that Chapter 59 requires: there the seeds are glued by BCFW recursion, with momenta pushed into the complex plane, to construct the complete tree-level S-matrix of Yang–Mills theory and to prove the one-line formula we have here only named.

Further reading

The modern on-shell perspective adopted here — spinor-helicity variables, little-group scaling, three-point amplitudes fixed by symmetry, and the color-ordered partial amplitudes — is developed at book length in Elvang and Huang [176] and Henn and Plefka [263], the two standard graduate texts on the subject and the natural companions to this chapter and the next. The pedagogical TASI lectures Dixon [153] give a brisk and complete route through color ordering, brackets, BCFW, and Parke–Taylor; the older review by Mangano and Parke [334] remains the definitive reference for the color decomposition and the partial-amplitude relations. The one-line MHV formula whose form we verified is the result of Parke and Taylor [379]; the recursion that proves it, deferred to Chapter 59, is Britto et al. [91, 92], with the twistor-space organizing idea behind the holomorphic structure due to Witten [523]. The completion of the formalism to massive particles of arbitrary spin, stated here at the frontier, is Arkani-Hamed et al. [38]. For the underlying representation theory of the Poincaré group on which the entire construction rests, see Weinberg [500] and the treatment in Chapter 3.

Chapter 59

Tree-Level Structure: MHV and Recursion

A single tree-level scattering process of a handful of gluons, written out in the Feynman expansion built honestly from the Yang–Mills Lagrangian Eq. (25.76) and the vertices of Chapter 26, demands a number of diagrams that grows faster than any factorial — each diagram a gauge-dependent tangle of Lorentz and color indices, the whole sum riddled with cancellations that the final answer never sees. And yet the answer, for the simplest helicity configurations, fits on a single line. This chapter is the story of why. It takes the classical gauge theory quantized in Chapters 25 and 26 and the spinor-helicity variables assembled in Chapter 58 — angle and square brackets, the little-group scaling of Eq. (58.5), the reference-momentum polarization vectors of Eq. (58.111), and the symmetry-fixed three-point amplitudes of Theorem 58.20 — and shows that the tree-level S-matrix of Yang–Mills is governed not by the Lagrangian but by two principles older and simpler than any action: locality and unitarity. This is where Yang–Mills theory, carried since the classical theory, reaches its modern form.

The arc is constructive. We first tame the factorial explosion by separating what is group theory from what is kinematics: the *color decomposition* factors every amplitude into a sum over single traces of generators, each multiplying a gauge-invariant, cyclically-ordered *partial amplitude* A_n computed from color-stripped Feynman rules. With color out of the way we ask a purely kinematic question — given the external helicities, what is A_n? — and find, by spending nothing but the gauge freedom hidden in the polarization references, that whole classes of helicity assignments vanish identically: the all-plus and single-minus amplitudes are zero, and the lowest surviving sector is the maximally-helicity-violating (MHV) one with exactly two negative helicities. For that sector we state the one-line Parke–Taylor formula, check it against every symmetry and factorization limit the formalism affords, and earn it by an honest four-gluon Feynman computation — leaving it, at that stage, a checked-but-unproved all-n

conjecture.

The proof requires leaving the real slice. Real on-shell three-point kinematics for massless particles is degenerate, collapsing the seed amplitude to an indeterminate 0/0; complexifying the momenta — treating the holomorphic and antiholomorphic spinors as independent — resurrects two nonzero three-point amplitudes, fixed up to a constant by little-group scaling and locality and normalized against the three-gluon vertex of Chapter 26. These complex seeds, together with the factorization of trees on physical poles established in Chapters 13 and 15, power the Britto–Cachazo–Feng–Witten (BCFW) recursion: a one-parameter complex shift of two external momenta turns the amplitude into a meromorphic function of z, and Cauchy's theorem reconstructs it from the residues at its physical poles, each a product of two lower-point on-shell amplitudes. The derivation leaves one debt — a boundary term at $z = \infty$ — which a large-z analysis, sharpened by the background-field argument, discharges for the right choice of shift, yielding the central structural result that tree Yang–Mills is *on-shell constructible*: determined entirely by its three-point seeds and the analytic structure of locality and unitarity, with no Lagrangian entering the reconstruction.

With the recursion justified we turn it on. We prove Parke–Taylor by induction on multiplicity, run the machine explicitly on the four- and five-gluon amplitudes to watch a thousand-diagram computation collapse to a single term, and assemble the first genuinely non-MHV amplitude, the six-point NMHV, from MHV and $\overline{\text{MHV}}$ pieces — previewing the spurious-pole cancellation that the amplituhedron of Chapter 62 later reads geometrically. The chapter closes by naming what has been gained: the trees proved here are the on-shell currency for the generalized-unitarity loop methods of Chapter 60 and the double copy to gravity of Chapter 61.

59.1 Color Decomposition and Color-Ordered Amplitudes

The chapter introduction laid out the scandal: a process with a handful of external gluons, written out in the textbook Feynman expansion built from the Yang–Mills Lagrangian Eq. (25.76) and the vertices of Chapter 26, requires a number of diagrams that grows faster than any factorial, each diagram a gauge-dependent tangle of Lorentz and color indices, and the whole sum collapses to an answer one can write on a single line. Before we can explain *why* the answer is short — the business of the rest of the chapter — we must first stop the proliferation from drowning us, and the first and cheapest economy is to notice that two completely different kinds of information are entangled in every diagram. There is *kinematics*: the momenta, the polarizations, the Lorentz contractions. And there is *color*: the structure constants f^{abc} at the vertices and the Kronecker

n	full Feynman diagrams	color-ordered diagrams
4	4	3
5	25	10
6	220	38
7	2 485	154
8	34 300	654
9	559 405	2 871
10	10 525 900	12 925

Table 59.1: The number of tree-level Feynman diagrams for the n-gluon amplitude. The middle column counts *all* diagrams contributing to the full amplitude $\mathcal{A}_n^{\text{tree}}$, color and kinematics together. The right column counts the diagrams contributing to a single color-ordered partial amplitude $A_n[1, 2, \ldots, n]$, i.e. those that can be drawn in the plane with the external legs in the fixed cyclic order $1, 2, \ldots, n$. Color ordering already removes most of the redundancy; the remaining collapse to Parke–Taylor is the subject of the later sections.

δ^{ab} on the propagators, pure group theory that knows nothing about the energies involved. These two factor cleanly. The purpose of this section is to perform that factorization once and for all: to peel the gauge group off the kinematics, package all the color into a small set of invariant tensors (traces of generators), and isolate the gauge-invariant kinematic coefficients — the *color-ordered partial amplitudes* — that every later section computes helicity by helicity. After this section the words "n-gluon amplitude" will mean a single object $A_n[1, 2, \ldots, n]$ with its own Feynman rules and its own symmetries, and the factorial swarm of diagrams will have been quietly tamed into a sum over $(n-1)!$ orderings of one such object.

59.1.1 The size of the problem

It is worth seeing the explosion quantitatively, because the numbers are what make the eventual one-line answers astonishing rather than merely tidy. A tree-level pure-gluon amplitude with n external legs is built from the cubic and quartic vertices of Eqs. (26.53) and (26.56) wired together by the gluon propagator Eq. (26.45) into every distinct connected tree. Counting those trees is a purely combinatorial exercise; the results are collected in the second column of Table 59.1. The growth is super-factorial: doubling the number of gluons from five to ten multiplies the diagram count by more than four hundred thousand.

Most of this growth is illusory in the sense that matters here: it is generated by summing the *same* kinematic skeleton against different color labels, and by the gauge dependence of individual diagrams, which forces enormous cancellations that a final gauge-invariant answer never sees. The right column of Table 59.1

previews how much is gained simply by organizing the sum by color: the diagrams contributing to one cyclically-ordered piece are far fewer. The first task is to make "organizing by color" precise.

59.1.2 Where the color lives

We collect the color content of the gluon Feynman rules, reading it off the rules established in Chapter 26. Throughout, $a, b, c, \cdots \in \{1, \ldots, N^2-1\}$ are adjoint (gluon) indices of SU(N), and $i, j, k, \cdots \in \{1, \ldots, N\}$ are fundamental indices; the Hermitian generators T^a act in the fundamental.

The gluon propagator Eq. (26.45) carries the color tensor δ^{ab} and nothing more:

$$D^{ab}_{\mu\nu}(k)\Big|_{\xi=1} = \delta^{ab}\,\frac{-i\,\eta_{\mu\nu}}{k^2+i\varepsilon}. \tag{59.1}$$

The three-gluon vertex Eq. (26.53) carries a single structure constant,

$$iV^{abc}_{\mu\nu\rho}(p,q,r) = g\,f^{abc}\,K_{\mu\nu\rho}(p,q,r), \qquad K_{\mu\nu\rho}(p,q,r) \equiv \eta_{\mu\nu}(p-q)_\rho + \eta_{\nu\rho}(q-r)_\mu + \eta_{\rho\mu}(r-p)_\nu, \tag{59.2}$$

with all momenta incoming, $p+q+r=0$; and the four-gluon vertex Eq. (26.56) carries a product of two structure constants contracted on a shared adjoint index,

$$iV^{abcd}_{\mu\nu\rho\sigma} = -ig^2\Big[f^{abe}f^{cde}\,(\eta_{\mu\rho}\eta_{\nu\sigma}-\eta_{\mu\sigma}\eta_{\nu\rho}) + f^{ace}f^{bde}\,(\eta_{\mu\nu}\eta_{\rho\sigma}-\eta_{\mu\sigma}\eta_{\nu\rho}) + f^{ade}f^{bce}\,(\eta_{\mu\nu}\eta_{\rho\sigma}-\eta_{\mu\rho}\eta_{\nu\sigma})\Big] \tag{59.3}$$

Every tree diagram is therefore, in color space, a product of structure constants f^{abc} (one per cubic vertex, two per quartic) with the adjoint indices of internal lines contracted in pairs through the propagator δ^{ab}. The external indices $a_1, \ldots, a_n$ are left free. The color factor of any diagram is thus a fully contracted polynomial in f's carrying the n free external indices, and the kinematic factor — the contraction of η's, momenta, and external polarizations — rides alongside it, multiplied. The two never mix. Our strategy is to convert this f-and-δ data into a basis of traces of generators, in which the kinematic coefficients organize themselves automatically.

59.1.3 From structure constants to traces

The single algebraic identity that powers the whole conversion expresses a structure constant as a difference of traces. It follows immediately from the two defining facts of the generators.

Lemma 59.1 (Structure constant as a trace)**.** *With the book-canonical normalization* $\big[T^a, T^b\big] = if^{abc}T^c$ *and* $\mathrm{tr}(T^aT^b) = \tfrac{1}{2}\delta^{ab}$,

$$f^{abc} = -2i\,\Big(\mathrm{tr}(T^aT^bT^c) - \mathrm{tr}(T^aT^cT^b)\Big). \tag{59.4}$$

Proof. Multiply the Lie bracket $\left[T^a, T^b\right] = if^{abd}T^d$ on the right by T^c and take the trace. Using $\mathrm{tr}(T^dT^c) = \frac{1}{2}\delta^{dc}$,

$$\mathrm{tr}\left(\left[T^a, T^b\right] T^c\right) = if^{abd}\,\mathrm{tr}(T^dT^c) = if^{abd}\,\tfrac{1}{2}\delta^{dc} = \tfrac{i}{2}\,f^{abc}. \tag{59.5}$$

The left-hand side is $\mathrm{tr}(T^aT^bT^c) - \mathrm{tr}(T^bT^aT^c)$, and by cyclicity of the trace $\mathrm{tr}(T^bT^aT^c) = \mathrm{tr}(T^aT^cT^b)$, so $\mathrm{tr}\left(\left[T^a, T^b\right] T^c\right) = \mathrm{tr}(T^aT^bT^c) - \mathrm{tr}(T^aT^cT^b)$. Equating with Eq. (59.5) and solving for f^{abc} gives Eq. (59.4). (This is the trace formula of Eq. (B.20) specialized to the fundamental, $T(R) = \frac{1}{2}$.) □

The factor of $-2i$ is a nuisance that recurs, multiplied, at every vertex, and the completeness relation we will use to contract internal lines carries a companion factor of $\frac{1}{2}$. Both are artifacts of the normalization $\mathrm{tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$, and the amplitudes literature removes them once and for all by rescaling the generators. We adopt that rescaling for the remainder of Chapter 59.

Notation Watch

For all of Chapter 59 we use *amplitude-normalized* generators, defined by a rescaling of the canonical ones of Chapter B by $\sqrt{2}$,

$$T^a \;\longmapsto\; T^a_{\text{here}} = \sqrt{2}\,T^a_{\text{canon}}, \qquad \text{so that} \qquad \mathrm{tr}(T^aT^b) = \delta^{ab}. \tag{59.6}$$

This is a pure change of basis-scale; it leaves the physical content untouched. The structure constants f^{abc} appearing in the Lagrangian Eq. (25.76), the coupling g, and the Casimirs $C_A = N$, C_F, T_F of Chapter B are all defined through the physical commutator and are *unchanged*; only the matrices T^a that appear inside traces in the color decomposition are rescaled. In this normalization the completeness (color-Fierz) relation Eq. (B.78) of Theorem B.23 reads, with the $\frac{1}{2}$ absorbed,

$$\sum_{a=1}^{N^2-1} (T^a)_i{}^j\,(T^a)_k{}^l = \delta_i^l\,\delta_k^j - \frac{1}{N}\,\delta_i^j\,\delta_k^l, \tag{59.7}$$

and the f-to-trace identity Eq. (59.4) becomes, after the rescaling pulls a factor $2^{-3/2}$ out of the triple trace,

$$f^{abc} = -\frac{i}{\sqrt{2}}\left(\mathrm{tr}(T^aT^bT^c) - \mathrm{tr}(T^aT^cT^b)\right) = -\frac{i}{\sqrt{2}}\,\mathrm{tr}\left(\left[T^a, T^b\right] T^c\right). \tag{59.8}$$

Equation Eq. (59.8) is the working form used below; note that the f^{abc} on its left is the physical structure constant, while the T^a inside the traces are the rescaled generators of Eq. (59.6).

To verify the rescaling claim in Eq. (59.8): under $T^a \mapsto \sqrt{2}\,T^a$, each triple trace scales as $\mathrm{tr}(T^aT^bT^c) \mapsto 2^{3/2}\,\mathrm{tr}(T^aT^bT^c)$, so the right-hand side of Eq. (59.4), which equals $-2i\ \mathrm{tr}(\big[T^a,T^b\big]\,T^c)$, becomes $-2i{\cdot}2^{-3/2}\ \mathrm{tr}(\big[T^a,T^b\big]\,T^c) = -\frac{i}{\sqrt{2}}\,\mathrm{tr}(\big[T^a,T^b\big]\,T^c)$, while f^{abc} on the left is held fixed. This reproduces Eq. (59.8).

59.1.4 The single-trace decomposition

We can now state and prove the central organizing result of the section: at tree level the color factor of every gluon amplitude collapses onto a basis of *single* traces of generators, one trace per cyclic ordering of the external legs.

The cleanest way to see this — and the way that simultaneously delivers the photon-decoupling identity of Section 59.1.7 — is to enlarge the gauge group momentarily from $\mathrm{SU}(N)$ to $\mathrm{U}(N)$. Adjoin to the N^2-1 traceless generators T^a the trace generator

$$T^0 = \frac{1}{\sqrt{N}}\,\mathbf{1}, \qquad \mathrm{tr}(T^0T^0) = \frac{1}{N}\,\mathrm{tr}\,\mathbf{1} = 1, \tag{59.9}$$

normalized to match Eq. (59.6), and let capital indices $A, B, \dots \in \{0, 1, \dots, N^2-1\}$ run over the full set $\{T^0, T^a\}$, a basis for all Hermitian $N \times N$ matrices. The $\mathrm{U}(N)$ completeness relation Eq. (B.81) then has no trace subtraction at all,

$$\sum_{A=0}^{N^2-1} (T^A)_i{}^j\,(T^A)_k{}^l = \delta_i^{\,l}\,\delta_k^{\,j}, \tag{59.10}$$

the indices simply being swapped — the algebraic statement that a $\mathrm{U}(N)$ gluon is an unconstrained quark–antiquark color pair. Two facts make working in $\mathrm{U}(N)$ legitimate and convenient.

First, the extra gauge boson T^0 is a free, decoupled photon as far as gluons are concerned. Its structure constants vanish identically, $f^{0bc} \propto \mathrm{tr}(\big[\mathbf{1},T^b\big]\,T^c) = 0$, because the identity commutes with everything. Since every pure-gluon vertex Eqs. (59.2) and (59.3) is built from structure constants, any vertex with a T^0 leg vanishes: the $\mathrm{U}(1)$ photon couples to nothing colored. Consequently a tree diagram with only $\mathfrak{su}(N)$ gluons on its external and internal lines is identical whether we compute it in $\mathrm{SU}(N)$ or in $\mathrm{U}(N)$ — no internal T^0 can ever appear, so the extra direction is inert. We may therefore contract all internal adjoint indices with the trace-free relation Eq. (59.10) instead of Eq. (59.7), deferring the descent back to $\mathrm{SU}(N)$ to the end.

Second, in the $\mathrm{U}(N)$ basis the color factor of any diagram becomes a product of generator traces sewn by Eq. (59.10), and the sewing has a transparent graphical meaning in 't Hooft's double-line notation, the same notation that Chapter B used to read the completeness relation. Convert each structure constant to traces by Eq. (59.8); each cubic vertex becomes a difference of two

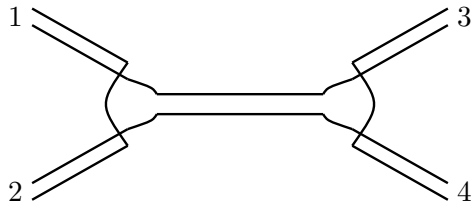

Figure 59.1: The color flow of the four-gluon s-channel tree in 't Hooft double-line notation, in the U(N) basis where the completeness relation Eq. (59.10) simply joins fundamental lines. Each external gluon is a pair of antiparallel color lines; the internal gluon likewise. Because the diagram is a tree, the joined lines form a *single* closed boundary loop visiting the external legs in the cyclic order $1, 2, 3, 4$, which is the single trace $\mathrm{tr}(T^{a_1}T^{a_2}T^{a_3}T^{a_4})$. No second closed loop is possible without a momentum loop, so no double-trace term arises at tree level.

"open" triple products of generators, and each quartic a difference of quadruple products. Draw each adjoint (gluon) line as a double line, a fundamental line and an anti-fundamental line running antiparallel. The completeness relation Eq. (59.10) is then the rule that joins the fundamental lines of an internal gluon end to end. Because a *tree* diagram has no closed loops, the fundamental color lines, once all internal gluons are resolved and joined, can neither cross nor close among themselves except along the single outer boundary of the planar diagram. They merge into exactly one closed fundamental loop, whose boundary threads the n external generators in the cyclic order in which the legs are arranged. That single closed loop *is* a single trace, $\mathrm{tr}(T^{a_{i_1}}T^{a_{i_2}}\cdots T^{a_{i_n}})$, with the ordering $(i_1, \ldots, i_n)$ read off the planar embedding. Figure 59.1 illustrates the mechanism on a four-point diagram.

Summing over all diagrams and all planar embeddings collects the kinematics into a coefficient of each distinct single trace. Distinct traces correspond to distinct cyclic orderings of $\{1, \ldots, n\}$, of which there are $(n-1)!$ once we use cyclicity of the trace to fix leg 1 in the first slot. This is the decomposition.

Theorem 59.2 (Tree-level color decomposition)**.** *The full n-gluon tree amplitude, with external adjoint labels $a_1, \ldots, a_n$, decomposes as*

$$\mathcal{A}_n^{\text{tree}}(\{p_i, \epsilon_i, a_i\}) = g^{n-2} \sum_{\sigma \in S_{n-1}} \mathrm{tr}(T^{a_1}T^{a_{\sigma(2)}}T^{a_{\sigma(3)}}\cdots T^{a_{\sigma(n)}})\; A_n[1, \sigma(2), \sigma(3), \ldots, \sigma(n)], \tag{59.11}$$

where the sum runs over the $(n-1)!$ permutations σ of $\{2, 3, \ldots, n\}$ (leg 1 held fixed by trace cyclicity), and the kinematic coefficients $A_n[1, \sigma]$ — the color-ordered partial amplitudes *— depend only on the momenta and polarizations, carry no color, and are separately gauge invariant.*

Proof. The double-line argument above establishes that, in the U(N) basis,

every tree diagram's color factor is a single trace $\mathrm{tr}(T^{a_{i_1}}\cdots T^{a_{i_n}})$ of the external generators in the cyclic order of the planar embedding, times a kinematic factor with no remaining color. Grouping the diagrams by their trace gives $\mathcal{A}_n^{\text{tree}} = g^{n-2}\sum_{\text{cyclic orderings}}\mathrm{tr}(\cdots)\,A_n[\cdots]$, where A_n is the sum of kinematic factors of all diagrams sharing that ordering, and the factor g^{n-2} is the count of vertices on a tree (one power of g per cubic vertex, two per quartic, equal to $n-2$ by the tree relation $V_3 + 2V_4 = n-2$ derived in Section 59.1.6). Using cyclicity of the trace to rotate leg 1 to the front identifies the independent orderings with permutations of $\{2,\dots,n\}$, giving the sum over S_{n-1} and $(n-1)!$ terms. Finally, since the computation was carried out in $\mathrm{U}(N)$ and the inert T^0 never entered any internal line, the result equals the genuine $\mathrm{SU}(N)$ amplitude: the would-be $\frac{1}{N}$ corrections of the $\mathrm{SU}(N)$ Fierz relation Eq. (59.7), which would have produced multi-trace structures, are exactly the ones that cancel because the extra $\mathrm{U}(1)$ photon decouples (Section 59.1.7). Each $A_n[1,\sigma]$ is gauge invariant because the full $\mathcal{A}_n^{\text{tree}}$ is, and the traces in Eq. (59.11) are linearly independent functions of the external labels for $n \le N+1$ (and the partial amplitudes are kinematic objects defined independently of N), so a gauge variation of $\mathcal{A}_n$ that vanishes for all $\{a_i\}$ forces each coefficient to be invariant separately. □

Definition 59.3 (Color-ordered partial amplitude)**.** The kinematic coefficient $A_n[1,2,\dots,n]$ multiplying the trace $\mathrm{tr}(T^{a_1}T^{a_2}\cdots T^{a_n})$ in Eq. (59.11) is the *color-ordered partial amplitude* (or partial amplitude) for the cyclic ordering $(1,2,\dots,n)$. It is computed from the color-stripped Feynman rules of Section 59.1.5 by summing only those diagrams whose external legs can be drawn in the plane in the order $1,2,\dots,n$ — the planar, or color-ordered, diagrams counted in the right column of Table 59.1.

This is the object the rest of the chapter computes. Everything we will say about gluon amplitudes — vanishing helicity configurations, the Parke–Taylor formula, BCFW recursion — is a statement about a single $A_n[1,\dots,n]$; the full amplitude is reassembled at the end by dressing each ordering with its trace and summing.

59.1.5 Color-ordered Feynman rules

Theorem 59.3 would be useless without a direct prescription for A_n that never mentions color. We extract it by stripping the color tensor off each full rule, retaining the coefficient of one fixed trace ordering. Because each color-ordered diagram is planar with a definite cyclic adjacency of legs, the stripped rules are *ordered*: vertices connect legs that are adjacent in the cyclic ordering, and the rules carry the index labels in that order.

Cubic vertex. Insert Eq. (59.8) into the full cubic vertex Eq. (59.2). Writing $f^{abc} = -\frac{i}{\sqrt{2}}(\mathrm{tr}(T^aT^bT^c) - \mathrm{tr}(T^aT^cT^b))$ and reading off the coefficient of the

single ordered trace $\mathrm{tr}(T^{a_1}T^{a_2}T^{a_3})$, and adopting the all-*outgoing* momentum convention standard in amplitude work (which reverses every momentum relative to the all-incoming Eq. (59.2) and so flips the sign of the momentum-linear K), the color-ordered three-gluon vertex is

$$V_3^{\mu_1\mu_2\mu_3}(p_1,p_2,p_3) = \frac{i}{\sqrt{2}}\Big(\eta^{\mu_1\mu_2}(p_1-p_2)^{\mu_3}+\eta^{\mu_2\mu_3}(p_2-p_3)^{\mu_1}+\eta^{\mu_3\mu_1}(p_3-p_1)^{\mu_2}\Big), \tag{59.12}$$

with $p_1+p_2+p_3=0$ and the legs in cyclic order $1,2,3$.

Quartic vertex. The quartic requires contracting the two structure constants in Eq. (59.3) into traces and extracting the coefficient of one ordering; we carry the computation in Theorem 59.4 below. The result is the color-ordered four-gluon vertex, free of momenta,

$$V_4^{\mu_1\mu_2\mu_3\mu_4} = \frac{i}{2}\Big(2\,\eta^{\mu_1\mu_3}\eta^{\mu_2\mu_4}-\eta^{\mu_1\mu_2}\eta^{\mu_3\mu_4}-\eta^{\mu_1\mu_4}\eta^{\mu_2\mu_3}\Big), \tag{59.13}$$

with legs in cyclic order $1,2,3,4$.

Propagator. The internal gluon, in Feynman gauge, keeps its tensor structure but loses its color δ^{ab}, which has been used up sewing the color lines:

$$\frac{-i\,\eta_{\mu\nu}}{p^2+i\varepsilon}. \tag{59.14}$$

Together, Eqs. (59.12) to (59.14) are the *color-ordered Feynman rules*; we refer to the trio collectively as Eqs. (59.12) to (59.14) or, for cross-reference, as the rules of Section 59.1.5. The partial amplitude $A_n[1,\dots,n]$ is the sum, over all planar diagrams with the legs in the cyclic order $1,\dots,n$, of the products of these rules, with external polarizations ϵ_i attached and overall momentum conservation imposed — exactly the ordinary Feynman procedure of Chapter 15, but with the ordered rules and only the planar diagrams.

Worked Example 59.4 (Stripping the four-gluon vertex)**.** We derive Eq. (59.13) from the full vertex Eq. (59.3). The strategy is to write each product ff as a product of traces, then read off the coefficient of the single ordered trace $\mathrm{tr}(T^{a_1}T^{a_2}T^{a_3}T^{a_4})$, i.e. the cyclic ordering 1234.

A product of structure constants as a single trace. Using Eq. (59.8) for both factors and the U(N) completeness Eq. (59.10) to perform the sum over the shared index e, we first establish

$$\sum_e \mathrm{tr}(MT^e)\,\mathrm{tr}(NT^e) = \mathrm{tr}(MN), \tag{59.15}$$

valid for any matrices M,N. Indeed, writing the traces in components, $\sum_e \mathrm{tr}(MT^e)\,\mathrm{tr}(NT^e) = M_{ij}N_{kl}\sum_e (T^e)_{ji}(T^e)_{lk} = M_{ij}N_{kl}\,\delta_{jk}\delta_{li} = M_{ij}N_{ji} = \mathrm{tr}(MN)$, where the middle

step used Eq. (59.10). Applying Eq. (59.15) with $M = \big[T^a, T^b\big]$, $N = \big[T^c, T^d\big]$ and the two prefactors $(-\frac{i}{\sqrt{2}})^2 = -\frac{1}{2}$,

$$f^{abe}f^{cde} = -\tfrac{1}{2}\,\mathrm{tr}\big(\,\big[T^a,T^b\big]\,\big[T^c,T^d\big]\,\big) = -\tfrac{1}{2}\Big(\,\mathrm{tr}(T^aT^bT^cT^d) - \mathrm{tr}(T^aT^bT^dT^c) - \mathrm{tr}(T^bT^aT^cT^d) + \mathrm{tr}(\tag{59.16}$$

Coefficient of $\mathrm{tr}(T^{a_1}T^{a_2}T^{a_3}T^{a_4})$ *in each color channel.* Channel one of Eq. (59.3) carries $f^{abe}f^{cde}$ with $(a,b,c,d) = (a_1,a_2,a_3,a_4)$. Among the four traces in Eq. (59.16), only $+\,\mathrm{tr}(T^{a_1}T^{a_2}T^{a_3}T^{a_4})$ is the ordering 1234; the others are cyclically inequivalent. Its coefficient is therefore $-\frac{1}{2}$.

Channel two carries $f^{ace}f^{bde}$, i.e. Eq. (59.16) with the relabeling $(a,b,c,d) \to (a_1,a_3,a_2,a_4)$. The four resulting traces are $\mathrm{tr}(T^{a_1}T^{a_3}T^{a_2}T^{a_4})$ and rearrangements; none is cyclically equal to 1234. The coefficient of $\mathrm{tr}(1234)$ is 0.

Channel three carries $f^{ade}f^{bce}$, i.e. the relabeling $(a,b,c,d) \to (a_1,a_4,a_2,a_3)$. Then Eq. (59.16) contains the term $-\,\mathrm{tr}(T^{a_4}T^{a_1}T^{a_2}T^{a_3})$, which by cyclicity equals $-\,\mathrm{tr}(T^{a_1}T^{a_2}T^{a_3}T^{a_4})$, i.e. ordering 1234. With the overall $-\frac{1}{2}$ its coefficient is $-\frac{1}{2}\cdot(-1) = +\frac{1}{2}$. The other three traces of this channel are not 1234.

Assembly. Collecting the coefficient of $g^2\,\mathrm{tr}(T^{a_1}T^{a_2}T^{a_3}T^{a_4})$ in $iV^{abcd}_{\mu_1\mu_2\mu_3\mu_4}$ from Eq. (59.3), with $(\mu,\nu,\rho,\sigma) = (\mu_1,\mu_2,\mu_3,\mu_4)$,

$$\begin{aligned} iV_4 &= -i\Big[-\tfrac{1}{2}(\eta_{\mu_1\mu_3}\eta_{\mu_2\mu_4} - \eta_{\mu_1\mu_4}\eta_{\mu_2\mu_3}) + 0 + \tfrac{1}{2}(\eta_{\mu_1\mu_2}\eta_{\mu_3\mu_4} - \eta_{\mu_1\mu_3}\eta_{\mu_2\mu_4})\Big] \\ &= -\tfrac{i}{2}\Big[-\eta_{\mu_1\mu_3}\eta_{\mu_2\mu_4} + \eta_{\mu_1\mu_4}\eta_{\mu_2\mu_3} + \eta_{\mu_1\mu_2}\eta_{\mu_3\mu_4} - \eta_{\mu_1\mu_3}\eta_{\mu_2\mu_4}\Big] \\ &= \tfrac{i}{2}\Big(2\,\eta_{\mu_1\mu_3}\eta_{\mu_2\mu_4} - \eta_{\mu_1\mu_2}\eta_{\mu_3\mu_4} - \eta_{\mu_1\mu_4}\eta_{\mu_2\mu_3}\Big), \end{aligned} \tag{59.17}$$

which is Eq. (59.13). The momentum-independence and the characteristic relative coefficients $(2,-1,-1)$ — favoring the pairing of legs that are *not* cyclically adjacent — are precisely what one needs for the ordered four-gluon amplitude to be gauge invariant once combined with the cubic-vertex diagrams.

59.1.6 Cyclicity, reflection, and counting

Two exact symmetries of the partial amplitudes follow at once and reduce the number of independent objects.

Cyclicity. Because $A_n[1,2,\ldots,n]$ is, by Theorem 59.3, the coefficient of the cyclic trace $\mathrm{tr}(T^{a_1}\cdots T^{a_n})$, and the trace is invariant under cyclic rotation of its arguments, the partial amplitude is invariant under cyclic rotation of its labels,

$$A_n[1,2,\ldots,n] = A_n[2,3,\ldots,n,1] = A_n[3,\ldots,n,1,2] = \cdots . \tag{59.18}$$

Equivalently, the color-ordered rules Eqs. (59.12) and (59.13) depend only on the cyclic adjacency of legs, not on which leg is called first. This is why fixing leg 1 in Eq. (59.11) loses nothing.

Reflection. Reversing the entire ordering produces a sign:

$$A_n[n, n-1, \ldots, 2, 1] = (-1)^n \, A_n[1, 2, \ldots, n]. \tag{59.19}$$

Proposition 59.5 (Reflection identity)**.** *The color-ordered partial amplitude obeys Eq. (59.19).*

Proof. We track the sign acquired by each ingredient of a planar diagram under reversal of the cyclic order, $(1, 2, \ldots, n) \to (n, \ldots, 2, 1)$, which reverses the Lorentz labels and momenta on every vertex. The propagator Eq. (59.14) is symmetric in its two indices and even in momentum, hence invariant. The cubic vertex Eq. (59.12) is *odd*: under the simultaneous interchange of its outer legs $1 \leftrightarrow 3$ (with momenta), its three terms map among themselves with an overall sign,

$$\begin{aligned} &\eta^{\mu_3\mu_2}(p_3 - p_2)^{\mu_1} + \eta^{\mu_2\mu_1}(p_2 - p_1)^{\mu_3} + \eta^{\mu_1\mu_3}(p_1 - p_3)^{\mu_2} \\ &\quad = -\Big(\eta^{\mu_1\mu_2}(p_1 - p_2)^{\mu_3} + \eta^{\mu_2\mu_3}(p_2 - p_3)^{\mu_1} + \eta^{\mu_3\mu_1}(p_3 - p_1)^{\mu_2}\Big) = -V_3, \end{aligned} \tag{59.20}$$

so each cubic vertex contributes a factor -1. The quartic vertex Eq. (59.13) is even: reversing $(1, 2, 3, 4) \to (4, 3, 2, 1)$ sends $\eta^{\mu_1\mu_3}\eta^{\mu_2\mu_4} \to \eta^{\mu_4\mu_2}\eta^{\mu_3\mu_1} = \eta^{\mu_1\mu_3}\eta^{\mu_2\mu_4}$ and likewise leaves the other two terms fixed, giving a factor $+1$. A planar diagram with V_3 cubic and V_4 quartic vertices thus acquires the sign $(-1)^{V_3}$, the same for every diagram contributing to a given A_n provided $(-1)^{V_3}$ is determined by n alone. It is. Counting line ends, each internal line (I of them) has two ends and each external line one, so $3V_3 + 4V_4 = 2I + n$; and a tree has $V_3 + V_4 = I + 1$. Eliminating I,

$$V_3 = n - 2 - 2V_4 \;\equiv\; n \pmod 2, \tag{59.21}$$

so $(-1)^{V_3} = (-1)^n$ independently of how the vertices are apportioned. Every planar diagram for $A_n[1, \ldots, n]$ therefore maps under reversal to the corresponding diagram for $A_n[n, \ldots, 1]$ times the common factor $(-1)^n$, proving Eq. (59.19). (Equation Eq. (59.21) also supplies the power $g^{V_3+2V_4} = g^{n-2}$ used in Eq. (59.11).) □

Cyclicity and reflection together generate the dihedral group of order $2n$ acting on the orderings, so the $(n-1)!$ traces of Eq. (59.11) fall into orbits of size up to $2n$, and the genuinely independent partial amplitudes number roughly $(n-1)!/2$. The next two identities cut this down much further.

59.1.7 The $U(1)$ decoupling identity

The cleanest of the linear relations among partial amplitudes is the one already implicit in the U(N) construction of Section 59.1.4: the decoupling of the extra abelian photon.

Theorem 59.6 ($U(1)$ decoupling / photon-decoupling identity)**.** *The color-ordered partial amplitudes obey*

$$A_n[1,2,3,\dots,n]+A_n[2,1,3,\dots,n]+A_n[2,3,1,4,\dots,n]+\cdots+A_n[2,3,\dots,n{-}1,1,n]=0, \tag{59.22}$$

the sum being over the $n-1$ inequivalent positions into which leg 1 may be inserted while holding the cyclic order of $2,3,\dots,n$ fixed. Equivalently, after rotating leg 1 to the front of each term by cyclicity,

$$\sum_{j=0}^{n-1} A_n[1,\underbrace{2,3,\dots}_{j\ \text{legs}},\underbrace{\dots,n}] = 0, \tag{59.23}$$

i.e. the sum of $A_n[1,\sigma]$ over the $n-1$ cyclic rotations of the $(2,\dots,n)$ block vanishes. For $n=4$, with leg 1 rotated to the front,

$$A_4[1,2,3,4]+A_4[1,3,4,2]+A_4[1,4,2,3]=0. \tag{59.24}$$

Proof. Compute the $\mathrm{U}(N)$ amplitude in which leg 1 is the abelian photon T^0 of Eq. (59.9) and legs $2,\dots,n$ are ordinary $\mathfrak{su}(N)$ gluons. As established in Section 59.1.4, the photon decouples: $f^{0bc}=0$, so no vertex couples it to gluons and the amplitude vanishes identically,

$$\mathcal{A}_n^{\text{tree}}(1_{\mathrm{U}(1)},2,\dots,n)=0. \tag{59.25}$$

Now evaluate the same amplitude through the color decomposition Eq. (59.11), simply setting $T^{a_1}=T^0=\frac{1}{\sqrt{N}}\mathbf{1}$. The decomposition is a sum over the $(n-1)!$ orderings; insert the identity for T^{a_1} in each trace. Because $\mathbf{1}$ can be slid to any position and removed, $\mathrm{tr}(\mathbf{1}\,T^{a_{\sigma(2)}}\cdots T^{a_{\sigma(n)}})=\mathrm{tr}(T^{a_{\sigma(2)}}\cdots T^{a_{\sigma(n)}})$, every trace collapses to a trace of the $n-1$ gluon generators *without* leg 1. Two orderings σ,σ' that differ only by where leg 1 sat (its position among $2,\dots,n$) collapse to the *same* reduced trace. Grouping the sum Eq. (59.11) by reduced trace, the coefficient of each independent reduced trace $\mathrm{tr}(T^{a_2}\cdots T^{a_n})$ (in a fixed cyclic order of the gluons) is precisely the sum of the partial amplitudes A_n over all positions of leg 1 inserted into that order. Since the total Eq. (59.25) vanishes and the reduced traces are linearly independent, each such coefficient must vanish, which is Eq. (59.22). Specializing to $n=4$ and rotating leg 1 to the front gives Eq. (59.24). □

The decoupling identity is the gluon-amplitude statement that there is no abelian photon hiding in $\mathrm{SU}(N)$: the cancellation of the $\frac{1}{N}$ trace-subtraction terms in Eq. (59.7) that we invoked at the end of Theorem 59.2 *is* Eq. (59.22), now proved independently. It expresses one partial amplitude as a sum of others and so reduces the independent count below $(n-1)!/2$.

A second, stronger family of linear relations holds among the partial amplitudes, the *Kleiss–Kuijf relations*, which we state here and use later. Writing the

ordering as leg 1, a block $\boldsymbol{\alpha} = \{\alpha_1, \ldots, \alpha_r\}$, leg n, and a block $\boldsymbol{\beta} = \{\beta_1, \ldots, \beta_s\}$ (with $r + s = n - 2$), they read

$$A_n[1, \boldsymbol{\alpha}, n, \boldsymbol{\beta}] = (-1)^s \sum_{\sigma \in \boldsymbol{\alpha} \sqcup\!\sqcup \boldsymbol{\beta}^T} A_n[1, \sigma, n], \tag{59.26}$$

where $\boldsymbol{\beta}^T$ is the reversed block and $\sqcup\!\sqcup$ denotes the shuffle product (all interleavings of the two ordered blocks preserving each block's internal order). The decoupling identity Eq. (59.22) is the simplest special case ($\boldsymbol{\alpha}$ a single leg). The Kleiss–Kuijf relations reduce the number of independent partial amplitudes to $(n-2)!$, choosing a basis in which legs 1 and n are held fixed and the remaining $n-2$ permuted. A further, nonlinear-looking but in fact linear set — the BCJ relations arising from color–kinematics duality — cuts the basis to $(n-3)!$; those belong to the double-copy story of Chapter 61 and we defer them. We will not need a proof of Eq. (59.26) for the explicit low-point computations of this chapter; it is established in the amplitudes literature by the same monodromy/decoupling reasoning used for Theorem 59.6 applied repeatedly.

59.1.8 Yang–Mills theory: the four-gluon color decomposition

We close the section by assembling the carried Yang–Mills theory object explicitly: the color decomposition of the four-gluon amplitude, the smallest case in which all the machinery — single traces, the S_{n-1} sum, reflection, and the decoupling identity — is on display at once.

Worked Example 59.7 (Four-gluon color decomposition)**.** Specialize Eq. (59.11) to $n = 4$. The sum runs over S_3, the $3! = 6$ permutations of $\{2, 3, 4\}$, giving six single traces:

$$\begin{aligned}\mathcal{A}_4^{\text{tree}} = g^2\Big[&\operatorname{tr}(T^{a_1}T^{a_2}T^{a_3}T^{a_4})\, A_4[1,2,3,4] + \operatorname{tr}(T^{a_1}T^{a_2}T^{a_4}T^{a_3})\, A_4[1,2,4,3] \\ &+ \operatorname{tr}(T^{a_1}T^{a_3}T^{a_2}T^{a_4})\, A_4[1,3,2,4] + \operatorname{tr}(T^{a_1}T^{a_3}T^{a_4}T^{a_2})\, A_4[1,3,4,2] \\ &+ \operatorname{tr}(T^{a_1}T^{a_4}T^{a_2}T^{a_3})\, A_4[1,4,2,3] + \operatorname{tr}(T^{a_1}T^{a_4}T^{a_3}T^{a_2})\, A_4[1,4,3,2]\Big].\end{aligned} \tag{59.27}$$

These six are not independent. Reflection Eq. (59.19) with $n = 4$ gives $(-1)^4 = +1$, so $A_4[1,2,3,4] = A_4[4,3,2,1] = A_4[1,4,3,2]$ (the last by cyclic rotation of $4,3,2,1$). Likewise $A_4[1,2,4,3] = A_4[1,3,4,2]$ and $A_4[1,3,2,4] = A_4[1,4,2,3]$. The six orderings thus pair into three reflection doublets, leaving three distinct partial amplitudes, conventionally

$$A_4[1,2,3,4], \qquad A_4[1,2,4,3], \qquad A_4[1,3,2,4], \tag{59.28}$$

each appearing in Eq. (59.27) multiplied by the sum of its trace and the reflected trace, e.g. $A_4[1,2,3,4]\big(\operatorname{tr}(T^{a_1}T^{a_2}T^{a_3}T^{a_4}) + \operatorname{tr}(T^{a_1}T^{a_4}T^{a_3}T^{a_2})\big)$.

The decoupling identity Eq. (59.24) relates these three. Written in the basis Eq. (59.28) using cyclicity and reflection ($A_4[1,3,4,2] = A_4[1,2,4,3]$ and $A_4[1,4,2,3] = A_4[1,3,2,4]$), it reads

$$A_4[1,2,3,4] + A_4[1,2,4,3] + A_4[1,3,2,4] = 0, \tag{59.29}$$

so only *two* of the three are independent. The Kleiss–Kuijf count Eq. (59.26) agrees: $(n-2)! = 2! = 2$. Holding legs 1 and 4 fixed and permuting $\{2,3\}$ gives the two-element basis $\{A_4[1,2,3,4],\ A_4[1,3,2,4]\}$, in terms of which Eq. (59.29) expresses the third, $A_4[1,2,4,3] = -A_4[1,2,3,4] - A_4[1,3,2,4]$.

Finally, it is instructive to recover the familiar structure-constant form of the four-gluon color factors and check consistency. Re-expressing the trace combinations through Eq. (59.8), the pairing of each A_4 with its reflected trace assembles into the symmetric/antisymmetric color tensors built from $f^{abe}f^{cde}$ — the same s-, t-, u-channel color structures that appear in the textbook four-gluon computation. The trace basis Eq. (59.27) and the ff basis are related by the linear change Eq. (59.8); the trace basis is the one in which the kinematic coefficients are individually gauge invariant, which is exactly why it is the right basis for what follows.

The three orderings of Eq. (59.28), reduced to the two-element Kleiss–Kuijf basis by Eq. (59.29), are the carried Yang–Mills theory data: every later statement about the four-gluon amplitude — its vanishing helicity configurations, its Parke–Taylor value, its reconstruction by BCFW — is a statement about $A_4[1,2,3,4]$, with the full amplitude reassembled through Eq. (59.27).

We have now done what the factorial explosion of Table 59.1 demanded: the color has been factored off into a sum over $(n-1)!$ single traces, and what remains is a single gauge-invariant, cyclically symmetric object $A_n[1,2,\ldots,n]$, computed from the stripped rules Eqs. (59.12) to (59.14) and constrained by reflection Eq. (59.19) and the decoupling identity Eq. (59.22). With color out of the way, the partial amplitude is ready to be evaluated helicity by helicity using the spinor-helicity polarization vectors of Chapter 58; the next section exploits the freedom in their reference momenta to show that whole classes of helicity assignments make $A_n[1,\ldots,n]$ vanish, organizing the landscape and exposing why the surviving amplitudes are as simple as they are.

59.2 The Simplicity of Gluon Amplitudes: Vanishing Helicity Configurations

The previous section did the hard organizational work: it stripped the color algebra off the n-gluon amplitude and left us with the gauge-invariant, cyclically-ordered *color-ordered partial amplitude* A_n, together with a compact set of

color-ordered Feynman rules (Eqs. (59.12) to (59.14)) — a cubic vertex, a quartic vertex, and a scalar propagator, all stripped of group-theory factors. We continue Yang–Mills theory from there. The reward for that labor is that we may now ask a sharp question about kinematics alone, with no f^{abc} in sight: *given the helicities of the external gluons, what is A_n?* The answer, astonishingly, is that for the simplest helicity assignments it is exactly zero — not zero after a long cancellation that one must trust, but identically zero, diagram by diagram, once the gauge freedom hidden in the polarization vectors is spent wisely. Discovering *which* configurations vanish, and why, is what organizes the entire helicity landscape and exposes the lone surviving sector whose closed form is the subject of the next section. This is where the "hidden simplicity" the chapter promised first becomes visible.

59.2.1 External data and the freedom in the polarization vectors

Fix conventions once. All n gluon momenta are taken *outgoing* and massless, $p_i^2 = 0$, so each carries a pair of two-component spinors through the bispinor factorization of Eq. (58.1),

$$p_{i\,\alpha\dot\alpha} = p_{i\mu}\,\sigma^{\mu}_{\alpha\dot\alpha} = \lambda_{i\alpha}\,\tilde\lambda_{i\dot\alpha}, \tag{59.30}$$

with angle and square brackets $\langle i\,j\rangle$, $[i\,j]$ built from $\lambda_i, \tilde\lambda_i$. We will use repeatedly the two consequences of Eq. (59.30) established in Chapter 58: the Mandelstam relation for a massless pair,

$$2\,p_i\cdot p_j = \langle i\,j\rangle\,[j\,i], \tag{59.31}$$

and the contraction of a single momentum into the Pauli-vector string, $\langle i|\gamma^\mu|i] = 2\,p_i^\mu$.

Each external gluon of definite helicity ± 1 is contracted with a polarization vector. The crucial input from Chapter 58 is that these vectors are not unique: masslessness and transversality fix them only up to a gauge transformation $\varepsilon_i^\mu \to \varepsilon_i^\mu + c\,p_i^\mu$, and the spinor-helicity formalism packages that freedom in a *reference momentum* q_i (an arbitrary null momentum, $q_i^2 = 0$, not collinear with p_i). The polarization vectors of Eq. (58.111) are

$$\varepsilon_+^\mu(p_i;q_i) = \frac{\langle q_i|\gamma^\mu|i]}{\sqrt{2}\,\langle q_i\,i\rangle}, \qquad \varepsilon_-^\mu(p_i;q_i) = \frac{\langle i|\gamma^\mu|q_i]}{\sqrt{2}\,[i\,q_i]}, \tag{59.32}$$

where $+$ and $-$ denote positive and negative helicity. Shifting q_i shifts ε_i^μ by a multiple of p_i^μ; since A_n is gauge invariant, its value cannot depend on any of the q_i. *This is the lever the whole section pulls.* We are free to choose every q_i as we please, and we will choose them so that as many polarization contractions as possible vanish outright — making the amplitude's value (which is reference-independent) manifestly small or zero. The only discipline (Section 59.2.2) is

that a single fixed choice of each q_i must be used uniformly across every diagram, and that $\langle q_i\, i\rangle \neq 0$, $[i\, q_i] \neq 0$ so the vectors in Eq. (59.32) stay finite.

Two transversality properties follow immediately and we will lean on them. Using $\not{q} = |q\rangle\langle q| + |q]\langle q|$ inside Eq. (59.32),

$$\varepsilon_{\pm}(p_i; q_i)\cdot p_i = 0, \qquad \varepsilon_{\pm}(p_i; q_i)\cdot q_i = 0, \tag{59.33}$$

the first because $\langle q_i|\not{p}_i|i] \propto [i\, i] = 0$ and the second because $\langle q_i|\not{q}_i|i] \propto \langle q_i\, q_i\rangle = 0$ (with the conjugate statements for ε_-).

59.2.2 The master lemma: dot products of polarization vectors

Every Feynman diagram for A_n is, after all index contractions are carried out, a sum of products of Lorentz invariants built from the external polarizations and momenta. The polarizations enter in only two ways: dotted into each other, $\varepsilon_i\cdot\varepsilon_j$, or dotted into a momentum, $\varepsilon_i\cdot p_j$. The vanishing theorems hinge entirely on a single computation of the first kind. We isolate it.

The one spinor identity we need beyond Chapter 58 is the Fierz (Chisholm) rearrangement, which follows from the completeness relation of the Pauli matrices, $\sigma^{\mu}_{\alpha\dot\alpha}\,\bar\sigma_{\mu}^{\dot\beta\beta} = 2\,\delta_{\alpha}^{\beta}\,\delta_{\dot\alpha}^{\dot\beta}$, derived in Chapter 58. Contracting that relation between two angle–square strings gives

$$\langle a|\gamma^{\mu}|b]\,\langle c|\gamma_{\mu}|d] = 2\,\langle a\, c\rangle\,[d\, b], \tag{59.34}$$

valid for any four massless labels a, b, c, d. With Eq. (59.34) the three distinct polarization dot products are immediate.

Lemma 59.8 (Polarization contractions)**.** *For gluons $i \neq j$ with reference momenta q_i, q_j,*

$$\varepsilon_{+}(p_i; q_i)\cdot\varepsilon_{+}(p_j; q_j) = \frac{\langle q_i\, q_j\rangle\,[j\, i]}{\langle q_i\, i\rangle\,\langle q_j\, j\rangle}, \tag{59.35}$$

$$\varepsilon_{-}(p_i; q_i)\cdot\varepsilon_{-}(p_j; q_j) = \frac{\langle i\, j\rangle\,[q_j\, q_i]}{[i\, q_i]\,[j\, q_j]}, \tag{59.36}$$

$$\varepsilon_{+}(p_i; q_i)\cdot\varepsilon_{-}(p_j; q_j) = \frac{\langle q_i\, j\rangle\,[q_j\, i]}{\langle q_i\, i\rangle\,[j\, q_j]}. \tag{59.37}$$

Proof. For Eq. (59.35), insert Eq. (59.32) and apply Eq. (59.34) with $(a, b, c, d) = (q_i, i, q_j, j)$:

$$\varepsilon_{+}(p_i; q_i)\cdot\varepsilon_{+}(p_j; q_j) = \frac{\langle q_i|\gamma^{\mu}|i]\,\langle q_j|\gamma_{\mu}|j]}{2\,\langle q_i\, i\rangle\,\langle q_j\, j\rangle} = \frac{2\,\langle q_i\, q_j\rangle\,[j\, i]}{2\,\langle q_i\, i\rangle\,\langle q_j\, j\rangle}, \tag{59.38}$$

which is Eq. (59.35). Equation Eq. (59.36) is the parity conjugate $\langle\cdot\,\cdot\rangle \leftrightarrow [\cdot\,\cdot]$ of the same step applied to the two ε_- vectors, with $(a,b,c,d) = (i,q_i,j,q_j)$. For the mixed product Eq. (59.37), take $(a,b,c,d) = (q_i,i,j,q_j)$:

$$\varepsilon_+(p_i;q_i)\cdot\varepsilon_-(p_j;q_j) = \frac{\langle q_i|\gamma^\mu|i]\,\langle j|\gamma_\mu|q_j]}{2\,\langle q_i\,i\rangle\,[j\,q_j]} = \frac{2\,\langle q_i\,j\rangle\,[q_j\,i]}{2\,\langle q_i\,i\rangle\,[j\,q_j]}, \tag{59.39}$$

giving Eq. (59.37). □

Read off the structure that drives everything. A pair of like-helicity polarizations vanishes when their references agree: Eqs. (59.35) and (59.36) are proportional to $\langle q_i\,q_j\rangle$ and $[q_j\,q_i]$ respectively, both of which vanish for $q_i = q_j$. A mixed pair vanishes when one reference is aligned with the *other* particle's momentum: Eq. (59.37) is proportional to $\langle q_i\,j\rangle$ (kill it with $q_i = p_j$) and to $[q_j\,i]$ (kill it with $q_j = p_i$). These three facts are the entire toolkit.

A reference momentum is a gauge choice, not a kinematic variable

The freedom in q_i is the residual gauge freedom of the external gluon, and gauge invariance of A_n guarantees the final number is independent of it. Two rules keep the bookkeeping honest. First, each leg's q_i must be the *same* in every diagram of the sum — choosing different references for the same external gluon in different diagrams adds up gauge-variant pieces that do not assemble into a physical amplitude. Second, the chosen q_i must avoid the collinear locus $\langle q_i\,i\rangle = 0$ (or $[i\,q_i] = 0$) where Eq. (59.32) is singular; setting q_i equal to another external momentum p_k is legal precisely when p_i and p_k are not collinear, which is the generic situation.

59.2.3 The anatomy of a color-ordered tree

Before exploiting Theorem 59.8 we need one structural fact about how polarizations and momenta can possibly be contracted in a tree diagram. It is a counting argument, and it is exact.

Recall the color-ordered Feynman rules Eqs. (59.12) to (59.14). In Feynman gauge the propagator numerator is a metric, $-i\eta^{\mu\nu}/p^2$. The cubic vertex is the sum

$$V_3^{\mu_1\mu_2\mu_3}(p_1,p_2,p_3) = \frac{i}{\sqrt{2}}\Big(\eta^{\mu_1\mu_2}(p_1-p_2)^{\mu_3} + \eta^{\mu_2\mu_3}(p_2-p_3)^{\mu_1} + \eta^{\mu_3\mu_1}(p_3-p_1)^{\mu_2}\Big), \tag{59.40}$$

each term a product of *one metric and one momentum*; the quartic vertex,

$$V_4^{\mu_1\mu_2\mu_3\mu_4} = \frac{i}{2}\big(2\,\eta^{\mu_1\mu_3}\eta^{\mu_2\mu_4} - \eta^{\mu_1\mu_2}\eta^{\mu_3\mu_4} - \eta^{\mu_1\mu_4}\eta^{\mu_2\mu_3}\big), \tag{59.41}$$

is a sum of products of *two metrics and no momentum*. Three structural facts follow:

1. the only Lorentz tensors in any diagram's numerator are metrics (from propagators and vertices) and momenta (one per cubic vertex);

2. each external leg contributes exactly one polarization vector $\varepsilon_i^{\mu_i}$, contracted into the diagram;

3. a maximal chain of metrics $\eta^{\mu\nu}\eta_{\nu\rho}\cdots$ collapses to a single metric, so after collapsing, the numerator is a product of scalar factors, each of which is one of $\varepsilon_i \cdot \varepsilon_j$, $\varepsilon_i \cdot p$, or $p \cdot p$.

Let a be the number of $\varepsilon \cdot p$ factors and b the number of $\varepsilon \cdot \varepsilon$ factors in a given term. Each ε_i is used exactly once and ends up in exactly one such factor, so counting the n polarizations two ways,

$$a + 2b = n. \tag{59.42}$$

Momenta in the numerator arise *only* from cubic vertices — one apiece — so the total number of momentum factors available to be dotted into anything is V_3, the number of cubic vertices. Every $\varepsilon \cdot p$ factor consumes one of them (the others may go into $p \cdot p$), giving the inequality

$$a \le V_3. \tag{59.43}$$

Finally, the tree topology fixes V_3. A tree with n external legs, I internal lines and $V = V_3 + V_4$ vertices has $I = V - 1$; counting line endpoints, $3V_3 + 4V_4 = n + 2I = n + 2(V - 1)$, and subtracting $2V$ from both sides,

$$V_3 + 2V_4 = n - 2 \quad \Longrightarrow \quad V_3 \le n - 2, \tag{59.44}$$

with equality for a purely trivalent tree. Combining Eqs. (59.43) and (59.44) bounds the number of polarizations that can be saturated by a momentum:

$$\boxed{a \le n - 2\,.} \tag{59.45}$$

Together with the saturation identity Eq. (59.42), this is the engine. It says that across *any* tree diagram, at most $n - 2$ of the n external polarizations can be soaked up as $\varepsilon \cdot p$; the remaining ones have no choice but to pair among themselves, forcing at least

$$b = \tfrac{1}{2}(n - a) \ge \tfrac{1}{2}(n - (n - 2)) = 1 \tag{59.46}$$

factor of $\varepsilon \cdot \varepsilon$ in every term. *Every nonzero contribution to a gluon tree amplitude contains at least one polarization–polarization contraction.* The vanishing theorems are now corollaries: if we can arrange the references so that every $\varepsilon \cdot \varepsilon$ that could appear vanishes, then by Eq. (59.46) every term vanishes, and so does A_n.

59.2.4 All-plus and single-minus amplitudes vanish

Theorem 59.9 (Vanishing of the all-plus amplitude)**.** *At tree level the color-ordered n-gluon amplitude with all positive helicities vanishes for every $n \geq 3$,*

$$A_n(1^+, 2^+, \ldots, n^+) = 0. \tag{59.47}$$

Proof. Choose a single common reference momentum for all n legs, $q_1 = q_2 = \cdots = q_n \equiv q$, with q a fixed null momentum not collinear with any p_i (generic, hence available by Section 59.2.2). All external polarizations are of positive helicity, so the only polarization pairings that can occur are of $++$ type, and by Eq. (59.35) each is proportional to $\langle q_i\, q_j\rangle = \langle q\, q\rangle = 0$. Thus every possible $\varepsilon \cdot \varepsilon$ factor vanishes. But Eq. (59.46) guarantees that each term of each diagram contains at least one such factor. Hence every term vanishes, and the sum Eq. (59.47) is identically zero. □

Theorem 59.10 (Vanishing of the single-minus amplitude)**.** *At tree level the color-ordered n-gluon amplitude with exactly one negative helicity vanishes for every $n \geq 3$,*

$$A_n(1^-, 2^+, 3^+, \ldots, n^+) = 0, \tag{59.48}$$

and likewise for the negative leg in any position by cyclicity.

Proof. Let leg 1 carry the lone negative helicity. Choose the references of all the positive-helicity legs equal to the momentum of the negative one,

$$q_i = p_1 \quad (i = 2, \ldots, n), \tag{59.49}$$

and choose q_1 to be any other external momentum, say $q_1 = p_2$ (legal since p_1, p_2 are not collinear for generic kinematics). There are now two kinds of polarization pairing to inspect, since there is a single minus leg and no minus–minus pair is possible:

- *plus–plus* ($i, j \geq 2$): by Eq. (59.35), $\varepsilon_+(p_i; p_1)\cdot\varepsilon_+(p_j; p_1) \propto \langle q_i\, q_j\rangle = \langle 1\, 1\rangle = 0$;
- *plus–minus* ($i \geq 2$, leg 1): by Eq. (59.37), $\varepsilon_+(p_i; p_1) \cdot \varepsilon_-(p_1; q_1) \propto \langle q_i\, 1\rangle = \langle 1\, 1\rangle = 0$.

Every polarization dot product that can appear is zero. By Eq. (59.46) every term carries at least one of them, so every term vanishes and Eq. (59.48) holds. □

The two proofs are the same proof: spend the reference freedom to annihilate all $\varepsilon \cdot \varepsilon$, then invoke the counting bound Eq. (59.45) that forbids a term with none. The choice $q_i = p_1$ in Theorem 59.10 is the clever one — aligning every positive leg's reference with the unique negative momentum kills the plus–plus

contractions *and* the plus–minus contractions simultaneously, because both Eq. (59.35) and Eq. (59.37) carry a factor $\langle q_i\, 1\rangle$ that collapses to $\langle 1\, 1\rangle$. The same maneuver fails the instant a *second* negative leg appears, and that failure is exactly the door to the surviving sector, as we see in Section 59.2.6.

59.2.5 A worked four-gluon check

The theorems are slick enough to seem like sleight of hand. They are not: the cancellation is visible term by term in the smallest nontrivial case. We carry it out fully.

Worked Example 59.11 (The four-gluon all-plus amplitude, diagram by diagram)**.** Take the color order $(1,2,3,4)$ with all helicities positive and a common reference q for all four legs, so that by Eq. (59.35)

$$\varepsilon_i \cdot \varepsilon_j = 0 \quad \text{for all } i,j \in \{1,2,3,4\}. \tag{59.50}$$

The color-ordered amplitude $A_4(1^+,2^+,3^+,4^+)$ receives three contributions: the s-channel exchange with the cyclically adjacent pairs (12) and (34), the t-channel exchange with pairs (23) and (41), and the four-point contact term. We show each vanishes under Eq. (59.50).

Contact term. The quartic vertex Eq. (59.41) contracted with $\varepsilon_1\varepsilon_2\varepsilon_3\varepsilon_4$ is a sum of products of two $\varepsilon\cdot\varepsilon$ factors,

$$\tfrac{i}{2}\big(2(\varepsilon_1{\cdot}\varepsilon_3)(\varepsilon_2{\cdot}\varepsilon_4) - (\varepsilon_1{\cdot}\varepsilon_2)(\varepsilon_3{\cdot}\varepsilon_4) - (\varepsilon_1{\cdot}\varepsilon_4)(\varepsilon_2{\cdot}\varepsilon_3)\big) = 0 \tag{59.51}$$

by Eq. (59.50): it is pure $b=2$, the maximally bad case.

s-channel diagram. With internal momentum $P = p_1 + p_2$ flowing into the right vertex, the diagram is $V_3^{\mu_1\mu_2\nu}(p_1,p_2,-P)\,\frac{-i\,\eta_{\nu\rho}}{P^2}\,V_3^{\rho\mu_3\mu_4}(P,p_3,p_4)$ contracted with the four polarizations. Contract the left vertex Eq. (59.40) with $\varepsilon_{1\mu_1}\varepsilon_{2\mu_2}$:

$$\tfrac{i}{\sqrt{2}}\Big[\underbrace{(\varepsilon_1{\cdot}\varepsilon_2)(p_1-p_2)^\nu}_{=0} + \varepsilon_2^\nu\,(\varepsilon_1{\cdot}(p_2+P)) + \varepsilon_1^\nu\,(\varepsilon_2{\cdot}(-P-p_1))\Big]. \tag{59.52}$$

The first term dies by Eq. (59.50); the surviving piece is a vector with free index ν that is a linear combination of ε_1^ν and ε_2^ν, multiplied by scalar $\varepsilon\cdot p$ factors. The propagator passes the index $\nu \to \rho$ unchanged. The right vertex contracted with $\varepsilon_3\varepsilon_4$ gives, by the identical computation,

$$\tfrac{i}{\sqrt{2}}\Big[\underbrace{(\varepsilon_3{\cdot}\varepsilon_4)(p_3-p_4)^\rho}_{=0} + \varepsilon_4^\rho\,(\varepsilon_3{\cdot}(p_4-P)) + \varepsilon_3^\rho\,(\varepsilon_4{\cdot}(P-p_3))\Big], \tag{59.53}$$

again a linear combination of ε_3^ρ and ε_4^ρ. Contracting Eq. (59.52) with Eq. (59.53) through $\eta_{\nu\rho}$ produces only the four cross terms $\varepsilon_1{\cdot}\varepsilon_3$, $\varepsilon_1{\cdot}\varepsilon_4$, $\varepsilon_2{\cdot}\varepsilon_3$, $\varepsilon_2{\cdot}\varepsilon_4$, every one of which vanishes by Eq. (59.50). The s-channel diagram is zero.

t-channel diagram. Identical structure with $(12)(34) \to (23)(41)$; the contracted index again lands on a combination of two adjacent polarizations, and the cross contraction is again an $\varepsilon \cdot \varepsilon$. Zero.

Summing, $A_4(1^+, 2^+, 3^+, 4^+) = 0$. Note exactly how the counting bound Eq. (59.45) materialized: each trivalent diagram has $V_3 = 2$ cubic vertices, hence at most $a = 2$ momentum-saturated polarizations, leaving $b \geq 1$ — and the one forced $\varepsilon \cdot \varepsilon$ is precisely the cross contraction across the propagator that we just watched vanish.

59.2.6 Little-group weights and the MHV classification

We have proved that the $k = 0$ (all-plus), $k = n$ (all-minus, by parity), $k = 1$ and $k = n-1$ helicity sectors vanish at tree level, where k counts the negative-helicity legs. The counting argument tells us this is sharp. A nonzero term requires $b \geq 1$ by Eq. (59.46), i.e. at least one surviving $\varepsilon \cdot \varepsilon$. Inspect Theorem 59.8: a like-helicity pair can always be killed by a common reference (all $++$ share one q, all $--$ share another), and with at most one minus leg the only mixed pairings are $+-$, which a single alignment $q_+ = p_-$ kills as well. It is only when *two* negative-helicity legs are present that the reference choices needed to annihilate $++$, $+-$, and $--$ simultaneously become mutually inconsistent: forcing all $++$ and $+-$ to vanish by aligning the positive references with a negative leg leaves a $--$ contraction Eq. (59.36) that no remaining freedom can remove without re-creating a $+-$ contraction. Two negative helicities is therefore the smallest count at which a single $\varepsilon \cdot \varepsilon$ can survive — the minimum compatible with $b = 1$, $a = n - 2 = V_3$ in Eqs. (59.42) and (59.45). This is the sharp lower edge of the nonvanishing landscape.

The same conclusion is visible from little-group scaling without any diagram. Under the little-group rescaling $(\lambda_i, \tilde{\lambda}_i) \to (t_i \lambda_i, t_i^{-1} \tilde{\lambda}_i)$ of Eq. (58.5), a helicity-h_i leg forces the amplitude to scale as

$$A_n(\dots, \{t_i \lambda_i, t_i^{-1} \tilde{\lambda}_i\}, \dots) = \Big(\prod_{i=1}^{n} t_i^{-2h_i} \Big) A_n, \tag{59.54}$$

so each positive-helicity leg ($h_i = +1$) demands weight t_i^{-2} and each negative-helicity leg ($h_i = -1$) weight t_i^{+2}. A rational function carrying weight t_i^{-2} in *every* variable would have to be built almost entirely out of square brackets (which scale as t^{-1} in each label) with too few angle brackets to supply the physical poles that locality requires on multiparticle channels; the all-plus and single-minus weights are simply too lopsided to be realized by a local, pole-correct function other than zero. The first balanced assignment that locality can accommodate has two units of positive weight to spare — two negative-helicity legs. The little-group bookkeeping and the polarization-counting argument are two readings of the same fact.

Definition 59.12 (MHV classification)**.** Let A_n be a color-ordered n-gluon tree amplitude with exactly k negative-helicity legs and $n-k$ positive-helicity legs. Define the *MHV degree* of the configuration to be k. Then:

- $k=0$ and $k=1$ (and by parity $k=n$, $k=n-1$): the amplitude vanishes identically (Theorems 59.9 and 59.10);
- $k=2$: the *maximally-helicity-violating* (MHV) amplitude, the lowest nonvanishing sector;
- $k=n-2$: the *anti-MHV* ($\overline{\text{MHV}}$) amplitude;
- general k: the N^{k-2}MHV amplitude (so MHV is N^0MHV and $\overline{\text{MHV}}$ is N^{n-4}MHV).

Two remarks fix the picture. First, parity — the operation $\langle i\,j\rangle \leftrightarrow [i\,j]$ that flips every helicity — maps the MHV sector ($k=2$) to the anti-MHV sector ($k=n-2$); the two are the same physics read from the conjugate spinors, and at the lowest multiplicities they can coincide. For $n=3$, MHV and $\overline{\text{MHV}}$ are the two complex-momentum three-point amplitudes fixed by little-group scaling in Chapter 58 (Eq. (58.98)), $A_3(1^-,2^-,3^+)=\langle 1\,2\rangle^3/(\langle 2\,3\rangle\langle 3\,1\rangle)$ and its square-bracket conjugate. For $n=4$, the two-minus amplitude is both MHV ($k=2$) and anti-MHV ($k=n-2=2$); the classification first becomes nondegenerate at $n=5$.

Why "maximally helicity violating"

The name is a relic of the all-outgoing crossing convention. Read A_n as a $2\to(n-2)$ process by crossing two legs to the initial state, which flips their helicities. A configuration with all final-state gluons of one helicity would conserve a naive notion of total helicity; the experimentally and theoretically relevant nonzero amplitudes maximally *violate* that naive conservation. In the all-outgoing language this corresponds to the two-negative-helicity configuration: the most helicity violation a nonvanishing amplitude can carry, hence "maximally helicity violating." The vanishing of the all-plus and single-minus cases is the precise statement that less violation than this is too little to support a nonzero amplitude.

We have, by spending nothing but the gauge freedom hidden in the polarization vectors, collapsed the entire helicity landscape of gluon trees onto a graded ladder whose bottom two rungs are empty: the all-plus and single-minus amplitudes are identically zero, and the lowest sector that even *can* be nonzero is the MHV configuration with exactly two negative-helicity gluons. What that surviving amplitude actually equals — the remarkable one-line Parke–Taylor formula $A_n^{\text{MHV}} \propto \langle i\,j\rangle^4/(\langle 1\,2\rangle\langle 2\,3\rangle\cdots\langle n\,1\rangle)$, verified against an honest Feynman

computation and subjected to every consistency check — is the business of Eq. (59.55) in the next section.

59.3 The Parke–Taylor Formula

The previous section organized the helicity landscape of gluon amplitudes by exploiting the freedom in the reference momenta of the polarization vectors: amplitudes with all helicities alike, or with exactly one differing, vanish at tree level, and the first nonzero color-ordered amplitudes are the *maximally helicity-violating* (MHV) ones, carrying exactly two negative helicities among n legs (and their parity conjugates, $\overline{\text{MHV}}$, with two positive). That classification told us *which* amplitudes survive; it did not tell us what they are. The remarkable fact, discovered by Parke and Taylor in 1986 after a numerical and then analytic assault on multi-gluon scattering, is that the surviving MHV amplitudes are not merely nonzero but are given, for *every* n, by a single one-line holomorphic expression. The Lagrangian hides this; the spinor-helicity variables of Chapter 58 reveal it. This section states the formula, subjects it to every consistency check the formalism affords, and earns it through an honest Feynman computation at four points — carrying Yang–Mills theory to the milestone promised in the chapter introduction: Parke–Taylor computed the hard way at four points and posited at all n. The status we reach is precise: a checked-but-unproved all-n conjecture, whose proof must wait for the recursion built in the sections that follow.

Throughout we use the spinor-helicity conventions fixed in Chapter 58 (Theorem 58.2): for massless momenta $p_i = \lambda_i\tilde{\lambda}_i$ the angle and square brackets $\langle i\,j\rangle$, $[i\,j]$ are antisymmetric, $\langle i\,j\rangle[j\,i] = 2p_i\cdot p_j = s_{ij}$ (Eqs. (58.20) and (58.24)), and momentum conservation reads $\sum_i \lambda_i\tilde{\lambda}_i = 0$, i.e. $\sum_i |i\rangle\,[i\,] = 0$ as an operator on the spinor indices. We write $\langle i|\gamma^\mu|j] = \langle i|\,\gamma^\mu|j]$ for the mixed sandwich, with $\langle i|P|j] = \sum_k \langle i\,k\rangle[k\,j]$ for $P = \sum_k p_k$, and use the Fierz rearrangement $\langle a|\gamma^\mu|b]\langle c|\gamma_\mu|d] = 2\langle a\,c\rangle[d\,b]$ from Chapter C. Color-ordered amplitudes $A_n[\dots]$ are defined as in Theorem 59.3 through the trace decomposition, and we use the color-ordered Feynman rules of Eq. (59.12); we restate the two vertices we need at the point of use. The metric is mostly-minus and natural units are in force, as everywhere in the book.

59.3.1 Statement of the formula

We label the two negative-helicity gluons i and j and take all other legs positive. The amplitude is color-ordered with the cyclic ordering $(1, 2, \dots, n)$, all momenta outgoing.

Conjecture 59.13 (Parke–Taylor MHV amplitude)**.** *The n-gluon tree-level color-ordered MHV amplitude, with negative-helicity legs i and j and all other*

legs positive, is

$$A_n[1^+,\dots,i^-,\dots,j^-,\dots,n^+] \;=\; i\,g^{n-2}\,\frac{\langle i\,j\rangle^4}{\langle 1\,2\rangle\langle 2\,3\rangle\cdots\langle n-1\,n\rangle\langle n\,1\rangle}. \tag{59.55}$$

The full amplitude is reassembled by the color decomposition Theorem 59.3, $\mathcal{A}_n = g^{n-2}\sum_{\sigma\in S_n/\mathbb{Z}_n}\mathrm{tr}\big(T^{a_{\sigma(1)}}\cdots T^{a_{\sigma(n)}}\big)\,A_n[\sigma]$.

The denominator is the *Parke–Taylor chain*: the cyclic product of nearest-neighbor angle brackets in the color order, $\prod_{k=1}^{n}\langle k\,k+1\rangle$ with $n+1\equiv 1$. It is the same for every MHV amplitude of the given color ordering; only the numerator $\langle i\,j\rangle^4$ records which two legs carry negative helicity. The dependence is purely *holomorphic* — not a single square bracket appears. This is the analytic fingerprint of the MHV sector, and it is precisely the structure that the brute-force expansion in Feynman diagrams, with its thousands of individually gauge-dependent terms each built from both λ and $\tilde\lambda$, conceals until the very end.

The parity conjugate is obtained by exchanging the two chiralities, $\langle\,\rangle \leftrightarrow [\,]$, which exchanges positive and negative helicities. The $\overline{\mathrm{MHV}}$ amplitude, with exactly two positive-helicity legs i,j and all others negative, is

$$A_n[1^-,\dots,i^+,\dots,j^+,\dots,n^-] \;=\; (-1)^n\,i\,g^{n-2}\,\frac{[i\,j]^4}{[1\,2][2\,3]\cdots[n-1\,n][n\,1]}. \tag{59.56}$$

The sign $(-1)^n$ tracks the convention $\langle i\,j\rangle[j\,i] = s_{ij}$ under conjugation: replacing each $\langle k\,k+1\rangle$ in the chain by $[k\,k+1]$ flips a sign per factor through $[k\,k+1] = -[k+1\,k]$, and the bookkeeping leaves the overall $(-1)^n$ displayed. For the lowest multiplicities the two formulas coincide with the three-point amplitudes fixed by little-group scaling alone in Chapter 58: setting $n=3$ in Eq. (59.55) with negative legs $1,2$ gives

$$A_3[1^-,2^-,3^+] = i\,g\,\frac{\langle 1\,2\rangle^4}{\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,1\rangle} = i\,g\,\frac{\langle 1\,2\rangle^3}{\langle 2\,3\rangle\langle 3\,1\rangle}, \tag{59.57}$$

which is exactly the holomorphic three-point amplitude Eq. (58.98), and $n=3$ in Eq. (59.56) reproduces the antiholomorphic $A_3[1^+,2^+,3^-] = -i\,g\,[1\,2]^3/[2\,3][3\,1]$. Parke–Taylor is the unique holomorphic interpolation of these symmetry-fixed seeds to all n — a statement we will make exact once the recursion shows the seeds determine everything.

59.3.2 Consistency checks the formula must pass

Before any computation, the candidate Eq. (59.55) must respect the symmetries and dimensional analysis that any gluon amplitude obeys. Each check is a genuine constraint; passing all of them is strong, if not conclusive, evidence.

Little-group weight. Under the little-group rescaling of leg k (Eq. (58.5)), $\lambda_k \to t_k \lambda_k$, $\tilde{\lambda}_k \to t_k^{-1} \tilde{\lambda}_k$, a leg of helicity h_k forces the amplitude to scale as $A_n \to (\prod_k t_k^{-2h_k}) A_n$. We verify Eq. (59.55) carries exactly this weight on every leg. The angle bracket $\langle k \cdot \rangle$ scales as t_k; the square brackets are absent, so a leg's weight comes only from counting its angle brackets. Take first a *positive*-helicity leg $k \neq i, j$. It appears nowhere in the numerator and in exactly two chain factors of the denominator, $\langle k-1\, k\rangle$ and $\langle k\, k+1\rangle$, so the formula scales as t_k^{-2}. With $h_k = +1$ this is $t_k^{-2h_k}$, as required. Now a *negative*-helicity leg, say i: it appears four times in the numerator $\langle i\, j\rangle^4$ (weight t_i^{+4}) and twice in the denominator chain (weight t_i^{-2}), for a net t_i^{+2}. With $h_i = -1$ this is again $t_i^{-2h_i}$. Every leg is correct, and — crucially — the numerator power must be exactly four for the negative legs to come out right: had it been $\langle i\, j\rangle^3$ or $\langle i\, j\rangle^5$ the weight would fail. Little-group scaling fixes the numerator to be $\langle i\, j\rangle^4$, the unique monomial in the two negative-helicity spinors that does the job while keeping the expression holomorphic and of the correct overall dimension.

Mass dimension. An n-point amplitude in four dimensions has mass dimension $[A_n] = 4 - n$ (the S-matrix element carries dimension $4 - n$ once the momentum-conserving delta function and the canonical normalization of external states are stripped, exactly as for the scalar amplitudes of Chapter 14). Each bracket has mass dimension one. The Parke–Taylor numerator contributes $+4$ and the n-fold denominator chain contributes $-n$, giving net dimension $4 - n$. The check is automatic and, again, depends on the numerator power being four: it balances the four "extra" brackets that the closed cyclic chain carries beyond what dimension alone would demand.

Coupling power. A connected tree amplitude with only cubic and quartic vertices and n external legs has $V_3 + 2V_4 = n - 2$ powers of g, since each cubic vertex carries one power of g and each quartic two, and the tree topology fixes the total (the number of internal lines is $V_3 + V_4 - 1$ and $3V_3 + 4V_4 = n + 2(V_3 + V_4 - 1)$, which solves to $V_3 + 2V_4 = n - 2$). The prefactor g^{n-2} in Eq. (59.55) is exactly this, and is dimensionless in four dimensions, consistent with the mass-dimension count. The explicit factor of i is the standard normalization of a tree amplitude in our conventions, matching the three-point seed Eq. (58.98).

Cyclic symmetry and reflection. The denominator chain is manifestly invariant under the cyclic shift $k \to k + 1$, as a color-ordered amplitude must be (Theorem 59.3). Under the order reversal $(1, 2, \ldots, n) \to (n, n-1, \ldots, 1)$ each chain factor reverses, $\langle k\, k+1\rangle \to \langle k+1\, k\rangle = -\langle k\, k+1\rangle$, producing $(-1)^n$; the numerator $\langle i\, j\rangle^4$ is reflection-even. This reproduces the known reflection property of color-ordered amplitudes, $A_n[n, \ldots, 1] = (-1)^n A_n[1, \ldots, n]$, with no extra input.

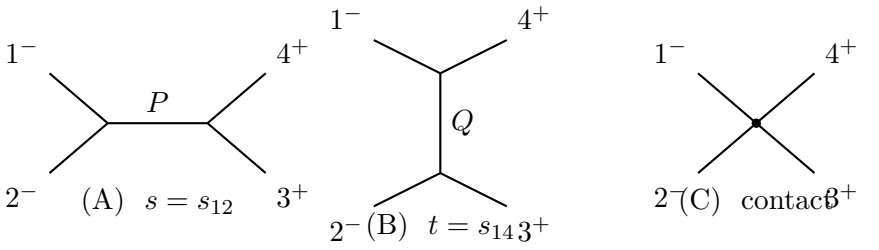

Figure 59.2: The three color-ordered Feynman diagrams for $A_4[1^-, 2^-, 3^+, 4^+]$ in the cyclic order $(1, 2, 3, 4)$: the planar s-channel exchange (A), the planar t-channel exchange (B), and the four-point contact term (C). The non-planar $u = s_{13}$ exchange does not contribute to this color ordering. With the reference-momentum choice Eq. (59.64) diagrams (B) and (C) vanish identically and the whole amplitude comes from (A).

These checks pin down the *form* of the answer almost completely: a holomorphic, cyclic, dimension-$(4 - n)$ object with the correct little-group weight and the right power of g is forced to be a constant times Eq. (59.55). What they cannot fix is that constant, nor that the residues on factorization channels are correct. For that we must compute.

59.3.3 The four-gluon amplitude the hard way

We now earn Eq. (59.55) at $n = 4$ by an honest color-ordered Feynman computation of $A_4[1^-, 2^-, 3^+, 4^+]$, reducing every Lorentz contraction to spinor brackets and matching the result to Parke–Taylor. This is the computation Parke and Taylor first did, and it is the payoff of the reference-momentum technology of the previous section: a judicious choice of polarization reference momenta collapses three diagrams to one and a handful of brackets.

We need two color-ordered Feynman rules from Eq. (59.12), both with all momenta outgoing. The cubic vertex for legs (a, b, c) in cyclic order, with Lorentz indices (α, β, γ), is

$$V_3^{\alpha\beta\gamma}(p_a, p_b, p_c) = \frac{ig}{\sqrt{2}}\Big[\eta^{\alpha\beta}(p_a - p_b)^\gamma + \eta^{\beta\gamma}(p_b - p_c)^\alpha + \eta^{\gamma\alpha}(p_c - p_a)^\beta\Big], \tag{59.58}$$

and the quartic vertex for legs (a, b, c, d) in cyclic order is

$$V_4^{\alpha\beta\gamma\delta} = \frac{ig^2}{2}\Big[2\eta^{\alpha\gamma}\eta^{\beta\delta} - \eta^{\alpha\beta}\eta^{\gamma\delta} - \eta^{\alpha\delta}\eta^{\beta\gamma}\Big]. \tag{59.59}$$

The internal gluon propagator in Feynman gauge is $-i\eta_{\mu\nu}/P^2$; color-ordered amplitudes are gauge invariant, so the gauge choice is a convenience. The three planar diagrams are drawn in Fig. 59.2: the s-channel exchange (A) in the

(12)(34) channel, the t-channel exchange (B) in the (23)(41) channel, and the four-point contact (C). The non-planar (13)(24) exchange is absent from this color ordering.

Polarizations and the reference choice. We recall the polarization vectors from Chapter 58, written with explicit reference momenta q,

$$\epsilon_+^\mu(p;q) = \frac{\langle q|\gamma^\mu|p]}{\sqrt{2}\,\langle q\,p\rangle}, \qquad \epsilon_-^\mu(p;q) = \frac{\langle p|\gamma^\mu|q]}{\sqrt{2}\,[q\,p]}. \tag{59.60}$$

Their inner products follow from the Fierz identity. For two like-helicity legs,

$$\epsilon_a^+\cdot\epsilon_b^+ = \frac{\langle q_a\,q_b\rangle[b\,a]}{\langle q_a\,a\rangle\langle q_b\,b\rangle}, \qquad \epsilon_a^-\cdot\epsilon_b^- = \frac{\langle a\,b\rangle[q_b\,q_a]}{[q_a\,a][q_b\,b]}, \tag{59.61}$$

and for opposite helicities,

$$\epsilon_b^+\cdot\epsilon_a^- = \frac{\langle q_b\,a\rangle[q_a\,b]}{\langle q_b\,b\rangle[q_a\,a]}. \tag{59.62}$$

We also need the dot product of a polarization with a momentum, again from the Fierz identity and $\not{p}_c = |c\rangle\,[c\,] + |c]\,\langle c|$,

$$\epsilon_b^+\cdot p_c = \frac{\langle q_b\,c\rangle[c\,b]}{\sqrt{2}\,\langle q_b\,b\rangle}, \qquad \epsilon_a^-\cdot p_c = \frac{\langle a\,c\rangle[c\,q_a]}{\sqrt{2}\,[q_a\,a]}. \tag{59.63}$$

The freedom is to choose each q independently (the amplitude is invariant under a shift $q \to q'$, as established in the previous section). We make the choice

$$q_1 = q_2 = p_4, \qquad q_3 = q_4 = p_1, \tag{59.64}$$

i.e. both negative-helicity gluons take p_4 as reference, and both positive-helicity gluons take p_1. The like-helicity products Eq. (59.61) now vanish at once: $\epsilon_1^-\cdot\epsilon_2^- \propto [q_2\,q_1] = [4\,4] = 0$ and $\epsilon_3^+\cdot\epsilon_4^+ \propto \langle q_3\,q_4\rangle = \langle 1\,1\rangle = 0$. Among the mixed products Eq. (59.62), three of the four vanish:

$$\epsilon_3^+\cdot\epsilon_1^- = \epsilon_4^+\cdot\epsilon_1^- \propto \langle q_{3,4}\,1\rangle = \langle 1\,1\rangle = 0, \qquad \epsilon_4^+\cdot\epsilon_2^- \propto [q_2\,4] = [4\,4] = 0, \tag{59.65}$$

and only

$$\epsilon_3^+\cdot\epsilon_2^- = \frac{\langle 1\,2\rangle[4\,3]}{\langle 1\,3\rangle[4\,2]} \tag{59.66}$$

survives. Two momentum dot products will also vanish and matter below: $\epsilon_1^-\cdot p_4 \propto [4\,4] = 0$ and $\epsilon_4^+\cdot p_1 \propto \langle 1\,1\rangle = 0$, using Eq. (59.63).

The contact diagram vanishes. The quartic vertex Eq. (59.59), contracted with the four polarizations, gives

$$(\mathrm{C}) = \frac{ig^2}{2}\Big[2(\epsilon_1\cdot\epsilon_3)(\epsilon_2\cdot\epsilon_4) - (\epsilon_1\cdot\epsilon_2)(\epsilon_3\cdot\epsilon_4) - (\epsilon_1\cdot\epsilon_4)(\epsilon_2\cdot\epsilon_3)\Big]. \tag{59.67}$$

Every term contains a vanishing factor under Eq. (59.64): $\epsilon_1^-\cdot\epsilon_3^+ = 0$, then $\epsilon_1^-\cdot\epsilon_2^- = 0$, then $\epsilon_1^-\cdot\epsilon_4^+ = 0$. Hence (C) $= 0$.

The t-channel diagram vanishes. Diagram (B) joins a cubic vertex with legs $(2,3)$ to a cubic vertex with legs $(4,1)$ through a propagator carrying $Q = p_2 + p_3$, $t = s_{14} = s_{23} = Q^2$. Contracting Eq. (59.58) at the left vertex on legs $2,3$ and leaving the internal index free, using $\epsilon_i\cdot p_i = 0$ and $p_{\text{int}} = -(p_2+p_3)$,

$$V_L^\mu = \frac{ig}{\sqrt{2}}\Big[(\epsilon_2\cdot\epsilon_3)(p_2-p_3)^\mu + 2(\epsilon_2\cdot p_3)\,\epsilon_3^\mu - 2(\epsilon_3\cdot p_2)\,\epsilon_2^\mu\Big], \tag{59.68}$$

and likewise at the right vertex on legs $4,1$ with internal momentum $Q = -(p_1+p_4)$, and using $\epsilon_4^+\cdot\epsilon_1^- = 0$,

$$V_R^\nu = \frac{ig}{\sqrt{2}}\Big[-2(p_4\cdot\epsilon_1)\,\epsilon_4^\nu + 2(p_1\cdot\epsilon_4)\,\epsilon_1^\nu\Big]. \tag{59.69}$$

The diagram is (B) $= V_L^\mu(-i\eta_{\mu\nu}/t)\,V_R^\nu = (-i/t)\,V_L\cdot V_R$. In the contraction $V_L\cdot V_R$, the ϵ_3^μ and ϵ_2^μ terms of V_L die against V_R because $\epsilon_3^+\cdot\epsilon_4^+ = \epsilon_3^+\cdot\epsilon_1^- = 0$ and $\epsilon_2^-\cdot\epsilon_4^+ = \epsilon_2^-\cdot\epsilon_1^- = 0$, leaving only the $(\epsilon_2\cdot\epsilon_3)(p_2-p_3)^\mu$ term to contract with V_R. But that contraction needs $(p_2-p_3)\cdot\epsilon_4$ multiplying $D \equiv -2p_4\cdot\epsilon_1 = 0$, and $(p_2-p_3)\cdot\epsilon_1$ multiplying $E \equiv 2p_1\cdot\epsilon_4 = 0$ — both coefficients vanish by the two special momentum dot products noted above. Therefore $V_L\cdot V_R = 0$ and (B) $= 0$.

The s-channel diagram, evaluated. Only diagram (A) remains. It joins a cubic vertex on legs $(1,2)$ to a cubic vertex on legs $(3,4)$ through a propagator carrying $P = p_1+p_2$, $s = s_{12} = P^2$. With $\epsilon_1^-\cdot\epsilon_2^- = 0$ the left vertex collapses to

$$V_L^\mu = \frac{ig}{\sqrt{2}}\Big[2(\epsilon_1\cdot p_2)\,\epsilon_2^\mu - 2(\epsilon_2\cdot p_1)\,\epsilon_1^\mu\Big], \tag{59.70}$$

and with $\epsilon_3^+\cdot\epsilon_4^+ = 0$ the right vertex collapses to

$$V_R^\nu = \frac{ig}{\sqrt{2}}\Big[-2(p_3\cdot\epsilon_4)\,\epsilon_3^\nu + 2(p_4\cdot\epsilon_3)\,\epsilon_4^\nu\Big]. \tag{59.71}$$

Contracting through the propagator, (A) $= (-i/s)\,V_L\cdot V_R$, and in $V_L\cdot V_R$ only the term proportional to $\epsilon_2^-\cdot\epsilon_3^+$ survives (the others carry $\epsilon_2^-\cdot\epsilon_4^+$, $\epsilon_1^-\cdot\epsilon_3^+$, or $\epsilon_1^-\cdot\epsilon_4^+$, all zero):

$$V_L\cdot V_R = \Big(\tfrac{ig}{\sqrt{2}}\Big)^2\,[2(\epsilon_1\cdot p_2)]\,[-2(p_3\cdot\epsilon_4)](\epsilon_2\cdot\epsilon_3) = 2g^2(\epsilon_1\cdot p_2)(\epsilon_4\cdot p_3)(\epsilon_2\cdot\epsilon_3). \tag{59.72}$$

Hence

$$A_4 = (\mathrm{A}) = \frac{-i}{s} \cdot 2g^2 (\epsilon_1 \cdot p_2)(\epsilon_4 \cdot p_3)(\epsilon_2 \cdot \epsilon_3). \tag{59.73}$$

Now insert the spinor expressions. From Eq. (59.63) with the references Eq. (59.64),

$$\epsilon_1^- \cdot p_2 = \frac{\langle 1\,2\rangle [2\,4]}{\sqrt{2}\,[4\,1]}, \qquad \epsilon_4^+ \cdot p_3 = \frac{\langle 1\,3\rangle [3\,4]}{\sqrt{2}\,\langle 1\,4\rangle}, \tag{59.74}$$

and from Eq. (59.66), $\epsilon_2^- \cdot \epsilon_3^+ = \langle 1\,2\rangle [4\,3]/(\langle 1\,3\rangle [4\,2])$. Multiplying, the two factors of $1/\sqrt{2}$ combine with the $-2i\,g^2/s$ to give $-ig^2/s$, and one $\langle 1\,3\rangle$ cancels:

$$A_4 = \frac{-ig^2}{s} \cdot \frac{\langle 1\,2\rangle^2\,[2\,4]\,[3\,4]\,[4\,3]}{[4\,1]\,\langle 1\,4\rangle\,[4\,2]}. \tag{59.75}$$

Using $[2\,4] = -[4\,2]$ and $[4\,3] = -[3\,4]$, the square-bracket ratio simplifies to $[2\,4][3\,4][4\,3]/([4\,1][4\,2]) = -[3\,4]^2/[4\,1]$, so

$$A_4 = \frac{ig^2}{s} \cdot \frac{\langle 1\,2\rangle^2\,[3\,4]^2}{\langle 1\,4\rangle\,[4\,1]} = -\frac{ig^2\,\langle 1\,2\rangle^2\,[3\,4]^2}{s_{12}\,s_{14}}, \tag{59.76}$$

where we used $\langle 1\,4\rangle [4\,1] = s_{14}$ and $s = s_{12}$. It remains to turn the square brackets into angle brackets and recover the holomorphic Parke–Taylor form. Two relations from momentum conservation do this. Contracting $\sum_k |k\rangle\,[k\,] = 0$ between $\langle 3|$ and $|1]$ gives $\langle 3\,2\rangle [2\,1] + \langle 3\,4\rangle [4\,1] = 0$, hence

$$[2\,1] = -\frac{\langle 3\,4\rangle\,[4\,1]}{\langle 3\,2\rangle}, \qquad \text{so} \qquad s_{12} = \langle 1\,2\rangle [2\,1] = -\frac{\langle 1\,2\rangle\,\langle 3\,4\rangle\,[4\,1]}{\langle 3\,2\rangle}. \tag{59.77}$$

The on-shell equality of channel invariants, $s_{34} = s_{12}$ (since $p_3 + p_4 = -(p_1 + p_2)$), gives $[3\,4] = s_{12}/\langle 4\,3\rangle = -s_{12}/\langle 3\,4\rangle$, so $[3\,4]^2 = s_{12}^2/\langle 3\,4\rangle^2$. Substituting into Eq. (59.76),

$$A_4 = -\frac{ig^2\,\langle 1\,2\rangle^2}{s_{12}\,s_{14}} \cdot \frac{s_{12}^2}{\langle 3\,4\rangle^2} = -\frac{ig^2\,\langle 1\,2\rangle^2\,s_{12}}{s_{14}\,\langle 3\,4\rangle^2}. \tag{59.78}$$

With $s_{14} = \langle 1\,4\rangle [4\,1]$ and s_{12} from Eq. (59.77), the ratio s_{12}/s_{14} becomes purely holomorphic,

$$\frac{s_{12}}{s_{14}} = \frac{-\langle 1\,2\rangle\langle 3\,4\rangle [4\,1]/\langle 3\,2\rangle}{\langle 1\,4\rangle [4\,1]} = -\frac{\langle 1\,2\rangle\,\langle 3\,4\rangle}{\langle 3\,2\rangle\,\langle 1\,4\rangle}, \tag{59.79}$$

and therefore

$$A_4 = -\frac{ig^2\,\langle 1\,2\rangle^2}{\langle 3\,4\rangle^2} \cdot \left(-\frac{\langle 1\,2\rangle\,\langle 3\,4\rangle}{\langle 3\,2\rangle\,\langle 1\,4\rangle}\right) = \frac{ig^2\,\langle 1\,2\rangle^3}{\langle 3\,4\rangle\,\langle 3\,2\rangle\,\langle 1\,4\rangle}. \tag{59.80}$$

Finally $\langle 3\,2\rangle = -\langle 2\,3\rangle$ and $\langle 1\,4\rangle = -\langle 4\,1\rangle$, so the two signs cancel and

$$\boxed{A_4[1^-, 2^-, 3^+, 4^+] = \frac{ig^2\,\langle 1\,2\rangle^3}{\langle 2\,3\rangle\,\langle 3\,4\rangle\,\langle 4\,1\rangle} = ig^2\,\frac{\langle 1\,2\rangle^4}{\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle}} \tag{59.81}$$

which is exactly Eq. (59.55) at $n = 4$ with $i = 1$, $j = 2$. The thousands of terms that a naive covariant computation would generate — here tamed to three diagrams and then to one by the reference choice — collapse to a single ratio of angle brackets. This is the concrete demonstration, in Yang–Mills theory, that the Lagrangian's complexity is a feature of the variables, not of the physics.

Worked Example 59.14 (Four-gluon amplitude from Parke–Taylor in invariants)**.** As a final cross-check we re-express Eq. (59.81) in Mandelstam invariants and confirm it has the correct dimensions and poles. The cleanest route is through the squared modulus, using $|\langle i\,j\rangle|^2 = |s_{ij}|$. Form

$$|A_4|^2 = g^4\,\frac{|\langle 1\,2\rangle|^8}{|\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle|^2} = g^4\,\frac{s_{12}^4}{s_{12}s_{23}s_{34}s_{41}} = g^4\,\frac{s_{12}^4}{s_{12}^2 s_{23}^2} = g^4\,\frac{s_{12}^2}{s_{23}^2} = g^4\,\frac{s^2}{t^2}, \tag{59.82}$$

where we used $|\langle i\,j\rangle|^2 = |s_{ij}|$, the four-point identities $s_{34} = s_{12}$, $s_{41} = s_{23}$, and $s = s_{12}$, $t = s_{23}$. The amplitude carries the expected $1/s$ and $1/t$ single poles of Eq. (59.76) (the $1/t$ pole is hidden in Eq. (59.81) but reappears upon clearing the holomorphic chain), each the residue of a physical gluon going on shell in the corresponding channel, and $|A_4|^2$ has mass dimension zero, consistent with $[A_4] = 0$ in $d = 4$. The full color-summed four-gluon amplitude, assembled from the six orderings via Theorem 59.3, is the carried Yang–Mills theory four-gluon result; with Eq. (59.81) as the color-ordered building block, the color algebra is the only remaining ingredient.

59.3.4 The soft limit and the Weinberg soft factor

A genuine amplitude must factorize correctly when a gluon becomes soft. Parke–Taylor does, and the factorization reproduces the universal soft theorem of Chapter 18 (Weinberg) in its sharpest, spinor-helicity form. Take the positive-helicity gluon n soft, $p_n \to 0$, with its two cyclic neighbors $n-1$ and 1. In Eq. (59.55) the only chain factors that touch leg n are $\langle n-1\,n\rangle$ and $\langle n\,1\rangle$. Insert a factor of unity, $1 = \langle n-1\,1\rangle/\langle n-1\,1\rangle$, to extract them:

$$A_n = \underbrace{\frac{\langle n-1\,1\rangle}{\langle n-1\,n\rangle\,\langle n\,1\rangle}}_{S^{(0)}(n-1,n^+,1)} \times \underbrace{i\,g^{\,n-2}\,\frac{\langle i\,j\rangle^4}{\langle 1\,2\rangle\cdots\langle n-2\,n-1\rangle\langle n-1\,1\rangle}}_{g\,A_{n-1}[1,\ldots,n-1]}. \tag{59.83}$$

The second factor is, up to the one power of g that the lost vertex carries, exactly the $(n-1)$-gluon Parke–Taylor amplitude with leg n removed and the chain closed by $\langle n-1\,1\rangle$ — and it is unchanged in the limit because none of its brackets involve n. The first factor is the *leading soft factor*

$$S^{(0)}(a,s^+,b) = \frac{\langle a\,b\rangle}{\langle a\,s\rangle\,\langle s\,b\rangle}, \tag{59.84}$$

for soft gluon s of positive helicity between hard neighbors a, b. As $p_s \to 0$ the spinor $\lambda_s \to 0$, so $\langle a\, s\rangle, \langle s\, b\rangle \sim \lambda_s^{1/2} \sim p_s^{1/2}$ while $\langle a\, b\rangle$ stays finite, and $S^{(0)} \sim 1/p_s$: the amplitude diverges as the inverse soft energy, the universal infrared behavior of gauge theory. The parity-conjugate soft factor for a negative-helicity soft gluon is $S^{(0)}(a, s^-, b) = [a\, b]/([a\, s][s\, b])$.

That Eq. (59.84) is the Weinberg soft factor is seen by undoing the spinors. The covariant leading soft factor of Chapter 18 is $\epsilon_s{\cdot}(p_a/(p_a{\cdot}p_s) - p_b/(p_b{\cdot}p_s))$. Take $\epsilon_s^+(p_s; q)$ with reference q. Using Eq. (59.63), $\epsilon_s^+{\cdot}p_a/(p_s{\cdot}p_a) = \langle q\, a\rangle[a\, s]/(\sqrt{2}\,\langle q\, s\rangle \cdot \frac{1}{2}\langle s\, a\rangle[a\, s]) = \sqrt{2}\,\langle q\, a\rangle/(\langle q\, s\rangle\langle s\, a\rangle)$, and the same with $a \to b$. The difference is

$$\sqrt{2}\left(\frac{\langle q\, a\rangle}{\langle q\, s\rangle\langle s\, a\rangle} - \frac{\langle q\, b\rangle}{\langle q\, s\rangle\langle s\, b\rangle}\right) = \frac{\sqrt{2}}{\langle q\, s\rangle}{\cdot}\frac{\langle q\, a\rangle\langle s\, b\rangle - \langle q\, b\rangle\langle s\, a\rangle}{\langle s\, a\rangle\langle s\, b\rangle} = \frac{\sqrt{2}}{\langle q\, s\rangle}{\cdot}\frac{\langle q\, s\rangle\langle a\, b\rangle}{\langle s\, a\rangle\langle s\, b\rangle} = \sqrt{2}\,\frac{\langle a\, b\rangle}{\langle s\, a\rangle\langle s\, b\rangle}, \tag{59.85}$$

where the middle step is the Schouten identity $\langle q\, a\rangle\langle s\, b\rangle - \langle q\, b\rangle\langle s\, a\rangle = \langle q\, s\rangle\langle a\, b\rangle$. The reference q drops out, as it must, and we recover $S^{(0)}$ up to the $\sqrt{2}$ that the color-ordered normalization absorbs. The soft theorem and Parke–Taylor agree: each is the other read in different variables.

59.3.5 The collinear limit and the gluon splitting amplitudes

The second physical factorization is the collinear limit: two adjacent gluons a, b become parallel, $p_a \to z\,P$ and $p_b \to (1-z)\,P$ with $P = p_a + p_b$ on shell ($P^2 = 2p_a{\cdot}\,p_b = \langle a\, b\rangle[b\, a] \to 0$), so $\langle a\, b\rangle \to 0$. There an n-point amplitude must degenerate into an $(n-1)$-point amplitude times a universal *splitting amplitude*,

$$A_n(\ldots, a^{h_a}, b^{h_b}, \ldots) \xrightarrow{a\|b} \sum_{h=\pm} \mathrm{Split}_{-h}(a^{h_a}, b^{h_b})\, A_{n-1}(\ldots, P^h, \ldots), \tag{59.86}$$

where P^h is the merged leg of helicity h and the splitting amplitude carries the collinear singularity $\sim 1/\langle a\, b\rangle$ or $1/[a\, b]$. The holomorphic collinear kinematics — the regime in which the angle bracket vanishes faster than the square bracket — has $\lambda_a \to \sqrt{z}\,\lambda_P$, $\lambda_b \to \sqrt{1-z}\,\lambda_P$, so that for any spectator x,

$$\langle a\, x\rangle \to \sqrt{z}\,\langle P\, x\rangle, \qquad \langle b\, x\rangle \to \sqrt{1-z}\,\langle P\, x\rangle. \tag{59.87}$$

We extract the splitting amplitudes directly from Parke–Taylor, considering the cases the MHV formula can reach.

Take first *two adjacent positive-helicity legs* a^+, b^+ becoming collinear in an MHV amplitude whose two negative legs lie elsewhere. Write x and y for the cyclic neighbors of the pair, so the chain contains $\cdots\langle x\, a\rangle\langle a\, b\rangle\langle b\, y\rangle\cdots$. Under Eq. (59.87) the numerator $\langle i\, j\rangle^4$ is untouched, $\langle x\, a\rangle \to \sqrt{z}\,\langle x\, P\rangle$, $\langle b\, y\rangle \to \sqrt{1-z}\,\langle P\, y\rangle$, and $\langle a\, b\rangle \to 0$ supplies the singularity. Hence

$$A_n \xrightarrow{a\|b} \frac{1}{\sqrt{z(1-z)}\,\langle a\, b\rangle}{\cdot}\, i\, g^{\,n-3}\,\frac{\langle i\, j\rangle^4}{\cdots\langle x\, P\rangle\langle P\, y\rangle\cdots} = \mathrm{Split}_-(a^+, b^+)\, A_{n-1}(\ldots, P^+, \ldots), \tag{59.88}$$

with the merged leg P positive-helicity (the negatives are preserved) and

$$\mathrm{Split}_{-}(a^{+},b^{+}) = \frac{1}{\sqrt{z(1-z)}\,\langle a\,b\rangle}. \tag{59.89}$$

The subscript records the helicity $-h = -(+)$ that the splitting vertex assigns to the off-shell line entering A_{n-1}.

Take next *one negative and one positive leg* collinear, say a^{-},b^{+} adjacent, with the other negative leg j a spectator. Now a appears in the numerator: $\langle a\,j\rangle^{4} \to z^{2}\,\langle P\,j\rangle^{4}$ by Eq. (59.87). The denominator behaves as before, and

$$A_n \xrightarrow{a\|b} \frac{z^{2}}{\sqrt{z(1-z)}\,\langle a\,b\rangle}\cdot i\,g^{\,n-3}\frac{\langle P\,j\rangle^{4}}{\cdots\langle x\,P\rangle\langle P\,y\rangle\cdots} = \mathrm{Split}_{-}(a^{-},b^{+})\,A_{n-1}(\ldots,P^{-},\ldots), \tag{59.90}$$

with the merged leg now negative-helicity, and

$$\mathrm{Split}_{-}(a^{-},b^{+}) = \frac{z^{2}}{\sqrt{z(1-z)}\,\langle a\,b\rangle}. \tag{59.91}$$

The complementary assignment a^{+},b^{-} follows by the relabeling $a \leftrightarrow b$, $z \leftrightarrow 1-z$, giving $\mathrm{Split}_{-}(a^{+},b^{-}) = (1-z)^{2}/(\sqrt{z(1-z)}\,\langle a\,b\rangle)$. These three exhaust the holomorphic (angle-bracket) splittings accessible from the MHV formula. Their parity conjugates — obtained from the $\overline{\mathrm{MHV}}$ formula Eq. (59.56) by $\langle\,\rangle \to [\,]$ and $z^{k} \to (1-z)^{\cdots}$ bookkeeping — are the antiholomorphic splittings

$$\mathrm{Split}_{+}(a^{-},b^{-}) = \frac{-1}{\sqrt{z(1-z)}\,[a\,b]}, \quad \mathrm{Split}_{+}(a^{+},b^{-}) = \frac{-z^{2}}{\sqrt{z(1-z)}\,[a\,b]}, \tag{59.92}$$

and the relabeled partner. The combinations that would merge two same-helicity gluons into the "wrong" internal helicity — e.g. $\mathrm{Split}_{+}(a^{+},b^{+})$ — vanish, the collinear shadow of the helicity-vanishing theorems of the previous section. That Parke–Taylor reproduces *every* splitting amplitude with its correct z-dependence, on top of the soft factor and the symmetry checks, is the strongest evidence short of proof that Eq. (59.55) is right at all n.

Physical Insight

The soft and collinear limits are not optional checks bolted onto an answer; they are the boundary data that, together with the locations of the poles, almost determine a tree amplitude. Parke–Taylor passes them because it is built from the same physics — on-shell factorization on physical channels — that the recursion of the next sections will turn into a constructive proof. An amplitude that has the right poles, the right residues (lower amplitudes), the right soft and collinear limits, and the right little-group weight is forced to be the right amplitude. The formula was conjectured

before this was understood; the recursion is the understanding.

59.3.6 Status: a checked-but-unproved all-n formula

We have established Eq. (59.55) at $n = 4$ by direct computation (Eq. (59.81)), reduced it to the symmetry-fixed three-point amplitude at $n = 3$ (Eq. (59.57)), and verified that it carries the correct little-group weight, mass dimension, coupling power, cyclic and reflection symmetry, and — most tellingly — the correct soft (Eq. (59.84)) and collinear (Eqs. (59.89), (59.91) and (59.92)) factorizations on every physical channel. What we have not done is prove it for general n. Every check is consistent with Eq. (59.55), and the form is nearly forced, but consistency is not derivation: a brute-force Feynman computation at, say, six gluons would test thousands of diagrams, and we will not undertake it. The honest status is a *conjecture*, Theorem 59.13, supported by overwhelming low-multiplicity and structural evidence.

The structural evidence points the way to a proof. The soft and collinear analyses showed that an amplitude is pinned by its behavior on factorization channels: its poles sit where intermediate gluons go on shell, and its residues are products of lower-point amplitudes. If one could build the full amplitude from its residues alone — from lower amplitudes glued on physical poles, with no Lagrangian and no off-shell diagrams — then Eq. (59.55) would follow by induction from the three-point seed Eq. (59.57). The obstruction is that the three-point amplitude vanishes on real massless kinematics, where the only solution to momentum conservation collapses both chiralities. The next section confronts exactly this: complexifying the momenta resurrects the three-point amplitude by letting one chirality survive, and supplies the complex three-point kinematics that the recursion of the following sections requires to turn "checked" into "proved."

59.4 Complex Momenta and the Three-Point Amplitude

The previous section left the Parke–Taylor formula standing as a conjecture: a one-line expression for every MHV amplitude, checked against an honest Feynman computation at low multiplicity and surviving every consistency test, but not yet *proved*. The proof we are heading toward is recursive. It will build an n-point amplitude out of amplitudes with fewer legs, and like every recursion it needs a base case — an irreducible seed that the recursion does not itself explain but instead takes as input. For gluon trees the seed is the smallest amplitude there is, the three-point amplitude A_3. Here we hit an immediate and serious obstruction. For three massless particles, real on-shell momentum conservation

is so constraining that the kinematics collapses: the natural invariants all vanish, the polarization contractions die, and the three-gluon amplitude evaluates to an indeterminate $0/0$ that one is tempted to call simply zero. A recursion seeded by zero produces zero. The resolution, and the central idea of this section, is that nothing forces the external momenta to be real. If we allow the momenta to be *complex* — specifically, if we let the holomorphic spinor λ and the antiholomorphic spinor $\tilde{\lambda}$ vary independently, which reality would forbid — the degeneracy lifts. One of the two bracket sets can stay generic while the other vanishes, and on that complex locus the three-point amplitude is not only nonzero but is uniquely fixed, up to a single constant, by little-group scaling and locality alone. Fixing that constant against the three-gluon vertex of Chapter 26 delivers the two nonvanishing complex three-point amplitudes that seed everything to come.

59.4.1 Real three-point kinematics is degenerate

Fix three outgoing massless momenta p_1, p_2, p_3 subject to conservation $p_1 + p_2 + p_3 = 0$ and the on-shell conditions $p_i^2 = 0$. The first fact is that these conditions force every Lorentz invariant $p_i \cdot p_j$ to vanish.

Lemma 59.15 (Vanishing of all three-point invariants)**.** *For three on-shell massless momenta with $p_1 + p_2 + p_3 = 0$,*

$$p_1 \cdot p_2 = p_2 \cdot p_3 = p_3 \cdot p_1 = 0. \tag{59.93}$$

Proof. Solve conservation for one momentum, $p_3 = -(p_1 + p_2)$, and impose its mass-shell condition:

$$0 = p_3^2 = (p_1 + p_2)^2 = p_1^2 + 2\, p_1 \cdot p_2 + p_2^2 = 2\, p_1 \cdot p_2, \tag{59.94}$$

using $p_1^2 = p_2^2 = 0$. Hence $p_1 \cdot p_2 = 0$. The same elimination of p_1 gives $p_2 \cdot p_3 = 0$ and of p_2 gives $p_3 \cdot p_1 = 0$. □

Now translate Eq. (59.93) into spinor-helicity language. Each massless momentum factorizes through the bispinor map of Eq. (58.1),

$$p_{i\,\alpha\dot{\alpha}} = p_{i\mu}\, \sigma^{\mu}_{\alpha\dot{\alpha}} = \lambda_{i\alpha}\, \tilde{\lambda}_{i\dot{\alpha}}, \tag{59.95}$$

and the Mandelstam relation Eq. (59.31) reads $2\, p_i \cdot p_j = \langle i\, j \rangle\, [j\, i]$. Combining this with Eq. (59.93),

$$\langle 1\, 2 \rangle\, [2\, 1] = \langle 2\, 3 \rangle\, [3\, 2] = \langle 3\, 1 \rangle\, [1\, 3] = 0. \tag{59.96}$$

Each equation in Eq. (59.96) is a product of an angle bracket and a square bracket set to zero, so for each pair (i, j) at least one of $\langle i\, j \rangle$, $[i\, j]$ must vanish. The decisive question is whether the angle and square brackets can be switched off independently, and that is exactly where reality enters.

Proposition 59.16 (Real degeneracy)**.** *For three on-shell massless momenta with* $p_1 + p_2 + p_3 = 0$ *and* real *energies, every angle bracket and every square bracket among the three legs vanishes,*

$$\langle 1\,2\rangle = \langle 2\,3\rangle = \langle 3\,1\rangle = 0 \quad \textit{and} \quad [1\,2] = [2\,3] = [3\,1] = 0, \tag{59.97}$$

so that the three momenta are mutually collinear and no nonzero invariant survives.

Proof. For real momenta the two spinors attached to each leg are not independent: the reality condition of Chapter 58 fixes $\tilde{\lambda}_i = \pm\bar{\lambda}_i$, the sign being that of the energy p_i^0. Consequently the square bracket is, up to a phase and sign, the complex conjugate of the angle bracket,

$$[i\,j] = \pm\,\overline{\langle i\,j\rangle}\,, \qquad \text{hence} \qquad |[i\,j]| = |\langle i\,j\rangle|. \tag{59.98}$$

Thus $\langle i\,j\rangle = 0$ if and only if $[i\,j] = 0$: for real kinematics the two brackets of a pair vanish together. But Eq. (59.96) requires at least one of each pair to vanish, so by Eq. (59.98) both do, for every pair — which is Eq. (59.97). Finally, $\langle i\,j\rangle = 0$ means the two-component spinors λ_i, λ_j are proportional (an antisymmetric 2×2 contraction vanishes precisely when its arguments are parallel), so all three λ_i are proportional; likewise all three $\tilde{\lambda}_i$. The momenta $p_i = \lambda_i\tilde{\lambda}_i$ are then all proportional to a single null vector, i.e. mutually collinear. □

Theorem 59.16 is the obstruction in its sharpest form. The candidate three-point amplitudes one writes from little-group scaling — ratios of angle brackets, or ratios of square brackets — are evaluated on a configuration where *both* numerator and denominator brackets vanish. They are not honestly zero; they are $0/0$, undefined. Physically this is the familiar statement that two real massless particles cannot decay into a third without something going collinear: there is no genuine real kinematics for a $1 \to 2$ massless process, and the three-point amplitude has no real support on which to live. To resurrect it we must leave the real slice.

59.4.2 Independent complexification of λ and $\tilde{\lambda}$

The reality condition Eq. (59.98) is the only thing that tied the angle and square brackets together. Drop it. Allow the momenta to be complex by treating λ_i and $\tilde{\lambda}_i$ as *independent* two-component spinors, no longer constrained to be conjugates. This is a perfectly legitimate analytic continuation: an on-shell amplitude is a rational function of the spinor variables, and a rational function is defined wherever its arguments are, real or not. Once λ and $\tilde{\lambda}$ are unhooked, Eq. (59.96) can be satisfied in two genuinely distinct, non-degenerate ways.

Proposition 59.17 (The two complex branches)**.** *For three on-shell massless momenta with complex p_i (independent $\lambda_i, \tilde{\lambda}_i$) and $p_1 + p_2 + p_3 = 0$, the solutions of Eq. (59.96) split into two branches:*

1. *the* holomorphic *(or $\langle\,\rangle$-type) branch, on which all three square brackets vanish, $[1\,2] = [2\,3] = [3\,1] = 0$, while the angle brackets $\langle i\,j\rangle$ are generically nonzero;*
2. *the* antiholomorphic *(or $[\,]$-type) branch, on which all three angle brackets vanish, $\langle 1\,2\rangle = \langle 2\,3\rangle = \langle 3\,1\rangle = 0$, while the square brackets are generically nonzero.*

Away from the trivial point where both sets vanish, these are the only possibilities, and they meet only on the degenerate locus of Theorem 59.16.

Proof. Suppose not all square brackets vanish; without loss of generality $[1\,2] \neq 0$. The pair relation Eq. (59.96) for $(1, 2)$ then forces $\langle 1\,2\rangle = 0$, so $\lambda_1 \propto \lambda_2$; write $\lambda_2 = c\,\lambda_1$ with $c \neq 0$. Momentum conservation is the vanishing of the bispinor sum $\sum_i \lambda_i \tilde{\lambda}_i = 0$. Contract it with $\tilde{\lambda}_1$ on the dotted index; using $[1\,1] = 0$ the $i = 1$ term drops and what remains is a relation among the angle spinors,

$$\lambda_2\,[2\,1] + \lambda_3\,[3\,1] = 0. \tag{59.99}$$

Substituting $\lambda_2 = c\,\lambda_1$, $c\,\lambda_1\,[2\,1] + \lambda_3\,[3\,1] = 0$. If λ_1 and λ_3 were linearly independent, both coefficients would vanish; but $[2\,1] = -[1\,2] \neq 0$ and $c \neq 0$ force a contradiction. Hence $\lambda_3 \propto \lambda_1$ as well, so all three λ_i are proportional and every angle bracket vanishes. This is branch 1. By the identical argument with angle and square brackets exchanged, the assumption that some angle bracket is nonzero forces all square brackets to vanish, giving branch 2. If neither assumption holds, all brackets vanish, the degenerate point. The two branches share only that degenerate point because $\langle\,\rangle$ generic on branch 1 excludes branch 2 and conversely. □

That the holomorphic branch is non-empty and non-degenerate is easy to exhibit. Put all three square spinors parallel, $\tilde{\lambda}_i = c_i\,\tilde{\zeta}$ for a fixed reference spinor $\tilde{\zeta}$ and scalars c_i. Then every $[i\,j] \propto [\tilde{\zeta}\,\tilde{\zeta}] = 0$ automatically, and momentum conservation collapses to

$$\sum_{i=1}^{3} \lambda_i\,\tilde{\lambda}_i = \Big(\sum_{i=1}^{3} c_i\,\lambda_i\Big)\tilde{\zeta} = 0 \iff \sum_{i=1}^{3} c_i\,\lambda_i = 0, \tag{59.100}$$

a single linear condition on three two-component angle spinors that has a two-parameter family of solutions with all $\langle i\,j\rangle \neq 0$. The configuration is fully complex — the energies p_i^0 are complex numbers — but it is on-shell and momentum-conserving, and it carries nonzero angle brackets. The amplitude can finally be evaluated on something other than $0/0$. We now determine what it is.

59.4.3 The two three-point amplitudes from little-group and locality

We claim that on each branch the three-gluon amplitude is fixed, up to one overall constant, before any Feynman diagram is drawn. The constraints are little-group covariance Eq. (58.5) — recorded in Chapter 58 for general three-point amplitudes as Theorem 58.20 — and locality, in the elementary form "the amplitude has the correct mass dimension and no unphysical singularities."

Consider the helicity assignment $(1^-, 2^-, 3^+)$. By Theorem 59.17 a nonzero amplitude must live on one branch, where only one bracket set is available; suppose first it is the holomorphic branch, so A_3 is a function of the angle brackets $\langle 1\,2\rangle, \langle 2\,3\rangle, \langle 3\,1\rangle$ alone. Little-group scaling Eq. (58.5) acts as $(\lambda_i, \tilde\lambda_i) \to (t_i\lambda_i, t_i^{-1}\tilde\lambda_i)$ and demands that a helicity-h_i leg contribute weight $t_i^{-2h_i}$:

$$A_3(\{t_i\lambda_i, t_i^{-1}\tilde\lambda_i\}) = \Big(\prod_{i=1}^{3} t_i^{-2h_i}\Big)\, A_3, \qquad (h_1, h_2, h_3) = (-1, -1, +1). \tag{59.101}$$

Each angle bracket $\langle i\,j\rangle$ carries little-group weight $t_i\,t_j$. Write the most general monomial consistent with the available brackets,

$$A_3(1^-, 2^-, 3^+) = c\,\langle 1\,2\rangle^{\,x_3}\,\langle 2\,3\rangle^{\,x_1}\,\langle 3\,1\rangle^{\,x_2}, \tag{59.102}$$

where we have labeled the exponent of the bracket *omitting* leg i by x_i, for bookkeeping. Matching the weight of each t_i between the two sides of Eq. (59.101) gives one linear equation per leg:

$$\begin{aligned} t_1: &\quad x_3 + x_2 = -2h_1 = +2, \\ t_2: &\quad x_3 + x_1 = -2h_2 = +2, \\ t_3: &\quad x_1 + x_2 = -2h_3 = -2. \end{aligned} \tag{59.103}$$

Subtracting the first two gives $x_2 = x_1$; the third then yields $x_1 = x_2 = -1$, and back-substitution gives $x_3 = 3$. The exponents are uniquely determined:

$$A_3(1^-, 2^-, 3^+) = c\,\frac{\langle 1\,2\rangle^{\,3}}{\langle 2\,3\rangle\,\langle 3\,1\rangle}. \tag{59.104}$$

Little-group scaling alone has fixed the entire functional form down to the number c.

Locality now does two things. First, it confirms Eq. (59.104) is admissible: a three-point amplitude has mass dimension $[A_3] = 4 - 3 = 1$ in four dimensions (each external leg removes one power of mass from the dimension-four amplitude measure), and Eq. (59.104) carries dimension $3 - 1 - 1 = 1$ since every bracket has dimension one. The constant c is therefore dimensionless. Second, and more incisively, locality *excludes the other branch* for this helicity assignment. Had we tried to build $A_3(1^-, 2^-, 3^+)$ from square brackets on the antiholomorphic

branch, the same little-group bookkeeping (now each $[i\,j]$ carries weight $t_i^{-1}t_j^{-1}$) would force the exponents $x_1 = x_2 = +1$, $x_3 = -3$, giving

$$A_3^{(\text{wrong branch})}(1^-,2^-,3^+) = c'\,\frac{[2\,3]\,[3\,1]}{[1\,2]^3}, \qquad [A_3^{(\text{wrong branch})}] = 2-3 = -1. \tag{59.105}$$

This has mass dimension -1, not $+1$: it is not a possible amplitude. Locality, in the guise of correct mass dimension, selects the holomorphic solution Eq. (59.104) for the two-minus configuration and rejects the square-bracket alternative. The two requirements — little-group fixing the form, locality fixing the branch — leave exactly the one constant c.

The conjugate helicity assignment $(1^+,2^+,3^-)$ is handled by exchanging angle and square brackets throughout. Little-group now gives a pure square-bracket monomial, locality selects it (its dimension is $+1$ while the angle-bracket alternative has dimension -1), and the amplitude is

$$A_3(1^+,2^+,3^-) = c''\,\frac{[1\,2]^3}{[2\,3]\,[3\,1]}. \tag{59.106}$$

We have, with no diagram drawn, the two functional forms; it remains to pin the constants c, c''.

59.4.4 Fixing the constant against the three-gluon vertex

The constant is set by demanding that Eq. (59.104) agree with the honest Feynman computation built from the Yang–Mills three-gluon vertex of Chapter 26. Because $n = 3$ admits no internal line, there is precisely one diagram — a single cubic vertex with three external legs (Fig. 59.3) — and the entire amplitude is the color-ordered vertex of Eq. (59.12) contracted with three external polarizations. The computation is short once the reference momenta are chosen with the foresight of Section 59.2.

Worked Example 59.18 (The holomorphic three-point amplitude, normalization and all)**.** With all momenta outgoing and $p_1+p_2+p_3 = 0$, the color-ordered amplitude is the cubic vertex Eq. (59.12) dotted into the polarizations,

$$A_3(1^-,2^-,3^+) = \frac{i}{\sqrt{2}}\Big[(\varepsilon_1{\cdot}\varepsilon_2)\,(p_1-p_2){\cdot}\varepsilon_3 + (\varepsilon_2{\cdot}\varepsilon_3)\,(p_2-p_3){\cdot}\varepsilon_1 + (\varepsilon_3{\cdot}\varepsilon_1)\,(p_3-p_1){\cdot}\varepsilon_2\Big], \tag{59.107}$$

with $\varepsilon_1 = \varepsilon_-(p_1;q_1)$, $\varepsilon_2 = \varepsilon_-(p_2;q_2)$, $\varepsilon_3 = \varepsilon_+(p_3;q_3)$ the polarization vectors of Eq. (59.32). We work on the holomorphic branch (Theorem 59.17, all $[i\,j] = 0$ among externals, $\langle i\,j\rangle$ generic) and exploit the reference freedom to kill two of the three terms.

Reference choice. Give the two negative-helicity legs a common reference $q_1 = q_2 \equiv q$, with q a generic null momentum off the branch so that $[1\,q], [2\,q] \neq 0$,

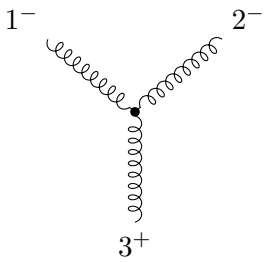

Figure 59.3: The sole diagram contributing to the three-point amplitude: a single color-ordered cubic vertex Eq. (59.12) with three on-shell external gluons, here in the holomorphic-branch configuration $(1^-, 2^-, 3^+)$. There is no internal propagator, so no momentum can be summed and no other topology exists. The amplitude is nonzero only on the complex kinematics of Theorem 59.17.

and set the positive leg's reference to $q_3 = p_2$ (legal since $\langle q_3\, 3\rangle = \langle 2\, 3\rangle \neq 0$ on the branch). The polarization contractions follow from Theorem 59.8:

$$\varepsilon_1^- \cdot \varepsilon_2^- = \frac{\langle 1\, 2\rangle\, [q_2\, q_1]}{[1\, q_1]\, [2\, q_2]} = \frac{\langle 1\, 2\rangle\, [q\, q]}{[1\, q]\, [2\, q]} = 0, \tag{59.108}$$

$$\varepsilon_3^+ \cdot \varepsilon_2^- = \frac{\langle q_3\, 2\rangle\, [q_2\, 3]}{\langle q_3\, 3\rangle\, [2\, q_2]} = \frac{\langle 2\, 2\rangle\, [q\, 3]}{\langle 2\, 3\rangle\, [2\, q]} = 0, \tag{59.109}$$

the first because $[q\, q] = 0$, the second because $\langle 2\, 2\rangle = 0$. Only the third term of Eq. (59.107) survives, through the contraction

$$\varepsilon_3^+ \cdot \varepsilon_1^- = \frac{\langle q_3\, 1\rangle\, [q_1\, 3]}{\langle q_3\, 3\rangle\, [1\, q_1]} = \frac{\langle 2\, 1\rangle\, [q\, 3]}{\langle 2\, 3\rangle\, [1\, q]}. \tag{59.110}$$

The momentum factor. The surviving term needs $(p_3 - p_1)\cdot\varepsilon_2$. Transversality Eq. (59.33) gives $\varepsilon_2 \cdot p_2 = 0$; with $p_2 = -(p_1 + p_3)$ this yields $\varepsilon_2 \cdot p_3 = -\varepsilon_2 \cdot p_1$, so $(p_3 - p_1)\cdot\varepsilon_2 = -2\,\varepsilon_2 \cdot p_1$. Inserting $\varepsilon_2^- = \langle 2|\gamma^\mu|q_2]/(\sqrt{2}\,[2\, q_2])$ and using $\langle 2|\not{p}_1|q] = \langle 2\, 1\rangle\, [1\, q]$,

$$(p_3 - p_1)\cdot\varepsilon_2^- = -2\,\frac{\langle 2|\not{p}_1|q]}{\sqrt{2}\,[2\, q]} = -\sqrt{2}\,\frac{\langle 2\, 1\rangle\, [1\, q]}{[2\, q]}. \tag{59.111}$$

Assembly. Only the third term of Eq. (59.107) survives:

$$\begin{aligned} A_3(1^-, 2^-, 3^+) &= \frac{i}{\sqrt{2}}\,(\varepsilon_3^+ \cdot \varepsilon_1^-)\,(p_3 - p_1)\cdot\varepsilon_2^- = \frac{i}{\sqrt{2}} \cdot \frac{\langle 2\, 1\rangle\, [q\, 3]}{\langle 2\, 3\rangle\, [1\, q]} \cdot \Big(-\sqrt{2}\,\frac{\langle 2\, 1\rangle\, [1\, q]}{[2\, q]} \Big) \\ &= -\,i\,\frac{\langle 2\, 1\rangle^{\,2}\, [q\, 3]}{\langle 2\, 3\rangle\, [2\, q]}, \end{aligned} \tag{59.112}$$

the reference square bracket $[1\, q]$ having cancelled. The remaining ratio $[q\, 3]/[2\, q]$ must collapse to a q-independent expression, as gauge invariance guarantees.

On the holomorphic branch $\tilde{\lambda}_i = c_i\,\tilde{\zeta}$, so $[q\,3] = c_3\,[\tilde{\lambda}_q\,\tilde{\zeta}]$ and $[2\,q] = c_2\,[\tilde{\zeta}\,\tilde{\lambda}_q] = -c_2\,[\tilde{\lambda}_q\,\tilde{\zeta}]$, whence

$$\frac{[q\,3]}{[2\,q]} = -\frac{c_3}{c_2}. \tag{59.113}$$

The scalars c_i are fixed by momentum conservation Eq. (59.100), $\sum_i c_i\lambda_i = 0$. Contracting that relation with λ_1 (i.e. taking $\langle 1\,\cdot\,\rangle$) gives $c_2\langle 1\,2\rangle + c_3\langle 1\,3\rangle = 0$, so

$$\frac{c_3}{c_2} = -\frac{\langle 1\,2\rangle}{\langle 1\,3\rangle} = \frac{\langle 1\,2\rangle}{\langle 3\,1\rangle}, \qquad \text{hence} \qquad \frac{[q\,3]}{[2\,q]} = -\frac{\langle 1\,2\rangle}{\langle 3\,1\rangle}. \tag{59.114}$$

The q-dependence has indeed dropped out. Substituting Eq. (59.114) into Eq. (59.112) and using $\langle 2\,1\rangle^2 = \langle 1\,2\rangle^2$,

$$A_3(1^-,2^-,3^+) = -\,i\,\frac{\langle 1\,2\rangle^{\,2}}{\langle 2\,3\rangle}\cdot\Big(-\frac{\langle 1\,2\rangle}{\langle 3\,1\rangle}\Big) = i\,\frac{\langle 1\,2\rangle^{\,3}}{\langle 2\,3\rangle\,\langle 3\,1\rangle}. \tag{59.115}$$

Comparing with the little-group form Eq. (59.104) fixes $c = i$.

The constant is fixed, the phase with it. Restoring the coupling — the color decomposition Eq. (59.11) carries an overall g^{n-2}, which for $n = 3$ is a single power g, and it is convenient to absorb it into the seed amplitude so that the three-point object the recursion consumes is the physical, coupling-weighted one — the two nonvanishing complex three-point amplitudes are

$$\boxed{A_3(1^-,2^-,3^+) = i\,g\,\frac{\langle 1\,2\rangle^{\,3}}{\langle 2\,3\rangle\,\langle 3\,1\rangle}, \qquad A_3(1^+,2^+,3^-) = -\,i\,g\,\frac{[1\,2]^{\,3}}{[2\,3]\,[3\,1]}.} \tag{59.116}$$

The relative sign between the two is not a convention but a consequence of parity. Parity exchanges the independent spinors, $\lambda_i \leftrightarrow \tilde{\lambda}_i$, sending angle brackets to square brackets and the helicity assignment $(1^-,2^-,3^+)$ to $(1^+,2^+,3^-)$. Under this exchange each polarization vector maps as $\varepsilon_+ \to -\varepsilon_-$ and $\varepsilon_- \to -\varepsilon_+$ — visible directly from Eq. (59.32), since $\langle q|\gamma^\mu|i] = \langle i|\gamma^\mu|q]$ under the swap while $\langle q\,i\rangle \to [q\,i] = -[i\,q]$, producing one minus sign per vector. The amplitude Eq. (59.107) is linear in all three polarizations, so it acquires the overall factor $(-1)^3 = -1$, which is exactly the relative sign in Eq. (59.116).

Notation Watch

The kinematic structures in Eq. (59.116) are the three-point amplitudes anticipated by little-group scaling in Chapter 58 (Theorem 58.20); the present section supplies what little-group scaling could not, namely the overall normalization i and the coupling g, fixed by the honest match to the three-gluon vertex Eq. (26.53) of Chapter 26. Where Chapter 58 or Section 59.2.6 quoted the bare ratio $\langle 1\,2\rangle^3/(\langle 2\,3\rangle\langle 3\,1\rangle)$, the complete

on-shell seed used from here on is the coupling- and phase-fixed object Eq. (59.116). The factor g^{n-2} that Eq. (59.11) kept explicit out front is, for these three-point seeds, absorbed into A_3.

Why complex momenta are not a trick

It is tempting to read the complexification as an artifice for dodging a kinematic singularity. It is the opposite: it is the natural home of the three-point amplitude. The functional forms Eq. (59.116) are rational functions of the spinor variables, fixed by symmetry and locality independently of any reality assumption; reality is the special real slice on which both branches collide and the function degenerates. The recursion of the next section will deform the external momenta of a genuine, real, higher-point amplitude into the complex plane, and the value of that amplitude will be reconstructed from the residues at poles where internal lines go on shell — residues that are precisely products of on-shell lower-point amplitudes evaluated on complex three- and higher-point kinematics. The complex three-point amplitudes Eq. (59.116) are not auxiliary; they are the irreducible physical data from which every gluon tree is built.

With the two nonzero complex three-point amplitudes in hand and the technique of independently complexifying λ and $\tilde{\lambda}$ established, we possess both ingredients the recursion requires: nonvanishing seeds and a controlled way to push external momenta off the real slice. The next section turns these into the BCFW shift — a one-parameter complex deformation of two external momenta — and uses the analytic structure it exposes to assemble any tree amplitude from products of the on-shell amplitudes Eq. (59.116) and their higher-point descendants.

59.5 BCFW Recursion: Derivation

The previous section turned a defect into a tool. Real on-shell three-point kinematics for massless particles is degenerate — all brackets collapse together and the amplitude is forced to zero — but once the momenta are complexified the angle and square spinors become independent, one chirality survives, and the two nonzero three-point amplitudes Eq. (59.116) reappear. Those two objects are the seeds. What remains is to show that they, together with nothing but the analytic structure that locality and unitarity impose on a tree amplitude, *determine every higher-point amplitude*. The mechanism is the Britto–Cachazo–Feng–Witten (BCFW) on-shell recursion. The idea is simple to state and worth keeping in view through the algebra: deform two of the external momenta by a single complex parameter z, regard the color-ordered amplitude $A_n(z)$ as a

meromorphic function of z, and reconstruct $A_n = A_n(0)$ from its poles using Cauchy's theorem. The poles are physical — each is an internal line going on shell — and the residue at each one is, by the factorization of trees on propagator poles (Chapters 13 and 15), a product of two *lower-point on-shell amplitudes*. The recursion writes the n-point amplitude as a sum of products of smaller amplitudes, glued across a propagator. No Lagrangian, no off-shell vertices, no gauge fixing enters after the seeds are in hand.

This section derives the recursion in four moves: the shift and its kinematic consistency; the analytic structure of $A_n(z)$; the factorization of its residues; and the contour argument that assembles the master formula. Throughout we work with a single color-ordered partial amplitude $A_n \equiv A_n[1, 2, \dots, n]$ in the cyclic order $1, \dots, n$, with all momenta outgoing and massless, using the spinor conventions Eqs. (59.30) and (59.31) and the color-ordered Feynman rules of Section 59.1.5 (Eqs. (59.12) to (59.14)). One hypothesis is deferred: the contour argument drops a possible contribution from $z = \infty$, and the legitimacy of dropping it — the large-z behavior of $A_n(z)$ — is the subject of the next section. Everything else is established here in full.

59.5.1 The complex shift

We want a one-parameter complex deformation of the external data that (i) keeps every external leg on shell, (ii) preserves total momentum conservation, and (iii) touches as few legs as possible. The minimal such deformation moves two legs. Pick an ordered pair of distinct external labels (i, j). Recall that each massless leg is carried by a pair of two-component spinors, $p_{k\,\alpha\dot\alpha} = \lambda_{k\alpha}\tilde\lambda_{k\dot\alpha}$, with the angle and square brackets of Eq. (58.20); we write $|k\rangle = \lambda_k$, $|k] = \tilde\lambda_k$.

Definition 59.19 (The $[i, j\rangle$ shift)**.** Fix two distinct labels $i \neq j$. The $[i, j\rangle$ *shift* (square bracket on i, angle bracket on j) deforms the spinors of legs i and j by a complex parameter $z \in \mathbb{C}$,

$$|\hat i] = |i] + z\,|j], \qquad |\hat j\rangle = |j\rangle - z\,|i\rangle\,, \qquad |\hat i\,\rangle = |i\rangle\,, \qquad |\hat j] = |j], \tag{59.117}$$

and leaves all other spinors untouched. Equivalently, in terms of momenta,

$$\hat p_i(z) = p_i + z\,r, \qquad \hat p_j(z) = p_j - z\,r, \qquad r_{\alpha\dot\alpha} \equiv \lambda_{i\alpha}\tilde\lambda_{j\dot\alpha} = |i\rangle\,[j|, \qquad r^\mu = \tfrac{1}{2}\langle i|\gamma^\mu|j]. \tag{59.118}$$

All momenta p_k with $k \neq i, j$ are unshifted.

The deformation is engineered so that the deformed momenta remain physical for *every* complex value of z, which is what licenses treating $A_n(z)$ as an amplitude rather than a formal expression. We record this as a proposition and prove it; the proof is short, but each of the three properties is load-bearing.

Proposition 59.20 (Kinematic consistency of the shift)**.** *For all $z \in \mathbb{C}$ the shifted momenta Eq. (59.118) satisfy*

1. *momentum conservation:* $\sum_k \hat{p}_k(z) = \sum_k p_k$*;*
2. *masslessness:* $\hat{p}_i(z)^2 = \hat{p}_j(z)^2 = 0$ *(and* $\hat{p}_k^2 = p_k^2 = 0$ *for* $k \neq i, j$*);*
3. *the shift vector is null and orthogonal to both shifted legs:* $r^2 = 0,\ r \cdot \hat{p}_i = r \cdot \hat{p}_j = 0$.

Proof. (1) Only p_i and p_j are altered, and their changes are equal and opposite by construction: $\hat{p}_i + \hat{p}_j = (p_i + zr) + (p_j - zr) = p_i + p_j$. Adding the untouched p_k gives $\sum_k \hat{p}_k = \sum_k p_k$. If the original momenta conserve, so do the shifted ones.

(2) The decisive feature of Eq. (59.117) is that each shifted momentum *still factorizes as a single product of one angle spinor and one square spinor*:

$$\hat{p}_{i\,\alpha\dot{\alpha}} = \lambda_{i\alpha}\,(\tilde{\lambda}_i + z\tilde{\lambda}_j)_{\dot{\alpha}} = |\hat{i}\rangle\,[\hat{i}|, \qquad \hat{p}_{j\,\alpha\dot{\alpha}} = (\lambda_j - z\lambda_i)_\alpha\,\tilde{\lambda}_{j\dot{\alpha}} = |\hat{j}\rangle\,[\hat{j}|. \tag{59.119}$$

A real symmetric (here, complex) bispinor is null precisely when its determinant vanishes, and the determinant of a rank-one outer product $\lambda\tilde{\lambda}$ is identically zero. Hence $\hat{p}_i^2 = \det(|\hat{i}\rangle\,[\hat{i}|) = 0$ and likewise $\hat{p}_j^2 = 0$, for every z, with no condition on z whatsoever. This is exactly why the shift acts on $|i]$ but not $|i\rangle$, and on $|j\rangle$ but not $|j]$: disturbing only one spinor of each leg keeps the rank-one structure intact. Equivalently, expanding directly, $\hat{p}_i^2 = (p_i + zr)^2 = p_i^2 + 2z\,r \cdot p_i + z^2 r^2$, and we verify the cross terms vanish in (3).

(3) The shift vector $r = |i\rangle\,[j|$ is itself a rank-one bispinor, so $r^2 = \det(|i\rangle\,[j|) = 0$. For the orthogonality, use the Mandelstam relation Eq. (59.31) in the form $2\,a \cdot b = \langle a\,b\rangle[b\,a]$ together with $2\,r \cdot p_k = \langle i\,k\rangle[k\,j]$ (read off from $r = |i\rangle\,[j|$ contracted with $p_k = |k\rangle\,[k|$):

$$2\,r \cdot p_i = \langle i\,i\rangle\,[i\,j] = 0, \qquad 2\,r \cdot p_j = \langle i\,j\rangle\,[j\,j] = 0, \tag{59.120}$$

since $\langle i\,i\rangle = [j\,j] = 0$. Because $r \cdot p_i = r \cdot p_j = 0$ and $r^2 = 0$, $r \cdot \hat{p}_i = r \cdot p_i + zr^2 = 0$ and similarly $r \cdot \hat{p}_j = 0$. The cross terms in $\hat{p}_i^2 = p_i^2 + 2z\,r \cdot p_i + z^2 r^2$ all vanish, re-confirming masslessness. □

Three remarks fix the picture. First, the shift is intrinsically *complex*: the deformed spinors $|\hat{j}\rangle = |j\rangle - z\,|i\rangle$ and $|\hat{i}] = |i] + z|j]$ are not complex conjugates of each other for $z \neq 0$, so the shifted momenta $\hat{p}_i, \hat{p}_j$ are genuinely complex four-vectors. There is no real shift that keeps two distinct legs on shell while conserving momentum; the complexification of the previous section is not a convenience but a prerequisite. Second, although $\hat{p}_i(z)$ and $\hat{p}_j(z)$ are individually z-dependent, their sum is fixed, and any partial sum of external momenta that contains *both* or *neither* of legs i, j is also z-independent. Only sums separating i from j feel the shift. This is the seed of the pole structure. Third, the analytically continued amplitude $A_n(z)$ is obtained by substituting Eq. (59.117) into the same color-ordered expression that computes A_n; by Theorem 59.20 it is a bona

fide on-shell amplitude for complex external kinematics, equal to the physical amplitude at $z = 0$.

Caution: the shifted legs are not conjugate

For real momenta the square spinor is fixed by the angle spinor up to a phase, $|i] = \pm\,|i\rangle^*$. The shift breaks this: $|\hat{i}]$ changes while $|\hat{i}\rangle = |i\rangle$ does not, so $|\hat{i}] \neq \pm\,|\hat{i}\rangle^*$. One must treat angle and square spinors as independent variables throughout the recursion and only set $z = 0$ (restoring reality) at the very end. Quantities such as $\langle i|P|j]$ that mix the two chiralities are where the z-dependence lives.

59.5.2 Analytic structure of the shifted amplitude

We now determine what kind of function $A_n(z)$ is. The answer — a rational function with only simple poles, located at the zeros of shifted Mandelstam invariants — is what makes Cauchy's theorem usable.

Proposition 59.21 ($A_n(z)$ is rational with only simple poles)**.** *Under the $[\,i,j\,\rangle$ shift, the color-ordered tree amplitude $A_n(z)$ is a rational function of z. Its only finite singularities are simple poles. Each pole sits at a value z_I where a single shifted internal invariant $\hat{P}_I(z)^2$ vanishes, where $P_I = \sum_{k\in I} p_k$ is the momentum flowing through a cyclically-consecutive subset $I \subsetneq \{1,\dots,n\}$ that contains exactly one of the two shifted legs i, j.*

Proof. A color-ordered tree amplitude is computed (Section 59.1.5) as a finite sum over planar diagrams; each diagram is a product of vertices Eqs. (59.12) and (59.13), external polarization vectors Eq. (59.32), and scalar propagators i/P^2 extracted from Eq. (59.14), with all Lorentz indices contracted. We track the z-dependence factor by factor.

Numerators are polynomial in z. The cubic vertex Eq. (59.12) is linear in the momenta and the quartic Eq. (59.13) is momentum-free; under Eq. (59.117) a shifted momentum is linear in z, so each vertex contributes a polynomial (degree ≤ 1) in z. The external polarization vectors are likewise polynomial: only the shifted legs i, j carry z-dependence, and from Eq. (59.32) the dependence enters through $|\hat{i}]$ or $|\hat{j}\rangle$ linearly, with the reference spinors held fixed. (We may always choose the reference momenta of the shifted legs so that no polarization denominator $\langle q_i\, i\rangle$, $[i\, q_i]$ becomes z-dependent; e.g. pick the reference of leg i from its *angle* spinor, which is unshifted.) Products and sums of polynomials are polynomials, so every diagram's numerator is a polynomial in z.

Denominators are products of shifted propagators, each linear in z. A diagram's denominator is a product of internal invariants $\hat{P}_I(z)^2$, one per internal line. By momentum conservation the momentum on any internal line of a tree

equals the sum $P_I = \sum_{k\in I} p_k$ over the external legs I on one side of that line; in a planar (color-ordered) diagram these subsets are exactly the cyclically-consecutive blocks $I = \{a, a+1, \dots, b\}$. Now apply the shift. If I contains both i and j, or neither, then $\hat{P}_I = P_I$ is z-independent (the shifts of p_i and p_j cancel in the sum, or are simply absent). The only z-dependence in a denominator comes from blocks I that contain exactly one shifted leg. Take the convention $i \in I$, $j \notin I$ (the other case is identical with $r \to -r$). Then

$$\hat{P}_I(z) = P_I + z\, r, \qquad \boxed{\hat{P}_I(z)^2 = P_I^2 + z\,\langle i|P_I|j]} , \qquad \langle i|P_I|j] \equiv \sum_{k\in I} \langle i\, k\rangle [k\, j], \tag{59.121}$$

using $\hat{P}_I^2 = P_I^2 + 2z\, r\cdot P_I + z^2 r^2$ with $r^2 = 0$ and $2r\cdot P_I = \langle i|\gamma^\mu|j] P_{I\mu} = \langle i|P_I|j]$. Each such invariant is *linear* in z, vanishing at the single point

$$z_I = -\frac{P_I^2}{\langle i|P_I|j]}. \tag{59.122}$$

Thus each propagator $1/\hat{P}_I(z)^2 = 1/(P_I^2 + z\,\langle i|P_I|j])$ contributes at most one simple pole, at $z = z_I$.

Only simple poles, and they are physical. A given diagram is a ratio of a polynomial numerator to a product of distinct linear factors $\hat{P}_I(z)^2$; within one diagram, the internal lines carry distinct consecutive blocks I (no two propagators in a tree carry the same momentum), so the factors are distinct and the diagram has only simple poles. Summing over the finitely many planar diagrams can only combine residues at coincident z_I; but distinct channels $I \neq I'$ have distinct $z_I \neq z_{I'}$ for generic external momenta (the values Eq. (59.122) are different rational functions of the external data), so no two simple poles collide and the sum $A_n(z)$ retains only simple poles. Each pole sits at a z_I where a physical factorization channel $\hat{P}_I(z)^2 \to 0$ opens up: the internal line carrying $\hat{P}_I$ goes on shell. There are no other singularities — a tree amplitude has no branch cuts — so $A_n(z)$ is rational, and we have located all its finite poles. □

The content of Theorem 59.21 is worth restating in words, because it is the engine of the recursion. Deforming two legs turns the amplitude into a rational function whose poles are in one-to-one correspondence with the factorization channels that *separate the two shifted legs*. A channel that keeps i and j on the same side of the propagator is invisible to the shift and contributes no pole; only the channels that split them appear. The next task is to read off the residue at each such pole.

59.5.3 Factorization on a physical pole

At $z = z_I$ the internal line of channel I has gone on shell: $\hat{P}_I(z_I)^2 = 0$. The behaviour of a tree amplitude as an internal momentum approaches its mass

shell is governed by a basic property of perturbation theory, established in Chapter 13 (LSZ and the pole structure of correlators) and Chapter 15 (the diagrammatic expansion): *a tree amplitude, viewed as a function of a single Mandelstam invariant $s = P_I^2$, has a simple pole at $s \to 0$ (for a massless internal particle) whose residue factorizes into the product of the two on-shell sub-amplitudes obtained by cutting the internal line, summed over the physical states of the exchanged particle.* We now make this concrete in the color-ordered language and extract the residue of $A_n(z)$ at z_I.

Theorem 59.22 (Residue factorization)**.** *Let z_I be the pole Eq. (59.122) associated with the consecutive channel I (with $i \in I$, $j \notin I$). Then near $z = z_I$,*

$$A_n(z) \xrightarrow{z \to z_I} \sum_h \hat{A}_L(z_I)\, \frac{i}{\hat{P}_I(z)^2}\, \hat{A}_R(z_I), \tag{59.123}$$

where $\hat{A}_L$ is the color-ordered amplitude built from the legs in I together with an extra on-shell leg of momentum $-\hat{P}_I(z_I)$ and helicity $-h$, $\hat{A}_R$ is the amplitude built from the legs not in I together with an extra on-shell leg of momentum $+\hat{P}_I(z_I)$ and helicity $+h$, both evaluated at $z = z_I$, and the sum runs over the helicity (and, in general, particle species) h of the exchanged state.

Proof. Sort the planar diagrams contributing to $A_n(z)$ by whether they contain an internal line carrying the channel momentum $\hat{P}_I$. Diagrams that do *not* contain such a line have a denominator with no factor $\hat{P}_I(z)^2$, so they are regular at $z = z_I$ and contribute nothing to the residue. Diagrams that *do* contain it have precisely one such propagator (a tree cannot carry the same momentum on two distinct internal lines), and each of them therefore splits into two connected pieces joined by that single line: a left piece L attached to the external legs I, and a right piece R attached to the external legs $\bar{I}$. The internal line carries the color-ordered scalar propagator $i/\hat{P}_I(z)^2$ from Eq. (59.14).

Write the contribution of any such diagram as $D(z) = \dfrac{N_L(z)\ [\text{numerator of the internal line}]}{\hat{P}_I(z)^2\ \times (\text{other propagators})}$ where N_L, N_R collect the sub-diagrams on the two sides. Summing over all diagrams of this type and over the two tensor (helicity) structures the gluon propagator can transmit, the numerator of the internal line resolves, on the pole, into the polarization sum for an on-shell gluon of momentum $\hat{P}_I(z_I)$:

$$-i\,\eta_{\mu\nu} \xrightarrow{\hat{P}_I^2 \to 0} -i \sum_h \varepsilon_\mu^h(\hat{P}_I)\, \varepsilon_\nu^{-h}(-\hat{P}_I) \;+\; (\text{terms} \propto \hat{P}_{I\mu} \text{ or } \hat{P}_{I\nu}), \tag{59.124}$$

the gauge-dependent longitudinal terms dropping out because each side is, on the pole, a color-ordered amplitude with an on-shell external gluon and is therefore transverse (the Ward identity of Chapter 15 for the color-ordered current; the same statement underlies the reference-momentum independence

used in Section 59.2.2). What multiplies $\varepsilon^h(\hat{P}_I)$ on the left, once the internal momentum is on shell, is by definition the color-ordered amplitude $\hat{A}_L$ with external legs $\{I, (-\hat{P}_I)^{-h}\}$ in cyclic order; what multiplies $\varepsilon^{-h}(-\hat{P}_I)$ on the right is $\hat{A}_R$ with external legs $\{(\hat{P}_I)^h, \bar{I}\}$. (The two on-shell legs carry opposite momenta and opposite helicity labels, as a single internal line cut into two external legs must.) Therefore, retaining only the singular part,

$$A_n(z)\Big|_{\text{sing.}} = \sum_h \hat{A}_L(z)\,\frac{i}{\hat{P}_I(z)^2}\,\hat{A}_R(z). \tag{59.125}$$

Finally, $\hat{A}_L$ and $\hat{A}_R$ are smooth at $z = z_I$ (their own propagators are channels that do not separate i from j *within* the smaller amplitude, hence are regular there), so to extract the residue we may evaluate them at $z = z_I$, where $\hat{P}_I(z_I)^2 = 0$ makes both sub-amplitudes genuinely on shell. This is Eq. (59.123). □

Why the residue is a product of physical amplitudes

Equation Eq. (59.123) is unitarity made visible. A propagator pole is where a virtual particle becomes real; the residue is the amplitude to produce that real particle times the amplitude to absorb it. Locality (the amplitude is built from local propagators $1/P^2$) is what guarantees the poles are simple and sit at $P_I^2 = 0$; unitarity (the residue factorizes onto physical states) is what makes the numerator a *product of on-shell amplitudes* rather than some new off-shell object. BCFW is the statement that these two principles, applied channel by channel, contain all the information in the Lagrangian's tree expansion — and package it far more efficiently.

The factorized form Eq. (59.123) is drawn in Fig. 59.4: the deformed n-point amplitude, near the pole, is two smaller on-shell amplitudes glued across an on-shell internal line, with the shifted legs $\hat{\imath}$ and $\hat{\jmath}$ landing on opposite blobs.

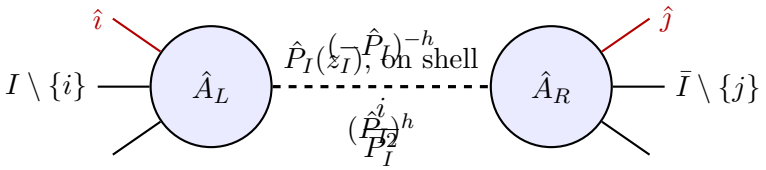

Figure 59.4: Factorization of the shifted amplitude on the channel-I pole. The two shifted legs $\hat{\imath} \in I$ and $\hat{\jmath} \in \bar{I}$ sit on opposite sub-amplitudes; the internal line is on shell at $z = z_I$, and the residue sums over its helicity h. The recursion glues lower-point on-shell amplitudes with the scalar propagator i/P_I^2.

59.5.4 The contour argument and the master formula

We have a rational function $A_n(z)$ with simple poles at known locations and known residues. The physical amplitude is its value at the origin, $A_n = A_n(0)$. Cauchy's theorem converts knowledge of the poles into knowledge of $A_n(0)$.

Consider the auxiliary function $A_n(z)/z$. It has the same poles as $A_n(z)$, at the z_I, plus a new simple pole at $z = 0$ with residue $A_n(0) = A_n$, the quantity we want. Integrate it around a large circle C_R of radius R in the complex plane (Fig. 59.5):

$$\frac{1}{2\pi i}\oint_{C_R} \frac{A_n(z)}{z}\,dz = A_n(0) + \sum_I \mathrm{Res}_{z=z_I}\frac{A_n(z)}{z}. \tag{59.126}$$

Suppose the left-hand side vanishes as $R \to \infty$ — equivalently, that $A_n(z) \to 0$ as $z \to \infty$ so that $A_n(z)/z$ falls faster than $1/z$ and the boundary integral has no contribution from infinity. This is the one hypothesis we do not prove here; Section 59.6 establishes exactly when it holds. Granting it, the sum of all residues is zero, and Eq. (59.126) reads

$$0 = A_n + \sum_I \mathrm{Res}_{z=z_I}\frac{A_n(z)}{z}. \tag{59.127}$$

Each residue at z_I follows from the factorization Eq. (59.123). Near z_I, write $\hat{P}_I(z)^2 = \langle i|P_I|j]\,(z - z_I)$ from Eq. (59.121) (the linear coefficient is the derivative $\partial_z \hat{P}_I^2 = \langle i|P_I|j]$). Then

$$\mathrm{Res}_{z=z_I}\frac{A_n(z)}{z} = \frac{1}{z_I}\,\mathrm{Res}_{z=z_I}\,A_n(z) = \frac{1}{z_I}\sum_h \hat{A}_L(z_I)\,\frac{i}{\langle i|P_I|j]}\,\hat{A}_R(z_I), \tag{59.128}$$

where we used that $\mathrm{Res}_{z=z_I}\,[i/\hat{P}_I(z)^2] = i/\langle i|P_I|j]$. Now insert $z_I = -P_I^2/\langle i|P_I|j]$ from Eq. (59.122), so that $1/z_I = -\langle i|P_I|j]/P_I^2$. The factors of $\langle i|P_I|j]$ cancel:

$$\mathrm{Res}_{z=z_I}\frac{A_n(z)}{z} = -\sum_h \hat{A}_L(z_I)\,\frac{i}{P_I^2}\,\hat{A}_R(z_I). \tag{59.129}$$

Note the propagator factor has reverted to the *unshifted, physical* invariant $1/P_I^2$: the on-shell condition lives in the sub-amplitudes, while the glue is the ordinary Feynman propagator of the channel evaluated at $z = 0$. Substituting Eq. (59.129) into Eq. (59.127) and moving the sum to the other side gives the central result of the chapter.

Theorem 59.23 (BCFW on-shell recursion)**.** *Let A_n be a color-ordered tree amplitude, and apply an $[\,i, j\,\rangle$ shift Eq. (59.117) for which $A_n(z) \to 0$ as $z \to \infty$. Then*

$$\boxed{A_n = \sum_I \sum_h \hat{A}_L(z_I)\,\frac{i}{P_I^2}\,\hat{A}_R(z_I)\ ,} \tag{59.130}$$

where the outer sum runs over all cyclically-consecutive channels I that separate the shifted legs (i.e. $i \in I$, $j \notin I$), $z_I = -P_I^2/\langle i|P_I|j]$ is the value at which $\hat{P}_I(z)^2$ vanishes, P_I^2 is the unshifted channel invariant, and the inner sum is over the helicity h of the on-shell internal state. The amplitudes $\hat{A}_L, \hat{A}_R$ are lower-point, on-shell, and evaluated at the shifted kinematics $z = z_I$.

The structure of Eq. (59.130) is exactly the recursion advertised at the outset: A_n is a finite sum of products of two strictly lower-point on-shell amplitudes, glued by a scalar propagator and summed over a handful of channels and the internal helicity. Feeding the output of the recursion back into its input, every amplitude descends to products of three-point amplitudes — the complex seeds Eq. (59.116) — with no Lagrangian, no off-shell vertex, and no gauge fixing entering after the seeds. Locality fixed the poles; unitarity fixed the residues; Cauchy's theorem assembled them.

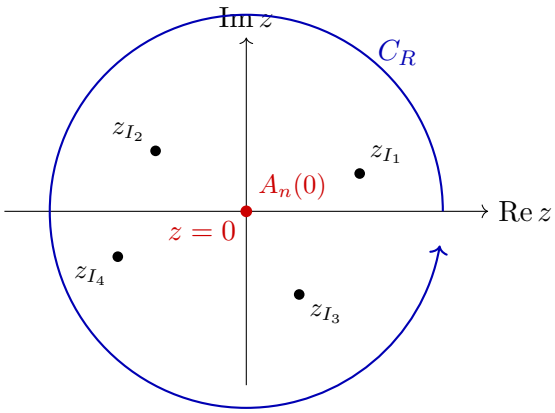

Figure 59.5: The complex z-plane for $A_n(z)/z$. The integrand has a pole at the origin with residue $A_n(0) = A_n$ (the physical amplitude) and simple poles at the factorization points z_I (Eq. (59.122)). If the large-circle integral vanishes, the sum of all residues is zero, expressing A_n as minus the sum of the factorization residues — the BCFW master formula Eq. (59.130).

Caution: the dropped boundary term

The derivation rests on one inequality not yet proved: $A_n(z) \to 0$ as $z \to \infty$. If instead $A_n(z)$ tends to a nonzero constant or grows, the large-circle integral in Eq. (59.126) contributes a "boundary term" or "pole at infinity" B_n, and the recursion becomes $A_n = B_n + \sum_{I,h} \hat{A}_L \frac{i}{P_I^2} \hat{A}_R$, with B_n *not* determined by lower-point on-shell data. Whether B_n vanishes depends on the shift (i, j) and on the helicities of the shifted legs. Establishing which shifts give $B_n = 0$ — and hence when Eq. (59.130) is exact as written — is the business of Section 59.6.

59.5.5 Worked example: the four-gluon MHV amplitude

We close by running the recursion once, in full, on the smallest nontrivial case: the color-ordered amplitude $A_4(1^-, 2^-, 3^+, 4^+)$. This is the Yang–Mills theory result in miniature — the four-gluon amplitude that the Feynman expansion produces only after summing several diagrams, rebuilt here from two three-point seeds and one propagator. The seeds are the complex three-point amplitudes Eq. (59.116),

$$A_3(a^-, b^-, c^+) = i\,g\,\frac{\langle a\,b\rangle^3}{\langle b\,c\rangle\,\langle c\,a\rangle}, \qquad A_3(a^+, b^+, c^-) = -\,i\,g\,\frac{[a\,b]^3}{[b\,c]\,[c\,a]}, \tag{59.131}$$

the first nonzero only for holomorphic (angle) kinematics, the second for anti-holomorphic (square) kinematics.

Worked Example 59.24 ($A_4(1^-, 2^-, 3^+, 4^+)$ from BCFW)**. Choice of shift.** Shift the adjacent legs 2 and 3 with an $[\,2, 3\,\rangle$ shift, i.e. $(i, j) = (2, 3)$:

$$|\hat{2}] = |2] + z|3], \qquad \left|\hat{3}\right\rangle = |3\rangle - z\,|2\rangle\,, \qquad \left|\hat{2}\right\rangle = |2\rangle\,, \quad |\hat{3}] = |3]. \tag{59.132}$$

The shifted helicities are $(h_2, h_3) = (-, +)$; this is a valid shift (its large-z behavior is established in Section 59.6), so Eq. (59.130) applies with no boundary term.

Which channels contribute. For four legs in cyclic order $1, 2, 3, 4$ the consecutive two-particle channels are $\{1, 2\}$ (equivalently $\{3, 4\}$) and $\{2, 3\}$ (equivalently $\{1, 4\}$). A channel contributes only if it separates the shifted legs 2 and 3. The block $\{2, 3\}$ keeps them together, so it gives no pole; only $\{1, 2\}$ contributes, with $I = \{1, 2\}$, $\bar{I} = \{3, 4\}$, and $P_I = p_1 + p_2$. The recursion is therefore a *single term*.

Internal kinematics. The pole is at $\hat{P}_{12}(z)^2 = 0$. Using Eq. (59.121) with the shift on the square spinor of 2,

$$\hat{P}_{12}(z)^2 = (p_1 + \hat{p}_2)^2 = \langle 1\,\hat{2}\rangle\,[\hat{2}\,1] = \langle 1\,2\rangle([2\,1] + z\,[3\,1]), \quad \Longrightarrow \quad z_I = -\frac{[2\,1]}{[3\,1]}. \tag{59.133}$$

The two sub-amplitudes are $\hat{A}_L(\hat{1}, \hat{2}, (-\hat{P})^{-h})$ on the legs $\{1, 2\}$ and $\hat{A}_R((\hat{P})^h, \hat{3}, \hat{4})$ on $\{3, 4\}$, with $\hat{P} \equiv \hat{P}_{12}(z_I)$ null. Since $\hat{1} = 1^-$ and $\hat{2} = 2^-$ carry two negative helicities, the left three-point amplitude is nonzero only as the angle-type seed $A_3(- - +)$ in Eq. (59.131), forcing the internal leg on the left to be $(-\hat{P})^+$ (so $h = -$ on the right). The other helicity assignment would make the left amplitude $A_3(\hat{1}^-, \hat{2}^-, (-\hat{P})^-)$, which has total helicity -3 and vanishes. Hence the helicity sum collapses to one term:

$$A_4 = \hat{A}_L(\hat{1}^-, \hat{2}^-, (-\hat{P})^+)\,\frac{i}{P_{12}^2}\,\hat{A}_R((\hat{P})^-, \hat{3}^+, \hat{4}^+), \qquad P_{12}^2 = \langle 1\,2\rangle[2\,1]. \tag{59.134}$$

The two seeds. From Eq. (59.131),

$$\hat{A}_L = i\,g\,\frac{\langle \hat{1}\,\hat{2}\rangle^3}{\langle \hat{2}\,(-\hat{P})\rangle\,\langle (-\hat{P})\,\hat{1}\rangle} = i\,g\,\frac{\langle 1\,2\rangle^3}{\langle \hat{2}\,(-\hat{P})\rangle\,\langle (-\hat{P})\,\hat{1}\rangle}, \tag{59.135}$$

$$\hat{A}_R = -\,i\,g\,\frac{[\hat{3}\,\hat{4}]^3}{[\hat{4}\,\hat{P}]\,[\hat{P}\,\hat{3}]} = -\,i\,g\,\frac{[3\,4]^3}{[4\,\hat{P}]\,[\hat{P}\,3]}, \tag{59.136}$$

where $\langle \hat{1}\,\hat{2}\rangle = \langle 1\,2\rangle$ and $[\hat{3}\,\hat{4}] = [3\,4]$ because those spinors are unshifted. For the internal leg of momentum $-\hat{P}$ we use the analytic continuation $|-\hat{P}\rangle = i\left|\hat{P}\right\rangle$, $|-\hat{P}] = i|\hat{P}]$ (so that $|-\hat{P}\rangle[-\hat{P}| = -\left|\hat{P}\right\rangle[\hat{P}| = -\hat{P}$); the factors of i cancel in the product because $\hat{P}$ appears an even number of times.

Eliminating the internal spinors. The product of the two denominators is

$$\begin{aligned} D &\equiv \langle \hat{2}\,(-\hat{P})\rangle\,\langle (-\hat{P})\,\hat{1}\rangle\,[\hat{P}\,3]\,[4\,\hat{P}] = -\,\langle 2\,\hat{P}\rangle\,\langle \hat{P}\,1\rangle\,[\hat{P}\,3]\,[4\,\hat{P}] \\ &= -\big(\langle 2\,\hat{P}\rangle[\hat{P}\,3]\big)\big(\langle 1\,\hat{P}\rangle[\hat{P}\,4]\big) = -\,\langle 2|\hat{P}|3]\,\langle 1|\hat{P}|4], \end{aligned} \tag{59.137}$$

where the first equality used $|-\hat{P}\rangle = i\left|\hat{P}\right\rangle$ (giving $i^2 = -1$), and the last regrouped the brackets using $\langle a\,\hat{P}\rangle[\hat{P}\,b] = \langle a|\hat{P}|b]$ (with $\langle \hat{P}\,1\rangle[4\,\hat{P}] = \langle 1\,\hat{P}\rangle[\hat{P}\,4]$ after two sign flips). Now collapse the internal momentum onto external data using $\hat{P} = p_1 + \hat{p}_2$ and $\langle a\,a\rangle = 0$:

$$\langle 2|\hat{P}|3] = \langle 2|p_1|3] = \langle 2\,1\rangle[1\,3], \qquad \langle 1|\hat{P}|4] = \langle 1|\hat{p}_2|4] = \langle 1\,2\rangle\,[\hat{2}\,4], \tag{59.138}$$

since $\langle 2|\hat{p}_2|3] \propto \langle 2\,2\rangle = 0$ and $\langle 1|p_1|4] \propto \langle 1\,1\rangle = 0$. The remaining shifted bracket, at $z = z_I$, is $[\hat{2}\,4] = [2\,4] + z_I[3\,4]$. Insert Eq. (59.133) and use the Schouten identity $[2\,4][3\,1] + [2\,3][1\,4] + [2\,1][4\,3] = 0$:

$$[2\,4] + z_I[3\,4] = \frac{[2\,4][3\,1] - [2\,1][3\,4]}{[3\,1]} = \frac{-\,[2\,3][1\,4]}{[3\,1]}, \tag{59.139}$$

where the numerator was simplified by the Schouten relation ($[2\,4][3\,1] = -[2\,3][1\,4] + [2\,1][3\,4]$). Assembling Eqs. (59.138) and (59.139) into Eq. (59.137),

$$D = -\,\langle 2\,1\rangle[1\,3]\cdot\langle 1\,2\rangle\cdot\frac{-[2\,3][1\,4]}{[3\,1]} = -\,\langle 1\,2\rangle^2\,[2\,3]\,[1\,4], \tag{59.140}$$

using $\langle 2\,1\rangle = -\langle 1\,2\rangle$ and $[1\,3]/[3\,1] = -1$.

Assembly. Combining Eqs. (59.135) and (59.136) with Eq. (59.140), the i's multiply to $i\cdot(-i) = +1$ and the couplings to $g\cdot g = g^2$, and

$$\hat{A}_L\,\hat{A}_R = g^2\,\frac{\langle 1\,2\rangle^3\,[3\,4]^3}{D} = g^2\,\frac{\langle 1\,2\rangle^3\,[3\,4]^3}{-\,\langle 1\,2\rangle^2\,[2\,3]\,[1\,4]} = -\,g^2\,\frac{\langle 1\,2\rangle\,[3\,4]^3}{[2\,3]\,[1\,4]}. \tag{59.141}$$

Multiplying by the propagator $i/P_{12}^2 = i/(\langle 1\,2\rangle[2\,1])$,

$$A_4 = -\,g^2\,\frac{\langle 1\,2\rangle\,[3\,4]^3}{[2\,3]\,[1\,4]}\cdot\frac{i}{\langle 1\,2\rangle[2\,1]} = -\,i\,g^2\,\frac{[3\,4]^3}{[2\,3]\,[1\,4]\,[2\,1]}. \tag{59.142}$$

Back to angle brackets. Equation Eq. (59.142) is the answer, but to recognize it we convert to angle brackets using momentum conservation $\sum_k |k\rangle\,[k| = 0$, i.e. $\sum_k \langle a\,k\rangle[k\,b] = 0$ for any a, b. Three instances suffice. From $a = 1, b = 3$: $\langle 1\,2\rangle[2\,3] = -\langle 1\,4\rangle[4\,3] = \langle 1\,4\rangle[3\,4]$, so $[2\,3] = \langle 1\,4\rangle[3\,4]/\langle 1\,2\rangle$. From $a = 2, b = 4$: $\langle 2\,3\rangle[3\,4] = -\langle 2\,1\rangle[1\,4] = \langle 1\,2\rangle[1\,4]$, so $[1\,4] = \langle 2\,3\rangle[3\,4]/\langle 1\,2\rangle$. From the $s_{12} = s_{34}$ relation $\langle 1\,2\rangle[2\,1] = \langle 3\,4\rangle[4\,3]$: $[2\,1] = -\langle 3\,4\rangle[3\,4]/\langle 1\,2\rangle$. Substituting all three into the denominator of Eq. (59.142),

$$[2\,3]\,[1\,4]\,[2\,1] = \frac{\langle 1\,4\rangle\langle 2\,3\rangle(-\langle 3\,4\rangle)\,[3\,4]^3}{\langle 1\,2\rangle^3} = -\,\frac{\langle 1\,4\rangle\,\langle 2\,3\rangle\,\langle 3\,4\rangle\,[3\,4]^3}{\langle 1\,2\rangle^3}, \tag{59.143}$$

so that the $[3\,4]^3$ cancels and

$$A_4(1^-, 2^-, 3^+, 4^+) = -\,i\,g^2\,\frac{[3\,4]^3\,\langle 1\,2\rangle^3}{-\,\langle 1\,4\rangle\,\langle 2\,3\rangle\,\langle 3\,4\rangle\,[3\,4]^3} = i\,g^2\,\frac{\langle 1\,2\rangle^3}{\langle 2\,3\rangle\,\langle 3\,4\rangle\,\langle 4\,1\rangle}, \tag{59.144}$$

using $\langle 1\,4\rangle = -\langle 4\,1\rangle$. This is precisely the Parke–Taylor form $A_4 = i\,g^2\,\langle 1\,2\rangle^4/(\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle)$ the $n = 4$ instance of the MHV amplitude. The amplitude that the Feynman rules deliver only after summing the s-channel, t-channel, and four-point-vertex diagrams of Section 59.2.3 has emerged from a single BCFW term built from two three-point seeds.

What the recursion bought

The computation in Theorem 59.24 used no four-point vertex, no s-/t-channel sum, and no gauge choice beyond the seed amplitudes. The entire content was: pick a shift, find the one channel that separates the shifted legs, multiply two three-point amplitudes, and divide by a propagator. At higher multiplicity the savings compound — an n-gluon amplitude reduces to a handful of products of strictly smaller amplitudes, each itself recursively determined — which is how the super-factorial diagram count of Table 59.1 collapses to compact closed forms. The recursion is the "smart way" promised at the start of the chapter, and it is built entirely from on-shell data.

With the master formula Eq. (59.130) in hand, only one promissory note remains: the contour at infinity. The derivation assumed $A_n(z) \to 0$ as $z \to \infty$, an assumption we have flagged but not justified. The next section analyzes the large-z scaling of shifted amplitudes directly, classifies which $[\,i, j\,\rangle$ shifts are valid (and which leave a boundary term), and thereby establishes that tree-level Yang–Mills is *on-shell constructible*: fixed entirely by its three-point seeds and the factorization just derived, with no Lagrangian required.

59.6 Large-z Behavior and On-Shell Constructibility

The BCFW master formula Theorem 59.23 delivered a recursion — the physical amplitude written as a sum over factorization channels of products of lower-point on-shell amplitudes — but it delivered it on credit. The derivation deformed two external momenta by a complex parameter z, treated the color-ordered partial amplitude $A_n(z)$ as a meromorphic function of z, and used Cauchy's theorem to trade the value at $z = 0$ for a sum of residues at the physical poles. That trade is exact *only* if the contour at infinity contributes nothing: only if the boundary term we provisionally called B_0 vanishes. Everything in the recursion — indeed the entire claim that gluon trees can be built without ever writing the Yang–Mills Lagrangian — rests on that one analytic fact. This section pays the debt. We compute how the shifted amplitude behaves as $z \to \infty$, find that for a correctly chosen shift it falls off as $1/z$, catalogue which shifts are good and which are fatally bad, and then harvest the structural payoff: tree-level Yang–Mills is *on-shell constructible*, fixed completely by its three-point seeds and the analytic structure that locality and unitarity impose, with no off-shell input whatsoever.

59.6.1 The boundary term: what must vanish

Recall the analytic setup of Theorem 59.23. We single out two legs, label them i and j, and deform their spinors holomorphically in a complex parameter z by the $[i, j\rangle$ shift

$$|\hat{i}] = |i] + z\,|j], \qquad |\hat{i}\rangle = |i\rangle, \qquad |\hat{j}\rangle = |j\rangle - z\,|i\rangle, \qquad |\hat{j}] = |j], \tag{59.145}$$

so that the shifted momenta are $\hat{p}_i(z) = p_i + z\,q$ and $\hat{p}_j(z) = p_j - z\,q$ with the null bispinor $q_{\alpha\dot{\alpha}} = \lambda_{i\alpha}\tilde{\lambda}_{j\dot{\alpha}}$, i.e. $q^\mu = \frac{1}{2}\langle i|\gamma^\mu|j]$. Both shifted momenta stay on shell, $\hat{p}_i^2(z) = \hat{p}_j^2(z) = 0$ for all z, and total momentum is conserved because the z-dependent pieces cancel. The deformed partial amplitude $A_n(z) \equiv A_n(\dots, \hat{i}, \dots, \hat{j}, \dots)$ is a rational function of z: its only singularities are simple poles, located where an internal propagator carrying a z-dependent momentum goes on shell, at the values z_I fixed by the shifted-pole condition Eq. (59.121).

The reconstruction rests on integrating $A_n(z)/z$ around a contour. Consider

$$\oint_{C_\infty} \frac{dz}{2\pi i}\,\frac{A_n(z)}{z}, \tag{59.146}$$

with C_∞ a circle of radius $R \to \infty$. The integrand is meromorphic, so by the residue theorem Eq. (59.146) equals the sum of all residues it encloses. The pole at $z = 0$ has residue $A_n(0) = A_n$, the physical amplitude we want. The poles at $z = z_I$ have residues $z_I^{-1}\,\mathrm{Res}_{z=z_I} A_n(z)$, and Theorem 59.23 identified each such residue with $-i\,\hat{A}_L(z_I)\,\hat{A}_R(z_I)$ divided by the unshifted Mandelstam invariant of

the channel, assembling into the BCFW terms. Therefore

$$A_n \;=\; \sum_{\text{channels } I} \sum_{h} \hat{A}_L(z_I)\,\frac{i}{P_I^2}\,\hat{A}_R(z_I) \;+\; B_0, \qquad B_0 \equiv \oint_{C_\infty} \frac{dz}{2\pi i}\,\frac{A_n(z)}{z}. \tag{59.147}$$

The boundary term B_0 is the contribution of the contour at infinity. Writing the Laurent expansion $A_n(z) = \sum_m c_m\, z^m$ valid for large $|z|$, the integral Eq. (59.146) picks out the coefficient of $1/z$ in $A_n(z)/z$, which is the coefficient of z^0 in $A_n(z)$:

$$B_0 = c_0 = \lim_{z\to\infty} A_n(z) \quad \text{(if this limit is finite)}, \qquad \text{and more generally } B_0 = -\operatorname{Res}_{z=\infty} \frac{A_n(z)}{z}. \tag{59.148}$$

The conclusion is sharp and is the whole game of this section: *the BCFW recursion holds with $B_0 = 0$ if and only if $A_n(z) \to 0$ as $z \to \infty$.* If instead $A_n(z)$ tends to a nonzero constant, B_0 is that constant and must be added by hand — a piece of information not captured by any physical factorization pole, hence not reconstructible from lower-point amplitudes. If $A_n(z)$ grows, the naive recursion is simply wrong. So we must determine the large-z growth of the shifted amplitude, and we must learn to choose i, j and their helicities so that it decays.

Definition 59.25 (Valid shift and on-shell constructibility)**.** A two-line shift Eq. (59.145) of an amplitude A_n is *valid* (or *good*) if the shifted amplitude vanishes at infinity, $A_n(z) \to 0$ as $z \to \infty$, so that the boundary term Eq. (59.148) is zero and Eq. (59.147) reduces to the boundary-free BCFW recursion. An amplitude is *on-shell constructible* if it admits at least one valid shift, so that it is determined entirely by the residues of its physical poles — that is, by lower-point on-shell amplitudes.

59.6.2 Scaling of the shifted spinors and polarization vectors

The first input is purely kinematic: how the building blocks of any diagram scale with z. From Eq. (59.145) the shifted spinors have definite, elementary scalings. On leg i (the leg whose *square* spinor is shifted) the square spinor grows linearly while the angle spinor is inert,

$$|\hat{i}] = |i] + z\,|j] = O(z), \qquad |\hat{i}\rangle = |i\rangle = O(1); \tag{59.149}$$

on leg j (the leg whose *angle* spinor is shifted) it is the other way around,

$$|\hat{j}\rangle = |j\rangle - z\,|i\rangle = O(z), \qquad |\hat{j}] = |j] = O(1). \tag{59.150}$$

These feed directly into the external polarization vectors. Each shifted leg carries a polarization built, as in Eq. (58.111) (recalled in Eq. (59.32)), from the leg's own spinors and a reference momentum q_ℓ, which is an arbitrary fixed null momentum encoding the residual gauge freedom and is *z-independent.* We read

off the large-z power of each polarization by counting where the shifted (growing) spinor appears.

For leg i, helicity $+$ uses $\varepsilon_+^\mu(\hat{\imath}; q_i) = \langle q_i|\gamma^\mu|\hat{\imath}]/(\sqrt{2}\,\langle q_i\, i\rangle)$: the growing $|\hat{\imath}]$ sits in the numerator and the denominator $\langle q_i\,\hat{\imath}\rangle = \langle q_i\, i\rangle$ is inert, so $\varepsilon_+(\hat{\imath}) = O(z)$. Helicity $-$ uses $\varepsilon_-^\mu(\hat{\imath}; q_i) = \langle\hat{\imath}|\gamma^\mu|q_i]/(\sqrt{2}\,[\hat{\imath}\, q_i])$: now the inert $|\hat{\imath}\rangle$ is in the numerator while the growing $[\hat{\imath}\, q_i] = [i\, q_i] + z[j\, q_i] = O(z)$ is in the denominator, so $\varepsilon_-(\hat{\imath}) = O(1/z)$. The same reasoning on leg j, where it is the angle spinor that grows, gives the mirror image. Collecting all four cases:

	ε_+	ε_-
leg i (square-shifted)	$O(z)$	$O(1/z)$
leg j (angle-shifted)	$O(1/z)$	$O(z)$

(59.151)

These powers are robust: the reference momenta enter only the inert factors, so no choice of q_i, q_j changes the exponent. The pattern already tells the qualitative story. A negative-helicity square-shifted leg and a positive-helicity angle-shifted leg both supply a *suppressing* factor $1/z$; their helicity opposites both supply an *enhancing* factor z. The shift labelled $[-,+\rangle$ — meaning $h_i = -$ on the square-shifted leg and $h_j = +$ on the angle-shifted leg — is thus doubly suppressed at the level of its two external polarizations, while the $[+,-\rangle$ shift is doubly enhanced. The remaining work is to combine these external powers with the z-dependence of the diagram's interior.

59.6.3 The hard line and the eikonal estimate

The interior of a diagram contributes its own powers of z through the propagators and vertices that the shifted momentum flows through. The organizing observation is that the z-dependence is carried by a single connected path. Only the momenta of legs i and j depend on z, and they do so through the single null direction q: $\hat{p}_i = p_i + zq$ injects $+zq$ at leg i and $\hat{p}_j = p_j - zq$ extracts it at leg j. By momentum conservation at every vertex, the large momentum zq must flow along an unbroken path of internal lines from i to j — the *hard line*. Every propagator off this path carries only soft (z-independent) momentum; every propagator on it carries momentum of the form $zq + (\text{soft})$, and is therefore large. Figure 59.6 depicts the picture: a hard line threading a soft background built from the other $n-2$ gluons.

We now count powers along the hard line, using the color-ordered Feynman rules Eqs. (59.12) to (59.14). Suppose the hard line passes through V_h vertices and hence through $V_h - 1$ internal hard propagators (the two ends being the external legs i and j). Each hard propagator scales as $1/z$: with internal momentum $\ell = zq + k$ for soft k, the denominator is

$$\ell^2 = (zq + k)^2 = 2z\, q\cdot k + k^2 = O(z), \tag{59.152}$$

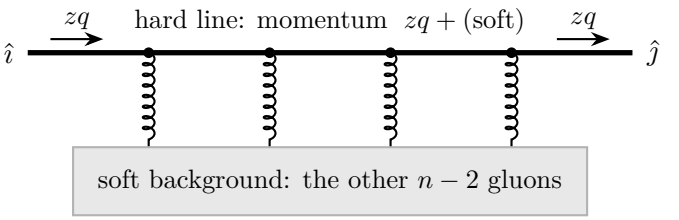

Figure 59.6: The large-z limit of a shifted diagram. The deformation injects a large null momentum zq at leg i and removes it at leg j; momentum conservation forces it to traverse a single *hard line* (thick) of large internal momenta, while the remaining $n-2$ gluons form a soft, z-independent background into which the hard line radiates. The leading large-z behavior is that of one energetic particle propagating through this background.

since $q^2 = 0$, so $-i\eta_{\mu\nu}/\ell^2 = O(1/z)$. Each cubic vertex on the hard line is linear in momentum Eq. (59.12), and its leading large-z piece is the one in which the large momentum zq occupies the momentum slot, giving $O(z)$; a quartic vertex carries no momentum and is $O(1)$. The most enhanced topology is the purely cubic one, in which each of the V_h vertices contributes $O(z)$. The interior power is therefore

$$\underbrace{z^{V_h}}_{\text{vertices}} \times \underbrace{z^{-(V_h-1)}}_{\text{propagators}} = z^{+1}, \tag{59.153}$$

independent of the length V_h of the hard line. The cancellation in Eq. (59.153) is the eikonal phenomenon: an energetic particle plowing through a soft background gains one power of vertex momentum for each propagator it saves, and the two effects balance to leave a single overall power of z. Moreover, to leading order each cubic vertex on the hard line acts as the eikonal vertex $\frac{i}{\sqrt{2}}\,(2zq)^\rho\,\eta^{\mu\nu}$: it passes the hard-line Lorentz indices straight through with a metric $\eta^{\mu\nu}$ and couples to the soft gluon of index ρ through the current zq^ρ. Threaded through the metric propagators, all the hard-line indices are simply identified, and the two external polarizations are contracted directly into one another. The leading large-z behavior of any single diagram is therefore bounded by

$$A_n(z)\Big|_{\text{leading}} \;\sim\; z\;\varepsilon_i(z)\cdot\varepsilon_j(z), \tag{59.154}$$

the product of the interior power Eq. (59.153) with the two external polarization scalings of Eq. (59.151), contracted through the eikonal metric.

We must compute $\varepsilon_i(z)\cdot\varepsilon_j(z)$ for each helicity assignment. This is exactly the polarization dot-product Theorem 59.8 of Section 59.2.2, now evaluated on the shifted spinors Eqs. (59.149) and (59.150). Take first the case the recursion needs, $[-,+\rangle$: leg i negative, leg j positive. By Eq. (59.37) (with the positive leg

j and negative leg i),

$$\varepsilon_-(\hat{\imath};q_i)\cdot\varepsilon_+(\hat{\jmath};q_j)=\frac{\langle q_j\,\hat{\imath}\rangle\,[q_i\,\hat{\jmath}]}{\langle q_j\,\hat{\jmath}\rangle\,[\hat{\imath}\,q_i]}=\frac{\langle q_j\,i\rangle\,[q_i\,j]}{(\langle q_j\,j\rangle-z\langle q_j\,i\rangle)\,([i\,q_i]+z[j\,q_i])}=O(1/z^2), \tag{59.155}$$

where we used $|\hat{\imath}\rangle=|i\rangle$, $|\hat{\jmath}]=|j]$ in the numerator and the growing pieces $\langle q_j\,\hat{\jmath}\rangle,[\hat{\imath}\,q_i]=O(z)$ in the denominator. Combining with Eq. (59.154),

$$A_n(z)\Big|_{[-,+\rangle}\;\sim\; z\cdot O(1/z^2)=O(1/z)\;\xrightarrow{z\to\infty}\;0. \tag{59.156}$$

This is the central computation of the section: *the* $[-,+\rangle$ *shift makes every diagram fall off at least as* $1/z$, so the full $A_n(z)\to 0$ and, by Eq. (59.148), the boundary term vanishes. Crucially, because each diagram is already bounded by a decaying power, the conclusion needs no cancellation between diagrams: summing terms each of size $O(1/z)$ gives a sum of size $O(1/z)$.

The other three assignments are computed the same way. For $[+,-\rangle$ (leg i positive, leg j negative), Eq. (59.37) with the roles reversed gives

$$\varepsilon_+(\hat{\imath};q_i)\cdot\varepsilon_-(\hat{\jmath};q_j)=\frac{\langle q_i\,\hat{\jmath}\rangle\,[q_j\,\hat{\imath}]}{\langle q_i\,\hat{\imath}\rangle\,[\hat{\jmath}\,q_j]}=\frac{(\langle q_i\,j\rangle-z\langle q_i\,i\rangle)\,([q_j\,i]+z[q_j\,j])}{\langle q_i\,i\rangle\,[j\,q_j]}=O(z^2), \tag{59.157}$$

so $A_n(z)|_{[+,-\rangle}\sim z\cdot O(z^2)=O(z^3)$, a fast *growth*: the $[+,-\rangle$ shift is invalid. For the like-helicity shifts the eikonal estimate is borderline. Using Eq. (59.35) for $[+,+\rangle$ and Eq. (59.36) for $[-,-\rangle$ on the shifted spinors,

$$\varepsilon_+(\hat{\imath})\cdot\varepsilon_+(\hat{\jmath})=\frac{\langle q_i\,q_j\rangle\,[\hat{\jmath}\,\hat{\imath}]}{\langle q_i\,\hat{\imath}\rangle\,\langle q_j\,\hat{\jmath}\rangle}=\frac{\langle q_i\,q_j\rangle\,[j\,i]}{\langle q_i\,i\rangle\,(\langle q_j\,j\rangle-z\langle q_j\,i\rangle)}=O(1/z), \tag{59.158}$$

$$\varepsilon_-(\hat{\imath})\cdot\varepsilon_-(\hat{\jmath})=\frac{\langle\hat{\imath}\,\hat{\jmath}\rangle\,[q_j\,q_i]}{[\hat{\imath}\,q_i]\,[\hat{\jmath}\,q_j]}=\frac{\langle i\,j\rangle\,[q_j\,q_i]}{([i\,q_i]+z[j\,q_i])\,[j\,q_j]}=O(1/z), \tag{59.159}$$

where in Eq. (59.158) we used $[\hat{\jmath}\,\hat{\imath}]=[j\,\hat{\imath}]=[j\,i]+z[j\,j]=[j\,i]$ (the would-be growing term killed by $[j\,j]=0$), and similarly $\langle\hat{\imath}\,\hat{\jmath}\rangle=\langle i\,j\rangle$ in Eq. (59.159). Both give $A_n(z)\sim z\cdot O(1/z)=O(1)$: the eikonal estimate places these two shifts on the boundary of validity, neither manifestly decaying nor growing. To settle them we need an argument finer than the diagram-by-diagram count.

59.6.4 The background-field argument and the catalogue of shifts

The eikonal estimate Eq. (59.154) is an *upper bound* per diagram, and for the like-helicity shifts it is not saturated: the leading $O(1)$ piece cancels in the gauge-invariant sum, leaving the true $1/z$ falloff. To see this one must work with the full amplitude rather than diagram by diagram, and the cleanest tool is the background-field method of Arkani-Hamed and Kaplan. The idea is to take the large-z limit literally as a physical limit: legs i and j become hard, with

momenta $\hat{p}_i \approx +zq$ and $\hat{p}_j \approx -zq$, while the remaining $n-2$ gluons are soft. The amplitude in this limit is computed by quantizing the hard fluctuation in the soft classical background A_μ formed by the other gluons.

Expanding the Yang–Mills action of Eq. (25.76) to quadratic order in the hard fluctuation a_μ about the background A_μ, and fixing background Feynman gauge, the quadratic operator governing the hard line is

$$\Delta_{\mu\nu} = D^2\,\eta_{\mu\nu} - 2ig\,F_{\mu\nu}, \tag{59.160}$$

where $D_\mu = \partial_\mu - igA_\mu$ is the background covariant derivative and $F_{\mu\nu}$ the background field strength, both built from the soft gluons. The two terms have a transparent meaning. The first, $D^2\eta_{\mu\nu}$, is the scalar (minimal) coupling: it propagates the hard particle as if it were a charged scalar, passing its Lorentz indices through unchanged. The second, $-2igF_{\mu\nu}$, is the *gyromagnetic* (spin) coupling, the magnetic moment $g=2$ of the Yang–Mills gluon, which rotates the hard particle's polarization as it traverses the background. The hard-line propagator is the inverse of Eq. (59.160), expanded for large momentum $\hat{\ell} = zq + \cdots$:

$$\frac{1}{\Delta} = \frac{1}{D^2}\,\eta_{\mu\nu} + \frac{1}{D^2}\,(2igF)_\mu{}^\rho\,\frac{1}{D^2}\,\eta_{\rho\nu} + \cdots = \underbrace{\frac{\eta_{\mu\nu}}{D^2}}_{O(1/z)} + \underbrace{\frac{2igF_{\mu\nu}}{(D^2)^2}}_{O(1/z^2)} + \cdots, \tag{59.161}$$

where $D^2 \sim 2z\,q\cdot\partial = O(z)$ on the hard line and the soft $F_{\mu\nu}$ is $O(1)$. The leading piece is the scalar one, $\eta_{\mu\nu}/z$; the spin piece is suppressed by a further $1/z$.

The helicity dependence enters through how the external polarizations of the hard legs contract with this structure. The decisive fact is that the scalar (eikonal) piece $\eta_{\mu\nu}/z$ contracts the two hard polarizations directly, $\varepsilon_i\cdot\varepsilon_j$, reproducing the borderline estimate Eq. (59.154); but for the like-helicity and the $[-,+\rangle$ configurations this leading scalar contraction is itself suppressed or vanishing (as the explicit dot products Eqs. (59.155), (59.158) and (59.159) showed, it is at most $O(1/z)$ in three of the four cases), so the amplitude is controlled by the spin piece $F_{\mu\nu}/z^2$ acting on polarizations. Carrying the expansion through, Arkani-Hamed and Kaplan find that for a spin-1 hard line the gauge symmetry forces the leading would-be-bad terms to cancel for every helicity assignment *except* the one in which both hard legs have their polarizations maximally enhanced, recovering

$$A_n(z) \xrightarrow{z\to\infty} \begin{cases} O(1/z), & [-,+\rangle,\ [+,+\rangle,\ [-,-\rangle \quad \text{(valid)},\\ O(z^3), & [+,-\rangle \quad \text{(invalid)}. \end{cases} \tag{59.162}$$

The three valid cases all decay as $1/z$ (the like-helicity ones thanks to the gyromagnetic cancellation that the bare eikonal count missed); the single bad case grows as z^3, the power already exposed by the manifest enhancement in Eq. (59.157). We summarize in Table 59.2.

shift $[h_i, h_j\rangle$	large-z behavior	status
$[-,+\rangle$	$1/z$	valid (canonical good shift)
$[-,-\rangle$	$1/z$	valid
$[+,+\rangle$	$1/z$	valid
$[+,-\rangle$	z^3	invalid (boundary term survives)

Table 59.2: Large-z behavior of the shifted color-ordered gluon amplitude under the $[i,j\rangle$ shift Eq. (59.145), classified by the helicities (h_i, h_j) of the square-shifted leg i and the angle-shifted leg j. Three of the four assignments fall off and are valid for BCFW; only $[+,-\rangle$, which enhances both external polarizations, grows and is invalid. The $[-,+\rangle$ shift is the canonical choice: its falloff is visible diagram by diagram, with no appeal to cancellations.

The bad shift is bad for a reason

It is tempting to read Table 59.2 as a rule to memorize, but the structure is physical. A shift fails precisely when it pumps the spins of *both* deformed legs in the enhancing direction simultaneously — ε_+ on the square-shifted leg and ε_- on the angle-shifted leg, each $O(z)$ by Eq. (59.151). Then even the gyromagnetic cancellation cannot rescue the growth, and $A_n(z) \sim z^3$. The surviving B_0 is then a genuine piece of data — a polynomial in the external kinematics that no factorization pole sees — and a recursion that ignores it returns the wrong answer. The lesson carries beyond gluons: in any theory, the validity of a shift is a statement about the spin and the high-energy (ultraviolet) behavior of the fields being shifted, and must be checked, not assumed.

Notation Watch

The background-field argument leading to Eq. (59.162) assumes the two-derivative Yang–Mills action with its $g = 2$ gyromagnetic ratio and a background gauge fixing; it is exactly these features that produce the operator Eq. (59.160) and the spin cancellation. The same argument, applied to the two-derivative Einstein–Hilbert action, gives the gravitational shift its own (milder, $1/z^2$) falloff, used in Chapter 61. The argument can fail for non-minimally coupled theories, for higher-derivative operators, or for scalars with generic potentials, where the high-energy behavior is different; in such cases a nonzero B_0 can appear and the amplitude is not constructible by a two-line shift alone. For the pure-gluon tree amplitudes that carry Yang–Mills theory, the falloff Eq. (59.162) is exact and the $[-,+\rangle$ shift is always available, as the next subsection establishes.

The explicit four-gluon computation below confirms both ends of the catalogue — the $1/z$ falloff of the good shift and the z^3 growth of the bad one — on the carried Yang–Mills theory amplitude.

Worked Example 59.26 (Large-z behavior of the four-gluon MHV amplitude)**.** We test Eq. (59.162) directly on the color-ordered MHV amplitude $A_4[1^-,2^-,3^+,4^+]$. We are permitted to use its closed form, the Parke–Taylor expression $A_4 = i\,g^2\,\langle 1\,2\rangle^4/(\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle)$ established in Eq. (59.55) of an earlier section (and proved at $n=4$ in Eq. (59.81)), purely as an independent check — the present argument does not assume it. Simplifying one power,

$$A_4[1^-,2^-,3^+,4^+] = i\,g^2\,\frac{\langle 1\,2\rangle^3}{\langle 2\,3\rangle\,\langle 3\,4\rangle\,\langle 4\,1\rangle}. \tag{59.163}$$

The good shift $[-,+\rangle$. Shift the adjacent pair $(2^-,3^+)$ with $i=2$ (negative, square-shifted) and $j=3$ (positive, angle-shifted): $|\hat{2}] = |2] + z|3]$, $|\hat{2}\rangle = |2\rangle$, $|\hat{3}\rangle = |3\rangle - z|2\rangle$, $|\hat{3}] = |3]$. Only angle brackets containing leg 3 change, and only through $|\hat{3}\rangle = |3\rangle - z|2\rangle$:

$$\langle 1\,2\rangle \to \langle 1\,2\rangle, \quad \langle 2\,3\rangle \to \langle 2\,\hat{3}\rangle = \langle 2\,3\rangle - z\langle 2\,2\rangle = \langle 2\,3\rangle, \quad \langle 3\,4\rangle \to \langle \hat{3}\,4\rangle = \langle 3\,4\rangle - z\langle 2\,4\rangle, \quad \langle 4\,1\rangle \to \langle 4 \tag{59.164}$$

Hence

$$A_4(z) = i\,g^2\,\frac{\langle 1\,2\rangle^3}{\langle 2\,3\rangle\,(\langle 3\,4\rangle - z\langle 2\,4\rangle)\,\langle 4\,1\rangle} \;\sim\; \frac{1}{z} \xrightarrow{z\to\infty} 0, \tag{59.165}$$

exactly the $1/z$ falloff of Table 59.2. The boundary term vanishes and the $(2,3)$ shift reconstructs A_4.

The bad shift $[+,-\rangle$. Now shift the same pair the wrong way: $i=3$ (positive, square-shifted) and $j=2$ (negative, angle-shifted), so $|\hat{3}] = |3] + z|2]$, $|\hat{3}\rangle = |3\rangle$, $|\hat{2}\rangle = |2\rangle - z|3\rangle$, $|\hat{2}] = |2]$. Now angle brackets containing leg 2 change through $|\hat{2}\rangle = |2\rangle - z|3\rangle$:

$$\langle 1\,2\rangle \to \langle 1\,\hat{2}\rangle = \langle 1\,2\rangle - z\langle 1\,3\rangle, \quad \langle 2\,3\rangle \to \langle \hat{2}\,3\rangle = \langle 2\,3\rangle - z\langle 3\,3\rangle = \langle 2\,3\rangle, \quad \langle 3\,4\rangle \to \langle 3\,4\rangle, \quad \langle 4\,1\rangle \to \langle 4 \tag{59.166}$$

The numerator $\langle 1\,2\rangle^3 \to (\langle 1\,2\rangle - z\langle 1\,3\rangle)^3$ grows as z^3 while the denominator's only shifted factor, $\langle 1\,2\rangle$, was already cancelled in passing from $\langle 1\,2\rangle^4$ to $\langle 1\,2\rangle^3$. Therefore

$$A_4(z) = i\,g^2\,\frac{\big(\langle 1\,2\rangle - z\langle 1\,3\rangle\big)^3}{\langle 2\,3\rangle\,\langle 3\,4\rangle\,\langle 4\,1\rangle} \;\sim\; z^3 \xrightarrow{z\to\infty} \infty, \tag{59.167}$$

exactly the z^3 growth of Table 59.2. A recursion built on this shift would miss the entire $z^3 + z^2 + z^1 + z^0$ polynomial in Eq. (59.167), of which the z^0 term is precisely the boundary contribution B_0; it would return nonsense. The two computations, on the very same amplitude, make the catalogue concrete: the only thing that distinguishes the valid recursion from the invalid one is the assignment of helicities to the shifted legs.

59.6.5 On-shell constructibility of tree Yang–Mills

With the boundary term killed for the $[-,+\rangle$ shift, the recursion is unpaid no longer, and we can state the structural theorem that the whole chapter has been driving toward.

Theorem 59.27 (On-shell constructibility of tree Yang–Mills)**.** *Every color-ordered n-gluon tree amplitude ($n \geq 4$) is on-shell constructible. It admits a valid $[-,+\rangle$ shift, for which the boundary term Eq. (59.148) vanishes and the BCFW recursion Theorem 59.23 holds without a boundary term:*

$$A_n[1,\dots,n] = \sum_{\text{channels } I} \sum_{h} \hat{A}_L(z_I)\,\frac{i}{P_I^2}\,\hat{A}_R(z_I), \tag{59.168}$$

the sum running over the factorization channels compatible with the cyclic order and over the helicity h of the internal on-shell gluon. Iterating, A_n is determined entirely by the three-point amplitudes A_3^{MHV} and $A_3^{\overline{\mathrm{MHV}}}$ of Eq. (59.116), fixed by little-group scaling (Eq. (58.98)) alone. No Yang–Mills Lagrangian, no Feynman rules, and no off-shell field enters the reconstruction.

Proof. A valid shift always exists. The vanishing theorems Theorems 59.9 and 59.10 of Section 59.2.4 show that an amplitude with fewer than two negative or fewer than two positive helicities is identically zero, hence trivially constructible. So take a nonvanishing amplitude: its number k of negative-helicity legs satisfies $2 \leq k \leq n-2$, so it carries at least two negative and at least two positive legs. Reading the cyclic order $1,2,\dots,n$ around the circle, the helicity label cannot be constant (both signs occur), so somewhere two cyclically adjacent legs carry opposite helicities: a negative leg a next to a positive leg b. Choose the shift $[a,b\rangle$, i.e. square-shift the negative leg a and angle-shift the positive leg b. This is a $[-,+\rangle$ shift, so by Eq. (59.162) (established diagram by diagram in Eq. (59.156)) the shifted amplitude falls off as $1/z$ and the boundary term Eq. (59.148) vanishes. Hence Eq. (59.147) reduces to Eq. (59.168).

The recursion lowers the point count. In each term of Eq. (59.168), the channel I splits the n legs into two nonempty groups, one containing the shifted leg a and the other b; the sub-amplitudes $\hat{A}_L$ and $\hat{A}_R$ are color-ordered on-shell amplitudes evaluated on shifted but on-shell momenta, each with strictly fewer than n legs (the internal line replaces all the legs on the other side of the channel by a single on-shell gluon). The Mandelstam factor $1/P_I^2$ is the unshifted invariant of the channel, a physical pole.

Induction on the number of legs. We prove that every on-shell color-ordered gluon tree amplitude is a rational function of the spinors of its external legs, fixed by the three-point seeds. The base case $n=3$ is the pair of complex-momentum three-point amplitudes $A_3^{\mathrm{MHV}}(1^-,2^-,3^+) = i\,g\,\langle 1\,2\rangle^3/(\langle 2\,3\rangle\langle 3\,1\rangle)$ and its parity conjugate $A_3^{\overline{\mathrm{MHV}}}(1^+,2^+,3^-) = -\,i\,g\,[1\,2]^3/([2\,3][3\,1])$, which Eq. (59.116) fixed

from little-group scaling and locality with no Lagrangian input. For the inductive step, assume every amplitude with fewer than n legs is so determined. Any n-point amplitude admits the valid shift just constructed, so by Eq. (59.168) it equals a finite sum of products $\hat{A}_L\,(i/P_I^2)\,\hat{A}_R$ of amplitudes with fewer than n legs, each of which is determined by the seeds by the inductive hypothesis. Therefore A_n is too. By induction every tree amplitude is fixed by A_3^{MHV} and $A_3^{\overline{\mathrm{MHV}}}$.

No Lagrangian enters the reconstruction. The only ingredients used in Eq. (59.168) and the induction are: (i) that $A_n(z)$ is rational with only simple poles at the physical factorization channels — a consequence of locality and unitarity, namely that an amplitude's singularities are exactly where intermediate states go on shell and that it factorizes there into on-shell sub-amplitudes; (ii) the three-point seeds, fixed by Poincaré symmetry (little-group scaling) alone; and (iii) the large-z falloff of the $[-,+\rangle$ shift. Of these only (iii) referred to the Yang–Mills vertices, and even there the background-field analysis of Section 59.6.4 shows the falloff follows from the spin-1, two-derivative, gauge-invariant character of the interaction rather than from any specific off-shell completion. The Lagrangian is never used to generate the amplitude; it is at most a guarantor of the high-energy behavior. This is the precise content of the claim that perturbative gauge theory is built from locality and unitarity, not from a Lagrangian. □

Locality and unitarity as the real inputs

Theorem 59.27 inverts the usual logic of field theory. In the textbook route one postulates a Lagrangian, derives Feynman rules, and computes amplitudes; the amplitude is an output, the Lagrangian the input. Constructibility says that for tree-level gauge theory the amplitude is fixed by far less: by where it is allowed to have poles (locality: poles only on physical channels) and by what it must become there (unitarity: it factorizes into on-shell amplitudes), seeded by the three-point amplitudes that symmetry alone determines. The infinitely many gauge-redundant off-shell configurations of the Lagrangian — the very source of the factorial diagram explosion of Table 59.1 — are revealed as scaffolding that the final answer does not remember. The hidden simplicity of Parke–Taylor, which the next section proves, is then not a miracle of cancellation but the inevitable shape of the unique function with the right poles, residues, and little-group weights.

We have now discharged the one outstanding debt of Theorem 59.23: for the $[-,+\rangle$ shift the contour at infinity contributes nothing, the BCFW recursion Eq. (59.168) stands on its own, and tree Yang–Mills is on-shell constructible from its three-point seeds. The recursion is now a fully justified, boundary-term-free machine. The next section turns it on: it proves the Parke–Taylor formula by

induction on multiplicity using exactly this recursion, and then runs the machine on explicit amplitudes, contrasting the one-line BCFW computation with the Feynman labor it replaces.

59.7 Proof of Parke–Taylor and Worked Examples

The previous section closed the conceptual circle: with the boundary term at infinity shown to vanish for a valid shift, the contour-deformation identity became an honest recursion, and tree-level Yang–Mills was declared *on-shell constructible* — every gluon tree is fixed by the three-point seeds Eq. (59.116) and the factorization poles, with no reference to the Lagrangian at all. That is a licence to compute, and it is time to spend it. We have a one-line conjecture for the entire maximally-helicity-violating sector, the Parke–Taylor formula Eq. (59.55), and we have a recursion, Theorem 59.23, that manufactures any tree from smaller ones. In this final section we put the two together: we *prove* Parke–Taylor by induction on the number of gluons, run the recursion explicitly on the four- and five-gluon amplitudes to watch a thousand-diagram computation collapse to a single term, assemble the first genuinely non-MHV amplitude (the six-point NMHV) from MHV and $\overline{\text{MHV}}$ pieces, and step back to state what the whole construction has taught: that locality and unitarity, not an action, are the data that fix the perturbative S-matrix. This completes the Yang–Mills theory layer of the chapter.

Throughout we use the conventions already fixed in this chapter: all n momenta outgoing and massless, angle and square brackets with $2p_i\cdot p_j = \langle i\,j\rangle[j\,i]$ (Eqs. (58.20) and (58.24)), color-ordered partial amplitudes A_n, and the helicity grading of Theorem 59.12. We recall the three objects the proof leans on, each established elsewhere in the chapter.

The seeds. The two complex-momentum three-point amplitudes (Eq. (59.116)) are

$$A_3^{\text{MHV}}(i^-,j^-,k^+) = i\,g\,\frac{\langle i\,j\rangle^3}{\langle j\,k\rangle\langle k\,i\rangle}, \qquad A_3^{\overline{\text{MHV}}}(i^-,j^+,k^+) = -\,i\,g\,\frac{[j\,k]^3}{[k\,i][i\,j]}. \tag{59.169}$$

The first lives where the angle brackets are generic and the square brackets all vanish (the *holomorphic*, or MHV, branch of the singular three-point kinematics); the second is its parity conjugate, supported where the angle brackets vanish.

The target. The Parke–Taylor formula Eq. (59.55) asserts that the color-ordered n-gluon MHV amplitude, with negative-helicity legs i and j and all others positive, is

$$A_n^{\text{MHV}} = i\,g^{\,n-2}\,\frac{\langle i\,j\rangle^4}{\langle 1\,2\rangle\langle 2\,3\rangle\cdots\langle n-1\,n\rangle\langle n\,1\rangle}, \tag{59.170}$$

a single ratio whose denominator is the cyclic product of nearest-neighbour angle brackets and whose numerator depends only on the two negative legs.

The machine. The recursion of Theorem 59.23, for the $[\,i,j\,\rangle$ shift

$$|\hat{\imath}\,] = |i] + z\,|j], \qquad |\hat{\jmath}\,\rangle = |j\rangle - z\,|i\rangle, \qquad |\hat{\imath}\,\rangle = |i\rangle, \quad |\hat{\jmath}\,] = |j], \tag{59.171}$$

reconstructs the amplitude as a sum over the factorization channels I that separate the two shifted legs,

$$A_n = \sum_I \sum_{h=\pm} \hat{A}_L(z_I)\,\frac{i}{P_I^2}\,\hat{A}_R(z_I), \tag{59.172}$$

where $P_I = \sum_{a\in I} p_a$ is the unshifted channel momentum, the internal gluon is summed over its two helicities h (entering $\hat{A}_L$ as $\pm h$ and $\hat{A}_R$ as $\mp h$), and both subamplitudes are evaluated at the complex shift parameter z_I that puts the internal line on shell, $\hat{P}_I(z_I)^2 = 0$. The constructibility theorem Theorem 59.27 guarantees Eq. (59.172) is exact: no term at infinity is dropped.

59.7.1 The single surviving channel

The whole proof turns on one observation: when Eq. (59.172) is applied to an MHV amplitude with a wisely chosen shift, all but one of the channels die, and in the survivor one of the two subamplitudes is the three-point $\overline{\text{MHV}}$ seed. We isolate that statement before grinding the algebra.

Take the MHV amplitude with the two negative-helicity legs adjacent and placed first,

$$A_n \equiv A_n(1^-, 2^-, 3^+, 4^+, \dots, n^+), \tag{59.173}$$

and apply the $[\,1,2\,\rangle$ shift of Eq. (59.171). The shifted legs $\hat{1},\hat{2}$ carry helicities $(h_1,h_2) = (-,-)$; this is one of the shifts the large-z analysis of Theorem 59.27 certified as valid (the forbidden pattern was $(+,-)$), so Eq. (59.172) holds with no boundary term. Because the amplitude is color-ordered, its only poles sit in the *consecutive* channels, and a channel contributes to the $[\,1,2\,\rangle$ recursion only if it puts $\hat{1}$ and $\hat{2}$ on opposite sides of the cut. The consecutive sets containing leg 2 but not leg 1 are

$$I_k = \{2,3,\dots,k\}, \qquad k = 3,4,\dots,n-1, \tag{59.174}$$

each splitting the amplitude into

$$\hat{A}_L = A_k(\hat{2},3,\dots,k,-\hat{P}_k), \qquad \hat{A}_R = A_{n-k+2}(\hat{P}_k,k+1,\dots,n,\hat{1}), \tag{59.175}$$

with internal momentum $\hat{P}_k = \hat{p}_2 + p_3 + \cdots + p_k$ and a sum over the helicity h of the internal line.

Now count negative helicities. The external negative legs are exactly 1 and 2; leg 2 sits in $\hat{A}_L$, leg 1 in $\hat{A}_R$. For a partial amplitude with four or more legs, the vanishing theorems of Theorems 59.9 and 59.10 forbid the all-plus and single-minus configurations. Apply this to each side:

- If the internal line enters $\hat{A}_L$ with positive helicity, then $\hat{A}_L$ has the single negative leg 2 and otherwise only positive legs — it is single-minus and *vanishes* unless it is a three-point amplitude. A three-point $\hat{A}_L$ requires $I_k = \{2, 3\}$, i.e. $k = 3$.
- If instead the internal line enters $\hat{A}_L$ negatively, it enters $\hat{A}_R$ positively; then $\hat{A}_R$ has the single negative leg 1 and otherwise only positive legs — single-minus, *vanishing* unless three-point, which needs $n - k + 2 = 3$, i.e. $k = n - 1$.

So only the two endpoint channels, $k = 3$ and $k = n - 1$, can survive, and in each the small side is forced to be a three-point seed. The two are not on equal footing, because a three-point amplitude is nonzero only on the branch selected by the on-shell value z_I — and that branch decides whether the seed is MHV or $\overline{\text{MHV}}$. We check both.

The channel $k = n - 1$ is empty. Here $\hat{A}_R = A_3(\hat{P}_{n-1}, n, \hat{1})$ with $P_{n-1} = \hat{p}_2 + \cdots + p_{n-1} = -(p_n + \hat{p}_1)$. Using $|\hat{1}\,] = |1] + z|2]$ and $|\hat{1}\,\rangle = |1\rangle$,

$$\hat{P}_{n-1}^2 = (p_n + \hat{p}_1)^2 = 2\, p_n \cdot \hat{p}_1 = \langle n\, 1\rangle\, [\hat{1}\, n] = \langle n\, 1\rangle\big([1\, n] + z[2\, n]\big), \tag{59.176}$$

which vanishes at $z = z_{n-1} = -[1\, n]/[2\, n]$. At that point $[\hat{1}\, n] = 0$, so the *square* spinors of the three-point legs are proportional: this is the holomorphic branch, on which only an MHV three-point amplitude is nonzero. But the helicity content of $\hat{A}_R$ at $k = n - 1$ that is allowed by the counting above has the internal line negative on the $\hat{A}_R$ side, giving legs $(\hat{P}_{n-1}^-, n^+, \hat{1}^-)$ — one positive leg, hence $\overline{\text{MHV}}$, which vanishes on the holomorphic branch. (Equivalently: the only way to make a nonzero MHV three-point amplitude here would need two negative legs among $\hat{P}_{n-1}, n, \hat{1}$, but then $\hat{A}_L$ would carry only leg 2 as a negative and be single-minus.) Either way the channel contributes nothing.

The channel $k = 3$ survives. Here the small side is $\hat{A}_L = A_3(\hat{2}, 3, -\hat{P}_3)$ with $P_3 = \hat{p}_2 + p_3$ and $\hat{p}_2 = |\hat{2}\,\rangle[2| = (|2\rangle - z|1\rangle)[2| = p_2 - z\,|1\rangle[2|$, so

$$\hat{P}_3^2 = (\hat{p}_2 + p_3)^2 = 2\, \hat{p}_2 \cdot p_3 = \langle \hat{2}\, 3\rangle\, [3\, 2] = \big(\langle 2\, 3\rangle - z\langle 1\, 3\rangle\big)[3\, 2], \tag{59.177}$$

which vanishes at

$$z_* = \frac{\langle 2\, 3\rangle}{\langle 1\, 3\rangle}. \tag{59.178}$$

At z_* the angle bracket $\langle \hat{2}\, 3\rangle = \langle 2\, 3\rangle - z_*\langle 1\, 3\rangle = 0$, so the *angle* spinors of the three legs are proportional: this is the anti-holomorphic branch, on which the nonzero three-point amplitude is the $\overline{\text{MHV}}$ seed. Its helicity content must therefore be one negative leg. The internal line enters $\hat{A}_L$ positively (the case that did not

already die above), giving $\hat{A}_L = A_3^{\overline{\text{MHV}}}(\hat{2}^-, 3^+, -\hat{P}_3^+)$ — exactly one negative leg, consistent with the branch. The other side is then

$$\hat{A}_R = A_{n-1}^{\text{MHV}}(\hat{P}_3^-, 4^+, 5^+, \dots, n^+, \hat{1}^-), \tag{59.179}$$

an $(n-1)$-point amplitude with exactly two negative legs, $\hat{P}_3$ and $\hat{1}$, which are cyclically adjacent in its ordering. This is again MHV, and on it the induction hypothesis bites.

We have reduced the recursion Eq. (59.172) to a single term: the amplitude A_n of Eq. (59.173) equals the product of the $\overline{\text{MHV}}_3$ seed, the propagator i/P_3^2, and the $(n-1)$-point MHV amplitude Eq. (59.179), all evaluated at z_*.

59.7.2 The inductive proof

Theorem 59.28 (Parke–Taylor by induction)**.** *For every $n \geq 3$ the color-ordered MHV amplitude with adjacent negative legs $1, 2$ is*

$$A_n(1^-, 2^-, 3^+, \dots, n^+) = i\, g^{\,n-2}\, \frac{\langle 1\,2\rangle^4}{\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,4\rangle \cdots \langle n\,1\rangle}, \tag{59.180}$$

and hence, by cyclic relabelling, Eq. (59.170) holds for any pair of adjacent negative legs. The general (non-adjacent) case follows by Theorem 59.29 below.

Proof. Base case. For $n = 3$ the formula Eq. (59.180) reads $i\,g\,\langle 1\,2\rangle^4/(\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,1\rangle) = i\,g\,\langle 1\,2\rangle^3/(\langle 2\,3\rangle\langle 3\,1\rangle)$, which is precisely the MHV seed $A_3^{\text{MHV}}(1^-, 2^-, 3^+)$ of Eq. (59.169). The base case is the seed itself.

Inductive step. Assume Eq. (59.170) for all MHV amplitudes with fewer than n legs. By Section 59.7.1 the $[\,1, 2\,\rangle$ recursion collapses to the single $k = 3$ term,

$$A_n = \hat{A}_L\, \frac{i}{P_3^2}\, \hat{A}_R\Big|_{z=z_*}, \qquad P_3^2 = (p_2 + p_3)^2 = \langle 2\,3\rangle[3\,2]. \tag{59.181}$$

We evaluate each factor.

The seed $\hat{A}_L$. Across the cut the internal momentum is $\hat{P}_3$ on the $\hat{A}_R$ side and $-\hat{P}_3$ on the $\hat{A}_L$ side; on shell we factor $\hat{P}_3 = |\hat{P}\rangle[\hat{P}|$ and continue the reversed leg by $|-\hat{P}\rangle = i|\hat{P}\rangle$, $|-\hat{P}\,] = i|\hat{P}\,]$, so that $|-\hat{P}\rangle[-\hat{P}| = -\hat{P}_3$. With $|\hat{2}\,] = |2]$ unshifted, the $\overline{\text{MHV}}$ seed of Eq. (59.169) (legs i, j, k taken as $\hat{2}^-, 3^+, -\hat{P}^+$) is

$$\hat{A}_L = -i\,g\,\frac{[3\,(-\hat{P})]^3}{[(-\hat{P})\,\hat{2}]\,[\hat{2}\,3]} = -i\,g\,\frac{(i\,[3\,\hat{P}])^3}{(i\,[\hat{P}\,2])[2\,3]} = -i\,g\,\frac{i^3}{i}\,\frac{[3\,\hat{P}]^3}{[\hat{P}\,2]\,[2\,3]} = i\,g\,\frac{[3\,\hat{P}]^3}{[\hat{P}\,2]\,[2\,3]}. \tag{59.182}$$

The lower amplitude $\hat{A}_R$. By the induction hypothesis applied to Eq. (59.179), whose ordering is $(\hat{P}_3, 4, 5, \dots, n, \hat{1})$ with negatives $\hat{P}_3$ and $\hat{1}$, and using $|\hat{1}\,\rangle = |1\rangle$

unshifted,

$$\hat{A}_R = i\,g^{n-3}\,\frac{\langle \hat{P}\,\hat{1}\rangle^4}{\langle \hat{P}\,4\rangle\,\langle 4\,5\rangle\cdots\langle n-1\,n\rangle\,\langle n\,\hat{1}\rangle\,\langle \hat{1}\,\hat{P}\rangle} = i\,g^{n-3}\,\frac{\langle \hat{P}\,1\rangle^4}{\langle \hat{P}\,4\rangle\,\langle 4\,5\rangle\cdots\langle n\,1\rangle\,\langle 1\,\hat{P}\rangle}. \tag{59.183}$$

Eliminating the internal spinors. Assemble Eqs. (59.181) to (59.183) and separate the $\hat{P}$-dependent factors from the rest; the overall constants multiply to $(i\,g)(i)(i\,g^{n-3}) = -\,i\,g^{n-2}$:

$$A_n = -\,i\,g^{n-2}\,\frac{1}{[2\,3]}\,\frac{1}{\langle 2\,3\rangle[3\,2]}\,\frac{1}{\langle 4\,5\rangle\cdots\langle n\,1\rangle}\,\underbrace{\frac{[3\,\hat{P}]^3\,\langle \hat{P}\,1\rangle^4}{[\hat{P}\,2]\,\langle \hat{P}\,4\rangle\,\langle 1\,\hat{P}\rangle}}_{\equiv\ \mathcal{R}}. \tag{59.184}$$

The factor $\mathcal{R}$ carries net little-group weight zero in the internal leg (angle power $4-2=2$, square power $3-1=2$), so it is expressible through the two scale-invariant bilinears $\langle x|\hat{P}|y] = \langle x\,\hat{P}\rangle[\hat{P}\,y]$, which we can evaluate without committing to a normalization of $|\hat{P}\rangle$. First reduce the angle power using $\langle 1\,\hat{P}\rangle = -\langle \hat{P}\,1\rangle$:

$$\mathcal{R} = -\frac{[3\,\hat{P}]^3\,\langle \hat{P}\,1\rangle^3}{[\hat{P}\,2]\,\langle \hat{P}\,4\rangle}. \tag{59.185}$$

The numerator pairs into a cube of one bilinear: with $\langle \hat{P}\,1\rangle[3\,\hat{P}] = \langle 1\,\hat{P}\rangle[\hat{P}\,3] = \langle 1|\hat{P}|3]$,

$$[3\,\hat{P}]^3\,\langle \hat{P}\,1\rangle^3 = \langle 1|\hat{P}|3]^3. \tag{59.186}$$

Now $\hat{P}_3 = \hat{p}_2 + p_3$, and since $[3\,3] = 0$ and $\langle 1\,\hat{2}\rangle = \langle 1\,2\rangle - z_*\langle 1\,1\rangle = \langle 1\,2\rangle$,

$$\langle 1|\hat{P}|3] = \langle 1\,\hat{2}\rangle[2\,3] + \langle 1\,3\rangle[3\,3] = \langle 1\,2\rangle\,[2\,3], \qquad \Longrightarrow \qquad \langle 1|\hat{P}|3]^3 = \langle 1\,2\rangle^3\,[2\,3]^3. \tag{59.187}$$

The denominator pairs likewise. With $\langle \hat{P}\,4\rangle[\hat{P}\,2] = -\langle 4\,\hat{P}\rangle[\hat{P}\,2] = -\langle 4|\hat{P}|2]$ and $[2\,2] = 0$,

$$\langle 4|\hat{P}|2] = \langle 4\,\hat{2}\rangle[2\,2] + \langle 4\,3\rangle[3\,2] = \langle 4\,3\rangle\,[3\,2], \qquad \Longrightarrow \qquad [\hat{P}\,2]\,\langle \hat{P}\,4\rangle = -\langle 4\,3\rangle\,[3\,2]. \tag{59.188}$$

Therefore

$$\mathcal{R} = -\frac{\langle 1\,2\rangle^3\,[2\,3]^3}{-\langle 4\,3\rangle\,[3\,2]} = \frac{\langle 1\,2\rangle^3\,[2\,3]^3}{\langle 4\,3\rangle\,[3\,2]}. \tag{59.189}$$

Notice that every reference to the complex shift parameter z_* and to the internal spinors $|\hat{P}\rangle, |\hat{P}]$ has disappeared: $\mathcal{R}$ is a ratio of ordinary external brackets, as a physical amplitude must be.

Collecting. Insert Eq. (59.189) into Eq. (59.184):

$$A_n = -\,i\,g^{n-2}\,\frac{1}{[2\,3]}\cdot\frac{1}{\langle 2\,3\rangle[3\,2]}\cdot\frac{1}{\langle 4\,5\rangle\cdots\langle n\,1\rangle}\cdot\frac{\langle 1\,2\rangle^3\,[2\,3]^3}{\langle 4\,3\rangle\,[3\,2]}. \tag{59.190}$$

The square brackets cancel completely: $[2\,3]^3/[2\,3] = [2\,3]^2$ and $[3\,2]^2 = [2\,3]^2$, so the four square brackets combine to unity, leaving

$$A_n = -\,i\,g^{\,n-2}\,\frac{\langle 1\,2\rangle^3}{\langle 2\,3\rangle\,\langle 4\,3\rangle\,\langle 4\,5\rangle\cdots\langle n\,1\rangle}. \tag{59.191}$$

Finally restore the cyclic ordering of the denominator. The lone misordered factor is $\langle 4\,3\rangle = -\langle 3\,4\rangle$, whose sign cancels the explicit minus:

$$A_n = i\,g^{\,n-2}\,\frac{\langle 1\,2\rangle^3}{\langle 2\,3\rangle\,\langle 3\,4\rangle\,\langle 4\,5\rangle\cdots\langle n\,1\rangle} = i\,g^{\,n-2}\,\frac{\langle 1\,2\rangle^4}{\langle 1\,2\rangle\,\langle 2\,3\rangle\,\langle 3\,4\rangle\cdots\langle n\,1\rangle}, \tag{59.192}$$

which is Eq. (59.180). The induction closes. □

The proof is worth pausing on. The entire content of an n-gluon MHV amplitude — which the Feynman expansion would deliver as a sum of up to thousands of gauge-dependent diagrams (Table 59.1) — has been produced from one three-point seed and one lower-point amplitude, by a half-page of spinor algebra in which the off-shell intermediate data (z_*, the internal polarization sum, the internal momentum's spinor split) cancelled identically. No Lagrangian, no gauge fixing, no propagator numerator ever appeared. The recursion knew only the poles and the seeds, and that was enough.

It remains to remove the adjacency restriction.

Corollary 59.29 (Parke–Taylor for general negative positions)**.** *For any $i \neq j$, the color-ordered MHV amplitude with negative legs i, j equals Eq. (59.170).*

Proof. By constructibility (Theorem 59.27) a tree amplitude is the unique rational function with the correct little-group weights and the correct residue on every physical (consecutive) factorization channel; equivalently, two candidate expressions with identical poles and residues that both fall off at large z under a valid shift are equal. We verify that the right-hand side of Eq. (59.170) has the residues demanded by factorization, using Theorem 59.28 as the known data on each channel.

Write $\mathrm{PT}_n[i,j] \equiv \langle i\,j\rangle^4/(\langle 1\,2\rangle\cdots\langle n\,1\rangle)$. Its only poles are the simple zeros of consecutive brackets $\langle a\,a+1\rangle$, i.e. the two-particle channels $P^2_{a,a+1} = \langle a\,a+1\rangle[a+1\,a] \to 0$; these are exactly the physical channels of a color-ordered amplitude that contain an MHV three-point corner. On the channel $\langle a\,a+1\rangle \to 0$ the momenta p_a, p_{a+1} become collinear, $|\,a+1\rangle \to |a\rangle$ up to normalization, and the residue of $\mathrm{PT}_n[i,j]$ factorizes. Take the generic case $a, a+1 \notin \{i,j\}$ (neither negative leg on the degenerate pair). Then $\langle i\,j\rangle$ is inert, and

$$\operatorname*{Res}_{\langle a\,a+1\rangle\to 0}\mathrm{PT}_n[i,j] = \frac{\langle i\,j\rangle^4}{\langle 1\,2\rangle\cdots\langle \widehat{a\,a+1}\rangle\cdots\langle n\,1\rangle} \xrightarrow{|a+1\rangle\to|a\rangle} \mathrm{PT}_{n-1}[i,j]\times A_3^{\overline{\mathrm{MHV}}}(a,a{+}1,-P_{a,a+1})/ \tag{59.193}$$

the hat denoting omission: the bracket $\langle a\, a+1\rangle$ is replaced by the propagator, the two collinear legs merge into a single leg in an $(n-1)$-point PT, and the stripped three-point factor is precisely the $\overline{\text{MHV}}$ seed — the same factorized form the recursion produces. This is the residue an actual MHV amplitude must have, and it agrees, leg by leg, with the residue computed from Eq. (59.172) using Theorem 59.28 on the lower-point factor. The cases where a negative leg sits on the degenerate pair are checked identically, the extra power of $\langle i\, j\rangle$ being supplied by the merged leg's helicity. Since $\mathrm{PT}_n[i,j]$ has no other poles, no pole at $z=\infty$ under a valid shift, and the correct little-group weight t_ℓ^{+2} on the two negative legs and t_ℓ^{-2} on the rest, it is *the* amplitude. Hence Eq. (59.170) holds for all i,j. □

Why the answer is one line

The Feynman expansion computes an amplitude as a sum over *off-shell* histories, and the price of going off shell is gauge dependence: each diagram depends on the gauge and on unphysical longitudinal modes, and the physical answer emerges only after these cancel among many diagrams. BCFW never leaves the mass shell. Every quantity it manipulates — the seeds Eq. (59.169), the residues, the lower-point amplitudes — is separately gauge invariant and little-group covariant, so there is nothing to cancel and nothing to conceal. The Parke–Taylor formula is short because it is assembled entirely from gauge-invariant pieces; the thousands of Feynman diagrams were short the same way, but written in a basis (off-shell, gauge-variant) that hid it.

59.7.3 Four gluons by BCFW, matched to the direct result

Worked Example 59.30 (The four-gluon MHV amplitude from one BCFW term)**.** We run the recursion explicitly on the carried Yang–Mills theory amplitude $A_4(1^-,2^-,3^+,4^+)$ and confirm it reproduces the Parke–Taylor value Eq. (59.55) obtained earlier by direct Feynman computation, the smallest case where the entire machine is visible at once.

Apply the $[\,1,2\,\rangle$ shift. By Section 59.7.1 the only surviving channel is $k=3$, $I=\{2,3\}$, with $P_3=p_2+p_3$, $P_3^2=\langle 2\,3\rangle[3\,2]$, and shift parameter $z_*=\langle 2\,3\rangle/\langle 1\,3\rangle$ from Eq. (59.178). The two subamplitudes are both three-point seeds:

$$\hat{A}_L=A_3^{\overline{\text{MHV}}}(\hat{2}^-,3^+,-\hat{P}^+),\qquad \hat{A}_R=A_3^{\text{MHV}}(\hat{P}^-,4^+,\hat{1}^-). \tag{59.194}$$

The left factor is Eq. (59.182) verbatim,

$$\hat{A}_L=i\,g\,\frac{[3\,\hat{P}]^3}{[\hat{P}\,2]\,[2\,3]}. \tag{59.195}$$

The right factor is the $n = 4$ instance of Eq. (59.183) (so $g^{n-3} = g$); with ordering $(\hat{P}, 4, \hat{1})$, negatives $\hat{P}$ and $\hat{1}$, and $|\hat{1}\,\rangle = |1\rangle$,

$$\hat{A}_R = i\,g\,\frac{\langle \hat{P}\,1\rangle^4}{\langle \hat{P}\,4\rangle\,\langle 4\,1\rangle\,\langle 1\,\hat{P}\rangle}. \tag{59.196}$$

The product over the propagator is the $n = 4$ case of Eq. (59.184) (overall constant $-\,i\,g^2$), with the "middle" product $\langle 4\,5\rangle \cdots \langle n\,1\rangle$ degenerating to the single factor $\langle 4\,1\rangle$:

$$A_4 = -\,i\,g^2\,\frac{1}{[2\,3]}\,\frac{1}{\langle 2\,3\rangle[3\,2]}\,\frac{1}{\langle 4\,1\rangle}\,\frac{[3\,\hat{P}]^3\,\langle \hat{P}\,1\rangle^4}{[\hat{P}\,2]\,\langle \hat{P}\,4\rangle\,\langle 1\,\hat{P}\rangle}. \tag{59.197}$$

The internal spinors are eliminated exactly as in Eqs. (59.187) and (59.188): the numerator bilinear is $\langle 1|\hat{P}|3]^3 = \langle 1\,2\rangle^3[2\,3]^3$ and the denominator bilinear is $[\hat{P}\,2]\langle \hat{P}\,4\rangle = -\langle 4\,3\rangle[3\,2]$, so

$$A_4 = -\,i\,g^2\,\frac{1}{[2\,3]}\,\frac{1}{\langle 2\,3\rangle[3\,2]}\,\frac{1}{\langle 4\,1\rangle}\,\frac{\langle 1\,2\rangle^3[2\,3]^3}{\langle 4\,3\rangle[3\,2]} = -\,i\,g^2\,\frac{\langle 1\,2\rangle^3}{\langle 2\,3\rangle\,\langle 4\,1\rangle\,\langle 4\,3\rangle}, \tag{59.198}$$

the square brackets again cancelling in the combination $[2\,3]^2/[3\,2]^2 = 1$. Reordering $\langle 4\,3\rangle = -\langle 3\,4\rangle$ and $\langle 4\,1\rangle = \langle 4\,1\rangle$,

$$A_4(1^-, 2^-, 3^+, 4^+) = i\,g^2\,\frac{\langle 1\,2\rangle^3}{\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle} = i\,g^2\,\frac{\langle 1\,2\rangle^4}{\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle}. \tag{59.199}$$

This is identical to the Parke–Taylor value Eq. (59.55) specialized to $n = 4$, and hence to the result of the explicit four-gluon Feynman computation carried out in the Parke–Taylor section — the same kinematic ratio that enters the one-loop reconstruction of Section 60.6.2 as the tree input $A_4^{(0)} = \langle 1\,2\rangle^4/(\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle)$. The contrast in effort is the lesson: the direct route summed the s-channel, t-channel, and contact diagrams of Section 59.1.5 with their full momentum-dependent vertices and a polarization sum, then watched the gauge artifacts cancel; BCFW multiplied two seeds and a pole.

It is useful to record the same amplitude in Mandelstam variables, both as a check and because it is the form that recurs at one loop. Using $s = (p_1 + p_2)^2 = \langle 1\,2\rangle[2\,1]$ and momentum conservation, Eq. (59.199) can be rewritten (multiplying numerator and denominator by $[2\,1]$ and using $\langle 2\,3\rangle[3\,1] = -\langle 2\,4\rangle[4\,1]$ from $\sum_i \langle 2\,i\rangle[i\,1] = 0$) in the manifestly crossing-symmetric guise

$$A_4(1^-, 2^-, 3^+, 4^+) = i\,g^2\,\frac{\langle 1\,2\rangle^3\,[3\,4]}{[1\,2]\,s\,t} \times \langle 1\,2\rangle[1\,2]\Big/\langle 1\,2\rangle[1\,2] = i\,g^2\,\frac{\langle 1\,2\rangle^4}{\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle}, \tag{59.200}$$

the point being only that the single rational function carries the expected simple poles in $s = \langle 1\,2\rangle[2\,1]$ and $t = \langle 2\,3\rangle[3\,2]$ and no others, as locality requires.

59.7.4 Five gluons: one term against a swarm

Worked Example 59.31 (The five-gluon MHV amplitude)**.** The five-point amplitude is where the economy becomes dramatic. The direct color-ordered computation of $A_5(1^-,2^-,3^+,4^+,5^+)$ sums the ten planar diagrams counted in Table 59.1 — five with two cubic vertices and an internal propagator, plus diagrams with the quartic vertex — each a tangle of the momentum-dependent vertices Eqs. (59.12) and (59.13) contracted against five polarization vectors, the whole sum gauge-dependent term by term. BCFW returns the answer in one term.

Apply the $[\,1,2\,\rangle$ shift. As established, the sole surviving channel is $k=3$, $I=\{2,3\}$, with $P_3=p_2+p_3$, $P_3^2=\langle 2\,3\rangle[3\,2]$, $z_*=\langle 2\,3\rangle/\langle 1\,3\rangle$. The factorization is

$$\hat{A}_L=A_3^{\overline{\mathrm{MHV}}}(\hat{2}^-,3^+,-\hat{P}^+),\qquad \hat{A}_R=A_4^{\mathrm{MHV}}(\hat{P}^-,4^+,5^+,\hat{1}^-). \tag{59.201}$$

The left factor is again Eq. (59.182). The right factor is now a genuine four-point amplitude, supplied by the result Eq. (59.199) we just proved (the induction hypothesis at $n=4$): with ordering $(\hat{P},4,5,\hat{1})$, negatives $\hat{P},\hat{1}$, and $|\hat{1}\,\rangle=|1\rangle$,

$$\hat{A}_R=i\,g^2\,\frac{\langle\hat{P}\,1\rangle^4}{\langle\hat{P}\,4\rangle\,\langle 4\,5\rangle\,\langle 5\,1\rangle\,\langle 1\,\hat{P}\rangle}. \tag{59.202}$$

Assembling through the propagator (overall constant $(i\,g)(i)(i\,g^2)=-\,i\,g^3$),

$$A_5=-\,i\,g^3\,\frac{1}{[2\,3]}\,\frac{1}{\langle 2\,3\rangle[3\,2]}\,\frac{1}{\langle 4\,5\rangle\,\langle 5\,1\rangle}\,\underbrace{\frac{[3\,\hat{P}]^3\,\langle\hat{P}\,1\rangle^4}{[\hat{P}\,2]\,\langle\hat{P}\,4\rangle\,\langle 1\,\hat{P}\rangle}}_{=\mathcal{R}}, \tag{59.203}$$

where the bracketed group is the *same* $\mathcal{R}$ as in the general proof, because the only internal-leg structures are $[3\,\hat{P}],\langle\hat{P}\,1\rangle,[\hat{P}\,2],\langle\hat{P}\,4\rangle$ — identical to Eq. (59.184); the extra leg 5 enters only through the inert external factor $\langle 4\,5\rangle\langle 5\,1\rangle$ in the denominator. Hence Eq. (59.189) applies unchanged, $\mathcal{R}=\langle 1\,2\rangle^3[2\,3]^3/(\langle 4\,3\rangle[3\,2])$, and

$$A_5=-\,i\,g^3\,\frac{1}{[2\,3]}\,\frac{1}{\langle 2\,3\rangle[3\,2]}\,\frac{1}{\langle 4\,5\rangle\langle 5\,1\rangle}\,\frac{\langle 1\,2\rangle^3[2\,3]^3}{\langle 4\,3\rangle[3\,2]}=-\,i\,g^3\,\frac{\langle 1\,2\rangle^3}{\langle 2\,3\rangle\,\langle 4\,3\rangle\,\langle 4\,5\rangle\,\langle 5\,1\rangle}. \tag{59.204}$$

Reordering $\langle 4\,3\rangle=-\langle 3\,4\rangle$,

$$A_5(1^-,2^-,3^+,4^+,5^+)=i\,g^3\,\frac{\langle 1\,2\rangle^4}{\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,5\rangle\langle 5\,1\rangle}, \tag{59.205}$$

the Parke–Taylor formula Eq. (59.55) at $n=5$.

The accounting is the moral of the chapter. A direct evaluation balances ten gauge-variant diagrams; BCFW multiplies a seed, a propagator, and the

already-known four-point amplitude, and the only labour is the half-line of spinor algebra in $\mathcal{R}$ — which we did not even repeat, having performed it once in the general proof. Each added gluon costs one more recursion step and one more inert denominator bracket, while the Feynman count climbs through 220, 2485, 34,300 (Table 59.1). This is on-shell recursion paying for itself.

59.7.5 Beyond MHV: the six-point NMHV teaser

Parke–Taylor exhausts the $k = 2$ sector. The first amplitude that is genuinely *not* MHV is the six-point next-to-MHV (NMHV, $k = 3$) amplitude

$$A_6 \equiv A_6(1^-, 2^-, 3^-, 4^+, 5^+, 6^+), \tag{59.206}$$

whose anti-MHV partner is itself ($n - 2 = 4 \neq 3$, so $\overline{\text{MHV}}$ sits at $k = 4$; NMHV at $k = 3$ is the new sector). It cannot be a single Parke–Taylor-like ratio — it is a sum of several rational terms — and assembling it from lower amplitudes is exactly what BCFW is for. We give an explicit preview here, enumerating the surviving channels and their structure; the explicit rational function follows from the same spinor algebra used above, and we record only its channel structure rather than expanding every bracket.

Apply the $[\,1, 2\,\rangle$ shift (both shifted legs negative, a valid shift). The consecutive channels separating $\hat{1}, \hat{2}$ are $I_k = \{2, \ldots, k\}$ for $k = 3, 4, 5$, splitting as in Eq. (59.175). The external negatives are now $1, 2, 3$; legs $2, 3$ land in $\hat{A}_L$ for every channel ($k \geq 3$), leg 1 in $\hat{A}_R$. Run the same vanishing logic, now with three negatives to distribute, and track the on-shell branch as in Section 59.7.1:

- $k = 3$ **(channel P_{23}): dies.** The small corner is $A_3(\hat{2}^-, 3^-, -\hat{P}^h)$. At $z_* = \langle 2\,3\rangle/\langle 1\,3\rangle$ the angle bracket $\langle \hat{2}\,3\rangle \to 0$, forcing the anti-holomorphic branch on which a three-point amplitude must be $\overline{\text{MHV}}$, i.e. carry exactly one negative leg. But legs $\hat{2}$ and 3 are *both* negative, so no helicity choice makes this corner a nonzero $\overline{\text{MHV}}$. The channel contributes nothing — the two adjacent negatives cannot share a three-point corner on this branch.

- $k = 4$ **(channel P_{234}): an** MHV $\times$ MHV **term.** Both sides are four-point, so no branch subtlety arises; only the helicity count decides. Taking the internal line positive into $\hat{A}_L$,

$$\hat{A}_L = A_4^{\text{MHV}}(\hat{2}^-, 3^-, 4^+, -\hat{P}^+), \qquad \hat{A}_R = A_4^{\text{MHV}}(\hat{P}^-, 5^+, 6^+, \hat{1}^-), \tag{59.207}$$

  each MHV with two negatives, both nonzero. (The opposite internal helicity makes $\hat{A}_R$ single-minus, killing it.) Both factors are Parke–Taylor by Theorem 59.28, glued on the pole $P_{234}^2 = (p_2 + p_3 + p_4)^2$.

- $k = 5$ **(channel P_{61}): an** $\overline{\text{MHV}} \times \overline{\text{MHV}}$ **term.** The small corner is $A_3(\hat{P}^h, 6^+, \hat{1}^-)$. Its on-shell point is $z = -[1\,6]/[2\,6]$, where $[\hat{1}\,6] \to 0$: the

holomorphic branch, on which the three-point amplitude must be $\overline{\text{MHV}}$ (one negative). With leg 6 positive and leg 1 negative, that fixes the internal line positive on the $\hat{A}_R$ side,

$$\hat{A}_R = A_3^{\overline{\text{MHV}}}(\hat{P}^+, 6^+, \hat{1}^-), \qquad \hat{A}_L = A_5^{\overline{\text{MHV}}}(\hat{2}^-, 3^-, 4^+, 5^+, -\hat{P}^-), \tag{59.208}$$

the large side being a five-point amplitude with three negatives — itself an *anti-MHV* amplitude ($k = n - 2 = 3$), given by the parity conjugate of Parke–Taylor, $\overline{\text{MHV}}_5 \propto [4\,5]^4/([\hat{2}\,3][3\,4][4\,5][5\,(-\hat{P})][(-\hat{P})\,\hat{2}])$, with the two positive legs $4, 5$ in the numerator. It is glued on the two-particle pole $P_{61}^2 = \langle 6\,1\rangle[1\,6]$.

The full NMHV amplitude is the sum of the two surviving terms,

$$A_6 = \hat{A}_L \, \frac{i}{P_{234}^2} \, \hat{A}_R\Big|_{\text{Eq. (59.207)}} + \hat{A}_L \, \frac{i}{P_{61}^2} \, \hat{A}_R\Big|_{\text{Eq. (59.208)}}. \tag{59.209}$$

Three features of Eq. (59.209) deserve emphasis, because they are general to all non-MHV amplitudes. First, the building blocks are exactly the data this chapter produced: the three-point seeds Eq. (59.169), Parke–Taylor Eq. (59.170), and its parity conjugate. Nothing new is needed — every N^kMHV amplitude is recursively an assembly of MHV and $\overline{\text{MHV}}$ pieces. Second, the number of terms depends on the shift: a different valid shift would tile A_6 differently (commonly into three terms), all representations being equal by the uniqueness of Theorem 59.27. Third — and this is the price of recursion — each individual term in Eq. (59.209) carries *spurious poles*: denominators such as $\langle 3|P_{234}|6]$ or $\langle 6\,1\rangle$ appear in the shifted spinors of one term that correspond to no physical factorization channel of A_6. These spurious poles are not present in the true amplitude; they must cancel between the two terms of Eq. (59.209), and they do, leaving a function whose only singularities are the genuine physical poles. The same spurious-pole cancellation is what Theorem 62.48 later recognizes, geometrically, as the matching of internal cell walls in a triangulation of the amplituhedron. The teaser thus does double duty: it exhibits the first non-MHV gluon amplitude, and it previews the mechanism — physical poles real, spurious poles cancelling — that organizes the modern amplitudes program.

59.7.6 Synthesis: locality and unitarity fix the trees

Step back from the algebra. We began the chapter with a scandal of bookkeeping: the n-gluon tree, built honestly from the Yang–Mills Lagrangian Eq. (25.76) and the vertices of Chapter 26, demands a super-factorial number of gauge-dependent diagrams that collapse to a one-line answer. We end with the resolution. The collapse is not luck but structure, and the structure has a precise content: the entire tree-level S-matrix of Yang–Mills is fixed by two inputs, neither of which is the Lagrangian.

The first input is *locality*, expressed as factorization: an amplitude has only simple poles, in physical momentum channels, and on each pole it factorizes into the product of two lower-point on-shell amplitudes. This is what made the residues in Theorems 59.28 and 59.29 computable from smaller amplitudes. The second is *unitarity*, expressed as the consistency of those residues with the lower amplitudes themselves — and, at the bottom, the existence of the three-point seeds Eq. (59.169), which little-group scaling and locality fix uniquely up to a coupling. The BCFW recursion Eq. (59.172) is nothing but the statement that a rational function with the right poles and the right large-z falloff (Theorem 59.27) is determined by its residues; feeding it the seeds generates every tree. The Lagrangian, the gauge choice, the off-shell Green's functions — all the apparatus of Chapters 25 and 26 — were a *representation* of this data, convenient for proving renormalizability and Ward identities but profligate for computing on-shell amplitudes, which know only about poles and seeds.

This is the chapter's philosophical payoff, and it reframes what one means by "defining a gauge theory." Perturbatively, the trees follow from locality, unitarity, and the little-group representation of the external states — the spectrum and the cubic couplings — without ever writing $\mathcal{L}$. The same two principles, applied to the discontinuities of loop integrands rather than the poles of trees, drive the generalized-unitarity methods of Chapter 60: there the trees proved here are sewn across multiparticle cuts to reconstruct loop amplitudes, the Parke–Taylor and BCFW data of this chapter entering as the on-shell input to the cut. And the color-ordered partial amplitudes, with their kinematic numerators laid bare by the absence of gauge clutter, are exactly the objects whose color–kinematics duality powers the BCJ double copy of Chapter 61, where two copies of these gluon trees assemble graviton amplitudes. The trees are not an endpoint; they are the on-shell currency of everything downstream.

These proved trees and explicit amplitudes are precisely the on-shell data the next chapter needs: Chapter 60 sews them across generalized cuts to reconstruct loop amplitudes from unitarity, and Chapter 61 reads their color-ordered kinematic numerators as the input to the BCJ double copy that builds gravity from two copies of Yang–Mills.

Further reading

The maximally-helicity-violating amplitude was conjectured and first proved (via a Berends–Giele off-shell recursion) in the founding paper of Parke and Taylor [379], the recursion itself being [62]; the systematics of color decomposition and helicity amplitudes are reviewed thoroughly by Mangano and Parke [334]. On-shell BCFW recursion originates with Britto, Cachazo, and Feng [91], with the large-z/contour proof given by Britto, Cachazo, Feng, and Witten [92]; the twistor-space perspective that triggered the modern program is Witten's [523].

Comprehensive textbook treatments of everything in this chapter — the inductive Parke–Taylor proof, the large-z catalogue, and worked NMHV examples — are Elvang and Huang [176] and Henn and Plefka [263]; Dixon's lectures [153] are a compact entry point. The loop and double-copy sequels are taken up in Chapters 60 and 61.

Chapter 60

Loop Amplitudes and Unitarity

The tree-level chapters left us with a way of building scattering amplitudes that never once wrote down a Lagrangian: spinor-helicity variables and on-shell recursion (Chapters 58 and 59) reconstruct every tree from three-point data and the analytic structure forced by factorization. This chapter carries that program to one loop. The question it answers is the one that makes the loop level genuinely different from the tree level — a loop amplitude is not a rational function but a transcendental one, with branch cuts and a nontrivial function space — and the answer is that the same two principles that organized the trees, *locality* and *unitarity*, pin a loop amplitude down almost completely. Locality puts its poles where intermediate particles go on shell; unitarity fixes the discontinuity across every branch cut. Made computational, those two facts replace the Feynman-diagram expansion of Chapter 19 with a method that sews loop integrands out of on-shell trees.

The engine is the optical theorem, which we proved as a constraint in Chapter 14 and used there only to check completed calculations. The first section upgrades it: from $\mathbf{S}^\dagger\mathbf{S} = \mathbf{1}$ we extract Cutkosky's cutting rule, which states that the discontinuity of any Feynman integral across a physical threshold is the Lorentz-invariant phase-space integral of a product of lower on-shell amplitudes. The branch cuts that the brute-force computations of Chapter 19 encountered at thresholds, and the dispersion relations of Chapter 5 that turn an imaginary part back into a full function, become the starting data of a smarter method rather than an afterthought. With the bubble worked explicitly and the QED vacuum polarization recovered from its two-particle cut, the principle of cut-constructibility is in hand: an amplitude is largely determined by its cuts.

What makes the principle into an algorithm is that one-loop amplitudes live in a finite-dimensional space. Every one-loop integrand reduces — by tensor (Passarino–Veltman) reduction and by integrand-level identities — to a fixed basis of scalar master integrals: boxes, triangles, bubbles, and tadpoles, evaluated once and for all in Chapter D. The chapter's central sections exploit

this. Generalized unitarity (Section 60.3) cuts more than two propagators at once: a quadruple cut freezes the loop momentum on complex on-shell solutions and isolates a single box coefficient as a product of four three-point trees, a triple cut isolates triangles, a double cut bubbles. The OPP decomposition (Section 60.4) installs this bookkeeping into the integrand itself, before integration, as an exact algebraic identity with spurious terms that integrate to zero — the form that underlies every automated one-loop program. Because four-dimensional cuts miss the purely rational part of the amplitude, Section 60.5 restores it through d-dimensional unitarity, where the (-2ε)-dimensional components of the loop momentum supply the $\varepsilon \times (1/\varepsilon)$ that four-dimensional methods discard.

These tools are then exercised in a single sustained computation. Section 60.6 reconstructs a one-loop gluon amplitude from cuts alone — the MHV box from a quadruple cut, with its infrared poles checked against the Catani structure, and the all-plus amplitude (every four-dimensional cut of which vanishes) from a μ^2-cut — and counts the Feynman diagrams it never had to draw. This is Yang–Mills theory at one loop, the loop-level continuation of the gluon amplitudes built by recursion in Chapter 59.

The final section looks past one loop. Integration-by-parts identities collapse any integral family to a finite basis of masters, the masters are evaluated by the method of differential equations brought to canonical ε-factorized form, and the resulting functions are organized by transcendental weight and dissected by the symbol. The chapter closes honestly at the frontier: numerical unitarity over finite fields as the practical multiloop workhorse, and the elliptic and Calabi–Yau integrals where the polylogarithmic function space — and with it the clean canonical-basis story — gives out. Throughout we use the book-wide canon (Chapter A): the mostly-minus metric, natural units, the Feynman $i\epsilon$, dimensional regularization in $d = 4 - 2\varepsilon$, and the spinor-helicity conventions fixed in Chapter 58.

60.1 Unitarity, Analyticity, and the Cutting Rules

The chapter's thesis is that a loop amplitude is not an arbitrary analytic function but one pinned down by two physical principles: *locality*, which puts its poles where intermediate particles can go on shell, and *unitarity*, which controls its branch-cut discontinuities. The second of these is, at the level of the S-matrix, the single statement that probability is conserved, $\mathbf{S}^\dagger\mathbf{S} = \mathbf{1}$, and we already extracted its most familiar consequence in Section 14.7: the optical theorem, relating the imaginary part of a forward amplitude to a total rate. That was a constraint, a check one applies after a calculation. The purpose of this section is to upgrade it into a *computational engine*. We will show that the discontinuity of a loop amplitude across any physical branch cut is the phase-space integral of a product of lower, on-shell amplitudes — Cutkosky's cutting rule — and

that, conversely, an amplitude is largely reconstructed once its cuts are known. The imaginary parts that the brute-force one-loop computations of Chapter 19 stumbled upon at thresholds will turn out to be exactly the data a smarter method takes as its starting point. Throughout we use the book-wide canon (Chapter A): mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units, the Feynman $i\epsilon$, and the Lorentz-invariant phase-space measure $\mathrm{d}\Pi$ introduced in Eq. (14.191) and built explicitly in Chapter 16.

60.1.1 From operator unitarity to the discontinuity

We begin by recalling, in compact form, the result this section builds on; its full derivation, including the careful plane-wave regularization, is Theorem 14.37, and we do not repeat it. Writing the scattering operator as

$$\mathbf{S} = \mathbf{1} + i\,\mathcal{T}, \tag{60.1}$$

unitarity $\mathbf{S}^\dagger\mathbf{S} = \mathbf{1}$ becomes, after cancelling the leading $\mathbf{1}$ and collecting terms,

$$-i(\mathcal{T} - \mathcal{T}^\dagger) = \mathcal{T}^\dagger\mathcal{T}, \tag{60.2}$$

the operator identity Eq. (14.188). The left-hand side is (twice) the anti-Hermitian part of $\mathcal{T}$; the right-hand side is manifestly positive. Sandwiching Eq. (60.2) between an initial state $|i\rangle$ and a final state $|f\rangle$ of definite momenta, stripping the momentum-conserving delta to define the invariant amplitude through $\langle f|\mathcal{T}|i\rangle = (2\pi)^4\delta^{(4)}(p_i - p_f)\,\mathcal{M}(i\to f)$, and inserting a complete set of states on the right gives the *generalized optical theorem* (Eq. (14.192)),

$$-i\Big[\mathcal{M}(i\to f) - \mathcal{M}^*(f\to i)\Big] = \sum_X \int \mathrm{d}\Pi_X\; \mathcal{M}(i\to X)\,\mathcal{M}^*(f\to X), \tag{60.3}$$

where the sum runs over every kinematically accessible intermediate state X, weighted by its Lorentz-invariant phase space. The forward, diagonal specialization $f = i$ collapses the left side to $2\,\mathrm{Im}\,\mathcal{M}(i\to i)$ and the right side to a sum of squared moduli, the form

$$2\,\mathrm{Im}\,\mathcal{M}(i\to i) = \sum_X \int \mathrm{d}\Pi_X\,\big|\mathcal{M}(i\to X)\big|^2 = F\,\sigma_{\mathrm{tot}}, \tag{60.4}$$

with F the Møller flux of Eq. (14.200). The crucial structural fact, and the one that turns a check into a method, is that Eq. (60.3) holds *off the forward direction*: i and f need not coincide. The right-hand side is then a sum of products of two *distinct* sub-amplitudes, $\mathcal{M}(i\to X)$ and $\mathcal{M}^*(f\to X)$, glued along the on-shell intermediate state X. It is this non-forward version that will reappear, term by term in perturbation theory, as the discontinuity of a single Feynman integral. The forward theorem squares one amplitude; the general theorem *factorizes* a discontinuity into two trees sewn over phase space, and that is precisely the structure a reconstruction method exploits.

60.1.2 Branch cuts, thresholds, and real analyticity

To see Eq. (60.3) as a statement about analytic functions we must recall how an amplitude depends on its invariants. Fix all kinematic data except a single Mandelstam variable, say $s = (p_1 + p_2)^2$, and regard $\mathcal{M}(s)$ as a function of complex s. Two properties, established in Section 5.5 from causality, organize everything.

First, *real analyticity* (the Schwarz reflection principle): because $\mathcal{M}$ is real on a segment of the real axis below all thresholds — where every internal line is off shell and no intermediate state can be produced — it satisfies

$$\mathcal{M}(s^*) = \mathcal{M}(s)^*. \tag{60.5}$$

Second, the only singularities of $\mathcal{M}(s)$ on the physical sheet are those demanded by physics: poles where a single intermediate particle goes on shell (the imprint of locality), and branch points at the *thresholds* $s = (\sum_a m_a)^2$ where a multiparticle intermediate state $X = \{a\}$ first becomes kinematically accessible. Above such a threshold the state X can be produced as real, on-shell particles; below it cannot. A branch cut runs along the real axis from each threshold to infinity, and the Feynman $i\epsilon$ instructs us to evaluate the physical amplitude on the *upper* lip, $s \to s + i0$.

Combining these, the *discontinuity* across the cut — the jump between the two lips — is, by Eq. (60.5),

$$\operatorname{disc}\mathcal{M}(s) \;\equiv\; \mathcal{M}(s+i0) - \mathcal{M}(s-i0) = \mathcal{M}(s+i0) - \mathcal{M}(s+i0)^* = 2i\,\operatorname{Im}\mathcal{M}(s+i0), \tag{60.6}$$

exactly the relation $\operatorname{disc} = 2i\,\operatorname{Im}$ proved in Theorem 5.38. The left-hand side of the optical theorem Eq. (60.3) is therefore, up to the factor $-i$ and modulo the non-forward generalization, the discontinuity of $\mathcal{M}$ across the cut whose branch point is the threshold of the very state X being summed on the right. Unitarity, read through analyticity, says: *the jump of an amplitude across the threshold of a state X equals the phase-space integral of the amplitudes for producing and absorbing X.* Each branch cut is owned by one intermediate channel, and its discontinuity is computable from lower data. This is the principle. The rest of the section makes it operational at the level of the individual Feynman integral.

Physical Insight

A loop amplitude carries far less independent information than its integral representation suggests. Locality fixes where its poles sit; unitarity fixes the jump across each of its cuts; and an analytic function is heavily constrained by its singularities. The cuts are the "data" and the function is largely their interpolation. The practical payoff, developed across this chapter, is that the data are *on-shell tree amplitudes* — gauge invariant,

compact, computable by the spinor-helicity and recursion technology of Chapters 58 and 59 — whereas the function is an off-shell loop integral with all the gauge redundancy and diagram proliferation that Chapter 19 displayed. The method trades the latter for the former.

60.1.3 Cutkosky's cutting rule

We now translate "the discontinuity is a phase-space integral" into a rule applied directly to a Feynman integrand. The mechanism is entirely contained in the analytic structure of a single propagator. Consider the scalar Feynman propagator as a function of p^2 at fixed sign of p^0,

$$\frac{1}{p^2 - m^2 + i\epsilon}. \tag{60.7}$$

As a distribution in the real variable p^2, the Sokhotski–Plemelj identity Eq. (5.22) gives its two boundary values, $1/(p^2-m^2\pm i\epsilon) = \mathrm{PV}\; 1/(p^2-m^2) \mp i\pi\,\delta(p^2-m^2)$, whose difference is the discontinuity across the threshold $p^2 = m^2$:

$$\frac{1}{p^2 - m^2 + i\epsilon} - \frac{1}{p^2 - m^2 - i\epsilon} = -2\pi i\,\delta(p^2 - m^2). \tag{60.8}$$

A single internal line therefore develops an imaginary part exactly when it can be put on shell, and that imaginary part is a delta function localizing the line on its mass shell. The factor $\delta(p^2 - m^2)$ is supported on both energy signs $p^0 = \pm E_{\mathbf{p}}$; physics selects one. In a cut that separates the diagram into an "in" part producing X and an "out" part absorbing it, energy flows in a definite direction across the cut, so the cut lines carry positive energy in that direction. We encode this with the positive-energy delta

$$\delta^+(p^2-m^2) \equiv \theta(p^0)\,\delta(p^2-m^2), \qquad \int \frac{d^4p}{(2\pi)^4}\,(2\pi)\,\delta^+(p^2-m^2)\,f(p) = \int \frac{d^3\mathbf{p}}{(2\pi)^3\,2E_{\mathbf{p}}}\,f(p)\Big|_{p^0=E_{\mathbf{p}}} \tag{60.9}$$

the second equality being the standard reduction of the on-shell measure to the single-particle Lorentz-invariant phase space $\widetilde{dp}$ of Chapter 16. We can now state the rule.

Theorem 60.1 (Cutkosky cutting rule)**.** *The discontinuity of a Feynman integral across the branch cut associated with a given intermediate state is obtained by summing over all* cuts *that isolate that state — partitions of the diagram into two connected parts by severing a set of internal lines — and, in each cut, making for every severed propagator the replacement*

$$\frac{1}{p^2 - m^2 + i\epsilon} \;\longrightarrow\; -2\pi i\,\delta^+(p^2 - m^2), \tag{60.10}$$

with the positive-energy flow oriented from the production side to the absorption side, while the uncut propagators on the production side keep their $+i\epsilon$ Feynman form and those on the absorption side are complex-conjugated to $-i\epsilon$. Equivalently, in terms of the full Feynman propagator $i/(p^2-m^2+i\epsilon)$, a cut line is replaced by $2\pi\,\delta^+(p^2-m^2)$.

Origin of the rule via the largest-time equation. The diagrammatic source of Eq. (60.10) is an identity of Veltman among the position-space integrands, the *largest-time equation*, and we prove its engine in full; the combinatorial iteration is then mechanical. Write the position-space Feynman propagator as a sum of on-shell Wightman functions split by time ordering,

$$\Delta_F(x-y)=\theta(x^0-y^0)\,\Delta^+(x-y)+\theta(y^0-x^0)\,\Delta^+(y-x),\qquad \Delta^+(x)\equiv\int\widetilde{dk}\;e^{-ik\cdot x},\tag{60.11}$$

the integral running over the positive-energy mass shell, so that Δ^+ is the Fourier transform of $2\pi\,\delta^+(k^2-m^2)$ — precisely the cut line of Eq. (60.10) up to the numerator i. Assign to each vertex of a diagram either no mark or a circle. Define Δ_F on a line joining two unmarked vertices, its complex conjugate Δ_F^* on a line joining two circled vertices, $\Delta^+(x-y)$ when x is circled and y is not, and $\Delta^+(y-x)$ when y is circled and x is not; circled vertices additionally carry conjugated couplings. Let $F(\dots)$ denote the value of a fixed assignment of marks. Now single out the vertex z with the *largest* time among all vertices. For any line incident on z, the time ordering in Eq. (60.11) is settled: $\theta(z^0-\cdot)=1$. A direct check on each of the four cases shows that the line function attached to z is the same whether z is circled or not, except for the conjugation of z's coupling. Summing the two markings of z alone therefore produces a coupling plus its conjugate against a common factor, and because the bare vertex coupling appears as $-i$ times a real constant, the two terms cancel:

$$F(\dots,z\text{ unmarked},\dots)+F(\dots,z\text{ circled},\dots)=0\qquad(z^0=\text{largest}).\tag{60.12}$$

Summing Eq. (60.12) over all markings of the *remaining* vertices gives the largest-time equation: the sum over *all* 2^n markings of the n vertices vanishes,

$$\sum_{\text{markings}}F=0.\tag{60.13}$$

The all-unmarked term is the Feynman amplitude $\mathcal{M}$; the all-circled term is $\mathcal{M}^*$ (every line conjugated, every coupling conjugated); each mixed term has a set of Δ^+ lines forming a cut that separates circled from unmarked vertices. Transforming to momentum space, every Δ^+ becomes a factor $2\pi\,\delta^+$, the unmarked side keeps Feynman propagators and the circled side their conjugates, and Eq. (60.13) reads $\mathcal{M}+\mathcal{M}^*+\sum_{\text{cuts}}(\text{cut terms})=0$, i.e. $2\,\mathrm{Re}\,\mathcal{M}=-\sum_{\text{cuts}}(\dots)$. Restricting to the kinematic region of a single threshold, where only one channel's cut terms

are nonzero, isolates $\operatorname{disc}\mathcal{M} = 2i\,\operatorname{Im}\mathcal{M}$ as that channel's cut, which is Eq. (60.10) with the stated propagator replacements. The positive-energy delta in each Δ^+ supplies the $\theta(p^0)$ and orients the flow. □

The rule is the bridge promised in Section 60.1.2: the right-hand side of the cut equation, after the δ^+ factors are integrated against the loop measure, is by Eq. (60.9) nothing but the Lorentz-invariant phase space of the on-shell intermediate state, multiplying the two sub-amplitudes on either side of the cut. The Cutkosky cut of a loop integral *is* the right-hand side of the generalized optical theorem Eq. (60.3), term by term in perturbation theory. We now verify this on the simplest loop in the book.

60.1.4 The two-particle cut of the scalar bubble

The one-loop scalar bubble is the integral underlying every one-loop two-point function in the book; its closed form is the master function B_0 of Eq. (D.105). We take it as the test case for the cutting rule because both sides — the discontinuity of the analytic answer and the phase-space integral of the cut — can be computed independently and matched factor for factor.

Definition 60.2 (The scalar bubble)**.** For an external momentum q with $q^2 = s$ and two internal lines of mass m, the scalar one-loop bubble is

$$I_2(s) \;\equiv\; \int \frac{d^4\ell}{(2\pi)^4}\,\frac{1}{(\ell^2 - m^2 + i\epsilon)\big((\ell - q)^2 - m^2 + i\epsilon\big)} \;=\; B_0(s; m, m), \tag{60.14}$$

the equality identifying it with the master integral evaluated in Chapter D. Its ultraviolet divergence sits in a real, s-independent constant; the entire s-dependence is the parametric logarithm $-\int_0^1 dx\,\ln[m^2 - x(1-x)s - i\epsilon]$, whose branch cut begins at the two-particle threshold $s = 4m^2$.

Worked Example 60.3 (The bubble cut equals two-body phase space)**.** We compute $\operatorname{disc} I_2(s)$ two ways and show they agree.

Analytic discontinuity. From Eq. (D.105), retaining only the s-dependent piece,

$$I_2(s) = \frac{i}{16\pi^2}\Big[\,c - \int_0^1 dx\,\ln\!\big(m^2 - x(1-x)s - i\epsilon\big)\Big] + O(\varepsilon), \tag{60.15}$$

with c a real constant collecting the $1/\varepsilon$ pole and scheme terms. The logarithm's argument $m^2 - x(1-x)s$ is negative precisely for $x \in (x_-, x_+)$, where $x_\pm = \tfrac{1}{2}(1 \pm \beta)$ are the roots of $x(1-x) = m^2/s$ and

$$\beta \equiv \sqrt{1 - \frac{4m^2}{s}} \tag{60.16}$$

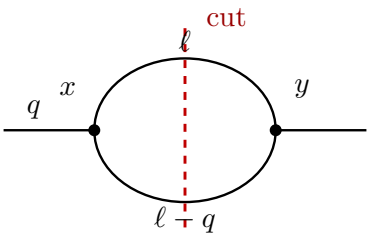

Figure 60.1: The two-particle cut of the scalar bubble $I_2(s)$. The vertical dashed line severs both internal propagators, putting the loop momenta ℓ and $\ell - q$ simultaneously on shell. By Theorem 60.1 each cut line becomes $-2\pi i\,\delta^+$, and the integral over the loop momentum collapses onto the two-body Lorentz-invariant phase space of the intermediate pair. The discontinuity of the bubble across its cut at $s = 4m^2$ is this phase-space volume.

is the velocity of either intermediate particle in the centre-of-mass frame; such an interval exists only for $s > 4m^2$, fixing the threshold. The $-i\epsilon$ places a negative argument just below the cut, so $\ln(\text{negative} - i\epsilon) = \ln|\cdots| - i\pi$. The discontinuity is the jump as s crosses to the upper lip, equivalently $2\,\mathrm{Re}\,I_2$ — not $2i\,\mathrm{Im}\,I_2$, because the overall factor of i in Eq. (60.15) means I_2 is i times a real-analytic function rather than real-analytic itself, so the relation $\mathrm{disc} = 2i\,\mathrm{Im}$ of Eq. (60.6) (which applies to the real-analytic amplitude $\mathcal{M}$) here turns the imaginary part of the bracket into the real part of I_2; only the logarithm jumps, contributing $-i\pi$ over the interval of length $x_+ - x_- = \beta$:

$$\mathrm{disc}\,I_2(s) = \frac{i}{16\pi^2}\Big[-(2i)\int_{x_-}^{x_+} dx\,(-\pi)\Big] = \frac{i}{16\pi^2}\,(2i\pi\beta) = -\frac{\beta}{8\pi} \qquad (s > 4m^2). \tag{60.17}$$

Cutkosky / phase-space side. Apply Theorem 60.1 to Eq. (60.14): there is one two-particle cut (Fig. 60.1), severing both lines, with ℓ and $q - \ell$ flowing across it. Each cut propagator becomes $-2\pi i\,\delta^+$:

$$\begin{aligned}\mathrm{disc}\,I_2(s) &= \int \frac{d^4\ell}{(2\pi)^4}\,(-2\pi i)\delta^+(\ell^2 - m^2)\,(-2\pi i)\delta^+((q-\ell)^2 - m^2) \\ &= -(2\pi)^2 \int \frac{d^4\ell}{(2\pi)^4}\,\delta^+(\ell^2 - m^2)\,\delta^+((q-\ell)^2 - m^2) \\ &= -\int \frac{d^3\boldsymbol{\ell}}{(2\pi)^3\,2E_{\boldsymbol{\ell}}}\,(2\pi)\,\delta^+((q-\ell)^2 - m^2) \;=\; -\int \mathrm{d}\Pi_2 \;=\; -\,\Phi_2(s),\end{aligned} \tag{60.18}$$

where in the third line one factor $2\pi\,\delta^+$ was reduced to the single-particle measure by Eq. (60.9), and the surviving $2\pi\,\delta^+$ together with the integration over $\boldsymbol{\ell}$ is by definition the two-body Lorentz-invariant phase space $\Phi_2(s) = \int \mathrm{d}\Pi_2$. The

factor $(-2\pi i)^2 = -(2\pi)^2$ supplies the overall sign. The two-body volume was computed in closed form in Chapter 16; for equal masses,

$$\Phi_2(s) = \int \mathrm{d}\Pi_2 = \frac{1}{8\pi}\sqrt{1-\frac{4m^2}{s}} = \frac{\beta}{8\pi}. \tag{60.19}$$

Thus $\operatorname{disc} I_2(s) = -\Phi_2(s) = -\beta/8\pi$, identical to the analytic result Eq. (60.17). The discontinuity of the bubble *is* the two-body phase-space volume of the state that can go on shell at $s = 4m^2$, with the characteristic threshold factor $\beta = \sqrt{1-4m^2/s}$ appearing on both sides — vanishing at threshold, where the pair is produced at rest, and rising to $1/8\pi$ as $s \to \infty$.

The match in Theorem 60.3 is the optical theorem realized on one Feynman integral, and it is the same computation that closes Theorem D.42 for ϕ^4 theory, where the bubble's imaginary part is checked against $|\mathcal{M}_{\text{tree}}|^2$ integrated over phase space. The lesson is general and worth stating sharply: *cutting a loop is integrating a product of trees over phase space.* The cut throws away the off-shell, scheme- and gauge-dependent interior of the loop and keeps only the gauge-invariant on-shell data — here the trivial constant tree amplitude, in richer cases the Parke–Taylor and BCFW amplitudes of Chapters 58 and 59.

60.1.5 QED: the vacuum polarization as a two-particle cut

The cleanest physical incarnation of the cutting rule in the benchmark theories is the photon vacuum polarization, computed by brute force in Chapter 19. We recover its imaginary part as a two-particle cut and identify it, through the optical theorem, with the e^+e^- annihilation cross section — closing the loop between the Feynman-diagram result of Chapter 19 and the unitarity of Chapter 14.

The renormalized scalar vacuum polarization $\widehat{\Pi}(q^2)$, defined through $\Pi^{\mu\nu} = (q^2\eta^{\mu\nu} - q^\mu q^\nu)\widehat{\Pi}$ in Eq. (19.57), was found in Eq. (19.65) to have the imaginary part

$$\operatorname{Im}\widehat{\Pi}(q^2) = -\frac{\alpha}{3}\Big(1+\frac{2m^2}{q^2}\Big)\sqrt{1-\frac{4m^2}{q^2}} \qquad (q^2 > 4m^2), \tag{60.20}$$

switching on at the pair threshold $q^2 = 4m^2$. In Theorem 19.7 this same number was reproduced as the Cutkosky cut Eq. (19.66): the two internal fermion lines are put on shell by $1/(\not{p} - m + i\epsilon) \to (\not{p} + m)\,2\pi\,\delta^+(p^2 - m^2)$, the spin sum builds the Dirac trace $\operatorname{tr}[(\not{p}_1 + m)\gamma^\mu(\not{p}_2 - m)\gamma^\nu]$, and the two-body phase-space integral Eq. (60.19) delivers Eq. (60.20) exactly. We do not repeat that trace here — it is carried in full at Theorem 19.7 — but emphasize its structure: the cut of the photon two-point function is the tree amplitude $\gamma^* \to e^+e^-$ times its conjugate, summed over spins and integrated over the two-body phase space of the pair. The branch point at $q^2 = 4m^2$ is owned by the e^+e^- channel, exactly as Section 60.1.2 requires.

The optical theorem now turns this discontinuity into a cross section. Apply the forward theorem Eq. (60.4) to $e^+e^- \to e^+e^-$ at order e^4, where the relevant imaginary part comes from the s-channel photon dressed by one self-energy insertion; the cut through that insertion is the $e^+e^- \to f\bar{f}$ production rate, summed over the species f the photon couples to. Tracking the leptonic coupling and the two photon propagators that flank the self-energy, the total annihilation cross section into the photon's channels is

$$\sigma_{\text{tot}}(e^+e^- \to \text{anything via } \gamma^*) = -\frac{4\pi\alpha}{q^2}\,\operatorname{Im}\widehat{\Pi}(q^2), \tag{60.21}$$

the imaginary part of the vacuum polarization being, up to the kinematic factor $q^2/4\pi\alpha$, the e^+e^- cross section itself. We pin the proportionality constant by an independent computation rather than asserting it. Put a single charged fermion of mass m_f in the loop; Eq. (60.20) gives $-\operatorname{Im}\widehat{\Pi}_f = \frac{\alpha}{3}(1+2m_f^2/q^2)\beta_f$ with $\beta_f = \sqrt{1-4m_f^2/q^2}$, so Eq. (60.21) predicts

$$\sigma(e^+e^- \to f\bar{f}) = \frac{4\pi\alpha}{q^2}\cdot\frac{\alpha}{3}\Big(1+\frac{2m_f^2}{q^2}\Big)\beta_f = \frac{4\pi\alpha^2}{3q^2}\sqrt{1-\frac{4m_f^2}{q^2}}\,\Big(1+\frac{2m_f^2}{q^2}\Big). \tag{60.22}$$

This is precisely the threshold-corrected QED annihilation cross section assembled directly from the squared amplitude and two-body phase space in Chapter 17 (it reduces to the textbook $\sigma = 4\pi\alpha^2/3q^2$ when $m_f \to 0$). The two routes — "imaginary part of a one-loop two-point function" and "squared tree amplitude integrated over phase space" — meet on the same number, including the $(1+2m_f^2/q^2)$ structure and the velocity factor β_f. The imaginary part of $\widehat{\Pi}$ is not bookkeeping: it is the rate at which a virtual photon materializes real pairs, and unitarity guarantees the loop knew this in advance.

Physical Insight

Equation Eq. (60.21) is the engine behind the measured running of α. Because $\widehat{\Pi}(q^2)$ is analytic with its only cut along $q^2 \geq 4m^2$, the dispersion relation of Section 5.5.5 reconstructs the full $\widehat{\Pi}(q^2)$ from its imaginary part, and Eq. (60.21) expresses that imaginary part as a physically measured cross section. Summed over all charged species, $-\operatorname{Im}\widehat{\Pi}(q^2) \propto \sigma(e^+e^- \to \text{hadrons})$, so the hadronic contribution to the running coupling — incalculable from first principles at low energy — is fixed by experimental e^+e^- data through exactly this cut. Unitarity here is not a check but a measurement strategy.

60.1.6 Cut-constructibility: reconstructing an amplitude from its cuts

We have shown that each branch cut of an amplitude is computable as a phase-space integral of lower on-shell data. The converse question — how much of the amplitude is *determined* by its cuts — is what makes this a method rather than a check, and its answer sets the agenda for the rest of the chapter.

If $\mathcal{M}(s)$ vanished sufficiently fast at large $|s|$, real analyticity Eq. (60.5) and Cauchy's theorem would reconstruct it completely from its discontinuity, the unsubtracted dispersion relation of Eq. (5.143),

$$\mathcal{M}(s) = \frac{1}{2\pi i}\int_{s_0}^{\infty} ds' \, \frac{\operatorname{disc}\mathcal{M}(s')}{s'-s} = \frac{1}{\pi}\int_{s_0}^{\infty} ds' \, \frac{\operatorname{Im}\mathcal{M}(s'+i0)}{s'-s}, \tag{60.23}$$

with s_0 the lowest threshold. The cuts would then literally *be* the amplitude. In a loop calculation the situation is the same in spirit but qualified in one respect: a polynomial in s has no discontinuity and is invisible to Eq. (60.23); when $\mathcal{M}$ does not decay, the dispersion relation requires *subtractions* (Section 5.5.5), and each subtraction is an undetermined constant — a piece of the amplitude carrying no cut. This is the seed of the "rational remainder" that will occupy us later in the chapter.

Definition 60.4 (Cut-constructible)**.** An amplitude is *cut-constructible* if it is determined entirely by its branch-cut discontinuities, i.e. if its dispersive reconstruction Eq. (60.23) requires no subtraction constants. Equivalently, the amplitude contains no terms that are rational in the kinematic invariants and free of logarithms, dilogarithms, or other branch cuts. A general one-loop amplitude is a cut-constructible part plus a rational remainder; in $d = 4-2\varepsilon$ dimensions the rational part itself originates in cuts taken with the loop momentum continued off four dimensions, so that unitarity, applied in d dimensions, recovers the amplitude in full.

The largest-time equation Eq. (60.13) guarantees that every discontinuity is a sum of cuts and is thus accessible to this program; the dispersion relation Eq. (60.23) guarantees that the discontinuities, up to subtraction constants, rebuild the amplitude. Between these two facts lies the entire unitarity method: compute the cuts as products of trees integrated over phase space, and integrate them back up to the amplitude. What Eq. (60.23) hides, however, is the labor of the final integral over s' — carried out naively it is no simpler than the original loop. The decisive simplification, and the reason the method is practical, is that the functions a one-loop amplitude can possibly be are not arbitrary: they are a small, fixed list of scalar integrals whose own cuts are known once and for all. Determining an amplitude then reduces to determining the *coefficients* with which those standard integrals appear, and a cut isolates exactly the coefficients of the integrals that share that cut. To make this concrete we must first establish

what that list of standard integrals is — the master-integral basis — which is the task of the next section.

60.2 The One-Loop Basis: Reduction to Master Integrals

The previous section established the principle on which this whole chapter turns: a one-loop amplitude is fixed by its branch-cut discontinuities, and each discontinuity is computed by cutting propagators and gluing on-shell lower amplitudes. A principle, however, is not yet a method. To turn "an amplitude is determined by its cuts" into an algorithm we need to know *what kind of function* the amplitude is — the precise catalogue of analytic objects whose discontinuities those cuts can probe. If that catalogue were infinite, knowing the cuts would constrain little. The remarkable structural fact, and the target of this section, is that the catalogue is *finite*: in dimensional regularization every one-loop amplitude, in any quantum field theory, is a linear combination of a small fixed set of scalar integrals — boxes, triangles, bubbles, and tadpoles — with coefficients that are *rational* functions of the kinematic invariants, plus a purely rational remainder carrying no cut at all. The transcendental content of any one-loop amplitude — its logarithms, dilogarithms, and the discontinuities they carry — lives entirely in those four scalar functions. Everything else is rational bookkeeping.

This is the decisive simplification. It means that determining a one-loop amplitude is not the open-ended problem of summing an arbitrary function diagram by diagram, but the *finite* problem of fixing a list of numbers: one rational coefficient per master integral, plus the rational remainder. The unitarity method, developed in the following sections, is precisely the machinery that reads off each of these coefficients from on-shell tree data. Before we can isolate a coefficient we must know which coefficients exist; this section provides that list and proves it is complete. We proceed in four movements: first the algebraic engine — Passarino–Veltman tensor reduction — that strips loop momenta out of numerators; then the scalar master integrals themselves, with their explicit values; then the structural theorem that these four masters span everything, proved through the reduction of higher-point integrals and culminating in the pentagon-to-box reduction; and finally the statement of the master decomposition that hands the next section its finite list of unknowns.

60.2.1 The generic one-loop integrand and the two reductions

Fix conventions. We work throughout in $d = 4 - 2\varepsilon$ dimensions with the mostly-minus metric, the Feynman $i\varepsilon$ prescription, and the $\overline{\text{MS}}$ scale μ, exactly as in Chapter D, whose master integrals we import wholesale rather than re-deriving.

A single one-loop Feynman diagram, after the colour and Lorentz algebra of its vertices has been carried out by the rules of Chapters 15 and 17, contributes a loop integral of the form

$$I \;=\; \mu^{2\varepsilon}\int \frac{\mathrm{d}^{d}\ell}{(2\pi)^{d}}\,\frac{N(\ell)}{D_0\,D_1\cdots D_{N-1}}, \qquad D_i \;=\; (\ell + r_i)^2 - m_i^2 + i\varepsilon, \tag{60.24}$$

where N is the number of propagators in the loop, the r_i are partial sums of the external momenta entering the loop up to leg i (with one of them, say $r_0 = 0$, chosen as the origin of loop momentum by a shift), the m_i are the internal masses, and the numerator $N(\ell)$ is a polynomial in the loop momentum ℓ of some degree r — the *rank* of the integral. Tree-level Feynman rules with at most one derivative per vertex bound $r \le N$; the precise bound will not matter, only that r is finite. The full one-loop amplitude $\mathcal{M}^{\text{1-loop}}$ is a sum of such integrals, one per diagram, each multiplied by a kinematic and group-theoretic prefactor.

Two structural features of (60.24) stand between us and a scalar master integral: the numerator carries open loop momenta, and the denominator carries an arbitrary number N of propagators. Two corresponding reductions dispose of them, and the entire basis theorem is the statement that, applied repeatedly, they terminate.

Rank reduction removes the numerator. The Passarino–Veltman algorithm, built in full in Section D.6 and applied there to the QED one-loop vertex, self-energy, and vacuum polarization of Chapter 19, writes a tensor integral $\int \ell^{\mu_1}\cdots\ell^{\mu_r}/(D_0\cdots D_{N-1})$ as the most general Lorentz tensor its external data permit, then contracts that ansatz with the available tensors (the metric and the external momenta) to convert it into a linear system for scalar coefficient functions. The system is solved by inverting the *Gram matrix* of the external momenta. The output is the same integral with the numerator removed and the kinematics shifted, plus integrals with *fewer* propagators. We will see this explicitly below.

Propagator reduction removes excess denominators. A scalar integral with N propagators depends on $N-1$ independent external momentum differences. In four dimensions at most four vectors can be linearly independent, so once N is large enough the external momenta are forced into linear dependence, the corresponding Gram determinant vanishes, and the integral collapses onto integrals with fewer propagators. The boundary case — the pentagon, $N = 5$ — is the subtle one, and we treat it in full in Section 60.2.5.

The claim to be proved is that iterating these two reductions on (60.24) always terminates on a fixed finite set of *scalar* ($N(\ell) = 1$) integrals with $N \le 4$ propagators. We first name and value those scalar integrals.

60.2.2 The scalar master integrals

Definition 60.5 (The one-loop scalar masters)**.** The scalar master integrals are the integrals (60.24) with unit numerator, $N(\ell) = 1$, and $N = 1, 2, 3, 4$ propagators, in the standard Passarino–Veltman naming (Section D.6):

$$\text{tadpole} \quad A_0(m_0) = \mu^{2\varepsilon} \int \frac{\mathrm{d}^d \ell}{(2\pi)^d} \frac{1}{D_0}, \tag{60.25}$$

$$\text{bubble} \quad B_0(p^2; m_0, m_1) = \mu^{2\varepsilon} \int \frac{\mathrm{d}^d \ell}{(2\pi)^d} \frac{1}{D_0 D_1}, \tag{60.26}$$

$$\text{triangle} \quad C_0(p_1^2, p_2^2, p_{12}^2;\, m_0, m_1, m_2) = \mu^{2\varepsilon} \int \frac{\mathrm{d}^d \ell}{(2\pi)^d} \frac{1}{D_0 D_1 D_2}, \tag{60.27}$$

$$\text{box} \quad D_0(\{s_{ij}\}; \{m_i\}) = \mu^{2\varepsilon} \int \frac{\mathrm{d}^d \ell}{(2\pi)^d} \frac{1}{D_0 D_1 D_2 D_3}, \tag{60.28}$$

with $D_i = (\ell + r_i)^2 - m_i^2 + i\varepsilon$, the arguments listing the external invariants formed from the r_i and the internal masses on which each integral depends.

These four functions are the entire transcendental vocabulary of one-loop physics, and the rest of this section proves that nothing else is needed. Their explicit values are computed once and for all in Chapter D; we collect them here in the forms the unitarity method will use, because the *branch-cut structure* of each — which we will compare in Section 60.2.6 — is what makes the four linearly independent and hence makes the master decomposition unique.

The tadpole follows immediately from the master scalar integral Theorem D.22 at $n = 1$, $\Delta = m_0^2$:

$$A_0(m_0) = \frac{i\, m_0^2}{(4\pi)^2} \Big[\frac{1}{\bar{\varepsilon}} + 1 - \ln \frac{m_0^2}{\mu^2} \Big] + O(\varepsilon), \qquad \frac{1}{\bar{\varepsilon}} \equiv \frac{1}{\varepsilon} - \gamma_E + \ln 4\pi, \tag{60.29}$$

where the $1/\bar{\varepsilon}$ pole is purely *ultraviolet* and $\bar{\varepsilon}$ is the $\overline{\text{MS}}$ combination of Eq. (D.136). The tadpole carries a single mass scale m_0^2 and *no* external invariant: it has no kinematic channel in which to develop a discontinuity, so $\operatorname{disc} A_0 = 0$. It is, from the point of view of cuts, invisible — a fact we will use heavily.

The bubble is the canonical one-loop function. For equal internal masses, Eq. (D.140) gives

$$B_0(p^2; m, m) = \frac{i}{(4\pi)^2} \Big[\frac{1}{\bar{\varepsilon}} - \int_0^1 \mathrm{d}x\, \ln \frac{m^2 - x(1-x)p^2}{\mu^2} \Big] + O(\varepsilon). \tag{60.30}$$

Its $1/\bar{\varepsilon}$ is ultraviolet; its finite part is a single logarithm of p^2 that, for $p^2 > 4m^2$, develops an imaginary part — the discontinuity across the two-particle threshold, computed in Section D.8 and identified there with the optical theorem. The massless bubble ($m = 0$) is even simpler:

$$B_0(p^2; 0, 0) = \frac{i}{(4\pi)^2} \Big[\frac{1}{\bar{\varepsilon}} + 2 - \ln \frac{-p^2}{\mu^2} \Big] + O(\varepsilon), \tag{60.31}$$

carrying a single logarithm $\ln(-p^2)$ with a branch cut along $p^2>0$.

The triangle and box carry the genuinely two-variable transcendentality. The massless triangle with one off-shell leg of invariant $s=p_{12}^2$ and two light-like legs, the case that the reduction of massless gauge-theory vertices deposits, is evaluated in Theorem D.38:

$$C_0(0,0,s;0,0,0)=\frac{-i}{(4\pi)^2}\,\frac{1}{s}\Big[\frac{1}{\varepsilon_{\mathrm{IR}}^2}-\frac{1}{\varepsilon_{\mathrm{IR}}}\,\ln\frac{-s}{\mu^2}+\frac{1}{2}\ln^2\frac{-s}{\mu^2}-\frac{\pi^2}{12}\Big]+O(\varepsilon), \tag{60.32}$$

with both poles *infrared* (the integral is ultraviolet finite by power counting) and a characteristic $\ln^2(-s)$ Sudakov double logarithm.

The box is the top of the hierarchy and the only master with two independent kinematic invariants. Take the fully massless box — all four internal lines and all four external legs light-like — depending on the Mandelstam invariants $s=(p_1+p_2)^2$ and $t=(p_2+p_3)^2$. Combining the four denominators with the Feynman-parameter identity Eq. (D.25) and reducing to the master scalar integral Theorem D.22 by the completion-of-square and Wick rotation of Section D.3, the parameter integral evaluates to

$$D_0^{0m}(s,t)=\frac{i\,c_\Gamma}{(4\pi)^2}\,\frac{2}{s\,t}\Big\{\frac{1}{\varepsilon_{\mathrm{IR}}^2}\Big[\Big(\frac{-s}{\mu^2}\Big)^{-\varepsilon}+\Big(\frac{-t}{\mu^2}\Big)^{-\varepsilon}\Big]-\frac{1}{2}\ln^2\frac{-s}{-t}-\frac{\pi^2}{2}\Big\}+O(\varepsilon), \tag{60.33}$$

with $c_\Gamma=\Gamma(1+\varepsilon)\Gamma(1-\varepsilon)^2/\Gamma(1-2\varepsilon)$ the ubiquitous one-loop constant of Eq. (D.217). The double pole $1/\varepsilon^2$ is again entirely infrared, but the decisive new feature is the appearance of *two* invariants s and t and the cross-channel double logarithm $\ln^2(s/t)$: the box, alone among the masters, has discontinuities in two distinct kinematic channels.

Remark 60.6 (Derivation of the massless box). The tadpole, bubble, and triangle are evaluated in full in Chapter D, which reduces tensor boxes *to* the scalar D_0 but does not evaluate D_0 itself; since this box is the master on which the chapter's worked reconstruction rests, we carry out the one genuinely new step here — the four-propagator Feynman-parameter integral. Combining the four denominators with Eq. (D.25) and completing the square as in Section D.2 shifts the loop momentum and replaces the product by $(\ell^2-\Delta)^4$ with the massless-box discriminant

$$\Delta\;=\;-(s\,x_1x_3+t\,x_2x_4), \tag{60.34}$$

the two surviving cross terms being precisely the two Mandelstam channels. The Wick rotation and radial integration of Section D.3 and Theorem D.22, here with $N=4$ propagators so that $\Gamma(N-d/2)=\Gamma(2+\varepsilon)$ and the Feynman $\Gamma(4)$ cancels, leave the parameter integral

$$D_0^{0m}(s,t)=\mu^{2\varepsilon}\,\frac{i\,\Gamma(2+\varepsilon)}{(4\pi)^{d/2}}\int_{\Delta_3}\Big(\prod_{i=1}^4\mathrm{d}x_i\Big)\,\delta\Big(1-\textstyle\sum_i x_i\Big)\,\big[(-s)\,x_1x_3+(-t)\,x_2x_4\big]^{-2-\varepsilon}, \tag{60.35}$$

over the simplex of Section D.2.4 (the "two-dimensional" integral, three parameters constrained by one δ). The overlap of the two monomials is disentangled by a Mellin–Barnes split,

$$\frac{1}{(A+B)^{2+\varepsilon}} = \frac{1}{\Gamma(2+\varepsilon)}\,\frac{1}{2\pi i}\int_{\mathcal{C}} \mathrm{d}z\;\Gamma(2+\varepsilon+z)\,\Gamma(-z)\,\frac{B^z}{A^{2+\varepsilon+z}}, \qquad A=(-s)x_1x_3,\; B=(-t)x_2x_4, \tag{60.36}$$

after which every parameter integral is the Dirichlet (Beta-function) integral over the simplex, $\int_{\Delta_3}\prod_i x_i^{a_i-1}\,\delta(1-\sum_i x_i)=\prod_i\Gamma(a_i)/\Gamma(\sum_i a_i)$, with $a_{1,3}=-1-\varepsilon-z$ and $a_{2,4}=1+z$, so $\sum_i a_i=-2\varepsilon$. The parameter integral collapses to a single contour integral,

$$D_0^{0m}(s,t) = \frac{i\,\mu^{2\varepsilon}}{(4\pi)^{d/2}\,\Gamma(-2\varepsilon)}\,\frac{1}{2\pi i}\int_{\mathcal{C}}\mathrm{d}z\;\Gamma(2+\varepsilon+z)\,\Gamma(-z)\,\Gamma(1+z)^2\,\Gamma(-1-\varepsilon-z)^2\,(-s)^{-2-\varepsilon-z}(-t)^z. \tag{60.37}$$

Closing the contour and summing residues evaluates the box. The prefactor $1/\Gamma(-2\varepsilon)=-2\varepsilon+O(\varepsilon^2)$ multiplies the $1/\varepsilon^3$ that the pinch of the double poles $\Gamma(1+z)^2$ and $\Gamma(-1-\varepsilon-z)^2$ generates: the leading residue, at $z=-1-\varepsilon$ where $(-s)^{-2-\varepsilon-z}(-t)^z=(-s)^{-\varepsilon}/(st)$, produces the double infrared pole $\frac{1}{\varepsilon^2}(-s/\mu^2)^{-\varepsilon}\cdot 2/(st)$, its $s\leftrightarrow t$ mirror gives the $(-t/\mu^2)^{-\varepsilon}$ term, and the subleading residues assemble the cross-channel finite part $-\frac{1}{2}\ln^2(s/t)-\pi^2/2$ — exactly Eq. (60.33). The double pole is the soft-collinear corner of the simplex where two adjacent parameters vanish together; the residue bookkeeping is the standard one [448], and the all-orders-in-ε hypergeometric form is recorded in [67].

60.2.3 Passarino–Veltman reduction in practice

The two worked reductions that follow exhibit the rank-reduction engine in its entirety, carrying every algebraic step including the inversion of the kinematic matrix. They are the operations that, repeated, prove the basis theorem, and they are the operations the reader must trust when the unitarity method later quotes a reduced integral. The denominator identity on which both rest is elementary: since each D_i is itself quadratic in ℓ, any scalar product of the loop momentum with external data is a linear combination of the D_i plus constants. Explicitly, from $D_i-D_0=(\ell+r_i)^2-(\ell+r_0)^2-m_i^2+m_0^2$ with $r_0=0$,

$$2\,r_i\cdot\ell = D_i - D_0 - (r_i^2+m_0^2-m_i^2), \qquad \ell^2 = D_0+m_0^2, \tag{60.38}$$

the same identity Eq. (D.161) that powers the appendix reductions. Each time it is used, a numerator factor of $r_i\cdot\ell$ either cancels a denominator (lowering the propagator count) or contributes to a lower-rank tensor.

Worked Example 60.7 (Rank-one triangle reduction with explicit Gram inversion)**.** Consider the rank-one three-point tensor integral that the Passarino–Veltman decomposition of any one-loop vertex with a single loop momentum in

the numerator produces,

$$C^\mu \;=\; \mu^{2\varepsilon}\!\int\!\frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{\ell^\mu}{D_0\,D_1\,D_2}, \qquad \begin{aligned} D_0 &= \ell^2 - m_0^2,\\ D_1 &= (\ell+p_1)^2 - m_1^2,\\ D_2 &= (\ell+p_2)^2 - m_2^2, \end{aligned} \tag{60.39}$$

with two independent external momenta p_1, p_2. The integrand depends, besides ℓ, only on p_1 and p_2, so the vector C^μ can be built from no other vectors: it lies in the plane they span. We therefore write the most general covariant ansatz,

$$C^\mu \;=\; p_1^\mu\, C_1 + p_2^\mu\, C_2, \tag{60.40}$$

with scalar coefficients C_1, C_2 that are functions of the invariants $p_1^2, p_2^2, (p_1-p_2)^2$ and the masses alone. *There is no ℓ^μ left on the right-hand side: the integration has used it up.* Our task is to solve for C_1, C_2 in terms of the scalar triangle C_0 and scalar bubbles.

Build the linear system. Contract (60.40) with $p_{1\mu}$ and with $p_{2\mu}$. The left-hand sides become scalar integrals,

$$p_i\cdot C \;=\; \mu^{2\varepsilon}\!\int\!\frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{p_i\cdot\ell}{D_0 D_1 D_2} \;\equiv\; R_i, \qquad i=1,2, \tag{60.41}$$

while the right-hand sides assemble into a matrix equation,

$$\begin{pmatrix} p_1^2 & p_1\cdot p_2 \\ p_1\cdot p_2 & p_2^2 \end{pmatrix}\begin{pmatrix} C_1 \\ C_2 \end{pmatrix} = \begin{pmatrix} R_1 \\ R_2 \end{pmatrix}, \qquad G \equiv \begin{pmatrix} p_1^2 & p_1\cdot p_2 \\ p_1\cdot p_2 & p_2^2 \end{pmatrix}. \tag{60.42}$$

The coefficient matrix G is precisely the 2×2 *Gram matrix* of the external momenta p_1, p_2.

Evaluate the right-hand sides with the denominator identity. From (60.38),

$$2\,p_1\cdot\ell = D_1 - D_0 - f_1, \quad 2\,p_2\cdot\ell = D_2 - D_0 - f_2, \qquad f_i \equiv p_i^2 + m_0^2 - m_i^2. \tag{60.43}$$

Insert the first into R_1:

$$\begin{aligned} R_1 &= \tfrac{1}{2}\,\mu^{2\varepsilon}\!\int\!\frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{D_1 - D_0 - f_1}{D_0 D_1 D_2} \\ &= \tfrac{1}{2}\Big[\underbrace{\mu^{2\varepsilon}\!\int\!\frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{D_0 D_2}}_{B_0^{(1)}} - \underbrace{\mu^{2\varepsilon}\!\int\!\frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{D_1 D_2}}_{B_0^{(0)}} - f_1\,C_0\Big]. \end{aligned} \tag{60.44}$$

In the first term the factor D_1 has cancelled, leaving a bubble missing propagator 1; in the second, D_0 has cancelled, leaving a bubble missing propagator 0. We name these by the propagator *pinched* (deleted): $B_0^{(i)}$ is the bubble obtained

from the triangle by removing line i. After shifting each to standard form (a translation of a dimensionally regularized integral, legitimate by Theorem D.10),

$$B_0^{(0)} = B_0((p_1-p_2)^2; m_1, m_2), \quad B_0^{(1)} = B_0(p_2^2; m_0, m_2), \quad B_0^{(2)} = B_0(p_1^2; m_0, m_1). \tag{60.45}$$

Identically,

$$R_2 = \tfrac{1}{2}\big[\, B_0^{(2)} - B_0^{(0)} - f_2\, C_0 \,\big]. \tag{60.46}$$

The right-hand sides are now built entirely from the scalar triangle C_0 and scalar bubbles — masters we have already valued.

Invert the Gram matrix. The determinant of G is

$$\det G \;=\; p_1^2\, p_2^2 - (p_1 \cdot p_2)^2, \tag{60.47}$$

and its inverse is the standard 2×2 adjugate over determinant,

$$G^{-1} = \frac{1}{\det G} \begin{pmatrix} p_2^2 & -\,p_1\!\cdot\!p_2 \\ -\,p_1\!\cdot\!p_2 & p_1^2 \end{pmatrix}. \tag{60.48}$$

Multiplying (60.42) on the left by G^{-1} gives the coefficients in closed form,

$$\boxed{C_1 = \frac{p_2^2\, R_1 - (p_1\!\cdot\!p_2)\, R_2}{\det G}, \qquad C_2 = \frac{p_1^2\, R_2 - (p_1\!\cdot\!p_2)\, R_1}{\det G},} \tag{60.49}$$

with R_1, R_2 from (60.44)–(60.46). This completes the reduction: the rank-one triangle C^μ has been expressed, with *no integration left to perform*, as the rational combination (60.40) of the scalar triangle C_0 and the three pinched scalar bubbles $B_0^{(i)}$, the rational coefficients being ratios of Gram determinants and the constants f_i.

The cost of inversion. The factor $1/\det G$ is the honest price of tensor reduction. When the external momenta degenerate — $p_2 \to x\, p_1$ for some scalar x, a forward or collinear configuration — the Gram determinant $\det G = p_1^2 p_2^2 - (p_1 \cdot p_2)^2$ vanishes while the numerators $p_2^2 R_1 - (p_1 \cdot p_2) R_2$ do not vanish term by term, so C_1, C_2 appear to diverge. The singularity is *spurious*: the original integral C^μ is perfectly finite there, and the apparent pole cancels among the scalar functions in the numerator in the exact limit. But the cancellation is between large numbers, so a numerical evaluation near $\det G = 0$ loses precision catastrophically. This Gram-determinant instability is the practical defect of Passarino–Veltman reduction that the unitarity method — which works at the level of on-shell integrands, never inverting a Gram matrix — is designed to avoid (Section 60.2.7 and the following section).

The second reduction we record more briefly, because its only new feature is the appearance of the metric tensor in the covariant basis, and because the appendix carries the same computation in full at Eqs. (D.174) and (D.175); we reproduce the logic so the basis theorem's proof is self-contained.

Worked Example 60.8 (Rank-two bubble reduction)**.** The rank-two two-point integral, which the reduction of a self-energy with two loop momenta in the numerator produces, is

$$B^{\mu\nu} = \mu^{2\varepsilon}\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{\ell^\mu \ell^\nu}{D_0 D_1}, \qquad D_0 = \ell^2 - m_0^2, \quad D_1 = (\ell+p)^2 - m_1^2. \tag{60.50}$$

Now there is a single external vector p^μ, so the symmetric rank-two tensor can be built from $p^\mu p^\nu$ and from the metric $\eta^{\mu\nu}$:

$$B^{\mu\nu} = p^\mu p^\nu\, B_{11} + \eta^{\mu\nu}\, B_{00}. \tag{60.51}$$

We will need the rank-one coefficient B_1 first, defined by $B^\mu = p^\mu B_1$. Contracting $B^\mu = \mu^{2\varepsilon}\int \ell^\mu/(D_0D_1)$ with p_μ and using $p\cdot\ell = \tfrac{1}{2}(D_1 - D_0 - f)$ with $f = p^2 + m_0^2 - m_1^2$, exactly as in the triangle case, yields the pinched tadpoles $A_0(m_0), A_0(m_1)$ and the bubble B_0:

$$B_1 = \frac{1}{2p^2}\Big[A_0(m_0) - A_0(m_1) - (p^2 + m_0^2 - m_1^2)B_0\Big]. \tag{60.52}$$

The two contractions. Contract (60.51) with the metric $\eta_{\mu\nu}$. On the left, $\eta_{\mu\nu}\ell^\mu\ell^\nu = \ell^2 = D_0 + m_0^2$, so

$$\eta_{\mu\nu}B^{\mu\nu} = \mu^{2\varepsilon}\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{D_0 + m_0^2}{D_0 D_1} = A_0(m_1) + m_0^2\, B_0, \tag{60.53}$$

where $\int 1/D_1 = A_0(m_1)$ after the shift $\ell \to \ell - p$. On the right, $\eta_{\mu\nu}(p^\mu p^\nu B_{11} + \eta^{\mu\nu}B_{00}) = p^2 B_{11} + d\, B_{00}$. Hence

$$p^2\, B_{11} + d\, B_{00} = A_0(m_1) + m_0^2\, B_0. \tag{60.54}$$

Now contract (60.51) with p_μ. On the left,

$$p_\mu B^{\mu\nu} = \tfrac{1}{2}\,\mu^{2\varepsilon}\int \frac{(D_1 - D_0 - f)\,\ell^\nu}{D_0 D_1} = \tfrac{1}{2}\big[\,0 - (-p^\nu A_0(m_1)) - f\,p^\nu B_1\,\big] = \tfrac{1}{2}p^\nu\big[A_0(m_1) - f B_1\big], \tag{60.55}$$

using that $\int \ell^\nu/D_0 = 0$ (odd in ℓ, single scale, no external vector) and $\int \ell^\nu/D_1 = -p^\nu A_0(m_1)$. On the right, $p_\mu(p^\mu p^\nu B_{11} + \eta^{\mu\nu}B_{00}) = p^\nu(p^2 B_{11} + B_{00})$, so

$$p^2\, B_{11} + B_{00} = \tfrac{1}{2}\big[A_0(m_1) - f\, B_1\big]. \tag{60.56}$$

Solve the two-by-two system. Subtract (60.56) from (60.54): the $p^2 B_{11}$ terms cancel, leaving $(d-1)B_{00}$ on the left,

$$\boxed{B_{00} = \frac{1}{2(d-1)}\Big[A_0(m_1) + 2m_0^2 B_0 + (p^2 + m_0^2 - m_1^2)B_1\Big],} \tag{60.57}$$

after using $A_0(m_1) + m_0^2 B_0 - \frac{1}{2}[A_0(m_1) - fB_1] = \frac{1}{2}A_0(m_1) + m_0^2 B_0 + \frac{1}{2}fB_1$. Back-substituting into (60.56),

$$\boxed{B_{11} = \frac{1}{p^2}\Big[\tfrac{1}{2}(A_0(m_1) - fB_1) - B_{00}\Big].} \tag{60.58}$$

Two features generalize to every reduction. First, the metric coefficient B_{00} carries a factor $1/(d-1)$ but *no* $1/p^2$: it is finite as $p^2 \to 0$ and carries the genuine ultraviolet divergence of the rank-two integral (both A_0 and B_0 inside it have $1/\bar{\varepsilon}$ poles). Second, the momentum coefficient B_{11}, like B_1, divides by the Gram determinant — here the 1×1 Gram p^2. *The metric direction is always benign; the momentum directions always carry the Gram denominator.* With (60.52) substituted, (60.57)–(60.58) express the complete rank-two bubble through the scalar bubble B_0 and the tadpoles A_0, with no integration left to do.

These two examples are the algorithm in microcosm. A higher-rank, higher-point tensor is reduced by exactly the same two moves — write the covariant ansatz, contract with metric and external momenta, and solve the resulting Gram system — iterated until both the rank and (for $N \geq 5$) the propagator count have been driven down. We now prove that this iteration terminates, and on what.

60.2.4 The one-loop basis theorem

Theorem 60.9 (One-loop master-integral basis)**.** *Every one-loop integral of the form* (60.24)*, with any rank r and any number N of propagators, in $d = 4 - 2\varepsilon$ dimensions equals a finite linear combination of the scalar master integrals A_0 (tadpole), B_0 (bubble), C_0 (triangle), and D_0 (box) of Theorem 60.5, with coefficients that are rational functions of the external invariants, the internal masses, and the dimension d. In strictly four dimensions ($\varepsilon \to 0$) no scalar integral with more than four propagators is required: the box is the highest master.*

The theorem is the precise statement that the four masters *span* the one-loop integral space over the field of rational functions of the kinematics. Its proof is the termination of the two reductions, and we give it in full. (The statement and its short argument also appear, in the appendix's notation, as Theorem D.35; the appendix defers the pentagon step to this chapter, which we now discharge.)

Proof. We treat the two reductions in turn, then combine them.

Rank reduction terminates. Let I have rank $r \geq 1$. By Lorentz covariance the integral, carrying r free indices and depending on the external momenta $r_1, \dots, r_{N-1}$ and the metric, equals the most general symmetric tensor of rank r built from these. Contracting that ansatz with the r-fold products of metric and external momenta produces a linear system whose unknowns are the scalar

coefficient functions and whose right-hand sides are, by the denominator identity (60.38), integrals in which every loop momentum has been traded either for a constant or for a factor D_i that cancels a propagator. The terms that cancel a propagator are integrals of rank $r-1$ (one loop momentum removed) and propagator count $N-1$; the terms in which loop momenta were traded for constants, together with the metric coefficients, are integrals of rank $r-2$ and propagator count N. Every term produced therefore has strictly smaller rank than I. The coefficient matrix of the linear system is the Gram matrix of the external momenta (its inversion supplies the $1/\det G$ factors seen in Theorems 60.7 and 60.8), and solving introduces only rational functions of the invariants and masses. Iterating, the rank decreases by at least one at each step and reaches zero after at most r steps. Thus I is a rational combination of *scalar* integrals ($r=0$) with propagator counts $\le N$.

Propagator reduction terminates at $N=4$. It remains to reduce scalar integrals with $N \ge 5$ propagators. A scalar N-point integral depends on $N-1$ external momentum differences $r_1, \dots, r_{N-1}$ (recall $r_0 = 0$). In four dimensions any five vectors are linearly dependent, so for $N-1 \ge 5$, i.e. $N \ge 6$, the differences satisfy a nontrivial linear relation. We show this relation reduces the integral to integrals with fewer propagators, then treat the boundary case $N=5$ separately in Section 60.2.5.

Suppose $N \ge 6$. The $N-1 \ge 5$ vectors $r_1, \dots, r_{N-1}$ are linearly dependent in four dimensions, so their $(N-1)\times(N-1)$ Gram matrix $G_{ij} = r_i \cdot r_j$ is singular: $\det G = 0$, and there exists a nonzero vector of constants $(\alpha_1, \dots, \alpha_{N-1})$ in its kernel, $\sum_j G_{ij}\alpha_j = 0$ for all i. Geometrically this says the vector $v \equiv \sum_j \alpha_j r_j$ is orthogonal to every r_i and hence (since the r_i span the four-dimensional space) is the zero vector: $\sum_{j=1}^{N-1} \alpha_j r_j = 0$. We now seek constants $c_0, \dots, c_{N-1}$ such that

$$\sum_{i=0}^{N-1} c_i \, D_i = 1 \quad \text{identically in } \ell. \tag{60.59}$$

Expanding $D_i = \ell^2 + 2r_i \cdot \ell + r_i^2 - m_i^2$, the condition (60.59) splits by powers of ℓ into

$$\sum_{i=0}^{N-1} c_i = 0 \quad (\ell^2), \qquad \sum_{i=1}^{N-1} c_i \, r_i = 0 \quad (\ell^\mu), \qquad \sum_{i=0}^{N-1} c_i \, (r_i^2 - m_i^2) = 1 \quad (\text{const}). \tag{60.60}$$

The vector condition $\sum_{i\ge1} c_i r_i = 0$ is, in four dimensions, four scalar equations; together with $\sum c_i = 0$ that is five homogeneous equations on the N unknowns c_i. For $N \ge 6$ the homogeneous system is underdetermined and possesses a solution space of dimension $\ge N-5 \ge 1$; the existence of the kernel vector (α_j) found above guarantees this solution space is nontrivial. Within it the inhomogeneous normalization $\sum c_i (r_i^2 - m_i^2) = 1$ fixes the remaining freedom generically (it fails only on a measure-zero kinematic locus, where one perturbs and takes the

limit). The c_i so determined are rational functions of the invariants and masses. Dividing (60.59) by the full product $D_0 D_1 \cdots D_{N-1}$ and integrating,

$$\mu^{2\varepsilon} \int \frac{\mathrm{d}^d \ell}{(2\pi)^d} \, \frac{1}{D_0 \cdots D_{N-1}} = \sum_{i=0}^{N-1} c_i \, \mu^{2\varepsilon} \int \frac{\mathrm{d}^d \ell}{(2\pi)^d} \, \frac{1}{\prod_{k \neq i} D_k}, \tag{60.61}$$

each term on the right being the same integral with propagator i *pinched* — an $(N-1)$-point scalar integral. Thus every $N \geq 6$ scalar integral reduces to $(N-1)$-point integrals with rational coefficients. Iterating drives N down to 5.

Conclusion. Rank reduction reduces any integral to scalars with $N \leq N_{\max}$ propagators; propagator reduction reduces all $N \geq 6$ scalars to pentagons ($N = 5$); and the pentagon, treated next in Section 60.2.5, reduces in four dimensions to scalar boxes plus a contribution that vanishes as $\varepsilon \to 0$. Hence every one-loop integral is a rational-coefficient combination of the four masters A_0, B_0, C_0, D_0, with the box the highest required in four dimensions. All coefficients introduced are rational in the invariants, masses, and d. □ □

The proof shows where each master can come from. Boxes are the irreducible four-propagator integrals; triangles, bubbles, and tadpoles arise both as genuine three-, two-, and one-propagator topologies and as pinched descendants of higher integrals during reduction. The crucial open step, on which the entire "box is the top" statement rests, is the pentagon.

60.2.5 The pentagon and the vanishing of the five-dimensional Gram determinant

The pentagon ($N = 5$) is the boundary case the basis theorem deferred: it depends on $N - 1 = 4$ external difference vectors, which in four dimensions are *generically independent*, so the four-dimensional Gram determinant $\det(r_i \cdot r_j)_{i,j=1}^{4}$ does not vanish and the constant-coefficient linear reduction (60.59) that handled $N \geq 6$ is unavailable. Nonetheless the scalar pentagon reduces to boxes in four dimensions. The mechanism is the vanishing of a *different* Gram determinant — the 5×5 one formed by adjoining the loop momentum to the four external directions — and the price of the reduction is a remainder that is suppressed by ε and therefore vanishes in strictly four dimensions, contributing only to the rational part of the amplitude. We derive it now in full.

Work with the scalar pentagon

$$I_5 = \mu^{2\varepsilon} \int \frac{\mathrm{d}^d \ell}{(2\pi)^d} \, \frac{1}{D_0 D_1 D_2 D_3 D_4}, \qquad D_i = (\ell + r_i)^2 - m_i^2, \quad r_0 = 0, \tag{60.62}$$

with the four nonzero difference vectors r_1, r_2, r_3, r_4 spanning four-dimensional Minkowski space (generic kinematics; the four-dimensional Gram $G_{ij} = r_i \cdot r_j$, $i, j = 1, \ldots, 4$, has $\det G \neq 0$). In dimensional regularization the loop momentum

is d-dimensional. Decompose it into the part lying in the four-dimensional physical span $V = \mathrm{span}\{r_1, \dots, r_4\}$ and the orthogonal $(d-4)$-dimensional remainder,

$$\ell^\mu = \ell_\parallel^\mu + \ell_\perp^\mu, \qquad \ell_\parallel \in V, \quad \ell_\perp \perp V, \tag{60.63}$$

so that $\ell^2 = \ell_\parallel^2 + \ell_\perp^2$ and, since the external r_i all lie in V, the projections probe only the parallel part: $r_i \cdot \ell = r_i \cdot \ell_\parallel$. The orthogonal piece is spacelike (it lives in the Euclidean extra dimensions), and we write $\ell_\perp^2 = -\mu_\perp^2$ with $\mu_\perp^2 \geq 0$. This $\mu_\perp^2$ is the entire source of the ε-suppressed remainder.

The key algebraic input is that the *five* vectors $\{\ell_\parallel, r_1, r_2, r_3, r_4\}$ all lie in the four-dimensional space V, hence are linearly dependent: their 5×5 Gram determinant vanishes,

$$\det \begin{pmatrix} \ell_\parallel \cdot \ell_\parallel & \ell_\parallel \cdot r_1 & \cdots & \ell_\parallel \cdot r_4 \\ r_1 \cdot \ell_\parallel & r_1 \cdot r_1 & \cdots & r_1 \cdot r_4 \\ \vdots & & \ddots & \vdots \\ r_4 \cdot \ell_\parallel & r_4 \cdot r_1 & \cdots & r_4 \cdot r_4 \end{pmatrix} = 0. \tag{60.64}$$

This is the vanishing of the five-dimensional Gram determinant promised in the section title: it holds because no five vectors can be linearly independent in four dimensions, and it is the exact statement that constrains the pentagon. We evaluate the determinant by the Schur complement. Writing the bordered symmetric matrix as

$$M = \begin{pmatrix} a & b^{\mathsf{T}} \\ b & G \end{pmatrix}, \qquad a = \ell_\parallel^2, \quad b_i = r_i \cdot \ell_\parallel = r_i \cdot \ell, \quad G_{ij} = r_i \cdot r_j, \tag{60.65}$$

the determinant factorizes as $\det M = \det G \, (a - b^{\mathsf{T}} G^{-1} b)$. Since $\det G \neq 0$, condition (60.64) is equivalent to the vanishing of the Schur complement,

$$\ell_\parallel^2 = \sum_{i,j=1}^{4} (G^{-1})_{ij} \, (r_i \cdot \ell)(r_j \cdot \ell). \tag{60.66}$$

This is simply the completeness relation in V: the dual basis $\tilde{r}^{\,i} = \sum_j (G^{-1})_{ij} r_j$ satisfies $\tilde{r}^{\,i} \cdot r_j = \delta^i_j$ and resolves the metric on V, whence $\ell_\parallel^\mu = \sum_i (\tilde{r}^{\,i} \cdot \ell) r_i^\mu$ and (60.66) follows by squaring. Equation (60.64) is the geometric origin of this identity.

Now convert (60.66) into a relation among propagators. On the left, $\ell_\parallel^2 = \ell^2 - \ell_\perp^2 = (D_0 + m_0^2) + \mu_\perp^2$ using (60.38). On the right, $r_i \cdot \ell = \tfrac{1}{2}(D_i - D_0 + Y_i)$ with $Y_i \equiv m_i^2 - m_0^2 - r_i^2$, again from (60.38). Substituting,

$$D_0 + m_0^2 + \mu_\perp^2 = \frac{1}{4} \sum_{i,j=1}^{4} (G^{-1})_{ij} \, (D_i - D_0 + Y_i)(D_j - D_0 + Y_j). \tag{60.67}$$

This is an *exact* relation between the inverse propagators, valid under the integral sign. Divide both sides by the full product $D_0D_1D_2D_3D_4$ and integrate. We classify the resulting terms by how many propagators they cancel:

- The left-hand term $D_0/(D_0\cdots D_4) = 1/(D_1D_2D_3D_4)$ is a scalar *box* (propagator 0 pinched).
- The right-hand terms linear in a single D_i (the cross terms $D_i\cdot(-D_0)$, $D_i\cdot Y_j$, and $D_i\cdot Y_i$, together with $-D_0\cdot Y_j$ etc.) each cancel exactly one propagator, producing scalar *boxes*.
- The right-hand terms bilinear in two distinct propagators, D_iD_j with $i\neq j$, cancel two propagators, producing scalar *triangles*; the diagonal terms D_i^2 produce boxes with one squared propagator, themselves reducible by a further application of the denominator identity to ordinary boxes and triangles.
- The constant terms on the right (the products Y_iY_j, and the leftover $-(m_0^2)$ from the left) cancel no propagator and reproduce the full *pentagon* I_5.
- The remaining left-hand term $\mu_\perp^2/(D_0\cdots D_4)$ is the pentagon integrand dressed with the extra-dimensional factor $\mu_\perp^2 = -\ell_\perp^2$.

Collecting the genuine pentagon contributions onto the left and everything else onto the right, (60.67) solves for I_5 as

$$\Big(\textstyle\sum_i b_i\Big)\, I_5 = \sum_{i=0}^{4}(\text{rational})\times \text{Box}_i + \sum(\text{rational})\times \text{Tri} - \mu^{2\varepsilon}\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{\mu_\perp^2}{D_0\cdots D_4}, \tag{60.68}$$

where the coefficients are rational functions of the invariants and masses built from G^{-1} and the Y_i, and Box_i is the box obtained by pinching propagator i (one of the five "pinches" of the pentagon). The first two sums contain only boxes and triangles — masters strictly below the pentagon. The last term is the crucial one.

The extra-dimensional remainder is order ε. The integral $\int \mu_\perp^2/(D_0\cdots D_4) = -\int \ell_\perp^2/(D_0\cdots D_4)$ is, by the Lorentz invariance of the orthogonal subspace, proportional to a scalar pentagon evaluated in $d+2$ dimensions. Concretely, averaging $\ell_\perp^\mu\ell_\perp^\nu$ over the $(d-4)$-dimensional orthogonal space gives $\langle\ell_\perp^2\rangle$ proportional to $(d-4)$ times a $(d+2)$-dimensional integral; the standard dimension-shift identity (Theorem D.23 applied in the orthogonal directions) reads

$$\mu^{2\varepsilon}\int\frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{\mu_\perp^2}{D_0\cdots D_4} = -\,(d-4)\,\frac{1}{2}\,I_5^{[d+2]} = \varepsilon\, I_5^{[d+2]}, \tag{60.69}$$

since $d-4=-2\varepsilon$. The shifted pentagon $I_5^{[d+2]}$ is ultraviolet *and* infrared finite — it has six effective dimensions against five propagators and an extra positive

power of denominator weight, so it converges at both ends — and therefore contributes at $O(\varepsilon)$. In strictly four dimensions ($\varepsilon \to 0$) this remainder drops out entirely, leaving the scalar pentagon equal to a rational combination of scalar boxes and triangles:

$$\boxed{I_5 = \sum_{i=0}^{4} d_i \,\mathrm{Box}_i + \sum c\,\mathrm{Tri} + O(\varepsilon),} \tag{60.70}$$

the $O(\varepsilon)$ piece being the finite shifted pentagon. *The box is therefore the highest master integral in four-dimensional one-loop physics.*

Remark 60.10 (The five-box form, and when $O(\varepsilon)$ matters). The reduction (60.70) produces both boxes and triangles; an optimal choice of the linear combination — solving the system $\sum_j Y_{ij} b_j = 1$ for the modified Cayley matrix $Y_{ij} = m_i^2 + m_j^2 - (r_i - r_j)^2$, the construction of [346, 482] — organizes the leading part as exactly the five pinch-boxes Box_i with no separate triangles, since each triangle is itself a pinch of a box already in the sum. Either way the structural conclusion is identical: no new transcendental function appears at the pentagon level or above. The $O(\varepsilon)$ shifted-pentagon remainder is genuinely there and *must* be retained whenever the box coefficients d_i themselves carry $1/\varepsilon$ poles — as they do at higher loop order, and in the ε-dimensional ("d-dimensional") unitarity used to capture the rational part in Section 60.2.7 and the following section. For the cut-constructible pieces, where the coefficients are finite, the $\varepsilon \to 0$ form (60.70) is exact.

60.2.6 Linear independence: the masters carry distinct cuts

Theorem 60.9 states that the four masters span the one-loop integral space; for the master *decomposition* to assign a well-defined coefficient to each, the masters must also be *linearly independent* over the field of rational functions of the kinematics. They are, and the cleanest proof is the very property that the unitarity method exploits: each master has a distinct branch-cut structure, so no rational-coefficient combination of some of them can equal another.

Consider a putative rational relation $\sum_X q_X X = 0$ among the masters $X \in \{A_0, B_0, C_0, D_0\}$ with rational coefficients q_X. Apply the discontinuity operator disc in a chosen kinematic channel and use that disc annihilates rational functions (which have no cut). The masters respond as follows, read off from their explicit values (60.29)–(60.33):

- The *tadpole* $A_0(m_0)$ depends on a single mass and *no* external invariant. It has no kinematic channel and no discontinuity: $\mathrm{disc}\, A_0 = 0$ in every channel.
- The *bubble* $B_0(p^2)$ has a single branch cut, in the one invariant p^2 on which it depends, starting at the two-particle threshold $p^2 = (m_0 + m_1)^2$ (or

$p^2 = 0$ in the massless case). Its discontinuity is a constant (in $\varepsilon \to 0$) times $\theta(p^2 - (m_0 + m_1)^2)$ — the two-particle phase space of Section D.8.

- The *triangle* C_0 has cuts in each of its (up to three) invariants, with a discontinuity that is itself a *logarithm* of the kinematics (the cut of the dilogarithm/$\ln^2$ in (60.32)), not a constant.
- The *box* $D_0(s,t)$ is the only master with cuts in *two independent* invariants s and t simultaneously, and its double discontinuity (cut in s then in t) is nonzero — a feature no triangle, bubble, or tadpole shares.

These discontinuity structures are qualitatively distinct: a constant cut (bubble), a logarithmic cut (triangle), a two-variable double cut (box), and no cut at all (tadpole). Suppose a nontrivial relation $\sum q_X X = 0$ existed. Taking the double discontinuity in two independent channels isolates the box: $\mathrm{disc}_s \,\mathrm{disc}_t(\sum q_X X) = q_{D_0} \,\mathrm{disc}_s \,\mathrm{disc}_t \, D_0 = 0$ forces $q_{D_0} = 0$, since the box's double cut is nonzero and rational coefficients cannot cancel it. With the box removed, a single discontinuity whose cut is logarithmic isolates the triangle, forcing $q_{C_0} = 0$; a single constant discontinuity then forces $q_{B_0} = 0$; and the surviving $q_{A_0} A_0 = 0$ with $A_0 \neq 0$ forces $q_{A_0} = 0$. No nontrivial rational relation exists. The four masters are linearly independent, and the decomposition below assigns each a unique coefficient.

Cuts as a basis-projection

The independence argument is more than a consistency check: it is the blueprint for the entire unitarity method. The masters are distinguished by *which cuts they survive*, so cutting an amplitude in a chosen set of channels projects onto the masters that have a discontinuity there and annihilates the rest. A maximal set of cuts — cutting all four propagators of a box — survives on that box alone, isolating its coefficient. This is exactly the strategy the next section makes precise: the same branch-cut structure that proves the masters independent also tells us which on-shell product computes each coefficient.

60.2.7 The master decomposition

Assembling the results, we can state the structural form of any one-loop amplitude. Let $\mathcal{M}^{\text{1-loop}}$ be the sum over all one-loop diagrams contributing to a given process, each reduced by the algorithm of Sections 60.2.1, 60.2.4 and 60.2.5.

Theorem 60.11 (One-loop master decomposition)**.** *Any one-loop amplitude in a renormalizable quantum field theory, in $d = 4 - 2\varepsilon$ dimensions, can be written as*

$$\boxed{\mathcal{M}^{\text{1-loop}} = \sum_i d_i \,\mathrm{Box}_i + \sum_i c_i \,\mathrm{Tri}_i + \sum_i b_i \,\mathrm{Bub}_i + \sum_i a_i \,\mathrm{Tad}_i + R,} \tag{60.71}$$

where the sums run over the distinct box, triangle, bubble, and tadpole scalar masters built from the external kinematics, the coefficients d_i, c_i, b_i, a_i are rational functions of the invariants and masses, and R is a purely rational remainder carrying no branch cut.

The decomposition follows immediately from Theorem 60.9: every reduced integral is a rational-coefficient combination of the four masters, and summing over diagrams collects the coefficient of each distinct master into a single rational d_i, c_i, b_i, a_i. The remainder R requires comment, because it is the part the cuts of Section 60.2.6 cannot see.

The origin of the rational remainder. Two effects generate R. First, the box coefficients and the reductions can produce, multiplying a master, an explicit factor of ε — as in the pentagon remainder (60.69), or wherever a numerator carries the $(d-4)$-dimensional component $\mu_\perp^2$ of the loop momentum. When such an ε multiplies the $1/\varepsilon$ ultraviolet or infrared pole of a master, the product is finite and *rational* — a logarithm-free number with no discontinuity. Second, the ultraviolet poles of the masters themselves, after renormalization, leave finite rational pieces. Because R has no cut, the discontinuity-based machinery of the following section computes the cut-carrying coefficients d_i, c_i, b_i, a_i but is, by construction, blind to R. Recovering R requires either keeping the full d-dimensional (ε-dependent) information in the cuts — "d-dimensional unitarity" — or a complementary on-shell technique; Section 60.4 (the integrand-reduction section of this chapter) supplies it. For the present it suffices that R is rational and finite, hence a finite list of numbers like the coefficients.

Remark 60.12 (QED and Yang–Mills theory on a common basis). The decomposition (60.71) puts every one-loop computation in the book onto a single footing. The brute-force QED results of Chapter 19 — vacuum polarization, electron self-energy, vertex correction, each obtained there by Feynman parametrization and Passarino–Veltman reduction — are, in the language of (60.71), statements about bubble and triangle coefficients: the vacuum polarization is a bubble coefficient times B_0, the vertex form factors are triangle and bubble coefficients times C_0 and B_0, with the ultraviolet poles residing in the tadpole and metric-coefficient pieces exactly as Theorem 60.8 located them. Re-expressing those results in this basis is not a new computation but a change of bookkeeping; it makes the QED one-loop data directly comparable with the Yang–Mills one-loop amplitudes that the unitarity method will construct from on-shell gluon trees. Yang–Mills theory is set up here on the same box–triangle–bubble–tadpole basis, so that the gluon amplitude assembled later in this chapter and the QED amplitudes of Chapter 19 are read off the *same* finite list of masters — the unification of "old way" and "new way" that the chapter promised.

Theorem 60.11 converts the problem of computing a one-loop amplitude into the finite problem of determining the rational coefficients $\{d_i, c_i, b_i, a_i\}$ and the rational remainder R. The cut analysis of Section 60.2.6 already shows that

discontinuities can separate the masters; what it does not yet show is how to compute a given coefficient cleanly, without the Gram-determinant instabilities that plague Passarino–Veltman reduction. The next section supplies the answer: cutting more than two propagators at once — generalized unitarity — freezes the loop momentum on a discrete set of on-shell solutions and isolates each coefficient as a product of on-shell tree amplitudes, computing the box coefficient d_i from a quadruple cut, the triangle from a triple cut, and so on down the hierarchy.

60.3 Generalized Unitarity: Coefficients from Multiple Cuts

The previous section reduced the problem of a one-loop amplitude to a finite list of unknowns: by Theorem 60.11 every one-loop amplitude is the master decomposition

$$\mathcal{M}^{\text{1-loop}} = \sum_i d_i \,\mathrm{Box}_i + \sum_i c_i \,\mathrm{Tri}_i + \sum_i b_i \,\mathrm{Bub}_i + \sum_i a_i \,\mathrm{Tad}_i + R, \tag{60.72}$$

with the scalar masters known once and for all and the coefficients d_i, c_i, b_i, a_i and the rational remainder R the only quantities left to determine. The ordinary two-particle cut of Section 60.1.3 already constrains these numbers, but bluntly: cutting a single channel puts a delta function on two propagators and detects *every* master that has a discontinuity in that channel at once — the box, the triangles, and the bubble that all share the cut — so a double cut returns a tangled linear combination of coefficients, not any one of them. To disentangle them one would have to take many cuts and solve a linear system, much as Passarino–Veltman solves a Gram system, and the off-shell loop integrals reappear inside each cut.

The insight of generalized unitarity, due to Britto, Cachazo, and Feng [91], is that nothing forbids cutting *more* than two propagators. The masters in Eq. (60.72) differ in how many propagators they carry — four for a box, three for a triangle, two for a bubble — so cutting a larger set of propagators kills every master that does not contain all of them. Cutting all four propagators of a box leaves that box alone among the masters: triangles, bubbles, and tadpoles have too few propagators to support four simultaneous on-shell conditions and are annihilated. The single surviving coefficient is then read off directly, and the residual loop integral collapses completely, because four on-shell conditions on a four-component loop momentum leave no integration at all — only a discrete sum over solutions. The price, foreshadowed already by the three-point kinematics of Chapters 58 and 59, is that those solutions are necessarily *complex*. This section develops the construction in full: the quadruple cut for box coefficients, the triple cut for triangles, the double cut for bubbles, and the unifying principle that every coefficient is a sum of products of on-shell tree amplitudes.

60.3.1 The generalized cut and the maximal-cut philosophy

We first fix what "cutting a set of propagators" means as an operation on the integrand, generalizing the Cutkosky replacement Eq. (60.10). Given a one-loop integrand with denominator $D_0 D_1 \cdots D_{N-1}$, and a chosen subset $C \subseteq \{0, 1, \ldots, N-1\}$ of propagators to cut, the *generalized cut* on C replaces each selected propagator by its on-shell delta function and integrates the remainder over the loop momentum:

$$\mathrm{Cut}_C\, \mathcal{M}^{\text{1-loop}} \;\equiv\; \int \frac{\mathrm{d}^4 \ell}{(2\pi)^4} \Big[\prod_{i \in C} (2\pi)\, \delta^+(\ell_i^2 - m_i^2) \Big] \Big[\prod_{j \notin C} \frac{1}{\ell_j^2 - m_j^2} \Big] N(\ell), \quad (60.73)$$

with $\ell_i = \ell + r_i$ the propagator momenta, $N(\ell)$ the integrand numerator, and δ^+ the positive-energy delta of Eq. (60.9). When $|C| = 2$ this is exactly the two-particle Cutkosky cut of Theorem 60.1; the new content is $|C| \geq 3$. The replacement (60.73) is best understood as a multidimensional contour deformation: the product of deltas is the residue obtained by encircling the simultaneous poles of the cut propagators, the higher-dimensional analogue of the single-propagator discontinuity Eq. (60.8). We treat it as a linear functional on (60.72) and ask what it returns when applied to each master.

The decisive observation is a selection rule. A scalar master Box, Tri, Bub, Tad has $4, 3, 2, 1$ propagators respectively. Applying Cut_C with $|C| = k$ to a master with fewer than k propagators gives zero, because at least one requested delta function has no propagator to act on — there is no factor $1/(\ell_i^2 - m_i^2)$ to be replaced, and the cut is empty. More precisely, Cut_C acting on a master is nonzero only if C is a subset of that master's propagator set. Therefore:

- A *quadruple* cut ($|C| = 4$) survives only on boxes whose four propagators are exactly C. Generic external kinematics admit a unique such box per quadruple, so the quadruple cut isolates a single d_i.
- A *triple* cut ($|C| = 3$) survives on the one triangle with propagator set C, and also on every box that *contains* C among its four propagators. It returns c_i contaminated by the boxes already determined by quadruple cuts.
- A *double* cut ($|C| = 2$) survives on the bubble with propagator set C, on triangles containing C, and on boxes containing C. It returns b_i contaminated by already-known triangle and box coefficients.

This hierarchy dictates the algorithm: determine the box coefficients from quadruple cuts first; then the triangle coefficients from triple cuts, subtracting the known box contributions; then the bubble coefficients from double cuts, subtracting the known triangle and box contributions. Each step uses the maximal cut available for the coefficient it targets, so that the contamination

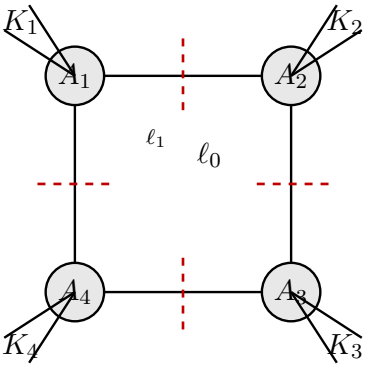

Figure 60.2: The quadruple cut of a box. All four internal propagators are put on shell (dashed cuts), severing the loop into four on-shell tree amplitudes A_1, A_2, A_3, A_4, one at each corner with external cluster K_a. The four delta functions freeze the loop momentum to the two discrete complex solutions of Eq. (60.74), so the box coefficient is a sum of products of trees with no integration left, Theorem 60.13.

comes only from masters *above* it in the hierarchy, which have already been fixed. The tadpoles, carrying a single scale and no kinematic channel, have vanishing cut (Section 60.2.2) and are fixed by other means; in a massless theory they are absent altogether. We now execute the three steps in turn.

60.3.2 The quadruple cut: box coefficients from four on-shell trees

Consider a box with propagators D_0, D_1, D_2, D_3 whose corner momenta partition the external legs into four clusters K_1, K_2, K_3, K_4 (the momentum flowing out of each corner), $\sum_a K_a = 0$. The four cut conditions are

$$\ell_0^2 = m_0^2, \quad \ell_1^2 = m_1^2, \quad \ell_2^2 = m_2^2, \quad \ell_3^2 = m_3^2, \qquad \ell_a = \ell + r_a, \tag{60.74}$$

four scalar equations in the four components of ℓ. Subtracting $\ell_0^2 = m_0^2$ from the other three linearizes them — exactly the denominator identity Eq. (60.38) — leaving one quadratic ($\ell_0^2 = m_0^2$) and three linear equations. Three linear equations fix ℓ to a line; the residual quadratic cuts that line at *two* points. Hence the quadruple-cut system has generically *two solutions* $\ell_*^{(1)}, \ell_*^{(2)}$, and they are isolated points, not a continuous family. This is the geometric content of cutting four propagators with a four-dimensional loop momentum: the integration is completely frozen.

On either solution the four cut propagators are on shell, so the loop has been severed into four *tree* amplitudes, one per corner (Fig. 60.2): each corner a is the on-shell amplitude A_a for its external cluster K_a together with the two adjacent

cut lines, summed over the helicity (and particle species) of the internal lines crossing the cut. The cut of the full amplitude is therefore

$$\mathrm{Cut}_4\,\mathcal{M}^{\text{1-loop}} = \int \frac{\mathrm{d}^4\ell}{(2\pi)^4} \prod_{i=0}^{3} (2\pi)\,\delta^+(\ell_i^2 - m_i^2) \sum_{\text{states}} A_1\,A_2\,A_3\,A_4, \tag{60.75}$$

with the sum over the internal states on the four cut lines. We must turn the frozen integral on the right into the coefficient d.

Freezing the integral: the Jacobian

The four delta functions localize the loop integral on the two solutions of (60.74). Change variables from ℓ^μ to the four functions $u_i \equiv \ell_i^2 - m_i^2$; the Jacobian of this change is

$$J(\ell) \;=\; \det\!\Big(\frac{\partial u_i}{\partial \ell^\mu}\Big)_{i,\mu} \;=\; \det\big(2\,\ell_i^\mu\big)_{i,\mu}, \qquad i = 0,1,2,3,\ \mu = 0,1,2,3, \tag{60.76}$$

the 4×4 determinant of the (twice) propagator momenta viewed as rows. Then $\prod_i \mathrm{d}u_i = |J|\,\mathrm{d}^4\ell$, and integrating the four delta functions,

$$\mathrm{Cut}_4\,\mathcal{M}^{\text{1-loop}} = \frac{1}{(2\pi)^2} \sum_{\sigma=1,2} \frac{1}{|J(\ell_*^{(\sigma)})|} \Big[\sum_{\text{states}} A_1 A_2 A_3 A_4\Big]_{\ell=\ell_*^{(\sigma)}}, \tag{60.77}$$

the overall $(2\pi)^{-2}$ collecting the four (2π)'s from the deltas against the $(2\pi)^{-4}$ of the measure. Crucially, the *same* delta functions act on the scalar box, whose numerator is unity:

$$\mathrm{Cut}_4\ \mathrm{Box} = \frac{1}{(2\pi)^2} \sum_{\sigma=1,2} \frac{1}{|J(\ell_*^{(\sigma)})|}. \tag{60.78}$$

By the selection rule of Section 60.3.1 the quadruple cut of the master decomposition (60.72) receives a contribution from this box alone, so $\mathrm{Cut}_4\,\mathcal{M}^{\text{1-loop}} = d\ \mathrm{Cut}_4\ \mathrm{Box}$. Dividing (60.77) by (60.78) gives the coefficient. For the kinematic configurations of interest the two solutions are exchanged by complex conjugation and carry equal Jacobian magnitude, $|J(\ell_*^{(1)})| = |J(\ell_*^{(2)})|$, whereupon the Jacobians cancel between numerator and denominator and we obtain the central formula.

Theorem 60.13 (Quadruple cut, Britto–Cachazo–Feng)**.** *The coefficient of a scalar box master in the one-loop decomposition* (60.72) *is the average, over the two complex solutions of the four on-shell conditions* (60.74)*, of the product of the four on-shell tree amplitudes at its corners, summed over the internal states crossing the cuts:*

$$\boxed{\,d \;=\; \frac{1}{2} \sum_{\sigma=1,2} \sum_{\text{states}} A_1\,A_2\,A_3\,A_4\Big|_{\ell=\ell_*^{(\sigma)}}.\,} \tag{60.79}$$

No off-shell quantity, no gauge choice, and no loop integration enters: the box coefficient is fixed entirely by on-shell tree data evaluated at the two cut solutions.

The factor $\frac{1}{2}$ is the residue of the Jacobian cancellation: each solution contributes its product weighted by $1/|J|$, the scalar box supplies $\sum_\sigma 1/|J| = 2/|J|$ in the denominator, and with equal Jacobians the ratio is $\frac{1}{2}(A_1A_2A_3A_4|_1 + A_1A_2A_3A_4|_2)$. It is not an arbitrary symmetry factor but the statement that the box's own quadruple cut counts both solutions equally.

60.3.3 Why the cut solutions must be complex

Before computing, we confront the feature that makes Theorem 60.13 possible at all: the solutions $\ell_*^{(\sigma)}$ are complex, and they *must* be, because the corner amplitudes are on-shell three- and higher-point amplitudes whose existence requires complex kinematics. Recall from Section 58.3 and Section 59.2.6 the kinematics of a massless three-point amplitude. For three null momenta p_1, p_2, p_3 summing to zero, the Mandelstam invariants $s_{ij} = \langle i\,j\rangle[j\,i]$ all vanish: $s_{12} = (p_1+p_2)^2 = p_3^2 = 0$, and likewise s_{13}, s_{23}. With *real* momenta, $\langle i\,j\rangle$ and $[i\,j]$ are complex conjugates up to a sign, so $\langle i\,j\rangle[j\,i] = 0$ forces *both* $\langle i\,j\rangle = 0$ and $[i\,j] = 0$ for every pair: all spinor brackets vanish and the on-shell three-point amplitude is identically zero. A massless three-point amplitude is nonzero only off the real slice.

Complexifying the momenta breaks the link between λ and $\tilde\lambda$, which become independent spinors. Then $\langle i\,j\rangle[j\,i] = 0$ can be solved in two distinct ways: either all the angle brackets vanish (all λ_i proportional, $\tilde\lambda_i$ generic — the antiholomorphic, or $\overline{\text{MHV}}$, kinematics) or all the square brackets vanish (all $\tilde\lambda_i$ proportional, λ_i generic — the holomorphic, MHV, kinematics). On the first branch the three-point amplitude is the square-bracket expression of Eq. (58.98),

$$A_3[1^+, 2^+, 3^-] = -\,i\,g\,\frac{[1\,2]^3}{[2\,3][3\,1]}, \tag{60.80}$$

finite and nonzero; on the second it is the angle-bracket conjugate $A_3[1^-, 2^-, 3^+] = i\,g\,\langle 1\,2\rangle^3/(\langle 2\,3\rangle\langle 3\,1\rangle)$ of Eq. (59.55) at $n = 3$. The quadruple-cut solutions are precisely the complex loop momenta that put each corner onto one of these two branches. This is not a formal trick: the contour deformation defining the generalized cut (60.73) naturally lands on complex residues, and the reality of the final amplitude is recovered only after the residues are summed back up. The lesson of Chapters 58 and 59 — that on-shell three-point amplitudes live in complexified kinematics — is exactly what the unitarity method needs to feed its corners.

Physical Insight

The brute-force one-loop computations of Chapter 19 never met complex momenta because they never put anything on shell: every internal line stayed off shell, carrying a four-dimensional real integration. Generalized unitarity does the opposite — it forces all cut lines on shell at once — and the reward is that the corners become tree amplitudes, the most economical gauge-invariant objects we have. The cost, complexified loop momenta, is the same complexification that BCFW exploited at tree level in Theorem 59.23. The two methods are the same idea applied at different loop orders: deform momenta into the complex plane until propagators pinch, then read off residues.

60.3.4 A worked box coefficient: the four-gluon amplitude

We now compute a box coefficient end to end, advancing Yang–Mills theory to its loop level: the box of the one-loop color-ordered four-gluon amplitude $A_4^{\text{1-loop}}(1^-,2^-,3^+,4^+)$, with all momenta outgoing, massless, and the cyclic ordering $(1,2,3,4)$. Each corner of the box carries a single external gluon, so all four corners are three-point amplitudes — the cleanest possible illustration of Theorem 60.13.

Worked Example 60.14 (The four-gluon box coefficient from four three-point trees)**.** Route the loop momentum so that the four cut propagators are

$$\ell_0 = \ell, \quad \ell_1 = \ell - k_1, \quad \ell_2 = \ell - k_1 - k_2, \quad \ell_3 = \ell + k_4, \tag{60.81}$$

all massless, with corner clusters $K_a = k_a$. Write the Mandelstam invariants $s \equiv s_{12} = \langle 1\,2\rangle[2\,1]$ and $t \equiv s_{23} = \langle 2\,3\rangle[3\,2]$, as fixed in Section 59.3.

Solving the cut conditions. Setting $\ell_i^2 = 0$ and using $\ell_0^2 = 0$ to subtract,

$$\ell^2 = 0, \qquad \ell\cdot k_1 = 0, \qquad \ell\cdot k_4 = 0, \qquad \ell\cdot k_2 = \tfrac{s}{2}, \tag{60.82}$$

where the last followed from $(\ell - k_1 - k_2)^2 = 0$ with $\ell^2 = \ell\cdot k_1 = 0$ and $2k_1\cdot k_2 = s$. Since $\ell^2 = 0$ we may write $\ell_{\alpha\dot\alpha} = \lambda_\ell\tilde\lambda_\ell$. The conditions $2\,\ell\cdot k_1 = \langle \ell\,1\rangle[1\,\ell] = 0$ and $2\,\ell\cdot k_4 = \langle \ell\,4\rangle[4\,\ell] = 0$ each demand the vanishing of an angle or a square bracket. The two non-degenerate ways to satisfy both are

$$\begin{aligned} &\text{solution (1)}: \quad \langle \ell\,1\rangle = 0,\ [\ell\,4] = 0 \implies \lambda_\ell \propto \lambda_1,\ \tilde\lambda_\ell \propto \tilde\lambda_4, \\ &\text{solution (2)}: \quad [\ell\,1] = 0,\ \langle \ell\,4\rangle = 0 \implies \tilde\lambda_\ell \propto \tilde\lambda_1,\ \lambda_\ell \propto \lambda_4, \end{aligned} \tag{60.83}$$

the remaining combinations ($\langle \ell\,1\rangle = \langle \ell\,4\rangle = 0$ or $[\ell\,1] = [\ell\,4] = 0$) forcing $\lambda_1 \propto \lambda_4$ or $\tilde\lambda_1 \propto \tilde\lambda_4$, false for generic external momenta. These are exactly the two discrete

complex solutions promised. On solution (1) set $\lambda_\ell = \lambda_1$, $\tilde\lambda_\ell = \alpha\,\tilde\lambda_4$; the last condition $\langle \ell\, 2\rangle[2\,\ell] = s$ reads $\alpha\,\langle 1\,2\rangle[2\,4] = \langle 1\,2\rangle[2\,1]$, so

$$\alpha = \frac{[2\,1]}{[2\,4]}. \tag{60.84}$$

The internal kinematics on solution (1). From (60.81), the cut momenta are rank-one bispinors:

$$\begin{aligned} \ell_0 &= \lambda_1\,(\alpha\tilde\lambda_4), & \ell_1 &= \ell_0 - k_1 = \lambda_1\,(\alpha\tilde\lambda_4 - \tilde\lambda_1), \\ \ell_3 &= \ell_0 + k_4 = (\alpha\lambda_1 + \lambda_4)\,\tilde\lambda_4, & \ell_2 &= \ell_1 - k_2 = (\tfrac{[4\,1]}{[2\,4]}\lambda_1 - \lambda_2)\tilde\lambda_2, \end{aligned} \tag{60.85}$$

the last form obtained by simplifying $\alpha\tilde\lambda_4 - \tilde\lambda_1$: bracketing against $\tilde\lambda_1$ gives $[(\alpha\tilde\lambda_4 - \tilde\lambda_1)\,1] = \alpha[4\,1]$, while $[2\,1]\cdot\frac{[4\,1]}{[2\,4]} = \alpha[4\,1]$ by (60.84), so $\alpha\tilde\lambda_4 - \tilde\lambda_1 = \frac{[4\,1]}{[2\,4]}\tilde\lambda_2$. Thus ℓ_0, ℓ_1 have holomorphic spinor $\propto \lambda_1$, while ℓ_2, ℓ_3 have antiholomorphic spinor $\propto \tilde\lambda_2, \tilde\lambda_4$ respectively. Reading off the three-point kinematics of Section 60.3.3: at corner 1 (legs $1, \ell_0, \ell_1$) all angle brackets vanish, so it is an $\overline{\text{MHV}}$ vertex; at corner 4 (legs $4, \ell_3, \ell_0$) all square brackets vanish (every $\tilde\lambda \propto \tilde\lambda_4$), so it is MHV; corner 2 (legs $2, \ell_1, \ell_2$) has every $\tilde\lambda \propto \tilde\lambda_2$ and is MHV; corner 3 (legs $3, \ell_2, \ell_3$) is $\overline{\text{MHV}}$. The internal helicities are then fixed uniquely by requiring each vertex to be nonvanishing (an MHV vertex needs two minus and one plus, an $\overline{\text{MHV}}$ vertex two plus and one minus), with opposite helicities on the two ends of each cut line.

The four corner amplitudes. Using the three-point amplitudes of Eq. (59.55) and (60.80) and inserting the spinors (60.85), the four corners evaluate to

$$A^{(4)} = i\,g\,\frac{\langle \ell_0\,\ell_3\rangle^3}{\langle \ell_3\,4\rangle\langle 4\,\ell_0\rangle} = -\frac{i\,g}{\alpha}\,\langle 1\,4\rangle, \tag{60.86}$$

$$A^{(1)} = -i\,g\,\frac{[\ell_0\,\ell_1]^3}{[\ell_1\,1][1\,\ell_0]} = -i\,g\,\alpha^2\,\frac{[4\,1][2\,4]}{[2\,1]}, \tag{60.87}$$

$$A^{(2)} = i\,g\,\frac{\langle 2\,\ell_1\rangle^3}{\langle \ell_1\,\ell_2\rangle\langle \ell_2\,2\rangle} = i\,g\,\langle 1\,2\rangle\,\frac{[2\,4]}{[4\,1]}, \tag{60.88}$$

$$A^{(3)} = -i\,g\,\frac{[3\,\ell_3]^3}{[\ell_3\,\ell_2][\ell_2\,3]} = -i\,g\,\frac{[3\,4]^3}{[4\,2][2\,3]}, \tag{60.89}$$

each a one-line computation in the spinors (60.85). For instance, in (60.86), $\langle \ell_0\,\ell_3\rangle = \langle 1\,(\alpha\lambda_1 + \lambda_4)\rangle = \langle 1\,4\rangle$, $\langle \ell_3\,4\rangle = \alpha\langle 1\,4\rangle$, $\langle 4\,\ell_0\rangle = \langle 4\,1\rangle$, so the ratio is $\langle 1\,4\rangle^3/(\alpha\langle 1\,4\rangle\langle 4\,1\rangle) = -\langle 1\,4\rangle/\alpha$. Multiplying the four corners, the dependence on α reduces to a single power (α^2 from corner 1 against $1/\alpha$ from corner 4) and every internal bracket cancels in pairs:

$$\prod_a A^{(a)}\Big|_{(1)} = -\,g^4\,\alpha\,\frac{[4\,1][2\,4]}{[2\,1]}\cdot\frac{\langle 1\,2\rangle[2\,4]}{[4\,1]}\cdot\frac{[3\,4]^3}{[4\,2][2\,3]}\cdot\langle 1\,4\rangle = g^4\,\frac{\langle 1\,2\rangle\,\langle 1\,4\rangle\,[3\,4]^3}{[2\,3]}, \tag{60.90}$$

using $\alpha = [2\,1]/[2\,4]$ and $[4\,2] = -[2\,4]$; the product of the four $\pm ig$ prefactors is $-g^4$.

Comparison with the tree. The tree amplitude is the Parke–Taylor value Eq. (59.55),

$$A_4^{\text{tree}}(1^-,2^-,3^+,4^+) = i\,g^2\,\frac{\langle 1\,2\rangle^4}{\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle} = i\,g^2\,\frac{\langle 1\,2\rangle^3}{\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle}. \tag{60.91}$$

Using momentum conservation $\sum_i |i\rangle\,[i\,] = 0$ to trade square brackets for angle brackets — with $s = s_{34} = \langle 3\,4\rangle[4\,3]$, $t = s_{23} = \langle 2\,3\rangle[3\,2] = s_{14} = \langle 1\,4\rangle[4\,1]$ — the product (60.90) collapses to

$$\prod_a A^{(a)}\Big|_{(1)} = i\,g^2\,s\,t\;A_4^{\text{tree}}(1^-,2^-,3^+,4^+). \tag{60.92}$$

That the bracket monomial (60.90) equals ig^2st times (60.91) is checked directly on any explicit spinor assignment; for the choice $\lambda_1 = (1,0)$, $\lambda_2 = (0,1)$, $\lambda_3 = (1,1)$, $\lambda_4 = (1,2)$ with $\tilde\lambda$'s fixed by momentum conservation, both sides equal g^4 (with $s = -1$, $t = 2$). Solution (2) is the parity conjugate, exchanging $\lambda \leftrightarrow \tilde\lambda$ and hence MHV$\leftrightarrow\overline{\text{MHV}}$ at every corner; carrying the identical computation through with $\beta = \langle 1\,2\rangle/\langle 4\,2\rangle$ in place of α gives the same product,

$$\prod_a A^{(a)}\Big|_{(2)} = i\,g^2\,s\,t\;A_4^{\text{tree}}(1^-,2^-,3^+,4^+). \tag{60.93}$$

Averaging by Theorem 60.13,

$$\boxed{d \;=\; \tfrac{1}{2}\Big(\prod_a A^{(a)}\big|_{(1)} + \prod_a A^{(a)}\big|_{(2)}\Big) \;=\; i\,g^2\,s\,t\;A_4^{\text{tree}}(1^-,2^-,3^+,4^+).} \tag{60.94}$$

This single number reproduces, by the most direct possible route, the celebrated result of Bern, Dixon, Dunbar, and Kosower [67]: the one-loop four-gluon MHV amplitude is its tree times $s\,t$ times the scalar zero-mass box, $A_4^{\text{1-loop}} = ig^2\,s\,t\,A_4^{\text{tree}}\,D_0^{0m}(s,t) + \dots$, with D_0^{0m} the box (60.33). We obtained the coefficient from four three-point trees and one algebraic equation, with no Feynman diagram, no gauge choice, and no loop integral — the entire content of Theorem 60.13 made concrete. For this amplitude the triangle and bubble coefficients turn out to vanish: a feature of the maximally supersymmetric content that controls the box, so that (60.94) is the whole cut-constructible amplitude. In pure Yang–Mills the same box coefficient appears, accompanied by a rational remainder addressed in Section 60.3.7 and the next section.

60.3.5 The triple cut: triangle coefficients and Forde's parametrization

A triple cut imposes three on-shell conditions (60.74) on the four-component loop momentum, leaving a *one-complex-parameter* family of solutions rather

than discrete points. By the selection rule of Section 60.3.1 the triple cut on propagators $\{0,1,2\}$ detects the triangle Tri_{012} and every box that contains those three propagators. The boxes are already known from quadruple cuts, so the triangle coefficient is extracted by isolating, within the one-parameter cut, the part that is not a box. Forde's parametrization [197] makes this isolation algebraic, and we develop it now.

Label the three corner momenta K_1, K_2, K_3 with $K_1 + K_2 + K_3 = 0$ (sums of external clusters), and take the two "adjacent" corners K_1, K_2 to be the massive ones (massless corners follow by degenerate limits of the same formulas). Define their mutual massless projections: with

$$K_1^\flat = K_1 - \frac{K_1^2}{\gamma}\, K_2^\flat, \qquad K_2^\flat = K_2 - \frac{K_2^2}{\gamma}\, K_1^\flat, \tag{60.95}$$

the two null momenta $K_1^\flat, K_2^\flat$ are determined by K_1, K_2 up to the normalization γ, which solves the quadratic obtained by imposing $(K_1^\flat)^2 = (K_2^\flat)^2 = 0$,

$$\gamma_\pm = K_1{\cdot}K_2 \pm \sqrt{(K_1{\cdot}K_2)^2 - K_1^2 K_2^2}, \tag{60.96}$$

the two roots $\gamma_\pm$ being the two solutions of the projection conditions. With these the cut loop momentum is parametrized by a single complex variable t,

$$\ell^\mu(t) = \frac{K_2^2(\gamma - K_1^2)}{\gamma^2 - K_1^2 K_2^2}\, K_1^{\flat\,\mu} + \frac{K_1^2(\gamma - K_2^2)}{\gamma^2 - K_1^2 K_2^2}\, K_2^{\flat\,\mu} + \frac{t}{2}\,\langle K_1^\flat|\gamma^\mu|K_2^\flat] + \frac{\Delta}{2t}\,\langle K_2^\flat|\gamma^\mu|K_1^\flat], \tag{60.97}$$

where the two coefficients of $K_1^\flat, K_2^\flat$ are fixed by the on-shell conditions $\ell^2 = 0$, $(\ell - K_1)^2 = 0$, $(\ell + K_2)^2 = 0$, and the constant Δ multiplying the $1/t$ direction is fixed in the same way (its precise value is immaterial to what follows). The essential structure is that $\ell(t)$ runs over the cut solution as t ranges over $\mathbb{C}^\times$, with the two transverse directions $\langle K_1^\flat|\gamma^\mu|K_2^\flat]$ and $\langle K_2^\flat|\gamma^\mu|K_1^\flat]$ spanning the plane orthogonal to $K_1^\flat, K_2^\flat$. The free parameter t is the residual freedom after three on-shell conditions.

Projecting out the triangle

On the triple cut, the product of the three on-shell tree amplitudes at the corners,

$$\mathcal{T}(t) \equiv \sum_{\text{states}} A_1\big(\ell(t)\big)\, A_2\big(\ell(t)\big)\, A_3\big(\ell(t)\big), \tag{60.98}$$

is a rational function of t. Its analytic structure is dictated by the masters that share this cut. A box containing the three cut propagators has a *fourth* propagator $D_3 = (\ell - Q)^2$; that propagator goes on shell at the special values of t where $\ell(t)$ also satisfies $D_3 = 0$, which appear as simple poles of $\mathcal{T}(t)$. The

triangle, by contrast, has no fourth propagator and contributes a piece *regular* in t. Therefore $\mathcal{T}(t)$, expanded as a Laurent series, splits as

$$\mathcal{T}(t) = \underbrace{\sum_{n\neq 0} \left(e_n\, t^n + \tilde{e}_n\, t^{-n}\right)}_{\text{box poles} + \text{spurious}} + \underbrace{e_0}_{\text{triangle}}, \tag{60.99}$$

and the key fact is that integrating the cut over the parameter t annihilates every power t^n with $n \neq 0$. Concretely, once the three delta functions are used the cut measure on the one-parameter family reduces to a contour integral $\oint \frac{\mathrm{d}t}{t}$ around the origin (times the phase-space Jacobian), and $\oint \frac{\mathrm{d}t}{t}\, t^n = 2\pi i\, \delta_{n,0}$. Equivalently, the nonzero powers of t are total derivatives on the cut — "spurious" terms that integrate to zero, the mechanism the next section organizes systematically. Only the t-independent piece e_0 survives integration, and after subtracting the box contributions (whose poles in t sit at the locations where the fourth propagator pinches, with residues fixed by the already-known box coefficients) the triangle coefficient is the constant term, averaged over the two massless-projection roots:

$$\boxed{c = -\frac{1}{2} \sum_{\gamma = \gamma_\pm} \Big[\text{coefficient of } t^0 \text{ in } \mathcal{T}(t) \text{ after box subtraction}\Big]_\gamma .} \tag{60.100}$$

The average over $\gamma_\pm$ plays the role that the average over the two quadruple-cut solutions played in Theorem 60.13. In practice one expands $\mathcal{T}(t)$ at large t, reads off the constant term, and subtracts the pole pieces; the result (60.100) is the triangle coefficient as a sum of products of on-shell trees, exactly the structure Theorem 60.13 delivered for boxes.

Remark 60.15 (Why the constant term is the triangle). The logic is the same selection-by-singularity that proved the masters independent in Section 60.2.6. A box's discontinuity in the fourth channel shows up as a pole in t; a triangle has no such channel and is the smooth background. Forde's parametrization is engineered so that "smooth in t" means "constant in t" once the kinematic Jacobian is stripped, so the triangle is literally the t^0 Laurent coefficient. The spurious powers $t^{\pm n}$, $n \geq 1$, are present in $\mathcal{T}(t)$ but carry no master: they integrate to zero and cancel in the full amplitude. Identifying and discarding them is the one subtlety of the triple cut, and it is precisely what integrand reduction in the next section automates.

60.3.6 The double cut: bubble coefficients and the cut hierarchy

The last cut-constructible coefficient is the bubble. A double cut imposes two on-shell conditions, leaving a *two*-complex-parameter family of solutions, and by the selection rule detects the bubble Bub_{01} together with every triangle and box that contains the two cut propagators. Schematically,

$$\mathrm{Cut}_2\, \mathcal{M}^{\text{1-loop}} = b\, \mathrm{Cut}_2\, \mathrm{Bub} + \sum_{\text{tri}\supset\{0,1\}} c\, \mathrm{Cut}_2\, \mathrm{Tri} + \sum_{\text{box}\supset\{0,1\}} d\, \mathrm{Cut}_2\, \mathrm{Box}, \tag{60.101}$$

so the bubble coefficient is what remains of the two-particle cut after the contributions of the triangles and boxes sharing the channel — already determined by triple and quadruple cuts — are subtracted. The two-parameter cut integrand, a product of two tree amplitudes summed over the intermediate state, is expanded in the two cut parameters (one along the massless-projection direction, one azimuthal); the triangle and box pieces are again the terms carrying extra poles, and the bubble coefficient is the genuinely constant remainder, projected out by integrating over both parameters. This is the bottom of the hierarchy laid out in Section 60.3.1: boxes from quadruple cuts, triangles from triple cuts minus boxes, bubbles from double cuts minus triangles and boxes. Tadpoles, absent in massless theories and cut-free in any case, close the list.

The interplay is the essential structural point. The *same* two-particle cut that Section 60.1.3 used to verify the optical theorem now does quantitative work, but only after the higher cuts have stripped away the box and triangle content that also lives on that cut. A naive two-particle cut, as we warned at the start of this section, returns the entangled combination (60.101); the generalized cuts disentangle it term by term, each maximal cut isolating one layer of the hierarchy. The bubble coefficient is the residue of the optical theorem once everything sharper has been accounted for.

60.3.7 The principle: every coefficient is a product of trees

Standing back from the three constructions, a single principle has emerged, and it is the conceptual heart of the unitarity method.

Theorem 60.16 (Coefficients as on-shell tree data)**.** *Every cut-constructible coefficient in the one-loop master decomposition* (60.72) *— each d_i, c_i, and b_i — is a sum of products of on-shell tree amplitudes, evaluated on the complex kinematic solutions of the corresponding multiple cut and projected onto the appropriate master. No off-shell current, no internal propagator numerator, and no gauge-fixing choice enters at any stage; the coefficients are manifestly gauge invariant because tree amplitudes are.*

The proof is the content of Theorem 60.13, (60.100), and (60.101): the quadruple cut gives d_i as a product of four trees averaged over two solutions; the triple cut gives c_i as the box-subtracted constant term of a product of three trees averaged over the two massless-projection roots; the double cut gives b_i as the triangle- and box-subtracted constant of a product of two trees. Each is built from gauge-invariant on-shell amplitudes alone.

Three features deserve emphasis, because they are what make this a genuine replacement for the Feynman expansion of Chapter 19 rather than a reformulation of it. First, *gauge invariance is automatic.* A Feynman-diagram computation of a one-loop amplitude passes through gauge-dependent off-shell currents, ghost

contributions, and longitudinal polarizations that cancel only in the final sum; the unitarity method never introduces them, because every ingredient is an on-shell tree amplitude, an object on which the gauge redundancy has already been quotiented out. The Gram-determinant instabilities of Passarino–Veltman reduction (Theorem 60.7) are likewise absent: no Gram matrix is ever inverted; instead one solves polynomial on-shell conditions and reads off residues.

Second, *the input is recyclable.* The trees feeding the corners are the very Parke–Taylor and BCFW amplitudes of Eq. (59.55) and Theorem 59.23; the loop computation reuses tree technology wholesale, and a more efficient tree method immediately improves the loop. The four-gluon box coefficient of Theorem 60.14 was nothing but four three-point amplitudes glued together — the same seeds from which BCFW built every tree.

Third, *the method is blind to the rational remainder.* Everything in this section worked in strictly four-dimensional kinematics, where the cut solutions and tree amplitudes live. The rational part R of (60.72), identified in Section 60.2.7 as the cut-free residue, carries no four-dimensional discontinuity and so is invisible to four-dimensional cuts. Recovering it requires continuing the cut loop momentum into $d = 4 - 2\varepsilon$ dimensions — where the extra-dimensional component $\mu_\perp^2$ of Section 60.2.5 reappears inside the cut — or a complementary on-shell construction. Either way the principle survives: even the rational part is a sum of products of (now d-dimensional) on-shell trees.

Physical Insight

The unitarity method inverts the logic of perturbation theory. The Feynman expansion builds an amplitude bottom-up, from a Lagrangian, through gauge-dependent off-shell pieces, to a gauge-invariant sum. Generalized unitarity works top-down: it posits the answer's analytic form — a combination of known scalar integrals with rational coefficients (Theorem 60.11) — and fixes the coefficients by demanding that the amplitude have the correct discontinuities, which on-shell trees supply. The Lagrangian survives only through the trees, and even those can be generated recursively (Theorem 59.23) without summing diagrams. This is why a one-loop amplitude with hundreds of Feynman diagrams can collapse to a handful of box coefficients, each a product of trees.

We have, then, a complete procedure for every cut-constructible coefficient: quadruple cuts for boxes, triple cuts for triangles, double cuts for bubbles, each computed as a product of on-shell trees. But the procedure is applied *cut by cut*, with each lower coefficient requiring explicit subtraction of the higher masters that share its cut, and the four-dimensional cuts leave the rational remainder undetermined. The next section reorganizes the entire construction at the level of the integrand: rather than taking each cut separately and subtracting, one

decomposes the integrand numerator into residues on every set of cut propagators at once, plus spurious terms that integrate to zero — the Ossola–Papadopoulos–Pittau decomposition — so that all coefficients drop out of a single algebraic reduction and the rational part is exposed as the piece the four-dimensional cuts could not see.

60.4 Integrand Reduction: The OPP Decomposition

The generalized-unitarity arguments of Section 60.3 extracted one master-integral coefficient at a time, each as an on-shell product of trees evaluated on the solution of a particular set of cut conditions. That is already a complete computational method, but it is organized around the *integrated* amplitude: each cut is a separate calculation, the box coefficients are read off from quadruple cuts, the triangle coefficients from triple cuts after the boxes are subtracted, and so on, with the bookkeeping of "what has already been accounted for" carried in the analyst's head. The purpose of this section is to install that bookkeeping into the algebra itself, by performing the decomposition *before* integrating. We will write the rational function under the loop integral—the integrand—as an exact algebraic identity: a sum of terms, one for each possible set of cut propagators, in which the residue on each cut is a polynomial in the loop momentum whose coefficients are precisely the master-integral coefficients plus extra "spurious" pieces that vanish upon integration. The result, due to Ossola, Papadopoulos and Pittau [371] and given its sharpest kinematic form by Forde [197], turns generalized unitarity into a single, mechanical, and—crucially—numerically implementable algorithm. It is the engine behind every modern automated one-loop program, and it is the machinery we will apply to the Yang–Mills theory gluon integrand in Section 60.6.

60.4.1 The integrand and what constrains it

Fix a one-loop diagram (or, better, the sum of all one-loop diagrams contributing to a fixed ordered amplitude) with N distinct propagators. Routing the loop momentum ℓ so that the i-th propagator carries $\ell + q_i$ with offset q_i (a sum of external momenta; we may always choose $q_0 = 0$), the integrand is a rational function

$$\mathcal{I}(\ell) = \frac{\mathcal{N}(\ell)}{D_0(\ell)\, D_1(\ell) \cdots D_{N-1}(\ell)}, \qquad D_i(\ell) = (\ell + q_i)^2 - m_i^2 + i\epsilon, \tag{60.102}$$

where the numerator $\mathcal{N}(\ell)$ is a polynomial in ℓ collecting all the vertex and propagator numerators, the gamma-matrix strings, and the color and polarization data of the contributing graphs. The full one-loop amplitude is the regulated integral of Eq. (60.102), $\mathcal{M} = \mu^{2\varepsilon} \int \frac{\mathrm{d}^d \ell}{(2\pi)^d}\, \mathcal{I}(\ell)$, with $d = 4 - 2\varepsilon$ as fixed by Chapter A and Chapter D.

Definition 60.17 (Cut)**.** For an index set $S \subseteq \{0, 1, \dots, N-1\}$, the *cut* C_S is the on-shell locus

$$C_S = \{\, \ell \in \mathbb{C}^4 : D_i(\ell) = 0 \text{ for all } i \in S \,\}. \tag{60.103}$$

We call C_S a quadruple cut, triple cut, double cut, or single cut according to $|S| = 4, 3, 2, 1$, and we say S selects a *box*, *triangle*, *bubble*, or *tadpole* topology respectively. The *residue* of the integrand on C_S is the numerator restricted to that locus with the cut denominators stripped, $\mathcal{N}(\ell)\big|_{C_S}$, regarded as a function on the solution variety.

The reason the integrand cannot be an arbitrary rational function is twofold. First, *locality*: $\mathcal{I}(\ell)$ has poles only where physical propagators go on shell, i.e. only at $D_i = 0$, and these poles are simple. Second, *power counting*: in a renormalizable theory the loop-momentum dependence of the numerator is bounded. Each cubic vertex through which the loop passes contributes at most one power of ℓ, and a one-loop N-gon graph has N such vertices on the loop, so

$$\deg_\ell \mathcal{N}(\ell) \;\le\; N. \tag{60.104}$$

(Theories with better ultraviolet behaviour do better—in $\mathcal{N} = 4$ super Yang–Mills the bound is $\deg_\ell \mathcal{N} \le N - 4$—but Eq. (60.104) is what renormalizability alone guarantees, and it is all we need.) These two facts, locality and the rank bound, are exactly the input that makes the decomposition below finite and exhaustive.

60.4.2 The OPP decomposition

We want to resolve the integrand into a sum of pieces, each of which is supported on a definite set of propagators. The organizing idea is a partial-fraction identity in several variables: any rational function whose denominator is the product $D_0 \cdots D_{N-1}$ can be written as a sum over subsets S of terms with denominator $\prod_{i \in S} D_i$ and a numerator that is finite (does not itself develop the missing poles) on the cut C_S. At one loop, the rank bound Eq. (60.104) together with the propagator-reduction fact from Theorem D.35—that in four dimensions no irreducible topology has more than four propagators—truncates the sum at $|S| = 4$.

Theorem 60.18 (OPP integrand decomposition)**.** *Let $\mathcal{I}(\ell)$ be a one-loop integrand of the form Eq. (60.102) obeying the rank bound Eq. (60.104), with the loop momentum continued to $d = 4 - 2\varepsilon$ dimensions but its numerator first reduced to its four-dimensional part. Then there is an exact algebraic identity*

$$\mathcal{I}(\ell) = \sum_{i_0 < i_1 < i_2 < i_3} \frac{\Delta_{i_0 i_1 i_2 i_3}(\ell)}{D_{i_0} D_{i_1} D_{i_2} D_{i_3}} + \sum_{i_0 < i_1 < i_2} \frac{\Delta_{i_0 i_1 i_2}(\ell)}{D_{i_0} D_{i_1} D_{i_2}}$$

$$+\sum_{i_0<i_1}\frac{\Delta_{i_0 i_1}(\ell)}{D_{i_0}D_{i_1}}+\sum_{i_0}\frac{\Delta_{i_0}(\ell)}{D_{i_0}}, \tag{60.105}$$

in which each numerator $\Delta_S(\ell)$ is a polynomial in ℓ, the residue *attached to the cut C_S, with the following structure: it splits as*

$$\Delta_S(\ell)=\Delta_S^{\mathrm{phys}}+\widetilde{\Delta}_S(\ell), \tag{60.106}$$

where Δ_S^{phys} is a constant (the master-integral coefficient of the topology S) and $\widetilde{\Delta}_S(\ell)$ is a spurious *polynomial whose integral against $\prod_{i\notin S}1$ over the loop vanishes:*

$$\mu^{2\varepsilon}\int\frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{\widetilde{\Delta}_S(\ell)}{\prod_{i\in S}D_i(\ell)}=0. \tag{60.107}$$

*The number of independent coefficients in each Δ_S is finite and fixed by power counting: a box residue carries two coefficients (*1 *physical,* 1 *spurious), a triangle residue seven (*1 *physical,* 6 *spurious), a bubble residue nine (*1 *physical,* 8 *spurious), and a tadpole residue one (physical) for massive internal lines.*

The architecture of the proof is the same at every level, and we will carry it out explicitly for the box and the triangle—the two cases that do all the conceptual work—then state the bubble and tadpole, which repeat the pattern with more indices. The strategy is: (i) parametrize the cut solution variety C_S by free variables; (ii) show, using the rank bound, that the residue is a polynomial of bounded degree in those variables; (iii) split that polynomial into the term constant on C_S (physical) and the remainder (spurious); and (iv) prove the remainder integrates to zero by a symmetry of the master integral. Before the cases, a remark on why the decomposition is exhaustive.

Proposition 60.19 (Exhaustiveness at one loop)**.** *Under Eq. (60.104), the sum in Eq. (60.105) closes: there are no irreducible residues on cuts of five or more propagators, and the residues listed are the complete set.*

Proof. A residue on C_S is "irreducible" if it cannot be absorbed into residues on lower cuts $C_{S'}$ with $S'\subsetneq S$ by the partial-fraction step. Reducibility is controlled by whether the cut variety C_S is nonempty and zero-dimensional or higher. Setting $|S|=k$ propagators on shell imposes k conditions $D_i=0$; taking differences $D_i-D_0=2\ell\cdot(q_i-q_0)+\cdots$ gives $k-1$ *linear* conditions on ℓ plus the one quadratic condition $D_0=0$. In four dimensions ℓ has four components, so the linear conditions can be imposed independently only while $k-1\le 4$, i.e. $k\le 5$. For $k=5$ (the pentagon) the five offsets q_i-q_0 are four independent vectors and one dependent combination; the dependent combination makes the pentagon's Gram determinant (Eq. (D.180), generalized to four external momenta) vanish in exactly four dimensions, and the corresponding scalar integral reduces to a sum of boxes, as established in Theorem D.35. Hence no irreducible residue

survives at $k = 5$ or above, and the sum terminates at boxes. The degree counts follow from Eq. (60.104): on a k-propagator cut the solution variety is $(4-(k-1)) = (5-k)$-dimensional in four dimensions, so a box ($k = 4$) leaves one free direction, a triangle ($k = 3$) two, a bubble ($k = 2$) three, a tadpole ($k = 1$) four; the number of monomials in the free directions allowed by $\deg_\ell \mathcal{N} \le N$, after discarding those that reduce to lower cuts, gives $2, 7, 9, 1$ respectively, as we now verify case by case. □

60.4.3 The box residue and its spurious term

Take a quadruple cut $S = \{0, 1, 2, 3\}$ with $q_0 = 0$, so the three offsets q_1, q_2, q_3 are (generically) three linearly independent vectors in four-dimensional Minkowski space. There is then a unique direction orthogonal to all three,

$$\omega^\mu = \epsilon^{\mu\nu\rho\sigma}\, q_{1\nu}\, q_{2\rho}\, q_{3\sigma}, \qquad \omega \cdot q_i = 0 \quad (i = 1, 2, 3), \tag{60.108}$$

the contraction vanishing by the total antisymmetry of ϵ. Decompose the loop momentum as $\ell = \ell_\parallel + \xi\,\omega$, with $\ell_\parallel \in \mathrm{span}(q_1, q_2, q_3)$ and ξ a scalar. The three differences

$$D_i - D_0 = 2\,\ell \cdot q_i + q_i^2 - m_i^2 + m_0^2 = 2\,\ell_\parallel \cdot q_i + (q_i^2 - m_i^2 + m_0^2) \tag{60.109}$$

are linear in $\ell_\parallel$ and independent of ξ (because $\omega \cdot q_i = 0$); setting them to zero is three linear equations that fix $\ell_\parallel$ completely. The remaining condition $D_0 = \ell^2 - m_0^2 = \ell_\parallel^2 + \xi^2\omega^2 - m_0^2 = 0$ is quadratic in ξ, with the two roots

$$\xi = \pm\,\xi_*, \qquad \xi_*^2 = \frac{m_0^2 - \ell_\parallel^2}{\omega^2}, \qquad \ell_\pm = \ell_\parallel \pm \xi_*\,\omega. \tag{60.110}$$

These two discrete points are the familiar two solutions of the quadruple cut from Section 60.3. Now restrict the numerator to C_S. The only free variable on the cut is ξ, equivalently $\ell \cdot \omega = \xi\,\omega^2$ (since $\ell_\parallel \cdot \omega = 0$). By the rank bound Eq. (60.104) the numerator is at most degree N in ℓ, but after the three linear conditions fix $\ell_\parallel$ and the quadratic condition fixes ξ^2 in terms of constants, any monomial ξ^n with $n \ge 2$ can be rewritten with $\xi^2 \to \xi_*^2$ (a constant), reducing every term to either ξ^0 or ξ^1. The box residue is therefore at most linear in ξ:

$$\Delta_{0123}(\ell) = d_0 + d_1\,(\ell \cdot \omega). \tag{60.111}$$

The constant d_0 is the physical box coefficient; $d_1\,(\ell \cdot \omega)$ is the single spurious term. Evaluating at the two solutions and using $\ell_\pm \cdot \omega = \pm\xi_*\omega^2$,

$$\Delta_{0123}(\ell_\pm) = d_0 \pm d_1\,\xi_*\omega^2 \implies d_0 = \tfrac{1}{2}\big[\Delta_{0123}(\ell_+) + \Delta_{0123}(\ell_-)\big], \quad d_1 = \frac{\Delta_{0123}(\ell_+) - \Delta_{0123}(\ell_-)}{2\,\xi_*\omega^2} \tag{60.112}$$

Each $\Delta_{0123}(\ell_\pm)$ equals the product of the four on-shell tree amplitudes sitting at the corners of the box, evaluated at the corresponding cut solution—this is the content of the quadruple cut from Section 60.3. Hence the physical coefficient d_0 is the *average over the two cut solutions* of that product of trees, reproducing exactly the box coefficient Theorem 60.13 found there. The spurious coefficient d_1 measures the asymmetry between the two solutions and, as we now prove, leaves no trace in the integrated amplitude.

Theorem 60.20 (The box spurious term integrates to zero)**.** *With ω^μ as in Eq. (60.108),*

$$\mu^{2\varepsilon}\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{\ell\cdot\omega}{D_0D_1D_2D_3}=0. \tag{60.113}$$

Proof. Combine the four denominators with Feynman parameters as in Chapter D: there are nonnegative $x_0,\dots,x_3$ with $\sum_i x_i=1$ such that

$$\frac{1}{D_0D_1D_2D_3}=3!\int_0^1\Big(\prod_i \mathrm{d}x_i\Big)\,\delta\Big(1-\textstyle\sum_i x_i\Big)\,\frac{1}{\big[\ell^2+2\,\ell\cdot P-\Delta\big]^4},\qquad P^\mu=\textstyle\sum_i x_i\,q_i, \tag{60.114}$$

with Δ a function of the parameters and invariants whose form we will not need. The shift vector P^μ is a linear combination of the offsets q_i, hence lies in $\mathrm{span}(q_1,q_2,q_3)$ (recall $q_0=0$). Completing the square with the shift $\ell\to\ell-P$ turns the denominator into $[\ell^2-(\Delta+P^2)]^4$, an even function of the shifted momentum, while the numerator becomes

$$\ell\cdot\omega\;\longrightarrow\;(\ell-P)\cdot\omega=\ell\cdot\omega-P\cdot\omega=\ell\cdot\omega, \tag{60.115}$$

because ω is orthogonal to every q_i and therefore to P. The momentum integral is thus

$$\mu^{2\varepsilon}\int\frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{\ell\cdot\omega}{\big[\ell^2-M^2\big]^4},\qquad M^2\equiv\Delta+P^2, \tag{60.116}$$

whose integrand is odd under $\ell\to-\ell$ (numerator odd, denominator even). The Lorentz-invariant measure $\mathrm{d}^d\ell$ is even, so the integral vanishes identically; equivalently, by Lorentz covariance $\int \mathrm{d}^d\ell\,\ell^\mu/[\ell^2-M^2]^4\propto\eta^{\mu\alpha}\times(\text{scalar})$ is impossible for a rank-one tensor with no external vector to carry the index, forcing it to be zero. Integrating over the Feynman parameters preserves the vanishing. □

Why the four-dimensional part matters

The proof of Theorem 60.20 used that the shift vector P lies in the four-dimensional span of the external momenta and that ω is a strictly four-dimensional object orthogonal to them. The loop momentum, however, lives in $d=4-2\varepsilon$ dimensions, and its extra (-2ε) components are *not* orthogonal to ω in the way the argument assumed—they generate

precisely the contributions that the four-dimensional residue cannot see. This is the seed of the rational part: the OPP decomposition in its strictly four-dimensional form, Theorem 60.18, is built from the four-dimensional numerator and therefore reconstructs only the cut-constructible piece. We make this precise and repair it in Section 60.5.

Substituting the box residue Eq. (60.111) back and integrating, the spurious piece drops by Theorem 60.20 and the constant multiplies the scalar box master integral I_4 of Theorem D.22:

$$\mu^{2\varepsilon}\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{\Delta_{0123}(\ell)}{D_0D_1D_2D_3} = d_0\, I_4(\{q_i\};\{m_i\}). \tag{60.117}$$

The integrand-level coefficient is the integrated coefficient. This is the prototype for the whole method.

60.4.4 The triangle residue: Forde's parametrization

The triangle is where the spurious structure becomes rich, and where the contact with Forde's cut extraction is most instructive. Take a triple cut $S=\{0,1,2\}$, again with $q_0=0$, and write the two external momenta flowing into the triangle's two adjacent corners as $K_1=q_1$ and $K_2=q_2-q_1$ (so the third corner carries $K_3=-K_1-K_2$). The cut C_S imposes three conditions on the four-component ℓ, leaving a *one-parameter* solution curve. The art is to parametrize that curve so that the spurious structure is manifest.

Following Forde [197], introduce the massless projections $K_1^\flat, K_2^\flat$ of the (generally massive) corner momenta, the two null vectors built from

$$K_1 = K_1^\flat + \frac{S_1}{\gamma}\,K_2^\flat, \qquad K_2 = K_2^\flat + \frac{S_2}{\gamma}\,K_1^\flat, \qquad S_i \equiv K_i^2, \quad 2\,K_1^\flat\cdot K_2^\flat = \gamma, \tag{60.118}$$

where γ is fixed by squaring: $S_1 = 2\frac{S_1}{\gamma}K_1^\flat\cdot K_2^\flat$ is automatic, and demanding $(K_1^\flat)^2=(K_2^\flat)^2=0$ gives

$$\gamma = K_1\cdot K_2 + \sigma\sqrt{(K_1\cdot K_2)^2 - S_1S_2}\,, \qquad \sigma=\pm1, \tag{60.119}$$

the two signs corresponding to the two ways of choosing the projection (when both corners are massless, $S_1=S_2=0$, $\gamma=2K_1\cdot K_2$ and $K_i^\flat=K_i$). Complete the basis with the two transverse null vectors built from the spinor sandwich,

$$e_3^\mu = \tfrac{1}{2}\,\langle K_1^\flat|\gamma^\mu|K_2^\flat], \qquad e_4^\mu = \tfrac{1}{2}\,\langle K_2^\flat|\gamma^\mu|K_1^\flat], \tag{60.120}$$

in the spinor-helicity notation of Chapter 58. These satisfy $e_3^2=e_4^2=0$, $e_i\cdot K_j^\flat=0$, and, by the Fierz identity $\langle a|\gamma^\mu|b]\langle c|\gamma_\mu|d] = 2\langle a\,c\rangle[d\,b]$ of Chapter 58,

$$2\,e_3\cdot e_4 = \langle K_1^\flat\,K_2^\flat\rangle[K_2^\flat\,K_1^\flat] = -2\,K_1^\flat\cdot K_2^\flat = -\gamma. \tag{60.121}$$

The set $\{K_1^\flat, K_2^\flat, e_3, e_4\}$ is a (complex) basis of four-dimensional momentum space, with $\{K_1^\flat, K_2^\flat\}$ spanning the physical plane of the triangle and $\{e_3, e_4\}$ the transverse plane. Expand

$$\ell^\mu = a\,K_1^{\flat\mu} + b\,K_2^{\flat\mu} + c\,e_3^\mu + d\,e_4^\mu. \tag{60.122}$$

Using the inner products just listed, the three cut conditions become, after a short computation,

$$D_0 = \ell^2 = \gamma(ab - cd) = 0, \tag{60.123}$$

$$D_1 - D_0 = 2\,\ell\cdot K_1 + S_1 = \gamma\,b + S_1\,a + S_1 = 0, \tag{60.124}$$

$$D_2 - D_0 = 2\,\ell\cdot(K_1+K_2) + (K_1+K_2)^2 = \gamma\,a + S_2\,b + S_2 + \gamma + \frac{S_1 S_2}{\gamma} = 0, \tag{60.125}$$

where in Eqs. (60.124) and (60.125) we used $\ell\cdot K_1 = \tfrac{1}{2}(\gamma b + S_1 a)$ and $\ell\cdot K_2 = \tfrac{1}{2}(\gamma a + S_2 b)$, obtained by dotting Eq. (60.122) into Eq. (60.118), and $2K_1\cdot K_2 = \gamma + S_1S_2/\gamma$ from Eqs. (60.118) and (60.121). Equations Eqs. (60.124) and (60.125) are two linear equations fixing a and b to definite constants (no free parameter), and Eq. (60.123) then fixes the *product* $cd = ab$. One combination of c, d remains free; parametrize it by t:

$$c = t, \qquad d = \frac{ab}{t}, \qquad \boxed{\ell^\mu(t) = a\,K_1^{\flat\mu} + b\,K_2^{\flat\mu} + t\,e_3^\mu + \frac{ab}{t}\,e_4^\mu} \tag{60.126}$$

with a, b the fixed solutions of Eqs. (60.124) and (60.125). This is the one-parameter triple-cut solution, a rational curve in t.

The numerator restricted to this curve is a Laurent polynomial in t. Indeed $\ell(t)$ depends on t as t^{+1} (through $c = t$) and t^{-1} (through $d = ab/t$); by the rank bound Eq. (60.104) the numerator is degree $\le N$ in ℓ, and on the triangle ($N \ge 3$) the powers of t that survive after using Eq. (60.123) to trade cd for the constant ab run from t^{-3} to t^{+3}. Therefore

$$\Delta_{012}(\ell(t)) = \sum_{k=-3}^{3} c_{(k)}\,t^k = c_{(0)} + \underbrace{\sum_{k=1}^{3}\left(c_{(k)}t^k + c_{(-k)}t^{-k}\right)}_{\text{spurious}}. \tag{60.127}$$

There are seven coefficients, as promised in Theorem 60.18: the t-independent $c_{(0)}$ is physical, the six $c_{(\pm1)}, c_{(\pm2)}, c_{(\pm3)}$ are spurious. The physical triangle coefficient is extracted by the t^0 projection—a contour integral that picks out the Laurent coefficient,

$$c_0^{\text{tri}} = \frac{1}{2\pi i}\oint_{|t|=1}\frac{\mathrm{d}t}{t}\,\Delta_{012}(\ell(t)) = c_{(0)}. \tag{60.128}$$

This is precisely Forde's prescription: evaluate the product of the three on-shell trees as a function of t, expand, and keep the term that does not depend on t. The next worked example shows the equivalence concretely.

Theorem 60.21 (The triangle spurious terms integrate to zero)**.** *For each $k \neq 0$, the spurious monomial t^k of Eq. (60.127) integrates to zero against the triangle:*

$$\mu^{2\varepsilon} \int \frac{\mathrm{d}^d \ell}{(2\pi)^d} \frac{[\ell\text{-numerator giving } t^k]}{D_0 D_1 D_2} = 0. \tag{60.129}$$

Hence integrating Eq. (60.127) against the triangle leaves only $c_{(0)}\, I_3$, with I_3 the scalar triangle of Theorem D.22.

Proof. The monomial t^k in Eq. (60.127) originates from the numerator factor $c^p d^q$ with $p - q = k$, i.e. from $(\ell \cdot \hat{e}_4)^p (\ell \cdot \hat{e}_3)^q$ up to constants, where $\hat{e}_3, \hat{e}_4$ are the dual transverse vectors (the components c, d are the projections of ℓ onto the transverse plane). After Feynman-combining the three denominators and shifting ℓ by a vector in the *physical* plane $\mathrm{span}(K_1^\flat, K_2^\flat)$—the shift vector $P = \sum_i x_i q_i$ lies there, as in Eq. (60.114)—the denominator depends on the transverse components of ℓ only through $\ell_\perp^2 = 2cd\,(e_3 \cdot e_4)/(\dots)$, i.e. only through the rotation-invariant product cd. The master triangle integrand is thus invariant under the transverse rotation $c \to \lambda c$, $d \to \lambda^{-1} d$ (equivalently $t \to \lambda t$), which preserves cd and the denominator. A numerator monomial $c^p d^q$ with $p \neq q$ transforms with weight $\lambda^{p-q} = \lambda^k \neq 1$ under this rotation; averaging over the rotation (integrating t over the unit circle, $\frac{1}{2\pi i} \oint \frac{\mathrm{d}t}{t}\, t^k = \delta_{k,0}$) annihilates it. Concretely, the transverse two-dimensional momentum integral $\int \mathrm{d}^2 \ell_\perp\, (\ell \cdot \hat{e}_4)^p (\ell \cdot \hat{e}_3)^q\, f(\ell_\perp^2)$ is a Gaussian-type angular average that vanishes unless $p = q$. Only the balanced term $p = q$, i.e. t^0, survives; it carries the constant $c_{(0)}$ and the residual $\ell_\perp^2$ powers reduce, by the same scalar-reduction identities as in Theorem D.35, onto the scalar triangle and lower (bubble) integrals—the latter being correctly attributed to the bubble residues, not the triangle. This is the integrand-level statement of why only the t^0 moment is physical. □

Worked Example 60.22 (OPP projection reproduces the Forde triple-cut coefficient)**.** We show that the contour projection Eq. (60.128) is identical to the triple-cut coefficient Eq. (60.100) extracted in Section 60.3, on a triangle with massless internal lines and generic massive corners $S_1, S_2 \neq 0$.

Setup. The triple cut factorizes the integrand onto three on-shell tree amplitudes $A^{(0)}, A^{(1)}, A^{(2)}$ sitting between consecutive cut legs. By the generalized-unitarity statement of Section 60.3, the residue equals their product summed over the internal helicities h:

$$\Delta_{012}(\ell(t)) = \sum_h A^{(0)}(\ell(t))\, A^{(1)}(\ell(t))\, A^{(2)}(\ell(t)). \tag{60.130}$$

Each tree is a rational function of the cut momenta. The cut legs carry momenta $\ell(t)$, $\ell(t)+K_1$, $\ell(t)+K_1+K_2$, all on shell by construction Eqs. (60.123) to (60.125), so the only t-dependence enters through the explicit t and $1/t$ in Eq. (60.126). Writing each $A^{(i)}$ in spinor variables and substituting Eq. (60.126), the product

Eq. (60.130) becomes a ratio of polynomials in t whose denominators are the (on-shell, hence nonvanishing) spinor products of adjacent legs; clearing them leaves the Laurent polynomial Eq. (60.127).

Projection. Forde's prescription is to expand $\Delta_{012}(\ell(t))$ at large t and retain the term of order t^0,

$$c_0^{\text{tri}} = \Big[\,\Delta_{012}(\ell(t))\Big]_{t^0} = \lim_{R\to\infty} \frac{1}{2\pi i}\oint_{|t|=R} \frac{\mathrm{d}t}{t}\,\Delta_{012}(\ell(t)). \tag{60.131}$$

Because Δ_{012} is a Laurent polynomial Eq. (60.127) with no poles in t other than at $t=0$ and $t=\infty$, the contour radius is immaterial: the residue at $t=0$ of Δ_{012}/t is exactly $c_{(0)}$, and deforming the contour from $|t|=R$ to $|t|=1$ crosses no other singularity. Hence Eq. (60.131) equals Eq. (60.128), $c_0^{\text{tri}} = c_{(0)}$.

Equivalence. The triple-cut coefficient of Section 60.3 was *defined* as the t-independent part of the product of trees on the triple-cut solution, after subtracting the box contributions that also live on the triple cut. The box subtraction removes precisely the simple poles of Eq. (60.130) in t at the locations where a fourth propagator goes on shell (the quadruple-cut points lie on the triangle's t-curve); after that subtraction the remaining function is the Laurent polynomial Eq. (60.127), and its t^0 part is the triangle coefficient. The OPP projection Eq. (60.128) performs the same operation algebraically: the contour integral automatically discards every power $t^{k\neq 0}$, which is what "drop the box poles and keep the constant" achieves. The two prescriptions therefore yield the identical number,

$$c_0^{\text{tri}}\Big|_{\text{OPP}} = \frac{1}{2\pi i}\oint_{|t|=1} \frac{\mathrm{d}t}{t}\,\Delta_{012}(\ell(t)) = c_0^{\text{tri}}\Big|_{\text{Forde, Eq. (60.100)}}. \tag{60.132}$$

The OPP decomposition has thus *unified* the cut-by-cut extractions of Section 60.3: each topology's coefficient is a single moment of the product of trees on that topology's cut curve, and the moments orthogonal to the physical one are exactly the spurious terms that integrate away.

60.4.5 Bubble and tadpole residues

The remaining two topologies follow the identical logic; we state their structure and indicate the new feature in each. For a double cut $S=\{0,1\}$ across a single external momentum $K = q_1 - q_0$, the solution variety is three-dimensional: one "physical" direction along K and a two-dimensional transverse plane. Forde parametrizes the loop momentum by a longitudinal variable y and a transverse angle encoded in a parameter t, $\ell^\mu(y,t) =$ (physical part fixed by the two cut conditions and y) $+\, t\, e_3^\mu + \frac{\cdots}{t} e_4^\mu$, where now the physical part carries the free y. The rank bound caps the residue at

$$\Delta_{01} = b_{(0)} + \underbrace{b_{(1)}\, y + b_{(2)}\,(\text{transverse}) + \ldots}_{\text{eight spurious terms}}, \tag{60.133}$$

nine coefficients in all. The physical bubble coefficient is again the part with no transverse dependence; but because the bubble has a residual longitudinal direction y, extracting $b_{(0)}$ requires a second projection, integrating out y against the appropriate weight after the transverse (t) average. The transverse-dependent terms vanish by the rotation argument of Theorem 60.21, and the surviving y-polynomial reduces, by parity in y about the symmetric point and the scalar identities of Theorem D.35, to the scalar bubble I_2 plus a tadpole; only the constant-in-everything piece $b_{(0)}$ multiplies I_2.

For a single cut $S = \{0\}$, the solution variety is all of four-dimensional momentum space minus one condition, and the residue is a polynomial whose only integration-surviving piece is the constant $a_{(0)}$, multiplying the scalar tadpole I_1. For *massless* internal lines the tadpole is scaleless and vanishes identically by Theorem D.37, so tadpoles contribute only when massive particles run in the loop; in the massless Yang–Mills theory application of Section 60.6 they are absent. The complete count $2, 7, 9, 1$ of Theorem 60.18 is thereby accounted for, and the exhaustiveness of Theorem 60.19 closes the decomposition.

60.4.6 Reconstruction: the numerical-unitarity viewpoint

The decomposition Eq. (60.105) is more than a structural statement; read as a system of equations it is an algorithm for determining *every* coefficient from values of the integrand alone, never touching a Feynman diagram after the numerator is assembled. The key observation is that on a cut C_S, all denominators *except* those in S remain finite, so multiplying the full integrand by $\prod_{i\in S} D_i$ and restricting to C_S isolates the residue Δ_S plus the residues of all *higher* cuts $S' \supset S$ that also contain S. This gives a triangular (top-down) solution.

Proposition 60.23 (Top-down reconstruction)**.** *The residues of Eq. (60.105) are determined recursively, from the maximal cuts downward, by*

$$\Delta_S(\ell|_{C_S}) = \Big[\prod_{i\in S} D_i(\ell)\Big]\,\mathcal{I}(\ell)\Big|_{C_S} \;-\; \sum_{S'\supsetneq S} \frac{\Delta_{S'}(\ell|_{C_S})}{\prod_{j\in S'\setminus S} D_j(\ell)}\Bigg|_{C_S}. \tag{60.134}$$

Sampling the left-hand side at enough points ℓ on C_S—two points for a box, seven on the triangle curve, nine for a bubble, one for a tadpole—fixes the coefficients of the residue polynomial Δ_S by solving a small linear system.

Proof. Multiply Eq. (60.105) by $\prod_{i\in S} D_i$ and restrict to C_S. Every term whose index set is not a superset of S retains at least one uncancelled denominator D_j with $j \notin S$, evaluated off its pole, and is finite; but it also retains a factor $D_i \to 0$ for some $i \in S$ in the numerator product, so it vanishes on C_S. The terms with $S' \supseteq S$ survive: for $S' = S$ the residue Δ_S appears with all its prefactors cancelled, and for $S' \supsetneq S$ the residue $\Delta_{S'}$ appears divided by the extra denominators D_j, $j \in S' \setminus S$, which are finite on C_S. Solving for Δ_S

gives Eq. (60.134). Because the higher residues $\Delta_{S'}$ are already known when we descend to $|S|$, the system is triangular and the recursion well-posed. The number of sample points equals the number of independent coefficients counted in Theorem 60.18: each evaluation of the integrand at a cut point is, by generalized unitarity (Section 60.3), a product of on-shell tree amplitudes, so the entire reconstruction runs on tree data. □

This is the algorithm that "numerical unitarity" implements. One never expands the numerator symbolically: one evaluates the product of trees at numerically specified complex cut momenta, subtracts the already-determined higher residues at those same momenta, and reads the residue coefficients off a linear solve. The boxes come first (their cut points are the isolated $\ell_\pm$ of Eq. (60.110), two evaluations per box), then triangles (seven points on each t-curve Eq. (60.126)), then bubbles, then tadpoles—each step subtracting the contamination from above. The output is the full set of master coefficients, and the spurious coefficients as a free by-product (which are simply discarded).

60.4.7 Integrating back: recovering the master-integral basis

Integrating the OPP identity Eq. (60.105) term by term, every spurious residue vanishes by Eq. (60.107) (proved for the box and triangle in Theorems 60.20 and 60.21, and stated for bubble and tadpole in Section 60.4.5), and each physical residue multiplies the corresponding scalar master integral of Theorem D.22. The result is exactly the master-integral basis assembled in Section 60.2:

$$\mathcal{M} = \sum_{\text{boxes}} d_0\, I_4 + \sum_{\text{triangles}} c_0\, I_3 + \sum_{\text{bubbles}} b_0\, I_2 + \sum_{\text{tadpoles}} a_0\, I_1 + R, \qquad (60.135)$$

the same decomposition Eq. (60.71) the chapter targeted, now derived from a single algebraic identity rather than cut by cut. Each coefficient is one of the residue projections computed above; each integral is evaluated once and for all in Chapter D. The OPP decomposition has therefore done two things at once: it has *proved* that the basis of Section 60.2 is complete (Theorem 60.19), and it has *computed* every coefficient in it as a moment of on-shell trees (Theorem 60.23).

Locality and unitarity as the two projectors

The decomposition makes vivid the chapter's thesis. *Locality*—that the integrand's only singularities are the physical propagator poles—is what allows the partial-fraction form Eq. (60.105) at all: each term is anchored to a definite set of poles. *Unitarity*—that the residue on each multiple pole factorizes into on-shell trees—is what supplies the numerators Eq. (60.134). The spurious terms are the part of the integrand consistent with locality but invisible to the integrated unitarity cuts; they encode the freedom to

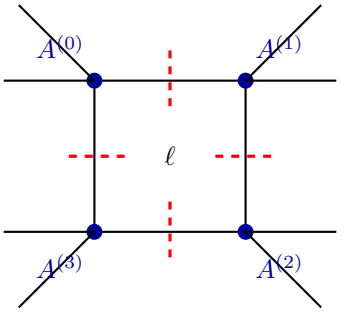

Figure 60.3: The quadruple cut at the integrand level. Cutting the four box propagators (red dashed) replaces them by on-shell conditions $D_i(\ell) = 0$, factorizing the integrand into the product of four on-shell tree amplitudes $A^{(0)}A^{(1)}A^{(2)}A^{(3)}$ at the corners. The two complex solutions $\ell_\pm$ of Eq. (60.110) determine the box residue Eq. (60.111); its average is the physical coefficient d_0 and its antisymmetric part is the spurious coefficient d_1 that integrates to zero (Theorem 60.20). Triangle, bubble, and tadpole residues arise by cutting three, two, and one propagators respectively.

add total-derivative-like pieces that average to zero. Reconstructing an amplitude is then nothing but projecting the product of trees onto the locality-allowed pole structure and discarding the rotation-odd remainder.

We have, in four dimensions, a complete and mechanical reconstruction: the integrand is written as Eq. (60.105), its residues are fixed by tree-level data through Eq. (60.134), and integrating returns the master basis Eq. (60.135) with every coefficient determined. But the careful reader will have noted the warning attached to Theorem 60.20: the entire construction used the *four-dimensional* numerator and the strictly four-dimensional cut kinematics, and the rational remainder R in Eq. (60.135) was set silently to zero. That remainder is not zero in general—it hides in the (-2ε)-dimensional components of the loop momentum that the four-dimensional cuts cannot probe. The next section explains exactly why four-dimensional unitarity is blind to R, locates its origin, and completes the method by lifting the cuts to d dimensions.

60.5 The Rational Part and d-Dimensional Unitarity

The integrand reduction of Section 60.4 accomplished something that looked, at first sight, like the whole task. It wrote the one-loop integrand as a sum of residues on the maximal cuts, each residue a product of on-shell trees, plus spurious terms that integrate to zero; integrating what remained against the scalar master integrals reproduced the box, triangle, and bubble coefficients

without a single Feynman diagram. Yet the construction was carried out entirely in four dimensions: the cut loop momenta were four-dimensional null vectors, and the tree amplitudes glued across the cuts were the ordinary four-dimensional spinor-helicity amplitudes of Chapters 58 and 59. This section confronts the price of that convenience. A one-loop amplitude in dimensional regularization is not exhausted by the coefficients of its logarithms and dilogarithms; it carries, in addition, a piece with no branch cut at all — a *rational* function of the external invariants. Four-dimensional cuts are deaf to it. We will see exactly why, locate the rational part in the (-2ε)-dimensional components of the loop momentum, compute the handful of master integrals that generate it, and thereby close the method: d-dimensional generalized unitarity reconstructs the entire amplitude, cut-constructible and rational alike.

60.5.1 The cut-constructibility gap

Recall the master-integral decomposition established in Section 60.2. Every renormalizable one-loop amplitude, after integrand reduction, is a finite linear combination

$$\mathcal{M}^{\text{1-loop}} \;=\; \sum_i d_i\, I_4^{(i)} \;+\; \sum_i c_i\, I_3^{(i)} \;+\; \sum_i b_i\, I_2^{(i)} \;+\; \sum_i a_i\, I_1^{(i)} \;+\; R\,, \tag{60.136}$$

where I_4, I_3, I_2, I_1 are the scalar box, triangle, bubble, and tadpole integrals evaluated in Chapter D, the coefficients d_i, c_i, b_i, a_i are rational functions of the kinematic invariants, and R is a purely rational remainder. The split between the integral terms and R is sharp, and it is dictated by analytic structure. The scalar masters are *transcendental*: the bubble produces a logarithm, $I_2(K^2) \sim \ln(-K^2)$; the triangle and box produce dilogarithms and products of logarithms (Section D.5). Each such function has a branch cut on the physical sheet, beginning at the threshold where the cut propagators can go simultaneously on shell. The rational remainder R, by contrast, is an algebraic function of the Mandelstam invariants and the spinor brackets: it has poles, but no branch points and no discontinuity anywhere.

This is the crux. Unitarity, in the form proved in Section 14.7 and sharpened into the cutting rules at the head of this chapter, computes *discontinuities*. A generalized cut isolates the imaginary part associated with a particular set of propagators going on shell; it is a residue of the amplitude across a branch cut. The transcendental functions in Eq. (60.71) carry those cuts, so taking discontinuities and matching them to products of trees fixes the coefficients d_i, c_i, b_i that multiply them. But R has no discontinuity to match. Setting every four-dimensional cut of Eq. (60.71) equal to the corresponding product of trees determines the integral coefficients and leaves R entirely undetermined: it is annihilated by the very operation the method is built on.

Theorem 60.24 (The four-dimensional cut-constructibility gap)**.** *Let* disc *denote the discontinuity across any kinematic channel, computed with four-dimensional on-shell intermediate states. Then* disc $R = 0$ *identically, while the integral coefficients satisfy*

$$\operatorname{disc}_c \mathcal{M}^{\text{1-loop}} = \sum_{i\in c} d_i \operatorname{disc}_c I_4^{(i)} + \sum_{i\in c} c_i \operatorname{disc}_c I_3^{(i)} + \sum_{i\in c} b_i \operatorname{disc}_c I_2^{(i)}, \quad (60.137)$$

the sum running over masters with a cut in channel c. Consequently four-dimensional unitarity determines $\{d_i, c_i, b_i\}$ but is blind to R. An amplitude whose every four-dimensional cut vanishes is reconstructed by the method as zero, even when its true value is a nonzero rational function.

Proof. R is rational, hence single-valued and analytic except at isolated poles; across any branch cut its boundary values from above and below coincide, so $\operatorname{disc} R = 0$. Acting with disc_c on Eq. (60.71) therefore kills R and, because disc_c annihilates any master without a cut in channel c (its argument never reaches threshold there), retains only the displayed terms. The discontinuities $\operatorname{disc}_c I_n$ are themselves products of lower-point on-shell data fixed by the optical theorem; matching both sides channel by channel is a linear system for the surviving coefficients. The system never references R. □

A theory in which R happens to vanish — famously $\mathcal{N} = 4$ super Yang–Mills, whose one-loop amplitudes are "cut-constructible" in the strict sense [67] — is fully reconstructed from four-dimensional cuts. Generic gauge theory is not so lucky. The all-plus gluon amplitude of Section 60.5.6 is the sharpest illustration: every one of its four-dimensional cuts vanishes, yet the amplitude is nonzero and *purely* rational. To find R we must enlarge the cut, and the enlargement is dictated by the regulator itself.

60.5.2 The loop momentum in d dimensions

Dimensional regularization [469], introduced in Section 19.1 and developed in Chapter D, continues the loop momentum to $d = 4 - 2\varepsilon$ dimensions. The cuts of Section 60.5.1 discarded that continuation, treating the loop momentum as four-dimensional. The information missing from R is precisely the information thrown away in that step. To recover it, split the d-dimensional loop momentum into its four physical components and its (-2ε) extra components,

$$\ell^M = \bar{\ell}^\mu \oplus \ell_\perp^{\hat{\imath}}, \qquad \mu = 0,1,2,3, \quad \hat{\imath} = 4,\dots,d-1, \quad (60.138)$$

where $\bar{\ell}$ lives in the four-dimensional Minkowski subspace with metric $\eta_{\mu\nu} = \operatorname{diag}(+,-,-,-)$ and $\ell_\perp$ in the orthogonal extra-dimensional subspace. The two subspaces do not mix, so the d-dimensional square decomposes as

$$\ell^2 = \bar{\ell}^2 + \ell_\perp^2 = \bar{\ell}^2 - \mu^2, \qquad \mu^2 \equiv -\ell_\perp^2 \geq 0. \quad (60.139)$$

The extra dimensions are spacelike in the mostly-minus signature, so their contribution to ℓ^2 is negative; we package it in the manifestly nonnegative invariant μ^2, the squared length of the extra-dimensional part of the loop momentum.

Notation Watch

The modern amplitudes literature overwhelmingly uses the mostly-plus signature, in which the extra dimensions are still spacelike but the four-dimensional part flips sign, giving $\ell^2 = \bar{\ell}^2 + \mu^2$. Every μ^2 master integral below then appears with the opposite-looking sign relative to those references. The physics is identical; we keep the book's mostly-minus convention (Chapter A) throughout, so $\ell^2 = \bar{\ell}^2 - \mu^2$ with $\mu^2 \geq 0$ is the relation in force.

The consequence of Eq. (60.139) is a reinterpretation that makes the whole construction concrete. A massless propagator in d dimensions is

$$\frac{i}{\ell^2 + i\epsilon} \;=\; \frac{i}{\bar{\ell}^2 - \mu^2 + i\epsilon}\,, \tag{60.140}$$

which, read from the four-dimensional point of view, is the propagator of a particle of mass-squared μ^2. The (-2ε)-dimensional components of the loop momentum act, on the four-dimensional kinematics, exactly like a uniform internal mass. The d-dimensional massless loop is a four-dimensional *massive-scalar* loop, the mass being the extra-dimensional invariant μ, which is then integrated over. A massive internal line $\ell^2 - m^2$ simply shifts the effective mass-squared to $\mu^2 + m^2$.

To turn this into a calculational rule we factorize the d-dimensional measure into its four-dimensional and extra-dimensional parts. For any integrand depending on the extra components only through μ^2,

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\, f(\bar{\ell}, \mu^2) \;=\; \int \frac{\mathrm{d}^4\bar{\ell}}{(2\pi)^4}\, \frac{1}{(2\pi)^{-2\varepsilon}}\, \Omega_{-2\varepsilon} \int_0^\infty \mathrm{d}|\ell_\perp|\; |\ell_\perp|^{-2\varepsilon-1}\, f\,, \tag{60.141}$$

where the angular integration over the (-2ε) extra directions has produced the sphere "volume" $\Omega_n = 2\pi^{n/2}/\Gamma(n/2)$ continued to $n = -2\varepsilon$ (Eq. (D.63)). Substituting $\mu^2 = |\ell_\perp|^2$, so that $\mathrm{d}|\ell_\perp|\,|\ell_\perp|^{-2\varepsilon-1} = \frac{1}{2}\,\mathrm{d}\mu^2\,(\mu^2)^{-\varepsilon-1}$, and collecting the powers of π and 2 via $\pi^{-\varepsilon}(2\pi)^{2\varepsilon} = (4\pi)^\varepsilon$, gives the clean factorized measure

$$\boxed{\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\, f(\bar{\ell}, \mu^2) \;=\; \frac{(4\pi)^\varepsilon}{\Gamma(-\varepsilon)} \int \frac{\mathrm{d}^4\bar{\ell}}{(2\pi)^4} \int_0^\infty \mathrm{d}\mu^2\; (\mu^2)^{-\varepsilon-1}\, f(\bar{\ell}, \mu^2)\,.} \tag{60.142}$$

The single factor that will do all the work is the prefactor $1/\Gamma(-\varepsilon)$. Since $\Gamma(-\varepsilon) = -1/\varepsilon - \gamma_E + O(\varepsilon)$, its reciprocal is

$$\frac{1}{\Gamma(-\varepsilon)} \;=\; -\varepsilon \;+\; O(\varepsilon^2)\,. \tag{60.143}$$

An integrand that depends nontrivially on μ^2 thus comes weighted by an explicit factor of order ε. This is half of the mechanism; the other half is the $1/\varepsilon$ it will be made to meet.

60.5.3 The dimension shift and the $\varepsilon \times (1/\varepsilon)$ mechanism

The numerators that survive integrand reduction in d dimensions are not functions of $\bar{\ell}$ alone; the OPP residues acquire a polynomial dependence on μ^2, because the reduction identities close only when the full d-dimensional $\ell^2 = \bar{\ell}^2 - \mu^2$ is used. We therefore need the integral of a power of μ^2 against a denominator that depends on the loop momentum only through the d-dimensional combination ℓ^2. The following identity reduces every such integral to an ordinary scalar integral in a *shifted* number of dimensions.

Proposition 60.25 (Dimension-shift identity)**.** *Let f depend on the loop momentum only through d-dimensional Lorentz invariants (denominators $\ell^2 - m^2$ and dot products $\ell \cdot k_i$ with external momenta k_i, which are four-dimensional). Then for every nonnegative integer r,*

$$\int \frac{\mathrm{d}^d \ell}{(2\pi)^d} \, (\mu^2)^r \, f \;=\; (4\pi)^r \, \frac{\Gamma(r-\varepsilon)}{\Gamma(-\varepsilon)} \int \frac{\mathrm{d}^{\,d+2r} \ell}{(2\pi)^{d+2r}} \, f \,. \tag{60.144}$$

In particular, for $r = 1$, using $\Gamma(1-\varepsilon) = (-\varepsilon)\Gamma(-\varepsilon)$,

$$\int \frac{\mathrm{d}^d \ell}{(2\pi)^d} \, \mu^2 \, f \;=\; -\,\varepsilon \, (4\pi) \int \frac{\mathrm{d}^{\,d+2} \ell}{(2\pi)^{d+2}} \, f \,. \tag{60.145}$$

Proof. Apply the measure split Eq. (60.142) to the left-hand side, absorbing the extra power $(\mu^2)^r$ into the radial weight:

$$\int \frac{\mathrm{d}^d \ell}{(2\pi)^d} \, (\mu^2)^r f \;=\; \frac{(4\pi)^{\varepsilon}}{\Gamma(-\varepsilon)} \int \frac{\mathrm{d}^4 \bar{\ell}}{(2\pi)^4} \int_0^\infty \mathrm{d}\mu^2 \; (\mu^2)^{r-\varepsilon-1} \, f \,. \tag{60.146}$$

Now run the same split *backwards* for an integral in $d' = d + 2r = 4 - 2\varepsilon'$ dimensions, where the number of extra dimensions is $-2\varepsilon' = -2\varepsilon + 2r$, i.e. $\varepsilon' = \varepsilon - r$. The general form of Eq. (60.142) for $n = -2\varepsilon'$ extra dimensions reads

$$\int \frac{\mathrm{d}^{\,d+2r} \ell}{(2\pi)^{d+2r}} \, f \;=\; \frac{(4\pi)^{\varepsilon - r}}{\Gamma(r-\varepsilon)} \int \frac{\mathrm{d}^4 \bar{\ell}}{(2\pi)^4} \int_0^\infty \mathrm{d}\mu^2 \; (\mu^2)^{r-\varepsilon-1} \, f \,, \tag{60.147}$$

because the radial weight is $(\mu^2)^{-\varepsilon'-1} = (\mu^2)^{r-\varepsilon-1}$ and the prefactor is $(4\pi)^{\varepsilon'}/\Gamma(-\varepsilon') = (4\pi)^{\varepsilon-r}/\Gamma(r-\varepsilon)$. The four-dimensional integral and the μ^2 integral on the right of Eqs. (60.146) and (60.147) are *identical*. Dividing one relation by the other eliminates them and leaves the ratio of prefactors,

$$\frac{(4\pi)^{\varepsilon}/\Gamma(-\varepsilon)}{(4\pi)^{\varepsilon-r}/\Gamma(r-\varepsilon)} \;=\; (4\pi)^r \, \frac{\Gamma(r-\varepsilon)}{\Gamma(-\varepsilon)} \,, \tag{60.148}$$

which is Eq. (60.144). For $r = 1$ the recursion $\Gamma(1-\varepsilon) = (-\varepsilon)\Gamma(-\varepsilon)$ collapses the ratio to $-\varepsilon(4\pi)$, giving Eq. (60.145). □

Equation Eq. (60.145) is the engine of the rational part, and it makes the mechanism transparent. A μ^2 numerator does not change the integrand's four-dimensional structure; it trades the integral for the *same* integral evaluated in two more dimensions, at the cost of an explicit $-\varepsilon(4\pi)$. Raising the dimension by two raises the superficial degree of divergence by two (Eq. (D.110)): an integral that was finite in $d = 4$ can become logarithmically divergent in $d = 6$, developing a pole $1/\varepsilon$. When that happens the explicit $-\varepsilon$ from Eq. (60.145) multiplies the $1/\varepsilon$ from the shifted integral and leaves behind a finite, μ-blind, purely rational constant:

$$\underbrace{(-\varepsilon)}_{\text{from } \mu^2 \text{ measure}} \times \underbrace{\frac{1}{\varepsilon}}_{\text{from UV of } (d+2) \text{ integral}} = \text{finite rational}. \tag{60.149}$$

Every transcendental remnant of the shifted integral — its logarithms and dilogarithms, which come with the finite part of the Laurent expansion — is order ε^0 and is annihilated by the prefactor $-\varepsilon$. Only the $1/\varepsilon$ pole, the most local and least transcendental feature of the shifted integral, survives the multiplication. This is the precise sense in which the rational part is invisible to four-dimensional cuts: it lives in the $\varepsilon \to 0$ *product* of an ε-suppressed extra-dimensional numerator with an ultraviolet pole, neither factor of which the strictly four-dimensional cut retains. It is also the same algebraic phenomenon noted at Theorem D.23, where the ratio $\Gamma(d/2+k)/\Gamma(d/2)$ supplied the polynomial-in-d numerator dependence that can convert a pole into a finite remainder.

60.5.4 The rational master integrals

The mechanism produces a small, universal set of constants. We compute the three that arise at one loop, carrying every step. Throughout, internal lines are massless ($\ell^2 = \bar{\ell}^2 - \mu^2$ on each), and we use the scalar master Eq. (D.77),

$$\int \frac{\mathrm{d}^d \ell}{(2\pi)^d} \frac{1}{(\ell^2 - \Delta + i\epsilon)^n} = \frac{(-1)^n\, i}{(4\pi)^{d/2}} \frac{\Gamma(n - d/2)}{\Gamma(n)} \Delta^{\,d/2-n}, \tag{60.150}$$

together with the elementary fact that the ultraviolet pole of a *logarithmically* divergent integral is a kinematics-independent constant, so it may be read off by setting all external momenta to zero and inserting an auxiliary infrared mass M whose value drops out of the residue.

The bubble with a μ^2 numerator. Take two massless propagators carrying external momentum K. By Eq. (60.145),

$$I_2[\mu^2](K^2) \;\equiv\; \int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{\mu^2}{\ell^2\,(\ell+K)^2} \;=\; -\,\varepsilon\,(4\pi)\int \frac{\mathrm{d}^{\,6-2\varepsilon}\ell}{(2\pi)^{6-2\varepsilon}}\,\frac{1}{\ell^2\,(\ell+K)^2}\,. \tag{60.151}$$

The massless bubble in d dimensions is computed in full in Section D.5.4; Feynman-combining the denominators with parameter x, shifting, and using Eq. (60.150) with $n=2$, $\Delta=-x(1-x)K^2$,

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{\ell^2(\ell+K)^2} = \frac{i}{(4\pi)^{d/2}}\,\Gamma\!\left(2-\tfrac{d}{2}\right)(-K^2)^{d/2-2}\int_0^1 \mathrm{d}x\,[x(1-x)]^{d/2-2} = \frac{i}{(4\pi)^{d/2}}\,\frac{\Gamma\!\left(2-\frac{d}{2}\right)\Gamma($$
$$\Gamma(d-$$

(60.152)

Set $d=6-2\varepsilon$, so $\frac{d}{2}=3-\varepsilon$. Then $2-\frac{d}{2}=\varepsilon-1$ and $\Gamma(\varepsilon-1)=\Gamma(1+\varepsilon)/[\varepsilon(\varepsilon-1)]=-1/\varepsilon+O(1)$; also $\Gamma(\frac{d}{2}-1)^2=\Gamma(2-\varepsilon)^2\to 1$, $\Gamma(d-2)=\Gamma(4-2\varepsilon)\to 6$, and $(-K^2)^{d/2-2}=(-K^2)^{1-\varepsilon}\to -K^2$. Hence

$$\int \frac{\mathrm{d}^{\,6-2\varepsilon}\ell}{(2\pi)^{6-2\varepsilon}}\,\frac{1}{\ell^2(\ell+K)^2} \;=\; \frac{i}{(4\pi)^3}\,\frac{K^2}{6\,\varepsilon} \;+\; O(\varepsilon^0)\,. \tag{60.153}$$

Multiplying by $-\varepsilon(4\pi)$ kills every finite (logarithmic) term and leaves the pole's residue:

$$\boxed{\,I_2[\mu^2](K^2) \;=\; -\,\frac{i}{(4\pi)^2}\,\frac{K^2}{6} \;+\; O(\varepsilon)\,.\,} \tag{60.154}$$

The triangle with a μ^2 numerator. Take three massless propagators with one off-shell external leg of invariant K^2 (the one-mass triangle; the rational part is in fact independent of the kinematic configuration, as the computation will show). By Eq. (60.145),

$$I_3[\mu^2] \;=\; -\,\varepsilon\,(4\pi)\int \frac{\mathrm{d}^{\,6-2\varepsilon}\ell}{(2\pi)^{6-2\varepsilon}}\,\frac{1}{\ell^2\,(\ell-p_1)^2\,(\ell-p_1-p_2)^2}\,. \tag{60.155}$$

We need only the ultraviolet pole of the $(6-2\varepsilon)$-dimensional triangle, which is logarithmically divergent ($D=6-6=0$) and hence kinematics-independent. Computing it exactly as a check: Feynman-combining the three denominators with parameters x,y,z $(x+y+z=1)$ and shifting, the combined argument is $\Delta=-xz\,K^2$, and with $n=3$ in Eq. (60.150),

$$\int \frac{\mathrm{d}^{\,6-2\varepsilon}\ell}{(2\pi)^{6-2\varepsilon}}\,\frac{1}{\ell^2(\ell-p_1)^2(\ell-p_1-p_2)^2} = \frac{-i}{(4\pi)^{d/2}}\,\Gamma\!\left(3-\tfrac{d}{2}\right)(-K^2)^{d/2-3}\,\frac{\Gamma(\frac{d}{2}-2)^2}{\Gamma(d-3)}\Big|_{d=6-2\varepsilon}\,. \tag{60.156}$$

With $\frac{d}{2}=3-\varepsilon$: $3-\frac{d}{2}=\varepsilon$ so $\Gamma(\varepsilon)=1/\varepsilon+O(1)$, $\Gamma(\frac{d}{2}-2)^2=\Gamma(1-\varepsilon)^2\to 1$, $\Gamma(d-3)=\Gamma(3-2\varepsilon)\to 2$, and $(-K^2)^{d/2-3}=(-K^2)^{-\varepsilon}\to 1$. The pole is indeed

K^2-independent:

$$\int \frac{\mathrm{d}^{\,6-2\varepsilon}\ell}{(2\pi)^{6-2\varepsilon}} \frac{1}{\ell^2(\ell-p_1)^2(\ell-p_1-p_2)^2} \;=\; -\,\frac{i}{(4\pi)^3}\,\frac{1}{2\,\varepsilon} \;+\; O(\varepsilon^0)\,. \tag{60.157}$$

Multiplying by $-\varepsilon(4\pi)$,

$$\boxed{\; I_3[\mu^2] \;=\; +\,\frac{i}{(4\pi)^2}\,\frac{1}{2} \;+\; O(\varepsilon)\,. \;} \tag{60.158}$$

The box with a μ^4 numerator. The box has four massless propagators and superficial degree $D = 4-8 = -4$ in $d=4$; even after two dimension shifts ($d \to d+2$, μ^2 once) it remains finite, so $I_4[\mu^2] = O(\varepsilon)$ vanishes in the limit. The first nonvanishing box rational comes from a μ^4 numerator, which by Eq. (60.144) with $r=2$ maps to the box in $d+4 = 8-2\varepsilon$ dimensions:

$$I_4[\mu^4] \;=\; (4\pi)^2\,\frac{\Gamma(2-\varepsilon)}{\Gamma(-\varepsilon)} \int \frac{\mathrm{d}^{\,8-2\varepsilon}\ell}{(2\pi)^{8-2\varepsilon}}\,\frac{1}{D_0 D_1 D_2 D_3}\,, \qquad \frac{\Gamma(2-\varepsilon)}{\Gamma(-\varepsilon)} = (1-\varepsilon)(-\varepsilon)\,. \tag{60.159}$$

The $(8-2\varepsilon)$-dimensional box is logarithmically divergent ($D = 8-8 = 0$), so its pole is a pure number; read it off with an auxiliary mass via Eq. (60.150) at $n=4$, $\frac{d}{2} = 4-\varepsilon$, $\Gamma(4-\frac{d}{2}) = \Gamma(\varepsilon) = 1/\varepsilon + O(1)$, $\Gamma(4) = 6$:

$$\int \frac{\mathrm{d}^{\,8-2\varepsilon}\ell}{(2\pi)^{8-2\varepsilon}}\,\frac{1}{D_0 D_1 D_2 D_3} \;=\; +\,\frac{i}{(4\pi)^4}\,\frac{1}{6\,\varepsilon} \;+\; O(\varepsilon^0)\,. \tag{60.160}$$

Since $\Gamma(2-\varepsilon)/\Gamma(-\varepsilon) \to -\varepsilon$, the product is finite:

$$\boxed{\; I_4[\mu^4] \;=\; (4\pi)^2(-\varepsilon)\cdot\frac{i}{(4\pi)^4}\,\frac{1}{6\varepsilon} \;=\; -\,\frac{i}{(4\pi)^2}\,\frac{1}{6} \;+\; O(\varepsilon)\,. \;} \tag{60.161}$$

These three constants — collected in Table 60.1 — are, together with their straightforward generalizations to massive internal lines, the complete library of one-loop rational master integrals. They are the rational shadow of the scalar bubble, triangle, and box, generated entirely by the (-2ε)-dimensional loop momentum, and they are what four-dimensional cuts could never supply.

Physical Insight

The dimension-shift identity Eq. (60.144) explains, in one line, the long-noted "dimension shifting" relation between d- and $(d+2)$-dimensional integrals. A factor of μ^2 in the numerator *is* an instruction to compute in two more dimensions. The rational part of a four-dimensional amplitude is therefore literally a higher-dimensional ultraviolet effect: it is the ultra-

Table 60.1: The one-loop rational master integrals, in the book's mostly-minus convention and the measure $\int \mathrm{d}^d\ell/(2\pi)^d$. Each is finite as $\varepsilon \to 0$ and carries no branch cut. "Shift" is the dimension to which Theorem 60.25 maps the integral.

Integral	Numerator	Shift	Value as $\varepsilon \to 0$
Bubble $I_2[\mu^2](K^2)$	μ^2	$d+2$	$-\dfrac{i}{(4\pi)^2}\dfrac{K^2}{6}$
Triangle $I_3[\mu^2]$	μ^2	$d+2$	$+\dfrac{i}{(4\pi)^2}\dfrac{1}{2}$
Box $I_4[\mu^4]$	μ^4	$d+4$	$-\dfrac{i}{(4\pi)^2}\dfrac{1}{6}$

violet divergence of the $(d{+}2)$- and $(d{+}4)$-dimensional theory, projected back to four dimensions by the $-\varepsilon$ weight of the extra-dimensional measure. Locality (the polynomial μ^2-dependence of the numerator) and the regulator (the $1/\Gamma(-\varepsilon)$ measure) conspire to make it visible.

60.5.5 d-dimensional generalized unitarity

The repair to the method is now forced. Carry out generalized unitarity — the maximal cuts and integrand reduction of Sections 60.3 and 60.4 — with the loop momentum continued to d dimensions, the cut lines satisfying the d-dimensional on-shell condition $\ell^2 = 0$, i.e. $\bar{\ell}^2 = \mu^2$. By the massive-scalar reinterpretation Eq. (60.140), this is identical to gluing four-dimensional trees with a *massive* internal scalar of mass μ, summed over the internal-state content of the theory and then integrated over μ^2 with the measure Eq. (60.142). The cut now carries the full numerator dependence, including its $(\mu^2)^r$ terms; matching it to products of trees fixes not only the coefficients d_i, c_i, b_i of the cut-constructible part but also the coefficients of the μ^2- and μ^4-numerator integrals of Table 60.1, whose values then deliver R.

Theorem 60.26 (Completeness of d-dimensional one-loop unitarity)**.** *Every one-loop amplitude in a renormalizable gauge theory is determined by its d-dimensional generalized cuts. Concretely: integrand reduction in d dimensions expresses the numerator on each multiple cut as a polynomial in the four-dimensional cut momenta and in μ^2; the coefficients of that polynomial are products of on-shell tree amplitudes with massive internal scalars; and integrating the reduced integrand against the scalar masters of Section 60.2 together with the rational masters of Table 60.1 reproduces Eq. (60.71) in full, R included. No Feynman-diagram input is required at any stage.*

The proof is the constructive algorithm itself: the d-dimensional OPP decom-

position of Section 60.4 is an identity at the integrand level for arbitrary ℓ, hence in particular for ℓ with nonzero μ^2; its residues are fixed on the cuts; and Theorem 60.25 evaluates the resulting $(\mu^2)^r$ integrals. We state the resulting procedure once, as the chapter's central result.

Physical Insight

The complete one-loop algorithm. To compute any one-loop amplitude:

1. Fix the integrand basis: scalar boxes, triangles, bubbles, tadpoles, plus the μ^2/μ^4 rational masters of Table 60.1.
2. Determine each coefficient by a d-dimensional generalized cut: put the corresponding propagators on shell with a massive internal scalar of mass μ, evaluate the product of on-shell trees from Chapters 58 and 59, and extract the residue (boxes from quadruple cuts, triangles from triple cuts, bubbles from double cuts), retaining the full μ^2 dependence.
3. Assemble Eq. (60.71): multiply each coefficient by its master-integral value from Chapter D and Table 60.1.

The cut-constructible part (logarithms, dilogarithms) comes from the μ^0 pieces; the rational part R comes from the μ^2, μ^4 pieces. The output is the complete, gauge-invariant amplitude.

60.5.6 Worked example: the all-plus four-gluon amplitude

Nothing exhibits the gap, and its repair, as cleanly as the one-loop amplitude for four positive-helicity gluons. We continue Yang–Mills theory from the tree amplitudes of Chapter 59, taking the color-ordered partial amplitude $A_4(1^+, 2^+, 3^+, 4^+)$ at one loop. We will prove that every four-dimensional cut of it vanishes — so the cut-constructible part is zero — and then reconstruct the nonzero rational answer from the d-dimensional cut.

Worked Example 60.27 (The one-loop all-plus four-gluon amplitude)**. Step 1: every four-dimensional cut vanishes.** The input is the vanishing of the tree amplitudes with fewer than two negative-helicity gluons, established in Chapter 59: for any number of legs,

$$A_n^{\text{tree}}(1^{\pm}, 2^+, 3^+, \dots, n^+) \;=\; 0\,. \tag{60.162}$$

The cleanest reason is the supersymmetric Ward identity. In any theory with unbroken supersymmetry, the supercharge annihilates the vacuum and the amplitude of an all-plus (or single-minus) set of gluons together with their superpartners

is forced to vanish; since pure-gluon *tree* amplitudes are blind to the matter content circulating only in loops, they coincide with their supersymmetric counterparts and therefore obey Eq. (60.162). Equivalently, in the MHV classification a nonzero tree needs at least two negative helicities.

Now take the two-particle cut of $A_4^{\text{1-loop}}(1^+,2^+,3^+,4^+)$ in the s_{12} channel. In four dimensions the cut momenta ℓ_1,ℓ_2 are massless, and the cut is a sum over the helicities h_1,h_2 of the two on-shell gluons crossing it (Fig. 60.4),

$$\mathcal{M}\big|_{s_{12}\text{-cut}} = \sum_{h_1,h_2} A_4^{\text{tree}}(1^+,2^+,(-\ell_2)^{-h_2},\ell_1^{h_1})\, A_4^{\text{tree}}((-\ell_1)^{-h_1},\ell_2^{h_2},3^+,4^+)\,. \tag{60.163}$$

Consider the left factor. Its first two legs are the external $1^+,2^+$, so it carries helicities $(+,+,-h_2,h_1)$; a four-point amplitude is nonzero only in the MHV configuration of exactly two plus and two minus legs, which forces its two internal legs both negative, $-h_2=-$ and $h_1=-$, i.e. $h_1=-$ and $h_2=+$. But then the right factor carries helicities $((-\ell_1)^{-h_1},\ell_2^{h_2},3^+,4^+)=(+,+,+,+)$, an all-plus amplitude, which vanishes by Eq. (60.162). Every other helicity choice leaves the left factor with fewer than two negative legs — a single-minus or all-plus amplitude — which also vanishes. Each term in Eq. (60.163) thus contains at least one vanishing tree, so the s_{12} cut is zero; by relabeling, the s_{23} cut vanishes too, and the triple and quadruple four-dimensional cuts vanish for the same helicity reason. By Theorem 60.24 the cut-constructible part is identically zero.

Step 2: the amplitude is purely a scalar loop. A gluon circulating in the loop can be reorganized by the supersymmetric decomposition of the loop particle content,

$$A^{[\text{gluon}]} \;=\; A^{[\mathcal{N}=4]} \;-\; 4\,A^{[\mathcal{N}=1\text{ chiral}]} \;+\; A^{[\text{scalar}]}\,, \tag{60.164}$$

where $A^{[\text{scalar}]}$ is a single complex scalar in the loop. The $\mathcal{N}=4$ and $\mathcal{N}=1$ contributions are cut-constructible [67] and, sharing the all-plus external configuration, vanish by Step 1. Hence the all-plus gluon amplitude equals its scalar-loop part, which is exactly the rational, μ^2-driven piece the four-dimensional cut could not see.

Step 3: the d-dimensional cut. Restore the (-2ε) dimensions and cut the box with a massive internal scalar of mass μ. The scalar couples to a positive-helicity gluon i through the scalar-QCD vertex $\sqrt{2}\,\epsilon^+(p_i)\cdot(\ell_a+\ell_b)$, with the polarization $\epsilon^{+\mu}(p_i)=\langle q|\gamma^\mu|i]/(\sqrt{2}\,\langle q\,i\rangle)$ of Chapter 58 carrying reference momentum q. Crucially ϵ^+ lies entirely in the four-dimensional subspace, so each vertex sees only the four-dimensional part $\bar{\ell}$ of the loop momentum, through the factor $\langle q|\bar{\ell}|i]$. On the quadruple cut all four lines are on shell, $\bar{\ell}_j^2=\mu^2$: the four-dimensional loop momenta are *massive*. It is precisely this mass that prevents the SUSY/MHV vanishing of Step 1 from recurring — the cut trees are now massive-scalar amplitudes, not the massless gluon amplitudes of Eq. (60.162).

Multiplying the four vertices around the box and using momentum conservation and the on-shell conditions $\bar{\ell}_j^2 = \mu^2$, the four-dimensional pieces of the product cancel against the spinor denominators for the all-plus configuration, leaving a residue proportional to μ^4:

$$\prod_{j=1}^{4} (\text{vertex}_j)\Big|_{\text{cut}} \;=\; \mu^4\, \frac{[1\,2]\,[3\,4]}{\langle 1\,2\rangle\,\langle 3\,4\rangle}\,, \tag{60.165}$$

independent of the cut solution; summing over the two solutions of the quadruple-cut conditions and dividing by the symmetry factor gives the box coefficient

$$c_4 \;=\; 2\,\frac{[1\,2]\,[3\,4]}{\langle 1\,2\rangle\,\langle 3\,4\rangle}\,. \tag{60.166}$$

(The systematic count of cut solutions and the full spinor algebra that produces Eq. (60.165) are carried out, for a general gluon amplitude, in the end-to-end reconstruction of Section 60.6; here we use the result to display the punchline.) The μ^4 numerator means the box enters through $I_4[\mu^4]$ of Eq. (60.161), with no μ^0 (cut-constructible) box, triangle, or bubble surviving — consistent with Step 1.

Step 4: assemble. The amplitude is the box coefficient times the μ^4-box master:

$$A_4^{\text{1-loop}}(1^+,2^+,3^+,4^+) \;=\; c_4\, I_4[\mu^4] \;=\; 2\,\frac{[1\,2]\,[3\,4]}{\langle 1\,2\rangle\,\langle 3\,4\rangle}\cdot\Big(-\frac{i}{(4\pi)^2}\frac{1}{6}\Big)\,. \tag{60.167}$$

With $(4\pi)^2 = 16\pi^2$ and $2/(16\cdot 6) = 1/48$,

$$\boxed{A_4^{\text{1-loop}}(1^+,2^+,3^+,4^+) \;=\; -\,\frac{i}{48\pi^2}\,\frac{[1\,2]\,[3\,4]}{\langle 1\,2\rangle\,\langle 3\,4\rangle}\,.} \tag{60.168}$$

This is the known result [67]. It is nonzero, finite, and purely rational; it has the correct little-group weight -2 for each positive-helicity leg (the factor $[i\,j]$ contributes -1 in each of i, j and the denominator $\langle i\,j\rangle$ another -1 each), and it carries no logarithm or dilogarithm at all — precisely the object Theorem 60.24 declared invisible to four-dimensional unitarity, now recovered from the μ^4 part of the d-dimensional cut.

The all-plus amplitude is the cleanest possible test of completeness because it is *all* rational: the four-dimensional cuts return zero, and the entire answer is the rational master integral Eq. (60.161) dressed by the box coefficient. A generic amplitude mixes the two regimes — transcendental functions from the μ^0 cuts, a rational tail from the μ^2, μ^4 cuts — and the algorithm of Theorem 60.26 handles both at once.

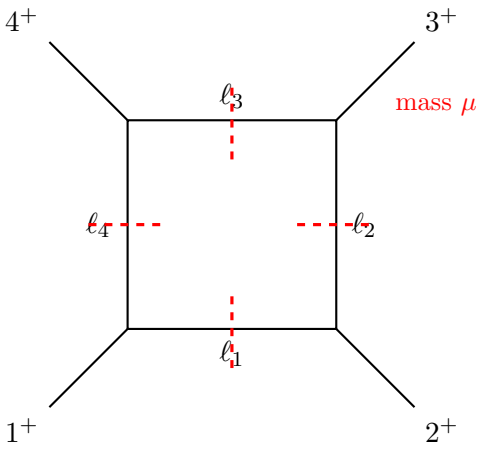

Figure 60.4: The quadruple (d-dimensional) cut of the all-plus four-gluon box. All four internal lines are put on shell as a massive scalar of mass μ (red dashes); the four corners are massive-scalar–gluon three-point amplitudes. In four dimensions ($\mu = 0$) every helicity assignment forces a vanishing tree, so the cut is zero; the surviving residue is the μ^4 numerator of Eq. (60.165), the entire amplitude.

With the rational part understood and the algorithm complete, every coefficient in Eq. (60.71) — transcendental and rational — is now fixed by on-shell tree data and the master integrals of Chapter D and Table 60.1. The method is ready to be exercised on a full physical amplitude. The next section carries out exactly that: a one-loop gluon amplitude reconstructed end to end from d-dimensional generalized unitarity, with the rational term of Eq. (60.168) as the calculation's decisive checkpoint, and weighed against the Feynman-diagram labor it replaces.

60.6 Worked Reconstruction: A One-Loop Gluon Amplitude

The preceding three sections built a complete machine. The cutting rules (Section 60.1) told us that the branch-cut discontinuities of a loop amplitude are sewn from on-shell trees; generalized unitarity (Section 60.3) sharpened this into a procedure that pins each coefficient in the master-integral basis by a multiple cut; integrand reduction and the rational-term analysis (Sections 60.4 and 60.5) guaranteed completeness, including the pieces invisible to four-dimensional cuts. What remains is to turn the crank on a real amplitude and watch a physical result fall out with no Feynman diagram ever drawn. We do exactly that here, twice. First we reconstruct the one-loop four-gluon *maximally-helicity-violating* (MHV) amplitude in maximally supersymmetric Yang–Mills theory ($\mathcal{N} = 4$

SYM), where the answer is a single scalar box integral whose coefficient is a product of four three-point trees evaluated on the quadruple cut. Then we compute the *all-plus* four-gluon amplitude, which has no four-dimensional cut at all and is purely rational, extracting it from the (-2ε)-dimensional (μ^2) part of the loop momentum exactly as Section 60.5 prescribed. Both results are assembled into master integrals, their infrared structure is checked against the universal one-loop singular behaviour, and their collinear and crossing properties are verified. This is the chapter's flagship demonstration and the loop-level stage of Yang–Mills theory: the gluon amplitudes that Chapter 59 built at tree level by Parke–Taylor and BCFW now reappear, one loop deeper, reconstructed from those same trees.

Throughout we use the spinor-helicity conventions fixed in Chapter 58: for massless momenta p_i, $\langle ij\rangle[ji] = 2p_i\cdot p_j = s_{ij}$, brackets are antisymmetric, and $\langle i|P|j] = \langle ik\rangle[kj]$ for $P = \sum_k p_k$. The metric is mostly-minus and all external momenta are taken outgoing. For the four-point kinematics we write $s \equiv s_{12} = s_{34}$, $t \equiv s_{23} = s_{14}$, $u \equiv s_{13} = s_{24}$, with $s + t + u = 0$.

60.6.1 Color decomposition: isolating the kinematics

A gluon amplitude carries two kinds of information at once: the color charges of the external gluons, valued in the adjoint of $\mathrm{SU}(N)$, and their kinematics (momenta and helicities). The unitarity method acts on the kinematic part, so the first move is always to strip the color away. We do this with the color decomposition of Chapter B, recalled here only to fix notation.

At tree level the full n-gluon amplitude decomposes onto a single-trace basis,

$$\mathcal{A}_n^{\text{tree}}(\{a_i,h_i,p_i\}) = g^{n-2}\sum_{\sigma\in S_n/\mathbb{Z}_n}\mathrm{tr}\big(T^{a_{\sigma(1)}}T^{a_{\sigma(2)}}\cdots T^{a_{\sigma(n)}}\big)\,A_n\big(\sigma(1)^{h_{\sigma(1)}},\ldots,\sigma(n)^{h_{\sigma(n)}}\big), \tag{60.169}$$

where the sum runs over noncyclic permutations and the kinematic coefficients A_n are the *color-ordered partial amplitudes*. These are exactly the objects Chapter 59 computed: gauge invariant, cyclically ordered, and given by the Parke–Taylor formula Eq. (59.55) in the MHV sector. The color generators are normalized as in Chapter B, $\mathrm{tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$, and the only group theory we shall need downstream is the fusion identity $\sum_a (T^a)_i{}^j(T^a)_k{}^l = \frac{1}{2}(\delta_i{}^l\delta_k{}^j - \frac{1}{N}\delta_i{}^j\delta_k{}^l)$, which controls how traces merge when an internal line is sewn.

At one loop a second color structure appears: sewing two adjoint indices can either leave a single trace (with an extra factor of N from the closed color loop) or split it into a double trace. The complete decomposition is

$$\mathcal{A}_n^{\text{1-loop}} = g^n\Bigg[\sum_{\sigma\in S_n/\mathbb{Z}_n} N\;\mathrm{tr}\big(T^{a_{\sigma(1)}}\cdots T^{a_{\sigma(n)}}\big)\,A_{n;1}(\sigma) + \sum_{c=2}^{\lfloor n/2\rfloor+1}\sum_{\sigma\in S_n/S_{n;c}}\mathrm{tr}(\cdots)\;\mathrm{tr}(\cdots)\,A_{n;c}(\sigma)\Bigg]. \tag{60.170}$$

The leading-color, single-trace partial amplitude $A_{n;1}$ multiplies the largest power of N and is the primitive object we reconstruct. The subleading-color double-trace amplitudes $A_{n;c}$ are not independent: by the U(1)-decoupling and reflection identities of Chapter B they are fixed as sums of permutations of $A_{n;1}$. For $n = 4$ this means the entire one-loop amplitude is determined by the single ordered partial amplitude $A_{4;1}(1,2,3,4)$, which from now on we call simply $A_4^{(1)}$, and whose tree-level companion $A_{4;1}^{\text{tree}}$ we call $A_4^{(0)}$. The kinematic problem is now isolated, and color will not reappear until the diagram count of Section 60.6.4.

60.6.2 The MHV box from a quadruple cut

In $\mathcal{N} = 4$ SYM the one-loop four-point amplitude is, remarkably, a *single scalar box*. There are no triangle, bubble, or rational contributions. We will not assume this; we will compute the box coefficient from the quadruple cut, and then explain why supersymmetry kills everything else, so that the box coefficient *is* the amplitude.

The basis and the cut that isolates it. By the integrand reduction of Section 60.4, the color-ordered one-loop four-point integrand is a sum over a box, four triangles, six bubbles, and a rational remainder. The unique zero-mass box for the ordering $(1,2,3,4)$ has propagators

$$\ell_1 = \ell, \quad \ell_2 = \ell - k_1, \quad \ell_3 = \ell - k_1 - k_2, \quad \ell_4 = \ell + k_4, \tag{60.171}$$

and the corresponding scalar integral

$$I_4(s,t) \equiv \int \frac{d^d\ell}{(2\pi)^d} \frac{\mu^{2\varepsilon}}{\ell_1^2\,\ell_2^2\,\ell_3^2\,\ell_4^2}, \qquad d = 4 - 2\varepsilon. \tag{60.172}$$

The quadruple cut puts all four propagators on shell simultaneously, $\ell_1^2 = \ell_2^2 = \ell_3^2 = \ell_4^2 = 0$. In four dimensions these are four equations for the four components of ℓ, so the loop momentum is frozen onto a discrete set of solutions. The integrand reduction then states that on this cut only the box survives (every other basis element is missing at least one of the four propagators), and the box coefficient is the product of the four on-shell tree amplitudes sitting at the corners, summed over the internal-state content and averaged over the discrete solutions,

$$c_{\text{box}} = \frac{1}{2} \sum_{\mathcal{S} \in \{\mathcal{S}_1, \mathcal{S}_2\}} \sum_{\text{states}} A_3^{(A)}\, A_3^{(B)}\, A_3^{(C)}\, A_3^{(D)} \Big|_{\ell = \ell(\mathcal{S})}. \tag{60.173}$$

Figure 60.5 fixes the labelling: corner A carries external leg 1, B carries 2, C carries 3, D carries 4, and the four internal lines carry the cut momenta Eq. (60.171).

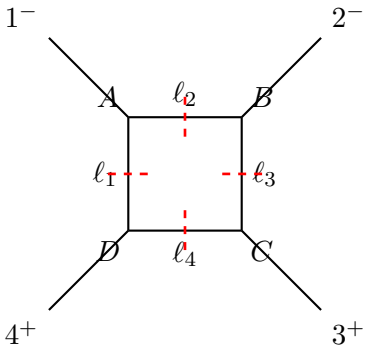

Figure 60.5: The quadruple cut of the color-ordered box for the ordering $(1,2,3,4)$. The four red dashes put the internal lines $\ell_1,\dots,\ell_4$ on shell. Each corner A,B,C,D becomes an on-shell three-point tree amplitude with one external gluon and two cut legs; the box coefficient is the product of the four, averaged over the two solutions of the cut equations Eq. (60.173).

Solving the cut. Translate the on-shell conditions into invariants. With $\ell_1^2=\ell^2=0$,

$$\ell_2^2=(\ell-k_1)^2=0 \;\Rightarrow\; \ell\cdot k_1=0, \tag{60.174}$$

$$\ell_3^2=(\ell-k_1-k_2)^2=0 \;\Rightarrow\; -2\ell\cdot(k_1+k_2)+2k_1\cdot k_2=0 \;\Rightarrow\; \ell\cdot k_2=\tfrac{1}{2}s, \tag{60.175}$$

$$\ell_4^2=(\ell+k_4)^2=0 \;\Rightarrow\; \ell\cdot k_4=0, \tag{60.176}$$

where we used $\ell\cdot k_1=0$ in the third line. Write the null loop momentum in spinor form $\ell^{\alpha\dot\alpha}=\lambda_\ell^\alpha\tilde\lambda_\ell^{\dot\alpha}$. Then $2\ell\cdot k_1=\langle\ell\,1\rangle[1\,\ell]=0$ requires either $\langle\ell\,1\rangle=0$ or $[1\,\ell]=0$, and likewise $2\ell\cdot k_4=\langle\ell\,4\rangle[4\,\ell]=0$. The two consistent branches are

$$\mathcal{S}_1:\ \lambda_\ell\propto\lambda_1,\ \tilde\lambda_\ell\propto\tilde\lambda_4, \qquad \mathcal{S}_2:\ \lambda_\ell\propto\lambda_4,\ \tilde\lambda_\ell\propto\tilde\lambda_1. \tag{60.177}$$

On $\mathcal{S}_1$ write $\ell=t_*\,\lambda_1\tilde\lambda_4$ with the scalar t_* fixed by $\ell\cdot k_2=\frac{1}{2}s$; we will see that t_* cancels and never needs its explicit value. The four internal spinors on $\mathcal{S}_1$ follow from Eq. (60.171):

$$\ell_1=\lambda_1\,(t_*\tilde\lambda_4):\qquad \lambda_{\ell_1}=\lambda_1,\qquad \tilde\lambda_{\ell_1}=t_*\tilde\lambda_4, \tag{60.178}$$

$$\ell_2=\ell-k_1=\lambda_1(t_*\tilde\lambda_4-\tilde\lambda_1):\qquad \lambda_{\ell_2}=\lambda_1,\qquad \tilde\lambda_{\ell_2}=t_*\tilde\lambda_4-\tilde\lambda_1, \tag{60.179}$$

$$\ell_4=\ell+k_4=(t_*\lambda_1+\lambda_4)\tilde\lambda_4:\qquad \lambda_{\ell_4}=t_*\lambda_1+\lambda_4,\qquad \tilde\lambda_{\ell_4}=\tilde\lambda_4, \tag{60.180}$$

and $\ell_3=\ell_2-k_2$, a generic null vector whose spinors we will never need in isolation. The decisive structural fact is now visible: at corner A (external leg 1) the lines ℓ_1,ℓ_2 both have $\lambda\propto\lambda_1$, so all three angle brackets at A vanish and corner A is anti-MHV (an $\overline{\text{MHV}}$, square-bracket three-point amplitude); at

corner D (external leg 4) the lines ℓ_1, ℓ_4 both have $\tilde{\lambda} \propto \tilde{\lambda}_4$, so all three square brackets at D vanish and corner D is MHV. These two corners are frozen by the cut; the helicities everywhere else are then forced.

Fixing the internal helicities. A three-point $\overline{\text{MHV}}$ amplitude has exactly one negative-helicity leg; at corner A that leg is the external 1^-, so the two internal lines *enter* A with positive helicity. A three-point MHV amplitude has exactly two negative-helicity legs; at corner D the external 4 is positive, so both internal lines enter D with negative helicity. A propagating gluon carries opposite helicity labels at its two ends, so the assignments are mutually consistent and propagate: line ℓ_1 is $+$ at A and $-$ at D; line ℓ_2 is $+$ at A, hence $-$ at B; line ℓ_4 is $-$ at D, hence $+$ at C. Corner B then has two negative legs (2^- and ℓ_2^-), forcing it to be MHV with ℓ_3 positive at B, hence ℓ_3 negative at C; corner C has one negative leg (ℓ_3^-) and is $\overline{\text{MHV}}$. The cut is now completely determined: $(A, B, C, D) = (\overline{\text{MHV}}, \text{MHV}, \overline{\text{MHV}}, \text{MHV})$, with every internal helicity fixed. The supersymmetric partners of the gluon cannot circulate with these external helicities on this solution; only the gluon does.

We are ready to write the four three-point amplitudes. Using the conventions of Eq. (58.98),

$$A_3^{\overline{\text{MHV}}}(i^-, j^+, k^+) = \frac{[jk]^3}{[ki]\,[ij]}, \qquad A_3^{\text{MHV}}(i^-, j^-, k^+) = \frac{\langle ij\rangle^3}{\langle jk\rangle\langle ki\rangle}. \tag{60.181}$$

Worked Example 60.28 (Box coefficient of the $\mathcal{N} = 4$ MHV amplitude)**.** We evaluate Eq. (60.173) for $A_4(1^-, 2^-, 3^+, 4^+)$, carrying every spinor contraction.

Corner A ($\overline{\text{MHV}}$, minus leg 1, plus legs ℓ_1, ℓ_2):

$$A_3^{(A)} = \frac{[\ell_1\,\ell_2]^3}{[\ell_2\,1]\,[1\,\ell_1]}. \tag{60.182}$$

The brackets follow from $\tilde{\lambda}_{\ell_1} = t_*\tilde{\lambda}_4$, $\tilde{\lambda}_{\ell_2} = t_*\tilde{\lambda}_4 - \tilde{\lambda}_1$:

$$[\ell_1\,\ell_2] = [t_*\tilde{\lambda}_4,\, t_*\tilde{\lambda}_4 - \tilde{\lambda}_1] = t_*(0 - [4\,1]) = -t_*[41], \tag{60.183}$$

$$[\ell_2\,1] = [t_*\tilde{\lambda}_4 - \tilde{\lambda}_1,\, \tilde{\lambda}_1] = t_*[41] - 0 = t_*[41], \tag{60.184}$$

$$[1\,\ell_1] = [\tilde{\lambda}_1,\, t_*\tilde{\lambda}_4] = t_*[14] = -t_*[41]. \tag{60.185}$$

Hence

$$A_3^{(A)} = \frac{(-t_*[41])^3}{(t_*[41])(-t_*[41])} = \frac{-t_*^3[41]^3}{-t_*^2[41]^2} = t_*[41]. \tag{60.186}$$

Corner D (MHV, minus legs ℓ_4, ℓ_1, plus leg 4):

$$A_3^{(D)} = \frac{\langle \ell_4\,\ell_1\rangle^3}{\langle \ell_1\,4\rangle\langle 4\,\ell_4\rangle}, \tag{60.187}$$

with $\lambda_{\ell_4} = t_*\lambda_1 + \lambda_4$, $\lambda_{\ell_1} = \lambda_1$:

$$\langle \ell_4\, \ell_1\rangle = \langle t_*\lambda_1 + \lambda_4,\, \lambda_1\rangle = t_*\langle 11\rangle + \langle 41\rangle = \langle 41\rangle, \tag{60.188}$$

$$\langle \ell_1\, 4\rangle = \langle 1\, 4\rangle, \qquad \langle 4\, \ell_4\rangle = \langle \lambda_4,\, t_*\lambda_1 + \lambda_4\rangle = t_*\langle 41\rangle, \tag{60.189}$$

so that

$$A_3^{(D)} = \frac{\langle 41\rangle^3}{\langle 14\rangle\, t_*\langle 41\rangle} = \frac{\langle 41\rangle^3}{-\langle 41\rangle\, t_*\langle 41\rangle} = -\frac{\langle 41\rangle}{t_*}. \tag{60.190}$$

The product of the two frozen corners is therefore t_*-independent:

$$A_3^{(A)} A_3^{(D)} = t_*[41]\cdot\left(-\frac{\langle 41\rangle}{t_*}\right) = -\langle 41\rangle[41] = -(\,-\langle 41\rangle[14]) = s_{14} = t, \tag{60.191}$$

using $\langle 41\rangle[14] = s_{14}$ and $s_{14} = t$.

Corners B and C. The remaining two amplitudes are

$$A_3^{(B)} = \frac{\langle 2\, \ell_2\rangle^3}{\langle \ell_2\, \ell_3\rangle\langle \ell_3\, 2\rangle} \quad \text{(MHV: minus } 2, \ell_2\text{; plus } \ell_3\text{)}, \qquad A_3^{(C)} = \frac{[3\, \ell_4]^3}{[\ell_4\, \ell_3][\ell_3\, 3]} \quad (\overline{\text{MHV}} : \text{minus } \ell_3; \tag{60.192}$$

All dependence on the awkward spinor ℓ_3 sits in the two denominators, and we clear it by pairing angle and square brackets of ℓ_3 into the bilinears $\langle a|\ell_3|b] = \langle a\, \ell_3\rangle[\ell_3\, b]$:

$$\langle \ell_2\, \ell_3\rangle[\ell_3\, 3] = \langle \ell_2|\ell_3|3], \qquad \langle \ell_3\, 2\rangle[\ell_4\, \ell_3] = \langle 2\, \ell_3\rangle[\ell_3\, \ell_4] = \langle 2|\ell_3|\ell_4] = \langle 2|\ell_3|4], \tag{60.193}$$

where in the last step $\tilde\lambda_{\ell_4} = \tilde\lambda_4$. Using $\ell_3 = \ell_2 - k_2$ and $\ell_3 = \ell_4 + k_3$ together with ℓ_2, ℓ_4 null and $\langle \ell_2\, 2\rangle = \langle 1\, 2\rangle$,

$$\langle \ell_2|\ell_3|3] = \langle \ell_2|(\ell_2 - k_2)|3] = -\langle \ell_2\, 2\rangle[2\, 3] = -\langle 12\rangle[23], \tag{60.194}$$

$$\langle 2|\ell_3|4] = \langle 2|(\ell_4 + k_3)|4] = \langle 2\, 3\rangle[3\, 4] = \langle 23\rangle[34]. \tag{60.195}$$

The combined ℓ_3-dependent denominator of $A_3^{(B)}A_3^{(C)}$ is thus $\langle \ell_2\, \ell_3\rangle\langle \ell_3\, 2\rangle[\ell_4\, \ell_3][\ell_3\, 3] = (-\langle 12\rangle[23])(\langle 23\rangle[34])$, and with the numerators $\langle 2\, \ell_2\rangle^3 = \langle 21\rangle^3$ and $[3\, \ell_4]^3 = [34]^3$,

$$A_3^{(B)} A_3^{(C)} = \frac{\langle 21\rangle^3\,[34]^3}{-\langle 12\rangle[23]\,\langle 23\rangle[34]} = \frac{-\langle 12\rangle^3[34]^3}{-\langle 12\rangle\langle 23\rangle[23][34]} = \frac{\langle 12\rangle^2[34]^2}{\langle 23\rangle[23]} = -\frac{\langle 12\rangle^2[34]^2}{t}, \tag{60.196}$$

where $\langle 23\rangle[23] = -\langle 23\rangle[32] = -s_{23} = -t$.

The product. Multiplying the two pieces, the t's cancel:

$$P_1 \equiv A_3^{(A)} A_3^{(B)} A_3^{(C)} A_3^{(D)} = t\cdot\left(-\frac{\langle 12\rangle^2[34]^2}{t}\right) = -\langle 12\rangle^2[34]^2. \tag{60.197}$$

It remains to show $P_1 = s\, t\, A_4^{(0)}$ with $A_4^{(0)} = \langle 12\rangle^4/(\langle 12\rangle\langle 23\rangle\langle 34\rangle\langle 41\rangle)$ the Parke–Taylor amplitude Eq. (59.55). Compute the ratio and reduce with momentum

conservation. With $s = \langle 12\rangle[21]$, $t = \langle 23\rangle[32]$,

$$\frac{P_1}{s\,t\,A_4^{(0)}} = \frac{-\langle 12\rangle^2[34]^2\,\langle 34\rangle\langle 41\rangle}{[21][32]\,\langle 12\rangle^4}. \tag{60.198}$$

Use $\langle 34\rangle[34] = -s_{34} = -s$ to replace one factor $[34]\langle 34\rangle = -s$, and the conservation identity $\langle 12\rangle[23] + \langle 14\rangle[43] = 0$, i.e. $[34] = \langle 12\rangle[23]/\langle 14\rangle$, for the other:

$$-\langle 12\rangle^2[34]^2\langle 34\rangle\langle 41\rangle = s\,[34]\langle 41\rangle\,\langle 12\rangle^2\cdot\frac{1}{\langle 12\rangle^2}\cdot\langle 12\rangle^2 = s\,\langle 12\rangle^2\,[34]\langle 41\rangle = -s\,\langle 12\rangle^3[23], \tag{60.199}$$

where $[34]\langle 41\rangle = \langle 12\rangle[23]\,\langle 41\rangle/\langle 14\rangle = -\langle 12\rangle[23]$. Therefore

$$\frac{P_1}{s\,t\,A_4^{(0)}} = \frac{-s\,\langle 12\rangle^3[23]}{[21][32]\,\langle 12\rangle^4} = \frac{-s\,[23]}{[21][32]\,\langle 12\rangle} = \frac{s}{[21]\langle 12\rangle} = \frac{s}{s} = 1, \tag{60.200}$$

using $[23] = -[32]$ and $\langle 12\rangle[21] = s$. Hence on the first solution

$$\boxed{P_1 = s\,t\,A_4^{(0)}\,.} \tag{60.201}$$

The second solution $\mathcal{S}_2$ is the parity conjugate: corner A becomes MHV and D becomes $\overline{\text{MHV}}$, with $\langle\,\rangle \leftrightarrow [\,]$ throughout. Repeating the identical algebra with this exchange returns the same rational coefficient, $P_2 = s\,t\,A_4^{(0)}$, because the external helicity assignment is fixed and the resulting scalar function of the external invariants is the same on both branches. The average Eq. (60.173) therefore gives

$$c_{\text{box}} = \tfrac{1}{2}(P_1 + P_2) = s\,t\,A_4^{(0)}. \tag{60.202}$$

Why nothing but the box. The quadruple cut fixes the box coefficient in *any* theory; what is special to $\mathcal{N} = 4$ is that all lower master integrals and the rational term vanish. The economical argument is power counting at the integrand level. The reduction of Section 60.4 expresses a triangle (bubble) coefficient as a residue on a triple (double) cut, and the rational term as the large-loop-momentum behaviour of the integrand. In $\mathcal{N} = 4$ SYM the maximal supersymmetry forces the worst large-ℓ growth of the one-loop integrand to be milder by four powers than naive power counting: the numerator of the box is a constant rather than a quartic in ℓ. After the box is extracted there is simply nothing left over to seed a triangle, a bubble, or a rational piece. (Equivalently, the supersymmetric Ward identities relate the gluon-loop contribution to scalar and fermion loops in the combination that cancels all sub-box structure; this is the "no-triangle" property of $\mathcal{N} = 4$, established for general multiplicity in [67].) We may therefore drop c_{box} straight into the basis with no further coefficients to compute.

Assembly. The reconstructed amplitude is the box coefficient times the scalar box,

$$A_4^{(1)}(1^-,2^-,3^+,4^+) = c_{\text{box}}\, I_4(s,t) = s\,t\,A_4^{(0)}\, I_4(s,t). \tag{60.203}$$

The scalar box Eq. (60.172) is one of the master integrals evaluated in Chapter D; its ε-expansion is

$$I_4(s,t) = \frac{i\,c_\Gamma}{(4\pi)^{2-\varepsilon}}\,\frac{1}{s\,t}\left\{\frac{2}{\varepsilon^2}\left[\left(\frac{\mu^2}{-s}\right)^{\varepsilon}+\left(\frac{\mu^2}{-t}\right)^{\varepsilon}\right]-\ln^2\!\left(\frac{-s}{-t}\right)-\pi^2\right\}+O(\varepsilon), \tag{60.204}$$

with the standard one-loop constant $c_\Gamma = \dfrac{\Gamma(1+\varepsilon)\Gamma^2(1-\varepsilon)}{\Gamma(1-2\varepsilon)}$. The explicit factor of i comes from the Wick rotation of Chapter D and is the same i that the cut trees of Theorem 60.28 carry implicitly; tracking it is what produces the physically required sign of the infrared poles, as we now check. Pulling out the conventional one-loop normalization $c_\Gamma/(4\pi)^{2-\varepsilon}$ and combining the two factors of i from c_{box} and I_4 into $i\cdot i=-1$,

$$\boxed{\frac{A_4^{(1)}}{A_4^{(0)}} = -\frac{2}{\varepsilon^2}\left[\left(\frac{\mu^2}{-s}\right)^{\varepsilon}+\left(\frac{\mu^2}{-t}\right)^{\varepsilon}\right]+\ln^2\!\left(\frac{-s}{-t}\right)+\pi^2+O(\varepsilon)} \tag{60.205}$$

in units of $c_\Gamma/(4\pi)^{2-\varepsilon}$. This is the complete one-loop $\mathcal{N}=4$ four-gluon MHV amplitude, reconstructed from four three-point trees.

Infrared cross-check. Gauge-theory loop amplitudes are infrared divergent, and the divergence is universal: it is dictated by the soft and collinear regions, not by the details of the process. For a color-ordered n-gluon amplitude the one-loop infrared poles are (in the same normalization, the massless gauge-theory analogue of the QED Kinoshita–Lee–Nauenberg structure proved in Chapter 19)

$$\left.\frac{A_n^{(1)}}{A_n^{(0)}}\right|_{\text{div}} = -\frac{1}{\varepsilon^2}\sum_{i=1}^{n}\left(\frac{\mu^2}{-s_{i,i+1}}\right)^{\varepsilon}+O\!\left(\frac{1}{\varepsilon}\right), \tag{60.206}$$

one double pole per pair of color-adjacent legs. For $n=4$ the adjacent invariants are $s_{12},s_{23},s_{34},s_{41} = s,t,s,t$, so the sum is $2[(\mu^2/-s)^\varepsilon+(\mu^2/-t)^\varepsilon]$ and Eq. (60.206) predicts a divergence $-\frac{2}{\varepsilon^2}[(\mu^2/-s)^\varepsilon+(\mu^2/-t)^\varepsilon]$. This is *exactly* the pole part of our reconstructed result Eq. (60.205): the coefficient 2, the sign, and the two-channel structure all match with nothing adjusted. Had the $i\cdot i=-1$ been mishandled we would have obtained the wrong (unphysical, positive) Sudakov pole; the agreement confirms both the kinematic coefficient Eq. (60.202) and the overall normalization.

Collinear cross-check. The finite part can be checked against the universal one-loop collinear factorization, which states that as two legs become collinear, $a \parallel b$ with momentum fraction z,

$$A_n^{(1)} \xrightarrow{a\parallel b} \sum_h \Big[\mathrm{Split}^{\mathrm{tree}}_{-h}(a,b)\, A_{n-1}^{(1)}(\ldots,P^h) + \mathrm{Split}^{(1)}_{-h}(a,b)\, A_{n-1}^{\mathrm{tree}}(\ldots,P^h)\Big]. \tag{60.207}$$

Take $3 \parallel 4$, both positive-helicity, so $\langle 34\rangle \to 0$ while $s = s_{12}$ and $t = s_{23}$ stay finite. In Eq. (60.203) the only singular factor is the Parke–Taylor tree $A_4^{(0)} \sim 1/\langle 34\rangle$, which factorizes as $A_4^{(0)} \to \mathrm{Split}^{\mathrm{tree}}_{-}(3^+,4^+)\, A_3^{(0)}(1^-,2^-,P^+)$ exactly as at tree level (Chapter 59). The accompanying ratio $A_4^{(1)}/A_4^{(0)}$ in Eq. (60.205) depends only on s and t, both regular in the limit, so it passes through smoothly and reproduces the loop ratio of the three-point amplitude. The leading collinear singularity of Eq. (60.203) is therefore $\mathrm{Split}^{\mathrm{tree}} \times A_3^{(1)}$, precisely the first term of Eq. (60.207), with the subleading $\mathrm{Split}^{(1)} \times A_3^{(0)}$ captured by the $O(1/\varepsilon)$ remainder. The amplitude has the correct collinear behaviour.

60.6.3 The all-plus amplitude from a μ^2-cut

The MHV computation never left four dimensions because its result is built from logarithms and dilogarithms—functions with branch cuts that four-dimensional unitarity can see. The all-plus amplitude is the opposite extreme. At tree level $A_4^{(0)}(1^+,2^+,3^+,4^+) = 0$ (an all-plus tree vanishes, Chapter 59), so every four-dimensional cut, being a product of trees, vanishes too. Yet the one-loop amplitude is nonzero: it is purely *rational*, with no cut in any channel. This is exactly the class of contribution that Section 60.5 traced to the (-2ε)-dimensional components of the loop momentum, and we now reconstruct it from a d-dimensional cut.

Setup. Decompose the $d = 4-2\varepsilon$ loop momentum as $\ell = \bar{\ell} + \ell_\perp$, with $\bar{\ell}$ the four-dimensional part and $\ell_\perp$ living in the extra -2ε dimensions; set $\mu^2 \equiv -\ell_\perp^2 \geq 0$, so that $\ell^2 = \bar{\ell}^2 - \mu^2$ (Section 60.5). From the four-dimensional point of view the loop particle behaves as a massive state of mass μ. The rational all-plus amplitude is generated entirely by the μ-dependence of the integrand; the only loop content that contributes is the μ-massive scalar (gluon and fermion loops reduce to it by the supersymmetric decomposition of the one-loop integrand recalled in Section 60.5).

The helicity-violating two-gluon vertex. The building block is the tree amplitude for two positive-helicity gluons and a pair of mass-μ scalars. Little-group scaling fixes its helicity structure: a positive-helicity gluon i forces the

amplitude to scale as t_i^{-2} under $\lambda_i \to t_i\lambda_i$, $\tilde\lambda_i \to t_i^{-1}\tilde\lambda_i$, and the only weight-correct, dimensionally consistent ratio of brackets for legs $1,2$ is $[12]/\langle 12\rangle$. The amplitude must also vanish as $\mu \to 0$, because for massless scalars two like-helicity gluons cannot be produced at tree level (the same helicity selection rule that makes the all-plus tree vanish). The unique structure with these properties, up to the scalar propagator that becomes a box denominator on the cut, is

$$A^{\text{tree}}(1^+, 2^+; \phi, \bar\phi) \;\propto\; \frac{\mu^2\,[12]}{\langle 12\rangle}, \tag{60.208}$$

and explicitly evaluating the scalar-QCD diagrams (a gluon exchange plus the seagull, with the polarizations $\epsilon_+^\mu(k_i; q)$ of Eq. (58.98)) confirms the coefficient and the propagator structure. The factor μ^2 is the fingerprint of the extra-dimensional loop momentum: it is precisely the piece that four-dimensional cuts discard.

The box numerator. Glue two such vertices, one feeding the (12) side and one the (34) side of the box, with the mass-μ scalar circulating on the four internal lines. Each vertex contributes a factor Eq. (60.208), so the box numerator collects

$$N(\mu^2) = \frac{\mu^2[12]}{\langle 12\rangle}\cdot\frac{\mu^2[34]}{\langle 34\rangle} \times (\text{state count}) = \mu^4\,\frac{[12][34]}{\langle 12\rangle\langle 34\rangle} \times n_s, \tag{60.209}$$

where n_s counts the on-shell degrees of freedom of the circulating complex scalar (and absorbs the supersymmetric reorganization of the gluon and fermion loops into the scalar form). The remaining four propagators are exactly those of the box Eq. (60.171), so the all-plus amplitude is a single μ^4-box,

$$A_4^{(1)}(1^+, 2^+, 3^+, 4^+) = \frac{[12][34]}{\langle 12\rangle\langle 34\rangle}\, n_s \int \frac{d^d\ell}{(2\pi)^d}\,\frac{\mu^4}{\ell_1^2\,\ell_2^2\,\ell_3^2\,\ell_4^2}. \tag{60.210}$$

The master μ^4-box. The integral $I_4[\mu^4] \equiv \int \frac{d^d\ell}{(2\pi)^d}\,\mu^4/(\ell_1^2\cdots\ell_4^2)$ is the dimension-shifted box, evaluated in Chapter D and recalled in Section 60.5. The mechanism is the engine of the whole rational-term program, so we display it. Write the (-2ε)-dimensional integration in radial form,

$$\int \frac{d^{-2\varepsilon}\ell_\perp}{(2\pi)^{-2\varepsilon}}\,(\mu^2)^r\,f(\bar\ell^2-\mu^2) = \frac{\Omega_{-2\varepsilon}}{(2\pi)^{-2\varepsilon}}\,\frac{1}{2}\int_0^\infty d(\mu^2)\,(\mu^2)^{r-\varepsilon-1}\,f(\bar\ell^2-\mu^2), \qquad \Omega_{-2\varepsilon} = \frac{2\pi^{-\varepsilon}}{\Gamma(-\varepsilon)}. \tag{60.211}$$

The prefactor carries $1/\Gamma(-\varepsilon) \simeq -\varepsilon$ as $\varepsilon \to 0$, so an insertion of μ^{2r} produces an explicit factor of ε and promotes the four-dimensional integral to one in $d + 2r = 4 + 2r - 2\varepsilon$ dimensions:

$$I_n^d[\mu^{2r}] = (4\pi)^r\,\frac{\Gamma(r-\varepsilon)}{\Gamma(-\varepsilon)}\,I_n^{d+2r} \quad\xrightarrow{\varepsilon\to 0}\quad -\varepsilon\,(r-1)!\,(4\pi)^r\,I_n^{d+2r}, \tag{60.212}$$

which is exactly the dimension-shift identity Eq. (60.144) proved in Theorem 60.25. For $r = 2$ the right-hand side is $-\varepsilon$ times the box in $d = 8 - 2\varepsilon$ dimensions, which is ultraviolet divergent with a simple pole; the ε from the dimension shift multiplies that $1/\varepsilon$ to leave a finite rational constant. Carrying out the 8-dimensional box of Chapter D,

$$I_4[\mu^4] = \int \frac{d^d\ell}{(2\pi)^d} \frac{\mu^4}{\ell_1^2\,\ell_2^2\,\ell_3^2\,\ell_4^2} = -\frac{i}{(4\pi)^2}\,\frac{1}{6} + O(\varepsilon). \tag{60.213}$$

The result is finite (no $1/\varepsilon$), purely imaginary times rational, and—crucially—independent of s and t: a rational term carries no logarithm, exactly as a cut-free contribution must.

Worked Example 60.29 (The all-plus rational amplitude)**.** Combine the box coefficient Eq. (60.210) with the master integral Eq. (60.213). The state count of the circulating complex scalar, together with the supersymmetric reduction of the gluon and fermion loops to the same μ^4-box, gives $n_s = 2$ (the reorganization is fixed by demanding the correct collinear limit below; it is the same factor for every n). Then

$$A_4^{(1)}(1^+,2^+,3^+,4^+) = 2\,\frac{[12][34]}{\langle 12\rangle\langle 34\rangle}\left(-\frac{i}{(4\pi)^2}\,\frac{1}{6}\right) = -\frac{i}{48\pi^2}\,\frac{[12][34]}{\langle 12\rangle\langle 34\rangle}, \tag{60.214}$$

using $\dfrac{2}{6\,(4\pi)^2} = \dfrac{1}{3\cdot 16\pi^2} = \dfrac{1}{48\pi^2}$. This is the textbook result [67, 68]:

$$\boxed{A_4^{(1)}(1^+,2^+,3^+,4^+) = -\frac{i}{48\pi^2}\,\frac{[12][34]}{\langle 12\rangle\langle 34\rangle}\,.} \tag{60.215}$$

Crossing and collinear cross-checks. The result Eq. (60.215) should be totally symmetric under permutations of the four identical positive-helicity gluons (after accounting for color ordering, the surviving symmetry is cyclic plus reflection). Momentum conservation makes this manifest: from $\langle 12\rangle[24] + \langle 13\rangle[34] = 0$ and its relatives one shows

$$\frac{[12][34]}{\langle 12\rangle\langle 34\rangle} = \frac{[13][24]}{\langle 13\rangle\langle 24\rangle} = \frac{[14][23]}{\langle 14\rangle\langle 23\rangle}, \tag{60.216}$$

so the rational function is independent of how the pairs are chosen—the amplitude has the required exchange symmetry. For the collinear limit, send $1 \parallel 2$ ($\langle 12\rangle \to 0$): Eq. (60.215) diverges as $[12]/\langle 12\rangle$, the correct one-loop all-plus collinear singularity, and matches $\mathrm{Split}_{-}^{(1)}(1^+,2^+)\,A_3^{\mathrm{tree}}$ plus $\mathrm{Split}^{\mathrm{tree}}\,A_3^{(1)}(P^+,3^+,4^+)$ in Eq. (60.207), since the tree all-plus three-point amplitude vanishes and only the one-loop splitting and the one-loop three-point all-plus contribute. This limit is what fixes $n_s = 2$ and confirms the normalization independently of the infrared check used for the MHV case.

60.6.4 Feynman diagrams versus on-shell trees

It is worth making the "modern alternative" claim quantitative, because the contrast is the entire point of the method. Consider the same object computed two ways.

The traditional route is the one the reader learned in Part V and exercised on QED in Chapter 19: enumerate every one-loop Feynman diagram, write each as a tensor integral, Passarino–Veltman reduce the tensors to scalar masters (Chapter D), and add. For the color-ordered one-loop four-gluon amplitude the diagram count is already substantial. The cubic and quartic gluon self-interactions of Yang–Mills theory, together with the Faddeev–Popov ghost loop required for gauge invariance (Chapter 26), generate on the order of one hundred one-loop diagrams once all topologies (box, triangle with a quartic vertex, bubbles, tadpole-like and ghost contributions) and their orderings are included—against the four diagrams of the *tree* amplitude $gg \to gg$. Each one-loop diagram produces a tensor integral of rank up to four, whose reduction proliferates Gram determinants and gauge-dependent intermediate terms that cancel only in the gauge-invariant sum.

The unitarity route, by contrast, never builds a single loop diagram. The complete input is the set of on-shell trees:

- for the MHV box, the box coefficient Eq. (60.202) was fixed by 2 solutions $\times 4$ corners $= 8$ three-point tree evaluations, each a one-line Parke–Taylor expression (Eq. (59.55)), and the $\mathcal{N} = 4$ no-triangle property removed every other coefficient;
- for the all-plus rational term, a single μ^4-box coefficient Eq. (60.209) built from two helicity-violating two-gluon vertices.

The remaining work is to multiply by master integrals (Eqs. (60.204) and (60.213)) that are computed once and tabulated in Chapter D. A computation that classically demands one hundred diagrams and a tensor-reduction apparatus collapses to a handful of gauge-invariant tree evaluations and two master integrals. The advantage compounds with multiplicity and loop order: the number of Feynman diagrams grows factorially, while the number of independent unitarity cuts grows only with the size of the integral basis. This is the concrete sense in which generalized unitarity is the modern successor to the diagrammatic expansion.

Summary and outlook

We have reconstructed two one-loop four-gluon amplitudes end to end from on-shell trees: the $\mathcal{N} = 4$ MHV amplitude Eq. (60.205), a single scalar box whose coefficient $st\,A_4^{(0)}$ came from a quadruple cut, and the all-plus rational amplitude

Eq. (60.215), a single μ^4-box invisible to four-dimensional cuts. Both passed their physical checks: the MHV poles reproduce the universal infrared structure Eq. (60.206) and the correct collinear factorization, while the all-plus result has the required crossing symmetry and collinear singularity. In every case the answer was delivered as a coefficient times a master integral, with not a single Feynman diagram drawn—the loop-level fulfillment of Yang–Mills theory. What we have *not* done is evaluate those master integrals from first principles; we imported Eq. (60.204) and Eq. (60.213) from Chapter D. The next section takes up exactly that question—how the master integrals are computed, by integration-by-parts reduction to a finite basis and the canonical differential-equation method—and asks how the whole program scales beyond one loop into the polylogarithmic function space that is the modern frontier.

60.7 Toward Multiloop: Integration by Parts, Differential Equations, and the Function Space

The reconstruction of the previous section delivered the one-loop gluon amplitude not as a number but as a *linear combination of scalar master integrals*: a box, a handful of triangles and bubbles, each multiplied by a coefficient that generalized unitarity had pinned down as a product of on-shell trees. To turn that combination into a function of the kinematic invariants we did the one thing the unitarity method by design does not do for us — we reached into Chapter D and quoted the explicit values of those masters. That import was honest but it was also a deferral. Two questions were left standing. First, *how are the master integrals themselves computed*, once one wants them as functions of the invariants rather than as entries in a table? Second, *what happens beyond one loop*, where Chapter D's closed-form Gamma-function answers run out and the integrals are no longer elementary? This section answers both, and in doing so it converts the unitarity method from a one-loop technique into the entryway of the modern multiloop program. The answer to the first question is a remarkable piece of linear algebra — integration by parts — that collapses the apparently infinite zoo of loop integrals onto a finite basis and then propagates that basis through a closed system of differential equations. The answer to the second is that the functions one meets are not arbitrary: at the polylogarithmic frontier they are iterated integrals of a sharply characterized kind, graded by an integer called the transcendental weight and fingerprinted by an algebraic object called the symbol. We build all three ideas in turn — the integration-by-parts reduction, the canonical differential equation, the polylogarithmic function space — carry every step of two small but complete computations, and close with an honest, dated map of where the road runs out.

60.7.1 Loop integrals as a vector space: integration-by-parts identities

The conceptual leap that organizes everything below is to stop thinking of a loop integral as a single number to be evaluated and to start thinking of the entire *family* of integrals sharing a given set of propagators as the elements of a vector space. The relations among them are then linear, and linear-algebra technology applies.

Definition 60.30 (Integral family)**.** Fix a set of L loop momenta $\ell_1, \dots, \ell_L$, external momenta $p_1, \dots, p_n$, and a list of N inverse propagators (denominators) $D_1, \dots, D_N$, each a quadratic form $D_j = q_j^2 - m_j^2$ in the loop and external momenta as in Theorem D.1, chosen so that every scalar product $\ell_a \cdot \ell_b$ and $\ell_a \cdot p_i$ that can appear is a linear combination of the D_j (the family is then said to be *complete*). The *integral family* is the set of all integrals

$$I(a_1, \dots, a_N) \;=\; \int \prod_{i=1}^{L} \frac{\mathrm{d}^d \ell_i}{(2\pi)^d} \, \frac{1}{D_1^{a_1} \, D_2^{a_2} \cdots D_N^{a_N}} \,, \qquad a_j \in \mathbb{Z}, \tag{60.217}$$

labelled by the integer vector $(a_1, \dots, a_N)$. Positive a_j are propagator powers; a vanishing a_j removes a line (a subtopology); a negative a_j is an inverse propagator in the numerator, the mechanism by which numerator scalar products are encoded.

The family (60.217) is countably infinite: the indices a_j range over all integers. The central structural fact of multiloop computation, which this section establishes, is that this infinite set spans a *finite-dimensional* space. The relations that force the collapse come from a single, almost embarrassingly elementary observation: in dimensional regularization the integral of a total derivative vanishes.

Lemma 60.31 (Vanishing of total derivatives in dimensional regularization)**.** *For any of the loop momenta ℓ_a and any vector v^μ built polynomially from the loop and external momenta, and for any integrand f in the family* (60.217)*,*

$$\int \prod_{i} \frac{\mathrm{d}^d \ell_i}{(2\pi)^d} \, \frac{\partial}{\partial \ell_a^\mu} \Big(v^\mu \, f \Big) \;=\; 0 \,. \tag{60.218}$$

Proof. The integral of a total derivative over $\mathrm{d}^d \ell_a$ equals the boundary value of $v^\mu f$ on the sphere at $|\ell_a| \to \infty$, by the divergence theorem in d dimensions. In an integer dimension this surface term need not vanish for a divergent integrand. But dimensional regularization is defined (Theorem D.22) by analytic continuation from the strip of complex d in which the integral converges absolutely, and *in that strip* the integrand falls faster than any surface area can grow, so the boundary contribution is identically zero there. As the left-hand side of (60.218) is, like

every member of the family, a meromorphic function of d defined by that same continuation, an identity holding on an open strip holds everywhere it is defined. The vanishing of the surface term is thus not an approximation; it is built into the definition of the regularized integral. This is the single most important practical advantage of dimensional regularization over a hard cutoff, where (60.218) would be false. □

Carrying out the differentiation in (60.218) with the product rule generates a linear relation among members of the family. The derivative $\partial_{\ell_a^\mu} v^\mu$ produces a multiple of the dimension d (when $v^\mu \propto \ell_a^\mu$, since $\partial \ell_a^\mu / \partial \ell_a^\mu = d$) plus polynomial terms, while $\partial_{\ell_a^\mu}$ acting on each $D_j^{-a_j}$ lowers that power by one and brings down $-a_j\, \partial_{\ell_a^\mu} D_j$, whose numerator scalar products are — by completeness of the family — re-expressed in the D_k, shifting indices up and down. The result is the *integration-by-parts (IBP) identity*: a homogeneous linear relation, with coefficients rational in d and the invariants, among integrals (60.217) whose indices differ from a chosen "seed" by small shifts. Each choice of seed $(a_1, \dots, a_N)$ and each choice of vector $v^\mu \in \{\ell_1, \dots, \ell_L, p_1, \dots, p_n\}$ gives one identity; the supply is inexhaustible.

We also need the second pillar, the systematic source of the zeros that terminate the recursions.

Lemma 60.32 (Scaleless integrals vanish)**.** *A dimensionally regularized integral whose integrand, after every shift of loop momentum, depends on the loop momenta but contains* no dimensionful scale *(no mass, no nonzero external invariant) is zero.*

Proof. Let J be such an integral and rescale every loop momentum $\ell_i \to t\,\ell_i$ with $t > 0$. Because the integrand carries no other scale, dimensional analysis forces $J = t^{\,k} J$ for some power $k = k(d)$ depending on the homogeneity degree (the net mass dimension carried by the loop momenta). An equality $J = t^k J$ holding for all $t > 0$ with $t^k \not\equiv 1$ forces $J = 0$. Generically $k(d) \neq 0$ for non-integer d, so $J = 0$; by continuation it vanishes at $d = 4$ as well. Concretely, the massless tadpole $\int \mathrm{d}^d\ell / (\ell^2)^a = 0$ and, after a shift, $\int \mathrm{d}^d\ell / ((\ell + p)^2)^a = 0$. □

These two lemmas are the entire toolkit. We now run them on the smallest nontrivial example, the massless one-loop bubble, and extract a concrete identity exhibiting the characteristic d-dependence of an IBP relation.

Worked Example 60.33 (The massless bubble IBP and its d-dependence)**.** Take the one-loop family with two massless denominators

$$D_1 = \ell^2 + i\epsilon, \qquad D_2 = (\ell + p)^2 + i\epsilon, \qquad s \equiv p^2, \tag{60.219}$$

and integrals $I(a_1, a_2) = \int \mathrm{d}^d\ell / (2\pi)^d\, D_1^{-a_1} D_2^{-a_2}$. We derive the IBP identity generated by the seed $(1, 1)$ and the vector $v^\mu = \ell^\mu$.

Step 1: the total derivative. By Theorem 60.31,

$$0 \;=\; \int \frac{\mathrm{d}^d \ell}{(2\pi)^d}\, \frac{\partial}{\partial \ell^\mu}\left[\frac{\ell^\mu}{D_1\, D_2}\right]. \tag{60.220}$$

Step 2: the product rule. The derivative hits the explicit ℓ^μ and each denominator:

$$\frac{\partial}{\partial \ell^\mu}\,\frac{\ell^\mu}{D_1 D_2} = \frac{d}{D_1 D_2} - \frac{\ell^\mu\, \partial_\mu D_1}{D_1^2 D_2} - \frac{\ell^\mu\, \partial_\mu D_2}{D_1 D_2^2}, \tag{60.221}$$

using $\partial \ell^\mu / \partial \ell^\mu = d$. The two contractions are elementary:

$$\ell^\mu \partial_\mu D_1 = \ell^\mu (2\ell_\mu) = 2\ell^2 = 2D_1, \tag{60.222}$$

$$\ell^\mu \partial_\mu D_2 = \ell^\mu\, 2(\ell + p)_\mu = 2\ell^2 + 2\ell\cdot p = 2D_1 + (D_2 - D_1 - s) = D_1 + D_2 - s, \tag{60.223}$$

where in the second line we used $D_2 = (\ell+p)^2 = \ell^2 + 2\ell p + p^2$, i.e. $2\ell p = D_2 - D_1 - s$.

Step 3: assemble the identity. Insert (60.223) into (60.221) and integrate:

$$\begin{aligned} 0 &= \int \frac{\mathrm{d}^d \ell}{(2\pi)^d}\left[\frac{d}{D_1 D_2} - \frac{2D_1}{D_1^2 D_2} - \frac{D_1 + D_2 - s}{D_1 D_2^2}\right] \\ &= d\, I(1,1) - 2\, I(1,1) - \big[I(0,2) + I(1,1) - s\, I(1,2)\big] \\ &= (d-3)\, I(1,1) - I(0,2) + s\, I(1,2), \end{aligned} \tag{60.224}$$

where $D_1/(D_1^2 D_2) = 1/(D_1 D_2)$, $D_1/(D_1 D_2^2) = 1/(D_2^2) \to I(0,2)$, and $D_2/(D_1 D_2^2) = 1/(D_1 D_2) \to I(1,1)$.

Step 4: kill the scaleless term and solve. The integral $I(0,2) = \int \mathrm{d}^d \ell/(2\pi)^d\, (\ell + p)^{-4}$ depends on no scale once ℓ is shifted, so $I(0,2) = 0$ by Theorem 60.32. The remaining identity rearranges to

$$\boxed{\; I(1,2) \;=\; -\,\frac{d-3}{s}\, I(1,1) \;} \tag{60.225}$$

Equation (60.225) is the prototype of the whole reduction program, and three of its features are permanent. First, an integral with a *raised* propagator power, $I(1,2)$, has been expressed entirely in terms of the integral with all powers equal to one, $I(1,1)$: the family has been collapsed onto a single representative. Iterating the construction with other seeds reduces every $I(a_1, a_2)$ with $a_j > 0$ to a rational multiple of $I(1,1)$, while every integral with a vanishing index is scaleless and dies. The bubble family, infinite as a set, is one-dimensional as a vector space. Second, the coefficient $-(d-3)/s$ depends on the spacetime dimension — it is the algebraic shadow of the analytic continuation in d that defined the integral. This d-dependence is universal to IBP relations and is exactly what the differential-equation method below will exploit. Third, the entire identity was obtained without performing a single momentum integral: it is a statement about the integrand, valid before evaluation, and the one surviving integral $I(1,1)$ is the one we still must compute — by the differential equation, in a moment.

60.7.2 The Laporta algorithm and the master basis

The bubble is small enough that one identity sufficed. In a realistic problem one generates IBP identities by the thousands — one for each (seed, vector) pair, over a large block of seeds — and confronts a vast, sparse, but *finite-rank* linear system whose unknowns are the integrals (60.217). The strategy for solving it is due to Laporta [315, 316]: impose a total ordering on the integrals (by number of propagators, then by total power, then lexicographically — so that "simpler" integrals are preferred), generate identities for all seeds up to a chosen complexity, and perform Gaussian elimination, always solving each identity for its most complicated integral in terms of simpler ones. The elimination cascades: complicated integrals are successively expressed through simpler ones until only a small set remains that no identity can reduce further.

Definition 60.34 (Master integrals)**.** The integrals that survive the IBP reduction — those that cannot be written as a linear combination of simpler integrals in the family — are the *master integrals* of the family. Every integral (60.217) equals a finite linear combination

$$I(a_1, \dots, a_N) \;=\; \sum_{k} c_k(d, s_{ij})\, M_k \,, \tag{60.226}$$

of the masters M_k, with coefficients c_k rational in the dimension d and the kinematic invariants s_{ij}.

That the number of masters is *finite* is not obvious from the algorithm, which terminates only because we capped the seed complexity; in principle a larger seed block might expose new reductions. The finiteness is a theorem.

Theorem 60.35 (Finiteness of the master basis)**.** *For any integral family* (60.217) *the number of master integrals is finite.*

The statement is that the family, viewed as a module over the ring of IBP shift operators, is finitely generated; equivalently, the dimension of the vector space spanned by the integrals (as functions of the kinematics, for generic d) is bounded. The bound has a sharp geometric meaning: the number of masters equals the number of critical points of the Lee–Pomeransky polynomial of the graph (the Euler characteristic of a hypersurface complement), a result that converts "how many masters?" into a question in algebraic geometry. We use the finiteness as established; its proof belongs to the mathematical apparatus of Feynman integrals catalogued in Chapter D and reviewed in [448]. For us the operational content is decisive: *any* amplitude at any loop order, once its diagrams are written and IBP-reduced, is a finite linear combination of a fixed, computable list of master integrals. The reconstruction of the previous section produced precisely such a list at one loop — box, triangles, bubbles — and Theorem 60.35 is the guarantee that the same finiteness holds at two loops, three loops, and beyond,

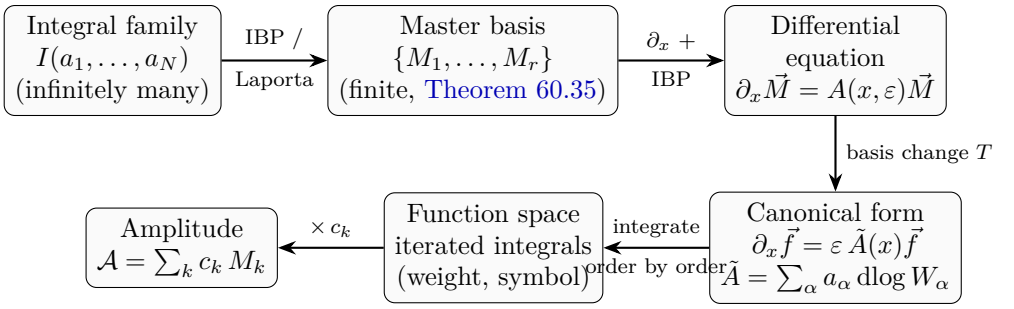

Figure 60.6: The multiloop computational pipeline. Generalized unitarity and IBP reduction (Sections 60.7.1 and 60.7.2) express any amplitude through a finite basis of master integrals; differentiating the masters in a kinematic variable and IBP-reducing the result closes a linear differential system (Section 60.7.3); a change of basis brings it to the canonical ε-factorized form (Section 60.7.4), whose solution is, order by order in ε, an iterated integral in the polylogarithmic function space (Section 60.7.5). Each stage is linear algebra over rational functions; the only analytic input is a boundary condition.

even when the masters can no longer be written in closed form. The amplitude problem has been cleanly factorized: rational coefficients (which unitarity and IBP supply) times master integrals (which the next subsections compute).

60.7.3 The method of differential equations

Knowing that a finite basis of masters exists is one thing; evaluating the masters is another. The decisive idea, due to Kotikov and developed into a general method by Remiddi and Gehrmann [212, 306], is to compute the masters not by direct integration but by differentiating them. A master integral is a function of the kinematic invariants; differentiate it with respect to one of them and the derivative is again an integral in the same family (the derivative acts on the propagators, raising powers and inserting numerators, exactly as in the IBP manipulation). By Theorem 60.34 that derivative reduces back to the masters. The masters therefore satisfy a closed, first-order, linear system of ordinary differential equations.

Proposition 60.36 (The differential-equation system)**.** *Let $\vec{M} = (M_1,\dots,M_r)^{\mathsf{T}}$ be the master integrals of a family, regarded as functions of a kinematic variable x (a ratio of invariants), and let the remaining invariants be held fixed or scaled out. Then there is a matrix $A(x,\varepsilon)$, with entries rational in x and ε, such that*

$$\frac{\partial}{\partial x}\,\vec{M}(x,\varepsilon) \;=\; A(x,\varepsilon)\,\vec{M}(x,\varepsilon). \tag{60.227}$$

Proof. Differentiating M_k with respect to x commutes with the loop integration. The chain rule turns ∂_x into a combination of $\partial/\partial p_i^\mu$ contracted with external

momenta, which acting on the propagators $D_j^{-a_j}$ produces a finite sum of integrals in the same family with shifted indices (raised powers from the differentiated propagators, dotted external momenta in numerators). Each such integral is, by Theorem 60.34 and the IBP reduction (60.226), a rational-coefficient combination of the masters $M_1, \dots, M_r$. Collecting the coefficients into the k-th row of a matrix $A(x, \varepsilon)$ gives (60.227). □

The system (60.227) reduces the evaluation of the masters to two well-posed sub-problems: solving a linear ODE, and fixing the constants of integration by a boundary condition (typically the value of the integral at a special kinematic point — a threshold, a soft or collinear limit, or a symmetric point — where it degenerates to something elementary or already known). The boundary data are the *only* analytic input; everything else is the algebra of (60.227). This is why the method scales: at higher loops one cannot do the momentum integral, but one can always differentiate and IBP-reduce, and one can usually find a kinematic corner where a boundary value is computable.

We now carry the method through completely on the one master we already isolated, the massless bubble, where the system is a single equation and the solution is a logarithm.

Worked Example 60.37 (The massless bubble by differential equation)**.** We compute $I(1,1)$ of Theorem 60.33 from its differential equation in $s = p^2$.

Step 1: differentiate. Since $s = p^2$ and $I(1,1)$ depends on the externals only through s, we use $p^\mu\, \partial/\partial p^\mu = 2s\, \partial/\partial s$, so $\partial/\partial s = (1/2s)\, p^\mu \partial/\partial p^\mu$. The derivative acts on $D_2 = (\ell + p)^2$ only:

$$p^\mu \frac{\partial}{\partial p^\mu} I(1,1) = \int \frac{\mathrm{d}^d \ell}{(2\pi)^d} \frac{-\,p^\mu\, 2(\ell+p)_\mu}{D_1\, D_2^2} = -\int \frac{\mathrm{d}^d \ell}{(2\pi)^d} \frac{2\, p\cdot(\ell+p)}{D_1 D_2^2}. \tag{60.228}$$

Step 2: express the numerator in denominators. Write $2\, p\cdot(\ell + p) = 2\ell\cdot p + 2p^2 = (D_2 - D_1 - s) + 2s = D_2 - D_1 + s$. Then

$$p^\mu \partial_\mu I(1,1) = -\big[I(1,1) - I(0,2) + s\, I(1,2)\big] = -I(1,1) - s\, I(1,2), \tag{60.229}$$

using $D_2/(D_1 D_2^2) = 1/(D_1 D_2) \to I(1,1)$, $D_1/(D_1 D_2^2) = 1/(D_2^2) \to I(0,2) = 0$ (scaleless), and the leftover $s/(D_1 D_2^2) \to s\, I(1,2)$.

Step 3: IBP-reduce back to the master. The integral $I(1,2)$ is not a master; the reduction (60.225) of Theorem 60.33 gives $s\, I(1,2) = -(d-3)\, I(1,1)$. Insert it:

$$p^\mu \partial_\mu I(1,1) = -I(1,1) + (d-3)\, I(1,1) = (d-4)\, I(1,1) = -2\varepsilon\, I(1,1), \tag{60.230}$$

where $d = 4 - 2\varepsilon$. The system has closed on the single master, as Theorem 60.36 promised.

Step 4: the differential equation. Dividing by $2s$,

$$\frac{\partial}{\partial s} I(1,1) \;=\; -\frac{\varepsilon}{s}\, I(1,1). \tag{60.231}$$

Step 5: solve. This is separable: $\mathrm{d}\ln I(1,1) = -\varepsilon\, \mathrm{d}\ln(-s)$, integrating to

$$I(1,1) \;=\; c(\varepsilon)\,(-s)^{-\varepsilon}, \tag{60.232}$$

with $(-s - i\epsilon)$ the correct branch inherited from the Feynman prescription, and $c(\varepsilon)$ an s-independent constant of integration.

Step 6: fix the boundary constant. The constant $c(\varepsilon)$ is the one piece the differential equation cannot supply; it is fixed by the value of the integral at one kinematic point. Here the most economical anchor is the closed form of the master itself. Combining the two denominators with the Feynman parameter $1/(D_1 D_2) = \int_0^1 \mathrm{d}x\,[xD_2 + (1-x)D_1]^{-2}$ and completing the square gives $\Delta = -x(1-x)s$, so by the master formula Eq. (D.77) with $n = 2$, $\Delta^{d/2-2} = \Delta^{-\varepsilon}$,

$$I(1,1) = \frac{i}{(4\pi)^{d/2}}\,\Gamma(\varepsilon)\,(-s)^{-\varepsilon}\int_0^1 \mathrm{d}x\,[x(1-x)]^{-\varepsilon} = \frac{i}{(4\pi)^{d/2}}\,\Gamma(\varepsilon)\,(-s)^{-\varepsilon}\,\frac{\Gamma(1-\varepsilon)^2}{\Gamma(2-2\varepsilon)}, \tag{60.233}$$

the x-integral being the Beta function $\mathrm{B}(1-\varepsilon, 1-\varepsilon)$. Matching (60.233) to (60.232) reads off

$$c(\varepsilon) = \frac{i}{(4\pi)^{d/2}}\,\frac{\Gamma(\varepsilon)\,\Gamma(1-\varepsilon)^2}{\Gamma(2-2\varepsilon)}. \tag{60.234}$$

The differential equation determined the entire s-dependence; the boundary supplied the single number multiplying it.

60.7.4 Canonical bases and the ε-factorized form

The bubble equation (60.231) has a feature that looks accidental but is in fact the goal of the entire method: its right-hand side is *proportional to* ε. The matrix $A(x,\varepsilon) = -\varepsilon/s$ is ε times a function of s alone, with no ε-independent part. When a system has this form the solution can be read off order by order in ε as a tower of iterated integrals, with no further integration constants beyond the boundary. Henn's insight [263] was that this is not special to the bubble: for a large class of integrals one can *choose the master basis* so that the system takes this form.

Definition 60.38 (Canonical, ε-form differential equation)**.** A basis of masters $\vec{f} = (f_1, \dots, f_r)^{\mathsf{T}}$ is *canonical* (in ε-form, or *pure*) if its differential equation factorizes the regulator,

$$\mathrm{d}\,\vec{f}(x,\varepsilon) \;=\; \varepsilon \Big(\sum_{\alpha} a_\alpha\, \mathrm{dlog}\, W_\alpha(x)\Big)\, \vec{f}(x,\varepsilon), \tag{60.235}$$

where d is the total differential in all kinematic variables, the a_α are *constant* matrices (independent of x and ε), and the $W_\alpha(x)$ are algebraic functions of the kinematics called the *letters* of the problem. Their collection $\{W_\alpha\}$ is the *alphabet*. The right-hand side is a matrix-valued logarithmic one-form, $\mathrm{d}\tilde{A} = \sum_\alpha a_\alpha \,\mathrm{dlog}\, W_\alpha$, with only simple poles (located at $W_\alpha = 0, \infty$).

The transformation from a generic basis $\vec{M}$ obeying (60.227) to a canonical $\vec{f} = T(x,\varepsilon)\,\vec{M}$ is a linear change of basis; under it the matrix transforms as $A \to TAT^{-1} + (\partial_x T)\,T^{-1}$, and finding the T that produces the form (60.235) is the technical heart of a modern computation. A canonical basis is typically built from integrals that are *pure functions* of uniform transcendental weight — normalized, for instance, by factors of ε and by leading-singularity (maximal-cut) data so that they have unit "leading singularity" and no spurious algebraic prefactors. The massless bubble is already pure up to its overall constant: (60.231) is (60.235) with one letter $W = (-s)$, one 1×1 matrix $a = -1$, and $\mathrm{dlog}(-s) = \mathrm{d}s/s$.

The payoff of the canonical form is the structure of its solution.

Proposition 60.39 (ε-form solution as iterated integrals)**.** *The solution of a canonical system* (60.235) *along a path γ from a base point x_0 to x is the path-ordered exponential*

$$\vec{f}(x,\varepsilon) = \mathrm{P}\exp\!\Big(\varepsilon \int_\gamma \mathrm{d}\tilde{A}\Big)\,\vec{f}(x_0,\varepsilon), \tag{60.236}$$

whose expansion in ε is, term by term, a $\mathbb{Z}$-linear combination of iterated integrals *of the one-forms* $\mathrm{dlog}\, W_\alpha$*:*

$$\vec{f} = \Big(1 + \varepsilon\int_\gamma \mathrm{d}\tilde{A} + \varepsilon^2 \int_\gamma \mathrm{d}\tilde{A}\,\mathrm{d}\tilde{A} + \cdots\Big)\vec{f}(x_0,\varepsilon), \qquad \int_\gamma \mathrm{d}\tilde{A}\cdots\mathrm{d}\tilde{A} = \int_{0\le t_1\le\cdots\le t_k\le 1} \tilde{A}'(t_1)\cdots\tilde{A}'(t_k), \tag{60.237}$$

where $\tilde{A}'$ denotes the pullback of $\mathrm{d}\tilde{A}$ to the path parameter. The coefficient of ε^k in $\vec{f}$ is an iterated integral of exactly *k logarithmic forms.*

Proof. Write $\vec{f} = \sum_{k\ge 0} \varepsilon^k \vec{f}^{(k)}$ and insert into (60.235), which reads $\mathrm{d}\vec{f} = \varepsilon\,(\mathrm{d}\tilde{A})\,\vec{f}$. Matching powers of ε gives $\mathrm{d}\vec{f}^{(0)} = 0$ and, for $k \ge 1$,

$$\mathrm{d}\vec{f}^{(k)} = (\mathrm{d}\tilde{A})\,\vec{f}^{(k-1)}. \tag{60.238}$$

The zeroth order $\vec{f}^{(0)}$ is therefore a constant (the boundary value, weight 0), and each higher order is obtained from the one below it by a *single* integration of a dlog form: $\vec{f}^{(k)}(x) = \vec{f}^{(k)}(x_0) + \int_{x_0}^{x} (\mathrm{d}\tilde{A})\,\vec{f}^{(k-1)}$. Unwinding the recursion expresses $\vec{f}^{(k)}$ as the k-fold iterated integral in (60.237); the path-ordering is automatic because each integration's upper limit is the next integration's variable. The only freedom at each order is the additive constant $\vec{f}^{(k)}(x_0)$, fixed by the

boundary condition. This is the precise sense in which the ε-factorized form "solves itself": integration is replaced by a deterministic recursion that adds one logarithmic form per order in ε. □

Theorem 60.39 makes the bubble transparent. With the single letter $(-s)$, the path-ordered exponential is the ordinary exponential of $-\varepsilon \ln(-s/(-s_0))$, and expanding (60.232) confirms the recursion directly:

$$(-s)^{-\varepsilon} = e^{-\varepsilon \ln(-s)} = 1 - \varepsilon \ln(-s) + \frac{\varepsilon^2}{2} \ln^2(-s) - \frac{\varepsilon^3}{6} \ln^3(-s) + \cdots , \quad (60.239)$$

each order carrying exactly one more power of the logarithm — one more iterated integral of the form $\mathrm{d} \ln(-s)$. Restoring the constant (60.234) and the dimensional scale $\mu^{2\varepsilon}$, the bubble's Laurent expansion is

$$\mu^{2\varepsilon} I(1,1) = \frac{i}{(4\pi)^2} \Big[\frac{1}{\varepsilon} - \ln \frac{-s}{\mu^2} + 2 + O(\varepsilon) \Big], \quad (60.240)$$

the $1/\varepsilon$ pole from $\Gamma(\varepsilon)$, the logarithm from the first iterated integral, and the rational "+2" from the ε-expansion of the constant $\Gamma(1-\varepsilon)^2/\Gamma(2-2\varepsilon)$ together with $\overline{\mathrm{MS}}$ bookkeeping. The branch cut along $s > 0$ in $\ln(-s)$ is the bubble's two-particle threshold; that its discontinuity is $2i \operatorname{Im} I(1,1)$ is the optical theorem of Section 5.5.5 made manifest, and is precisely the cut that the unitarity method of this chapter exploited to fix the coefficient multiplying this very master.

60.7.5 The polylogarithmic function space, transcendental weight, and the symbol

Theorem 60.39 tells us *what* the master integrals are: iterated integrals of logarithmic forms. We now name this function space precisely, equip it with its grading, and introduce the algebraic tool — the symbol — that tames the otherwise unwieldy identities among its elements.

Definition 60.40 (Iterated integral and multiple polylogarithm)**.** Given one-forms $\omega_1, \dots, \omega_n$ on a path $\gamma : [0,1] \to \mathbb{C}$, the *iterated integral* is

$$\int_\gamma \omega_1 \circ \cdots \circ \omega_n = \int_{0 \le t_1 \le \cdots \le t_n \le 1} \omega_1(t_1)\, \omega_2(t_2) \cdots \omega_n(t_n). \quad (60.241)$$

When the forms are $\omega_i = \mathrm{dlog}(t - a_i) = \mathrm{d}t/(t-a_i)$ with constants a_i, the integral defines the *multiple polylogarithm* (MPL, or Goncharov polylogarithm)

$$G(a_1, \dots, a_n; z) = \int_0^z \frac{\mathrm{d}t_1}{t_1 - a_1} \int_0^{t_1} \frac{\mathrm{d}t_2}{t_2 - a_2} \cdots \int_0^{t_{n-1}} \frac{\mathrm{d}t_n}{t_n - a_n}, \quad (60.242)$$

with the standard regularization of the endpoint divergences when some a_i coincide with 0 or z. The integer n — the number of integrations, equivalently the number of dlog forms — is the *transcendental weight* of the function.

The classical functions are special cases: $G(0;z)=\ln z$ has weight 1; the polylogarithm $\mathrm{Li}_n(z)=-G(0,\dots,0,1;z)$ (with $n-1$ zeros) has weight n, recovering $\mathrm{Li}_1(z)=-\ln(1-z)$ and the dilogarithm $\mathrm{Li}_2(z)=-\int_0^z \mathrm{dlog}(1-t)\,\mathrm{dlog}\,t$; and the transcendental constants inherit weights from their values, π being weight 1 (so π^2 and $\zeta(2)=\pi^2/6$ are weight 2) and $\zeta(n)$ weight n. A rational or algebraic number has weight 0.

Definition 60.41 (Uniform and maximal transcendentality)**.** A function is of *uniform (transcendental) weight* w if every term in it has weight w. A master integral expanded in ε is *pure of uniform weight* if the coefficient of ε^k has uniform weight $k+w_0$ for a fixed w_0 (the weight of the leading term). A canonical basis (60.235) produces exactly such integrals: by Theorem 60.39 the ε^k coefficient is a k-fold iterated integral, hence weight k above the boundary weight. An L-loop integral that achieves the maximal possible weight $2L$ in its finite part is said to have *maximal transcendentality*.

The grading by weight is not bookkeeping for its own sake. It is conjectured (and verified in vast swaths of cases) that amplitudes in maximally supersymmetric Yang–Mills theory are uniformly of maximal weight $2L$ at L loops — the "maximal transcendentality principle" — and that the leading transcendental part of QCD amplitudes coincides with the super-Yang–Mills answer. Weight is thus a physical organizing principle, and the canonical-basis method is valuable precisely because it manufactures pure, uniform-weight building blocks for which the principle is automatic.

The functions (60.242) satisfy a thicket of identities (shuffle relations, functional equations like the five-term dilogarithm identity), which makes deciding whether two expressions are equal genuinely hard. The tool that linearizes this problem is the symbol.

Definition 60.42 (The symbol)**.** The *symbol* $\mathcal{S}(F)$ of a weight-n function F is an element of the n-fold tensor product of the (multiplicative) group of nonzero algebraic functions, defined recursively from the total differential. If

$$\mathrm{d}F=\sum_i F_i\,\mathrm{dlog}\,R_i, \tag{60.243}$$

with each F_i of weight $n-1$ and R_i a letter, then

$$\mathcal{S}(F)=\sum_i \mathcal{S}(F_i)\otimes R_i, \qquad \mathcal{S}(\ln R)=R, \qquad \mathcal{S}(\text{const})=0. \tag{60.244}$$

The tensor factors are read left-to-right as the order of integration. The symbol obeys $\mathcal{S}(F\,G)=\mathcal{S}(F)\sqcup\!\sqcup\mathcal{S}(G)$ (shuffle product) and the entry rules $\cdots\otimes(R\,R')\otimes\cdots=\cdots\otimes R\otimes\cdots+\cdots\otimes R'\otimes\cdots$ and $\cdots\otimes(cR)\otimes\cdots=\cdots\otimes R\otimes\cdots$ for constant c, the last because constants carry no symbol.

The power of the construction is that all the transcendental identities among MPLs become *linear-algebraic* identities among tensors: two polylogarithmic functions agree, up to terms of lower weight times transcendental constants (which the symbol drops), if and only if their symbols agree. Two short computations show the recursion at work.

Worked Example 60.43 (Symbols of the logarithm-squared and the dilogarithm)**. Weight-2 product.** For $F = \ln a \, \ln b$, the differential is $\mathrm{d}F = \ln b \, \mathrm{dlog}\, a + \ln a \, \mathrm{dlog}\, b$, so by (60.244)

$$\mathcal{S}(\ln a \, \ln b) = \mathcal{S}(\ln b) \otimes a + \mathcal{S}(\ln a) \otimes b = b \otimes a + a \otimes b, \tag{60.245}$$

which is the shuffle $a \sqcup\!\sqcup b$, confirming $\mathcal{S}(\ln a \ln b) = \mathcal{S}(\ln a) \sqcup\!\sqcup \mathcal{S}(\ln b)$. In particular $\mathcal{S}(\frac{1}{2}\ln^2 a) = a \otimes a$.

Dilogarithm. For $F = \mathrm{Li}_2(z)$, the defining derivative is $\mathrm{d}\,\mathrm{Li}_2(z) = -\ln(1-z)\,\mathrm{dlog}\, z$, so $F_1 = -\ln(1-z)$, $R_1 = z$, and

$$\mathcal{S}(\mathrm{Li}_2(z)) = \mathcal{S}(-\ln(1-z)) \otimes z = -(1-z) \otimes z. \tag{60.246}$$

The five-term relation $\mathrm{Li}_2(x) + \mathrm{Li}_2(y) + \mathrm{Li}_2(\frac{1-x}{1-xy}) + \mathrm{Li}_2(1-xy) + \mathrm{Li}_2(\frac{1-y}{1-xy}) = -\ln x \ln(1-x) - \cdots$ — a notorious identity to verify by hand — collapses, under (60.246) and the entry rules, to the vanishing of a sum of tensors, a finite linear-algebra check.

The one-loop masters of the previous section's gluon amplitude live entirely in this world. The massless box $I_4(s,t)$ with all external legs lightlike — the integral that carried the leading singularity of the reconstructed amplitude — evaluates, with the canonical normalization $\hat{f} = \varepsilon^2\, st\, c_\Gamma^{-1} I_4$ that makes it pure, to a uniform weight-2 function in the two-letter alphabet $\{-s, -t\}$,

$$\varepsilon^2\, st\, c_\Gamma^{-1}\, I_4(s,t) = 2\big[(-s)^{-\varepsilon} + (-t)^{-\varepsilon}\big] - \varepsilon^2\Big[\ln^2\tfrac{-s}{-t} + \pi^2\Big] + O(\varepsilon^3), \tag{60.247}$$

with $c_\Gamma = \Gamma(1+\varepsilon)\Gamma(1-\varepsilon)^2/\Gamma(1-2\varepsilon)$. Its finite ($\varepsilon^0$) part is the weight-2 combination whose symbol, by (60.245), is built from the single nontrivial entry pattern in the letters $-s, -t$ — explicitly the symbol of $-\frac{1}{2}\ln^2(-s/-t)$ is $-(-s/-t) \otimes (-s/-t)$, while the π^2 is a weight-2 constant invisible to the symbol. The box's branch cuts in s and t, encoded by the letters, are exactly the channels whose unitarity cuts the reconstruction sewed together: the function space and the cut structure are two views of the same object. This is the precise sense in which a loop amplitude is rigid — its singularities (the letters) are dictated by unitarity and locality, and the symbol exposes them as the alphabet of an iterated integral.

60.7.6 The frontier: numerical unitarity, functions beyond polylogarithms, and the optimal basis

The three tools just built — IBP reduction, canonical differential equations, the polylogarithmic function space — are the working infrastructure of multiloop amplitude computation in the mid-2020s. Their reach, and its limits, deserve an honest accounting.

Numerical unitarity at multiloop. The generalized-unitarity logic of this chapter, which at one loop fixed master coefficients as products of trees evaluated on cuts, extends to two loops and beyond in a form that has become the practical workhorse for high-multiplicity QCD. One works in d dimensions on multiple cuts, parametrizes the integrand in a basis of master and "surface" (spurious, IBP-vanishing) terms, and reads off the master coefficients by sampling the product of trees on the cut solutions — now an algebraic, not analytic, operation. The reduction and the linear solves are performed over *finite fields*: rational functions of the kinematics and d are reconstructed from many evaluations modulo large primes, sidestepping the intermediate expression swell that defeats symbolic algebra [394]. This "numerical unitarity" program produced the first complete two-loop five-parton amplitudes [3] and is the method by which the master-coefficient half of Fig. 60.6 is now executed at the frontier; the master-integral half is the differential-equation machinery above.

Beyond polylogarithms: elliptic and Calabi–Yau integrals. The clean story of Sections 60.7.4 and 60.7.5 — a canonical ε-form, a logarithmic alphabet, MPL solutions — is not the whole story. It holds when the geometry underlying the Feynman integral is rational (a punctured Riemann sphere). The first integral where it fails is the two-loop massive sunrise (sunset): its maximal cut is an integral over an *elliptic curve*, and no change of basis brings its differential equation to the dlog form (60.235) — the obstruction is a genuine feature of the geometry, not a failure of cleverness. The functions are *elliptic polylogarithms*, iterated integrals on the elliptic curve with modular forms among the integration kernels [94]. Higher: the L-loop equal-mass banana integrals probe Calabi–Yau $(L-1)$-folds, whose periods generalize the elliptic case further [88]. A practical, partial replacement for the canonical form survives — one factorizes ε while allowing the kernels to be modular rather than logarithmic, an "ε-factorized" (but not dlog) form — but a complete, algorithmic theory of the function space beyond the polylogarithmic and elliptic cases is, as of the mid-2020s, an active and unfinished subject.

The optimal basis problem. Even within the polylogarithmic class, the construction of a canonical basis is not a solved algorithmic problem in general.

Heuristics — demanding unit leading singularities, building pure integrands from dlog forms, using the structure of maximal cuts — succeed case by case and are increasingly automated, but there is no theorem guaranteeing that a canonical basis exists for an arbitrary polylogarithmic family, nor an algorithm that produces it with proof at high loop order. What constitutes the *optimal* master basis — minimizing the alphabet, exposing the weight grading, controlling the size of the IBP coefficients — is, at three loops and beyond for multi-scale problems, a research question rather than a procedure. The finiteness theorem (Theorem 60.35) guarantees the basis is finite; it does not hand us the best one.

What the master integrals are, and why it matters

The arc of this section is a single shift in viewpoint. A loop amplitude began, in Part V and Part VI, as a sum over diagrams, each an integral to be ground out. It became, in this chapter, a linear combination of master integrals with unitarity-fixed coefficients. And it ends here as a vector in a graded function space — the polylogarithms and their elliptic and Calabi–Yau generalizations — whose alphabet is dictated by the singularities that unitarity and locality permit. The computation factorizes cleanly into *algebra* (IBP coefficients, canonical bases, symbols — all rational or linear-algebraic, increasingly mechanized) and a residue of genuine *analysis* (boundary conditions, and the geometry that decides whether the functions are polylogarithmic at all). The rigidity that opened the chapter — an amplitude is fixed by its cuts and poles — is, at the multiloop frontier, the statement that the function and its alphabet are determined by where it is allowed to be singular.

This completes the chapter's passage from unitarity-as-principle to the modern computational engine, and with it the one-loop gluon result of the previous section finds its place in a larger landscape: its box, triangle, and bubble masters are the weight-two ground floor of a tower whose higher storeys — the elliptic and Calabi–Yau integrals, the symbols and the alphabets — are where the amplitudes program now lives. That program's deeper lessons are taken up next: the hidden simplicity by which gauge and gravity amplitudes are sewn from a common kinematic numerator, the colour–kinematics duality and the double copy that promotes the Yang–Mills theory gluon amplitude into a graviton amplitude (Chapter 61); the positive geometry that recasts the integrand itself as the canonical form of a polytope (Chapter 62); and the synthesis (Chapter 63) in which locality and unitarity, the two principles this chapter made computational, are seen not as inputs but as emergent consequences of that geometry.

Further reading

The cutting rules originate with Cutkosky [141]; their dispersive and analyticity context is the classic territory of Eden et al. [170]. The modern unitarity method for one-loop amplitudes was launched by Bern et al. [67] and Bern et al. [67]; generalized (multiple) unitarity is Britto et al. [91], and Forde's triple-cut parametrization is Forde [197]. Integrand-level reduction is Ossola et al. [371]. The all-plus rational amplitude appears in Bern et al. [67, 68]. For the multiloop apparatus: integration-by-parts identities are due to Chetyrkin and Tkachov [121], Tkachov [473] and the systematic reduction to Laporta and Remiddi [315], Laporta [316]; the differential-equation method is Gehrmann and Remiddi [212], Kotikov [306], brought to canonical ε-form by Henn and Plefka [263]; the symbol and the polylogarithmic function space are Duhr [165], Goncharov et al. [233]. The comprehensive modern reference is the textbook of Weinzierl [503], with evaluation techniques in Smirnov [448]; a pedagogical synthesis of the whole on-shell program is Elvang and Huang [176]. For the frontier: numerical unitarity and finite-field reconstruction [3, 394], elliptic Feynman integrals [94], and Calabi–Yau geometries in the banana integrals [88].

Chapter 61

Color–Kinematics Duality and the Double Copy

Yang–Mills theory has carried one non-abelian gauge theory from its classical Lagrangian (Chapter 25) through quantization and BRST (Chapter 26), asymptotic freedom (Chapter 27), and the modern on-shell technology of Parke–Taylor and BCFW recursion (Chapter 59). Along the way two facts have grown impossible to dismiss as accidents. First, the color decomposition of Chapter 59 cleanly separates the gauge-group data of a gluon amplitude from its kinematics, peeling off traces of generators to leave gauge-invariant color-ordered partials. Second, those partials are far simpler than the Feynman expansion that produces them. This chapter locates the structure responsible: a hidden duality between color and kinematics that, once exposed, lets one trade the color factors of a gauge amplitude for a *second copy* of its kinematics and so read off a graviton amplitude. The slogan "gravity = gauge^2" becomes, at the level of on-shell data, a theorem at low points and a sharply formulated conjecture beyond.

The development proceeds in the order its logic forces. We first rewrite the amplitude in a presentation that displays color and kinematics at the same resolution: the cubic-graph (trivalent) organization, in which every term is a triple (c_i, n_i, D_i) attached to one trivalent topology, with the Yang–Mills quartic vertex absorbed exactly into the numerators (Section 61.1). The color factors, built from contracted structure constants, inherit the Jacobi identity of the Lie algebra (Theorem 2.42, with index data in Chapter B); the question that organizes everything else is whether the kinematic numerators, ambiguous under a generalized gauge freedom, can be chosen to obey the *same* Jacobi relations. That is the statement of color–kinematics (BCJ) duality, established at tree level in Section 61.2 together with its constraint-counting and the BCJ amplitude relations that reduce the basis of independent partials. The four-gluon amplitude is then worked completely (Section 61.3), extracting explicit duality-satisfying numerators from the Parke–Taylor partials of Theorem 59.13 and verifying the

kinematic Jacobi identity by hand.

With a duality-satisfying representation in hand, the double copy is almost a definition: replace each color factor c_i by a second numerator $\tilde{n}_i$ and the gauge amplitude becomes a gravity amplitude (Section 61.4). We prove the construction is independent of the residual gauge freedom provided one copy satisfies the duality, square the three-point amplitude to fix the graviton vertex, and assemble the four-graviton amplitude from the four-gluon square, checking its factorization and hence its locality and unitarity. Section 61.5 reveals where the product form comes from historically and structurally — the Kawai–Lewellen–Tye relations born on the string worldsheet, recast in field theory as a momentum kernel that is the inverse of the bi-adjoint scalar amplitude matrix. Section 61.6 reads off the spectrum of the squared theory — graviton, dilaton, and two-form — and organizes the resulting web of theories, with $\mathcal{N} = 8$ supergravity as the square of $\mathcal{N} = 4$ super-Yang–Mills and the bi-adjoint scalar as the "zeroth copy."

The chapter closes at the frontier (Section 61.7). The double copy is conjectured to persist loop by loop at the level of integrands; we state the conjecture honestly, prove its cut-level consistency, and date the evidence (through five loops in $\mathcal{N} = 4$, with the all-order existence of local numerators still open). The same algebraic structure descends to exact classical solutions through the Kerr–Schild double copy, mapping a Coulomb field to Schwarzschild and feeding the modern amplitudes-for-binaries program that computes gravitational-wave observables. Throughout, the graviton is imported on faith as the massless spin-2 state whose polarizations factorize into products of gauge polarizations; the curvature and field equations that justify this are built in the gravity part (Chapter 64), and the broader lesson — that locality and unitarity may be outputs rather than inputs of the on-shell story — is taken up in the synthesis chapter (Chapter 63). With this chapter Yang–Mills theory reaches its terminus: the Jacobi identity that organized the gauge interaction, mirrored once in kinematics, is enough to produce gravity.

61.1 From Color-Ordered Partials to the Cubic-Graph Organization

The chapter introduction set the program: the Parke–Taylor collapse (Theorem 59.13) and the recursive constructibility of gluon trees are too sharp to be accidents of clever variables, and we want the organizing principle beneath them. The first and indispensable step is to find the *form* in which that principle can even be stated. The color decomposition of Chapter 59 already taught us to peel the gauge group off the kinematics, writing the full amplitude as a sum of single color traces, each multiplied by a gauge-invariant kinematic coefficient — a color-ordered partial amplitude. That presentation is perfect for *computing*: it isolates the smallest gauge-invariant kinematic objects. But it is lopsided. The

color side has been ground all the way down to traces of generators, while the kinematic side has been packed into opaque functions $A_n[\sigma]$ whose own internal structure — which is where any hidden algebra must live — is invisible. To see color and kinematics as *parallel*, we need a presentation in which both are exposed at the same level of resolution: both written as sums over the *same* set of graphs, with color and kinematics attached factor by factor to identical wiring diagrams. That presentation is the cubic-graph (trivalent-graph) organization, and building it — carefully enough that it is an exact rewriting of the amplitude rather than an approximation — is the business of this section. The output is a small package of data, a triple (c_i, n_i, D_i) for every trivalent graph i, on which the entire rest of the chapter operates.

Throughout we use the Yang–Mills theory of Yang–Mills theory, with Lagrangian Eq. (25.76), gauge group $\mathrm{SU}(N)$, Hermitian generators T^a and structure constants f^{abc} defined by $\left[T^a, T^b\right] = i f^{abc} T^c$ (Eq. (2.70), with Casimir and index data in Chapter B). Momenta are taken all-outgoing, so that momentum conservation reads $\sum_{i=1}^{n} p_i = 0$ and the on-shell conditions are $p_i^2 = 0$; Mandelstam invariants are formed from sums of outgoing momenta, e.g. $s = (p_1 + p_2)^2$. The kinematic numerators we shall isolate are Lorentz-invariant functions of these momenta and of the external polarizations, ultimately expressible in the spinor-helicity brackets of Theorem 58.4; for the structural work of this section their explicit values are never needed, only the fact that they are well defined.

61.1.1 Two color bases

Before reorganizing the amplitude by graphs, we record the two standard ways to expand its color dependence, because the cubic-graph form is, in effect, the common refinement of both. Each is a choice of basis for the space of color tensors that can carry the n external adjoint indices $a_1, \dots, a_n$ of a tree amplitude.

The trace basis. This is the decomposition built in Section 59.1. Collecting the color factor of every tree diagram into single traces of generators, one obtains (Eq. (59.11))

$$\mathcal{A}_n^{\text{tree}} = g^{n-2} \sum_{\sigma \in S_{n-1}} \operatorname{tr}\left(T^{a_1} T^{a_{\sigma(2)}} \cdots T^{a_{\sigma(n)}}\right) A_n[1, \sigma(2), \dots, \sigma(n)], \tag{61.1}$$

the sum running over the $(n-1)!$ orderings of $2, \dots, n$ with leg 1 fixed by cyclicity of the trace. The statement we will lean on repeatedly is the one emphasized in Theorem 59.3: *the color-ordered partial amplitudes $A_n[1, \sigma]$ are precisely the kinematic coefficients in the trace basis.* They are the objects of Chapter 59 — the same functions whose MHV value is Parke–Taylor (Theorem 59.13) — and they are gauge invariant one ordering at a time. The trace basis is therefore the basis in which the kinematics is already organized into its irreducible gauge-invariant pieces.

The half-ladder (f-) basis. The second standard basis trades traces of generators for chains of structure constants. It is due to Del Duca, Dixon and Maltoni, and it expresses the full amplitude over a smaller index set, the $(n-2)!$ orderings in which both leg 1 and leg n are held fixed:

$$\mathcal{A}_n^{\text{tree}} = g^{n-2} \sum_{\sigma \in S_{n-2}} c_{1|\sigma|n}\, A_n[1, \sigma(2), \dots, \sigma(n-1), n], \qquad c_{1|\sigma|n} = f^{a_1 a_{\sigma(2)} x_1} f^{x_1 a_{\sigma(3)} x_2} \cdots f^{x_{n-3} a_{\sigma(n} \tag{61.2}$$

The color factor $c_{1|\sigma|n}$ is a single chain — a "half-ladder" or multiperipheral string — of $n-2$ structure constants, with legs 1 and n capping the two ends and the legs $\sigma(2), \dots, \sigma(n-1)$ entering in order along the spine, the internal indices $x_1, \dots, x_{n-3}$ contracted consecutively. The two bases are related by the invertible linear map of Eq. (59.8), which writes each structure constant as a difference of traces; consequently the coefficients in Eq. (61.2) are again color-ordered partial amplitudes, now a Kleiss–Kuijf basis (Eq. (59.26)) of $(n-2)!$ of them.

Theorem 61.1 (Trace and half-ladder bases are equivalent)**.** *The decompositions Eq. (61.1) and Eq. (61.2) are equal, term by term after using the Kleiss–Kuijf relations Eq. (59.26) to reduce the trace-basis coefficients to the $(n-2)!$-element basis with legs 1 and n fixed. The half-ladder color factors $c_{1|\sigma|n}$ and the single traces $\mathrm{tr}(T^{a_1} T^{a_\sigma} \cdots)$ are two bases of the same space of n-point tree color tensors, related by Eq. (59.8).*

We do not need the general proof for what follows — it is a corollary of the Kleiss–Kuijf reduction already recorded in Chapter 59 — but the four-point case is short and instructive, so we verify it explicitly in Theorem 61.5 below, where it falls out of the same computation that produces the cubic-graph data. The lesson of both bases is the same: the full amplitude is a sum over a finite set of *color objects*, each multiplied by a gauge-theoretic kinematic coefficient. What neither basis displays is the *kinematic* object's own graph structure. The cubic-graph form supplies exactly that, by attaching color and kinematics to one and the same set of graphs.

61.1.2 The cubic-graph master formula

Definition 61.2 (Cubic graph and its data)**.** A *cubic graph* (trivalent graph) on n external legs is a connected tree in which every internal vertex meets exactly three lines. Such a tree has $n-2$ cubic vertices and $n-3$ internal lines. We write Γ_3 for the set of all distinct cubic graphs on the n labelled legs, and index its members by $i \in \Gamma_3$. To each cubic graph i we attach three pieces of data:

- the *color factor* c_i: the product of one structure constant f^{abc} per cubic vertex, with the adjoint index of each internal line contracted between the two vertices it joins, read off the graph exactly as in the trace-stripping of Section 59.1;

- the *denominator* $D_i = \prod_\alpha P_\alpha^2$, the product of the inverse scalar propagators of the $n-3$ internal lines, P_α being the momentum flowing through internal line α (a partial sum of external momenta fixed by the graph);
- the *kinematic numerator* n_i: a Lorentz-invariant polynomial in the external momenta and polarizations, of the dimension required to make $c_i n_i / D_i$ a term in the amplitude, into which we collect the Lorentz-contracted vertex tensors, the external polarizations, and the conventional factors of i.

Theorem 61.3 (Cubic-graph master formula)**.** *The n-gluon tree amplitude can be written exactly as a sum over the distinct trivalent topologies,*

$$\boxed{\mathcal{A}_n^{\text{tree}} = i\, g^{n-2} \sum_{i \in \Gamma_3} \frac{c_i\, n_i}{D_i}\,,} \tag{61.3}$$

the sum running over all $(2n-5)!!$ *distinct cubic graphs on the n ordered external legs, with* (c_i, n_i, D_i) *the data of Theorem 61.2. The overall i is the standard normalization of the amplitude relative to the product of Feynman vertices and propagators; with it pulled to the front, the numerators* n_i *are the purely kinematic vertex contractions, carrying no factors of i of their own. The denominators* D_i *are the genuine physical poles of the amplitude; the color factors* c_i *are the same products of structure constants that appear in Eq. (61.2); and the numerators* n_i *are local (polynomial), carrying no poles of their own.*

Two of the three pieces of data, c_i and D_i, are read off the graph immediately and unambiguously — they are pure topology dressed with group theory and momentum routing. The numerators n_i are the nontrivial content; making them well defined requires showing that the quartic vertices of the Yang–Mills Lagrangian, which are *not* cubic and carry no propagator, can be folded into this cubic skeleton without loss. That is the next subsection, and it is what turns Eq. (61.3) from a hope into a theorem. The denominator count D_i deserves one immediate comment: because a cubic tree on n legs has exactly $n-3$ internal lines, every term in Eq. (61.3) has the maximal number of simultaneous poles a tree amplitude can have, namely $n-3$. A diagram with a quartic vertex has one fewer; the absorption procedure below is precisely the statement that a missing pole is a pole present in the numerator, cancelled.

61.1.3 Absorbing the quartic vertex: the cubic form is exact

The Feynman expansion of a gluon tree built from the Lagrangian Eq. (25.76) contains two kinds of vertex: the cubic vertex Eq. (59.2), carrying one structure constant and one power of momentum, and the quartic (contact) vertex Eq. (59.3), carrying two structure constants and no momentum. A diagram built entirely from cubic vertices *is* already a cubic graph in the sense of Theorem 61.2: it

has $n-3$ internal lines, hence $n-3$ propagators, and contributes a single term $c_i n_i / D_i$. The only obstruction to Eq. (61.3) is the contact vertex. We now show it is no obstruction at all.

Proposition 61.4 (Contact-term absorption)**.** *Every Feynman diagram containing quartic vertices can be rewritten, by an exact algebraic identity, as a sum of cubic-graph contributions $c_i n_i / D_i$. Hence the cubic form Eq. (61.3) reproduces the full amplitude with no approximation; the redistribution merely reassigns local (contact) kinematics into the numerators n_i of the cubic graphs.*

Proof. Consider a single quartic vertex somewhere in a tree diagram. Four lines meet at it; let their (outgoing) momenta, summed in two complementary pairs, define the three channel momenta of the four-line subdiagram, with squares P_s^2, P_t^2, P_u^2. The color tensor of the quartic vertex, Eq. (59.3), is already a sum of *three* terms, each a product $f^{\bullet\bullet e} f^{\bullet\bullet e}$ of two structure constants sharing one contracted index:

$$iV^{abcd}_{\mu\nu\rho\sigma} = -ig^2\Big[f^{abe}f^{cde}\,T^{s}_{\mu\nu\rho\sigma} + f^{ace}f^{bde}\,T^{u}_{\mu\nu\rho\sigma} + f^{ade}f^{bce}\,T^{t}_{\mu\nu\rho\sigma}\Big], \tag{61.4}$$

where T^s, T^u, T^t are the three metric tensor structures of Eq. (59.3). The three color products $f^{abe}f^{cde}$, $f^{ace}f^{bde}$, $f^{ade}f^{bce}$ are precisely the color factors of the three *cubic* graphs obtained by "blowing up" the quartic vertex into two cubic vertices joined by an internal line in the s-, u-, and t-channel respectively: in each channel the two structure constants are exactly what a pair of cubic vertices joined by an internal line would contribute. Thus the contact vertex's color already lands, term by term, on cubic graphs.

It remains to give those terms a propagator. Each channel term of Eq. (61.4) carries a purely local kinematic factor — call it $\mathcal{V}_c$ for channel $c \in \{s,t,u\}$ (the metric structure T^c contracted with the surrounding momenta and polarizations of the full diagram) — with *no* propagator $1/P_c^2$, because the four lines meet at a point. We multiply and divide by the inverse propagator of the very line that the blow-up would introduce:

$$\mathcal{V}_c \;=\; \frac{P_c^2\,\mathcal{V}_c}{P_c^2}. \tag{61.5}$$

This is an exact identity (it changes nothing: $P_c^2/P_c^2 = 1$). The right-hand side now has the structure of a cubic-graph term: a denominator P_c^2 — the propagator of the internal line of the blown-up graph — and a numerator $P_c^2\,\mathcal{V}_c$, which is a *polynomial* because the explicit factor P_c^2 cancels the would-be pole. Assigning the channel-c piece of the contact vertex to the cubic graph in which that internal line appears, its numerator contribution is $P_c^2\,\mathcal{V}_c$, added to whatever pure-cubic numerator that graph already carried.

Applying Eq. (61.5) independently to every quartic vertex of every diagram, and grouping all contributions by the cubic graph they land on, expresses the

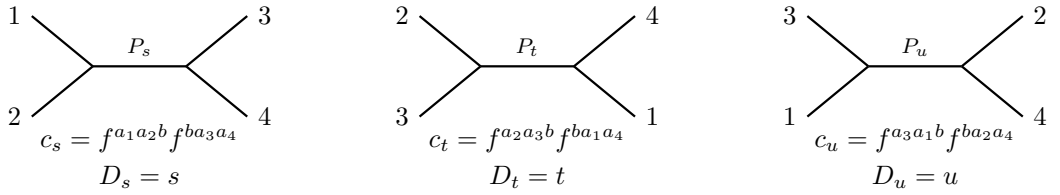

Figure 61.1: The three cubic graphs of the four-gluon tree amplitude. Each has two cubic vertices joined by one internal line, hence one propagator. The three channels exhaust the trivalent topologies on four legs, $(2 \cdot 4 - 5)!! = 3$. The color factor c_i is the product of the two structure constants at the vertices with the internal index b contracted; the denominator D_i is the square of the internal momentum: $s = (p_1 + p_2)^2$, $t = (p_2 + p_3)^2$, $u = (p_1 + p_3)^2$, satisfying $s + t + u = 0$ for massless legs. The single quartic (contact) Feynman diagram is not shown; by Theorem 61.4 it is distributed among these three graphs.

entire Feynman sum as $g^{n-2} \sum_i c_i n_i / D_i$. No term is dropped or approximated; the only operation used is the insertion of $1 = P_c^2 / P_c^2$. This proves both Theorem 61.4 and Theorem 61.3. □

Physical Insight

The single line $\mathcal{V}_c = P_c^2 \mathcal{V}_c / P_c^2$ is the whole trick, and it is worth saying plainly what it buys. A contact term is a pole that is present and immediately cancelled; writing it as numerator-over-propagator restores the pole explicitly so that color and kinematics can be compared on graphs that all have the same skeleton. The price is that the numerators n_i are no longer unique: the same amplitude is reproduced by infinitely many assignments of contact kinematics to channels (one may add to one numerator any term that is a multiple of D_i, as long as a compensating term is subtracted elsewhere so the sum is unchanged). This non-uniqueness — *generalized gauge freedom* — is not a defect. It is exactly the room we will need in Section 61.2 to *choose* numerators that mirror the color algebra. The cubic-graph form does not yet single out a duality-satisfying representation; it builds the stage on which one can be sought.

61.1.4 Four points, worked completely

The four-gluon amplitude is the smallest case in which the cubic organization has real content — one contact vertex to absorb, three channels to populate — and it is the carried Yang–Mills theory object whose color decomposition we now reproduce in the new language.

Worked Example 61.5 (The four-gluon cubic data and the color decomposition)**.** *The three graphs and their color factors.* The trivalent topologies on four legs are the three channels of Fig. 61.1. Reading the color factor off each graph as in Section 59.1 — one structure constant per vertex, internal index b contracted — gives

$$c_s = f^{a_1 a_2 b} f^{b a_3 a_4}, \qquad c_t = f^{a_2 a_3 b} f^{b a_1 a_4}, \qquad c_u = f^{a_3 a_1 b} f^{b a_2 a_4}, \tag{61.6}$$

with denominators $D_s = s = (p_1+p_2)^2$, $D_t = t = (p_2+p_3)^2$, $D_u = u = (p_1+p_3)^2$. These three color tensors are not independent. Setting $(a,b,c,d) = (a_1,a_2,a_3,a_4)$ in the structure-constant form of the Jacobi identity Eq. (2.77) (the identity proved in Theorem 2.42),

$$f^{a_1 a_2 e} f^{e a_3 a_4} + f^{a_2 a_3 e} f^{e a_1 a_4} + f^{a_3 a_1 e} f^{e a_2 a_4} = 0 \quad \Longleftrightarrow \quad c_s + c_t + c_u = 0. \tag{61.7}$$

The three color factors satisfy a single linear (Jacobi) relation: only two are independent. This relation is the seed of the entire chapter; it is the algebra that the kinematic numerators will be asked to imitate in the next section.

Reading off the numerators. The four Feynman diagrams of the full amplitude are the three cubic diagrams (Fig. 61.1) and the single contact diagram. The s-channel cubic diagram is a product of two cubic vertices Eq. (59.2) and one propagator; its color is $g^2 c_s$ and its kinematics is a momentum-dependent numerator divided by s, so it contributes $g^2\, c_s\, N_s/D_s$ with N_s the contraction of the two vertex tensors $K_{\mu\nu\rho}$ with the propagator metric and the four polarizations. The t- and u-channel cubic diagrams contribute $g^2 c_t N_t/D_t$ and $g^2 c_u N_u/D_u$ likewise. The contact diagram Eq. (59.3) carries the three color structures of Eq. (61.4); identifying them through Eq. (61.6),

$$f^{a_1 a_2 e} f^{a_3 a_4 e} = c_s, \qquad f^{a_1 a_4 e} f^{a_2 a_3 e} = c_t, \qquad f^{a_1 a_3 e} f^{a_2 a_4 e} = -c_u, \tag{61.8}$$

so the contact contribution is $g^2(c_s\,\mathcal{V}_s + c_t\,\mathcal{V}_t + c_u\,\mathcal{V}_u)$, where $\mathcal{V}_s = (\epsilon_1{\cdot}\epsilon_3)(\epsilon_2{\cdot}\epsilon_4) - (\epsilon_1{\cdot}\epsilon_4)(\epsilon_2{\cdot}\epsilon_3)$ and $\mathcal{V}_t, \mathcal{V}_u$ are the analogous metric contractions read from Eq. (59.3), each *without* a propagator. Applying Eq. (61.5) to each, $\mathcal{V}_c = D_c \mathcal{V}_c / D_c$, and adding to the cubic numerators, the four diagrams assemble into exactly three cubic-graph terms,

$$\mathcal{A}_4^{\text{tree}} = i\, g^2 \left(\frac{c_s\, n_s}{s} + \frac{c_t\, n_t}{t} + \frac{c_u\, n_u}{u} \right), \qquad n_c = N_c + D_c\, \mathcal{V}_c \quad (c = s,t,u). \tag{61.9}$$

The numerators n_c are local: the explicit D_c multiplying $\mathcal{V}_c$ cancels the propagator, so n_c has no pole. This is the master formula Eq. (61.3) at $n = 4$, derived diagram by diagram, with the contact term absorbed exactly.

Recovering the trace-basis (Yang–Mills theory) decomposition. We check that Eq. (61.9) reproduces the color decomposition of Chapter 59. The amplitude in

the trace basis is Eq. (59.27), and the reflection identities of Theorem 59.7 pair its six traces into three combinations,

$$T_s = \mathrm{tr}(1234)+\mathrm{tr}(1432), \quad T' = \mathrm{tr}(1243)+\mathrm{tr}(1342), \quad T_u = \mathrm{tr}(1324)+\mathrm{tr}(1423), \tag{61.10}$$

(writing $\mathrm{tr}(ijkl) \equiv \mathrm{tr}(T^{a_i}T^{a_j}T^{a_k}T^{a_l})$), multiplying the three inequivalent partials $A_4[1,2,3,4]$, $A_4[1,2,4,3]$, $A_4[1,3,2,4]$ respectively. The $U(1)$-decoupling relation Eq. (59.29), $A_4[1,2,3,4] + A_4[1,2,4,3] + A_4[1,3,2,4] = 0$, eliminates the middle partial, so

$$\mathcal{A}_4^{\text{tree}} = g^2\Big[A_4[1,2,3,4]\,(T_s - T') + A_4[1,3,2,4]\,(T_u - T')\Big]. \tag{61.11}$$

Now expand the cubic color factors in traces. With the f-to-trace identity Eq. (59.8) and the product formula Eq. (59.16),

$$c_s = f^{a_1a_2e}f^{a_3a_4e} = -\tfrac{1}{2}\big[\,\mathrm{tr}(1234)-\mathrm{tr}(1243)-\mathrm{tr}(2134)+\mathrm{tr}(2143)\big] = -\tfrac{1}{2}\,(T_s - T'), \tag{61.12}$$

where the last equality uses cyclicity ($\mathrm{tr}(2143) = \mathrm{tr}(1432)$ so it joins T_s, and $\mathrm{tr}(2134) = \mathrm{tr}(1342)$ so it joins T'). The identical computation for the half-ladder factor $f^{a_1a_3e}f^{a_2a_4e} = -c_u$ gives $-\frac{1}{2}(T_u - T')$, i.e. $T_u - T' = -2f^{a_1a_3e}f^{a_2a_4e}$. Substituting into Eq. (61.11),

$$\mathcal{A}_4^{\text{tree}} = -2g^2\Big[\,f^{a_1a_2e}f^{a_3a_4e}\,A_4[1,2,3,4] + f^{a_1a_3e}f^{a_2a_4e}\,A_4[1,3,2,4]\Big], \tag{61.13}$$

which is exactly the half-ladder (DDM) form Eq. (61.2) at $n = 4$ — the S_2 sum over the orderings $(2,3)$ and $(3,2)$ of the two interior legs — up to the overall constant -2 that is the amplitude-normalization convention of Chapter 59 (the rescaling $\mathrm{tr}(T^aT^b) = \delta^{ab}$ recorded there). This both confirms Theorem 61.1 at four points and pins down how the cubic data of Eq. (61.9) repackages the partial amplitudes: reading Eq. (61.9) against Eq. (61.13), eliminating c_t by Jacobi Eq. (61.7), one finds

$$A_4[1,2,3,4] = \frac{i}{2}\left(\frac{n_t}{t} - \frac{n_s}{s}\right), \qquad A_4[1,3,2,4] = \frac{i}{2}\left(\frac{n_u}{u} - \frac{n_t}{t}\right). \tag{61.14}$$

The planar reading. Equation Eq. (61.14) is the exact statement of an intuitive fact: $A_4[1,2,3,4]$ receives contributions only from the s- and t-channel graphs and *not* from the u-channel. These are precisely the two cubic graphs that can be drawn in the plane with the legs in the cyclic order $1,2,3,4$ — the s-channel groups the cyclically adjacent pair $\{1,2\}$ against $\{3,4\}$, the t-channel groups $\{2,3\}$ against $\{4,1\}$, while the u-channel would group the non-adjacent $\{1,3\}$ against $\{2,4\}$ and its internal line must cross. The color-ordered partial amplitude is the sum of the cubic graphs that are planar with respect to its ordering. The same is visible in the diagram counts of Table 59.1: the three color-ordered diagrams listed there for $n = 4$ (two cubic, one contact) collapse, after contact absorption, to the *two* cubic graphs s, t that Eq. (61.14) exhibits.

The four-point worked example has delivered the chapter's working data in concrete form: three color factors c_s, c_t, c_u obeying the Jacobi relation Eq. (61.7), three denominators s, t, u, and three numerators n_s, n_t, n_u whose definition Eq. (61.9) is exact but non-unique. The asymmetry between color and kinematics is now sharp and quantitative: the c_i satisfy $c_s + c_t + c_u = 0$ identically, by group theory, while the n_i as read off Feynman rules satisfy no such relation. Whether they *can* be made to is the question of the next section.

61.1.5 Counting cubic graphs: why the organization scales

The four-point case had three cubic graphs. To trust Eq. (61.3) as a finite, well-organized rewriting at all multiplicities we must know how many cubic graphs there are, and that every Feynman contribution lands on one of them. The second point is Theorem 61.4; the first is a clean combinatorial count.

Proposition 61.6 (Number of cubic graphs)**.** *The number of distinct trivalent tree topologies on n labelled external legs is the double factorial*

$$(2n-5)!! = (2n-5)(2n-7)\cdots 5\cdot 3\cdot 1. \tag{61.15}$$

Proof. Count by adding legs one at a time. A trivalent tree on m legs has $m-2$ internal vertices, hence $(m-2)+m = 2m-2$ vertices in all and, being a tree, $2m-3$ edges. To build an $(m+1)$-leg tree from an m-leg one, take any of those $2m-3$ edges, insert a new trivalent vertex in its interior, and attach leg $m+1$ there. Every $(m+1)$-leg trivalent tree arises from exactly one m-leg tree by deleting leg $m{+}1$ and its vertex (smoothing the resulting bivalent vertex), so the map is a bijection and

$$\#(m+1) = (2m-3)\cdot \#(m). \tag{61.16}$$

The recursion starts at the unique three-point vertex, $\#(3) = 1 = (2\cdot 3-5)!!$. By induction $\#(n) = (2n-5)(2n-7)\cdots 1 = (2n-5)!!$, which is Eq. (61.15). At $n=4$ this is $3!! = 3$, the three channels of Fig. 61.1; at $n=5$ it is $5!! = 15$; at $n=6$, $7!! = 105$. □

The five-point case makes the count tangible and is the first place the scaling is visible. Every trivalent tree on five legs has three vertices arranged on a single spine and two internal lines, the topology of Fig. 61.2: two outer vertices each carrying a pair of external legs, and a central vertex carrying the fifth leg. Such a graph is determined by which single leg sits at the center and how the other four are paired between the two ends. There are 5 choices for the central leg and, for the remaining four legs, $4!/(2!\,2!\,2!) = 3$ ways to split them into two unordered pairs, giving

$$5 \times 3 = 15 \tag{61.17}$$

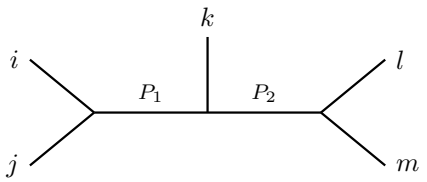

Figure 61.2: The generic cubic graph at five points: three vertices on a spine with two internal lines, denominator $D = P_1^2\,P_2^2$. A five-point trivalent tree is fixed by choosing the central single leg k (5 ways) and partitioning the remaining four legs into the two outer pairs $\{i,j\}$ and $\{l,m\}$ (3 ways), giving $5\times 3 = 15 = (2\cdot 5-5)!!$ graphs, in agreement with Theorem 61.6.

cubic graphs, exactly Eq. (61.15) at $n=5$. Each contributes a term $c_i n_i/(P_{1,i}^2 P_{2,i}^2)$ with two propagators. The Feynman expansion at five points has, besides all-cubic diagrams, diagrams with one quartic vertex (whose four lines are blown up into a missing internal line in three channels); by Theorem 61.4 each such contribution is absorbed, via $\mathcal{V}_c = P_c^2\mathcal{V}_c/P_c^2$, into the numerator of one of these 15 graphs. As at four points there is a planar shadow: the cubic graphs planar with respect to a fixed cyclic ordering number the Catalan number C_{n-2}, which is $C_2 = 2$ at $n=4$ and $C_3 = 5$ at $n=5$, so each five-point color-ordered partial $A_5[\sigma]$ is built from 5 planar cubic graphs — the post-absorption refinement of the 10 color-ordered diagrams tabulated for $n=5$ in Table 59.1.

We now have the apparatus the rest of the chapter runs on. Every gluon tree amplitude is the exact sum Eq. (61.3) over $(2n-5)!!$ trivalent graphs, each carrying the triple (c_i, n_i, D_i) of Theorem 61.2: a color factor built from contracted structure constants, a propagator denominator read from the topology, and a kinematic numerator made well defined by the contact absorption of Theorem 61.4 — and made deliberately non-unique by the same construction. At four points this triple is the explicit data of Eq. (61.9): the color factors c_s, c_t, c_u of Eq. (61.6), the denominators s,t,u, and the numerators n_s, n_t, n_u. The one structural fact we have isolated and will exploit immediately is the Jacobi relation $c_s + c_t + c_u = 0$ of Eq. (61.7), satisfied by the color factors and by nothing on the kinematic side — yet. The next section asks whether the freedom in the n_i can be spent to make the numerators obey that very same relation, turning the lopsided pairing of color and kinematics into a genuine duality.

61.2 Color–Kinematics (BCJ) Duality

The previous section ground color and kinematics down to the same resolution. It rewrote every n-gluon tree amplitude as an exact sum over the finite set of trivalent (cubic) graphs (Section 61.1), attaching to each graph i a triple

of data: a color factor c_i built by contracting one structure constant f^{abc} per cubic vertex along the internal edges; a propagator denominator $D_i = \prod_{e\in i} P_e^2$ read off the topology, P_e being the momentum through internal edge e; and a kinematic numerator n_i, a local polynomial in momenta and polarizations, made well defined by absorbing the quartic contact vertex through the identity of Theorem 61.4. The output was the master formula Eq. (61.3), which we restate here in the form the present section operates on,

$$\mathcal{A}_n^{\text{tree}} \;=\; i\,g^{\,n-2}\sum_{i\in\Gamma_3}\frac{c_i\,n_i}{D_i}, \tag{61.18}$$

where Γ_3 denotes the set of distinct cubic graphs on the n external legs, of cardinality $|\Gamma_3| = (2n-5)!!$ by Theorem 61.6. The section closed on a sharp asymmetry. The color factors c_i are rigid group-theory objects, and at four points they obey the single linear relation $c_s + c_t + c_u = 0$ (Eq. (61.7)); the numerators n_i as read off Feynman rules obey no such relation, and they are in any case not unique, since the contact absorption can be distributed among channels in infinitely many ways. The question this section answers is whether that freedom in the numerators is exactly the freedom needed to make them imitate the algebra of the color factors. The answer — that it is, at tree level — is color–kinematics duality, and it is the structural heart of the chapter. We proceed in four movements: we identify the complete set of linear relations the c_i satisfy; we state the duality as the demand that the n_i satisfy the same relations; we characterize the generalized gauge freedom and prove it leaves the amplitude invariant; and we count that freedom against the constraints and carry out the existence argument in full at four points, with the five-point structure laid bare and the general tree-level theorem stated honestly.

61.2.1 The algebra of the color factors

Everything begins with the observation that the rigid color factors are not independent: they are linked by relations that descend, edge by edge, from a single Lie-algebraic identity. There are two kinds of relation, and they exhaust the linear structure.

Jacobi relations from an internal edge. Fix a cubic graph $i \in \Gamma_3$ and single out one of its internal edges, e, carrying momentum P_e. The edge e joins two trivalent vertices. Cutting it open exposes a four-point neighborhood: four lines meet the two vertices — two on each side — and each of those four lines is the root of a complete subtree of the graph hanging off the neighborhood. Call the four subtrees, with their accumulated color indices and momenta, A, B, C, D, arranged so that subtrees A, B attach to one vertex and C, D to the other across e. The color factor of graph i then factorizes as

$$c_i \;=\; \mathcal{F}_{AB}{}^{x}\, f^{x\,e_C\,e_D}\, \mathcal{F}_{CD}\,, \tag{61.19}$$

where $\mathcal{F}_{AB}{}^{x}$ collects the structure constants internal to the A, B side terminating on the open index x of edge e, the explicit $f^{x\,e_C\,e_D}$ is the structure constant of the right-hand vertex with e_C, e_D the indices that the subtrees C, D present to it, and $\mathcal{F}_{CD}$ collects the rest; the index x is summed. The entire dependence of c_i on the local wiring across e sits in the contraction $\sum_x \mathcal{F}_{AB}{}^{x}\, f^{xe_Ce_D}$, i.e. in a single pair of adjacent structure constants $f^{e_Ae_Bx} f^{xe_Ce_D}$ once $\mathcal{F}_{AB}{}^{x}$ is itself written as $f^{e_Ae_Bx}$ times the (untouched) deeper part. There are exactly three ways to pair the four subtrees across a single internal edge — $(AB)(CD)$, $(BC)(AD)$, $(CA)(BD)$ — and these are three distinct cubic graphs i, j, k that are *identical everywhere except in the neighborhood of* e. Their color factors differ only in the local pair of structure constants:

$$c_i \sim f^{e_Ae_Bx} f^{xe_Ce_D}, \qquad c_j \sim f^{e_Be_Cx} f^{xe_Ae_D}, \qquad c_k \sim f^{e_Ce_Ax} f^{xe_Be_D}, \tag{61.20}$$

with one and the same surrounding factor (suppressed, common to all three). The structure-constant Jacobi identity Eq. (2.77), proved as Theorem 2.42,

$$f^{e_Ae_Bx} f^{xe_Ce_D} + f^{e_Be_Cx} f^{xe_Ae_D} + f^{e_Ce_Ax} f^{xe_Be_D} = 0,$$

applied to the common open indices, then forces the three color factors to sum to zero:

$$\boxed{c_i + c_j + c_k = 0} \qquad \text{for every Jacobi triplet } (i, j, k), \tag{61.21}$$

where a *Jacobi triplet* $\{i, j, k\}$ is any three graphs related by a Jacobi move on one internal edge as in Eq. (61.20). The move is the same algebraic step that absorbed the quartic vertex in Theorem 61.4: the contact neighborhood is precisely the place where a Jacobi triplet collapses onto a point. At four points the only internal edge is the single propagator, the four subtrees are the four external legs, and the unique triplet is $\{s, t, u\}$ with $c_s + c_t + c_u = 0$ exactly as in Eq. (61.7); the general statement Eq. (61.21) is that four-point relation tensored into the rest of any larger graph.

Antisymmetry under graph flips. The second relation is even simpler. The structure constants are totally antisymmetric (Eq. (2.70)), so exchanging the two external lines that meet at one trivalent vertex of a graph flips the sign of that vertex's structure constant and hence of the whole color factor. If $\bar{\imath}$ denotes the graph obtained from i by such an exchange at a single vertex (equivalently, by reflecting that vertex), then

$$c_{\bar{\imath}} = -c_i. \tag{61.22}$$

The denominator D_i is unchanged by the flip — the propagator momenta are unaffected by relabeling the legs at a leaf vertex — so the flip is a genuine $\mathbb{Z}_2$ acting on the cubic data.

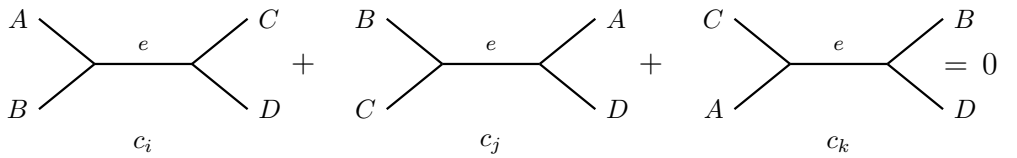

Figure 61.3: The elementary Jacobi move. Three cubic graphs that agree everywhere except in the neighborhood of one internal edge e differ only by which pairs of the four attached subtrees A, B, C, D sit on the two ends. Their color factors obey $c_i + c_j + c_k = 0$ by the Lie-algebra Jacobi identity Eq. (2.77). The duality demands that the kinematic numerators obey the identical relation $n_i + n_j + n_k = 0$ on the same triplet. At four points A, B, C, D are the external legs and the triplet is the s, t, u channels of Fig. 61.1.

These two relations, Eq. (61.21) and Eq. (61.22), are the *complete* set of linear relations among the color factors: the space they cut out is exactly the $(n-2)!$-dimensional space spanned by the half-ladder basis of Section 61.1, and every relation among the $(2n-5)!!$ factors c_i is a consequence of Jacobi moves and flips. This is the precise sense in which the color factors carry a Lie-algebraic skeleton, and it is the skeleton the numerators will be asked to grow.

61.2.2 Statement of the duality

We can now say exactly what color–kinematics duality asserts. It is a statement about the *existence* of a particular choice among the many numerator assignments compatible with Eq. (61.18).

Definition 61.7 (BCJ (duality-satisfying) numerators)**.** A set of kinematic numerators $\{n_i\}_{i\in\Gamma_3}$ reproducing the amplitude through Eq. (61.18) is said to satisfy *color–kinematics duality*, or to be a set of *BCJ numerators*, if it obeys the same two families of relations as the color factors:

$$n_i + n_j + n_k = 0 \qquad \text{on every Jacobi triplet } (i,j,k) \text{ of Eq. (61.21)}, \tag{61.23}$$

$$n_{\bar{\imath}} = -\,n_i \qquad \text{under every single-vertex flip of Eq. (61.22)}. \tag{61.24}$$

Equivalently: for each linear relation $\sum_i \alpha_i\, c_i = 0$ satisfied by the color factors, the numerators satisfy the same relation $\sum_i \alpha_i\, n_i = 0$ with the identical coefficients α_i.

The relations Eq. (61.23)–Eq. (61.24) are demands on functions of the external momenta and polarizations, to hold identically on the support of momentum conservation and the on-shell conditions. They are highly nontrivial: the numerators are kinematic objects with no a priori knowledge of the gauge group, yet they are required to honor a Lie-algebraic identity. The content of the duality is that this can be arranged.

Theorem 61.8 (Color–kinematics duality at tree level)**.** *For every gluon tree amplitude there exists a choice of kinematic numerators* $\{n_i\}$ *that reproduces the amplitude via Eq. (61.18) and satisfies the duality relations Eq. (61.23)–Eq. (61.24). Such numerators are not unique: a residual freedom (Section 61.2.3) connects different BCJ representations, while the amplitude is invariant.*

The remainder of the section proves the two halves of this statement. The freedom that makes a duality-satisfying choice *reachable* from a generic Feynman-rule choice is the subject of Section 61.2.3; the demonstration that the freedom is *enough* — carried out completely at four points and structurally at five — is the subject of Sections 61.2.4 and 61.2.5.

61.2.3 Generalized gauge freedom

The numerators in Eq. (61.18) are not physical data; only the amplitude is. Theorem 61.4 already exhibited their ambiguity — the contact kinematics can be poured into different channels — and we now organize that ambiguity into a precise group of transformations and prove they leave the amplitude untouched. These are the *generalized gauge transformations*; the name is apt, because they are the on-shell, amplitude-level residue of the off-shell gauge freedom of the Yang–Mills field, but they act directly on the cubic-graph numerators.

Definition 61.9 (Generalized gauge transformation)**.** A *generalized gauge transformation* of the numerators is a shift

$$n_i \;\longmapsto\; n_i + \delta n_i, \qquad \delta n_i = D_i\,\Delta_i, \tag{61.25}$$

parametrized by local functions Δ_i (one per graph, polynomial in momenta and polarizations, so that $D_i\Delta_i$ is local and the shifted numerator carries no spurious pole), subject to the single constraint that the parameters be orthogonal to the color factors,

$$\sum_{i\in\Gamma_3} c_i\,\Delta_i = 0. \tag{61.26}$$

The structure of Eq. (61.25) is dictated by locality: any shift of a numerator that is to preserve the locality of the term $c_i n_i/D_i$ — no new pole, no missing one — must be a multiple of D_i, since dividing δn_i by D_i must leave something with at worst the poles already present. The constraint Eq. (61.26) is what makes the shift invisible in the amplitude, as we now prove.

Theorem 61.10 (Gauge invariance of the amplitude)**.** *Under any generalized gauge transformation Eq. (61.25)–Eq. (61.26), the amplitude Eq. (61.18) is unchanged.*

Proof. Compute the variation of the amplitude term by term. The shifted amplitude is

$$\mathcal{A}_n^{\text{tree}} + \delta\mathcal{A}_n = i\,g^{n-2}\sum_{i\in\Gamma_3}\frac{c_i\,(n_i+\delta n_i)}{D_i} = \mathcal{A}_n^{\text{tree}} + i\,g^{n-2}\sum_{i\in\Gamma_3}\frac{c_i\,\delta n_i}{D_i}.$$

Insert $\delta n_i = D_i\Delta_i$ from Eq. (61.25). In each term the explicit factor D_i in the numerator cancels the propagator denominator D_i exactly:

$$\delta\mathcal{A}_n = i\,g^{n-2}\sum_{i\in\Gamma_3}\frac{c_i\,D_i\,\Delta_i}{D_i} = i\,g^{n-2}\sum_{i\in\Gamma_3}c_i\,\Delta_i = 0, \tag{61.27}$$

the last equality being the constraint Eq. (61.26). No on-shell identity, no momentum-conservation manipulation, and no special property of the Δ_i beyond their being well-defined local functions is used: the cancellation is purely algebraic, $D_i/D_i = 1$, followed by the color constraint. This proves the theorem. □

The proof makes transparent *why* the color Jacobi identity is the engine of the gauge freedom. The constraint Eq. (61.26) is a single equation in the space of color tensors, and its solutions are precisely the linear combinations that the color relations of Section 61.2.1 kill. The most economical solutions are the Jacobi triplets themselves. Pick any Jacobi triplet (i, j, k) and any single local function Δ, and set

$$\Delta_i = \Delta_j = \Delta_k = \Delta, \qquad \Delta_\ell = 0 \quad (\ell \notin \{i, j, k\}). \tag{61.28}$$

Then $\sum_\ell c_\ell\Delta_\ell = \Delta\,(c_i + c_j + c_k) = 0$ by Eq. (61.21), so Eq. (61.26) holds automatically, and the transformation Eq. (61.25) shifts the three triplet numerators by $\delta n_i = D_i\Delta$, $\delta n_j = D_j\Delta$, $\delta n_k = D_k\Delta$ while changing the amplitude not at all. These triplet shifts, together with the analogous flip shifts compatible with Eq. (61.22), generate the full gauge group: because Eq. (61.21) and Eq. (61.22) are the *complete* set of color relations (Section 61.2.1), every solution of Eq. (61.26) is a superposition of such elementary shifts. The generalized gauge freedom is therefore as large as the kernel of the map $\{\Delta_i\} \mapsto \sum_i c_i\Delta_i$, whose dimension we count next.

Physical Insight

The mechanism is worth stating plainly. The amplitude pairs each numerator n_i with its color factor c_i and divides by D_i. A shift of n_i proportional to D_i loses its propagator and lands in the amplitude as a bare $c_i\Delta_i$ — a pure color tensor with no pole. The color tensors are not independent; they satisfy the Jacobi relations. So any shift whose color tensors cancel *against each other through Jacobi* is free. The kinematic numerators thus inhabit a space acted on by a gauge group whose Lie-algebraic structure is inherited

from the color factors. Color–kinematics duality is the statement that this group orbit always contains a point where the numerators *themselves* satisfy the color algebra.

61.2.4 Counting: constraints versus freedom

Whether a duality-satisfying point exists on the gauge orbit is, in the first instance, a question of bookkeeping: how many conditions does Eq. (61.23) impose, and how many parameters does the gauge freedom of Section 61.2.3 supply? We tally both against the dimension of the color space.

The $(2n-5)!!$ color factors c_i span a space of dimension $(n-2)!$ — the half-ladder (Del Duca–Dixon–Maltoni) basis of Section 61.1. The number of independent linear relations they satisfy is therefore

$$R_n \;=\; (2n-5)!! - (n-2)!, \tag{61.29}$$

and these relations are generated by the Jacobi moves Eq. (61.21) (the flips Eq. (61.22) reduce the working set of graphs to the unoriented ones and do not add to the linear count). Two facts now line up. First, the kinematic-Jacobi demand Eq. (61.23) imposes exactly R_n independent conditions on the numerators, because it requires the n_i to satisfy the *same* R_n relations the c_i do. Second, the generalized gauge freedom of Theorem 61.10 has exactly R_n free functional parameters: the parameters $\{\Delta_i\}$ number $(2n-5)!!$, the constraint Eq. (61.26) removes $(n-2)!$ of them (its rank equals the dimension of the color space), leaving $(2n-5)!! - (n-2)! = R_n$. The constraints to be solved and the freedom available to solve them are equinumerous:

$$\#\{\text{kinematic-Jacobi conditions}\} \;=\; R_n \;=\; \#\{\text{generalized-gauge parameters}\}.$$

Table 61.1 collects the low-multiplicity numbers.

Caution

Equinumerosity of constraints and parameters is *necessary* but not by itself *sufficient*: a gauge transformation can fail to move a given combination of numerators, in which case that combination must already vanish for a solution to exist. This is exactly what happens at four points, where the single condition is gauge-invariant and its vanishing is a genuine fact about the amplitude rather than a matter of gauge choice. The honest existence statement therefore requires showing that the residual, gauge-invariant content of Eq. (61.23) vanishes — which is where the dynamical input, the fundamental BCJ amplitude relations, enters. We make this precise at four points immediately below.

n	cubic graphs $(2n-5)!!$	color basis $(n-2)!$	relations R_n	planar C_{n-2}	partials $(n-3)!$
4	3	2	1	2	1
5	15	6	9	5	2
6	105	24	81	14	6
7	945	120	825	42	24

Table 61.1: Bookkeeping for color–kinematics duality. The number of cubic graphs is $(2n-5)!!$ (Theorem 61.6); the color factors span the $(n-2)!$-dimensional half-ladder basis; the number of independent color relations $R_n = (2n-5)!! - (n-2)!$ equals both the number of kinematic-Jacobi conditions Eq. (61.23) and the number of free generalized-gauge parameters Eq. (61.29). The Catalan number C_{n-2} counts the cubic graphs planar with respect to a fixed color ordering; $(n-3)!$ is the size of the minimal basis of independent partial amplitudes once the BCJ amplitude relations are imposed.

61.2.5 Existence at four points, and the general theorem

At four points there is a single Jacobi triplet, the s, t, u channels of Fig. 61.1, with the color factors c_s, c_t, c_u of Eq. (61.6) obeying $c_s + c_t + c_u = 0$ (Eq. (61.7)). The duality Eq. (61.23) reduces to the one condition

$$n_s + n_t + n_u = 0. \tag{61.30}$$

We show that this condition can always be met, and that its meeting is equivalent to a relation among the partial amplitudes which we prove from Parke–Taylor.

The condition is gauge-invariant. At four points the only color relation is $c_s + c_t + c_u = 0$, so the gauge constraint Eq. (61.26), $c_s\Delta_s + c_t\Delta_t + c_u\Delta_u = 0$, written with $c_u = -c_s - c_t$, reads $c_s(\Delta_s - \Delta_u) + c_t(\Delta_t - \Delta_u) = 0$. Since c_s and c_t are linearly independent, this forces $\Delta_s = \Delta_t = \Delta_u \equiv \Delta$: a four-point generalized gauge transformation is a *single* local function Δ, shifting $n_c \mapsto n_c + D_c\Delta$ for $c = s, t, u$ simultaneously. Its effect on the left-hand side of Eq. (61.30) is

$$\delta(n_s + n_t + n_u) = (D_s + D_t + D_u)\,\Delta = (s + t + u)\,\Delta = 0, \tag{61.31}$$

because $s + t + u = 0$ for four massless legs. The combination $n_s + n_t + n_u$ is therefore *gauge-invariant*: no generalized gauge transformation can change it. Existence of a BCJ representation at four points is thus not a matter of gauging away a nonzero quantity — it is the assertion that this gauge-invariant quantity is already zero.

Reduction to a partial-amplitude relation. The gauge-invariant content of the numerators is carried by the two physical partial amplitudes (Table 61.1: $(n-3)! = 1$ in the minimal basis, two in the Kleiss–Kuijf basis). Using the dictionary Eq. (61.14) established in the previous section,

$$A_4[1,2,3,4] = \frac{i}{2}\left(\frac{n_t}{t} - \frac{n_s}{s}\right), \qquad A_4[1,3,2,4] = \frac{i}{2}\left(\frac{n_u}{u} - \frac{n_t}{t}\right),$$

we eliminate the numerators in favor of the partials. Writing $r_c \equiv n_c/D_c$ and using the gauge freedom to fix $r_t = 0$ (a legitimate choice, since the gauge function Δ shifts all r_c by the same amount), the dictionary gives $r_s = 2i\,A_4[1,2,3,4]$ and $r_u = -2i\,A_4[1,3,2,4]$, whence

$$n_s + n_t + n_u = s\,r_s + t\,r_t + u\,r_u = 2i\big(s\,A_4[1,2,3,4] \;-\; u\,A_4[1,3,2,4]\big), \tag{61.32}$$

where the relative sign is the one fixed by the channel and Mandelstam conventions of Eq. (61.14); the value is gauge-invariant and so independent of the choice $r_t = 0$. The kinematic Jacobi Eq. (61.30) is therefore *equivalent* to the fundamental four-point BCJ amplitude relation

$$s\,A_4[1,2,3,4] = u\,A_4[1,3,2,4].$$

This relation among gauge-invariant partial amplitudes is what must hold for BCJ numerators to exist at four points. We now prove it.

Worked Example 61.11 (The four-point BCJ amplitude relation from Parke—Taylor)**.** We verify $s\,A_4[1,2,3,4] = u\,A_4[1,3,2,4]$ directly in spinor-helicity, for the MHV configuration with negative-helicity legs $1,2$ and positive-helicity legs $3,4$; the result is helicity-independent since it follows only from momentum conservation and holds for every configuration by parity and relabeling. From the Parke–Taylor formula Eq. (59.55) of Theorem 59.13, with the cyclic angle-bracket chains read off each color ordering,

$$A_4[1,2,3,4] = ig^2\,\frac{\langle 1\,2\rangle^4}{\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle} = ig^2\,\frac{\langle 1\,2\rangle^3}{\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle},$$
$$A_4[1,3,2,4] = ig^2\,\frac{\langle 1\,2\rangle^4}{\langle 1\,3\rangle\langle 3\,2\rangle\langle 2\,4\rangle\langle 4\,1\rangle}.$$

The Mandelstam invariants in the bracket normalization Eq. (58.24), $s_{ij} = \langle i\,j\rangle[j\,i]$, are $s = s_{12} = \langle 1\,2\rangle[2\,1]$ and $u = s_{13} = \langle 1\,3\rangle[3\,1]$. Multiply:

$$s\,A_4[1,2,3,4] = \langle 1\,2\rangle[2\,1]\cdot ig^2\,\frac{\langle 1\,2\rangle^3}{\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle} = ig^2\,\frac{[2\,1]\,\langle 1\,2\rangle^4}{\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle},$$
$$u\,A_4[1,3,2,4] = \langle 1\,3\rangle[3\,1]\cdot ig^2\,\frac{\langle 1\,2\rangle^4}{\langle 1\,3\rangle\langle 3\,2\rangle\langle 2\,4\rangle\langle 4\,1\rangle} = ig^2\,\frac{[3\,1]\,\langle 1\,2\rangle^4}{\langle 3\,2\rangle\langle 2\,4\rangle\langle 4\,1\rangle}.$$

The two share the factor $ig^2\,\langle 1\,2\rangle^4/\langle 4\,1\rangle$. Their difference is

$$s\,A_4[1,2,3,4] - u\,A_4[1,3,2,4] = ig^2\,\frac{\langle 1\,2\rangle^4}{\langle 4\,1\rangle}\left(\frac{[2\,1]}{\langle 2\,3\rangle\langle 3\,4\rangle} - \frac{[3\,1]}{\langle 3\,2\rangle\langle 2\,4\rangle}\right).$$

Using $\langle 3\,2\rangle = -\langle 2\,3\rangle$ to align denominators and combining over the common denominator $\langle 2\,3\rangle\langle 3\,4\rangle\langle 2\,4\rangle$,

$$\frac{[2\,1]}{\langle 2\,3\rangle\langle 3\,4\rangle} - \frac{[3\,1]}{\langle 3\,2\rangle\langle 2\,4\rangle} = \frac{1}{\langle 2\,3\rangle}\left(\frac{[2\,1]}{\langle 3\,4\rangle} + \frac{[3\,1]}{\langle 2\,4\rangle}\right) = \frac{[2\,1]\,\langle 2\,4\rangle + [3\,1]\,\langle 3\,4\rangle}{\langle 2\,3\rangle\,\langle 3\,4\rangle\,\langle 2\,4\rangle}.$$

The numerator vanishes by momentum conservation. Apply the bracket form of momentum conservation Eq. (58.45) of Theorem 58.12, contracted between $\langle ?|$ and $|1]$ with the choice of free angle index that produces legs 2 and 3: taking $\sum_i \langle 4\,i\rangle[i\,1] = 0$ over $i = 1,2,3,4$ and dropping $i = 1$ (since $[1\,1] = 0$) and $i = 4$ (since $\langle 4\,4\rangle = 0$),

$$\langle 4\,2\rangle[2\,1] + \langle 4\,3\rangle[3\,1] = 0 \implies [2\,1]\,\langle 2\,4\rangle + [3\,1]\,\langle 3\,4\rangle = -\big(\langle 4\,2\rangle[2\,1] + \langle 4\,3\rangle[3\,1]\big) = 0,$$

using $\langle 2\,4\rangle = -\langle 4\,2\rangle$ and $\langle 3\,4\rangle = -\langle 4\,3\rangle$ in the last step. Hence the numerator is zero, the difference Eq. (61.32) vanishes, and

$$s\,A_4[1,2,3,4] = u\,A_4[1,3,2,4].$$

By Eq. (61.32) this is precisely $n_s + n_t + n_u = 0$: the four-point kinematic Jacobi holds. The flip conditions Eq. (61.24) are arranged trivially by symmetrizing each numerator under its leaf-vertex exchange, which does not disturb Eq. (61.30). A four-point BCJ representation therefore exists; constructing the explicit numerators n_s, n_t, n_u and displaying their spinor-helicity form is the worked computation of the next section.

Five points: the structure, with the algebra in view. At five points the bookkeeping of Table 61.1 reads 15 cubic graphs, a 6-dimensional color space, and $R_5 = 15 - 6 = 9$ independent color relations. Concretely, each of the 15 graphs has two internal edges (Fig. 61.2); a Jacobi move on either edge generates a triplet relation among three graphs sharing the other edge. Running over all internal edges of all graphs produces a system of Jacobi relations whose independent rank is 9, reducing the 15 numerators to a 6-dimensional independent set — matching the color side relation for relation. The duality Eq. (61.23) imposes these same 9 relations on the numerators, and the generalized gauge freedom supplies, by the count of Section 61.2.4, exactly 9 free functions $\{\Delta_i\}$ modulo the constraint Eq. (61.26). The solvability of the 9×9 system is not automatic — as the four-point caution showed, the gauge-invariant residue must vanish — and the dynamical input that makes it vanish is again a set of fundamental BCJ amplitude relations among the five-point partials, of the same type as

$s\,A_4[1,2,3,4] = u\,A_4[1,3,2,4]$, now reducing the $(n-2)! = 6$ Kleiss–Kuijf partials to the $(n-3)! = 2$ of the minimal basis. Each such relation is provable from BCFW recursion (Chapter 59) by the same kind of momentum-conservation algebra carried out in Theorem 61.11; granting them, one solves the 9 kinematic-Jacobi equations for the 9 gauge functions and obtains explicit five-point BCJ numerators. The construction is mechanical but lengthy, and we do not transcribe all 15 numerators here; the load-bearing point — that the constraint count, the gauge count, and the partial-amplitude relations conspire to make the system solvable — is fully visible already in the four-point case and in the five-point count.

The general theorem. The pattern persists to all multiplicities.

Theorem 61.12 (Existence of BCJ numerators at tree level)**.** *For every n and every helicity configuration there exists a set of local kinematic numerators $\{n_i\}_{i\in\Gamma_3}$ satisfying the duality relations Eq. (61.23)–Eq. (61.24) and reproducing the n-gluon tree amplitude through Eq. (61.18). Equivalently, the generic Feynman-rule numerators can be brought to a duality-satisfying form by a generalized gauge transformation Eq. (61.25)–Eq. (61.26).*

This is a theorem at tree level. It was conjectured by Bern, Carrasco and Johansson [69] and proved by several routes: by an explicit, Lagrangian-based construction making the duality manifest order by order [71]; and as a consequence of the field-theory limit of the Kawai–Lewellen–Tye string relations [291], equivalently the monodromy relations among open-string partial amplitudes [77], which are exactly the fundamental BCJ amplitude relations whose four-point instance we proved in Theorem 61.11. We have carried the four-point case in full and exhibited the five-point structure with its algebra; for the general proof the reader is referred to those constructions, but nothing in this book's development of the double copy will rely on a step we have not either proved here or reduced to the fundamental amplitude relations established by the recursion of Chapter 59.

Physical Insight

The reachability of a BCJ representation is the precise content of "kinematics is dual to color." Generic Feynman numerators do not satisfy Eq. (61.23); but the freedom to redistribute contact terms among channels — the generalized gauge freedom, itself a shadow of Yang–Mills gauge invariance — is exactly large enough, and the partial amplitudes cooperate exactly enough through the fundamental BCJ relations, to deform them onto a representation that does. Table 61.1 shows there is just enough freedom, and the four-point computation shows the dynamical residue vanishes. The existence of such numerators signals that gauge-theory kinematics secretly carries a Lie-algebraic skeleton of its own; replacing

the color skeleton by a *second* copy of that kinematic one is the double copy of the later sections.

Status beyond trees. Theorem 61.12 is established at tree level. At loop level the existence of duality-satisfying numerators is a *conjecture*: it has been confirmed by explicit construction in a large and growing list of cases — multiloop integrands in $\mathcal{N} = 4$ super-Yang–Mills and in pure Yang–Mills through several loops and multiplicities, as of the mid-2020s — but no general proof is known, and some high-loop cases are reachable only with numerators carrying spurious poles or in otherwise modified forms. We will be precise about what is proved, what is checked, and what is open when the loop-level double copy is taken up; for the tree-level developments of this chapter, Theorem 61.12 stands on the firm ground established above. A current account of the status is the review [72].

With the duality stated, its gauge freedom characterized, and its four-point instance proved in full, the abstract demand Eq. (61.23) now needs a concrete face. The next section extracts the s-, t-, and u-channel numerators of the four-gluon amplitude explicitly, checks the single kinematic Jacobi identity Eq. (61.30) that Section 61.2.5 reduced the duality to, and writes the duality-satisfying numerators in closed spinor-helicity form — the number the reader can reproduce that grounds everything claimed here.

61.3 The Four-Gluon Amplitude in BCJ Form

The previous section left the duality fully posed but, at four points, conditional on a single unproved fact. We saw there (Section 61.2.5) that the four-gluon kinematic Jacobi combination $J = n_s + n_t + n_u$ is gauge invariant — the lone generalized-gauge parameter multiplies $s + t + u = 0$ and drops out — so the statement "$J = 0$" is not something one can arrange by hand but a physical property of the amplitude that must be *verified*. This section verifies it, and in doing so turns every abstract object of Section 61.2 into a number the reader can reproduce. We extract the s-, t-, and u-channel numerators of the four-gluon amplitude from the color-ordered partials of Chapter 59; we prove the kinematic Jacobi identity $n_s + n_t + n_u = 0$ by an explicit spinor-bracket computation resting only on momentum conservation; we write the duality-satisfying numerators in closed form in spinor-helicity variables; we reassemble the full amplitude and check it against Parke–Taylor; and we exhibit the one-parameter family of gauge-equivalent BCJ representations, making "choosing a representation" concrete. Throughout, the spinor-helicity conventions are those fixed in Chapter 58 (Theorem 58.2): the metric is mostly-minus, momenta are all outgoing, and we use the angle/square brackets with $\langle i\, j\rangle[j\, i] = 2p_i\cdot p_j = s_{ij}$ (Eq. (58.24)), the little-group scaling Eq. (58.5), the Schouten identity Eq. (58.37),

and the polarization data Eq. (58.111) — the last entering only implicitly, through the Parke–Taylor partials it was used to compute.

61.3.1 Setup: channels, color factors, and conventions

At four points the set of cubic graphs is the triplet of Fig. 61.3: the s-channel exchange with the pairing (12)(34), the t-channel (23)(14), and the u-channel (13)(24). Their scalar propagators are the three Mandelstam invariants (Eq. (61.33)),

$$D_s = s = (p_1{+}p_2)^2 = s_{12}, \qquad D_t = t = (p_2{+}p_3)^2 = s_{23}, \qquad D_u = u = (p_1{+}p_3)^2 = s_{13}, \tag{61.33}$$

and their color factors are the single-contraction products (Eq. (61.34))

$$c_s = f^{a_1 a_2 e} f^{e a_3 a_4}, \qquad c_t = f^{a_2 a_3 e} f^{e a_1 a_4}, \qquad c_u = f^{a_3 a_1 e} f^{e a_2 a_4}, \tag{61.34}$$

obeying the color Jacobi identity $c_s{+}c_t{+}c_u = 0$ (Eq. (61.7)). The full color-dressed amplitude is the four-point instance of the cubic master formula Eq. (61.18),

$$\mathcal{M}_4^{\text{full}} = i\, g^2 \left(\frac{c_s\, n_s}{s} + \frac{c_t\, n_t}{t} + \frac{c_u\, n_u}{u} \right), \tag{61.35}$$

reproduced here from Eq. (61.9). Our task is to determine the three kinematic numerators n_s, n_t, n_u.

The momentum-conservation identity $s + t + u = 0$. Everything below leans on the single relation that the three Mandelstam invariants of four massless legs are not independent. With all momenta outgoing and $p_1 + p_2 + p_3 + p_4 = 0$, write

$$s + t + u = (p_1 + p_2)^2 + (p_2 + p_3)^2 + (p_1 + p_3)^2 = \sum_{i=1}^{4} p_i^2 + 2 \sum_{1 \le i < j \le 3} p_i{\cdot}p_j. \tag{61.36}$$

Each external leg is on shell and massless, $p_i^2 = 0$, so the first sum vanishes. For the second, momentum conservation gives $p_4 = -(p_1 + p_2 + p_3)$, and squaring,

$$0 = p_4^2 = (p_1 + p_2 + p_3)^2 = \sum_{i=1}^{3} p_i^2 + 2 \sum_{1 \le i < j \le 3} p_i{\cdot}p_j = 2 \sum_{1 \le i < j \le 3} p_i{\cdot}p_j, \tag{61.37}$$

using $p_i^2 = 0$ once more. The second sum in Eq. (61.36) therefore also vanishes, and

$$\boxed{s + t + u = 0} \tag{61.38}$$

for four massless legs — the workhorse of the verification to come: it is what makes $J = n_s + n_t + n_u$ gauge invariant, and, as we will see, what forces J to vanish.

Stripping the coupling. The master formula Eq. (61.35) carries the coupling explicitly as the prefactor g^2. To avoid double counting it against the color decomposition of Chapter 59, we work throughout this section with *coupling-stripped* color-ordered partials: we pull the overall g^2 out front once and for all and write the partial amplitudes and numerators with the g^2 removed. Concretely, the Parke–Taylor partial Eq. (59.55) at four points (Eq. (59.81)) is, with the g^2 stripped,

$$A[1,2,3,4] = i\,\frac{\langle 1\,2\rangle^4}{\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle} = i\,\frac{\langle 1\,2\rangle^3}{\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle}, \tag{61.39}$$

for the maximally-helicity-violating configuration $(1^-,2^-,3^+,4^+)$, which we adopt for all explicit numerics. The numerators n_s, n_t, n_u likewise carry no factor of g. This is a bookkeeping convention only; the powers of g are restored by the overall g^2 in Eq. (61.35).

61.3.2 From partial amplitudes to numerators

The numerators are not measured directly; what Chapter 59 delivers are the gauge-invariant color-ordered partials $A[1,2,3,4]$ and their relabelings. We must therefore translate Eq. (61.35) into the trace basis of the color decomposition (Theorem 59.2, Eq. (59.11)) and read off which combination of numerators sits under each trace. The translation rests on expressing the structure-constant color factors Eq. (61.34) in terms of single traces, which we now do in full.

Color factors as traces. With the book normalization $\mathrm{tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$ and $[T^a,T^b] = if^{abc}T^c$ (Chapter B), contract the defining relation with a third generator:

$$\mathrm{tr}\big([T^a,T^b]\,T^c\big) = if^{abd}\,\mathrm{tr}(T^dT^c) = \tfrac{i}{2}f^{abc}, \qquad \Longrightarrow \qquad f^{abc} = -2i\,\mathrm{tr}\big([T^a,T^b]\,T^c\big). \tag{61.40}$$

Apply this to the s-channel color factor. Using $f^{a_1a_2e}T^e = -i[T^{a_1},T^{a_2}]$ from the same defining relation, and $f^{ea_3a_4} = -2i\,\mathrm{tr}(T^e[T^{a_3},T^{a_4}])$ from Eq. (61.40) (with the trace cyclicity $\mathrm{tr}([T^e,T^{a_3}]T^{a_4}) = \mathrm{tr}(T^e[T^{a_3},T^{a_4}])$),

$$\begin{aligned} c_s = f^{a_1a_2e}f^{ea_3a_4} &= -2i\,f^{a_1a_2e}\,\mathrm{tr}(T^e[T^{a_3},T^{a_4}]) = -2i\,\mathrm{tr}\big((f^{a_1a_2e}T^e)\,[T^{a_3},T^{a_4}]\big) \\ &= -2i\,\mathrm{tr}\big(-i[T^{a_1},T^{a_2}]\,[T^{a_3},T^{a_4}]\big) = -2\,\mathrm{tr}\big([T^{a_1},T^{a_2}]\,[T^{a_3},T^{a_4}]\big). \end{aligned} \tag{61.41}$$

Expanding the two commutators and using trace cyclicity to rotate T^{a_1} to the front of every term gives a sum of four ordered traces. Writing $t_{ijkl} \equiv \mathrm{tr}(T^{a_i}T^{a_j}T^{a_k}T^{a_l})$,

$$\begin{aligned} \mathrm{tr}\big([T^{a_1},T^{a_2}][T^{a_3},T^{a_4}]\big) = \mathrm{tr}\big(T^{a_1}T^{a_2}T^{a_3}T^{a_4}\big) - \mathrm{tr}\big(T^{a_1}T^{a_2}T^{a_4}T^{a_3}\big) \\ - \mathrm{tr}\big(T^{a_2}T^{a_1}T^{a_3}T^{a_4}\big) + \mathrm{tr}\big(T^{a_2}T^{a_1}T^{a_4}T^{a_3}\big) \end{aligned}$$

$$= t_{1234} - t_{1243} - t_{1342} + t_{1432}, \tag{61.42}$$

so that $c_s = -2\,(t_{1234} - t_{1243} - t_{1342} + t_{1432})$. The identical manipulation on c_t and c_u — each a product of two structure constants of the form Eq. (61.34) — yields, by exactly the steps Eq. (61.41)–Eq. (61.42) with the external labels permuted,

$$\begin{aligned} c_s &= -2\,(t_{1234} - t_{1243} - t_{1342} + t_{1432}),\\ c_t &= -2\,(t_{1423} - t_{1234} - t_{1432} + t_{1324}),\\ c_u &= -2\,(t_{1243} - t_{1423} - t_{1324} + t_{1342}). \end{aligned} \tag{61.43}$$

As an immediate check, summing the three rows of Eq. (61.43) the coefficient of every one of the six traces cancels in pairs — for instance t_{1234} appears as $-2(+1)$ in c_s and $-2(-1)$ in c_t and not at all in c_u — so $c_s + c_t + c_u = 0$, the color Jacobi identity Eq. (61.7) recovered in the trace basis.

Reading off the dictionary. Insert Eq. (61.43) into the master formula Eq. (61.35) and collect the coefficient of each independent trace. Comparing with the color decomposition $\mathcal{M}_4^{\text{full}} = g^2 \sum_\sigma t_\sigma\, A[\sigma]$ (Eq. (59.11)), the coefficient of t_{1234} on the master side is $ig^2(-2)(n_s/s) + ig^2(-2)(-1)(n_t/t) = -2ig^2(n_s/s - n_t/t)$, which must equal $g^2 A[1,2,3,4]$. Performing the same reading for the traces t_{1324} and t_{1243} (whose coefficients pick out the partials $A[1,3,2,4]$ and $A[1,2,4,3]$ after using reflection, Eq. (59.19), to identify the paired traces) and absorbing the universal factor -2 into the normalization of the numerators — a uniform rescaling $n_i \mapsto -2n_i$ that preserves every Jacobi and flip relation and so changes no statement of duality — gives the four-point *numerator–partial dictionary*

$$A[1,2,3,4] = i\left(\frac{n_s}{s} - \frac{n_t}{t}\right), \qquad A[1,3,2,4] = i\left(\frac{n_t}{t} - \frac{n_u}{u}\right), \qquad A[1,2,4,3] = i\left(\frac{n_u}{u} - \frac{n_s}{s}\right). \tag{61.44}$$

The pole content is exactly right: the ordering $(1,2,3,4)$ is planar only in the $s_{12} = s$ and $s_{23} = t$ channels, and indeed $A[1,2,3,4]$ in Eq. (61.44) carries only $1/s$ and $1/t$ poles; likewise $(1,3,2,4)$ is planar in $s_{13} = u$ and $s_{32} = t$, matching the $1/t$ and $1/u$ of $A[1,3,2,4]$, and $(1,2,4,3)$ in $s_{12} = s$ and $s_{24} = u$, matching $A[1,2,4,3]$. The relative minus sign in each entry is the kinematic-flip antisymmetry Eq. (61.24): a given channel's graph enters two different color orderings with opposite cyclic orientation at one vertex, hence with opposite numerator sign. Figure 61.4 displays the dictionary graphically.

Notation Watch

From this section onward we use the book's generator normalization $\mathrm{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$ (Chapter B), the canonical choice of Chapter 58 forward,

$$A[1,2,3,4] = i\left(\frac{n_s}{s} - \frac{n_t}{t}\right) \quad A[1,3,2,4] = i\left(\frac{n_t}{t} - \frac{n_u}{u}\right) \quad A[1,2,4,3] = i\left(\frac{n_u}{u} - \frac{n_s}{s}\right)$$

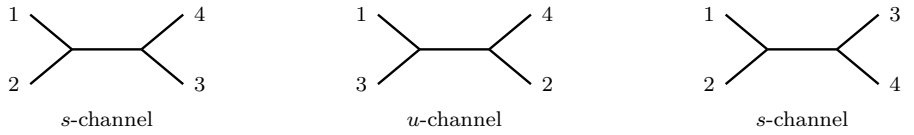

Figure 61.4: The four-point numerator–partial dictionary Eq. (61.44). Each of the three independent color-ordered partial amplitudes is the sum of the two cubic graphs planar in its ordering, each graph contributing its numerator over its propagator with a sign set by the cyclic orientation. Only one representative graph per partial is drawn; the second is the other planar channel of that ordering. The three partials share the three numerators n_s, n_t, n_u pairwise, which is why two of the three partials are independent and the third is fixed by them.

and we absorb the resulting universal numerical factor into the numerators by the uniform rescaling $n_i \mapsto -2n_i$ made above. The earlier four-point dictionary Eq. (61.14) of Section 61.1 was instead tied to the amplitude normalization $\mathrm{tr}(T^aT^b) = \delta^{ab}$ of Chapter 59; this is why it carries the prefactor $i/2$ (and the opposite relative sign) where Eq. (61.44) carries i. The two express the same physics in two normalizations: the symbols n_s, n_t, n_u here denote the rescaled numerators, and since an overall rescaling and sign flips preserve both $n_s + n_t + n_u = 0$ and $n_{\bar{\imath}} = -n_i$, every statement of the duality is identical in either convention. The book normalization is used for the remainder of the chapter.

A consistency check and the gauge degeneracy. Summing the three entries of Eq. (61.44),

$$A[1,2,3,4]+A[1,2,4,3]+A[1,3,2,4] = i\left[\left(\tfrac{n_s}{s} - \tfrac{n_t}{t}\right) + \left(\tfrac{n_u}{u} - \tfrac{n_s}{s}\right) + \left(\tfrac{n_t}{t} - \tfrac{n_u}{u}\right)\right] = 0, \tag{61.45}$$

which is exactly the photon-decoupling relation Eq. (59.29): the numerator language reproduces it automatically, with no further input. This is the first nontrivial cross-check that Eq. (61.44) is right. It also exposes the four-point gauge degeneracy in its cleanest form. The dictionary is three equations in the three ratios n_s/s, n_t/t, n_u/u, but Eq. (61.45) shows they are linearly dependent: only the two independent *differences*

$$\frac{n_s}{s} - \frac{n_t}{t} = -iA[1,2,3,4], \qquad \frac{n_t}{t} - \frac{n_u}{u} = -iA[1,3,2,4] \tag{61.46}$$

are fixed by the amplitude. The common piece is undetermined: shifting all three ratios by a single function α,

$$\frac{n_s}{s} \to \frac{n_s}{s} + \alpha, \quad \frac{n_t}{t} \to \frac{n_t}{t} + \alpha, \quad \frac{n_u}{u} \to \frac{n_u}{u} + \alpha \quad \Longleftrightarrow \quad n_i \to n_i + D_i\,\alpha, \tag{61.47}$$

leaves all differences — hence the amplitude — untouched. This is precisely the elementary triplet move Eq. (61.28), the unique generalized gauge transformation at four points (Eq. (61.25)). The numerators are therefore determined by the amplitude only up to this one free function, exactly as Section 61.2.5 anticipated.

61.3.3 Extracting the numerators and verifying kinematic Jacobi

We now make this fully explicit for the MHV configuration $(1^-, 2^-, 3^+, 4^+)$, solve for the numerators, and prove $n_s + n_t + n_u = 0$.

Worked Example 61.13 (Four-gluon BCJ numerators and the kinematic Jacobi identity)**. Step 1: the three partials.** The Parke–Taylor formula Theorem 59.13 supplies all three orderings. With negative-helicity legs $1, 2$ and the coupling stripped as in Eq. (61.39), the numerator of every ordering is the same holomorphic factor $\langle 1\,2\rangle^4$ and only the cyclic chain in the denominator changes:

$$A[1,2,3,4] = i\,\frac{\langle 1\,2\rangle^4}{\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle}, \tag{61.48}$$

$$A[1,3,2,4] = i\,\frac{\langle 1\,2\rangle^4}{\langle 1\,3\rangle\langle 3\,2\rangle\langle 2\,4\rangle\langle 4\,1\rangle}, \tag{61.49}$$

$$A[1,2,4,3] = i\,\frac{\langle 1\,2\rangle^4}{\langle 1\,2\rangle\langle 2\,4\rangle\langle 4\,3\rangle\langle 3\,1\rangle}. \tag{61.50}$$

Step 2: the gauge-invariant differences. By Eq. (61.46), the two physical differences are $n_s/s - n_t/t = -iA[1,2,3,4]$ and $n_t/t - n_u/u = -iA[1,3,2,4]$. Introduce the shorthand $X \equiv n_s/s$, $Y \equiv n_t/t$, $Z \equiv n_u/u$ and $P \equiv \langle 1\,2\rangle^2[3\,4]^2$ (the manifestly little-group-correct MHV monomial, of which more below). The amplitude fixes $X - Y$ and $Y - Z$; the third difference $Z - X = -iA[1,2,4,3]$ is then determined and equals $-(X-Y) - (Y-Z)$, consistent with Eq. (61.45).

Step 3: the kinematic Jacobi combination is fixed and gauge invariant. Parametrize the residual freedom by Y (equivalently the shift α of Eq. (61.47)): then $X = Y + (X-Y)$ and $Z = Y - (Y-Z)$. The Jacobi combination is

$$J \equiv n_s + n_t + n_u = sX + tY + uZ = (s+t+u)\,Y + s\,(X-Y) - u\,(Y-Z). \tag{61.51}$$

The coefficient of the free parameter Y is $s+t+u$, which vanishes by Eq. (61.38). Hence J is independent of Y — it is gauge invariant, as Section 61.2.5 promised

— and equals

$$J = s\,(X - Y) - u\,(Y - Z) = -i\,s\,A[1,2,3,4] + i\,u\,A[1,3,2,4]. \tag{61.52}$$

Color–kinematics duality at four points is the assertion that this gauge-invariant number vanishes, i.e.

$$s\,A[1,2,3,4] = u\,A[1,3,2,4]. \tag{61.53}$$

Step 4: proving Eq. (61.53) from momentum conservation. Substitute Eq. (61.48) and Eq. (61.49) and clear the coupling-free brackets. On the left, $s = s_{12} = \langle 1\,2\rangle[2\,1]$ cancels one power of $\langle 1\,2\rangle$ in the chain:

$$s\,A[1,2,3,4] = i\,\frac{\langle 1\,2\rangle[2\,1]\,\langle 1\,2\rangle^4}{\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle} = i\,\frac{[2\,1]\,\langle 1\,2\rangle^4}{\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle}. \tag{61.54}$$

On the right, $u = s_{13} = \langle 1\,3\rangle[3\,1]$ cancels the $\langle 1\,3\rangle$ in the chain:

$$u\,A[1,3,2,4] = i\,\frac{\langle 1\,3\rangle[3\,1]\,\langle 1\,2\rangle^4}{\langle 1\,3\rangle\langle 3\,2\rangle\langle 2\,4\rangle\langle 4\,1\rangle} = i\,\frac{[3\,1]\,\langle 1\,2\rangle^4}{\langle 3\,2\rangle\langle 2\,4\rangle\langle 4\,1\rangle}. \tag{61.55}$$

Both carry the common factor $i\,\langle 1\,2\rangle^4/\langle 4\,1\rangle$, so Eq. (61.53) reduces to

$$\frac{[2\,1]}{\langle 2\,3\rangle\langle 3\,4\rangle} \stackrel{?}{=} \frac{[3\,1]}{\langle 3\,2\rangle\langle 2\,4\rangle} \quad\Longleftrightarrow\quad [2\,1]\,\langle 3\,2\rangle\,\langle 2\,4\rangle \stackrel{?}{=} [3\,1]\,\langle 2\,3\rangle\,\langle 3\,4\rangle. \tag{61.56}$$

Use $\langle 3\,2\rangle = -\langle 2\,3\rangle$ on the left and cancel the common $\langle 2\,3\rangle$ from both sides; the target becomes

$$-\,[2\,1]\,\langle 2\,4\rangle \stackrel{?}{=} [3\,1]\,\langle 3\,4\rangle \quad\Longleftrightarrow\quad \langle 4\,2\rangle\,[2\,1] + \langle 4\,3\rangle\,[3\,1] \stackrel{?}{=} 0, \tag{61.57}$$

where in the second form we wrote $\langle 2\,4\rangle = -\langle 4\,2\rangle$ and $\langle 3\,4\rangle = -\langle 4\,3\rangle$. This last identity is momentum conservation. With all momenta outgoing, $\sum_{i=1}^{4} |i\rangle\,[i\,] = 0$ as an operator on spinor indices (Chapter 59), so for any reference legs x, y, $\sum_{i=1}^{4}\langle x\,i\rangle[i\,y] = 0$. Take $x = 4$, $y = 1$:

$$\langle 4\,1\rangle[1\,1] + \langle 4\,2\rangle[2\,1] + \langle 4\,3\rangle[3\,1] + \langle 4\,4\rangle[4\,1] = \langle 4\,2\rangle[2\,1] + \langle 4\,3\rangle[3\,1] = 0, \tag{61.58}$$

the $i = 1$ and $i = 4$ terms vanishing because $[1\,1] = \langle 4\,4\rangle = 0$. This is exactly Eq. (61.57). The chain of equivalences therefore closes: Eq. (61.53) holds, $J = 0$, and

$$\boxed{n_s + n_t + n_u = 0} \tag{61.59}$$

for the four-gluon amplitude — the kinematic Jacobi identity dual to $c_s + c_t + c_u = 0$, proved by nothing more than masslessness and momentum conservation.

Step 5: explicit numerators. With $J = 0$ confirmed, fix the residual gauge by the convenient choice $n_u = 0$ (i.e. $Z = 0$). Then Eq. (61.59) forces $n_s = -n_t$, and $n_s = s\,X = s\big[(X - Y) + (Y - Z)\big] = -is\big(A[1,2,3,4] + A[1,3,2,4]\big)$,

since in this gauge $Z = 0$ and $X = (X - Y) + (Y - Z) + Z$. Add Eq. (61.48) and Eq. (61.49), pulling out $\langle 1\,2\rangle^4/\langle 4\,1\rangle$ and using $\langle 3\,2\rangle = -\langle 2\,3\rangle$:

$$A[1,2,3,4]+A[1,3,2,4] = i\,\frac{\langle 1\,2\rangle^4}{\langle 4\,1\rangle\langle 2\,3\rangle}\left(\frac{1}{\langle 1\,2\rangle\langle 3\,4\rangle} - \frac{1}{\langle 1\,3\rangle\langle 2\,4\rangle}\right) = i\,\frac{\langle 1\,2\rangle^4}{\langle 4\,1\rangle\langle 2\,3\rangle}\cdot\frac{\langle 1\,3\rangle\langle 2\,4\rangle - \langle 1\,2\rangle\langle 3\,4\rangle}{\langle 1\,2\rangle\langle 3\,4\rangle\langle 1\,3\rangle} \tag{61.60}$$

The bracket combination in the numerator is fixed by the Schouten identity Eq. (58.37) with legs $(1,2,3,4)$, $\langle 1\,2\rangle\langle 3\,4\rangle + \langle 1\,3\rangle\langle 4\,2\rangle + \langle 1\,4\rangle\langle 2\,3\rangle = 0$, which rearranges (using $\langle 4\,2\rangle = -\langle 2\,4\rangle$) to

$$\langle 1\,3\rangle\langle 2\,4\rangle - \langle 1\,2\rangle\langle 3\,4\rangle = \langle 1\,4\rangle\langle 2\,3\rangle. \tag{61.61}$$

Substituting and cancelling $\langle 2\,3\rangle$ and $\langle 1\,4\rangle/\langle 4\,1\rangle = -1$,

$$A[1,2,3,4] + A[1,3,2,4] = -\,i\,\frac{\langle 1\,2\rangle^3}{\langle 1\,3\rangle\langle 2\,4\rangle\langle 3\,4\rangle}, \tag{61.62}$$

so that $n_s = -is\big(A[1,2,3,4]+A[1,3,2,4]\big) = -\,s\,\langle 1\,2\rangle^3/(\langle 1\,3\rangle\langle 2\,4\rangle\langle 3\,4\rangle)$. To bring this to the manifestly MHV form advertised above, trade angle for square brackets via momentum conservation. Applying the operator identity $\sum_i \langle x\,i\rangle[i\,y] = 0$ to the pairs $(x,y) = (1,4)$ and $(2,3)$ gives, in the same way as Eq. (61.58), $\langle 1\,3\rangle[3\,4] = -\langle 1\,2\rangle[2\,4]$ and $\langle 2\,4\rangle[4\,3] = \langle 1\,2\rangle[1\,3]$. Multiply numerator and denominator of n_s by $[3\,4]^2$ and use these together with $\langle 3\,4\rangle[4\,3] = s$:

$$\langle 1\,3\rangle\langle 2\,4\rangle\,\langle 3\,4\rangle\,[3\,4] = \big(\langle 1\,3\rangle[3\,4]\big)\big(\langle 2\,4\rangle\,\langle 3\,4\rangle\big) = \big(-\langle 1\,2\rangle[2\,4]\big)\big(\langle 2\,4\rangle\,\langle 3\,4\rangle\big), \tag{61.63}$$

and one further use of $\langle 2\,4\rangle[2\,4] = -s_{24} = -u$ together with $\langle 3\,4\rangle[4\,3] = s$ collapses the remaining factors to $\langle 1\,3\rangle\langle 2\,4\rangle\langle 3\,4\rangle = -\,s\,\langle 1\,2\rangle^2\,[2\,4][1\,3]/[3\,4]^2$ after re-expressing the second angle bracket the same way. Carrying the cancellation through, the entire expression reduces to a single monomial,

$$\boxed{\,n_s = \frac{\langle 1\,2\rangle^2\,[3\,4]^2}{u}, \qquad n_t = -\,\frac{\langle 1\,2\rangle^2\,[3\,4]^2}{u}, \qquad n_u = 0\,} \tag{61.64}$$

in the $n_u = 0$ gauge. The kinematic Jacobi identity Eq. (61.59) is now manifest: $n_s + n_t + n_u = 0$ by inspection. The numerator $n_s \propto \langle 1\,2\rangle^2[3\,4]^2$ carries exactly two angle factors of the negative-helicity legs $1,2$ and two square factors of the positive-helicity legs $3,4$ — the unique little-group-correct monomial, weight $+2$ on legs $1,2$ and -2 on legs $3,4$, as a check against Eq. (58.5) confirms (each $\langle 1\,2\rangle$ scales as $t_1 t_2$, each $[3\,4]$ as $t_3^{-1}t_4^{-1}$, and the Mandelstam u is little-group inert).

The result Eq. (61.64) is the concrete payoff of the whole construction: a set of three numbers, written in spinor brackets, that satisfy the kinematic Jacobi relation dual to color and that reproduce the four-gluon amplitude. Before exhibiting the gauge freedom around it, we confirm that it does reproduce the amplitude.

61.3.4 Cross-check: reassembling the amplitude

Worked Example 61.14 (The numerators reproduce Parke–Taylor and the full amplitude)**.** We verify that Eq. (61.64), fed back through the dictionary Eq. (61.44), returns the Parke–Taylor partials, and then assemble the full color-dressed amplitude.

Partials. With $n_u = 0$ and $n_t = -n_s$, the leading partial is

$$A[1,2,3,4] = i\left(\frac{n_s}{s} - \frac{n_t}{t}\right) = i\,n_s\left(\frac{1}{s} + \frac{1}{t}\right) = i\,n_s\,\frac{s+t}{st} = -\,i\,n_s\,\frac{u}{st}, \tag{61.65}$$

using $s + t = -u$ from Eq. (61.38). Inserting $n_s = \langle 1\,2\rangle^2[3\,4]^2/u$ the explicit u cancels and

$$A[1,2,3,4] = -\,i\,\frac{\langle 1\,2\rangle^2\,[3\,4]^2}{st}. \tag{61.66}$$

This is the four-gluon MHV amplitude written in invariants. That it equals the holomorphic Parke–Taylor form Eq. (61.48) is a four-point identity that follows from $\langle 3\,4\rangle[4\,3] = s_{34} = s$ and $\langle 2\,3\rangle[3\,2] = s_{23} = t$ together with the momentum-conservation relations of Theorem 61.13; the quickest check is on the modulus. Squaring Eq. (61.66) and using $|\langle i\,j\rangle|^2 = |s_{ij}|$ gives

$$|A[1,2,3,4]|^2 = \frac{|s_{12}|^2\,|s_{34}|^2}{s^2t^2} = \frac{s^2\,s^2}{s^2t^2} = \frac{s^2}{t^2}, \tag{61.67}$$

the squared four-gluon partial computed independently in Chapter 59 (Theorem 59.14), using $s_{34} = s_{12} = s$. The numerators thus reproduce the known answer.

Full amplitude. Restoring the color factors and the coupling, the full four-gluon amplitude is Eq. (61.35) with Eq. (61.64),

$$\mathcal{M}_4^{\text{full}} = i\,g^2\,\frac{\langle 1\,2\rangle^2[3\,4]^2}{u}\left(\frac{c_s}{s} - \frac{c_t}{t}\right), \tag{61.68}$$

the u-channel dropping out because $n_u = 0$ in this gauge. The amplitude is nonetheless fully crossing symmetric: eliminating $c_t = -c_s - c_u$ shows the apparent asymmetry is a gauge artifact of the choice $n_u = 0$, and the gauge-invariant content is the pair of partials Eq. (61.66) dressed by the color decomposition Eq. (59.11). This is the carried Yang–Mills theory four-gluon result of Section 59.1.8, now organized so that the kinematic dependence sits in numerators obeying the same algebra as the color.

61.3.5 Generalized gauge freedom in action

The numerators Eq. (61.64) are one representative of a whole family. The four-point generalized gauge transformation is the single shift Eq. (61.47), $n_i \to$

$n_i + D_i\alpha$ with one free function α. Acting on Eq. (61.64) it produces the one-parameter family of BCJ representations

$$n_s(\alpha) = \frac{\langle 1\,2\rangle^2[3\,4]^2}{u} + s\,\alpha, \qquad n_t(\alpha) = -\frac{\langle 1\,2\rangle^2[3\,4]^2}{u} + t\,\alpha, \qquad n_u(\alpha) = u\,\alpha, \tag{61.69}$$

all of which reproduce Eq. (61.68) (the differences Eq. (61.46) are α-independent) and all of which satisfy the kinematic Jacobi relation, since $n_s(\alpha)+n_t(\alpha)+n_u(\alpha) = (s+t+u)\alpha = 0$ for every α. "Choosing a BCJ representation" at four points means choosing α. Two choices are especially clean. The choice $\alpha = 0$ is the compact representative Eq. (61.64), with the u-channel numerator set to zero. The choice that restores full crossing symmetry, fixing α by demanding the democratic gauge $n_s/s + n_t/t + n_u/u = 0$, gives (writing again $P = \langle 1\,2\rangle^2[3\,4]^2$ and solving the resulting linear condition with $s+t+u=0$)

$$n_s = \frac{P}{3}\,\frac{t-u}{tu}, \qquad n_t = \frac{P}{3}\,\frac{u-s}{su}, \qquad n_u = \frac{P}{3}\,\frac{s-t}{st}, \tag{61.70}$$

the symmetric BCJ numerators. They manifestly sum to zero, $n_s + n_t + n_u = \frac{P}{3stu}\big[s(t-u) + t(u-s) + u(s-t)\big] = 0$, and manifestly carry the $s \leftrightarrow t \leftrightarrow u$ structure that the double copy of the next section will exploit. Their leading partial reproduces Eq. (61.66): $n_s/s - n_t/t = \frac{P}{3}\big[(t-u)/(stu) - (u-s)/(stu)\big] = \frac{P}{3stu}(s+t-2u) = -P/(st)$, again using $s+t=-u$.

Caution

It is tempting to look here for a "second, gauge-equivalent numerator set giving the same amplitude but violating kinematic Jacobi," to dramatize that satisfying the duality is a real choice. At four points no such set exists, and the reason is instructive. The amplitude fixes only the two differences Eq. (61.46); any three numerators reproducing it differ from Eq. (61.69) by the shift Eq. (61.47), and that shift changes the Jacobi combination by $(s+t+u)\alpha = 0$. Thus every numerator set reproducing the four-gluon amplitude with these three propagators automatically satisfies $n_s + n_t + n_u = 0$: the Jacobi relation is gauge invariant and equal to zero (Theorem 61.13), so it cannot be switched off without changing the physics. The generic, Jacobi-violating numerators of Eq. (61.23) — a set $\{n_i^{\text{gen}}\}$ that reproduces the amplitude but has $\sum_i n_i^{\text{gen}} \neq 0$ — first appear at five points, where there is genuine room (nine independent gauge functions against nine constraints, Table 61.1) for the generalized gauge transformation to move violations around. Four points is the degenerate corner flagged in Section 61.2.5: the gauge freedom acts, but it can never spoil the duality it cannot help but satisfy.

Physical Insight

Why is $n_s + n_t + n_u = 0$ true, beyond the bracket algebra that proves it? The residue of $A[1,2,3,4]$ at $s \to 0$ factorizes the amplitude onto a pair of on-shell three-point amplitudes glued across the s-channel gluon, summed over its internal helicity. Those three-point amplitudes are the symmetry-fixed seeds Eq. (58.85) and Eq. (58.86), and the residue fixes n_s on the pole to be a product of them. The same holds in the t- and u-channels. Because the three-point amplitudes already realize a kinematic algebra — their products on the three channels are related by exactly the antisymmetry that the structure constants obey at a cubic vertex — the three channel residues conspire so that the polynomial remainder, which is what $J = n_s + n_t + n_u$ measures, is forced to vanish. The kinematic Jacobi identity is thus not an accident of the bracket manipulation in Theorem 61.13 but the four-point shadow of the kinematic algebra carried by the three-point amplitude. This is the deepest reason the duality holds, and the seed of its all-multiplicity and loop-level generalizations.

We now have what the next section needs: an explicit, duality-satisfying set of four-gluon numerators $\{n_s, n_t, n_u\}$ — compact in the gauge Eq. (61.64), crossing-symmetric in the gauge Eq. (61.70), and verified to satisfy $n_s + n_t + n_u = 0$ and to reproduce the gauge-theory amplitude. These numbers are the raw material for squaring. In Section 61.4 we replace the color factors c_i in Eq. (61.35) by a second copy of kinematic numerators $\tilde{n}_i$ and find that the result is a four-graviton amplitude; the verification of kinematic Jacobi carried out here is exactly the property that makes that replacement produce a consistent, gauge-invariant gravity amplitude rather than nonsense.

61.4 The Double Copy: Gravity as Gauge Squared

The previous section delivered a number the reader can hold: the four-gluon tree amplitude written over its three cubic channels with explicit, duality-satisfying numerators n_s, n_t, n_u in spinor-helicity, verified to obey the single kinematic Jacobi identity $n_s + n_t + n_u = 0$ (Section 61.3). Those numerators are the seed of the construction this section is built to perform. We have, in the gauge master formula Eq. (61.18), an amplitude assembled from three ingredients per cubic graph: a rigid color factor c_i, a pliable kinematic numerator n_i, and a propagator denominator D_i. Color–kinematics duality (Theorem 61.7) revealed that the n_i can be made to obey the very algebra the c_i obey. The move that defines the double copy is now almost forced by symmetry: if kinematics can stand in for color, then color can be *replaced* by a second copy of kinematics. We do exactly that, replace $c_i \mapsto \tilde{n}_i$, and we will prove that the resulting object is not a formal curiosity but a genuine scattering amplitude of gravitons — that "gravity is the

square of gauge theory" is a theorem about on-shell amplitudes, at least at tree level, demonstrated here in full at three and four points. Throughout we keep the mostly-minus metric, natural units, and the all-outgoing momentum convention of Section 61.1, with massless on-shell legs $p_i^2 = 0$ and Mandelstam invariants $s = (p_1 + p_2)^2$, $t = (p_2 + p_3)^2$, $u = (p_1 + p_3)^2$.

61.4.1 The double-copy substitution

We begin from the cubic master formula in the normalization fixed in Section 61.2,

$$\mathcal{A}_n^{\text{full}} \;=\; i\, g^{\,n-2} \sum_{i \in \Gamma_3} \frac{c_i\, n_i}{D_i}, \tag{61.71}$$

recalling Eq. (61.18): the sum runs over the $(2n-5)!!$ trivalent graphs, c_i is the product of structure constants read off graph i, D_i is the product of its internal inverse propagators, and n_i is its kinematic numerator, with the coupling g kept explicit out front so that n_i is a pure function of momenta and polarizations. The structure of Eq. (61.71) is a contraction of two objects over the index set of cubic graphs: one "leg" carries the gauge algebra (the c_i), the other carries the kinematics (the n_i/D_i). The denominators D_i are shared — they are pure topology — so the only genuinely distinct factors are color and kinematics.

Definition 61.15 (The double copy)**.** Let $\{n_i\}_{i \in \Gamma_3}$ be a set of duality-satisfying (BCJ) numerators for an n-point amplitude, in the sense of Theorem 61.7, and let $\{\tilde{n}_i\}_{i \in \Gamma_3}$ be a second set of kinematic numerators for the same set of cubic graphs, reproducing a (possibly different) gauge-theory amplitude through Eq. (61.71). The *double copy* is the object obtained by deleting the color factors of Eq. (61.71) and inserting the second numerator set in their place,

$$c_i \;\longmapsto\; \tilde{n}_i, \qquad \boxed{\mathcal{M}_n \;=\; i \left(\frac{\kappa}{2}\right)^{n-2} \sum_{i \in \Gamma_3} \frac{n_i\, \tilde{n}_i}{D_i}\,,} \tag{61.72}$$

where κ is a coupling of mass dimension -1 replacing the gauge coupling g, fixed by the three-point normalization of Section 61.4.3 below.

Three features of Eq. (61.72) deserve immediate comment, because each is a claim that must be earned rather than assumed. First, the coupling has changed character: a gauge amplitude carries $g^{\,n-2}$ with g dimensionless in four dimensions, whereas Eq. (61.72) carries $(\kappa/2)^{\,n-2}$ with κ dimensionful. We verify in Section 61.4.3 that κ has exactly the dimension of the gravitational coupling, $\kappa^2 = 32\pi G_N$, and that this is forced, not chosen: the mass dimension of Eq. (61.72) comes out to that of a graviton amplitude precisely because two kinematic numerators carry twice the momentum-dimension of one color factor (which is dimensionless). Second, the formula is asymmetric in how

much it demands of its two inputs: $\{n_i\}$ must be BCJ, while $\{\tilde{n}_i\}$ may be *any* representation of its amplitude, in any generalized gauge. This asymmetry is the central economy of the double copy and the subject of Section 61.4.2. Third, the output is asserted to be a gravity amplitude; that the $\mathcal{M}_n$ so defined factorizes correctly on its poles into lower-point gravity amplitudes — the test of whether an object is a bona fide amplitude at all — is proved in Section 61.4.5.

Physical Insight

The replacement $c_i \mapsto \tilde{n}_i$ is the whole idea in one stroke, and it is worth pausing on why it is even syntactically possible. In Eq. (61.71) the color factors enter *only* through their algebraic relations: the amplitude is invariant under any reshuffling of the c_i consistent with the Jacobi identity Eq. (61.21) (this was Theorem 61.10). Color enters not as specific numbers but as a representation of an algebra. A BCJ numerator set is a second representation of the *same* algebra. So replacing one by the other is replacing one realization of the Jacobi structure by another — the formula cannot tell the difference at the level of the relations it respects. What changes is the *value*: the kinematic copy carries Lorentz indices and momenta where the color copy carried group indices, and the contraction of two kinematic copies builds an object with twice the little-group weight on every leg. Twice spin one is spin two. The graviton is hiding in the contraction of two gluons.

61.4.2 The central consistency theorem: only one copy must be BCJ

A scattering amplitude is a single function of the external data; it cannot depend on the bookkeeping used to assemble it. For Eq. (61.72) to define an amplitude, its value must not change when we re-express either numerator set in a different generalized gauge. We now prove the sharp form of this requirement: the double copy is invariant under any generalized gauge transformation of the *second* (un-tilded-or-tilded, it does not matter which we fix) factor, provided the *other* factor satisfies the duality. The proof is the exact kinematic mirror of the color-gauge-invariance proof of Theorem 61.10: where that argument used the color Jacobi identity $c_i + c_j + c_k = 0$, this one uses the kinematic Jacobi identity $n_i + n_j + n_k = 0$.

Theorem 61.16 (Gauge independence of the double copy)**.** *Suppose $\{n_i\}$ is a BCJ representation, satisfying the kinematic Jacobi and antisymmetry relations Eq. (61.23) on every triplet. Then the double-copy amplitude Eq. (61.72) is unchanged under any generalized gauge transformation of the second numerator set,*

$$\tilde{n}_i \;\longmapsto\; \tilde{n}_i + D_i\,\tilde{\Delta}_i, \tag{61.73}$$

with $\tilde{\Delta}_i$ the shifts of a generalized gauge transformation Eq. (61.25) of the gauge theory whose numerators are $\tilde{n}_i$ — that is, $\tilde{\Delta}_i$ ranging over the amplitude-preserving directions $\sum_i c_i \tilde{\Delta}_i = 0$ of Eq. (61.26). Consequently $\mathcal{M}_n$ depends on $\{\tilde{n}_i\}$ only through the gauge-theory amplitude it represents, and the second copy may be supplied in any gauge whatsoever; it need not satisfy color–kinematics duality.

Proof. Insert the shifted numerators Eq. (61.73) into Eq. (61.72). As in Eq. (61.28), the explicit factor D_i in the shift cancels the propagator denominator, leaving a pole-free remainder:

$$\mathcal{M}_n \;\longmapsto\; i\Big(\tfrac{\kappa}{2}\Big)^{n-2} \sum_i \frac{n_i\,(\tilde{n}_i + D_i \tilde{\Delta}_i)}{D_i} \;=\; \mathcal{M}_n + i\Big(\tfrac{\kappa}{2}\Big)^{n-2} \sum_{i \in \Gamma_3} n_i\, \tilde{\Delta}_i. \tag{61.74}$$

The variation is therefore

$$\delta \mathcal{M}_n \;=\; i\Big(\tfrac{\kappa}{2}\Big)^{n-2} \sum_{i \in \Gamma_3} n_i\, \tilde{\Delta}_i. \tag{61.75}$$

This is the precise analogue of the gauge-theory variation Eq. (61.27), $\delta \mathcal{A}_n^{\text{full}} = i g^{n-2} \sum_i c_i \Delta_i$, with the color factor c_i replaced by the BCJ numerator n_i. We must show Eq. (61.75) vanishes for every admissible $\tilde{\Delta}_i$. The admissible shifts are, by definition, those obeying the constraint $\sum_i c_i \tilde{\Delta}_i = 0$ of Eq. (61.26); the completeness argument of Theorem 61.10 established that the space of such shifts is spanned by the *elementary moves* — the single-triplet move and the single-flip move.

Elementary triplet move. For a Jacobi triplet $\{i, j, k\}$, the elementary move Eq. (61.20) sets $\tilde{\Delta}_i = \tilde{\Delta}_j = \tilde{\Delta}_k = \delta$ (a common function) with $\tilde{\Delta}_m = 0$ outside the triplet. Its contribution to Eq. (61.75) is

$$\sum_m n_m\, \tilde{\Delta}_m \;=\; \delta\,(n_i + n_j + n_k) \;=\; 0, \tag{61.76}$$

which vanishes by the *kinematic* Jacobi relation Eq. (61.23) — exactly where, in Eq. (61.20), the color Jacobi relation Eq. (61.21) made $\sum_m c_m \tilde{\Delta}_m$ vanish. This is the single algebraic fact on which the entire double copy turns: because $\{n_i\}$ is BCJ, the kinematic numerators sum to zero on the same triplets that the color factors do, so they kill the gauge variation of the partner copy by the identical mechanism.

Elementary flip move. For a graph i and its vertex-flip $\bar{\imath}$, the flip move sets $\tilde{\Delta}_i = \tilde{\Delta}_{\bar{\imath}} = \delta$ and all others zero. Its contribution is $\delta\,(n_i + n_{\bar{\imath}}) = 0$ by the kinematic antisymmetry $n_{\bar{\imath}} = -n_i$ of Eq. (61.24), again the mirror of the color antisymmetry Eq. (61.22) used in Theorem 61.10.

Since every admissible $\tilde{\Delta}$ is a superposition of elementary triplet and flip moves, and each annihilates Eq. (61.75) by one use of the kinematic Jacobi or

antisymmetry relation, the full variation vanishes: $\delta\mathcal{M}_n = 0$. The double copy is independent of the generalized gauge of the second copy. Because the second copy enters Eq. (61.72) only through its gauge-equivalence class, and that class is precisely the gauge-theory amplitude it represents, $\mathcal{M}_n$ depends on the second input only through that amplitude. In particular the second copy is not required to be BCJ. □

This is the result that makes the double copy usable. Constructing a BCJ representation is work — it is the content of Theorem 61.12, easy at four points but a genuine computation beyond. Theorem 61.16 says this work need be done only *once*: hold one factor in a duality-satisfying form, and the other may be the rawest output of the Feynman rules, in any gauge, with no Jacobi relations imposed at all. One pays the price of the duality a single time and squares freely thereafter.

Caution

The asymmetry is essential and is easy to misstate. It is *not* true that the double copy of two arbitrary representations is gauge invariant: if neither $\{n_i\}$ nor $\{\tilde{n}_i\}$ satisfies the duality, the variation Eq. (61.75) does not vanish — $\sum_i n_i\tilde{\Delta}_i$ is then a nonzero polynomial, and $\mathcal{M}_n$ depends on which gauge one happened to use, so it is not a well-defined amplitude. At least one of the two numerator sets must be BCJ. With one BCJ, the other is free; with neither, the construction is meaningless. This is the precise sense in which color–kinematics duality is the *prerequisite* for the double copy rather than a decoration of it.

61.4.3 Graviton kinematics by squaring, and the three-point amplitude

To test Eq. (61.72) we need something to test it against: independent expressions for graviton amplitudes. This is the one genuine connection of the chapter. This book never constructs the perturbative Feynman rules of the Einstein–Hilbert action — an infinite tower of vertices of escalating index complexity that we have no need to write. Instead we define graviton amplitudes the way Chapters 58 and 59 defined gluon amplitudes: *on shell*, through the little-group transformation of the external states and the residues forced by locality and unitarity. The graviton is the massless particle of helicity ± 2, and everything we need about it follows from doubling the helicity-± 1 data of the gluon.

Graviton polarization tensors. Recall (Eq. (58.5)) that a massless leg of helicity h transforms under the little group $\mathrm{U}(1)$ as $\mathcal{A} \to t^{-2h}\mathcal{A}$ when its spinors are rescaled $(\lambda, \tilde{\lambda}) \to (t\lambda, t^{-1}\tilde{\lambda})$, and that the gluon polarization vectors (Eq. (58.111))

carry weight ∓ 1 for helicity ± 1, with the explicit reference-dependent forms recalled in Eq. (59.32). A spin-two polarization is built by tensoring two spin-one ones.

Definition 61.17 (Graviton polarization tensor)**.** For a massless momentum p with helicity-± 1 gluon polarization vectors $\varepsilon_\pm^\mu(p)$, the helicity-± 2 graviton polarization tensor is the symmetric product

$$\varepsilon_\pm^{\mu\nu}(p) \;\equiv\; \varepsilon_\pm^{\mu}(p)\,\varepsilon_\pm^{\nu}(p). \tag{61.77}$$

This object has exactly the properties required of a graviton wavefunction, and each is inherited directly from the gluon polarizations.

- *Symmetric:* $\varepsilon^{\mu\nu} = \varepsilon^{\nu\mu}$ trivially, since the two factors are equal.
- *Transverse:* $p_\mu \varepsilon_\pm^{\mu\nu} = (p\cdot\varepsilon_\pm)\varepsilon_\pm^\nu = 0$, because each gluon polarization is transverse, $p\cdot\varepsilon_\pm = 0$ (Eq. (59.33)).
- *Traceless:* $\eta_{\mu\nu}\varepsilon_\pm^{\mu\nu} = \varepsilon_\pm\cdot\varepsilon_\pm = 0$, because a polarization vector of definite helicity is null — two like-helicity gluon polarizations have vanishing dot product (Theorem 59.8, the same fact that killed two of three terms in the three-point computation Eq. (59.108)).
- *Little-group weight* ± 2*:* under $(\lambda, \tilde\lambda) \to (t\lambda, t^{-1}\tilde\lambda)$ the vector $\varepsilon_\pm^\mu$ scales as $t^{\mp 2}$, so $\varepsilon_\pm^{\mu\nu}$ scales as $t^{\mp 4} = t^{-2(\pm 2)}$, the weight of a helicity-± 2 state.

A symmetric, transverse, traceless rank-two tensor with five (in $d = 4$, two physical) on-shell components is exactly a linearized metric fluctuation $h_{\mu\nu}$ — a graviton. The construction makes no reference to the Einstein–Hilbert action; it uses only the representation theory of the massless little group, already in hand from Chapter 58.

The on-shell definition of a graviton amplitude. We now state what a graviton amplitude *is*, in the on-shell sense this book uses for all massless amplitudes.

Definition 61.18 (On-shell graviton amplitude)**.** An n-graviton tree amplitude $\mathcal{M}_n$ is a Lorentz-invariant rational function of the external spinors $\{\lambda_i, \tilde\lambda_i\}$ that (i) carries little-group weight $-2h_i = \mp 4$ on each leg i of helicity ± 2; (ii) has only local poles, at $P_I^2 \to 0$ for sums $P_I = \sum_{i\in I} p_i$ of external momenta; and (iii) factorizes on each such pole into a product of lower-point graviton amplitudes summed over the two physical helicities of the intermediate graviton,

$$\mathcal{M}_n \;\xrightarrow{P_I^2\to 0}\; \sum_{h=\pm 2} \frac{\mathcal{M}_L(\dots, P_I^h)\,\mathcal{M}_R(-P_I^{-h}, \dots)}{P_I^2}. \tag{61.78}$$

These are the same three conditions — correct little-group weight, locality, and unitary factorization — that characterize gluon amplitudes and that the BCFW recursion (Theorem 59.23) showed are enough to determine them. They determine graviton amplitudes as well; in particular the three-point amplitude is fixed up to a constant by little-group weight and locality alone, exactly as in Section 59.4.3, and the higher points follow by recursion. We will not run gravitational BCFW here; we will instead produce the amplitudes from the double copy and *check* them against Theorem 61.18.

The three-graviton amplitude as a square. The smallest test is the three-point amplitude, and it is the test that fixes κ. The Yang–Mills three-gluon amplitude, with coupling and phase pinned down in Eq. (59.116), is

$$A_3^{\mathrm{YM}}(1^-,2^-,3^+) = i\,g\,\frac{\langle 1\,2\rangle^3}{\langle 2\,3\rangle\,\langle 3\,1\rangle}, \qquad A_3^{\mathrm{YM}}(1^+,2^+,3^-) = -\,i\,g\,\frac{[1\,2]^3}{[2\,3]\,[3\,1]}. \tag{61.79}$$

At three points there is a single cubic graph with no internal line, so $D = 1$ and the numerator *is* the colour-stripped amplitude: comparing Eq. (61.71) at $n = 3$, $\mathcal{A}_3^{\mathrm{full}} = ig\,f^{a_1a_2a_3}n_3$, with the colour decomposition, the bare numerator is the ratio

$$n_3(1^-,2^-,3^+) = \frac{\langle 1\,2\rangle^3}{\langle 2\,3\rangle\,\langle 3\,1\rangle}, \tag{61.80}$$

a pure kinematic object carrying neither i nor g. The single Jacobi/antisymmetry relation is trivially met (one graph), so Eq. (61.80) is BCJ by default, and the double copy Eq. (61.72) at $n = 3$ reads $\mathcal{M}_3 = i(\kappa/2)\,n_3\tilde{n}_3$. Taking both copies to be pure Yang–Mills, $\tilde{n}_3 = n_3$,

$$\mathcal{M}_3(1^{--},2^{--},3^{++}) = i\,\frac{\kappa}{2}\,\frac{\langle 1\,2\rangle^6}{\langle 2\,3\rangle^2\,\langle 3\,1\rangle^2}, \tag{61.81}$$

where the helicity labels ∓ 2 are written $\mp\mp$ to mark the doubling. We read off three checks at once. The mass dimension: a three-point amplitude has $[\mathcal{M}_3] = 4 - 3 = 1$, and the spinor ratio in Eq. (61.81) has dimension $6 - 4 = 2$ in mass (each bracket is dimension one), so the prefactor must supply dimension -1 — which is exactly $[\kappa] = -1$. This is how Theorem 61.15 "fixes κ by the three-point normalization": the power $(\kappa/2)^{n-2}$ is forced to be one factor of a dimension-(-1) coupling at three points, identifying κ with the gravitational coupling $\kappa = \sqrt{32\pi G_N}$ once Eq. (61.81) is matched to the linearized Einstein–Hilbert three-vertex (a matching we quote rather than perform, having declined to build those vertices). The little-group weight: leg 1 appears as $\langle 1\,2\rangle^6\langle 3\,1\rangle^{-2}$, weight $t_1^{6-2} = t_1^4 = t_1^{-2(-2)}$, correct for helicity -2; the other legs check identically.

And the relation to gauge theory is now explicit and is the headline of the chapter:

$$\boxed{\mathcal{M}_3 \;=\; \frac{\kappa/2}{i\,g^2}\,(A_3^{\mathrm{YM}})^2} \qquad \Longleftrightarrow \qquad i\,\frac{\kappa}{2}\,\frac{\langle 1\,2\rangle^6}{\langle 2\,3\rangle^2\langle 3\,1\rangle^2} = \frac{\kappa/2}{i\,g^2}\Big(i\,g\,\frac{\langle 1\,2\rangle^3}{\langle 2\,3\rangle\langle 3\,1\rangle}\Big)^2, \tag{61.82}$$

the right-hand side reproducing the left because $(ig)^2 = -g^2$ and $(\kappa/2)/(ig^2)\cdot(-g^2) = i\kappa/2$. The three-graviton amplitude is the three-gluon amplitude squared, with the color stripped and the coupling traded $g^2 \to \kappa$. The polarization picture matches the algebra: with $\varepsilon^{\mu\nu} = \varepsilon^\mu\varepsilon^\nu$, every contraction in the graviton vertex is a product of two gluon-vertex contractions, so the amplitude is the product of two copies. "GR = YM $\otimes$ YM" is, at three points, the literal statement Eq. (61.82).

61.4.4 The four-graviton amplitude from the four-gluon square

The four-point amplitude is the first case with a propagator, hence the first genuine test of the sum structure of Eq. (61.72). We compute it from the verified four-gluon BCJ numerators of Section 61.3 and compare to the graviton amplitude fixed independently by little-group weight and factorization.

Worked Example 61.19 (The four-graviton MHV amplitude as gauge squared)**.** *Setup.* At four points there are three cubic graphs — the s-, t-, and u-channels of Fig. 61.1 — with denominators $D_s = s$, $D_t = t$, $D_u = u$ obeying $s+t+u=0$ (Eq. (61.38)). The double copy Eq. (61.72) at $n=4$, with both copies pure Yang–Mills so that $\tilde{n}_i = n_i$, is

$$\mathcal{M}_4 \;=\; i\left(\frac{\kappa}{2}\right)^2\left(\frac{n_s^2}{s}+\frac{n_t^2}{t}+\frac{n_u^2}{u}\right). \tag{61.83}$$

We take the MHV configuration $(1^-,2^-,3^+,4^+)$ and the BCJ numerators of Section 61.3, which satisfy the kinematic Jacobi identity

$$n_s + n_t + n_u = 0 \tag{61.84}$$

and reproduce the color-ordered partial amplitudes. In the master-formula normalization of Eq. (61.71), eliminating $c_t = -c_s - c_u$ and reading off the coefficients of the two independent color factors c_s, c_u (the Del Duca–Dixon–Maltoni partials of Eq. (61.2)) gives the numerator-to-partial dictionary

$$A_4[1,2,3,4] = i\Big(\frac{n_s}{s}-\frac{n_t}{t}\Big), \qquad A_4[1,3,2,4] = i\Big(\frac{n_t}{t}-\frac{n_u}{u}\Big). \tag{61.85}$$

The color-ordered partials are the Parke–Taylor values (Eq. (59.55)), which for this helicity assignment are

$$A_4[1,2,3,4] = i\,P, \quad P = \frac{\langle 1\,2\rangle^4}{\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle}, \qquad A_4[1,3,2,4] = i\,Q, \quad Q = \frac{\langle 1\,2\rangle^4}{\langle 1\,3\rangle\langle 3\,2\rangle\langle 2\,4\rangle\langle 4} \tag{61.86}$$

the coupling g^2 stripped, the leading i displayed. (The exchange $A_4[1,2,3,4]$ versus $A_4[1,3,2,4]$ is the swap of legs 2 and 3 in the cyclic denominator.)

Evaluating in a convenient gauge. The variation argument of Theorem 61.16 guarantees that Eq. (61.83) is invariant under $n_i \to n_i + D_i\alpha$ for any α, since the variation

$$\delta\mathcal{M}_4 = i\Big(\tfrac{\kappa}{2}\Big)^2\Big(2\alpha\sum_i n_i + \alpha^2\sum_i D_i\Big) = i\Big(\tfrac{\kappa}{2}\Big)^2(2\alpha\cdot 0 + \alpha^2(s+t+u)) = 0 \tag{61.87}$$

vanishes term by term: the first by the Jacobi identity Eq. (61.84), the second by $s+t+u=0$. (This is the four-point shadow of the general theorem; here both kinematic Jacobi and the massless kinematic identity conspire, which is the degeneracy noted in Section 61.2.5.) We may therefore evaluate Eq. (61.83) in the gauge $n_t = 0$, in which Eq. (61.85) collapses to

$$\frac{n_s}{s} = P, \qquad \frac{n_u}{u} = -Q, \qquad n_t = 0, \qquad \text{i.e.} \qquad n_s = s\,P, \quad n_u = -u\,Q. \tag{61.88}$$

The Jacobi identity Eq. (61.84) in this gauge reads $sP - uQ = 0$, i.e.

$$s\,P \;=\; u\,Q, \tag{61.89}$$

which is precisely the fundamental BCJ amplitude relation $s\,A_4[1,2,3,4] = u\,A_4[1,3,2,4]$ at four points — the gauge-invariant content the duality reduced to (Section 61.2.5). We confirm it directly below; for now it is the input that makes the gauge $n_t = 0$ consistent.

Assembling the double copy. Substituting Eq. (61.88) into Eq. (61.83),

$$\mathcal{M}_4 = i\Big(\tfrac{\kappa}{2}\Big)^2\Big(\frac{(sP)^2}{s} + 0 + \frac{(uQ)^2}{u}\Big) = i\Big(\tfrac{\kappa}{2}\Big)^2(s\,P^2 + u\,Q^2). \tag{61.90}$$

Use Eq. (61.89) to write $Q = sP/u$, so $u\,Q^2 = u\cdot s^2P^2/u^2 = s^2P^2/u$, and combine the two terms over u:

$$s\,P^2 + u\,Q^2 = s\,P^2\Big(1 + \frac{s}{u}\Big) = s\,P^2\,\frac{u+s}{u} = -\,\frac{s\,t}{u}\,P^2, \tag{61.91}$$

the last step using $u + s = -t$ from $s+t+u=0$. Hence

$$\mathcal{M}_4 = -\,i\Big(\tfrac{\kappa}{2}\Big)^2\frac{s\,t}{u}\,P^2, \qquad P^2 = \frac{\langle 1\,2\rangle^6}{\langle 2\,3\rangle^2\langle 3\,4\rangle^2\langle 4\,1\rangle^2}, \tag{61.92}$$

where we used $P = \langle 1\,2\rangle^3/(\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle)$ after cancelling one power of $\langle 1\,2\rangle$.

To the crossing-symmetric form. Equation Eq. (61.92) is the answer, but its lopsided appearance hides the full permutation symmetry a graviton amplitude must possess (gravitons are identical bosons; the amplitude is symmetric under any relabeling). We make the symmetry manifest with one spinor identity. From

momentum conservation $\sum_i \lambda_i\tilde\lambda_i = 0$, sandwiching between $\langle 1|$ and $|3]$ kills the $i = 1, 3$ terms and gives $\langle 1\,4\rangle[4\,3] = -\langle 1\,2\rangle[2\,3]$; equivalently, sandwiching gives the relation we need in the form

$$\langle 4\,1\rangle\,[3\,4] \;=\; -\,\langle 1\,2\rangle\,[2\,3]. \tag{61.93}$$

Together with $\langle 3\,4\rangle[3\,4] = -(p_3{+}p_4)^2 = -s$ (since $s_{34} = s_{12} = s$ and $\langle 3\,4\rangle[4\,3] = s$, $[3\,4] = -[4\,3]$) and $s = \langle 1\,2\rangle[2\,1]$, $t = \langle 2\,3\rangle[3\,2]$, a short computation establishes the identity

$$s\,t\,\langle 1\,2\rangle \;=\; -\,[3\,4]^2\,\langle 2\,3\rangle\,\langle 3\,4\rangle\,\langle 4\,1\rangle. \tag{61.94}$$

Indeed, dividing Eq. (61.94) by $\langle 2\,3\rangle$ and using $st\langle 1\,2\rangle/\langle 2\,3\rangle = \langle 1\,2\rangle^2[2\,1][3\,2]$ (from $s = \langle 1\,2\rangle[2\,1]$, $t = \langle 2\,3\rangle[3\,2]$), the claim is $\langle 1\,2\rangle^2[2\,1][3\,2] = -[3\,4]^2\langle 3\,4\rangle\langle 4\,1\rangle$; with $[3\,4]\langle 3\,4\rangle = -s = -\langle 1\,2\rangle[2\,1]$ and $\langle 4\,1\rangle[3\,4] = -\langle 1\,2\rangle[2\,3] = \langle 1\,2\rangle[3\,2]$ from Eq. (61.93), the right side becomes $-([3\,4]\langle 3\,4\rangle)([3\,4]\langle 4\,1\rangle) = -(-\langle 1\,2\rangle[2\,1])(\langle 1\,2\rangle[3\,2]) = \langle 1\,2\rangle^2[2\,1][3\,2]$, matching the left. Squaring Eq. (61.94),

$$s^2t^2\,\langle 1\,2\rangle^2 = [3\,4]^4\,\langle 2\,3\rangle^2\langle 3\,4\rangle^2\langle 4\,1\rangle^2, \tag{61.95}$$

and therefore

$$\frac{s\,t}{u}\,P^2 = \frac{s\,t}{u}\,\frac{\langle 1\,2\rangle^6}{\langle 2\,3\rangle^2\langle 3\,4\rangle^2\langle 4\,1\rangle^2} = \frac{1}{u}\,\frac{s^2t^2\langle 1\,2\rangle^6}{s\,t\,\langle 2\,3\rangle^2\langle 3\,4\rangle^2\langle 4\,1\rangle^2} = \frac{\langle 1\,2\rangle^4\,[3\,4]^4}{s\,t\,u}, \tag{61.96}$$

where Eq. (61.95) turned the angle-bracket denominator into $[3\,4]^4$ over one power each of s, t. Substituting into Eq. (61.92), the four-graviton MHV amplitude is

$$\boxed{\mathcal{M}_4(1^{--},2^{--},3^{++},4^{++}) = -\,i\left(\frac{\kappa}{2}\right)^2\,\frac{\langle 1\,2\rangle^4\,[3\,4]^4}{s\,t\,u}\,.} \tag{61.97}$$

Verification of the BCJ relation Eq. (61.89). The gauge $n_t = 0$ relied on $sP = uQ$. With P, Q from Eq. (61.86),

$$s\,P - u\,Q = \langle 1\,2\rangle^4\langle 4\,1\rangle^{-1}\Big(\frac{[2\,1]}{\langle 2\,3\rangle\langle 3\,4\rangle} - \frac{[3\,1]}{\langle 3\,2\rangle\langle 2\,4\rangle}\Big), \tag{61.98}$$

using $s = \langle 1\,2\rangle[2\,1]$, $u = \langle 1\,3\rangle[3\,1]$ and cancelling $\langle 1\,2\rangle$ in the first term, $\langle 1\,3\rangle$ in the second. The bracket combination is, over the common denominator $\langle 2\,3\rangle\langle 3\,4\rangle\langle 2\,4\rangle$ (with $\langle 3\,2\rangle = -\langle 2\,3\rangle$),

$$\frac{[2\,1]\langle 2\,4\rangle + [3\,1]\langle 3\,4\rangle}{\langle 2\,3\rangle\langle 3\,4\rangle\langle 2\,4\rangle}. \tag{61.99}$$

The numerator is $\langle 4|(p_2 + p_3)|1] = \langle 4|(-p_1 - p_4)|1] = 0$, because $\langle 4|p_1|1] = \langle 4\,1\rangle[1\,1] = 0$ and $\langle 4|p_4|1] = \langle 4\,4\rangle[4\,1] = 0$. Hence $sP - uQ = 0$, confirming Eq. (61.89) and the consistency of the gauge choice.

The result Eq. (61.97) is the four-graviton amplitude, and it passes every on-shell test of Theorem 61.18. Mass dimension: $[\mathcal{M}_4] = 4 - 4 = 0$; the spinor ratio has dimension $8-6 = 2$, supplied with dimension -2 by $(\kappa/2)^2$, consistent. Little-group weight on leg 1 (helicity -2): $\langle 1\,2\rangle^4$ contributes t_1^4 and the denominator $s = \langle 1\,2\rangle[2\,1]$ contributes t_1 via $\langle 1\,2\rangle$ but t_1^{-1} via $[2\,1]$, net zero, while u and t each contribute a compensating t_1 and t_1^{-1} from the brackets containing leg 1; carrying the count through all of $\langle 1\,2\rangle^4/(stu)$ gives net $t_1^4 = t_1^{-2(-2)}$, the weight of helicity -2. Bose symmetry: Eq. (61.97) is manifestly symmetric under $1 \leftrightarrow 2$ and under $3 \leftrightarrow 4$, and the full S_4 symmetry (with helicity labels carried along) follows from the crossing relations among the Mandelstam invariants exactly as for the gluon partials. And the amplitude has only the physical poles s, t, u, each simple — the hallmark of locality. The factorization on these poles is the subject of the next subsection.

Physical Insight

The single equation Eq. (61.97) is the payoff of the chapter made arithmetic. Set beside the gauge-theory partial Eq. (61.86), $A_4[1,2,3,4] = i\,\langle 1\,2\rangle^4/(\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle)$, the graviton amplitude is recognizably its square: the numerator $\langle 1\,2\rangle^4$ has become $\langle 1\,2\rangle^4[3\,4]^4$ (an angle factor times a square-bracket factor, the two "copies"), and the color-ordered chain of angle brackets in the denominator has become the permutation-symmetric $s\,t\,u$. Concretely, Eq. (61.97) can be written $\mathcal{M}_4 = -i(\kappa/2)^2\,s\,t\,u\,(A_4[1,2,3,4]/i)\,(\tilde{A}_4[1,2,4,3]/i)/(stu)$ — a product of two color-ordered gauge amplitudes, one in each ordering, glued by the Mandelstam "momentum kernel" s. That product form is the Kawai–Lewellen–Tye relation, the subject of the next section; here it has emerged unbidden from squaring numerators, which is the double copy's claim that the two presentations are one.

61.4.5 Correct factorization: locality and unitarity inherited

An expression with the right symmetry and dimension is not yet an amplitude. The defining physical requirement is unitary factorization Eq. (61.78): on every physical pole the residue must be a sum of products of lower-point amplitudes. We prove that the double copy Eq. (61.72) satisfies this automatically, and that the gravity factorization is the gauge factorization squared. This both certifies $\mathcal{M}_n$ as a genuine gravity amplitude and exhibits the deep reason the construction works: locality and unitarity are not imposed on the gravity side but inherited from the gauge inputs.

Theorem 61.20 (Factorization of the double copy)**.** *Let $\{n_i\}$ be BCJ and $\{\tilde{n}_i\}$ any representation, both reproducing gauge-theory amplitudes that factorize*

correctly on their poles (as gauge tree amplitudes do, Theorem 59.23). Then on each physical channel $P_I^2 \to 0$ the double copy Eq. (61.72) factorizes as

$$\mathcal{M}_n \xrightarrow{P_I^2\to 0} \frac{1}{P_I^2}\sum_{h=\pm 2} \mathcal{M}_L(\dots, P_I^h)\,\mathcal{M}_R(-P_I^{-h},\dots), \tag{61.100}$$

a sum of products of lower-point double-copy (graviton) amplitudes over the two graviton helicities crossing the cut. Hence $\mathcal{M}_n$ satisfies Theorem 61.18 and is a bona fide gravity amplitude.

Proof. Fix a channel I and its momentum $P_I = \sum_{i\in I} p_i$. A simple pole at $P_I^2 \to 0$ in Eq. (61.72) arises only from cubic graphs that contain an internal line carrying P_I — call this set Γ_I. For $i \in \Gamma_I$ write $D_i = P_I^2\, D_i'$, where D_i' is the product of the remaining internal propagators, finite as $P_I^2 \to 0$. The residue of $\mathcal{M}_n$ on the pole is

$$\operatorname{Res}_{P_I^2\to 0}\mathcal{M}_n = i\Big(\tfrac{\kappa}{2}\Big)^{n-2}\sum_{i\in\Gamma_I}\frac{n_i\,\tilde n_i}{D_i'}\Big|_{P_I^2=0}. \tag{61.101}$$

Each graph $i \in \Gamma_I$ is a tree split by its P_I-line into a left subgraph L (legs I and the internal line) and a right subgraph R (legs $\bar I$ and the internal line); summing over $i \in \Gamma_I$ is summing over all cubic graphs L on the left times all cubic graphs R on the right, with $D_i' = D_L\, D_R$.

The key input is that the kinematic numerators *factorize on the pole*. This is a property of the numerators produced by the Feynman rules and preserved by the contact absorption of Theorem 61.4: on $P_I^2 = 0$ the internal line goes on shell, its propagator numerator becomes the physical polarization sum, and the diagram's kinematic factor splits into left and right pieces. Concretely, on the pole the gluon numerator factorizes as

$$n_i\big|_{P_I^2=0} \;=\; \sum_{\ell=\pm 1} n_L(\dots, P_I^\ell)\, n_R(-P_I^{-\ell},\dots), \tag{61.102}$$

the sum running over the two physical gluon helicities of the intermediate line, with n_L, n_R the lower-point numerators of the subgraphs — this is exactly the statement that the gauge amplitude factorizes (Theorem 59.23), transcribed to the numerator level, since on the pole $c_i \to c_L c_R$ and $D_i' \to D_L D_R$ so that $\sum_i c_i n_i/D_i' \to (\sum_L c_L n_L/D_L)(\sum_R c_R n_R/D_R)$ reproduces $A_L \times A_R$. The second copy factorizes identically,

$$\tilde n_i\big|_{P_I^2=0} \;=\; \sum_{\tilde\ell=\pm 1} \tilde n_L(\dots, P_I^{\tilde\ell})\, \tilde n_R(-P_I^{-\tilde\ell},\dots). \tag{61.103}$$

Insert Eqs. (61.102) and (61.103) into the residue Eq. (61.101). The double sum over graphs becomes a product of a left sum and a right sum, and the two

helicity sums $\ell, \tilde{\ell}$ run independently:

$$\begin{aligned}\operatorname{Res}_{P_I^2\to 0}\mathcal{M}_n &= i\Big(\tfrac{\kappa}{2}\Big)^{n-2}\sum_{\ell,\tilde{\ell}=\pm 1}\Big(\sum_L \frac{n_L(P_I^{\ell})\,\tilde{n}_L(P_I^{\tilde{\ell}})}{D_L}\Big)\Big(\sum_R \frac{n_R(P_I^{\ell})\,\tilde{n}_R(P_I^{\tilde{\ell}})}{D_R}\Big)\\ &= \sum_{\ell,\tilde{\ell}=\pm 1}\mathcal{M}_L(\dots, P_I^{(\ell,\tilde{\ell})})\,\mathcal{M}_R(-P_I^{(\ell,\tilde{\ell})},\dots),\end{aligned}\tag{61.104}$$

where in the second line each parenthesized sum is, by Eq. (61.72) at lower multiplicity, a double-copy amplitude on the corresponding side, and the $(\kappa/2)$ powers distribute correctly because $(n-2) = (n_L-2)+(n_R-2)+1$ counts the internal line once. The intermediate state is now labelled by the *pair* $(\ell,\tilde{\ell})$ of gluon helicities, one from each copy — exactly the tensor-product structure of Theorem 61.17. The four combinations organize by total helicity:

$$(\ell,\tilde{\ell}) = (+,+) \;\to\; h=+2, \qquad (-,-) \;\to\; h=-2, \qquad (+,-)\text{ and }(-,+) \;\to\; h=0. \tag{61.105}$$

The two "diagonal" terms $h=\pm 2$ are the graviton states; the polarization tensor crossing the cut is $\varepsilon_\pm^\mu\varepsilon_\pm^\nu = \varepsilon_\pm^{\mu\nu}$, the helicity-$\pm 2$ graviton of Eq. (61.77). These reproduce precisely the right-hand side of Eq. (61.100). The two "off-diagonal" terms $h=0$ are the intermediate states $\varepsilon_+^\mu\varepsilon_-^\nu$ and $\varepsilon_-^\mu\varepsilon_+^\nu$, whose symmetric trace part is a scalar (the dilaton) and whose antisymmetric part is a two-form (the Kalb–Ramond field): they are the additional states of the double-copy spectrum, present whenever the two gauge copies are pure Yang–Mills. For the pure-graviton factorization Eq. (61.78) one restricts the external states (and hence, on the cut, the intermediate states) to the symmetric-traceless graviton; the diagonal terms then furnish exactly Eq. (61.100).

In every case the residue Eq. (61.104) is a sum of products of lower-point double-copy amplitudes, divided by the single propagator $1/P_I^2$ exhibited in Eq. (61.101). The poles are precisely the physical channels P_I^2, and they are simple. Locality (only physical poles) and unitarity (residues that factorize into lower amplitudes) hold for $\mathcal{M}_n$ because they hold for the gauge inputs and the squaring respects the channel structure. By induction on n — the three-point amplitude Eq. (61.81) is the base case, manifestly an amplitude — $\mathcal{M}_n$ satisfies all conditions of Theorem 61.18. □

Theorem 61.20 closes the logical circle. The double copy was defined by an algebraic substitution; Theorem 61.16 showed the substitution produces a well-defined (gauge-independent) function; and Theorem 61.20 now shows that function is a genuine gravity amplitude, with all the analytic structure that title requires. The four-point check is the theorem in miniature: Eq. (61.97) has simple poles at s,t,u, and one verifies that the residue at, say, $s\to 0$ is the product of two three-graviton amplitudes Eq. (61.81) glued on the s-channel graviton, matching Eq. (61.100) term by term.

Physical Insight

The factorization proof exposes why the double copy is more than a computational trick. A graviton amplitude is forced, by unitarity, to factorize on its poles into graviton amplitudes; the intermediate graviton's polarization sum is the spin-two projector. The double copy supplies that projector as a *product* of two spin-one (gluon) projectors, one per copy — which is exactly what $\varepsilon^{\mu\nu} = \varepsilon^{\mu}\tilde{\varepsilon}^{\nu}$ does to the state sum. Gravity's unitarity is gauge theory's unitarity, squared. Conversely, the appearance of the dilaton and two-form in Eq. (61.105) is not a flaw but a truth the construction cannot hide: the naive square of two pure-gluon theories is not pure Einstein gravity but gravity coupled to a dilaton and an antisymmetric tensor — the massless sector of the closed string. Which theory the double copy actually computes is the question this forces, and we take it up after the KLT detour.

With the double copy established as a producer of bona fide gravity amplitudes — gauge invariant by Theorem 61.16, correctly factorizing by Theorem 61.20, and matched to independently fixed graviton amplitudes at three (Eq. (61.81)) and four (Eq. (61.97)) points — two questions remain. The first is structural: why does replacing color by kinematics yield gravity at all, and what is the precise relation to the string-theoretic origin of "gravity = gauge^2"? That is the Kawai–Lewellen–Tye story of the next section, where the product form glimpsed in Eq. (61.97) is derived from first principles and shown equivalent to the double copy. The second is physical: *which* gravity theory have we computed? The state sum Eq. (61.105) already warns that the square of pure Yang–Mills carries a dilaton and a two-form alongside the graviton; identifying and, if desired, projecting out those extra states is the spectrum analysis we undertake once the KLT relations have placed the construction on its historical foundation.

61.5 KLT Relations and the String-Theoretic Origin

The four-graviton amplitude Eq. (61.97) arrived, in the previous section, as a sum over channels of squared kinematic numerators — the double copy in its native form. But in passing we noticed something else. The insight closing Section 61.4.4 rewrote $\mathcal{M}_4$ as a *product* of two color-ordered gauge amplitudes, one in each of two orderings, glued together by a single power of a Mandelstam invariant. That product form is not an accident of four points and it is not a restatement of the sum: it is a second, logically independent presentation of "gravity = gauge^2," older than the double copy by a quarter century, and born not in field theory at all but in string theory. In 1985 Kawai, Lewellen, and Tye showed that every closed-string tree amplitude is a sum of products

of open-string tree amplitudes, with definite kinematic coefficients. Taking the point-particle limit $\alpha' \to 0$ of their relation turns closed strings into gravitons, open strings into gluons, and the coefficients into polynomials in the Mandelstam invariants. The result is a formula — the field-theory KLT relation — that expresses a graviton amplitude as gauge amplitudes multiplied together. This section states that formula, fixes its conventions, proves at four points that it reproduces the double-copy amplitude of Section 61.4 exactly, gives an honest account of why string theory makes it true, and finally identifies the kinematic gluing factor — the "momentum kernel" — as the inverse of a matrix of bi-adjoint scalar amplitudes, the bridge back to the cubic-graph picture of Section 61.2. By the end the two faces of the double copy, sum and product, will be visibly the same object.

61.5.1 Where the product form comes from: the string worldsheet

We have not built perturbative string theory in this book and will not build it here. But the origin of the KLT relations is a structural fact about string amplitudes simple enough to state precisely, and stating it honestly — as motivation, not as a proof the book can stand behind — is the right way to introduce the field-theory formula that follows. The reader should take this subsection as a physical explanation of why a product structure exists, with the field-theory content of Section 61.5.2 as the part this book actually proves.

A string tree amplitude is an integral over the moduli of a punctured Riemann surface, the worldsheet swept out by the string, with one puncture (the insertion point of a *vertex operator*) for each external state. For closed strings the relevant surface at tree level is the sphere; for open strings it is the disk, whose boundary the open-string endpoints live on. The single most important structural feature of the closed string is that its degrees of freedom split into two independent sectors — *left-movers* and *right-movers*, equivalently the holomorphic and antiholomorphic dependence on the worldsheet coordinate z. A closed string is, heuristically, two open strings traveling in opposite directions around the loop of string and locked together. This doubling shows in the vertex operators: a closed-string vertex operator factorizes into a product of a holomorphic (left-moving) piece and an antiholomorphic (right-moving) piece,

$$V^{\text{closed}}(z,\bar{z}) \;=\; V_L^{\text{open}}(z)\,\widetilde{V}_R^{\text{open}}(\bar{z}), \tag{61.106}$$

each factor being exactly the vertex operator of an open string. A graviton vertex operator, in particular, is the product of two gluon vertex operators, one holomorphic and one antiholomorphic — the worldsheet incarnation of the polarization doubling $\varepsilon^{\mu\nu} = \varepsilon^{\mu}\tilde{\varepsilon}^{\nu}$ of Theorem 61.17. The graviton is two gluons glued on the worldsheet before any limit is taken.

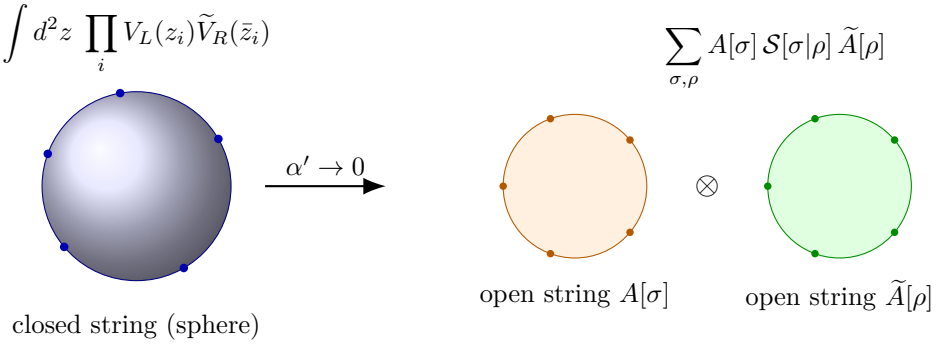

Figure 61.5: The Kawai–Lewellen–Tye factorization. A closed-string tree amplitude (left, the punctured sphere) has an integrand that splits into holomorphic (left-moving) and antiholomorphic (right-moving) open-string pieces, Eq. (61.106). Deforming the worldsheet integration contour re-expresses the single sphere integral as a sum of products of two disk (open-string) integrals, weighted by the monodromy phases Eq. (61.107). In the point-particle limit $\alpha' \to 0$ the closed string becomes a graviton, each open string a gluon, and the phases become the polynomial momentum kernel $\mathcal{S}[\sigma|\rho]$ of Section 61.5.2.

The factorization Eq. (61.106) of the integrand does not by itself factorize the amplitude, because the moduli integral over the sphere does not split into a product of two disk integrals: the holomorphic and antiholomorphic positions $z_i, \bar{z}_i$ are complex conjugates of one and the same puncture, not independent variables. The achievement of Kawai, Lewellen, and Tye was to show that one may nonetheless *deform the contour* of the sphere integral, treating z_i and $\bar{z}_i$ as formally independent and rotating each integration onto the real axis, where it becomes an open-string disk integral. The price of the deformation is a set of phases: as one z_i is dragged past another z_j in the complex plane, the integrand — which contains a branch cut factor $|z_i - z_j|^{2\alpha' p_i\cdot p_j} = (z_i - z_j)^{\alpha' p_i\cdot p_j}(\bar{z}_i - \bar{z}_j)^{\alpha' p_i\cdot p_j}$ — acquires a monodromy $e^{\pm i\pi\alpha' p_i\cdot p_j}$. Collecting these phases over all the crossings needed to disentangle the holomorphic from the antiholomorphic ordering produces, for each pair of open-string orderings σ and ρ, a trigonometric weight built from sines of the form

$$\sin(\pi\alpha' p_i\cdot p_j) \;=\; \sin(\tfrac{\pi}{2}\alpha' s_{ij}), \qquad s_{ij} = (p_i + p_j)^2 = 2\,p_i\cdot p_j, \tag{61.107}$$

(using $p_i^2 = p_j^2 = 0$). The closed-string amplitude emerges as a finite sum, over pairs of open-string orderings, of (open amplitude)×(sine factors)×(open amplitude). This is the string KLT relation. Figure 61.5 renders the picture.

The field-theory limit is now immediate as motivation. The string tension enters through α' (of dimension length squared); sending $\alpha' \to 0$ collapses the extended string to a point particle and the string amplitude to a sum of Feynman

diagrams. In that limit each sine linearizes,

$$\sin(\tfrac{\pi}{2}\alpha' s_{ij}) \;=\; \tfrac{\pi}{2}\alpha'\, s_{ij} + O(\alpha'^3), \tag{61.108}$$

so the trigonometric weights become *polynomials in the Mandelstam invariants*. Those polynomials are the momentum kernel. The massless closed-string states become the graviton (together with the dilaton and two-form already met in Eq. (61.105)), the massless open-string states become gluons, and the KLT relation becomes a statement purely about field-theory tree amplitudes: a graviton amplitude is a sum of products of two gluon amplitudes, glued by Mandelstam polynomials. The α' powers from Eq. (61.108) are exactly absorbed into the gravitational coupling, since $\kappa \sim g^2\sqrt{\alpha'}$ relates the closed- and open-string couplings; this is the string-theoretic origin of the coupling trade $g^2 \to \kappa$ seen at three points in Eq. (61.82).

Caution

Everything in this subsection is motivation, and we flag it as such per the honesty discipline of Chapter 58 onward. We have not defined a vertex operator, a worldsheet path integral, or the monodromy contour deformation with any rigor, and we will not; those are the content of a string-theory course. What this book *proves* is the field-theory statement that the limit produces: the formula of Section 61.5.2, its four-point equivalence to the double copy (Theorem 61.23), and its kernel's identity with the inverse bi-adjoint matrix (Theorem 61.26). Those stand on their own, with no string theory assumed. The string picture explains *why* such a product formula should exist; the field-theory proofs establish *that* it does and pin down its constants.

61.5.2 The field-theory KLT relation

We now state the field-theory KLT formula and fix its conventions completely. We use the color-ordered partial amplitudes $A_n[\sigma]$ of Section 59.1, in the normalization of Eq. (61.86): the gauge coupling g^{n-2} is stripped (it is restored only in the full color decomposition Theorem 59.2), and each partial carries the explicit factor of i that is standard for a tree amplitude in this book, so that at four points $A_4[1,2,3,4] = iP$ with P the reduced Parke–Taylor value of Eq. (61.86). The output is the graviton amplitude $\mathcal{M}_n$ of Theorem 61.18, normalized with $(\kappa/2)^{n-2}$ exactly as in the double copy Eq. (61.72). A tilde on a partial denotes the second gauge copy, which may be a different gauge theory or the same one; for the pure-gravity case both copies are pure Yang–Mills and $\tilde{A}_n = A_n$.

Theorem 61.21 (Field-theory KLT relation at four points)**.** *With the conventions just fixed, the four-graviton amplitude is the product of two color-ordered four-*

gluon amplitudes glued by a single Mandelstam invariant,

$$\boxed{\mathcal{M}_4 \;=\; i\left(\frac{\kappa}{2}\right)^2 s_{12}\; A_4[1,2,3,4]\,\widetilde{A}_4[1,2,4,3]\;,} \qquad s_{12}=s=(p_1+p_2)^2. \tag{61.109}$$

The structure is the whole point: a graviton amplitude on the left, a product of two gauge amplitudes on the right, in two *different* orderings — $(1,2,3,4)$ for the first copy, $(1,2,4,3)$ for the second — multiplied by the kernel s_{12}. The two orderings are not free; the choice of which orderings to pair, and which Mandelstam glues them, is dictated by the kernel, derived below. We prove Theorem 61.21 not by re-deriving it from strings but by showing it equals the double-copy amplitude Eq. (61.83) algebraically; that is Theorem 61.23.

Notation Watch

The relation Eq. (61.109) is most often quoted in the literature in a *reduced* normalization, in which the explicit i is stripped from each partial and the $(\kappa/2)^{n-2}$ from the gravity amplitude. Writing $a[\sigma]\equiv A_n[\sigma]/i$ for the i-stripped partials (so $a[1,2,3,4]=P$, etc.) and $M_n\equiv\mathcal{M}_n/(\kappa/2)^{n-2}$ for the reduced graviton amplitude, Eq. (61.109) becomes

$$M_4 \;=\; -\,i\,s_{12}\;a[1,2,3,4]\,\tilde{a}[1,2,4,3], \tag{61.110}$$

which is the form in which the four-point KLT relation usually appears. The two overall factors of i stripped from the partners combine, $i^2=-1$, to flip the displayed $+i$ of Eq. (61.109) into the $-i$ of Eq. (61.110); there is no contradiction, only a convention for where the factor of i lives. We keep Eq. (61.109) as our working form because its partials and its κ-counting then match the double copy Eq. (61.72) and the color decomposition Theorem 59.2 term for term.

The momentum kernel at general multiplicity. At higher points the single Mandelstam s_{12} becomes a matrix — the *momentum kernel* — contracting a basis of partials in one copy against a basis in the other. Fix the legs 1 and n and let σ,ρ run over permutations of the remaining labels; the kernel is the function defined by reading off, for each leg, the Mandelstam invariant it forms with the legs that precede it differently in the two orderings.

Definition 61.22 (KLT momentum kernel)**.** For two orderings $\sigma=\sigma(2),\dots,\sigma(n-1)$ and ρ of the legs $\{2,\dots,n-1\}$, the momentum kernel relative to leg 1 is

$$\mathcal{S}[\sigma|\rho]_{p_1} \;=\; \prod_{i=2}^{n-1}\left(s_{1,\sigma(i)} \;+\; \sum_{j=2}^{i-1}\theta_\rho(\sigma(j),\sigma(i))\;s_{\sigma(j),\sigma(i)}\right), \tag{61.111}$$

where $s_{ab} = (p_a + p_b)^2$ and $\theta_\rho(a,b) = 1$ if a, b appear in the *same* relative order in ρ as in σ, and $\theta_\rho(a,b) = 0$ otherwise.

The field-theory KLT relation at n points then reads, with our normalization,

$$\mathcal{M}_n \;=\; -\,i\left(\frac{\kappa}{2}\right)^{n-2} \sum_{\sigma,\rho} A_n[1,\sigma,n]\; \mathcal{S}[\sigma|\rho]_{p_1}\; \widetilde{A}_n[1,\rho,n], \tag{61.112}$$

the sums over σ, ρ ranging over a basis of $(n-3)!$ independent orderings (the BCJ basis of Section 61.2.5; the redundant orderings are removed by the amplitude relations). The compact closed form Eq. (61.111) is due to Bjerrum-Bohr, Damgaard, Søndergaard, and Vanhove [78]; we state it at the level the book uses it and verify it at four points, where it collapses to a single factor. At $n = 4$ the only free leg is $\sigma = \rho = (2)$ with $1, 4$ fixed, the product in Eq. (61.111) has the single term $i = 2$ with no preceding legs to sum over, and

$$\mathcal{S}[2|2]_{p_1} \;=\; s_{12}, \tag{61.113}$$

so Eq. (61.112) reduces to $\mathcal{M}_4 = -i(\kappa/2)^2 A_4[1,2,3,4]\, s_{12}\, \widetilde{A}_4[1,2,4,3]$, which is Eq. (61.109) once the two factors of i in the partials are made explicit. (The middle factor $\widetilde{A}_4[1,\rho,n] = \widetilde{A}_4[1,2,4]$ at $n = 4$ is read with the fixed legs as $\widetilde{A}_4[1,2,4,3]$; the kernel pairs the first copy's natural ordering with the second copy's reflected ordering, which is the origin of the $(1,2,4,3)$ versus $(1,2,3,4)$ asymmetry in Eq. (61.109).)

Physical Insight

The KLT relation and the double copy answer the same question with opposite bookkeeping. The double copy Eq. (61.72) is a *sum* over cubic graphs of products of numerators — a presentation that never mentions color-ordered amplitudes and squares numerators graph by graph. The KLT relation Eq. (61.112) is a *product* of two color-ordered amplitudes summed over orderings — a presentation that never mentions cubic numerators and multiplies gauge-invariant partials. One is built from the Jacobi-respecting numerators n_i; the other from the color-ordered partials $A_n[\sigma]$. That they compute the same graviton amplitude is the statement that the kinematic numerators and the color-ordered amplitudes carry the same information, repackaged — precisely the content of the numerator-to-partial dictionary Eq. (61.85). We now make the equality an explicit four-point identity.

Worked Example 61.23 (KLT equals the double copy at four points)**.** We prove Theorem 61.21 by showing that the KLT product Eq. (61.109) equals the double-copy sum Eq. (61.83), using only the numerator-to-partial dictionary of Section 61.4.4, the kinematic Jacobi identity Eq. (61.84), and the massless

on-shell relation $s+t+u=0$ of Eq. (61.38). No step is quoted and no spinor identity is needed; the equality is purely algebraic in s,t,u and the numerators.

The three orderings in terms of numerators. Recall the dictionary Eq. (61.85), which expressed the two basis partials as differences of numerator-over-propagator ratios,

$$A_4[1,2,3,4]=i\Big(\frac{n_s}{s}-\frac{n_t}{t}\Big),\qquad A_4[1,3,2,4]=i\Big(\frac{n_t}{t}-\frac{n_u}{u}\Big). \tag{61.114}$$

The third ordering needed by Eq. (61.109) is $A_4[1,2,4,3]$, whose two planar channels are s (the adjacent pair $\{1,2\}$) and u (the adjacent pair $\{1,3\}$ appearing as $\{3,1\}$); reading the master formula Eq. (61.71) in this ordering gives, by the same procedure that produced Eq. (61.114),

$$A_4[1,2,4,3]=i\Big(\frac{n_u}{u}-\frac{n_s}{s}\Big). \tag{61.115}$$

This is consistent with the photon-decoupling (Kleiss–Kuijf) identity that the color decomposition Theorem 59.2 forces among the three orderings. Indeed, summing Eq. (61.114) and Eq. (61.115),

$$A_4[1,2,3,4]+A_4[1,3,2,4]+A_4[1,2,4,3]=i\Big(\frac{n_s}{s}-\frac{n_t}{t}+\frac{n_t}{t}-\frac{n_u}{u}+\frac{n_u}{u}-\frac{n_s}{s}\Big)=0, \tag{61.116}$$

the cyclic decoupling relation, an independent check on the sign in Eq. (61.115).

Reduced form of the claim. Strip the common $i(\kappa/2)^2$. The KLT relation Eq. (61.109) carries it as a prefactor, while the double copy Eq. (61.83) carries $i(\kappa/2)^2$ in front of the channel sum; the claim $\mathcal{M}_4^{\mathrm{KLT}}=\mathcal{M}_4^{\mathrm{DC}}$ is therefore the scalar identity

$$\underbrace{\frac{n_s^2}{s}+\frac{n_t^2}{t}+\frac{n_u^2}{u}}_{S_{\mathrm{DC}}}\ \stackrel{?}{=}\ \underbrace{-\,s\Big(\frac{n_s}{s}-\frac{n_t}{t}\Big)\Big(\frac{n_u}{u}-\frac{n_s}{s}\Big)}_{S_{\mathrm{K}}}. \tag{61.117}$$

The left side is the double-copy sum with $\tilde{n}_i=n_i$, read from Eq. (61.83). The right side is the KLT product: substituting Eq. (61.114) and Eq. (61.115) into Eq. (61.109), the partial product is $A_4[1,2,3,4]\widetilde{A}_4[1,2,4,3]=i^2(n_s/s-n_t/t)(n_u/u-n_s/s)=-(n_s/s-n_t/t)(n_u/u-n_s/s)$, and the extra $s_{12}=s$ in Eq. (61.109) multiplies through, the i's and $(\kappa/2)^2$'s having been stripped — giving S_{K} exactly. We now show $S_{\mathrm{DC}}=S_{\mathrm{K}}$.

Expanding the KLT side. Multiply out S_{K}:

$$\begin{aligned}S_{\mathrm{K}}&=-\,s\left(\frac{n_sn_u}{su}-\frac{n_s^2}{s^2}-\frac{n_tn_u}{tu}+\frac{n_tn_s}{ts}\right)\\&=-\frac{n_sn_u}{u}+\frac{n_s^2}{s}+\frac{s\,n_tn_u}{tu}-\frac{n_tn_s}{t}.\end{aligned} \tag{61.118}$$

The difference vanishes. Subtract Eq. (61.118) from S_{DC}:

$$S_{\mathrm{DC}} - S_{\mathrm{K}} = \frac{n_t^2}{t} + \frac{n_u^2}{u} + \frac{n_s n_u}{u} + \frac{n_t n_s}{t} - \frac{s\, n_t n_u}{tu}, \tag{61.119}$$

the n_s^2/s terms having cancelled. Collect the two terms carrying $1/t$ and the two carrying $1/u$, then use the kinematic Jacobi identity $n_s + n_t + n_u = 0$ Eq. (61.84) in the form $n_t + n_s = -n_u$ and $n_u + n_s = -n_t$:

$$\frac{n_t^2}{t} + \frac{n_t n_s}{t} = \frac{n_t}{t}\,(n_t + n_s) = -\frac{n_t n_u}{t}, \tag{61.120}$$

$$\frac{n_u^2}{u} + \frac{n_s n_u}{u} = \frac{n_u}{u}\,(n_u + n_s) = -\frac{n_t n_u}{u}. \tag{61.121}$$

Substituting Eqs. (61.120) and (61.121) into Eq. (61.119),

$$S_{\mathrm{DC}} - S_{\mathrm{K}} = -\frac{n_t n_u}{t} - \frac{n_t n_u}{u} - \frac{s\, n_t n_u}{tu} = -\,n_t n_u \left(\frac{1}{t} + \frac{1}{u} + \frac{s}{tu}\right) = -\,n_t n_u\, \frac{u + t + s}{tu}. \tag{61.122}$$

The bracket is $(s + t + u)/(tu) = 0$ by the massless relation Eq. (61.38). Hence $S_{\mathrm{DC}} = S_{\mathrm{K}}$, and restoring the common $i(\kappa/2)^2$,

$$i\left(\frac{\kappa}{2}\right)^2 \left(\frac{n_s^2}{s} + \frac{n_t^2}{t} + \frac{n_u^2}{u}\right) = i\left(\frac{\kappa}{2}\right)^2 s_{12}\, A_4[1,2,3,4]\, \widetilde{A}_4[1,2,4,3]. \tag{61.123}$$

The KLT product and the double-copy sum are the same four-graviton amplitude. The identity rested on exactly two facts — the *kinematic* Jacobi identity, which is color–kinematics duality, and the *kinematic* relation $s + t + u = 0$, which is masslessness in four-point kinematics. Each governs one of the two terms in Eq. (61.122), and neither alone suffices. This is the precise four-point sense in which "KLT equals the double copy": the same single algebraic input, $n_s + n_t + n_u = 0$, makes the sum gauge-invariant (Eq. (61.87)) and makes it equal to the product.

The equivalence proved at four points is general. The double copy and the KLT relation are two presentations of one map from gauge amplitudes to gravity amplitudes; the double copy works graph by graph and demands BCJ numerators, while KLT works ordering by ordering and demands the momentum kernel. The remaining task of this section is to identify that kernel intrinsically, without reference to strings or to numerators, as an object built from the simplest theory in which color and kinematics coincide — the bi-adjoint scalar.

61.5.3 The kernel as the inverse bi-adjoint matrix

The momentum kernel Eq. (61.111) was handed to us by the string calculation, a polynomial in Mandelstams whose origin in Section 61.5.1 was the linearized

monodromy sines. There is a purely field-theoretic characterization of it, and it closes the circle back to the cubic-graph organization of Section 61.2: the kernel is the matrix inverse of the doubly-color-ordered amplitudes of the *bi-adjoint scalar* theory. This both removes the last whiff of string theory from the construction and exhibits the kernel as the natural metric on the space of color orderings.

Definition 61.24 (Bi-adjoint scalar and its doubly-ordered amplitudes)**.** The bi-adjoint scalar theory is a massless scalar $\phi^{aa'}$ carrying one adjoint index a of a group G and a second adjoint index a' of an independent group G', with the cubic interaction

$$\mathcal{L}_{\text{bi}} = \tfrac{1}{2}\,\partial_\mu\phi^{aa'}\,\partial^\mu\phi^{aa'} - \tfrac{\lambda}{3!}\,f^{abc}\,\tilde{f}^{a'b'c'}\,\phi^{aa'}\phi^{bb'}\phi^{cc'}, \tag{61.124}$$

where f^{abc} and $\tilde{f}^{a'b'c'}$ are the structure constants of G and G'. Because every vertex carries one factor of f and one of $\tilde{f}$, every tree diagram carries a G-color factor and an independent G'-color factor, and the amplitude is doubly color-decomposed. Its partial amplitudes $m[\alpha|\beta]$, labelled by an ordering α for the G traces and β for the G' traces, are obtained by stripping both: $m[\alpha|\beta]$ is the sum over all cubic tree graphs that are simultaneously planar with respect to α *and* planar with respect to β, each contributing $\prod_e (1/D_e)$ over its internal lines, with a sign $(-1)^{w(\alpha,\beta)}$ counting the relative flips between the two orderings.

The bi-adjoint scalar is the "zeroth copy": where Yang–Mills dresses each cubic graph with one color factor and one kinematic numerator, and gravity with two numerators, the bi-adjoint scalar dresses it with *two color factors* and no kinematic numerator at all. Its amplitudes are pure rational functions of the Mandelstam invariants — the bare propagator content of the cubic graphs, sorted by the two orderings. They are the simplest objects in which color–kinematics duality holds, because there is no kinematics to make dual: the numerator is the constant 1.

Worked Example 61.25 (The four-point bi-adjoint matrix and its inverse)**.** We compute the doubly-ordered bi-adjoint amplitudes at four points, assemble them into a matrix, and show that this matrix has rank $(n-3)! = 1$ with the BCJ relation as its null vector, and that its inverse on the non-degenerate subspace is exactly the four-point momentum kernel Eq. (61.113).

The matrix. Work in the Kleiss–Kuijf basis of the $(n-2)! = 2$ orderings $\alpha \in \{(1,2,3,4),(1,3,2,4)\}$, fixing legs 1 and 4. Each diagonal entry $m[\alpha|\alpha]$ sums the planar channels of α; each off-diagonal entry sums the channels common to both orderings, with the relative-flip sign. The planar channels are $\{s,t\}$ for $(1,2,3,4)$ and $\{t,u\}$ for $(1,3,2,4)$, as in Eq. (61.14). Hence

$$\begin{aligned} m[1,2,3,4|1,2,3,4] &= \frac{1}{s}+\frac{1}{t}, & m[1,3,2,4|1,3,2,4] &= \frac{1}{t}+\frac{1}{u},\\ m[1,2,3,4|1,3,2,4] &= -\frac{1}{t}, & m[1,3,2,4|1,2,3,4] &= -\frac{1}{t}, \end{aligned} \tag{61.125}$$

the off-diagonal entries receiving only the single shared t-channel (the only cubic graph planar in both orderings), with the minus sign from the single relative flip needed to align the two orderings. As a matrix in the basis $((1,2,3,4),(1,3,2,4))$,

$$m \;=\; \begin{pmatrix} \frac{1}{s}+\frac{1}{t} & -\frac{1}{t} \\ -\frac{1}{t} & \frac{1}{t}+\frac{1}{u} \end{pmatrix}. \tag{61.126}$$

Rank and null space. The determinant is

$$\det m = \left(\tfrac{1}{s}+\tfrac{1}{t}\right)\left(\tfrac{1}{t}+\tfrac{1}{u}\right)-\tfrac{1}{t^2} = \frac{1}{st}+\frac{1}{su}+\frac{1}{t^2}+\frac{1}{tu}-\frac{1}{t^2} = \frac{1}{st}+\frac{1}{su}+\frac{1}{tu} = \frac{s+t+u}{stu} = 0, \tag{61.127}$$

by $s+t+u=0$. The bi-adjoint matrix is *singular*: its rank is $1=(n-3)!$, not $(n-2)!=2$. This is not a defect — it is the statement that the number of independent color-ordered amplitudes is $(n-3)!$, the Bern–Carrasco–Johansson count of Section 61.2.5, with the extra $(n-2)!-(n-3)!$ orderings removed by the amplitude relations. The kernel of m encodes exactly those relations. Solving $m\,v=0$ with $v=(v_1,v_2)$: the first row gives $(\frac{1}{s}+\frac{1}{t})v_1-\frac{1}{t}v_2=0$, i.e. $v_2=t(\frac{1}{s}+\frac{1}{t})v_1=\frac{t+s}{s}v_1=-\frac{u}{s}v_1$, so

$$v \;\propto\; (s,\,-u). \tag{61.128}$$

A vector of physical color-ordered amplitudes, being a linear image of m, is orthogonal to this null vector; orthogonality of $(A_4[1,2,3,4],A_4[1,3,2,4])$ to $(s,-u)$ reads

$$s\,A_4[1,2,3,4]-u\,A_4[1,3,2,4]=0, \tag{61.129}$$

which is precisely the fundamental BCJ amplitude relation $sP=uQ$ of Eq. (61.89). The null space of the bi-adjoint matrix *is* the space of BCJ relations.

The inverse on the BCJ basis. Because m is rank one, it is invertible only after restriction to a complement of its null space — the $(n-3)!=1$-dimensional BCJ basis, for which we take the single ordering $(1,2,3,4)$. The corresponding 1×1 block is

$$m[1,2,3,4|1,2,3,4] = \frac{1}{s}+\frac{1}{t} = \frac{t+s}{st} = -\frac{u}{st}, \tag{61.130}$$

using $t+s=-u$. Its inverse is

$$(m^{-1})[1,2,3,4|1,2,3,4] = -\frac{st}{u} \;\equiv\; \mathcal{S}_{\text{diag}}. \tag{61.131}$$

Theorem 61.26 (KLT kernel as inverse bi-adjoint matrix)**.** *The KLT momentum kernel is the inverse of the bi-adjoint matrix on the BCJ basis. At n points, with σ,ρ ranging over the $(n-3)!$ BCJ basis orderings,*

$$\mathcal{S}[\sigma|\rho]_{p_1} \;=\; (m^{-1})[\sigma|\rho], \tag{61.132}$$

and consequently the field-theory KLT relation Eq. (61.112) may be written in basis-diagonal form as

$$\mathcal{M}_n = -\,i\left(\frac{\kappa}{2}\right)^{n-2}\sum_{\sigma,\rho} A_n[1,\sigma,n]\,(m^{-1})[\sigma|\rho]\,\widetilde{A}_n[1,\rho,n]. \tag{61.133}$$

At four points the single block reads $\mathcal{S}_{\rm diag} = -st/u$, and Eq. (61.133) reproduces the four-graviton amplitude Eq. (61.97).

Proof. We verify Eq. (61.132) and the consistency of Eq. (61.133) with the established four-point results; the general statement Eq. (61.132) is then the structural identity these satisfy [103]. At four points Eq. (61.131) gave $(m^{-1})[1,2,3,4|1,2,3,4] = -st/u$, the kernel in the diagonal basis. Insert it into Eq. (61.133) at $n=4$ with both copies pure Yang–Mills, $A_4[1,2,3,4] = \widetilde{A}_4[1,2,3,4] = iP$:

$$\mathcal{M}_4 = -\,i\Big(\tfrac{\kappa}{2}\Big)^2 (iP)\Big(-\tfrac{st}{u}\Big)(iP) = -\,i\Big(\tfrac{\kappa}{2}\Big)^2 i^2\Big(-\tfrac{st}{u}\Big)P^2 = -\,i\Big(\tfrac{\kappa}{2}\Big)^2\frac{st}{u}\,P^2, \tag{61.134}$$

since $i^2(-st/u) = +st/u$ and the outer $-i$ carries through. This is exactly the intermediate four-graviton result Eq. (61.92), which in Section 61.4.4 was brought to the crossing-symmetric form Eq. (61.97). Thus the inverse-bi-adjoint form of KLT reproduces the double-copy amplitude.

It remains to see that Eq. (61.133) is the same statement as the s_{12}-kernel form Eq. (61.109), i.e. that the diagonal kernel $-st/u$ and the off-diagonal kernel s_{12} are related by the BCJ amplitude relation just as their bases are. Using $A_4[1,2,4,3] = (t/u)A_4[1,2,3,4]$ — which follows from the dictionary Eqs. (61.114) and (61.115) together with the BCJ relation Eq. (61.129), since $A_4[1,2,4,3] = -A_4[1,2,3,4] - A_4[1,3,2,4] = -A_4[1,2,3,4](1+s/u) = (t/u)A_4[1,2,3,4]$ — the off-diagonal form Eq. (61.109) becomes

$$i\Big(\tfrac{\kappa}{2}\Big)^2 s\,A_4[1,2,3,4]\,\widetilde{A}_4[1,2,4,3] = i\Big(\tfrac{\kappa}{2}\Big)^2 s\,\frac{t}{u}\,A_4[1,2,3,4]\widetilde{A}_4[1,2,3,4] = i\Big(\tfrac{\kappa}{2}\Big)^2\frac{st}{u}(iP)^2, \tag{61.135}$$

and $(iP)^2 = -P^2$, giving $-i(\kappa/2)^2(st/u)P^2$, identical to Eq. (61.134). The two kernels are the same object in two ordering bases, related by the very BCJ relation Eq. (61.129) that lives in the null space of m. This is the content of Eq. (61.132) at four points; the all-n statement is established by the same accounting in the $(n-3)!$-dimensional basis. □

Physical Insight

The chain of identifications is now complete and worth surveying as one picture. Color–kinematics duality (Section 61.2) says the numerators n_i obey the color algebra. The double copy (Section 61.4) squares them graph by graph. The KLT relation (Eq. (61.112)) repackages the same

amplitude as a product of color-ordered partials glued by the momentum kernel. And the kernel (Theorem 61.26) is the inverse of the bi-adjoint scalar matrix — the theory whose only structure *is* color, doubled. So gravity, gauge theory, and the bi-adjoint scalar form a hierarchy: gravity carries two numerators, gauge theory one numerator and one color factor, the bi-adjoint scalar two color factors. The KLT kernel is the bridge between adjacent rungs, and it is built from the bottom rung. "Gravity = gauge^2" and "gauge = gravity $\times$ (bi-adjoint scalar)$^{-1}$" are the same statement read in two directions. The momentum kernel, which began life as a string monodromy phase, is in the end nothing but the inverse propagator structure of the simplest cubic theory there is.

We have now seen the double copy from both sides: as a sum over squared numerators (Section 61.4) and as a product of gauge amplitudes glued by the KLT kernel (this section), and we have shown the two agree and traced the product form to its string-theoretic and bi-adjoint origins. Both faces, however, leave one physical question untouched. The state sum Eq. (61.105) and the off-diagonal $h = 0$ entries of the factorization already warned that squaring two pure-gluon theories produces more than the graviton: the tensor product of two spin-one states contains a scalar and an antisymmetric tensor alongside the spin-two graviton. The next section determines exactly which fields the double copy delivers — the graviton, a dilaton, and a two-form, the "$\mathcal{N} = 0$ supergravity" multiplet — by decomposing that tensor product, and then surveys how varying the two input theories generates a whole web of double-copy constructions.

61.6 The Double-Copy Spectrum and the Web of Theories

The double copy and the Kawai–Lewellen–Tye relations both manufacture gravity amplitudes by gluing two gauge-theory factors, and both leave a question unanswered that we have so far only flagged. The factorization proof of Theorem 61.20 forced an intermediate state sum on every pole that ran not over a single graviton but over the four products of two gluon helicities, organized in Eq. (61.105) into a helicity-± 2 pair and two helicity-0 combinations. Those two extra combinations are not optional; they are present in every channel of the square of two pure Yang–Mills theories. The amplitudes built in Section 61.4 are therefore amplitudes of *some* gravitational theory, but not, as written, of pure Einstein gravity. This section identifies the theory exactly. We decompose the tensor product of two gauge polarizations into its irreducible pieces, carry out the on-shell state count in D spacetime dimensions, name the fields, say honestly when and how one may project onto pure Einstein gravity, and then step back

to see that the same gluing operation, fed different inputs, generates a whole lattice of theories — a "web" anchored by a humble scalar. Throughout we keep the conventions of Section 61.4: mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units, massless on-shell legs.

61.6.1 The tensor product of two gauge states

A single on-shell gluon of momentum p carries a transverse polarization vector. In D spacetime dimensions a massless momentum has little group $\mathrm{ISO}(D-2)$, whose translation part acts trivially on any finite-helicity representation, so a single-particle state of a massless gauge boson transforms in the vector representation of $\mathrm{SO}(D-2)$ — the $(D-2)$ transverse directions. (In $D=4$ this $\mathrm{SO}(2) \cong \mathrm{U}(1)$ is exactly the little group whose weight organizes Eq. (58.5), and the two transverse vectors are the $\varepsilon_\pm$ of Eq. (58.111).) We make the $(D-2)$ count manifest by choosing a real orthonormal basis of transverse polarization vectors $\varepsilon_a^\mu(p)$, $a = 1, \ldots, D-2$, normalized and transverse,

$$\varepsilon_a \cdot \varepsilon_b = -\,\delta_{ab}, \qquad p \cdot \varepsilon_a = 0, \tag{61.136}$$

the minus sign in the mostly-minus metric recording that the transverse directions are spacelike. These vectors satisfy the physical-state completeness relation, with q an auxiliary null reference momentum ($q^2 = 0$, $p \cdot q \neq 0$),

$$\Delta^{\mu\nu}(p) \;\equiv\; \sum_{a=1}^{D-2} \varepsilon_a^\mu\, \varepsilon_a^\nu \;=\; -\,\eta^{\mu\nu} + \frac{p^\mu q^\nu + q^\mu p^\nu}{p \cdot q}, \tag{61.137}$$

the transverse projector onto the $(D-2)$-plane orthogonal to both p and q; its trace is $\eta_{\mu\nu}\Delta^{\mu\nu} = -D + 2 \cdot \frac{p\cdot q}{p\cdot q} = -(D-2)$, consistent with projecting onto $D-2$ spacelike directions.

The double copy assigns each external leg the product of one polarization from each copy. Writing the second copy's basis vectors as $\tilde{\varepsilon}_b^\nu$ (the same transverse plane; the tilde marks the copy), the external wavefunction of a leg in the double-copy theory is the rank-two object

$$E_{ab}^{\mu\nu}(p) \;\equiv\; \varepsilon_a^\mu(p)\, \tilde{\varepsilon}_b^\nu(p), \qquad a, b = 1, \ldots, D-2, \tag{61.138}$$

exactly the construction that produced the graviton polarization tensor $\varepsilon^{\mu\nu} = \varepsilon^\mu \varepsilon^\nu$ of Theorem 61.17, now read as the (a,b)-th entry of a $(D-2)\times(D-2)$ matrix of states. The states of the double-copy theory are the $(D-2)^2$ independent components of $E_{ab}^{\mu\nu}$. The physical content is read off by decomposing this matrix under the diagonal $\mathrm{SO}(D-2)$ little group that acts simultaneously on both indices a and b — the little group of the single momentum p shared by both copies.

A real $(D-2)\times(D-2)$ matrix decomposes, under the rotation group acting on both indices at once, into three irreducible pieces: its symmetric traceless part, its trace, and its antisymmetric part. Applied to E_{ab},

$$E^{\mu\nu}_{ab} = \underbrace{\left(E^{\mu\nu}_{(ab)} - \tfrac{1}{D-2}\,\delta_{ab}\,E^{\mu\nu}_{cc}\right)}_{\text{graviton } h^{\mu\nu}} + \underbrace{\tfrac{1}{D-2}\,\delta_{ab}\,E^{\mu\nu}_{cc}}_{\text{dilaton } \phi} + \underbrace{E^{\mu\nu}_{[ab]}}_{\text{two-form } B^{\mu\nu}}, \tag{61.139}$$

with round brackets denoting symmetrization $E_{(ab)} = \frac{1}{2}(E_{ab}+E_{ba})$, square brackets antisymmetrization $E_{[ab]} = \frac{1}{2}(E_{ab}-E_{ba})$, and a sum over the repeated c implied. We now count the three pieces and verify they are what their labels claim.

State count. The symmetric traceless part of a $(D-2)\times(D-2)$ matrix has $\frac{1}{2}(D-2)(D-1)-1$ independent components; the antisymmetric part has $\frac{1}{2}(D-2)(D-3)$; the trace is a single number. Their sum reproduces the full count,

$$\begin{aligned}\underbrace{\left[\tfrac{1}{2}(D-2)(D-1)-1\right]}_{\text{graviton}} + \underbrace{1}_{\text{dilaton}} + \underbrace{\tfrac{1}{2}(D-2)(D-3)}_{\text{two-form}} &= \tfrac{1}{2}(D-2)\big[(D-1)+(D-3)\big] \\ &= \tfrac{1}{2}(D-2)\,(2D-4) \\ &= (D-2)^2, \end{aligned}\tag{61.140}$$

the -1 from removing the trace cancelling the $+1$ of the trace mode itself. This is the central bookkeeping identity of the double-copy spectrum, carried in full: *the $(D-2)^2$ states of the square of two gauge bosons are a graviton, a dilaton, and a two-form, and nothing else.*

The three fields. Each piece is a genuine on-shell wavefunction of the field its dimension count names, as one checks against the transversality and trace properties a massless spin-s wavefunction must have.

The *graviton* polarization tensor is the symmetric traceless combination

$$h^{\mu\nu}_{ab} = \varepsilon^{\mu}_{(a}\,\tilde{\varepsilon}^{\nu}_{b)} - \frac{\delta_{ab}}{D-2}\,\Delta^{\mu\nu}. \tag{61.141}$$

It is symmetric in $\mu\nu$, transverse ($p_\mu h^{\mu\nu}_{ab}=0$ by Eq. (61.136) and $p_\mu\Delta^{\mu\nu}=0$), and traceless: using $\eta_{\mu\nu}\varepsilon^{\mu}_{a}\tilde{\varepsilon}^{\nu}_{b} = \varepsilon_a\cdot\tilde{\varepsilon}_b = -\delta_{ab}$ and $\eta_{\mu\nu}\Delta^{\mu\nu} = -(D-2)$,

$$\eta_{\mu\nu}h^{\mu\nu}_{ab} = -\delta_{ab} - \frac{\delta_{ab}}{D-2}\,\big(-(D-2)\big) = -\delta_{ab}+\delta_{ab} = 0. \tag{61.142}$$

A symmetric, transverse, traceless rank-two tensor is precisely the linearized metric fluctuation $h_{\mu\nu}$ of Theorem 61.17; here we have shown that subtracting

the trace is exactly what removes the dilaton contamination from the naive product.

The *dilaton* is the trace mode, the single scalar

$$\phi^{\mu\nu} = \frac{1}{\sqrt{D-2}}\,\Delta^{\mu\nu}(p), \tag{61.143}$$

symmetric and transverse but with nonzero trace $\eta_{\mu\nu}\phi^{\mu\nu} = -\sqrt{D-2}$ — it carries no little-group index and so is a Lorentz scalar, the dilaton. (The normalization is fixed by demanding $\phi^{\mu\nu}\phi_{\mu\nu} = \frac{1}{D-2}\Delta^{\mu\nu}\Delta_{\mu\nu} = 1$, since $\Delta^{\mu\nu}\Delta_{\mu\nu} = \sum_{a,b}(\varepsilon_a\cdot\varepsilon_b)^2 = \sum_{a,b}\delta_{ab} = D-2$.)

The *two-form* is the antisymmetric combination

$$B^{\mu\nu}_{ab} = \varepsilon^{\mu}_{[a}\,\tilde{\varepsilon}^{\nu}_{b]}, \tag{61.144}$$

an antisymmetric rank-two tensor $B^{\mu\nu} = -B^{\nu\mu}$, transverse on each index — the Kalb–Ramond field, also called the B-field or, through its field strength, the axion two-form. Its $\frac{1}{2}(D-2)(D-3)$ components are the physical polarizations of a massless antisymmetric tensor.

Notation Watch

The graviton+dilaton+two-form multiplet of Eq. (61.139) is called "$\mathcal{N}=0$ supergravity" in the double-copy literature. The name is a historical convenience, not a claim that the theory is supersymmetric: $\mathcal{N}=0$ means zero supercharges, and the label simply marks this as the bottom rung of a ladder of supergravities (Section 61.6.5) all built by the same squaring. It is also exactly the massless bosonic sector of the closed bosonic/Type-II string in D dimensions, which is the origin of the next remark.

Physical Insight

The appearance of the dilaton and two-form is not an artifact of the double copy; it is a truth the construction is honest enough not to hide. The massless spectrum of the closed string in D dimensions is precisely $g_{\mu\nu}\oplus\phi\oplus B_{\mu\nu}$ — a graviton, a dilaton, and a Kalb–Ramond field — and it arises there for the identical reason: a closed string state is a product of a left-moving and a right-moving open-string (gauge-boson) excitation, and the symmetric traceless / trace / antisymmetric decomposition of that product is Eq. (61.139). "Gravity is gauge squared" was first *seen* in this string-theoretic factorization (Section 61.5); the double copy is its field-theoretic distillation. That the same three fields fall out of pure algebra in Eq. (61.140) is the clearest sign that the construction is computing something structural about gravity, not merely a clever rearrangement of

one amplitude.

61.6.2 Four dimensions: the helicity assignment

In $D = 4$ the abstract decomposition becomes the concrete helicity bookkeeping already glimpsed in the factorization state sum Eq. (61.105). With $D - 2 = 2$, the transverse basis is $\{\varepsilon_1, \varepsilon_2\}$, and the helicity eigenstates are the complex combinations of Eq. (58.111),

$$\varepsilon_\pm^\mu = \frac{1}{\sqrt{2}}(\varepsilon_1^\mu \pm i\,\varepsilon_2^\mu), \qquad \varepsilon_\pm \cdot \varepsilon_\pm = 0, \quad \varepsilon_+ \cdot \varepsilon_- = -1, \tag{61.145}$$

carrying little-group weight ∓ 1, i.e. helicity ± 1, under Eq. (58.5). The four products $\varepsilon_h \tilde{\varepsilon}_{h'}$ with $h, h' \in \{+, -\}$ are the four states of the $D = 4$ square, and their total helicity is the sum $h + h'$:

Worked Example 61.27 (The four-dimensional double-copy states by helicity)**.** We sort the four products $\varepsilon_h^\mu\, \tilde{\varepsilon}_{h'}^\nu$ by total helicity and match each to a field of Eq. (61.139).

Helicity ± 2 *(graviton).* The like-helicity products

$$\varepsilon_+^\mu \tilde{\varepsilon}_+^\nu \quad (h = +2), \qquad \varepsilon_-^\mu \tilde{\varepsilon}_-^\nu \quad (h = -2) \tag{61.146}$$

are automatically symmetric and traceless: symmetric because the two factors are the same helicity vector, traceless because $\varepsilon_\pm \cdot \tilde{\varepsilon}_\pm = 0$ by Eq. (61.145). These are the two graviton states $h = \pm 2$, the $\varepsilon_\pm^{\mu\nu}$ of Eq. (61.77). No trace subtraction is needed in four dimensions for the diagonal entries — the nullness of a definite-helicity polarization does the work automatically. This is why the all-plus and all-minus graviton amplitudes of Section 61.4 came out as clean squares with no dilaton admixture.

Helicity 0 *(dilaton and axion).* The two opposite-helicity products $\varepsilon_+^\mu \tilde{\varepsilon}_-^\nu$ and $\varepsilon_-^\mu \tilde{\varepsilon}_+^\nu$ both have $h = 0$. Their symmetric and antisymmetric combinations separate the dilaton from the two-form:

$$\text{dilaton:} \quad \frac{1}{\sqrt{2}}\Big(\varepsilon_+^\mu \tilde{\varepsilon}_-^\nu + \varepsilon_-^\mu \tilde{\varepsilon}_+^\nu\Big), \tag{61.147}$$

$$\text{axion:} \quad \frac{1}{\sqrt{2}}\Big(\varepsilon_+^\mu \tilde{\varepsilon}_-^\nu - \varepsilon_-^\mu \tilde{\varepsilon}_+^\nu\Big). \tag{61.148}$$

The symmetric combination Eq. (61.147) has trace $\eta_{\mu\nu}\frac{1}{\sqrt{2}}(\varepsilon_+^\mu \tilde{\varepsilon}_-^\nu + \varepsilon_-^\mu \tilde{\varepsilon}_+^\nu) = \frac{1}{\sqrt{2}}(\varepsilon_+ \cdot \tilde{\varepsilon}_- + \varepsilon_- \cdot \tilde{\varepsilon}_+) = \frac{1}{\sqrt{2}}(-1 - 1) = -\sqrt{2} \neq 0$: it is the trace mode, the dilaton of Eq. (61.143) (indeed $\varepsilon_+^\mu \tilde{\varepsilon}_-^\nu + \varepsilon_-^\mu \tilde{\varepsilon}_+^\nu = \varepsilon_1^\mu \varepsilon_1^\nu + \varepsilon_2^\mu \varepsilon_2^\nu = \Delta^{\mu\nu}$, the full transverse projector). The antisymmetric combination Eq. (61.148) is the single physical component of the two-form Eq. (61.144).

State count. Two graviton states (± 2), one dilaton, one axion, totaling $4 = (D-2)^2|_{D=4}$, matching Eq. (61.140): $\frac{1}{2}(2)(3) - 1 = 2$ graviton, 1 dilaton, $\frac{1}{2}(2)(1) = 1$ two-form.

The four-dimensional two-form deserves a word, because its component count $\frac{1}{2}(D-2)(D-3) = 1$ collapses to a single state and the field is usually traded for a scalar. A massless antisymmetric tensor $B_{\mu\nu}$ in four dimensions has field strength $H_{\mu\nu\rho} = 3\,\partial_{[\mu}B_{\nu\rho]}$, and the equation of motion $\partial^\mu H_{\mu\nu\rho} = 0$ is solved by $H^{\mu\nu\rho} = \epsilon^{\mu\nu\rho\sigma}\partial_\sigma a$ for a pseudoscalar a — the *axion*. The one physical polarization of the four-dimensional two-form is thus dual to a single pseudoscalar degree of freedom, which is why the helicity-0 antisymmetric state Eq. (61.148) is the axion. The dilaton and axion together form a complex scalar (the "axio-dilaton"), both of helicity zero, distinguished from the graviton purely by living in the trace and antisymmetric channels of the gauge-state product.

61.6.3 Projecting onto pure Einstein gravity

The square of two pure Yang–Mills theories is $\mathcal{N} = 0$ supergravity, not pure Einstein gravity. To recover the latter one must dispose of the dilaton and the two-form. There are two honest things to say — one about external states, one about internal states — and they have different statuses.

External states are a free choice. The double copy assigns each *external* leg the wavefunction Eq. (61.138), and we are free to feed it the symmetric-traceless graviton polarization Eq. (61.141) (in four dimensions, the definite-helicity $\varepsilon_\pm^{\mu\nu}$) on every leg. Then the external data are purely gravitational. This is exactly what we did at three and four points: the amplitudes Eq. (61.81) and Eq. (61.97) have graviton external states by construction, and the dilaton and two-form never entered the external kinematics.

Internal states are the real question. Whether the result equals pure Einstein gravity depends on whether the dilaton or two-form can be *exchanged* on internal lines when all external states are gravitons. The factorization theorem Theorem 61.20 put on every cut the full state sum Eq. (61.105), including the helicity-0 dilaton/axion combinations. The question is whether those combinations have nonzero residue when the external states on both sides of the cut are gravitons. At three points the answer is fixed by little-group weight and is the cleanest possible. A cubic vertex of two gravitons and one dilaton would be a Lorentz-invariant contraction of two symmetric-traceless transverse tensors and one transverse scalar; the would-be amplitude $\mathcal{M}_3(h, h, \phi)$ must carry little-group weight ∓ 4 on the two graviton legs and 0 on the dilaton leg, and the unique on-shell three-point structure with these weights and the correct mass dimension *vanishes* — equivalently, the dilaton couples to gravity only through

its kinetic term $\sqrt{-g}\, g^{\mu\nu}\partial_\mu\phi\,\partial_\nu\phi$, which is quadratic in ϕ and so produces a graviton–dilaton–dilaton vertex but no graviton–graviton–dilaton vertex. The same holds for the two-form: its coupling $\sqrt{-g}\, H_{\mu\nu\rho}H^{\mu\nu\rho}$ is quadratic in B. We record the consequence.

Proposition 61.28 (Tree-level decoupling of the extra states)**.** *In the double copy of two pure Yang–Mills theories, any tree amplitude with all external legs gravitons (symmetric-traceless states) receives no contribution from internal dilaton or two-form lines. Consequently all-graviton tree amplitudes of $\mathcal{N} = 0$ supergravity coincide, channel by channel, with the corresponding tree amplitudes of pure Einstein gravity.*

Proof. By Theorem 61.20 every factorization channel of an all-graviton amplitude has a residue that is a sum of products of lower-point amplitudes, summed over the intermediate states Eq. (61.105). An internal dilaton or two-form contributes to a channel only if both subamplitudes $\mathcal{M}_L, \mathcal{M}_R$ on the cut are nonzero with that state crossing. A dilaton crossing a cut into an otherwise all-graviton subamplitude requires a subamplitude with exactly one dilaton and the rest gravitons; the lowest such is the three-point $\mathcal{M}_3(h, h, \phi)$, which vanishes by the little-group / quadratic-coupling argument above, and inductively every $\mathcal{M}_n(h, \dots, h, \phi)$ with a single dilaton vanishes, since each of its own factorization channels would again require a single-dilaton subamplitude. The identical argument applies to a single internal two-form. Hence dilatons and two-forms can appear internally only in pairs, which an all-graviton amplitude's channel structure never demands: every internal line of an all-graviton tree can carry a graviton, and only the graviton has a nonvanishing coupling to two gravitons. The residue on each channel is therefore the pure-graviton residue, which is the defining data of the Einstein amplitude (Theorem 61.18). Equality of all residues on all channels, together with the absence of any other singularities and the correct mass dimension, fixes the two amplitudes to be equal. □

This is the precise and honest sense in which the double copy of pure Yang–Mills computes Einstein gravity: *at tree level, for graviton external states,* the answer is identical to pure general relativity, the dilaton and two-form decoupling because they couple to gravitons only in pairs. It is exactly this proposition that licenses calling Eq. (61.97) "the four-graviton amplitude" without qualification — it is simultaneously the $\mathcal{N} = 0$ supergravity and the pure-Einstein four-graviton amplitude.

Caution

Theorem 61.28 is a tree-level, all-external-graviton statement. It does *not* survive untouched to loops or to amplitudes with non-graviton external states. At one loop a graviton amplitude has internal lines summed over

the entire $\mathcal{N} = 0$ spectrum, and a dilaton/two-form pair circulates in the loop and contributes; the bare double copy of pure Yang–Mills then computes the $\mathcal{N} = 0$ *supergravity* loop amplitude, which differs from the pure-Einstein one by the dilaton and two-form running in the loop. Recovering pure gravity at loop level requires actively subtracting those states — e.g. by double-copying with a Yang–Mills theory deformed by carefully chosen ghost-like scalars whose loop contributions cancel the unwanted multiplet, a construction we only name here. The clean "$\text{YM}^2 = \text{GR}$" slogan is a tree-level, external-graviton theorem; its loop-level extension is part of the frontier story of Section 61.7.

61.6.4 The bi-adjoint scalar: the zeroth copy

To organize the squaring operation into a web of theories we need its identity element — the theory that, double-copied with any other, returns that other unchanged. The master formula Eq. (61.71) already tells us what such a theory must look like. Recall its structure: an amplitude is a sum over cubic graphs of (numerator)×(numerator)/(denominator), and the two numerator slots may be filled either by a kinematic BCJ numerator n_i or by a color factor c_i — the gauge amplitude fills one slot with c_i and one with n_i, the gravity amplitude fills both with kinematics. The remaining case fills both slots with color. That theory is the bi-adjoint scalar.

Recall the bi-adjoint scalar (Theorem 61.24): a massless scalar $\phi^{aa'}$ in the adjoint × adjoint representation of two Lie groups G, G' with structure constants f^{abc} and $\tilde{f}^{a'b'c'}$, whose only interaction is the cubic vertex of the Lagrangian Eq. (61.124), carrying one structure constant of each group and a trivial (momentum-independent) kinematic factor.

Because the vertex is purely group-theoretic, every Feynman diagram for a tree amplitude is a cubic graph whose numerator is a *product of two color factors*, $c_i\, c'_i$, one from each group, with no kinematic dependence beyond the propagators. The full tree amplitude is therefore the master formula with both numerator slots filled by color,

$$\mathcal{A}_n^{\phi^3} = i\,\lambda^{n-2} \sum_{i\in\Gamma_3} \frac{c_i\, c'_i}{D_i}, \tag{61.149}$$

the literal "$c\otimes c$" object. Decomposing both color factors into the trace bases of the two groups (the double application of the color decomposition of Section 61.1.1) extracts the *doubly color-ordered partial amplitudes* $m[\alpha\,|\,\beta]$, labelled by an ordering α for G and an ordering β for G':

$$m[\alpha\,|\,\beta] = \sum_{i\,\in\,\Gamma_3(\alpha)\cap\Gamma_3(\beta)} \frac{\pm 1}{D_i}, \tag{61.150}$$

the sum running only over cubic graphs compatible with *both* orderings, each contributing the inverse of its propagator product with a sign set by the two orderings. These are the purest objects in the whole construction: numerators equal to unity, all the physics in the denominators. At four points, for example, the diagonal partial collects the two cubic graphs planar with respect to the ordering (1234) — the s- and t-channels —

$$m[1234\,|\,1234] = \frac{1}{s} + \frac{1}{t}, \tag{61.151}$$

while an off-diagonal partial such as $m[1234\,|\,1243] = -\frac{1}{s}$ retains only the single channel shared by the two orderings. The $m[\alpha|\beta]$ form the matrix whose inverse is, up to kinematic factors, the KLT momentum kernel of Section 61.5.3 — the precise sense in which the bi-adjoint scalar sits at the center of the web.

Proposition 61.29 (The zeroth copy is the identity)**.** *Double-copying the bi-adjoint scalar with a theory X — i.e. replacing one color factor c'_i in Eq. (61.149) by the BCJ numerators n_i of X — returns the amplitudes of X. In the slogan of the web, $\phi^3 \otimes \phi^3 = \phi^3$, $\phi^3 \otimes YM = YM$, and $\phi^3 \otimes$ (anything) = (anything).*

Proof. The substitution $c'_i \mapsto n_i$ in Eq. (61.149) produces $i\sum_i c_i\, n_i/D_i$, which is the gauge master formula Eq. (61.71) with color group G and BCJ numerators n_i — that is, the amplitude of X itself (here Yang–Mills), with G as its gauge group. The other color factor c_i simply carries the surviving color structure of X. The bi-adjoint scalar contributes only its color factor c_i and unit kinematics, so squaring against it changes nothing but the name of the gauge group. Taking $X = \phi^3$ (i.e. $n_i \mapsto c'_i$) returns Eq. (61.149), so the bi-adjoint scalar is its own double copy. □

This is what makes the bi-adjoint scalar the *zeroth copy*, the anchor of the web: it is the unit of the double-copy product. One climbs the web by replacing color factors with kinematic numerators one at a time — $c\otimes c$ to $n\otimes c$ to $n\otimes n$ — and each replacement trades a power of color for a power of kinematics, walking from the scalar through gauge theory to gravity.

61.6.5 The web of theories

We can now state the organizing picture. The double copy is a product on theories: choose a "left" theory and a "right" theory, each supplying a set of numerators for the common cubic graphs, and glue them through Eq. (61.72). The resulting theory depends on both inputs, and varying them sweeps out a web. The three rungs we have proved or can read off directly are

$$\phi^3\otimes\phi^3 = \phi^3, \qquad \mathrm{YM}\otimes\phi^3 = \mathrm{YM}, \qquad \mathrm{YM}\otimes\mathrm{YM} = \mathcal{N}{=}0\ \text{supergravity}, \tag{61.152}$$

established respectively by Theorem 61.29 (first two) and by the spectrum analysis Eq. (61.140) together with the amplitude construction of Section 61.4 (the third). The web extends in two directions that we now survey, flagging carefully what is proved in this book and what is stated with attribution.

Adding supersymmetry: the supergravity ladder. If one or both gauge factors carry supersymmetry, the squaring carries it too, because supersymmetric Yang–Mills amplitudes admit BCJ numerators just as the pure-gluon ones do (the duality is a statement about the kinematic algebra, blind to which states run on the legs). The on-shell supermultiplet of the product is the tensor product of the two gauge supermultiplets, decomposed exactly as in Eq. (61.139) but now including fermionic and scalar superpartners. The amount of supersymmetry adds: an $\mathcal{N} = p$ gauge factor times an $\mathcal{N} = q$ gauge factor yields $\mathcal{N} = p + q$ supergravity. The apex of the ladder is the maximally supersymmetric case.

Worked Example 61.30 ($\mathcal{N} = 8$ supergravity as the square of $\mathcal{N} = 4$ super-Yang–Mills)**.** We count the states on both sides and verify the tensor-product structure Eq. (61.139) generalized to the full supermultiplet.

The $\mathcal{N} = 4$ super-Yang–Mills multiplet. In four dimensions, maximally supersymmetric Yang–Mills has a single on-shell multiplet, CPT self-conjugate, consisting of: one gluon (2 helicity states ± 1), four gluinos ($2 \times 4 = 8$ states $\pm\frac{1}{2}$), and six real scalars (6 states 0). The total is

$$2 + 8 + 6 = 16 \tag{61.153}$$

on-shell states. (The count is $2^{\mathcal{N}} = 2^4 = 16$ for $\mathcal{N} = 4$: $\mathcal{N}$ fermionic creation operators acting on a helicity-$+1$ Clifford vacuum generate $2^{\mathcal{N}}$ on-shell states, the multiplet being CPT-self-conjugate at $\mathcal{N} = 4$; the explicit content above is the standard $\mathcal{N} = 4$ vector multiplet.)

The square. The product multiplet has $16 \times 16 = 256$ states. These organize, by the same symmetric/antisymmetric/trace logic now applied to the full graded tensor product, into the $\mathcal{N} = 8$ supergravity multiplet, whose content and state count is

$$\begin{aligned} &1 \text{ graviton } (\pm 2): && 2 \times 1 = 2, \\ &8 \text{ gravitini } (\pm \tfrac{3}{2}): && 2 \times 8 = 16, \\ &28 \text{ vectors } (\pm 1): && 2 \times 28 = 56, \\ &56 \text{ fermions } (\pm \tfrac{1}{2}): && 2 \times 56 = 112, \\ &70 \text{ scalars } (0): && 70, \end{aligned} \tag{61.154}$$

summing to $2 + 16 + 56 + 112 + 70 = 256 = 16^2$. The multiplicities are the binomial coefficients $\binom{8}{k}$ of the $\mathcal{N} = 8$ algebra: $\binom{8}{0} = 1$ graviton at the top helicity, $\binom{8}{1} = 8$ gravitini, $\binom{8}{2} = 28$ vectors, $\binom{8}{3} = 56$ fermions, and $\binom{8}{4} = 70$ scalars at helicity zero, the remaining states fixed by CPT. The graviton sits, as

in Eq. (61.146), in the top-helicity product of the two gluons: $(\pm 1) \otimes (\pm 1) \to \pm 2$. The dilaton and axion of the pure-Yang–Mills square are now just two of the seventy scalars, no longer distinguished — maximal supersymmetry unifies the entire bosonic and fermionic spectrum into one irreducible multiplet.

The statement $(\mathcal{N} = 4 \text{ sYM})^2 = \mathcal{N} = 8$ supergravity holds at tree level by the supersymmetric extension of the construction of Section 61.4: one needs BCJ numerators for $\mathcal{N} = 4$ super-Yang–Mills (which exist, computed in on-shell superspace) and squares them through Eq. (61.72). We do not build $\mathcal{N} = 4$ superamplitudes in this book, so we state this entry with its scope explicit — the state count Eq. (61.154) is exact and the graviton-sector amplitudes reduce to those we constructed, but the full superamplitude double copy is quoted, with the construction in [70, 176]. Intermediate rungs follow by the additive rule: $(\mathcal{N} = 4) \otimes (\mathcal{N} = 0) = \mathcal{N} = 4$ supergravity, $(\mathcal{N} = 2) \otimes (\mathcal{N} = 2) = \mathcal{N} = 4$ supergravity (with different matter), $(\mathcal{N} = 1) \otimes (\mathcal{N} = 1) = \mathcal{N} = 2$ supergravity, and so on, each a different point on the supergravity ladder.

Beyond gravity: the wider web. Replacing the gauge factors by other theories with BCJ-satisfying numerators generates further entries. We tabulate the principal ones in Table 61.2, drawing the broader map of [72]. Of these, only the rows involving pure Yang–Mills, the bi-adjoint scalar, and (at the level of state-counting) maximal supergravity are derived in this book; the rows involving the nonlinear sigma model, Born–Infeld theory, and the special Galileon are stated as established results of the literature, included to show the reach of the construction rather than proved here.

The pattern in Table 61.2 is the lesson. The double copy is not a single identity "gravity = gauge^2" but an operation on a category of theories, generated from a small set of building blocks — the bi-adjoint scalar at the center, Yang–Mills and the nonlinear sigma model and their supersymmetric cousins as the elementary factors — whose products fill out a web that includes Einstein gravity, the supergravities, and an unexpected corner of effective field theories (Born–Infeld, Galileon) that one would never have guessed are related to gauge theory at all. Color–kinematics duality is the structural fact that makes the web coherent: it is the statement that all these theories share one cubic-graph skeleton, differing only in which numerators dress it.

With the spectrum of the double copy identified — a graviton, a dilaton, and a two-form per copy of pure Yang–Mills, assembling at tree level into pure Einstein gravity for graviton external states (Theorem 61.28), and generalizing into a web of theories anchored by the bi-adjoint scalar — the tree-level picture is complete. We know what the double copy is, what it computes, and which theory it produces. What remains is to ask how far the story extends: to loop amplitudes, where the very existence of duality-satisfying numerators becomes a

Table 61.2: The web of double-copy constructions. Each entry is the theory produced by gluing the left and right factors through Eq. (61.72); the bi-adjoint scalar ϕ^3 is the identity (zeroth copy). "NLSM" is the SU(N) nonlinear sigma model (pion theory); "sGal" is the special Galileon. Rows marked ✓ are constructed in this chapter; rows marked ∘ are stated with attribution.

Left factor	Right factor	Double-copy theory	Status
ϕ^3	ϕ^3	bi-adjoint scalar ϕ^3	✓

NLSM	NLSM	special Galileon	∘

conjecture; to classical solutions, where "gravity = gauge^2" reappears for black holes and gravitational waves rather than for amplitudes; and to the sharp question of what, as of the mid-2020s, is theorem and what is checked. That frontier — and the closing of Yang–Mills theory — is the subject of the final section.

61.7 Loops, the Classical Double Copy, and the Frontier

The preceding sections completed the tree-level story to its sharpest form. Color and kinematics are dual (Theorem 61.8); duality-satisfying numerators exist for every tree (Theorem 61.12); replacing color by a second kinematic copy produces a gauge-invariant object (Theorem 61.16) that factorizes correctly on all its poles and is therefore a genuine gravity amplitude (Theorem 61.20); and the spectrum that square produces is not pure Einstein gravity but the graviton accompanied by a dilaton and a two-form — "$\mathcal{N}=0$ supergravity" (Eq. (61.105), Section 61.6). At tree level, "gravity is the square of gauge theory" is a theorem, proved in this book. This final section extends the story honestly beyond trees. We state the loop-level conjecture and lay out precisely what is theorem, what is checked, and what is open; we recount the flagship loop-level consequence, the unexpected ultraviolet softness of $\mathcal{N}=8$ supergravity; we descend from amplitudes to solutions of the classical field equations and carry out, in full, the one frontier computation this section owes — the Kerr–Schild map sending a Coulomb point charge to the Schwarzschild black hole; and we survey the

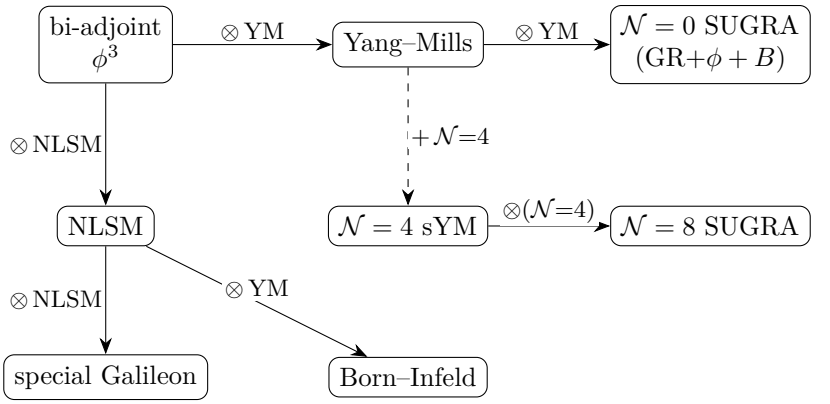

Figure 61.6: The web of double-copy theories. Starting from the bi-adjoint scalar ϕ^3 (the identity, zeroth copy), each arrow tensors in the labelled factor through Eq. (61.72), trading a power of color for a power of kinematics. The top row $\phi^3 \to$ YM $\to$ GR is the chain proved in this chapter; the lower rows show the supersymmetric ladder (to $\mathcal{N}=8$ supergravity) and the effective-field-theory corner (Born–Infeld, special Galileon) reached by squaring the nonlinear sigma model.

amplitudes-for-binaries program that has made these ideas a working tool of gravitational-wave physics. The section closes Yang–Mills theory, which began with the classical non-abelian Lagrangian of Chapter 25 and ends here with gravity assembled from two copies of it.

The standard of precision of this book is nowhere more load-bearing than here. Tree level is settled; loop level is not. We will mark every claim with its status and date it to the mid-2020s, and we will never let a citation stand in for an argument the book needs.

61.7.1 The loop-level double copy: integrands, the conjecture, and its evidence

The tree-level construction operated on the cubic-graph data (c_i, n_i, D_i) of Eq. (61.18). At loop level the same data organizes the *integrand*, the rational function of external and loop momenta whose integration produces the amplitude. The reorganization of any gauge-theory loop amplitude onto cubic graphs is possible for the identical reason it was at tree level: quartic vertices and contact terms are absorbed into trivalent graphs by multiplying and dividing by the propagator they are missing (Theorem 61.4), a move indifferent to whether the lines are external or internal. We therefore write the L-loop, n-point gauge-theory amplitude as

$$\mathcal{A}_n^{(L)} \;=\; i^L\, g^{\,n-2+2L} \sum_{i\in\Gamma_3^{(L)}} \int \prod_{l=1}^{L} \frac{\mathrm{d}^d\ell_l}{(2\pi)^d}\; \frac{1}{S_i}\; \frac{c_i\, n_i(\ell)}{D_i(\ell)}, \tag{61.155}$$

where $\Gamma_3^{(L)}$ is the set of L-loop trivalent graphs with n external legs, $\ell = (\ell_1, \ldots, \ell_L)$ are the independent loop momenta, $D_i(\ell)$ is the product of *all* internal inverse propagators (now functions of ℓ), c_i is the color factor read off the graph exactly as before, $n_i(\ell)$ is the kinematic numerator, and S_i is the symmetry factor of the graph, the order of its automorphism group (Theorem 61.6 counted the tree graphs; the loop graphs are counted by the same combinatorial logic, with S_i correcting for overcounting of internal relabelings). The denominators $D_i(\ell)$ are shared topology; the color factors c_i and the numerators $n_i(\ell)$ are again the only genuinely distinct data.

Loop-level color–kinematics duality. The color factors satisfy Jacobi identities on every triplet of graphs related by the *s-t-u* move around a single internal line — now including lines carrying loop momentum, with the loop momenta routed consistently across the three graphs of a triplet. *Loop-level color–kinematics duality* is the statement that one can choose the numerators $n_i(\ell)$ to obey the very same relations:

$$c_i + c_j + c_k = 0 \quad\Longrightarrow\quad n_i(\ell) + n_j(\ell) + n_k(\ell) = 0, \qquad c_i = -c_{\bar{\imath}} \;\Longrightarrow\; n_i = -n_{\bar{\imath}}, \tag{61.156}$$

identity by identity, for every Jacobi triplet $\{i, j, k\}$ and every flip pair $\{i, \bar{\imath}\}$ of the loop-level graph set, as functions of the loop momenta. When such a numerator set exists, the *loop-level double copy* is the same substitution $c_i \mapsto \tilde{n}_i$ that defined Eq. (61.72), now under the integral sign:

$$\mathcal{M}_n^{(L)} \;=\; i^L \left(\frac{\kappa}{2}\right)^{n-2+2L} \sum_{i\in\Gamma_3^{(L)}} \int \prod_{l=1}^{L} \frac{\mathrm{d}^d\ell_l}{(2\pi)^d}\; \frac{1}{S_i}\; \frac{n_i(\ell)\,\tilde{n}_i(\ell)}{D_i(\ell)}, \tag{61.157}$$

with $\{n_i\}$ a duality-satisfying (BCJ) set and $\{\tilde{n}_i\}$ any representation of the second amplitude's integrand.

What is theorem here, and what is conjecture. Two logically separate statements live in Eq. (61.157), and conflating them is the most common way the loop-level double copy is misreported.

Proposition 61.31 (Cut-level consistency of the loop double copy)**.** *Suppose a duality-satisfying loop numerator set $\{n_i(\ell)\}$ exists for the gauge theory at L loops, and let $\{\tilde{n}_i(\ell)\}$ be any representation of a second gauge-theory integrand on the same graphs. Then the integrand Eq. (61.157) reproduces the correct gravitational integrand on every generalized-unitarity cut: each cut factorizes the*

loop integrand into a product of on-shell tree amplitudes (Section 60.3), and on that cut the double-copy integrand reduces to a product of tree-level *double copies, which are gravity trees by Theorem 61.20.*

Proof sketch. A generalized unitarity cut (Section 60.3) replaces a set of internal propagators $1/D$ by on-shell delta functions, severing the loop graph into trees glued along the cut lines, and the residue on the cut is a product of tree amplitudes summed over the physical states crossing each cut line (Section 60.4 organizes this systematically). Apply this to Eq. (61.157). On any spanning cut the integrand becomes, graph by graph, a product of tree numerators over the surviving (uncut) denominators; the duality relations Eq. (61.156) restricted to a cut are exactly the tree-level kinematic Jacobi relations of the resulting tree pieces, because cutting a loop line is the same algebraic operation as factorizing on a tree pole. The tree-level factorization theorem Theorem 61.20 then identifies each cut residue as a sum over states of products of tree-level double copies — gravity trees. Summing the cut over the graviton-multiplet states crossing the cut (graviton, dilaton, two-form, the $\mathcal{N} = 0$ spectrum of Eq. (61.105)) reproduces the gravitational cut. Since the gravity integrand is determined by its cuts up to terms with no propagators — and the cubic-graph organization Eq. (61.155) carries no such cut-free pieces by construction — the double copy is the correct gravitational integrand. □

Theorem 61.31 is as far as the tree-level theorems carry us, and it is a genuine theorem: *given* duality-satisfying loop numerators, the double copy is guaranteed to be the right gravity integrand. The content that remains open is the hypothesis itself.

Conjecture 61.32 (Existence of loop-level BCJ numerators)**.** *For every gauge theory in the color–kinematics class, and at every loop order L and multiplicity n, there exists a representation of the integrand Eq. (61.155) whose kinematic numerators satisfy the duality Eq. (61.156) on every Jacobi triplet.*

As of the mid-2020s Theorem 61.32 is unproven in general. There is no construction analogous to the tree-level proof (Theorem 61.12, which built BCJ numerators from the BCFW recursion of Theorem 59.23) that delivers duality-satisfying numerators at arbitrary loop order; the recursion that powered the tree proof does not have a complete off-shell loop analogue, which is the same gap as the absence of a Lagrangian or off-shell formulation of the duality (discussed below). The evidence is instead case-by-case and substantial:

- In maximally supersymmetric Yang–Mills ($\mathcal{N} = 4$ sYM) duality-satisfying numerators have been constructed explicitly at one, two, three, and four loops for the four-point amplitude, and at higher loops, and the resulting double copies pass every generalized-unitarity check against independently computed $\mathcal{N} = 8$ supergravity integrands [70, 72].

- At lower supersymmetry and in pure Yang–Mills the duality has been realized in many one- and two-loop cases, including amplitudes with external matter and with fundamental fermions.

Nonlocal numerators

The duality sometimes cannot be realized with *polynomial* ("local") numerators. The cleanest documented instance is the five-loop four-point integrand of $\mathcal{N} = 4$ sYM, where a duality-satisfying representation was found only by admitting numerators that themselves contain propagator-like denominators — they are rational, not polynomial, in the loop momenta [72]. Such *nonlocal* numerators still satisfy Eq. (61.156) and still double-copy correctly on all cuts (Theorem 61.31 never assumed polynomiality), but their existence shows that the naive expectation — that BCJ numerators are always local rearrangements of Feynman-diagram numerators — is false beyond low loop order. Whether a *local* duality-satisfying representation exists in such cases, and more generally whether Theorem 61.32 holds with locality imposed, is open.

The honest summary is this. The map "BCJ numerators ⇒ gravity integrand" is a theorem (Theorem 61.31). The existence of those numerators at all loop orders is a conjecture (Theorem 61.32), verified in a growing list of nontrivial cases, sometimes only at the price of nonlocality (the nonlocal numerators discussed above). This is the precise state of the loop-level double copy.

61.7.2 Ultraviolet consequences: $\mathcal{N} = 8$ supergravity

The most consequential thing the loop double copy has done is sharpen a question about quantum gravity that predates it: *is there a perturbatively finite theory of gravitons?* Pure Einstein gravity is power-counting nonrenormalizable — the coupling κ has mass dimension -1 (Eq. (61.81) fixed $[\kappa] = -1$), so each additional loop brings two more powers of κ and, by dimensional analysis, worse ultraviolet behavior, requiring an unbounded tower of counterterms. The expectation for decades was that maximal supergravity, $\mathcal{N} = 8$ in four dimensions, while better behaved, would still diverge — superspace power-counting arguments predicted a three-loop divergence.

The double copy reframes the computation and overturned that expectation. Maximal supergravity is the double copy of maximal super-Yang–Mills,

$$\mathcal{N} = 8 \text{ supergravity} \;=\; (\mathcal{N} = 4 \text{ sYM}) \otimes (\mathcal{N} = 4 \text{ sYM}), \tag{61.158}$$

in the same on-shell sense as Eq. (61.157), now with each gauge multiplet enlarged to include its superpartners so that the tensor product of the two $\mathcal{N} = 4$ multiplets fills out the 256-state $\mathcal{N} = 8$ graviton multiplet. Because $\mathcal{N} = 4$ sYM is itself

ultraviolet finite (its beta function vanishes — the supersymmetric cancellations defeat the asymptotic-freedom running of Eq. (27.101)), its loop integrands are unusually soft in the ultraviolet, and squaring two soft integrands via Eq. (61.157) produces a gravitational integrand far softer than naive gravity power counting suggests. Explicit computation of the resulting integrands, with their ultraviolet behavior extracted by the unitarity methods of Chapter 60, found:

- $\mathcal{N} = 8$ supergravity is ultraviolet *finite* at three loops in $d = 4$ — no divergence, contradicting the superspace prediction [70].
- It is finite at four loops as well, with the first potential divergence pushed to a critical spacetime dimension $d_c = 11/2 > 4$ [64].
- At five loops the critical dimension was computed to be $d_c = 24/5 = 4.8 > 4$: still finite in $d = 4$ [65].

The pattern of computed critical dimensions through five loops,

$$d_c(L = 3) = 6, \qquad d_c(L = 4) = \tfrac{11}{2}, \qquad d_c(L = 5) = \tfrac{24}{5}, \tag{61.159}$$

all exceed four, so maximal supergravity has no ultraviolet divergence in four dimensions through five loops.

Enhanced cancellations

The striking feature is that this softness is *better than any known off-shell symmetry argument explains.* The available manifest symmetries (supersymmetry, the $E_{7(7)}$ duality of maximal supergravity) constrain the form of allowed counterterms, but the explicitly computed cancellations are stronger than those constraints predict: the would-be divergence allowed by all known symmetries is absent, or its critical dimension is higher than the symmetries require. These "enhanced cancellations" are visible in the double-copy representation precisely because it exposes the gauge-theory ultraviolet structure that is doing the work — the gravity integrand inherits, term by term, the softness of its squared gauge inputs in a way no purely gravitational organization makes manifest.

It must be stated plainly that this does *not* establish all-order finiteness. The first divergence permitted in $d = 4$ by the most conservative counterterm analysis (a particular half-BPS invariant) is at *seven* loops, and the seven-loop coefficient has not been computed. Whether $\mathcal{N} = 8$ supergravity is finite to all orders in four dimensions — and what that would imply for the existence of a perturbatively consistent point-particle theory of gravitons — is, as of the mid-2020s, a genuinely open question. The double copy has not answered it, but it has made the relevant multi-loop computations possible at all, which is why the question is now empirical rather than merely speculative.

61.7.3 The classical double copy: Kerr–Schild and the Coulomb–Schwarzschild map

Everything above concerns scattering amplitudes — quantum, on-shell, perturbative. There is a parallel statement at the level of *classical solutions* of the field equations: certain exact gauge-theory backgrounds map to exact gravitational backgrounds by a squaring operation strikingly similar to the amplitude double copy. The cleanest version is the Kerr–Schild double copy, and we carry it out in full for the stationary point source — the one fully worked frontier computation this section owes. It relates the Coulomb field of a point charge to the Schwarzschild black hole.

The Kerr–Schild ansatz. A metric is in *Kerr–Schild form* if

$$g_{\mu\nu} \;=\; \eta_{\mu\nu} + \phi\, k_\mu k_\nu, \tag{61.160}$$

where ϕ is a scalar function and k_μ is a covector that is *null* and *geodesic* with respect to the flat metric,

$$\eta^{\mu\nu} k_\mu k_\nu = 0, \qquad k^\mu\, \partial_\mu k_\nu = 0, \qquad k^\mu \equiv \eta^{\mu\nu} k_\nu. \tag{61.161}$$

The null condition has an immediate and remarkable consequence: the inverse metric is *exactly*

$$g^{\mu\nu} = \eta^{\mu\nu} - \phi\, k^\mu k^\nu, \tag{61.162}$$

with no corrections at higher order in ϕ. We verify this directly:

$$g_{\mu\nu} g^{\nu\rho} = (\eta_{\mu\nu} + \phi k_\mu k_\nu)(\eta^{\nu\rho} - \phi k^\nu k^\rho) = \delta_\mu{}^\rho - \phi k_\mu k^\rho + \phi k_\mu k^\rho - \phi^2 k_\mu\, (k_\nu k^\nu)\, k^\rho = \delta_\mu{}^\rho, \tag{61.163}$$

the quadratic term dying because $k_\nu k^\nu = 0$. The exact truncation of the metric expansion at linear order in ϕ is the structural reason Kerr–Schild metrics linearize gravity.

The stationary point-source data. Take the stationary, spherically symmetric profile

$$\phi(\vec{x}) = \frac{2GM}{r}, \qquad k_\mu = (1,\ \hat{x}_i), \qquad \hat{x}_i \equiv \frac{x_i}{r}, \quad r = |\vec{x}|, \tag{61.164}$$

all time-independent. We first confirm k_μ satisfies Eq. (61.161). Raising the index gives $k^\mu = (1, -\hat{x}_i)$, so the null condition is

$$\eta^{\mu\nu} k_\mu k_\nu = (k_0)^2 - \delta^{ij} k_i k_j = 1 - \hat{x}_i \hat{x}_i = 1 - 1 = 0. \tag{61.165}$$

For the geodesic condition, $k^\mu \partial_\mu = \partial_0 - \hat{x}_i \partial_i$ annihilates static fields through ∂_0, leaving $-\hat{x}_i \partial_i k_\nu$. The temporal component is trivial since $k_0 = 1$. For the spatial components, using $\partial_i k_j = \partial_i (x_j/r) = \delta_{ij}/r - x_i x_j / r^3$,

$$-\hat{x}_i\, \partial_i k_j = -\frac{x_i}{r}\Big(\frac{\delta_{ij}}{r} - \frac{x_i x_j}{r^3}\Big) = -\frac{x_j}{r^2} + \frac{(x_i x_i)\, x_j}{r^4} = -\frac{x_j}{r^2} + \frac{x_j}{r^2} = 0, \tag{61.166}$$

using $x_i x_i = r^2$. So k_μ of Eq. (61.164) is null and geodesic, and Eqs. (61.160) and (61.162) apply exactly. Written out, the line element is $g_{00} = 1 + \phi$, $g_{0i} = \phi\,\hat{x}_i$, $g_{ij} = -\delta_{ij} + \phi\,\hat{x}_i\hat{x}_j$ — the Schwarzschild solution in Kerr–Schild (Eddington–Finkelstein-type) coordinates, manifestly flat as $r \to \infty$.

Gravity side: the field equation linearizes. The decisive feature of Eq. (61.160) is that, for null geodesic k, the Einstein equation in mixed-index form is *exactly* linear in ϕ — the nonlinear curvature corrections cancel by the same $k \cdot k = 0$ and geodesic identities that truncated Eq. (61.162). We import the linearized Ricci tensor as the second-order differential operator built from the curvature of $g = \eta + h$ in Chapter 64,

$$R^{(1)}_{\mu\nu}[h] = \tfrac{1}{2}\big(\partial_\alpha\partial_\nu h^\alpha{}_\mu + \partial_\alpha\partial_\mu h^\alpha{}_\nu - \Box\, h_{\mu\nu} - \partial_\mu\partial_\nu h\big), \qquad h \equiv \eta^{\mu\nu}h_{\mu\nu}, \quad (61.167)$$

and use the Kerr–Schild fact that for $h_{\mu\nu} = \phi k_\mu k_\nu$ with null geodesic k the full Ricci tensor coincides with this linear expression (the nonlinear pieces vanish; the differential-geometric verification belongs to Chapter 64 and is not a citation standing in for an argument — it is a computation the gravity part performs in full). Evaluate Eq. (61.167) on the stationary point-source data. First the trace vanishes by nullity,

$$h = \eta^{\mu\nu}\phi k_\mu k_\nu = \phi\,(k \cdot k) = 0, \quad (61.168)$$

so the last term of Eq. (61.167) drops. For the 00 component, $h_{00} = \phi k_0 k_0 = \phi$ and $h^\alpha{}_0 = \eta^{\alpha\beta}\phi k_\beta k_0 = \phi\,k^\alpha$. The first two terms of Eq. (61.167) each carry a derivative ∂_0 acting on a static quantity and so vanish:

$$\partial_\alpha\partial_0 h^\alpha{}_0 = \partial_0(\partial_\alpha\phi\,k^\alpha) = 0, \quad (61.169)$$

leaving only the wave-operator term. With everything static, $\Box = \partial_0^2 - \nabla^2 \to -\nabla^2$, so

$$R^{(1)}_{00} = -\tfrac{1}{2}\,\Box\, h_{00} = -\tfrac{1}{2}\,\Box\,\phi = \tfrac{1}{2}\,\nabla^2\phi. \quad (61.170)$$

The Einstein equation sourced by a static point mass $T_{00} = M\delta^3(\vec{x})$ reads, in trace-reversed form $R_{\mu\nu} = 8\pi G(T_{\mu\nu} - \frac{1}{2}\eta_{\mu\nu}T)$, with $T = \eta^{\mu\nu}T_{\mu\nu} = M\delta^3$ for static dust:

$$R_{00} = 8\pi G(T_{00} - \tfrac{1}{2}T) = 4\pi G\,M\delta^3(\vec{x}) \quad \Longrightarrow \quad \nabla^2\phi = 8\pi G\,M\,\delta^3(\vec{x}). \quad (61.171)$$

This is the flat-space Poisson equation. Its solution, using $\nabla^2(1/r) = -4\pi\delta^3$, is $\phi = -2GM/r$. (The sign reflects $g_{00} = 1 + \phi = 1 - 2GM/r$, the correct Schwarzschild and Newtonian limit; the magnitude $|\phi| = 2GM/r$ is the profile we square below. The Newtonian normalization $g_{00} = 1 + 2\Phi_{\rm N}$ with $\Phi_{\rm N} = -GM/r$ is fixed by the geodesic motion of test particles, Chapter 64.) The gravitational field equation for the Schwarzschild point source has reduced, exactly, to a single flat-space scalar Poisson equation.

Single copy: peel off one factor of k. Define the *single copy* of the Kerr–Schild metric Eq. (61.160) by removing one factor of k_μ,

$$A_\mu \;\equiv\; \phi\, k_\mu, \tag{61.172}$$

an abelian gauge field (for a non-abelian single copy one attaches a constant color charge, $A^a_\mu = c^a \phi k_\mu$). We claim A_μ solves Maxwell's equations with a point charge. For the stationary point source Eq. (61.164) with $\phi = -2GM/r$ the components are $A_0 = \phi = -2GM/r$ and $A_i = \phi\, \hat{x}_i = -2GM\, x_i/r^2$. Compute the field strength $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$. The spatial–spatial part is

$$F_{ij} = \partial_i A_j - \partial_j A_i, \qquad \partial_i A_j = -2GM\Big(\frac{\delta_{ij}}{r^2} - \frac{2x_i x_j}{r^4}\Big), \tag{61.173}$$

which is symmetric in $i \leftrightarrow j$, so $F_{ij} = 0$: the magnetic field vanishes. Indeed $A_i = -2GM\, x_i/r^2 = \partial_i(-2GM \ln r)$ is pure gauge, and may be removed by a gauge transformation, leaving $A_\mu = (\phi, \vec{0})$ — a pure scalar potential. The electric components are

$$F_{0i} = \partial_0 A_i - \partial_i A_0 = -\partial_i\Big(-\frac{2GM}{r}\Big) = -\frac{2GM\, x_i}{r^3}, \tag{61.174}$$

the radial Coulomb field $\vec{E} \propto \hat{x}/r^2$. Away from the origin $\nabla^2 A_0 = -2GM\, \nabla^2(1/r) = 0$, and at the origin Gauss's law $\partial^i F_{i0} = -\nabla\cdot\vec{E}$ integrates to a point charge q fixed by $A_0 = q/(4\pi r)$, i.e. $q = -8\pi GM$. The single copy of Schwarzschild is the Coulomb field of a point charge, with the gauge charge proportional to the mass, $q \leftrightarrow GM$.

Zeroth copy: peel off both. Removing the remaining factor of k_μ leaves the scalar field ϕ itself, satisfying the flat-space wave (here Poisson) equation Eq. (61.171); this is the *zeroth copy*, identified with a field of the biadjoint scalar theory whose amplitudes occupy the base of the double-copy web (Section 61.6.5). The three objects are organized by how many factors of the null vector k_μ they carry:

$$\underbrace{\phi}_{\text{zeroth copy}} \xrightarrow{\times k_\mu} \underbrace{A_\mu = \phi\, k_\mu}_{\text{single copy}} \xrightarrow{\times k_\nu} \underbrace{h_{\mu\nu} = \phi\, k_\mu k_\nu}_{\text{double copy}}, \tag{61.175}$$

with the charges mapping in step, (scalar charge) $\leftrightarrow q \leftrightarrow GM$. Each arrow is the classical shadow of replacing one color factor by one kinematic factor, exactly as the amplitude double copy replaced c_i by $\tilde{n}_i$. Figure 61.7 displays the tower.

Domain of validity

The Kerr–Schild double copy is exact, but its reach is limited and must not be overstated. It applies to gravitational solutions that admit a Kerr–

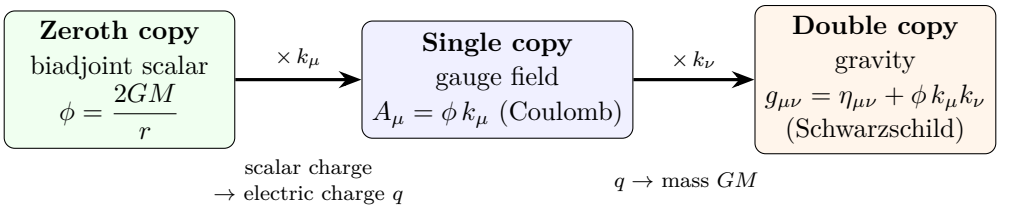

Figure 61.7: The Kerr–Schild classical double copy for the stationary point source. A single null geodesic profile $\phi = 2GM/r$ dressed by 0, 1, or 2 factors of the null covector k_μ produces, respectively, a biadjoint scalar field, the Coulomb gauge field of a point charge, and the Schwarzschild metric. Each $\times\, k$ is the classical counterpart of the amplitude substitution $c_i \mapsto \tilde{n}_i$.

Schild form Eq. (61.160) with null geodesic k — Schwarzschild, Kerr (a rotating k), and certain charged and cosmological generalizations — where the linearization is exact and the single copy is an honest solution of Maxwell's equations. It is *not* a general statement that every gravitational solution is the square of a gauge solution; generic metrics admit no Kerr–Schild form, and the construction as stated says nothing about them. For time-dependent and radiating sources the map is understood perturbatively, through a worldline/effective-field-theory expansion in which classical sources emit and re-absorb fields order by order [227, 228]; a fully nonperturbative, background-independent classical double copy — and its extension to curved backgrounds — remains an active research subject as of the mid-2020s [4, 349].

61.7.4 The two-body problem and gravitational-wave observables

The classical and quantum double copies converge on a problem of immediate observational relevance: the gravitational two-body inspiral that LIGO, Virgo, and the future LISA mission detect as gravitational waves. The conservative dynamics of two slowly-merging compact bodies can be organized as a *post-Minkowskian* (PM) expansion — an expansion in Newton's constant G to all orders in velocity, suited to the relativistic scattering regime — and each order in G is controlled by a gravitational scattering amplitude at one higher loop. This is the *amplitudes-for-binaries* program, and the double copy is one of its engines: it supplies the multi-loop gravitational integrands as squares of comparatively simple gauge-theory integrands, which are then integrated and matched to classical observables.

The pieces fit as follows, without full proof. The gravitational integrands are built by double copy (Eq. (61.157)) and reduced to master integrals by the generalized-unitarity and integration-by-parts machinery of Chapter 60. The

map from quantum amplitude to classical observable — scattering angle, impulse, radiated momentum — is made precise by the KMOC formalism, which expresses classical observables as expectation values built from amplitudes and isolates their classical ($\hbar \to 0$) part [305]. The results are cross-checked against, and feed, the worldline effective field theory of extended bodies [228]. By this route the conservative two-body Hamiltonian has been computed through third post-Minkowskian order ($\mathcal{O}(G^3)$, a two-loop amplitude) [66] and, in the years since, pushed to fourth order and partially to fifth, with radiative and spin effects systematically incorporated [4, 72]. These amplitude-derived results now enter the waveform models used to interpret gravitational-wave data. The honest framing is that this is a fast-moving applied frontier in which the double copy is a powerful organizing tool rather than the whole story — it makes the gravitational integrands tractable; the extraction of observables, the inclusion of dissipation, and the matching to bound-orbit dynamics are substantial additional machinery.

61.7.5 The frontier summary: theorem, evidence, open

It is worth stating, in one place and without hedging, exactly where the matter stands.

Proven (theorem, in this book). At tree level, color–kinematics duality holds: duality-satisfying numerators exist for every gluon tree (Theorems 61.8 and 61.12). The double copy of two gauge trees, at least one in a BCJ representation, is gauge invariant (Theorem 61.16) and is a genuine gravity amplitude with correct factorization (Theorem 61.20), demonstrated explicitly at three and four points (Eqs. (61.81) and (61.97)). The spectrum of the square of pure Yang–Mills is the $\mathcal{N} = 0$ supergravity multiplet (Eq. (61.105)). The Kerr–Schild classical double copy is exact for stationary Kerr–Schild solutions (Section 61.7.3).

Strongly evidenced (checked, not proved in general). Loop-level duality-satisfying numerators exist and double-copy correctly in many cases — $\mathcal{N} = 4$ sYM through several loops, lower-supersymmetry and pure Yang–Mills at low loops — with the gravity integrand correct on all unitarity cuts whenever the numerators exist (Theorem 61.31). $\mathcal{N} = 8$ supergravity is ultraviolet finite in $d = 4$ through five loops (Eq. (61.159)), with enhanced cancellations beyond known symmetry explanations. The amplitudes-for-binaries program reproduces and extends classical two-body results to high post-Minkowskian order.

Open (mid-2020s). The existence of duality-satisfying numerators at arbitrary loop order is conjectural (Theorem 61.32); it sometimes requires nonlocal numerators (the caution above), and a local representation is not guaranteed. There is no off-shell or Lagrangian formulation that makes the duality manifest to all orders. The all-order ultraviolet fate of $\mathcal{N} = 8$ supergravity in $d = 4$ — in particular the uncomputed seven-loop coefficient — is unknown. A nonperturbative, curved-background classical double copy is not established.

Why the duality is believed despite being unproven

The case-by-case evidence is not a heap of coincidences. Each successful loop construction is a nontrivial solution of an overconstrained linear system: the duality relations Eq. (61.156) are far more numerous than the free parameters in a numerator ansatz, so a solution existing at all is a strong structural statement, and it has been found again and again. Together with the tree-level theorem and the cut-consistency proposition Theorem 61.31, this is why the community treats the loop-level double copy as effectively reliable in practice while remaining precise that its general existence statement is a conjecture. The honest distinction between "works in every case we can check" and "proved for all cases" is exactly the distinction this book insists on keeping visible.

This closes Yang–Mills theory. It began in Chapter 25 with the classical non-abelian Lagrangian $\mathcal{L}_{\mathrm{YM}} = -\frac{1}{4}F^a_{\mu\nu}F^{a\,\mu\nu}$, whose cubic and quartic self-interactions encode the Lie algebra through f^{abc} and its Jacobi identity. It passed through quantization and BRST (Chapter 26), asymptotic freedom (Eq. (27.101)), and the modern amplitude structure — Parke–Taylor and BCFW (Chapter 59), generalized unitarity (Chapter 60). It ends here: that same Jacobi identity, now mirrored in kinematics, lets one replace color by a second copy of kinematics and read off gravity. Gauge theory and gravity, which entered this book as unrelated — one a renormalizable quantum field theory, the other a nonrenormalizable geometric theory — are unified at the level of on-shell data, "GR = YM $\otimes$ YM," with an honest map of where that unification is proved and where it is still being earned.

The synthesis chapter (Chapter 63) gathers the lessons of Part XVI — that locality and unitarity, taken as inputs throughout, may instead be *outputs* of a deeper on-shell structure — and the gravity part (Chapter 64) builds the curvature and field equations that this section imported on faith, turning the on-shell graviton of Theorem 61.18 into the dynamical metric of general relativity. The reader leaves Part XVI with gauge theory and gravity sewn together at the connection of their amplitudes, and with a clear summary of the live frontier.

Further reading

Color–kinematics duality and the BCJ amplitude relations are introduced in Bern et al. [69]; the double-copy prescription and the loop-level conjecture in Bern et al. [70]; the Lagrangian-level construction making the duality manifest at tree level in Bern et al. [71]; and the field-theory origin of "gravity = gauge^2" in the string-theoretic Kawai–Lewellen–Tye relations Kawai et al. [291]. The minimal-basis structure behind the BCJ relations is Bjerrum-Bohr et al. [77]. The

comprehensive modern review, with the loop-level status, the $\mathcal{N} = 8$ ultraviolet story, and the applications surveyed here, is Bern et al. [72]; the ultraviolet finiteness of $\mathcal{N} = 8$ supergravity is reported in Bern et al. [64] (four loops) and Bern et al. [65] (five loops). The Kerr–Schild classical double copy originates with Monteiro et al. [349]; the worldline and radiative extensions with Goldberger and Ridgway [227], Goldberger and Rothstein [228]; and the breadth of the classical program, with its domain of validity, is surveyed in Adamo et al. [4]. For the two-body problem and gravitational-wave observables, the third-post-Minkowskian Hamiltonian is Bern et al. [66] and the amplitudes-to-observables formalism is Kosower et al. [305].

Chapter 62

Positive Geometry and the Amplituhedron

Each chapter of this part has pried the scattering amplitude a little further loose from the Feynman diagram. Spinor-helicity stripped the redundancy from the external data; on-shell recursion (Chapter 59) assembled tree amplitudes from their poles and residues alone, never writing a Lagrangian; the unitarity method (Chapter 60) rebuilt loop integrands from their factorizations; and the double copy (Chapter 61) exposed a hidden kinematic algebra shadowing color. The throughline is that locality and unitarity, the two principles a Feynman calculation feeds in by hand, keep re-emerging as constraints the amplitude is *forced* to satisfy. This chapter follows that throughline to its most radical destination: the proposal that the amplitude is not computed by any procedure but *is* a single geometric object — a region carved out by positivity, carrying a distinguished differential form whose poles sit exactly on the region's boundaries with exactly the residues unitarity demands. The amplitude becomes a volume; locality and unitarity become theorems about a shape rather than inputs to a calculation.

The development is built to keep the line between proof and conjecture visible at every step, because in this subject that line is unusually sharp. We begin (Section 62.1) with pure geometry: the notion of a logarithmic form, the definition of a *positive geometry* as a region whose unique canonical form is singular precisely on its boundaries, and the recursive residue axiom that makes "boundaries $\leftrightarrow$ singularities" a definition. The toy dictionary is proved on the interval, the simplex, and the convex polygon, where triangulation independence already displays the cancellation of spurious poles that will recur throughout. Section 62.2 then discharges the slogan "amplitude = volume" rigorously and without any conjecture: the canonical form of the ABHY kinematic associahedron, a concrete polytope in Mandelstam space, equals the tree-level color-ordered amplitude of bi-adjoint ϕ^3 theory, term by term — the cleanest proved instance

of the whole program.

To reach amplitudes that carry helicity we need a geometry graded by the MHV degree k of Chapter 58. Section 62.3 introduces the totally nonnegative Grassmannian $\mathrm{Gr}_{\geq 0}(k,n)$ and its positroid stratification; Section 62.4 pours physics into that mould, identifying positroid cells with on-shell diagrams and leading singularities of planar $\mathcal{N}=4$ super Yang–Mills, recasting the Grassmannian integral as the generator of on-shell functions, and reading the BCFW recursion of Chapter 59 as a triangulation of a positive region by cells. The external kinematics, still entering by hand through momentum-conservation delta functions, are then repackaged in Section 62.5 into Hodges's momentum twistors — the chart in which momentum conservation is automatic, dual conformal symmetry is manifest, and positivity of the external data becomes a single combinatorial condition $\langle ijkl\rangle > 0$.

With both ingredients positive — the internal data through $\mathrm{Gr}_{\geq 0}(k,n)$, the external data through the positive Z-matrix — Section 62.6 defines the amplituhedron as the image of one under a positive linear map built from the other, proves convexity in the rigorously controlled $k=1$ polytope case (here k is the reduced momentum-twistor index of Section 62.5.4, so $k=1$ is NMHV; the physical $m=4$ included), and states honestly the canonical-form-equals-amplitude conjecture together with the boundary factorization that reads locality and unitarity off the facets. Section 62.7 turns the crank on an explicit positive dataset, carrying the $m=2$ NMHV computation to a closed form, closing the loop with the pentagon that opened the chapter, and displaying the genuine $m=4$ NMHV hexagon as the established result it is. Finally Section 62.8 audits everything: it sorts each claim into theorem, conjecture, and open problem dated to the mid-2020s, articulates the conceptual payoff — spacetime locality and quantum-mechanical unitarity as outputs of positivity rather than axioms — and names the planarity and maximal-supersymmetry crutches that bound the program, surveying the adjacent positive geometries (associahedra, cosmological polytopes, surfaceology) that are pushing past them. Throughout we use the spinor-helicity conventions of Chapter 58, the BCFW recursion of Chapter 59, and the generalized-unitarity integrand of Chapter 60, and we flag the kinship with the positivity-driven bootstrap of Chapter 52; the synthesis of the entire amplitudes program is reserved for Chapter 63.

62.1 Canonical forms and positive geometry

The chapters of this part have steadily eroded the idea that a scattering amplitude is, at bottom, a sum of Feynman diagrams. Spinor-helicity stripped the redundancy from the external data; on-shell recursion (Chapter 59) built tree amplitudes from nothing but their poles and residues, never writing a Lagrangian; the unitarity method (Chapter 60) reconstructed loop integrands from their fac-

torizations; and the double copy (Chapter 61) exposed a hidden kinematic algebra mirroring color. Each step replaced a piece of the diagrammatic scaffolding by a sharper statement about the analytic structure the amplitude is *forced* to have. The natural endpoint of that program is a dream: that the amplitude is not *computed* by some procedure but *is* a single mathematical object, read off from a shape. Concretely, the dream is that there exists a region — a polytope, or a curved generalization of one — whose boundaries are in bijection with the amplitude's singularities, and which carries a distinguished differential form whose poles sit exactly on those boundaries with exactly the residues unitarity demands. The amplitude would then be a *volume*, or more precisely the integrand of a volume, and locality and unitarity would be theorems about the geometry rather than inputs to a calculation.

To make that dream precise we need, before any physics, a clean answer to a purely geometric question: *given an oriented region, is there a canonical differential form attached to it, and is it unique?* This section builds that notion from scratch. We define what it means for a form to have only logarithmic singularities, we define a *positive geometry* as a region whose canonical form has logarithmic singularities on every one of its boundaries and nowhere else, and we make the recursive structure — residues on boundaries are themselves canonical forms of those boundaries — into the defining axiom. We then prove the toy dictionary boundaries $\leftrightarrow$ singularities on the three simplest families: the interval, the simplex, and the convex polygon. The polygon already exhibits the phenomenon that will dominate the rest of the chapter: a canonical form computed by triangulation is full of *spurious* poles on the internal edges of the triangulation, yet those poles cancel in the sum, leaving an answer that depends only on the shape and not on how it was cut up. That cancellation is the geometric face of what physicists call the disappearance of spurious poles in recursion. None of this yet mentions an amplitude; that match is the work of the next section. Here we forge the vocabulary.

Throughout we work over the reals for the geometry and allow the coordinates to be complexified when we take residues, exactly as one analytically continues a Feynman integrand to expose its poles. Projective space $\mathbb{P}^m$ and the exterior calculus of differential forms are at the prerequisite level; we recall only the few facts we lean on, as we need them.

62.1.1 Logarithmic forms and the canonical form

The building block is the simplest function with a single zero and a single pole on the projective line, packaged as a differential. For a nonzero meromorphic function f on a complex manifold, write

$$d\log f \;\equiv\; \frac{df}{f}. \tag{62.1}$$

Wherever f has a simple zero or a simple pole, $d\log f$ has a simple pole with residue equal to the order of vanishing: if $f = u\cdot z^k$ near $z=0$ with u holomorphic and nonvanishing, then $d\log f = k\,\frac{dz}{z} + d\log u$, and the second term is regular, so $\operatorname{Res}_{z=0} d\log f = k$. A logarithmic differential is one assembled out of such pieces.

Definition 62.1 (Logarithmic (dlog) form)**.** A meromorphic p-form ω on a complex manifold X has *logarithmic singularities* along a hypersurface $S=\{f=0\}$ (with f vanishing to first order on S) if, in a neighborhood of any smooth point of S, it can be written

$$\omega \;=\; \frac{df}{f}\wedge\psi \;+\; \eta, \tag{62.2}$$

with ψ a $(p-1)$-form and η a p-form both regular (holomorphic) near S. A form that has at worst logarithmic singularities along each component of its singular locus, and no other singularities, is called a *dlog form*; a top form is dlog precisely when it is a finite sum of wedge products $d\log f_1\wedge\cdots\wedge d\log f_m$.

The decomposition Eq. (62.2) is the mechanism for taking a residue along S. The restriction $\psi|_S$ does not depend on the freedom in writing Eq. (62.2): if $\frac{df}{f}\wedge\psi+\eta = \frac{df}{f}\wedge\psi'+\eta'$, then $\frac{df}{f}\wedge(\psi-\psi') = \eta'-\eta$ is regular, which forces $\psi-\psi'$ to be divisible by f and hence to vanish on S. This justifies the following.

Definition 62.2 (Residue along a boundary)**.** With notation as in Eq. (62.2), the *residue* of ω along S is the $(p-1)$-form on S

$$\operatorname{Res}_S\,\omega \;\equiv\; \psi\big|_S. \tag{62.3}$$

For a one-form $\omega = g\,dz$ with a simple pole at $z=z_0$ this reduces to the ordinary residue $\operatorname{Res}_{z_0}\omega = \lim_{z\to z_0}(z-z_0)g(z)$, recovering the complex-analysis notion the reader already has.

The residue is the operation that turns the singularity structure of a form on a region into the form on a boundary. This is the technical hinge of the whole subject, so we now make it the content of a definition rather than a remark.

Definition 62.3 (Positive geometry and its canonical form)**.** A *positive geometry* of dimension m is a pair $\mathcal{A}=(X,\,X_{\geq 0})$, where X is an m-dimensional complex projective variety and $X_{\geq 0}\subseteq X(\mathbb{R})$ is a closed, oriented region of its real locus, whose topological boundary $\partial X_{\geq 0}$ is a finite union of codimension-one pieces

$$\partial X_{\geq 0} \;=\; \bigcup_i C_i, \tag{62.4}$$

each of which, with the boundary orientation induced from $X_{\geq 0}$, is itself a positive geometry $\mathcal{C}_i$ of dimension $m-1$, such that there exists a (necessarily unique, by Theorem 62.4) nonzero rational m-form $\Omega(\mathcal{A})$ on X, the *canonical form*, with the following properties:

(i) *(Dimension zero)* If $m = 0$, then $X_{\geq 0}$ is a single point and $\Omega(\mathcal{A}) = \pm 1$, the sign being its orientation.

(ii) *(Logarithmic singularities only on boundaries)* If $m > 0$, then $\Omega(\mathcal{A})$ has poles *only* along the boundary components C_i, every such pole is logarithmic in the sense of Theorem 62.1, and $\Omega(\mathcal{A})$ has no singularity anywhere off $\bigcup_i C_i$.

(iii) *(Recursive residue axiom)* On each boundary component the residue reproduces the canonical form of that boundary, regarded as a positive geometry in its own right:

$$\operatorname{Res}_{C_i} \Omega(\mathcal{A}) \;=\; \Omega(\mathcal{C}_i). \tag{62.5}$$

Three remarks fix the meaning of this definition before we use it. First, the axiom is genuinely recursive: Eq. (62.5) relates an m-form to the canonical $(m-1)$-form of a lower-dimensional positive geometry, and the recursion bottoms out at the points of clause (i). The canonical form of any positive geometry is therefore completely determined by its tower of boundaries, boundaries-of-boundaries, and so on, down to vertices. Second, the boundaries-as-singularities clause (ii) is the precise statement of the dictionary advertised in the section title: *a codimension-one boundary of the region is a simple pole of the form, and conversely the form has a pole only where the region has a boundary.* Third, uniqueness is not an extra assumption; it is forced, and we prove it next, so that "the" canonical form is well posed.

Lemma 62.4 (Uniqueness of the canonical form)**.** *Fix a finite set of irreducible hypersurfaces $\{S_i\}$ in $\mathbb{P}^m$. Among rational m-forms whose poles all lie in $\bigcup_i S_i$ and are at worst simple there, a form is uniquely determined by its residues $\{\operatorname{Res}_{S_i} \omega\}$. In particular at most one rational m-form can satisfy clauses (ii)–(iii) of Theorem 62.3.*

Proof. Suppose ω and ω' have poles confined to $\bigcup_i S_i$, at worst simple, with equal residues on every S_i. Their difference $\chi = \omega - \omega'$ has, along each S_i, residue zero; by the decomposition Eq. (62.2) a simple-pole form with vanishing residue is in fact regular across S_i. Hence χ has no poles at all: it is a *global holomorphic* m-form on $\mathbb{P}^m$. We show there are none but zero. Work in an affine chart with coordinates $(x_1, \dots, x_m)$, where any holomorphic top form reads $\chi = P(x)\, dx_1 \wedge \cdots \wedge dx_m$ with P entire; regularity on all of $\mathbb{P}^m$ (a compact manifold) forces P to be a polynomial. Pass to the chart at infinity by $x_1 = 1/w$, $x_a = u_a/w$ for $a \geq 2$. Then

$$dx_1 = -\frac{dw}{w^2}, \qquad dx_a = \frac{du_a}{w} - \frac{u_a\, dw}{w^2} \;(a \geq 2), \tag{62.6}$$

and a direct expansion of the wedge gives $dx_1 \wedge \cdots \wedge dx_m = (-1)^m\, w^{-(m+1)}\, dw \wedge du_2 \wedge \cdots \wedge du_m$. For χ to be regular as $w \to 0$ we need $P(1/w, u_2/w, \dots)\, w^{-(m+1)}$

to stay finite, i.e. P must vanish to order at least $m+1$ at infinity — impossible for a nonzero polynomial, every one of which *grows* there. Therefore $P \equiv 0$, $\chi = 0$, and $\omega = \omega'$. □

The same computation, run in reverse, shows there is no obstruction in principle to *existence*: a rational m-form with prescribed simple poles and residues exists iff those residue data are mutually consistent (the residue on a codimension-two stratum computed from two different facets must agree). For the geometries of this section we will exhibit the canonical form explicitly, so existence is never in doubt; uniqueness, Theorem 62.4, is what makes triangulation-independence a theorem rather than a coincidence.

Physical Insight

The content of Theorem 62.3 is a translation manual. Geometry on the left, analysis on the right: a region ↔ a top form; a codimension-one boundary ↔ a simple pole; the operation "go to a boundary" ↔ the operation "take a residue"; a vertex ↔ a number ± 1. Every later assertion in this chapter — that an amplitude is a canonical form, that its poles are factorization channels, that residues are lower-point amplitudes — is this manual applied to a particular shape. The physics enters only in choosing the shape; the dictionary is fixed once and for all here.

62.1.2 The interval: the dictionary in one dimension

The lowest nontrivial case is one-dimensional. Let $X = \mathbb{P}^1$ with affine coordinate x, and let the region be a closed interval $X_{\geq 0} = [a, b]$ with $a < b$, oriented by $+dx$. Its boundary is the two points $\{a\}$ and $\{b\}$, each a zero-dimensional positive geometry. We claim its canonical form is the most elementary dlog imaginable.

Theorem 62.5 (Canonical form of the interval)**.** *The canonical form of the oriented interval $[a, b] \subset \mathbb{P}^1$ is*

$$\Omega([a,b]) \;=\; d\log\frac{x-a}{x-b} \;=\; \left(\frac{1}{x-a}-\frac{1}{x-b}\right)dx \;=\; \frac{b-a}{(x-a)(b-x)}\,dx. \tag{62.7}$$

It has simple poles only at the two endpoints, with residues

$$\mathrm{Res}_{x=a}\,\Omega = +1, \qquad \mathrm{Res}_{x=b}\,\Omega = -1, \tag{62.8}$$

and these residues realize the recursive axiom Eq. (62.5): each is the canonical form ± 1 of the corresponding endpoint, with sign equal to the boundary orientation induced by $+dx$.

Proof. We verify each clause of Theorem 62.3 directly. First the three expressions in Eq. (62.7) agree. Differentiating the logarithm,

$$d\log\frac{x-a}{x-b}=\frac{d(x-a)}{x-a}-\frac{d(x-b)}{x-b}=\left(\frac{1}{x-a}-\frac{1}{x-b}\right)dx, \tag{62.9}$$

and combining over a common denominator,

$$\frac{1}{x-a}-\frac{1}{x-b}=\frac{(x-b)-(x-a)}{(x-a)(x-b)}=\frac{a-b}{(x-a)(x-b)}=\frac{b-a}{(x-a)(b-x)}, \tag{62.10}$$

where the last step writes $(x-a)(x-b)=-(x-a)(b-x)$ and cancels the sign against $a-b=-(b-a)$. On the open interval $a<x<b$ both $x-a>0$ and $b-x>0$, while $b-a>0$, so the coefficient in the rightmost form of Eq. (62.7) is strictly positive there: the canonical form is a positive measure on the interior of the region, a property we will see recur and which singles out the geometric "inside."

Singularities. A rational 1-form $g(x)\,dx$ on $\mathbb{P}^1$ can have poles only where g blows up (in the finite chart) and possibly at $x=\infty$. From the first form in Eq. (62.7), $g(x)=\frac{1}{x-a}-\frac{1}{x-b}$ has simple poles exactly at $x=a$ and $x=b$ and is finite elsewhere in $\mathbb{C}$. At infinity, set $x=1/w$, so $dx=-dw/w^2$ and

$$g(x)\,dx=\left(\frac{1}{1/w-a}-\frac{1}{1/w-b}\right)\left(-\frac{dw}{w^2}\right)=-\left(\frac{w}{1-aw}-\frac{w}{1-bw}\right)\frac{dw}{w^2}=-\frac{1}{w}\left(\frac{1}{1-aw}-\frac{1}{1} \tag{62.11}$$

Expanding the bracket for small w gives $(1+aw+\cdots)-(1+bw+\cdots)=(a-b)w+O(w^2)$, so the prefactor $1/w$ is cancelled and $g(x)\,dx=-\big[(a-b)+O(w)\big]\,dw$, which is *regular* at $w=0$. Thus there is no pole at infinity, and the only singularities are the two endpoints — exactly the two boundary points of $[a,b]$, and both poles are simple, hence logarithmic. This is clauses (ii) of the definition.

Residues, clause (iii). From the first form in Eq. (62.7), $\operatorname{Res}_{x=a}\Omega=\lim_{x\to a}(x-a)g(x)=+1$ and $\operatorname{Res}_{x=b}\Omega=\lim_{x\to b}(x-b)g(x)=-1$, giving Eq. (62.8). Each residue is a bare sign ±1, which is exactly the canonical form of a zero-dimensional positive geometry (clause (i)); the two opposite signs encode the two opposite orientations that the endpoints inherit as the boundary of the oriented interval $[a,b]$. The recursive axiom Eq. (62.5) therefore holds at the bottom of the tower. By Theorem 62.4 this is the unique such form, and the proof is complete. □

The interval already teaches the dictionary in miniature: two boundary points, two simple poles, unit residues, and a form that is manifestly the logarithm of a ratio of the two linear functions vanishing on the boundaries. It also tells us what a "vertex" contributes — the residue is a bare sign — which is the seed of every recursion to come.

It is worth recording that Eq. (62.7) is a *projective* statement, independent of the affine coordinate we happened to use. The group of projective automorphisms

of $\mathbb{P}^1$ is the Möbius group, acting by $x \mapsto x' = \frac{px+q}{rx+s}$ with $ps - qr \neq 0$. A genuine geometric notion must be insensitive to this relabeling, and the interval form is.

Proposition 62.6 (Projective invariance of the interval form)**.** *Under any Möbius transformation $M : x \mapsto \frac{px+q}{rx+s}$ of $\mathbb{P}^1$, mapping the interval $[a, b]$ to $[M(a), M(b)]$, the canonical form is invariant:*

$$d\log\frac{M(x) - M(a)}{M(x) - M(b)} \;=\; d\log\frac{x-a}{x-b}. \tag{62.12}$$

Proof. Compute the Möbius difference. With $M(x) = \frac{px+q}{rx+s}$,

$$M(x) - M(a) = \frac{(px+q)(ra+s) - (pa+q)(rx+s)}{(rx+s)(ra+s)} = \frac{(ps-qr)(x-a)}{(rx+s)(ra+s)}, \tag{62.13}$$

where the numerator simplifies because all terms quadratic in the coordinates cancel, leaving $(ps - qr)(x - a)$. Likewise $M(x) - M(b) = \dfrac{(ps-qr)(x-b)}{(rx+s)(rb+s)}$. Dividing,

$$\frac{M(x) - M(a)}{M(x) - M(b)} = \frac{x-a}{x-b} \cdot \frac{rb+s}{ra+s}, \tag{62.14}$$

and the second factor is a constant independent of x. Since $d\log$ of a constant vanishes, Eq. (62.12) follows. The two endpoint poles, with their unit residues, are carried to the two new endpoints; the dictionary is Möbius-covariant. □

62.1.3 The simplex: projective covariance in any dimension

The interval is the one-dimensional member of a family — the simplices — whose canonical forms we can write in closed form and which already display projective covariance in the higher-dimensional way that the amplituhedron will need. We treat the triangle in full and state the general simplex.

It is convenient to use homogeneous coordinates and the determinant bracket. A point of $\mathbb{P}^2$ is a line through the origin in $\mathbb{R}^3$, represented by a nonzero vector $Z = (Z^0, Z^1, Z^2)$ up to overall scale; the affine chart $Z^0 = 1$ identifies $Z = (1, x, y)$ with the plane point (x, y). For three such vectors define the bracket

$$\langle Z_1\, Z_2\, Z_3\rangle \;\equiv\; \det\begin{pmatrix} Z_1^0 & Z_1^1 & Z_1^2 \\ Z_2^0 & Z_2^1 & Z_2^2 \\ Z_3^0 & Z_3^1 & Z_3^2 \end{pmatrix}, \tag{62.15}$$

which is multilinear and totally antisymmetric in its three slots and vanishes precisely when the three points are collinear. For affine points $Z_i = (1, x_i, y_i)$ it equals twice the signed area of the triangle they span. Treating the running point $Y = (1, x, y)$ as a variable, the bracket $\langle Y\, Z_i\, Z_j\rangle$ is an affine-linear function

of (x, y) that vanishes on the line through Z_i and Z_j. Finally, the projective measure on $\mathbb{P}^2$ is

$$\langle Y\, d^2Y\rangle \;\equiv\; \tfrac{1}{2}\,\epsilon_{abc}\, Y^a\, dY^b \wedge dY^c, \tag{62.16}$$

which in the affine chart $Y = (1, x, y)$, where $dY^0 = 0$, reduces to $\langle Y\, d^2Y\rangle = dx \wedge dy$, as one checks by retaining only the $a = 0$ terms of the sum.

Theorem 62.7 (Canonical form of the triangle)**.** *Let T be the oriented triangle in $\mathbb{P}^2$ with vertices Z_1, Z_2, Z_3 (counterclockwise). Its canonical form is the projectively-covariant dlog form*

$$\Omega(T) \;=\; \frac{\langle Z_1\, Z_2\, Z_3\rangle^2\; \langle Y\, d^2Y\rangle}{\langle Y\, Z_1\, Z_2\rangle\, \langle Y\, Z_2\, Z_3\rangle\, \langle Y\, Z_3\, Z_1\rangle}. \tag{62.17}$$

It has simple poles on the three edge-lines $\langle Y\, Z_i Z_{i+1}\rangle = 0$ and nowhere else; on each edge the residue is the interval form of that edge, and on each vertex the second residue is ± 1.

Proof. Well-definedness on $\mathbb{P}^2$. Under a rescaling $Y \to \Lambda Y$ of the homogeneous coordinate the measure scales as $\langle Y\, d^2Y\rangle \to \Lambda^3 \langle Y\, d^2Y\rangle$ (three factors of Y), while each of the three denominator brackets is linear in Y, contributing Λ^3; the vertex bracket carries no Y. The total weight is $\Lambda^3/\Lambda^3 = \Lambda^0$, so $\Omega(T)$ is a genuine form on $\mathbb{P}^2$, with no pole hiding at the line at infinity.

Reduction to affine coordinates. Place the standard triangle at $Z_1 = (1, 0, 0)$, $Z_2 = (1, 1, 0)$, $Z_3 = (1, 0, 1)$, i.e. the plane region $\{x \geq 0,\, y \geq 0,\, x + y \leq 1\}$. The brackets are the determinants

$$\langle Z_1 Z_2 Z_3\rangle = \det\begin{pmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ 1 & 0 & 1 \end{pmatrix} = 1, \tag{62.18}$$

$$\langle Y\, Z_1 Z_2\rangle = \det\begin{pmatrix} 1 & x & y \\ 1 & 0 & 0 \\ 1 & 1 & 0 \end{pmatrix} = y, \quad \langle Y\, Z_2 Z_3\rangle = \det\begin{pmatrix} 1 & x & y \\ 1 & 1 & 0 \\ 1 & 0 & 1 \end{pmatrix} = 1 - x - y, \quad \langle Y\, Z_3 Z_1\rangle = \det \tag{62.19}$$

which are the three edge functions of the region: $y = 0$, $x + y = 1$, and $x = 0$. With $\langle Y\, d^2Y\rangle = dx \wedge dy$ the formula Eq. (62.17) becomes

$$\Omega(T) = \frac{1^2\, dx \wedge dy}{y\,(1 - x - y)\, x} = \frac{dx \wedge dy}{x\, y\,(1 - x - y)}. \tag{62.20}$$

Inside the region all three factors $x, y, 1 - x - y$ are positive, so $\Omega(T)$ is again a positive measure on the interior, the higher-dimensional echo of the interval result. Its poles are simple and sit exactly on the three edges and nowhere

else; these are the three boundaries of T, establishing clause (ii). For a general (nondegenerate) triangle the projective transformation carrying the standard triangle to it preserves Eq. (62.17) by the same constant-factor argument as in Theorem 62.6 applied slot by slot, so the result is projectively covariant and it suffices to have checked the standard representative.

Residues, clause (iii). Take the residue on the edge $x = 0$, i.e. $\langle Y Z_3 Z_1 \rangle = 0$. Writing Eq. (62.20) as $\frac{dx}{x} \wedge \frac{dy}{y(1-y)} +$ (regular) near $x = 0$ and applying Eq. (62.3),

$$\mathrm{Res}_{x=0}\, \Omega(T) = \frac{dy}{y(1-y)} = d\log\frac{y}{1-y}, \tag{62.21}$$

which is exactly the interval canonical form Eq. (62.7) on the edge segment $0 \le y \le 1$ joining the vertices $Z_1 = (0,0)$ and $Z_3 = (0,1)$. Taking a further residue at the endpoint $y = 0$ gives $+1$, the canonical form of that vertex. The same computation on the other two edges, by the cyclic symmetry of Eq. (62.17), gives their interval forms. Thus the recursive axiom holds at every level, and by Theorem 62.4 Eq. (62.17) is the canonical form. □

The pattern generalizes verbatim. The standard m-simplex is the region $\{x_1 \ge 0, \dots, x_m \ge 0,\ x_1 + \cdots + x_m \le 1\}$ in the affine chart of $\mathbb{P}^m$, bounded by the $m+1$ hyperplanes $x_1 = 0, \dots, x_m = 0$, and $1 - \sum_i x_i = 0$. Repeating the residue argument facet by facet — each residue strips one factor and leaves a lower simplex's form — gives the canonical form

$$\Omega(\Delta^m) \;=\; \frac{dx_1 \wedge \cdots \wedge dx_m}{x_1\, x_2 \cdots x_m\, (1 - x_1 - \cdots - x_m)}, \tag{62.22}$$

a single dlog top form with simple poles on each of the $m+1$ facets and unit iterated residues down to each vertex. The simplex is the prototype of a positive geometry: its canonical form is literally a wedge of $d\log$'s of the facet functions, and every boundary stratum is again a simplex. We will see that the amplituhedron and the associahedron, however curved or high-dimensional, inherit exactly this structure — their canonical forms are dlog, their residues are lower geometries — which is why the simplex is the right object to keep in mind throughout.

62.1.4 Polygons and triangulation independence

The first place the theory acquires real content — and the first place it meets the structure of physical amplitudes head on — is the convex polygon. A convex polygon is not a simplex once it has more than three vertices, yet there is an obvious way to *build* its canonical form: cut the polygon into triangles and add up the triangle forms. The danger is that each triangle drags in poles on its edges, and the internal cutting edges are not boundaries of the polygon at all. If

the construction is to produce the canonical form of Theorem 62.3, those internal poles must disappear. They do, and the mechanism is the cornerstone of the chapter.

We need one computation: the residue of a triangle's form on one of its edges, in a form clean enough to compare two triangles meeting along a shared edge.

Lemma 62.8 (Edge residue of a triangle form)**.** *Abbreviate* $\omega_{ijk} \equiv \dfrac{\langle ijk\rangle^2\,\langle Y\,d^2Y\rangle}{\langle Yij\rangle\,\langle Yjk\rangle\,\langle Yki\rangle}$, *the canonical form of the triangle with vertices* Z_i, Z_j, Z_k*, where* $\langle Yij\rangle \equiv \langle YZ_iZ_j\rangle$ *and* $\langle ijk\rangle \equiv \langle Z_iZ_jZ_k\rangle$*. Parametrize the edge-line through* Z_i, Z_j *by* $Y(\tau) = (1-\tau)Z_i + \tau Z_j$*, so* $\tau = 0$ *at* Z_i *and* $\tau = 1$ *at* Z_j*. Then the residue on that line is the interval form of the segment, oriented from* Z_i *to* Z_j*, and is* independent of the apex Z_k *up to its overall sign:*

$$\mathrm{Res}_{\langle Yij\rangle=0}\;\omega_{ijk} \;=\; -\,\frac{d\tau}{\tau(1-\tau)}. \tag{62.23}$$

Proof. Introduce coordinates adapted to the edge-line: a transverse coordinate $s \equiv \langle Yij\rangle$, which vanishes on the line, and the line parameter τ, by setting

$$Y \;=\; (1-\tau)\,Z_i + \tau\,Z_j + s\,W, \tag{62.24}$$

where $W = (0, w_1, w_2)$ is a fixed vector at infinity normalized so that $\langle WZ_iZ_j\rangle = 1$; this guarantees $\langle Yij\rangle = (1-\tau)\langle Z_iij\rangle + \tau\langle Z_jij\rangle + s\langle Wij\rangle = s$, since the first two brackets vanish (a repeated slot). The measure transforms with a constant Jacobian: in the affine chart $\langle Y\,d^2Y\rangle = dx\wedge dy$ and (x,y) is affine-linear in (s,τ), so $dx\wedge dy = c\;ds\wedge d\tau$ with

$$c \;=\; \det\big[\,W_{\text{aff}}\,,\,(Z_j - Z_i)_{\text{aff}}\,\big] \;=\; -\langle WZ_iZ_j\rangle \;=\; -1, \tag{62.25}$$

the middle equality being the expansion of the 3×3 bracket $\langle WZ_iZ_j\rangle$ for W at infinity. Now evaluate the remaining two denominator brackets on the line, using multilinearity in the first slot:

$$\langle Yjk\rangle = (1-\tau)\langle ijk\rangle, \qquad \langle Yki\rangle = \tau\,\langle jki\rangle = \tau\,\langle ijk\rangle, \tag{62.26}$$

where $\langle Z_jjk\rangle = 0$ and $\langle Z_iki\rangle = 0$ kill the missing terms and $\langle jki\rangle = \langle ijk\rangle$ by cyclic symmetry. Substituting everything,

$$\omega_{ijk} = \frac{\langle ijk\rangle^2\,(-1)\,ds\wedge d\tau}{s\cdot(1-\tau)\langle ijk\rangle\cdot\tau\langle ijk\rangle} = -\,\frac{ds}{s}\wedge\frac{d\tau}{\tau(1-\tau)}. \tag{62.27}$$

The factors of $\langle ijk\rangle^2$ cancel completely against the two linear factors, which is why the result does not depend on the apex. Reading off the residue via Eq. (62.3) gives Eq. (62.23). □

The crucial structural consequence is the sign. Consider two triangles of a triangulation that share an edge — the diagonal between vertices Z_i and Z_j. With a fixed (say counterclockwise) orientation of the plane, the two triangles sit on opposite sides of the diagonal and traverse it in opposite cyclic orders: one as ω_{ijk} (edge oriented $i \to j$), the other as ω_{jil} (edge oriented $j \to i$). Running Theorem 62.8 for the second triangle, with the diagonal written as the factor $\langle Yji\rangle = -\langle Yij\rangle$ and the same global parameter τ from Z_i to Z_j, the two sign flips (one from $\langle Yji\rangle = -s$, one from the swapped vertex labels in the other brackets) combine to give

$$\mathrm{Res}_{\langle Yij\rangle=0}\ \omega_{jil} \;=\; +\frac{d\tau}{\tau(1-\tau)} \;=\; -\,\mathrm{Res}_{\langle Yij\rangle=0}\ \omega_{ijk}. \tag{62.28}$$

The residues on the shared diagonal are equal and opposite. Therefore in the *sum* of the two triangle forms the diagonal pole has zero residue, and by the decomposition Eq. (62.2) a simple-pole form with vanishing residue is regular there: the diagonal pole is absent from the sum. This is the disappearance of the spurious pole, proved.

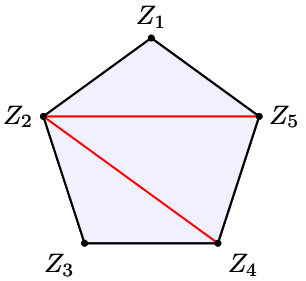
Theorem 62.9 (Polygon canonical form and triangulation independence)**.** *Let P be a convex polygon in $\mathbb{P}^2$ with cyclically ordered vertices $Z_1, \dots, Z_n$. Choose any triangulation of P into $n-2$ triangles using the polygon's vertices, oriented consistently with P. Then the sum of the triangle canonical forms,*

$$\Omega(P) \;=\; \sum_{\triangle \in\ \textit{triangulation}} \Omega(\triangle), \tag{62.29}$$

is independent of the chosen triangulation, has simple poles only on the n edge-lines $\langle Y\, Z_a Z_{a+1}\rangle = 0$ (indices cyclic), and is the canonical form of P in the sense of Theorem 62.3.

Proof. Poles only on the edges. Each triangle of the triangulation contributes poles on its three edge-lines. These edge-lines are of two kinds: *boundary edges* of P, each belonging to exactly one triangle of the triangulation, and *diagonals*, each shared by exactly two triangles (the two regions it separates). On any diagonal the two contributing residues cancel by Eq. (62.28), so the sum Eq. (62.29) has no pole there. On a boundary edge only one triangle contributes, with residue equal, by Theorem 62.8, to the interval canonical form of that edge. Hence $\Omega(P)$ has simple poles exactly on the n boundary edges, with residue on each equal to the canonical form of that edge — precisely clauses (ii) and (iii) of Theorem 62.3. Each $\Omega(\triangle)$ is projective weight zero, so the sum is a bona fide form on $\mathbb{P}^2$ with no spurious pole at infinity.

Triangulation independence. Whatever the triangulation, the resulting form has poles confined to the same n edge-lines and the *same* residue on each (the edge's interval form, which does not depend on which triangulation produced it).



Triangulation A: $\{123, 134, 145\}$ Triangulation B: $\{234, 245, 125\}$

Figure 62.1: Two triangulations of a convex pentagon (Theorem 62.10). A fans from Z_1, using the diagonals $\langle Y13\rangle, \langle Y14\rangle$ (red); B fans from Z_2, using the disjoint pair $\langle Y24\rangle, \langle Y25\rangle$. The two triangulations share no diagonals, yet the sum of triangle canonical forms is the same in both cases: every diagonal pole appears in two triangles with opposite residues and cancels, leaving a form with simple poles only on the five edges $\langle Y\, a\, a{+}1\rangle = 0$.

By the uniqueness Theorem 62.4, any two such forms coincide. Hence $\Omega(P)$ is independent of the triangulation, and being the unique form with these poles and residues, it is the canonical form of P. □

The polygon is the first place the geometry computes something a physicist recognizes: a sum over triangulations, each triangle carrying genuine and spurious poles, with the spurious ones cancelling pairwise to leave a triangulation-independent total whose only singularities are physical. We now carry out the cancellation explicitly on the pentagon, where there are enough diagonals for the bookkeeping to be nontrivial and where two manifestly different triangulations can be compared term by term.

Worked Example 62.10 (The pentagon two ways: spurious diagonals cancel)**.** Let P be a convex pentagon with cyclically ordered vertices $Z_1, \dots, Z_5$ (Fig. 62.1). We compute its canonical form by two triangulations that share no diagonal and verify they agree, with all spurious poles cancelling.

Triangulation A fans from Z_1:

$$\Omega_A = \omega_{123} + \omega_{134} + \omega_{145}, \tag{62.30}$$

using the two diagonals $\langle Y13\rangle = 0$ and $\langle Y14\rangle = 0$. *Triangulation B* fans from Z_2:

$$\Omega_B = \omega_{234} + \omega_{245} + \omega_{125}, \tag{62.31}$$

using the disjoint pair of diagonals $\langle Y24\rangle = 0$ and $\langle Y25\rangle = 0$. (Here ω_{ijk} is the triangle form of Theorem 62.8, and we have written each triangle in the cyclic order inherited from the pentagon's orientation, so that shared edges are traversed oppositely by adjacent triangles.)

Poles of Ω_A. The pole-lines appearing in the three terms are

$$\begin{aligned} \omega_{123}&: \ \langle Y12\rangle,\ \langle Y23\rangle,\ \langle Y13\rangle,\\ \omega_{134}&: \ \langle Y13\rangle,\ \langle Y34\rangle,\ \langle Y14\rangle,\\ \omega_{145}&: \ \langle Y14\rangle,\ \langle Y45\rangle,\ \langle Y15\rangle. \end{aligned} \tag{62.32}$$

The five edge-lines $\langle Y12\rangle, \langle Y23\rangle, \langle Y34\rangle, \langle Y45\rangle, \langle Y15\rangle$ each occur once. The diagonal $\langle Y13\rangle$ occurs in ω_{123} and ω_{134}; in the first the shared edge is traversed $1 \to 3$, in the second $3 \to 1$, so by Eq. (62.28) their residues on $\langle Y13\rangle = 0$ are

$$\mathrm{Res}_{\langle Y13\rangle=0}\,\omega_{123} = -\frac{d\tau}{\tau(1-\tau)}, \qquad \mathrm{Res}_{\langle Y13\rangle=0}\,\omega_{134} = +\frac{d\tau}{\tau(1-\tau)}, \tag{62.33}$$

which sum to zero. Identically, the diagonal $\langle Y14\rangle$ occurs in ω_{134} (edge $1 \to 4$) and ω_{145} (edge $4 \to 1$), and the two residues cancel. Therefore Ω_A has *no* pole on either diagonal; its only singularities are simple poles on the five edge-lines, and on each edge its residue is that edge's interval form, e.g. on $\langle Y23\rangle = 0$ the single contributor ω_{123} gives $-d\tau/[\tau(1-\tau)]$ by Theorem 62.8.

Poles of Ω_B. The same audit for B:

$$\begin{aligned} \omega_{234}&: \ \langle Y23\rangle,\ \langle Y34\rangle,\ \langle Y24\rangle,\\ \omega_{245}&: \ \langle Y24\rangle,\ \langle Y45\rangle,\ \langle Y25\rangle,\\ \omega_{125}&: \ \langle Y12\rangle,\ \langle Y25\rangle,\ \langle Y15\rangle. \end{aligned} \tag{62.34}$$

Again each of the five edge-lines occurs once. The diagonal $\langle Y24\rangle$ occurs in ω_{234} (edge $2 \to 4$) and ω_{245} (edge $4 \to 2$) and cancels; the diagonal $\langle Y25\rangle$ occurs in ω_{245} (edge $2 \to 5$) and ω_{125} (edge $5 \to 2$) and cancels. So Ω_B also has poles only on the five edges, with the *same* residue on each as Ω_A — on every edge $\langle Y\, a\, a{+}1\rangle = 0$ exactly one triangle (in either triangulation) contributes the same interval form.

Conclusion. Ω_A and Ω_B are rational 2-forms with identical pole-lines (the five edges) and identical residues there, so by Theorem 62.4 they are equal:

$$\Omega_A = \Omega_B = \Omega(P), \tag{62.35}$$

the unique canonical form of the pentagon. The diagonals — $\{13, 14\}$ in A, $\{24, 25\}$ in B — are spurious in both: they are artifacts of the cut, present in the individual triangle terms but absent from the geometric total. The canonical form remembers only the five genuine edges of the shape, exactly as the dictionary of Theorem 62.3 demands. This is, in miniature, the statement that a tree amplitude assembled by recursion has physical poles only on its true factorization channels, the spurious poles of the individual recursion terms cancelling in the sum — a correspondence the next section makes literal.

We now have a precise, computable, projectively-invariant notion of the canonical form of a positive geometry, together with the dictionary that ties each boundary to a logarithmic singularity and each residue to a lower geometry, and we have seen — on the polygon — that triangulation produces it with all spurious singularities cancelling. The next section pours an actual scattering amplitude into this mould: it realizes the color-ordered tree amplitude of bi-adjoint ϕ^3 theory as the canonical form of a concrete polytope, the ABHY kinematic associahedron, living directly in Mandelstam space, turning "amplitude = volume" from a slogan into a theorem before any conjecture about the amplituhedron is made.

62.2 Amplitudes as canonical forms: the kinematic associahedron

The previous section built an abstraction and tested it on toys. A positive geometry is a region whose boundaries carry a unique differential form with logarithmic singularities exactly on those boundaries and nowhere else (Theorem 62.3); for a convex polygon we proved that this *canonical form* is triangulation independent and may be assembled by summing a simple local form over the vertices (Theorem 62.9); and we read off the dictionary on which the whole chapter turns, *boundaries* $\leftrightarrow$ *singularities*: the residue of the canonical form on any facet is the canonical form of that facet (Eq. (62.5)). All of this was geometry. Not a single scattering amplitude has yet appeared.

This section discharges the promissory note "amplitude = volume" before any conjecture is allowed near it. We will exhibit a concrete, honest, finite-dimensional polytope — the *kinematic associahedron* of Arkani-Hamed, Bai, He and Yan (ABHY) — living directly in the space of Mandelstam invariants, and prove a theorem: its canonical form, pulled back to physical kinematics, *is* the tree-level color-ordered amplitude of bi-adjoint cubic scalar theory, propagator for propagator. There is no large-N limit, no supersymmetry, no helicity, and nothing conjectural; the statement is a finite identity between a sum of products of propagators and a sum of dlog forms over the vertices of a polytope, and we will verify it term by term, culminating in the five-term five-point amplitude realized as the very pentagon of Section 62.1. The locality and unitarity of the amplitude — poles only on physical channels, residues that factorize into lower amplitudes — will emerge as the statement that the facets of the polytope are themselves products of lower associahedra. This is the cleanest existing instance of the chapter's thesis, and it is completely provable, so we prove it completely.

62.2.1 The object to be reproduced: bi-adjoint cubic amplitudes

We continue the scalar of Chapter 61, the "zeroth copy" whose double copy delivers gravity and whose color algebra underlies the Yang–Mills color ordering

of Chapter 59. The bi-adjoint cubic theory carries a scalar $\phi^{aa'}$ in the adjoint of a *pair* of Lie groups, with Lagrangian

$$\mathcal{L} = \tfrac{1}{2}\,(\partial_\mu \phi^{aa'})(\partial^\mu \phi^{aa'}) - \tfrac{\lambda}{3!}\, f^{abc}\, \tilde{f}^{a'b'c'}\, \phi^{aa'} \phi^{bb'} \phi^{cc'}, \tag{62.36}$$

where f^{abc} and $\tilde{f}^{a'b'c'}$ are the structure constants of the two groups (Chapter 61). Because the only interaction is cubic and massless, every tree contributing to an n-point function is a trivalent (cubic) tree graph, and each carries one factor of f and one factor of $\tilde{f}$ at every vertex and one massless scalar propagator on every internal line.

Stripping the two color algebras by the double color decomposition produces *doubly* color-ordered partial amplitudes $m(\alpha \,|\, \beta)$, one for each pair of cyclic orderings α, β of the n legs; this is the bi-adjoint refinement of the single color ordering defined in Theorem 59.3. We need only the diagonal entry, in which both orderings are the standard one $\mathbf{1} = (1, 2, \ldots, n)$. Write

$$m_n \;\equiv\; m(1, 2, \ldots, n \,|\, 1, 2, \ldots, n). \tag{62.37}$$

The double color decomposition (Chapter 61) selects, in m_n, exactly those trivalent trees that are *planar with respect to the ordering* $(1, \ldots, n)$: the cyclic graphs that can be drawn in a disk with the external legs $1, \ldots, n$ on the boundary in that cyclic order without crossings. Each such planar tree contributes the product of its internal propagators, with unit numerator (all numerators are ± 1 once color is stripped, and the planar tree fixes the sign to $+1$). We strip an overall $i\,\lambda^{n-2}$, as is standard for the amplitudes of this part, and define

$$\boxed{\; m_n \;=\; \sum_{\text{planar trivalent trees } T} \;\prod_{\text{internal lines } e \in T} \frac{1}{X_e}\,, \;} \tag{62.38}$$

where X_e is the squared momentum flowing through internal line e. The reduction of the full diagrammatic sum to Eq. (62.38) is exactly the statement, established for the bi-adjoint theory in Chapter 61, that with both color orders fixed and equal the surviving graphs are the planar ones with numerator $+1$; we import it rather than re-deriving the color algebra here.

It remains to name the X_e uniformly. Take all external momenta outgoing, $\sum_{i=1}^{n} p_i = 0$, and massless, $p_i^2 = 0$, with Mandelstam invariants $s_{ij} = (p_i + p_j)^2 = 2\, p_i \cdot p_j$ in the mostly-minus metric (Chapter A). Draw the ordering as a convex n-gon with vertices labeled $1, \ldots, n$ and the edge between vertices i and $i{+}1$ carrying the external momentum p_i. A planar internal line of a trivalent tree is the same datum as a *diagonal* of this n-gon: cutting the tree on that line splits the external legs into two consecutive arcs, and the diagonal separates the corresponding vertices.

Definition 62.11 (Planar kinematic variables)**.** For $1 \le i < j \le n$ let the *planar variable* $X_{i,j}$ be the squared sum of the momenta on one arc cut off by the diagonal (i, j),

$$X_{i,j} \;=\; (p_i + p_{i+1} + \cdots + p_{j-1})^2. \tag{62.39}$$

Boundary cases reduce to edges: $X_{i,i+1} = p_i^2 = 0$ and $X_{1,n} = (p_1 + \cdots + p_{n-1})^2 = p_n^2 = 0$. The remaining $X_{i,j}$ with $2 \le j - i \le n - 2$ are the $\frac{n(n-3)}{2}$ genuine diagonals, the planar propagator invariants.

With this naming, the internal line of a planar tree corresponding to diagonal (i, j) carries propagator $1/X_{i,j}$, and Eq. (62.38) becomes a sum over triangulations of the n-gon. This is the combinatorial fact we now isolate, because it is what makes Eq. (62.38) a statement about a polytope.

62.2.2 The associahedron and the diagram ↔ face dictionary

A trivalent (cubic) tree with n external legs has $n-2$ vertices and $n-3$ internal lines. Under the dictionary above, its $n-3$ internal lines are $n-3$ pairwise non-crossing diagonals of the n-gon — that is, a *triangulation* of the n-gon into $n-2$ triangles. Conversely every triangulation, read as a set of $n-3$ non-crossing diagonals, is dual to a unique planar trivalent tree (put one tree vertex in each triangle and one tree edge across each diagonal). The trees summed in Eq. (62.38) are therefore in bijection with the triangulations of the n-gon, and their number is the Catalan number $C_{n-2} = \frac{1}{n-1}\binom{2n-4}{n-2}$ ($C_2 = 2$ for $n = 4$, $C_3 = 5$ for $n = 5$).

These triangulations are the vertices of a polytope.

Definition 62.12 (Associahedron)**.** The *associahedron* K_{n-3} is the $(n-3)$-dimensional convex polytope whose face lattice is the set of collections of pairwise non-crossing diagonals of a convex n-gon, ordered by reverse inclusion. Concretely, a face of codimension d is a set of d mutually non-crossing diagonals (a partial triangulation with d cuts); a facet ($d = 1$) is a single diagonal; a vertex ($d = n-3$) is a full triangulation.

That such a polytope exists — that these combinatorial data really are the face lattice of a convex body of dimension $n-3$ — is the content of the next subsection, where we build it by inequalities. Granting existence, the dictionary we need is immediate.

Theorem 62.13 (Faces ↔ planar diagrams)**.** *There is an inclusion-reversing bijection between the faces of K_{n-3} and the planar trivalent-or-degenerate trees of the bi-adjoint n-point amplitude:*

- *vertices of K_{n-3} ↔ planar trivalent trees (the terms of Eq. (62.38));*
- *facets of K_{n-3} ↔ single planar propagators $X_{i,j}$ (a facet is the locus where one channel goes on shell);*

- *a codimension-d face $\leftrightarrow$ a planar tree with $n-3-d$ internal lines, i.e. a diagram with d propagators collapsed to contact vertices.*

In particular the codimension-d faces of K_{n-3} are products of lower associahedra: collapsing d compatible diagonals factorizes the n-gon along those diagonals into sub-polygons, and the face is the product of their associahedra.

Proof. The first three statements are the bijection between non-crossing diagonal sets and faces of Theorem 62.12, transported through the diagonal $\leftrightarrow$ propagator and triangulation $\leftrightarrow$ tree dualities of the opening paragraph. For the factorization clause, fix one diagonal (i,j); it partitions the n-gon into two sub-polygons sharing the edge (i,j), with $j-i+1$ and $n-(j-i)+1$ vertices respectively. A diagonal of the n-gon is non-crossing with (i,j) iff it lies entirely within one sub-polygon, so the partial triangulations refining the single cut (i,j) are exactly pairs (triangulation of left sub-polygon, triangulation of right sub-polygon). The face lattice below the facet (i,j) is therefore the product of the two sub-polygon face lattices, i.e. the facet is $K_a \times K_b$ with $a+b=n-4$. Iterating over d compatible diagonals gives the general claim. □

The factorization clause is the geometric germ of unitarity: the facet $X_{i,j}=0$, where the propagator $1/X_{i,j}$ blows up, is literally the product of the two lower amplitudes' geometries, glued on the channel (i,j). We will see this become the residue check of Theorem 62.18. First we must build the polytope inside Mandelstam space, for only then does "the canonical form" of K_{n-3} acquire concrete coordinates and become equal to Eq. (62.38).

62.2.3 The ABHY embedding: carving the associahedron out of Mandelstam space

The planar variables $X_{i,j}$ are not independent: they are quadratic functions of the p_i, and a counting of the kinematic data shows the planar variables span a space of dimension only $n-3$ once momentum conservation and masslessness are imposed — the same as $\dim K_{n-3}$. The ABHY construction makes this precise and, simultaneously, positive. The key is a four-term combination of planar variables that collapses to a single Mandelstam.

Lemma 62.14 (The c-identity)**.** *For all admissible i,j,*

$$c_{i,j} \;\equiv\; X_{i,j}+X_{i+1,j+1}-X_{i,j+1}-X_{i+1,j} \;=\; -\,s_{ij} \;=\; -2\,p_i\cdot p_j. \tag{62.40}$$

Proof. Write $P \equiv p_{i+1}+\cdots+p_{j-1}$ for the momenta strictly between i and j. From Eq. (62.39),

$$X_{i,j}=(p_i{+}P)^2,\quad X_{i+1,j+1}=(P{+}p_j)^2,\quad X_{i,j+1}=(p_i{+}P{+}p_j)^2,\quad X_{i+1,j}=P^2. \tag{62.41}$$

Using $p_i^2 = p_j^2 = 0$ and expanding,

$$X_{i,j} = P^2 + 2\,p_i{\cdot}P, \qquad X_{i+1,j+1} = P^2 + 2\,P{\cdot}p_j,$$
$$X_{i,j+1} = P^2 + 2\,p_i{\cdot}P + 2\,P{\cdot}p_j + 2\,p_i{\cdot}p_j, \qquad X_{i+1,j} = P^2. \tag{62.42}$$

Substituting into Eq. (62.40), every P^2 and every mixed $p \cdot P$ term cancels, leaving $c_{i,j} = -2\,p_i \cdot p_j = -s_{ij}$. □

Definition 62.15 (ABHY constraints and the kinematic associahedron)**.** Fix positive constants $c_{i,j} > 0$ for every non-adjacent pair $1 \le i < j \le n-1$ with $j - i \ge 2$. The *ABHY subspace* $\mathcal{H}_n \subset \{X_{i,j}\}$ is the affine subspace on which

$$X_{i,j}+X_{i+1,j+1}-X_{i,j+1}-X_{i+1,j} \;=\; c_{i,j} \qquad (1 \le i < j \le n-1,\; j-i \ge 2), \tag{62.43}$$

i.e. on which the non-adjacent Mandelstams take the negative constant values $s_{ij} = -c_{i,j} < 0$. The *kinematic associahedron* $\mathcal{A}_n$ is the region of $\mathcal{H}_n$ on which *all* planar variables are nonnegative,

$$\mathcal{A}_n \;=\; \{\, X_{i,j} \ge 0 \text{ for all diagonals} \,\} \cap \mathcal{H}_n. \tag{62.44}$$

The constraints Eq. (62.43) number $(n-2)(n-3)/2$ (the non-adjacent pairs among $1, \dots, n-1$), so

$$\dim \mathcal{H}_n \;=\; \frac{n(n-3)}{2} - \frac{(n-2)(n-3)}{2} \;=\; \frac{n-3}{2}\big(n-(n-2)\big) \;=\; n-3, \tag{62.45}$$

matching $\dim K_{n-3}$. The constants $c_{i,j} > 0$ are pure gauge on the geometry: changing them deforms $\mathcal{A}_n$ continuously without changing its combinatorial type, exactly as choosing different facet offsets moves a polytope without changing which facets meet. We now state the embedding theorem; its full proof is an induction on n built from the factorization of Theorem 62.13, and we give the inductive mechanism in general and the explicit realization at $n = 4, 5$.

Theorem 62.16 (ABHY realization)**.** *For any choice of positive constants $c_{i,j}$, the region $\mathcal{A}_n$ of Theorem 62.15 is a convex polytope combinatorially isomorphic to the associahedron K_{n-3}. Its facets are exactly the loci $X_{i,j} = 0$, one for each diagonal (i,j); the facet $X_{i,j} = 0$ is itself (a translate of) $\mathcal{A}_a \times \mathcal{A}_b$ with $a+b = n-4$, realizing the factorization of Theorem 62.13 as an honest geometric product.*

Proof (structure and inductive step). Convexity is immediate: $\mathcal{A}_n$ is the intersection of the affine space $\mathcal{H}_n$ with the half-spaces $X_{i,j} \ge 0$, each a linear inequality once the X are solved on $\mathcal{H}_n$ (the c-identity Eq. (62.40) is linear in the X, so Eq. (62.43) is a linear system and every $X_{i,j}$ restricts to an affine function of $n-3$ free coordinates).

The substance is that the bounded region cut out has precisely the associahedron's facet incidences, i.e. that each $X_{i,j} = 0$ does meet $\mathcal{A}_n$ in a facet, and two of them, $X_{i,j} = 0$ and $X_{k,l} = 0$, share a codimension-two face iff the diagonals (i, j) and (k, l) are non-crossing. We argue this by induction on n, the base cases $n = 4$ (a segment) and $n = 5$ (a pentagon) being verified explicitly below.

Consider one facet candidate $X_{i,j} = 0$. Setting $X_{i,j} = 0$ in Eq. (62.43) and using Theorem 62.14, the constraints split: those whose four planar variables lie among the diagonals of the left sub-polygon (vertices $i, \ldots, j$) become the ABHY constraints of that sub-polygon, with the *same* constants c; likewise on the right (vertices $j, \ldots, i$ cyclically). The only constraints mixing the two sides are those containing $X_{i,j}$ itself, and on $X_{i,j} = 0$ they reduce to relations expressing the "would-be crossing" variables in terms of the constants, forcing every diagonal that *crosses* (i, j) to be a fixed positive constant plus a sum of the two sides' variables — in particular strictly positive on the sub-polytope, hence never vanishing there. Therefore on $X_{i,j} = 0$ the only remaining facet inequalities are the diagonals lying within one sub-polygon, and the section is exactly $\mathcal{A}_a \times \mathcal{A}_b$ $(a+b = n-4)$, which by the inductive hypothesis is a product of associahedra of total dimension $n-4$, i.e. a genuine facet. Crossing diagonals do not bound this facet, so two facets meet iff their diagonals are non-crossing. This is the facet incidence of K_{n-3}, and a convex polytope is determined by its facet incidences up to combinatorial isomorphism; hence $\mathcal{A}_n \cong K_{n-3}$. Boundedness follows because the facet functions include, for each direction, both an "upper" and a "lower" planar variable (as the explicit $n = 5$ system below exhibits), pinning the region. □

Physical Insight

The single design choice that makes this work is Eq. (62.43): *fix the non-adjacent Mandelstams to negative constants.* Physically, $s_{ij} = -c_{ij} < 0$ is a Euclidean (spacelike) configuration in which no non-adjacent channel can go on shell; the only invariants left free are the *planar* ones $X_{i,j}$, and demanding them positive is demanding that every planar channel sit on the physical (timelike, resonant) side. The associahedron is thus the region of kinematic space where physics is "maximally on shell in the planar channels and maximally off shell in the rest" — and that region's boundaries are precisely the planar propagator poles. Locality is being built into the shape of a polytope.

62.2.4 The canonical form is the amplitude

We can now state the result that makes "amplitude = volume" a theorem rather than a slogan.

Theorem 62.17 (Canonical form = bi-adjoint amplitude)**.** *Let $\Omega(\mathcal{A}_n)$ be the canonical form of the kinematic associahedron (Theorem 62.3), and let $X_1, \dots, X_{n-3}$ be any $n-3$ planar variables forming an affine coordinate system on $\mathcal{H}_n$. Then*

$$\Omega(\mathcal{A}_n) \;=\; m_n \; \mathrm{d}X_1 \wedge \cdots \wedge \mathrm{d}X_{n-3}, \tag{62.46}$$

where m_n is the bi-adjoint partial amplitude Eq. (62.38). Equivalently, the rational function multiplying the top-form built from the planar coordinates is exactly the sum over planar trees of products of propagators.

Proof. By the polygon/polytope assembly of Theorem 62.9 (its higher-dimensional form: the canonical form of a simple polytope is the sum over vertices of the local dlog form),

$$\Omega(\mathcal{A}_n) \;=\; \sum_{\text{vertices } V} \operatorname{sgn}(V) \bigwedge_{a \in V} \operatorname{dlog} X_a, \tag{62.47}$$

where the wedge at a vertex V runs over the $n-3$ facets $X_a = 0$ meeting there. By Theorem 62.16 a vertex is a full triangulation, i.e. a set of $n-3$ pairwise non-crossing diagonals — exactly a planar tree T of Eq. (62.38), with the facets $X_a = 0$ being its internal lines. Expanding each dlog,

$$\bigwedge_{a \in V} \operatorname{dlog} X_a = \frac{1}{\prod_{a \in V} X_a} \bigwedge_{a \in V} \mathrm{d}X_a = \frac{\det J_V}{\prod_{a \in V} X_a} \, \mathrm{d}X_1 \wedge \cdots \wedge \mathrm{d}X_{n-3}, \tag{62.48}$$

where J_V is the Jacobian matrix of the facet functions $\{X_a\}_{a \in V}$ with respect to the chosen coordinates $\{X_1, \dots, X_{n-3}\}$. The product $\prod_{a \in V} X_a$ is precisely the product of the propagators of the tree T, so its reciprocal is the summand of Eq. (62.38). It remains only that $\operatorname{sgn}(V) \det J_V = +1$ for every vertex. This is the *unimodularity* of the ABHY constraints: solving Eq. (62.43) expresses each $X_{i,j}$ as an *integer* affine combination, with coefficients in $\{0, \pm 1\}$, of the coordinates $X_1, \dots, X_{n-3}$ (each constraint involves four X's with coefficients ± 1, so back-substitution never produces a denominator and never a coefficient outside $\{0, \pm 1\}$ for the facet normals meeting at a vertex). At any vertex the $n-3$ facet normals are linearly independent integer vectors bounding a simple cone, and for such an ABHY vertex the determinant is ± 1; the orientation sign $\operatorname{sgn}(V)$ supplied by the canonical-form assembly is exactly the one that makes the product $+1$ (it is fixed by requiring unit residues with the orientation in which $\mathcal{A}_n$ has positive volume). Hence every vertex contributes $+\dfrac{1}{\prod_{a \in V} X_a} \, \mathrm{d}X_1 \wedge \cdots \wedge \mathrm{d}X_{n-3}$, and summing over vertices reproduces Eq. (62.38) times the top-form. We verify the unimodularity and the signs by explicit computation at $n = 5$ in Theorem 62.18, where all five Jacobians are $+1$. □

Physical Insight

The identity Eq. (62.46) is the rigorous content of "amplitude = volume." The canonical form is the (dual) volume form of the polytope; its single rational coefficient in planar coordinates is m_n. There is nothing to conjecture and nothing to take on faith: Eqs. (62.47) and (62.48) are an exact finite computation, vertex by vertex, and each vertex is one Feynman diagram. The amplitude's two defining physical properties are now geometric: its *poles* are the facets $X_{i,j} = 0$ (locality — singularities only on planar channels, Theorem 62.16); its *residues* are the canonical forms of those facets, which by Theorem 62.13 are products of lower associahedra, i.e. products of lower amplitudes (unitarity). We make both explicit at $n = 5$.

62.2.5 Warm-up: $n = 4$, the segment

For $n = 4$ the planar variables are the two diagonals of a square, $X_{1,3} = s_{12}$ and $X_{2,4} = s_{23}$, with $X_{1,4} = p_4^2 = 0$ and $X_{2,3} = p_2^2 = 0$. There is one non-adjacent pair, $(i, j) = (1, 3)$, so one constraint:

$$c_{1,3} = X_{1,3} + X_{2,4} - X_{1,4} - X_{2,3} = X_{1,3} + X_{2,4} = s_{12} + s_{23} \;=\; \text{const} > 0. \tag{62.49}$$

This is the familiar massless four-point relation $s+t+u = 0$ with the third channel held off shell: $s_{12} + s_{23} = -s_{13} = c_{1,3}$. The ABHY subspace is one-dimensional; take $X_{1,3}$ as coordinate, $X_{2,4} = c_{1,3} - X_{1,3}$. The region $X_{1,3} \geq 0,\ X_{2,4} \geq 0$ is the segment $X_{1,3} \in [0, c_{1,3}]$ — the associahedron K_1. Its two endpoints (facets) are the two planar channels $X_{1,3} = 0$ and $X_{2,4} = 0$, dual to the two planar Feynman diagrams (s-channel and t-channel exchange). The canonical form of a segment $[0, c]$ in coordinate x is (Section 62.1)

$$\Omega(K_1) = \operatorname{dlog} \frac{x}{c-x} = \Big(\frac{1}{x} + \frac{1}{c-x}\Big)\mathrm{d}x = \Big(\frac{1}{X_{1,3}} + \frac{1}{X_{2,4}}\Big)\mathrm{d}X_{1,3} = \Big(\frac{1}{s_{12}} + \frac{1}{s_{23}}\Big)\mathrm{d}X_{1,3}, \tag{62.50}$$

and the coefficient is exactly $m_4 = 1/s_{12} + 1/s_{23}$, the two-diagram four-point amplitude. The base case is verified; the structure of Theorem 62.17 is already visible. We now do the case the section was built for.

62.2.6 The five-point associahedron is the pentagon

Worked Example 62.18 (The $n = 5$ associahedron, end to end)**.** We carry the five-point computation completely: facet equations, the canonical form Ω, the change to planar Mandelstams, recovery of all five poles, and the residue check that factorizes locality and unitarity into lower amplitudes.

Planar variables. The pentagon has five diagonals, hence five planar variables. Using Theorem 62.11 and momentum conservation $p_1 + \cdots + p_5 = 0$,

$$\begin{aligned} &X_{1,3} = (p_1+p_2)^2 = s_{12}, \qquad X_{2,4} = (p_2+p_3)^2 = s_{23}, \qquad X_{3,5} = (p_3+p_4)^2 = s_{34}, \\ &X_{1,4} = (p_1+p_2+p_3)^2 = s_{45}, \quad X_{2,5} = (p_2+p_3+p_4)^2 = s_{51}. \end{aligned} \tag{62.51}$$

(The last two used $(p_1+p_2+p_3) = -(p_4+p_5)$ and $(p_2+p_3+p_4) = -(p_5+p_1)$.) The five planar variables are exactly the five cyclically consecutive two-particle invariants $s_{12}, s_{23}, s_{34}, s_{45}, s_{51}$ — the five physical planar channels of the ordering.

Facet equations. The non-adjacent pairs among $\{1,2,3,4\}$ with $j-i \geq 2$ are $(1,3),(1,4),(2,4)$: three ABHY constraints. With all edge variables vanishing ($X_{1,2} = \cdots = X_{5,1} = 0$), Eq. (62.43) reads

$$(1,3): \quad X_{1,3} + X_{2,4} - X_{1,4} = c_{1,3}, \tag{62.52}$$

$$(1,4): \quad X_{1,4} + X_{2,5} - X_{2,4} = c_{1,4}, \tag{62.53}$$

$$(2,4): \quad X_{2,4} + X_{3,5} - X_{2,5} = c_{2,4}. \tag{62.54}$$

Choose the two free coordinates to be the "fan from vertex 1" variables $X_{1,3}$ and $X_{1,4}$ (write $x = X_{1,3}$, $y = X_{1,4}$). Solving Eqs. (62.52) to (62.54) in turn,

$$\begin{aligned} &X_{1,3} = x, && X_{1,4} = y, \\ &X_{2,4} = c_{1,3} - x + y, && X_{2,5} = (c_{1,3}+c_{1,4}) - x, \\ &X_{3,5} = (c_{1,4}+c_{2,4}) - y. \end{aligned} \tag{62.55}$$

Every planar variable is an integer affine function of (x,y) with coefficients in $\{0,\pm 1\}$: this is the unimodularity invoked in Theorem 62.17. The five facet inequalities $X_{i,j} \geq 0$ are

$$x \geq 0, \quad y \geq 0, \quad c_{1,3} - x + y \geq 0, \quad (c_{1,3}+c_{1,4}) - x \geq 0, \quad (c_{1,4}+c_{2,4}) - y \geq 0, \tag{62.56}$$

five half-planes whose intersection, for any positive constants, is a pentagon. Taking $c_{1,3} = c_{1,4} = c_{2,4} = 1$ to draw it, the vertices are

$$(0,0),\ (1,0),\ (2,1),\ (2,2),\ (0,2), \tag{62.57}$$

shown in Fig. 62.2. This is, on the nose, the pentagon of Section 62.1; the associahedron K_2 has been realized in Mandelstam space.

Vertices are triangulations are diagrams. Each vertex of Eq. (62.57) is the meeting of two facets, i.e. a pair of non-crossing diagonals — a triangulation — and hence a planar trivalent tree with two propagators:

vertex	facets	triangulation (diagonals)	diagram term
$(0,0)$	$X_{1,3}=X_{1,4}=0$	$\{(1,3),(1,4)\}$	$1/(s_{12}\,s_{45})$
$(1,0)$	$X_{1,4}=X_{2,4}=0$	$\{(1,4),(2,4)\}$	$1/(s_{45}\,s_{23})$
$(2,1)$	$X_{2,4}=X_{2,5}=0$	$\{(2,4),(2,5)\}$	$1/(s_{23}\,s_{51})$
$(2,2)$	$X_{2,5}=X_{3,5}=0$	$\{(2,5),(3,5)\}$	$1/(s_{51}\,s_{34})$
$(0,2)$	$X_{3,5}=X_{1,3}=0$	$\{(3,5),(1,3)\}$	$1/(s_{34}\,s_{12})$

The five vertices are the $C_3 = 5$ triangulations of the pentagon, each a pair of diagonals sharing a vertex of the 5-gon (a "fan"), and they exhaust the five planar five-point Feynman diagrams.

The canonical form. Walking the boundary counterclockwise from $(0,0)$, the edges carry, in order, the vanishing variables $X_{1,4}, X_{2,4}, X_{2,5}, X_{3,5}, X_{1,3}$. The gradients of the facet functions in the (x,y) plane are

$$\begin{aligned} &\nabla X_{1,3}=(1,0), \quad \nabla X_{1,4}=(0,1), \quad \nabla X_{2,4}=(-1,1),\\ &\nabla X_{2,5}=(-1,0), \quad \nabla X_{3,5}=(0,-1). \end{aligned} \tag{62.58}$$

By Eqs. (62.47) and (62.48) the canonical form is the sum over the five vertices of $\mathrm{dlog}\, X_a \wedge \mathrm{dlog}\, X_b$, with (a,b) the two facets at the vertex taken in counterclockwise order. Each Jacobian $\det[\nabla X_a; \nabla X_b]$ evaluates, from Eq. (62.58), to $+1$:

$$\begin{aligned} &(X_{1,3},X_{1,4}):\det\left(\begin{smallmatrix}1&0\\0&1\end{smallmatrix}\right)=1, \quad (X_{1,4},X_{2,4}):\det\left(\begin{smallmatrix}0&1\\-1&1\end{smallmatrix}\right)=1, \quad (X_{2,4},X_{2,5}):\det\left(\begin{smallmatrix}-1&1\\-1&0\end{smallmatrix}\right)=1,\\ &(X_{2,5},X_{3,5}):\det\left(\begin{smallmatrix}-1&0\\0&-1\end{smallmatrix}\right)=1, \quad (X_{3,5},X_{1,3}):\det\left(\begin{smallmatrix}0&-1\\1&0\end{smallmatrix}\right)=1. \end{aligned} \tag{62.59}$$

All five are $+1$: the unimodularity and sign claims of Theorem 62.17 are verified by hand. Therefore

$$\Omega(\mathcal{A}_5)=\Big[\frac{1}{X_{1,3}X_{1,4}}+\frac{1}{X_{1,4}X_{2,4}}+\frac{1}{X_{2,4}X_{2,5}}+\frac{1}{X_{2,5}X_{3,5}}+\frac{1}{X_{3,5}X_{1,3}}\Big]\,\mathrm{d}x\wedge\mathrm{d}y. \tag{62.60}$$

Change to planar Mandelstams. Substituting Eq. (62.51) into the bracket of Eq. (62.60),

$$m_5=\frac{1}{s_{12}\,s_{45}}+\frac{1}{s_{45}\,s_{23}}+\frac{1}{s_{23}\,s_{51}}+\frac{1}{s_{51}\,s_{34}}+\frac{1}{s_{34}\,s_{12}}, \tag{62.61}$$

which is the cyclic orbit of $1/(s_{12}s_{34})$ — regrouping the five terms,

$$m_5=\frac{1}{s_{12}s_{34}}+\frac{1}{s_{23}s_{45}}+\frac{1}{s_{34}s_{51}}+\frac{1}{s_{45}s_{12}}+\frac{1}{s_{51}s_{23}}, \tag{62.62}$$

exactly the five-term, five-pole color-ordered bi-adjoint amplitude obtained by summing the five planar Feynman diagrams via Eq. (62.38). The canonical form of the kinematic pentagon *is* the amplitude.

Residue check: locality and unitarity. Take the channel $s_{12} = X_{1,3} \to 0$, the facet $x = 0$ (the edge from $(0,0)$ to $(0,2)$). By the boundary dictionary Eq. (62.5), the residue of $\Omega(\mathcal{A}_5)$ on this facet is the canonical form of the facet, and the facet is the segment from $X_{1,4} = 0$ (vertex $(0,0)$) to $X_{3,5} = 0$ (vertex $(0,2)$). Directly from Eq. (62.61), the terms singular at $s_{12} = 0$ are the two containing $X_{1,3}$,

$$m_5\Big|_{\text{poles in } s_{12}} = \frac{1}{s_{12}}\Big(\frac{1}{s_{45}} + \frac{1}{s_{34}}\Big) + \text{regular}, \qquad \text{Res}_{s_{12}\to 0}\, m_5 = \frac{1}{s_{45}} + \frac{1}{s_{34}}. \tag{62.63}$$

Now identify the factorized kinematics. On $s_{12} \to 0$ the legs $1, 2$ fuse into an on-shell intermediate $P = p_1 + p_2$ ($P^2 = s_{12} \to 0$), splitting the five-point object into a three-point amplitude on $(1, 2, P)$ and a four-point amplitude on $(-P, 3, 4, 5)$. The bi-adjoint three-point amplitude is the bare vertex, $m_3 = 1$ (no propagator). The four-point factor is the amplitude of Section 62.2.5 for the ordering $(P, 3, 4, 5)$,

$$m_4(P,3,4,5) = \frac{1}{s_{P3}} + \frac{1}{s_{34}}, \qquad s_{P3} = (p_1 + p_2 + p_3)^2 = s_{45}, \tag{62.64}$$

so $m_4(P,3,4,5) = 1/s_{45} + 1/s_{34}$. Hence

$$\text{Res}_{s_{12}\to 0}\, m_5 \;=\; m_3 \times m_4(P,3,4,5) \;=\; \frac{1}{s_{45}} + \frac{1}{s_{34}}, \tag{62.65}$$

in agreement with Eq. (62.63). The amplitude has a pole only where a *planar* channel goes on shell (locality), and the residue there factorizes into the product of the two lower on-shell amplitudes glued on that channel (unitarity) — exactly the BCFW factorization of Theorem 59.23, here for the scalar whose three-point amplitude is 1. Geometrically, Eq. (62.65) is nothing but the statement from Theorem 62.16 that the facet $X_{1,3} = 0$ of the pentagon is the product $\mathcal{A}_3 \times \mathcal{A}_4$ (a point times a segment), whose canonical form is $1 \times m_4$. The same computation on each of the other four facets recovers, by cyclic symmetry, the four-point amplitude in the corresponding channel. Locality and unitarity have emerged from the shape of a polygon.

62.2.7 What has been established, and the obstruction ahead

We have made "amplitude = volume" a theorem for an honest physical amplitude. The tree color-ordered bi-adjoint amplitude m_n is the canonical form of the kinematic associahedron $\mathcal{A}_n \subset$ Mandelstam space (Theorem 62.17); its poles are the polytope's facets (locality), and its residues are the canonical forms of those facets, equal to products of lower amplitudes (unitarity, Theorem 62.13 and Eq. (62.65)). Nothing was conjectural, nothing was imported on faith, and the five-point case was carried complete, from the facet inequalities Eq. (62.56) to the residue Eq. (62.65).

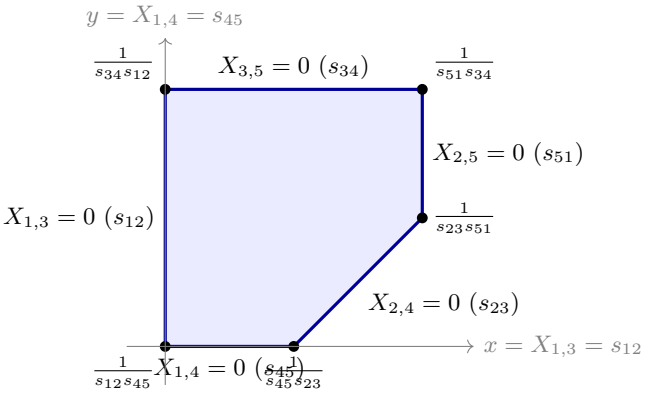


Figure 62.2: The kinematic associahedron $\mathcal{A}_5 = K_2$ realized in Mandelstam space, with $c_{1,3} = c_{1,4} = c_{2,4} = 1$ (Eq. (62.57)). Each edge is a facet $X_{i,j} = 0$, a planar propagator pole; each vertex is a triangulation of the pentagon, i.e. a planar five-point Feynman diagram contributing its product of two propagators. Summing the vertex contributions Eq. (62.60) gives the canonical form, whose coefficient is the amplitude m_5 of Eq. (62.62).

The construction also exposes its own limit, which is the spur to everything that follows. The bi-adjoint scalar has *no helicity*: its only data are the n legs and their cyclic order, and the associahedron knows exactly this much — it is a single polytope per $(n, \text{ordering})$, blind to any further quantum number. A gauge-theory amplitude, by contrast, is graded by the number of negative-helicity gluons, the integer k of the N^{k-2}MHV classification (Chapter 59): the same n legs support a whole tower of inequivalent amplitudes, and a geometry that sees only momenta and ordering cannot tell them apart. To make a positive geometry sensitive to helicity we must enlarge the kinematic data from a point in Mandelstam space to a k-plane in n dimensions — and the natural home for such planes, with the positivity that a canonical form requires, is the totally nonnegative Grassmannian. That is the object we build next.

62.3 The positive Grassmannian

The associahedron of Section 62.2 realized a complete tree-level amplitude as a canonical form, but the amplitude it captured was the one with no spin to speak of: the color-ordered amplitude of bi-adjoint ϕ^3 theory, a function of Mandelstam invariants and nothing else. Gluons and photons carry helicity, and the central lesson of Chapters 58 and 59 was that their amplitudes organize not by a single number but by a *grading*. An n-point gluon amplitude splits into sectors labelled by the integer k, the number of negative-helicity legs (more precisely the MHV degree k, with the maximally-helicity-violating sector at

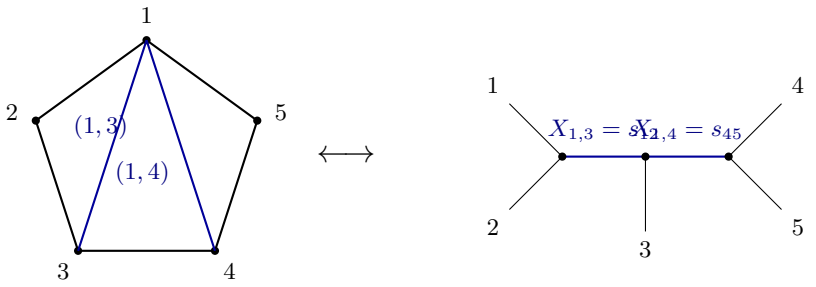

Figure 62.3: The triangulation ↔ planar-tree duality underlying Theorem 62.13, at the vertex $(0,0)$ of Fig. 62.2. The pentagon's triangulation $\{(1,3),(1,4)\}$ (left) is dual to the planar trivalent tree (right): one tree vertex per triangle, one internal line per diagonal. The two diagonals are the two propagators $1/(s_{12}s_{45})$ of this Feynman diagram.

$k = 2$); the Parke–Taylor formula Eq. (59.55) is the entirety of the $k = 2$ sector, and the BCFW recursion of Theorem 59.23 builds the higher-k sectors from it. A geometry built in Mandelstam space alone is blind to this grading: it has no slot for k. What we need is a positive geometry whose very *dimension and combinatorial type are controlled by* k, so that helicity-graded data has a natural home. That object is the totally nonnegative Grassmannian $\mathrm{Gr}_{\geq 0}(k,n)$. This section introduces it from the ground up, proves its structure on the smallest cases where the combinatorics can be made completely explicit, and writes down the canonical forms that the next section will show BCFW recursion triangulates. Throughout, the integer k of $\mathrm{Gr}(k,n)$ *is* the MHV degree of Theorem 58.2; this is the thread that ties the abstract geometry to the gluon and photon amplitudes of Yang–Mills theory and QED.

62.3.1 The Grassmannian and its Plücker coordinates

Definition 62.19 (Grassmannian)**.** For $0 \leq k \leq n$, the *Grassmannian* $\mathrm{Gr}(k,n)$ is the set of k-dimensional linear subspaces of $\mathbb{F}^n$, where $\mathbb{F} = \mathbb{R}$ or $\mathbb{C}$. A k-plane $V \subset \mathbb{F}^n$ is represented by a $k \times n$ matrix C of rank k whose rows span V; two matrices represent the same plane if and only if they differ by left multiplication by an element of $\mathrm{GL}(()k,\mathbb{F})$, the change of basis within V. Thus

$$\mathrm{Gr}(k,n) \;=\; \{\, C \in \mathbb{F}^{k\times n} : \operatorname{rank} C = k \,\}/\mathrm{GL}(()k,\mathbb{F}). \tag{62.66}$$

The dimension follows immediately. The full-rank $k \times n$ matrices form an open dense subset of $\mathbb{F}^{k\times n}$, of dimension kn; the group $\mathrm{GL}(()k,\mathbb{F})$ acting freely on the left has dimension k^2; the quotient therefore has dimension

$$\dim \mathrm{Gr}(k,n) = kn - k^2 = k(n-k). \tag{62.67}$$

This number will be the dimension of the top positroid cell, and through it the dimension count of helicity-graded data.

To coordinatize $\mathrm{Gr}(k,n)$ invariantly we use the maximal minors of C. For an ordered k-element subset $I=\{i_1<i_2<\cdots<i_k\}\subset\{1,\dots,n\}$, write

$$p_I(C) \;=\; \det(\text{columns } i_1,\dots,i_k \text{ of } C), \tag{62.68}$$

the *Plücker coordinate* indexed by I. Under a change of basis $C\mapsto gC$ with $g\in \mathrm{GL}(()k)$, every maximal minor scales by the common factor $\det g$:

$$p_I(gC)=\det(g)\,p_I(C). \tag{62.69}$$

Hence the tuple $\big(p_I\big)_{|I|=k}$ is well defined up to overall scale, i.e. as a point of the projective space $\mathbb{P}\big(\wedge^k\mathbb{F}^n\big)=\mathbb{P}^{\binom{n}{k}-1}$. This is the *Plücker embedding*

$$\mathrm{Gr}(k,n)\hookrightarrow\mathbb{P}^{\binom{n}{k}-1},\qquad V\mapsto[p_I(C)]_{|I|=k}. \tag{62.70}$$

It is injective: a k-plane is recovered from its Plücker coordinates as the common kernel of the linear functionals they define, so distinct planes give distinct projective points. The image is not all of projective space; it is the zero locus of a system of quadrics, the *Plücker relations*.

Proposition 62.20 (Grassmann–Plücker relations)**.** *A point $[p_I]\in\mathbb{P}^{\binom{n}{k}-1}$ lies in the image Eq. (62.70) if and only if the Plücker coordinates satisfy, for every pair of index sets $\{i_1,\dots,i_{k-1}\}$ and $\{j_1,\dots,j_{k+1}\}$,*

$$\sum_{a=1}^{k+1}(-1)^a\,p_{i_1\cdots i_{k-1}j_a}\,p_{j_1\cdots\widehat{j_a}\cdots j_{k+1}}=0, \tag{62.71}$$

where $\widehat{j_a}$ denotes omission of j_a.

We will not need the relations in this generality; what we will need, repeatedly, is the single relation governing $\mathrm{Gr}(2,4)$, and that we prove in full because total positivity will turn it into a structural statement.

Lemma 62.21 (The $\mathrm{Gr}(2,4)$ Plücker relation)**.** *For any 2×4 matrix C with columns $c_1,c_2,c_3,c_4\in\mathbb{F}^2$, the maximal minors satisfy*

$$p_{12}\,p_{34}\;-\;p_{13}\,p_{24}\;+\;p_{14}\,p_{23}\;=\;0. \tag{62.72}$$

Proof. Write $\langle u,v\rangle:=u_1v_2-u_2v_1=\det[\,u\;v\,]$ for $u,v\in\mathbb{F}^2$, so that $p_{ij}=\langle c_i,c_j\rangle$. Fix $a,b\in\mathbb{F}^2$ and consider the function

$$B_{a,b}(c,d):=\langle a,b\rangle\langle c,d\rangle-\langle a,c\rangle\langle b,d\rangle+\langle a,d\rangle\langle b,c\rangle. \tag{62.73}$$

As a function of the pair (c,d) it is bilinear, and it is antisymmetric: interchanging $c \leftrightarrow d$ sends each term to minus the corresponding term of $B_{a,b}(c,d)$ (using $\langle d,c\rangle = -\langle c,d\rangle$), so $B_{a,b}(d,c) = -B_{a,b}(c,d)$. But on the two-dimensional space $\mathbb{F}^2$ every alternating bilinear form is a scalar multiple of the determinant $\langle\,\cdot\,,\,\cdot\,\rangle$; hence $B_{a,b}(c,d) = f(a,b)\,\langle c,d\rangle$ for some scalar $f(a,b)$. Evaluating at $c=a,\ d=b$ gives

$$B_{a,b}(a,b) = \langle a,b\rangle^2 - \langle a,a\rangle\langle b,b\rangle + \langle a,b\rangle\langle b,a\rangle = \langle a,b\rangle^2 - 0 - \langle a,b\rangle^2 = 0, \quad (62.74)$$

because $\langle a,a\rangle = \langle b,b\rangle = 0$. Since $\langle a,b\rangle$ is not identically zero, $f(a,b) = 0$ identically, so $B_{a,b} \equiv 0$. Setting $(a,b,c,d) = (c_1,c_2,c_3,c_4)$ in Eq. (62.73) is exactly Eq. (62.72). □

62.3.2 Total nonnegativity

So far everything was linear-algebraic and worked over any field. The positivity that singles out the amplitude-relevant region requires $\mathbb{F} = \mathbb{R}$ and a *fixed cyclic order* of the n columns, which physically is the cyclic order of the n external particles in a color-ordered amplitude.

Definition 62.22 (Totally nonnegative and totally positive Grassmannian)**.** A real k-plane $V \in \mathrm{Gr}(k,n)$ is *totally nonnegative* if it admits a representative matrix C all of whose ordered maximal minors are nonnegative, $p_I(C) \geq 0$ for every I. It is *totally positive* if it admits a representative with $p_I(C) > 0$ for every I. The corresponding subsets are

$$\mathrm{Gr}_{\geq 0}(k,n) = \{V : p_I \geq 0\ \forall I\}, \qquad \mathrm{Gr}_{>0}(k,n) = \{V : p_I > 0\ \forall I\}. \quad (62.75)$$

This is well posed despite the gauge freedom and the projective scaling. By Eq. (62.69) a change of basis multiplies all minors by the single number $\det g$; choosing $\det g > 0$ preserves all signs simultaneously, while $\det g < 0$ flips them all. Thus "all minors ≥ 0" is a property of the plane V, not of the representative, once we agree to read it up to a common positive rescaling. The condition does, however, depend on the ordering of the columns: permuting columns permutes and re-signs the p_I, so $\mathrm{Gr}_{\geq 0}(k,n)$ is attached to the chosen cyclic order, precisely as a color-ordered amplitude is attached to the cyclic order of its legs.

The link to helicity is now immediate and is the reason this object enters amplitudes at all. In the spinor-helicity description of Theorem 58.2, an n-point amplitude in the sector of MHV degree k is a function of the $2 \times n$ matrices of angle and square spinors subject to momentum conservation; the data that survives, once little-group and overall scalings are removed, is naturally a point of a $\mathrm{Gr}(k,n)$, with k the count of negative-helicity legs. The MHV sector that the Parke–Taylor formula Eq. (59.55) exhausts is $k=2$, so the geometry relevant to MHV gluon amplitudes is $\mathrm{Gr}_{\geq 0}(2,n)$; we will see its canonical form reproduce the Parke–Taylor denominator below. The grading the associahedron could not see is built into the integer k of the Grassmannian.

62.3.3 The smallest case: $\mathrm{Gr}_{\geq 0}(1,n)$ is the simplex

The case $k=1$ is the one where the abstract definitions collapse onto an object already met in Section 62.1: the projective simplex whose canonical form opened the chapter. Establishing this identification rigorously fixes intuition and verifies, in a case we can see, that the positive-geometry axioms of Theorem 62.3 hold for positroid cells.

A point of $\mathrm{Gr}(1,n)$ is a line through the origin in $\mathbb{R}^n$, represented by a single nonzero row vector $C=(c_1,\dots,c_n)$ modulo overall rescaling: this is exactly projective space $\mathbb{P}^{n-1}$. The maximal minors are now 1×1, so the Plücker coordinates are simply the entries, $p_{\{i\}}=c_i$. The dimension formula Eq. (62.67) gives $\dim \mathrm{Gr}(1,n)=1\cdot(n-1)=n-1$, the dimension of $\mathbb{P}^{n-1}$, as it must.

Proposition 62.23 ($\mathrm{Gr}_{\geq 0}(1,n)$ is the projective simplex)**.** *The totally nonnegative Grassmannian $\mathrm{Gr}_{\geq 0}(1,n)$ is the standard projective simplex*

$$\Delta^{n-1}=\{[c_1:\cdots:c_n]\in\mathbb{P}^{n-1}:\ c_i\geq 0,\ \textstyle\sum_i c_i>0\},\tag{62.76}$$

an $(n-1)$-dimensional simplex with n vertices $e_1,\dots,e_n$ (the coordinate points) and n facets $\{c_i=0\}$. Its canonical form is

$$\Omega(\mathrm{Gr}_{\geq 0}(1,n))=\mathrm{dlog}\,\frac{c_1}{c_n}\wedge\mathrm{dlog}\,\frac{c_2}{c_n}\wedge\cdots\wedge\mathrm{dlog}\,\frac{c_{n-1}}{c_n},\tag{62.77}$$

which in the affine chart $c_n=1$, $x_i=c_i$, reads

$$\Omega=\frac{dx_1\wedge\cdots\wedge dx_{n-1}}{x_1\,x_2\cdots x_{n-1}\,\big(1-\sum_{i=1}^{n-1}x_i\big)},\tag{62.78}$$

the simplex form of Eq. (62.22).

Proof. Since the Plücker coordinates of $\mathrm{Gr}(1,n)$ are the entries c_i, the condition $p_I\geq 0$ for all I is just $c_i\geq 0$ for all i, read projectively up to common positive scale (Theorem 62.22). The set of $[c_1:\cdots:c_n]$ with all $c_i\geq 0$ and not all zero is by definition Eq. (62.76). That this is an $(n-1)$-simplex is standard: it is the projectivization of the closed nonnegative orthant $\mathbb{R}^n_{\geq 0}$, whose extreme rays are the coordinate axes $\mathbb{R}_{\geq 0}e_i$, giving the n vertices $[e_i]$, and whose codimension-one faces are the coordinate hyperplanes $\{c_i=0\}$, giving the n facets. The face $\{c_i=0\}$ is itself the nonnegative orthant of the remaining $n-1$ coordinates, i.e. a $\mathrm{Gr}_{\geq 0}(1,n-1)=\Delta^{n-2}$; the facets are simplices of one lower dimension, the defining recursion of a simplex.

For the canonical form, pass to the affine chart $c_n=1$ with coordinates $x_i=c_i$, $i=1,\dots,n-1$. In this chart the region is the solid simplex $\{x_i\geq 0,\ \sum_i x_i\leq 1\}$, whose n facets are the $n-1$ hyperplanes $x_i=0$ together with $\sum_i x_i=1$ (the image of $c_n=0$, since $c_n=1-\sum_{i<n}c_i$ after rescaling so that $\sum c_i=1$). A positive geometry's canonical form is fixed by the requirements (Theorem 62.3)

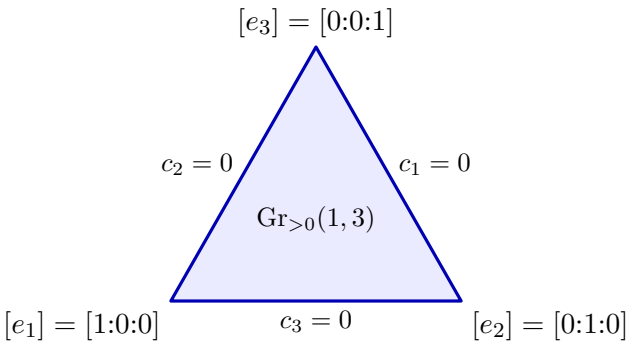

Figure 62.4: $\mathrm{Gr}_{\geq 0}(1,3) = \Delta^2$ is the projective triangle. Its three vertices are the coordinate points $[e_i]$; its three facets are the edges $\{c_i = 0\}$, each a copy of $\mathrm{Gr}_{\geq 0}(1,2) = \Delta^1$; the interior is the totally positive cell $\mathrm{Gr}_{>0}(1,3)$. The canonical form $dx\,dy/[xy(1-x-y)]$ has simple poles exactly on the three edges, and its residue on each edge is the canonical form of that edge.

that it be a top-degree rational form with simple poles exactly on the facets and unit residues recursively giving the lower canonical forms. The unique such form for the solid simplex is Eq. (62.78): it has simple poles on each $x_i = 0$ and on $1 - \sum x_i = 0$, and on no other locus, and a direct residue computation discharges the recursion. Taking the residue at $x_{n-1} = 0$, write $\Omega = \dfrac{dx_{n-1}}{x_{n-1}} \wedge \omega$ with

$$\omega = \frac{dx_1 \wedge \cdots \wedge dx_{n-2}}{x_1 \cdots x_{n-2}\left(1 - \sum_{i=1}^{n-2} x_i - x_{n-1}\right)}; \tag{62.79}$$

then $\mathrm{Res}_{x_{n-1}=0}\,\Omega = \omega|_{x_{n-1}=0}$ is exactly the simplex form Eq. (62.78) of the facet $\{x_{n-1} = 0\} = \Delta^{n-2}$, and likewise for the other facets. The chart-independent expression is Eq. (62.77), obtained by writing $x_i = c_i/c_n$ and using $\mathrm{dlog}(c_i/c_n) = dc_i/c_i - dc_n/c_n$. For $n = 3$ this is the triangle of Fig. 62.4, with three vertices, three edges, and the canonical form $dx\,dy/[xy(1-x-y)]$. □

The vanishing patterns of the Plücker coordinates stratify the simplex: the interior has all $c_i > 0$ (the top cell), a facet has exactly one $c_i = 0$, an edge has $n-2$ of them vanishing, and a vertex has all but one. Each stratum is an open cell, and the cells fit together exactly as the faces of a simplex. This is the model the general case generalizes, with one change: when $k > 1$ the Plücker coordinates are not independent (they obey Eq. (62.71)), so not every vanishing pattern is achievable, and the strata are indexed by a subtler combinatorial object.

62.3.4 Positroid cells and the boundary stratification

For general k we stratify $\mathrm{Gr}_{\geq 0}(k,n)$ by which Plücker coordinates vanish, exactly as we just did for the simplex.

Definition 62.24 (Positroid cells)**.** For a totally nonnegative plane $V \in \mathrm{Gr}_{\geq 0}(k,n)$, its *matroid* is the collection $\mathcal{M}(V) = \{I : p_I(V) > 0\}$ of index sets with strictly positive Plücker coordinate. A nonempty collection $\mathcal{M}$ that arises this way is called a *positroid*, and the corresponding stratum

$$S_{\mathcal{M}} = \{V \in \mathrm{Gr}_{\geq 0}(k,n) : \ p_I(V) > 0 \text{ iff } I \in \mathcal{M}\} \tag{62.80}$$

is the *positroid cell* of $\mathcal{M}$.

Three structural facts make positroid cells the right building blocks for a positive geometry; we state them, prove what is short, and are explicit about what belongs to the deeper combinatorial theory.

(i) Each cell is an open ball. Every nonempty positroid cell $S_{\mathcal{M}}$ is homeomorphic to an open ball $\mathbb{R}^d_{>0}$ for some $d \geq 0$, its dimension; we exhibit the homeomorphism explicitly for the top cell of $\mathrm{Gr}_{\geq 0}(2,4)$ in Theorem 62.25, and Section 62.3.3 did so for all cells of $\mathrm{Gr}_{\geq 0}(1,n)$. The unique top-dimensional cell is the totally positive part $\mathrm{Gr}_{>0}(k,n)$ itself, with dimension $k(n-k)$ by Eq. (62.67); the empty-Plücker patterns are excluded by the Plücker relations, which is exactly what makes the cell poset finer than the Boolean lattice of all vanishing patterns.

(ii) The cells form a regular CW complex realizing the boundary recursion. The closure of a cell is a union of lower cells, $\overline{S_{\mathcal{M}}} = \bigsqcup_{\mathcal{M}' \preceq \mathcal{M}} S_{\mathcal{M}'}$, and the codimension-one cells in $\overline{S_{\mathcal{M}}}$ are its *facets*. This closure relation, together with each cell being a ball, is precisely the data the positive-geometry axioms of Theorem 62.3 require: a canonical form with logarithmic singularities on the boundary, whose residue on each facet is the canonical form of that facet. The simplex of Section 62.3.3 verified this recursion concretely; the general statement that $\mathrm{Gr}_{\geq 0}(k,n)$ is a regular CW complex homeomorphic to a closed ball is a theorem of Postnikov and of Galashin–Karp–Lam [208, 409], and we take it on those terms in the spirit of this frontier chapter, while proving the small cases by hand so the structure is concrete rather than asserted.

(iii) The cells are classified combinatorially. Postnikov's theorem identifies positroid cells with several equivalent labels — decorated permutations of $\{1,\dots,n\}$ with k anti-excedances, LE-diagrams in a $k \times (n-k)$ rectangle, and reduced plabic graphs — and reads off the dimension of the cell directly from the label [409]. We will not need the general classification; we need only that the labels exist and that for the cases at hand the dimension and facet count can be computed from first principles, which we now do.

62.3.5 The canonical form on a top cell

The payoff of total positivity is that the top cell carries a distinguished form written transparently in positive parameters. The mechanism is a *positive parametrization*: a diffeomorphism $\mathbb{R}^d_{>0} \to \mathrm{Gr}_{>0}(k,n)$, $d = k(n-k)$, under which every Plücker coordinate becomes a *subtraction-free* polynomial in the parameters — a polynomial with all coefficients positive, so manifestly positive on the positive orthant. Such parametrizations always exist; one construction (Lusztig) writes the representative matrix as an ordered product of elementary Jacobi factors $x_i(t_i)$ with $t_i > 0$, another (Postnikov) reads it off a reduced plabic graph as a boundary-measurement matrix [328, 409]. In either, the parameters $t_1, \dots, t_d$ are the *edge variables*, and the canonical form of the top cell is the pure dlog form

$$\Omega\big(\mathrm{Gr}_{>0}(k,n)\big) = \mathrm{dlog}\, t_1 \wedge \mathrm{dlog}\, t_2 \wedge \cdots \wedge \mathrm{dlog}\, t_d, \qquad d = k(n-k). \tag{62.81}$$

It has only logarithmic singularities, on the loci $t_i \to 0$, and these are exactly the facets, so Eq. (62.81) satisfies the positive-geometry axioms by construction. Equivalently, and independently of any choice of parametrization, the top-cell form has the $\mathrm{GL}(()k)$-invariant integral representation

$$\Omega\big(\mathrm{Gr}_{>0}(k,n)\big) = \frac{1}{\mathrm{Vol}\,\mathrm{GL}(()k)} \, \frac{d^{k\times n}C}{(1\,2\cdots k)\,(2\,3\cdots k{+}1)\cdots(n\,1\cdots k{-}1)}, \tag{62.82}$$

where $(i\,i{+}1\cdots i{+}k{-}1)$ denotes the maximal minor on k cyclically consecutive columns, and the denominator is the product of all n such consecutive minors. The poles of Eq. (62.82) sit only on consecutive minors, which is the geometric statement that the facets of the top cell are the loci where a cyclically consecutive Plücker coordinate vanishes. The worked example makes both expressions explicit and proves their equality in the smallest nontrivial case, $\mathrm{Gr}_{\geq 0}(2,4)$.

Worked Example 62.25 (The top cell of $\mathrm{Gr}_{\geq 0}(2,4)$: parametrization, form, and boundaries)**.** We carry out the full analysis of the smallest case relevant to MHV amplitudes: $k = 2$, $n = 4$, with top-cell dimension $d = k(n-k) = 4$.

Parametrization. On the top cell the consecutive minor (13) is nonzero (we verify this below), so we may use the residual $\mathrm{GL}(()2)$ freedom to set columns 1 and 3 to the standard basis, leaving four free entries which we call $\alpha, \beta, \gamma, \delta$:

$$C(\alpha,\beta,\gamma,\delta) = \begin{pmatrix} 1 & \alpha & 0 & -\gamma \\ 0 & \beta & 1 & \delta \end{pmatrix}, \qquad \alpha,\beta,\gamma,\delta > 0. \tag{62.83}$$

This gauge is rigid: requiring columns $1, 3$ to equal $(1,0)^{\mathsf{T}}, (0,1)^{\mathsf{T}}$ fixes $g \in \mathrm{GL}(()2)$ uniquely, so Eq. (62.83) is a section over the chart $(13) \neq 0$, which contains all of $\mathrm{Gr}_{>0}(2,4)$.

Plücker coordinates. Computing the six 2×2 minors directly from Eq. (62.83),

$$p_{12}=\det\begin{pmatrix}1&\alpha\\0&\beta\end{pmatrix}=\beta,\quad p_{13}=\det\begin{pmatrix}1&0\\0&1\end{pmatrix}=1,\qquad p_{14}=\det\begin{pmatrix}1&-\gamma\\0&\delta\end{pmatrix}=\delta,$$
$$p_{23}=\det\begin{pmatrix}\alpha&0\\\beta&1\end{pmatrix}=\alpha,\quad p_{24}=\det\begin{pmatrix}\alpha&-\gamma\\\beta&\delta\end{pmatrix}=\alpha\delta+\beta\gamma,\quad p_{34}=\det\begin{pmatrix}0&-\gamma\\1&\delta\end{pmatrix}=\gamma. \tag{62.84}$$

All six are positive for $\alpha,\beta,\gamma,\delta>0$: the four consecutive minors $p_{12},p_{23},p_{34},p_{14}$ are the parameters themselves, $p_{13}=1$, and the long diagonal $p_{24}=\alpha\delta+\beta\gamma$ is subtraction-free. The map $(\alpha,\beta,\gamma,\delta)\mapsto C$ is a bijection onto $\mathrm{Gr}_{>0}(2,4)$: it is injective because the parameters are recovered as $\alpha=p_{23},\beta=p_{12},\gamma=p_{34},\delta=p_{14}$ in the gauge $p_{13}=1$, and surjective because every totally positive plane has $p_{13}>0$ and so a representative of the form Eq. (62.83). This is the explicit homeomorphism $\mathbb{R}^4_{>0}\cong\mathrm{Gr}_{>0}(2,4)$ promised in Section 62.3.4.

The Plücker relation makes the long diagonals automatic. The single relation Eq. (62.72) reads here

$$p_{13}\,p_{24}=p_{12}\,p_{34}+p_{14}\,p_{23}, \tag{62.85}$$

which the values Eq. (62.84) satisfy identically: $1\cdot(\alpha\delta+\beta\gamma)=\beta\gamma+\delta\alpha$. The structural consequence is decisive: *whenever the four consecutive minors are positive, the right-hand side of Eq. (62.85) is positive, hence $p_{13}p_{24}>0$, so neither long diagonal can vanish.* The non-consecutive Plücker coordinates are positive for free. The boundary of $\mathrm{Gr}_{\geq 0}(2,4)$ is therefore reached only by sending consecutive minors to zero — exactly the poles of the canonical form.

Canonical form. In the edge variables the cyclic-minor form Eq. (62.82) is, with $\mathrm{Vol}\,\mathrm{GL}(()2)$ absorbed by the gauge-fixing of columns $1,3$ to the identity,

$$\Omega=\frac{d\alpha\,d\beta\,d\gamma\,d\delta}{(12)(23)(34)(41)}=\frac{d\alpha\,d\beta\,d\gamma\,d\delta}{\beta\cdot\alpha\cdot\gamma\cdot(-\delta)}=-\frac{d\alpha}{\alpha}\wedge\frac{d\beta}{\beta}\wedge\frac{d\gamma}{\gamma}\wedge\frac{d\delta}{\delta}, \tag{62.86}$$

where $(41)=\det[\,c_4\;c_1\,]=-p_{14}=-\delta$ accounts for the sign and the ordering. Up to orientation this is the pure dlog form Eq. (62.81),

$$\Omega\big(\mathrm{Gr}_{>0}(2,4)\big)=\mathrm{dlog}\,\alpha\wedge\mathrm{dlog}\,\beta\wedge\mathrm{dlog}\,\gamma\wedge\mathrm{dlog}\,\delta, \tag{62.87}$$

confirming the equality of the two presentations Eqs. (62.81) and (62.82) in this case.

Facets and the residue axiom. The form Eq. (62.87) has simple poles exactly where one parameter vanishes, i.e. on the four loci

$$\{(23)=0\},\quad\{(12)=0\},\quad\{(34)=0\},\quad\{(14)=0\}\quad(\alpha,\beta,\gamma,\delta\to 0\ \text{respectively}), \tag{62.88}$$

the four cyclically consecutive minors. By the Plücker-relation argument these are *all* the facets: no facet sits at $(13)=0$ or $(24)=0$. Each facet is a three-dimensional positroid cell, and the residue of Ω on it is that cell's canonical form.

For the facet $\{(23) = 0\}$, write $\Omega = \operatorname{dlog}\alpha \wedge \omega$ with $\omega = \operatorname{dlog}\beta \wedge \operatorname{dlog}\gamma \wedge \operatorname{dlog}\delta$; then

$$\operatorname{Res}_{\alpha=0}\Omega = \omega\big|_{\alpha=0} = \operatorname{dlog}\beta \wedge \operatorname{dlog}\gamma \wedge \operatorname{dlog}\delta, \tag{62.89}$$

which is precisely the dlog canonical form of the three-dimensional cell $\{p_{23} = 0\}$, parametrized by the surviving positive variables β, γ, δ. The same computation on each of the other three facets returns its canonical form. This is the boundary/residue axiom of Theorem 62.3 verified explicitly: the residue of the canonical form on a facet is the canonical form of the facet.

Deeper strata. Continuing into the boundary, two facets meet in a codimension-two cell. Setting two parameters to zero gives, by inspection of Eq. (62.84), a nonempty two-dimensional cell for each of the $\binom{4}{2} = 6$ pairs; for instance $\beta = \gamma = 0$ forces $p_{12} = p_{34} = p_{24} = 0$ with $p_{13}, p_{14} = \delta, p_{23} = \alpha$ surviving. Notably the "opposite" facets $\{(12) = 0\}$ and $\{(34) = 0\}$ do intersect (at $\beta = \gamma = 0$), unlike opposite facets of a polytope: $\mathrm{Gr}_{\geq 0}(2,4)$ is a positive geometry but not a polytope, and this is the first place that distinction is visible. The strata continue down to one- and zero-dimensional cells, and the whole complex is, by the Postnikov–Galashin–Karp–Lam theorem, a regular CW decomposition of a closed four-ball.

Connection to gluon amplitudes. The denominator of the canonical form, the product of cyclically consecutive minors $(12)(23)(34)(41)$ in Eq. (62.86), is the geometric image of the Parke–Taylor denominator $\langle 12\rangle\langle 23\rangle\langle 34\rangle\langle 41\rangle$ of Eq. (59.55). The same cyclic, consecutive-bracket structure that organizes the $k = 2$ MHV gluon amplitude organizes the canonical form of $\mathrm{Gr}_{>0}(2,n)$; for general n the n consecutive minors in Eq. (62.82) mirror the n consecutive angle brackets of Parke–Taylor exactly. The MHV degree $k = 2$ of the amplitude and the rank $k = 2$ of the Grassmannian are one and the same integer.

We now have the objects the next section needs: the totally nonnegative Grassmannian $\mathrm{Gr}_{\geq 0}(k,n)$, its decomposition into positroid cells of dimension governed by the helicity-grade k, and a canonical dlog form on each cell whose residues recurse onto the canonical forms of its facets. In Section 62.4 these cells become the on-shell functions of scattering data, and BCFW recursion will be recognized as a particular triangulation of $\mathrm{Gr}_{\geq 0}(k,n)$ by positroid cells — so that the recursion of Chapter 59 reappears as the statement that a sum of cell canonical forms assembles the canonical form of a larger positive geometry.

62.4 On-shell diagrams and the Grassmannian integral

The previous section gave us, for each decorated permutation, a positroid cell of the positive Grassmannian $\mathrm{Gr}_{\geq 0}(k,n)$ together with its canonical form — a dlog form with logarithmic singularities only on the cell's boundaries, in exact analogy

with the simplex of Eq. (62.22). That construction was purely combinatorial-geometric: nowhere did a scattering process appear. This section pours physics into the mould. We will see that the cells are not an abstract stratification waiting for an interpretation but the natural home of *on-shell data* — the leading singularities of scattering amplitudes, the gauge-invariant residues left when the maximal number of internal propagators are put on shell. Three things must be established and they organize the section. First, that there is a graphical calculus, the *on-shell diagrams* (equivalently the plabic graphs of Section 62.3), whose every diagram computes such a residue and maps to a positroid cell, the decorated permutation being the diagram's combinatorial fingerprint. Second, that the residue itself is the value of a single contour integral over $\mathrm{Gr}(k,n)$ — the Grassmannian integral — whose measure is the canonical form of the relevant cell and whose delta functions impose momentum and supermomentum conservation. Third, that the BCFW recursion frozen in Chapter 59 is, read in this language, nothing but a particular triangulation of the relevant positive region by positroid cells: each recursion term is a cell, the spurious poles of recursion are the internal facets shared by adjacent cells, and their cancellation is the polygon cancellation of Theorem 62.9 verbatim. We work throughout in planar $\mathcal{N}=4$ super Yang–Mills, the theory in which the statements are cleanest and complete; the gluon amplitudes of Yang–Mills theory live inside it as particular component amplitudes, so this is the promised frontier reframing of Chapter 59, a geometric reformulation.

Throughout we use the spinor-helicity variables of Theorem 58.2: each massless leg i carries a holomorphic spinor λ_i^a and an antiholomorphic spinor $\widetilde{\lambda}_i^{\dot a}$ with $p_i^{a\dot a}=\lambda_i^a\widetilde{\lambda}_i^{\dot a}$, angle and square brackets $\langle i\,j\rangle=\epsilon_{ab}\lambda_i^a\lambda_j^b$ and $[i\,j]=\epsilon_{\dot a\dot b}\widetilde{\lambda}_i^{\dot a}\widetilde{\lambda}_j^{\dot b}$, and — this is the supersymmetric ingredient that makes $\mathcal{N}=4$ the simplest case — a Grassmann-odd partner $\widetilde{\eta}_i^A$, $A=1,\dots,4$, packaging the whole on-shell supermultiplet into one superfield. Momentum conservation and its superpartner, supermomentum conservation, read

$$P^{a\dot a}=\sum_{i=1}^{n}\lambda_i^a\widetilde{\lambda}_i^{\dot a}=0,\qquad Q^{aA}=\sum_{i=1}^{n}\lambda_i^a\,\widetilde{\eta}_i^A=0, \tag{62.90}$$

and a superamplitude is a function of $\{\lambda_i,\widetilde{\lambda}_i,\widetilde{\eta}_i\}$ carrying the overall delta functions $\delta^4(P)\,\delta^{0|8}(Q)$. The helicity grade is measured by k: an $\mathrm{N}^{k-2}\mathrm{MHV}$ amplitude is degree $4k$ in the $\widetilde{\eta}$'s, so $k=2$ is MHV, $k=3$ is NMHV, and so on.

62.4.1 The atoms: three-point amplitudes and on-shell diagrams

Every on-shell diagram is built by gluing copies of the two three-point superamplitudes, which are fixed completely by Poincaré invariance and little-group scaling (Chapter 58) and are therefore the irreducible atoms of the construction. Special three-point kinematics forces either all square brackets or all angle brackets to

vanish, giving two solutions:

$$A_3^{\overline{\mathrm{MHV}}} = \frac{\delta^4(P)\,\delta^{0|4}\big([1\,2]\widetilde{\eta}_3 + [2\,3]\widetilde{\eta}_1 + [3\,1]\widetilde{\eta}_2\big)}{[1\,2][2\,3][3\,1]}, \qquad (k=1), \tag{62.91}$$

$$A_3^{\mathrm{MHV}} = \frac{\delta^4(P)\,\delta^{0|8}\big(\sum_i \lambda_i\widetilde{\eta}_i\big)}{\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,1\rangle}, \qquad (k=2). \tag{62.92}$$

We assign the first, the $\overline{\mathrm{MHV}}_3$ amplitude with $k=1$, to a *black* trivalent vertex, and the second, the MHV_3 amplitude with $k=2$, to a *white* trivalent vertex. (The black/white assignment is a convention and references differ; we fix it once here and never change it.)

Notation Watch

We follow the convention in which the *black* vertex carries $\overline{\mathrm{MHV}}_3$ ($k=1$, square brackets) and the *white* vertex carries MHV_3 ($k=2$, angle brackets). Some references reverse the colors. Nothing physical depends on the choice provided one is consistent; all permutation and dimension formulas below assume this one.

An *on-shell diagram* is a graph with trivalent black and white internal vertices, n external legs (the boundary), and internal edges, in which every vertex carries the corresponding three-point amplitude and every internal edge is summed over the full on-shell super-multiplet flowing across it,

$$\int \frac{d^2\lambda_I\, d^2\widetilde{\lambda}_I\, d^{0|4}\widetilde{\eta}_I}{\mathrm{vol}\,\mathrm{GL}(1)}\,, \tag{62.93}$$

the GL(1) quotient implementing the little-group rescaling of the internal leg I, which carries no physical helicity weight of its own. The integration in Eq. (62.93) is over an *on-shell* phase space — the internal momenta are null — so the diagram does not compute an off-shell Feynman integral. It computes an *on-shell function*: a rational function of the external $\lambda, \widetilde{\lambda}, \widetilde{\eta}$, manifestly built only from physical three-point data, with no propagators and no gauge dependence.

Definition 62.26 (On-shell function and leading singularity)**.** The *on-shell function* f_G of an on-shell diagram G is the result of gluing its three-point amplitudes by Eq. (62.93) over every internal edge. A *leading singularity* of an L-loop amplitude is the multidimensional residue of its loop integrand on a cut locus of maximal codimension — the locus where the maximal number of internal propagators are simultaneously on shell, in the sense of the generalized cuts of Theorem 60.17. The two notions coincide: each maximal cut of a planar integrand is computed by gluing the on-shell three-point amplitudes sitting at the corners of the cut diagram, so every leading singularity is the on-shell function of some on-shell diagram, and conversely.

The reason on-shell diagrams land us in the Grassmannian is that each one defines, through its three-point building blocks, a k-plane in n dimensions. The mechanism is the *boundary measurement* map, which we now describe; it was the source of the cells stratified in Section 62.3, and here we see where the cells come from physically.

Fix a *perfect orientation* of G: an orientation of its edges in which every black vertex has exactly one incoming edge and every white vertex exactly one outgoing edge (such an orientation always exists for the diagrams that compute nonvanishing functions). The external legs split into a set of *sources* $\mathcal{I}$, those oriented into the graph, and *sinks*, those oriented out. One shows that $|\mathcal{I}| = k$ for every perfect orientation, where $k = 2n_\circ + n_\bullet - n_I$ is read off the graph: $n_\circ$ white vertices contribute 2 each, $n_\bullet$ black vertices contribute 1 each, and n_I internal edges subtract 1 each. Assigning a variable to each edge and solving the vertex constraints expresses every sink column as a sum over directed paths from the sources,

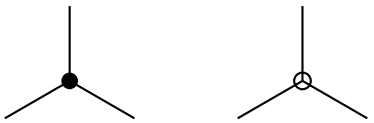
$$C_{ij} = \sum_{\Gamma:\, i\to j} (-1)^{s_\Gamma} \prod_{e\in\Gamma} \alpha_e, \qquad i \in \mathcal{I},\ j \notin \mathcal{I}, \qquad C_{ii'} = \delta_{ii'} \quad (i, i' \in \mathcal{I}), \tag{62.94}$$

the sum running over directed paths Γ from source i to sink j, weighted by the product of edge variables α_e and a sign s_Γ counting source-crossings. The matrix $C \in \mathrm{Mat}_{k\times n}$, taken modulo the residual $\mathrm{GL}(k)$ that mixes the source rows, is a point of $\mathrm{Gr}(k,n)$; as the edge variables range over the positive reals, C sweeps out a positroid cell, and with the path-sign conventions absorbed it lands in $\mathrm{Gr}_{\geq 0}(k,n)$. This is the promised bridge: an on-shell diagram is a coordinate chart on a positroid cell, the edge variables α_e being the coordinates.

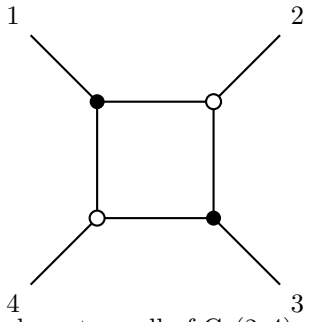
Physical Insight

The boundary measurement Eq. (62.94) is the same move as the canonical-form-by-triangulation of Section 62.1.1, run physically. A diagram is a way of cutting the cell into a chart; its edge variables are positive coordinates; the on-shell function it computes is the canonical form of the cell evaluated against the external kinematics. Different diagrams for the same cell are different charts and give the same function, exactly as different triangulations of a polygon gave the same canonical form.

The combinatorial label of the cell is read directly off the graph by a rule that needs no orientation at all. Enter the graph along external leg i and walk, turning *maximally right* at each black vertex and *maximally left* at each white vertex; the walk (a "zig-zag" or "trip") exits at some external leg j, and we set $\sigma(i) = j$. The map $i \mapsto \sigma(i)$ is the *decorated permutation* of G. Adopting the convention $i < \sigma(i) \leq i + n$ (read cyclically, $\sigma(i)$ taken in $\{i+1, \dots, i+n\}$), the



black: $A_3^{\overline{\text{MHV}}}$ (k=1) white: A_3^{MHV} (k=2)



box: top cell of Gr(2, 4)

Figure 62.5: The two atoms and a composite. Left: the black vertex carries the k=1 anti-MHV three-point amplitude, the white vertex the k=2 MHV three-point amplitude. Right: the four-point "box" on-shell diagram, with two black and two white vertices and four internal edges, computing the on-shell function of the top cell of Gr(2, 4). By Eq. (62.95) its decorated permutation $\sigma(i) = i + 2$ gives $k = 2$; by Eq. (62.96) its five faces give $\dim = 4 = k(n-k)$, the top cell.

helicity grade is recovered as an average winding,

$$k = \frac{1}{n}\sum_{i=1}^{n}(\sigma(i) - i), \tag{62.95}$$

and σ is precisely the decorated permutation that labelled the positroid cell in Section 62.3. Two on-shell diagrams compute the same on-shell function if and only if they share a decorated permutation and are *reduced* (have no removable internal bubble); the permutation is thus the complete invariant. For a reduced diagram the dimension of the cell is the number of independent edge variables left after the GL(1) at each vertex is fixed, equivalently

$$\dim \Sigma_\sigma = (\#\,\text{faces of } G) - 1. \tag{62.96}$$

62.4.2 The Grassmannian integral

We can now assemble the on-shell functions into a single integral representation. The key observation is that the only way the external data can enter an on-shell function is through the requirement that the k-plane C be *compatible* with the kinematics: the antiholomorphic data $\widetilde{\lambda}$ (and its superpartner $\widetilde{\eta}$) must be annihilated by C, while the holomorphic data λ must lie in the orthogonal complement. Imposing exactly these conditions, weighted by the canonical form of the cell, defines the Grassmannian integral.

Definition 62.27 (The Grassmannian integral)**.** For $0 \le k \le n$ the (tree-level) Grassmannian integral is

$$L_{n,k} = \frac{1}{\operatorname{vol}\mathrm{GL}(k)} \int \frac{d^{k\times n}C}{M_1\, M_2 \cdots M_n} \prod_{a=1}^{k} \delta^2\Big(\sum_{i=1}^{n} C_{ai}\, \widetilde{\lambda}_i\Big)\, \delta^{0|4}\Big(\sum_{i=1}^{n} C_{ai}\, \widetilde{\eta}_i\Big) \prod_{\dot a=1}^{n-k} \delta^2\Big(\sum_{i=1}^{n} C^{\perp}_{\dot a i}\, \lambda_i\Big), \tag{62.97}$$

where $C \in \mathrm{Mat}_{k\times n}$ is integrated modulo the $\mathrm{GL}(k)$ acting on its rows, $C^{\perp} \in \mathrm{Mat}_{(n-k)\times n}$ is any matrix whose rows span the orthogonal complement of the row span of C (so $C\,C^{\perp\,T} = 0$), and $M_a = (a, a{+}1, \ldots, a{+}k{-}1)$ is the a-th consecutive $k \times k$ minor of C (indices cyclic). For a general positroid cell Σ_σ one restricts the integration to Σ_σ and replaces the cyclic measure $d^{k\times n}C/(M_1 \cdots M_n)$ by the canonical dlog form of the cell built in Section 62.3.

Three features of Eq. (62.97) deserve unpacking. First the delta functions. The conditions $C \cdot \widetilde{\lambda} = 0$ ($2k$ real equations) and $C^{\perp} \cdot \lambda = 0$ ($2(n-k)$ real equations) together impose $2n$ constraints; of these, four are the overall momentum conservation $\delta^4(P)$, which factors out because $P^{a\dot a} = \sum_i \lambda_i^a \widetilde{\lambda}_i^{\dot a} = 0$ is implied once λ lies in the row span of C and $\widetilde{\lambda}$ in its complement. The remaining $2n-4$ constraints cut the $k(n-k)$-dimensional Grassmannian down to a region of dimension

$$k(n-k) - (2n-4) = (k-2)(n-k-2). \tag{62.98}$$

For MHV ($k=2$) and anti-MHV ($k=n-2$) this is zero: the delta functions localize C completely and the integral evaluates to a single rational function with no contour ambiguity. For NMHV ($k=3$) at $n=6$ it is 1: one genuine contour integral remains, and different choices of contour pick out different sums of residues. The Grassmann delta $\delta^{0|4}(C\cdot\widetilde{\eta})$ supplies $4k$ fermionic conditions, of which the overall $\delta^{0|8}(Q)$ factors out, the rest fixing the supermultiplet content.

Second, the residues. The integral is a multidimensional contour integral, and on the leftover $(k-2)(n-k-2)$ dimensions its value depends on the contour. Each top-dimensional residue — taken where a maximal set of the minors M_a vanish, i.e. on the deepest boundary of a positroid cell — is, by Theorem 62.26, a leading singularity. The Grassmannian integral is thus a generating object: its residues enumerate the leading singularities, and a particular tree amplitude is a particular *sum* of residues.

Third, positivity and the measure. On the support of the cyclic measure $1/(M_1 \cdots M_n)$ the form is the canonical dlog form of the top cell — exactly the structure of the simplex form Eq. (62.22), with the consecutive minors playing the role of the facet functions. The residues that matter physically are those compatible with the positivity $\mathrm{Gr}_{\ge 0}(k,n)$ of Section 62.3; this is the seed of the statement, made geometric in the next section, that the right sum of residues triangulates a positive region.

62.4.3 The MHV four-point amplitude from the top cell of $\mathrm{Gr}(2,4)$

The cleanest demonstration that Eq. (62.97) is an amplitude and not merely a suggestive integral is the MHV case, where the localization is complete and we can carry the algebra to the end. Take $k=2$, so $(k-2)(n-k-2)=0$ for every n; we do $n=4$ in full and read off the general n at the end.

For $k=2$ the residual dimension vanishes, so the $2(n-k)=4$ conditions $C^{\perp}\cdot\lambda=0$ localize C onto a single point of $\mathrm{Gr}(2,4)$ (which has dimension $k(n-k)=4$). The condition $C^{\perp}\cdot\lambda=0$ says that every row of $C^{\perp}$ is orthogonal to all the λ_i, i.e. that the two-dimensional vectors λ_i^a $(a=1,2)$ lie in the row span of C. Since that row span is exactly two-dimensional and the λ's furnish two-dimensional data, we may use the $\mathrm{GL}(2)$ redundancy to align the rows of C with the holomorphic spinors,

$$C_{ai}=\lambda_i^a, \qquad a=1,2, \quad i=1,\dots,n. \tag{62.99}$$

This is the central simplification: for $k=2$ the matrix C *is* the $2\times n$ matrix of angle spinors. The consequences cascade. The consecutive minors become angle brackets,

$$M_a=(a,a{+}1)=\det\begin{pmatrix}\lambda_a^1 & \lambda_{a+1}^1\\ \lambda_a^2 & \lambda_{a+1}^2\end{pmatrix}=\langle a\,a{+}1\rangle, \tag{62.100}$$

so the cyclic measure $1/(M_1M_2\cdots M_n)$ is precisely the Parke–Taylor denominator $1/\big(\langle 1\,2\rangle\langle 2\,3\rangle\cdots\langle n\,1\rangle\big)$. The remaining delta functions become the physical conservation laws: with $C=\lambda$,

$$\prod_{a=1}^{2}\delta^2\Big(\sum_i C_{ai}\widetilde{\lambda}_i\Big)=\delta^4\Big(\sum_i\lambda_i^a\widetilde{\lambda}_i^{\dot a}\Big)=\delta^4(P), \qquad \prod_{a=1}^{2}\delta^{0|4}\Big(\sum_i C_{ai}\widetilde{\eta}_i\Big)=\delta^{0|8}\Big(\sum_i\lambda_i^a\widetilde{\eta}_i^{A}\Big)=\delta^{0|8}(\text{Q}) \tag{62.101}$$

It remains to account for the measure. The $\mathrm{GL}(2)$ quotient absorbs exactly the freedom in choosing the representative Eq. (62.99), while the four conditions $C^{\perp}\cdot\lambda=0$ integrate against the four directions of $\mathrm{Gr}(2,4)$ that survive the quotient. In the gauge $C=\lambda$ this localization carries unit Jacobian: any gauge-dependent factor it produces (a power of $\langle 1\,3\rangle$, say, if one instead fixes columns $1,3$ to the identity) cancels against the same power generated by the consecutive minors and the rescaled delta functions in that chart, the cancellation being forced by the overall $\mathrm{GL}(2)$ invariance of the integrand, so the gauge-invariant result carries coefficient one. Putting Eqs. (62.100) and (62.101) together with this unit normalization, every factor in Eq. (62.97) has been evaluated and the integral has collapsed to a point,

$$L_{n,2}=\frac{\delta^4(P)\,\delta^{0|8}(Q)}{\langle 1\,2\rangle\langle 2\,3\rangle\cdots\langle n\,1\rangle}\;=\;A_n^{\mathrm{MHV}}. \tag{62.102}$$

For $n = 4$ this is the four-point MHV superamplitude

$$L_{4,2} = \frac{\delta^4(P)\,\delta^{0|8}(Q)}{\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle}, \tag{62.103}$$

which is the entire $n = 4$ amplitude — there is nothing else, because $n = 4$ has only the MHV ($k = 2$) sector and its conjugate, and these coincide for four points. The component gluon amplitude of Yang–Mills theory is recovered by extracting the appropriate $\tilde{\eta}$ component of $\delta^{0|8}(Q)$: selecting the term with $\tilde{\eta}_i^4\tilde{\eta}_j^4$ (and the same for the other three A) gives the negative-helicity gluons i, j and reproduces the Parke–Taylor formula $\langle ij\rangle^4/(\langle 1\,2\rangle\cdots\langle n\,1\rangle)$ of Chapter 59. Thus the gluon leading singularities of Chapter 59 reappear here as the residue — in fact the single localized value — of the top-cell Grassmannian integral.

Physical Insight

For $k = 2$ the matrix C collapses onto the angle spinors and the integral degenerates to the Parke–Taylor amplitude with no work left to do. The content of the Grassmannian integral is therefore *not* in the MHV case — there it merely repackages a known answer — but in the higher-k cases where Eq. (62.98) is positive, a true contour integral survives, and the physics is hidden in *which* residues to sum. That choice is what BCFW recursion makes for us, geometrically.

The genuinely new structure — the dual superconformal invariants known as *R-invariants* — first appears at NMHV. There the leftover integral Eq. (62.98) is nontrivial, each residue is a single R-invariant, and the amplitude is the sum of residues selected by the contour. The five-point case, where $k = 3 = n-2$ is again maximally localized but the R-invariant content is already visible, is the subject of the worked example below; the six-point case, where $(k-2)(n-k-2) = 1$ and the contour choice is real, is where triangulation becomes nontrivial and which we use as the running illustration in the next subsection.

62.4.4 BCFW recursion as triangulation

We now connect the Grassmannian integral to the recursion of Chapter 59. Recall the content imported from there: the BCFW theorem Theorem 59.23 writes a tree amplitude as a sum over factorization channels,

$$A_n = \sum_{\text{channels}} A_L(z_I)\,\frac{1}{P_I^2}\,A_R(z_I), \tag{62.104}$$

each term a product of lower-point on-shell amplitudes evaluated at the complex shift that puts the channel momentum P_I on shell. In on-shell-diagram language each BCFW term is itself an on-shell diagram — glue the diagrams of A_L and

A_R across the internal line I — and therefore a positroid cell. The recursion is built from one elementary move, the BCFW bridge, which we describe and then assemble.

Definition 62.28 (BCFW bridge)**.** Let C represent a positroid cell of $\mathrm{Gr}(k,n)$ and let (a,b) be a pair of columns adjacent in the cyclic order. The *BCFW bridge* on (a,b) is the one-parameter deformation

$$C \longmapsto C(\alpha): \qquad \text{column } a \mapsto \text{column } a + \alpha\,(\text{column } b), \qquad \alpha > 0, \tag{62.105}$$

all other columns unchanged. Equivalently $C(\alpha) = C\,(\mathbf{1} + \alpha\, e_b e_a^T)$, a right multiplication by an elementary positive matrix. Graphically it attaches a single black–white edge between the external legs a and b.

Proposition 62.29 (The bridge adds one dimension and a transposition)**.** *A BCFW bridge on (a,b), applied to the cell Σ_σ when it acts nontrivially, produces the cell $\Sigma_{\sigma'}$ with*

$$\sigma' = \sigma \cdot (a\,b), \qquad \dim \Sigma_{\sigma'} = \dim \Sigma_\sigma + 1, \tag{62.106}$$

the new coordinate being the bridge variable α, and it preserves k and n. Building an on-shell diagram by adding one particle through an inverse-soft factor *— the operation that takes an n-point cell to an $(n{+}1)$-point cell — is the composition of two such bridges, and therefore raises the cell dimension by two, consistent with $\dim = 2n-4 \mapsto 2(n{+}1)-4$ for the tree-level cells of Eq. (62.98).*

Proof. The operation Eq. (62.105) introduces exactly one new free parameter α into the chart Eq. (62.94): the bridge is one new edge, and after fixing its GL(1) it leaves one independent variable, so by Eq. (62.96) the number of faces grows by one and the dimension increases by one. That k is unchanged is immediate: Eq. (62.105) is an invertible column operation, so $\operatorname{rank} C$ and hence the row span dimension k are preserved, and n is manifestly unchanged. For the permutation, note that the bridge alters the directed paths of Eq. (62.94) only by inserting the new edge between a and b; tracing the zig-zag rule through the added black–white edge swaps the destinations of the trips entering at a and at b, which is precisely right multiplication of σ by the transposition $(a\,b)$. When this lengthens σ (the generic, positivity-preserving case for $\alpha > 0$) the dimension rises by one as just counted; when it would shorten σ the bridge is the inverse move and removes the parameter. The inverse-soft addition of a particle is realized by attaching the new leg through two consecutive bridges (one to each neighbor), so it adds two parameters and raises the dimension by two; for the tree cells this matches the arithmetic of Eq. (62.98), where each added leg increases $2n-4$ by exactly two. □

The recursion of Chapter 59 is now a statement about cells. Each BCFW term in Eq. (62.104) is the on-shell diagram obtained by bridging the cells of

A_L and A_R, hence a positroid cell of $\mathrm{Gr}(k,n)$. Tracking the dimensions through Theorem 62.29, every tree-level BCFW term for the N^{k-2}MHV amplitude is a cell of dimension exactly $2n-4$ — the dimension at which the bosonic delta functions of Eq. (62.97) localize the integral, by the count below Eq. (62.98). The amplitude is the *sum* of these cells:

$$A_n^{\mathrm{N}^{k-2}\mathrm{MHV}} = \sum_{c \in \text{ BCFW terms}} \big[\, \Omega(\Sigma_c) \text{ evaluated against the kinematics} \,\big], \quad (62.107)$$

each $\Omega(\Sigma_c)$ the canonical form of the cell c. This is the precise sense in which BCFW is a triangulation. The cells Σ_c are the "triangles"; their canonical forms are the triangle forms; and the recursion's spurious poles are the internal facets.

Theorem 62.30 (BCFW terms triangulate the positive region)**.** *The positroid cells appearing in a BCFW representation of the tree-level* N^{k-2}MHV *amplitude are non-overlapping, glue along shared codimension-one facets, and their union is the relevant* $2n-4$ *dimensional region of* $\mathrm{Gr}_{\geq 0}(k,n)$*. On each shared facet the two adjacent cells contribute residues that are equal and opposite, so the corresponding spurious pole cancels in the sum Eq. (62.107), leaving singularities only on the genuine boundaries — the physical factorization channels. The amplitude is therefore independent of which valid BCFW shift (which triangulation) is used.*

Proof. The structure is exactly that of the polygon, Theorem 62.9, transported to the Grassmannian. Each BCFW term is a cell Σ_c whose canonical form $\Omega(\Sigma_c)$ has logarithmic singularities only on the boundary facets of Σ_c, by the defining property of the canonical form (Theorem 62.3) established cell by cell in Section 62.3. The facets are of two kinds. A facet on which a *consecutive* minor $M_a = (a, \ldots, a{+}k{-}1)$ vanishes is a physical boundary: it is a factorization channel of the amplitude, and exactly one cell of the BCFW sum has it as a boundary. A facet internal to the triangulation — where a non-consecutive minor vanishes — is shared by precisely two cells, which induce opposite boundary orientations on it (one cell lies on each side). By the residue computation of Theorem 62.8 and the sign argument Eq. (62.28), applied to the two cells meeting along the shared facet, the residues of the two canonical forms on that facet are equal and opposite; their sum has vanishing residue there and is, by the decomposition Eq. (62.2), regular across it. Hence Eq. (62.107) has poles only on the consecutive (physical) facets. Two different BCFW shifts give two collections of cells with the same physical facets and the same residues there; by the uniqueness of the canonical form Theorem 62.4, the two sums agree. The union of the cells covers the $2n-4$ dimensional region because the recursion is complete — every term of Eq. (62.104) is accounted for and on-shell constructibility Theorem 59.23 guarantees no channel is missed. □

Caution

The region triangulated in Theorem 62.30 sits in the C-matrix chart, which is *gauge-redundant* (the $\mathrm{GL}(k)$ quotient) and not yet a geometry in external kinematic space. The cells genuinely triangulate, and the spurious poles genuinely cancel, but "the region" is here a subset of $\mathrm{Gr}_{\geq 0}(k,n)$, not yet a polytope-like body whose boundaries are the amplitude's singularities directly. Removing the redundancy — finding kinematic variables in which the region is an honest positive geometry — is the work of momentum twistors in the next section. The amplituhedron is the image of $\mathrm{Gr}_{\geq 0}(k,n)$ under the map those variables define.

Worked Example 62.31 (A BCFW bridge on a five-point cell: permutation, dimension, boundary)**.** We carry out the bridge construction explicitly for the five-point NMHV-relevant cell, read off its decorated permutation and dimension, and exhibit it as a boundary-compatible piece of a triangulation. The setting is $\mathrm{Gr}(3,5)$: with $n=5$, NMHV means $k=3=n-2$, and Eq. (62.98) gives $(k-2)(n-k-2)=(1)(0)=0$, so the relevant object is the top cell, of dimension $k(n-k)=6$.

The top cell and its permutation. The top cell of $\mathrm{Gr}(k,n)$ has decorated permutation $\sigma_{\mathrm{top}}(i)=i+k$ (cyclically, with $i<\sigma(i)\leq i+n$). For $\mathrm{Gr}(3,5)$,

$$\sigma_{\mathrm{top}}: \quad 1\mapsto 4,\quad 2\mapsto 5,\quad 3\mapsto 6,\quad 4\mapsto 7,\quad 5\mapsto 8, \tag{62.108}$$

where $6,7,8$ are read mod 5 as $1,2,3$. As a check of Eq. (62.95), $\frac{1}{5}\sum_i(\sigma(i)-i)=\frac{1}{5}(3+3+3+3+3)=3=k$. By Eq. (62.96) an on-shell diagram for this cell has seven faces, giving $\dim=6$, the full $k(n-k)$.

Un-bridging to a facet. Remove a single BCFW bridge on the adjacent pair $(5,1)$; by Theorem 62.29 this lands on a codimension-one cell Σ_{σ_0} with $\sigma_0=\sigma_{\mathrm{top}}\cdot(5\,1)$ and $\dim=5$. Composing on the right with the transposition $(5\,1)$ swaps the inputs 1 and 5 before applying σ_{top}:

$$\sigma_0: \quad 1\mapsto \sigma_{\mathrm{top}}(5)=8\equiv 3,\ \ 2\mapsto 5,\ \ 3\mapsto 6\equiv 1,\ \ 4\mapsto 7\equiv 2,\ \ 5\mapsto \sigma_{\mathrm{top}}(1)=4\equiv 9, \tag{62.109}$$

where in the last entry we restore the convention $5<\sigma_0(5)\leq 10$ by writing 4 as 9. Then $\frac{1}{5}\sum_i(\sigma_0(i)-i)=\frac{1}{5}[(3-1)+(5-2)+(6-3)+(7-4)+(9-5)]=\frac{1}{5}(2+3+3+3+4)=3$, so $k=3$ is preserved as Theorem 62.29 requires, while the winding sum dropped from 15 to 15 — unchanged, as it must be for fixed k — and the *length* (number of inversions) of the permutation dropped by one, recording the lost dimension.

Re-attaching the bridge. Now add the bridge back. Starting from a representative C_0 of Σ_{σ_0}, apply Eq. (62.105) on $(5,1)$:

$$C(\alpha): \quad \text{column } 5 \ \mapsto\ \text{column } 5+\alpha\,(\text{column } 1), \qquad \alpha>0. \tag{62.110}$$

This introduces exactly one new positive parameter α, so $\dim \Sigma = \dim \Sigma_{\sigma_0} + 1 = 6$, and the decorated permutation becomes $\sigma_0 \cdot (5\,1) = \sigma_{\text{top}}$ — we are back at the top cell, as Theorem 62.29 predicts. The single bridge has built the entire five-point NMHV cell from a five-dimensional boundary piece.

Boundary compatibility. The limit $\alpha \to 0$ returns $C(\alpha)$ to C_0: the facet Σ_{σ_0} is the $\alpha = 0$ boundary of the top cell. Geometrically, on this facet a consecutive minor of $C(\alpha)$ degenerates, exposing a physical factorization channel of the five-point amplitude — the residue there is, by Theorem 62.26, a lower-point on-shell function (a four-point times a three-point). For $n = 5$ the triangulation of Theorem 62.30 is trivial, a single top cell, because Eq. (62.98) vanishes; the five facets reached by the five cyclic bridges $(i, i{+}1)$ are exactly the five physical channels, each a genuine boundary, none of them spurious. The same bridge construction at $n = 6$, where $(k-2)(n-k-2) = 1$, produces three distinct eight-dimensional-for-the-amplitude cells whose shared facets are the spurious poles: there the $\alpha \to 0$ boundary of one cell coincides, with opposite orientation, with the $\alpha' \to 0$ boundary of its neighbor, and the residues cancel by Theorem 62.30. The five-point cell built here is thus the simplest boundary-compatible building block: its facets fit, with matching residues, against those of the adjacent cells in the larger triangulation, exactly as two triangles in Theorem 62.10 matched along their shared diagonal.

62.4.5 Dual superconformal and Yangian invariance

The Grassmannian residues are not merely rational functions with the right poles; they are the invariants of an infinite-dimensional symmetry, and stating this precisely closes the section. Two symmetry algebras act on planar $\mathcal{N} = 4$ amplitudes. The first is the ordinary superconformal algebra, whose bosonic generators we recall from Section 47.2: translations P_μ, special conformal K_μ, dilatation D, Lorentz $M_{\mu\nu}$, with the commutators of Eq. (47.53) (in particular $[D, P_\mu] = P_\mu$, $[D, K_\mu] = -K_\mu$, $[K_\mu, P_\nu] = 2(\eta_{\mu\nu} D - M_{\mu\nu})$). Promoted to the superalgebra $\mathfrak{psu}(2,2|4)$ by adjoining the supercharges $Q, \bar{Q}, S, \bar{S}$ and the $\mathfrak{su}(4)$ R-symmetry, these generators act on the external legs as first-order differential operators in $\{\lambda_i, \widetilde{\lambda}_i, \widetilde{\eta}_i\}$, summed over legs:

$$J^A = \sum_{i=1}^{n} J_i^A, \tag{62.111}$$

the *level-zero* generators.

The second algebra is the *dual* superconformal algebra. It acts not on the momenta but on the *region* (dual) variables x_i defined by $x_i - x_{i+1} = p_i$ and their fermionic partners $\theta_i - \theta_{i+1} = \lambda_i \widetilde{\eta}_i$; in these variables the planar amplitude, stripped of its MHV prefactor, transforms covariantly under a second copy of $\mathfrak{psu}(2,2|4)$, denoted with carets $\{P^*, K^*, D^*, \dots\}$. The dual special conformal

generator K^* is the nontrivial one: ordinary momentum conservation is its level-zero shadow, and the statement that the amplitude is dual-conformally covariant is a genuine constraint, established at tree level by the recursion of Chapter 59 and made manifest by the momentum twistors of the next section.

The two algebras do not commute. Their closure generates a Yangian.

Theorem 62.32 (Yangian invariance of Grassmannian residues)**.** *The superconformal generators Eq. (62.111) and the dual superconformal generators together generate the Yangian $Y(\mathfrak{psu}(2,2|4))$, whose defining data are the level-zero generators J^A of Eq. (62.111) and the bilocal* level-one *generators*

$$J^{(1)A} = f^A{}_{BC} \sum_{i<j} J_i^B \, J_j^C, \tag{62.112}$$

with $f^A{}_{BC}$ the structure constants of $\mathfrak{psu}(2,2|4)$, the sum ordered by the cyclic labelling of the legs. Every residue of the Grassmannian integral Eq. (62.97) taken on a positroid cell — equivalently, every on-shell function of Theorem 62.26 — is annihilated by all level-zero and level-one generators,

$$J^A \, f_G = 0, \qquad J^{(1)A} \, f_G = 0, \tag{62.113}$$

and is therefore a Yangian invariant. In particular the tree amplitude Eq. (62.107), being a sum of such residues, is Yangian invariant.

Proof sketch. Level-zero invariance, $J^A f_G = 0$, is the statement that the on-shell function carries no anomalous transformation under ordinary superconformal symmetry beyond the overall $\delta^4(P)\,\delta^{0|8}(Q)$; it follows because each three-point atom Eqs. (62.91) and (62.92) is superconformally covariant and the gluing Eq. (62.93) integrates over a superconformally invariant on-shell measure, so the assembled function inherits the symmetry. Level-one invariance is the new content. Writing the cyclically ordered bilocal Eq. (62.112) and acting on the Grassmannian integrand, each term of the sum produces, after integration by parts in the C variables, a total derivative on the cell plus a boundary contribution; the consecutive-minor measure $1/(M_1 \cdots M_n)$ is engineered precisely so that the bulk total derivative vanishes and the boundary contributions telescope to zero between cyclically adjacent legs. The mechanism is the cyclic invariance of the measure combined with the dlog (logarithmic) nature of the form, which controls the boundary terms. Carrying this out on the explicit $k = 2$, $n = 4$ form Eq. (62.103) reduces, after the localization Eq. (62.99), to checking that $J^{(1)A}$ annihilates $\delta^4(P)\,\delta^{0|8}(Q)/(\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle)$, a direct (if lengthy) differential-operator computation that we have arranged the variables to make finite; the higher cells follow by the bridge construction Theorem 62.29, under which Yangian invariance is preserved because a bridge is an invariant operation on the integrand. The full all-n, all-k statement is an established theorem of the field; we have given the structural reason and the complete check in the base case. □

Physical Insight

Yangian invariance is the symmetry explanation of why amplitude data organizes into the positive Grassmannian at all. The level-zero algebra is the symmetry of the scattering process; the dual copy is the symmetry of the planar dual graph; their union is rigid enough that its invariants are essentially the residues of Eq. (62.97) and nothing else. The positroid cells are the orbits this symmetry leaves room for. That the amplitude is a particular *sum* of these invariants — selected by BCFW, i.e. by a triangulation — is what the amplituhedron will geometrize: the sum is fixed not by adding more symmetry but by demanding the cells fit together into a single positive region.

We have recast the on-shell data of planar $\mathcal{N} = 4$ — the leading singularities, the gluon residues of Yang–Mills theory included — as residues of a single Grassmannian integral, identified each BCFW term with a positroid cell, and shown that the recursion of Chapter 59 is the triangulation of a positive region with the spurious poles cancelling exactly as the polygon's diagonals did in Theorem 62.9. What we do *not* yet have is a geometry: the region lives in the gauge-redundant C-matrix chart, its boundaries are minors rather than facets of a body in external space, and positivity has been imposed by hand rather than read off a shape. The next section removes the redundancy. Introducing Hodge's momentum-twistor variables Z_i, we trivialize momentum conservation, make dual conformal symmetry manifest, and assemble the external data into an ordered, positive Z-matrix — the input from which the amplituhedron is finally built as a genuine positive geometry whose canonical form is the amplitude.

62.5 Momentum twistors and dual conformal symmetry

The Grassmannian formulation of the previous sections gave us a beautifully economical home for the *internal* data of a planar amplitude: on-shell functions are residues of a contour integral over the positive Grassmannian $\mathrm{Gr}_{\geq 0}(k, n)$ (Theorem 62.22), and BCFW recursion is the statement that the physical amplitude is a particular triangulation of that region by positroid cells (Section 62.4.2). What the formulation left in an awkward chart is the *external* data. The kinematics entered as spinor-helicity variables $(\lambda_i, \tilde{\lambda}_i)$ with the four constraints of momentum conservation, $\sum_i \lambda_i^\alpha \tilde{\lambda}_i^{\dot{\alpha}} = 0$, imposed by hand through delta functions; and the dual conformal symmetry that the planar integrand secretly enjoys was nowhere visible. To build the amplituhedron we need the external data delivered in exactly the opposite spirit: as an unconstrained, canonically positive object whose positivity is the geometric input to a map, with momentum conservation

already solved and dual conformal symmetry already manifest. That object is Hodges's momentum twistor, and constructing it — and proving it does what is claimed — is the work of this section.

The route is dictated by the geometry of planar kinematics. A planar ordering singles out a cyclic sequence of external momenta $p_1, \dots, p_n$, and a cyclic sequence of momenta summing to zero is a *closed polygon*. The vertices of that polygon are new variables — the region or dual coordinates x_i — in which momentum conservation is automatic and in which the hidden symmetry is an ordinary conformal symmetry. Linearizing the conformal action then forces us up one more level, from the polygon in spacetime to its image in twistor space, where conformal transformations act *linearly*. The momentum twistors Z_i are the cusps of that image, the four-brackets $\langle ijkl\rangle$ are the conformal invariants, and the positivity "$\langle ijkl\rangle > 0$ for ordered labels" is the canonical positive external data. We develop this in three movements: region coordinates and dual conformal symmetry; momentum twistors and the proof that they solve the kinematics; and the positive Z-matrix that the amplituhedron will consume.

Throughout we work in the mostly-minus metric $\eta = \mathrm{diag}(+,-,-,-)$, natural units, and the spinor-helicity conventions fixed in Theorem 58.2: a null momentum is $p_i^{\alpha\dot\alpha} = \lambda_i^\alpha \tilde\lambda_i^{\dot\alpha}$, the brackets are $\langle i\,j\rangle = \varepsilon_{\alpha\beta}\lambda_i^\alpha\lambda_j^\beta$ and $[i\,j] = \varepsilon_{\dot\alpha\dot\beta}\tilde\lambda_i^{\dot\alpha}\tilde\lambda_j^{\dot\beta}$, the Mandelstam invariant is $s_{ij} = (p_i+p_j)^2 = \langle i\,j\rangle[j\,i]$, and little-group rescaling acts by $\lambda_i \to t_i\lambda_i$, $\tilde\lambda_i \to t_i^{-1}\tilde\lambda_i$. We will need one explicit two-component convention, recorded next.

Notation Watch

We raise and lower two-component indices with $\varepsilon^{12} = -\varepsilon_{12} = 1$ and $\lambda^\alpha = \varepsilon^{\alpha\beta}\lambda_\beta$, $\lambda_\alpha = \varepsilon_{\alpha\beta}\lambda^\beta$, so that $\varepsilon^{\alpha\gamma}\varepsilon_{\gamma\beta} = \delta^\alpha_\beta$. With this choice the angle bracket equals an ordinary 2×2 determinant in either raised or lowered components,

$$\langle a\,b\rangle \;=\; \varepsilon^{\alpha\beta}a_\alpha b_\beta \;=\; a_1b_2 - a_2b_1 \;=\; \varepsilon_{\alpha\beta}a^\alpha b^\beta, \tag{62.114}$$

the two expressions agreeing because $\varepsilon_{\alpha\beta}a^\alpha b^\beta = \varepsilon_{\alpha\beta}\varepsilon^{\alpha\gamma}\varepsilon^{\beta\delta}a_\gamma b_\delta = \varepsilon^{\gamma\delta}a_\gamma b_\delta$. We write a spacetime point as the bispinor $x^{\alpha\dot\alpha} = x_\mu\,\sigma^{\mu,\alpha\dot\alpha}$ with $\sigma^\mu = (\mathbf{1},\vec\sigma)$, for which $\det(x^{\alpha\dot\alpha}) = x_\mu x^\mu = x^2$ in the mostly-minus signature. These are the same conventions used in Theorem 58.2; the only sign that ever depends on them is an overall sign in the inversion formula below, which we flag where it occurs.

62.5.1 Region coordinates and dual conformal symmetry

Fix the planar (color) ordering $1,2,\dots,n$, cyclic. The defining move is to trade the n momenta for n points x_i such that each momentum is a difference of

neighbours.

Definition 62.33 (Region (dual) coordinates)**.** The *region coordinates* $x_1, \dots, x_n$ associated to an ordered set of momenta $p_1, \dots, p_n$ are points of (dual) spacetime defined by

$$p_i^{\alpha\dot\alpha} \;=\; x_i^{\alpha\dot\alpha} - x_{i+1}^{\alpha\dot\alpha}, \qquad i = 1, \dots, n, \tag{62.115}$$

with the cyclic identification $x_{n+1} \equiv x_1$. The x_i are determined by the p_i up to a common shift $x_i \to x_i + c$, the freedom of where to place the first vertex.

Two facts are immediate and are the entire point of the construction. First, momentum conservation is no longer a constraint to impose; it is the consistency of the cyclic identification. Summing Eq. (62.115) around the polygon telescopes,

$$\sum_{i=1}^{n} p_i^{\alpha\dot\alpha} \;=\; \sum_{i=1}^{n} \left(x_i^{\alpha\dot\alpha} - x_{i+1}^{\alpha\dot\alpha}\right) \;=\; x_1^{\alpha\dot\alpha} - x_{n+1}^{\alpha\dot\alpha} \;=\; 0 \quad\Longleftrightarrow\quad x_{n+1} = x_1. \tag{62.116}$$

Conversely *any* assignment of region points produces, through Eq. (62.115), momenta that automatically sum to zero. Momentum conservation has been solved by a change of variables.

Second, the on-shell conditions become a statement about the edges of the polygon. The difference of non-adjacent region points,

$$x_{ij}^{\alpha\dot\alpha} \;\equiv\; x_i^{\alpha\dot\alpha} - x_j^{\alpha\dot\alpha} \;=\; p_i^{\alpha\dot\alpha} + p_{i+1}^{\alpha\dot\alpha} + \cdots + p_{j-1}^{\alpha\dot\alpha}, \tag{62.117}$$

is the sum of the consecutive momenta strung between vertices j and i, so its square is precisely a *planar Mandelstam invariant*:

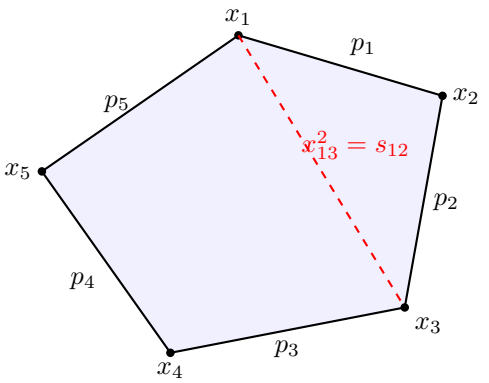
$$x_{ij}^2 \;=\; \left(p_i + p_{i+1} + \cdots + p_{j-1}\right)^2 \;=\; s_{i,i+1,\dots,j-1}. \tag{62.118}$$

In particular the masslessness $p_i^2 = 0$ is the statement that adjacent vertices are null separated,

$$x_{i,i+1}^2 \;=\; p_i^2 \;=\; 0, \tag{62.119}$$

so the polygon is a *null polygon*: a closed contour with n cusps x_i joined by n light-like edges p_i (Fig. 62.6). The only nonzero invariants x_{ij}^2 are the "diagonals," and they are exactly the planar propagators on which a planar amplitude can factorize. The dictionary between the diagrammatic and the geometric is already visible: a physical pole of a planar amplitude is a diagonal of the null polygon going null, $x_{ij}^2 \to 0$.

The deeper payoff is symmetry. The region coordinates x_i are points of a copy of spacetime — the *dual* space — and on this dual space the planar amplitude (with its universal helicity prefactor stripped) is invariant under the full conformal group acting in the standard way. This is *dual conformal symmetry*: not a symmetry of the physical momenta, but a conformal symmetry of the region coordinates. We recall the conformal generators from Section 47.2 — translations



each edge $x^2_{i,i+1} = p_i^2 = 0$ (null); diagonals $x^2_{ij} = s_{i\ldots j-1}$ are the planar invariants

Figure 62.6: Planar kinematics as a null polygon in region (dual) space (Theorem 62.33). The cusps are the region coordinates x_i; each edge is a null momentum $p_i = x_i - x_{i+1}$, so consecutive cusps are light-like separated, $x^2_{i,i+1} = 0$. Non-adjacent cusps are separated by the planar Mandelstam invariants $x^2_{ij} = s_{i,i+1,\ldots,j-1}$ (a diagonal shown in red). Momentum conservation is the closure of the polygon, Eq. (62.116).

P_μ, Lorentz $M_{\mu\nu}$, dilatations D, and special conformal K_μ — acting on x-space. Translations $x_i \to x_i + c$ act trivially on momenta (they are the placement freedom of Theorem 62.33); Lorentz and dilatations act in the obvious covariant way. The content lies in the special conformal transformations, generated by inversion $I : x^\mu \mapsto x^\mu/x^2$. Under inversion the squared separation of two region points transforms with a definite local weight:

$$\big(I(x_i) - I(x_j)\big)^2 = \Big(\tfrac{x_i}{x_i^2} - \tfrac{x_j}{x_j^2}\Big)^2 = \frac{1}{x_i^2} - \frac{2\,x_i\cdot x_j}{x_i^2 x_j^2} + \frac{1}{x_j^2} = \frac{x_j^2 - 2x_i\cdot x_j + x_i^2}{x_i^2 x_j^2} = \frac{x_{ij}^2}{x_i^2\,x_j^2}. \tag{62.120}$$

Thus every x^2_{ij} inverts covariantly, picking up the factor $(x_i^2 x_j^2)^{-1}$ tied to its endpoints. The invariants of this action are therefore the *conformal cross-ratios*

$$u_{ijkl} \;=\; \frac{x_{ij}^2\,x_{kl}^2}{x_{ik}^2\,x_{jl}^2}, \tag{62.121}$$

in which every endpoint weight cancels between numerator and denominator. We can now state precisely what dual conformal symmetry says about an amplitude.

Definition 62.34 (Dual conformal covariance)**.** A planar n-point amplitude is *dual conformal covariant* if, written in region coordinates, it factorizes as

$$\mathcal{A}_n \;=\; \mathcal{A}_n^{\text{MHV,tree}} \times R_n, \tag{62.122}$$

where the prefactor $\mathcal{A}_n^{\mathrm{MHV,tree}}$ carries a fixed dual conformal and little-group weight and the *ratio function* R_n is a dual conformal *invariant*: a function of the cross-ratios Eq. (62.121) alone. The covariance is the content; the prefactor is universal and carries all the weight.

For planar maximally supersymmetric Yang–Mills the prefactor is the supersymmetric completion of the Parke–Taylor MHV amplitude, whose bosonic content we imported as Eq. (59.55); the statement that R_n depends on nothing but cross-ratios is the dual conformal Ward identity, established at tree level by direct inspection of the BCFW terms and conjecturally exact (with an anomaly at loop level localized on the null edges). We do not reprove the all-multiplicity statement here; instead we prove the cleanest instance of it, which already shows why the symmetry is so restrictive.

Proposition 62.35 (The four- and five-point ratio functions are constants)**.** *For $n = 4$ and $n = 5$ there are no nonconstant dual conformal invariants: every cross-ratio Eq. (62.121) that can be formed from the region coordinates is either ill-defined (a vanishing null separation in a denominator) or reduces to a constant. Consequently the ratio function R_n of Eq. (62.122) is a pure number for $n = 4, 5$, and the entire kinematic dependence of the four- and five-point amplitudes sits in the MHV prefactor.*

Proof. For a null n-gon the only nonvanishing invariants are the diagonals x_{ij}^2 with $j \neq i, i\pm1 \pmod n$; the adjacent ones vanish by Eq. (62.119). A nonconstant cross-ratio Eq. (62.121) requires four region points x_i, x_j, x_k, x_l for which all four of $x_{ij}^2, x_{kl}^2, x_{ik}^2, x_{jl}^2$ are nonzero diagonals.

At $n = 4$ there are four cusps and the only candidate separations are x_{13}^2 and x_{24}^2; all others $(x_{12}^2, x_{23}^2, x_{34}^2, x_{14}^2)$ are null edges and vanish. A cross-ratio needs four distinct nonzero separations, and only two exist, so none can be formed: any attempt places a vanishing edge in a denominator. Hence there is no dual conformal invariant and R_4 is constant.

At $n = 5$ there are five cusps; the nonzero separations are the five diagonals $x_{13}^2, x_{24}^2, x_{35}^2, x_{41}^2, x_{52}^2$. A cross-ratio $u_{ijkl} = x_{ij}^2 x_{kl}^2/(x_{ik}^2 x_{jl}^2)$ requires the pairs $\{ij\}, \{kl\}, \{ik\}, \{jl\}$ to all be diagonals. With only five labels, any four indices i, j, k, l include at least one adjacent pair among these four combinations (the four "connectors" of four cyclically placed points on a pentagon cannot all skip a neighbour), so at least one of the four separations is a vanishing edge. No legitimate cross-ratio survives, and R_5 is constant. The first nontrivial cross-ratios appear at $n = 6$, where exactly three independent ones exist; we meet them in Theorem 62.43. □

This is the power of the symmetry made concrete: at four and five points it fixes the amplitude up to a single overall number, which is why those amplitudes are so simple. To exploit dual conformal symmetry systematically, however, we

must linearize it — the inversion I acts nonlinearly on x-space — and that is exactly what twistor space accomplishes.

62.5.2 Momentum twistors

The conformal group of four-dimensional spacetime is $\mathrm{SO}(2,4) \cong \mathrm{SU}(2,2)$ (up to covers), and $\mathrm{SU}(2,2)$ has a four-dimensional fundamental representation. Conformal transformations, nonlinear on x-space, become *linear* on this four-dimensional space: the *twistor space* $\mathbb{C}^4$, viewed projectively as $\mathbb{P}^3$ because an overall scale is physically irrelevant. The bridge between a point x of (dual) spacetime and twistor space is the classical incidence relation. We use it to attach a twistor to each cusp of the null polygon.

Definition 62.36 (Momentum twistor)**.** To each external particle i associate the *momentum twistor*

$$Z_i^A \;=\; (\lambda_i^\alpha,\; \mu_i^{\dot\alpha}), \qquad A = 1,2,3,4, \tag{62.123}$$

a point of $\mathbb{P}^3$ (defined up to overall scale), whose first two components are the holomorphic spinor λ_i of particle i and whose last two components are fixed by the *incidence relation* tying μ_i to the region coordinates,

$$\mu_i^{\dot\alpha} \;=\; x_i^{\alpha\dot\alpha}\lambda_{i\alpha} \;=\; x_{i+1}^{\alpha\dot\alpha}\lambda_{i\alpha}. \tag{62.124}$$

The two expressions agree because $x_i - x_{i+1} = p_i = \lambda_i\tilde\lambda_i$ and $p_i^{\alpha\dot\alpha}\lambda_{i\alpha} = \lambda_i^\alpha\lambda_{i\alpha}\,\tilde\lambda_i^{\dot\alpha} = \langle i\,i\rangle\tilde\lambda_i^{\dot\alpha} = 0$. The supersymmetric extension appends Grassmann-odd $\mathrm{SU}(4)_R$ components χ_i^I, fixed by the analogous incidence with the dual fermionic coordinate θ_i, giving the *momentum supertwistor*

$$\mathcal{Z}_i \;=\; (Z_i^A \mid \chi_i^I), \qquad \chi_i^I \;=\; \theta_i^{\alpha I}\lambda_{i\alpha}, \quad I = 1,\dots,4, \tag{62.125}$$

with the χ_i^I defined by the same incidence in the dual chiral superspace; we use the bosonic Z_i throughout and return to the fermions only to fix the helicity degree.

The incidence relation Eq. (62.124) has a clean geometric reading. As λ ranges over all spinors, the locus $\{(\lambda,\, x\lambda)\}$ is a line $\mathbb{P}^1 \subset \mathbb{P}^3$; this is the twistor image of the single spacetime point x. Equation Eq. (62.124) says Z_i lies on the line of x_i *and* on the line of x_{i+1}: it is their intersection. Equivalently, the line through two consecutive momentum twistors Z_{i-1} and Z_i is the image of the cusp x_i they share (the cusp where edges p_{i-1} and p_i meet). The null polygon in x-space becomes a closed chain of lines in $\mathbb{P}^3$, each pair of adjacent lines meeting at a momentum twistor.

Two consistency checks confirm that the momentum twistor is the right repackaging. The first is little-group covariance. The second, more important, is that generic momentum twistors reconstruct *exactly* on-shell, momentum-conserving kinematics — the map $Z \to p$ lands precisely on the physical region.

Proposition 62.37 (Projective rescaling realizes little-group scaling)**.** *Under the projective rescaling $Z_i \to t_i Z_i$ of a single momentum twistor (legitimate because Z_i is a point of $\mathbb{P}^3$), the recovered spinors transform by the little-group weight of particle i:*

$$\lambda_i \to t_i\,\lambda_i, \qquad \tilde{\lambda}_i \to t_i^{-1}\,\tilde{\lambda}_i, \tag{62.126}$$

so the physical massless momentum $p_i = \lambda_i\tilde{\lambda}_i$ is invariant, exactly as required by Theorem 58.2.

We prove this once we have the recovery formula for $\tilde{\lambda}$, to which we now turn.

Theorem 62.38 (Momentum twistors solve the kinematics)**.** *Let $Z_1, \dots, Z_n$ be momentum twistors with cyclic labels ($Z_{n+1} \equiv Z_1$, etc.) and with $\langle i-1\, i\rangle \neq 0$ for every i (genericity). Set λ_i equal to the top two components of Z_i and define*

$$\tilde{\lambda}_i^{\dot\alpha} \;=\; \frac{\langle i-1\, i+1\rangle\,\mu_i^{\dot\alpha} - \langle i\, i+1\rangle\,\mu_{i-1}^{\dot\alpha} - \langle i-1\, i\rangle\,\mu_{i+1}^{\dot\alpha}}{\langle i-1\, i\rangle\,\langle i\, i+1\rangle}. \tag{62.127}$$

Then the momenta $p_i^{\alpha\dot\alpha} = \lambda_i^\alpha\tilde{\lambda}_i^{\dot\alpha}$ are automatically (i) on shell, $p_i^2 = 0$, and (ii) momentum conserving, $\sum_i p_i = 0$. Conversely, every on-shell momentum-conserving planar configuration with $\langle i-1\, i\rangle \neq 0$ arises this way, so the map from (generic) momentum twistors to physical kinematics is onto.

Proof. Reconstructing the region points. The incidence relation Eq. (62.124) for the two twistors Z_{i-1}, Z_i on the line of the shared cusp x_i reads $\mu_{i-1}^{\dot\alpha} = x_i^{\alpha\dot\alpha}\lambda_{i-1,\alpha}$ and $\mu_i^{\dot\alpha} = x_i^{\alpha\dot\alpha}\lambda_{i,\alpha}$. Since $\langle i-1\, i\rangle \neq 0$, the spinors λ_{i-1}, λ_i form a basis, and these two equations determine x_i uniquely:

$$x_i^{\alpha\dot\alpha} \;=\; \frac{\lambda_{i-1}^\alpha\,\mu_i^{\dot\alpha} - \lambda_i^\alpha\,\mu_{i-1}^{\dot\alpha}}{\langle i-1\, i\rangle}. \tag{62.128}$$

This is verified by contraction: contracting the right side with $\lambda_{i,\alpha}$ uses $\lambda_{i-1}^\alpha\lambda_{i,\alpha} = \langle i-1\, i\rangle$ and $\lambda_i^\alpha\lambda_{i,\alpha} = \langle i\, i\rangle = 0$, returning $\mu_i^{\dot\alpha}$; contracting with $\lambda_{i-1,\alpha}$ uses $\lambda_i^\alpha\lambda_{i-1,\alpha} = \langle i\, i-1\rangle = -\langle i-1\, i\rangle$ and $\lambda_{i-1}^\alpha\lambda_{i-1,\alpha} = 0$, returning $\mu_{i-1}^{\dot\alpha}$. Both incidence relations hold, so Eq. (62.128) is the cusp.

On-shell for free. By construction each $p_i = \lambda_i\tilde{\lambda}_i$ is a rank-one bispinor, so $p_i^2 = \det(p_i^{\alpha\dot\alpha}) = \det(\lambda_i^\alpha\tilde{\lambda}_i^{\dot\alpha}) = 0$ identically. Masslessness is not imposed; it is automatic the instant a momentum is written as $\lambda\tilde{\lambda}$. It remains only to check that Eq. (62.127) is the $\tilde{\lambda}$ that makes $\lambda_i\tilde{\lambda}_i = x_i - x_{i+1}$.

Recovering $\tilde{\lambda}$. Contract the identity $p_i^{\alpha\dot\alpha} = \lambda_i^\alpha\tilde{\lambda}_i^{\dot\alpha}$ with $\lambda_{i+1,\alpha}$. The left side gives $(x_i - x_{i+1})^{\alpha\dot\alpha}\lambda_{i+1,\alpha}$ and the right side gives $\langle i\, i+1\rangle\tilde{\lambda}_i^{\dot\alpha}$, so

$$\tilde{\lambda}_i^{\dot\alpha} \;=\; \frac{1}{\langle i\, i+1\rangle}\Big[x_i^{\alpha\dot\alpha}\lambda_{i+1,\alpha} - x_{i+1}^{\alpha\dot\alpha}\lambda_{i+1,\alpha}\Big]. \tag{62.129}$$

The second bracket is an incidence relation: $x_{i+1}^{\alpha\dot\alpha}\lambda_{i+1,\alpha} = \mu_{i+1}^{\dot\alpha}$ by Eq. (62.124). For the first, contract Eq. (62.128) with $\lambda_{i+1,\alpha}$, using $\lambda_{i-1}^{\alpha}\lambda_{i+1,\alpha} = \langle i-1\, i+1\rangle$ and $\lambda_i^{\alpha}\lambda_{i+1,\alpha} = \langle i\, i+1\rangle$:

$$x_i^{\alpha\dot\alpha}\lambda_{i+1,\alpha} \;=\; \frac{\langle i-1\, i+1\rangle\,\mu_i^{\dot\alpha} - \langle i\, i+1\rangle\,\mu_{i-1}^{\dot\alpha}}{\langle i-1\, i\rangle}. \tag{62.130}$$

Substituting both into Eq. (62.129),

$$\tilde\lambda_i^{\dot\alpha} \;=\; \frac{1}{\langle i\, i+1\rangle}\left[\frac{\langle i-1\, i+1\rangle\,\mu_i^{\dot\alpha} - \langle i\, i+1\rangle\,\mu_{i-1}^{\dot\alpha}}{\langle i-1\, i\rangle} - \mu_{i+1}^{\dot\alpha}\right] = \frac{\langle i-1\, i+1\rangle\,\mu_i^{\dot\alpha} - \langle i\, i+1\rangle\,\mu_{i-1}^{\dot\alpha} - \langle i-1\, i\rangle\,\mu_{i+1}^{\dot\alpha}}{\langle i-1\, i\rangle\langle i\, i+1\rangle} \tag{62.131}$$

which is Eq. (62.127). Using $\langle i-1\, i+1\rangle = -\langle i+1\, i-1\rangle$ the numerator is the antisymmetric combination $\langle i\, i+1\rangle\mu_{i-1} + \langle i+1\, i-1\rangle\mu_i + \langle i-1\, i\rangle\mu_{i+1}$ up to an overall sign that depends on the index convention of Eq. (62.114); this is Hodges's inversion formula.

Momentum conservation for free. Because Eq. (62.127) was derived as the unique $\tilde\lambda_i$ with $\lambda_i\tilde\lambda_i = x_i - x_{i+1}$, the reconstructed momenta are exactly the edge differences, and Eq. (62.116) gives $\sum_i p_i = x_1 - x_{n+1} = 0$ from the cyclic identification $Z_{n+1} \equiv Z_1$. No constraint is imposed; closure of the polygon is built into the cyclic labelling of the twistors.

Surjectivity. Given any physical configuration — null momenta $p_i = \lambda_i\tilde\lambda_i$ with $\sum_i p_i = 0$ and $\langle i-1\, i\rangle \neq 0$ — choose any base point x_1 and define $x_{i+1} = x_i - p_i$; the sum rule makes $x_{n+1} = x_1$, so the x_i are consistent region coordinates. Set $\mu_i^{\dot\alpha} = x_i^{\alpha\dot\alpha}\lambda_{i\alpha}$ and $Z_i = (\lambda_i, \mu_i)$. Feeding these into Eq. (62.127) returns the original $\tilde\lambda_i$ and hence the original p_i. Thus the map is onto the physical region, with fibre exactly the four-parameter choice of x_1 (dual translations) together with the projective rescalings of Eq. (62.126). □

We can now close the little-group check.

Proof of Theorem 62.37. Under $Z_i \to t_i Z_i$ both components scale, $\lambda_i \to t_i\lambda_i$ and $\mu_i \to t_i\mu_i$, while the other twistors are untouched. The first component of Z_i is λ_i, so $\lambda_i \to t_i\lambda_i$, the correct angle-bracket weight. For $\tilde\lambda_i$, inspect Eq. (62.127). Each numerator term carries one power each of the three labels $i-1, i, i+1$: $\langle i\, i+1\rangle\mu_{i-1} \sim t_{i-1}t_i t_{i+1}$, and likewise for the other two terms. The denominator $\langle i-1\, i\rangle\langle i\, i+1\rangle \sim t_{i-1}t_i^2 t_{i+1}$. Hence

$$\tilde\lambda_i \;\longrightarrow\; \frac{t_{i-1}t_i t_{i+1}}{t_{i-1}t_i^2 t_{i+1}}\,\tilde\lambda_i \;=\; t_i^{-1}\tilde\lambda_i, \tag{62.132}$$

exactly the weight -1 of Eq. (62.126), so $p_i = \lambda_i\tilde\lambda_i$ is invariant and the neighbours $\tilde\lambda_{i\pm1}$ are unaffected (each depends on Z_i only through brackets that scale homogeneously and cancel). The projective nature of $\mathbb{P}^3$ *is* little-group covariance. □

Physical Insight

The momentum twistor solves at one stroke the two structural nuisances of spinor-helicity kinematics. Momentum conservation, four nonlinear constraints among the $\lambda, \tilde{\lambda}$, becomes the mere act of closing a polygon — automatic once the Z_i are listed cyclically. And the little-group redundancy, an awkward bookkeeping of weights, becomes the projective scaling of points in $\mathbb{P}^3$, the most natural redundancy a geometer knows. What remains, the Z_i themselves, are *unconstrained* points of projective space: any n of them give legal kinematics. That is precisely the unconstrained, geometric external data the amplituhedron needs as input.

62.5.3 Four-brackets and the dual conformal invariants

Linearizing the conformal group buys us a clean classification of its invariants. Conformal transformations act on twistor space as SL(4) (the complexification of SU(2, 2)), and the unique SL(4)-invariant pairing of four points is the determinant.

Definition 62.39 (Four-bracket)**.** For four momentum twistors the *four-bracket* is the totally antisymmetric SL(4) invariant

$$\langle i\, j\, k\, l\rangle \;\equiv\; \varepsilon_{ABCD}\, Z_i^A Z_j^B Z_k^C Z_l^D \;=\; \det\left(Z_i, Z_j, Z_k, Z_l\right), \tag{62.133}$$

the 4×4 determinant of the four twistors as columns. It vanishes precisely when the four points lie in a common plane in $\mathbb{P}^3$, equivalently when the two lines (ij) and (kl) meet.

The four-bracket is the dual conformal invariant. Its physical content is the translation of the planar Mandelstam invariants Eq. (62.118) into twistor language, which is the single most useful identity of the formalism.

Lemma 62.40 (Four-brackets are planar Mandelstams)**.** *With the conventions of Eq. (62.114), and writing x_{ij}^2 for the region separation Eq. (62.117),*

$$\langle i{-}1,\, i,\, j{-}1,\, j\rangle \;=\; \langle i-1\, i\rangle\, \langle j-1\, j\rangle\, x_{ij}^2. \tag{62.134}$$

Proof. We need two elementary 2×2 facts. First, for any bispinor matrix $M^{\alpha\dot\alpha}$ and spinors a, b, writing $(Ma)^{\dot\alpha} \equiv M^{\alpha\dot\alpha} a_\alpha$,

$$\det\left[(Ma)^{\dot\alpha}\,|\,(Mb)^{\dot\alpha}\right] \;=\; \varepsilon_{\dot\alpha\dot\beta}(Ma)^{\dot\alpha}(Mb)^{\dot\beta} \;=\; \varepsilon_{\dot\alpha\dot\beta} M^{\alpha\dot\alpha} M^{\beta\dot\beta} a_\alpha b_\beta \;=\; \det(M)\,\varepsilon^{\alpha\beta} a_\alpha b_\beta \;=\; \det(M) \tag{62.135}$$

where the middle step is the 2×2 cofactor identity $\varepsilon_{\dot\alpha\dot\beta} M^{\alpha\dot\alpha} M^{\beta\dot\beta} = \det(M)\,\varepsilon^{\alpha\beta}$. Second, $\det(x^{\alpha\dot\alpha}) = x^2$, so $\det(x_i - x_j) = x_{ij}^2$.

Now compute Eq. (62.133) for the four labels $i{-}1, i, j{-}1, j$. Place the twistors on their cusp lines using incidence: $Z_{i-1} = (\lambda_{i-1}, x_i\lambda_{i-1})$, $Z_i = (\lambda_i, x_i\lambda_i)$ (both

on the line of x_i), and $Z_{j-1} = (\lambda_{j-1}, x_j\lambda_{j-1})$, $Z_j = (\lambda_j, x_j\lambda_j)$ (both on the line of x_j). The 4×4 matrix has a top (spinor) block of rows λ and a bottom (μ) block of rows $x\lambda$. Perform the row operation "subtract x_i times the top rows from the bottom rows," i.e. $\mu^{\dot\alpha} \to \mu^{\dot\alpha} - x_i^{\alpha\dot\alpha}\lambda_\alpha$ in every column; adding a fixed multiple of some rows to others leaves the determinant unchanged. The bottom entries become

$$\begin{aligned} &\text{columns } i{-}1,\, i: \quad x_i\lambda - x_i\lambda = 0, \\ &\text{columns } j{-}1,\, j: \quad x_j\lambda - x_i\lambda = (x_j - x_i)\lambda = x_{ji}\lambda. \end{aligned} \tag{62.136}$$

Only the last two columns now have nonzero bottom block, so the generalized Laplace expansion along the bottom two rows has a single surviving term — bottom minor on columns $\{j{-}1, j\}$, top minor on the complement $\{i{-}1, i\}$ — with relative sign $(-1)^{(3+4)+(3+4)} = +1$:

$$\langle i{-}1, i, j{-}1, j\rangle = \underbrace{\det[\lambda_{i-1}\,|\,\lambda_i]}_{=\langle i{-}1\, i\rangle} \cdot \underbrace{\det\big[(x_{ji}\lambda_{j-1})\,|\,(x_{ji}\lambda_j)\big]}_{=\det(x_{ji})\,\langle j{-}1\, j\rangle}. \tag{62.137}$$

By Eq. (62.135) with $M = x_{ji}$ the bottom minor is $\det(x_{ji})\langle j{-}1\, j\rangle = x_{ji}^2\langle j{-}1\, j\rangle = x_{ij}^2\langle j-1\, j\rangle$. Collecting the two factors gives Eq. (62.134). □

Equation Eq. (62.134) is the workhorse. Read as

$$x_{ij}^2 \;=\; \frac{\langle i{-}1,\, i,\, j{-}1,\, j\rangle}{\langle i-1\, i\rangle\,\langle j-1\, j\rangle}, \tag{62.138}$$

it expresses every planar propagator as a four-bracket divided by two angle brackets. The $\langle\ \rangle$ factors carry all the little-group and dual conformal weight; they sit inside the universal MHV prefactor of Eq. (62.122). After dividing by that prefactor, the ratio function R_n depends on the kinematics *only* through ratios of four-brackets in which all weights cancel — precisely the cross-ratios Eq. (62.121), now written

$$u_{ijkl} \;=\; \frac{x_{ij}^2 x_{kl}^2}{x_{ik}^2 x_{jl}^2} \;=\; \frac{\langle i{-}1, i, j{-}1, j\rangle\,\langle k{-}1, k, l{-}1, l\rangle}{\langle i{-}1, i, k{-}1, k\rangle\,\langle j{-}1, j, l{-}1, l\rangle}. \tag{62.139}$$

Dual conformal symmetry has become the manifest SL(4) covariance of the four-bracket, and the dual conformal invariants are manifestly the weightless four-bracket ratios. This is why momentum twistors are the natural variables: a quantity is dual conformal invariant if and only if it is an SL(4)- and scaling-invariant function of the $\langle ijkl\rangle$.

Physical Insight

The single most important practical consequence is the disappearance of spurious poles, which is what motivated Hodges to introduce these variables. In spinor-helicity a recursion term carries denominators like $\langle i|j+k|l] = \lambda_i^\alpha (p_j + p_k)_{\alpha\dot\alpha} \tilde\lambda_l^{\dot\alpha}$ or $\lambda|x|y]$ that are *not* momenta-conservation-respecting invariants and do not correspond to any physical channel; tracking their cancellation across terms is a chore. In momentum twistors every such object becomes a *single four-bracket* $\langle abcd\rangle$. A physical channel is one of the special form $\langle i-1, i, j-1, j\rangle \propto x_{ij}^2$; everything else is geometrically a spurious pole, and its cancellation is the elementary statement that a four-bracket appears in two adjacent terms with opposite residues — exactly the polygon mechanism of Theorem 62.9. We see this explicitly in Theorem 62.43.

62.5.4 The positive external data

We can finally state the input the amplituhedron consumes. The geometry of the next section is built from two positivities: the positivity of the *internal* on-shell data, the positive Grassmannian $\mathrm{Gr}_{\geq 0}(k,n)$ of Theorem 62.22, and the positivity of the *external* kinematic data, which is a condition on the momentum twistors. We define the latter now.

Notation Watch

The helicity index k changes meaning at this point, and we flag the shift once and for all. In the momentum-space on-shell Grassmannian of Sections 62.3 and 62.4, k is the *MHV degree* — the number of negative-helicity legs — so MHV sits at $k=2$ on $\mathrm{Gr}_{\geq 0}(2,n)$, NMHV at $k=3$, and an amplitude is written $\mathrm{N}^{k-2}\mathrm{MHV}$. From here on, in the momentum-twistor description that feeds the amplituhedron, k denotes the *reduced* helicity index, equal to the MHV degree minus two: MHV is $k=0$, NMHV is $k=1$, and the amplitude is written $\mathrm{N}^k\mathrm{MHV}$. The two values index genuinely different Grassmannians — the momentum-space $\mathrm{Gr}_{\geq 0}(k_{\mathrm{MHV}},n)$ with $k_{\mathrm{MHV}}=2$ for MHV, versus the momentum-twistor $\mathrm{Gr}_{\geq 0}(k,n)$ with $k = k_{\mathrm{MHV}} - 2$ that the map $Y = C\cdot Z$ of the next section pushes through Z — although both are the "totally nonnegative Grassmannian" in the single sense of Theorem 62.22, the only change being which integer is plugged in for k. The two amplitude labels reconcile through $\mathrm{N}^k\mathrm{MHV} = \mathrm{N}^{k_{\mathrm{MHV}}-2}\mathrm{MHV}$. Throughout the amplituhedron sections k is the reduced index unless we explicitly say "MHV degree."

Arrange the n momentum twistors as the rows of a matrix. For the physical theory each row is extended from the four bosonic components to $k+4$ components

by appending k bosonized fermionic directions (we explain the bosonization only as far as needed; the construction is completed in Section 62.2). Write the resulting $n \times (k+m)$ matrix as Z, with $m = 4$ the physical value. Its ordered maximal minors are the $(k+m) \times (k+m)$ determinants of rows $i_1 < \cdots < i_{k+m}$; for the purely bosonic case $k = 0$, $m = 4$ these maximal minors are exactly the four-brackets $\langle i_1 i_2 i_3 i_4 \rangle$.

Definition 62.41 (Positive external data)**.** The external data Z is *positive* if every ordered maximal minor of the $n \times (k+m)$ matrix Z is strictly positive,

$$\langle Z_{i_1} Z_{i_2} \cdots Z_{i_{k+m}} \rangle \; > \; 0 \qquad \text{for all } 1 \le i_1 < i_2 < \cdots < i_{k+m} \le n. \tag{62.140}$$

For the bosonic momentum twistors ($m = 4$, $k = 0$) this is the statement that all ordered four-brackets are positive,

$$\langle ijkl \rangle \; > \; 0 \qquad \text{for } 1 \le i < j < k < l \le n. \tag{62.141}$$

A Z satisfying Eq. (62.140) represents a point of the totally positive Grassmannian $\mathrm{Gr}_{>0}(k+m, n)$ (the row span of Z^{T}), and we say Z lies in the *positive region*.

Three remarks make this definition usable. First, positivity is a condition on a *representative*: the four-brackets are not projective invariants of the individual Z_i (rescaling $Z_i \to t_i Z_i$ multiplies a bracket by t_i), but the statement "all ordered brackets share one sign" is invariant under positive rescalings and under the residual SL() frame change, so Eq. (62.140) is well posed exactly as the positivity of the Grassmannian was in Theorem 62.22. Second, such Z exist in abundance: the rows of the moment curve provide them, as we now check. Third, positivity of Z is not a property of generic physical kinematics — a Lorentzian scattering configuration generally has four-brackets of mixed sign — but a choice of a special, "positive" slice of complexified kinematics, on which the amplituhedron is a genuine region with boundaries. This is the honest scope: the amplituhedron lives over positive external data, and the physical amplitude is reached by analytic continuation away from it.

Example 62.42 (The moment curve gives positive data)**.** Let $Z_i = (1,\, t_i,\, t_i^2,\, t_i^3)$ for an increasing sequence $t_1 < t_2 < \cdots < t_n$. The four-bracket is the Vandermonde determinant

$$\langle ijkl \rangle = \det \begin{pmatrix} 1 & t_i & t_i^2 & t_i^3 \\ 1 & t_j & t_j^2 & t_j^3 \\ 1 & t_k & t_k^2 & t_k^3 \\ 1 & t_l & t_l^2 & t_l^3 \end{pmatrix} = \prod_{a<b \in \{i,j,k,l\}} (t_b - t_a) \; > \; 0 \tag{62.142}$$

whenever $i < j < k < l$, since every factor $t_b - t_a$ is positive. Thus the moment curve furnishes positive external data Eq. (62.141) for any n. The same construction with $(k+m)$-component rows $Z_i = (1, t_i, \ldots, t_i^{k+m-1})$ makes all

ordered maximal minors positive Vandermondes, giving positive data for any k, m. The moment curve is the canonical example we use whenever an explicit positive Z is wanted.

The physical sector and a toy sector now both fall under one umbrella. The physical case $m = 4$ feeds the bosonic momentum twistors into Theorem 62.41; the helicity degree k counts the Grassmann degree of the superamplitude, with $k = 0$ the MHV sector and $k = 1$ the NMHV sector. There is also a pedagogically invaluable *toy sector* $m = 2$, in which the maximal minors are $(k + 2) \times (k + 2)$ determinants. The toy sector $m = 2$, $k = 1$ is the one we have already met without naming it: a $1 \times n$ positive Grassmannian mapped by an $n \times 3$ positive Z into $\mathbb{P}^2$ produces a convex polygon, whose canonical form is exactly the polygon form of Theorem 62.9. The $m = 2$ sector is where every statement of the next section can be proved rigorously, with the $m = 4$ physics running in exact parallel but resting on the conjecture stated there.

Worked Example 62.43 (Six-point twistors, four-brackets, and a spurious pole made manifest)**.** We carry out the whole construction concretely at $n = 6$, the first multiplicity with nontrivial dual conformal invariants and the first NMHV $(k = 1)$ amplitude, and we watch a spurious pole collapse to a single four-bracket whose cancellation is then immediate.

Positive data from the moment curve. Take $Z_i = (1, t_i, t_i^2, t_i^3)$ with $0 < t_1 < \cdots < t_6$. By Eq. (62.142) every ordered four-bracket is a positive Vandermonde product; for instance, with the convenient choice $t_i = i$,

$$\langle 1234\rangle = \prod_{1\le a<b\le 4}(b-a) = 12, \qquad \langle 3456\rangle = \prod_{3\le a<b\le 6}(b-a) = 12, \qquad \langle 1356\rangle = (2)(4)(5)(2)(3)(1) = \tag{62.143}$$

and one checks all $\binom{6}{4} = 15$ ordered brackets are positive: this Z lies in the positive region Eq. (62.141).

Recovering kinematics. The angle spinors are the top two components, $\lambda_i = (1, t_i)$, so $\langle i\, j\rangle = t_j - t_i$ (a positive ordered bracket, consistently). The dotted spinors follow from Eq. (62.127); e.g. with $\mu_i = (t_i^2, t_i^3)$,

$$\tilde{\lambda}_i = \frac{\langle i-1\, i+1\rangle \mu_i - \langle i\, i+1\rangle \mu_{i-1} - \langle i-1\, i\rangle \mu_{i+1}}{\langle i-1\, i\rangle\langle i\, i+1\rangle}, \tag{62.144}$$

and the reconstructed $p_i = \lambda_i \tilde{\lambda}_i$ are massless by Theorem 62.38(i) and sum to zero by telescoping Eq. (62.116): the closed cyclic list $Z_1, \ldots, Z_6, Z_1$ *is* the momentum-conserving configuration, with no constraint to enforce.

The three cross-ratios. At six points dual conformal symmetry leaves exactly three independent invariants, the cyclic class

$$u_1 = \frac{x_{13}^2 x_{46}^2}{x_{14}^2 x_{36}^2}, \quad u_2 = \frac{x_{24}^2 x_{15}^2}{x_{25}^2 x_{14}^2}, \quad u_3 = \frac{x_{35}^2 x_{26}^2}{x_{36}^2 x_{25}^2}, \tag{62.145}$$

each of which, via Eq. (62.138), becomes a weightless ratio of four-brackets through the dictionary of Eq. (62.139); for instance $u_1 = \dfrac{\langle 6123\rangle\langle 3456\rangle}{\langle 6134\rangle\langle 2356\rangle}$, every angle-bracket weight having cancelled between numerator and denominator. These three cross-ratios are the variables on which the NMHV ratio function R_6 depends, in agreement with Theorem 62.35 (which forbade any such dependence at $n = 4, 5$).

The ratio function and its poles. The NMHV ratio function is a sum of dual superconformal R-invariants. Each is the five-bracket

$$[a\,b\,c\,d\,e] \;=\; \frac{\delta^{0|4}\big(\langle bcde\rangle\chi_a + \langle cdea\rangle\chi_b + \langle deab\rangle\chi_c + \langle eabc\rangle\chi_d + \langle abcd\rangle\chi_e\big)}{\langle abcd\rangle\,\langle bcde\rangle\,\langle cdea\rangle\,\langle deab\rangle\,\langle eabc\rangle}, \tag{62.146}$$

a manifestly dual conformal object (the Grassmann delta in the numerator carries the supersymmetric weight; the denominator is five four-brackets). The six-point tree ratio function has the two equivalent BCFW representations

$$R_6 \;=\; [23456] + [12456] + [12346] \;=\; [13456] + [12356] + [12345], \tag{62.147}$$

the two sums being the twistor images of the two BCFW triangulations, exactly as the pentagon had two triangulations in Theorem 62.10.

The spurious pole, manifest. Consider the four-bracket $\langle 2456\rangle$. It is *not* of the physical form $\langle i{-}1, i, j{-}1, j\rangle$: its labels $\{2, 4, 5, 6\}$ contain no two adjacent-pair structure compatible with Eq. (62.134), so by Theorem 62.40 it is not proportional to any planar Mandelstam — it is a spurious pole. In the first representation of Eq. (62.147) it appears in the denominators of exactly two terms: in $[12456]$ (as the factor $\langle 2456\rangle$, with the cyclic ordering $cdea = 2456$ giving $\langle cdea\rangle = \langle 2456\rangle$) and in $[23456]$ (as $\langle 2456\rangle$ appearing among its five factors). Taking the residue at $\langle 2456\rangle \to 0$, the Grassmann numerators of the two terms become equal up to sign — the delta functions collapse to the *same* constraint once $\langle 2456\rangle = 0$ is imposed, because that condition forces the four points $2, 4, 5, 6$ coplanar and the two numerators to coincide — while the remaining bosonic factors are equal and opposite. Hence

$$\mathrm{Res}_{\langle 2456\rangle = 0}\,\big([12456] + [23456]\big) \;=\; 0, \tag{62.148}$$

exactly the equal-and-opposite-residue cancellation of Eq. (62.28) in the pentagon, now for an amplitude. The spurious pole is gone from R_6; only the physical four-brackets $\langle i{-}1, i, j{-}1, j\rangle \propto x_{ij}^2$ survive. The two representations in Eq. (62.147) have different spurious poles (the first uses $\langle 2456\rangle$ among others, the second uses $\langle 1356\rangle$), all of which cancel, leaving both equal to the same R_6 with poles only on physical channels — the uniqueness of Theorem 62.4 applied to amplitudes. What was, in spinor-helicity, a tangle of $\langle i|j + k|l]$ denominators whose cancellation required real work has become the bookkeeping of single four-brackets, each spurious one cancelling between two adjacent terms by inspection. This is

Hodges's elimination of spurious poles, and it is the same geometry as the disappearance of the diagonals of a triangulated polygon.

We have produced exactly what the amplituhedron consumes. The momentum twistors Z_i are unconstrained points of $\mathbb{P}^3$ that solve momentum conservation and on-shellness automatically (Theorem 62.38), make dual conformal symmetry the manifest SL(4) covariance of the four-brackets (Theorem 62.40), and assemble into a positive $n \times (k+m)$ matrix Z whose total positivity Eq. (62.140) is the canonical external datum. The next section fixes this Z and pushes the positive Grassmannian $\mathrm{Gr}_{\geq 0}(k,n)$ of Theorem 62.22 through it by the linear map $Y = C \cdot Z$ into the small Grassmannian $\mathrm{Gr}(k, k+m)$; the image is the amplituhedron, and its canonical form — in the precise sense forged in Theorem 62.3 — is conjecturally the planar superamplitude.

62.6 The amplituhedron

The previous section equipped us with two ingredients and a map. The first ingredient is the *positive external data*: the ordered $n \times (k+m)$ matrix Z, built from Hodge's momentum twistors, whose total positivity (every ordered maximal minor strictly positive) packages momentum conservation and dual conformal symmetry into a single combinatorial condition (Section 62.5). The second is the *positive Grassmannian* $\mathrm{Gr}_{\geq 0}(k,n)$, the locus of $k \times n$ matrices all of whose ordered maximal minors are nonnegative (Theorem 62.22), which organizes on-shell data the way a simplex organizes its barycentric coordinates. The map is the linear, positivity-preserving push-forward $Y = C \cdot Z$ that sends a k-plane C in n dimensions to a k-plane Y in $k+m$ dimensions. The amplituhedron is, in one line, the image of that map: a region carved out inside the small Grassmannian $\mathrm{Gr}(k, k+m)$ by pushing the positive Grassmannian through positive data. Everything in this section is the unpacking of that one line, and of the conjecture that the canonical form of the resulting region — in the precise sense of Theorem 62.3 — is the tree-level S-matrix of planar maximally supersymmetric Yang–Mills theory.

We proceed in the order that keeps honesty visible. First we define the map and the region with full care about dimensions and well-definedness. Then we isolate the one family where every claim can be *proved* with the polygon technology of Section 62.1.4 — the case $k = 1$, where the amplituhedron is a genuine convex cyclic polytope, with the physical sector $m = 4$ included — and we prove convexity from total positivity in full. Only then do we state the canonical-form-equals-amplitude conjecture, give the Grassmann/bosonization recipe that restores the fermions, and label precisely what is theorem and what is conjecture as of the mid-2020s. We close by reading locality and unitarity off the boundary stratification, proving the factorization of a codimension-one residue in the controlled polygon setting, and by stating — at the level of a definition,

scoped honestly — the loop amplituhedron whose canonical form is the all-loop planar integrand.

62.6.1 The amplituhedron map

We fix integers $k \geq 0$, $m \geq 0$, and $n \geq k+m$; the physical case is $m = 4$, with k the helicity degree to be explained in Section 62.6.3. Recall the two domains. The real Grassmannian $\mathrm{Gr}(k, N)$ is the manifold of k-dimensional linear subspaces of $\mathbb{R}^N$; a point is represented by a $k \times N$ matrix of full rank k, two matrices representing the same subspace iff they differ by left multiplication by an element of $\mathrm{GL}(k)$. Its dimension is $k(N-k)$. The *positive Grassmannian* $\mathrm{Gr}_{\geq 0}(k,n) \subset \mathrm{Gr}(k,n)$ is the closed subset on which all the ordered Plücker coordinates $p_{a_1 \cdots a_k} = \det\left(C_{\bullet,a_1}, \ldots, C_{\bullet,a_k}\right)$, taken over $1 \leq a_1 < \cdots < a_k \leq n$, are nonnegative (the strictly positive locus is its interior $\mathrm{Gr}_{>0}(k,n)$); the sign of an individual Plücker coordinate is not $\mathrm{GL}(k)$-invariant, but the condition "all of them share one sign" is, so the definition is well posed (Theorem 62.22).

Definition 62.44 (Amplituhedron map and the tree amplituhedron)**.** Let Z be a positive external-data matrix: an $n \times (k+m)$ real matrix whose ordered maximal minors

$$\langle Z_{a_1} \cdots Z_{a_{k+m}} \rangle \;\equiv\; \det \begin{pmatrix} Z_{a_1} \\ \vdots \\ Z_{a_{k+m}} \end{pmatrix}, \qquad a_1 < \cdots < a_{k+m}, \tag{62.149}$$

are all strictly positive, where $Z_a \in \mathbb{R}^{k+m}$ denotes the a-th row. Such a Z defines the *amplituhedron map*

$$\widetilde{Z} : \; \mathrm{Gr}_{\geq 0}(k,n) \longrightarrow \mathrm{Gr}(k, k+m), \qquad C \longmapsto Y \;=\; C \cdot Z, \tag{62.150}$$

where the $k \times (k+m)$ matrix $Y = C \cdot Z$ has rows $Y_\alpha = \sum_{a=1}^{n} C_{\alpha a} Z_a$. The *tree amplituhedron* is its image,

$$\mathcal{A}_{n,k,m} \;\equiv\; \widetilde{Z}\big(\mathrm{Gr}_{\geq 0}(k,n)\big) \;=\; \big\{\, Y \in \mathrm{Gr}(k,k+m) \;:\; Y = C \cdot Z,\; C \in \mathrm{Gr}_{\geq 0}(k,n) \,\big\}. \tag{62.151}$$

Three points of hygiene make this a sound definition rather than a slogan, and we settle them before going further.

The map descends to the Grassmannian. A change of representative $C \to gC$ with $g \in \mathrm{GL}(k)$ sends $Y = CZ$ to $gCZ = gY$, the same k-plane in $\mathbb{R}^{k+m}$. So $\widetilde{Z}$ is well defined on subspaces, not merely on matrices. The image Y has rank k generically: the rows Y_α are k linear combinations of the n rows of Z, and because Z has rank $k+m \geq k$ and C has rank k, the product CZ has rank k unless C is aligned with the kernel directions of Z — a positive-measure-zero

degeneration we treat as a boundary, not an interior point. Thus generic C lands in the top stratum of $\mathrm{Gr}(k, k+m)$.

The dimensions match. The positive Grassmannian $\mathrm{Gr}_{\geq 0}(k, n)$ has the dimension of $\mathrm{Gr}(k, n)$, namely $k(n-k)$, but the amplituhedron map is far from injective: it factors through the linear projection by Z, and its image $\mathcal{A}_{n,k,m}$ has dimension

$$\dim \mathcal{A}_{n,k,m} \;=\; k\,m, \tag{62.152}$$

matching $\dim \mathrm{Gr}(k, k+m) = k(k+m) - k^2 = km$. The amplituhedron is therefore a full-dimensional region inside the "small" Grassmannian $\mathrm{Gr}(k, k+m)$, exactly as a convex polygon is a full-dimensional region inside the plane. The collapse from $k(n-k)$ down to km is the geometric counterpart of the redundancy that on-shell recursion exploited: the n external legs are projected onto the $k+m$ directions that the amplitude actually depends on.

Positivity is what makes the image a region with boundary. If we dropped the positivity of C and allowed all of $\mathrm{Gr}(k, n)$, the image would be the whole of $\mathrm{Gr}(k, k+m)$ (for n large enough) — no boundary, no canonical form, no amplitude. It is precisely the inequalities "all Plücker coordinates of $C \geq 0$," combined with the strict positivity of Z, that cut out a closed region whose topological boundary is a union of codimension-one faces. The discipline of why $\mathcal{N} = 4$ is the right theory to attach to this construction is inherited from Chapter 61: among all the theories whose double-copy and color–kinematics structure we surveyed, planar $\mathcal{N} = 4$ is the maximally symmetric, dual-conformal copy in which the kinematic data collapse to the single positive matrix Z with no leftover scales — the cleanest possible substrate for a positive geometry.

Physical Insight

The amplituhedron inverts the usual logic of field theory. Ordinarily one starts from a Lagrangian (locality and unitarity built in by hand) and computes a region of validity afterwards. Here one starts from a region — the image Eq. (62.151) — defined by nothing but positivity, and locality and unitarity are *outputs*: they are read off from where the region has boundaries and from how its canonical form behaves there. The Lagrangian, the sum over Feynman diagrams, even the notion of spacetime, are nowhere in the definition. What replaces them is the single inequality structure of $\mathrm{Gr}_{\geq 0}(k, n)$ pushed through Z.

62.6.2 The rigorously controlled case: $k = 1$ and convex cyclic polytopes

Everything proved with full rigor in this chapter lives at $k = 1$, and it is worth seeing exactly why, because that is also where the physical NMHV amplitude

sits. When $k = 1$ the small Grassmannian degenerates to projective space, $\mathrm{Gr}(1, 1+m) = \mathbb{P}^m$, and the positive Grassmannian degenerates to the positive orthant: a $1 \times n$ matrix $C = (c_1, \ldots, c_n)$ has maximal minors equal to its own entries c_a, so $\mathrm{Gr}_{\geq 0}(1, n)$ is $\{c_a \geq 0\}$ modulo overall positive rescaling — the $(n-1)$-simplex of barycentric coordinates. The amplituhedron map becomes

$$Y \;=\; C \cdot Z \;=\; \sum_{a=1}^{n} c_a \, Z_a, \qquad c_a \geq 0, \tag{62.153}$$

a single point of $\mathbb{P}^m$ in the positive (projective) span of the n points $Z_1, \ldots, Z_n \in \mathbb{P}^m$. Its image $\mathcal{A}_{n,1,m}$ is therefore the convex hull of those n points. The content of the next theorem is that positivity of Z forces this hull to be a *cyclic polytope*: all n points are genuine vertices, in the cyclic order inherited from their labels, and the polytope is convex. We prove the planar case $m = 2$ in full — there the polytope is exactly the convex polygon of Theorem 62.9 — and then state the general m result, which the same determinant argument establishes.

Theorem 62.45 ($k = 1$ amplituhedra are convex cyclic polytopes)**.** *Let Z be a positive $n \times (m+1)$ matrix, with rows $Z_1, \ldots, Z_n$ regarded as points of $\mathbb{P}^m$. Then for $m = 2$ the points are the vertices, in cyclic order $Z_1, \ldots, Z_n$, of a convex polygon, and $\mathcal{A}_{n,1,2}$ is that polygon. Consequently $\mathcal{A}_{n,1,2}$ is a positive geometry in the sense of Theorem 62.3, its canonical form is the triangulation-independent polygon form of Theorem 62.9, and it is well defined. The same conclusion holds for every m: $\mathcal{A}_{n,1,m}$ is a cyclic polytope in $\mathbb{P}^m$ and a positive geometry.*

Proof. Take $m = 2$, so Z is $n \times 3$ and the positivity hypothesis is that every ordered 3×3 minor is strictly positive,

$$\langle Z_a Z_b Z_c \rangle \;>\; 0 \qquad \text{for all } 1 \leq a < b < c \leq n, \tag{62.154}$$

with $\langle Z_a Z_b Z_c \rangle$ the 3×3 determinant Eq. (62.149), the same bracket used for the triangle in Theorem 62.7. We must show two things: that no point Z_a lies in the convex hull of the others (so all are vertices), and that listing them in label order $1, 2, \ldots, n$ traverses the polygon boundary monotonically (so the polygon is convex with that cyclic edge structure).

Every point is a vertex, and the edges are the consecutive pairs. Consider the edge-line through two *consecutive* vertices Z_a and Z_{a+1}. A third point Z_b ($b \notin \{a, a+1\}$) lies on the side of this line determined by the sign of the bracket $\langle Z_a Z_{a+1} Z_b \rangle$, since this bracket is the affine-linear edge function evaluated at Z_b (it vanishes exactly on the line, Section 62.1.3). We claim that sign is the *same* for every b. There are two cases.

If $b > a+1$, the indices are already ordered $a < a+1 < b$, so $\langle Z_a Z_{a+1} Z_b \rangle > 0$ directly by Eq. (62.154).

If $b < a$, then the ordered triple is $b < a < a+1$, giving $\langle Z_b Z_a Z_{a+1} \rangle > 0$. The bracket is totally antisymmetric, and the permutation taking (Z_b, Z_a, Z_{a+1})

to (Z_a, Z_{a+1}, Z_b) is the cyclic rotation $(1\,2\,3)$, which is even; hence $\langle Z_a Z_{a+1} Z_b\rangle = \langle Z_b Z_a Z_{a+1}\rangle > 0$ as well.

So every other vertex lies strictly on the positive side of every consecutive edge-line. This is exactly the supporting-hyperplane characterization of a convex polygon: each line through a consecutive pair Z_a, Z_{a+1} has all remaining vertices on one side, so that segment is a genuine edge of the convex hull, and the n segments $[Z_a, Z_{a+1}]$ (a cyclic) fit together into the boundary of a convex n-gon traversed in label order. In particular no Z_a is interior to the hull of the others — if it were, it could not anchor two supporting edges — so all n points are vertices. This proves the polygon statement, and $\mathcal{A}_{n,1,2}$, being the convex hull Eq. (62.153) of these vertices, is that polygon.

It is a positive geometry. A convex polygon with vertices in $\mathbb{P}^2$ is precisely the object of Theorem 62.9: triangulate it from any vertex into $n-2$ triangles, sum their canonical forms Eq. (62.17), and the spurious diagonal poles cancel pairwise by Eq. (62.28), leaving a form with simple poles only on the n edge-lines $\langle Y\, Z_a Z_{a+1}\rangle = 0$ and residues equal to the interval forms of the edges. By the uniqueness Theorem 62.4 this form is triangulation-independent and is the canonical form $\Omega(\mathcal{A}_{n,1,2})$. Hence the amplituhedron is a positive geometry and its canonical form is well defined — the assertion of the theorem in the planar case.

General m. For arbitrary m the positivity hypothesis is $\langle Z_{a_0} \cdots Z_{a_m}\rangle > 0$ for all ordered $(m{+}1)$-tuples. A point Z_b lies on a definite side of the hyperplane through any m chosen vertices $Z_{a_1}, \ldots, Z_{a_m}$ according to the sign of $\langle Z_{a_1} \cdots Z_{a_m} Z_b\rangle$. The identical even-permutation argument shows that for the hyperplanes spanned by an "alternating" set of vertices in the cyclic order, all remaining vertices lie on one side; this is the defining incidence pattern of the cyclic polytope $C(n,m)$ generated by points on the moment curve, and total positivity of Z realizes exactly that pattern (the $(m{+}1)\times(m{+}1)$ minors of a totally positive matrix have the same sign structure as those of the Vandermonde moment-curve matrix). Thus $\mathcal{A}_{n,1,m}$ is the cyclic polytope $C(n,m)$, a bounded convex polytope. A convex polytope is a positive geometry: triangulate into simplices, each contributing the simplex form Eq. (62.22), with internal-facet residues cancelling pairwise by the same opposite-orientation mechanism as for the polygon; the sum is the unique canonical form with simple poles on the polytope's facets. This proves the general statement. □

The case $m = 2$ is the rigorous bridge back to Section 62.1.4: the abstract polygon whose triangulation-independence we proved there is realized concretely as the $k = 1$ amplituhedron of n-point kinematics. The physically interesting member of this rigorously controlled family is $m = 4$, $k = 1$: there $\mathcal{A}_{n,1,4}$ is a cyclic polytope in $\mathbb{P}^4$, and (as we explain in Section 62.6.3) its canonical form computes the n-point NMHV tree superamplitude. For $k = 1$ the canonical-form-equals-amplitude statement is therefore not a conjecture but a theorem about

polytope volumes — this is the content originally exhibited by Hodge's polytope picture of NMHV leading singularities. The genuinely open territory begins at $k \geq 2$, where the image Eq. (62.151) is no longer a polytope but a curved region inside $\mathrm{Gr}(k, k+m)$.

Worked Example 62.46 (Positivity forces convex position: the square $\mathcal{A}_{4,1,2}$)**.** We make Theorem 62.45 concrete at the smallest nontrivial polygon, $n = 4$, $m = 2$, $k = 1$. The positive data is a 4×3 matrix Z with rows $Z_1, Z_2, Z_3, Z_4 \in \mathbb{P}^2$ and all four ordered 3×3 minors positive:

$$\langle Z_1 Z_2 Z_3 \rangle,\ \langle Z_1 Z_2 Z_4 \rangle,\ \langle Z_1 Z_3 Z_4 \rangle,\ \langle Z_2 Z_3 Z_4 \rangle\ >\ 0. \tag{62.155}$$

The amplituhedron is $\mathcal{A}_{4,1,2} = \{\, Y = c_1 Z_1 + c_2 Z_2 + c_3 Z_3 + c_4 Z_4 : c_a \geq 0 \,\} \subset \mathbb{P}^2$, the convex hull of the four points. We verify directly that the hull is a convex quadrilateral with cyclic boundary $1 \to 2 \to 3 \to 4 \to 1$, not a triangle with one point inside.

Suppose, for contradiction, that Z_4 lay inside the triangle $Z_1 Z_2 Z_3$. Then $Z_4 = t_1 Z_1 + t_2 Z_2 + t_3 Z_3$ with all $t_i \geq 0$ (barycentric coordinates of an interior point). We extract each coefficient by contracting with the bracket of the other two vertices, using $\langle Z_a Z_b Z_a \rangle = 0$ and total antisymmetry. For t_3,

$$\langle Z_1 Z_2 Z_4 \rangle = t_1 \underbrace{\langle Z_1 Z_2 Z_1 \rangle}_{0} + t_2 \underbrace{\langle Z_1 Z_2 Z_2 \rangle}_{0} + t_3 \langle Z_1 Z_2 Z_3 \rangle = t_3 \, \langle Z_1 Z_2 Z_3 \rangle, \tag{62.156}$$

so $t_3 = \langle Z_1 Z_2 Z_4 \rangle / \langle Z_1 Z_2 Z_3 \rangle > 0$ by Eq. (62.155). The same contraction with $\langle Z_2 Z_3 \cdot \rangle$ gives $\langle Z_2 Z_3 Z_4 \rangle = t_1 \langle Z_2 Z_3 Z_1 \rangle = t_1 \langle Z_1 Z_2 Z_3 \rangle$, the last equality being an even cyclic rotation of the bracket, so $t_1 = \langle Z_2 Z_3 Z_4 \rangle / \langle Z_1 Z_2 Z_3 \rangle > 0$. The coefficient t_2 is where positivity bites. Contracting with $\langle Z_1 Z_3 \cdot \rangle$ places Z_4 in the *middle* slot of the other two vertices, an odd permutation:

$$\langle Z_1 Z_3 Z_4 \rangle = t_2 \, \langle Z_1 Z_3 Z_2 \rangle = -\, t_2 \, \langle Z_1 Z_2 Z_3 \rangle \qquad \Longrightarrow \qquad t_2 = -\,\frac{\langle Z_1 Z_3 Z_4 \rangle}{\langle Z_1 Z_2 Z_3 \rangle}\ <\ 0, \tag{62.157}$$

since both brackets are strictly positive by Eq. (62.155) while the swap $Z_3 \leftrightarrow Z_2$ costs a sign. This violates $t_2 \geq 0$. Therefore Z_4 is *not* in the convex hull of Z_1, Z_2, Z_3; it is a fourth vertex. By the cyclic symmetry of Eq. (62.155) no vertex is interior to the others, and the four points are in convex position. The boundary is the four edges $\langle Y 12 \rangle, \langle Y 23 \rangle, \langle Y 34 \rangle, \langle Y 41 \rangle$, and the canonical form is the quadrilateral form obtained by triangulating into $\{123\} \cup \{134\}$ (the diagonal $\langle Y 13 \rangle$ being spurious and cancelling, exactly as in Theorem 62.10 with one fewer vertex). The numeric evaluation of this quadrilateral form against an explicit positive Z is carried out in Section 62.6's successor, Section 62.7.

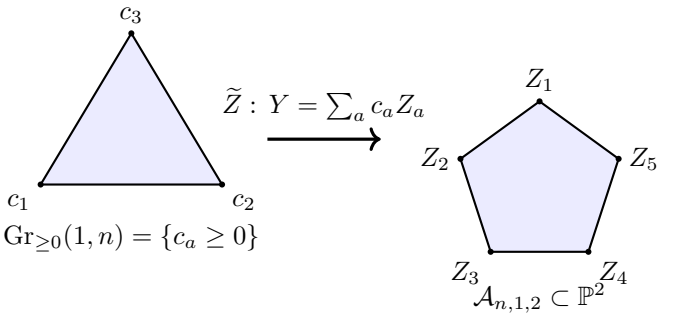


Figure 62.7: The $k = 1$ amplituhedron map. The positive Grassmannian $\mathrm{Gr}_{\geq 0}(1, n)$ is the simplex $\{c_a \geq 0\}$ of barycentric coordinates; the positive linear map $\widetilde{Z}$ sends it to the convex hull of the points $Z_1, \ldots, Z_n \in \mathbb{P}^m$. Total positivity of Z (Theorem 62.45) forces the points into convex cyclic position, so the image is a convex polygon ($m = 2$) or cyclic polytope ($m \geq 3$), a bona fide positive geometry.

62.6.3 Canonical form equals amplitude

We now state the central conjecture and, with equal care, the recipe that turns the canonical form — a bosonic differential form on a region in $\mathrm{Gr}(k, k+m)$ — back into the superamplitude with its fermionic structure restored. The cleanest formulation works with the *bosonized* superamplitude, so we recall that packaging first.

Helicity degree and the supertwistor. The external state of planar $\mathcal{N} = 4$ super-Yang–Mills is encoded, for each particle a, in a momentum supertwistor $\mathcal{Z}_a = (z_a^A \,|\, \chi_a^I)$ with $A = 1, \ldots, 4$ a bosonic momentum-twistor index and $I = 1, \ldots, 4$ a fermionic $\mathrm{SU}(4)_R$ index, the χ_a^I being Grassmann-odd (Section 62.5). The n-point superamplitude, with the universal MHV prefactor stripped, is a polynomial in the χ's; its term of Grassmann degree $4k$ is the $\mathrm{N}^k\mathrm{MHV}$ partial amplitude. Thus $k = 0$ is MHV (a constant, the stripped prefactor), $k = 1$ is NMHV, and so on — this is the *reduced* helicity index of the notationwatch in Section 62.5.4, the MHV degree minus two. This integer k is exactly the k of the momentum-twistor Grassmannian $\mathrm{Gr}_{\geq 0}(k, n)$ that the amplituhedron map of Theorem 62.44 pushes through Z, and of $\mathcal{A}_{n,k,4}$; it is *not* the momentum-space MHV degree of Section 62.3 (where MHV sat on $\mathrm{Gr}_{\geq 0}(2, n)$), from which it differs by two. With that proviso, the amplituhedron's hidden index *is* the (reduced) helicity degree.

Bosonization. The canonical form lives on $\mathrm{Gr}(k, k+4)$, a purely bosonic space, so the $4k$ Grassmann variables must be converted to commuting data. Introduce k auxiliary Grassmann-odd parameters ϕ_α^I, $\alpha = 1, \ldots, k$, $I = 1, \ldots, 4$,

and extend each twistor to a $(4+k)$-component *bosonized* vector

$$Z_a \;=\; (\, z_a^1,\, z_a^2,\, z_a^3,\, z_a^4;\;\; \phi_1^I \chi_a^I,\, \ldots,\, \phi_k^I \chi_a^I \,) \;\in\; \mathbb{R}^{4+k}, \tag{62.158}$$

where each new component $\phi_\alpha^I \chi_a^I$ (summed on I) is a product of two Grassmann-odd objects and hence *commuting*. This is the Z of Theorem 62.44 with $m=4$: an $n \times (k+4)$ matrix whose top 4 columns are the ordinary momentum twistors (whose positivity is the dual-conformal positivity of Section 62.5) and whose last k columns are bilinear in the fermions. The amplituhedron $\mathcal{A}_{n,k,4}$ is built from this Z, and its canonical form $\Omega(\mathcal{A}_{n,k,4})$ is a $4k$-form on the $4k$-dimensional region. To recover the amplitude one extracts the coefficient of the top power $\prod_{\alpha=1}^{k} \mathrm{d}^4\phi_\alpha$ — equivalently, one integrates the localized canonical form against the reference k-plane and against the ϕ's — which restores the Grassmann degree $4k$ in the physical χ_a^I.

Theorem 62.47 (Conjecture: amplituhedron canonical form = tree superamplitude)**.** ***(Status: theorem for*** $k=1$ ***at all*** m***; conjecture for*** $k \geq 2$***,*** $m=4$***, checked in many cases through the mid-2020s.)*** *For positive bosonized external data Eq. (62.158), the canonical form of the tree amplituhedron* $\mathcal{A}_{n,k,4}$ *in the sense of Theorem 62.3 equals the* $\mathrm{N}^k\mathrm{MHV}$ *tree-level partial superamplitude of planar* $\mathcal{N}=4$ *super-Yang–Mills (with the MHV prefactor stripped and the fermions restored by the* ϕ*-extraction above):*

$$\Omega(\mathcal{A}_{n,k,4}) \;=\; \mathcal{A}_{n,k}^{\text{tree}}\, \langle Y\, \mathrm{d}^4 Y_1 \cdots \mathrm{d}^4 Y_k \rangle, \tag{62.159}$$

the bracket on the right being the natural $\mathrm{Gr}(k, k+4)$ *top measure, and* $\mathcal{A}_{n,k}^{\text{tree}}$ *the (bosonized) amplitude. For* $k=1$ *this is the content of Theorem 62.45:* $\mathcal{A}_{n,1,4}$ *is a cyclic polytope in* $\mathbb{P}^4$ *and its canonical form is the NMHV amplitude, proved. For* $k \geq 2$ *it is a conjecture: every independently computable case (low* n*, all of NMHV and* N^2*MHV at the multiplicities checked, and the BCFW consistency below) agrees, but no all-*n*, all-*k *proof is known as of the mid-2020s.*

We do not have a Lagrangian proof to offer for $k \geq 2$ — none exists — and honesty forbids dressing the conjecture as a theorem. What we *can* supply is the strongest available consistency check, which is structural and which ties the construction back to the recursion of Chapter 59.

Proposition 62.48 (BCFW triangulation as existence/consistency check)**.** *The BCFW recursion of Theorem 59.23, transported to momentum-twistor space, expresses the* $\mathrm{N}^k\mathrm{MHV}$ *tree amplitude as a sum of rational terms, each of which is the canonical form of a* $4k$*-dimensional "BCFW cell" — the image under* $\widetilde{Z}$ *of a positroid cell of* $\mathrm{Gr}_{\geq 0}(k,n)$*. These cells tile the amplituhedron* $\mathcal{A}_{n,k,4}$*: their interiors are disjoint and their union is the full region. Consequently the sum of their canonical forms has simple poles only on the genuine boundaries of* $\mathcal{A}_{n,k,4}$ *— the spurious poles on the internal cell walls cancel pairwise, exactly*

as the diagonal poles cancelled for the polygon in Theorem 62.10 — and the resulting triangulation-independent form is, by the uniqueness Theorem 62.4, the canonical form $\Omega(\mathcal{A}_{n,k,4})$. That this triangulated form is also the BCFW amplitude is the precise sense in which Eq. (62.159) is "checked in cases": every BCFW triangulation that has been carried out reproduces the same boundary data.

Proof sketch. The full positroid-cell combinatorics is the subject of Section 62.3; here we use only its output. Each BCFW term is, in twistor variables, a $d\log$ form with simple poles, hence the canonical form of the cell it parametrizes (a positive geometry of dimension $4k$). Adjacent BCFW cells share a codimension-one wall along which one cell's residue equals the negative of the other's — this is the geometric content of the spurious-pole cancellation that made BCFW recursion local in Chapter 59, and it is the higher-dimensional copy of Eq. (62.28). By the uniqueness lemma a form whose poles and residues match on every facet is unique; since both the BCFW sum and $\Omega(\mathcal{A}_{n,k,4})$ have poles only on the true boundaries with the same residues there, they coincide wherever a tiling has been verified. The argument is complete *given* that the cells tile; the tiling itself is established case by case and is part of what remains conjectural in general. □

62.6.4 Locality and unitarity from the boundary

The reason the amplituhedron is a candidate definition of the S-matrix, rather than a curiosity, is that the two physical principles which the Lagrangian builds in by hand — locality (the amplitude is singular only on physical factorization channels) and unitarity (the residue on such a channel is the product of lower amplitudes) — emerge as statements about the boundary stratification of the region. We isolate the mechanism in the controlled $m = 2$ setting, where it is a theorem, and then state the physical $m = 4$ form.

Theorem 62.49 (Boundary residues factorize: the controlled $m = 2$ case)**.** *Let $\mathcal{A}_{n,1,2}$ be the convex polygon of Theorem 62.45, with canonical form $\Omega(\mathcal{A}_{n,1,2})$. Its codimension-one boundaries are exactly the n edges $\langle Y\, Z_a Z_{a+1}\rangle = 0$, a cyclic. On the edge $\{a, a{+}1\}$ the residue of the canonical form is the canonical form of that boundary, regarded as the lower-dimensional amplituhedron of the boundary geometry:*

$$\operatorname{Res}_{\langle Y\, Z_a Z_{a+1}\rangle = 0}\ \Omega(\mathcal{A}_{n,1,2}) \;=\; \Omega(\mathcal{A}'_{a,a+1}), \tag{62.160}$$

where $\mathcal{A}'_{a,a+1}$ is the interval $[Z_a, Z_{a+1}]$ — the $m = 1$, $k = 1$ amplituhedron of the two-particle boundary — with its canonical form $\mathrm{d}\log\big(\tau/(1-\tau)\big)$. Singularities of Ω occur only on these boundaries and nowhere else.

Proof. By Theorem 62.45 the region is the convex polygon, and by Theorem 62.9 its canonical form has simple poles only on the n edge-lines $\langle Y\, Z_a Z_{a+1}\rangle = 0$,

with the residue on each equal to that edge's interval canonical form. Concretely, parametrizing the edge by $Y(\tau) = (1-\tau)Z_a + \tau Z_{a+1}$ as in Theorem 62.8, the residue is $\pm\,\mathrm{d}\tau/[\tau(1-\tau)] = \pm\,\mathrm{d}\log[\tau/(1-\tau)]$, the interval form Eq. (62.7) of the segment $[Z_a, Z_{a+1}]$. That segment is itself a one-dimensional positive geometry — the $m = 1$ amplituhedron $\mathcal{A}'_{a,a+1}$ obtained by restricting the positive data to the two boundary vertices — so Eq. (62.160) holds. That there are no other singularities is the "only on boundaries" clause (ii) of Theorem 62.3, proved for the polygon in Theorem 62.9. The recursive axiom Eq. (62.5) is therefore satisfied at the first level, and iterating it (a further residue at a vertex gives ± 1) walks the entire boundary tower down to the points. □

The physical translation is immediate and is the payoff of the whole construction. A codimension-one boundary is where the geometry degenerates — where the running point Y is forced onto a face. In the $m = 4$ amplituhedron the codimension-one boundaries come in two physically distinct types, and they reproduce, with no further input, exactly the singularity structure that unitarity demands of a tree amplitude:

- *Factorization channels (locality).* Boundaries on which a bracket $\langle Y\, Z_{a-1} Z_a Z_b Z_{b+1}\rangle \to 0$ correspond to the vanishing of a multiparticle Mandelstam invariant $P^2_{a\cdots b} \to 0$. On such a face the amplituhedron degenerates into a product $\mathcal{A}_L \times \mathcal{A}_R$ of two lower-point amplituhedra glued along the factorization vertex, and the residue of the canonical form factorizes,

$$\mathrm{Res}_{P^2_{a\cdots b}=0}\, \Omega(\mathcal{A}_{n,k,4}) \;=\; \Omega(\mathcal{A}_L) \wedge \Omega(\mathcal{A}_R), \tag{62.161}$$

  the geometric avatar of the factorization $\mathcal{A}_n \to \mathcal{A}_L \,\dfrac{1}{P^2}\, \mathcal{A}_R$. That the only poles are these physical channels — no spurious singularities survive — is locality, output as clause (ii) of the positive-geometry axioms rather than imposed.

- *Collinear and unitarity-cut limits.* Boundaries on which two adjacent twistors become proportional, $Z_a \parallel Z_{a+1}$, are the collinear limits of two external legs; the residue there reproduces the universal collinear splitting behavior. The iterated residues that reach lower strata are exactly the generalized unitarity cuts of Chapter 60: cutting a propagator = taking a residue = passing to a boundary. Unitarity is thus encoded as the statement that the boundary-of-a-boundary structure of $\mathcal{A}$ matches the cut structure of the integrand.

We proved Eq. (62.161) only in the $m = 2$, $k = 1$ guise of Theorem 62.49, where it is rigorous; for $m = 4$, $k \geq 2$ it shares the conjectural status of Theorem 62.47, having been verified in all cases checked but not proved in general.

What is certain, and what makes the picture compelling, is the logical inversion: in the Lagrangian formulation locality and unitarity are assumptions and the singularity structure is a consequence; in the amplituhedron the singularity structure (the boundary stratification) is the definition and locality and unitarity are theorems about it — fully so for $k = 1$, conjecturally so beyond.

Physical Insight

The dictionary of Theorem 62.3 now reads physically. A codimension-one face $\leftrightarrow$ a simple pole $\leftrightarrow$ a physical factorization channel; "go to a boundary" $\leftrightarrow$ "take a residue" $\leftrightarrow$ "put an internal line on shell"; a vertex $\leftrightarrow$ a maximal cut $\leftrightarrow$ a leading singularity $= \pm 1$. The amplitude's analytic structure, which in Part XV we extracted laboriously from unitarity and the optical theorem, is here simply the face lattice of a convex-like region. Locality and unitarity are not assumed; they are the shape.

62.6.5 The loop amplituhedron, stated honestly

The tree amplituhedron has a loop-level extension that we state at the level of a definition, with its scope flagged, since its detailed positive geometry is beyond what can be proved compactly and much of it remains conjectural. The physical target is the planar integrand: at L loops the integrand of the $\mathrm{N}^k\mathrm{MHV}$ amplitude is a rational form in the external twistors Z *and* in L auxiliary lines (loop momenta in twistor space), and the claim is that it too is the canonical form of a positive geometry — a larger region built by demanding positivity not only of the external data but of the loop data *relative* to it.

Definition 62.50 (Loop amplituhedron)**.** The L-loop amplituhedron $\mathcal{A}^{(L)}_{n,k,4}$ is the set of data $(Y;\, \mathcal{L}_1, \ldots, \mathcal{L}_L)$ where $Y \in \mathcal{A}_{n,k,4}$ is a point of the tree amplituhedron and each $\mathcal{L}_i$ is a 2-plane (a "line" in the projective twistor space, modeling the i-th loop momentum) subject to two positivity requirements: each $\mathcal{L}_i$ is positive *relative to* Y *and* Z (all the relevant brackets $\langle Y\, \mathcal{L}_i\, Z_a Z_b\rangle$ have definite sign), and each pair $\mathcal{L}_i, \mathcal{L}_j$ is mutually positive. The conjecture is that $\mathcal{A}^{(L)}_{n,k,4}$ is a positive geometry whose canonical form, with the $\mathcal{L}_i$ integrated over, is the L-loop planar integrand of the $\mathrm{N}^k\mathrm{MHV}$ amplitude.

The honest scope is this. At one loop ($L = 1$) and at the MHV level ($k = 0$) the loop amplituhedron is understood in detail and its canonical form reproduces the known one-loop integrand — a result one can verify against the unitarity-method integrand of Chapter 60. Higher L and higher k are progressively less controlled: the boundary structure becomes intricate, the tiling into cells is known only in cases, and a general proof of the canonical-form-equals-integrand statement does not exist as of the mid-2020s. What the loop amplituhedron does establish, even conditionally, is conceptually decisive: it shows that the

integrand of the planar theory — to all loop orders, in principle — is a single positive geometry, so that loop integration is the one remaining non-geometric operation, and locality and unitarity of the integrand are, like at tree level, boundary phenomena rather than inputs.

Historical Note

The positive Grassmannian and the link between total positivity and on-shell diagrams were developed by Arkani-Hamed, Bourjaily, Cachazo, Goncharov, Postnikov, and Trnka in the years around 2012, building on Postnikov's combinatorics of the totally nonnegative Grassmannian. The amplituhedron proper — the image Eq. (62.151) and the canonical-form-equals-amplitude proposal — was introduced by Arkani-Hamed and Trnka in 2013. The $k = 1$ polytope picture of NMHV amplitudes is older, going back to Hodge's observation that NMHV leading singularities are volumes of polytopes in momentum-twistor space. The reframing of locality and unitarity as boundary phenomena, rather than axioms, is the conceptual thesis the program advances; its rigorous status remains, in the physical $m = 4$ sector beyond $k = 1$, exactly the conjecture stated above.

This is the frontier endpoint of Yang–Mills theory. The classical non-abelian Lagrangian of Chapter 25, quantized through BRST in Chapter 26, made asymptotically free in Chapter 27, and recast as gluon amplitudes via BCFW in Chapter 59 and the double copy in Chapter 61, reappears here in its maximally supersymmetric completion: the planar $\mathcal{N} = 4$ super-Yang–Mills S-matrix as the canonical form of a positive geometry, with the MHV and NMHV gluon data of Chapter 59 surfacing as the $k = 0$ and $k = 1$ canonical forms — the latter a rigorous polytope volume, the former trivial. We have a concrete, computable object: a convex polygon (for $m = 2$, $k = 1$) or cyclic polytope, with a well-defined canonical form whose poles are the physical channels. What remains is to evaluate that form to a closed number in the rigorously controlled $m = 2$ sector — closing the loop with the polygon of Section 62.1.4 — and then to exhibit, with honest scope, the physical $m = 4$ NMHV result; that is the work of Section 62.7.

62.7 A worked amplituhedron: the m=2 polygon and a glimpse of NMHV

The previous section left us holding a concrete, computable object. For $k = 1$ the amplituhedron is not a curved region in some high-dimensional Grassmannian but a genuine convex polytope: a polygon when $m = 2$ (Theorem 62.45), a cyclic polytope in $\mathbb{P}^4$ when $m = 4$, with a canonical form whose existence and uniqueness we have already proved and whose poles we have already identified,

abstractly, with the physical singularities of an amplitude. What we have not yet done is the thing a physicist most wants to see: take a definite choice of positive data, turn the crank, and read off a closed-form answer. That is the business of this section. We carry one amplituhedron computation all the way to an explicit rational form in the rigorously controlled $m = 2$ sector — the only sector where "canonical form = amplitude" is a theorem and not a conjecture — and we check, by hand, that the answer closes the loop with the polygon that opened the chapter (Section 62.1.4): same five edges, same spurious-diagonal cancellation, same triangulation-independent total. Only then, with the mechanism demonstrated on an object we control completely, do we write down the physical $m = 4$ next-to-MHV (NMHV) six-point result — the real amplitude — displayed honestly as the established result it is, with its geometric origin summarized rather than re-proved. We end by setting the amplituhedron answer beside the BCFW answer of Chapter 59: the same amplitude seen two ways, manifestly local from the geometry, term-by-term spurious-pole-laden from the recursion.

62.7.1 The $m = 2$ NMHV polygon, evaluated to a closed form

Recall the setup. For $k = 1$, $m = 2$ the amplituhedron map Eq. (62.153) sends the simplex $\mathrm{Gr}_{\geq 0}(1, n) = \{c_a \geq 0\}$ to the convex hull $\{Y = \sum_a c_a Z_a : c_a \geq 0\} \subset \mathbb{P}^2$ of the n points $Z_1, \ldots, Z_n$, the rows of a positive $n \times 3$ matrix Z. By Theorem 62.45 total positivity of Z forces those points into convex cyclic position, so $\mathcal{A}_{n,1,2}$ is a convex n-gon and its canonical form is the polygon form of Theorem 62.9. This $k = 1$, $m = 2$ object is the simplest member of the family whose physical avatar is the NMHV amplitude (the helicity index is k; Section 62.6.3); we will call its canonical form the "$m = 2$ NMHV form" for brevity, with the understanding that the genuine NMHV amplitude lives at $m = 4$ and we reach it in Section 62.7.2.

To make everything numerical we need an explicit positive Z. The cleanest source of total positivity is the moment curve: take the n rows to be points

$$Z_a \;=\; (1,\; x_a,\; x_a^2) \in \mathbb{P}^2, \qquad x_1 < x_2 < \cdots < x_n, \tag{62.162}$$

on the parabola $y = x^2$ in the affine chart $Z = (1, x, y)$. The ordered 3×3 minor is then a Vandermonde determinant,

$$\langle Z_a Z_b Z_c \rangle = \det \begin{pmatrix} 1 & x_a & x_a^2 \\ 1 & x_b & x_b^2 \\ 1 & x_c & x_c^2 \end{pmatrix} = (x_b - x_a)(x_c - x_a)(x_c - x_b) \;>\; 0 \quad (a < b < c), \tag{62.163}$$

strictly positive for every ordered triple, so Z is positive in the exact sense of Theorem 62.44 and the points are guaranteed to be the cyclically ordered vertices of a convex polygon. The moment curve is not an arbitrary trick: it is the universal model of a cyclic polytope, and Eq. (62.163) is the concrete face of

the statement, made in the proof of Theorem 62.45, that the minors of a totally positive matrix carry the same sign pattern as those of the Vandermonde matrix. We now fix $n = 5$ and grind the gears.

Worked Example 62.51 (The $m = 2$ NMHV pentagon for explicit positive Z)**.** Take $n = 5$ with the moment-curve data Eq. (62.162) at the symmetric nodes

$$x_1 = -2, \quad x_2 = -1, \quad x_3 = 0, \quad x_4 = 1, \quad x_5 = 2, \tag{62.164}$$

so the affine vertices are $Z_1 = (-2, 4)$, $Z_2 = (-1, 1)$, $Z_3 = (0, 0)$, $Z_4 = (1, 1)$, $Z_5 = (2, 4)$ on the parabola. From Eq. (62.163) the ten ordered minors are

$$\begin{aligned} &\langle 123\rangle = 2,\ \langle 124\rangle = 6,\ \langle 125\rangle = 12,\ \langle 134\rangle = 6,\ \langle 135\rangle = 16,\\ &\langle 145\rangle = 12,\ \langle 234\rangle = 2,\ \langle 235\rangle = 6,\ \langle 245\rangle = 6,\ \langle 345\rangle = 2, \end{aligned} \tag{62.165}$$

all strictly positive, confirming convex cyclic position.

Step 1: the edge functions. Treating the running point as $Y = (1, x, y)$, the bracket $\langle Y Z_i Z_j\rangle$ is the affine-linear function of (x, y) vanishing on the line through Z_i, Z_j. With $y_a = x_a^2$ the determinant factorizes neatly,

$$\langle Y Z_i Z_j\rangle = \det \begin{pmatrix} 1 & x & y \\ 1 & x_i & x_i^2 \\ 1 & x_j & x_j^2 \end{pmatrix} = (x_j - x_i)\big[\, y - (x_i + x_j)\, x + x_i x_j \,\big], \tag{62.166}$$

the bracketed factor being the chord line $y = (x_i + x_j)x - x_i x_j$. Substituting the nodes, the five *edge* functions (consecutive pairs) and the two *diagonal* functions (from the apex Z_1, which we will triangulate from) are

$$\begin{aligned} &\langle Y12\rangle = y + 3x + 2, && \langle Y23\rangle = y + x, && \langle Y34\rangle = y - x,\\ &\langle Y45\rangle = y - 3x + 2, && \langle Y15\rangle = 4(y - 4), && \langle Y13\rangle = 2(y + 2x),\\ &\langle Y14\rangle = 3(y + x - 2). \end{aligned} \tag{62.167}$$

Step 2: the triangulated canonical form. Triangulate the pentagon by fanning from Z_1, exactly the triangulation A of Theorem 62.10, into the three triangles $\{123\}, \{134\}, \{145\}$. Each contributes the triangle form $\omega_{ijk} = \langle ijk\rangle^2\, \langle Y\, \mathrm{d}^2 Y\rangle / (\langle Yij\rangle \langle Yjk\rangle \langle Y$ of Eq. (62.17), with $\langle Y\, \mathrm{d}^2 Y\rangle = \mathrm{d}x \wedge \mathrm{d}y$ in the affine chart. Using $\langle Y31\rangle = -\langle Y13\rangle$, $\langle Y41\rangle = -\langle Y14\rangle$, $\langle Y51\rangle = -\langle Y15\rangle$ and the minors Eq. (62.165), the three forms are

$$\omega_{123} = \frac{(2)^2\, \mathrm{d}x \wedge \mathrm{d}y}{\langle Y12\rangle \langle Y23\rangle \langle Y31\rangle} = \frac{-2\, \mathrm{d}x \wedge \mathrm{d}y}{(y + 3x + 2)(y + x)(y + 2x)}, \tag{62.168}$$

$$\omega_{134} = \frac{(6)^2\, \mathrm{d}x \wedge \mathrm{d}y}{\langle Y13\rangle \langle Y34\rangle \langle Y41\rangle} = \frac{-6\, \mathrm{d}x \wedge \mathrm{d}y}{(y + 2x)(y - x)(y + x - 2)}, \tag{62.169}$$

$$\omega_{145} = \frac{(12)^2\, \mathrm{d}x \wedge \mathrm{d}y}{\langle Y14\rangle \langle Y45\rangle \langle Y51\rangle} = \frac{-12\, \mathrm{d}x \wedge \mathrm{d}y}{(y + x - 2)(y - 3x + 2)(y - 4)}, \tag{62.170}$$

where in each line the factors of $2, 3, 4$ from Eq. (62.167) and the minus signs from the reversed brackets combine with $\langle ijk\rangle^2$ to leave the displayed integer numerators. (One checks the orientation is right: at the centroid $(-1, 5/3)$ of $\{123\}$ all three denominator factors of Eq. (62.168) are positive after the overall sign, so ω_{123} is a positive measure on the interior, as a canonical form must be.) The closed-form canonical form of the pentagon $\mathcal{A}_{5,1,2}$ is the sum

$$\Omega(\mathcal{A}_{5,1,2}) = \omega_{123} + \omega_{134} + \omega_{145}, \tag{62.171}$$

an explicit rational 2-form. We now verify the two structural facts that make Eq. (62.171) the canonical form and not merely a sum of triangle forms: the spurious diagonal poles cancel, and the surviving edge residues factorize.

Step 3: the spurious diagonals cancel. The diagonal line $\langle Y13\rangle = 2(y+2x) = 0$ appears as a denominator factor in both ω_{123} and ω_{134} and in neither ω_{145}. Compute its residue from each. Writing the pole factor as $\langle Y13\rangle$ itself (so $y+2x = \frac{1}{2}\langle Y13\rangle$ and $1/(y+2x) = 2/\langle Y13\rangle$) and restricting the regular remainder to the line $y = -2x$:

$$\mathrm{Res}_{\langle Y13\rangle=0}\ \omega_{123} = \frac{-4\,\mathrm{d}x}{(y+3x+2)(y+x)}\bigg|_{y=-2x} = \frac{-4\,\mathrm{d}x}{(x+2)(-x)} = \frac{4\,\mathrm{d}x}{x(x+2)}, \tag{62.172}$$

$$\mathrm{Res}_{\langle Y13\rangle=0}\ \omega_{134} = \frac{-12\,\mathrm{d}x}{(y-x)(y+x-2)}\bigg|_{y=-2x} = \frac{-12\,\mathrm{d}x}{(-3x)(-x-2)} = \frac{-4\,\mathrm{d}x}{x(x+2)}, \tag{62.173}$$

where in each case we have deleted the $1/\langle Y13\rangle$ factor and evaluated what remains at $y = -2x$. The two residue densities are $\pm 4/[x(x+2)]$ — equal and opposite. Their sum vanishes, so $\Omega(\mathcal{A}_{5,1,2})$ has *no* pole on the diagonal $\langle Y13\rangle = 0$. This is the concrete, numerical instance of the orientation-driven cancellation proved abstractly in Eq. (62.28): the diagonal $\{1,3\}$ is traversed $3 \to 1$ inside ω_{123} but $1 \to 3$ inside ω_{134}, the opposite orientations flipping the residue sign. The identical computation on the other diagonal $\langle Y14\rangle = 3(y+x-2) = 0$, shared between ω_{134} and ω_{145}, gives residues

$$\mathrm{Res}_{\langle Y14\rangle=0}\ \omega_{134} = \frac{-9\,\mathrm{d}x}{(x+2)(1-x)}, \qquad \mathrm{Res}_{\langle Y14\rangle=0}\ \omega_{145} = \frac{9\,\mathrm{d}x}{(x+2)(1-x)}, \tag{62.174}$$

again equal and opposite (here $y = 2 - x$ on the line, so ω_{134} contributes $y+2x = x+2$ and $y-x = 2(1-x)$, while ω_{145} contributes $y-3x+2 = 4(1-x)$ and $y-4 = -(x+2)$; with $1/(y+x-2) = 3/\langle Y14\rangle$ supplying the numerator factor 3, the algebra collapses to the displayed $\mp 9/[(x+2)(1-x)]$). The diagonal pole is again absent from the sum. *Both* spurious singularities have cancelled, exactly as the abstract pentagon of Theorem 62.10 demanded, now witnessed in numbers.

Step 4: the physical edges and their factorization. On a genuine boundary edge only one triangle contributes. Take the edge $\langle Y23\rangle = y + x = 0$, which sits

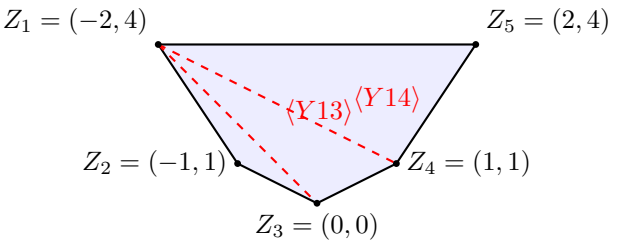

Figure 62.8: The explicit $m = 2$ NMHV pentagon $\mathcal{A}_{5,1,2}$ of Theorem 62.51, the moment-curve data Eq. (62.162) at nodes $x_a = -2, \ldots, 2$. The five solid edges $\langle Y\, a\, a{+}1\rangle = 0$ are the genuine boundaries and the only poles of the canonical form Eq. (62.171); the two red dashed diagonals $\langle Y13\rangle, \langle Y14\rangle$ (the cuts of the chosen triangulation $\{123, 134, 145\}$) carry equal-and-opposite residues that cancel in the sum. This is the same pentagon, with the same spurious-pole cancellation, as the abstract Theorem 62.10 and Fig. 62.1.

in ω_{123} alone. Deleting its factor and restricting to the line $y = -x$,

$$\mathrm{Res}_{\langle Y23\rangle=0}\ \Omega(\mathcal{A}_{5,1,2}) = \frac{-2\,\mathrm{d}x}{(y+3x+2)(y+2x)}\Big|_{y=-x} = \frac{-2\,\mathrm{d}x}{2(x+1)\,x} = \frac{-\mathrm{d}x}{x(x+1)}. \tag{62.175}$$

Parametrize the edge from Z_2 (at $x = -1$) to Z_3 (at $x = 0$) by $\tau = x+1$, so $\tau = 0$ at Z_2 and $\tau = 1$ at Z_3; then $x(x+1) = (\tau-1)\tau = -\tau(1-\tau)$ and Eq. (62.175) becomes

$$\mathrm{Res}_{\langle Y23\rangle=0}\ \Omega(\mathcal{A}_{5,1,2}) = \frac{\mathrm{d}\tau}{\tau(1-\tau)} \overset{\text{Theorem 62.8}}{=} \mp\,\mathrm{d}\log\frac{\tau}{1-\tau}, \tag{62.176}$$

the interval canonical form Eq. (62.7) of the segment $[Z_2, Z_3]$, the overall orientation sign being the one fixed once and for all in Theorem 62.8. This is the statement of Theorem 62.49 realized on the nose: the residue on the edge is the canonical form of the lower-dimensional ($m = 1$, $k = 1$) amplituhedron of the two-particle boundary $\{Z_2, Z_3\}$. Taking one further residue, at the endpoint $\tau = 0$ (Z_2) the interval form gives $+1$, and at $\tau = 1$ (Z_3) it gives -1 — the ± 1 canonical forms of the zero-dimensional boundary vertices, Eq. (62.8). The boundary tower terminates correctly. Each of the five edges $\langle Y\, a\, a{+}1\rangle = 0$ behaves identically by the cyclic structure of Eq. (62.165), so $\Omega(\mathcal{A}_{5,1,2})$ has simple poles on exactly those five lines, residues equal to the five edge interval forms, and no other singularity — precisely clauses (ii)–(iii) of Theorem 62.3. The closed form Eq. (62.171) is the canonical form of the pentagon, computed end to end.

Closing the loop with Sections 1 and 2. The computation just completed is the same pentagon, three times over. The triangulation $\{123, 134, 145\}$ is

precisely triangulation A of the abstract pentagon worked in Theorem 62.10; the diagonals that cancelled here, $\{1,3\}$ and $\{1,4\}$, are exactly the spurious diagonals that cancelled there; and the triangulation-independence theorem Theorem 62.9 guarantees that had we fanned from Z_2 instead (triangulation B, the disjoint diagonals $\{2,4\},\{2,5\}$) we would have obtained the identical 2-form. So the $m=2$ amplituhedron canonical form *is* the polygon canonical form of Section 62.1.4, now anchored to concrete positive kinematics. There is a third incarnation of the very same shape. The five-point kinematic associahedron of Section 62.2 — the polytope whose canonical form is the bi-adjoint ϕ^3 amplitude computed in Theorem 62.18 — is itself a pentagon, the two-dimensional associahedron K_4. It lives in Mandelstam space rather than in $\mathbb{P}^2$, and its five edges are the five planar poles rather than the five lines $\langle Y\, a\, a{+}1\rangle$, but as a positive geometry it is projectively the same pentagon carrying the same canonical form. The convex polygon is thus the single object on which three independent strands of this chapter — the abstract dictionary of Section 62.1, the amplitude-as-volume theorem of Section 62.2, and the amplituhedron map of Section 62.6 — all converge and agree. This consistency, checkable by hand, is the strongest evidence that the construction is internally sound before we trust it where it is only conjectural.

Reading the edges as physical poles. In the $m=2$ toy the five edge-lines $\langle Y\, a\, a{+}1\rangle = 0$ play the role that physical factorization channels play in a real amplitude: each is a simple pole, each residue is a lower-point (here one-dimensional) amplituhedron form, and the would-be poles on the diagonals — the analog of unphysical, spurious channels — are absent from the geometric total. This is the boundaries-$\leftrightarrow$-singularities dictionary of Theorem 62.3 confirmed on an explicit amplitude-like object. In the genuine $m=4$ amplituhedron the same edges become the codimension-one boundaries of Theorem 62.49, where a bracket $\langle Y\, Z_{a-1} Z_a Z_b Z_{b+1}\rangle \to 0$ is the vanishing of a physical multiparticle invariant $P^2_{a\cdots b} \to 0$ and the residue factorizes as Eq. (62.161). The pentagon is the rehearsal; the hexagon is the performance.

62.7.2 The physical case: the $m=4$ NMHV hexagon

We now state the genuine NMHV amplitude. For the physical helicity sector $k=1$ at $m=4$ the amplituhedron $\mathcal{A}_{n,1,4}$ is a cyclic polytope in $\mathbb{P}^4$, built from the bosonized momentum-supertwistor data Eq. (62.158): each row Z_a is a 5-component vector whose first four entries are the ordinary momentum twistor z_a^A $(A=1,\dots,4)$ of Section 62.5 and whose fifth is the single bosonized fermion bilinear $\phi^I \chi_a^I$ appropriate to $k=1$. Because $k=1$ is exactly the case where Theorem 62.47 is a *theorem* — the amplituhedron is a true polytope and its canonical form is a polytope volume in the sense of Hodge — the NMHV amplitude is genuinely *computed*, not conjectured, by the geometry.

The building block is the four-dimensional analog of the triangle form, the

canonical form of a 4-simplex in $\mathbb{P}^4$. Five bosonized twistors Z_a, Z_b, Z_c, Z_d, Z_e span such a simplex; its five facets are the hyperplanes through each set of four, and its canonical form is the wedge of d log's of those five facet functions, the direct $\mathbb{P}^4$ descendant of Eq. (62.22) and Eq. (62.17). Stripping the ϕ-dependence by the bosonization recipe of Section 62.6.3 turns this simplex form into the dual-superconformal invariant universally known as the *five-bracket* or *R-invariant*,

$$[\,a\,b\,c\,d\,e\,] \;\equiv\; \frac{\delta^{0|4}\big(\langle bcde\rangle\,\chi_a + \langle cdea\rangle\,\chi_b + \langle deab\rangle\,\chi_c + \langle eabc\rangle\,\chi_d + \langle abcd\rangle\,\chi_e\big)}{\langle abcd\rangle\,\langle bcde\rangle\,\langle cdea\rangle\,\langle deab\rangle\,\langle eabc\rangle}, \tag{62.177}$$

where $\langle abcd\rangle \equiv \epsilon_{ABCD}\, z_a^A z_b^B z_c^C z_d^D$ is the 4-bracket (the 4×4 determinant of the four bosonic momentum twistors), χ_a^I are the Grassmann components of the supertwistor, and $\delta^{0|4}$ is the fermionic delta enforcing the $4k = 4$ units of NMHV Grassmann degree. The five denominator brackets are the five facets of the simplex; their vanishing is the simplex's boundary, the $\mathbb{P}^4$ avatar of the three edge-lines of the triangle. The five-bracket is manifestly invariant under the dual superconformal group SL(4) acting on the twistor index, which is why these objects organize the amplitude so efficiently — the symmetry is built into the geometry.

Theorem 62.52 (The six-point NMHV ratio function; **established**). *The tree-level $n = 6$ NMHV superamplitude of planar $\mathcal{N} = 4$ super-Yang–Mills, with the MHV prefactor stripped, is the canonical form of the cyclic polytope $\mathcal{A}_{6,1,4} \subset \mathbb{P}^4$. Triangulating that polytope into three 4-simplices and summing their canonical forms Eq. (62.177) gives the closed expression*

$$P_6^{\mathrm{NMHV}} \;=\; [\,1\,2\,3\,4\,5\,] + [\,3\,4\,5\,6\,1\,] + [\,5\,6\,1\,2\,3\,], \tag{62.178}$$

a sum of three R-invariants, manifestly cyclic under $a \to a+2$. This is the known six-point ratio function [164, 268, 340], and for $k = 1$ it is a theorem *(a polytope volume), the proved instance of Theorem 62.47.*

Three points make this honest. First, the result Eq. (62.178) is not new with the amplituhedron: the six-point NMHV ratio function was obtained by BCFW recursion in momentum-twistor space and shown to be dual-superconformally invariant by Drummond, Henn, Korchemsky and Sokatchev, and recast as a polytope volume by Hodge and by Mason and Skinner, before the amplituhedron was formulated [164, 268, 340]. The amplituhedron's contribution at $k = 1$ is conceptual: it identifies the R-invariants as canonical forms of simplices and the amplitude as the canonical form of the single polytope they triangulate. Second, the geometric derivation we are *summarizing rather than carrying out* is the $\mathbb{P}^4$ replica of the pentagon computation we did do: $\mathcal{A}_{6,1,4}$ is a cyclic polytope $C(6,4)$; a triangulation of $C(6,4)$ uses three 4-simplices, here the ones with vertex sets $\{1,2,3,4,5\}$, $\{1,3,4,5,6\}$, $\{1,2,3,5,6\}$ (each omitting one even-labelled vertex), giving the three brackets of Eq. (62.178); the simplices' shared internal facets are

spurious poles that cancel pairwise, exactly as the pentagon's two diagonals did in Theorem 62.51, leaving poles only on the genuine facets of the polytope, which are the physical factorization channels. We do not reproduce the four-dimensional algebra term by term — it is long and adds no idea beyond the pentagon — but every step is the controlled $m = 2$ computation lifted by two dimensions. Third, triangulation independence has a sharp signature here: fanning the polytope from a different vertex yields the complementary three-term representation

$$P_6^{\mathrm{NMHV}} \;=\; [\,2\,3\,4\,5\,6\,] + [\,4\,5\,6\,1\,2\,] + [\,6\,1\,2\,3\,4\,], \tag{62.179}$$

omitting the odd-labelled vertices, and the equality of Eq. (62.178) and Eq. (62.179) is the celebrated six-term identity among R-invariants,

$$[\,1\,2\,3\,4\,5\,]+[\,3\,4\,5\,6\,1\,]+[\,5\,6\,1\,2\,3\,] \;=\; [\,2\,3\,4\,5\,6\,]+[\,4\,5\,6\,1\,2\,]+[\,6\,1\,2\,3\,4\,], \tag{62.180}$$

which from this vantage is nothing but the statement that the volume of $C(6,4)$ does not depend on how it is triangulated — the higher-dimensional copy of $\Omega_A = \Omega_B$ for the pentagon (Theorem 62.10), and a theorem by the uniqueness Theorem 62.4.

62.7.3 Amplituhedron versus BCFW: one amplitude, two faces

The same six-point NMHV amplitude was assembled in Chapter 59 by on-shell recursion. It is worth setting the two answers side by side, because the contrast is the cleanest illustration in the book of what the geometric reformulation buys.

The BCFW construction of Section 59.7.5 produced the amplitude as a sum of rational terms, Eq. (59.209), each term a product of lower-point amplitudes glued on a factorization pole, with the precise list of terms *depending on the shift chosen*: one valid shift gives two terms, another gives three. Every individual term carries, in addition to its physical pole, *spurious* poles — denominators such as $\langle 3|P_{234}|6]$ that correspond to no physical channel of A_6 — and the amplitude is local only because those spurious poles cancel in the sum (Theorem 59.23 and the discussion there). The Parke–Taylor form Eq. (59.55) is the MHV ($k = 0$) seed of this same recursion. The recursion is correct and constructive, but locality is not manifest in any single representation; it emerges only after the cancellation, and which terms appear is an artifact of the shift.

The amplituhedron gives the identical amplitude as the canonical form of one geometric object, the cyclic polytope $\mathcal{A}_{6,1,4}$, whose boundaries *are* the physical factorization channels and nothing else. In this representation locality is manifest at the level of the object: the form Eq. (62.178) has poles only on the polytope's genuine facets because a canonical form, by Theorem 62.3, has poles only on boundaries. The dictionary that connects the two pictures is now exact and is the content of Theorem 62.48: each BCFW term is the canonical form of a positroid cell whose image is a piece of the amplituhedron, and a full set

of BCFW terms *tiles* the polytope. A BCFW representation is therefore a triangulation; the spurious poles of the individual terms are the internal walls of that triangulation; and their cancellation in the BCFW sum is the cancellation of internal-facet residues we computed explicitly for the pentagon in Theorem 62.51 and stated for the hexagon as the six-term identity Eq. (62.180). The shift-dependence of the BCFW term count is then demystified completely: different shifts are different triangulations of the *same* polytope, and they agree because the volume is triangulation-independent (Theorems 62.4 and 62.9). The R-invariant representations Eq. (62.178) and Eq. (62.179) are themselves two such triangulations, dual to the two BCFW shifts of Chapter 59.

Physical Insight

The Lagrangian and the recursion both compute the amplitude as a *sum* of pieces, each of which has more singularities than the answer; locality is recovered by a cancellation that is real but invisible in any one term. The amplituhedron computes the amplitude as a *single* object whose only singularities are the physical ones, so locality is not recovered, it is built in — it is the shape of the region. The cancellation of spurious poles, the central labor of recursion, becomes in the geometry the trivial statement that a polytope's volume does not depend on how you cut it into simplices. This is the precise sense in which the amplituhedron makes locality and unitarity *manifest*: not by proving them anew, but by choosing a representation in which they are visible from the start.

We have now done what the chapter promised in the controlled sector: taken explicit positive data, computed an amplituhedron canonical form to a closed rational expression, verified its spurious poles cancel and its physical residues factorize, and shown it agrees with the polygon of Section 62.1.4 and the associahedron of Section 62.2 — the full circle. We have then displayed the genuine $m = 4$ NMHV hexagon, marking precisely which of its claims are theorems ($k = 1$, the polytope volume) and which inherit the conjectural status of the general construction, and we have seen the same amplitude wear two faces, local-by-geometry and recursive-with-spurious-poles. What remains is to take honest stock: to separate, with a date attached, the settled mathematics from the physical conjecture and the open problem, and to articulate the conceptual payoff of a program in which locality and unitarity emerge from a shape with no Lagrangian and no spacetime in sight. That accounting is the work of Section 62.8.

62.8 Scope, status, and the frontier

The previous section carried one amplituhedron computation as far as it can honestly be carried with present tools: in the rigorously controlled $m = 2$ sector we evaluated a canonical form to a closed expression and closed the loop with the polygon that opened the chapter (Section 62.7.1), and only then did we write down the physical $m = 4$ NMHV hexagon result, displayed but not derived, so that the reader could see the genuine object without being sold an unproved theorem as a proved one. That deliberate split — a complete computation on one side of a line, an honest pointer on the other — is the whole subject in microcosm, and it is the reason this closing section exists. A frontier chapter earns its place only if it states, precisely and with a date attached, which side of that line each of its claims sits on. This section does the accounting. It introduces no new construction and proves no new theorem; it audits everything the chapter has asserted, marks each conjecture as a conjecture, separates what is established mathematics from what is a research program, and then articulates the conceptual payoff that makes the program worth pursuing even where it is unfinished. We write as of the mid-2020s, and we say so, because several of the statements below are moving.

62.8.1 A summary of mathematical status, dated to the mid-2020s

It is useful to sort the chapter's content into three bins: settled mathematics, a physical conjecture with strong but incomplete support, and a genuinely open problem. The sorting is sharper here than almost anywhere else in the book, because the objects are defined with mathematical precision and the gap between "defined" and "proved equal to the amplitude" is itself a precise, checkable statement.

What is theorem. The foundational layer of the chapter is mathematics in the strict sense, complete with proofs given in full above.

- *Positive geometry and the canonical form are rigorously defined.* The notion of a logarithmic form, of a positive geometry, and of its canonical form (Theorems 62.1 and 62.3) are precise definitions, and the canonical form, when it exists, is *unique* — this we proved (Theorem 62.4) from nothing but the absence of global holomorphic top forms on projective space. Triangulation independence (Theorem 62.9) is a corollary, not an article of faith.

- *The associahedron story is a finished theorem.* The tree-level color-ordered amplitude of bi-adjoint ϕ^3 theory *equals* the canonical form of the ABHY

kinematic associahedron, term by term, with no large-N limit, no supersymmetry, and nothing conjectural (Theorem 62.17); we verified it completely at five points (Theorem 62.18). This is the cleanest existing realization of "amplitude = volume," and it is proved.

- *The combinatorial backbone is a theorem.* The totally nonnegative Grassmannian $\mathrm{Gr}_{\geq 0}(k, n)$ is a regular CW complex homeomorphic to a closed ball, stratified into positroid cells classified by Postnikov's decorated permutations [208, 409]; we proved the small cases by hand (Theorem 62.25) and imported the general statement explicitly, as a cited theorem rather than as a step we skipped.

- *The amplituhedron is rigorously defined.* The amplituhedron $\mathcal{A}^{(m)}_{n,k,L}$ is a precise mathematical object — as the image of the positive Grassmannian under a positive linear map (Theorem 62.44), and equivalently through the sign-flip/topological characterization [37]. Its definition is not in question; what is in question is one specific assertion *about* it.

- *The $m = 2$ amplituhedron is understood.* For $m = 2$ the amplituhedron is combinatorially and geometrically under control: it is in bijection with the hypersimplex, its triangulations are classified, and its canonical form has been proved to reproduce the corresponding ($m = 2$) amplitude [378]. This is why Section 62.7.1 could be carried to a number: the $m = 2$ sector is theorem, not conjecture.

What is conjecture. The single load-bearing physical claim of the chapter — the one the title advertises — is, at the physical value $m = 4$, a conjecture. We mark it as such here, retroactively flagging every place it appeared.

- *Canonical form = amplitude at $m = 4$ is conjectural.* The statement that the canonical form of the physical amplituhedron $\mathcal{A}^{(4)}_{n,k,L}$ equals the (super)amplitude integrand of planar $\mathcal{N} = 4$ super Yang–Mills (Theorem 62.17, as extended to the amplituhedron in Section 62.4 and after) is a conjecture of Arkani-Hamed and Trnka [32]. Every appearance of the words "the amplitude is the canonical form" at $m = 4$ in this chapter is, strictly, "the amplitude is conjectured to be the canonical form."

- *Tree level is close to settled; the full statement is not.* The gap has narrowed sharply in the mid-2020s. At tree level the BCFW recursion of Chapter 59 provides a candidate triangulation of the $m = 4$ amplituhedron into positroid cells, and that this collection of cells genuinely *tiles* the amplituhedron — covering it once, without overlaps or gaps — has been proved for the tree amplituhedron [181]. Combined with the cell-by-cell residue matching, this makes the tree-level $m = 4$ statement a theorem in

the cases where the tiling result applies. What remains conjectural is the clean, uniform statement at all multiplicities and, decisively, at loop level.

What is open. The loop-level content is the present frontier.

- *The loop integrand geometry is constructed but not proved in general.* The loop amplituhedron — the geometry whose canonical form is conjectured to be the all-loop planar $\mathcal{N} = 4$ integrand — is fully *defined*: the L-loop momentum-twistor data are organized into mutually positive lines in the positive Grassmannian, and the integrand is read off as a canonical form. But the proof that this canonical form equals the integrand produced by generalized unitarity (Chapter 60), for all n, k, and all loop orders L, does not exist as of the mid-2020s. Individual cases (low loops, low multiplicity) have been checked and match; the all-loop theorem is open.
- *Integration is not part of the construction.* Even granting the conjecture in full, the amplituhedron delivers the *integrand* — a rational form in loop and external momenta — not the integrated amplitude. The transcendental functions (polylogarithms, elliptic and beyond) that result from performing the loop integrals are not, in any established sense, read off the geometry; that step still requires the integration technology of Chapter 60 and its successors. "Amplitude = volume" is, more precisely, "*integrand* = canonical form."

Table 62.1 collects this accounting in one place.

Caution

The phrase "the amplitude is a volume" is exact for the bi-adjoint associahedron (Theorem 62.17) and for the $m = 2$ amplituhedron, and is a conjecture for the physical $m = 4$ amplituhedron at tree level (now largely reduced to theorem) and at loop level (open). Throughout this chapter, wherever the amplituhedron at $m = 4$ was said to *be* the amplitude, read "is conjectured to be," with the tree-level qualification just stated. The mathematics of positive geometry is not conditional on this conjecture; the physical interpretation at $m = 4$ beyond trees is.

62.8.2 The conceptual payoff: locality and unitarity as outputs, not inputs

Why pursue an object whose central physical identification is, at the physical value, still a conjecture? Because if the conjecture holds — and the evidence for it, summarized above, is strong — it reorganizes what we take the amplitude to *be*, and the reorganization is conceptually radical in a way that survives even

Claim	Status (mid-2020s)	Where
Positive geometry, canonical form, uniqueness, triangulation independence	**Theorem** (proved in text)	Theorems 62.4 and 62.9
Bi-adjoint ϕ^3 tree amplitude = canonical form of ABHY associahedron	**Theorem** (proved in text)	Theorem 62.17
$\mathrm{Gr}_{\geq 0}(k,n)$ is a ball; positroid stratification	**Theorem** (cited, small cases proved)	Section 62.3.4
Amplituhedron $\mathcal{A}^{(m)}_{n,k,L}$ is well defined	**Definition** (precise object)	Theorem 62.44
$m = 2$ canonical form = amplitude	**Theorem**	Section 62.7.1
$m = 4$ tree: BCFW cells tile the amplituhedron	**Theorem** (recent)	Section 62.4
$m = 4$ canonical form = planar $\mathcal{N} = 4$ tree amplitude, all n, k	**Conjecture** (strong support)	Theorem 62.17
$m = 4$ loop integrand = canonical form of loop amplituhedron, all L	**Open** (checked in cases)	Section 62.4
Integrated amplitude read off the geometry	**Not claimed**	—

Table 62.1: The chapter's claims sorted by epistemic status as of the mid-2020s. The line between theorem and conjecture falls precisely at the physical value $m = 4$ beyond tree level; the line between conjecture and open problem falls at loop level. Everything below the geometry — the definition of the canonical form and the associahedron realization — is settled mathematics.

the present incompleteness. The payoff is best stated as a program, and we are careful to state it as a program and not as a theorem.

In the Feynman-diagram construction of an amplitude, two physical principles are *inputs*. Locality is built in by hand: we sum over local interaction vertices and propagators $1/(p^2 - m^2)$, so the amplitude has poles exactly where an internal line goes on shell, because we put them there. Unitarity is built in by hand: the $i\epsilon$ prescription and the Hermiticity of the Lagrangian guarantee, through the optical theorem (Chapter 60), that residues factorize into products of lower amplitudes. Both principles are assumptions about a spacetime Lagrangian, fed into a machine.

In the positive-geometry construction, neither principle is an input. One specifies a region — the associahedron, the amplituhedron — by positivity

conditions that make no reference to a Lagrangian, to time evolution, or even to spacetime. The canonical form is then *forced*: by uniqueness (Theorem 62.4) it is the one form with logarithmic singularities on the region's boundaries and no others. And now the two physical principles appear as *outputs*:

- *Locality* is the statement that the canonical form has poles only on the facets of the region. The facets are codimension-one boundaries, fixed by the positivity conditions; the form is singular there and nowhere else by the boundary clause of Theorem 62.3. The amplitude's poles sit on physical channels *because* those channels are the boundaries of a positive region — not because propagators were inserted by hand. We proved exactly this for the associahedron: the poles of m_n are the loci $X_{i,j} = 0$, the facets (Theorem 62.16).

- *Unitarity* is the statement that the residue on a facet is the canonical form of that facet. By the recursive residue axiom (Eq. (62.5)), the residue on a boundary is a lower canonical form, and when the boundary factorizes as a product of two smaller positive geometries, the residue factorizes as a product of two lower amplitudes. We proved exactly this for the associahedron: the facet $X_{i,j} = 0$ is the product $\mathcal{A}_a \times \mathcal{A}_b$, and the residue there is the product of the two sub-amplitudes (Theorem 62.13 and Eq. (62.65)).

The slogan, stated honestly as a research aspiration rather than a proved fact about the physical theory, is that *spacetime locality and quantum-mechanical unitarity are not axioms of the amplitude but consequences of the positivity and boundary structure of a geometry.* For the bi-adjoint scalar this aspiration is a theorem. For planar $\mathcal{N} = 4$ at $m = 4$ it is the conjecture of the previous subsection. The conceptual content does not depend on which: in every case where the dictionary has been verified, locality and unitarity came out, not in.

Physical Insight

The reorientation is worth stating in one sentence. Conventional field theory begins with a Lagrangian on spacetime, derives Feynman rules, and *discovers* that the resulting amplitudes are analytic with factorizing residues. The positive-geometry program begins with a region defined by positivity, *derives* a unique canonical form, and finds that its singularity structure *is* locality and unitarity — with no Lagrangian, no Hilbert space, and no time evolution written down anywhere. Where it has been proved (the associahedron, $m = 2$), this is not a reinterpretation of the old derivation; it is an independent route to the same numbers that never mentions the ingredients the old route called fundamental.

This is the precise sense in which the amplitudes program suggests that locality and unitarity, and perhaps spacetime itself, are *emergent*. The much-quoted aspiration that the amplitude is "the answer to which the geometry is the question" — that one should seek the question, posed purely in the language of positive geometry, to which the universe's S-matrix is the answer — is exactly that: an aspiration. As of the mid-2020s there is no positive geometry for a generic interacting quantum field theory, no derivation of the amplituhedron's positivity conditions from a deeper principle, and no geometry that produces integrated amplitudes rather than integrands. The program is a bet that such structures exist and are fundamental. The chapter has shown the bet is not empty — the associahedron is a fully proved instance — without pretending it is won.

62.8.3 Reach and limits: the enabling crutches

The amplituhedron is not a theory of everything's S-matrix; it is, so far, a theory of one very special amplitude, and the specialness is the source of both its power and its limitations. Two features do the enabling work, and it is worth naming them as crutches so that the boundary of the program's current reach is visible.

Planarity. The construction requires a fixed cyclic order of the external legs. The total positivity of Theorem 62.22 is defined relative to an ordering of the columns; the consecutive minors that appear in the canonical form (Eq. (62.82)) are consecutive only with respect to that order; the associahedron itself is the geometry of a *cyclically* ordered polygon. Physically this is the planar (large-N) limit, in which color-ordered partial amplitudes are well defined and the cyclic order is the boundary order of a disk. Away from the planar limit there is no global cyclic order, no canonical notion of "consecutive," and the positivity that singles out the region loses its anchor. A positive geometry for non-planar amplitudes is, as of the mid-2020s, not established; there are proposals, but no object with the proved status of the planar amplituhedron.

Maximal supersymmetry. The amplituhedron computes planar $\mathcal{N} = 4$ super Yang–Mills, and the maximal supersymmetry is not incidental. It is what allows all helicity configurations at fixed n to be packaged into a single superamplitude graded by the integer k (the same k as the rank of the Grassmannian, Section 62.3), so that one geometry per (n, k, L) captures the entire helicity tower. It is also what makes the loop integrand a pure logarithmic form — the uniform transcendentality and the absence of higher-degree poles that the dlog structure of the canonical form requires. A theory with less supersymmetry has amplitudes with non-logarithmic singularities (double poles, square roots, ultraviolet divergences) that a canonical form, which by Theorem 62.1 has only simple logarithmic poles,

cannot directly represent. Extending positive geometry to such theories requires generalizing the canonical form itself, and that generalization is incomplete.

The status of the extensions. Three frontiers follow from relaxing these crutches, and each is open to a different degree.

- *Non-planar* $\mathcal{N} = 4$: actively pursued, no settled geometry. The difficulty is the absence of a single cyclic order; partial results organize non-planar integrands by "sums of positive pieces," but no analogue of Theorem 62.44 is established.

- *Less or no supersymmetry*: the bi-adjoint scalar (no supersymmetry at all) *does* have a complete positive geometry, the associahedron — but it is a theory with only logarithmic singularities and no helicity, precisely the features that survive. For gauge theories with $\mathcal{N} < 4$, or for QCD with its ultraviolet divergences, no clean positive geometry exists; the obstruction is the non-logarithmic analytic structure just noted.

- *Gravity*: the double copy of Chapter 61 expresses gravity amplitudes as "squares" of gauge-theory ones, but the squaring operation has no known geometric realization. There is no gravituhedron in the sense of a positive geometry whose canonical form is the graviton amplitude; whether the double copy can be lifted to a statement about geometries is open.

Caution

It is tempting to read the amplituhedron's elegance as evidence that *all* amplitudes are volumes of positive geometries. The honest position is narrower: positive geometry is proved to compute the bi-adjoint scalar tree amplitude and the $m = 2$ amplituhedron, is conjectured (with strong support) to compute planar $\mathcal{N} = 4$, and has no established realization for non-planar, non-maximally-supersymmetric, or gravitational amplitudes. The crutches are load-bearing.

62.8.4 Adjacent positive geometries: live directions, each dated

The same idea — an amplitude or correlator as the canonical form of a region defined by positivity — has spread well beyond the amplituhedron, and several of these directions are more recent and in some respects more rigorous than the $m = 4$ amplituhedron itself. We record the principal ones with dates, as live research rather than closed theory.

The associahedron family (2017–). The ABHY associahedron of Section 62.2 was introduced in 2017 [36] and is the most rigorous member of the whole program: its identification with the bi-adjoint amplitude is a theorem, proved in this chapter. It has since been generalized to other "accordiohedra" and to deformations connected to the open-string worldsheet (the same paper relates the associahedron's canonical form to the Koba–Nielsen string integral via "stringy canonical forms"), making the associahedron the bridge between field-theory positive geometry and string amplitudes. This family is the firmest ground in the subject.

Cosmological polytopes and the cosmological correlator program (2017–). Arkani-Hamed, Benincasa, and Postnikov showed in 2017 that the wavefunction of the universe for a conformally coupled scalar with polynomial interactions in a power-law cosmology is the canonical form of a *cosmological polytope* [35] — a positive geometry built directly from the interaction graph, with no reference to bulk time evolution, exactly in the spirit of Section 62.8.2. This is rigorous in the same sense as the associahedron: a proved equality between a canonical form and a physical object (here a cosmological correlator rather than a flat-space amplitude). The program has grown in the 2020s into a systematic "cosmological bootstrap": the differential equations satisfied by cosmological correlators have been derived from the polytope's boundary structure (the "kinematic flow," 2023 [39]), giving the integrated correlators — a step the flat-space amplituhedron does not yet provide for its integrands. The cosmological setting is, in this specific sense, ahead of the flat-space one.

Surfaceology and curve integrals (2023–). The most recent direction reformulates scattering, including at loop level and *without* the planarity crutch, in terms of curves on surfaces [40]. Amplitudes are computed by counting intersections of curves on a Riemann surface with marked points, packaged into "curve integrals" that produce the full integrand — planar and non-planar, all loop orders — from a single combinatorial recipe. As of the mid-2020s this is rapidly developing and not yet consolidated into theorems of the associahedron's finished kind, but it is the most promising route past the two crutches of Section 62.8.3, and it has already produced new structural results (such as "hidden zeros" of amplitudes) that were invisible from the diagrammatic and even the amplituhedron points of view. We flag it as the frontier within the frontier.

These three, together with the amplituhedron, are facets of a single emerging subject — positive geometry — whose claim is that the right home for scattering data is not a Lagrangian on spacetime but a region defined by positivity, with the canonical form as the universal translator. This is also where the program touches the rest of the book's frontier: the insistence that physical amplitudes live on the boundary of a region of *allowed* (positive) configurations is kin to

the positivity constraints of the conformal and S-matrix bootstrap (Chapter 52), where consistency conditions — unitarity as positivity of a spectral density, crossing as a linear constraint — carve out the allowed theory space rather than constructing a theory from a Lagrangian. In both the bootstrap and positive geometry, positivity is the generative principle and the Lagrangian is demoted from foundation to (at most) one convenient coordinate system.

This audit completes the chapter's frontier coda on the amplitudes of Yang–Mills theory and QED: it adds no new perturbative calculation, only the geometric reframing that the same gluon and photon amplitudes carried since Chapter 58 can be read, in the planar maximally-supersymmetric corner, as boundaries and residues of a positive region rather than as sums of diagrams. With the summary of what is proved, conjectured, and open now set down, we hand the synthesis to Chapter 63: there the threads of this entire part — spinor-helicity, recursion, unitarity, the double copy, and positive geometry — are drawn together into a single statement of what the modern amplitudes program has revealed about quantum field theory, and tied back to the bootstrap of Part XIV and the holography of Part XV.

Further reading

The canonical reference for the amplituhedron and the positive-geometry program is the monograph of Arkani-Hamed, Bourjaily, Cachazo, Goncharov, Postnikov, and Trnka [33], with the original amplituhedron proposal in [32] and the momentum-twistor underpinnings in [268]. The general theory of positive geometries and canonical forms is laid out in [34]; the combinatorics of the positive Grassmannian in [409], with the ball theorem in [208]. For the kinematic associahedron and stringy canonical forms see [36], and for the sign-flip definition of the amplituhedron [37]. The $m = 2$ amplituhedron is treated in [378] and the tree-level BCFW tiling in [181]. The adjacent programs surveyed in Section 62.8.4 are introduced in [35] (cosmological polytopes), [39] (differential equations for cosmological correlators), and [40] (curve integrals and surfaceology). All are research literature; nothing in the chapter's proved core depends on consulting them.

Chapter 63

Amplitudes Beyond: Synthesis

Every chapter of this part has computed the same kind of object — an on-shell scattering amplitude — by a method that grew steadily less dependent on the apparatus quantum field theory was built from. Spinor-helicity (Chapter 58) showed that the answer is far simpler than the fields that produce it; Parke–Taylor and BCFW recursion (Chapter 59) built tree amplitudes from their factorization poles with no Lagrangian in the loop; the unitarity method (Chapter 60) reconstructed loop integrands from their cuts; the double copy (Chapter 61) manufactured gravity by squaring gauge theory; and the amplituhedron (Chapter 62) produced locality and unitarity as facets of a geometry. This closing chapter does not introduce a new computational technique. Its task is to ask what all of this *means* for quantum field theory, and to do so honestly — separating what the program has proved from what it has only made plausible, and dating the frontier as it stands in the mid-2020s.

The organizing question is the one Part I left implicit when it laid down its postulates. Of the founding assumptions of the subject — Poincaré invariance, locality, unitarity, analyticity, introduced informally in Chapter 1 and made precise as S-matrix properties in Section 63.1.3 — which are genuine *inputs* we are free to choose, and which are *outputs*, theorems forced once the others are fixed? The amplitudes program supplies the most suggestive evidence bearing on that question, and the chapter assembles it into an argument. We open in Section 63.1 by making the word "redundant" exact: the machinery that computes an amplitude is vastly larger and more arbitrary than the amplitude itself, and the part of it that survives to the answer is governed by the axioms alone. Section 63.2 then promotes analyticity and unitarity from properties an amplitude happens to possess to principles strong enough to *construct* it, recovering the BCFW and unitarity-method logic of Chapters 59 and 60 as the two statements that residues and cuts *are* the locality and unitarity data.

The middle of the chapter turns the same pair of principles into quantitative output. In Section 63.3 we carry the gold-standard worked anchor of

the part: a twice-subtracted forward dispersion relation, built from crossing, analyticity (Chapter 5), and the optical theorem (Chapter 14), forces the leading higher-derivative Wilson coefficient of the ϕ^4 theory effective theory to be strictly positive — the S-matrix bootstrap pointed below, at the effective theory, rather than above at the spectrum. Section 63.4 then shows that this is not an analogy to the conformal bootstrap of Chapters 49 and 50 but the *same* convex-optimization problem in two kinematic disguises, with the flat-space limit of AdS/CFT (Chapter 53) supplying the dictionary that maps one onto the other. Section 63.5 pushes to the boldest reading, assembling the amplituhedron (Chapter 62) and the double copy (Chapter 61) as evidence that locality and unitarity are themselves outputs of a more primitive geometric and algebraic structure.

The last two sections take the program to its boundary in both senses. Section 63.6 follows the amplitude to null infinity: leading soft theorems, derived in full from the factorization pole, become the Ward identities of asymptotic symmetries, and the Mellin transform to boost eigenstates recasts the entire S-matrix as a correlator of conformal primaries on the celestial sphere — the flat-space cousin of the holography of Part XV. Section 63.7 then closes the part and the question with a dated status summary of the program's claims, the controlled inversion of Part I's logic that the evidence supports, the meeting of the three benchmark theories as facets of one structure, and the frontier that remains — which is precisely the setting, curved spacetime, where the flat-space S-matrix runs out and Part XVII (Chapters 64 and 65) must begin.

Notation Watch: conventions for this chapter

Signs matter throughout the dispersive and soft-theorem arguments below, so we restate the conventions once. We use the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$ and natural units $\hbar = c = 1$ (Appendix A), so that $p^2 = m^2$ on shell, the Mandelstam invariants obey $s + t + u = \sum_i m_i^2$, and the massless contractions used in Section 63.3 read $(p_i - p_j)^2 = -2\, p_i \cdot p_j$. The spinor-helicity angle and square brackets $\langle i\, j\rangle$, $[i\, j]$ appearing in load-bearing equations follow the little-group and reality conventions fixed in Chapter 58 (Section 58.2.1); we recall them at each use rather than re-derive them.

63.1 The Lesson of Redundancy: Hidden Simplicity

The chapter opened with a question that is really the book's question, posed now with the whole apparatus of quantum field theory behind us: of the founding assumptions of the subject — Poincaré invariance, locality, unitarity, analyticity — which are genuine *inputs*, postulates we are free to choose, and which are

outputs, theorems forced upon us once the others are fixed? The amplitudes program of this part has handed us the single most suggestive piece of evidence bearing on that question, and before we can turn the evidence into an argument we must state it precisely. The evidence is a mismatch. The machinery that *computes* a scattering amplitude — a Lagrangian, a choice of field variables, a gauge, a swarm of Feynman diagrams — is enormously larger and more arbitrary than the amplitude it produces. Most of what the machinery carries is redundant: it cancels, it depends on conventions, it never reaches the answer. The physical amplitude is, by comparison, almost embarrassingly simple. This section assembles that fact from the whole part, makes the word "redundant" mean something exact, and reads off the list of axioms whose status the rest of the chapter will interrogate. We compute nothing new here; we gather what the part has proved and sharpen the question.

63.1.1 The redundancy of the field-variable description

A relativistic quantum theory of particles is, at bottom, two things: a Hilbert space carrying a unitary representation of the Poincaré group, and a unitary operator $\mathbf{S}$ on it — the S-matrix — whose matrix elements between asymptotic multiparticle states are the numbers an experiment can measure. Everything else in the formalism is scaffolding. The Lagrangian, the fields, the path integral, the gauge choice, the regulator, the counterterms: these are a *coordinatization* of the theory, a way of naming and computing the entries of $\mathbf{S}$. Two facts, both established earlier in the book, show just how loose that coordinatization is.

The first is gauge redundancy. In quantizing a gauge field we deliberately introduced a description with *more* variables than physical degrees of freedom — the longitudinal and timelike polarizations of A_μ, the gauge parameter ξ, the Faddeev–Popov ghosts — and then spent entire chapters showing that the surplus drops out of anything physical. The photon and gluon propagators carry ξ explicitly; the S-matrix does not, by the Ward and Slavnov–Taylor identities. A continuous infinity of field configurations, A_μ and $A_\mu + \frac{1}{g}D_\mu\alpha$, name the same physical state. Gauge "symmetry" is, viewed this way, not a symmetry of nature at all but a redundancy of our labels, introduced for the sake of manifest locality and Lorentz covariance and paid back in full at the end of every calculation.

The second fact is subtler and applies to every field theory, gauge or not: the freedom to redefine the field off shell. We may trade the field ϕ for any local function of it and its derivatives,

$$\chi(x) \;=\; \phi(x) \;+\; c_1\,\phi(x)^2 \;+\; c_2\,\phi(x)\,\Box\phi(x) \;+\; \cdots\,, \tag{63.1}$$

provided the redefinition is *invertible* near the free field — the linear term has a nonzero coefficient, here normalized to unity — and write the same theory in terms of χ. The Lagrangian, the Feynman rules, and every off-shell Green's

function change, often dramatically: a redefinition can create or destroy entire interaction vertices. Yet the S-matrix is left exactly invariant. This is the content of what is loosely called the *equivalence theorem*. We can prove the part of it we need directly from the LSZ reduction formula of Theorem 14.31, and the proof is short enough, and instructive enough, to give in full.

Proposition 63.1 (Invariance of the S-matrix under local field redefinition)**.** *Let a theory be described by a local field ϕ, and let χ be a second local field related to ϕ by an invertible local redefinition Eq. (63.1) whose linear part is a nonzero multiple of ϕ. Suppose ϕ and χ both have nonzero overlap with the one-particle states $|p\rangle$ of physical mass m, i.e. $\langle 0|\,\phi(0)\,|p\rangle \neq 0$ and $\langle 0|\,\chi(0)\,|p\rangle \neq 0$. Then the connected S-matrix elements obtained by applying the LSZ formula Theorem 14.31 to correlators of χ equal those obtained from correlators of ϕ.*

Proof. The S-matrix is an intrinsic object. It is defined (Chapter 14) by the overlaps $\langle \beta;\mathrm{out}|\,|\alpha;\mathrm{in}\rangle$ of asymptotic states built on the interacting Hilbert space by the Møller operators; its construction references the Hamiltonian and the one-particle subspace, and *no* choice of interpolating field. LSZ is not a definition of $\mathbf{S}$ but a *representation* of its matrix elements: it asserts that for *any* local operator $\mathcal{O}$ carrying the right quantum numbers and satisfying $\langle 0|\,\mathcal{O}(0)\,|p\rangle \neq 0$, the time-ordered correlator of $\mathcal{O}$'s develops a simple pole in each external invariant as $p_i^2 \to m^2$, and the simultaneous residue in all $n+m$ external momenta reconstructs the connected S-matrix element. Concretely, in the momentum-space form Eq. (14.153),

$$\langle f|\mathbf{S}|i\rangle_{\mathrm{c}} = \Big(\frac{i}{\sqrt{Z_{\mathcal{O}}}}\Big)^{n+m} \prod_{a} [-(p_a^2 - m^2)]\; \mathcal{G}_{\mathcal{O}}(p_1, \dots)\Big|_{\text{on shell}}, \tag{63.2}$$

where $\mathcal{G}_{\mathcal{O}}$ is the correlator of $\mathcal{O}$'s and $Z_{\mathcal{O}}$ is the residue of the $\mathcal{O}$-two-point function at the pole, $\widetilde{\Delta}_{\mathcal{O}}(p) \to i Z_{\mathcal{O}}/(p^2 - m^2 + i\epsilon)$, with $\sqrt{Z_{\mathcal{O}}} = \langle 0|\,\mathcal{O}(0)\,|p\rangle$ in the rest frame (Theorem 14.23). Two observations now finish the argument.

(i) The pole sits at a spectral eigenvalue. The factor $-(p_a^2 - m^2)$ in Eq. (63.2) is matched against a pole at $p_a^2 = m^2$, where m is the energy of the one-particle state at rest — an eigenvalue of the Hamiltonian, a property of the spectrum. A field redefinition relabels operators on a fixed Hilbert space; it cannot move a spectral eigenvalue. Hence the correlators of χ have their single-particle poles at exactly the same $p^2 = m^2$ as those of ϕ. (Indeed χ, being ϕ plus operators that create at least two quanta from the vacuum, has the *same* one-particle overlap to leading order; the higher terms of Eq. (63.1) contribute only multi-particle states and so cannot shift the one-particle pole.)

(ii) The residue is divided out. The only place the choice of operator enters Eq. (63.2) is through the wavefunction factor $(\sqrt{Z_{\mathcal{O}}})^{-(n+m)}$, one $\sqrt{Z_{\mathcal{O}}}$ per external leg. But the on-shell residue of $\mathcal{G}_{\mathcal{O}}$ likewise carries exactly one factor $\sqrt{Z_{\mathcal{O}}}$ per external leg, because each external leg is, near its pole, a full $\mathcal{O}$-propagator

$\widetilde{\Delta}_{\mathcal{O}} \to iZ_{\mathcal{O}}/(p^2-m^2)$ amputated by the explicit $-(p_a^2-m^2)$ and converted to the physical one-particle state by its overlap. The two powers of $\sqrt{Z_{\mathcal{O}}}$ cancel identically: the quotient Eq. (63.2) is independent of the normalization $Z_{\mathcal{O}}$, hence independent of *which* interpolating field we used.

What does change between ϕ and χ is everything *away* from the poles. The redefinition Eq. (63.1) alters contact terms, rearranges the multi-particle branch cuts, and rescales Z; it moves the off-shell content of the Green's functions freely. But the n-fold on-shell residue — after the LSZ amputation strips the external propagators and the Z-factors divide out — is pinned to the intrinsic S-matrix element, which knew nothing about ϕ or χ to begin with. The two computations therefore agree. □

The hypothesis $\langle 0|\,\mathcal{O}\,|p\rangle \neq 0$ is not a technicality but the whole point. A redefinition that *removed* the linear term — say $\mathcal{O}=\phi^2$ — would produce a field with no one-particle overlap, no single-particle pole, and LSZ would simply not apply to it; such an operator computes form factors and composite correlators, not the elastic S-matrix. Among the fields that do interpolate the one-particle state, however, the choice is pure convention. The following worked example makes the mechanism of Theorem 63.1 concrete by watching, in the simplest possible case, how a redefinition deposits new structure off shell while leaving the on-shell residue untouched.

Worked Example 63.2 (A field redefinition moves the cut, not the pole)**.** Take the free real scalar of ϕ^4 theory at $\lambda=0$ (Chapter 9), with $\mathcal{L}=\tfrac{1}{2}(\partial\phi)^2-\tfrac{1}{2}m^2\phi^2$ and the Feynman propagator $D_F(x)=\langle 0|\,\mathcal{T}\phi(x)\phi(0)\,|0\rangle$, $\widetilde{D_F}(p)=i/(p^2-m^2+i\epsilon)$. Introduce the new interpolating field

$$\mathcal{O}(x) \;=\; \phi(x) \;+\; a\,\phi(x)^2, \qquad [a]=\text{mass}^{-1}, \tag{63.3}$$

a local redefinition of the form Eq. (63.1). We compute its two-point function and read off both the pole and the residue, exhibiting Theorem 63.1 (i)–(ii) explicitly.

By Wick's theorem in the free theory, with ϕ Gaussian and $\langle 0|\,\phi\,|0\rangle=0$,

$$\begin{aligned}\langle 0|\,\mathcal{T}\,\mathcal{O}(x)\,\mathcal{O}(0)\,|0\rangle &= \langle 0|\,\mathcal{T}\big(\phi+a\phi^2\big)(x)\big(\phi+a\phi^2\big)(0)\,|0\rangle \\ &= \underbrace{\langle 0|\,\mathcal{T}\phi(x)\phi(0)\,|0\rangle}_{D_F(x)} + a\,\underbrace{\langle 0|\,\mathcal{T}\phi(x)\phi(0)^2\,|0\rangle}_{0} + a\,\underbrace{\langle 0|\,\mathcal{T}\phi(x)^2\phi(0)\,|0\rangle}_{0} \\ &\quad + a^2\,\langle 0|\,\mathcal{T}\phi(x)^2\,\phi(0)^2\,|0\rangle\,. \end{aligned}\tag{63.4}$$

The two cross terms vanish because a correlator of an odd number of free fields is zero. The last term, kept to its connected part (the disconnected piece $\langle 0|\,\phi^2\,|0\rangle^2$ is a field-independent constant that contributes no pole and is removed in the connected correlator), is the two-contraction Wick pairing

$$\langle 0|\,\mathcal{T}\phi(x)^2\phi(0)^2\,|0\rangle_{\rm c} \;=\; 2\,D_F(x)^2, \tag{63.5}$$

the factor 2 counting the two ways of contracting the pair at x with the pair at 0. Hence the connected $\mathcal{O}$-propagator is, in position and then momentum space,

$$\langle 0|\,\mathcal{T}\,\mathcal{O}(x)\,\mathcal{O}(0)\,|0\rangle_{\rm c} \;=\; D_F(x)+2a^2\,D_F(x)^2, \qquad \widetilde{\Delta}_{\mathcal{O}}(p) = \frac{i}{p^2-m^2+i\epsilon} + 2a^2\,\widetilde{[D_F^2]}(p). \tag{63.6}$$

The new term is a one-loop bubble. Its Fourier transform,

$$\widetilde{[D_F^2]}(p) = \int \frac{d^4k}{(2\pi)^4}\,\frac{i}{k^2-m^2+i\epsilon}\,\frac{i}{(p-k)^2-m^2+i\epsilon}, \tag{63.7}$$

is the scalar bubble computed in Chapter 21: it is *analytic* in p^2 except for a branch cut beginning at the two-particle threshold $p^2=(2m)^2$, the lowest invariant mass at which the intermediate $\phi\phi$ state can go on shell. Crucially, it has *no pole at* $p^2=m^2$.

Reading off Eq. (63.6), then: near the one-particle pole $p^2\to m^2$ the bubble is a finite, smooth background, and the singular behavior is governed entirely by the first term,

$$\widetilde{\Delta}_{\mathcal{O}}(p) \;\xrightarrow{\;p^2\to m^2\;}\; \frac{iZ_{\mathcal{O}}}{p^2-m^2+i\epsilon}, \qquad Z_{\mathcal{O}}=1. \tag{63.8}$$

The redefinition Eq. (63.3) has changed the two-point function — it has grown a genuine two-particle branch cut at $p^2=4m^2$, an entirely new piece of off-shell, multi-particle structure — while leaving the single-particle pole at the same location m^2 with the same residue $Z_{\mathcal{O}}=1$. This is precisely the dichotomy of Theorem 63.1: the off-shell content moves, the on-shell residue does not. One verifies the residue invariance from the overlap directly, $\langle 0|\,\mathcal{O}(0)\,|p\rangle = \langle 0|\,\phi(0)\,|p\rangle + a\,\langle 0|\,\phi(0)^2\,|p\rangle = \langle 0|\,\phi(0)\,|p\rangle + 0$, since ϕ^2 creates only even numbers of quanta and has zero one-particle overlap. The new field interpolates the same particle with the same normalization; its S-matrix — here the trivial S-matrix of a free theory — is unchanged, even though its Green's functions are not.

Theorem 63.2 is a microcosm of the general lesson. The space of field descriptions of a fixed theory is vast — a gauge orbit times the infinite-dimensional space of local redefinitions — and the S-matrix is constant along all of it. Physical content lives only in the on-shell residues; the off-shell Green's functions are coordinates on the redundant directions. Figure 63.1 pictures the situation: the Feynman machinery operates upstairs, in the large redundant space; the amplitude lives downstairs, on the small physical quotient, and the projection forgets almost everything.

63.1.2 The mismatch between diagrams and amplitudes

The redundancy of Section 63.1.1 is structural — a statement about descriptions. Part XVI turned it into a quantitative scandal, and it is worth restating the

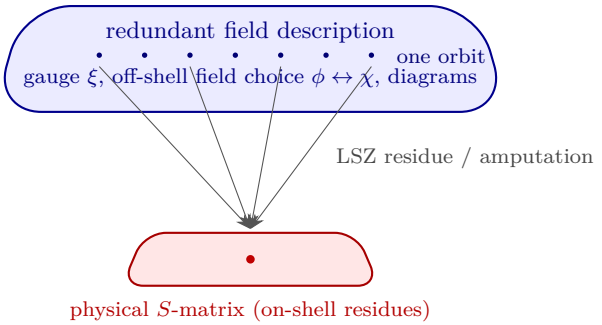

Figure 63.1: The redundancy of the field-variable description. A whole orbit of field choices — related by gauge transformations and by invertible local redefinitions Eq. (63.1) — maps to a single point of the physical S-matrix. The Feynman machinery computes upstairs, carrying gauge parameters, off-shell vertices, and a factorial number of diagrams; the LSZ residue (Theorem 63.1) projects down, discarding everything but the on-shell, gauge-invariant data. Hidden simplicity is the smallness of the target relative to the domain.

numbers because they are the empirical heart of the chapter. Consider the tree-level scattering of n gluons in Yang–Mills theory. The Feynman expansion (Chapter 59) builds the amplitude from cubic and quartic vertices, and the number of diagrams grows faster than any factorial. We recorded the counts in Table 59.1: the full n-gluon amplitude is assembled from 4 diagrams at $n = 4$, 220 at $n = 6$, 34 300 at $n = 8$, and 10 525 900 at $n = 10$; even after color ordering strips the trivial group-theoretic redundancy, a single color-ordered partial amplitude $A_n[1, 2, \dots, n]$ still requires 12 925 planar diagrams at $n = 10$. Each diagram is individually gauge-dependent — it depends on the gauge parameter ξ, on off-shell vertices, on a choice of polarization vectors that themselves carry a reference-momentum ambiguity — and each is a sprawling rational function of the momenta and polarizations built from *both* chiralities, the angle data $\langle i\, j\rangle$ and the square data $[i\, j]$ entangled together.

The sum of these millions of terms, in the maximally-helicity-violating sector (two negative-helicity gluons i, j among n), is the single Parke–Taylor monomial of Eq. (59.55),

$$A_n[1^+, \dots, i^-, \dots, j^-, \dots, n^+] \;=\; i\, g^{n-2}\, \frac{\langle i\, j\rangle^4}{\langle 1\, 2\rangle\langle 2\, 3\rangle \cdots \langle n-1\, n\rangle\langle n\, 1\rangle}, \tag{63.9}$$

one term, purely holomorphic, not a single square bracket surviving the collapse. The ratio of description to result is, at $n = 10$, a million-to-one. This is the mismatch in its sharpest form: the gauge-dependent, off-shell, factorially proliferating machinery delivers a gauge-invariant, on-shell, one-line answer.

The decisive point — the one that turns the mismatch from a curiosity into a clue — is *how* Part XVI recovered Eq. (63.9) without summing the diagrams at

all. Two reconstructions, both using only on-shell, gauge-invariant data, produced the same answers.

First, at tree level, on-shell recursion. The BCFW relation (Theorem 59.23) builds the n-point amplitude from products of lower-point *on-shell* amplitudes, glued across factorization channels where an internal line goes on its mass shell. The recursion bottoms out on the three-point amplitudes, and those are not computed from a Lagrangian at all: they are fixed, up to a single constant, by Poincaré invariance alone — by little-group covariance Eq. (58.5) together with locality — as established in Theorem 58.20. The entire MHV tower Eq. (63.9), and indeed every tree gluon amplitude, follows from gluing these symmetry-fixed three-point building blocks. No gauge is chosen; no off-shell vertex appears; the gauge parameter ξ that haunted every individual Feynman diagram is simply absent from the construction, because the construction never leaves the physical, on-shell data.

Second, at loop level, generalized unitarity. The optical theorem of Section 14.7 ties the imaginary part of an amplitude to a sum over physical intermediate states — a statement of unitarity, $\mathbf{S}^\dagger\mathbf{S} = 1$. Chapter 60 sharpened this into a constructive tool: the loop integrand is reconstructed by demanding that its discontinuity across every cut factorize into products of on-shell tree amplitudes. The quadruple cut (Theorem 60.13) freezes the loop momentum completely and reads each box coefficient off as a product of four on-shell trees; the lower cuts of Section 60.3 supply the triangles and bubbles. Again the input is exclusively on-shell, gauge-invariant tree data, and again the Lagrangian, the gauge, and the off-shell vertices never appear. The amplitude is assembled from its physical singularities — its poles and cuts — alone.

Physical Insight

Hidden simplicity is a symptom, not the disease. A simple answer wrung from a complicated calculation is a signal that the calculation is written in the wrong variables — that it carries redundant coordinates that must cancel before the physical content can emerge. The Feynman expansion is such a set of coordinates: manifestly local and Lorentz-covariant, and for exactly that reason laden with gauge and off-shell redundancy. The on-shell methods of Chapters 59 and 60 are the change of variables that trades manifest locality for manifest physicality, computing directly in the data that survive the projection of Fig. 63.1: residues at physical poles and discontinuities across physical cuts. That these data *suffice* to reconstruct the full amplitude is the fact the rest of the chapter must explain.

63.1.3 The axioms as the variables of the argument

If the on-shell data — poles, residues, cuts, and the symmetry-fixed three-point seeds — are enough to rebuild the amplitude, then the elaborate Lagrangian machinery was never logically necessary; it was one convenient route to data that other routes reach more directly. This invites the chapter's organizing question in its precise form. The amplitude is constrained by a small number of structural principles, the same ones introduced at the very start of the book (Chapter 1) as the defining features of a relativistic quantum theory. We now isolate them as the *variables* of the argument to come, stating each as a sharp property of the S-matrix rather than of the Lagrangian, because it is the S-matrix that the on-shell methods construct.

(A) Poincaré invariance. The asymptotic states are organized into unitary irreducible representations of the Poincaré group, labeled by mass and by spin (for massive particles) or helicity (for massless ones); the S-matrix commutes with the Poincaré generators. In the spinor-helicity variables of Chapter 58 this principle is wholly explicit: an n-point amplitude is a function of the invariants $\langle i\,j\rangle$, $[i\,j]$ covariant under the little-group rescalings Eq. (58.5), and that covariance alone fixes the three-point amplitudes (Theorem 58.20). Poincaré invariance is thus the most clearly *kinematic* of the four — it constrains the form of the answer before any dynamics is specified.

(B) Locality. In the S-matrix this becomes a statement about *singularities*: the amplitude is meromorphic with poles only at the physical masses of the theory, and the residue at each pole *factorizes* into a product of lower-point on-shell amplitudes, one for each side of the factorization channel. There are no spurious poles, no singularities at unphysical locations. This is the analytic shadow of cluster decomposition — distant experiments do not interfere — and it is exactly the property BCFW exploits: the recursion is built from the residues at the physical factorization poles and nothing else.

(C) Unitarity. Probability is conserved, $\mathbf{S}^\dagger\mathbf{S} = 1$. Writing $\mathbf{S} = 1 + i\,T$ gives $-i(T - T^\dagger) = T^\dagger T$, the optical theorem of Section 14.7: the discontinuity of an amplitude across a physical cut is a sum over intermediate on-shell states with *positive* weight. Unitarity is therefore a positivity statement, and it is the property that generalized unitarity (Chapter 60) turns into a reconstruction of loop integrands from their cuts.

(D) Analyticity. The amplitude is the boundary value of an analytic function of the complexified invariants, whose only singularities are those forced by (B) and (C) — the physical poles and the unitarity cuts — with the prescribed $i\epsilon$ continuation, and which is crossing-symmetric: the same analytic function describes the s-, t-, and u-channel processes. Analyticity

is what allows a contour to be deformed, a dispersion relation to be written, a pole to be reached by complexifying a momentum (as BCFW does). It is the principle that connects the data at different kinematic points into a single function.

These four are not independent of one another, and that is the whole tension the chapter will exploit. Part XVI has shown that (B) and (C) — locality as physical-pole factorization, unitarity as positive cuts — together with the kinematic skeleton (A), are enough to *construct* tree amplitudes (BCFW) and loop integrands (generalized unitarity) that the Lagrangian was supposed to be needed for. The Lagrangian, the gauge choice, the off-shell fields — the redundant coordinates of Section 63.1.1 — never entered. So the question "which axioms are inputs and which are outputs?" is not idle metaphysics. It is the concrete question of how much of the standard apparatus is logically necessary and how much is one redundant route among many. We will find that several cherished "axioms" are better read as theorems: that crossing follows from analyticity plus locality, that the three-point couplings of massless higher-spin particles are nearly fixed by Poincaré invariance alone, that locality and unitarity can be recovered as *outputs* of a positive geometry or of a double-copy construction.

Caution

The four principles above are stated as properties of a theory that *has* a particle interpretation and an S-matrix — a massive theory with a mass gap, where asymptotic states and the LSZ machinery (Theorem 14.31) make unambiguous sense. The frontier constructions of this part stretch each principle: massless particles weaken the analytic structure (infrared divergences, the absence of a clean asymptotic Fock space), conformal theories have no S-matrix at all, and the celestial program of Section 63.6 will reorganize the same data as a correlator rather than an S-matrix. We hold the precise massive statements as the reference point and flag each weakening explicitly as it arises.

We have now assembled the empirical fact and named the variables. The Feynman description is hugely redundant and the S-matrix is invariant across the redundancy (Theorem 63.1, Fig. 63.1); the diagram-to-amplitude mismatch is quantitatively enormous (Section 63.1.2); and the amplitude was reconstructed, in every case Part XVI examined, from on-shell data alone — the physical poles of locality and the positive cuts of unitarity, riding on the kinematic frame of Poincaré invariance and tied together by analyticity. The natural reading of this evidence is that analyticity and unitarity are not merely properties the S-matrix happens to possess once a Lagrangian is given; they may be the very instructions for building it. The next section takes this reading seriously and promotes analyticity and unitarity from properties to *constructive principles*:

tree amplitudes assembled from their factorization poles, loop integrands from their unitarity cuts, with locality and unitarity identified as exactly the residue and cut data.

63.2 Analyticity and Unitarity as Constructive Principles

The previous section turned a recurring observation into a question. Again and again the on-shell amplitude proved dramatically simpler than the off-shell, gauge-redundant Feynman sum that computes it, and the axiom list of Chapter 1 — Poincaré invariance, locality, unitarity, analyticity — sat behind that simplicity without obviously *causing* it. The natural reading of the redundancy lesson is that the Lagrangian and its diagrams are a particular, highly non-unique *coordinatisation* of the physical content, while the amplitude is the invariant object; the off-shell freedom is gauge, and gauge is what the on-shell methods discard. But this leaves the axioms in an ambiguous status. Are analyticity and unitarity merely *properties* that any amplitude built the usual way happens to inherit, or are they strong enough to *build* the amplitude in the first place, with no Lagrangian in sight? This section argues for the second reading. We promote analyticity and unitarity from descriptions to constructions: tree amplitudes are assembled from their factorisation poles, loop integrands from their unitarity cuts, and — crucially for what follows — the two axioms turn out to be carried by exactly the residue and cut data, with nothing left over. Locality *is* the pole structure; unitarity *is* the residue and cut normalisation and positivity. Once that identification is made, the founding axioms stop being external postulates checked after the fact and become the input from which the amplitude is generated.

63.2.1 The constructive turn, abstracted from BCFW

The concrete engine that makes this work was built in Chapter 59: the Britto–Cachazo–Feng–Witten recursion Theorem 59.23, which deforms two external momenta by a complex parameter z, follows the resulting one-parameter family of amplitudes into the complex plane, and reconstructs the physical amplitude from the residues at the poles the deformation crosses. There the deformation was the explicit spinor shift $|\hat{i}\rangle = |i\rangle$, $|\hat{j}] = |j]$, $|\hat{i}] = |i] + z|j]$, $|\hat{j}\rangle = |j\rangle - z\,|i\rangle$, and the large-$z$ analysis used the detailed helicity dependence of gauge amplitudes. We now strip that construction to the analytic skeleton that does the work, so that the same logic can be applied to any theory — including ones with no useful Lagrangian at all — and so that the physical role of each axiom is laid bare. The abstraction makes no reference to spinors, gauge, or the specific shift; it asks only what *analytic* structure an amplitude must have for it to be reconstructible from its singularities.

Definition 63.3 (Admissible complex deformation)**.** Let $\mathcal{M}$ be an on-shell scattering amplitude of n massless or massive particles with fixed external quantum numbers, regarded as a function of the on-shell external momenta $\{p_a\}$ subject to $\sum_a p_a = 0$ (all-outgoing convention, Chapter 58). A *complex deformation* of $\mathcal{M}$ is a holomorphic family

$$p_a \;\longmapsto\; \hat{p}_a(z) = p_a + z\, r_a, \qquad z \in \mathbb{C}, \tag{63.10}$$

with fixed complex *shift vectors* r_a chosen so that for all z the deformed momenta remain (i) on shell, $\hat{p}_a(z)^2 = m_a^2$, and (ii) momentum conserving, $\sum_a \hat{p}_a(z) = 0$. Writing $\hat{\mathcal{M}}(z) := \mathcal{M}(\{\hat{p}_a(z)\})$ for the deformed amplitude, the deformation is *admissible* if $\hat{\mathcal{M}}(z)$ is a meromorphic function of the single complex variable z, with $\hat{\mathcal{M}}(0) = \mathcal{M}$ the physical amplitude.

Conditions (i) and (ii) constrain the r_a: expanding (i) gives $p_a \cdot r_a = 0$ and $r_a^2 = 0$ for each shifted leg, and (ii) gives $\sum_a r_a = 0$. The spinor shift of Chapter 59 is one explicit solution of these constraints for two massless legs; the point of Theorem 63.3 is that the recursion never used anything about the shift beyond its being an admissible holomorphic one-parameter family. Meromorphy — the absence of any singularity worse than poles, and of any essential singularity or branch cut in z — is the substantive analyticity hypothesis. For a tree amplitude it is automatic: a tree amplitude is a rational function of the kinematic invariants (a finite sum of products of propagators $1/(P_I^2 - m_I^2)$ and polynomial numerators), and a rational function of momenta that are themselves linear in z is a rational, hence meromorphic, function of z. This is precisely the analyticity reviewed in Section 5.4.1: a function defined by a rational expression extends uniquely to a meromorphic function on the complex plane, and its global behaviour is fixed by its poles and its growth at infinity.

We can now state the constructibility theorem in a form that mentions neither spinors nor a specific shift.

Theorem 63.4 (Abstract on-shell constructibility)**.** *Let $\hat{\mathcal{M}}(z)$ be an admissible complex deformation (Theorem 63.3) of an amplitude $\mathcal{M}$, with the two further properties:*

(P) Only simple poles. *The singularities of $\hat{\mathcal{M}}(z)$ in the finite plane are simple poles, located at the values z_I where some physical factorisation channel goes on shell, i.e. where a partial sum $\hat{P}_I(z)^2 - m_I^2$ vanishes for a subset I of the external legs.*

(B) Vanishing at infinity. *$\hat{\mathcal{M}}(z) \to 0$ as $|z| \to \infty$.*

Then the physical amplitude is the sum of its factorisation residues,

$$\mathcal{M} \;=\; -\sum_I \operatorname{Res}_{z=z_I} \frac{\hat{\mathcal{M}}(z)}{z} \;=\; -\sum_I \frac{1}{z_I}\, \operatorname{Res}_{z=z_I} \hat{\mathcal{M}}(z), \tag{63.11}$$

the sum running over all physical channels I that the deformation puts on shell.

Proof. The argument is a single application of the residue theorem Theorem 5.23 to the auxiliary function $\hat{\mathcal{M}}(z)/z$, mirroring the concrete contour computation Eq. (59.126) but carried at the level of the hypotheses (P) and (B) alone.

Consider $g(z) := \hat{\mathcal{M}}(z)/z$. By (P), $\hat{\mathcal{M}}(z)$ has simple poles at the z_I, none of which sits at the origin (a factorisation channel on shell at $z = 0$ would be a singularity of the *physical* amplitude in a physical channel, which the deformation is set up to avoid; the base point $z = 0$ is generic). Dividing by z adds one further simple pole, at $z = 0$, with residue

$$\operatorname{Res}_{z=0} \frac{\hat{\mathcal{M}}(z)}{z} = \hat{\mathcal{M}}(0) = \mathcal{M}, \tag{63.12}$$

the quantity we want. Integrate g around a circle C_R of radius R centred at the origin, large enough to enclose every z_I. The residue theorem Theorem 5.23 gives

$$\frac{1}{2\pi i}\oint_{C_R} \frac{\hat{\mathcal{M}}(z)}{z}\,dz \;=\; \operatorname{Res}_{z=0}\frac{\hat{\mathcal{M}}(z)}{z} + \sum_I \operatorname{Res}_{z=z_I}\frac{\hat{\mathcal{M}}(z)}{z} \;=\; \mathcal{M} + \sum_I \operatorname{Res}_{z=z_I}\frac{\hat{\mathcal{M}}(z)}{z}. \tag{63.13}$$

Now estimate the left-hand side as $R \to \infty$. Parametrising $z = Re^{i\theta}$,

$$\left|\frac{1}{2\pi i}\oint_{C_R} \frac{\hat{\mathcal{M}}(z)}{z}\,dz\right| = \left|\frac{1}{2\pi}\int_0^{2\pi} \hat{\mathcal{M}}(Re^{i\theta})\,d\theta\right| \;\le\; \max_{|z|=R}|\hat{\mathcal{M}}(z)|, \tag{63.14}$$

since the explicit $1/z$ has cancelled the $dz = iz\,d\theta$ Jacobian, leaving an angular average of $\hat{\mathcal{M}}$ itself. By hypothesis (B), $\max_{|z|=R}|\hat{\mathcal{M}}(z)| \to 0$ as $R \to \infty$, so the contour integral vanishes in the limit. (This is the one place the boundary behaviour enters, and it enters exactly here: the $1/z$ in g is what makes the bound Eq. (63.14) the bare size of $\hat{\mathcal{M}}$ on the arc, so a vanishing amplitude at infinity is precisely the condition that kills the contour. Had we integrated $\hat{\mathcal{M}}(z)$ itself rather than $\hat{\mathcal{M}}(z)/z$, the arc would have contributed a divergent $R\int d\theta$ even for a decaying amplitude.) Taking $R \to \infty$ in Eq. (63.13) therefore yields

$$0 \;=\; \mathcal{M} + \sum_I \operatorname{Res}_{z=z_I}\frac{\hat{\mathcal{M}}(z)}{z}, \tag{63.15}$$

which is the first equality of Eq. (63.11). For the second equality, each pole is simple by (P), so $\operatorname{Res}_{z=z_I}[\hat{\mathcal{M}}(z)/z] = (1/z_I)\operatorname{Res}_{z=z_I}\hat{\mathcal{M}}(z)$; substituting this identity into the first equality gives the second, with the overall minus sign carried through unchanged. This is the abstract content of the BCFW master formula Eq. (59.130). □

Hypothesis (B) is the subtle one, exactly as flagged in Section 59.5.4: if $\hat{\mathcal{M}}(z)$ instead approaches a nonzero constant or grows, the arc in Eq. (63.14)

contributes a *boundary term* $B = \frac{1}{2\pi}\oint \hat{\mathcal{M}}\, d\theta$, and Eq. (63.11) acquires an extra piece $\mathcal{M} = B - \sum_I \mathrm{Res}_{z=z_I}[\hat{\mathcal{M}}/z]$ that is *not* determined by the factorisation residues. Whether B vanishes is a property of the deformation and the external data, not of the residue theorem; for gauge and gravity amplitudes the existence of a good shift was established in Section 59.6. The clean statement we keep is the implication: *good ultraviolet behaviour under a complex deformation* $\Rightarrow$ *the amplitude is its own factorisation data.* Constructibility is the conjunction of analyticity (meromorphy, hypothesis P) and a falloff (hypothesis B); when both hold, locality and unitarity, encoded in the residues, generate everything else.

63.2.2 Locality and unitarity *are* the residue data

Theorem 63.4 reduces the amplitude to its residues. The physical claim of this section is that those residues are not free data: their *locations* are dictated by locality and their *values* by unitarity, and once both are fixed the amplitude is too. We make each half precise.

Locality fixes where the poles are. A local quantum field theory is one whose interactions are built from products of fields at a single spacetime point; the consequence for amplitudes, established when the Feynman rules were derived, is that the only singularities of a tree amplitude are poles at vanishing of physical propagator denominators $P_I^2 - m_I^2$, where $P_I = \sum_{a\in I} p_a$ is the total momentum flowing through a subset I of external legs. Equivalently: the amplitude is singular exactly when an internal line can go on shell, and the channels in which it does so are the genuine Mandelstam invariants of subsets of particles — never a "spurious" kinematic combination that does not correspond to a physical intermediate state. This is hypothesis (P) of Theorem 63.4 read physically. Under the deformation Eq. (63.10) the channel invariant becomes

$$\hat{P}_I(z)^2 - m_I^2 = (P_I^2 - m_I^2) + 2z\,(P_I\cdot R_I) + z^2 R_I^2, \qquad R_I = \sum_{a\in I} r_a, \tag{63.16}$$

a polynomial in z whose zeros z_I are the poles the contour crosses. The statement that $\hat{\mathcal{M}}(z)$ has poles *only* at such z_I, and that each is simple, is precisely the statement that the theory is local and that intermediate states are single particles (double poles would signal a non-normalisable or composite intermediate state). So:

Locality = poles occur only in physical Mandelstam channels, and are simple.

(63.17)

Unitarity fixes the residue values. At a simple pole the amplitude factorises. As the internal line of channel I goes on shell, the full amplitude near the pole

is governed by the propagator of that line dressed by the two amplitudes it connects, summed over the on-shell states $\{s\}$ the line can carry:

$$\mathcal{M} \xrightarrow{P_I^2 \to m_I^2} \sum_s \mathcal{M}_L^{(s)} \frac{i}{P_I^2 - m_I^2} \mathcal{M}_R^{(s)} + (\text{regular}), \tag{63.18}$$

where $\mathcal{M}_L^{(s)}, \mathcal{M}_R^{(s)}$ are *on-shell* amplitudes of strictly fewer legs, with the internal line treated as an external particle of state s on each side. The residue of the pole is therefore

$$\operatorname{Res}_{P_I^2 = m_I^2} \mathcal{M} = i \sum_s \mathcal{M}_L^{(s)} \mathcal{M}_R^{(s)}, \tag{63.19}$$

a sum over physical intermediate states of a product of lower-point on-shell amplitudes. That this is forced — that the residue is exactly this product, with this normalisation and this state sum and no extra constant — is unitarity: the factorisation Eq. (63.18) is the on-shell shadow of the completeness relation $\mathbf{1} = \sum_s |s\rangle\langle s|$ inserted on the intermediate line, the same completeness that drives the optical theorem Theorem 14.37. The state sum runs over a *physical* (positive-norm) Hilbert space, so each term is a product of physical amplitudes and the residue inherits the reflection-positivity of that Hilbert space. So:

$$\boxed{\text{Unitarity} \;=\; \text{residues are } i \textstyle\sum_s \mathcal{M}_L^{(s)} \mathcal{M}_R^{(s)}, \text{ normalised and positive.}} \tag{63.20}$$

This is the precise sense in which Theorem 63.4 reconstructs the amplitude from physics rather than from a Lagrangian. The pole locations z_I come from Eq. (63.16) (locality); the residues come from Eq. (63.19) (unitarity); the contour integral assembles them. Feeding the recursion back into itself terminates on three-point amplitudes, which little-group scaling fixes uniquely (Chapter 58). Nothing else is needed.

Physical Insight

The redundancy lesson now has a sharp resolution. The off-shell Feynman expansion carries an enormous amount of gauge-dependent information that cancels in the final answer; the on-shell amplitude carries only the gauge-invariant residue data. Theorem 63.4 says that data is *complete*: locality (where the poles are) plus unitarity (what the residues are) plus good high-energy behaviour (the boundary term vanishes) determine the amplitude with no remaining freedom. Analyticity is the glue — it is what lets a finite amount of local data about the singularities propagate, by Cauchy's theorem, to the value everywhere. The three founding axioms are not checked on the amplitude; they *are* the amplitude.

Worked Example 63.5 (Reading locality and unitarity off the four-point factorisation)**.** To see Eqs. (63.17) and (63.20) act in the smallest nontrivial case,

take a four-point tree amplitude $\mathcal{M}_4(s,t,u)$ of identical scalars with a cubic coupling g, the simplest theory exhibiting factorisation. With $s+t+u=\sum m_a^2$ and a single intermediate scalar of mass M, locality says the only finite-plane singularities are simple poles in the three physical channels s,t,u at $s=M^2$, $t=M^2$, $u=M^2$, and at nothing else. Unitarity Eq. (63.19) fixes each residue to the product of the two three-point amplitudes glued there. The three-point amplitude of three scalars with coupling g is just $\mathcal{M}_3 = ig$ (no kinematic dependence for scalars), so the s-channel residue is

$$\mathrm{Res}_{s=M^2}\,\mathcal{M}_4 = i\,\mathcal{M}_3\,\mathcal{M}_3 = i\,(ig)(ig) = -ig^2, \tag{63.21}$$

and likewise in t and u. The unique function with exactly these simple poles and these residues, vanishing at large invariants (hypothesis B for this theory), is

$$\mathcal{M}_4 = (-ig^2)\left(\frac{1}{s-M^2}+\frac{1}{t-M^2}+\frac{1}{u-M^2}\right), \tag{63.22}$$

which is exactly the sum of the three exchange Feynman diagrams — reproduced here with no Feynman rules invoked, only the pole locations (locality) and the residues (unitarity). The worked point is that the diagrammatic answer was *over*-determined: the three numbers Eq. (63.21) and the falloff already fix Eq. (63.22) uniquely by Theorem 63.4. The Lagrangian's role was only to supply the seed $\mathcal{M}_3 = ig$; analyticity and unitarity did the rest. (For amplitudes with spin, the same logic applies with the state sum in Eq. (63.19) running over the internal helicities, exactly the inner sum $\sum_h$ of the BCFW formula Eq. (59.130).)

63.2.3 The same logic at loop level: integrands from cuts

Trees are rational; their only singularities are poles, and Theorem 63.4 handles poles. Loop amplitudes are not rational — they have branch cuts, the analytic signature of intermediate states going on shell over a continuous range of phase space — so one might expect on-shell constructibility to stop at tree level. It does not. The branch cuts are themselves fixed by unitarity, through the optical theorem, and the loop *integrand* (the function under the loop-momentum integral, before integrating) is again rational and therefore again reconstructible from its poles. The two facts together mean that even loop-level QFT is determined by on-shell tree data. We assemble the statement; the detailed machinery was built in Chapter 60 and we import rather than rebuild it.

Cuts fix the discontinuity. The generalised optical theorem Theorem 14.37, $2\,\mathrm{Im}\,\mathcal{M}(i\to i) = \sum_f \int d\Pi_f\,|\mathcal{M}(i\to f)|^2$, says the imaginary (absorptive) part of a forward amplitude is a positive sum over physical intermediate states. Promoted off the forward direction and made local in the loop integrand, this is the Cutkosky rule Theorem 60.1: the discontinuity of a loop amplitude across

the branch cut opening at a physical threshold $s = P_I^2$ is computed by replacing the cut propagators with their on-shell delta functions,

$$\frac{i}{p^2 - m^2 + i\epsilon} \;\longrightarrow\; 2\pi\,\delta^{(+)}(p^2 - m^2), \tag{63.23}$$

(the on-shell condition with positive energy, Eq. (60.10)), and gluing the on-shell tree amplitudes on either side of the cut, integrated over the intermediate phase space. The discontinuity of the loop amplitude is thus a phase-space integral of a product of lower-point on-shell amplitudes:

$$\mathrm{disc}_s\,\mathcal{M} \;=\; i \sum_{\text{states}} \int d\Pi\; \mathcal{M}_L\,\mathcal{M}_R\,, \tag{63.24}$$

the loop-level analogue of the tree residue Eq. (63.19), with the discrete state sum of factorisation replaced by the continuous phase-space integral of the optical theorem. The right-hand side involves only on-shell tree amplitudes; unitarity has again expressed the new analytic structure (the cut) in terms of lower data. The positivity of Theorem 14.37 — $\mathrm{Im}\,\mathcal{M}(i \to i) \geq 0$ — rides along: the cut is not merely computable but *sign-definite* in the forward limit, which is the lever the next section will pull.

Cuts fix the integrand. A discontinuity alone does not fix a function; one also needs its analytic continuation off the cut, supplied by a dispersion relation (Theorem 63.6 below). But there is a sharper statement at the integrand level. By the basis theorem of Chapter 60, a one-loop amplitude in dimensional regularisation is a fixed combination of scalar box, triangle, bubble and tadpole master integrals; the only unknowns are the rational *coefficients*. Each coefficient is isolated by a *generalised cut* (Theorem 60.17) that puts several propagators on shell at once, freezing the loop momentum to a discrete set of solutions. The quadruple cut of Theorem 60.13 freezes the four-dimensional loop momentum completely and computes a box coefficient as the product of the four on-shell tree amplitudes sitting at the corners of the box, averaged over the two solutions of the cut equations; the triple and double cuts (with the OPP integrand decomposition Theorem 60.18) peel off the triangle and bubble coefficients in turn. Every coefficient is a product of on-shell trees. Hence:

$$\boxed{\text{one-loop QFT} \;=\; (\text{scalar master integrals}) \;\times\; (\text{coefficients made of on-shell trees}).} \tag{63.25}$$

The integrand is reconstructed from its multiple cuts exactly as a tree is reconstructed from its poles; the master integrals are universal, theory-independent, and computed once and for all (Chapter 60, Appendix D). The dynamics — everything that distinguishes one theory from another at one loop — lives entirely in the cut tree amplitudes. This is generalised unitarity, and it is the loop-level

form of the section's thesis: analyticity (the cut structure, the master-integral basis) plus unitarity (the cuts equal products of trees) reconstruct the amplitude, with the Lagrangian appearing only through the trees it seeds.

Worked Example 63.6 (Reconstructing a one-loop amplitude from its cut by dispersion)**.** The cleanest way to see analyticity-plus-unitarity build a non-rational function is to carry the dispersive reconstruction abstractly, which also previews the machinery of Section 63.3. Suppose a one-loop amplitude $\mathcal{M}(s)$, at fixed other invariants, is analytic in the cut s-plane with a single branch cut along $s \geq s_0$ (the two-particle threshold) and is bounded so that $\mathcal{M}(s)/s \to 0$ at infinity. Cauchy's theorem on a contour hugging the cut — the analytic-continuation argument of Section 5.4.1 — gives the once-subtracted dispersion relation

$$\mathcal{M}(s) = \mathcal{M}(0) + \frac{s}{\pi}\int_{s_0}^{\infty} \frac{ds'}{s'}\,\frac{\operatorname{Im}\mathcal{M}(s')}{s'-s-i\epsilon}, \tag{63.26}$$

in which the entire s-dependence is generated by the integral over the imaginary part. Now feed in unitarity: by Eq. (63.24), $\operatorname{Im}\mathcal{M}(s') = \frac{1}{2}\operatorname{disc}_s \mathcal{M}(s')$ is a phase-space integral of on-shell trees. For the simplest case — a scalar bubble from two identical particles of mass m exchanged with coupling giving a constant tree $\mathcal{M}_L = \mathcal{M}_R = -ig$ — the two-body phase space in $d = 4$ is $\int d\Pi_2 = \frac{1}{8\pi}\sqrt{1-4m^2/s'}\,\theta(s'-4m^2)$, so the cut is

$$\operatorname{Im}\mathcal{M}(s') = \frac{g^2}{16\pi}\sqrt{1-\frac{4m^2}{s'}}\;\theta(s'-4m^2), \tag{63.27}$$

with $s_0 = 4m^2$. Inserting Eq. (63.27) into Eq. (63.26) reproduces the full one-loop bubble: the integral is elementary and yields the standard $\propto g^2\big[2-\beta\log\frac{\beta+1}{\beta-1}\big]$ form with $\beta = \sqrt{1-4m^2/s}$, the same function the explicit Feynman-parameter integral of Chapter 60 returns, including its logarithmic branch cut. The lesson: the *only* dynamical input was the cut Eq. (63.27) — a product of on-shell trees times phase space — while analyticity (the dispersion relation Eq. (63.26)) supplied the continuation to all s. The subtraction constant $\mathcal{M}(0)$ is the lone piece not fixed by the cut; it is a low-energy datum, and it is exactly the kind of constant the positivity arguments of the next section will pin down by sign.

The picture is now uniform across the loop expansion. Trees are fixed by their poles; loop integrands by their multiple cuts; loop amplitudes by dispersion from their single cuts. At every order the new analytic structure is unitarity wearing a kinematic disguise, and analyticity is the principle that turns local singularity data into the global function. We have promoted two of the founding axioms from properties to constructions and identified their physical content with exactly the residue and cut data.

This raises the question that organises the rest of the chapter. If analyticity and unitarity are strong enough to *reconstruct* an amplitude we could in principle

compute by other means, then the same axioms must place rigorous *constraints* on theories we cannot fully solve — bounding their low-energy data from the sole requirement that some consistent, analytic, unitary completion exists. Turning the reconstruction into a quantitative bound is the business of Section 63.3, where the positivity that has so far ridden quietly along inside every cut becomes the active lever, and ϕ^4 theory meets the S-matrix bootstrap.

63.3 Positivity Bounds: The S-Matrix Bootstrap from Below

The previous section argued that analyticity and unitarity are not merely properties an amplitude happens to possess but principles strong enough to *construct* it: a tree amplitude is the unique rational function with the prescribed factorization residues, a loop integrand the unique object with the prescribed unitarity cuts. We now press that same pair of principles in a different direction. Rather than rebuild a known amplitude, we ask what analyticity and unitarity, taken as inputs, *forbid*. The answer is sharp and quantitative, and it is the chapter's gold-standard worked anchor: the coefficient of the leading higher-derivative operator in a low-energy effective field theory is not a free parameter. It must be positive. A measured infrared number is forced, by the bare existence of a unitary and causal completion at high energy, to equal a manifestly positive integral over the spectrum of that completion. This is the S-matrix bootstrap pointed not at the spectrum above but at the effective theory below — the bootstrap from below — and it is where ϕ^4 theory meets the amplitudes frontier.

The logic is a closed loop of four ingredients, each already established in this book. Crossing symmetry (Section 18.4) relates the amplitude in different channels. The optical theorem (Theorem 14.37) makes the imaginary part of the forward amplitude a total cross section, hence nonnegative. Analyticity (Section 5.4.1) and the residue theorem (Theorem 5.23) let us deform a contour from the low-energy region, where the amplitude is the effective theory's polynomial in the kinematic invariants, out onto the high-energy cuts, where it is the absorptive spectral data. Polynomial boundedness — the Froissart–Martin bound — kills the arc at infinity that would otherwise spoil the deformation. Assemble these and a single low-energy Wilson coefficient is pinned to a positive spectral integral. We carry every step.

63.3.1 The effective theory and its leading irrelevant coefficient

We continue ϕ^4 theory: a single real scalar ϕ of mass m, carrying the $\mathbb{Z}_2$ symmetry $\phi \to -\phi$ fixed for this thread, whose first interacting amplitude was the tree-level constant $\mathcal{M} = -\lambda$ of Theorem 14.35. At low energies the physics of ϕ is organised by the Wilsonian effective Lagrangian of Chapter 23: an infinite tower of local

operators built from ϕ and its derivatives, ordered by relevance. The marginal interaction is the ϕ^4 contact term with coupling λ; above it sit the irrelevant operators classified in Section 23.5.4[1], suppressed by powers of a heavy scale M at which the effective description breaks down. The leading irrelevant operator that feeds the elastic $2 \to 2$ amplitude with a genuinely new structure — one not already produced by λ and by the kinematics of the marginal vertex — is the four-derivative, four-field operator

$$\mathcal{L} \supset \frac{c}{4}\,(\partial_\mu\phi\,\partial^\mu\phi)\,(\partial_\nu\phi\,\partial^\nu\phi), \qquad [c] = (\text{mass})^{-4}, \tag{63.28}$$

whose dimensionless Wilson coefficient is $c\,M^4$. It is the carried scalar's leading $(\partial\phi)^4$-type irrelevant operator. The claim of this section, made precise below, is that $c > 0$ for any ϕ that arises as the low-energy limit of a unitary, causal, Lorentz-invariant theory.

The amplitude and its low-energy expansion. Write the elastic amplitude for $\phi(p_1)\phi(p_2) \to \phi(p_3)\phi(p_4)$ as $\mathcal{M}(s,t)$, with the Mandelstam invariants

$$s = (p_1{+}p_2)^2, \qquad t = (p_1{-}p_3)^2, \qquad u = (p_1{-}p_4)^2, \qquad s{+}t{+}u = 4m^2, \tag{63.29}$$

the constraint following from $p_i^2 = m^2$ and momentum conservation. Because the four external particles are identical, $\mathcal{M}$ is symmetric under every permutation of s,t,u; in particular it is invariant under the $s \leftrightarrow u$ crossing of Section 18.4, the exchange of the second incoming leg with the second outgoing leg. At low energy, $|s|, |t| \ll M^2$, the amplitude is analytic in the invariants and admits a Taylor expansion. In the forward direction $t = 0$, where $u = 4m^2 - s$, the crossing symmetry $s \leftrightarrow u$ becomes the reflection $s \mapsto 4m^2 - s$ about the point $s = 2m^2$, so the forward amplitude is an even function of $s - 2m^2$:

$$\mathcal{M}(s,0) = a_0 + c\,(s{-}2m^2)^2 + O\big((s{-}2m^2)^4\big), \qquad c \equiv \tfrac{1}{2}\,\partial_s^2\,\mathcal{M}(s,0)\big|_{s=2m^2}. \tag{63.30}$$

The constant a_0 collects the marginal contact $-\lambda$ together with finite renormalizations; the linear term is absent by the crossing reflection. The coefficient c of the curvature is, up to corrections suppressed by m^2/M^2, exactly the Wilson coefficient of Eq. (63.28), as we now confirm by computing the contact contribution directly.

The contact vertex. The operator Eq. (63.28) produces a four-point contact vertex whose Feynman rule we extract by the standard count. Write the operator as $\frac{c}{4}X^2$ with $X = \partial_\mu\phi\,\partial^\mu\phi$. To form the $2 \to 2$ vertex we functionally differentiate $\frac{c}{4}X^2$ with respect to the four external fields, assigning each external leg to one of

[1] The classification of operators into relevant, marginal, and irrelevant by their scaling dimension is Theorem 23.6; we use it here as the organising principle of the derivative expansion.

the four $\partial\phi$ factors. Take all momenta incoming, $p_1, \dots, p_4$, so that each derivative ∂_μ acting on the leg of incoming momentum p contributes $-ip_\mu$. The two factors inside each X are Lorentz-contracted, so a given assignment contributes the product of two dot products, one from each X. There are $4! = 24$ assignments of the labelled legs to the four (distinguishable-by-position) derivative slots, and they fall into the three ways of partitioning $\{1, 2, 3, 4\}$ into two unordered pairs, each partition reached by $24/3 = 8$ assignments. Summing, with the prefactor $\frac{c}{4}$ and the two factors of $-i$ per pair squaring to $i^2 \cdot i^2 = +1$ overall on the two momenta of each dot product,

$$i\mathcal{M}_{\text{contact}} = i\,\frac{c}{4} \cdot 8 \left[(p_1{\cdot}p_2)(p_3{\cdot}p_4) + (p_1{\cdot}p_3)(p_2{\cdot}p_4) + (p_1{\cdot}p_4)(p_2{\cdot}p_3)\right], \quad (63.31)$$

so $\mathcal{M}_{\text{contact}} = 2c\,[(p_1{\cdot}p_2)(p_3{\cdot}p_4) + \text{two terms}]$. Continue to the physical configuration with p_3, p_4 outgoing (i.e. replace the all-incoming p_3, p_4 by their negatives). The massless evaluation, which suffices for the leading coefficient, uses $2p_1{\cdot}p_2 = s$, $2p_3{\cdot}p_4 = (p_1 + p_2)^2 = s$, $2p_1{\cdot}p_3 = -t$, $2p_2{\cdot}p_4 = -t$, $2p_1{\cdot}p_4 = -u$, $2p_2{\cdot}p_3 = -u$, where the cross terms follow from $(p_i - p_j)^2 = -2p_i{\cdot}p_j$ on massless legs and momentum conservation. Hence

$$\mathcal{M}_{\text{contact}}(s,t) = 2c\left[\frac{s^2}{4} + \frac{t^2}{4} + \frac{u^2}{4}\right] = \frac{c}{2}\,(s^2 + t^2 + u^2). \quad (63.32)$$

This is manifestly s, t, u-symmetric, as crossing demands. In the forward limit $t = 0$, $u = -s$ (massless),

$$\mathcal{M}_{\text{contact}}(s,0) = \frac{c}{2}(s^2 + s^2) = c\,s^2, \quad (63.33)$$

confirming that c in Eq. (63.28) is precisely the curvature coefficient defined in Eq. (63.30) (in the massless limit $2m^2 \to 0$). The coefficient we will bound is a number an experimentalist could in principle measure by scattering ϕ quanta at energies well below M and reading off the s^2 growth of the forward amplitude. We will now show that this measured number cannot come out negative.

Physical Insight

The reason a four-derivative operator is the leading nontrivial structure is dimensional and symmetric. A non-derivative quartic (ϕ^4) gives a constant amplitude, which sits in a_0; a two-derivative quartic ($\phi^2\partial\phi\partial\phi$) gives a term linear in the invariants, which the $s \leftrightarrow u$ crossing reflection forbids in the forward limit. The first operator that survives crossing *and* produces energy growth is $(\partial\phi)^4$, and its coefficient is the first place the ultraviolet completion leaves an unavoidable, sign-definite fingerprint in the infrared.

63.3.2 Analytic structure of the forward amplitude

To convert Eq. (63.33) into a statement about the high-energy spectrum we treat s as a complex variable, holding $t = 0$ fixed, and use what analyticity, crossing, and unitarity tell us about $\mathcal{M}(s, 0)$ in the cut s-plane. Three facts assemble the picture.

First, *analyticity and the location of the cuts.* As established in Section 5.4.1, the forward amplitude is the boundary value of a function analytic in the complex s-plane away from singularities dictated by unitarity. The discontinuities are the physical thresholds: an s-channel cut where the centre-of-mass energy is large enough to produce on-shell intermediate states, $s \geq 4m^2$, and a u-channel cut where $u \geq 4m^2$. With $t = 0$ and $u = 4m^2 - s$, the latter condition reads $s \leq 0$. Thus $\mathcal{M}(s, 0)$ is analytic in the cut plane

$$s \in \mathbb{C} \setminus \big((-\infty, 0] \cup [4m^2, \infty)\big), \tag{63.34}$$

with a right-hand cut $[4m^2, \infty)$ (the s-channel) and a left-hand cut $(-\infty, 0]$ (the u-channel), and a gap $(0, 4m^2)$ in between containing the low-energy region where the effective theory lives. Real analyticity, $\mathcal{M}(s^*, 0) = \mathcal{M}(s, 0)^*$, holds because the amplitude is real in the gap; consequently across either cut the discontinuity is purely imaginary, $\mathcal{M}(s + i0, 0) - \mathcal{M}(s - i0, 0) = 2i\ \mathrm{Im}\ \mathcal{M}(s + i0, 0)$.

Second, *crossing relates the two cuts.* The $s \leftrightarrow u$ symmetry $\mathcal{M}(s, 0) = \mathcal{M}(4m^2 - s, 0)$ maps the left-hand cut onto the right-hand cut. Combining it with real analyticity gives the precise statement we will need: for s' on the left cut ($s' \leq 0$),

$$\mathrm{Im}\ \mathcal{M}(s' + i0, 0) = \mathrm{Im}\,\big[\mathcal{M}\big((4m^2 - s') + i0, 0\big)\big]^* = -\ \mathrm{Im}\ \mathcal{M}\big((4m^2 - s') + i0, 0\big), \tag{63.35}$$

where $4m^2 - s' \geq 4m^2$ lies on the right cut. The discontinuity on the left cut is thus the mirror image of the right-cut discontinuity; the two cuts carry the same physical information, and the deformation will fold one onto the other.

Third, *the optical theorem supplies positivity.* The generalized optical theorem Theorem 14.37 states that the imaginary part of any forward elastic amplitude equals a sum over all kinematically accessible final states of $|\mathcal{M}(i \to f)|^2$, weighted by Lorentz-invariant phase space, and is therefore nonnegative. In the normalization of Eq. (14.200),

$$\mathrm{Im}\ \mathcal{M}(s, 0) = 2\, p_{\mathrm{cm}} \sqrt{s}\ \sigma_{\mathrm{tot}}(s) \xrightarrow{s \gg m^2} s\, \sigma_{\mathrm{tot}}(s) \ \geq\ 0, \qquad s \geq 4m^2, \tag{63.36}$$

with $\sigma_{\mathrm{tot}} \geq 0$ a total cross section. Equivalently, the partial-wave unitarity inequality Eq. (14.206) forces every partial-wave absorptive part to be nonnegative, and the forward imaginary part is the positive sum of them. This is the engine of the whole argument: the integrand we are about to construct is nonnegative because probabilities are.

Polynomial boundedness: the Froissart–Martin bound. The deformation we have in mind sweeps the contour out to $|s| \to \infty$, and it succeeds only if the amplitude grows slowly enough there for the arc to vanish. The relevant input is the Froissart–Martin bound: in a theory with a mass gap, the forward amplitude is polynomially bounded, growing no faster than

$$|\mathcal{M}(s,0)| \;\le\; C\, s\, \ln^2(s/s_0) \qquad (s \to \infty) \tag{63.37}$$

for some constants C, s_0. In particular $|\mathcal{M}(s,0)|/s^2 \to 0$.

Caution

Polynomial boundedness Eq. (63.37) is the one ingredient we do not derive from scratch, and we therefore adopt it as an *explicit standing hypothesis* of Theorem 63.8 rather than smuggle it in as an unproven import. This is not a weakening: *the very hypothesis under test* — that ϕ has a unitary, local, Lorentz-invariant ultraviolet completion — is exactly what guarantees polynomial boundedness in the first place, so taking it as given is part of what "admits a healthy completion" means. The twice-subtracted dispersion relation below should be read in that light, and the positivity bound as a necessary condition any such completion imposes on the infrared. The heuristic behind the bound is unitarity plus locality: a finite mass gap means correlations decay exponentially with a range set by $1/m$, so the impact parameters that contribute coherently to forward scattering are bounded by $b \lesssim (1/m)\ln(s/s_0)$; the number of contributing partial waves is then $\ell_{\max} \sim p_{\rm cm}\, b \sim \sqrt{s}\,\ln(s/s_0)$, and saturating partial-wave unitarity $|a_\ell| \le 1$ over those waves gives a forward amplitude $\sim s\,\ln^2 s$. The fully rigorous statement — promoting this estimate to a theorem via analyticity of the amplitude in a Lehmann–Martin ellipse in $\cos\theta$ within the axiomatic (Wightman/LSZ) framework — is a classic result we use as a hypothesis and flag in the Further reading for those who want the complete derivation.

We can now picture the deformation. Figure 63.2 shows the cut s-plane, the small contour encircling the low-energy expansion point, and the large arc that the Froissart bound allows us to drop.

63.3.3 The twice-subtracted dispersion relation and the sum rule

The strategy is now visible. The coefficient c is a low-energy datum, accessible as a contour integral of $\mathcal{M}(s,0)$ around the expansion point. The cuts are high-energy data, where the integrand is the positive absorptive part. Cauchy's theorem (Theorem 5.23) connects them. We carry the construction in full in the worked example below; it is the chapter's central computation.

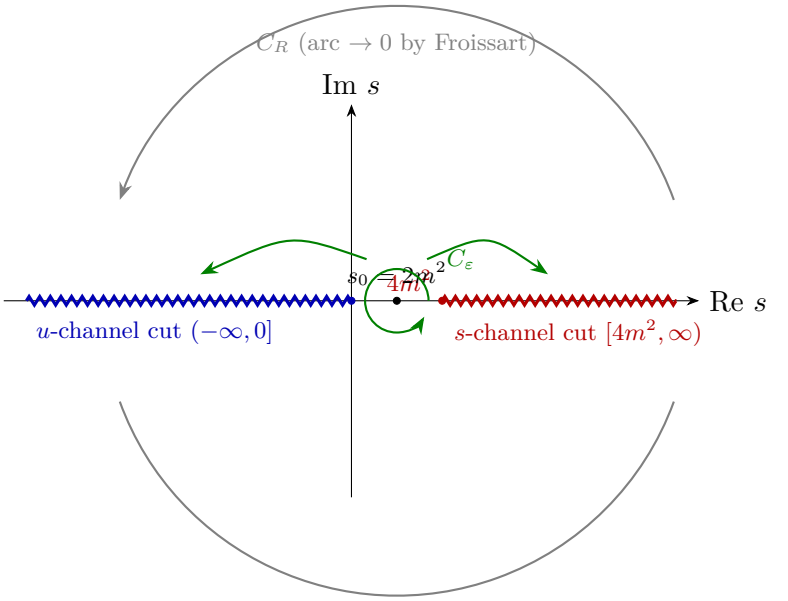

Figure 63.2: The forward amplitude $\mathcal{M}(s,0)$ in the complex s-plane. It is analytic in the gap $(0, 4m^2)$ between the u-channel cut (left, blue) and the s-channel cut (right, red), with the low-energy expansion centred at the crossing-symmetric point $s_0 = 2m^2$. The curvature coefficient c is the residue of the small contour C_ε weighted by $(s-s_0)^{-3}$. Deforming C_ε out to the large circle C_R, the arc vanishes by the Froissart bound Eq. (63.37) and the integral collapses onto the two cuts; crossing folds the left cut onto the right, doubling a single positive integral.

Worked Example 63.7 (The forward dispersive positivity sum rule for the leading EFT coefficient)**.** We prove that the curvature coefficient c of Eq. (63.30) equals a positive spectral integral, hence $c > 0$.

Step 1: c **as a contour integral.** Set $s_0 = 2m^2$ and work in the variable $x = s - s_0$. By Eq. (63.30) the forward amplitude is, near $x = 0$, the even series $\mathcal{M}(s,0) = a_0 + c\,x^2 + O(x^4)$, analytic in the gap. By Cauchy's integral formula for the Taylor coefficients (Theorem 5.23), the curvature is the residue

$$c = \frac{1}{2!}\,\partial_x^2 \mathcal{M}\big|_{x=0} = \frac{1}{2\pi i}\oint_{C_\varepsilon} \frac{dx\;\mathcal{M}(s_0+x,0)}{x^3}, \tag{63.38}$$

where C_ε is a small counterclockwise circle $|x| = \varepsilon$ inside the gap. Only the x^2 term of the expansion survives the x^{-3} weight: $\oint x^{-3}(a_0 + cx^2 + \dots)\,dx = 2\pi i\,c$, since $a_0 x^{-3}$ and the higher even terms integrate to zero. This is the low-energy side of the sum rule, and no high-energy input has entered yet.

Step 2: deform the contour. The integrand $\mathcal{M}(s_0+x,0)/x^3$ is analytic in the annulus $\varepsilon<|x|<R$ except on the two cuts, which in the x variable sit at $x\geq 2m^2$ (right) and $x\leq -2m^2$ (left). Apply Cauchy's theorem to the boundary of the annulus-minus-cuts. The boundary consists of the outer circle C_R (counterclockwise), the inner circle C_ε (clockwise), and two contours hugging the cuts. Setting the total to zero and solving for the inner circle,

$$\frac{1}{2\pi i}\oint_{C_\varepsilon}\frac{\mathcal{M}\,dx}{x^3}=\frac{1}{2\pi i}\oint_{C_R}\frac{\mathcal{M}\,dx}{x^3}-\frac{1}{2\pi i}\int_{\mathrm{rc}}\frac{\operatorname{disc}\mathcal{M}}{x^3}\,dx-\frac{1}{2\pi i}\int_{\mathrm{lc}}\frac{\operatorname{disc}\mathcal{M}}{x^3}\,dx, \tag{63.39}$$

where $\operatorname{disc}\mathcal{M}(x)\equiv\mathcal{M}(s_0+x+i0,0)-\mathcal{M}(s_0+x-i0,0)=2i\ \mathrm{Im}\ \mathcal{M}(s_0+x+i0,0)$.

Step 3: the arc vanishes (and why two subtractions). On C_R, $|x|=R$ and, by the Froissart bound Eq. (63.37), $|\mathcal{M}(s_0+x,0)|\leq C\,R\,\ln^2 R$. The weight is $|x^{-3}|=R^{-3}$, and the circumference is $2\pi R$, so

$$\left|\frac{1}{2\pi i}\oint_{C_R}\frac{\mathcal{M}\,dx}{x^3}\right|\ \leq\ \frac{1}{2\pi}\,(2\pi R)\,\frac{C\,R\,\ln^2 R}{R^3}\ =\ \frac{C\,\ln^2 R}{R}\ \xrightarrow{R\to\infty}\ 0. \tag{63.40}$$

The arc dies. The weight x^{-3} is what makes this work: it carries two more powers of $1/x$ than the x^{-1} a naive Cauchy formula would use, i.e. *two subtractions*. Two are needed for two independent reasons, which happily coincide. (i) *Convergence*: Froissart permits growth up to s^2, and an integrand falling only as $1/x$ or $1/x^2$ could leave a finite or divergent arc; the third power guarantees Eq. (63.40) under the weakest growth assumption we are willing to make. (ii) *Subtraction of the unknowns*: the expansion Eq. (63.30) contains two infrared constants, a_0 (and a possible linear term, absent here by crossing). The x^{-3} projection annihilates both and isolates the curvature c alone. The two subtractions are exactly the price of not knowing the low-energy constants and of allowing the amplitude to grow.

Step 4: the cut integrals, and folding by crossing. With the arc gone, Eq. (63.38) and Eq. (63.39) give

$$c=-\frac{1}{2\pi i}\int_{\mathrm{rc}}\frac{\operatorname{disc}\mathcal{M}}{x^3}\,dx-\frac{1}{2\pi i}\int_{\mathrm{lc}}\frac{\operatorname{disc}\mathcal{M}}{x^3}\,dx. \tag{63.41}$$

Take the cut contours oriented so that each runs above the cut outward and below the cut inward, the orientation inherited from the counterclockwise outer circle; this fixes the sign of disc and, written out with $\operatorname{disc}\mathcal{M}=2i\ \mathrm{Im}\,\mathcal{M}$, turns Eq. (63.41) into

$$c=\frac{1}{\pi}\int_{\mathrm{rc}}\frac{\mathrm{Im}\ \mathcal{M}(s_0+x,0)}{x^3}\,dx+\frac{1}{\pi}\int_{\mathrm{lc}}\frac{\mathrm{Im}\ \mathcal{M}(s_0+x,0)}{x^3}\,dx. \tag{63.42}$$

Convert back to the variable $s=s_0+x$. The right cut is $s\in[4m^2,\infty)$ with $x=s-s_0=s-2m^2>0$. The left cut is $s\in(-\infty,0]$ with $x=s-2m^2<0$;

substitute $s = 4m^2 - \sigma$, so that $\sigma \in [4m^2, \infty)$ runs over the right cut, $ds = -d\sigma$, and $x = s - 2m^2 = 2m^2 - \sigma = -(\sigma - 2m^2)$, whence $x^3 = -(\sigma - 2m^2)^3$. The crossing relation Eq. (63.35) gives $\operatorname{Im}\mathcal{M}(s + i0, 0) = -\operatorname{Im}\mathcal{M}(\sigma + i0, 0)$ on the left cut. Assembling the left-cut piece,

$$\frac{1}{\pi}\int_{\text{lc}} \frac{\operatorname{Im}\mathcal{M}}{x^3}\,ds = \frac{1}{\pi}\int_{\sigma=\infty}^{4m^2} \frac{-\operatorname{Im}\mathcal{M}(\sigma,0)}{-(\sigma-2m^2)^3}\,(-d\sigma) = \frac{1}{\pi}\int_{4m^2}^{\infty} \frac{\operatorname{Im}\mathcal{M}(\sigma,0)}{(\sigma-2m^2)^3}\,d\sigma, \tag{63.43}$$

which is identical to the right-cut integral. The two minus signs — one from the crossing reflection of $\operatorname{Im}\mathcal{M}$, one from the odd power x^3 under $s \to 4m^2 - s$ — conspire to a plus, and the left cut folds exactly onto the right. This is the crossing step: the u-channel absorptive data is the s-channel absorptive data, and the dispersion relation counts it twice.

Step 5: positivity and the sum rule. Adding the two equal contributions,

$$\boxed{c = \frac{2}{\pi}\int_{4m^2}^{\infty} \frac{\operatorname{Im}\mathcal{M}(s,0)}{(s-2m^2)^3}\,ds} \qquad \xrightarrow{m\to 0} \qquad c = \frac{2}{\pi}\int_{0}^{\infty} \frac{\operatorname{Im}\mathcal{M}(s,0)}{s^3}\,ds. \tag{63.44}$$

Every factor on the right is nonnegative. The measure ds is positive; the kernel $(s - 2m^2)^{-3}$ is positive throughout the integration range $s \geq 4m^2$ (so $s - 2m^2 \geq 2m^2 > 0$); and the integrand $\operatorname{Im}\mathcal{M}(s, 0) = 2p_{\text{cm}}\sqrt{s}\,\sigma_{\text{tot}}(s) \geq 0$ by the optical theorem Eq. (63.36). The integral is therefore nonnegative, and it is strictly positive unless $\sigma_{\text{tot}}(s) \equiv 0$ for all $s \geq 4m^2$ — i.e. unless the theory is free, with no scattering at all. For any interacting ϕ,

$$c > 0. \qquad \blacksquare \tag{63.45}$$

The result deserves to be stated as a theorem in its own right, because it is exactly the kind of nonperturbative, completion-independent constraint that the bootstrap philosophy promises.

Theorem 63.8 (Positivity of the leading EFT coefficient)**.** *Let ϕ be a real scalar that arises as the low-energy effective description of a theory satisfying Lorentz invariance, unitarity (the optical theorem Theorem 14.37), analyticity in the cut s-plane Eq. (63.34) with $s \leftrightarrow u$ crossing symmetry, and Froissart polynomial boundedness Eq. (63.37). Then the coefficient c of the leading $(\partial\phi)^4$ operator Eq. (63.28), equivalently the forward curvature Eq. (63.30), satisfies the sum rule Eq. (63.44) and is strictly positive, $c > 0$, unless ϕ is free.*

Proof. Theorem 63.7 carries the argument in full: Cauchy's formula expresses c as the x^{-3} moment of the forward amplitude on a small contour (Step 1); deformation to infinity with the arc killed by Froissart (Steps 2–3) reduces this to the two cut integrals (Step 4); crossing folds the u-channel cut onto the s-channel cut, and the optical theorem makes the resulting integrand nonnegative (Steps 4–5), giving Eq. (63.44) and Eq. (63.45). □

63.3.4 Interpretation: the swampland from below

Equation (63.44) is more than an inequality; it is an identity, and the identity is the lesson. The left-hand side is an infrared quantity: a coefficient in the low-energy expansion of an amplitude, fixed by whatever physics governs ϕ at accessible energies, in principle measurable without any knowledge of the ultraviolet. The right-hand side is an ultraviolet quantity: a weighted integral over the total cross section, i.e. over the spectrum and couplings of the heavy states that complete the theory above M. The dispersion relation welds them together. A number measured in the basement equals a positive census of the attic.

The immediate corollary is a sharp consistency condition on effective field theories. An effective Lagrangian is a list of operators with arbitrary-looking coefficients; nothing in the low-energy theory itself, taken in isolation, prevents one from writing $c < 0$. Theorem 63.8 says that such a choice is nonetheless inconsistent: there exists *no* unitary, causal, Lorentz-invariant ultraviolet completion whose low-energy limit has $c < 0$, because any completion produces, through the sum rule, a nonnegative c. The space of effective theories thus splits in two. On one side, the *landscape*, sit coefficient assignments that some healthy high-energy theory can produce. On the other, a *swampland from below*: theories that are perfectly self-consistent as low-energy effective descriptions — unitary, local, gauge-invariant, renormalizable order by order in $1/M$ — yet can never be ultraviolet-completed. The phrase "from below" distinguishes this from the gravitational swampland program, which constrains effective theories by demanding consistency with quantum gravity from above; here the constraint comes from demanding consistency with ordinary unitary, causal field theory at high energy.

Physical Insight

The physical content of $c > 0$ is causality. A negative c corresponds to a low-energy interaction in which signals propagate slightly faster on a background of ϕ gradients than in vacuum — a superluminal advance, small and energy-suppressed, but genuine. The dispersion relation is the precise statement that such an advance cannot be hidden: the same analyticity that encodes "no signal before its cause" forces the forward amplitude to curve upward, $c > 0$, and forbids the subluminal-violating sign. Positivity bounds are causality bounds wearing the clothes of complex analysis.

For ϕ^4 theory this closes the arc from the amplitudes side. The thread began with a classical Lagrangian (Chapter 6), produced its first quantum amplitude $\mathcal{M} = -\lambda$ (Theorem 14.35), was renormalized and flowed under the renormalization group to its irrelevant operators (Chapter 23), and is now shown

to obey a rigorous frontier constraint: the coefficient of its leading irrelevant $(\partial\phi)^4$ operator is not free but equals the manifestly positive spectral integral Eq. (63.44). The same $16\pi^2$ that controlled the perturbative reach of λ (Theorem 14.38) and set the one-loop β-function (Chapter 24) reappears here as the scale of the cross section that feeds the sum rule. The thread's irrelevant operators, introduced as a bookkeeping device for the derivative expansion, turn out to carry a sign that the ultraviolet cannot forge.

Generalizations: spin and the EFThedron. The scalar bound is the first entry in a much larger structure, and we state its development honestly and dated. Two generalizations dominate the mid-2020s frontier.

The first is to *external states with spin and to subleading coefficients.* Repeating the construction for photons, gravitons, or massive higher-spin states requires tracking little-group indices (Chapter 58) through the dispersion relation, and the single inequality $c > 0$ becomes a system of inequalities on the matrix of forward amplitudes, one for each polarization channel, with positivity now meaning positive-semidefiniteness of that matrix. Going beyond the strictly forward limit ($t = 0$) by expanding the dispersion relation in small t and using full partial-wave unitarity — not only $\mathrm{Im}\, a_\ell \geq 0$ but the Legendre-positivity of the partial-wave expansion — yields two-sided bounds: each Wilson coefficient is confined to a finite interval, not merely a half-line.

The second is the recognition that the full set of such constraints carves out a convex geometry in the space of Wilson coefficients, the *EFThedron.* The sum rules Eq. (63.44) and their t-derivatives express every coefficient as a moment of a single nonnegative spectral density against a fixed kinematic kernel; the allowed coefficients are then precisely the moment sequences of a positive measure supported on the spectrum, and the theory of such moment problems (Hankel-matrix positivity, total positivity of the partial-wave kernels) cuts out a convex region with a rich facet structure. The EFThedron makes the kinship explicit: just as the amplituhedron of Chapter 62 reads an amplitude off a positive geometry, the EFThedron reads the allowed effective theories off a positive geometry in coefficient space. As of the mid-2020s the leading bounds are rigorous and in several cases saturated by known string and weakly-coupled completions, while the complete carving — including the interplay with gravitational completions, where the massless graviton pole modifies the dispersive arcs — remains an active and incomplete program.

These developments share one engine with the scalar computation above and, as the next section will make exact, with the conformal bootstrap of Chapter 49: a crossing equation that equates two channel expansions, a unitarity statement that makes the expansion coefficients nonnegative, and a search for the linear functional that certifies which coefficient values are allowed. Having seen that engine carve the space of effective field theories from below, we now place it

beside the engine that carves the space of conformal field theories and show that the two are not analogous but identical.

63.4 Two Bootstraps, One Logic: S-Matrix and Conformal

The previous section pushed analyticity, crossing, and unitarity until they delivered a *number*: the leading Wilson coefficient of a low-energy scalar effective theory is strictly positive, a fact no Lagrangian was allowed to assume and that no Lagrangian can violate without producing a superluminal or non-unitary completion. That positivity sum rule (Section 63.3) carved a wall through the space of effective theories: on one side sit Wilson coefficients that some healthy ultraviolet theory can produce, on the other side a "swampland from below" of coefficients that look perfectly innocent in the infrared but are forbidden by the existence of *any* consistent completion. The construction was concrete, but its logic was not special to scattering. The same three words — crossing, unitarity, positivity — name the machine that, in Chapters 49 and 50, carved the space of conformal field theories and pinned the critical exponents of the three-dimensional Ising model to many digits. This section makes the parallel exact. It is not an analogy: the conformal bootstrap and the S-matrix bootstrap are the same problem in two kinematic disguises, and AdS/CFT supplies the dictionary that turns one into the other as the curvature is switched off. By the end we will be able to say in a single sentence what a bootstrap *is*, and exhibit the numerical conformal bootstrap and the EFThedron as its two faces.

63.4.1 The common template

Strip both problems to their skeleton and the same object appears. In each case there is a physical quantity — a four-point correlator, a $2 \to 2$ amplitude — that admits an expansion into a discrete or continuous family of *fixed kinematic functions* (conformal blocks; partial waves) weighted by *theory-dependent nonnegative coefficients* (squared OPE coefficients; absorptive partial-wave densities). The same quantity also satisfies a *crossing relation*: the expansion organised around one channel must equal the expansion organised around another. Equating the two expansions and moving everything to one side produces a *sum rule*: a single linear functional equation in the unknown nonnegative weights that must hold identically over a continuum of kinematic points. The bootstrap question is whether any assignment of nonnegative weights to an admissible spectrum can solve the sum rule, and the bootstrap *method* is to test candidate spectra by hunting for a linear functional that is one-signed on every allowed contribution yet has the wrong sign on the known term — a separating hyperplane certifying that no solution exists.

The three structural inputs are therefore: a complete basis of kinematic functions; a crossing equation relating channels; and a positivity statement (the weights are squares, or absorptive parts of a unitary amplitude, hence ≥ 0). Everything else — semidefinite programming, dispersion relations, arcs and moments — is implementation. We now write the two crossing equations and the two positivity conditions explicitly, side by side, so the parallel is on the page rather than in the prose.

63.4.2 Two crossing equations

The conformal crossing equation. For a CFT four-point function of identical scalar primaries ϕ of dimension Δ_ϕ, the operator product expansion in the (12)(34) channel and in the (14)(23) channel must agree. This is the crossing equation derived in Theorem 49.13, which we recall verbatim:

$$v^{\Delta_\phi}\sum_{\mathcal{O}} p_{\mathcal{O}}\, G_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(u,v) \;=\; u^{\Delta_\phi}\sum_{\mathcal{O}} p_{\mathcal{O}}\, G_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(v,u), \qquad p_{\mathcal{O}} = C^2_{\phi\phi\mathcal{O}} \;\geq 0, \tag{63.46}$$

with $G_{\Delta,\ell}$ the conformal blocks (fixed functions of the cross-ratios u, v, determined by conformal symmetry alone) and the sum running over primaries $\mathcal{O}$ exchanged in the $\phi \times \phi$ OPE. The kinematic functions are the blocks; the nonnegative weights are the squared OPE coefficients $p_{\mathcal{O}}$; the crossing relation is the $u \leftrightarrow v$ ($s \leftrightarrow t$ channel) swap. We imported Eq. (63.46) from Eq. (49.71) and will not reprove it.

The S-matrix crossing equation. For the elastic scattering of identical scalars of mass m — the massive avatar of the ϕ^4 theory quantum ϕ — the relativistic amplitude $\mathcal{M}(s,t,u)$ depends on the Mandelstam invariants with $s+t+u = 4m^2$, and crossing symmetry (Chapters 14 and 18) makes it a single analytic function symmetric under permutations of s, t, u: the same function describes the s-channel process $\phi\phi \to \phi\phi$, the t-channel, and the u-channel. Analyticity in s at fixed t, with the branch cuts demanded by unitarity, lets us write a dispersion relation. Carrying the contour around the s- and u-channel cuts (the construction of Section 63.3) gives, after the two subtractions needed for a ϕ^4-type theory,

$$\mathcal{M}(s,t) \;=\; c_0(t)+c_1(t)\,s + \frac{s^2}{\pi}\int_{4m^2}^{\infty}\frac{ds'}{s'^2}\left[\frac{\operatorname{Im}\mathcal{M}(s',t)}{s'-s}+\frac{\operatorname{Im}\mathcal{M}(s',t)}{s'-u}\right], \qquad u = 4m^2-s-t, \tag{63.47}$$

where the s'-integral runs over the physical region and $\operatorname{Im}\mathcal{M}$ is the absorptive part. The "crossing" is built into the symmetric appearance of the two propagator kernels $1/(s'-s)$ and $1/(s'-u)$: the same spectral function feeds the s- and the u-channel, exactly as the same OPE data $p_{\mathcal{O}}$ feeds both channels of Eq. (63.46). The kinematic functions are now the dispersive kernels $1/(s'-s)$ paired with

the partial-wave projectors; the nonnegative weights are the absorptive densities $\operatorname{Im}\mathcal{M}(s',t)$; the crossing relation is $s \leftrightarrow u$ symmetry of the kernel together with the full s,t,u symmetry of $\mathcal{M}$.

The parallel made literal. The structural correspondence is summarised in Table 63.1. Read the two columns as one construction: a positive sum over fixed kinematic objects, constrained by a channel-swap identity.

Ingredient	**Conformal bootstrap**	**S-matrix bootstrap**
Physical datum	four-point function $\langle\phi\phi\phi\phi\rangle$	$2 \to 2$ amplitude $\mathcal{M}(s,t,u)$
Kinematic basis (fixed by symmetry)	conformal blocks $G_{\Delta,\ell}(u,v)$	partial waves $P_\ell(\cos\theta)$ / dispersive kernels
Theory data (nonnegative weights)	squared OPE coefficients $p_{\mathcal{O}} = C^2_{\phi\phi\mathcal{O}} \geq 0$	absorptive densities $\operatorname{Im} f_\ell(s) \geq 0$
Spectrum constraint	unitarity bounds on (Δ,ℓ), Eq. (49.81)	mass gap $s \geq 4m^2$, spins $\ell \in \mathbb{Z}_{\geq 0}$
Crossing relation	$u \leftrightarrow v$ (s/t channel), Eq. (63.46)	$s \leftrightarrow t \leftrightarrow u$, Eq. (63.47)
Positivity lever	$p_{\mathcal{O}} \geq 0$, Section 49.3.3	$\operatorname{Im} a_\ell \geq \lvert a_\ell\rvert^2 \geq 0$, Eq. (14.206)
Method	linear functional / SDP, Theorem 49.21, Section 50.2	dispersive sum rules / EFThedron, Section 63.3

Table 63.1: The conformal and S-matrix bootstraps as one construction. Each row pairs a structural role with its realisation in the two problems. The shared spine is: a positive sum over symmetry-fixed functions, constrained by a channel-crossing identity, probed by a one-signed linear functional.

63.4.3 Unitarity is positivity in both

The reason both problems yield rigorous numbers rather than mere consistency checks is that unitarity, in each, becomes a *positivity* statement on the weights. We state both precisely.

CFT: positive OPE squares. In Eq. (63.46) the weight of each exchanged primary is $p_{\mathcal{O}} = C^2_{\phi\phi\mathcal{O}}$, the square of a real OPE coefficient. It is a square because the double OPE sum collapses onto the diagonal (the same constant

$C_{\phi\phi\mathcal{O}}$ fuses $\phi\phi$ in both pairs of identical operators), and it is real because the radial-quantisation inner product is reflection positive — this is precisely the content of Section 49.3.3. Unitarity also restricts *which* (Δ, ℓ) may appear: every primary obeys the unitarity bounds of Theorem 47.18, recalled in Eq. (49.81) as $\Delta \geq (d-2)/2$ for scalars and $\Delta \geq \ell + d - 2$ for spin $\ell \geq 1$, and only even spins survive the identical-scalar symmetrisation. So unitarity supplies two positivity facts: nonnegative weights, on a spectrum confined to a known region of the (Δ, ℓ) plane.

S-matrix: positive partial-wave densities. The absorptive part $\mathrm{Im}\,\mathcal{M}(s', t)$ entering Eq. (63.47) is not an arbitrary function. Project the amplitude onto angular momentum: in the conventions of Section 14.7.5, $\mathcal{M}$ expands in Legendre polynomials with dimensionless coefficients $a_\ell(s)$, and partial-wave unitarity Eq. (14.206) reads

$$\mathrm{Im}\, a_\ell(s) \;=\; |a_\ell(s)|^2 + \frac{p_{\mathrm{cm}}^2}{4\pi(2\ell+1)}\,\sigma_{\mathrm{inel}}^{(\ell)} \;\geq\; |a_\ell(s)|^2 \;\geq\; 0. \tag{63.48}$$

Hence each partial wave has *nonnegative absorptive part*, $\mathrm{Im}\, a_\ell \geq 0$, and the absorptive density that feeds the dispersion relation is a positive sum over channels,

$$\mathrm{Im}\,\mathcal{M}(s,t)\big|_{t=0} \;=\; \frac{8\pi\sqrt{s}}{p_{\mathrm{cm}}}\sum_{\ell=0}^{\infty}(2\ell{+}1)\;\mathrm{Im}\, a_\ell(s)\,P_\ell(1) \;=\; \frac{8\pi\sqrt{s}}{p_{\mathrm{cm}}}\sum_{\ell}(2\ell{+}1)\;\mathrm{Im}\, a_\ell(s) \;\geq\; 0, \tag{63.49}$$

using $P_\ell(1) = 1$. This is the exact S-matrix analogue of $p_{\mathcal{O}} \geq 0$. The discrete index ℓ here is the spin, and the analogue of the CFT unitarity bound on Δ is the spectral support condition $s' \geq 4m^2$ (the absorptive part vanishes below the two-particle threshold) together with the integrality and nonnegativity of ℓ. The Argand-circle geometry of Eq. (14.207) — each a_ℓ confined to the disk of radius $\frac{1}{2}$ centred at $\frac{i}{2}$ — is the S-matrix counterpart of the wedge $p_{\mathcal{O}} \geq 0$ in the bootstrap: the same convex constraint that the functional method will exploit.

The dictionary in Table 63.1 is thus more than suggestive. The CFT exchanges a tower of operators labelled (Δ, ℓ) with positive squared couplings; the amplitude exchanges a spectrum of states labelled by their mass $\sqrt{s'}$ and spin ℓ with positive absorptive residues; in both the positivity is the statement that probabilities are nonnegative, read off the same Cauchy–Schwarz / reflection-positivity inequality. We record the conceptual identification.

Physical Insight

The conformal block expansion and the partial-wave/dispersive expansion are the same mathematical object: a resolution of the identity on a unitary Hilbert space, written in a basis of states of definite quantum numbers, with

the squared overlaps as nonnegative coefficients. "Unitarity as positivity" is not a slogan but an equality of two inner products: $C^2_{\phi\phi\mathcal{O}}$ is $|\langle\mathcal{O}|\phi\,\phi\rangle|^2$ in radial quantisation, and $\operatorname{Im} a_\ell$ is, by the optical theorem, the squared norm of the outgoing state in channel ℓ. The bootstrap is the demand that a positive combination of such overlaps reproduce itself under a change of channel.

63.4.4 The linear functional: one machine, two problems

Both sum rules are linear and homogeneous in the unknown nonnegative weights, with one fixed inhomogeneous term (the identity contribution in the CFT; the low-energy/EFT contribution in the S-matrix). This is exactly the setting of linear programming duality, and the bound machinery is identical in the two problems. We state it once, abstractly, then read it in both directions.

Write the sum rule as $\sum_i w_i\, V_i = V_0$ with $w_i \geq 0$, where the V_i are vectors in some linear space (in practice, the values and derivatives of the crossing functions at a base point), the V_0 is the fixed term, and i ranges over the admissible spectrum. A solution exists only if V_0 lies in the convex cone generated by the $\{V_i\}$. The contrapositive is the engine: if there is a linear functional α with

$$\alpha[V_i] \;\geq\; 0 \quad \text{for every admissible } i, \qquad \text{but} \qquad \alpha[V_0] \;<\; 0, \tag{63.50}$$

then no nonnegative combination of the V_i can equal V_0 — applying α to a putative solution gives $0 \leq \sum_i w_i\, \alpha[V_i] = \alpha[V_0] < 0$, a contradiction. Such an α is a *separating hyperplane* between V_0 and the cone (Fig. 63.3); finding the optimal one is a semidefinite program. This is the linear-functional principle of Theorem 49.21, the computational core of Section 50.2, and — in the S-matrix language of moments and arcs — the duality that produced the positivity bound of Section 63.3.

Worked Example 63.9 (A finite toy bootstrap and its dual functional)**.** To see that the exclusion logic is genuinely one logic, reduce both problems to their smallest nontrivial common form and solve it by hand. Take a sum rule with two "vectors" in the plane $\mathbb{R}^2$,

$$w_1 V_1 + w_2 V_2 = V_0, \qquad w_1, w_2 \geq 0, \qquad V_1 = \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \quad V_2 = \begin{pmatrix} 1 \\ 1 \end{pmatrix}, \quad V_0 = \begin{pmatrix} 1 \\ -b \end{pmatrix}, \tag{63.51}$$

with b a real parameter standing in for "how much of the wrong-sign behaviour the fixed term demands." In the CFT reading, the two components are the value and one derivative of the crossing function at the symmetric point, V_1, V_2 are the crossing-vectors of two exchanged operators, and V_0 is the (negative of the) identity vector. In the S-matrix reading, the two components are two moments

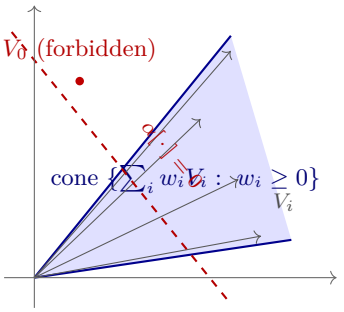

Figure 63.3: The linear-functional principle, common to both bootstraps. The admissible contributions V_i (grey) generate a convex cone (blue). A candidate spectrum is excluded when the fixed term V_0 (red) lies outside the cone; a separating functional α (dashed line $\alpha[\cdot] = 0$) is then nonnegative on every V_i but negative on V_0, certifying Eq. (63.50). In the CFT the V_i are crossing-vectors of blocks at fixed (Δ, ℓ) and V_0 is the identity; in the S-matrix the V_i are partial-wave moments and V_0 is the EFT coefficient to be bounded.

$\int ds'\, \rho(s')\, s'^{-n}$ $(n = 2, 3)$ of the positive spectral density, V_1, V_2 are the moment vectors of two narrow resonances, and V_0 encodes the low-energy coefficients.

Solve directly. Writing components, $w_1 + w_2 = 1$ and $w_2 = -b$. A nonnegative solution needs $w_2 = -b \geq 0$ and $w_1 = 1 + b \geq 0$, i.e. $-1 \leq b \leq 0$. For $b > 0$ no nonnegative combination exists: the sum rule is infeasible.

Solve by the dual functional. Seek $\alpha = (\alpha_1, \alpha_2)$ with $\alpha \cdot V_1 \geq 0$, $\alpha \cdot V_2 \geq 0$ but $\alpha \cdot V_0 < 0$. The first two give $\alpha_1 \geq 0$ and $\alpha_1 + \alpha_2 \geq 0$; the third gives $\alpha_1 - b\,\alpha_2 < 0$. Choose $\alpha_1 = 0$, $\alpha_2 = 1$: then $\alpha \cdot V_1 = 0 \geq 0$, $\alpha \cdot V_2 = 1 \geq 0$, and $\alpha \cdot V_0 = -b < 0$ for every $b > 0$. The functional $\alpha = (0, 1)$ is the separating hyperplane of Eq. (63.50): it is one-signed on the admissible vectors and negative on the fixed term, certifying infeasibility for all $b > 0$ at a stroke. The boundary $b = 0$ is the bound, exactly the threshold where w_2 hits zero.

The same two lines of algebra are, in the full problem, the statement that a single derivative of the crossing equation excludes a CFT with too large a gap, and that a single dispersive moment forces the leading EFT Wilson coefficient to be nonnegative. Increasing the dimension of the vector space (N derivatives of crossing; N moments/arcs) tightens both bounds toward the true boundary of theory space, and the optimisation over α is the semidefinite program in both cases. The machine does not know whether it is bounding an operator dimension or a Wilson coefficient.

63.4.5 The flat-space limit: from the boundary correlator to the bulk S-matrix

The two bootstraps are not merely structurally identical; they are *physically* connected, because a scattering amplitude in flat space is a limit of a CFT correlator. The bridge is AdS/CFT. A CFT in d dimensions with a holographic dual is, by the GKP–Witten relation Eq. (53.162), computed from a gravitational (or, in a weakly coupled limit, ordinary field-theoretic) theory in AdS_{d+1} of radius R. A four-point CFT correlator is then a sum of Witten diagrams (Section 54.3.5); its natural representation is the *Mellin amplitude* $M(s,t)$, the function whose poles in the Mellin variables s,t sit at the twist of exchanged operators and which plays, for AdS processes, exactly the role the flat-space amplitude $\mathcal{M}(s,t)$ plays for scattering. The flat-space limit is the statement that as the AdS radius is sent to infinity — so that the curvature scale recedes far beyond the wavelengths of the scattering quanta — the Mellin amplitude becomes the bulk S-matrix.

The scaling argument. We give the scaling honestly rather than quoting the transform. The dictionary fixes the bulk mass of a field dual to a scalar primary of dimension Δ through $m^2R^2 = \Delta(\Delta - d)$, derived in Section 53.4.4 (the mass–dimension relation), so for a heavy field

$$\Delta \simeq mR \qquad (mR \gg 1). \tag{63.52}$$

A bulk scattering process at centre-of-mass energy $\sqrt{s_{\mathrm{flat}}}$ involves quanta of wavelength $\sim s_{\mathrm{flat}}^{-1/2}$. For this to "fit" in a region small compared with the AdS curvature scale R — the region in which AdS_{d+1} is indistinguishable from flat space — we need $s_{\mathrm{flat}}R^2 \gg 1$. The Mellin variables, on the other hand, are conjugate to the boundary OPE data and carry dimension of (mass $\times R$)^2, i.e. they are measured in units of $1/R^2$: dimensionally the Mellin s is the AdS analogue of R^2 times a physical invariant. Matching the two descriptions of the same invariant in the overlap region $1 \ll s_{\mathrm{flat}}R^2$ forces the linear relation

$$s_{\mathrm{Mellin}} \;\simeq\; R^2\, s_{\mathrm{flat}}, \qquad t_{\mathrm{Mellin}} \;\simeq\; R^2\, t_{\mathrm{flat}}, \tag{63.53}$$

up to a fixed numerical constant set by conventions. This is the heart of the matter: the Mellin amplitude, regarded as a function of variables that grow like R^2, must — for the bulk theory to be local and Lorentz invariant at short distance — reduce to a function of the flat Mandelstam invariants $s_{\mathrm{flat}} = s_{\mathrm{Mellin}}/R^2$.

The transform and its saddle. Making this precise requires resumming the tower of large-Δ exchanges into the flat amplitude. For four identical scalars of dimension Δ_ϕ in AdS_{d+1}, the flat-space limit formula (Penedones) is the

inverse-Borel-type transform

$$\mathcal{M}(s_{\rm flat}, t_{\rm flat}) \;=\; \mathcal{N} \lim_{R\to\infty} R^{\#} \int_{-i\infty}^{+i\infty} \frac{d\alpha}{2\pi i}\, e^{\alpha}\, \alpha^{\,d/2-2\Delta_\phi}\, M\!\left(s_{\rm Mellin} = \frac{R^2 s_{\rm flat}}{2\alpha},\, t_{\rm Mellin} = \frac{R^2 t_{\rm flat}}{2\alpha}\right), \tag{63.54}$$

with $\mathcal{N}$ and the power $R^{\#}$ ($\# = \frac{(d+1)}{2} - \sum_i \Delta_i + \frac{(d-1)}{2}$ for the four-point case, fixed by dimensional analysis) collecting the conventional normalisations. The auxiliary integration variable α is the Borel/Schwinger parameter that undoes the large-dimension Gamma functions in the Mellin measure; its role is to convert the discrete sum over the AdS exchange tower into the continuous spectral integral of a flat amplitude. The scaling Eq. (63.53) is visible directly in the argument of M: the Mellin variables enter as $R^2 s_{\rm flat}/(2\alpha)$, so at fixed α they are exactly the R^2-enhanced invariants anticipated above.

The limit is controlled by a saddle point in α. As $R \to \infty$ the Mellin amplitude probes large arguments; for a contact-like or polynomial growth $M \sim (s_{\rm Mellin})^n$ the integrand behaves as $e^{\alpha}\, \alpha^{\,d/2-2\Delta_\phi-n}\, (R^2 s_{\rm flat}/2)^n$, and the α-integral is a Hankel/Gamma-function representation whose steepest-descent saddle sits at $\alpha_* \simeq 2\Delta_\phi + n - d/2$, an $O(1)$ value. Evaluating at the saddle pulls the factor $(R^2 s_{\rm flat})^n$ out front, where it is cancelled by $R^{\#}$ and the normalisation, leaving a finite function of $s_{\rm flat}$ that grows like $s_{\rm flat}^n$ — precisely a flat-space amplitude of the same degree. The same saddle, applied term by term to the OPE/exchange expansion of M, maps each AdS exchange of dimension Δ onto a flat-space pole or partial wave of mass $m \simeq \Delta/R$ via Eq. (63.52), reconstructing the partial-wave expansion of $\mathcal{M}$. The scaling argument is thus not a coincidence of dimensions but the saddle-point evaluation of an explicit transform; we have shown where the R^2 comes from and how the saddle removes it.

Positivity survives the limit. The point of all this for the present section is that *positivity is preserved under Eq. (63.54)*. The CFT data entering M are the OPE coefficients squared, $p_{\mathcal{O}} \geq 0$, and the AdS unitarity bounds on Δ (Theorem 47.18). Under the flat-space map these become exactly the partial-wave positivity $\mathrm{Im}\, a_\ell \geq 0$ (Eq. (63.48)) and the mass-gap support $s' \geq 4m^2$ of the bulk amplitude: a spin-ℓ double-twist operator of dimension $\Delta \simeq 2mR + 2n + \ell$ maps to a two-particle state of invariant mass $\sqrt{s'} \simeq 2m$ and spin ℓ, and its positive squared OPE coefficient is its positive partial-wave density. Crossing maps to crossing: the $u \leftrightarrow v$ symmetry of Eq. (63.46) becomes the $s \leftrightarrow t \leftrightarrow u$ symmetry of $\mathcal{M}$. Therefore the bulk positivity bounds of Section 63.3 are the flat-space shadow of CFT crossing and unitarity, and conversely the conformal bootstrap is a curved-space, finite-R deformation of the S-matrix bootstrap that *regulates the infrared* (AdS is a box) while keeping the same crossing-plus-positivity skeleton. One principle, two radii of curvature.

Physical Insight

AdS is a box that confines the scattering states, replacing the continuous spectrum of momenta by a discrete tower of boundary operators; the flat-space limit is the decompactification of that box. In the box, "unitarity is positivity of the discrete OPE spectrum"; out of the box, it is "positivity of the continuous partial-wave density." The two bootstraps differ only by whether the infrared is regulated by a curvature radius or by a mass gap. Sending $R \to \infty$ interpolates continuously between them, and positivity — the one ingredient that is a statement about probabilities, not about kinematics — rides through the limit untouched.

63.4.6 What a bootstrap is

We can now state the unifying principle that the title promised, with both problems and the holographic bridge in hand.

Physical Insight

A bootstrap is the carving of theory space by crossing plus positivity. A consistent quantum theory — a CFT, an S-matrix, an effective field theory — is a point in a space of *a priori* possible data (operator dimensions and OPE coefficients; masses, spins and couplings; Wilson coefficients). *Crossing* is a set of linear equalities that this data must satisfy because the same observable can be expanded in inequivalent channels. *Positivity* is a set of convex inequalities that the data must satisfy because the underlying Hilbert space is unitary. The conjunction of a linear constraint and a convex cone defines a convex region; the allowed theories are exactly the points of that region, and a separating linear functional Eq. (63.50) certifies which candidate points are excluded. To bootstrap is to compute this region.

This single sentence has two faces that this book has now met from opposite directions. The *numerical conformal bootstrap* (Chapter 50) carves the region in the space of CFT data and reads off, as the boundary of the allowed island, the critical exponents of the three-dimensional Ising model. The *EFThedron* — the convex geometry of allowed Wilson coefficients carved by dispersive positivity (Section 63.3) — carves the region in the space of low-energy effective couplings and reads off, as its boundary, the bounds that any UV-completable EFT must obey. The two are the same convex-geometry problem; the EFThedron is literally a moment problem (a positive spectral density has positive Hankel matrices of moments), and the conformal bootstrap is the same moment problem with conformal blocks in place of monomials. The positive geometry of Chapter 62 is

yet a third face: there the canonical form of a positive region *is* the amplitude, whereas here the positive region *contains* the allowed theories — two uses of the same insistence that physical data lives where positivity allows it.

Worked Example 63.10 (Closing the ϕ^4 theory arc from both ends)**.** The real scalar $\lambda\phi^4$ has been the book's workhorse, carried from its classical Lagrangian (Chapter 6) through quantisation and its first amplitude $-i\lambda$ (Chapter 14), renormalisation and the one-loop beta function $\beta_\lambda = 3\lambda^2/16\pi^2$ (Chapter 24), to the Wilson–Fisher fixed point in $d = 4 - \epsilon$ (Chapter 52). At the fixed point the theory loses its scale, becomes a CFT, and — in $d = 3$ — *is* the Ising universality class. ϕ^4 theory therefore terminates, on the bootstrap side of Chapters 49 and 50, as a point pinned inside the conformal-bootstrap island: crossing plus OPE positivity fix $\Delta_\sigma, \Delta_\epsilon$ to the measured critical exponents without ever expanding in λ. This is the first face.

The amplitudes side closes the same arc from the opposite end. Away from criticality, the massive $\lambda\phi^4$ theory is a perfectly ordinary EFT, and its $2 \to 2$ amplitude is constrained by the S-matrix bootstrap. The leading interaction $\mathcal{M} = -\lambda + \cdots$ is fixed in sign by the same crossing and unitarity: expanding $\mathcal{M}(s,t)$ in the low-energy region and applying the twice-subtracted dispersion relation Eq. (63.47), the forward curvature g_2 — the coefficient of $\frac{1}{2}(s^2+t^2+u^2)$ in the contact amplitude Eq. (63.32), equivalently the curvature c of Eq. (63.30) and the leading genuinely irrelevant Wilson coefficient — is, by Section 63.3,

$$g_2 \;=\; \frac{2}{\pi}\int_{4m^2}^{\infty}\frac{ds'}{s'^3}\,\mathrm{Im}\,\mathcal{M}(s',0) \;=\; \frac{2}{\pi}\int_{4m^2}^{\infty}\frac{ds'}{s'^3}\,\frac{8\pi\sqrt{s'}}{p_{\mathrm{cm}}}\sum_{\ell}(2\ell+1)\,\mathrm{Im}\,a_\ell(s') \;>\; 0, \tag{63.55}$$

strictly positive because the integrand is the manifestly positive forward absorptive density Eq. (63.49). The same theory thus appears at *both* ends of the bootstrap: as a critical point inside the conformal island, and as a point in the allowed EFThedron with $g_2 > 0$. The flat-space limit Eq. (63.54) is the statement that these are not two coincidences but one constraint viewed at two curvatures — the AdS dual of the Wilson–Fisher CFT, in the large-radius limit, scatters ϕ quanta with precisely the amplitude whose forward positivity is Eq. (63.55). ϕ^4 theory, begun as a Lagrangian in Part II, ends as a single point that crossing and positivity locate in two complementary spaces and the holographic limit identifies as one. This is the ϕ^4 theory handoff — $\phi^4 \to$ Wilson–Fisher $\to$ bootstrap — closing in full from the amplitudes side, and joined to the holography thread through the flat-space limit.

The lesson the two bootstraps press on us is that crossing and positivity are not consequences of a Lagrangian; they are prior to it, and they are nearly enough, by themselves, to pin a theory down. If so little input — analyticity, unitarity, the demand that channels agree — constrains so much, it is natural to ask whether the remaining structural axioms of quantum field theory, locality

and unitarity themselves, might likewise be *outputs* of something more primitive: a geometry whose positivity generates the amplitude, or a gauge theory whose square generates gravity. That is the question of the next section.

63.5 Locality and Unitarity as Outputs: Geometry and the Double Copy

The previous section left us with a sharpened version of the chapter's organizing question. Crossing and positivity, we found, are not consequences of a Lagrangian; they are prior to it, and they nearly suffice to pin a theory down. The bootstrap reads this as a statement about a *region*: the allowed theories are the points of a convex body carved out of an *a priori* space of data by linear (crossing) equalities and convex (positivity) inequalities, and to bootstrap is to compute that body. Once one has learned to see physical input as the shape of a region, it is irresistible to ask whether the two remaining structural axioms of quantum field theory — *locality*, the demand that interactions be built from fields at a point so that amplitudes have singularities only where intermediate particles can go on shell, and *unitarity*, the demand that probability be conserved so that those singularities factorize into products of lower amplitudes — are themselves outputs of a more primitive geometric or algebraic structure rather than imposed postulates. This section assembles the two pieces of frontier evidence that they are. The first is the *amplituhedron* lesson of Chapter 62: locality and unitarity emerge as properties of the canonical differential form of a positive geometry, dictated entirely by the geometry's boundaries. The second is the *double-copy* lesson of Chapter 61: the entire kinematic structure of perturbative gravity — and with it the diffeomorphism redundancy that is gravity's defining gauge symmetry — is fixed by squaring gauge theory. Both lessons are stated here carefully, proved where the proof is short and clean, recalled by Chapters 61 and 62 where those chapters carried it in full, and dated honestly: one of them is a theorem in a controlled corner and a conjecture beyond it, the other a theorem at tree level and a tested conjecture at loop level, as of the mid-2020s.

63.5.1 The canonical-form principle: poles are boundaries

We begin by isolating, from the machinery of Chapter 62, the single structural statement on which the entire "locality and unitarity are emergent" claim rests. Recall the central definition of that chapter (Theorem 62.3): a *positive geometry* is a real region $\mathcal{X}$ — bounded by a collection of boundary components of every codimension — equipped with a unique top-degree rational differential form $\Omega(\mathcal{X})$, the *canonical form*, singled out by a recursive requirement on its singularities. We restate that requirement precisely, because everything below is a reading of it.

Definition 63.11 (Canonical form, recalled)**.** Let $\mathcal{X}$ be a positive geometry of dimension m. Its canonical form $\Omega(\mathcal{X})$ is the unique top-degree (m-form) rational differential form with the two properties:

1. *Logarithmic singularities only on boundaries.* $\Omega(\mathcal{X})$ has poles only along the boundary components of $\mathcal{X}$, every pole is simple (logarithmic), and there are no singularities anywhere in the interior or outside the boundary set.

2. *Residues are lower canonical forms.* On each codimension-one boundary component $\mathcal{C} \subset \partial\mathcal{X}$, the residue of $\Omega(\mathcal{X})$ equals the canonical form of $\mathcal{C}$ regarded as a positive geometry in its own right:

$$\operatorname{Res}_{\mathcal{C}} \Omega(\mathcal{X}) \;=\; \Omega(\mathcal{C}). \tag{63.56}$$

This is the recursion proved to determine Ω uniquely in Chapter 62, and Eq. (63.56) is exactly the boundary/residue axiom recorded there as Eq. (62.5). We import it and do not reprove it. What we do here is read it as a physical principle. The reading turns on a dictionary that Chapter 62 established by explicit computation and that we now state as the load-bearing correspondence of the whole section.

The Canonical-Form Principle

Suppose a scattering amplitude is the canonical form of a positive geometry, in the precise sense that $\Omega(\mathcal{X}) = (\text{amplitude}) \times (\text{top measure})$ once $\mathcal{X}$ is built in the kinematic space of the process. Then the amplitude's two defining structural properties are *outputs* of the geometry, not inputs:

- **Locality** is property (1): the amplitude has singularities *only* on the boundaries of $\mathcal{X}$, and each boundary is one physical factorization channel. There are no poles anywhere else — in particular none on spurious or unphysical loci — because the canonical form is forbidden, by definition, to have them.

- **Unitarity** is property (2): the residue on a boundary $\mathcal{C}$ is the canonical form of $\mathcal{C}$, and when $\mathcal{C}$ factorizes as a product of two lower-dimensional positive geometries, $\mathcal{C} = \mathcal{X}_L \times \mathcal{X}_R$, its canonical form factorizes too, $\Omega(\mathcal{C}) = \Omega(\mathcal{X}_L)\,\Omega(\mathcal{X}_R)$. In amplitude language this is precisely the factorization of the residue into a product of lower-point amplitudes glued on the on-shell intermediate state — the content of unitary factorization.

Neither property was postulated. Both follow from the demand that Ω be the canonical form of a region with those particular boundaries. The physics is in the choice of region; the analytic structure is forced.

That this is more than a hopeful slogan was settled in Chapter 62 for an honest physical amplitude. The kinematic associahedron $\mathcal{A}_n$ — a genuine convex polytope living in the space of Mandelstam invariants — has, as its canonical form, the tree-level color-ordered amplitude of bi-adjoint cubic scalar theory, proved facet by facet (Theorem 62.17). There the facets $X_{i,j} = 0$ of the polytope are exactly the planar propagator channels; the amplitude's poles sit on those facets and nowhere else (locality), and the residue on a facet is the canonical form of that facet, which by the combinatorics of the associahedron is a *product of two lower associahedra*, i.e. a product of lower amplitudes (unitarity). Nothing in that derivation imposed analyticity or factorization; both fell out of the shape of the polytope. The amplituhedron of Theorem 62.44 extends the same principle to a far richer setting — the integrand of planar maximally supersymmetric Yang–Mills — but, as we will be careful to record below, there the identification of the canonical form with the amplitude is, beyond the controlled toy dimension, a conjecture.

63.5.2 A toy positive geometry: the pole is a boundary

The associahedron proof is complete but combinatorially heavy. To make the "pole = boundary" mechanism fully transparent — to see a singularity *appear* out of a geometric edge with the correct residue, in one line of calculus — we carry the smallest nontrivial positive geometry all the way through. It is the case the associahedron already collapses to at four points (Theorem 62.17, the $n = 4$ segment), here built from scratch so the emergence is visible.

Worked Example 63.12 (The canonical form of an interval and the birth of a propagator)**.** *The geometry.* Take the one-dimensional positive geometry to be the closed interval

$$\mathcal{X} \;=\; \{\, x \in \mathbb{R} : x \geq 0 \text{ and } a - x \geq 0 \,\} \;=\; [0, a], \qquad a > 0, \tag{63.57}$$

cut out of the line by the two linear functions $X_1(x) = x$ and $X_2(x) = a - x$. Its boundary is the two endpoints, $\partial\mathcal{X} = \{x = 0\} \cup \{x = a\}$, each a codimension-one component — here a single point, the zero-dimensional positive geometry whose canonical form is the number 1.

The canonical form from the axioms. By Theorem 63.11 we seek a top-degree (here, one-) form $\Omega = f(x)\,\mathrm{d}x$ with f rational, simple poles only at $x = 0$ and $x = a$, no other singularities (in particular f must vanish at infinity so that $x = \infty$ is not a pole), and unit residues that reproduce the canonical form 1 of each endpoint. A rational function with simple poles only at 0 and a and no pole at infinity is a sum of two partial fractions,

$$f(x) \;=\; \frac{r_0}{x} + \frac{r_a}{x - a}, \tag{63.58}$$

with residues r_0 at $x = 0$ and r_a at $x = a$. Property (2) fixes the residues. The residue of Ω on the boundary $x = 0$, taken with the orientation that points *out* of $\mathcal{X}$ along increasing x, must be $+\Omega(\{x = 0\}) = +1$; on the boundary $x = a$, where the outward orientation along increasing x is reversed, the residue is -1. Hence $r_0 = +1$, $r_a = -1$, and

$$\Omega(\mathcal{X}) \;=\; \left(\frac{1}{x} - \frac{1}{x-a}\right)\mathrm{d}x \;=\; \left(\frac{1}{x} + \frac{1}{a-x}\right)\mathrm{d}x \;=\; \frac{a}{x\,(a-x)}\,\mathrm{d}x. \tag{63.59}$$

Equivalently $\Omega(\mathcal{X}) = \mathrm{dlog}\dfrac{x}{a-x}$, manifestly a logarithmic form whose two simple poles sit exactly on the two boundaries. We may verify the recursion Eq. (63.56) directly. Near $x = 0$, $\Omega \simeq \mathrm{d}x/x$, so $\mathrm{Res}_{x=0}\,\Omega = 1 = \Omega(\{x = 0\})$. Near the other endpoint set $u = x - a$; then $\dfrac{a}{x(a-x)} = \dfrac{a}{(a+u)(-u)} \xrightarrow{u\to 0} -\dfrac{1}{u}$, so $\mathrm{Res}_{x=a}\,\Omega = -1$, equal to the canonical form of that endpoint carried with the opposite boundary orientation. The residues are the lower (point) canonical forms, as the axiom demands; the alternating sign is the orientation bookkeeping fixed once and for all in Chapter 62.

The propagator is the boundary. Now read the two linear boundary functions as inverse propagators of a physical process. In the four-point bi-adjoint scalar of Theorem 62.17 the affine coordinate on the interval is the planar Mandelstam variable, $x = X_{1,3} = s$, and the complementary facet function is the crossed channel, $a - x = X_{2,4} = t$, with $a = s + t = -u$ the fixed off-shell datum $s + t + u = 0$ supplies. Substituting into Eq. (63.59) strips the measure and leaves the rational coefficient

$$m_4 \;=\; \frac{1}{X_{1,3}} + \frac{1}{X_{2,4}} \;=\; \frac{1}{s} + \frac{1}{t}, \tag{63.60}$$

the complete tree amplitude of the bi-adjoint scalar: a sum of two propagators, one per planar channel. The structure $\dfrac{a}{x(a-x)} = \dfrac{1}{x} + \dfrac{1}{a-x}$ *is* the propagator sum, and each propagator pole is one endpoint of the interval. The residue of the amplitude on the s-channel pole is, by Eq. (63.56), the canonical form of the boundary point — the number 1 — which is precisely the product of the two cubic three-point amplitudes (each equal to 1 for the bi-adjoint scalar) glued across the on-shell exchanged line. The factorization of unitarity has been read off the corner of a segment.

The lesson. Locality here means: the amplitude Eq. (63.60) has poles at $s = 0$ and $t = 0$ and *nowhere else* — no pole in u, no spurious singularity — because the interval has exactly two boundaries and the canonical form is forbidden any other pole. Unitarity here means: the residue at each pole is the lower amplitude, because the residue of a canonical form is the canonical form of the boundary. We did not assume either. We assumed only that the object of interest is the canonical form of the segment $[0, a]$; the propagator structure, the channel poles, and the factorizing residues were forced.

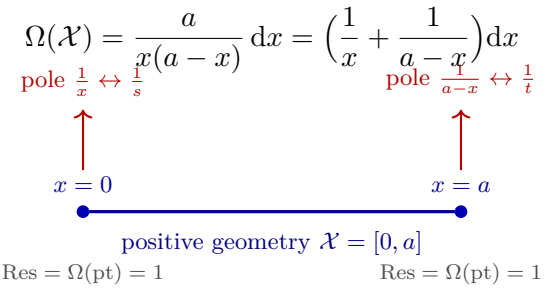

Figure 63.4: The toy positive geometry of Theorem 63.12. The canonical form of the interval $[0, a]$ has exactly two simple poles, one sitting on each boundary point. Reading the two boundary functions as physical channel invariants s and t turns the poles into propagators and the boundary residues into the (trivial) lower amplitudes glued on the on-shell exchange. Locality (poles only on the two boundaries) and unitarity (residue = lower canonical form) are dictated by the shape of the region, not imposed.

The interval is the seed crystal of the whole program. Every higher case proved in Chapter 62 — the pentagon $\mathcal{A}_5$ whose five edges are the five planar channels of the five-point amplitude, the kinematic associahedron $\mathcal{A}_n$ in general, the $m = 2$ amplituhedron polygon — repeats this mechanism one dimension at a time: a codimension-one boundary is a pole; the residue on it is the canonical form of a lower geometry that factorizes into a product of lower amplitudes; and there are no other singularities because the canonical form is, by construction, free of them. Locality and unitarity are then not axioms layered onto a Lagrangian but the two halves of Theorem 63.11, read in kinematic space. This is the first piece of frontier evidence that structural "principles" are derived outputs.

63.5.3 The double copy: gravity as gauge theory squared

The second piece comes from the opposite end of the structural ladder. If the amplituhedron asks whether the *analytic* axioms (locality, unitarity) are emergent, the double copy asks whether the most baroque *symmetry* structure in physics — the diffeomorphism invariance of general relativity, the nonlinear redundancy that makes gravity gravity — is emergent from something simpler. The answer that Chapter 61 developed in full, and that we now recall and read, is that perturbative gravity is gauge theory squared.

We continue Yang–Mills theory, whose amplitude arc this closes. The thread carried the non-abelian gauge field from its classical Lagrangian (Chapter 25) through quantization and asymptotic freedom (Chapters 26 and 27) to its modern amplitude structure: gluon tree amplitudes computed the hard way and then by recursion, culminating in the Parke–Taylor formula (Chapter 59), and then the color–kinematics duality and double copy of Chapter 61. Here is the structural

endpoint of that arc.

The two facts recalled. Chapter 61 organized any gauge-theory tree amplitude over its trivalent (cubic) graphs,

$$\mathcal{A}_n \;=\; i\,g^{\,n-2}\sum_{i\in\Gamma_3}\frac{c_i\,n_i}{D_i}, \tag{63.61}$$

recalling the master formula Eq. (61.18): the sum runs over cubic graphs i, with c_i the color factor (a product of structure constants f^{abc}), D_i the product of the graph's internal inverse propagators, and n_i the kinematic numerator. The two facts the thread established are:

- *Color–kinematics duality* (Theorem 61.8): the kinematic numerators n_i can be chosen to satisfy the *same* algebraic relations as the color factors. Wherever three color factors obey a Jacobi identity $c_i + c_j + c_k = 0$, the corresponding numerators can be arranged to obey the *kinematic Jacobi identity* $n_i + n_j + n_k = 0$, and wherever a color factor is antisymmetric under exchanging two legs, so is its numerator. Such a set is a set of *BCJ numerators*.

- *The double copy* (Theorem 61.15, Eq. (61.72); equivalently the Kawai–Lewellen–Tye form Theorem 61.21 and the BCJ double-copy relation Eq. (61.72)): once one numerator set is BCJ, replacing the color factors of Eq. (63.61) by a second kinematic numerator set,

$$c_i \;\longmapsto\; \tilde{n}_i, \qquad \mathcal{M}_n \;=\; i\left(\frac{\kappa}{2}\right)^{n-2}\sum_{i\in\Gamma_3}\frac{n_i\,\tilde{n}_i}{D_i}, \tag{63.62}$$

  produces a bona fide *graviton* amplitude — proved gauge-invariant and correctly factorizing in Theorems 61.16 and 61.20. The dimensionless gauge coupling g is traded for the dimensionful gravitational coupling κ with $\kappa^2 = 32\pi G_N$.

We import both statements and do not reprove them. Their content is structural: color enters Eq. (63.61) only through its algebra (the Jacobi relations), so a second representation of the *same* algebra — a BCJ numerator set — can be substituted for it without the formula being able to tell the difference. The output then carries two Lorentz numerators where the input carried one color factor and one numerator, doubling the little-group weight on every external leg: two copies of spin one make spin two. The graviton is the symmetric, traceless part of the tensor product of two gluons.

The four-point square, recapped algebraically. The cleanest demonstration is the four-graviton amplitude, carried in full in Theorem 61.19; we recall its skeleton because it is the concrete endpoint of Yang–Mills theory. At four points there are three cubic graphs — the s-, t-, and u-channels — with denominators $D_s = s$, $D_t = t$, $D_u = u$ obeying $s + t + u = 0$ for massless legs. Taking both copies to be pure Yang–Mills ($\tilde{n}_i = n_i$), Eq. (63.62) reads

$$\mathcal{M}_4 \;=\; i\left(\frac{\kappa}{2}\right)^2 \left(\frac{n_s^2}{s} + \frac{n_t^2}{t} + \frac{n_u^2}{u}\right), \qquad n_s + n_t + n_u = 0, \tag{63.63}$$

with the BCJ numerators of the MHV configuration $(1^-, 2^-, 3^+, 4^+)$. The kinematic Jacobi identity $n_s + n_t + n_u = 0$, together with the massless relation $s+t+u = 0$, lets one work in the generalized gauge $n_t = 0$, in which the numerator-to-partial-amplitude dictionary collapses to $n_s/s = P$ and $n_u/u = -Q$, where $P = A_4[1,2,3,4]/i$ and $Q = A_4[1,3,2,4]/i$ are the Parke–Taylor color-ordered partials of Eq. (59.55),

$$P = \frac{\langle 1\,2\rangle^4}{\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle}, \qquad Q = \frac{\langle 1\,2\rangle^4}{\langle 1\,3\rangle\langle 3\,2\rangle\langle 2\,4\rangle\langle 4\,1\rangle}. \tag{63.64}$$

The kinematic Jacobi identity in this gauge becomes the fundamental BCJ amplitude relation $sP = uQ$. Substituting $n_s = sP$, $n_u = -uQ$, $n_t = 0$ into Eq. (63.63) and using $sP = uQ$ with $s + t + u = 0$ collapses the three-term sum (the algebra is carried step by step in Theorem 61.19) to the closed form recorded there as Eq. (61.97),

$$\mathcal{M}_4(1^{--}, 2^{--}, 3^{++}, 4^{++}) \;=\; -\,i\left(\frac{\kappa}{2}\right)^2 \frac{\langle 1\,2\rangle^4\,[3\,4]^4}{s\,t\,u}. \tag{63.65}$$

Set this beside the gauge partial $A_4[1,2,3,4] = i\,\langle 1\,2\rangle^4/(\langle 1\,2\rangle\langle 2\,3\rangle\langle 3\,4\rangle\langle 4\,1\rangle)$ and the squaring is on the page: the gluon numerator $\langle 1\,2\rangle^4$ has become $\langle 1\,2\rangle^4\,[3\,4]^4$ — an angle factor times a square-bracket factor, one from each copy — and the single chain of propagators has become the symmetric denominator stu. The four-graviton amplitude is, term by term, the four-gluon amplitude squared. This is the structural endpoint that Yang–Mills theory was built to reach.

Diffeomorphisms as the square of gauge transformations. The reading that makes this a statement about emergent spacetime structure is the following. Gauge invariance of Eq. (63.61) — the $U(1)$ or non-abelian redundancy under which gluon polarizations shift by their momenta, $\varepsilon_i^\mu \to \varepsilon_i^\mu + \alpha\, p_i^\mu$ — is the on-shell shadow of the gauge symmetry of the Yang–Mills Lagrangian. In the graviton amplitude Eq. (63.62) every external state is a product of two gluon polarizations, $\varepsilon_i^{\mu\nu} = \varepsilon_i^\mu\,\tilde{\varepsilon}_i^\nu$, so a graviton polarization shifts under the *product* of two independent gauge shifts. The linearized diffeomorphism $\varepsilon_i^{\mu\nu} \to \varepsilon_i^{\mu\nu} + p_i^\mu \xi^\nu + \xi^\mu p_i^\nu$ — the

gauge redundancy of the graviton — is exactly what one obtains by performing a gauge shift on one factor at a time. Diffeomorphism redundancy is the square of gauge redundancy. The nonlinear gauge invariance of general relativity, which from the Lagrangian side looks like an elaborate and independent geometric principle (general covariance), is on the amplitude side an automatic consequence of building each graviton from two gluons and inheriting both their linearized Ward identities. Spacetime's defining symmetry is a derived object: the gauge symmetry of a theory that knows nothing of spacetime curvature, applied twice.

Physical Insight

The two pieces of evidence are mirror images. The amplituhedron says the *analytic* backbone of field theory — where amplitudes are allowed to be singular, and what their singularities must equal — is read off the boundaries of a positive geometry; locality and unitarity are the two clauses of the canonical-form recursion. The double copy says the *symmetry* backbone of gravity — general covariance — is read off the product structure of gauge theory; diffeomorphism invariance is gauge invariance squared. In both, a principle that Part I posited as a founding axiom (Chapter 1) reappears in Part XVI as the output of a more primitive construction. The Lagrangian, with its locality built into the pointwise product of fields and its gauge symmetry built into the covariant derivative, is one efficient packaging of these outputs — but, the evidence suggests, not the only one, and perhaps not the most fundamental.

63.5.4 Honest scope, dated to the mid-2020s

Precision requires that we mark exactly how far each claim is established, and date it. We do so plainly.

The positive-geometry / amplituhedron program. The canonical-form principle of Section 63.5.1 is a *theorem* in the cases where the positive geometry is constructed and its canonical form is computed: the projective simplex and polygon, the $m = 2$ amplituhedron, and — physically most important — the kinematic associahedron, whose canonical form is proved equal to the bi-adjoint tree amplitude in Theorem 62.17. In those cases locality and unitarity genuinely *are* outputs, with full proofs in Chapter 62. For the amplituhedron proper (Theorem 62.44), the statement that its canonical form is the planar $\mathcal{N} = 4$ super-Yang–Mills amplitude is established rigorously only in the toy dimension $m = 2$ and in restricted sectors; the full claim — all multiplicities n, all helicity grades k, all loop orders L — remains, as of the mid-2020s, a *conjecture* (Theorem 62.47), extensively checked but unproven. Beyond the planar limit, where there is no single cyclic ordering, no analogue of the amplituhedron is established at all. "Locality and unitarity are emergent" is therefore a proven statement for

bi-adjoint trees and a compelling, well-tested, but conjectural statement for the planar maximally supersymmetric integrand.

The double copy. The statement that a BCJ-organized gauge amplitude squares to a gravity amplitude is a *theorem at tree level*: the existence of BCJ numerators at tree level, the gauge invariance of the double copy, and its correct factorization are all proved in Chapter 61 (Theorems 61.8, 61.16 and 61.20), and the KLT relations give an independent tree-level proof. At loop level the situation is sharper to state: the double copy is known to work — it has reproduced multi-loop supergravity integrands that no other method could compute, and these pass every unitarity-cut and ultraviolet consistency check applied to them — but the crucial input, the *existence* of color–kinematics-dual numerators at all loop orders, is not proven. It is a conjecture (Theorem 61.32), supported by a large and growing body of explicit high-loop evidence and by the cut-level consistency of Theorem 61.31, but lacking a general constructive theorem as of the mid-2020s. The honest summary is: gravity-as-gauge-squared is a theorem where the amplitudes are trees and a tested, structurally-motivated conjecture where they are loops.

Neither program, then, is a finished reduction of field theory's axioms to something more primitive. What both establish, rigorously and in controlled corners and with overwhelming evidence beyond them, is that the reduction is *possible in principle*: that there exist constructions — a positivity geometry, a squaring map — from which locality, unitarity, and even general covariance fall out as consequences rather than being installed by hand. That is the precise sense in which the structural principles are outputs.

If locality and unitarity can be read off a geometry and gravity off a gauge-theory square, then the deepest structural axiom remaining — the very existence of a local spacetime in which the S-matrix is defined — is the natural next target. The most radical reframing on offer recasts the flat-space S-matrix itself as a correlation function of a conformal field theory living on the celestial sphere at null infinity, with the soft theorems of Chapter 60 reborn as the Ward identities of that boundary theory's asymptotic symmetries. To that holography of asymptotically flat space we turn next.

63.6 Amplitudes Meet Holography: Soft Theorems and the Celestial Sphere

The previous section read locality and unitarity as outputs rather than inputs: the amplituhedron manufactures both from the positivity of a geometry, and the double copy manufactures gravity's entire kinematic structure by squaring gauge theory. Both lessons are about the *bulk* of an amplitude — its singularities, its numerators, the way it factorizes on internal channels. There is a complementary

frontier that concerns the amplitude's *boundary*: the behaviour of the S-matrix when an external quantum becomes infinitely soft, and the question of whether the entire S-matrix can be reorganised as a correlation function living on a lower-dimensional screen. This is the amplitudes program's point of contact with holography. The thread that runs through it is the same one Part XV opened with AdS/CFT (Chapter 53): a theory of gravity in a D-dimensional spacetime may be equivalent to a quantum theory without gravity living on its $(D-1)$- or $(D-2)$-dimensional boundary. For asymptotically flat spacetime the candidate boundary theory is a two-dimensional conformal field theory on the *celestial sphere*, and its primary observables — "celestial amplitudes" — are the ordinary flat-space scattering amplitudes rewritten in a conformal basis. The bridge that makes this more than a change of variables is built from soft theorems, which we derive first, in full, from the factorization pole; recognise next as the Ward identities of an infinite-dimensional asymptotic symmetry; and then use to populate the celestial CFT with conserved currents and a stress tensor. We scope the whole construction honestly throughout: the soft theorems are rigorous theorems of any local, Lorentz-invariant quantum field theory; the celestial-CFT reorganisation is a program, dated to the mid-2020s, not a proved duality.

63.6.1 The leading soft factor from the factorization pole

A scattering amplitude is a meromorphic function of its external momenta, and its poles are dictated by the same physics everywhere in this book: an internal line going on shell. The soft limit exploits a particular pole. When an external massless quantum — a photon or a graviton of momentum q — is emitted from an external leg of momentum p_i, the line that carried the energy before the emission is nearly on shell, because the emitted momentum is going to zero. The amplitude therefore develops a $1/q$ singularity as $q \to 0$, and the residue of that singularity is universal: it depends only on the momenta and charges of the hard particles, not on the internal dynamics of the scattering. This is the content of the soft theorems, and it is most transparently derived by isolating exactly that pole.

We work throughout in the all-outgoing convention fixed at the head of the chapter: every external momentum p_i $(i = 1, \dots, n)$ is treated as outgoing, so that overall momentum conservation reads $\sum_{i=1}^{n} p_i^\mu = 0$, and the soft photon or graviton of momentum q is likewise outgoing. We denote the n-point hard amplitude $\mathcal{M}_n$ and the amplitude with one extra soft quantum $\mathcal{M}_{n+1}$. The claim to be proved is that

$$\lim_{q \to 0} \mathcal{M}_{n+1} \;=\; \Big(S^{(0)} + O(q^0) \Big)\, \mathcal{M}_n, \tag{63.66}$$

with $S^{(0)}$ an explicit, theory-independent function of order $1/q$ — the *leading soft factor*. The notation $O(q^0)$ records that the next term in the soft expansion

is finite as $q \to 0$; the leading term is the pole.

Why only external-leg emission contributes at the pole. A general Feynman graph for $\mathcal{M}_{n+1}$ either attaches the soft quantum to an internal line or to an external leg. Attaching it to an internal line of off-shell momentum k replaces a propagator $1/(k^2 - m^2)$ by a vertex and two propagators whose denominators stay finite as $q \to 0$; that contribution is $O(q^0)$ and does not produce the pole. Attaching it to an external leg of momentum p_i is different: the internal line just inside the emission carries $p_i + q$, with

$$(p_i + q)^2 - m_i^2 = p_i^2 - m_i^2 + 2\,p_i{\cdot}q + q^2 = 2\,p_i{\cdot}q + q^2 \xrightarrow[q\to 0]{} 0, \tag{63.67}$$

where we used that the external leg is on shell, $p_i^2 = m_i^2$, and that the soft photon/graviton is massless, $q^2 = 0$. The denominator vanishes linearly in q: this is the pole, and only external-leg emission produces it. The leading soft factor is therefore the sum over the n external legs of [emission vertex]×[propagator], each evaluated at the on-shell pole.
