Modern Quantum Field Theory

From Foundations to the Frontier

Preface

Why Another QFT Textbook?

Quantum Field Theory stands as one of humanity's greatest intellectual achievements. It provides a unified framework for understanding the fundamental forces of nature, has yielded predictions verified to extraordinary precision, and continues to generate deep connections between physics and mathematics. Yet despite its importance, learning QFT remains a notoriously challenging endeavor.

The existing textbooks on QFT are, by and large, excellent. Peskin and Schroeder's comprehensive treatment has trained generations of physicists. Weinberg's magisterial three volumes offer unparalleled depth and rigor. Schwartz provides a modern perspective with clarity and precision. Srednicki's streamlined organization makes the path to loop calculations concrete. Zee's intuitive approach brings joy to the subject, and Coleman's legendary lectures offer a masterclass in physical reasoning.

So why write another textbook? This book aims to fill several gaps in the existing literature:

(i) **Conceptual motivation before formalism.** Many texts plunge into the mathematical machinery of field quantization without adequately explaining *why* quantum field theory is necessary. We begin with Chapter 1, "Why Quantum Field Theory?," which demonstrates that QFT is not merely one possible approach to relativistic quantum mechanics—it is the *only* consistent approach.

(ii) **Complete, self-contained derivations.** Rather than leaving crucial steps as exercises or referring the reader to external sources for technical arguments, every theorem, loop integral, trace identity, and renormalization-group coefficient that the development relies upon is derived in full within the text or its six appendices. Worked examples and explicit computations carry every calculation from start to finish on the page.

(iii) **A complete path to the frontier.** Most textbooks stop at the Standard Model or one-loop QCD. This book continues at full technical depth

through supersymmetry, conformal field theory and the conformal bootstrap, holography and quantum information, modern on-shell scattering amplitude methods, and quantum field theory in curved spacetime.

(iv) **The modern perspective throughout.** Effective field theory and the renormalization group are not afterthoughts but organizing principles. Symmetry guides every development, and three recurring theories—real scalar $\lambda\phi^4$ theory, quantum electrodynamics, and non-Abelian Yang–Mills theory—serve as unifying threads from classical field theory through the research frontier.

Prerequisites

This book is designed for first-year graduate students in physics, though advanced undergraduates with strong preparation will also find it accessible. The required background includes:

- **Quantum mechanics:** Familiarity with Dirac notation, angular momentum, time-dependent perturbation theory, and elementary scattering theory.
- **Classical mechanics:** Lagrangian and Hamiltonian formulations, canonical transformations.
- **Electrodynamics:** Maxwell's equations in covariant form, potentials, and gauge transformations.
- **Special relativity:** Four-vector notation, Lorentz transformations, and relativistic kinematics.
- **Mathematics:** Linear algebra, multivariable calculus, Fourier analysis, and complex contour integration (reviewed and extended in Part I). Representation theory, functional methods, and differential-geometric tools are developed from scratch as needed.

How to Use This Book

The book is organized into seventeen parts (Chapters 1–65) and six technical appendices (Appendices A–F), progressing systematically from foundations to the research frontier:

Parts I–III: Foundations (Chapters 1–13). Why quantum fields are forced by relativity and quantum mechanics; representation theory of the Lorentz

and Poincaré groups, functional methods, and analytic tools; classical Lagrangian field theory, Noether's theorem, and the gauge principle; canonical and path-integral quantization of free scalar, Dirac, and electromagnetic fields.

Parts IV–VI: Interacting Fields, QED, and Renormalization (Chapters 14–24). The S-matrix, LSZ reduction, Wick's theorem, Feynman rules, and cross sections; tree-level and one-loop quantum electrodynamics, infrared divergences, and precision tests ($g-2$, the Lamb shift); ultraviolet divergences, perturbative renormalization, the Wilsonian renormalization group, and the Callan–Symanzik equation.

Parts VII–IX: Non-Abelian Gauge Theory and the Standard Model (Chapters Yang–Mills theory, Faddeev–Popov and BRST quantization, asymptotic freedom, and perturbative QCD; spontaneous symmetry breaking, Goldstone's theorem, the Higgs mechanism, electroweak unification, and CKM/PMNS flavor physics; the complete Standard Model, precision electroweak and Higgs tests, and physics beyond the Standard Model.

Parts X–XIII: Anomalies, EFT, Non-Perturbative Physics, and Supersymmetr Chiral and gauge anomalies, anomaly matching, and Wess–Zumino–Witten terms; the effective field theory paradigm, chiral perturbation theory, HQET, and SMEFT; solitons, monopoles, instantons, the θ-vacuum, and lattice gauge theory; supersymmetry algebras, supersymmetric gauge theories, Seiberg duality, and Seiberg–Witten theory.

Parts XIV–XVII: The Research Frontier (Chapters 47–65). Conformal field theory in general dimensions and in two dimensions, the numerical and analytic conformal bootstrap; AdS/CFT correspondence, holographic correlators, entanglement entropy, Ryu–Takayanagi and quantum extremal surfaces, and the black hole information problem; spinor-helicity methods, BCFW recursion, generalized unitarity, color-kinematics duality and the double copy, and positive geometries; quantum fields in curved spacetime, the Unruh effect, and Hawking radiation.

A standard two-semester graduate course can cover Parts I–IX (supplemented by Appendices A–D), with selected chapters from Parts X–XII. Parts XIII–XVII can be used for advanced graduate courses or independent study leading directly into current research literature.

Notation and Conventions

We use the "mostly minus" metric signature $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units with $\hbar = c = 1$, and Hermitian Lie algebra generators satisfying

$\left[T^a, T^b\right] = if^{abc}T^c$ with $\mathrm{tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$ in the fundamental representation. Complete convention tables, Fourier and propagator normalizations, group-theory invariants, gamma-matrix identities, master loop integrals, functional determinants, and Standard Model reference data are collected in Appendices A–F.

Acknowledgments

This book could not have been written without the profound influence of the authors whose works we build upon. We are especially indebted to the pedagogical insights of Sidney Coleman, whose lectures set a standard that all physics textbooks should aspire to match, and to the classic texts of Peskin and Schroeder, Weinberg, Schwartz, Srednicki, and Zee.

Contents

Preface iii

1 Why Quantum Field Theory? 1

1.1 Relativity versus the single particle . . . 2
1.2 The Klein–Gordon equation . . . 3
1.2.1 The conserved current, and why its density is not a probability 3
1.2.2 Negative energy and the absence of a ground state . . . 4
1.3 Dirac's equation and the sea . . . 5
1.3.1 A positive density at last . . . 5
1.3.2 But the negative energies remain . . . 6
1.3.3 Why the sea is not the final word . . . 6
1.4 Pair creation: particle number is not conserved . . . 7
1.5 Locality, causality, and microcausality . . . 9
1.5.1 Amplitudes leak outside the light cone . . . 9
1.5.2 How antiparticles restore causality . . . 10
1.5.3 Microcausality and the seed of spin-statistics . . . 10
1.6 Fields as the fundamental objects . . . 11
1.6.1 Particles as quanta . . . 11
1.6.2 The three theories that will recur . . . 13
1.7 A map of the book . . . 13

I Mathematical Foundations 17

2 Groups and Representations 19

2.1 Symmetry, Groups, and Why We Represent Them . . . 21
2.1.1 What a symmetry is, and why it must act linearly . . . 21
2.1.2 Groups . . . 22

2.1.3 Representations . . . 25
2.1.4 The Weyl unitarian trick . . . 28
2.2 Irreducibility, Schur's Lemma, and Characters . . . 32
2.2.1 Invariant subspaces and irreducibility . . . 33
2.2.2 Maschke's theorem . . . 34
2.2.3 Schur's lemma . . . 36
2.2.4 Characters . . . 38
2.2.5 Orthogonality of characters . . . 39
2.2.6 The regular representation and the sum-of-squares theorem 42
2.2.7 Worked example: the character table of S_3 . . . 44
2.2.8 From finite to continuous . . . 47
2.3 Lie Groups, Lie Algebras, and the Exponential Bridge . . . 48
2.3.1 Matrix Lie groups and the tangent space at the identity . 49
2.3.2 The matrix exponential and one-parameter subgroups . . 50
2.3.3 The Lie algebra: closure under the bracket . . . 53
2.3.4 Structure constants and the Hermitian-generator convention 54
2.3.5 The Jacobi identity and the adjoint representation . . . 56
2.3.6 The exponentiated adjoint and the action of the group on its algebra . . . 58
2.3.7 The Baker–Campbell–Hausdorff bridge . . . 59
2.3.8 Worked example: $\mathfrak{su}(2)$ and $\mathfrak{so}(3)$ exponentiated . . . 60
2.4 The Worked Spine: $\mathfrak{su}(2)$, Its Representations, and SU(2) over SO(3) . . . 63
2.4.1 The algebra, the Casimir, and the ladder operators . . . 63
2.4.2 The highest-weight construction . . . 66
2.4.3 The fundamental and adjoint matrices . . . 69
2.4.4 SU(2) over SO(3): the double cover and half-integer spin 71
2.5 Tensor Products, Clebsch–Gordan, and Invariants . . . 75
2.5.1 The tensor product of two representations . . . 75
2.5.2 Weights add: the $\mathfrak{su}(2)$ Clebsch–Gordan series . . . 77
2.5.3 Clebsch–Gordan coefficients . . . 79
2.5.4 Invariant tensors and the singlet . . . 81
2.5.5 Conjugate representations and the real/pseudoreal/complex trichotomy . . . 83
2.5.6 Worked example: $\frac{1}{2} \otimes \frac{1}{2} = 0 \oplus 1$ . . . 85
2.6 Cartan–Weyl: Cartan Subalgebra, Roots, and the Highest-Weight Theorem . . . 87
2.6.1 The Cartan subalgebra . . . 88

2.6.2 Weights of a representation . . . 89
2.6.3 The root-space decomposition of the algebra . . . 89
2.6.4 The form on weights and the $\mathfrak{su}(2)$ attached to each root 90
2.6.5 The root string and the master formula . . . 92
2.6.6 Root geometry: the allowed angles . . . 93
2.6.7 Simple roots and the Cartan matrix . . . 94
2.6.8 Dynkin diagrams . . . 95
2.6.9 The highest-weight theorem . . . 95
2.6.10 The classification of simple Lie algebras . . . 97
2.6.11 Worked examples . . . 98
2.7 su(3): The Physicist's Workhorse . . . 101
2.7.1 The algebra, the Cartan subalgebra, and the rank . . . 101
2.7.2 The root system: the $\mathfrak{su}(3)$ hexagon . . . 102
2.7.3 The fundamental **3**, the conjugate $\bar{\mathbf{3}}$, and why they differ 104
2.7.4 The adjoint **8** . . . 105
2.7.5 Tensor products by weight addition . . . 106
2.7.6 Dimensions and the Young-tableau shortcut . . . 107
2.7.7 The quadratic Casimir and the Dynkin index . . . 108

3 The Lorentz and Poincaré Groups 111
3.1 The Lorentz group: spacetime symmetry and its components . . 112
3.1.1 Minkowski space and the defining relation . . . 113
3.1.2 Two invariant signs: the determinant and the time component 114
3.1.3 The discrete operations and the four components . . . 117
3.1.4 A worked transformation: boosts, rotations, and rapidity 120
3.1.5 Non-compactness . . . 121
3.1.6 The fundamental group: a first look at the double cover . 122
3.2 The Lorentz Lie algebra . . . 124
3.2.1 Infinitesimal transformations and the antisymmetry constraint . . . 124
3.2.2 The six generators $M^{\mu\nu}$ . . . 125
3.2.3 The covariant commutation relations . . . 126
3.2.4 Rotations, boosts, and the J–K algebra . . . 128
3.2.5 Finite rotations and boosts . . . 130
3.3 $\mathfrak{su}(2) \oplus \mathfrak{su}(2)$ and the (j_-, j_+) classification of fields . . . 133
3.3.1 Complexifying the algebra: the two hidden $\mathfrak{su}(2)$'s . . . 134
3.3.2 The (j_-, j_+) classification . . . 136

3.3.3 The catalogue of low-spin fields . . . 138
3.3.4 Why none of these are unitary . . . 144
3.4 Spinors: Weyl, Dirac, Majorana, and the SL(2,$\mathbb{C}$) double cover . 145
3.4.1 The Pauli map: four-vectors as Hermitian matrices . . . 146
3.4.2 SL$(2,\mathbb{C})$ double covers SO$^+(1,3)$ . . . 147
3.4.3 Weyl spinors and their transformation laws . . . 149
3.4.4 The Dirac spinor and the Clifford algebra . . . 151
3.4.5 Parity and the necessity of the Dirac spinor . . . 153
3.4.6 The Majorana condition . . . 155
3.5 The Poincaré group and algebra . . . 157
3.5.1 Spacetime translations and the inhomogeneous Lorentz group . . . 157
3.5.2 The semidirect-product structure . . . 159
3.5.3 The Lie algebra: generators and the translation block . . 160
3.5.4 P^μ is a four-vector: the $[M,P]$ commutator . . . 161
3.5.5 The full Poincaré algebra . . . 163
3.5.6 Unitary representations are infinite-dimensional . . . 165
3.6 Casimir operators: mass and spin . . . 166
3.6.1 The first Casimir: P^2 and mass . . . 167
3.6.2 The Pauli–Lubanski vector and the second Casimir . . . 169
3.6.3 The little group and Wigner's induced representations . . 173
3.7 Wigner's classification: what a relativistic particle can be . . . 178
3.7.1 The orbits: where a momentum can live . . . 178
3.7.2 The massive case: little group SU(2) and spin . . . 181
3.7.3 The massless case: little group ISO(2) and helicity . . . 183
3.7.4 Helicity one cannot be a four-vector: the seed of gauge invariance . . . 186
3.7.5 The catalogue: fields to particles . . . 188

4 Functional Methods **191**
4.1 The Calculus of Functionals . . . 192
4.1.1 Functionals . . . 193
4.1.2 The functional derivative . . . 194
4.1.3 Computational rules . . . 197
4.1.4 The functional Taylor expansion . . . 200
4.1.5 The Euler–Lagrange equation as a stationarity condition . 202
4.2 Gaussian Integration in Finite Dimensions . . . 206
4.2.1 The one-dimensional Gaussian . . . 207

4.2.2 The multidimensional Gaussian and the determinant prefactor . . . 208
4.2.3 The source term and completing the square . . . 208
4.2.4 The complex Gaussian . . . 210
4.2.5 Moments and Wick's theorem . . . 211
4.2.6 The carried toy: the zero-dimensional ϕ^4 model . . . 215
4.3 From Finite to Infinite: The Functional Integral and Its Status . 216
4.3.1 Lattice discretization of a field on a finite box . . . 217
4.3.2 The free generating functional and the continuum propagator 220
4.3.3 The Minkowski integral and the oscillatory obstruction . . 223
4.3.4 The rigor summary: what is a theorem and what is formal 224
4.3.5 The Euclidean route and Osterwalder–Schrader reconstruction . . . 226
4.3.6 The carried toy: the one case where the path integral is an honest integral . . . 227
4.4 Generating Functionals and Connected Correlators . . . 229
4.4.1 Full correlators as derivatives of Z . . . 229
4.4.2 The connected generating functional W . . . 230
4.4.3 The linked-cluster theorem . . . 232
4.4.4 Low-order connected–full relations . . . 234
4.4.5 The classical field and the bridge to the Legendre transform 236
4.5 The Legendre Transform and the Effective Action . . . 239
4.5.1 The Legendre transform of a convex function . . . 239
4.5.2 The effective action and the conjugate relation . . . 243
4.5.3 Γ generates the one-particle-irreducible vertices . . . 246
4.5.4 $\Gamma = S$ at tree level and the loop expansion . . . 248
4.5.5 The carried toy: the effective action of the zero-dimensional ϕ^4 model . . . 250
4.6 Saddle Points, Functional Determinants, and the Loop Expansion 252
4.6.1 Laplace's method in one dimension . . . 253
4.6.2 Steepest descent in n dimensions and the determinant prefactor . . . 255
4.6.3 Restoring $\hbar$: the saddle expansion is the loop expansion . 258
4.6.4 The one-loop effective action and the functional determinant 259
4.6.5 The zero-dimensional ϕ^4 integral as an asymptotic series . 261

5 Analysis Tools: Distributions, Complex Analysis, Asymptotics 265
5.1 Distributions and the $i\epsilon$ prescription . . . 267
5.1.1 Test functions: $\mathcal{D}$ and $\mathcal{S}$ . . . 268
5.1.2 Distributions and tempered distributions . . . 269
5.1.3 The Dirac delta, multiplication, and the distributional derivative . . . 270
5.1.4 The Cauchy principal value . . . 273
5.1.5 The Sokhotski–Plemelj formula . . . 274
5.1.6 Order, support, and the structure of tempered distributions 277
5.2 Tempered distributions and the Fourier transform . . . 278
5.2.1 Why a new test space: Schwartz functions . . . 279
5.2.2 The Fourier transform on Schwartz space . . . 280
5.2.3 Extension to tempered distributions by duality . . . 284
5.2.4 The catalogue every propagator uses . . . 286
5.2.5 Why products of distributions are dangerous . . . 288
5.2.6 The Feynman propagator as a tempered distribution . . . 289
5.3 Contour integration and the propagator prescriptions . . . 290
5.3.1 The residue calculus, reviewed for deployment . . . 291
5.3.2 Jordan's lemma . . . 292
5.3.3 Pole structure of the momentum-space propagator . . . 294
5.3.4 The three propagators from one integrand . . . 296
5.3.5 The Feynman propagator and time ordering . . . 298
5.3.6 Poles versus branch points: a preview of cuts . . . 299
5.4 Analytic continuation and Wick rotation . . . 301
5.4.1 The principle of analytic continuation . . . 301
5.4.2 The Wick rotation . . . 303
5.4.3 Why the rotation is legal: the $i\epsilon$ does the work . . . 304
5.4.4 The Schwinger proper-time representation . . . 307
5.4.5 A worked Wick rotation: the scalar bubble integral . . . 308
5.5 Analyticity as physics: causality and dispersion relations . . . 310
5.5.1 Causality as a support condition . . . 311
5.5.2 The Kramers–Kronig relations . . . 313
5.5.3 Subtractions: the price of slow decay . . . 316
5.5.4 The discontinuity across a cut is twice the imaginary part 317
5.5.5 Dispersion relations: reconstructing an amplitude from its cut . . . 319
5.5.6 Two results stated, awaiting their proofs . . . 320

5.5.7 Worked computation: a two-point function from its discontinuity . . . 321
5.6 Asymptotic series, Watson's lemma, and steepest descent . . . 324
5.6.1 Asymptotic (Poincaré) series . . . 326
5.6.2 Watson's lemma . . . 329
5.6.3 Laplace's method and the method of steepest descent . . . 332
5.6.4 Stirling's formula from the saddle point . . . 336
5.6.5 Dyson's argument: why the QFT series must be asymptotic 338
5.7 Divergent series and Borel summation . . . 339
5.7.1 The Borel transform and the Borel sum . . . 340
5.7.2 When the Borel sum reproduces the function: the Nevanlinna–Sokal theorem . . . 342
5.7.3 Singularities in the Borel plane and nonperturbative ambiguity . . . 345
5.7.4 Physical identification: instanton and renormalon singularities . . . 348
5.7.5 Resurgence and transseries: the mid-2020s frontier . . . 349

II Classical Field Theory 353

6 Lagrangian and Hamiltonian Field Theory 355
6.1 From Particles to Fields: The Action Functional . . . 356
6.1.1 A mechanical system with infinitely many degrees of freedom 357
6.1.2 What a classical field is . . . 361
6.1.3 The action functional . . . 362
6.1.4 The three structural requirements . . . 362
6.1.5 The first protagonist: the free real scalar field . . . 367
6.2 Stationary Action and the Euler–Lagrange Field Equations . . . 369
6.2.1 The variational problem and admissible variations . . . 369
6.2.2 Derivation of the covariant Euler–Lagrange equations . . . 371
6.2.3 The functional-derivative restatement . . . 373
6.2.4 Total-derivative ambiguity of the Lagrangian . . . 373
6.2.5 The free scalar: the Klein–Gordon equation . . . 375
6.2.6 Scalar ϕ^4 theory: the interacting scalar and its equation of motion . . . 376
6.3 The Cast Assembled: Dirac and Maxwell Lagrangians . . . 378
6.3.1 The complex scalar and its global $U(1)$ . . . 379

6.3.2 The Dirac Lagrangian and equation of motion 381
6.3.3 The Maxwell Lagrangian and equation of motion 384
6.4 The Hamiltonian Formulation of Fields 388
6.4.1 The field Legendre transform and the canonical momentum density 388
6.4.2 Hamilton's field equations 390
6.4.3 The equal-time Poisson bracket 393
6.4.4 Worked example: the scalar field and ϕ^4 theory 395
6.4.5 Time translation as a canonical flow 397
6.5 Singular Lagrangians and Primary Constraints 398
6.5.1 Degenerate Lagrangians and the Hessian criterion 398
6.5.2 The Dirac field: a momentum that is a constraint 400
6.5.3 The Maxwell field: a non-dynamical potential and Gauss's law 401
6.5.4 The Dirac–Bergmann algorithm: statement and the bridge to quantization 404
6.6 The Stress–Energy Tensor and Conserved Energy–Momentum . . 408
6.6.1 Translation invariance and the canonical current 408
6.6.2 On-shell conservation, by direct computation 410
6.6.3 Charges: the conserved four-momentum 411
6.6.4 Scalar ϕ^4 theory: the scalar stress tensor in full 413
6.6.5 Two defects of the canonical tensor 415
6.6.6 The improvement program, and angular momentum . . . 417

7 Symmetries and Conservation Laws 419
7.1 What Is a Symmetry? Variations, Invariance, and Quasi-Symmetry 420
7.1.1 Two notions of variation 421
7.1.2 The first variation of the action: the master identity . . . 424
7.1.3 Symmetry, quasi-symmetry, and the boundary term . . . 427
7.1.4 Continuous families, generators, and the discrete foil . . . 430
7.2 Noether's First Theorem 432
7.2.1 From the master identity to a conservation law 432
7.2.2 The conserved charge and its time-independence 436
7.2.3 The improvement ambiguity 439
7.2.4 Several parameters: one current per generator 440
7.3 Internal Symmetries, Currents, and the Charge Algebra 442
7.3.1 Internal symmetries and the field response 442
7.3.2 The abelian case: U(1) of a complex scalar 443

7.3.3 The non-abelian case: a multiplet in a representation . . . 445
7.3.4 The charges generate the transformation 447
7.3.5 The charge algebra 448
7.3.6 Discrete symmetries: Scalar ϕ^4 theory's $\mathbb{Z}_2$ 450
7.4 Spacetime Symmetries: The Canonical Stress Tensor and Angular Momentum 453
7.4.1 Translations revisited: the canonical stress tensor as a Noether current 454
7.4.2 Lorentz invariance and the angular-momentum current . . 455
7.4.3 The non-symmetry of the canonical tensor and the spin current 457
7.4.4 The angular-momentum charges and the Poincaré generators 460
7.5 The Belinfante–Rosenfeld Symmetric Stress Tensor 463
7.5.1 What an improvement may and may not change 463
7.5.2 Constructing the superpotential from the spin current . . 464
7.5.3 The electromagnetic field: from canonical mess to gauge-invariant tensor 467
7.6 Noether's Second Theorem: Global versus Local Symmetry . . . 470
7.6.1 Local symmetries and the variational identity 471
7.6.2 The second theorem and its proof 472
7.6.3 The naive current and its on-shell triviality 473
7.6.4 The gauged example: electromagnetism 475
7.6.5 Where the genuine charge lives: global versus local in scalar QED 477
7.7 Scale, Conformal Symmetry, and the Trace of the Stress Tensor . 479
7.7.1 Dilatations and the scaling dimension of a field 480
7.7.2 The dilatation current and the trace of the stress tensor . 481
7.7.3 The improved, traceless stress tensor 483
7.7.4 Special conformal transformations and the conformal algebra 486
7.7.5 Scalar ϕ^4 theory: the classical scale symmetry of the massless theory 488

8 Gauge Invariance: Classical Electromagnetism 493
8.1 From Global to Local: The Gauge Principle 495
8.1.1 The global $U(1)$ symmetry, recalled 495
8.1.2 Localizing the phase: the obstruction 496
8.1.3 What the obstruction means: comparing fields in different internal frames 499

8.2 The Covariant Derivative and Minimal Coupling 502
8.2.1 The derivative as a comparator, and why it fails 503
8.2.2 The gauge potential and the covariant derivative 504
8.2.3 Minimal coupling: the matter–photon interaction, derived 506
8.2.4 The electron, and the interaction current 507
8.2.5 Worked verification of local invariance 509
8.3 The Field Strength as Curvature 511
8.3.1 The commutator of covariant derivatives 512
8.3.2 Gauge invariance of the field strength 514
8.3.3 The Bianchi identity 515
8.3.4 Electric and magnetic fields as components of $F_{\mu\nu}$ 517
8.3.5 Curvature, parallel transport, and holonomy 519
8.4 The Maxwell Action and Field Equations 522
8.4.1 What may appear in the Lagrangian 523
8.4.2 Coupling to a source: conservation forced by gauge invariance 527
8.4.3 The inhomogeneous Maxwell equations 528
8.4.4 The homogeneous equations from the Bianchi identity . . 530
8.4.5 Recovering the four three-vector Maxwell equations . . . 531
8.4.6 The Maxwell sector of classical QED 533
8.5 Gauge Redundancy, Gauge Fixing, and Physical Degrees of Freedom 534
8.5.1 Gauge redundancy: the configuration space is a quotient . 534
8.5.2 Counting the physical degrees of freedom 536
8.5.3 Lorenz gauge: covariant fixing 538
8.5.4 Coulomb, temporal, and axial gauges: the trade-off 540
8.5.5 Plane waves and the two physical polarizations 542
8.6 The Classical QED Lagrangian 544
8.6.1 Assembling the Lagrangian 545
8.6.2 The electromagnetic current as the $U(1)$ Noether current 546
8.6.3 The current is the Maxwell source 549
8.6.4 The coupled equations of motion 550
8.6.5 Gauge invariance of the full action 552
8.6.6 Recovering the Lorentz force 553
8.6.7 The classical structure of QED 554
8.7 Holonomy, the Aharonov–Bohm Effect, and Charge Quantization 555
8.7.1 Parallel transport and the Wilson line 556
8.7.2 The Wilson loop and its flux 557
8.7.3 The Aharonov–Bohm effect 559

8.7.4 Dirac's charge-quantization condition 562
8.7.5 The connection is fundamental 564

III Free Quantum Fields **567**

9 Quantization of the Scalar Field **569**
9.1 From Oscillators to Fields: Canonical Quantization 570
9.1.1 The classical free theory, imported 571
9.1.2 The oscillator template 572
9.1.3 The canonical quantization postulate 572
9.1.4 Why the Heisenberg picture is mandatory 574
9.1.5 The Heisenberg equations reproduce Klein–Gordon 575
9.1.6 Consistency: the canonical structure is conserved 578
9.2 The Mode Expansion and Ladder Operators 579
9.2.1 The Lorentz-invariant measure 580
9.2.2 The mode expansion of the field 582
9.2.3 Inversion: extracting the ladder operators 583
9.2.4 The ladder algebra 585
9.2.5 Two normalizations, one physics 587
9.3 Fock Space, the Vacuum, and the Particle Interpretation 588
9.3.1 The vacuum 589
9.3.2 One-particle states and covariant normalization 591
9.3.3 Multiparticle states, Bose symmetry, and Fock space . . . 593
9.3.4 Diagonalizing the energy and momentum 595
9.3.5 The spectrum and the particle interpretation 597
9.3.6 The Poincaré content: a relativistic spin-0 particle 599
9.4 The Vacuum Energy and Normal Ordering 602
9.4.1 The zero-point energy and its divergences 603
9.4.2 Operator ordering and the origin of the ambiguity 604
9.4.3 Normal ordering 605
9.4.4 Is the vacuum energy physical? 606
9.4.5 The Casimir effect: zero-point energy made visible 607
9.4.6 Frontier flag: the cosmological-constant problem 611
9.5 Correlation Functions and the Feynman Propagator 612
9.5.1 The Wightman two-point function 613
9.5.2 Time ordering and the Feynman propagator 614
9.5.3 The covariant momentum-space form via the p^0 contour . 615

9.5.4 Independent check: the operator time-ordered product . . 617
9.5.5 Locating the Feynman choice: retarded and advanced Green's functions 619
9.5.6 The propagator is the Green's function of the Klein–Gordon operator 620
9.6 Microcausality, the Commutator Function, and Spin-Statistics . . 623
9.6.1 The commutator is a c-number 623
9.6.2 Covariant form and Lorentz invariance 625
9.6.3 The microcausality theorem 626
9.6.4 Causality as the commuting of local observables 627
9.6.5 Spin and statistics: why the scalar must be Bose 629
9.6.6 The general spin-statistics theorem: statement and scope 631
9.7 The Charged Scalar: Antiparticles and Conserved Charge 634
9.7.1 The complex scalar as two real fields 635
9.7.2 Mode expansion and the two ladder sets 636
9.7.3 The conserved U(1) charge as an operator 638
9.7.4 The charged propagator and the flow of charge 641
9.7.5 The neutral scalar as its own antiparticle 643

10 The Path Integral for Scalar Fields 645
10.1 The Path Integral in Quantum Mechanics 647
10.1.1 The transition amplitude as the central object 648
10.1.2 Slicing time: the Trotter product formula 649
10.1.3 The short-time kernel 651
10.1.4 The phase-space path integral 652
10.1.5 Gaussian momentum integration and the configuration-space measure 653
10.1.6 The free particle 655
10.1.7 Consistency: recovery of the Schrödinger equation 656
10.1.8 The harmonic oscillator 658
10.2 Correlation Functions and the Generating Functional 661
10.2.1 Path-integral insertions are time-ordered products 662
10.2.2 Projecting onto the vacuum: the $i\varepsilon$ tilt 664
10.2.3 The source and the generating functional 666
10.2.4 The oscillator generating functional 668
10.3 The Generating Functional for a Scalar Field 672
10.3.1 From a lattice of oscillators to a spacetime lattice 673
10.3.2 The functional measure 674

10.3.3 The generating functional $Z[J]$ . . . 676
10.3.4 Vacuum projection and the $i\varepsilon$ prescription . . . 677
10.3.5 The n-point Green's functions . . . 679
10.4 The Free Generating Functional and the Feynman Propagator . . 683
10.4.1 The free action and its kinetic operator . . . 684
10.4.2 Gaussian functional integration: completing the square . 684
10.4.3 Inverting the kinetic operator: the propagator in momentum space . . . 687
10.4.4 The two-pillar agreement . . . 688
10.4.5 The prefactor as a functional determinant . . . 691
10.5 Wick's Theorem from Functional Derivatives . . . 692
10.5.1 The free n-point functions as derivatives of a Gaussian . . 693
10.5.2 The combinatorics: derivatives of e^W are sums over pairings 694
10.5.3 The two-point function and the four-point function . . . 697
10.5.4 Cross-check: recovering the operator Wick's theorem of Chapter 9 . . . 699
10.5.5 What Wick's theorem hands forward . . . 702
10.6 The Euclidean Path Integral . . . 703
10.6.1 Wick rotation as the completion of the $i\varepsilon$ tilt . . . 703
10.6.2 The Euclidean action of Scalar ϕ^4 theory . . . 706
10.6.3 The Euclidean generating functional and the convergence of its measure . . . 708
10.6.4 The Euclidean propagator and its continuation to D_F . . 710
10.6.5 The dictionary: quantum field theory as statistical mechanics 713
10.6.6 Reflection positivity and the return to Lorentzian operators 714
10.7 The Interacting Generating Functional and the Road Ahead . . . 716
10.7.1 Splitting the action: the master formula . . . 717
10.7.2 Perturbation theory and the birth of contractions . . . 719
10.7.3 The cancellation of vacuum bubbles . . . 722
10.7.4 Connected correlators: the functional $W[J]$ . . . 723
10.7.5 The effective action and the road ahead . . . 725

11 The Dirac Field **729**
11.1 Spinor Representations and the Dirac Equation . . . 730
11.1.1 The Dirac representation, recalled . . . 731
11.1.2 The Dirac equation as the forced first-order equation . . . 733
11.1.3 Lorentz covariance: form-invariance of the Dirac equation 735

11.1.4 Lagrangian, adjoint, canonical momentum, and the conserved current . . . 736
11.1.5 The sixteen bilinear covariants . . . 739
11.2 Plane-Wave Solutions, Spin Sums, and Projectors . . . 742
11.2.1 The momentum-space Dirac equation . . . 743
11.2.2 Rest-frame solutions and the boost . . . 744
11.2.3 Normalization and orthogonality . . . 747
11.2.4 Completeness: the spin sums . . . 749
11.2.5 Energy, chirality, and helicity projectors . . . 750
11.2.6 The Gordon decomposition . . . 752
11.3 Canonical Quantization and the Necessity of Anticommutators . . . 755
11.3.1 The Heisenberg mode expansion . . . 756
11.3.2 The conjugate momentum and the two candidate postulates . . . 757
11.3.3 Inverting the expansion . . . 758
11.3.4 The Hamiltonian, and why commutators fail . . . 759
11.3.5 The cure: anticommutators and the ladder algebra . . . 762
11.3.6 Consistency: the Heisenberg equation reproduces the Dirac equation . . . 765
11.4 Fock Space, the Charge, and the Electron . . . 767
11.4.1 The vacuum and its uniqueness . . . 768
11.4.2 One-particle states: the electron and the positron . . . 769
11.4.3 Pauli exclusion and the antisymmetric Fock space . . . 769
11.4.4 The Hamiltonian: normal ordering and the rescue by anticommutation . . . 771
11.4.5 Momentum . . . 775
11.4.6 The charge: electron and positron carry opposite charge . . . 776
11.4.7 The electron is a mass-m, spin-$\frac{1}{2}$ Poincaré particle . . . 778
11.5 The Dirac Propagator . . . 782
11.5.1 The fermion Wightman functions . . . 784
11.5.2 Time ordering with the fermionic minus sign . . . 786
11.5.3 Assembling S_F from the scalar propagator . . . 787
11.5.4 The momentum-space propagator and the $i\varepsilon$ contour . . . 788
11.5.5 The propagator is the Green's function of the Dirac operator . . . 792
11.6 Microcausality and the Spin–Statistics Theorem . . . 794
11.6.1 The anticommutator function . . . 795
11.6.2 Microcausality of the Dirac field . . . 797
11.6.3 Causality of bilinear observables . . . 798

11.6.4 The spin–statistics connection for spin $\frac{1}{2}$ 801
11.6.5 Completing the general spin–statistics theorem 804
11.7 Discrete Symmetries: C, P, T, and CPT 805
11.7.1 Parity 807
11.7.2 Charge conjugation 809
11.7.3 Time reversal 810
11.7.4 The transformation table of the bilinear covariants 812
11.7.5 Invariance of the Dirac Lagrangian, and the CPT theorem 815
11.7.6 The Majorana condition: a fermion that is its own antiparticle 817

12 Fermionic Path Integrals **821**
12.1 Why fermions need anticommuting integration variables 822
12.1.1 The path integral is an integral over numbers 823
12.1.2 A commuting Gaussian can only make symmetric two-point functions 824
12.1.3 The Pauli sign in multi-fermion amplitudes 826
12.1.4 The classical limit of an anticommuting operator 828
12.1.5 The four properties the fermionic integral must have . . . 829
12.2 Grassmann algebra and Grassmann calculus 830
12.2.1 The Grassmann algebra and its generators 831
12.2.2 Monomials, the basis, and the top form 832
12.2.3 The $\mathbb{Z}_2$ grading: even and odd 834
12.2.4 Grassmann differentiation 835
12.2.5 The canonical anticommutation relations of the calculus . 836
12.2.6 Complex conjugation and the independent conjugate variable 838
12.3 Berezin integration 840
12.3.1 The single variable: uniqueness forces Berezin's rule . . . 841
12.3.2 Several Grassmann variables 843
12.3.3 Change of variables: the inverse determinant 845
12.3.4 The Grassmann delta function 847
12.3.5 Conjugate pairs and reality conventions 848
12.4 Gaussian Grassmann integrals: determinants, Pfaffians, and Wick's theorem 849
12.4.1 The complex Gaussian: $\int e^{-\bar{\theta} A \theta} = \det A$ 850
12.4.2 The real Gaussian and the Pfaffian 854
12.4.3 The sourced generating identity 856
12.4.4 Wick's theorem for Grassmann variables 857

12.5 Fermionic coherent states and the path integral from canonical quantization . . . 860
12.5.1 One fermionic mode . . . 861
12.5.2 Coherent states require Grassmann eigenvalues . . . 861
12.5.3 The resolution of the identity . . . 863
12.5.4 Matrix elements of normal-ordered operators . . . 864
12.5.5 The trace, and where the minus sign comes from . . . 865
12.5.6 Time-slicing: the path integral for one mode . . . 866
12.5.7 The trace, antiperiodicity, and KMS . . . 868
12.5.8 From one mode to the Dirac field . . . 871
12.6 The Dirac generating functional and the fermion propagator . . . 872
12.6.1 The generating functional with Grassmann sources . . . 873
12.6.2 Performing the functional Gaussian integral . . . 873
12.6.3 The momentum-space fermion propagator . . . 875
12.6.4 The two-point function from functional differentiation . . . 876
12.6.5 The fermionic Wick theorem . . . 878
12.7 Functional determinants and the fermion loop . . . 881
12.7.1 The determinant is the exponential of the trace-log . . . 882
12.7.2 The loop expansion: Tr ln as a sum of closed fermion loops 883
12.7.3 The minus sign of a closed fermion loop, two ways . . . 885
12.7.4 The fermion determinant in a background: the one-loop effective action . . . 888
12.7.5 Honest regularization, and the limits of the formal measure 888
12.7.6 The sign made concrete: a single mode . . . 889

13 The Electromagnetic Field **893**
13.1 Maxwell as a Constrained System: The Obstruction to Quantization 894
13.1.1 The frozen photon sector and its conventions . . . 895
13.1.2 The singular Legendre transform and the primary constraint 896
13.1.3 The canonical Hamiltonian . . . 898
13.1.4 Consistency in time and the secondary Gauss constraint . 899
13.1.5 First-class constraints and the gauge generator . . . 900
13.1.6 The degree-of-freedom count . . . 902
13.1.7 Why naive canonical quantization is inconsistent . . . 904
13.2 Canonical Quantization in Coulomb Gauge . . . 905
13.2.1 Completing the gauge fixing: the Coulomb condition . . . 906
13.2.2 The canonical momentum and the obstruction to the naive bracket . . . 907

13.2.3 The transverse delta function . . . 907
13.2.4 The equal-time commutators . . . 908
13.2.5 Mode expansion over two transverse polarizations . . . 910
13.2.6 The Hamiltonian: two transverse oscillators plus the Coulomb energy . . . 912
13.2.7 The photon as a massless helicity-± 1 particle . . . 914
13.3 Covariant Quantization and the Gupta–Bleuler Construction . . 916
13.3.1 The gauge-fixing term and the restored Legendre map . . 917
13.3.2 Covariant equal-time commutators . . . 918
13.3.3 Four polarizations and the indefinite metric . . . 920
13.3.4 The Gupta–Bleuler subsidiary condition . . . 922
13.3.5 Physical states have non-negative norm . . . 923
13.3.6 Zero-norm states decouple . . . 925
13.3.7 The quotient and the isometry to the transverse space . . 926
13.3.8 The weak Lorenz condition and Maxwell's equations in the mean . . . 928
13.4 The Photon Propagator and Its Gauge Dependence . . . 931
13.4.1 The coordinate-space propagator in Feynman gauge . . . 932
13.4.2 The R_ξ family from inverting the quadratic operator . . . 934
13.4.3 Why the operator must be gauge-fixed: the non-invertible limit . . . 936
13.4.4 Gauge independence of physical amplitudes . . . 937
13.4.5 External photons: the polarization sum becomes $-\eta_{\mu\nu}$ . . 939
13.4.6 What has been built, and where the gauge term comes from 941
13.5 The Path Integral, Gauge Orbits, and Abelian Faddeev–Popov . 942
13.5.1 The naive photon path integral and its divergence . . . 942
13.5.2 Gauge orbits and the geometry of the redundancy . . . 944
13.5.3 The Faddeev–Popov identity . . . 946
13.5.4 Factoring out the gauge volume . . . 949
13.5.5 The Gaussian average over ω: origin of the gauge-fixing term 950
13.5.6 The R_ξ propagator from the Gaussian integral . . . 951
13.5.7 The free photon generating functional . . . 952
13.6 Synthesis: Coupling to Matter and the Recovery of the Coulomb Law . . . 954
13.6.1 Minimal coupling and the photon source current . . . 955
13.6.2 Quantum gauge invariance of the coupling, and a word on charge quantization . . . 957

13.6.3 The two routes agree: instantaneous Coulomb plus transverse equals covariant exchange . . . 958
13.6.4 The Coulomb law from one-photon exchange . . . 960
13.6.5 The interacting QED field content, assembled . . . 962

IV Interactions and Perturbation Theory 965

14 Interactions and the S-Matrix 967
14.1 The Interaction Picture and the Dyson Series . . . 968
14.1.1 Splitting the Hamiltonian . . . 969
14.1.2 The interaction picture and the free evolution of fields . . . 970
14.1.3 The interaction-picture evolution equation . . . 972
14.1.4 The Dyson series . . . 973
14.1.5 The group law and formal unitarity . . . 976
14.2 Asymptotic States and the S-Matrix . . . 979
14.2.1 What a scattering experiment prepares and measures . . . 979
14.2.2 In-states, out-states, and the adiabatic hypothesis . . . 980
14.2.3 The S-operator and its matrix elements . . . 982
14.2.4 Unitarity and the conservation of probability . . . 983
14.2.5 The trivial part, the invariant amplitude, and the momentum-conserving delta . . . 984
14.2.6 Honesty about the construction: Haag's theorem . . . 987
14.3 Correlation Functions and the Gell-Mann–Low Theorem . . . 988
14.3.1 From Heisenberg fields to interaction-picture fields . . . 989
14.3.2 Projecting the interacting vacuum from the free vacuum . . . 991
14.3.3 The Gell-Mann–Low formula . . . 993
14.3.4 The denominator removes the vacuum bubbles . . . 996
14.3.5 Reconciliation with the path-integral generating functional 999
14.3.6 Scalar ϕ^4 theory: the four-point correlator set up for Wick expansion . . . 1001
14.4 The Källén–Lehmann Spectral Representation . . . 1003
14.4.1 The spectral hypotheses . . . 1003
14.4.2 Inserting a complete set of states . . . 1004
14.4.3 The Källén–Lehmann representation . . . 1006
14.4.4 The pole, the continuum, and the residue Z . . . 1007
14.4.5 The sum rule and the bound $0 \le Z \le 1$ . . . 1009
14.4.6 Worked examples . . . 1011

14.4.7 Handing the pole to LSZ . . . 1012
14.5 The LSZ Reduction Formula . . . 1013
14.5.1 The asymptotic condition . . . 1013
14.5.2 Inverting the mode expansion . . . 1015
14.5.3 Single-particle reduction . . . 1016
14.5.4 Induction to all legs, and the emergence of time ordering 1018
14.5.5 Momentum space: amputation, poles, and the residue . . 1019
14.5.6 A worked check: one leg, and the disconnected term made explicit . . . 1022
14.5.7 Handoff . . . 1023
14.6 First Interacting Amplitude: $\phi\phi \to \phi\phi$ at $O(\lambda)$ . . . 1024
14.6.1 Assembling the three machines into one recipe . . . 1024
14.6.2 The leading-order four-point correlator . . . 1026
14.6.3 Reading the answer: kinematics, identical particles, and $|\mathcal{M}|^2$ . . . 1031
14.6.4 What the bookkeeping is telling us . . . 1031
14.7 Unitarity and the Optical Theorem . . . 1032
14.7.1 Unitarity in the transition operator . . . 1033
14.7.2 Matrix elements: the invariant amplitude and the sum over states . . . 1034
14.7.3 The generalized optical theorem . . . 1035
14.7.4 The forward amplitude and the total cross section . . . 1037
14.7.5 Partial-wave unitarity . . . 1038
14.7.6 Scalar ϕ^4 theory: the optical theorem to leading order, and where the real check lives . . . 1040

15 Feynman Diagrams **1043**
15.1 Wick's Theorem: Time Ordering as a Sum of Contractions . . . 1044
15.1.1 The contraction of two free fields . . . 1045
15.1.2 Wick's theorem as an operator identity . . . 1047
15.1.3 The vacuum corollary . . . 1049
15.1.4 The generalized theorem: normal-ordered insertions . . . 1050
15.1.5 The four-field case, term by term . . . 1052
15.1.6 Feeding the Dyson series . . . 1052
15.2 From Contractions to Pictures: Position-Space Feynman Rules . 1054
15.2.1 The correlator as a sum of fully contracted products . . . 1055
15.2.2 Reading a contraction as a graph . . . 1056
15.2.3 The combinatorial identity behind the rules . . . 1057

15.2.4 The four-point function at $O(\lambda)$: the tree vertex 1059
15.2.5 The two-point function at $O(\lambda)$: the tadpole 1061
15.2.6 The four-point function at $O(\lambda^2)$ 1062
15.3 Momentum Space, Amputation, and the Tree Amplitude 1064
15.3.1 The propagator in momentum space, and why a diagram is a convolution 1065
15.3.2 Vertex integration generates momentum conservation . . . 1066
15.3.3 Counting the loop integrations: $L = I - V + 1$ 1068
15.3.4 Connected, amputated Green's functions and the LSZ amputation 1070
15.3.5 The carried number: $\phi\phi \to \phi\phi$ at tree level 1072
15.4 Symmetry Factors Done Carefully 1075
15.4.1 Where the combinatorial factors come from 1075
15.4.2 The automorphism group and the counting theorem . . . 1077
15.4.3 A catalogue of symmetry factors from first principles . . . 1079
15.4.4 The one-loop ϕ^4 self-energy, in full 1082
15.5 The Path-Integral Route: Feynman Rules from $Z[J]$ 1084
15.5.1 The generating functional as the source of all diagrams . . 1084
15.5.2 The master formula 1085
15.5.3 The double expansion and how the rules emerge 1087
15.5.4 The four-point function at $O(\lambda)$: the tree diagram 1088
15.5.5 The symmetry factor, for free 1090
15.5.6 The same amplitude two ways 1093
15.6 The Architecture of Perturbation Theory: Connected, Vacuum, Amputated, 1PI 1094
15.6.1 The graph-theoretic vocabulary 1095
15.6.2 Disconnected diagrams exponentiate 1097
15.6.3 $W = -i \ln Z$ generates connected diagrams 1099
15.6.4 Vacuum bubbles and the linked-cluster cancellation 1101
15.6.5 Amputation: stripping the external propagators 1102
15.6.6 One-particle irreducibility and the effective action 1104
15.6.7 The hierarchy and the tree relation 1106
15.7 Fermions and Gauge Fields: Sign Rules and the Fermion Loop . 1109
15.7.1 The directed fermion line 1110
15.7.2 The fermion–boson vertex 1111
15.7.3 The relative sign between exchange diagrams 1113
15.7.4 The closed fermion loop: the -1 and the trace 1115

15.7.5 Worked example: the trace structure of the vacuum-polarization loop . . . 1117

16 Cross Sections, Decay Rates, and Amplitudes 1121

16.1 From amplitude to probability: transition rates and the squared delta function . . . 1122
16.1.1 The transition probability and the squared delta . . . 1123
16.1.2 Box and finite-time regularization . . . 1123
16.1.3 Relativistic normalization and the box dictionary . . . 1126
16.1.4 The master differential transition rate . . . 1128
16.2 Lorentz-invariant phase space . . . 1131
16.2.1 The on-shell single-particle measure . . . 1131
16.2.2 The n-body phase space and its invariance . . . 1133
16.2.3 Two-body phase space in the center-of-momentum frame . 1134
16.2.4 The phase-space recursion . . . 1137
16.3 The decay rate formula . . . 1140
16.3.1 From the rate skeleton to $d\Gamma$: where the $1/2M$ comes from 1141
16.3.2 Width, lifetime, partial widths, and branching ratios . . . 1142
16.3.3 Identical final particles: the $1/n!$ symmetry factor . . . 1144
16.3.4 The two-body width of a particle at rest . . . 1145
16.3.5 A worked decay: a heavy scalar into two light scalars . . . 1146
16.4 The flux factor and the master cross-section formula . . . 1148
16.4.1 The operational definition of a cross section . . . 1149
16.4.2 Assembling $d\sigma$ from the box rate . . . 1149
16.4.3 The covariant Møller flux and the proof of equality . . . 1152
16.4.4 The centre-of-momentum reduction . . . 1153
16.4.5 The master differential cross section . . . 1154
16.5 Two-to-two kinematics: Mandelstam variables and physical regions 1156
16.5.1 The Mandelstam invariants . . . 1157
16.5.2 Centre-of-mass kinematics and the Källén function . . . 1158
16.5.3 The scattering angle and the physical t-range . . . 1160
16.5.4 The two standard differential cross sections . . . 1161
16.5.5 The Mandelstam plane and the three channels . . . 1163
16.5.6 Worked kinematics . . . 1164
16.6 Worked computation: $\phi\phi \to \phi\phi$ scattering in $\lambda\phi^4$ . . . 1166
16.6.1 The amplitude and its square . . . 1166
16.6.2 Kinematics: the centre-of-mass momentum and the threshold 1167
16.6.3 The differential cross section . . . 1168

16.6.4 The total cross section and the identical-particle factor . . 1168
16.6.5 What the next order brings 1171
16.7 Unitarity, the optical theorem as a cross section, and partial waves 1172
16.7.1 From operator unitarity to a relation between cross sections 1173
16.7.2 Partial waves and the unitarity bound on cross sections . 1175
16.7.3 Scalar ϕ^4 theory: closing the stage with a unitarity self-check 1177

V Quantum Electrodynamics 1181

17 QED: Feynman Rules and First Processes 1183
17.1 The QED Lagrangian and its Feynman rules 1184
17.1.1 The gauge-fixed Lagrangian and the perturbative expansion 1185
17.1.2 The interaction vertex 1186
17.1.3 Internal lines: the propagators 1189
17.1.4 External lines: LSZ amputation and the wavefunction factors 1190
17.1.5 Fermion sign bookkeeping: loops and exchange 1192
17.1.6 Gauge independence of tree amplitudes and the tree-level Ward identity 1195
17.1.7 The QED rulebook assembled 1197
17.2 Spin sums, polarization sums, and trace technology 1198
17.2.1 The spin-averaged squared amplitude 1199
17.2.2 The completeness (spin-sum) relations 1199
17.2.3 Casimir's trick: from a squared bilinear to a trace 1201
17.2.4 The trace toolkit, instantiated 1202
17.2.5 Photon polarization sums and the $-\eta_{\mu\nu}$ replacement . . . 1204
17.2.6 The recipe 1206
17.3 Electron–positron annihilation to muons 1208
17.3.1 The amplitude from the rulebook 1208
17.3.2 Squaring and spin-averaging 1209
17.3.3 Evaluating the traces 1211
17.3.4 Mandelstam form 1212
17.3.5 The high-energy cross section 1213
17.3.6 Keeping the muon mass: the threshold factor 1214
17.4 Crossing symmetry and the t-channel 1216
17.4.1 Crossing symmetry as analytic continuation 1217
17.4.2 From the s-channel to the t-channel: identifying the crossed process 1219

17.4.3 Spin averaging and kinematic prefactors under crossing . 1220
17.4.4 Deriving the t-channel squared amplitude by trace continuation . . . 1221
17.4.5 Verification: positivity, the forward pole, and the high-energy limit . . . 1224
17.5 Electron–muon scattering and the Rutherford limit . . . 1225
17.5.1 The amplitude and its squared form . . . 1226
17.5.2 Consistency with the s-channel by crossing . . . 1227
17.5.3 Laboratory kinematics . . . 1228
17.5.4 From the squared amplitude to $d\sigma/d\Omega$ . . . 1229
17.5.5 The static-source limit: the Mott cross section . . . 1230
17.5.6 The nonrelativistic limit: the Rutherford formula . . . 1232
17.5.7 The $1/q^4$ as the Coulomb potential . . . 1232
17.6 Helicity structure and the high-energy limit . . . 1235
17.6.1 Chirality is conserved at the QED vertex . . . 1235
17.6.2 From chirality to the helicities of the external states . . . 1237
17.6.3 The nonzero helicity amplitudes, computed . . . 1238
17.6.4 The angular law from angular momentum: Wigner d-functions . . . 1241
17.6.5 Toward spinor-helicity: the covariant bookkeeping . . . 1244

18 Elementary QED Processes 1247
18.1 Anatomy of a tree-level QED amplitude . . . 1248
18.1.1 The QED Feynman rules, recalled . . . 1249
18.1.2 Three structural novelties . . . 1251
18.1.3 Two organizing principles . . . 1252
18.1.4 Kinematics and the cross-section wrapper . . . 1253
18.1.5 The averaged squared amplitude: the chapter's master formula . . . 1254
18.1.6 From spin sums to Dirac traces . . . 1256
18.1.7 Roadmap: which process exercises which feature . . . 1258
18.2 The tree-level Ward identity and photon polarization sums . . . 1259
18.2.1 The stripped amplitude and the statement of the identity 1260
18.2.2 Proof of the tree-level Ward identity . . . 1261
18.2.3 The canonical illustration: the Compton amplitude . . . 1264
18.2.4 Physical polarizations and the covariant completeness identity 1266
18.2.5 The polarization-sum replacement . . . 1267
18.3 Compton scattering and the Klein–Nishina formula . . . 1269

18.3.1 The two diagrams and the amplitude 1270
18.3.2 The explicit Ward-identity check 1271
18.3.3 Squaring: spin sums, polarization sums, and the traces . . 1273
18.3.4 Mandelstam form and Compton kinematics 1276
18.3.5 The lab-frame phase space and the Klein–Nishina formula 1277
18.4 Crossing symmetry and pair annihilation 1280
18.4.1 The crossing dictionary, completed for external photons . 1281
18.4.2 The fermion crossing sign for an odd number of crossed lines 1283
18.4.3 Compton and annihilation on the Mandelstam plane . . . 1284
18.4.4 $e^+e^- \to \gamma\gamma$ from Klein–Nishina 1286
18.4.5 The cross section and the identical-photon factor 1289
18.4.6 The crossing web of Chapter 18 1291
18.5 Møller and Bhabha scattering 1292
18.5.1 The Møller amplitude and the Fermi sign 1293
18.5.2 The unpolarized Møller cross section 1294
18.5.3 Bhabha scattering: annihilation plus scattering 1297
18.5.4 Bhabha as a crossing of Møller 1299
18.5.5 Differential cross sections and the Coulomb limit 1300
18.6 Polarized amplitudes, helicity, and the high-energy limit 1303
18.6.1 The spin projection operator 1303
18.6.2 Helicity, chirality, and the massless limit 1306
18.6.3 The helicity-conservation selection rule 1307
18.6.4 The helicity amplitudes of $e^+e^- \to \mu^+\mu^-$ 1309
18.6.5 Angular distributions and forward–backward structure . . 1312
18.7 Synthesis: the QED tree amplitude as one analytic object 1313
18.7.1 Tree amplitudes as boundary values of analytic functions 1314
18.7.2 The crossing web 1315
18.7.3 The Ward identity as the constraint that holds it together 1319
18.7.4 Forward map: loops, infrared structure, precision, and the on-shell viewpoint 1320

19 Radiative Corrections **1325**
19.1 Regularization and the One-Loop Program 1326
19.1.1 The three one-particle-irreducible building blocks 1327
19.1.2 Why a momentum cutoff fails and the regulator must be chosen 1328
19.1.3 The loop measure in $d = 4 - 2\varepsilon$ dimensions 1330
19.1.4 Combining denominators: the Feynman parametrization . 1331

19.1.5 Wick rotation and the scalar master integral 1333
19.1.6 Renormalized perturbation theory and the counterterms . 1335
19.2 Vacuum Polarization 1338
19.2.1 The amplitude and the fermion-loop sign 1339
19.2.2 The Dirac trace 1340
19.2.3 Feynman parametrization and the loop shift 1341
19.2.4 The loop integrals and the quadratic-divergence cancellation 1342
19.2.5 Transversality and the result for the scalar form factor . . 1343
19.2.6 On-shell renormalization and Z_3 1345
19.2.7 The two ends of the form factor 1346
19.2.8 Analytic structure: the cut at $q^2 = 4m^2$ and the imaginary part 1347
19.3 The Electron Self-Energy 1350
19.3.1 The amplitude and its Dirac decomposition 1351
19.3.2 On-shell renormalization: δm and Z_2 1354
19.3.3 The infrared divergence 1357
19.3.4 The renormalized propagator near its pole 1359
19.4 The Vertex Correction 1360
19.4.1 The one-loop vertex amplitude 1360
19.4.2 Form factors: the only two structures 1362
19.4.3 Feynman parametrization and the loop shift 1363
19.4.4 The ultraviolet divergence and the Dirac form factor . . . 1364
19.4.5 The convergent numerator and $Z_1 = Z_2$ 1366
19.4.6 The Pauli form factor and the bridge to $g - 2$ 1368
19.5 The Ward–Takahashi Identity 1370
19.5.1 From a conservation law to a quantum identity 1371
19.5.2 The generating-functional proof 1373
19.5.3 The diagrammatic proof at one loop 1375
19.5.4 The on-shell Ward identity as a corollary 1376
19.5.5 Corollary: $Z_1 = Z_2$ to all orders 1377
19.5.6 Corollary: charge renormalization lives in the photon . . . 1379
19.5.7 Closing the loop: the one-loop identity verified 1380
19.6 Infrared Divergences and Their Cancellation 1382
19.6.1 The surviving infrared divergences and the choice of regulator 1382
19.6.2 The virtual correction and the Sudakov double logarithm 1384
19.6.3 Real soft emission: the eikonal factor from the Ward identity 1385
19.6.4 The cancellation 1388
19.6.5 All orders: Bloch–Nordsieck, KLN, and exponentiation . . 1390

20 Precision QED **1393**

20.1 The Magnetic Moment and the Form Factors 1394
20.1.1 The on-shell electromagnetic vertex and what its two form factors mean 1395
20.1.2 Dirac's prediction: $g = 2$ from the squared Dirac equation 1398
20.1.3 From the form factors to the moment: $g = 2[F_1(0) + F_2(0)]$ 1400
20.1.4 The tree value, the radiative target, and the next step . . 1403
20.2 Setting Up Schwinger's Computation 1404
20.2.1 The one-loop vertex as a single three-propagator integral 1405
20.2.2 Feynman-combining the three denominators 1406
20.2.3 The numerator: symmetric integration and Dirac contraction 1407
20.2.4 Reducing the numerator on shell 1409
20.2.5 From $(p' + p)^\mu$ to $i\sigma^{\mu\nu}q_\nu$: the F_2 integrand 1411
20.3 Schwinger's Result: $a_e = \alpha/2\pi$ 1413
20.3.1 Ultraviolet finiteness: no counterterm is needed 1414
20.3.2 The loop integral done: the Pauli form factor 1415
20.3.3 Infrared finiteness: why F_2, unlike F_1, needs no regulator 1417
20.4 Beyond One Loop: the Precision Frontier of g-2 1419
20.4.1 The perturbative series for the anomaly 1420
20.4.2 The electron anomaly as a measurement of α 1422
20.4.3 Why the muon: the $(m_\ell/M)^2$ lever 1425
20.4.4 Anatomy of a_μ and the 2021–2025 status 1428
20.5 The Lamb Shift 1431
20.5.1 The Dirac degeneracy and the fact of its lifting 1432
20.5.2 Three radiative origins, three one-loop functions 1433
20.5.3 Welton's heuristic: the vacuum smears the electron 1434
20.5.4 The Bethe logarithm and the infrared cutoff 1438
20.5.5 Vacuum polarization: the Uehling contribution 1440
20.5.6 The anomalous moment and the vertex contribution . . . 1441
20.5.7 The sum, and what it teaches 1442
20.6 The Running of the Fine-Structure Constant 1444
20.6.1 Resumming the vacuum-polarization insertions 1444
20.6.2 The effective charge 1446
20.6.3 Leading-log running 1447
20.6.4 The Uehling potential and the screening picture 1448
20.6.5 The dispersive representation and the measured running . 1453
20.6.6 Handoff to the renormalization group 1454

VI Renormalization and the Renormalization Group 1457

21 The Origin of Divergences 1459

21.1 Where the Infinities Come From: Short-Distance Singularities . . 1460
21.1.1 Divergences live in loops, at large momentum 1461
21.1.2 The same divergence in position space: colliding vertices . 1462
21.1.3 Regulator independence of the degree 1464
21.1.4 The superficial degree of divergence as a working tool . . 1467
21.2 Power Counting: The Superficial Degree of Divergence of a Diagram 1469
21.2.1 The combinatorial data of a diagram 1470
21.2.2 The loop identity 1470
21.2.3 The degree of divergence as a topological integer 1472
21.2.4 Leg counting 1472
21.2.5 The master formula for the scalar thread 1473
21.2.6 Engineering dimensions of the fields 1476
21.2.7 The dimension-explicit master formula 1477
21.2.8 The QED count 1479
21.3 Engineering Dimensions and the Classification of Interactions . . 1481
21.3.1 Mass dimensions of fields and couplings 1482
21.3.2 The dimension-explicit power-counting theorem 1483
21.3.3 Verifying the formula 1485
21.3.4 The trichotomy: super-renormalizable, renormalizable, non-renormalizable 1486
21.3.5 Renormalizability $\iff$ finitely many divergent amplitudes 1488
21.3.6 The critical dimension and a table across d 1489
21.3.7 The dimensional-regularization corollary and the birth of μ 1491
21.4 The Locality of Divergences and the Renormalizable Miracle . . . 1493
21.4.1 The locality theorem 1493
21.4.2 The two divergent amplitudes of ϕ^4 1497
21.4.3 The divergent structures of QED 1499
21.4.4 The renormalizable miracle, stated precisely 1501
21.5 When Superficial Counting Lies: Subdivergences and Weinberg's Theorem 1503
21.5.1 Subdiagrams and the degree of divergence of a sub-integration 1503
21.5.2 The failure mode: a convergent-looking integral that diverges 1505
21.5.3 Classification: disjoint, nested, and overlapping subdivergences 1506

21.5.4 Worked diagnosis of the sunset: superficial counting versus the truth . . . 1508
21.5.5 A logarithmic subdivergence makes a double logarithm . . 1510
21.5.6 Weinberg's convergence theorem . . . 1511
21.5.7 The forest structure, handed to the next chapter . . . 1514
21.6 Scalar ϕ^4 theory: The One-Loop Divergences in Full . . . 1515
21.6.1 The two amplitudes and what power counting predicts of them . . . 1516
21.6.2 The four-point function: three bubbles and a logarithm . 1517
21.6.3 The two-point function: a momentum-independent tadpole 1520
21.6.4 The numbers, staged for handoff . . . 1523
21.7 What the Divergences Are Telling Us . . . 1524
21.7.1 A divergence is sensitivity to the unknown . . . 1525
21.7.2 The trichotomy in Wilsonian language . . . 1526
21.7.3 Insensitivity made precise: absorbing the cutoff . . . 1528
21.7.4 Non-renormalizable theories are effective field theories . . 1530
21.7.5 Scalar ϕ^4 theory: marginality and what the loop decides . 1531
21.7.6 What remains genuinely open . . . 1532

22 Renormalization Theory 1535
22.1 The Renormalization Program: Bare Parameters and Counterterms 1536
22.1.1 The bare Lagrangian: parameters no experiment measures 1537
22.1.2 Renormalized field and parameters: the multiplicative redefinition . . . 1538
22.1.3 Re-expressing the bare Lagrangian: the counterterm split 1539
22.1.4 Feynman rules for the counterterms . . . 1541
22.1.5 The renormalization principle: finiteness order by order . 1544
22.2 Renormalization Conditions and the One-Loop ϕ^4 Counterterms 1546
22.2.1 What a renormalization condition is . . . 1547
22.2.2 The one-loop self-energy: the tadpole . . . 1549
22.2.3 The one-loop four-point: the s, t, u bubbles . . . 1551
22.2.4 On-shell versus $\overline{\text{MS}}$: finite parts and scheme independence 1553
22.2.5 Finiteness of the renormalized Green's functions . . . 1554
22.3 Multiplicative Renormalization and Renormalized Green's Functions 1556
22.3.1 Bare quantities, renormalized quantities, and the rescaling 1556
22.3.2 The rescaling reproduces the counterterm Lagrangian . . 1558
22.3.3 The bare and renormalized generating functionals . . . 1559
22.3.4 What renormalizability says, exactly . . . 1563

22.3.5 One-loop consistency check . . . 1564
22.3.6 Independence of bare quantities from μ: the seed of the renormalization group . . . 1566
22.4 Subdivergences, Nested and Overlapping Divergences . . . 1567
22.4.1 Why locality is the whole game . . . 1568
22.4.2 The anatomy of multi-loop divergences: a classification . . . 1569
22.4.3 A two-loop four-point diagram and the nonlocal divergence 1570
22.4.4 Subdivergence subtraction restores locality . . . 1573
22.4.5 The overlapping case: the two-loop self-energy . . . 1575
22.5 BPHZ Subtraction and Zimmermann's Forest Formula . . . 1578
22.5.1 The objects: subgraphs, renormalization parts, and reduced graphs . . . 1579
22.5.2 The Taylor subtraction operator . . . 1580
22.5.3 Bogoliubov's recursion . . . 1581
22.5.4 Forests and the forest formula . . . 1582
22.5.5 Equivalence of the recursion and the forest formula . . . 1583
22.5.6 Locality of the counterterms . . . 1586
22.5.7 Convergence of the renormalized integrand . . . 1587
22.5.8 The R-operation on a two-loop ϕ^4 graph . . . 1590
22.6 Renormalizability of ϕ^4 to All Orders . . . 1592
22.6.1 The renormalizability criterion . . . 1593
22.6.2 The power-counting input: a finite divergent menu . . . 1594
22.6.3 The all-orders theorem and its inductive proof . . . 1595
22.6.4 Why δ_Z is needed, and from which order . . . 1599
22.6.5 Honest scoping: what "renormalizable to all orders" does and does not mean . . . 1601
22.7 Renormalizability of QED and Charge Universality . . . 1602
22.7.1 Power counting in QED . . . 1603
22.7.2 Gauge invariance I: transversality forbids a photon mass . 1605
22.7.3 Gauge invariance II: light-by-light is finite . . . 1606
22.7.4 The four renormalization constants and the counterterm Lagrangian . . . 1607
22.7.5 The Ward–Takahashi identity and $Z_1 = Z_2$ . . . 1608
22.7.6 Charge renormalization and universality . . . 1610
22.7.7 Renormalizability of QED to all orders . . . 1612

23 The Wilsonian Renormalization Group **1615**

23.1 The Cutoff as Part of the Definition: Theory Space 1616

23.1.1 The Euclidean path integral with a momentum cutoff . . 1617

23.1.2 The Wilsonian effective action 1620

23.1.3 Theory space 1622

23.1.4 The bare action as a point; lowering the cutoff as a trajectory 1624

23.1.5 Re-reading the divergences of Chapter 21: insensitivity to the UV completion 1625

23.2 Integrating Out a Momentum Shell: The Wilson Effective Action 1627

23.2.1 The field split and the exact integrating-out formula . . . 1628

23.2.2 Splitting the action: the Gaussian core and the mixing vertices 1630

23.2.3 The cumulant expansion and the linked-cluster theorem . 1631

23.2.4 The mass correction: the shell tadpole 1632

23.2.5 The coupling correction: the shell bubble 1633

23.2.6 Newly generated operators, and why they are small . . . 1635

23.2.7 Stacking shells: recovering the full one-loop results 1637

23.3 Rescaling and the Renormalization-Group Transformation 1639

23.3.1 The rescaling step 1640

23.3.2 Dimensionless couplings and the engineering flow 1641

23.3.3 The differential flow 1643

23.3.4 The anomalous dimension 1646

23.4 The Exact Renormalization Group Equation 1648

23.4.1 The cutoff effective action 1649

23.4.2 The Wegner–Houghton sharp-cutoff equation 1650

23.4.3 The Polchinski smooth-cutoff equation 1652

23.4.4 The structure of the equation 1655

23.4.5 Recovering the perturbative shell flow 1656

23.4.6 Why renormalizability follows from the equation 1659

23.5 Fixed Points and the Linearized Flow: Relevant, Marginal, Irrelevant 1661

23.5.1 Theory space, the flow, and its fixed points 1662

23.5.2 Linearizing the flow 1664

23.5.3 Scaling dimensions and the relation $y_i = d - \Delta_i$ 1665

23.5.4 The trichotomy 1667

23.5.5 Scalar ϕ^4 theory: classifying the operators at the Gaussian fixed point 1669

23.5.6 The marginal case decided: λ is marginally irrelevant . . . 1671

23.6 Universality, Critical Surfaces, and the Continuum Limit 1673
23.6.1 The renormalization-group flow, recalled in working form 1673
23.6.2 Universality: the forgetting of irrelevant couplings 1674
23.6.3 Critical surfaces and universality classes 1676
23.6.4 The correlation length and its divergence 1677
23.6.5 Critical exponents as universal data of a fixed point . . . 1679
23.6.6 The continuum limit and the renormalized trajectory . . . 1682
23.6.7 Scalar ϕ^4 theory: the prototype critical system 1684
23.7 The Modern Meaning of Renormalizability and the Wilson–Fisher Fixed Point 1686
23.7.1 Renormalizability, re-read 1687
23.7.2 The Wilson–Fisher mechanism 1689
23.7.3 Critical exponents and the status of the result 1694

24 The Callan–Symanzik Equation and Running Couplings 1699
24.1 Scale Independence as a Symmetry: The Renormalization-Group Equation 1700
24.1.1 The bare theory does not know what the subtraction scale is 1701
24.1.2 The three functions that drive scale dependence 1702
24.1.3 The renormalization-group equation for renormalized 1PI functions 1704
24.1.4 The dimensional-regularization route and 't Hooft's pole equation 1707
24.2 ϕ^4 theory: The One-Loop Beta Function and Anomalous Dimensions 1713
24.2.1 Renormalized perturbation theory and the counterterms to be determined 1714
24.2.2 The one-loop four-point function and the factor of three . 1715
24.2.3 The two-point function: a momentum-independent tadpole 1717
24.2.4 Assembling the beta function and the mass running . . . 1720
24.2.5 Where the field anomalous dimension first appears 1722
24.3 QED: Charge Renormalization, the Ward Identity, and β_e 1724
24.3.1 The structure of charge renormalization: $Z_e = Z_1 Z_2^{-1} Z_3^{-1/2}$ 1725
24.3.2 The Ward–Takahashi identity collapses the charge to the photon 1726
24.3.3 Importing Z_3 and extracting β_e 1728
24.3.4 Field and mass anomalous dimensions of the electron . . . 1732
24.3.5 A dispersive cross-check of the sign and coefficient of β_α . 1733
24.4 What Is Universal: Scheme Dependence of the Beta Function . . 1736

24.4.1 Scheme change as an analytic reparametrization of the coupling . . . 1737
24.4.2 The transformation law for the beta function . . . 1738
24.4.3 the benchmark theories: b_0 as a physical prediction . . . 1742
24.4.4 Fixed points: the location moves, existence and slope do not 1743
24.4.5 Contact with a measurable effective charge . . . 1745
24.4.6 What is convention and what is not . . . 1747
24.5 The Callan–Symanzik Equation: Broken Scale Invariance and the Trace Anomaly . . . 1749
24.5.1 Classical scale invariance and the trace of the stress tensor 1750
24.5.2 Quantization breaks scale invariance: the trace anomaly . 1751
24.5.3 The Callan–Symanzik equation from broken scale invariance 1753
24.5.4 Soft operator insertions and the inhomogeneous form . . . 1755
24.5.5 The large-momentum limit and equivalence to the RG equation . . . 1758
24.6 Solving the Renormalization Group: Running Couplings and Anomalous Scaling . . . 1760
24.6.1 The renormalization-group equation as a transport equation 1761
24.6.2 The running coupling and the method of characteristics . 1762
24.6.3 Reinstating the mass: the running mass . . . 1764
24.6.4 From scale running to momentum running . . . 1765
24.6.5 Anomalous scaling near a fixed point . . . 1766
24.6.6 Scalar ϕ^4 theory: the running quartic coupling . . . 1768
24.6.7 QED: the running fine-structure constant . . . 1769
24.6.8 Solving the RG is summing the leading logarithms . . . 1772
24.7 Asymptotic Behavior: Fixed Points, Landau Poles, Triviality, and Asymptotic Freedom . . . 1773
24.7.1 Fixed points and the linearized flow . . . 1774
24.7.2 Landau poles and the triviality problem . . . 1777
24.7.3 The opposite sign: asymptotic freedom previewed . . . 1780
24.7.4 Anomalous dimension at a fixed point: the critical exponent η 1782
24.7.5 The Wilson–Fisher fixed point in $d = 4 - \varepsilon$ . . . 1784

VII Non-Abelian Gauge Theories **1789**

25 Yang–Mills Theory **1791**
25.1 The Non-Abelian Gauge Principle . . . 1792

25.1.1 Matter in a representation of a compact group 1793
25.1.2 Localizing the symmetry: the matrix Leibniz obstruction 1795
25.1.3 No field redefinition repairs it: a connection is forced . . . 1796
25.1.4 Local invariance is a redundancy, not a new conservation law 1799
25.2 The Gauge Connection and Its Transformation Law 1800
25.2.1 The Lie-algebra-valued connection 1800
25.2.2 The finite transformation law 1801
25.2.3 Linearization: the infinitesimal law and the adjoint covariant derivative 1803
25.2.4 The abelian limit 1805
25.2.5 The connection is not a tensor 1806
25.2.6 Consistency: gauge transformations compose 1807
25.2.7 The transformation law for SU(2): a connection as an isovector 1808
25.3 Curvature: The Non-Abelian Field Strength 1809
25.3.1 The field strength as the commutator of covariant derivatives 1809
25.3.2 Covariant, not invariant: the transformation law of F . . 1812
25.3.3 The geometric picture: curvature and the non-abelian holonomy 1814
25.3.4 The non-abelian Bianchi identity 1816
25.4 The Yang–Mills Lagrangian and Field Equations 1819
25.4.1 The kinetic term: why the trace 1819
25.4.2 Minimal coupling and the model 1823
25.4.3 The Yang–Mills equations of motion 1823
25.4.4 Covariant versus ordinary conservation: the gluon is coloured 1825
25.5 Self-Interaction: The Gluon Vertices 1828
25.5.1 Splitting the field strength 1829
25.5.2 The full expansion 1829
25.5.3 What the three pieces are 1831
25.5.4 The interactions are forced: a gauge-variation conspiracy 1833
25.6 Wilson Lines, Wilson Loops, and Gauge-Invariant Observables . 1836
25.6.1 The non-abelian comparator and parallel transport 1837
25.6.2 The path-ordered exponential and why ordering is forced 1838
25.6.3 The transformation law and gauge invariance by tracing . 1840
25.6.4 The Wilson loop 1843
25.6.5 Small loops: the curvature recovered 1843
25.6.6 The non-abelian Stokes/holonomy picture 1847

25.6.7 The Wilson loop as confinement order parameter 1848
25.7 Gauge Orbits and the Global Structure of Configuration Space . 1849
25.7.1 The space of connections and its quotient 1850
25.7.2 Small and large gauge transformations 1851
25.7.3 The winding-number functional 1853
25.7.4 Why gauge fixing is mandatory — and subtle 1857
25.7.5 The classical theory is exact; the quantum theory is not yet defined 1859

26 Quantization of Yang–Mills 1861
26.1 The Obstruction: Why Naive Non-Abelian Quantization Fails . . 1862
26.1.1 The naive generating functional and the volume of the gauge group 1863
26.1.2 The Faddeev–Popov resolution of unity, non-abelian . . . 1864
26.1.3 The Faddeev–Popov operator in Lorenz gauge 1867
26.1.4 The honest caveat: the Gribov ambiguity 1870
26.2 The Faddeev–Popov Determinant and the Ghost Lagrangian . . 1871
26.2.1 Exponentiating the determinant: ghosts as a Grassmann Gaussian 1872
26.2.2 Why the ghosts must be anticommuting 1874
26.2.3 The ghost Lagrangian and the ghost–gluon vertex 1875
26.2.4 Averaging over the gauge slice: the R_ξ gauge-fixing term . 1877
26.2.5 Assembly: the complete gauge-fixed Yang–Mills Lagrangian 1879
26.3 Feynman Rules of Gauge-Fixed Yang–Mills 1880
26.3.1 Conventions for reading off a vertex 1881
26.3.2 The gluon propagator 1882
26.3.3 The ghost propagator 1883
26.3.4 The three-gluon vertex 1884
26.3.5 The four-gluon vertex 1886
26.3.6 The ghost-gluon vertex 1887
26.3.7 The quark-gluon vertex 1889
26.3.8 The closed-ghost-loop sign 1890
26.4 Ghosts and Unitarity 1891
26.4.1 Why the naive polarization sum fails for gluons 1892
26.4.2 The non-abelian Ward identity for two gluons 1893
26.4.3 The physical polarization sum and the ghost subtraction . 1896
26.4.4 Unitarity, the cut, and the role of the ghost 1898
26.4.5 Why diagram-by-diagram cancellation is not enough . . . 1900

26.5 BRST Symmetry . . . 1901
26.5.1 The Nakanishi–Lautrup field . . . 1902
26.5.2 The BRST transformation . . . 1903
26.5.3 Off-shell nilpotency: $s^2 = 0$ . . . 1904
26.5.4 The gauge-fixing and ghost sector is BRST-exact . . . 1907
26.5.5 The conserved BRST current and charge . . . 1909
26.6 Physical States from BRST Cohomology . . . 1911
26.6.1 The physical Hilbert space as a cohomology . . . 1912
26.6.2 Gauge-invariant observables are BRST-closed . . . 1914
26.6.3 The asymptotic free-field BRST algebra and the quartet . . . 1916
26.6.4 Positivity on the cohomology: the quartet decouples . . . 1919
26.6.5 Unitarity of the physical S-matrix . . . 1921
26.6.6 The abelian limit: recovering Gupta–Bleuler . . . 1922
26.6.7 Corollary: gauge-parameter independence of physical amplitudes . . . 1923
26.7 Slavnov–Taylor Identities . . . 1924
26.7.1 The master identity from BRST invariance of the path integral . . . 1925
26.7.2 Sources for composite variations: the Zinn-Justin construction . . . 1927
26.7.3 Transversality of the gluon self-energy . . . 1929
26.7.4 Renormalization-constant relations and the universal coupling . . . 1932

27 Asymptotic Freedom **1937**
27.1 The Sign Question and the Renormalization Strategy . . . 1938
27.1.1 What the sign decides . . . 1939
27.1.2 Reducing the chapter to one renormalization constant . . . 1941
27.1.3 The one-loop master formula: b_0 from a residue . . . 1942
27.1.4 The finite checklist, and which route to take . . . 1944
27.2 The Gluon Self-Energy at One Loop . . . 1947
27.2.1 Definitions, kinematics, and the divergence we are after . . . 1948
27.2.2 The quark loop: the QED bubble in color . . . 1950
27.2.3 The gluon loop . . . 1952
27.2.4 The gluon tadpole (seagull) . . . 1954
27.2.5 The ghost loop . . . 1955
27.2.6 Assembly, transversality, and Z_3 . . . 1956
27.2.7 Gauge dependence and what comes next . . . 1958

27.3 Quark Self-Energy, the Vertex, and the Failure of $Z_1 = Z_2$ 1959
27.3.1 The quark self-energy and Z_2 1960
27.3.2 The quark–gluon vertex: two graphs 1961
27.3.3 The failure of $Z_1 = Z_2$ and what it buys 1965
27.4 The Yang–Mills Beta Function 1967
27.4.1 Assembling Z_g from the three constants 1968
27.4.2 The one-loop beta function and the coefficient b_0 1969
27.4.3 Background-field cross-check: gauge invariance made manifest 1972
27.5 Asymptotic Freedom and Antiscreening 1978
27.5.1 Integrating the one-loop flow 1979
27.5.2 The mirror of screening: QED against QCD 1981
27.5.3 Why only non-abelian gauge theories: the Coleman–Gross theorem 1983
27.5.4 The physics of antiscreening: the paramagnetic vacuum . 1985
27.5.5 The license for perturbation theory 1990
27.6 The Running Coupling, Dimensional Transmutation, and Λ_{QCD} . 1991
27.6.1 From the beta function to the running coupling 1991
27.6.2 Dimensional transmutation and the scale Λ_{QCD} 1993
27.6.3 The SU(3) numbers 1997
27.6.4 Infrared honesty: the Landau pole and the failure of perturbation theory 1999
27.6.5 Loss of asymptotic freedom and the conformal window . . 2000
27.7 Confinement as a Statement: The Wilson-Loop Criterion 2002
27.7.1 The Wilson loop as an order parameter 2003
27.7.2 A rectangular loop measures the static potential 2004
27.7.3 Area law if and only if linear confinement 2007
27.7.4 Where the area law is proved: strong-coupling lattice gauge theory 2009
27.7.5 Honest scope: proved, evidenced, and open 2011
27.7.6 From running coupling to confinement: the boundary of perturbation theory 2013

28 QCD Phenomenology **2015**
28.1 Color Bookkeeping: The Group Theory of QCD Amplitudes . . . 2016
28.1.1 Where color enters: vertices, indices, and the two sums . . 2017
28.1.2 The master identity: completeness of the generators . . . 2018
28.1.3 The three constants as corollaries 2020

28.1.4 Color in cross sections: averaging in, summing out 2022
28.2 e^+e^- Annihilation to Hadrons and the R-Ratio 2024
28.2.1 Why the totally inclusive rate is calculable 2025
28.2.2 From muons to quarks: the partonic cross section 2026
28.2.3 The R-ratio and its threshold staircase 2028
28.2.4 The leading QCD correction and why it is finite 2029
28.2.5 Two readings of one measurement 2031
28.3 Deep Inelastic Scattering and the Parton Model 2032
28.3.1 The process and its kinematics 2033
28.3.2 The leptonic and hadronic tensors 2035
28.3.3 The structure-function decomposition 2036
28.3.4 The inclusive cross section 2038
28.3.5 The parton model and the impulse approximation 2040
28.3.6 The Callan–Gross relation and the spin of the partons . . 2042
28.3.7 The momentum sum rule and the discovery of gluons . . . 2044
28.3.8 Weak currents: the third structure function 2046
28.4 Scaling Violations and the DGLAP Equations 2047
28.4.1 The origin of the logarithm: collinear gluon emission . . . 2048
28.4.2 The quark splitting function P_{qq} 2049
28.4.3 The plus prescription and quark-number conservation . . 2051
28.4.4 The full set of splitting functions 2053
28.4.5 The DGLAP equations 2055
28.5 Factorization and the QCD-Improved Parton Model 2058
28.5.1 The factorization theorem 2059
28.5.2 The one-loop demonstration: a collinear pole becomes a parton distribution 2061
28.5.3 Cancellation of the factorization scale 2065
28.5.4 The second pillar: Drell–Yan 2066
28.6 Infrared Safety, Jets, and the Measurement of α_s 2069
28.6.1 The three-parton process $e^+e^- \to q\bar{q}g$ 2070
28.6.2 Dimensional regularization of the real emission 2072
28.6.3 The virtual correction and the cancellation 2075
28.6.4 The infrared-safety criterion 2076
28.6.5 The Sterman–Weinberg two-jet cross section 2078
28.6.6 Event shapes: thrust 2079
28.6.7 Sequential-recombination jet algorithms 2080
28.6.8 Measuring α_s and the running coupling 2082

VIII Spontaneous Symmetry Breaking 2087

29 Spontaneous Symmetry Breaking and Goldstone Theorem 2089

29.1 Vacuum Degeneracy and the Meaning of Spontaneous Breaking . 2090
29.1.1 Symmetry of the dynamics versus symmetry of the vacuum 2091
29.1.2 Scalar ϕ^4 theory in the broken phase: the double well . . 2092
29.1.3 The order-parameter criterion 2095
29.1.4 The symmetric superposition, and why it is not the answer 2097
29.1.5 Finite versus infinite volume: the vanishing of the tunneling splitting 2098
29.1.6 Cluster decomposition selects the pure vacua 2101
29.2 Continuous Breaking and the Linear Sigma Model: Massless Modes Appear 2104
29.2.1 From two vacua to a circle of them: the abelian complex scalar 2105
29.2.2 Why the flat direction is exactly flat: orbits of the symmetry 2109
29.2.3 The O(N) linear sigma model 2112
29.2.4 The current between the vacuum and the Goldstone: the decay constant 2116
29.3 Goldstone's Theorem 2118
29.3.1 Hypotheses, and a subtlety about the charge 2119
29.3.2 Statement of the theorem 2121
29.3.3 First proof: the current–field spectral representation . . . 2121
29.3.4 The Goldstone boson is spinless 2125
29.3.5 Counting: one boson per broken generator 2126
29.3.6 Second proof: curvature of the effective potential 2129
29.3.7 Scope: where the theorem holds, and where it does not . 2130
29.4 The Effective Potential and Radiative Symmetry Breaking 2131
29.4.1 Definition: the effective potential as the constant-field effective action 2132
29.4.2 What the effective potential computes: vacua, gap equations, masses 2133
29.4.3 Convexity, and the paradox of the double well 2135
29.4.4 The loop expansion of the effective potential 2137
29.4.5 The Coleman–Weinberg potential: the one-loop integral evaluated 2139
29.4.6 ϕ^4 theory: the broken-phase effective potential 2141
29.4.7 Radiative symmetry breaking and dimensional transmutation 2143

29.4.8 The effective-potential proof of Goldstone's theorem . . . 2145
29.5 The Nonlinear Sigma Model and Low-Energy Goldstone Dynamics 2148
29.5.1 The heavy-radial-mode limit of the linear sigma model . . 2148
29.5.2 Goldstones as coordinates on the coset G/H 2151
29.5.3 The nonlinear realization and the masslessness of derivative coupling 2153
29.5.4 The Adler zero: a low-energy theorem 2155
29.5.5 The geometric construction: Maurer–Cartan form and the CCWZ split 2157
29.5.6 Power counting and the scale $4\pi f$ 2159
29.6 Explicit Breaking, Pseudo-Goldstone Bosons, and Vacuum Alignment 2160
29.6.1 Spontaneous versus explicit breaking, sharpened 2161
29.6.2 The partially conserved current: the explicitly broken Ward identity 2162
29.6.3 Pseudo-Goldstone masses from the effective potential . . . 2163
29.6.4 The PCAC derivation and the Gell-Mann–Oakes–Renner relation 2165
29.6.5 Vacuum alignment 2167
29.6.6 Worked example: explicit breaking of the $O(N)$ model . . 2168
29.6.7 The pion as the paradigm pseudo-Goldstone 2169
29.6.8 Honest dimensional scope: Coleman–Mermin–Wagner . . 2171
29.6.9 Synthesis: where the broken-symmetry machinery goes . . 2173

30 The Higgs Mechanism 2175
30.1 The Problem: Massive Gauge Bosons, Goldstone Bosons, and the Way Out 2176
30.1.1 The naive cure and why gauge invariance refuses it 2177
30.1.2 The Proca propagator and its ultraviolet disease 2178
30.1.3 Degree-of-freedom bookkeeping: where the third polarization lives 2181
30.1.4 The loophole: why Goldstone's theorem need not apply to a gauge theory 2183
30.1.5 The two obstructions, and the object they force 2185
30.2 The Abelian Higgs Model: Classical Mass Generation 2186
30.2.1 The model and its vacuum 2186
30.2.2 Cartesian expansion: masses and the tell-tale mixing . . . 2188
30.2.3 The mixing term is the mechanism announcing itself . . . 2190

30.2.4 Polar parametrization: the Goldstone is pure gauge . . . 2191
30.2.5 The degree-of-freedom count balances . . . 2193
30.3 Unitary Gauge: The Physical Spectrum and Its Price . . . 2195
30.3.1 Fixing the gauge: $\chi = 0$ and the disappearance of the Goldstone . . . 2196
30.3.2 The unitary-gauge Lagrangian . . . 2197
30.3.3 The massive-vector (Proca) propagator from the broken theory . . . 2199
30.3.4 The price: the $k_\mu k_\nu / m_A^2$ term and the loss of manifest renormalizability . . . 2201
30.3.5 Apparent perturbative-unitarity violation in longitudinal scattering . . . 2203
30.3.6 Toward a gauge that keeps renormalizability manifest . . . 2206
30.4 R_ξ Gauges: Faddeev–Popov and the 't Hooft Trick . . . 2206
30.4.1 The mixing term, recalled and isolated . . . 2208
30.4.2 Faddeev–Popov in the broken theory . . . 2209
30.4.3 Averaging over ω: the gauge-fixing Lagrangian and the cancellation of the mixing . . . 2211
30.4.4 The gauge-field propagator: inverting the quadratic form 2212
30.4.5 The Goldstone and ghost propagators . . . 2213
30.4.6 The three gauges and the limits . . . 2214
30.4.7 Manifest renormalizability . . . 2215
30.5 Gauge Independence of Physical Quantities . . . 2218
30.5.1 BRST invariance of the gauge-fixed broken theory . . . 2218
30.5.2 The physical Hilbert space as BRST cohomology, and the quartet . . . 2220
30.5.3 Explicit cancellation of the unphysical pole . . . 2222
30.5.4 Nielsen identities: pole masses are ξ-independent . . . 2223
30.5.5 A two-gauge worked check . . . 2225
30.5.6 The upshot: any gauge will do . . . 2228
30.6 The Goldstone-Boson Equivalence Theorem . . . 2228
30.6.1 The longitudinal polarization vector at high energy . . . 2229
30.6.2 The unitarity puzzle, made quantitative . . . 2231
30.6.3 The Slavnov–Taylor identity for the abelian Higgs model . 2231
30.6.4 Statement of the theorem . . . 2234
30.6.5 Resolution of the unitary-gauge growth . . . 2235
30.6.6 Worked example: longitudinal scattering computed two ways 2236
30.7 The Non-Abelian Higgs Mechanism . . . 2239

30.7.1 The general setup . . . 2240
30.7.2 The gauge-boson mass matrix . . . 2241
30.7.3 Counting: broken generators, eaten Goldstones, and the residual symmetry . . . 2243
30.7.4 The general R_ξ gauge . . . 2245
30.7.5 Worked examples . . . 2249

31 Electroweak Theory **2253**
31.1 The Weak Interaction and the Need for $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ . . . 2254
31.1.1 The empirical face of the charged current . . . 2255
31.1.2 Fermi theory and its fatal dimension . . . 2256
31.1.3 Unitarity violation fixes the scale . . . 2257
31.1.4 From contact term to massive vector, and why that is not enough . . . 2258
31.1.5 The charged currents demand $\mathrm{SU}(2)_L$ . . . 2259
31.1.6 Electric charge is not an SU(2) generator: hypercharge is forced . . . 2260
31.2 Gauge Group, Matter Content, and the Electroweak Lagrangian 2263
31.2.1 The electroweak covariant derivative . . . 2264
31.2.2 Field content of one generation . . . 2265
31.2.3 Gauge kinetic terms . . . 2267
31.2.4 Fermion kinetic and gauge-interaction terms . . . 2267
31.2.5 The Higgs doublet and its potential . . . 2268
31.2.6 The Yukawa couplings . . . 2269
31.2.7 No explicit mass term is allowed . . . 2271
31.2.8 The complete pre-breaking Lagrangian . . . 2273
31.3 Spontaneous Breaking and the Gauge-Boson Spectrum . . . 2274
31.3.1 The vacuum expectation value and the unbroken charge . 2275
31.3.2 The gauge-boson mass matrix from the Higgs kinetic term 2277
31.3.3 The charged bosons $W^\pm$ . . . 2278
31.3.4 The neutral sector: full diagonalization and the weak mixing angle . . . 2279
31.3.5 The photon as the unbroken $\mathrm{U}(1)_{\mathrm{em}}$ — recovery of QED . 2281
31.3.6 Degree-of-freedom count and the physical Higgs . . . 2283
31.4 Fermion Masses and the Yukawa Sector . . . 2285
31.4.1 Why a bare Dirac mass is forbidden . . . 2286
31.4.2 The lepton Yukawa coupling and the electron mass . . . 2287
31.4.3 Quark masses: the down type, and the up type via $\widetilde{H}$ . . 2289

31.4.4 The central prediction: Higgs coupling proportional to mass 2291
31.4.5 Why the neutrino is massless in the minimal model 2293
31.4.6 The one-generation result and the road to many 2295
31.5 Electroweak Currents, Couplings, and the Fermi Limit 2296
31.5.1 The fermion gauge interaction in the broken basis 2296
31.5.2 The charged-current Lagrangian 2297
31.5.3 The neutral-current Lagrangian and the emergence of the photon 2298
31.5.4 Per-fermion vector and axial couplings 2300
31.5.5 Recovery of QED and the QED handoff 2300
31.5.6 The Fermi limit: fixing the vacuum value 2301
31.5.7 The tree-level prediction for M_W and M_Z 2303
31.6 Custodial Symmetry and the ρ Parameter 2305
31.6.1 The bidoublet rewriting of the Higgs sector 2305
31.6.2 Spontaneous breaking to the custodial $\mathrm{SU}(2)_V$ 2308
31.6.3 Why custodial symmetry forces $\rho = 1$ 2309
31.6.4 The two custodial-breaking spurions 2311
31.6.5 The leading correction $\Delta\rho$ 2313
31.7 Gauge Fixing, Unitarity, and Renormalizability 2315
31.7.1 R_ξ gauge fixing of the broken theory 2316
31.7.2 High-energy unitarity: the longitudinal cancellation . . . 2318
31.7.3 Renormalizability: the 't Hooft–Veltman theorem 2321
31.7.4 Gauge-anomaly cancellation 2323
31.7.5 The parameter count of the electroweak sector 2325

32 Flavor, the CKM Matrix, and CP Violation 2327
32.1 From One Generation to Three: The Yukawa Matrices and Flavor Symmetry 2328
32.1.1 The replicated matter content 2329
32.1.2 The three-generation Yukawa Lagrangian 2330
32.1.3 The gauge-kinetic sector is flavor-universal 2331
32.1.4 The Yukawa matrices are the unique source of flavor breaking 2332
32.1.5 Counting the raw parameters 2335
32.2 Mass and Flavor Bases: Bidiagonalization of the Yukawa Matrices 2337
32.2.1 The mass matrices and why they must be diagonalized . . 2337
32.2.2 The singular value decomposition, proved in full 2338
32.2.3 Mass eigenstates and the diagonal mass spectrum 2342

32.2.4 The rotations are invisible: kinetic, neutral-current, and Higgs terms . . . 2343
32.2.5 The lone survivor: the charged current and the matrix V 2346
32.2.6 The residual freedom: rephasing the mass eigenstates . . 2347
32.3 The CKM Matrix: Unitarity, Parameter Counting, and Parametrizations . . . 2349
32.3.1 The CKM matrix in the charged current . . . 2349
32.3.2 Unitarity . . . 2350
32.3.3 Counting the physical parameters . . . 2351
32.3.4 The standard parametrization . . . 2355
32.3.5 The Wolfenstein parametrization . . . 2357
32.3.6 Numerical magnitudes and the unitarity triangle . . . 2358
32.4 CP Violation and the Jarlskog Invariant . . . 2360
32.4.1 How CP acts on the charged current . . . 2361
32.4.2 Rephasing-invariant quartets and the unitarity triangle . 2363
32.4.3 Invariance of J . . . 2365
32.4.4 The Jarlskog determinant . . . 2366
32.4.5 The magnitude of J, and a worked extraction . . . 2370
32.5 The GIM Mechanism and the Suppression of Flavor-Changing Neutral Currents . . . 2372
32.5.1 Flavor-changing neutral currents: the definition and the tree-level theorem . . . 2372
32.5.2 One loop, and the GIM cancellation . . . 2374
32.5.3 The box diagram and the double-GIM structure of neutral-meson mixing . . . 2376
32.5.4 Parametric estimates: $K_L \to \mu^+\mu^-$ and the kaon mass difference . . . 2379
32.6 Neutral-Meson Mixing, the Unitarity Triangle, and CP Observables 2381
32.6.1 The effective two-state Hamiltonian . . . 2382
32.6.2 Mass and width eigenstates; the mixing parameter . . . 2383
32.6.3 CP eigenstates and the smallness of ϵ . . . 2385
32.6.4 The three faces of CP violation . . . 2386
32.6.5 The unitarity triangle . . . 2388
32.6.6 Overconstraint: the apex as a precision test . . . 2391
32.7 Neutrino Masses and the PMNS Matrix . . . 2394
32.7.1 The massless starting point and accidental lepton number 2394
32.7.2 Two minimal ways to make a neutrino massive . . . 2395
32.7.3 The seesaw mechanism . . . 2396

32.7.4 The PMNS matrix and the leptonic phase count 2398
32.7.5 Neutrino oscillations 2401
32.7.6 Experimental status and the open frontier 2404

IX The Standard Model 2407

33 The Complete Standard Model 2409
33.1 The Gauge Group and the Complete Matter Content 2411
33.1.1 The gauge group 2411
33.1.2 All fermions as left-handed Weyl fields 2413
33.1.3 The master table of one generation 2414
33.1.4 The content is chiral: no bare masses 2419
33.2 Assembling the Complete Standard Model Lagrangian 2420
33.2.1 The single covariant derivative 2421
33.2.2 The four-block decomposition 2422
33.2.3 Each block is invariant under the full $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ 2424
33.2.4 Near-uniqueness: nothing renormalizable is missing 2426
33.2.5 How many independent terms 2428
33.2.6 Convergence: QED and Yang–Mills theory are now one Lagrangian 2429
33.3 Consistency Fixes the Charges: Anomaly Cancellation and Charge Quantization 2430
33.3.1 The conditions consistency imposes 2431
33.3.2 Yukawa gauge invariance as additional constraints 2432
33.3.3 Solving the system 2433
33.3.4 Electric-charge quantization 2436
33.3.5 The global $\mathrm{SU}(2)_L$ anomaly 2438
33.3.6 The right-handed neutrino and $B - L$ as an anomaly-free direction 2439
33.4 Accidental Symmetries: Baryon and Lepton Number 2441
33.4.1 What “accidental” means 2441
33.4.2 The classical accidental symmetry of the renormalizable Lagrangian 2442
33.4.3 The quantum fate: $B + L$ is anomalous, $B - L$ is exact . 2445
33.4.4 The leading symmetry-violating operators: windows onto higher scales 2448
33.5 The Theta Term and the Strong-CP Question 2452

33.5.1 The one remaining renormalizable operator 2453
33.5.2 A total derivative that is not a total triviality 2454
33.5.3 Why only the colour theta survives 2457
33.5.4 The physical angle $\bar{\theta}$ 2458
33.5.5 The strong-CP problem 2459
33.6 The Parameters of the Standard Model 2461
33.6.1 The rigid sector: six parameters 2462
33.6.2 The flavor sector as a broken symmetry 2463
33.6.3 The thirteen flavor parameters 2464
33.6.4 The measured values 2467
33.6.5 The neutrino-mass extensions 2467
33.6.6 What the numbers leave unexplained: the flavor puzzle . 2470
33.7 The Standard Model as a Structure: What Is Explained and What Is Not 2471
33.7.1 The near-uniqueness of the Standard Model Lagrangian . 2471
33.7.2 Renormalizability as the engine of predictivity 2473
33.7.3 The summary: genuine explanations versus parametrizations 2475
33.7.4 The frontier: what the Standard Model does not address . 2478
33.7.5 Closing the gauge threads: QED and Yang–Mills become one theory 2479

34 Tests of the Standard Model **2485**
34.1 The Logic of Precision Tests 2486
34.1.1 Input schemes: what is measured and what is predicted . 2487
34.1.2 The tree-level web of relations 2489
34.1.3 The master relation and the radiative correction Δr . . . 2491
34.1.4 The anatomy of Δr: self-energies in the muon-decay relation 2492
34.1.5 The hierarchy of corrections, and why each piece is calculable 2500
34.2 Z-Pole Physics: Lineshape, Widths, and Asymmetries 2501
34.2.1 The neutral-current vertex and the spin-summed decay rate 2502
34.2.2 The resonant lineshape and the peak cross section 2505
34.2.3 The invisible width and the number of light neutrinos . . 2508
34.2.4 Asymmetries and the effective weak mixing angle 2510
34.2.5 The QCD correction to the hadronic width 2513
34.3 Oblique Corrections and the S, T, U Parameters 2514
34.3.1 The oblique approximation 2515
34.3.2 The four gauge self-energies and their low-q^2 expansion . 2516
34.3.3 Counting: exactly three physical parameters 2517

34.3.4 $\alpha T = \Delta\rho$ and custodial symmetry 2519
34.3.5 The leading top-quark contribution: full computation . . 2520
34.3.6 The logarithmic Higgs contribution and the screening theorem 2524
34.3.7 How S, T, U enter the observables 2525
34.3.8 Cornering m_t and m_h before discovery 2526
34.4 The Higgs Boson: Production and Decay 2528
34.4.1 The Higgs couplings: everything is fixed by mass 2528
34.4.2 Tree-level decay to fermions 2529
34.4.3 Decay to weak bosons through one off-shell leg 2531
34.4.4 The loop-induced gluonic decay $h \to gg$ 2534
34.4.5 The diphoton channel: W and top loops in destructive interference 2537
34.4.6 Gluon-fusion production: the gluonic decay run in reverse 2539
34.4.7 Branching ratios at 125 GeV and the signal strength . . . 2540
34.5 Properties of the Higgs Boson 2543
34.5.1 The mass from invariant-mass peaks 2543
34.5.2 The coupling-modifier framework and the coupling–mass law 2545
34.5.3 Spin and parity: $J^P = 0^+$ 2549
34.5.4 The total width and the off-shell method 2552
34.5.5 The Higgs self-coupling: the last unmeasured vertex . . . 2554
34.6 Flavor-Changing Neutral Currents and the Unitarity Triangle . . 2557
34.6.1 The $\Delta F = 2$ box as a local operator 2558
34.6.2 The loop integral and the Inami–Lim function 2559
34.6.3 From the box to the mass splitting 2562
34.6.4 Indirect CP violation: ϵ_K and the Jarlskog invariant . . . 2563
34.6.5 Mixing-induced CP violation: $\sin 2\beta$ from a time-dependent asymmetry 2564
34.6.6 The overconstrained triangle as a precision test 2565
34.7 The Global Fit: Where the Standard Model Triumphs 2567
34.7.1 The fit as a hypothesis test: pseudo-observables and the χ^2 2568
34.7.2 Linearization and the Gaussian solution 2569
34.7.3 The oblique parameters and the S–T plane 2571
34.7.4 Where the Standard Model triumphs 2573
34.7.5 Standing tensions, dated to the mid-2020s 2575
34.7.6 Reading a deviation: an oblique shift or a Wilson coefficient 2577

35 Beyond the Standard Model **2581**

35.1 The Standard Model as an Effective Field Theory 2582
35.1.1 The dimensional hierarchy and the SMEFT expansion . . 2583
35.1.2 Decoupling and the leading window onto the ultraviolet . 2585
35.1.3 The lowest rung: uniqueness of the dimension-five operator 2587
35.1.4 Reading the summary as the plan of the chapter 2589
35.2 Neutrino Mass and the Seesaw Mechanism 2590
35.2.1 The Weinberg operator is a Majorana mass 2591
35.2.2 Majorana, not Dirac: lepton number violation by two units 2593
35.2.3 The type-I seesaw as the ultraviolet completion 2594
35.2.4 Diagonalizing the seesaw matrix 2596
35.2.5 Integrating out the heavy neutrino: tree-level matching . 2597
35.2.6 The other tree completions: type II and type III 2600
35.2.7 The light spectrum and the PMNS matrix 2600
35.2.8 The decisive test: neutrinoless double-beta decay 2601
35.3 The Hierarchy Problem and Naturalness 2602
35.3.1 The Higgs mass is the SM's unique relevant coupling . . . 2603
35.3.2 Quantifying the sensitivity: the one-loop δm_H^2 2604
35.3.3 't Hooft's criterion: why scalars are different 2609
35.3.4 Supersymmetry: the boson–fermion cancellation made explicit 2610
35.3.5 The menu of resolutions, scoped and dated 2612
35.4 The Strong-CP Problem and the Axion 2615
35.4.1 The problem, recalled 2615
35.4.2 The shape of the vacuum energy 2616
35.4.3 The Peccei–Quinn mechanism 2618
35.4.4 The axion mass from current algebra 2619
35.4.5 Realizing the symmetry: visible and invisible axions . . . 2622
35.5 Grand Unification 2623
35.5.1 The minimal embedding: SU(5) 2624
35.5.2 Coupling normalization and the prediction $\sin^2\theta_{\mathrm{W}} = \frac{3}{8}$ . . 2627
35.5.3 Running the three couplings: does unification happen? . . 2629
35.5.4 Proton decay: the prediction that kills minimal SU(5) . . 2632
35.5.5 SO(10): one generation in a single irreducible multiplet . 2635
35.6 Cosmological Frontiers: Dark Matter and Baryogenesis 2636
35.6.1 Dark matter: the empirical case 2637
35.6.2 The Standard Model has no candidate 2639

35.6.3 The thermal relic: Boltzmann equation and freeze-out . . 2640
35.6.4 The baryon asymmetry: the number to be explained . . . 2644
35.6.5 Sakharov's conditions 2645
35.6.6 The Standard Model scorecard 2647
35.6.7 Leptogenesis 2649
35.7 The Landscape of BSM: A Critical Assessment 2653
35.7.1 One map: the operator tower against the scale axis 2654
35.7.2 SMEFT as the model-independent language 2657
35.7.3 The Assessment of Current Status, dated to the mid-2020s 2659
35.7.4 The live frontiers that will move the summary 2662
35.7.5 the three benchmark theories, drawn together 2663

X Anomalies 2665

36 Anomalies I: The Chiral Anomaly 2667
36.1 Classical chirality and the axial current 2668
36.1.1 The massless Dirac Lagrangian and its two phase symmetries 2669
36.1.2 Reformulation: independent rotations of the chiral halves 2670
36.1.3 The two Noether currents 2671
36.1.4 The classical divergence of the axial current 2673
36.1.5 The naive Ward identities and the coming clash 2674
36.2 The triangle diagram and the ABJ anomaly 2676
36.2.1 The two AVV amplitudes from the QED Feynman rules . 2677
36.2.2 Linear divergence and the momentum-routing ambiguity . 2678
36.2.3 The Ward identities and what fixes the routing 2680
36.2.4 From the amplitude to the operator equation 2681
36.2.5 Pauli–Villars: the same number with no ambiguity 2682
36.2.6 Adler–Bardeen: the coefficient is one-loop exact 2684
36.3 The anomaly from the measure: Fujikawa's method 2686
36.3.1 The classical chiral symmetry and the two tests of a quantum symmetry 2687
36.3.2 The Jacobian of a chiral rotation 2688
36.3.3 Why the anomaly function must be regularized, and how 2690
36.3.4 The heat-kernel evaluation 2691
36.3.5 Independence of the regulator 2694
36.3.6 The non-abelian anomaly 2695
36.4 The pion, PCAC, and the counting of colors 2696

36.4.1 The third axial-isospin current and its electromagnetic anomaly . . . 2697
36.4.2 PCAC: the pion as the interpolating field of the axial current 2699
36.4.3 Assembling the amplitude . . . 2701
36.4.4 The decay rate and the counting of colors . . . 2702
36.5 Topology: the index theorem and why the anomaly is exact . . . 2705
36.5.1 The topological charge as a total derivative . . . 2706
36.5.2 Winding, the instanton, and the θ term . . . 2709
36.5.3 The index theorem and the zero-mode pairing . . . 2711
36.5.4 Why the coefficient is exact: Adler–Bardeen from topology 2714
36.6 Non-abelian anomalies, gauge consistency, and the handoff . . . 2715
36.6.1 From external charges to generators: the non-abelian triangle 2716
36.6.2 Left versus right: the chiral structure . . . 2718
36.6.3 Why a gauge anomaly is fatal . . . 2720
36.6.4 Consistent versus covariant anomaly, and the Wess–Zumino condition . . . 2722
36.6.5 The Standard Model preview and the handoff . . . 2723

37 Anomalies II: Consistency and Matching 2725
37.1 From Curiosity to Constraint: Gauging an Anomalous Current . 2726
37.1.1 From a global axial current to three gauge currents . . . 2727
37.1.2 The effective action and the gauge-variation functional . . 2729
37.1.3 Why a gauge anomaly is fatal, I: loss of unitarity . . . 2731
37.1.4 Why a gauge anomaly is fatal, II: no symmetric counterterm 2734
37.1.5 The consistency condition reduced to a number . . . 2736
37.2 The Group Theory of Anomalies: The Cubic Invariant . . . 2738
37.2.1 Factorization of the chiral triangle . . . 2739
37.2.2 The cubic invariant and the anomaly index . . . 2741
37.2.3 Additivity and conjugation: the algebra of the index . . . 2743
37.2.4 Which gauge groups can be dangerous . . . 2745
37.3 Anomaly Cancellation in the Standard Model . . . 2747
37.3.1 The chiral spectrum of one generation . . . 2748
37.3.2 The complete list of dangerous triangles . . . 2749
37.3.3 The two triangles that vanish on group theory alone . . . 2750
37.3.4 The four conditions that constrain hypercharge . . . 2751
37.3.5 Reading the conditions backwards: charge quantization . 2753
37.4 The Structure of Consistency: Wess–Zumino Conditions and Descent 2756
37.4.1 Differential-form packaging of the gauge field . . . 2756

37.4.2 The consistent anomaly as a BRST cocycle 2758
37.4.3 Consistent versus covariant: the Bardeen–Zumino polynomial 2760
37.4.4 The descent equations 2762
37.4.5 Adler–Bardeen: the anomaly is one-loop exact 2767
37.5 't Hooft Anomaly Matching 2769
37.5.1 Global versus gauge anomalies, and the 't Hooft coefficient 2770
37.5.2 The matching theorem 2771
37.5.3 Proof: the spectator construction 2772
37.5.4 The same statement without spectators 2774
37.5.5 Only massless states contribute: decoupling and the persistent-mass condition 2775
37.5.6 Matching as a system of equations on candidate spectra . 2776
37.6 Matching in Action: Chiral Symmetry Breaking in QCD 2779
37.6.1 The global symmetry of N_f massless quarks 2780
37.6.2 The ultraviolet anomaly coefficients 2782
37.6.3 Scenario A: confinement with unbroken chiral symmetry . 2784
37.6.4 Scenario B: chiral symmetry breaks, and who carries the anomaly 2788
37.7 The Wess–Zumino–Witten Term 2790
37.7.1 The infrared theory and the matching demand 2791
37.7.2 The obstruction: no local invariant four-dimensional term will do 2792
37.7.3 Witten's five-dimensional construction 2793
37.7.4 Topological quantization: the level is an integer 2795
37.7.5 Gauging electromagnetism: $\pi^0 \to \gamma\gamma$ 2798
37.8 Mixed, Gravitational, and Global Anomalies: The Modern Landscape 2800
37.8.1 The mixed gauge–gravitational anomaly 2801
37.8.2 No pure gravitational anomaly in four dimensions 2804
37.8.3 Witten's global SU(2) anomaly 2806
37.8.4 The modern synthesis: anomalies as boundaries of invertible phases 2809

XI Effective Field Theories **2815**

38 The Effective Field Theory Paradigm **2817**
38.1 Separation of Scales and the Effective Lagrangian 2818

38.1.1 The insensitivity of the infrared to the ultraviolet 2819
38.1.2 From forgetting to constructing 2820
38.1.3 What an effective field theory is 2821
38.1.4 Weinberg's folk theorem: why the most general Lagrangian is enough 2824
38.1.5 Renormalizability reconsidered 2828
38.2 Power Counting and the Operator Expansion 2830
38.2.1 Canonical dimensions and the operator tower 2830
38.2.2 The power-counting master formula 2831
38.2.3 Naive dimensional analysis and the role of 4π 2834
38.2.4 Operator redundancy: field redefinitions and the equations of motion 2836
38.2.5 The minimal basis for the real scalar with $\mathbb{Z}_2$ symmetry . 2838
38.3 Integrating Out a Heavy Field: Tree-Level Matching 2841
38.3.1 The matching condition 2841
38.3.2 Integrating out a heavy scalar: the classical route 2843
38.3.3 The same answer from the path integral 2846
38.3.4 Generating ϕ^6: the nonlinear equation of motion 2848
38.3.5 Matching the physical amplitude 2850
38.3.6 Heavy vector exchange and the Fermi constant 2851
38.4 One-Loop Matching and the Decoupling Theorem 2854
38.4.1 The structure of one-loop matching 2855
38.4.2 The Appelquist–Carazzone decoupling theorem 2858
38.4.3 Decoupling in action: the heavy fermion in QED 2860
38.4.4 Non-decoupling in $\overline{\text{MS}}$ and the threshold cure 2861
38.4.5 The Euler–Heisenberg Lagrangian: integrating out the electron 2863
38.5 Running and Mixing of Wilson Coefficients 2868
38.5.1 Operator mixing under renormalization 2869
38.5.2 The anomalous-dimension matrix and the coefficient RGE 2870
38.5.3 Leading-logarithmic resummation 2871
38.5.4 Scalar ϕ^4 theory: running and mixing of the dimension-six coefficient 2873
38.5.5 Mixing down, and why the matrix is triangular 2875
38.6 Naturalness, Relevant Operators, and the Hierarchy Problem . . 2876
38.6.1 Relevant operators as the ultraviolet-sensitive directions . 2877
38.6.2 't Hooft's naturalness criterion 2879
38.6.3 The unprotected scalar mass (ϕ^4) 2880

38.6.4 Chiral protection of the fermion mass (QED) 2882
38.6.5 The hierarchy problem, stated precisely 2884
38.6.6 The cosmological-constant problem 2885

39 Chiral Perturbation Theory 2889
39.1 The Chiral Symmetry of QCD and Its Spontaneous Breaking . . 2890
39.1.1 Massless QCD and its left–right decomposition 2891
39.1.2 The Noether currents 2893
39.1.3 The axial anomaly and the fate of $\mathrm{U}(1)_A$ 2895
39.1.4 The quark condensate and the breaking pattern 2896
39.1.5 The Goldstone count: the pseudoscalar octet 2898
39.1.6 Physical evidence for the pattern 2899
39.2 The Leading-Order Chiral Lagrangian 2901
39.2.1 The Goldstone matrix and its transformation law 2902
39.2.2 Uniqueness of the leading Lagrangian 2904
39.2.3 The axial current and the identification $f = f_\pi$ 2907
39.2.4 Explicit breaking by the spurion method 2909
39.2.5 The pion mass, GMOR, and the Gell-Mann–Okubo relation 2910
39.3 Weinberg Power Counting and the Chiral Expansion 2914
39.3.1 The chiral order of the building blocks 2914
39.3.2 The power-counting theorem 2916
39.3.3 Leading and next-to-leading order 2917
39.3.4 The breakdown scale Λ_χ 2919
39.3.5 Predictivity from symmetry, not from weak coupling . . . 2921
39.4 Pion-Pion Scattering at Leading Order 2922
39.4.1 The four-pion vertex from $\mathcal{L}_2$ 2923
39.4.2 The Weinberg amplitude 2927
39.4.3 Isospin decomposition 2928
39.4.4 Scattering lengths: the parameter-free numbers 2929
39.4.5 The Adler zero, made manifest 2932
39.5 Loops, the Gasser–Leutwyler Lagrangian, and Low-Energy Constants 2934
39.5.1 The general $O(p^4)$ chiral Lagrangian 2934
39.5.2 Why one-loop divergences are local and of order p^4 2935
39.5.3 The chiral logarithm: the one-loop pion mass 2937
39.5.4 Renormalizing the LEC and its running 2939
39.5.5 Predictions versus parameters: what the chiral log means 2941
39.6 The Wess–Zumino–Witten Term and the Anomaly 2942

39.6.1 The intrinsic-parity problem . . . 2943
39.6.2 Construction of the Wess–Zumino–Witten term . . . 2945
39.6.3 Witten's quantization: the coefficient is N_c . . . 2947
39.6.4 Gauging to electromagnetism and the $\pi^0 \to \gamma\gamma$ vertex . . . 2949
39.6.5 The amplitude and the decay rate . . . 2951
39.6.6 What the WZW term completes . . . 2953

40 Heavy-Particle and Standard Model EFTs 2955
40.1 The heavy-quark expansion . . . 2956
40.1.1 Splitting the momentum: velocity as a label . . . 2957
40.1.2 The velocity projectors and the small components . . . 2958
40.1.3 The exact Lagrangian in residual variables . . . 2959
40.1.4 Integrating out the small components . . . 2960
40.1.5 The leading Lagrangian and its $1/m_Q$ corrections . . . 2961
40.1.6 Feynman rules: the static propagator and the eikonal vertex 2963
40.1.7 Power counting . . . 2965
40.2 Spin–flavor symmetry and heavy-hadron form factors . . . 2966
40.2.1 The emergent spin–flavor symmetry . . . 2966
40.2.2 Heavy-meson multiplets and the ground-state doublet . . . 2968
40.2.3 The Isgur–Wise reduction of $B \to D^{(*)}$ form factors . . . 2969
40.2.4 Normalization at zero recoil . . . 2973
40.2.5 Corrections at zero recoil: Luke's theorem . . . 2974
40.2.6 Extracting $|V_{cb}|$ . . . 2975
40.3 Matching and the 1/m expansion . . . 2977
40.3.1 The heavy-quark field and the expanded QCD Lagrangian 2977
40.3.2 Tree-level matching: the kinetic and chromomagnetic operators . . . 2979
40.3.3 Reparametrization invariance fixes the kinetic coefficient . 2981
40.3.4 The chromomagnetic coefficient and the heavy-hadron hyperfine splittings . . . 2983
40.3.5 The abelian analog: NRQED and Schwinger's number as a Wilson coefficient . . . 2986
40.3.6 NRQED scales and the organization of bound states . . . 2988
40.4 The Standard Model as an effective theory: building SMEFT . . . 2990
40.4.1 The defining data and the operator expansion . . . 2991
40.4.2 Dimension five: the Weinberg operator . . . 2992
40.4.3 The redundancy problem . . . 2995
40.4.4 Dimension six: the operator classes and the counting . . . 2998

40.4.5 The Warsaw basis and the invariance of observables . . . 2999
40.5 Matching: from heavy new physics to Wilson coefficients 3001
40.5.1 The matching principle 3002
40.5.2 The prototype: integrating out the W and the value of G_F 3003
40.5.3 Tree-level matching of a heavy BSM field 3006
40.5.4 Decoupling: heavy physics is local and suppressed 3008
40.5.5 Tree-level versus one-loop matching 3009
40.6 Running and operator mixing 3011
40.6.1 Operator renormalization and the mixing matrix 3012
40.6.2 The $\Delta S = 1$ effective Hamiltonian 3014
40.6.3 The one-loop anomalous-dimension matrix 3015
40.6.4 The same machine: dimension-six SMEFT 3019
40.7 The EFT view of precision physics 3020
40.7.1 From a measurement to a scale 3021
40.7.2 The oblique parameters as dimension-six coefficients . . . 3023
40.7.3 The live classes of observable 3028
40.7.4 The hierarchy problem through the EFT lens 3030
40.7.5 HQET and SMEFT as one method 3031
40.7.6 Status as of the mid-2020s 3033

XII Non-Perturbative Methods **3037**

41 Solitons and Topology **3039**
41.1 The Kink: A Soliton from a Double Well 3040
41.1.1 The model: a scalar line in a double well 3041
41.1.2 Finite energy forces the field into a vacuum at infinity . . 3042
41.1.3 The static equation, its first integral, and the kink profile 3043
41.1.4 The topological current and its integer charge 3045
41.1.5 The Bogomolny bound, the BPS equation, and the kink mass 3048
41.2 Topological Charge and the Homotopy Classification 3052
41.2.1 The vacuum manifold 3052
41.2.2 Finite energy and the asymptotic map 3054
41.2.3 Homotopy: deforming maps 3055
41.2.4 The winding number of a circle map, and $\pi_1(S^1) = \mathbb{Z}$ . . 3057
41.2.5 The degree formula and the general topological charge . . 3059
41.2.6 Invariance of the topological charge 3061

41.2.7 Worked example: the kink as the nontrivial class of π_0 . . 3062
41.3 Derrick's Theorem and the Need for Gauge Fields 3063
41.3.1 The static energy functional and its pieces 3064
41.3.2 The rescaling family and the scaling energy 3065
41.3.3 The theorem 3066
41.3.4 The evasion catalogue: gauge fields restore the balance . . 3069
41.4 The Vortex: Gauged Solitons and Flux Quantization 3074
41.4.1 The abelian Higgs model in two spatial dimensions 3074
41.4.2 Finite energy, the winding ansatz, and flux quantization . 3076
41.4.3 Radial profile equations and the structure of the core . . . 3078
41.4.4 The Bogomolny bound and the BPS vortex 3080
41.5 The 't Hooft–Polyakov Monopole 3084
41.5.1 The Georgi–Glashow model 3085
41.5.2 Finite energy and the boundary map 3086
41.5.3 The hedgehog ansatz 3087
41.5.4 The reduced energy and the profile equations 3088
41.5.5 The gauge-invariant electromagnetic field 3091
41.5.6 The topological current and the charge identity 3093
41.5.7 Dirac quantization from a regular field 3095
41.5.8 The monopole mass and the Bogomolny bound 3096
41.6 The Bogomolny Bound, BPS States, and Dyons 3097
41.6.1 The general Bogomolny completion 3098
41.6.2 The three instances and their central charges 3100
41.6.3 The Prasad–Sommerfield limit and the exact BPS monopole 3102
41.6.4 Dyons, the central charge, and the spectrum of allowed charges 3105
41.6.5 The Witten effect 3106

42 Instantons and the Vacuum **3111**
42.1 Tunneling and the Euclidean Path Integral 3112
42.1.1 The model problem: a particle in a double well 3113
42.1.2 Euclidean continuation of the path integral 3114
42.1.3 The instanton solution by quadrature 3115
42.1.4 The zero mode and collective coordinates 3118
42.1.5 The fluctuation determinant and the prefactor K 3121
42.1.6 The dilute instanton gas and the level splitting 3122
42.1.7 The bounce and the large-order connection 3125

42.2 The Topology of the Yang–Mills Vacuum 3127
42.2.1 Finite action forces a pure gauge at infinity 3128
42.2.2 Classification of the sectors: $\pi_3(\mathrm{SU}(N)) = \mathbb{Z}$ 3130
42.2.3 The topological charge and the Chern–Simons current . . 3131
42.2.4 The Bogomolny bound and self-duality 3136
42.3 The BPST Instanton 3138
42.3.1 The 't Hooft symbols 3139
42.3.2 The ansatz and its field strength 3141
42.3.3 Topological charge and action 3143
42.3.4 Collective coordinates and zero modes 3145
42.4 The theta-Vacuum 3149
42.4.1 Temporal gauge and the residual large gauge transformations 3150
42.4.2 The discrete vacua and the Chern–Simons number 3151
42.4.3 The instanton as a tunnelling event 3153
42.4.4 Diagonalizing the tunnelling Hamiltonian: the theta-vacuum 3154
42.4.5 Theta as a superselection label 3155
42.4.6 Equivalence to a Lagrangian theta-term 3158
42.4.7 P, T, and CP violation by the angle 3159
42.5 The Dilute Instanton Gas and the Vacuum Energy 3160
42.5.1 The single-instanton saddle and its collective coordinates 3161
42.5.2 Inserting the running coupling: ρ^{b_0-5} and the infrared breakdown 3165
42.5.3 Exponentiating the gas: $E(\theta) = -2K\cos\theta$ 3167
42.5.4 The topological susceptibility 3169
42.5.5 What is reliable, and a dated number 3170
42.6 Instantons, Fermions, and the $U(1)_A$ Problem 3172
42.6.1 The chiral symmetries of massless QCD and the missing meson 3172
42.6.2 Integrating the anomaly: $\Delta Q_5 = 2n_f Q$ 3174
42.6.3 Fermion zero modes and the vanishing of the determinant 3176
42.6.4 The 't Hooft effective vertex 3179
42.6.5 Resolution of the $U(1)_A$ problem 3181
42.6.6 The η' mass: the Witten–Veneziano relation 3182
42.7 The Strong-CP Problem and Its Resolutions 3184
42.7.1 The physical angle from an anomalous chiral rotation . . 3185
42.7.2 The neutron electric dipole moment and the bound on $\bar{\theta}$. 3187
42.7.3 The naturalness puzzle 3189
42.7.4 Resolutions 3190

43 Lattice Field Theory **3195**

43.1 The Euclidean lattice as a constructive regulator 3196
43.1.1 The hypercubic Euclidean lattice 3197
43.1.2 The Boltzmann dictionary: a quantum field theory as a statistical system 3199
43.1.3 The lattice is a complete ultraviolet regulator 3200
43.1.4 The transfer matrix and the reconstruction of a Hamiltonian 3202
43.1.5 Reflection positivity and the unitary continuation to Minkowski 3206
43.1.6 Worked example: the lattice scalar in zero space dimensions is the harmonic oscillator 3209
43.2 The lattice scalar and the continuum limit as an RG fixed point . 3211
43.2.1 The lattice action for the free and $\lambda\phi^4$ scalar 3211
43.2.2 The lattice free propagator 3213
43.2.3 The continuum limit of the propagator and its $O(a^2)$ artifact 3215
43.2.4 Dimensionless variables: the lattice as a pure statistical system 3216
43.2.5 Correlation length, the mass gap, and why the continuum limit is critical 3217
43.2.6 The continuum limit as a Wilsonian RG fixed point . . . 3219
43.2.7 The fate of ϕ^4 in four dimensions: triviality, stated and dated 3221
43.3 Gauge fields on the lattice: link variables and the Wilson action . 3223
43.3.1 The link variable as a lattice parallel transporter 3224
43.3.2 The plaquette and its exact gauge invariance 3225
43.3.3 The Wilson gauge action 3227
43.3.4 The classical continuum limit 3228
43.3.5 The Haar measure: exact gauge invariance with no gauge fixing 3231
43.4 Confinement at strong coupling: the area law and the string tension 3234
43.4.1 The single-link integrals: moments of the Haar measure . 3235
43.4.2 The strong-coupling expansion 3237
43.4.3 The area law from minimal-area tiling 3238
43.4.4 The string tension and the linear potential 3241
43.4.5 Convergence and the leading corrections 3243
43.4.6 Does it survive to the continuum? Honest scope 3243
43.5 Fermion doubling and the Nielsen–Ninomiya no-go theorem . . . 3246
43.5.1 The naive lattice Dirac action 3247
43.5.2 The momentum-space propagator and its poles 3248

43.5.3 Counting and identifying the doublers . . . 3249
43.5.4 Why the doublers are the anomaly . . . 3252
43.5.5 The topological obstruction: Poincaré–Hopf on the Brillouin torus . . . 3254
43.5.6 The Nielsen–Ninomiya theorem . . . 3255
43.6 Lattice fermions: Wilson, staggered, and the Ginsparg–Wilson resolution . . . 3258
43.6.1 The Wilson term: lifting the doublers by hand . . . 3259
43.6.2 Staggered (Kogut–Susskind) fermions: keeping a remnant chiral symmetry . . . 3262
43.6.3 The Ginsparg–Wilson relation and an exact lattice chiral symmetry . . . 3265
43.6.4 The lattice index theorem and the anomaly . . . 3268
43.6.5 Realizations: overlap and domain-wall fermions . . . 3270
43.7 What the lattice computes: Monte Carlo, the spectrum, and the continuum limit . . . 3273
43.7.1 Expectation values as ensemble averages . . . 3273
43.7.2 Extracting masses: spectral decomposition of a Euclidean correlator . . . 3277
43.7.3 Removing the regulator: scale setting and the continuum limit . . . 3280
43.7.4 What the lattice has delivered (mid-2020s) . . . 3284
43.7.5 What it has not delivered: the sign problem . . . 3286
43.8 Synthesis: the lattice as a definition of quantum field theory . . . 3287
43.8.1 The lattice as a complete definition . . . 3288
43.8.2 The existence dichotomy: triviality versus asymptotic freedom . . . 3290
43.8.3 What is proved and what is computed . . . 3293
43.8.4 Open frontiers . . . 3294

XIII Supersymmetry 3297

44 Supersymmetry: Algebra and Representations 3299
44.1 From Coleman–Mandula to Graded Symmetry . . . 3300
44.1.1 Symmetries of the S-matrix . . . 3301
44.1.2 The Coleman–Mandula theorem . . . 3302
44.1.3 The forward-scattering argument . . . 3303
44.1.4 Where the theorem does not reach: graded generators . . . 3306

44.1.5 Graded Lie superalgebras . . . 3307
44.1.6 Consistency of the graded Jacobi identity . . . 3308
44.2 The Haag–Łopuszański–Sohnius Theorem and the SUSY Algebra 3311
44.2.1 Graded Lie algebras and the precise statement . . . 3312
44.2.2 Two-component conventions . . . 3313
44.2.3 The central anticommutator $\left\{Q_\alpha, \bar{Q}_{\dot\beta}\right\}$ . . . 3315
44.2.4 The vanishing of $\{Q_\alpha, Q_\beta\}$ for $\mathcal{N} = 1$ . . . 3316
44.2.5 Translations commute with the supercharges . . . 3317
44.2.6 The Lorentz action and the closed $\mathcal{N} = 1$ algebra . . . 3318
44.2.7 The $\mathrm{U}(1)_R$ outer automorphism . . . 3319
44.2.8 Verifying the super-Jacobi identities . . . 3321
44.3 Immediate Consequences of the Algebra . . . 3323
44.3.1 Energy is non-negative . . . 3324
44.3.2 The vacuum energy as the order parameter for SUSY breaking 3325
44.3.3 Mass degeneracy within a multiplet . . . 3326
44.3.4 Equal numbers of bosons and fermions . . . 3327
44.3.5 A solvable laboratory: supersymmetric quantum mechanics 3330
44.4 Supermultiplets: Massless and Massive Representations . . . 3332
44.4.1 The massless multiplet as a Clifford module . . . 3333
44.4.2 Extended supersymmetry: state counting and the spin bound 3338
44.4.3 Massive multiplets . . . 3340
44.4.4 Central charges and BPS shortening . . . 3342
44.5 The Wess–Zumino Model: On-Shell and Off-Shell SUSY . . . 3343
44.5.1 The free Lagrangian and the SUSY transformations . . . 3344
44.5.2 On-shell closure, and its failure . . . 3346
44.5.3 The auxiliary field and off-shell closure . . . 3348
44.5.4 The superpotential, the Yukawa coupling, and the scalar potential . . . 3350
44.5.5 The cubic Wess–Zumino model . . . 3352
44.6 Superspace and Superfields . . . 3354
44.6.1 Superspace as a coset . . . 3355
44.6.2 The supercharges as differential operators . . . 3356
44.6.3 Covariant derivatives . . . 3358
44.6.4 The general superfield and its components . . . 3360
44.6.5 Berezin integration on superspace and invariant measures 3362
44.7 Chiral Superfields and the Superspace Wess–Zumino Action . . . 3366
44.7.1 The chiral constraint . . . 3366

44.7.2 Solving the constraint: chiral coordinates 3367
44.7.3 The component expansion and the off-shell multiplet . . . 3368
44.7.4 Products of chiral superfields and the superpotential . . . 3369
44.7.5 The F-term and its supersymmetry invariance 3370
44.7.6 The Kähler term: kinetic energy in superspace 3371
44.7.7 The full superspace Wess–Zumino action 3373
44.7.8 Holomorphy and the seed of nonrenormalization 3375

45 Supersymmetric Gauge Theories 3377
45.1 The Vector Superfield and the Abelian Gauge Multiplet 3379
45.1.1 Gauging a symmetry forces a chiral parameter 3379
45.1.2 The real vector superfield 3381
45.1.3 The super-gauge transformation in components and Wess–Zumino gauge 3381
45.1.4 The chiral field-strength superfield 3383
45.1.5 Component expansion of W_α 3385
45.1.6 The supersymmetric Maxwell action 3386
45.1.7 Coupling matter and recovering the Chapter 8 covariant derivative 3389
45.2 Nonabelian Super Yang–Mills 3390
45.2.1 The matrix vector superfield and the finite super-gauge transformation 3391
45.2.2 The covariant field strength W_α 3393
45.2.3 Component expansion in Wess–Zumino gauge 3395
45.2.4 The super Yang–Mills action and the holomorphic coupling 3396
45.2.5 Gauge fixing and BRST in Wess–Zumino gauge 3401
45.3 Supersymmetric QCD: Matter, the Scalar Potential, and the Classical Moduli Space 3403
45.3.1 The gauge-covariant Kähler term 3403
45.3.2 Component expansion in Wess–Zumino gauge 3405
45.3.3 The full SQCD Lagrangian 3407
45.3.4 The scalar potential from the auxiliary fields 3409
45.3.5 Classical supersymmetric vacua and the moduli space . . 3410
45.4 Nonrenormalization Theorems and the Exact NSVZ Beta Function 3415
45.4.1 Couplings as spurions: the holomorphy principle 3416
45.4.2 The perturbative nonrenormalization theorem 3417
45.4.3 The Kähler potential is renormalized 3419
45.4.4 The holomorphic gauge coupling runs only at one loop . . 3420

45.4.5 From holomorphic to canonical: the Konishi anomaly and the NSVZ formula . . . 3422
45.4.6 Reduction at one loop: the supersymmetric Yang–Mills theory coefficient . . . 3425
45.5 Soft Supersymmetry Breaking . . . 3428
45.5.1 The quadratic-divergence cancellation . . . 3429
45.5.2 The supertrace sum rule . . . 3432
45.5.3 The spurion method and the criterion for softness . . . 3434
45.5.4 The Girardello–Grisaru list of soft terms . . . 3436
45.5.5 Soft terms from spurion insertions . . . 3437
45.5.6 Mediation: where F_X comes from . . . 3438
45.6 The MSSM in Outline . . . 3439
45.6.1 Supermultiplet content and quantum numbers . . . 3440
45.6.2 Why two Higgs doublets . . . 3441
45.6.3 The superpotential, the μ problem, and R-parity . . . 3443
45.6.4 The soft-breaking Lagrangian . . . 3445
45.6.5 The Higgs sector and the tree-level mass bound . . . 3446
45.6.6 Gauge-coupling unification . . . 3450
45.6.7 Experimental status, dated . . . 3453

46 Exact Results in Supersymmetry 3455
46.1 Holomorphy as a Principle . . . 3456
46.1.1 Holomorphy in the fields and in the couplings . . . 3457
46.1.2 Symmetry-and-holomorphy selection rules . . . 3458
46.1.3 Seiberg's nonrenormalization theorem . . . 3460
46.1.4 Why the Kähler potential is not protected . . . 3462
46.1.5 The Wess–Zumino model worked through . . . 3464
46.2 The Holomorphic Gauge Coupling and the Exact Beta Function 3465
46.2.1 The complexified holomorphic coupling . . . 3466
46.2.2 One-loop exactness of the holomorphic coupling . . . 3468
46.2.3 Holomorphic versus canonical normalization . . . 3470
46.2.4 The NSVZ exact beta function . . . 3472
46.2.5 Consistency: one loop and the SUSY multiplet content . . . 3474
46.3 Dynamically Generated Superpotentials: SQCD and Affleck–Dine–Seiberg . . . 3476
46.3.1 The classical moduli space of SQCD . . . 3477
46.3.2 Holomorphy and symmetry fix the superpotential . . . 3480
46.3.3 The one-instanton computation for $N_f = N_c - 1$ . . . 3482

46.3.4 Reading off the physics: runaway, mass deformation, and gaugino condensation . . . 3485
46.4 The Phase Structure of SQCD and Seiberg Duality . . . 3489
46.4.1 The fields, the scale, and the global symmetries . . . 3490
46.4.2 Gauge invariants: the chiral ring . . . 3491
46.4.3 $N_f = N_c$: the quantum-modified moduli space . . . 3492
46.4.4 $N_f = N_c + 1$: s-confinement . . . 3495
46.4.5 Seiberg duality: the precise statement . . . 3496
46.4.6 Evidence I: 't Hooft anomaly matching . . . 3498
46.4.7 The conformal window and the unitarity bound . . . 3500
46.4.8 Evidence II: chiral ring, deformations, and the a-theorem 3503
46.5 BPS States and Central Charges . . . 3505
46.5.1 The centrally extended algebra . . . 3505
46.5.2 The BPS bound from positivity . . . 3507
46.5.3 Short multiplets and the protection of the mass . . . 3509
46.5.4 The central charge as electric and magnetic charge . . . 3511
46.6 The Seiberg–Witten Solution . . . 3514
46.6.1 The Coulomb branch and its low-energy effective theory . 3515
46.6.2 The perturbative prepotential and the monodromy obstruction . . . 3517
46.6.3 The strong-coupling singularities: massless monopoles and dyons . . . 3519
46.6.4 The Seiberg–Witten curve and the periods . . . 3522
46.6.5 Monopole condensation and confinement . . . 3526
46.7 Supersymmetry as a Controlled Laboratory . . . 3528
46.7.1 The exact-results toolkit . . . 3529
46.7.2 Theorem versus conjecture: an honest scope . . . 3534
46.7.3 The forward map: where this technology re-enters . . . 3535

XIV Conformal Field Theory and the Bootstrap 3539

47 Conformal Symmetry 3541
47.1 From Scale Invariance to Conformal Invariance . . . 3542
47.1.1 The local certificate of scale invariance . . . 3543
47.1.2 Conformal transformations as angle-preserving maps . . . 3544
47.1.3 The conformal Killing equation . . . 3545
47.1.4 Complete solution in $d \geq 3$ . . . 3547

47.1.5 One conserved current per conformal generator 3550
47.1.6 Does scale invariance imply conformal invariance? 3552
47.2 The Conformal Group and Algebra 3554
47.2.1 Finite transformations 3555
47.2.2 The generators as differential operators 3557
47.2.3 The conformal algebra 3557
47.2.4 Isomorphism with $\mathfrak{so}(d+1,1)$ 3560
47.2.5 Inversion preserves angles; the embedding null cone . . . 3562
47.3 Primary Operators, Descendants, and Unitarity Bounds 3566
47.3.1 Scaling dimension and spin from the Cartan generators . 3567
47.3.2 Momentum raises, special conformal lowers 3568
47.3.3 Primaries, descendants, and the conformal multiplet . . . 3569
47.3.4 The finite transformation law of a primary 3571
47.3.5 Unitarity bounds 3572
47.3.6 The dimension as RG data: setting up the thread 3576
47.4 Correlators Fixed by Conformal Symmetry 3576
47.4.1 The covariance law for correlators 3577
47.4.2 The two-point function 3579
47.4.3 Spinning two-point functions and conserved currents . . . 3582
47.4.4 The three-point function 3584
47.4.5 Cross-ratios: the invariants of four points 3585
47.4.6 The four-point function and the function $g(u,v)$ 3587
47.5 Radial Quantization 3589
47.5.1 The radial foliation and the Weyl map to the cylinder . . 3590
47.5.2 The dilatation as the radial Hamiltonian 3592
47.5.3 States from operator insertions and radial ordering 3594
47.5.4 The inner product from reflection positivity 3595
47.5.5 Hermiticity of the generators: $P_\mu^\dagger = K_\mu$ 3596
47.6 The State-Operator Map 3599
47.6.1 From an operator to a state 3600
47.6.2 Shrinking the ball: convergence of the insertion 3601
47.6.3 From a state back to an operator 3603
47.6.4 The map intertwines the conformal action 3604
47.6.5 One spectrum: the cylinder partition function and the gap 3607
47.7 The Operator Product Expansion and Its Convergence 3611
47.7.1 The operator product expansion from completeness 3611
47.7.2 The coefficients are the three-point data 3613

47.7.3 Convergence of the operator product expansion 3615
47.7.4 The four-point function and conformal blocks 3618
47.7.5 The conformal Casimir and the block equation 3620
47.8 The Free Scalar and the Wilson–Fisher Fixed Point as CFTs . . 3622
47.8.1 The free massless scalar is a conformal field theory 3622
47.8.2 The $\phi \times \phi$ OPE and the operator content of the free theory 3625
47.8.3 The equation of motion as a null descendant 3629
47.8.4 The Wilson–Fisher fixed point as an interacting CFT . . 3631
47.8.5 Closing the loop: two genuine CFTs, and the handoff . . . 3633

48 CFT in Two Dimensions **3635**
48.1 Local Conformal Symmetry in Two Dimensions: the Witt Algebra 3637
48.1.1 Complex coordinates on the Euclidean plane 3637
48.1.2 The conformal Killing equation collapses to Cauchy–Riemann 3638
48.1.3 The Witt algebra 3640
48.1.4 The global subalgebra: only $\mathfrak{sl}(2,\mathbb{C})$ survives on the sphere 3641
48.1.5 Conformal weights and primary fields 3643
48.1.6 Consistency: recovering the two- and three-point functions 3645
48.2 The Stress Tensor, Conformal Ward Identities, and the Central Charge 3647
48.2.1 Tracelessness and the holomorphic stress tensor 3648
48.2.2 The conformal Ward identity 3649
48.2.3 Primary fields and the T–O operator product 3652
48.2.4 The T–T operator product and the central charge 3653
48.2.5 The finite transformation of T: the Schwarzian 3654
48.2.6 Worked example: the free boson has $c = 1$ 3657
48.3 Radial Quantization and the Virasoro Algebra 3660
48.3.1 Mode expansion of the stress tensor 3661
48.3.2 Radial ordering and the commutator of modes 3661
48.3.3 The Virasoro algebra from the TT OPE 3662
48.3.4 The global subalgebra and the vanishing of the central term 3664
48.3.5 L_0 as the Hamiltonian and primary states 3665
48.3.6 Radial conjugation and the adjoint $L_n^\dagger = L_{-n}$ 3666
48.4 Highest-Weight Representations, Null States, and Unitarity . . . 3668
48.4.1 Verma modules and the level grading 3669
48.4.2 The contravariant form and the Gram matrix 3671
48.4.3 The Kac determinant 3674

48.4.4 Null vectors and degenerate representations 3676
48.4.5 Unitarity: the bound $c \geq 0$, $h \geq 0$ and the discrete series 3680
48.5 Minimal Models, Fusion Rules, and the BPZ Equations 3685
48.5.1 The minimal-model central charge and the Kac table . . . 3685
48.5.2 Null vectors as differential operators 3690
48.5.3 The level-two null vector 3691
48.5.4 The BPZ differential equations 3692
48.5.5 Fusion rules and the closure of the algebra 3695
48.6 The Ising CFT Worked in Full 3698
48.6.1 The three primaries from the Kac table 3699
48.6.2 The fusion algebra 3701
48.6.3 The spin four-point function from the BPZ equation . . . 3702
48.6.4 Where $c = \frac{1}{2}$ comes from: the free Majorana fermion . . . 3709
48.6.5 The dictionary to critical exponents: meeting Onsager . . 3712
48.7 Free-Field Realizations and the Coulomb Gas 3713
48.7.1 The free boson as a conformal field theory 3714
48.7.2 The compact boson, momentum and winding, and $R \to 1/R$ duality 3717
48.7.3 The free Majorana fermion and $c = \frac{1}{2}$ 3719
48.7.4 The Coulomb gas: background charge and the Feigin–Fuks construction 3721

49 The Conformal Bootstrap: Foundations 3729
49.1 Crossing Symmetry: The Four-Point Function as a Constraint . . 3730
49.1.1 The unknowns: CFT data 3731
49.1.2 The four-point function and its s-channel decomposition . 3732
49.1.3 The three OPE channels 3733
49.1.4 Crossing symmetry 3734
49.1.5 A worked check: the generalized free field 3737
49.2 Conformal Blocks in Closed Form 3738
49.2.1 Lightcone coordinates and the Casimir as a differential operator 3739
49.2.2 The collinear block 3740
49.2.3 The two-dimensional block 3742
49.2.4 The four-dimensional block 3744
49.2.5 The radial expansion in general dimension 3746
49.2.6 Limits: lightcone and diagonal 3748
49.2.7 Global versus Virasoro blocks 3750

49.3 The Crossing Equation and the Bootstrap Sum Rule 3751
49.3.1 The crossing equation in block form 3751
49.3.2 The convolved block: the F-function 3752
49.3.3 Positivity and the unitarity spectrum: a closed problem . 3755
49.3.4 Vectorization: the sum rule at the crossing-symmetric point 3757
49.3.5 Beyond identical scalars: multiple correlators and matrices of coefficients 3760
49.4 Unitarity, Positivity, and the Linear-Functional Method 3762
49.4.1 Linear functionals on the sum rule 3762
49.4.2 The functional/contradiction theorem 3763
49.4.3 How bounds arise: gaps and OPE coefficients 3765
49.4.4 A fully worked two-derivative bound 3766
49.4.5 The same bound in two dimensions: the Ising laboratory . 3769
49.4.6 Why the bound is a theorem, and the semidefinite reformulation 3772
49.5 Exact Solutions: Mean-Field Theory and the 2D Ising Check . . 3774
49.5.1 Mean-field theory solved: the double-twist spectrum . . . 3774
49.5.2 The OPE coefficients in closed form 3776
49.5.3 How the s-channel tower rebuilds the crossed-channel identity 3779
49.5.4 The 2D Ising crossing check 3781
49.5.5 Saturation of the unitarity bounds 3784
49.6 The 3D Ising CFT as the Bootstrap Target, and the Frontier . . 3785
49.6.1 The 3D Ising critical point as a unitary CFT 3786
49.6.2 The single-correlator crossing equation and the $\mathbb{Z}_2$ selection rule 3788
49.6.3 The gap assumption and how a functional carves out a region 3789
49.6.4 The headline outcome: the island 3791
49.6.5 Consistency with the ε-expansion 3792
49.6.6 The frontier, honestly 3793

50 The Numerical Bootstrap **3799**
50.1 Crossing as a Problem in Convex Geometry 3800
50.1.1 Crossing vectors and the bootstrap cone 3801
50.1.2 The master separation principle 3803
50.1.3 The exclusion lemma, both directions 3806
50.1.4 A separation computed by hand 3808
50.2 The Linear-Functional Method: Dimension and OPE Bounds . . 3810
50.2.1 The single-correlator problem, restated as an optimization 3811

50.2.2 Dimension bounds as a semi-infinite linear program . . . 3812
50.2.3 Monotonicity: more assumptions, smaller region 3815
50.2.4 Bounds on OPE coefficients 3817
50.2.5 A two-sided OPE bound computed by hand 3818
50.3 From Functionals to Semidefinite Programs 3822
50.3.1 The semi-infinite program 3823
50.3.2 The derivative basis and the radial acceleration 3825
50.3.3 Rational approximation of the blocks in the dimension . . 3827
50.3.4 Positive polynomials on a half-line 3830
50.3.5 The positivity-to-semidefiniteness dictionary and the SDP 3833
50.3.6 Primal, dual, and the rigor of weak duality 3835
50.3.7 SDPB and rigorous arithmetic 3837
50.4 The Single-Correlator Bound and the Ising Kink 3838
50.4.1 Assembling the single-correlator semidefinite program . . 3839
50.4.2 Tracing the bound: the feasibility scan 3841
50.4.3 The kink and the Ising point 3842
50.4.4 The fixed point identified: $\sigma = \phi$, $\varepsilon = :\phi^2:$ 3844
50.5 Mixed Correlators and the Ising Island 3847
50.5.1 Three correlators sharing one operator algebra 3847
50.5.2 The crossing equations and their matrix structure 3848
50.5.3 Positive semidefiniteness from unitarity 3851
50.5.4 The generalized sum rule and its rank-one core 3852
50.5.5 The semidefinite condition: positivity on a matrix of blocks 3853
50.5.6 Closing the wedge: the two gap assumptions and the island 3855
50.5.7 The record numbers and the meeting of two threads . . . 3856
50.6 Reading the Spectrum: Extremal Functionals, Rigor, and Scope . 3858
50.6.1 The dual reading: from a separating hyperplane to a spectrum 3859
50.6.2 The optimization and its dual 3860
50.6.3 Complementary slackness and the double-zero theorem . . 3861
50.6.4 Reading the leading Ising spectrum 3863
50.6.5 Rigor, honestly accounted 3864
50.6.6 The broader toolkit 3866
50.6.7 The frontier, dated 3867

51 The Analytic Bootstrap **3873**
51.1 Crossing in the Lightcone Limit 3874
51.1.1 The crossing equation in lightcone coordinates 3875

51.1.2 The collinear block . . . 3876
51.1.3 Identity dominance and the failure of a finite spectrum . . 3878
51.1.4 The minimal twist accumulates at $2\Delta_\phi$ . . . 3880
51.2 Double-Twist Operators and Generalized Free Fields . . . 3883
51.2.1 Double-twist operators . . . 3883
51.2.2 Generalized free fields . . . 3885
51.2.3 The mean-field OPE coefficients . . . 3887
51.3 Large-Spin Anomalous Dimensions from Crossing . . . 3892
51.3.1 The double lightcone limit . . . 3892
51.3.2 Zeroth order: the identity fixes the large-spin tail . . . 3894
51.3.3 First order: a minimal-twist exchange induces an anomalous dimension . . . 3896
51.3.4 Sign and convexity: unitarity makes the binding attractive 3898
51.3.5 The universal gravitational case: stress-tensor exchange . 3899
51.3.6 Scalar ϕ^4 theory: ϵ-exchange at Wilson–Fisher . . . 3901
51.3.7 Systematics, and why we need more . . . 3902
51.4 The Lorentzian Inversion Formula . . . 3902
51.4.1 The Euclidean inversion and why spin is not yet analytic 3903
51.4.2 The double discontinuity . . . 3905
51.4.3 The Lorentzian inversion formula . . . 3907
51.4.4 Derivation by contour deformation . . . 3909
51.5 Reading the Spectrum from the Inversion Formula . . . 3912
51.5.1 The inversion formula as a generating function for OPE data 3913
51.5.2 Why double-twist operators are reconstructed from the crossed channel . . . 3914
51.5.3 Inverting a single cross-channel block . . . 3916
51.5.4 The correction to the OPE coefficient . . . 3919
51.5.5 Scalar ϕ^4 theory: the Wilson–Fisher leading-twist anomalous dimension . . . 3921
51.5.6 Subleading orders and mixed double-twists . . . 3923
51.5.7 The Regge limit: the boundary of analyticity . . . 3925
51.6 Analytic Functionals and the Dispersive Bootstrap . . . 3926
51.6.1 Crossing as the vanishing of a linear functional, revisited . 3927
51.6.2 The solvable case: the one-dimensional bootstrap . . . 3928
51.6.3 The analytic extremal functionals: a dual basis to the generalized free field . . . 3930
51.6.4 The sum rules and the reproduction of the generalized free field . . . 3933

51.6.5 Dispersive functionals, double discontinuity, and the inversion formula . . . 3935
51.6.6 Polyakov–Mellin, the Mellin packaging, and the unified picture . . . 3937
51.7 Analytic Data for the 3D Ising and Wilson–Fisher CFTs . . . 3939
51.7.1 The data and the operators in play . . . 3939
51.7.2 The order-parameter tower $[\sigma\sigma]_{0,\ell}$ . . . 3940
51.7.3 The energy tower $[\epsilon\epsilon]_{0,\ell}$ . . . 3942
51.7.4 Wilson–Fisher: the ε-expansion match for $[\phi\phi]_{0,\ell}$ . . . 3944
51.7.5 What the analytic bootstrap adds, and what remains open 3946

52 Applications of CFT 3949
52.1 From Scale Invariance to Conformal Invariance at a Fixed Point 3950
52.1.1 The trace of the stress tensor as the local measure of scale breaking . . . 3951
52.1.2 Tracelessness generates the special conformal charges . . . 3952
52.1.3 The virial-current obstruction and the improvement that removes it . . . 3954
52.1.4 Polchinski's theorem: when scale invariance forces conformal invariance . . . 3956
52.1.5 The two-dimensional case in full . . . 3957
52.1.6 The loop with Part VI, closed . . . 3960
52.2 The RG Fixed-Point / CFT Dictionary . . . 3961
52.2.1 Local operators at a fixed point: primaries, descendants, and the full dimension . . . 3962
52.2.2 Couplings as operators: the eigenvalue $y = d - \Delta$ . . . 3963
52.2.3 Critical exponents are operator dimensions . . . 3964
52.2.4 Universality is the statement "the same CFT" . . . 3969
52.2.5 The two leading Ising primaries: $\sigma = \phi$ and $\varepsilon = \phi^2$ . . . 3970
52.3 The Wilson–Fisher Fixed Point as a CFT: the Epsilon-Expansion 3972
52.3.1 The engineering dimension and the fixed point . . . 3973
52.3.2 The field anomalous dimension from the two-loop sunset: η 3975
52.3.3 Renormalization of the composite operator ϕ^2: ν . . . 3977
52.3.4 The $O(N)$ family: Wilson–Fisher as one parameter among two . . . 3981
52.4 Closing the Loop: the Epsilon-Expansion Meets the Bootstrap (3D Ising) . . . 3982
52.4.1 The naive substitution, carried out honestly . . . 3983

52.4.2 Why the series diverges, and how it is resummed 3984
52.4.3 The comparison: three methods, one CFT 3986
52.4.4 Why the agreement is meaningful: two computations of the same object 3987
52.4.5 The correction-to-scaling exponent is a bootstrap operator dimension 3989
52.4.6 Cross-check from the analytic bootstrap: the large-spin tail 3991
52.5 RG Flows Between Fixed Points: the c- and a-Theorems 3993
52.5.1 The arrow of the renormalization group 3994
52.5.2 The two-dimensional c-theorem 3994
52.5.3 The four-dimensional a-theorem 4000
52.5.4 Scalar ϕ^4 theory: the a-anomaly check on Wilson–Fisher . 4004
52.5.5 Frontier: the monotone in general dimension 4005
52.6 Boundaries and Defects in CFT 4006
52.6.1 Conformal defects and the residual symmetry group . . . 4007
52.6.2 The new CFT data: bulk one-point functions and the near-boundary two-point function 4009
52.6.3 Two channels and the boundary bootstrap equation . . . 4011
52.6.4 The displacement operator 4013
52.6.5 Surface critical behavior and conformal boundary conditions 4015
52.6.6 Worked example: the free scalar in a half-space 4016
52.7 The Bridge to Holography 4019
52.7.1 The group-theory match: the conformal group is the AdS isometry group 4020
52.7.2 Holographic renormalization-group flow: the radial coordinate is the scale 4024
52.7.3 The preview dictionary: a primary is a bulk field 4025
52.7.4 When is the bulk classical gravity? Large central charge and a sparse spectrum 4026
52.7.5 Geometric irreversibility: the holographic c-function . . . 4028

XV Holography and Quantum Information 4033

53 The AdS/CFT Correspondence 4035
53.1 Large-N and the String in Disguise 4036
53.1.1 Matrices, not vectors: the 't Hooft limit 4037
53.1.2 Double-line notation 4038
53.1.3 Power counting: the genus expansion 4040

53.1.4 Planar dominance, and a worked count 4042
53.1.5 The string in disguise: $g_s \sim 1/N$ 4044
53.1.6 Factorization and the master field 4046
53.2 The Maldacena Argument, Scoped Honestly 4048
53.2.1 Two descriptions of a stack of branes 4049
53.2.2 The near-horizon limit: the throat is $\mathrm{AdS}_5 \times S^5$ 4051
53.2.3 The decoupling limit 4053
53.2.4 The conjecture and the parameter dictionary 4055
53.2.5 Why $\mathcal{N} = 4$ SYM is exactly conformal, and the symmetry match 4056
53.3 Anti-de Sitter Geometry and Its Conformal Boundary 4060
53.3.1 Anti-de Sitter space as a hyperboloid 4061
53.3.2 Three coordinate systems 4062
53.3.3 Curvature and maximal symmetry 4065
53.3.4 The isometry group $\mathrm{SO}()2, d)$ and the dimension match . 4068
53.3.5 The conformal boundary 4069
53.3.6 The match: bulk Killing vectors are boundary conformal Killing vectors 4071
53.4 Fields in AdS: Falloffs, Dimensions, and the Mass–Dimension Relation 4075
53.4.1 The scalar action and its equation of motion in Poincaré coordinates 4076
53.4.2 Near-boundary indicial analysis and the mass–dimension relation 4078
53.4.3 Source versus vacuum expectation value: the two modes . 4080
53.4.4 The Breitenlohner–Freedman bound and the alternate-quantization window 4082
53.4.5 Consistency with the CFT unitarity bound 4085
53.5 The Field–Operator Dictionary 4088
53.5.1 The map: bulk fields and boundary primaries 4089
53.5.2 The three canonical entries 4090
53.5.3 Gauge symmetries become global symmetries 4092
53.5.4 The parameter map 4095
53.5.5 Counting holographic degrees of freedom 4096
53.6 The GKP–Witten Relation and Holographic Two-Point Functions 4099
53.6.1 The master relation 4099
53.6.2 The bulk-to-boundary propagator 4101
53.6.3 The on-shell action and its divergences 4104

53.6.4 Holographic renormalization 4105
53.6.5 The two-point function and its coefficient 4106
53.6.6 A worked example: $d = 4$, $\Delta = 4$ 4108
53.7 What Is Established, What Is Conjecture: The Status of Holography 4110
53.7.1 The summary of evidence 4111
53.7.2 The epistemic status: a conjecture taken as a definition . 4115
53.7.3 Strong/weak duality: the power and the obstruction restated 4117
53.7.4 Bottom-up versus top-down holography 4117
53.7.5 Open frontiers, mid-2020s 4119

54 Holographic Correlators and Thermodynamics 4123
54.1 Witten Diagrams: Perturbative Holography 4124
54.1.1 The classical saddle computes connected correlators . . . 4125
54.1.2 The bulk-to-bulk propagator 4127
54.1.3 The bulk-to-boundary propagator as a boundary limit . . 4130
54.1.4 The Witten rules 4131
54.2 The Holographic Two-Point Function and Holographic Renormalization 4134
54.2.1 The near-boundary expansion 4135
54.2.2 The regulated on-shell action and its divergences 4137
54.2.3 Covariant counterterms and the holographic-renormalization theorem 4139
54.2.4 The two-point function in position space 4142
54.3 Three- and Four-Point Functions and OPE Data 4144
54.3.1 The contact diagram and the D-function 4144
54.3.2 The three-point function and the OPE coefficient 4146
54.3.3 Four points: contact versus exchange 4149
54.3.4 The conformal-block decomposition of the exchange diagram 4150
54.3.5 The Mellin amplitude and the link to the bootstrap . . . 4153
54.4 Black Holes and Finite Temperature 4155
54.4.1 The planar AdS–Schwarzschild black brane 4155
54.4.2 The Hawking temperature from Euclidean regularity . . . 4158
54.4.3 The renormalized free energy 4159
54.4.4 Entropy and the Bekenstein–Hawking area law 4163
54.4.5 The $\mathcal{N} = 4$ plasma and the factor of $\frac{3}{4}$ 4164
54.4.6 Global AdS and the Hawking–Page transition 4166
54.5 Real-Time Correlators and the Shear Viscosity Bound 4171
54.5.1 From Euclidean to retarded: the infalling prescription . . 4171

54.5.2 The Kubo formula for shear viscosity 4175
54.5.3 The transverse graviton is a massless scalar 4176
54.5.4 The horizon-flux computation of η 4178
54.5.5 The universal ratio $\eta/s = 1/4\pi$ 4180
54.5.6 Quasinormal modes and hydrodynamic dispersion 4182
54.5.7 The KSS bound: status, near-saturation, and violation . . 4184
54.6 The Holographic Renormalization Group: the Radial Direction as Energy Scale 4186
54.6.1 The radial coordinate is the scale 4187
54.6.2 Domain walls and the geometry of an RG flow 4188
54.6.3 First-order flow equations from a fake superpotential . . . 4190
54.6.4 The holographic beta function and the operator dimensions 4191
54.6.5 The holographic c-function and the a-theorem 4193
54.6.6 Wilsonian holography: the radial cutoff as a coarse-graining scale 4196

55 Entanglement Entropy in QFT **4201**
55.1 Reduced Density Matrices and the Entanglement Entropy 4202
55.1.1 Bipartition and the reduced density matrix 4203
55.1.2 The von Neumann and Rényi entropies 4204
55.1.3 The Schmidt decomposition and the equality of entropies 4206
55.1.4 Elementary properties, proved 4207
55.1.5 Mutual information: the finite diagnostic 4210
55.1.6 Two structural facts that make QFT subtle 4210
55.1.7 Two worked computations 4213
55.1.8 Where this leaves us 4216
55.2 The Replica Trick and the Path-Integral Construction 4216
55.2.1 The replica master formula 4217
55.2.2 The reduced density matrix as a cut path integral 4219
55.2.3 $\mathrm{Tr}\,\rho_A^n$ on the branched cover 4221
55.2.4 Rényi entropies as free energies on the replica geometry . 4223
55.2.5 The twist-operator reformulation 4224
55.2.6 The method exercised on a thermal spectrum 4227
55.2.7 What we now compute with 4228
55.3 The Rindler Wedge, the Modular Hamiltonian, and Vacuum Thermality 4229
55.3.1 The half-space, the Rindler wedge, and the cut path integral 4229
55.3.2 Polar coordinates and the angular evolution operator . . . 4231

55.3.3 The Rindler Hamiltonian is the boost generator 4231
55.3.4 The Unruh temperature 4234
55.3.5 The modular Hamiltonian, modular flow, and the KMS condition 4236
55.3.6 Vacuum entanglement entropy as thermal entropy and the area law 4238
55.4 Entanglement Entropy in Two-Dimensional CFT 4241
55.4.1 The replica surface and the twist operator, recalled 4241
55.4.2 The dimension of the twist operator from the conformal anomaly 4242
55.4.3 The single-interval entanglement entropy 4245
55.4.4 Finite size and finite temperature 4247
55.4.5 The universal coefficient, the c-function, and the Ising endpoint 4250
55.5 The Area Law and the Structure of UV Divergences 4252
55.5.1 The entanglement entropy of a Gaussian state 4253
55.5.2 The free scalar: correlators, the spherical region, and the area law 4256
55.5.3 The area-law coefficient from the Rindler thermal gas . . 4259
55.5.4 Recovering the 2D logarithm: the free boson has $c = 1$ . . 4260
55.5.5 The full divergence structure and what is universal 4261
55.5.6 Entropic monotonicity: c-, F-, and a-theorems 4264
55.6 Relative Entropy, the First Law, and Information Inequalities . . 4265
55.6.1 The modular decomposition and ultraviolet finiteness . . 4266
55.6.2 Klein's inequality from operator convexity 4268
55.6.3 Monotonicity, data processing, and strong subadditivity . 4269
55.6.4 The first law of entanglement 4274
55.6.5 The vacuum modular Hamiltonian of a ball in a CFT . . 4275
55.6.6 Modular flow beyond the solvable cases: a frontier note . 4277
55.6.7 From inequalities to energy conditions: the bridge to gravity 4278

56 Holographic Entanglement **4283**
56.1 Geometry from entanglement: the Ryu–Takayanagi proposal . . 4284
56.1.1 From horizon entropy to entanglement entropy: the heuristic 4285
56.1.2 The objects: anchored minimal surfaces and the homology constraint 4287
56.1.3 The Ryu–Takayanagi formula 4288
56.1.4 The validating computation: a single interval in AdS_3 . . 4290

56.2 Computing holographic entanglement entropy 4296
56.2.1 A single interval at finite temperature: the BTZ geodesic 4296
56.2.2 A spherical region in any dimension: the Casini–Huerta–Myers map 4300
56.2.3 A strip in any dimension: the area law and a nonlocal finite piece 4305
56.2.4 Two intervals: mutual information and the entanglement phase transition 4308
56.2.5 What the catalogue is telling us 4312
56.3 Entanglement inequalities from geometry 4312
56.3.1 Strong subadditivity: the statement and the geometric idea 4313
56.3.2 The mechanism in AdS_3: crossing geodesics 4314
56.3.3 The recutting lemma 4316
56.3.4 Monogamy of mutual information 4318
56.3.5 The holographic entropy cone 4322
56.4 Deriving Ryu–Takayanagi: the bulk replica trick 4324
56.4.1 The replica trick in the bulk 4325
56.4.2 Replica symmetry and the conical quotient 4327
56.4.3 The on-shell action of the conical defect 4329
56.4.4 Extremality and the homology constraint 4332
56.4.5 Ryu–Takayanagi as a generalized-entropy statement . . . 4334
56.5 Quantum corrections, covariance, and the quantum extremal surface 4335
56.5.1 The one-loop correction: the FLM formula 4336
56.5.2 Covariance: the HRT prescription 4339
56.5.3 The quantum extremal surface 4346
56.6 Subregion duality and the entanglement wedge 4351
56.6.1 Three bulk regions a boundary subsystem might encode . 4351
56.6.2 The subregion-duality conjecture 4354
56.6.3 The JLMS identity: boundary modular Hamiltonian = area + bulk modular Hamiltonian 4356
56.6.4 Relative-entropy positivity as a bulk energy condition . . 4359
56.6.5 Why the entanglement wedge, and not the causal wedge, is the reconstruction region 4362
56.7 Bulk reconstruction as quantum error correction 4363
56.7.1 HKLL: a bulk field as a smeared boundary operator . . . 4364
56.7.2 Entanglement-wedge reconstruction 4368
56.7.3 The error-correction paradigm of Almheiri, Dong, and Harlow 4369
56.7.4 The HaPPY pentagon code: an exactly solvable model . . 4372

56.8 Spacetime from entanglement: synthesis and frontier 4376
56.8.1 The first law of entanglement 4377
56.8.2 The modular Hamiltonian of a ball 4378
56.8.3 Linearized Einstein equations from the first law 4380
56.8.4 Connectivity is entanglement: Van Raamsdonk's argument 4384
56.8.5 Tensor networks and MERA: a discretization of the geometry 4386
56.8.6 ER = EPR 4387
56.8.7 The dated frontier handed to Chapter 57 4388

57 Black Holes and Quantum Information 4391
57.1 Black hole thermodynamics and the entropy of Hawking radiation 4392
57.1.1 The minimal geometric vocabulary: horizon and surface gravity 4393
57.1.2 The Hawking temperature from Euclidean regularity . . . 4394
57.1.3 The entropy from the on-shell Euclidean action 4398
57.1.4 The first law 4401
57.1.5 The radiation is thermal, and its coarse-grained entropy grows 4402
57.1.6 The Bekenstein bound: S_{BH} as a maximum fine-grained entropy 4403
57.2 The information paradox, stated precisely 4405
57.2.1 The Hawking-pair structure: why the radiation is mixed . 4406
57.2.2 Version 1: Hawking's statement (the entropy form) 4410
57.2.3 Version 2: the unitarity bound and the Page time 4411
57.2.4 Version 3: the AMPS firewall and the monogamy of entanglement 4413
57.2.5 The AdS/CFT sharpening: the answer must live in gravity 4416
57.3 The Page curve 4418
57.3.1 Random states as a model of a scrambled black hole . . . 4418
57.3.2 The Haar average of the purity 4419
57.3.3 From purity to entropy: Page's formula 4421
57.3.4 Typicality: why the average is the answer 4423
57.3.5 The Page curve of an evaporating black hole 4424
57.3.6 Hawking's line versus the Page curve: localizing the crisis 4425
57.4 Quantum extremal surfaces and the island formula 4427
57.4.1 The setup: gravity coupled to a bath, and the radiation region 4428
57.4.2 The island formula as a specialization of the QES prescription 4429

57.4.3 The two competing saddles 4431
57.4.4 The computation in JT gravity coupled to a bath 4432
57.4.5 From eternal to evaporating, and the match to the Page curve 4435
57.4.6 Reading the result: the radiation's wedge swallows the interior 4437
57.5 Replica wormholes and the gravitational path integral 4438
57.5.1 The radiation entropy as a gravitational replica partition function 4439
57.5.2 Two classes of saddle: the Hawking geometry and the replica wormhole 4440
57.5.3 The controlled computation: $\mathrm{Tr}\,\rho_R^2$ in JT gravity plus a bath 4441
57.5.4 The $n \to 1$ limit is the quantum extremal surface 4444
57.5.5 Honest scope: where this is a computation and where it is an argument 4446
57.6 What is settled, what is not 4447
57.6.1 The settled core: the Page curve from semiclassical gravity 4447
57.6.2 Entropy is not information: recovery time and complexity 4449
57.6.3 The factorization puzzle and the ensemble interpretation . 4452
57.6.4 Firewalls after islands 4455
57.6.5 What remains open: a dated summary of the frontier . . 4456

XVI Modern Scattering Amplitudes 4459

58 Spinor-Helicity Formalism 4461
58.1 Massless momenta as spinor squares 4462
58.1.1 The bispinor map 4464
58.1.2 The rank-one factorization theorem 4465
58.1.3 The spinors are the massless Weyl and Dirac spinors . . . 4468
58.2 The bracket algebra and its identities 4470
58.2.1 The two invariant brackets 4471
58.2.2 The bracket–Mandelstam dictionary 4472
58.2.3 The mixed sandwich and the Gordon identity 4474
58.2.4 The Fierz completeness relation 4475
58.2.5 The Schouten identity 4476
58.2.6 Momentum conservation in spinor variables 4478
58.2.7 Reality and the continuation to complex momenta 4478

58.2.8 Worked computations 4480
58.3 Little-group scaling as an organizing principle 4481
58.3.1 The t-rescaling is the massless little group 4482
58.3.2 The helicity-weight theorem 4484
58.3.3 Reading helicities off an expression 4487
58.3.4 Back to the seed of gauge invariance 4488
58.4 Three-point amplitudes fixed by symmetry 4489
58.4.1 The kinematic singularity of three massless particles . . . 4490
58.4.2 Solving the scaling constraints: uniqueness of the form . . 4493
58.4.3 The three-gluon amplitude 4495
58.4.4 QED: the electron–photon vertex 4498
58.4.5 Higher spin and the seed of the equivalence principle . . . 4500
58.5 Polarization vectors in spinor-helicity 4501
58.5.1 The construction 4502
58.5.2 The defining properties 4503
58.5.3 The completeness relation 4504
58.5.4 Reference freedom is gauge freedom 4506
58.5.5 Spin two by squaring: the graviton polarization 4508
58.6 QED reframed: helicity amplitudes that reproduce the cross section 4510
58.6.1 Massless fermion currents and the Fierz rearrangement . . 4511
58.6.2 $e^+e^- \to \mu^+\mu^-$ as helicity amplitudes 4512
58.6.3 Compton scattering and the reference-momentum trick . 4515
58.6.4 What the reframing bought, and what it points to 4519
58.7 Color ordering, gluons, and the massive frontier: handoff to recursion 4519
58.7.1 The trace color decomposition 4520
58.7.2 Properties of the partial amplitudes 4522
58.7.3 The gluon three-point amplitude in final form 4524
58.7.4 Parke–Taylor: the destination 4525
58.7.5 The massive frontier: bold spinors 4526
58.7.6 A map of Part XVI 4528

59 Tree-Level Structure: MHV and Recursion 4531
59.1 Color Decomposition and Color-Ordered Amplitudes 4532
59.1.1 The size of the problem 4533
59.1.2 Where the color lives 4534
59.1.3 From structure constants to traces 4534
59.1.4 The single-trace decomposition 4536

59.1.5 Color-ordered Feynman rules 4538
59.1.6 Cyclicity, reflection, and counting 4540
59.1.7 The $U(1)$ decoupling identity 4541
59.1.8 Yang–Mills theory: the four-gluon color decomposition . . 4543
59.2 The Simplicity of Gluon Amplitudes: Vanishing Helicity Configurations 4544
59.2.1 External data and the freedom in the polarization vectors 4545
59.2.2 The master lemma: dot products of polarization vectors . 4546
59.2.3 The anatomy of a color-ordered tree 4547
59.2.4 All-plus and single-minus amplitudes vanish 4549
59.2.5 A worked four-gluon check 4550
59.2.6 Little-group weights and the MHV classification 4551
59.3 The Parke–Taylor Formula 4553
59.3.1 Statement of the formula 4553
59.3.2 Consistency checks the formula must pass 4554
59.3.3 The four-gluon amplitude the hard way 4556
59.3.4 The soft limit and the Weinberg soft factor 4560
59.3.5 The collinear limit and the gluon splitting amplitudes . . 4561
59.3.6 Status: a checked-but-unproved all-n formula 4563
59.4 Complex Momenta and the Three-Point Amplitude 4563
59.4.1 Real three-point kinematics is degenerate 4564
59.4.2 Independent complexification of λ and $\tilde{\lambda}$ 4565
59.4.3 The two three-point amplitudes from little-group and locality 4567
59.4.4 Fixing the constant against the three-gluon vertex 4568
59.5 BCFW Recursion: Derivation 4571
59.5.1 The complex shift 4572
59.5.2 Analytic structure of the shifted amplitude 4574
59.5.3 Factorization on a physical pole 4575
59.5.4 The contour argument and the master formula 4578
59.5.5 Worked example: the four-gluon MHV amplitude 4580
59.6 Large-z Behavior and On-Shell Constructibility 4583
59.6.1 The boundary term: what must vanish 4583
59.6.2 Scaling of the shifted spinors and polarization vectors . . 4584
59.6.3 The hard line and the eikonal estimate 4585
59.6.4 The background-field argument and the catalogue of shifts 4587
59.6.5 On-shell constructibility of tree Yang–Mills 4591
59.7 Proof of Parke–Taylor and Worked Examples 4593

59.7.1 The single surviving channel . . . 4594
59.7.2 The inductive proof . . . 4596
59.7.3 Four gluons by BCFW, matched to the direct result . . . 4599
59.7.4 Five gluons: one term against a swarm . . . 4601
59.7.5 Beyond MHV: the six-point NMHV teaser . . . 4602
59.7.6 Synthesis: locality and unitarity fix the trees . . . 4603

60 Loop Amplitudes and Unitarity 4607
60.1 Unitarity, Analyticity, and the Cutting Rules . . . 4608
60.1.1 From operator unitarity to the discontinuity . . . 4609
60.1.2 Branch cuts, thresholds, and real analyticity . . . 4610
60.1.3 Cutkosky's cutting rule . . . 4611
60.1.4 The two-particle cut of the scalar bubble . . . 4613
60.1.5 QED: the vacuum polarization as a two-particle cut . . . 4615
60.1.6 Cut-constructibility: reconstructing an amplitude from its cuts . . . 4617
60.2 The One-Loop Basis: Reduction to Master Integrals . . . 4618
60.2.1 The generic one-loop integrand and the two reductions . . . 4618
60.2.2 The scalar master integrals . . . 4620
60.2.3 Passarino–Veltman reduction in practice . . . 4622
60.2.4 The one-loop basis theorem . . . 4626
60.2.5 The pentagon and the vanishing of the five-dimensional Gram determinant . . . 4628
60.2.6 Linear independence: the masters carry distinct cuts . . . 4631
60.2.7 The master decomposition . . . 4632
60.3 Generalized Unitarity: Coefficients from Multiple Cuts . . . 4634
60.3.1 The generalized cut and the maximal-cut philosophy . . . 4635
60.3.2 The quadruple cut: box coefficients from four on-shell trees 4636
60.3.3 Why the cut solutions must be complex . . . 4638
60.3.4 A worked box coefficient: the four-gluon amplitude . . . 4639
60.3.5 The triple cut: triangle coefficients and Forde's parametrization . . . 4641
60.3.6 The double cut: bubble coefficients and the cut hierarchy 4643
60.3.7 The principle: every coefficient is a product of trees . . . 4644
60.4 Integrand Reduction: The OPP Decomposition . . . 4646
60.4.1 The integrand and what constrains it . . . 4646
60.4.2 The OPP decomposition . . . 4647
60.4.3 The box residue and its spurious term . . . 4649

60.4.4 The triangle residue: Forde's parametrization 4651
60.4.5 Bubble and tadpole residues 4654
60.4.6 Reconstruction: the numerical-unitarity viewpoint 4655
60.4.7 Integrating back: recovering the master-integral basis . . 4656
60.5 The Rational Part and d-Dimensional Unitarity 4657
60.5.1 The cut-constructibility gap 4658
60.5.2 The loop momentum in d dimensions 4659
60.5.3 The dimension shift and the $\varepsilon \times (1/\varepsilon)$ mechanism 4661
60.5.4 The rational master integrals 4662
60.5.5 d-dimensional generalized unitarity 4665
60.5.6 Worked example: the all-plus four-gluon amplitude 4666
60.6 Worked Reconstruction: A One-Loop Gluon Amplitude 4669
60.6.1 Color decomposition: isolating the kinematics 4670
60.6.2 The MHV box from a quadruple cut 4671
60.6.3 The all-plus amplitude from a μ^2-cut 4677
60.6.4 Feynman diagrams versus on-shell trees 4680
60.7 Toward Multiloop: Integration by Parts, Differential Equations, and the Function Space 4681
60.7.1 Loop integrals as a vector space: integration-by-parts identities 4682
60.7.2 The Laporta algorithm and the master basis 4685
60.7.3 The method of differential equations 4686
60.7.4 Canonical bases and the ε-factorized form 4688
60.7.5 The polylogarithmic function space, transcendental weight, and the symbol 4690
60.7.6 The frontier: numerical unitarity, functions beyond polylogarithms, and the optimal basis 4693

61 Color–Kinematics Duality and the Double Copy 4697
61.1 From Color-Ordered Partials to the Cubic-Graph Organization . 4698
61.1.1 Two color bases 4699
61.1.2 The cubic-graph master formula 4700
61.1.3 Absorbing the quartic vertex: the cubic form is exact . . 4701
61.1.4 Four points, worked completely 4703
61.1.5 Counting cubic graphs: why the organization scales . . . 4706
61.2 Color–Kinematics (BCJ) Duality 4707
61.2.1 The algebra of the color factors 4708
61.2.2 Statement of the duality 4710

61.2.3 Generalized gauge freedom 4711
61.2.4 Counting: constraints versus freedom 4713
61.2.5 Existence at four points, and the general theorem 4714
61.3 The Four-Gluon Amplitude in BCJ Form 4718
61.3.1 Setup: channels, color factors, and conventions 4719
61.3.2 From partial amplitudes to numerators 4720
61.3.3 Extracting the numerators and verifying kinematic Jacobi 4723
61.3.4 Cross-check: reassembling the amplitude 4726
61.3.5 Generalized gauge freedom in action 4726
61.4 The Double Copy: Gravity as Gauge Squared 4728
61.4.1 The double-copy substitution 4729
61.4.2 The central consistency theorem: only one copy must be BCJ 4730
61.4.3 Graviton kinematics by squaring, and the three-point amplitude 4732
61.4.4 The four-graviton amplitude from the four-gluon square . 4735
61.4.5 Correct factorization: locality and unitarity inherited . . 4738
61.5 KLT Relations and the String-Theoretic Origin 4741
61.5.1 Where the product form comes from: the string worldsheet 4742
61.5.2 The field-theory KLT relation 4744
61.5.3 The kernel as the inverse bi-adjoint matrix 4748
61.6 The Double-Copy Spectrum and the Web of Theories 4752
61.6.1 The tensor product of two gauge states 4753
61.6.2 Four dimensions: the helicity assignment 4756
61.6.3 Projecting onto pure Einstein gravity 4757
61.6.4 The bi-adjoint scalar: the zeroth copy 4759
61.6.5 The web of theories 4760
61.7 Loops, the Classical Double Copy, and the Frontier 4763
61.7.1 The loop-level double copy: integrands, the conjecture, and its evidence 4764
61.7.2 Ultraviolet consequences: $\mathcal{N} = 8$ supergravity 4767
61.7.3 The classical double copy: Kerr–Schild and the Coulomb–Schwarzschild map 4769
61.7.4 The two-body problem and gravitational-wave observables 4772
61.7.5 The frontier summary: theorem, evidence, open 4773

62 Positive Geometry and the Amplituhedron **4777**

62.1 Canonical forms and positive geometry 4778
62.1.1 Logarithmic forms and the canonical form 4779
62.1.2 The interval: the dictionary in one dimension 4782
62.1.3 The simplex: projective covariance in any dimension . . . 4784
62.1.4 Polygons and triangulation independence 4786
62.2 Amplitudes as canonical forms: the kinematic associahedron . . . 4791
62.2.1 The object to be reproduced: bi-adjoint cubic amplitudes 4791
62.2.2 The associahedron and the diagram ↔ face dictionary . . 4793
62.2.3 The ABHY embedding: carving the associahedron out of Mandelstam space 4794
62.2.4 The canonical form is the amplitude 4796
62.2.5 Warm-up: $n = 4$, the segment 4798
62.2.6 The five-point associahedron is the pentagon 4798
62.2.7 What has been established, and the obstruction ahead . . 4801
62.3 The positive Grassmannian 4802
62.3.1 The Grassmannian and its Plücker coordinates 4803
62.3.2 Total nonnegativity 4805
62.3.3 The smallest case: $\mathrm{Gr}_{\geq 0}(1, n)$ is the simplex 4806
62.3.4 Positroid cells and the boundary stratification 4808
62.3.5 The canonical form on a top cell 4809
62.4 On-shell diagrams and the Grassmannian integral 4811
62.4.1 The atoms: three-point amplitudes and on-shell diagrams 4812
62.4.2 The Grassmannian integral 4815
62.4.3 The MHV four-point amplitude from the top cell of $\mathrm{Gr}(2, 4)$ 4817
62.4.4 BCFW recursion as triangulation 4818
62.4.5 Dual superconformal and Yangian invariance 4822
62.5 Momentum twistors and dual conformal symmetry 4824
62.5.1 Region coordinates and dual conformal symmetry 4825
62.5.2 Momentum twistors 4829
62.5.3 Four-brackets and the dual conformal invariants 4832
62.5.4 The positive external data 4834
62.6 The amplituhedron 4838
62.6.1 The amplituhedron map 4839
62.6.2 The rigorously controlled case: $k = 1$ and convex cyclic polytopes 4840
62.6.3 Canonical form equals amplitude 4844

62.6.4 Locality and unitarity from the boundary 4846
62.6.5 The loop amplituhedron, stated honestly 4848
62.7 A worked amplituhedron: the m=2 polygon and a glimpse of NMHV 4849
62.7.1 The $m = 2$ NMHV polygon, evaluated to a closed form . 4850
62.7.2 The physical case: the $m = 4$ NMHV hexagon 4854
62.7.3 Amplituhedron versus BCFW: one amplitude, two faces . 4856
62.8 Scope, status, and the frontier 4858
62.8.1 A summary of mathematical status, dated to the mid-2020s 4858
62.8.2 The conceptual payoff: locality and unitarity as outputs, not inputs 4860
62.8.3 Reach and limits: the enabling crutches 4863
62.8.4 Adjacent positive geometries: live directions, each dated . 4864

63 Amplitudes Beyond: Synthesis 4867
63.1 The Lesson of Redundancy: Hidden Simplicity 4868
63.1.1 The redundancy of the field-variable description 4869
63.1.2 The mismatch between diagrams and amplitudes 4872
63.1.3 The axioms as the variables of the argument 4875
63.2 Analyticity and Unitarity as Constructive Principles 4877
63.2.1 The constructive turn, abstracted from BCFW 4877
63.2.2 Locality and unitarity *are* the residue data 4880
63.2.3 The same logic at loop level: integrands from cuts 4882
63.3 Positivity Bounds: The S-Matrix Bootstrap from Below 4885
63.3.1 The effective theory and its leading irrelevant coefficient . 4885
63.3.2 Analytic structure of the forward amplitude 4888
63.3.3 The twice-subtracted dispersion relation and the sum rule 4889
63.3.4 Interpretation: the swampland from below 4893
63.4 Two Bootstraps, One Logic: S-Matrix and Conformal 4895
63.4.1 The common template 4895
63.4.2 Two crossing equations 4896
63.4.3 Unitarity is positivity in both 4897
63.4.4 The linear functional: one machine, two problems 4899
63.4.5 The flat-space limit: from the boundary correlator to the bulk S-matrix 4901
63.4.6 What a bootstrap is 4903
63.5 Locality and Unitarity as Outputs: Geometry and the Double Copy 4905
63.5.1 The canonical-form principle: poles are boundaries 4905
63.5.2 A toy positive geometry: the pole is a boundary 4907

63.5.3 The double copy: gravity as gauge theory squared 4909
63.5.4 Honest scope, dated to the mid-2020s 4912
63.6 Amplitudes Meet Holography: Soft Theorems and the Celestial Sphere 4913
63.6.1 The leading soft factor from the factorization pole 4914
63.6.2 Soft theorems as Ward identities of asymptotic symmetries 4919
63.6.3 Celestial amplitudes: the Mellin transform to boost eigenstates 4921
63.6.4 The flat-space holography program, scoped and dated . . 4924
63.7 Synthesis: What the Amplitudes Program Teaches 4926
63.7.1 A dated status summary of the program's claims 4927
63.7.2 The inversion of Part I's logic 4930
63.7.3 the three benchmark theories meet 4932
63.7.4 The frontier that remains: where the S-matrix runs out . 4934

XVII QFT in Curved Spacetime 4937

64 QFT in Curved Spacetime 4939
64.1 Free fields on a fixed curved background 4940
64.1.1 The geometric arena: globally hyperbolic spacetimes . . . 4941
64.1.2 The covariant action and the curvature coupling 4942
64.1.3 Weyl invariance singles out $\xi = 1/6$ 4944
64.1.4 The Klein–Gordon inner product and its slice independence4947
64.1.5 Mode expansion, quantization, and the Fock space 4949
64.1.6 The field is geometric; the particle split is not 4952
64.1.7 Why flat space was special 4954
64.2 Bogoliubov transformations and the non-uniqueness of the vacuum4955
64.2.1 Two mode bases and the coefficients that connect them . 4955
64.2.2 Preservation of the canonical structure: the Bogoliubov identities 4957
64.2.3 The particle content of the vacuum 4959
64.2.4 The in-vacuum as a squeezed condensate of out-pairs . . . 4960
64.2.5 When is the particle number unambiguous? 4963
64.3 Particle creation by an expanding universe 4965
64.3.1 The curved Klein–Gordon equation as one-dimensional scattering 4966
64.3.2 The adiabatic vacuum and the WKB hierarchy 4969

64.3.3 The Bernard–Duncan model and its exact modes 4970
64.3.4 Connection coefficients and the Bogoliubov mismatch . . 4972
64.3.5 The created-particle spectrum 4973
64.3.6 Limiting regimes: adiabatic, sudden, and the total number 4975
64.4 The Unruh effect 4977
64.4.1 Rindler coordinates and the accelerated observer 4978
64.4.2 Bogoliubov coefficients by analytic continuation 4979
64.4.3 The Euclidean/KMS derivation: temperature from periodicity 4984
64.4.4 The detector: a click for the accelerated, silence for the inertial 4987
64.4.5 Synthesis: the vacuum as a thermofield double 4990
64.5 The renormalized stress-energy tensor 4992
64.5.1 The classical stress tensor in curved space 4993
64.5.2 Point splitting and the universal short-distance singularity 4995
64.5.3 The Hadamard short-distance expansion 4996
64.5.4 Covariant subtraction: the renormalized tensor 4997
64.5.5 Conservation, and where the anomaly hides 4998
64.5.6 Wald's axioms and the uniqueness theorem 5000
64.5.7 The ambiguity is the renormalization of gravity 5002
64.5.8 Worked example: the Casimir energy of a conformal scalar 5003
64.6 The trace (conformal) anomaly 5007
64.6.1 The trace as the Weyl variation of the effective action . . 5008
64.6.2 Classical tracelessness of the conformal scalar 5008
64.6.3 What the answer must look like: the geometric invariants 5010
64.6.4 The heat-kernel route: the anomaly is $a_2(x)$ 5011
64.6.5 The Fujikawa route: the Weyl Jacobian of the measure . 5016
64.6.6 Reading the result: type A, type B, and the central charges 5019
64.6.7 The anomaly is intrinsic 5021
64.7 The effective action, the Euclidean path integral, and the road to Hawking 5022
64.7.1 The curved-space effective action and the master relation 5022
64.7.2 The Euclidean partition function as a thermodynamic generating functional 5026
64.7.3 The smoothness principle: $\beta = 2\pi/\kappa$ from regularity of the Euclidean section 5028
64.7.4 The semiclassical Einstein equation and the backreaction program 5031

64.7.5 Honest scope: where the semiclassical theory is trustworthy, and where it breaks 5033

65 Hawking Radiation and the Semiclassical Frontier 5037

65.1 The Collapse Geometry and the Geometric-Optics Map 5038
65.1.1 The exterior geometry and its surface gravity 5039
65.1.2 Null coordinates and the near-horizon relation 5042
65.1.3 The collapse spacetime and its causal structure 5044
65.1.4 Geometric optics and the backward ray-tracing 5045
65.1.5 Universality: why the late-time radiation forgets the collapse 5049
65.1.6 The Boulware, Unruh, and Hartle–Hawking vacua 5050
65.2 The Hawking Spectrum: Thermality from the Horizon 5051
65.2.1 The Bogoliubov coefficients of the collapse problem 5052
65.2.2 Evaluation of the overlap and the exact thermal ratio . . 5054
65.2.3 The occupation number and the Planck distribution . . . 5057
65.2.4 Cross-check: the KMS condition and the Hartle–Hawking state 5060
65.3 Greybody Factors, Luminosity, and Evaporation 5061
65.3.1 The field equation as a one-dimensional scattering problem 5062
65.3.2 Greybody factors and the spectrum at infinity 5064
65.3.3 Low-frequency s-wave transmission by matched asymptotics 5066
65.3.4 High frequencies and the geometric capture cross section . 5068
65.3.5 Luminosity and the Stefan–Boltzmann analogue 5070
65.3.6 The evaporation law and the lifetime 5072
65.3.7 Sparsity of the radiation 5073
65.3.8 The flux as the renormalised stress tensor at infinity . . . 5074
65.4 Black Hole Thermodynamics 5075
65.4.1 The geometric vocabulary: Killing horizons and surface gravity 5076
65.4.2 The zeroth law: κ is constant over the horizon 5077
65.4.3 The first law: $\mathrm{d}M = (\kappa/8\pi G)\,\mathrm{d}A + \Omega\,\mathrm{d}J + \Phi\,\mathrm{d}Q$ 5078
65.4.4 The second law: the area theorem 5080
65.4.5 Promotion to thermodynamics and the entropy coefficient 5082
65.4.6 The generalized second law 5084
65.4.7 The Bekenstein bound and entropy as an area 5086
65.4.8 Jacobson's inversion: the Einstein equation as an equation of state 5087

65.5 The Euclidean Path Integral and the Gravitational Partition Function . . . 5089
65.5.1 Wick rotation of Schwarzschild and the geometry of the horizon . . . 5089
65.5.2 The gravitational partition function and the saddle-point approximation . . . 5093
65.5.3 The on-shell action: the Gibbons–Hawking–York term and background subtraction . . . 5094
65.5.4 Thermodynamics from the on-shell action . . . 5097
65.5.5 One loop: the fluctuation determinant and zeta regularization 5099
65.6 Hawking Flux from Quantum Anomalies . . . 5100
65.6.1 Near-horizon dimensional reduction: a tower of two-dimensional fields . . . 5100
65.6.2 The trace anomaly fixes the flux: the Christensen–Fulling integration . . . 5102
65.6.3 The same flux from the anomalous (Schwarzian) transformation of T . . . 5105
65.6.4 Robinson–Wilczek: the chiral horizon and the gravitational anomaly . . . 5106
65.6.5 Consistent versus covariant anomalies and the horizon boundary term . . . 5108
65.6.6 Three derivations, one number . . . 5110
65.7 The Trans-Planckian Problem and the Robustness of the Effect . 5111
65.7.1 The trans-Planckian reservoir made quantitative . . . 5112
65.7.2 Robustness I: the near-horizon adiabatic argument . . . 5113
65.7.3 Robustness II: modified dispersion relations . . . 5114
65.7.4 Robustness III: analog horizons and Unruh's dumb holes . 5116
65.7.5 Robustness IV: Hawking radiation as tunneling with backreaction . . . 5118
65.7.6 The corrected spectrum: thermal limit, energy conservation, and correlations . . . 5122
65.8 The Information Problem and the Frontier . . . 5124
65.8.1 The paradox stated precisely . . . 5125
65.8.2 The entanglement structure of the Hawking pairs . . . 5126
65.8.3 The entropy ceiling and the sharpened contradiction . . . 5130
65.8.4 Page's theorem and the Page curve . . . 5130
65.8.5 The menu of proposals . . . 5132
65.8.6 Islands, replica wormholes, and the semiclassical path integral 5135
65.8.7 The bridge to holography . . . 5136

65.8.8 Synthesis: the convergence of the threads and the languages 5137

XVIII Appendices **5141**

A Conventions and Notation **5143**

A.1 Units, Dimensions, and the Counting of Mass Dimension 5144
A.1.1 Natural units and the collapse to a single dimension . . . 5145
A.1.2 Restoring physical units: the conversion factors 5146
A.1.3 The action is dimensionless 5146
A.1.4 Dimensions of the fields 5148
A.1.5 Dimensions of the couplings, and the general rule 5149
A.1.6 Relevant, marginal, irrelevant: the renormalizability classification 5150
A.1.7 Restoring units in practice: two worked computations . . 5153
A.1.8 The benchmark couplings, counted 5155
A.2 Spacetime, the Metric, and Index Conventions 5156
A.2.1 The signature and the metric tensor 5157
A.2.2 Four-vectors and the position–momentum pairing 5157
A.2.3 Raising, lowering, and contraction 5158
A.2.4 Derivative and d'Alembertian conventions 5159
A.2.5 The Levi-Civita tensor and its orientation 5160
A.2.6 The action, the kinetic sign, and why the signs are forced 5161
A.2.7 The benchmark Lagrangians in fixed signature 5163
A.3 Fourier Conventions, Distributions, and Invariant Measures . . . 5165
A.3.1 The Fourier transform and the (2π) bookkeeping 5165
A.3.2 The delta composed with a function 5168
A.3.3 Relativistic normalization of states 5169
A.3.4 The Lorentz-invariant phase-space measure 5170
A.4 Analytic Conventions: the i-epsilon Prescription, Propagators, and Wick Rotation 5174
A.4.1 The Feynman prescription and the displaced poles 5175
A.4.2 The propagators of the carried fields 5178
A.4.3 Wick rotation and the Euclidean conventions 5180
A.5 The Action, Generating Functionals, and Amplitude Normalization 5183
A.5.1 The source coupling and the partition functional 5184
A.5.2 The connected generator $W[J] = -i \ln Z[J]$ 5185
A.5.3 The effective action and the Legendre relations 5186

A.5.4 The S-matrix, the invariant amplitude, and the $-i\lambda$ vertex 5188
A.5.5 Cross sections, decay rates, and the invariant phase space 5190
A.6 Internal Symmetry and Gauge Conventions 5194
A.6.1 Generators, the Lie algebra, and the structure constants . 5194
A.6.2 The covariant derivative and the matter transformation law 5196
A.6.3 The field strength as the curvature of the connection . . . 5198
A.6.4 The Yang–Mills Lagrangian and the canonical $-\frac{1}{4}$ normalization 5200
A.6.5 The abelian reduction and the charge convention 5202
A.7 Regularization and Renormalization-Scheme Conventions 5204
A.7.1 Dimensional continuation: $d = 4 - 2\varepsilon$ 5204
A.7.2 Promotion of the couplings and the scale μ 5205
A.7.3 The generic one-loop structure and its ε-expansion 5207
A.7.4 MS versus $\overline{\text{MS}}$ 5208
A.7.5 A worked one-loop subtraction in $\overline{\text{MS}}$ 5210
A.8 A Translation Dictionary and the Master Glossary 5212
A.8.1 The one principle: a relabelling of the metric 5213
A.8.2 The conversion tables 5217
A.8.3 The translation procedure, step by step 5219
A.8.4 Conventions deliberately kept local 5221
A.8.5 The master glossary 5222

B Group Theory Data **5225**
B.1 Invariants of a Representation: The Index and the Quadratic Casimir 5226
B.1.1 Setup: the algebra, its generators, and a representation . 5226
B.1.2 Two scalars attached to a representation 5228
B.1.3 The master relation 5230
B.1.4 Structure constants: total antisymmetry, reality, and the Killing form 5232
B.1.5 Worked examples 5234
B.2 The Low-Rank Algebras: Pauli and Gell-Mann Matrices 5236
B.2.1 The Pauli matrices and the algebra $\mathfrak{su}(2)$ 5237
B.2.2 The representation invariants of $\mathfrak{su}(2)$ 5239
B.2.3 The Gell-Mann matrices and the algebra $\mathfrak{su}(3)$ 5241
B.2.4 Structure constants and symmetric symbols of $\mathfrak{su}(3)$ . . . 5242
B.2.5 The representation invariants of the $\mathfrak{su}(3)$ fundamental . . 5245
B.3 The Fundamental Completeness Relation and Color Fierz Identities 5247

B.3.1 The fundamental completeness relation 5248
B.3.2 The color-Fierz identity 5251
B.3.3 The trace-reduction algorithm 5252
B.4 Casimirs and Color Factors of SU(N) 5255
B.4.1 The three named invariants 5255
B.4.2 The fundamental Casimir C_F 5256
B.4.3 The structure-constant contraction and C_A 5257
B.4.4 The SU(3) values for QCD 5260
B.4.5 An independent numerical check: the master relation . . . 5260
B.4.6 Assembling the Yang–Mills color factors 5261
B.5 Symmetric Invariants and the Anomaly Coefficient 5263
B.5.1 The symmetrized trace and the cubic invariant 5263
B.5.2 Conjugation reverses the sign 5266
B.5.3 The adjoint is anomaly-free 5266
B.5.4 Which algebras carry a cubic invariant 5267
B.5.5 Computing A(fund) and the additive structure 5269
B.5.6 Higher invariants and where the ladder stops 5271
B.6 Roots, Weights, and a Master Table of Group-Theory Data . . . 5271
B.6.1 The Cartan–Weyl picture, at reference depth 5272
B.6.2 The Cartan classification and its physics dictionary 5273
B.6.3 Weights, Dynkin labels, and the invariant formulas 5275
B.6.4 Worked case: $\mathfrak{su}(3)$ from its weights 5276
B.6.5 The two-index tensors of SU(N) from a single generator . 5278
B.6.6 The master table 5279
B.6.7 Embedding indices and the role in unification 5282

C Gamma Matrices and Spinor Technology 5285
C.1 The Clifford Algebra and Its Lorentz Content 5286
C.1.1 The Clifford algebra defined by anticommutation 5287
C.1.2 The antisymmetrized basis and the dimension count . . . 5287
C.1.3 The Lorentz content: $\sigma^{\mu\nu}$ as a representation of $\mathfrak{so}(1,3)$. 5290
C.1.4 Finite Lorentz transformations of spinors 5291
C.1.5 Identification with the $(\frac{1}{2},0)\oplus(0,\frac{1}{2})$ representation 5293
C.1.6 Worked examples 5294
C.2 Existence and Uniqueness of the Representation 5295
C.2.1 Explicit construction by Kronecker products 5296
C.2.2 Tracelessness, completeness, and irreducibility 5298

C.2.3 Pauli's fundamental theorem 5301
C.2.4 The odd-dimensional case 5303
C.3 The Standard Representations: Dirac, Chiral, and Majorana . . . 5304
C.3.1 The Dirac (standard) representation 5305
C.3.2 The chiral (Weyl) representation 5306
C.3.3 The Majorana representation 5307
C.3.4 The unitary equivalences 5308
C.3.5 The chirality matrix γ^5 and its projectors 5310
C.3.6 The Hermiticity convention 5312
C.3.7 The chiral basis and the $(\frac{1}{2},0)\oplus(0,\frac{1}{2})$ decomposition . . 5314
C.4 Conjugation and Intertwining Matrices: Dirac, Charge, Parity, Time Reversal 5316
C.4.1 The four Clifford-equivalent representations 5317
C.4.2 The Dirac matrix and the parity matrix 5318
C.4.3 The charge-conjugation matrix: existence and uniqueness 5319
C.4.4 Symmetry of C and the bilinear symmetry table 5319
C.4.5 The explicit form $C = i\gamma^2\gamma^0$ 5321
C.4.6 Intertwining of γ^5 and $\sigma^{\mu\nu}$ 5322
C.4.7 Charge conjugation of spinors and the antiparticle solutions 5323
C.4.8 Time reversal and the reality matrix 5324
C.4.9 The Majorana reality condition 5325
C.5 The Sixteen Bilinear Covariants and Completeness 5327
C.5.1 The sixteen matrices and the index set A 5327
C.5.2 Elementary trace facts 5328
C.5.3 Each nontrivial Γ^A is traceless, and the set closes under multiplication 5329
C.5.4 Trace-orthogonality and the basis property 5330
C.5.5 Lorentz classification of the bilinears 5332
C.5.6 The completeness (Fierz) relation 5333
C.6 Trace and Contraction Technology in Four Dimensions 5335
C.6.1 The two pillars: cyclicity and the Clifford relation 5335
C.6.2 Vanishing of odd traces 5336
C.6.3 The even traces and the master recursion 5337
C.6.4 The reversal identity 5338
C.6.5 Traces with γ^5 and the Levi-Civita tensor 5338
C.6.6 Index-contraction identities 5340
C.6.7 The toolkit in slash notation, and a worked trace 5341

C.7 Continuation to $d = 4 - 2\varepsilon$ and the γ^5 Problem 5343
C.7.1 The formal Clifford algebra in d dimensions 5343
C.7.2 The d-dependent contraction identities 5344
C.7.3 Traces in d dimensions 5345
C.7.4 The γ^5 obstruction 5346
C.7.5 The 't Hooft–Veltman–Breitenlohner–Maison scheme . . . 5348
C.7.6 Naive dimensional regularization, Larin's scheme, and evanescent operators 5350
C.8 Fierz Identities and External-State Spinor Technology 5351
C.8.1 The Fierz rearrangement problem 5352
C.8.2 The master formula and the 16×16 Fierz matrix 5352
C.8.3 Canonical case I: the scalar$\times$scalar Fierz 5354
C.8.4 Canonical case II: the $V-A$ self-Fierz 5354
C.8.5 External-state spinors: solutions, normalization, orthogonality 5356
C.8.6 Spin sums and the energy projectors 5357
C.8.7 The Gordon decomposition 5358
C.8.8 Worked example: the spin-summed lepton tensor 5359
C.9 Two-Component Spinor Calculus and the Bridge to Helicity . . . 5361
C.9.1 Undotted and dotted indices and the ϵ spinor metric . . . 5361
C.9.2 The Pauli four-vectors and their algebra 5363
C.9.3 The completeness (Fierz) relation 5364
C.9.4 The chiral-basis dictionary 5366
C.9.5 The generators $\sigma^{\mu\nu}$, $\bar{\sigma}^{\mu\nu}$ and (anti)self-duality 5368

D Loop Integrals and Dimensional Regularization 5371
D.1 The anatomy of a loop integral and the case for analytic continuation in dimension 5373
D.1.1 The generic loop integral 5373
D.1.2 Superficial degree of divergence: the UV diagnosis 5375
D.1.3 Infrared, soft, and collinear divergences: the second diagnosis 5377
D.1.4 What a regulator must do, and why the obvious ones fail 5378
D.1.5 Dimensional analysis in d dimensions and the scale μ . . . 5380
D.1.6 Dimensional regularization as analytic continuation 5382
D.1.7 One-loop integrals in the three benchmark theories 5383
D.2 Combining denominators: Feynman and Schwinger parametrization 5386
D.2.1 The two-denominator Feynman identity 5387
D.2.2 The Schwinger (proper-time) representation 5388

D.2.3 Feynman's formula for N denominators with arbitrary powers 5390
D.2.4 The simplex and its volume 5392
D.2.5 Completing the square: the canonical form and Δ 5394
D.3 Wick rotation and the measure in d dimensions 5398
D.3.1 Pole positions and the legality of the rotation 5399
D.3.2 The solid angle and the radial measure in d dimensions . 5402
D.3.3 Carrying the ϕ^4 bubble across the rotation 5405
D.4 The master one-loop integral and its tensor descendants 5406
D.4.1 The radial integral and the master formula 5407
D.4.2 Numerator integrals: even powers of the loop momentum 5410
D.4.3 Tensor numerators and symmetric integration 5411
D.4.4 The standard scalar functions A_0 and B_0 5413
D.4.5 Analytic structure: where the poles are, and what they mean 5415
D.5 Expansion in ε: poles, finite parts, and the meaning of the scale . 5417
D.5.1 The gamma function near its poles 5417
D.5.2 The prefactor expansions 5421
D.5.3 The universal divergent combination and $\overline{\text{MS}}$ 5421
D.5.4 The fully expanded scalar bubble 5423
D.5.5 The imaginary part and the branch cut 5427
D.6 Tensor reduction: the Passarino–Veltman algorithm 5430
D.6.1 The generic one-loop integral and the reduction philosophy 5430
D.6.2 The two-point family: B^μ and $B^{\mu\nu}$ 5431
D.6.3 The three-point family and the Gram determinant 5433
D.6.4 Completeness: everything reduces to A_0, B_0, C_0, D_0 5435
D.6.5 QED: reducing the one-loop vertex 5436

Chapter 1

Why Quantum Field Theory?

"The career of a young theoretical physicist consists of treating the harmonic oscillator in ever-increasing levels of abstraction."
—Sidney Coleman

This book is about what happens when two of the deepest theories of twentieth-century physics are forced to share a single description of the world. The reader arrives already fluent in both. Nonrelativistic quantum mechanics supplies a Hilbert space of states, observables as Hermitian operators, the canonical commutator $[\hat{x}, \hat{p}] = i$, and unitary time evolution generated by a Hamiltonian. Special relativity supplies a spacetime in which no influence outruns light and in which the laws take the same form for every inertial observer. Each theory is, in its own arena, ruthlessly well tested. The thesis of this chapter is that one cannot simply bolt them together: the most natural attempt — a relativistic version of the single-particle Schrödinger equation — fails, and it fails not through a technical clumsiness to be patched but through a structural impossibility. What replaces it is a quantum theory not of particles but of *fields*, and particles emerge from it as a derived notion. Establishing why this replacement is forced, and not merely one option among many, is the whole business of Chapter 1.

The argument is constructive rather than axiomatic. We will write down the obvious relativistic wave equations, the Klein–Gordon equation and the Dirac equation, and watch each one break: negative energies with no stable ground state, probability densities that go negative, and amplitudes that leak outside the light cone. Each failure, examined closely, points the same direction. The energy uncertainty of a particle confined to its own Compton wavelength is enough to make a new particle–antiparticle pair, so particle number cannot be conserved; and the apparent acausality of relativistic propagation is repaired only when a particle going one way is allowed to interfere with an antiparticle going the other. Both repairs demand a framework with a variable number of particles and a local, causal structure built in from the start. That framework is quantum field theory,

and the principle that organizes it — microscopic causality, the commuting of observables at spacelike separation — is important enough that it earns its own section (Section 1.5), one that is referred back to from the amplitudes chapters at the very end of the book.

We fix conventions now, in force for the whole chapter and matching the book-wide canon collected in Appendix A. The metric is mostly-minus, $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, so that an on-shell particle satisfies $p^2 = m^2$; we work in natural units $\hbar = c = 1$, restoring factors only when we put numbers to an estimate and saying so when we do; and repeated indices are summed, with $p \cdot x = p^0 x^0 - \mathbf{p}\cdot\mathbf{x}$. Where this chapter previews a later construction we point forward honestly: the scalar field is quantized in Chapter 9, the Dirac field in Chapter 11, and the electromagnetic field in Chapter 13, and nothing asserted here as a preview is left unproved there. The three running examples that thread the book — the real scalar $\lambda\phi^4$ theory, quantum electrodynamics, and Yang–Mills theory — make their first appearance at the end of this chapter as destinations on a map, not yet as machinery.

1.1 Relativity versus the single particle

The Schrödinger equation is not Lorentz invariant, and the reason is plain on the face of it. Quantizing the nonrelativistic dispersion relation $E = \mathbf{p}^2/2m$ by the substitutions $E \to i\partial_t$ and $\mathbf{p} \to -i\nabla$ gives

$$i\,\frac{\partial\psi}{\partial t} = -\frac{1}{2m}\nabla^2\psi, \tag{1.1}$$

which is first order in time but second order in space. Under a Lorentz boost time and space are mixed, so an equation that treats ∂_t and ∇ so asymmetrically cannot retain its form in every frame. This is not a deficiency of Schrödinger's equation — it is an exact and superbly accurate description of slow electrons — but it tells us that any relativistic wave equation must put time and space derivatives on the same footing. The natural place to start is therefore not with the dynamics but with the relativistic dispersion relation it must encode,

$$E^2 = \mathbf{p}^2 + m^2, \tag{1.2}$$

which is just the statement $p^2 = m^2$ in mostly-minus signature, written out with $p^0 = E$. Equation (1.2) is the seed from which every candidate relativistic wave equation grows, and it already contains the germ of the trouble: solving it for the energy gives $E = \pm\sqrt{\mathbf{p}^2 + m^2}$, two branches, one of them negative. A nonrelativistic theory never has to confront the negative branch because $E = \mathbf{p}^2/2m \geq 0$ automatically. A relativistic theory cannot avoid it, because the square in (1.2) is exactly what Lorentz invariance requires. Holding this observation in mind, we now build the simplest equation consistent with (1.2) and follow its consequences without flinching.

1.2 The Klein–Gordon equation

Applying the operator substitutions $E \to i\partial_t$, $\mathbf{p} \to -i\nabla$ directly to the squared relation (1.2) gives a wave equation for a single complex function $\phi(x)$,

$$\boxed{\left(\partial_t^2 - \nabla^2 + m^2\right)\phi = 0} \qquad \Longleftrightarrow \qquad (\Box + m^2)\phi = 0, \tag{1.3}$$

the *Klein–Gordon equation*, where $\Box \equiv \partial_\mu \partial^\mu = \partial_t^2 - \nabla^2$ is the d'Alembertian. Because $\Box$ is a Lorentz scalar and m^2 a constant, (1.3) has manifestly the same form in every inertial frame: a solution in one frame is a solution in all. In this narrow sense Klein–Gordon succeeds where Schrödinger could not. As the equation of motion of a *classical* relativistic field it is entirely sound, and it reappears in exactly that role in Chapter 6 as the Euler–Lagrange equation of the free scalar Lagrangian. The difficulties we are about to expose are difficulties of *interpretation*: they arise only when one insists, as the analogy with Schrödinger's equation invites, on reading ϕ as the probability amplitude of a single particle.

1.2.1 The conserved current, and why its density is not a probability

A probability interpretation needs a conserved, positive density. In the non-relativistic theory the Schrödinger equation supplies one: $\rho = |\psi|^2 \geq 0$ obeys $\partial_t \rho + \nabla \cdot \mathbf{j} = 0$. We ask whether Klein–Gordon supplies an analogue, and we construct it honestly rather than quoting the answer. Multiply (1.3) by ϕ^* on the left, multiply the complex conjugate equation $(\Box + m^2)\phi^* = 0$ by ϕ, and subtract:

$$\phi^* \Box \phi - \phi \, \Box \phi^* = 0. \tag{1.4}$$

The mass terms cancel exactly because m^2 is real, which is the first hint that the surviving object is a genuine conservation law rather than an accident. The left-hand side is a total divergence. To see this, note

$$\partial_\mu(\phi^* \partial^\mu \phi - \phi \, \partial^\mu \phi^*) = \partial_\mu \phi^* \partial^\mu \phi + \phi^* \Box \phi - \partial_\mu \phi \, \partial^\mu \phi^* - \phi \, \Box \phi^* = \phi^* \Box \phi - \phi \, \Box \phi^*, \tag{1.5}$$

where the two gradient-cross terms cancel. Comparing (1.4) with (1.5), the four-current

$$j^\mu = i \left(\phi^* \partial^\mu \phi - \phi \, \partial^\mu \phi^*\right) \tag{1.6}$$

satisfies $\partial_\mu j^\mu = 0$; the factor of i is inserted so that j^μ is real, since under conjugation the bracket changes sign. Writing out the time component with $\partial^0 = \partial_t$ gives the candidate density

$$\rho \equiv j^0 = i \left(\phi^* \partial_t \phi - \phi \, \partial_t \phi^*\right), \tag{1.7}$$

and $\partial_t \rho + \nabla \cdot \mathbf{j} = 0$ with $\mathbf{j} = -i(\phi^* \nabla\phi - \phi \nabla\phi^*)$. So a conserved density exists. The fatal question is its sign.

Here the second-order character of (1.3) takes its revenge. Specifying a solution requires both ϕ and $\partial_t \phi$ as independent initial data, and (1.7) depends on both; nothing constrains their relative phase, so ρ may take either sign. The cleanest demonstration is to evaluate ρ on the plane-wave solutions of (1.3). Substituting $\phi = e^{-ip\cdot x} = e^{-iEt + i\mathbf{p}\cdot\mathbf{x}}$ into Klein–Gordon reproduces $E^2 = \mathbf{p}^2 + m^2$, so both signs $E = \pm E_{\mathbf{p}}$ with $E_{\mathbf{p}} \equiv +\sqrt{\mathbf{p}^2 + m^2}$ are admissible. For such a mode $\partial_t \phi = -iE\phi$, and (1.7) gives

$$\rho = i(\phi^*(-iE\phi) - \phi(iE\phi^*)) = 2E\,|\phi|^2. \tag{1.8}$$

The density is positive on the positive-energy branch and *negative* on the negative-energy branch, in lockstep with the sign of E. A negative probability is meaningless, and one cannot escape by discarding the negative-energy modes, both because that projection is not Lorentz invariant — a boost mixes the branches — and because, as (1.8) makes plain, the bad density is welded to the negative energies that (1.2) forced upon us in the first place. The two diseases, negative energy and negative probability, are one disease.

The density was never a probability

Equation (1.8) carries the resolution as well as the problem, though we cannot read it yet. The quantity $\rho = 2E|\phi|^2$ flips sign with E exactly as an electric *charge* density would for a particle versus its antiparticle. The Klein–Gordon current (1.6) is not a probability current at all; it is a *charge* current, and the field ϕ describes both a particle and an oppositely charged antiparticle on the same footing. This is invisible from inside single-particle quantum mechanics, where there is one particle and its norm must be a probability. It becomes the natural reading only once ϕ is an operator and j^μ a conserved Noether charge of a many-particle theory — the quantized complex scalar of Chapter 9.

1.2.2 Negative energy and the absence of a ground state

Even setting probability aside, the negative-energy branch is independently catastrophic for any would-be quantum theory. Quantum mechanics rests on the existence of a state of lowest energy, the ground state, both because the spectrum must be bounded below for the theory to be stable and because the whole edifice of thermodynamics and of perturbation theory is built on it. The dispersion relation (1.2) admits energies $E = -\sqrt{\mathbf{p}^2 + m^2}$ unbounded below as $|\mathbf{p}| \to \infty$. A single particle coupled to anything that can carry away energy — a photon, say — would cascade down this bottomless ladder forever, radiating without limit. No such cascade is observed; ordinary matter is stable. A consistent relativistic

quantum theory must therefore find a way to live with the negative-energy solutions of (1.2) that it cannot discard, while nonetheless possessing a stable lowest-energy state. Reconciling these two demands is the single technical knot that the rest of the chapter unties.

1.3 Dirac's equation and the sea

Dirac approached the negative-probability problem from a sharp diagnosis: the density (1.7) is dangerous because it involves $\partial_t\phi$, and it involves $\partial_t\phi$ because Klein–Gordon is second order in time. A first-order equation would give a density built from ψ alone, as in the nonrelativistic theory. The price of first order in time is, by Lorentz symmetry, first order in space as well; and an equation linear in all four derivatives that nonetheless squares to the Klein–Gordon operator cannot be satisfied by a single function. Demanding

$$(i\gamma^\mu\partial_\mu - m)(i\gamma^\nu\partial_\nu + m) = -(\Box + m^2) \tag{1.9}$$

forces $\gamma^\mu\gamma^\nu + \gamma^\nu\gamma^\mu = 2\eta^{\mu\nu}$, the Clifford algebra, whose lowest-dimensional realization in four spacetime dimensions is by 4×4 matrices. The wavefunction must accordingly carry four components, and Dirac's equation reads

$$\boxed{(i\gamma^\mu\partial_\mu - m)\psi = 0} \tag{1.10}$$

with ψ a four-component spinor. The full representation theory behind the γ^μ and the spinor ψ is developed in Chapter 11; here we need only the algebra $\{\gamma^\mu,\gamma^\nu\} = 2\eta^{\mu\nu}$ and the Dirac adjoint $\bar\psi = \psi^\dagger\gamma^0$.

1.3.1 A positive density at last

The promise of the first-order construction was a positive, conserved density, and we verify it in full rather than assert it. Begin with (1.10), written $i\gamma^\mu\partial_\mu\psi = m\psi$. Take the Hermitian conjugate, $-i\,\partial_\mu\psi^\dagger\gamma^{\mu\dagger} = m\psi^\dagger$, and use the identity $\gamma^{\mu\dagger} = \gamma^0\gamma^\mu\gamma^0$ (a consequence of the Clifford algebra together with $(\gamma^0)^2 = 1$, established in Chapter 11) after multiplying on the right by γ^0:

$$-i\,\partial_\mu\psi^\dagger\gamma^0\gamma^\mu = m\,\psi^\dagger\gamma^0, \qquad \text{i.e.} \qquad -i\,\partial_\mu\bar\psi\,\gamma^\mu = m\,\bar\psi. \tag{1.11}$$

Now contract the original equation with $\bar\psi$ on the left and the adjoint equation (1.11) with ψ on the right, and add:

$$i\,\bar\psi\gamma^\mu\partial_\mu\psi + i\,(\partial_\mu\bar\psi)\gamma^\mu\psi = m\,\bar\psi\psi - m\,\bar\psi\psi = 0 \implies \partial_\mu\Big(\bar\psi\gamma^\mu\psi\Big) = 0. \tag{1.12}$$

The Dirac current $j^\mu = \bar\psi\gamma^\mu\psi$ is conserved, and its time component is

$$j^0 = \bar\psi\gamma^0\psi = \psi^\dagger\gamma^0\gamma^0\psi = \psi^\dagger\psi = \sum_{a=1}^{4}|\psi_a|^2 \geq 0, \tag{1.13}$$

using $(\gamma^0)^2 = \eta^{00} = 1$. The density is manifestly non-negative. Dirac's equation has accomplished exactly what it set out to do: it has cured the negative-probability disease of Klein–Gordon.

1.3.2 But the negative energies remain

What it has *not* cured is the negative energies, because those came from the dispersion relation (1.2), which Dirac's equation reproduces component by component — that was the design requirement. Plane-wave solutions of (1.10) again come with $E = \pm E_{\mathbf{p}}$, and the negative-energy spinors cannot be thrown away: they are needed for the four-component spinor basis to be complete, so that an arbitrary initial ψ can be expanded at all. A positive density over a spectrum with no bottom is no improvement on the stability problem of Section 1.2; an electron in a positive-energy state could still radiate its way down into the negative-energy continuum.

Dirac's escape was as bold as the equation. Electrons are fermions, obeying the Pauli exclusion principle, so suppose that what we call the vacuum is in fact the state in which *every* negative-energy level is already occupied — an infinite filled "sea." A positive-energy electron then cannot fall into a negative-energy state because all of them are taken. The sea is by fiat the ground state. Excitations above it are of two kinds. Adding energy can promote a sea electron to a positive-energy state, leaving behind a *hole*: the absence of a negative-energy, negatively charged electron, which presents to the world as the presence of a positive-energy, positively charged particle of the *same mass*. The hole is an *antiparticle*.

From the proton to the positron

Dirac at first hoped the hole might be the proton, the only positively charged particle then known, reluctant to predict a new one. The identification was untenable: the hole must have the electron's mass, not the proton's two-thousand-fold larger one. By 1931 Dirac accepted the conclusion and predicted a positive electron [151]. Carl Anderson found it in cosmic-ray tracks in 1932. The episode is the first instance of a pattern that recurs throughout this book: a consistency requirement of relativistic quantum theory — here, what to do with the unavoidable negative-energy states — predicts new physics, and the new physics is there.

1.3.3 Why the sea is not the final word

The hole picture is a triumph, but it is scaffolding, not foundation, and it is worth being precise about why. First, it is irredeemably tied to the exclusion principle and so to fermions. Bosons — the quanta of the Klein–Gordon field,

for instance — have no exclusion principle; one cannot fill their negative-energy states to keep particles out, since any number of bosons may occupy each state. Yet charged spin-zero particles and their antiparticles plainly exist (charged pions, for one), and the negative-energy and negative-density problems of Section 1.2 are every bit as real for them. A construction that works only for fermions cannot be the general resolution. Second, the sea is an infinite reservoir of negative charge and energy whose properties must be quietly subtracted away to recover sensible answers; the bookkeeping is awkward and frame-dependent in just the way a fundamental description should not be. Third, and most tellingly, the very language has shifted under our feet: the moment we admit holes we have abandoned the single-particle theory we set out to build. A hole is a second excitation; pair-creation of an electron and a hole changes the particle count. The Dirac sea is a many-body system wearing single-particle clothing.

The lesson of the sea

The success of the hole picture and the awkwardness of its mechanism point past themselves to a cleaner statement. What relativistic quantum mechanics is really telling us is that *particle number is not a fixed label of a state*. Antiparticles must exist; particles and antiparticles can be made and unmade together; the natural arena is one in which the number of quanta is itself dynamical. The Dirac sea is one — fermion-only, frame-dependent — realization of this truth. Quantum field theory will be its frame-independent, species-blind realization, in which particle and antiparticle, boson and fermion, all appear symmetrically as excitations of a field and the vacuum needs no infinite reservoir at all.

1.4 Pair creation: particle number is not conserved

We have reached the central physical fact by two routes — negative-energy stability and the limits of the sea — and we now reach it a third way, by an estimate so elementary it can be made on the back of an envelope and so robust that no escape from it exists. The claim is that the attempt to localize a relativistic quantum particle within its own Compton wavelength supplies enough energy to create new particles, so that "one particle, sharply located" is not a state the theory can hold.

The estimate combines two principles the reader already trusts. From quantum mechanics, confining a particle to a spatial region of size Δx costs a momentum spread $\Delta p \gtrsim 1/\Delta x$ (this is $\hbar/\Delta x$ with $\hbar$ restored), and for a relativistic particle a momentum of order Δp carries an energy of order $\Delta E \sim \Delta p \sim 1/\Delta x$. From relativity, energy of order $2m$ (that is, $2mc^2$) deposited in a small region is enough to materialize a particle–antiparticle pair, since each member has rest

energy m. Setting the available energy equal to the pair threshold,

$$\Delta E \sim \frac{1}{\Delta x} \gtrsim 2m \qquad \Longleftrightarrow \qquad \Delta x \lesssim \frac{1}{2m}, \tag{1.14}$$

so as soon as one tries to pin a particle down to within (a fraction of) its reduced Compton wavelength $\lambda_C \equiv 1/m = \hbar/mc$, the localization energy suffices to make a new pair. The would-be single particle has spawned company. Probing shorter distances does not sharpen the picture of one particle; it guarantees many.

Worked Example 1.1 (title=Compton wavelengths and pair-creation thresholds)**.** We put numbers to (1.14) for three masses, which also fixes the distance and energy scales at which a single-particle description must be abandoned. The one constant needed is $\hbar c = 197.3\,\text{MeV fm}$, so the reduced Compton wavelength is $\lambda_C = \hbar c/(mc^2)$ and the pair threshold is $2mc^2$.

Electron ($mc^2 = 0.511\,\text{MeV}$):

$$\lambda_C = \frac{197.3\,\text{MeV fm}}{0.511\,\text{MeV}} \approx 386\,\text{fm}, \qquad 2mc^2 \approx 1.02\,\text{MeV}. \tag{1.15}$$

This is the scale of atomic and low-energy collision physics; it is exactly where positrons and pair production first intrude on the single-electron description, as in the 1.02 MeV threshold for e^+e^- production by a photon.

Proton ($mc^2 = 938\,\text{MeV}$):

$$\lambda_C = \frac{197.3}{938}\,\text{fm} \approx 0.21\,\text{fm}, \qquad 2mc^2 \approx 1.88\,\text{GeV}. \tag{1.16}$$

The proton's Compton wavelength is a fifth of a femtometre, smaller than the proton itself ($\sim 0.84\,\text{fm}$), a first sign that the proton is not elementary.

A light nucleus (carbon-12, $mc^2 \approx 11.2\,\text{GeV}$):

$$\lambda_C \approx \frac{197.3}{11200}\,\text{fm} \approx 1.8 \times 10^{-2}\,\text{fm}, \qquad 2mc^2 \approx 22\,\text{GeV}. \tag{1.17}$$

The heavier the object, the shorter the distance over which single-particle quantum mechanics survives and the higher the energy needed to break it — which is why nonrelativistic quantum mechanics is so accurate for nuclei and atoms in their ground states, and why it fails precisely in the relativistic, high-energy collisions where new particles are made.

The estimate is a threshold, not a switch

Equation (1.14) should not be read as "below the Compton wavelength, pairs; above it, none." Virtual pair creation contributes at *all* scales — it is responsible, for example, for the vacuum polarization that makes the electric charge run with energy (Chapter 13 and Part VI). What the

estimate establishes is the sharper, structural point: there is *no* regime in which a relativistic quantum theory can consistently hold particle number fixed, because the very act of localization that a single-particle wavefunction presupposes injects pair-creating energy. Particle number is not a good quantum number, full stop.

1.5 Locality, causality, and microcausality

A relativistic theory must respect causality: no measurement, no disturbance, no signal may propagate faster than light, because in another frame a superluminal influence runs backward in time and effect precedes cause. We now show that relativistic single-particle quantum mechanics violates this requirement, that the violation is repaired only by the existence of antiparticles, and that the repair is codified in a condition — microcausality — which a field theory must satisfy and which, remarkably, turns out to dictate the connection between spin and statistics. This section is the conceptual hinge of the chapter, and it is referred back to from the synthesis of scattering theory at the end of the book, where causality is reinstated as one of the small handful of inputs from which amplitudes can be reconstructed.

1.5.1 Amplitudes leak outside the light cone

Consider the amplitude for a particle prepared at the spacetime origin to be found at a point $\mathbf{x}$ a time t later. In nonrelativistic quantum mechanics this is the Schrödinger propagator

$$U(\mathbf{x},t) = \left\langle \mathbf{x}\middle| e^{-i\hat{H}t}\, 0\right\rangle = \int \frac{d^3p}{(2\pi)^3}\, e^{i\mathbf{p}\cdot\mathbf{x}}\, e^{-i\mathbf{p}^2 t/2m} = \left(\frac{m}{2\pi i t}\right)^{3/2} e^{\,im\mathbf{x}^2/2t}, \quad (1.18)$$

the last step being a Gaussian integral. This amplitude is nonzero for *every* $\mathbf{x}$ at any $t > 0$: a particle localized at the origin has instantly a nonzero amplitude to be found arbitrarily far away. Strictly this already violates relativity, but harmlessly, because the nonrelativistic theory makes no claim to relativistic causality and the offending amplitude is a pure phase of fixed modulus that carries no usable signal. The question is what becomes of (1.18) when we do the same computation relativistically, replacing the energy $\mathbf{p}^2/2m$ by the relativistic $E_{\mathbf{p}} = \sqrt{\mathbf{p}^2 + m^2}$:

$$U(\mathbf{x},t) = \int \frac{d^3p}{(2\pi)^3}\, e^{i\mathbf{p}\cdot\mathbf{x}}\, e^{-iE_{\mathbf{p}}t}. \quad (1.19)$$

This integral is evaluated in full in Chapter 9, where the propagator is studied as the central object of the free scalar theory; the result is that for a spacelike-separated final point, $\mathbf{x}^2 > t^2$, the amplitude does not vanish but falls off as $U \sim$

$e^{-m\sqrt{\mathbf{x}^2-t^2}}$. The amplitude to propagate outside the light cone is exponentially small — suppressed once the spacelike separation exceeds a Compton wavelength, the same scale as everywhere in this chapter — but it is not zero. Taken at face value as a single-particle propagation amplitude, (1.19) says a particle can be found beyond the reach of light. Causality appears to be broken.

1.5.2 How antiparticles restore causality

The resolution is the one foreshadowed by the negative-energy density of (1.8) and by the holes of Section 1.3, and it is worth stating precisely even though its proof must wait for the operator formalism of Chapter 9. Causality, in a quantum theory, is not the demand that out-of-cone amplitudes vanish individually; it is the demand that no *measurement* at one point can affect the statistics of a *measurement* at a spacelike-separated point. The amplitude (1.19) for a particle to travel from a point A to a spacelike-separated point B is, by itself, nonzero — but so is the amplitude for an *antiparticle* to travel from B to A. To a Lorentz observer the two processes are not even distinct: a boost can reverse the temporal order of two spacelike-separated events, turning "particle from A to B" into "antiparticle from B to A," since reversing the direction of travel of a particle of charge $+q$ in time is indistinguishable from a charge $-q$ moving the other way. Any frame-independent, causal quantity must therefore include both. When one computes the genuinely observable object — the commutator of two field operators at A and B — the particle and antiparticle contributions *cancel exactly* outside the light cone. The leftover noncausal tail of (1.19) is precisely the piece that the antiparticle process subtracts.

This cancellation is impossible to arrange in a single-particle theory, which has particles but no antiparticles to do the cancelling, and it requires the two species to have equal masses and opposite charges and to be created and destroyed in concert — exactly the content of antiparticle symmetry. It works only in a theory where both are present from the start, on equal footing, with no infinite sea: a quantum field theory. The full computation, including the exact form of the cancellation and the role of the time-ordering that defines the Feynman propagator, is carried out in Chapter 9; what matters here is the logic, that *causality forces antiparticles*, the converse of the lesson of Section 1.4 that pair creation forces a many-particle theory.

1.5.3 Microcausality and the seed of spin-statistics

We can now state the principle that the field-theoretic framework will be built to satisfy. Observables are represented by local operators $\mathcal{O}(x)$, built from fields at the point x. Two measurements at spacelike separation must not influence each other, which in quantum mechanics means their operators must be simultaneously diagonalizable — they must commute. This is the principle of *microcausality*, or

local commutativity:

$$\boxed{[\mathcal{O}_1(x), \mathcal{O}_2(y)] = 0 \qquad \text{whenever} \qquad (x-y)^2 < 0.} \tag{1.20}$$

Spacelike-separated observables commute; the commutator is the carrier of mutual influence, and outside the light cone there must be none. Equation (1.20) is not a theorem to be proved within single-particle quantum mechanics — it cannot be, as we have seen — but a structural requirement *imposed* on a relativistic quantum theory, and it is one of the load-bearing axioms of the subject.

Its consequences run deeper than causality alone. When the free fields are quantized in Part III, the requirement (1.20) that observables built from them commute at spacelike separation can be met for a spin-zero field only if the field is expanded with *commuting* creation and annihilation operators, and for a spin-one-half field only if it is expanded with *anticommuting* ones. Demanding causality thus forces integer-spin particles to be bosons and half-integer-spin particles to be fermions: this is the spin-statistics connection, and Chapter 9 exhibits it explicitly for the scalar while Chapter 11 does so for the Dirac field. The Pauli exclusion principle, postulated by Dirac as an external input to build his sea, is in the field-theoretic framework a *derived* consequence of relativistic causality. That a single principle — no influence outside the light cone — should both repair the causality paradox and explain why electrons exclude one another is among the deepest results in physics, and it is a result that has no home in single-particle quantum mechanics. It lives only in quantum field theory.

1.6 Fields as the fundamental objects

Every thread of the argument now converges on the same prescription. Particle number is not conserved (Section 1.4); antiparticles must exist and interfere with particles (Section 1.5); the negative-energy states cannot be discarded yet must not destabilize the vacuum (Sections 1.2 and 1.3). A framework meeting all of these at once cannot take "the position of the particle" as its basic variable, because there may be no definite number of particles to have positions. It must instead take as fundamental an object defined everywhere in spacetime, able to support any number of excitations, with a stable lowest-energy state. That object is a *quantum field*: an operator $\hat{\phi}(x)$, or $\hat{\psi}(x)$, attached to each spacetime point, acting on a single Hilbert space that accommodates states of zero, one, two, or arbitrarily many quanta.

1.6.1 Particles as quanta

The reader has, in fact, already met a quantum field and quantized it, perhaps without the name. The electromagnetic field is a classical field $\mathbf{E}(\mathbf{x}, t)$, $\mathbf{B}(\mathbf{x}, t)$

filling all of space, with energy

$$H_{\text{EM}} = \frac{1}{2}\int d^3x\,(\mathbf{E}^2 + \mathbf{B}^2). \tag{1.21}$$

Resolved into normal modes, this is a collection of independent harmonic oscillators, one for each wavevector and polarization. Quantizing each oscillator by the ladder method of elementary quantum mechanics gives a mode of frequency ω the energy spectrum $E = \omega\,(n + \frac{1}{2})$ with $n = 0, 1, 2, \ldots$, and we name the integer n the *number of photons* in that mode. The photon is not a primitive entity; it is a *quantized excitation of the electromagnetic field*, and the photon number is exactly the kind of dynamical, non-conserved quantity that Section 1.4 demanded. This construction — the quantization of the electromagnetic field and the emergence of the photon, together with the gauge subtleties unique to a massless spin-one field — is carried out in Chapter 13.

The same idea, applied to every species, is the ontology of the subject. Each kind of particle is the quantum of a field. Electrons and positrons are the excitations of the Dirac field $\psi(x)$ of Chapter 11; the spinless quanta of a real scalar field are the simplest case of all, quantized first in Chapter 9; quarks and gluons are excitations of quark and gluon fields. The field is primary; particles are what its quanta are called. In this language the vacuum is simply the state with no quanta in any mode — a unique, stable, lowest-energy state, with no infinite sea to subtract — and a multiparticle state is built by exciting modes above it. The negative-energy solutions that wrecked the single-particle reading are reinterpreted without contradiction: the negative-frequency part of the field operator multiplies an operator that *creates an antiparticle*, rather than describing a particle of negative energy. Every energy in the spectrum is positive; the ground state exists; antiparticles are automatic; particle number floats. The entire list of demands is met at one stroke.

Why "second quantization" is a misleading name

The passage from quantum mechanics to field theory is often called *second quantization*, and the term, though entrenched, misleads. In first quantization one promotes the classical phase-space variables of a particle to operators, $x, p \to \hat{x}, \hat{p}$ with $[\hat{x}, \hat{p}] = i$. In "second" quantization one promotes the wavefunction itself — already a quantum object — to an operator-valued field $\hat{\psi}(\mathbf{x})$ obeying $\left[\hat{\psi}(\mathbf{x}), \hat{\psi}^\dagger(\mathbf{y})\right] = \delta^{(3)}(\mathbf{x}-\mathbf{y})$ (anticommutators for fermions). But nothing is quantized twice. What has happened is a change of fundamental variable: the field, not the particle coordinate, is the thing whose modes are quantized. The single-particle Schrödinger wavefunction reappears only as the matrix element $\langle 0|\hat{\psi}(\mathbf{x})|1 \text{ particle}\rangle$, a derived quantity in a theory whose Hilbert space — the *Fock space*, the direct sum of the n-particle spaces for all $n \geq 0$ — contains states of every

particle number at once.

1.6.2 The three theories that will recur

Having argued for fields in general, we name the three specific field theories that will serve as the book's running examples, so the reader can recognize them as old friends when each returns, one layer deeper, throughout the chapters ahead. We do not develop them here; each is properly introduced as the logical development requires.

The simplest is a single real scalar field with a quartic self-interaction, the $\lambda\phi^4$ *theory*, whose classical Lagrangian

$$\mathcal{L} = \tfrac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4 \tag{1.22}$$

is the universal pedagogical workhorse: simple enough to compute everything explicitly, rich enough to exhibit nearly every phenomenon in the book. We will quantize its free part in Chapter 9, compute its first scattering amplitude, renormalize it, follow its coupling under the renormalization group, and finally meet it at a nontrivial fixed point that is a conformal field theory — the handoff from the textbook core to the frontier. The second is *quantum electrodynamics*, the theory of the electron field ψ coupled to the photon field A_μ, whose interaction we will derive in Chapter 13 and Part V from nothing but the principle of local U(1) gauge invariance; it carries us to the most precisely verified prediction in all of science, the electron's anomalous magnetic moment. The third is *Yang–Mills theory*, the non-abelian generalization in which the gauge group is SU(N) rather than U(1); it underlies both the strong force (SU(3)) and, in broken form, the weak force, and its peculiar property of growing weak at short distances — asymptotic freedom — is one of the high points of Part VII. These three theories, scalar, abelian gauge, and non-abelian gauge, are the spine along which the entire development is organized.

1.7 A map of the book

With the necessity of fields established, we close by laying out the route from here to the frontier, so the reader can see the destination from the trailhead. The logical order is cumulative: each part supplies tools the next one cannot do without.

We begin with *mathematical foundations* (Part I): the representation theory of the Lorentz and Poincaré groups, which classifies what a relativistic particle can be — the scalars, spinors, and vectors that became our fields above — together with the functional and analytic machinery the rest of the book quotes.

Classical field theory (Part II) then treats fields as classical dynamical systems: the action principle, Noether's theorem linking symmetries to conservation laws, and the gauge principle that derives electromagnetism from a symmetry. With the classical theory in hand we *quantize the free fields* (Part III), making rigorous the heuristic "modes are oscillators" of Section 1.6 for the scalar, Dirac, and electromagnetic fields, and proving there the microcausality and spin-statistics results promised in Section 1.5.

Interactions enter next (Parts IV–VI). The S-matrix and the Dyson series turn the interacting Hamiltonian into a perturbative expansion; Feynman diagrams organize that expansion; and the cross-section formulae connect it to what detectors measure. Applied to electrodynamics (Part V) this yields real numbers for real processes. The infinities that appear along the way are not a defect but a signpost, and *renormalization and the renormalization group* (Part VI) extract from them the modern understanding that every quantum field theory is an effective description valid up to some scale, with physics organized by how couplings flow as that scale changes. From there the structure of the Standard Model unfolds: *non-abelian gauge theories* (Part VII), *spontaneous symmetry breaking* and the Higgs mechanism (Part VIII), the *Standard Model* itself (Part IX), and the *anomalies* (Part X) that constrain which theories are even consistent. Beyond perturbation theory lie *effective field theories* (Part XI), genuinely *non-perturbative methods* — instantons, solitons, the lattice (Part XII) — and *supersymmetry* (Part XIII), where exact results become possible.

The final third of the book is the frontier, developed at the same depth as the core rather than surveyed. *Conformal field theory and the bootstrap* (Part XIV) study quantum field theories at their scale-invariant fixed points — where $\lambda\phi^4$ theory terminates, at the Wilson–Fisher fixed point and the three-dimensional Ising model — and reconstruct them from symmetry and consistency alone. *Holography* (Part XV) develops the correspondence by which a quantum field theory without gravity is exactly equivalent to a gravitational theory in one higher dimension, knitting together quantum information and spacetime geometry. *Modern scattering amplitudes* (Part XVI) returns to the gauge theories of QED and Yang–Mills theory and rebuilds their amplitudes from analyticity, unitarity, and the very causality of Section 1.5, revealing structures — the spinor-helicity formalism, on-shell recursion, the double copy relating gauge theory to gravity — invisible in the Feynman-diagram expansion that first produced them. A short final part treats *quantum field theory in curved spacetime*, where the vacuum itself becomes observer-dependent and black holes are found to radiate.

Some of these frontier results are settled mathematics and some are the live edge of current research; we will be explicit, and will date our claims, about which is which. The reader who reaches the end will have followed a single chain of reasoning, with no gaps and no external lookups, from the failure we diagnosed in this chapter — that quantum mechanics and special relativity cannot share a

single particle — all the way to the structures at the boundary of what is known. The first link in that chain is the one we have just forged: relativity and the quantum, taken together, are a theory of fields.

Further reading

The motivation for quantum field theory from the failure of single-particle relativistic quantum mechanics is given with particular care in Peskin and Schroeder [396] ch. 1–2 and Schwartz [432] ch. 1–2; the localization/pair-creation argument of Section 1.4 follows the spirit of both. Weinberg [500] ch. 1 tells the same story as intellectual history, from the Dirac equation through the discovery that fields, not particles, are fundamental, and is the definitive statement of the view that quantum field theory is the inevitable consequence of relativity, the quantum, and cluster decomposition. Zee [532] ch. I.1–I.2 gives the quickest physical route to the same conclusion. The original papers repay reading: Dirac's equation [150] and his prediction of the antielectron [151], and the Feynman–Stückelberg reinterpretation of antiparticles as negative-energy solutions running backward in time [191]. For the structural results previewed in Section 1.5 — microcausality and the spin-statistics connection at the axiomatic level — see Streater and Wightman [458]; the algebraic perspective on locality is developed in Haag [246]. Coleman [129] is unmatched as a sustained pedagogical companion to the whole of the textbook core.

Part I

Mathematical Foundations

Chapter 2

Groups and Representations

Chapter 1 argued that relativity and quantum mechanics cannot coexist as separate theories: insist on both, and the number of particles ceases to be conserved, localized one-particle wavefunctions lose their meaning, and we are forced to describe nature by quantum *fields* with infinitely many degrees of freedom. The question this raises is organizational. With so many degrees of freedom, what disciplines them? What tells us which fields can exist, how they combine, and which interactions are allowed? The answer, running through every chapter that follows, is *symmetry*. And the lesson that makes symmetry the north star of this book is Wigner's: an elementary particle is not a little ball with properties attached, but *is* an irreducible unitary representation of the symmetry group of spacetime. Mass and spin are not data we measure and tabulate; they are the two labels (the Casimir invariants) that classify those representations. Before we can say in Chapter 3 what a relativistic particle can possibly be, or in Chapters 8 and 25 how the gauge principle conjures the forces between particles out of a demand for local symmetry, we must first learn what a representation is and how to find them all. That is the work of this chapter.

We build the language from the group axioms upward, from first principles, without assuming prior acquaintance with representation theory. What *is* assumed is linear algebra—eigendecompositions, inner products, unitary and Hermitian operators—and the angular-momentum ladder of nonrelativistic quantum mechanics at the Sakurai level. The reader has met J^2, J_z, and the raising and lowering operators $J_\pm$, and has used the spin-j multiplets of dimension $2j+1$. Here those familiar objects are recast as what they honestly are: the complete representation theory of the Lie algebra $\mathfrak{su}(2)$. Nothing about the ladder is taken on faith as physics folklore; it is rederived as a theorem about how an abstract three-element bracket can be realized on a finite-dimensional space. This recasting is the single most important transferable skill in the chapter, because the method that solves $\mathfrak{su}(2)$ is the method that, suitably generalized, solves every compact simple Lie algebra.

The chapter is one road, not a list of topics. A symmetry acts on the quantum state space, and consistency with the probability interpretation forces that action to be *unitary*; a representation is exactly such a linear action, and the first task is to tame it. A general (reducible) action is a stack of indivisible pieces, so we isolate the atoms—the irreducible representations—and prove the structural facts that make the decomposition unique and computable: Maschke's complete-reducibility theorem, Schur's lemma, and the orthogonality of characters. We then pass from finite groups to *continuous* ones, where a single new idea does almost all the work: a continuous symmetry is captured near the identity by its linearization, the Lie algebra, and the full group element is recovered by exponentiation. With that bridge in hand we solve $\mathfrak{su}(2)$ completely—the worked spine of the chapter—and find the spin-j irreducibles falling out as the only possibilities. Combining two systems then forces the tensor product and its decomposition into irreducibles, the Clebsch–Gordan problem, which is where addition of angular momenta comes from. Finally the $\mathfrak{su}(2)$ method is industrialized: Cartan and Weyl replace the single ladder by a ladder for each *root*, and the highest-weight construction classifies the irreducibles of any compact simple algebra. We carry this far enough to solve $\mathfrak{su}(3)$ in full.

The payoff is that this foundations chapter is where two of the book's three benchmark theories receive their alphabet. The complete $\mathfrak{su}(2)$ representation theory built here is the template every later spin and isospin computation silently reuses; in particular the explicit spin-$\frac{1}{2}$ matrices seed QED, where the electron enters as a two-component object that Chapter 11 quantizes as a Dirac field. And $\mathfrak{su}(3)$, with its Hermitian generators T^a, structure constants f^{abc}, and quadratic Casimir, is the exact language of color that Yang–Mills theory will speak: the non-abelian gauge theory of Chapter 25 is built on precisely these data, and its color factors C_A and C_F are the Casimirs defined here. The hand-off to Chapter 3 is sharp: the Lie-algebra/exponential machinery and the full $\mathfrak{su}(2)$ representation theory are exactly what is needed to recognize the Lorentz algebra as $\mathfrak{so}(1,3) \cong \mathfrak{su}(2) \oplus \mathfrak{su}(2)$ and to read off the scalar, Weyl, Dirac, and vector fields as its representations.

Throughout we use the standing conventions of Chapter A. Generators of a Lie algebra are taken *Hermitian*, so that group elements $\exp(-i\theta_a T^a)$ are unitary, with the bracket and fundamental normalization

$$\left[T^a, T^b\right] = i f^{abc} T^c, \qquad \operatorname{tr}(T^a T^b) = \tfrac{1}{2}\delta^{ab} \quad \text{(fundamental representation)}. \tag{2.1}$$

The structural definitions live here; the catalogued numerical data—Casimirs and Dynkin indices for general $\mathrm{SU}(N)$, the $\mathrm{SU}(N)$ identities, and the explicit Gell-Mann and Pauli matrices—are arbitrated by Chapter B. With conventions fixed, we begin where all of group theory begins: with the idea of a symmetry and the axioms that pin it down.

2.1 Symmetry, Groups, and Why We Represent Them

The chapter opened with a claim that sounds more like a slogan than a theorem: an elementary particle *is* an irreducible unitary representation of the spacetime symmetry group. A slogan is only as good as the words in it, and three of these words have so far been used without being defined. What is a *representation*? When is one *unitary*? What does it mean for a representation to be *irreducible* — the property that, Wigner tells us, distinguishes an elementary particle from a composite one? This section answers the first two questions and sets up the third. We begin where the physics begins, with the notion of a symmetry, extract from it the abstract object a symmetry generates — a group — and then confront the fact that in quantum mechanics a group never acts on states directly but always through linear operators. That action is the representation. By the end of the section we will have a working vocabulary (group, homomorphism, representation, faithfulness, equivalence, unitarity, direct sum), a stocked zoo of examples to test every later statement against, and one genuine theorem: over a finite group, the word "unitary" costs nothing, because every representation can be made unitary by a change of basis. That theorem, due to Weyl, is the finite-group shadow of a fact that will organize the whole book.

Throughout we use the conventions fixed in Chapter A; the structural data (dimensions, Casimir eigenvalues, Dynkin indices) for the continuous groups named below are collected in Chapter B and will be derived where the development needs them.

2.1.1 What a symmetry is, and why it must act linearly

Physically, a symmetry is a transformation of a system that leaves its dynamics unchanged: rotate the apparatus, or translate it, or reflect it, and the same experiment gives statistically the same results. The transformations that qualify share a structure so rigid that it is worth isolating before we name it. First, doing nothing is a symmetry. Second, any symmetry can be undone — if a rotation by θ preserves the dynamics, so does the rotation by $-\theta$ that reverses it. Third, two symmetries performed in succession give a third: rotate, then rotate again, and the net operation is still a rotation that preserves the dynamics. Fourth, when we compose three of them the order of bracketing is irrelevant, because composition of transformations of a set is automatically associative. These four facts — an identity, inverses, closure under composition, and associativity — are not a coincidence of rotations. They are forced on *any* collection of invertible transformations closed under composition, and they are exactly the axioms of a group. The group is the abstract residue of the symmetry: it remembers how the transformations combine while forgetting what they act on.

But in quantum mechanics a symmetry cannot remain abstract, because the system it acts on is a definite mathematical object — a complex Hilbert space $\mathcal{H}$

whose rays (one-dimensional subspaces) are the physical states. A symmetry must send states to states in a way that preserves everything physically measurable, and the only physically measurable thing built from two states $|\psi\rangle, |\phi\rangle$ is the transition probability $|\langle\psi|\phi\rangle|^2 / (\langle\psi|\psi\rangle \langle\phi|\phi\rangle)$. So a quantum symmetry is, at minimum, a map of rays to rays that preserves all such probabilities. The content of Wigner's theorem — which we state here for orientation and prove in its proper home, the spacetime setting of Chapter 3 — is that any such map is induced by an operator U on $\mathcal{H}$ that is either *unitary* (linear, with $\langle U\psi|U\phi\rangle = \langle\psi|\phi\rangle$) or *antiunitary* (antilinear, with $\langle U\psi|U\phi\rangle = \langle\phi|\psi\rangle$), and that the operator is unique up to an overall phase. Antiunitary operators are needed only for symmetries that reverse the direction of time; every continuous symmetry, and every symmetry we build up from the identity, is realized unitarily.

Physical Insight

The lesson to carry forward is that the abstract group is never the real object of study in quantum mechanics. A group of symmetries is given to us, but what acts on the states is a family of unitary operators $U(g)$, one for each group element g, composing the way the group does: $U(g)U(h) = U(gh)$. That family — a homomorphism from the group into the unitary operators on $\mathcal{H}$ — is a *unitary representation*. The phase ambiguity in Wigner's theorem means the composition law need only hold up to a phase, $U(g)U(h) = e^{i\xi(g,h)}U(gh)$, giving a *projective* representation; we note this now and return to it for the rotation and Lorentz groups in Chapter 3, where the phases turn out to encode half-integer spin. Until then we work with honest (non-projective) representations, where $U(g)U(h) = U(gh)$ exactly.

This is why representation theory, and not abstract group theory, is the language of this book: the physics lives in how the symmetry group acts by linear operators on a vector space, and different actions of the same group are genuinely different physics. An electron and a photon are acted on by the same rotation group, but through inequivalent representations, and that inequivalence is the difference between spin $\frac{1}{2}$ and spin 1. We now make each italicized word precise.

2.1.2 Groups

Definition 2.1 (Group)**.** A *group* is a set G equipped with a binary operation $G \times G \to G$, written $(g, h) \mapsto gh$ and called the *product*, satisfying:

(G1) *Associativity:* $(gh)k = g(hk)$ for all $g, h, k \in G$.

(G2) *Identity:* there is an element $e \in G$ with $eg = ge = g$ for all $g \in G$.

(G3) *Inverses:* for each $g \in G$ there is an element $g^{-1} \in G$ with $g\,g^{-1} = g^{-1}g = e$.

The group is *abelian* (or commutative) if in addition $gh = hg$ for all g, h. The number of elements $|G|$ is the *order* of G; it may be finite or infinite. A *subgroup* is a subset $H \subseteq G$ that contains e and is closed under products and inverses, so that H is itself a group under the inherited operation.

The identity is unique, for if e and e' both satisfy (G2) then $e = ee' = e'$. Inverses are unique, for if h and h' both invert g then $h = h(gh') = (hg)h' = h'$. These one-line arguments are the reason we may speak of *the* identity and *the* inverse; we use them silently from now on. Two more facts of constant use: $(gh)^{-1} = h^{-1}g^{-1}$ (check: $(gh)(h^{-1}g^{-1}) = g(hh^{-1})g^{-1} = e$), and the *cancellation law* $gx = gy \Rightarrow x = y$, obtained by multiplying on the left by g^{-1}. Cancellation has an immediate consequence we will exploit repeatedly: for fixed g, the map $x \mapsto gx$ is a bijection of G onto itself, since it is injective by cancellation and surjective because $g^{-1}y$ maps to y. "Left translation permutes the group" is the engine behind both the regular representation and the averaging trick below.

The point of the axioms is the examples they govern, so we stock a zoo. We split it into the finite groups, where counting arguments rule, and the continuous (Lie) groups, where the physics of spacetime and gauge symmetry lives.

Finite groups. The simplest infinite family is the *cyclic group*.

Example 2.2 (Cyclic group $\mathbb{Z}_n$)**.** Fix an integer $n \geq 1$ and let $\mathbb{Z}_n = \{0, 1, \ldots, n-1\}$ with the product given by addition modulo n. Associativity is inherited from integer addition; the identity is 0; the inverse of k is $n - k$ (and of 0 is 0). The group is abelian and of order n. A more revealing model realizes the *same* group as the n-th roots of unity $\{\, \omega^k : k = 0, \ldots, n-1 \,\}$ with $\omega = e^{2\pi i/n}$, under multiplication of complex numbers: $\omega^j \omega^k = \omega^{j+k} = \omega^{(j+k) \bmod n}$ because $\omega^n = 1$. Geometrically these are the rotations of a regular n-gon about its center by multiples of $2\pi/n$. The cyclic group is generated by a single element (the rotation ω, or the integer 1): every element is a power of it. We meet $\mathbb{Z}_2$ again as the parity $\phi \to -\phi$ of ϕ^4 theory.

Allowing reflections as well as rotations of the n-gon enlarges $\mathbb{Z}_n$ to a non-abelian group, our first.

Example 2.3 (Dihedral group D_n)**.** The *dihedral group* D_n is the symmetry group of a regular n-gon, comprising the n rotations of $\mathbb{Z}_n$ and n reflections, so $|D_n| = 2n$. Write r for the rotation by $2\pi/n$ and s for any one reflection. Then $r^n = e$, $s^2 = e$, and the two generators fail to commute: reflecting, rotating, and reflecting back is the same as rotating the other way,

$$srs^{-1} = r^{-1}. \tag{2.2}$$

These relations determine the group completely — every element is uniquely r^k or $s\,r^k$ with $0 \le k < n$ — and Eq. (2.2) shows D_n is nonabelian for $n \ge 3$. A presentation like this, listing generators and the relations they satisfy, is often the most economical way to specify a finite group.

Example 2.4 (Symmetric group S_n)**.** The *symmetric group* S_n is the set of all bijections (permutations) of $\{1, 2, \dots, n\}$, with composition of functions as the product. The identity is the permutation that fixes everything; inverses exist because bijections are invertible; associativity is automatic for composition of maps. Its order is $|S_n| = n!$, and it is nonabelian for $n \ge 3$. The symmetric group is not an exotic special case but the universal one: *every* finite group of order n is a subgroup of S_n, because (by the cancellation law) left translation embeds G into the permutations of its own underlying set. This embedding is Cayley's theorem, and it is the prototype of the regular representation we build in Section 2.1.3. S_n also governs the quantum statistics of identical particles: the permutation symmetry of an n-body wavefunction is an action of S_n, and bosons and fermions are the two one-dimensional representations we will meet by name below.

Continuous groups. The groups that organize field theory are not finite but *continuous*: their elements are labeled by real parameters varying smoothly, and the group product and inversion are smooth functions of those parameters. Such a group is a *Lie group*; we treat the continuous parameters and the calculus they support systematically in Section 2.3, and here only name the cast and their defining conditions as matrix groups. A *matrix group* is a subgroup of the invertible $n \times n$ complex matrices $\mathrm{GL}(n, \mathbb{C})$ under matrix multiplication; the identity is the unit matrix $\mathbf{1}$ and inverses are matrix inverses, so the group axioms hold automatically and the only question is which matrices we keep.

Example 2.5 (The unitary and orthogonal families)**.** The following matrix groups recur throughout the book.

- $\mathrm{U}(1) = \{\, e^{i\theta} : \theta \in \mathbb{R} \,\}$, the unit circle of phases under multiplication, with $e^{i\theta}e^{i\theta'} = e^{i(\theta+\theta')}$. It is abelian, and is the gauge group of electromagnetism (QED): the phase rotations of a complex field. Topologically it is a circle.

- $\mathrm{SU}(N) = \{\, U \in \mathrm{GL}(N, \mathbb{C}) : U^\dagger U = \mathbf{1},\ \det U = 1 \,\}$, the special unitary group. The condition $U^\dagger U = \mathbf{1}$ preserves the Hermitian inner product $\langle u|v\rangle = u^\dagger v$ on $\mathbb{C}^N$; the condition $\det U = 1$ removes an overall phase. $\mathrm{SU}(2)$ is the group of spin (QED's electron) and the worked spine of this chapter; $\mathrm{SU}(3)$ is the color group of Yang–Mills theory and, separately, the approximate flavor symmetry of the light quarks. We solve $\mathrm{SU}(2)$ completely and reach $\mathrm{SU}(3)$ by the same method.

- $\mathrm{SO}(N) = \{\, R \in \mathrm{GL}(N,\mathbb{R}) : R^{\mathsf{T}}R = \mathbf{1},\ \det R = 1 \,\}$, the special orthogonal group, the rotations of real N-dimensional Euclidean space: $R^{\mathsf{T}}R = \mathbf{1}$ preserves the Euclidean length $|\mathbf{x}|^2 = \mathbf{x}^{\mathsf{T}}\mathbf{x}$, and $\det R = 1$ keeps orientation (excluding reflections). $\mathrm{SO}(3)$ is the rotation group of ordinary space.

The group that ultimately matters for relativistic physics is the *Lorentz group* $\mathrm{SO}(1,3)^{+}$, the analogue of $\mathrm{SO}(N)$ for the indefinite Minkowski metric of Chapter A. Its representations are the entire subject of Chapter 3; we name it here so the reader knows what the machinery of this chapter is being built to attack. A first hint of the trouble it will cause: $\mathrm{U}(1)$, $\mathrm{SU}(N)$ and $\mathrm{SO}(N)$ are *compact* (their parameter ranges are bounded and closed — the phases live on a circle, the unitary and orthogonal matrices in a bounded region), whereas the Lorentz group is *noncompact* because boosts run off to infinite rapidity. Compactness is exactly the property that will let us unitarize representations, first for finite groups in this section and then, by an integral in place of a sum, for compact Lie groups. Its failure for the Lorentz group is why a relativistic particle has no finite-dimensional unitary representation, a fact Chapter 3 must confront head-on.

To compare groups, and to recognize when two apparently different groups are "the same," we need the structure-preserving maps between them.

Definition 2.6 (Homomorphism, isomorphism)**.** A *homomorphism* of groups is a map $\varphi : G \to H$ that respects the products,

$$\varphi(g_1 g_2) = \varphi(g_1)\,\varphi(g_2) \qquad \text{for all } g_1, g_2 \in G. \tag{2.3}$$

It automatically respects the identity and inverses: $\varphi(e_G) = \varphi(e_G e_G) = \varphi(e_G)^2$ forces $\varphi(e_G) = e_H$ after cancellation, and then $\varphi(g)\varphi(g^{-1}) = \varphi(e_G) = e_H$ gives $\varphi(g^{-1}) = \varphi(g)^{-1}$. The *kernel* $\ker\varphi = \{\, g \in G : \varphi(g) = e_H \,\}$ and the *image* $\varphi(G) \subseteq H$ are subgroups. The map φ is injective if and only if $\ker\varphi = \{e_G\}$, since $\varphi(g_1) = \varphi(g_2) \Leftrightarrow \varphi(g_1 g_2^{-1}) = e_H$. An *isomorphism* is a bijective homomorphism; when one exists we write $G \cong H$ and treat the two groups as the same abstract object presented differently — exactly the relation between the two models of $\mathbb{Z}_n$ in Theorem 2.2.

Homomorphisms are the lens through which one group "sees" another. The representations of the next subsection are nothing but the homomorphisms into the most concrete target groups of all: the invertible linear operators on a vector space.

2.1.3 Representations

Definition 2.7 (Representation)**.** Let G be a group and V a finite-dimensional complex vector space. A *representation* of G on V is a homomorphism

$$\rho : G \longrightarrow \mathrm{GL}(V), \qquad \rho(g_1 g_2) = \rho(g_1)\rho(g_2), \tag{2.4}$$

where $\mathrm{GL}(V)$ is the group of invertible linear operators on V. The *dimension* of the representation is $\dim V$. Choosing a basis of V turns each $\rho(g)$ into an invertible matrix, and Eq. (2.4) becomes a statement about matrix products; we move freely between the basis-free operator picture and the matrix picture, calling the latter a *matrix representation*. The space V is the *representation space*, and its vectors carry the physical states (or fields) on which the symmetry acts.

A representation is precisely the realization of an abstract symmetry as honest linear operators, the object Wigner's theorem hands us in the quantum setting. The defining property Eq. (2.4) guarantees consistency: composing symmetries and then acting is the same as acting one after another, and $\rho(e) = \mathbf{1}_V$ while $\rho(g^{-1}) = \rho(g)^{-1}$, so the operators reproduce the group's bookkeeping faithfully. Three representations exist for *every* group and anchor all later examples.

Example 2.8 (Trivial, defining, and regular representations)**.** *(i) The trivial representation* sends every g to the identity on a one-dimensional space, $\rho(g) = 1$ on $V = \mathbb{C}$. It is the mathematical home of any quantity invariant under the symmetry (a scalar, a singlet). For S_n it is the symmetric (bosonic) one-dimensional representation; the *sign representation* $\rho(\pi) = \mathrm{sgn}(\pi) \in \{\pm 1\}$, which records the parity of a permutation, is the antisymmetric (fermionic) one.

(ii) The defining (fundamental) representation of a matrix group is the tautological one: $\rho(g) = g$ acting on the column vectors $\mathbb{C}^N$ (or $\mathbb{R}^N$) it is built from. For $\mathrm{SU}(N)$ this is the N-dimensional representation that quarks transform in; for $\mathrm{SO}(3)$ it is the action on ordinary vectors.

(iii) The regular representation is the universal construction that exists for any finite group G. Take $V = \mathbb{C}[G]$, the $|G|$-dimensional complex vector space with one basis vector $|h\rangle$ for each group element $h \in G$, and let G act by permuting the basis through left multiplication,

$$\rho_{\mathrm{reg}}(g)\ |h\rangle = |gh\rangle\,. \tag{2.5}$$

This is a representation: $\rho_{\mathrm{reg}}(g_1)\rho_{\mathrm{reg}}(g_2)\,|h\rangle = \rho_{\mathrm{reg}}(g_1)\,|g_2 h\rangle = |g_1 g_2 h\rangle = \rho_{\mathrm{reg}}(g_1 g_2)\,|h\rangle$, and each operator is invertible because left translation is a bijection (the cancellation law again). In a basis, $\rho_{\mathrm{reg}}(g)$ is a permutation matrix — exactly one 1 in each row and column. The regular representation packages the entire multiplication table of G into linear algebra, and we will see in Section 2.2.6 and the character section that it contains every irreducible representation of G, each appearing a number of times equal to its own dimension. It is the finite-group analogue of the statement that the space of functions on a symmetry group decomposes into all the field multiplets the group allows.

When does a representation lose information about the group? Exactly when its homomorphism collapses distinct elements.

Definition 2.9 (Faithful representation)**.** A representation $\rho : G \to \mathrm{GL}(V)$ is *faithful* if it is injective, equivalently if $\ker \rho = \{e\}$: distinct group elements act by distinct operators. A faithful representation is a perfect copy of G inside $\mathrm{GL}(V)$, so that the abstract group can be recovered entirely from its action.

The trivial representation is maximally unfaithful (its kernel is all of G); the regular representation is always faithful, because $\rho_{\mathrm{reg}}(g)\,|e\rangle = |g\rangle$ already distinguishes every g. Cayley's theorem, mentioned above, is the observation that this faithful permutation action embeds G into $S_{|G|}$. Faithfulness matters physically: the sign representation of S_n is unfaithful for $n \geq 3$ (it cannot tell a 3-cycle from the identity, both having $\mathrm{sgn} = +1$), so a quantity transforming in it sees only the parity of a permutation, not the permutation itself.

Two representations can be the same in all that matters yet look different because they are written in different bases. We must declare such pairs equivalent or the classification program is hopeless.

Definition 2.10 (Equivalence)**.** Two representations $\rho : G \to \mathrm{GL}(V)$ and $\rho' : G \to \mathrm{GL}(V')$ are *equivalent* (written $\rho \sim \rho'$) if there is an invertible linear map $S : V \to V'$ intertwining them,

$$\rho'(g) = S\,\rho(g)\,S^{-1} \qquad \text{for all } g \in G. \tag{2.6}$$

When $V = V'$ this is a change of basis: ρ and ρ' are the same operators expressed in coordinates related by S. Equivalence is an equivalence relation (reflexive with $S = \mathbf{1}$, symmetric with S^{-1}, transitive by composing intertwiners), and the real objects of representation theory are the equivalence classes, not the individual matrices.

Of all the bases one might choose, one class is singled out by physics. In quantum mechanics the representation space carries an inner product — it is (a piece of) a Hilbert space — and probabilities are inner products. A symmetry must preserve them.

Definition 2.11 (Unitary representation)**.** Let V carry a Hermitian inner product $\langle\,\cdot\,,\cdot\,\rangle$. A representation $\rho : G \to \mathrm{GL}(V)$ is *unitary* if every operator $\rho(g)$ is unitary,

$$\langle \rho(g)u,\, \rho(g)v\rangle = \langle u, v\rangle \qquad \text{for all } g \in G,\ u, v \in V, \tag{2.7}$$

equivalently $\rho(g)^{\dagger}\rho(g) = \mathbf{1}$ for every g, with the adjoint taken in $\langle\,\cdot\,,\cdot\,\rangle$. Unitarity is precisely the condition that the representation conserves quantum-mechanical probability: $\langle\psi,\psi\rangle$ is left invariant, so a normalized state stays normalized under the symmetry.

Unitarity is the property Wigner's theorem promises for quantum symmetries, and it is the reason the chapter's slogan reads "unitary representation" rather than just "representation." Finally, representations can be combined. The simplest combination stacks two systems that do not interact under the symmetry.

Definition 2.12 (Direct sum)**.** Given representations $\rho_1 : G \to \mathrm{GL}(V_1)$ and $\rho_2 : G \to \mathrm{GL}(V_2)$, their *direct sum* is the representation $\rho_1 \oplus \rho_2$ on $V_1 \oplus V_2$ acting blockwise,

$$(\rho_1 \oplus \rho_2)(g) = \begin{pmatrix} \rho_1(g) & 0 \\ 0 & \rho_2(g) \end{pmatrix}, \tag{2.8}$$

a $(\dim V_1 + \dim V_2)$-dimensional representation in which the two blocks never mix: V_1 and V_2 are each carried to themselves by every $\rho(g)$. A subspace with this last property — invariant under all of $\rho(G)$ — is called a *subrepresentation*, and a representation is a direct sum exactly when its space splits into two complementary subrepresentations. If a representation can be brought, by a single change of basis as in Eq. (2.6), to the block-diagonal form Eq. (2.8) with both blocks nonzero, it is *reducible*; if no nontrivial invariant subspace exists, it is *irreducible*.

The direct sum is the bookkeeping of "and": a spin-$\frac{1}{2}$ particle together with a spin-1 particle transforms in the direct sum of the two rotation representations. The deep question — which the rest of the chapter exists to answer — is the reverse one. Given a representation, can we always split it into a direct sum of irreducibles, the indivisible atoms out of which all others are assembled? If so, classifying the atoms classifies everything. Reducibility is a basis-dependent statement (Eq. (2.8) asks for a particular block form), and that is precisely where unitarity earns its keep: in a unitary representation, the orthogonal complement of an invariant subspace is again invariant, so every reducible unitary representation *does* split. We prove that complete reducibility, and the lemma of Schur that organizes the atoms, in the next section. The present section secures the prerequisite: that for a finite group, unitarity may always be arranged.

2.1.4 The Weyl unitarian trick

The decomposition program just sketched needs unitary representations to run. Yet Theorem 2.7 demands no inner-product compatibility at all — a generic representation by invertible matrices is not unitary. The remarkable fact, and the one substantial theorem of this section, is that for a finite group this never obstructs us: *every* finite-dimensional complex representation of a finite group is equivalent to a unitary one. The construction is averaging, the most characteristic move in the subject. An inner product handed to us need not be invariant under $\rho(G)$, but we can force invariance by averaging it over the group — and because the group is finite, the average is a finite sum that manifestly exists.

Theorem 2.13 (Unitarizability of finite-group representations; Weyl)**.** *Let G be a finite group and $\rho : G \to \mathrm{GL}(V)$ a finite-dimensional complex representation. Then ρ is equivalent to a unitary representation. Equivalently, there exists a Hermitian inner product on V with respect to which every $\rho(g)$ is unitary.*

Proof. Start with any Hermitian inner product $\langle \cdot, \cdot \rangle_0$ on V; one always exists — pick a basis and declare it orthonormal, so that $\langle u, v \rangle_0 = u^\dagger v$ in that basis. This inner product need not satisfy Eq. (2.7). Define a new pairing by averaging it over the group:

$$\langle u, v \rangle \;\equiv\; \frac{1}{|G|} \sum_{g \in G} \langle \rho(g)u,\, \rho(g)v \rangle_0. \tag{2.9}$$

Step 1: Eq. (2.9) is a Hermitian inner product. Each summand is linear in v and conjugate-linear in u (because $\langle \cdot, \cdot \rangle_0$ is, and $\rho(g)$ is linear), so the sum is sesquilinear. Conjugate symmetry, $\langle v, u \rangle = \overline{\langle u, v \rangle}$, follows termwise from that of $\langle \cdot, \cdot \rangle_0$. For positivity, set $u = v$:

$$\langle u, u \rangle = \frac{1}{|G|} \sum_{g \in G} \langle \rho(g)u,\, \rho(g)u \rangle_0 = \frac{1}{|G|} \sum_{g \in G} \|\rho(g)u\|_0^2 \;\geq\; 0, \tag{2.10}$$

a sum of nonnegative terms. It vanishes only if every term vanishes, in particular the $g = e$ term $\|u\|_0^2$, forcing $u = 0$. (Equivalently, each $\rho(g)$ is invertible, so $\rho(g)u = 0 \Leftrightarrow u = 0$.) Hence Eq. (2.9) is positive-definite and is a bona fide Hermitian inner product.

Step 2: the new inner product is G-invariant. Fix $h \in G$ and compute, using that ρ is a homomorphism so $\rho(g)\rho(h) = \rho(gh)$,

$$\langle \rho(h)u,\, \rho(h)v \rangle = \frac{1}{|G|} \sum_{g \in G} \langle \rho(g)\rho(h)u,\, \rho(g)\rho(h)v \rangle_0 = \frac{1}{|G|} \sum_{g \in G} \langle \rho(gh)u,\, \rho(gh)v \rangle_0. \tag{2.11}$$

As g runs once over G, the product gh also runs once over G — this is the bijection $g \mapsto gh$ established by the cancellation law. Reindexing the sum by $g' = gh$ therefore leaves it unchanged:

$$\langle \rho(h)u,\, \rho(h)v \rangle = \frac{1}{|G|} \sum_{g' \in G} \langle \rho(g')u,\, \rho(g')v \rangle_0 = \langle u, v \rangle. \tag{2.12}$$

Thus every $\rho(h)$ preserves $\langle \cdot, \cdot \rangle$: with respect to the averaged inner product, ρ is already unitary. This proves the second ("equivalently") form of the theorem. The averaging has built the invariance that the original inner product lacked.

Step 3: realize the invariance as a similarity to the standard unitary group. It remains to exhibit the intertwiner S of Eq. (2.6) that conjugates ρ into operators unitary for the *standard* inner product $\langle u, v \rangle_0 = u^\dagger v$ — this is what "equivalent to a unitary representation" means in matrix terms. Both inner products are written through a matrix: from Eq. (2.9),

$$\langle u, v \rangle = \frac{1}{|G|} \sum_{g \in G} \big(\rho(g)u\big)^\dagger \big(\rho(g)v\big) = u^\dagger\, H\, v, \qquad H \equiv \frac{1}{|G|} \sum_{g \in G} \rho(g)^\dagger \rho(g). \tag{2.13}$$

The matrix H is Hermitian, $H^\dagger = H$, since each $\rho(g)^\dagger \rho(g)$ is, and it is positive-definite because $u^\dagger H u = \langle u, u \rangle > 0$ for $u \neq 0$ by Step 1. The invariance Eq. (2.12),

written in matrix form $\langle \rho(h)u, \rho(h)v\rangle = (\rho(h)u)^\dagger H(\rho(h)v) = u^\dagger(\rho(h)^\dagger H\rho(h))v$ and equated to $u^\dagger Hv$ for all u, v, is the operator identity

$$\rho(h)^\dagger\, H\, \rho(h) = H \qquad \text{for all } h \in G. \tag{2.14}$$

Because H is positive-definite Hermitian it has a unique positive-definite Hermitian square root $S \equiv H^{1/2}$: diagonalize $H = UDU^\dagger$ with U unitary and D diagonal with strictly positive entries, and set $S = UD^{1/2}U^\dagger$, so that $S = S^\dagger$, S is invertible, and $S^2 = H$. Now define the equivalent representation $\rho'(g) \equiv S\,\rho(g)\,S^{-1}$. It is a representation (conjugation by a fixed S preserves products), and it is unitary for the standard inner product:

$$\begin{aligned}\rho'(g)^\dagger\rho'(g) &= \big(S\rho(g)S^{-1}\big)^\dagger\big(S\rho(g)S^{-1}\big) = S^{-1}\rho(g)^\dagger S \;\cdot\; S\rho(g)S^{-1} \\ &= S^{-1}\,\rho(g)^\dagger S^2\rho(g)\,S^{-1} = S^{-1}\,\rho(g)^\dagger H\rho(g)\,S^{-1} = S^{-1}HS^{-1} = S^{-1}S^2S^{-1} = \mathbf{1},\end{aligned} \tag{2.15}$$

where we used $S^\dagger = S$, $(S^{-1})^\dagger = S^{-1}$, then $S^2 = H$, then the invariance Eq. (2.14), and finally $S^2 = H$ once more. Hence ρ' is a unitary representation equivalent to ρ, which is the first form of the theorem. □

Physical Insight

Every line of the proof used finiteness in exactly one place: the average $\frac{1}{|G|}\sum_{g\in G}$ must converge. For a *compact* Lie group the finite sum is replaced by an integral against the (finite, normalized) invariant Haar measure, $\int_G dg\,(\cdots)$, and the same three steps go through verbatim — so compact Lie groups (in particular U(1), SU(N), SO(N)) also have only unitary representations, up to equivalence. This is the deep reason compactness was flagged in Theorem 2.5. The construction breaks for the noncompact Lorentz group precisely because its invariant measure has infinite total volume: there is no normalized average, no invariant inner product on a finite-dimensional space, and indeed no finite-dimensional unitary representation at all — the structural fact that forces the relativistic particle into an infinite-dimensional Hilbert space in Chapter 3.

The trick is best absorbed on a concrete representation that starts out non-unitary.

Worked Example 2.14 (Unitarizing a representation of $\mathbb{Z}_2$)**.** Let $G = \mathbb{Z}_2 = \{e, r\}$ with $r^2 = e$, and define a two-dimensional representation by

$$\rho(e) = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \qquad \rho(r) = \begin{pmatrix} 1 & 1 \\ 0 & -1 \end{pmatrix}. \tag{2.16}$$

This is a representation: $\rho(r)^2 = \left(\begin{smallmatrix} 1 & 1 \\ 0 & -1 \end{smallmatrix}\right)\left(\begin{smallmatrix} 1 & 1 \\ 0 & -1 \end{smallmatrix}\right) = \left(\begin{smallmatrix} 1 & 1-1 \\ 0 & 1 \end{smallmatrix}\right) = \mathbf{1} = \rho(e)$, as required by $r^2 = e$. It is *not* unitary, since $\rho(r)^\dagger\rho(r) = \left(\begin{smallmatrix} 1 & 0 \\ 1 & -1 \end{smallmatrix}\right)\left(\begin{smallmatrix} 1 & 1 \\ 0 & -1 \end{smallmatrix}\right) = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 2 \end{smallmatrix}\right) \neq \mathbf{1}$. We

unitarize it by the recipe of Theorem 2.13. The averaged metric matrix Eq. (2.13) is

$$H = \tfrac{1}{2}\Big(\rho(e)^\dagger\rho(e) + \rho(r)^\dagger\rho(r)\Big) = \tfrac{1}{2}\left[\begin{pmatrix}1&0\\0&1\end{pmatrix} + \begin{pmatrix}1&1\\1&2\end{pmatrix}\right] = \begin{pmatrix}1&\frac{1}{2}\\\frac{1}{2}&\frac{3}{2}\end{pmatrix}, \tag{2.17}$$

which is Hermitian and positive-definite (trace $\frac{5}{2} > 0$, determinant $\frac{3}{2} - \frac{1}{4} = \frac{5}{4} > 0$). We check the invariance Eq. (2.14) directly. First

$$H\rho(r) = \begin{pmatrix}1&\frac{1}{2}\\\frac{1}{2}&\frac{3}{2}\end{pmatrix}\begin{pmatrix}1&1\\0&-1\end{pmatrix} = \begin{pmatrix}1&1-\frac{1}{2}\\\frac{1}{2}&\frac{1}{2}-\frac{3}{2}\end{pmatrix} = \begin{pmatrix}1&\frac{1}{2}\\\frac{1}{2}&-1\end{pmatrix}, \tag{2.18}$$

and then

$$\rho(r)^\dagger(H\rho(r)) = \begin{pmatrix}1&0\\1&-1\end{pmatrix}\begin{pmatrix}1&\frac{1}{2}\\\frac{1}{2}&-1\end{pmatrix} = \begin{pmatrix}1&\frac{1}{2}\\1-\frac{1}{2}&\frac{1}{2}+1\end{pmatrix} = \begin{pmatrix}1&\frac{1}{2}\\\frac{1}{2}&\frac{3}{2}\end{pmatrix} = H, \tag{2.19}$$

confirming $\rho(r)^\dagger H\rho(r) = H$. So ρ is genuinely unitary with respect to the averaged inner product $\langle u, v\rangle = u^\dagger H v$, even though it was not unitary for the standard one. Taking the positive square root $S = H^{1/2}$ and forming $\rho'(g) = S\rho(g)S^{-1}$ produces, by Eq. (2.15), an equivalent representation built from ordinary unitary matrices — the same abstract representation, now written in an orthonormal basis adapted to the symmetry. The averaging has not changed the representation; it has changed the geometry of the space to one the symmetry respects.

A second example shows the trick's payoff: once unitarity is free, a representation visibly falls apart into atoms, which is the program of the next section.

Worked Example 2.15 (The regular representation of $\mathbb{Z}_n$ as a sum of atoms)**.** Take $G = \mathbb{Z}_n$ and its regular representation Eq. (2.5) on $V = \mathbb{C}[\mathbb{Z}_n]$, with basis $|0\rangle, |1\rangle, \ldots, |n-1\rangle$ and the generator acting as $\rho_{\text{reg}}(1)\,|j\rangle = |(j+1) \bmod n\rangle$ — a cyclic shift, hence the $n \times n$ permutation matrix with 1's on the (cyclic) subdiagonal. This is already unitary (permutation matrices are), and being abelian, $\mathbb{Z}_n$ can have its single generator diagonalized. The eigenvectors of a cyclic shift are the discrete Fourier modes

$$|\chi_k\rangle = \frac{1}{\sqrt{n}}\sum_{j=0}^{n-1}\omega^{-jk}\,|j\rangle\,, \qquad \omega = e^{2\pi i/n}, \quad k = 0, 1, \ldots, n-1, \tag{2.20}$$

for which $\rho_{\text{reg}}(1)\,|\chi_k\rangle = \frac{1}{\sqrt{n}}\sum_j \omega^{-jk}\,|j+1\rangle = \omega^k\,\frac{1}{\sqrt{n}}\sum_{j'}\omega^{-j'k}\,|j'\rangle = \omega^k\,|\chi_k\rangle$, after relabeling $j' = j+1$ and using $\omega^{-(j'-1)k} = \omega^k\omega^{-j'k}$. Thus the n-dimensional

regular representation decomposes, in the orthonormal Fourier basis, into a direct sum of n one-dimensional representations,

$$\rho_{\text{reg}} \cong \bigoplus_{k=0}^{n-1} \chi_k, \qquad \chi_k(m) = \omega^{mk} = e^{2\pi i m k/n}, \tag{2.21}$$

one for each character χ_k of $\mathbb{Z}_n$. Each χ_k is irreducible — a one-dimensional representation can have no nontrivial invariant subspace — so these are the atoms, and every one of them appears exactly once in the regular representation. This is the promised statement (Theorem 2.8) that the regular representation contains every irreducible, each with multiplicity equal to its dimension; for an abelian group all irreducibles are one-dimensional, so "each appears dim times" reads "each appears once," and the count $\sum_k (\dim \chi_k)^2 = n \cdot 1^2 = n = |G|$ already foreshadows the general dimension formula that the character theory of the next section will prove.

We have now fixed the language in which the rest of the chapter — and much of the book — is written: a symmetry acts on quantum states through a representation; physically that representation is unitary, and over a finite group (and, by averaging against an invariant measure, over a compact one) unitarity may always be arranged; representations combine by direct sum, and the same notion run backward asks whether a given representation splits. Theorem 2.15 has shown a representation visibly breaking into one-dimensional atoms, and Theorem 2.14 has shown unitarity manufactured where none was given. What remains is the heart of the matter, deferred to the next section: the proof that every finite-dimensional unitary representation splits completely into irreducible pieces, the lemma of Schur that pins down how those pieces can map to one another, and the character calculus that counts and identifies them — the bookkeeping that turns "a particle is an irreducible unitary representation" from a slogan into an algorithm.

2.2 Irreducibility, Schur's Lemma, and Characters

The previous section established the object we actually study: not the abstract group G, but a *representation*, a homomorphism $\rho\colon G \to \mathrm{GL}(V)$ realizing the symmetry by linear operators on a vector space, and we proved that for a finite group every representation may be taken unitary (Theorem 2.13). That left a question dangling. A representation can be a clumsy package: the operators $\rho(g)$ may leave some subspace of V untouched, so that the representation secretly contains a smaller one, padded out by directions the group never mixes into it. The natural impulse—the impulse behind essentially every use of symmetry in physics, from the angular-momentum multiplets of the hydrogen atom to the multiplets of the quark model—is to break a representation into its smallest

indivisible pieces and study those. This section makes "indivisible" precise (irreducibility), proves that for finite groups every representation is built cleanly out of indivisible pieces (Maschke's theorem), proves the two rigidity statements that make the indivisible pieces behave like atoms (Schur's lemma), and then introduces the bookkeeping device—the *character*—that lets us recognize which atoms appear in a given representation and with what multiplicity, by nothing more strenuous than computing a few traces. The whole apparatus is the template the rest of the chapter executes: for $\mathfrak{su}(2)$, for $\mathfrak{su}(3)$, and, ported to the continuous setting, for every symmetry algebra of the Standard Model.

We work over the complex numbers $\mathbb{C}$ throughout. This is not a convenience: the second half of Schur's lemma, and with it the entire clean theory of characters, depends on $\mathbb{C}$ being algebraically closed, and physics lives on complex Hilbert spaces in any case. Unless stated otherwise G is a finite group of order $|G|$ and every vector space is finite-dimensional over $\mathbb{C}$.

2.2.1 Invariant subspaces and irreducibility

Definition 2.16 (Invariant subspace)**.** Let (ρ, V) be a representation of G. A linear subspace $W \subseteq V$ is *invariant* (or a *subrepresentation*) if it is mapped into itself by every group element:

$$\rho(g)\, W \subseteq W \qquad \text{for all } g \in G. \tag{2.22}$$

Because each $\rho(g)$ is invertible and W is finite-dimensional, $\rho(g)W \subseteq W$ forces $\rho(g)W = W$; the restriction $\rho|_W(g) \equiv \rho(g)|_W$ is then itself a representation of G on W.

Every representation has two invariant subspaces for free: the zero subspace $\{0\}$ and the whole space V. These are the *trivial* invariant subspaces. A representation is interesting—indivisible—precisely when it has no others.

Definition 2.17 (Irreducible and completely reducible)**.** A representation (ρ, V) with $V \neq \{0\}$ is *irreducible* if its only invariant subspaces are $\{0\}$ and V. It is *reducible* otherwise. It is *completely reducible* (or *semisimple*) if V decomposes as a direct sum of invariant subspaces each of which is irreducible,

$$V = W_1 \oplus W_2 \oplus \cdots \oplus W_r, \qquad \text{each } W_k \text{ invariant and irreducible.} \tag{2.23}$$

The distinction between merely reducible and completely reducible is the crux. Reducibility says V contains a proper invariant subspace W. Complete reducibility demands more: that W have an invariant *complement* W', a second invariant subspace with $V = W \oplus W'$, so that the representation genuinely splits as the direct sum $\rho|_W \oplus \rho|_{W'}$ rather than merely containing W as a sub-block.

In a basis adapted to a single invariant subspace W, the matrices $\rho(g)$ are block upper-triangular,

$$\rho(g) \;=\; \begin{pmatrix} \rho|_W(g) & B(g) \\ 0 & C(g) \end{pmatrix}, \tag{2.24}$$

the lower-left block vanishing exactly because W is invariant. Reducibility only guarantees this triangular form. Complete reducibility is the statement that one can choose the complement so that the off-diagonal block $B(g)$ also vanishes for *all* g simultaneously, leaving the matrices block-*diagonal*. There is no reason in pure linear algebra to expect such a complement to exist—a single nilpotent operator already provides a counterexample to "every invariant subspace has an invariant complement." That it always exists for representations of a finite group is the content of the next theorem, and it is what makes the finite theory so clean.

2.2.2 Maschke's theorem

Theorem 2.18 (Maschke)**.** *Every representation of a finite group G on a complex vector space is completely reducible. Equivalently: every invariant subspace $W \subseteq V$ admits an invariant complement W', an invariant subspace with $V = W \oplus W'$.*

The two formulations are equivalent by an obvious induction. Given the complement statement, decompose any V: if V is irreducible we are done; if not, it has a proper nontrivial invariant W, which by hypothesis has an invariant complement W', and $\dim W, \dim W' < \dim V$, so by induction on dimension each splits into irreducibles, and their union is a decomposition Eq. (2.23) of V. So it suffices to prove the complement statement.

The mechanism is *averaging over the group*—the single most important trick of finite-group representation theory, and the discrete ancestor of the integration over a compact Lie group that will replace it in later sections. The idea: any gadget that is *not* G-invariant can be forced to become G-invariant by averaging its G-translates, and for a finite group the average is a genuine finite sum divided by $|G|$.

Proof. Let $W \subseteq V$ be invariant. Choose, by ordinary linear algebra, *any* linear complement U to W, so $V = W \oplus U$ as vector spaces (this ignores G entirely; U need not be invariant). Let $p\colon V \to V$ be the corresponding projection onto W along U: it satisfies $p(V) = W$, $p|_W = \mathrm{id}_W$, and $p^2 = p$. This p is generally not an intertwiner; it does not commute with the group action. We repair that by averaging. Define

$$P \;\equiv\; \frac{1}{|G|} \sum_{g \in G} \rho(g)\, p\, \rho(g)^{-1}. \tag{2.25}$$

We claim P is a G-equivariant projection onto W. There are three things to check.

(i) P maps V into W. For any $v \in V$ and any g, we have $\rho(g)^{-1}v \in V$, then $p\rho(g)^{-1}v \in W$, and then $\rho(g)$ maps W into W by invariance, so $\rho(g)p\rho(g)^{-1}v \in W$. A sum of vectors in W lies in W, so $Pv \in W$.

(ii) P acts as the identity on W. Let $w \in W$. Then $\rho(g)^{-1}w \in W$ (invariance again), so p acts on it as the identity: $p\,\rho(g)^{-1}w = \rho(g)^{-1}w$. Hence each term is $\rho(g)\rho(g)^{-1}w = w$, and

$$Pw = \frac{1}{|G|}\sum_{g\in G} w = w. \tag{2.26}$$

Combining (i) and (ii): $P(V) = W$, and $P^2 = P$ because P first lands in W and then fixes W pointwise. So P is a projection onto W.

(iii) P commutes with the representation. This is where the average earns its keep. For any $h \in G$,

$$\begin{aligned}\rho(h)\,P\,\rho(h)^{-1} &= \frac{1}{|G|}\sum_{g\in G}\rho(h)\rho(g)\,p\,\rho(g)^{-1}\rho(h)^{-1}\\ &= \frac{1}{|G|}\sum_{g\in G}\rho(hg)\,p\,\rho(hg)^{-1} \;=\; \frac{1}{|G|}\sum_{g'\in G}\rho(g')\,p\,\rho(g')^{-1} \;=\; P,\end{aligned} \tag{2.27}$$

where we used the homomorphism property $\rho(h)\rho(g) = \rho(hg)$ and then the substitution $g' = hg$, which is a bijection of G onto itself (left multiplication by a fixed h permutes the group), leaving the sum unchanged. Thus $\rho(h)P = P\rho(h)$ for all h.

Now set $W' \equiv \ker P$. Since P is a projection, $V = \operatorname{im} P \oplus \ker P = W \oplus W'$. And W' is invariant: if $Pv = 0$ then $P\rho(h)v = \rho(h)Pv = 0$ by Eq. (2.27), so $\rho(h)v \in \ker P = W'$. Thus W' is the desired invariant complement. □

Remark 2.19 (Two faces of the same averaging). The construction in Theorem 2.13 of an invariant inner product, and the construction Eq. (2.25) of an invariant projector, are the same averaging idea wearing different clothes. If one starts instead from a G-invariant Hermitian inner product $\langle\cdot,\cdot\rangle$ (built by averaging an arbitrary one, exactly as in the previous section) then the orthogonal complement $W^{\perp}$ of an invariant W is automatically invariant: for $w \in W$, $u \in W^{\perp}$, $g \in G$, invariance of the inner product gives $\langle w, \rho(g)u\rangle = \langle \rho(g)^{-1}w, u\rangle = 0$ because $\rho(g)^{-1}w \in W$. So $\rho(g)u \in W^{\perp}$, and $W^{\perp}$ is the invariant complement. This is Maschke's theorem proved through unitarity; we have given the projector proof in full because the projector Eq. (2.25) reappears, lightly disguised, in the orthogonality relations below.

Maschke's theorem reduces the study of all finite-group representations to the study of the irreducible ones: every representation is a direct sum of irreducibles,

so to "know all representations" it suffices to (a) list the irreducibles and (b) say how a given representation decomposes into them. Step (a) is a finite problem, as the sum-of-squares theorem below will show; step (b) is solved by characters. Before either, we need the rigidity statement that makes the decomposition essentially unique.

2.2.3 Schur's lemma

The organizing notion is the *intertwiner*: a linear map that respects two group actions.

Definition 2.20 (Intertwiner)**.** Let (ρ, V) and (σ, W) be representations of G. A linear map $\phi\colon V \to W$ is an *intertwiner* (or *G-equivariant map*, or morphism of representations) if it commutes with the group actions,

$$\phi\,\rho(g) = \sigma(g)\,\phi \qquad \text{for all } g \in G. \tag{2.28}$$

An invertible intertwiner is an *equivalence* (isomorphism) of representations; ρ and σ are *equivalent*, written $\rho \cong \sigma$, when one exists. Recall (Theorem 2.7) that equivalent representations are "the same representation in different coordinates," related by $\sigma(g) = S\rho(g)S^{-1}$ with $S = \phi$.

Theorem 2.21 (Schur's lemma)**.** *Let (ρ, V) and (σ, W) be irreducible representations of G over $\mathbb{C}$, and let $\phi\colon V \to W$ be an intertwiner.*

(I) *If ρ and σ are inequivalent, then $\phi = 0$. More generally, any intertwiner between irreducibles is either zero or an isomorphism.*

(II) *If $(\rho, V) = (\sigma, W)$ is one and the same irreducible representation, then ϕ is a scalar multiple of the identity: $\phi = \lambda\,\mathrm{id}_V$ for some $\lambda \in \mathbb{C}$.*

Proof. Part (I). The proof rests on a single observation: the kernel and image of an intertwiner are invariant subspaces. Consider $\ker\phi \subseteq V$. If $v \in \ker\phi$, then for any g,

$$\phi(\rho(g)v) = \sigma(g)\,\phi(v) = \sigma(g)\,0 = 0, \tag{2.29}$$

using the intertwining relation Eq. (2.28), so $\rho(g)v \in \ker\phi$. Thus $\ker\phi$ is invariant under ρ. Since (ρ, V) is irreducible, $\ker\phi$ is either $\{0\}$ or V.

Now consider $\mathrm{im}\,\phi \subseteq W$. If $w = \phi(v) \in \mathrm{im}\,\phi$, then for any g,

$$\sigma(g)\,w = \sigma(g)\,\phi(v) = \phi(\rho(g)v) \in \mathrm{im}\,\phi, \tag{2.30}$$

again by Eq. (2.28), so $\mathrm{im}\,\phi$ is invariant under σ. Since (σ, W) is irreducible, $\mathrm{im}\,\phi$ is either $\{0\}$ or W.

There are now two cases. Either $\phi = 0$ (then $\ker\phi = V$ and $\mathrm{im}\,\phi = \{0\}$, consistent), or $\phi \neq 0$. In the latter case $\ker\phi \neq V$, forcing $\ker\phi = \{0\}$, so ϕ is

injective; and $\operatorname{im}\phi \neq \{0\}$, forcing $\operatorname{im}\phi = W$, so ϕ is surjective. Hence a nonzero intertwiner between irreducibles is a bijection, i.e. an isomorphism, and then Eq. (2.28) reads $\sigma(g) = \phi\,\rho(g)\,\phi^{-1}$, exhibiting $\rho \cong \sigma$. Contrapositively, if $\rho \ncong \sigma$ then no nonzero intertwiner can exist, so $\phi = 0$. This proves (I).

Part (II). Here $\phi\colon V \to V$ is an intertwiner of an irreducible representation with itself, and we use that $\mathbb{C}$ is algebraically closed. The linear operator ϕ on the finite-dimensional complex space V has a characteristic polynomial, which (since $\mathbb{C}$ is algebraically closed) has a root $\lambda \in \mathbb{C}$; that root is an eigenvalue of ϕ, so $\phi - \lambda\,\mathrm{id}_V$ has nontrivial kernel. But $\phi - \lambda\,\mathrm{id}_V$ is itself an intertwiner: it is a linear combination of the intertwiner ϕ and the identity (the identity intertwines any representation with itself, trivially), and intertwiners form a vector space closed under linear combination, since

$$(\phi - \lambda\,\mathrm{id})\rho(g) = \phi\rho(g) - \lambda\rho(g) = \rho(g)\phi - \rho(g)\lambda\,\mathrm{id} = \rho(g)(\phi - \lambda\,\mathrm{id}). \tag{2.31}$$

By Part (I) applied to the intertwiner $\phi - \lambda\,\mathrm{id}\colon V \to V$ (same irreducible at both ends), it is either zero or an isomorphism. It is *not* an isomorphism, because it has nontrivial kernel (the λ-eigenspace). Therefore it is zero: $\phi = \lambda\,\mathrm{id}_V$. □

Algebraic closure is essential to Part (II)

Part (II) genuinely uses $\mathbb{C}$. Over $\mathbb{R}$ it can fail: the rotation representation of the cyclic group on $\mathbb{R}^2$ is irreducible, yet the rotation by 90° is an intertwiner that is manifestly *not* a real scalar multiple of the identity (it has no real eigenvalue). The complexification of that representation splits into two one-dimensional pieces, restoring Schur; this is exactly why the honest classification of fields by the Lorentz group in Chapter 3 is carried out over $\mathbb{C}$.

Schur's lemma is the engine of everything that follows. Two immediate consequences set the tone.

Corollary 2.22 (Irreducibles of an abelian group are one-dimensional)**.** *If G is abelian, every irreducible complex representation is one-dimensional.*

Proof. Let (ρ, V) be irreducible and fix any $h \in G$. For every $g \in G$, commutativity of G gives $\rho(h)\rho(g) = \rho(hg) = \rho(gh) = \rho(g)\rho(h)$, so $\rho(h)$ commutes with every $\rho(g)$; that is, $\rho(h)$ is an intertwiner of (ρ, V) with itself. By Schur (II), $\rho(h) = \lambda_h\,\mathrm{id}_V$ for some scalar $\lambda_h \in \mathbb{C}$. But then *every* subspace of V is invariant (a scalar multiplies any subspace into itself), so irreducibility forces $\dim V = 1$. □

This corollary is the abstract reason the irreducible representations of the translation/rotation phases U(1) are the single Fourier modes $e^{in\theta}$, and it is the seed of the weight-lattice picture: an abelian subalgebra (the Cartan subalgebra)

can be diagonalized simultaneously in any representation, and its eigenvalues are the weights that organize $\mathfrak{su}(2)$ and $\mathfrak{su}(3)$ in later sections.

Corollary 2.23 (Uniqueness of the intertwiner up to scale)**.** *If (ρ, V) and (σ, W) are equivalent irreducibles, the intertwiner between them is unique up to an overall complex scalar. In particular the decomposition of a representation into irreducibles is unique up to isomorphism and reordering.*

Proof. If $\phi_1, \phi_2 \colon V \to W$ are two nonzero intertwiners, both are isomorphisms by Schur (I), so $\phi_2^{-1}\phi_1 \colon V \to V$ is an intertwiner of ρ with itself, hence $\phi_2^{-1}\phi_1 = \lambda\,\mathrm{id}$ by Schur (II), i.e. $\phi_1 = \lambda\phi_2$. The uniqueness of the decomposition—that the list of irreducible constituents W_k in Eq. (2.23), with multiplicities, does not depend on how the decomposition was performed—follows because the multiplicity of a given irreducible U in V equals $\dim \mathrm{Hom}_G(U, V)$ (the dimension of the space of intertwiners $U \to V$), and Schur makes that dimension well defined: each irreducible summand isomorphic to U contributes exactly 1 by (I)+(II), each summand inequivalent to U contributes 0 by (I). We will recover this multiplicity far more cheaply as a character inner product in Theorem 2.28. □

2.2.4 Characters

We can now decompose anything into irreducibles in principle, but to do it in practice we need a computable fingerprint that identifies an irreducible and reads off multiplicities. That fingerprint is the trace of the representation matrices.

Definition 2.24 (Character)**.** The *character* of a representation (ρ, V) is the function $\chi_\rho \colon G \to \mathbb{C}$,

$$\chi_\rho(g) \;\equiv\; \mathrm{tr}\,\rho(g). \tag{2.32}$$

The trace discards a vast amount of information—it forgets everything about $\rho(g)$ except the sum of its eigenvalues—yet, remarkably, it retains *exactly* enough to identify a representation up to equivalence. The reason it is the right invariant is a short list of properties, each following from elementary trace identities.

Proposition 2.25 (Elementary properties of characters)**.** *Let (ρ, V), (σ, W) be representations of G with $d_\rho = \dim V$. Then:*

1. *$\chi_\rho(e) = d_\rho$ (the character at the identity is the dimension).*
2. *χ_ρ is a* class function*: it is constant on conjugacy classes, $\chi_\rho(hgh^{-1}) = \chi_\rho(g)$ for all g, h.*
3. *Equivalent representations have equal characters: $\rho \cong \sigma \Rightarrow \chi_\rho = \chi_\sigma$.*
4. *The character of a direct sum is the sum of characters: $\chi_{\rho\oplus\sigma} = \chi_\rho + \chi_\sigma$.*
5. *If ρ is unitary, $\chi_\rho(g^{-1}) = \overline{\chi_\rho(g)}$.*

Proof. (1) $\rho(e) = \mathrm{id}_V$, so $\operatorname{tr}\rho(e) = \dim V = d_\rho$.

(2) Using $\rho(hgh^{-1}) = \rho(h)\rho(g)\rho(h)^{-1}$ and the cyclicity of the trace, $\operatorname{tr}\big(\rho(h)\rho(g)\rho(h)^{-1}\big) = \operatorname{tr}\big(\rho(h)^{-1}\rho(h)\rho(g)\big) = \operatorname{tr}\rho(g)$. Conjugate group elements have equal character; the character is determined by its values on the conjugacy classes.

(3) If $\sigma(g) = S\rho(g)S^{-1}$ then $\operatorname{tr}\sigma(g) = \operatorname{tr}\big(S\rho(g)S^{-1}\big) = \operatorname{tr}\rho(g)$ by cyclicity.

(4) In a basis adapted to $V \oplus W$, $(\rho \oplus \sigma)(g)$ is block-diagonal with blocks $\rho(g)$ and $\sigma(g)$, so its trace is $\operatorname{tr}\rho(g) + \operatorname{tr}\sigma(g)$.

(5) A unitary $\rho(g)$ has $\rho(g)^{-1} = \rho(g)^\dagger$, and the eigenvalues of a unitary matrix are phases $e^{i\theta_k}$ with $\left|e^{i\theta_k}\right| = 1$, so the eigenvalues of $\rho(g)^{-1}$ are $e^{-i\theta_k} = \overline{e^{i\theta_k}}$. Hence $\chi_\rho(g^{-1}) = \operatorname{tr}\rho(g)^{-1} = \sum_k e^{-i\theta_k} = \overline{\sum_k e^{i\theta_k}} = \overline{\chi_\rho(g)}$. Since every finite-group representation may be taken unitary (Theorem 2.13), and characters are invariant under equivalence by (3), property (5) holds for the character of *any* finite-group representation. □

Property (2) tells us where characters live: in the space of *class functions*,

$$\mathcal{C}(G) \;\equiv\; \{\, f : G \to \mathbb{C} \;:\; f(hgh^{-1}) = f(g)\ \forall g, h \,\}, \tag{2.33}$$

a complex vector space whose dimension is the number of conjugacy classes of G (a class function is freely specified by one value per class). We equip $\mathcal{C}(G)$ with the Hermitian inner product

$$\langle f_1, f_2 \rangle \;\equiv\; \frac{1}{|G|} \sum_{g \in G} \overline{f_1(g)}\, f_2(g). \tag{2.34}$$

The central theorem of the subject is that the irreducible characters form an *orthonormal* set in this inner product. Everything practical—identifying irreducibles, extracting multiplicities, counting irreducibles—falls out of that one fact.

2.2.5 Orthogonality of characters

We prove orthogonality at the finer level of matrix entries first, because that form is what Schur's lemma directly delivers, and then trace down to characters. The tool is again averaging Eq. (2.25), now applied to an arbitrary linear map between two irreducibles.

Theorem 2.26 (Schur orthogonality for matrix coefficients)**.** *Let (ρ, V) and (σ, W) be irreducible* unitary *representations of G, of dimensions d_ρ and d_σ, with matrix entries $\rho_{ij}(g)$ and $\sigma_{kl}(g)$ in fixed orthonormal bases. Then:*

1. *if $\rho \not\cong \sigma$,*

$$\frac{1}{|G|} \sum_{g \in G} \overline{\rho_{ij}(g)}\, \sigma_{kl}(g) = 0 \qquad \text{for all } i, j, k, l; \tag{2.35}$$

2. if $\rho = \sigma$ (the same irreducible),

$$\frac{1}{|G|}\sum_{g\in G}\overline{\rho_{ij}(g)}\,\rho_{kl}(g) = \frac{1}{d_\rho}\,\delta_{ik}\,\delta_{jl}. \tag{2.36}$$

Proof. Let $A\colon W \to V$ be *any* linear map, and form its G-average

$$A^0 \;\equiv\; \frac{1}{|G|}\sum_{g\in G}\rho(g)\,A\,\sigma(g)^{-1}. \tag{2.37}$$

Exactly as in Eq. (2.27), A^0 is an intertwiner: for any h,

$$\rho(h)A^0\sigma(h)^{-1} = \frac{1}{|G|}\sum_{g}\rho(hg)A\sigma(hg)^{-1} = A^0, \tag{2.38}$$

so $\rho(h)A^0 = A^0\sigma(h)$ for all h. Schur's lemma now constrains A^0 completely.

Case $\rho \not\cong \sigma$. By Schur (I), $A^0 = 0$ for every choice of A.

Case $\rho = \sigma$ (so $V = W$, $d_\rho = d_\sigma \equiv d$). By Schur (II), $A^0 = \lambda(A)\,\mathrm{id}_V$ for some scalar $\lambda(A)$ depending linearly on A. Taking the trace of Eq. (2.37) and using cyclicity, $\operatorname{tr} A^0 = \frac{1}{|G|}\sum_g \operatorname{tr}(\rho(g)A\rho(g)^{-1}) = \frac{1}{|G|}\sum_g \operatorname{tr} A = \operatorname{tr} A$, while $\operatorname{tr}(\lambda\,\mathrm{id}_V) = \lambda d$; hence

$$\lambda(A) = \frac{\operatorname{tr} A}{d}, \qquad \text{i.e.} \qquad A^0 = \frac{\operatorname{tr} A}{d}\,\mathrm{id}_V. \tag{2.39}$$

To extract Eqs. (2.35) and (2.36) we choose A to be a single matrix unit: let $A = E_{jk}$, the linear map whose only nonzero entry is a 1 in row j, column k, so $(E_{jk})_{ab} = \delta_{aj}\delta_{bk}$. Then in components, using unitarity $\sigma(g)^{-1} = \sigma(g)^\dagger$ so that $\big(\sigma(g)^{-1}\big)_{lk'} = \overline{\sigma_{k'l}(g)}$,

$$\begin{aligned}(A^0)_{il} &= \frac{1}{|G|}\sum_g\sum_{a,b}\rho_{ia}(g)\,(E_{jk})_{ab}\,\big(\sigma(g)^{-1}\big)_{bl}\\ &= \frac{1}{|G|}\sum_g \rho_{ij}(g)\,\big(\sigma(g)^{-1}\big)_{kl} = \frac{1}{|G|}\sum_g \rho_{ij}(g)\,\overline{\sigma_{lk}(g)}.\end{aligned} \tag{2.40}$$

For inequivalent ρ, σ the left side vanishes, giving $\frac{1}{|G|}\sum_g \rho_{ij}(g)\overline{\sigma_{lk}(g)} = 0$; relabelling indices ($l \leftrightarrow k$, complex-conjugating the whole equation, which is allowed since the right side is 0) yields Eq. (2.35). For $\rho = \sigma$, Eq. (2.39) gives $(A^0)_{il} = \frac{\operatorname{tr} E_{jk}}{d}\delta_{il} = \frac{\delta_{jk}}{d}\delta_{il}$, so

$$\frac{1}{|G|}\sum_g \rho_{ij}(g)\,\overline{\rho_{lk}(g)} = \frac{1}{d}\,\delta_{il}\,\delta_{jk}. \tag{2.41}$$

Conjugating both sides and relabelling indices to match Eq. (2.36) (rename $i \to j$, $j \to i$, $l \to k$, $k \to l$ consistently) gives the stated form. The numbers $\delta_{ik}\delta_{jl}$ and $\delta_{il}\delta_{jk}$ on the two sides agree after the relabelling; both record that the average is nonzero only when the "row pattern" and the "column pattern" of the two matrix coefficients match. □

The character orthogonality relation is now a one-line contraction.

Theorem 2.27 (First orthogonality relation for characters)**.** *Let χ_i and χ_j be the characters of two irreducible representations of G. Then, in the inner product Eq. (2.34),*

$$\langle \chi_i, \chi_j \rangle = \frac{1}{|G|} \sum_{g \in G} \overline{\chi_i(g)}\, \chi_j(g) = \delta_{ij}, \tag{2.42}$$

where $\delta_{ij} = 1$ if the two representations are equivalent and 0 otherwise. The irreducible characters of G form an orthonormal system in $\mathcal{C}(G)$.

Proof. The character is the trace, $\chi_i(g) = \sum_a \rho^{(i)}_{aa}(g)$, so

$$\langle \chi_i, \chi_j \rangle = \frac{1}{|G|} \sum_g \sum_a \overline{\rho^{(i)}_{aa}(g)} \sum_b \rho^{(j)}_{bb}(g) = \sum_{a,b} \frac{1}{|G|} \sum_g \overline{\rho^{(i)}_{aa}(g)}\, \rho^{(j)}_{bb}(g). \tag{2.43}$$

If the two irreducibles are inequivalent, every inner sum vanishes by Eq. (2.35), so $\langle \chi_i, \chi_j \rangle = 0$. If they are equivalent we may take them equal (characters are equivalence invariants), and Eq. (2.36) with $i \to a$, $j \to a$, $k \to b$, $l \to b$ gives $\frac{1}{|G|} \sum_g \overline{\rho_{aa}(g)} \rho_{bb}(g) = \frac{1}{d} \delta_{ab} \delta_{ab} = \frac{1}{d} \delta_{ab}$, whence

$$\langle \chi_i, \chi_i \rangle = \sum_{a,b} \frac{1}{d} \delta_{ab} = \frac{1}{d} \sum_{a=1}^{d} 1 = \frac{d}{d} = 1. \tag{2.44}$$

Thus $\langle \chi_i, \chi_j \rangle = \delta_{ij}$. □

This single relation does all the bookkeeping the chapter promised.

Corollary 2.28 (Multiplicities and the irreducibility test)**.** *Let (ρ, V) be any representation of G, decomposed by Maschke as $V \cong \bigoplus_i m_i V_i$ where the V_i are the distinct irreducibles and $m_i \geq 0$ is the multiplicity of V_i. Then:*

1. *$\chi_\rho = \sum_i m_i \chi_i$, and the multiplicity is recovered by an inner product,*

$$m_i = \langle \chi_i, \chi_\rho \rangle = \frac{1}{|G|} \sum_{g \in G} \overline{\chi_i(g)}\, \chi_\rho(g). \tag{2.45}$$

2. *$\langle \chi_\rho, \chi_\rho \rangle = \sum_i m_i^2$. In particular ρ is irreducible* if and only if *$\langle \chi_\rho, \chi_\rho \rangle = 1$.*

3. *Two representations are equivalent if and only if they have the same character.*

Proof. (1) Additivity of the character over direct sums (Theorem 2.25(4)) gives $\chi_\rho = \sum_i m_i \chi_i$; taking $\langle \chi_i, \cdot \rangle$ and using orthonormality Eq. (2.42), $\langle \chi_i, \chi_\rho \rangle = \sum_j m_j \langle \chi_i, \chi_j \rangle = \sum_j m_j \delta_{ij} = m_i$.

(2) $\langle \chi_\rho, \chi_\rho \rangle = \sum_{i,j} m_i m_j \langle \chi_i, \chi_j \rangle = \sum_{i,j} m_i m_j \delta_{ij} = \sum_i m_i^2$. A sum of squares of non-negative integers equals 1 precisely when one $m_i = 1$ and the rest vanish, i.e. precisely when ρ is itself irreducible.

(3) If $\rho \cong \sigma$ then $\chi_\rho = \chi_\sigma$ by Theorem 2.25(3). Conversely if $\chi_\rho = \chi_\sigma$ then by Eq. (2.45) each irreducible occurs in both with the same multiplicity $m_i = \langle \chi_i, \chi_\rho \rangle = \langle \chi_i, \chi_\sigma \rangle$, so the two decompositions into irreducibles coincide and $\rho \cong \sigma$. □

Part (3) is the punchline that justifies calling the character a fingerprint: over $\mathbb{C}$, the trace function determines a finite-group representation completely. The infinite data of the matrices $\rho(g)$ is compressed, with no loss for classification purposes, into one number per conjugacy class.

2.2.6 The regular representation and the sum-of-squares theorem

How many irreducibles does a finite group have, and how big are they? Both questions are answered by decomposing one particularly rich representation in which every irreducible is guaranteed to appear: the regular representation, built from the group acting on itself.

Definition 2.29 (Regular representation)**.** Let $\mathbb{C}[G]$ be the $|G|$-dimensional complex vector space with basis $\{e_g\}_{g \in G}$ labelled by the group elements. The (left) *regular representation* ρ_{reg} acts by permuting the basis according to left multiplication,

$$\rho_{\mathrm{reg}}(h)\, e_g \;=\; e_{hg}. \tag{2.46}$$

This is a genuine representation: $\rho_{\mathrm{reg}}(h_1)\rho_{\mathrm{reg}}(h_2)e_g = \rho_{\mathrm{reg}}(h_1)e_{h_2 g} = e_{h_1 h_2 g} = \rho_{\mathrm{reg}}(h_1 h_2)e_g$. Its character is immediate.

Proposition 2.30 (Character of the regular representation)**.**

$$\chi_{\mathrm{reg}}(g) = \begin{cases} |G|\,, & g = e, \\ 0, & g \neq e. \end{cases} \tag{2.47}$$

Proof. $\chi_{\mathrm{reg}}(g) = \operatorname{tr} \rho_{\mathrm{reg}}(g)$ counts the diagonal entries of the permutation matrix of g, i.e. the number of basis vectors $e_{g'}$ left fixed: those with $gg' = g'$, equivalently $g = e$. For $g = e$ all $|G|$ basis vectors are fixed, giving $\operatorname{tr} = |G|$; for $g \neq e$ none are fixed (left multiplication by $g \neq e$ has no fixed point because $gg' = g' \Rightarrow g = e$), giving $\operatorname{tr} = 0$. □

Theorem 2.31 (Decomposition of the regular representation; sum of squares)**.** *Let $V_1, \dots, V_r$ be the distinct irreducible representations of the finite group G, of dimensions $d_1, \dots, d_r$ (so $d_i = \chi_i(e)$). Then the regular representation contains each irreducible with multiplicity equal to its dimension,*

$$\mathbb{C}[G] \;\cong\; \bigoplus_{i=1}^{r} d_i\, V_i, \tag{2.48}$$

and consequently the order of the group is the sum of the squares of the dimensions of its inequivalent irreducibles,

$$\boxed{\,|G| = \sum_{i=1}^{r} d_i^2\,.\,} \tag{2.49}$$

Proof. By Theorem 2.28(1) the multiplicity of V_i in $\mathbb{C}[G]$ is

$$m_i = \langle \chi_i, \chi_{\mathrm{reg}} \rangle = \frac{1}{|G|} \sum_{g} \overline{\chi_i(g)}\, \chi_{\mathrm{reg}}(g) = \frac{1}{|G|}\, \overline{\chi_i(e)}\; |G| = \overline{\chi_i(e)} = d_i, \tag{2.50}$$

where only the $g = e$ term of Eq. (2.47) survives, and $\chi_i(e) = d_i$ is real (a dimension). This is Eq. (2.48). Taking the dimension of both sides, $\dim \mathbb{C}[G] = |G|$ on the left and $\sum_i m_i \dim V_i = \sum_i d_i \cdot d_i = \sum_i d_i^2$ on the right, gives Eq. (2.49). □

The identity Eq. (2.49) is a powerful finiteness statement: it bounds both the number of irreducibles and their sizes by the group order, and frequently pins down the dimensions outright. For a group of order 6, for instance, the only ways to write 6 as a sum of positive squares are $6 = 1+1+1+1+1+1$ and $6 = 1+1+4$; the abelian case forces the first (all irreducibles one-dimensional, by Theorem 2.22), and a nonabelian group of order 6 is therefore forced into the second, with irreducible dimensions $1, 1, 2$. We will see this play out for S_3 in a moment.

One question remains for the counting: how many irreducibles r are there? The orthonormality Eq. (2.42) already shows $r \le \dim \mathcal{C}(G) = \#\{\text{conjugacy classes}\}$ (orthonormal vectors are linearly independent). The reverse inequality—that the irreducible characters *span* the class functions, so the count is exact—is the natural completion and is worth proving in full, because the chapter's strategy ("expand everything in irreducibles") is only as good as our ability to know we have found them all.

Theorem 2.32 (Completeness; number of irreducibles equals number of classes)**.** *The irreducible characters $\chi_1, \dots, \chi_r$ form an orthonormal* basis *of the space $\mathcal{C}(G)$ of class functions. Hence the number r of inequivalent irreducible representations of G equals the number of conjugacy classes of G.*

Proof. By Theorem 2.27 the χ_i are orthonormal, hence linearly independent; we must show they span $\mathcal{C}(G)$. It suffices to show that the only class function orthogonal to every χ_i is the zero function, for then the orthogonal complement of $\operatorname{span}\{\chi_i\}$ in $\mathcal{C}(G)$ is trivial.

Let $f \in \mathcal{C}(G)$ satisfy $\langle \chi_i, f\rangle = 0$ for all i. For each irreducible (ρ_i, V_i) form the operator

$$T_i \;\equiv\; \sum_{g\in G} \overline{f(g)}\,\rho_i(g). \tag{2.51}$$

Because f is a class function, T_i is an intertwiner of ρ_i with itself: for any h,

$$\rho_i(h)\,T_i\,\rho_i(h)^{-1} = \sum_{g} \overline{f(g)}\,\rho_i(hgh^{-1}) = \sum_{g'} \overline{f(h^{-1}g'h)}\,\rho_i(g') = \sum_{g'} \overline{f(g')}\,\rho_i(g') = T_i, \tag{2.52}$$

where we substituted $g' = hgh^{-1}$ (a bijection of G) and used $f(h^{-1}g'h) = f(g')$. Hence $\rho_i(h)T_i = T_i\rho_i(h)$, and Schur (II) gives $T_i = \mu_i \,\mathrm{id}_{V_i}$. Taking the trace, $\mu_i d_i = \operatorname{tr} T_i = \sum_g \overline{f(g)}\,\chi_i(g) = |G|\,\langle f, \chi_i\rangle = |G|\,\overline{\langle \chi_i, f\rangle} = 0$, so $\mu_i = 0$ and therefore $T_i = 0$ for every irreducible ρ_i.

Now $T_i = 0$ for all irreducibles means $\sum_g \overline{f(g)}\,\rho(g) = 0$ in every representation ρ, because every representation is a direct sum of irreducibles (Maschke) and the operator is block-diagonal across the sum. Apply this to the regular representation and act on the basis vector e_e:

$$0 = \sum_{g} \overline{f(g)}\,\rho_{\mathrm{reg}}(g)\,e_e = \sum_{g} \overline{f(g)}\,e_g. \tag{2.53}$$

The e_g are linearly independent, so every coefficient vanishes: $\overline{f(g)} = 0$ for all g, i.e. $f = 0$. Thus no nonzero class function is orthogonal to all irreducible characters, the χ_i span $\mathcal{C}(G)$, and $r = \dim \mathcal{C}(G) = \#\{\text{conjugacy classes}\}$. □

We now have a complete, finite algorithm for the representation theory of any finite group: list the conjugacy classes (their number is r); find r irreducible characters, orthonormal under Eq. (2.34), with dimensions satisfying $\sum d_i^2 = |G|$; assemble them into the *character table*, an $r \times r$ array of class-versus-irreducible values; and read off the decomposition of any representation by the inner products Eq. (2.45). The worked example below carries this out start to finish for the smallest nonabelian group.

2.2.7 Worked example: the character table of S_3

Worked Example 2.33 (Complete representation theory of S_3)**.** We determine, with no input beyond the theorems just proved, every irreducible representation of the symmetric group S_3—equivalently the symmetry group D_3 of the equilateral triangle (Fig. 2.1)—its character table, and the decomposition of two natural representations. This is the smallest nonabelian example and the prototype for the $\mathfrak{su}(2)$ and $\mathfrak{su}(3)$ multiplet analyses of later sections.

Step 1: conjugacy classes. S_3 consists of the 6 permutations of $\{1,2,3\}$. In a symmetric group, two permutations are conjugate iff they have the same cycle type, so the conjugacy classes are organized by cycle structure:

- the identity $\{e\}$, one element;
- the transpositions $\{(12),(13),(23)\}$, three elements (call a representative τ);
- the 3-cycles $\{(123),(132)\}$, two elements (call a representative c).

There are 3 conjugacy classes, with sizes $1+3+2=6=|S_3|$. By Theorem 2.32 there are exactly 3 inequivalent irreducible representations.

Step 2: dimensions. By the sum-of-squares theorem Eq. (2.49), $d_1^2+d_2^2+d_3^2=6$. The only solution in positive integers (up to ordering) is $1^2+1^2+2^2=6$. So S_3 has two one-dimensional irreducibles and one two-dimensional irreducible. We exhibit all three.

Step 3: the two one-dimensional irreducibles. A one-dimensional representation is a homomorphism $S_3\to\mathbb{C}^\times$; its image is abelian, so it factors through the abelianization, and concretely it must send each transposition to a root of unity squaring to 1 (since $\tau^2=e$). The two choices are:

- the *trivial* representation, $\rho_{\mathrm{triv}}(g)=1$ for all g, with character $\chi_{\mathrm{triv}}\equiv 1$;
- the *sign* representation, $\rho_{\mathrm{sgn}}(g)=\mathrm{sgn}(g)$, equal to $+1$ on even permutations (the identity and the 3-cycles) and -1 on the odd permutations (the transpositions), with character $\chi_{\mathrm{sgn}}(e)=1$, $\chi_{\mathrm{sgn}}(\tau)=-1$, $\chi_{\mathrm{sgn}}(c)=1$.

Both are manifestly homomorphisms and one-dimensional, hence irreducible.

Step 4: the two-dimensional irreducible. Realize $S_3=D_3$ geometrically as the rigid symmetries of an equilateral triangle centered at the origin (Fig. 2.1): a 3-cycle is a rotation by $2\pi/3$, a transposition is a reflection across an axis through one vertex. In an orthonormal frame of the plane, the rotation c by 120° and a reflection τ are

$$\rho_{\mathrm{std}}(c)=\begin{pmatrix}-\frac{1}{2} & -\frac{\sqrt{3}}{2}\\ \frac{\sqrt{3}}{2} & -\frac{1}{2}\end{pmatrix},\qquad \rho_{\mathrm{std}}(\tau)=\begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix}. \tag{2.54}$$

These two matrices generate a two-dimensional representation (every group element is a product of rotations and reflections). Its character is read off from the traces: $\chi_{\mathrm{std}}(e)=\mathrm{tr}\,\mathbf{1}_2=2$, $\chi_{\mathrm{std}}(\tau)=1+(-1)=0$, and $\chi_{\mathrm{std}}(c)=-\frac{1}{2}-\frac{1}{2}=-1$.

We verify irreducibility by the test of Theorem 2.28(2), weighting each class by its size in the inner product Eq. (2.34):

$$\langle \chi_{\text{std}}, \chi_{\text{std}} \rangle = \frac{1}{6}\Big[\underbrace{1 \cdot 2^2}_{e} + \underbrace{3 \cdot 0^2}_{\tau} + \underbrace{2 \cdot (-1)^2}_{c}\Big] = \frac{1}{6}(4 + 0 + 2) = 1, \tag{2.55}$$

so ρ_{std} is irreducible. It is the third irreducible, the "standard" representation.

Step 5: the character table. Collecting the three characters, with the class sizes recorded in the header:

	$\{e\}$	$\{\tau\}$	$\{c\}$
class size	1	3	2
χ_{triv}	1	1	1
χ_{sgn}	1	-1	1
χ_{std}	2	0	-1

Step 6: orthonormality check. The rows must be orthonormal under Eq. (2.34) (characters are real here, so conjugation is invisible). The diagonal entries are $\langle \chi_{\text{triv}}, \chi_{\text{triv}} \rangle = \frac{1}{6}(1 + 3 + 2) = 1$, $\langle \chi_{\text{sgn}}, \chi_{\text{sgn}} \rangle = \frac{1}{6}(1 + 3 + 2) = 1$, and $\langle \chi_{\text{std}}, \chi_{\text{std}} \rangle = 1$ from Step 4. The off-diagonal entries are

$$\begin{aligned}
\langle \chi_{\text{triv}}, \chi_{\text{sgn}} \rangle &= \tfrac{1}{6}\big[1 \cdot 1 \cdot 1 + 3 \cdot 1 \cdot (-1) + 2 \cdot 1 \cdot 1\big] = \tfrac{1}{6}(1 - 3 + 2) = 0, \\
\langle \chi_{\text{triv}}, \chi_{\text{std}} \rangle &= \tfrac{1}{6}\big[1 \cdot 1 \cdot 2 + 3 \cdot 1 \cdot 0 + 2 \cdot 1 \cdot (-1)\big] = \tfrac{1}{6}(2 + 0 - 2) = 0, \\
\langle \chi_{\text{sgn}}, \chi_{\text{std}} \rangle &= \tfrac{1}{6}\big[1 \cdot 1 \cdot 2 + 3 \cdot (-1) \cdot 0 + 2 \cdot 1 \cdot (-1)\big] = \tfrac{1}{6}(2 + 0 - 2) = 0.
\end{aligned} \tag{2.56}$$

All three vanish: the irreducible characters are orthonormal, as Theorem 2.27 demands. The dimension sum checks too: $1^2 + 1^2 + 2^2 = 6 = |S_3|$, in accord with Eq. (2.49).

Step 7: decomposing two representations. First, the *permutation representation* ρ_{perm} on $\mathbb{C}^3$, where S_3 permutes the standard basis vectors $\hat{e}_1, \hat{e}_2, \hat{e}_3$. Its character counts fixed basis vectors: $\chi_{\text{perm}}(g) = \#\{\text{points fixed by } g\}$, giving $\chi_{\text{perm}}(e) = 3$, $\chi_{\text{perm}}(\tau) = 1$ (a transposition fixes one point), $\chi_{\text{perm}}(c) = 0$ (a 3-cycle fixes none). The multiplicities follow from Eq. (2.45):

$$\begin{aligned}
m_{\text{triv}} &= \langle \chi_{\text{triv}}, \chi_{\text{perm}} \rangle = \tfrac{1}{6}(1 \cdot 3 + 3 \cdot 1 + 2 \cdot 0) = \tfrac{1}{6}(6) = 1, \\
m_{\text{sgn}} &= \langle \chi_{\text{sgn}}, \chi_{\text{perm}} \rangle = \tfrac{1}{6}(1 \cdot 3 + 3 \cdot (-1) \cdot 1 + 2 \cdot 1 \cdot 0) = \tfrac{1}{6}(0) = 0, \\
m_{\text{std}} &= \langle \chi_{\text{std}}, \chi_{\text{perm}} \rangle = \tfrac{1}{6}(1 \cdot 2 \cdot 3 + 3 \cdot 0 \cdot 1 + 2 \cdot (-1) \cdot 0) = \tfrac{1}{6}(6) = 1.
\end{aligned} \tag{2.57}$$

Hence $\rho_{\text{perm}} \cong \rho_{\text{triv}} \oplus \rho_{\text{std}}$, the familiar split of $\mathbb{C}^3$ into the diagonal line $\mathbb{C}(\hat{e}_1 + \hat{e}_2 + \hat{e}_3)$ (on which S_3 acts trivially) and its orthogonal complement, the plane

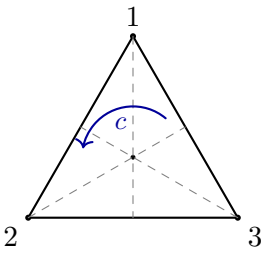

Figure 2.1: The equilateral triangle whose rigid symmetry group is $D_3 \cong S_3$. The three dashed lines are the reflection axes (each fixing one vertex and swapping the other two: the transpositions τ); the blue arc is the 120° rotation c, a 3-cycle. The three reflections form one conjugacy class and the two nontrivial rotations another, matching the class structure used in Theorem 2.33.

$\{x_1 + x_2 + x_3 = 0\}$ (on which it acts as the standard ρ_{std}). The arithmetic confirms what geometry suggested.

Second, the *regular representation* on $\mathbb{C}[S_3]$ (dim = 6). Theorem 2.31 predicts $\mathbb{C}[S_3] \cong d_{\text{triv}}V_{\text{triv}} \oplus d_{\text{sgn}}V_{\text{sgn}} \oplus d_{\text{std}}V_{\text{std}} = 1 \cdot V_{\text{triv}} \oplus 1 \cdot V_{\text{sgn}} \oplus 2 \cdot V_{\text{std}}$, of total dimension $1 \cdot 1 + 1 \cdot 1 + 2 \cdot 2 = 6$. As a check via characters, $\chi_{\text{reg}} = (6, 0, 0)$ on the three classes (Eq. (2.47)), and $\langle \chi_{\text{std}}, \chi_{\text{reg}} \rangle = \frac{1}{6}(2 \cdot 6) = 2 = d_{\text{std}}$, exactly the predicted multiplicity. Every irreducible appears in the regular representation precisely as many times as its dimension, and the books balance.

Why characters are the physicist's tool

The lesson the S_3 table makes concrete is the one that recurs for every symmetry in this book. To know how a symmetry G organizes a system, one does not need the full matrices of the action—one needs only the character, a single number per conjugacy class, and the orthonormal character table of G. Then "which multiplets appear, and how many of each" is the trivial linear-algebra problem of expanding a vector (χ_ρ) in an orthonormal basis (the χ_i), Eq. (2.45). When G is the rotation group, this is precisely how a reducible collection of angular-momentum states is sorted into spin multiplets; when G is a flavor or color group, it is how a tensor product of quarks is sorted into hadron multiplets. The discrete machinery of this section is the rehearsal; the continuous version, with sums over G replaced by invariant integrals, is the performance.

2.2.8 From finite to continuous

We have built the complete decomposition program for finite groups: Maschke guarantees that representations break into irreducible atoms, Schur's lemma

makes those atoms rigid, and characters—orthonormal class functions—let us name and count them with traces. The conceptual content is entirely portable. But the engine that drove every proof was the finite average $\frac{1}{|G|}\sum_{g\in G}$, and the symmetry groups of physics—rotations, Lorentz transformations, gauge groups—are continuous, with infinitely many elements and no finite sum to take. Two routes reopen the program in that setting. For *compact* continuous groups the average survives as an invariant integral $\int_G d\mu(g)$ over the group, and Maschke, Schur, and character orthogonality carry over almost verbatim (this is the path $\mathfrak{su}(2)$ will follow). More powerfully, a continuous group is determined near the identity by its *linearization*—the tangent space at the identity, with its commutator bracket—which is a finite-dimensional algebraic object even when the group is infinite. The next section makes that linearization precise, introduces the Lie algebra and the exponential map that climbs back to the group, and so converts the decomposition philosophy established here into the highest-weight machinery that will solve $\mathfrak{su}(2)$ and $\mathfrak{su}(3)$ completely.

2.3 Lie Groups, Lie Algebras, and the Exponential Bridge

The program assembled in the previous two sections — list the irreducible representations of a group, then expand every representation as a direct sum of those atoms (Section 2.2.1) — was built for finite groups, where the words "list" and "sum" are literal: there are finitely many irreducibles, characters are finite tables, and orthogonality relations are finite sums over group elements. The groups that organize physics are not finite. The rotations of space, the boosts of relativity, the phase rotations of electromagnetism, and the color rotations of the strong interaction all form *continua*: their elements are labelled by real parameters varying smoothly, and a sum over group elements becomes an integral over a manifold. We cannot tabulate such a group element by element. What saves the program is that a continuous group is almost entirely determined by its behaviour in an infinitesimal neighbourhood of the identity. Differentiating the group at the identity collapses the curved, infinite object into a flat, finite one — a vector space equipped with a single bilinear operation, the *Lie algebra* — and the exponential map climbs back from this linear shadow to the group itself. This section builds that bridge in both directions. We define a matrix Lie group and its Lie algebra, show that the algebra is closed under the commutator bracket, extract the structure constants f^{abc} in the Hermitian-generator convention that is canonical for the rest of this book, prove the Jacobi identity and use it to represent the algebra on itself through the adjoint representation, and finally read off from the Baker–Campbell–Hausdorff formula exactly how much of the group's multiplication law the bracket alone remembers.

Throughout, $\mathbf{1}$ denotes the $n\times n$ identity matrix and all matrices are complex

$n \times n$ unless stated otherwise; the matrix groups of interest sit inside the general linear group $\mathrm{GL}(n, \mathbb{C})$ of invertible such matrices.

2.3.1 Matrix Lie groups and the tangent space at the identity

The continuous groups of physics are without exception groups of matrices, and we lose nothing essential by restricting attention to those. The only structural input we need beyond the group axioms of Section 2.1.2 is that the group is a *closed* subset of $\mathrm{GL}(n, \mathbb{C})$: a limit of group elements that happens to remain invertible is again a group element.

Definition 2.34 (Matrix Lie group)**.** A *matrix Lie group* G is a subgroup of $\mathrm{GL}(n, \mathbb{C})$ that is closed as a subset: if $A_k \in G$ is a sequence of group elements and $A_k \to A$ with A invertible, then $A \in G$. The smallest n for which G arises this way fixes the *defining* (or *fundamental*) representation, the matrices being the representation of G on $\mathbb{C}^n$ already in the sense of Theorem 2.7.

The examples that carry the book are all defined by an algebraic constraint imposed on a matrix, and closedness is automatic because the constraint is preserved under limits. The unitary group $\mathrm{U}(n) = \{U : U^\dagger U = \mathbf{1}\}$, its unimodular subgroup $\mathrm{SU}(n) = \{U \in \mathrm{U}(n) : \det U = 1\}$, the orthogonal group $\mathrm{O}(n) = \{O \in \mathrm{GL}(n, \mathbb{R}) : O^{\mathsf{T}} O = \mathbf{1}\}$ and its identity component $\mathrm{SO}(n)$, and the Lorentz group $\mathrm{O}(1,3)$ of Theorem 3.1 are each cut out of $\mathrm{GL}(n)$ by polynomial equations in the matrix entries, hence closed. The defining relation in each case is the single equation we will now differentiate.

The strategic idea is geometric. A matrix Lie group is a smooth surface — a manifold — sitting inside the linear space of all $n \times n$ matrices, and it passes through the identity $\mathbf{1}$. Near $\mathbf{1}$ the surface is well approximated by its tangent plane at that point, and that tangent plane is a genuine linear space: we can add its vectors and scale them, even though we cannot add or scale group elements themselves (the sum of two unitary matrices is almost never unitary). The tangent plane is the linearization we are after.

Definition 2.35 (Tangent vector at the identity)**.** A matrix X is *tangent to G at the identity* if there is a smooth curve $\gamma : (-\delta, \delta) \to G$ in the group with $\gamma(0) = \mathbf{1}$ and $\gamma'(0) = X$. The set of all such X is the tangent space $T_{\mathbf{1}}G$.

To see what $T_{\mathbf{1}}G$ is concretely, differentiate the defining relation along such a curve. Take $G = \mathrm{SU}(n)$, the case that fixes our generator conventions. A curve $U(t) \in \mathrm{SU}(n)$ with $U(0) = \mathbf{1}$ obeys $U(t)^\dagger U(t) = \mathbf{1}$ and $\det U(t) = 1$ identically in t. Differentiating the first relation at $t = 0$ with $U(0) = \mathbf{1}$,

$$\dot{U}(0)^\dagger U(0) + U(0)^\dagger \dot{U}(0) = 0 \quad \Longrightarrow \quad X^\dagger + X = 0, \tag{2.58}$$

so the tangent vector $X = \dot{U}(0)$ is *anti-Hermitian*. Differentiating $\det U(t) = 1$ requires Jacobi's formula $\frac{d}{dt} \det M(t) = \det M(t)\ \mathrm{tr}\big(M(t)^{-1}\dot{M}(t)\big)$, which at $t = 0$ gives

$$\mathrm{tr}\, X = 0 : \tag{2.59}$$

the tangent vector is *traceless*. Thus the tangent space to $\mathrm{SU}(n)$ at the identity is the real vector space of traceless anti-Hermitian matrices. It is a *real* vector space — closed under real linear combinations, since a real combination of traceless anti-Hermitian matrices is again traceless and anti-Hermitian, but not closed under multiplication by i, which would turn anti-Hermitian into Hermitian. We record its dimension for $n = 2$, which we will need below: a traceless anti-Hermitian 2×2 matrix has the form i times a traceless Hermitian one, and the traceless Hermitian 2×2 matrices are spanned over $\mathbb{R}$ by the three Pauli matrices, so $\dim_{\mathbb{R}} T_{\mathbf{1}}\mathrm{SU}(2) = 3$.

This tangent space is the Lie algebra, but to make the definition independent of the choice of curve — and to provide the return route from algebra to group — we need the matrix exponential.

2.3.2 The matrix exponential and one-parameter subgroups

The exponential of a matrix is defined exactly as the scalar exponential, by its power series, and the same estimate that proves convergence of the scalar series proves convergence here.

Definition 2.36 (Matrix exponential)**.** For any $n \times n$ complex matrix X,

$$\exp(X) \;=\; \sum_{k=0}^{\infty} \frac{X^k}{k!} \;=\; \mathbf{1} + X + \tfrac{1}{2}X^2 + \tfrac{1}{6}X^3 + \cdots . \tag{2.60}$$

The series converges absolutely in any submultiplicative matrix norm, since $\sum_k \|X\|^k / k! = e^{\|X\|} < \infty$ bounds the partial sums; the limit is therefore a well-defined matrix, entire in X.

We collect the properties used below. Each is the matrix analogue of a familiar scalar fact, and each is proved by manipulating the absolutely convergent series.

Lemma 2.37 (Properties of the matrix exponential)**.** *Let X, Y be $n \times n$ matrices and A invertible. Then*

1. $\dfrac{d}{dt}\exp(tX) = X\exp(tX) = \exp(tX)\,X$ *and* $\exp(0) = \mathbf{1}$*;*
2. $\exp\big((s+t)X\big) = \exp(sX)\exp(tX)$*, so* $\exp(X)$ *is always invertible with inverse* $\exp(-X)$*;*

3. *if* $XY = YX$ *then* $\exp(X+Y) = \exp(X)\exp(Y)$ *(commutativity is required);*

4. $A\exp(X)A^{-1} = \exp(AXA^{-1})$ *and* $\exp(X)^\dagger = \exp(X^\dagger)$*;*

5. $\det\exp(X) = \exp(\operatorname{tr} X)$.

Proof. For (1), differentiate Eq. (2.60) term by term (legitimate by absolute and uniform convergence on compact t-intervals): $\frac{d}{dt}\sum_k t^k X^k/k! = \sum_{k\geq 1} t^{k-1}X^k/(k-1)! = X\sum_{j\geq 0} t^j X^j/j!$, and X may be pulled out on either side since it commutes with its own powers. For (2), both $t\mapsto \exp((s+t)X)$ and $t\mapsto \exp(sX)\exp(tX)$ satisfy the same first-order linear matrix differential equation $F' = XF$ (using (1)) with the same value $\exp(sX)$ at $t=0$; by uniqueness of solutions of linear ODEs they coincide, and setting $t=-s$ gives $\exp(sX)\exp(-sX) = \mathbf{1}$. Statement (3): when $XY=YX$ the binomial theorem holds for $(X+Y)^k$, and the Cauchy product of the absolutely convergent series for $\exp X$ and $\exp Y$ reproduces $\sum_k (X+Y)^k/k!$ exactly as in the scalar proof. Statement (4) follows from $AX^kA^{-1} = (AXA^{-1})^k$ applied term by term, and from $(X^k)^\dagger = (X^\dagger)^k$. For (5), let $f(t) = \det\exp(tX)$; by Jacobi's formula and (1), $f'(t) = f(t)\,\operatorname{tr}\big(\exp(-tX)\,X\exp(tX)\big) = f(t)\operatorname{tr}X$, using cyclicity of the trace, so $f' = (\operatorname{tr}X)f$ with $f(0)=1$, whence $f(t) = e^{t\operatorname{tr}X}$; set $t=1$. □

Property (2) says that $t\mapsto\exp(tX)$ is a group homomorphism from the additive group $(\mathbb{R},+)$ into $\mathrm{GL}(n,\mathbb{C})$. Such homomorphisms are the smooth threads through the identity, and they are *all* of exponential form.

Proposition 2.38 (One-parameter subgroups)**.** *Let* $\gamma:\mathbb{R}\to\mathrm{GL}(n,\mathbb{C})$ *be a continuous homomorphism, i.e.* $\gamma(s+t)=\gamma(s)\gamma(t)$ *and* $\gamma(0)=\mathbf{1}$*. Then* γ *is smooth and* $\gamma(t)=\exp(tX)$ *with* $X=\gamma'(0)$*. Conversely, every* X *gives such a homomorphism through Eq. (2.60).*

Proof. The converse is Theorem 2.37(2). For the forward direction, continuity of a homomorphism of $(\mathbb{R},+)$ into a matrix group upgrades to differentiability: choose τ small enough that $C=\int_0^\tau \gamma(u)\,du$ is invertible (it tends to $\tau\mathbf{1}$ as $\tau\to 0$), then $\gamma(t)C = \int_0^\tau \gamma(t+u)\,du = \int_t^{t+\tau}\gamma(v)\,dv$ is differentiable in t as an integral of a continuous function, so $\gamma(t) = \big(\int_t^{t+\tau}\gamma\big)C^{-1}$ is differentiable. Now differentiate the homomorphism property $\gamma(s+t)=\gamma(s)\gamma(t)$ with respect to s at $s=0$: $\gamma'(t) = \gamma'(0)\gamma(t) = X\gamma(t)$. This is the linear ODE whose unique solution with $\gamma(0)=\mathbf{1}$ is $\gamma(t)=\exp(tX)$ by Theorem 2.37(1). □

This is the bridge. A tangent direction X at the identity generates a whole one-parameter subgroup $\exp(tX)$ that lies on the curved group surface and is tangent to X at $t=0$; conversely every smooth one-dimensional "flow" through the identity is of this form. Figure 2.2 pictures the construction.

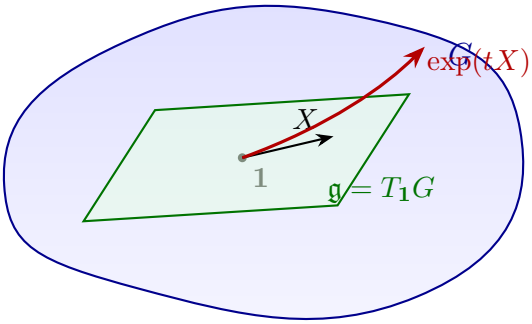

Figure 2.2: The exponential bridge. A matrix Lie group G is a curved surface through the identity $\mathbf{1}$; its tangent space there is the Lie algebra $\mathfrak{g} = T_{\mathbf{1}}G$, a flat vector space on which addition and scaling make sense. A tangent direction $X \in \mathfrak{g}$ generates the one-parameter subgroup $t \mapsto \exp(tX)$, a curve lying *on* G and tangent to X at the identity. The bracket on $\mathfrak{g}$, extracted in Section 2.3.3, records how two such flows fail to commute.

We can now define the Lie algebra so that it manifestly is a real vector space and so that the exponential genuinely maps it back into the group.

Definition 2.39 (Lie algebra of a matrix Lie group)**.** The *Lie algebra* $\mathfrak{g} = \mathrm{Lie}(G)$ of a matrix Lie group G is the set of matrices X such that $\exp(tX) \in G$ for *all* real t.

This set coincides with the tangent space $T_{\mathbf{1}}G$ of Theorem 2.35: if $\exp(tX) \in G$ for all t then $t \mapsto \exp(tX)$ is a curve in G through $\mathbf{1}$ with derivative X, so $X \in T_{\mathbf{1}}G$; conversely any tangent vector arises, by Theorem 2.38, from a one-parameter subgroup inside G. The definition through exp has the advantage that the return statement is built in: for every $X \in \mathfrak{g}$, setting $t = 1$ gives $\exp(X) \in G$. The exponential map genuinely climbs from the algebra to the group.

The earlier computation Eq. (2.58)–Eq. (2.59) can now be read forward as well as backward. If X is traceless and anti-Hermitian, then $\exp(X)$ is unitary and unimodular: $\exp(X)^\dagger \exp(X) = \exp(X^\dagger)\exp(X) = \exp(-X)\exp(X) = \mathbf{1}$ by Theorem 2.37(2),(4) (the two exponents commute), and $\det \exp(X) = \exp(\operatorname{tr} X) = \exp(0) = 1$ by Theorem 2.37(5). Hence exp carries the traceless anti-Hermitian matrices into $\mathrm{SU}(n)$, and we have identified

$$\mathfrak{su}(n) \;=\; \mathrm{Lie}\big(\mathrm{SU}(n)\big) \;=\; \{\, X \in M_n(\mathbb{C}) : X^\dagger = -X,\ \operatorname{tr} X = 0 \,\}, \qquad \dim_{\mathbb{R}} \mathfrak{su}(n) = n^2 - 1. \tag{2.61}$$

The dimension count is the number of independent real parameters in a traceless anti-Hermitian matrix: a Hermitian $n \times n$ matrix has n^2 real parameters, tracelessness removes one, and multiplication by i converts to anti-Hermitian.

2.3.3 The Lie algebra: closure under the bracket

So far $\mathfrak{g}$ is only a vector space. Its defining *algebraic* structure — the thing that remembers the non-commutativity of the group — emerges when we ask how two one-parameter subgroups fail to commute. Consider the group commutator

$$C(s,t) \;=\; \exp(sX)\,\exp(tY)\,\exp(-sX)\,\exp(-tY), \tag{2.62}$$

which equals $\mathbf{1}$ exactly when the two flows commute. Expanding each factor to second order using Eq. (2.60),

$$\begin{aligned}\exp(sX)\exp(tY) &= \Big(\mathbf{1} + sX + \tfrac{1}{2}s^2X^2\Big)\Big(\mathbf{1} + tY + \tfrac{1}{2}t^2Y^2\Big) + \cdots \\ &= \mathbf{1} + sX + tY + st\,XY + \tfrac{1}{2}s^2X^2 + \tfrac{1}{2}t^2Y^2 + \cdots,\end{aligned} \tag{2.63}$$

and similarly $\exp(-sX)\exp(-tY) = \mathbf{1} - sX - tY + st\,XY + \tfrac{1}{2}s^2X^2 + \tfrac{1}{2}t^2Y^2 + \cdots$. Multiplying the two and keeping terms through second order in (s,t), the linear terms cancel, the pure s^2 and t^2 terms cancel, and the surviving cross term is

$$C(s,t) \;=\; \mathbf{1} + st\,(XY - YX) + \cdots \;=\; \mathbf{1} + st\;[X,Y] + O\big((s,t)^3\big), \tag{2.64}$$

where the *commutator* (or *Lie bracket*) is

$$[X,Y] \;\equiv\; XY - YX. \tag{2.65}$$

The leading deviation of the group commutator from the identity is precisely st times the bracket. This is the sense in which the bracket measures the group's non-commutativity to leading order, and it is the reason the bracket — not the matrix product — is the intrinsic operation of the algebra.

The decisive fact is that the bracket stays inside the algebra.

Theorem 2.40 (Closure of the Lie algebra under the bracket)**.** *If $X, Y \in \mathfrak{g} = \mathrm{Lie}(G)$, then $[X,Y] \in \mathfrak{g}$. Together with its real vector-space structure this makes $\mathfrak{g}$ a* Lie algebra*: a real vector space equipped with a bilinear, antisymmetric bracket that, as we prove in Section 2.3.5, satisfies the Jacobi identity.*

Proof. We first confirm that $\mathfrak{g}$ is a real vector space. Closure under real scaling is immediate: if $\exp(tX) \in G$ for all t then $\exp\big(t(cX)\big) = \exp\big((tc)X\big) \in G$ for all t and any real c. Closure under addition uses the *Lie product formula*

$$\exp\big(t(X+Y)\big) \;=\; \lim_{m\to\infty}\Big(\exp\tfrac{tX}{m}\,\exp\tfrac{tY}{m}\Big)^m. \tag{2.66}$$

To prove Eq. (2.66), expand the single bracketed factor: $\exp(\frac{tX}{m})\exp(\frac{tY}{m}) = \mathbf{1} + \frac{t}{m}(X+Y) + O(1/m^2)$. Writing this as $\exp\big(\frac{t}{m}(X+Y) + O(1/m^2)\big)$ — valid since the logarithm series inverts the exponential near $\mathbf{1}$ — and raising to the m-th power multiplies the exponent by m, giving $\exp\big(t(X+Y) + O(1/m)\big) \to \exp\big(t(X+Y)\big)$

as $m \to \infty$. Now each factor $\exp(\frac{tX}{m})\exp(\frac{tY}{m})$ lies in G because $X, Y \in \mathfrak{g}$, so does its m-th power, and since G is closed (Theorem 2.34) the limit $\exp(t(X+Y))$ lies in G for every t. Hence $X + Y \in \mathfrak{g}$, and $\mathfrak{g}$ is a real vector space. Being a finite-dimensional subspace of $M_n(\mathbb{C})$, it is in particular topologically closed.

For the bracket, fix $X, Y \in \mathfrak{g}$ and consider, for each real s, the *conjugated* matrix

$$Y(s) \;\equiv\; \exp(sX)\, Y\, \exp(-sX). \tag{2.67}$$

We claim $Y(s) \in \mathfrak{g}$ for every s. Indeed, by Theorem 2.37(4),

$$\exp\big(t\,Y(s)\big) = \exp\big(t\,\exp(sX)\,Y\,\exp(-sX)\big) = \exp(sX)\,\exp(tY)\,\exp(-sX), \tag{2.68}$$

which is a product of three elements of G, hence in G, for all t; so $Y(s) \in \mathfrak{g}$ by Theorem 2.39. Thus $s \mapsto Y(s)$ is a differentiable curve lying entirely in the closed subspace $\mathfrak{g}$. The derivative of such a curve is a limit of difference quotients $(Y(s) - Y(0))/s$, each of which lies in the subspace $\mathfrak{g}$ (a subspace is closed under subtraction and scaling), and since $\mathfrak{g}$ is closed the limit lies in $\mathfrak{g}$ as well. Computing the derivative at $s = 0$ with Theorem 2.37(1),

$$\left.\frac{d}{ds}\right|_{s=0} Y(s) = \left.\frac{d}{ds}\right|_{s=0} \Big(\exp(sX)\,Y\,\exp(-sX)\Big) = XY - YX = [X, Y]\,. \tag{2.69}$$

Therefore $[X, Y] \in \mathfrak{g}$. Bilinearity and antisymmetry $[X, Y] = -\,[Y, X]$ of the bracket are immediate from its definition Eq. (2.65). □

Theorem 2.40 is what makes the linearization useful. The infinitely many group elements have been replaced by a finite-dimensional vector space, and the entire group multiplication law, to leading nontrivial order, has been compressed into one bilinear operation on that space. The next task is to write that operation in coordinates.

2.3.4 Structure constants and the Hermitian-generator convention

Choose a basis of the Lie algebra. Because $\mathfrak{g}$ is closed under the bracket, the bracket of two basis vectors is again a linear combination of basis vectors, and the coefficients are numbers intrinsic to the group. These numbers are the *structure constants*; they encode everything the Lie algebra knows.

Two conventions for the basis are in use, and they differ by a factor of i. The mathematician's convention takes the basis vectors to be elements of $\mathfrak{g}$ itself — for $\mathfrak{su}(n)$, traceless *anti*-Hermitian matrices — so that exp of a real combination lands in the group. The physicist's convention, which is the canon of this book (Chapter A, Chapter B), strips out the i and works with *Hermitian* generators T^a, writing a group element near the identity as $\exp(-i\alpha^a T^a)$ with

real parameters α^a. The two are related by $X = -i\alpha^a T^a$: the algebra element X is anti-Hermitian, while the generator $T^a = i\,\partial X/\partial\alpha^a$ is Hermitian. We adopt the physicist's convention once and for all.

Notation Watch

Hermitian generators T^a (with $T^{a\dagger} = T^a$) are *not* themselves elements of the real Lie algebra $\mathfrak{g}$; the algebra elements are the anti-Hermitian combinations iT^a. The Hermitian T^a are a convenience that makes the generators observables (they exponentiate to unitaries via $\exp(-i\alpha^a T^a)$) and keeps the structure constants real. Whenever this book writes "the generators T^a," the Hermitian convention with the normalization Eq. (2.72) below is meant, in agreement with Chapter B and Yang–Mills theory of Chapter 25. The mathematician's $\left[iT^a, iT^b\right] = -\left[T^a, T^b\right]$ accounts for every apparent sign discrepancy with the math literature.

In the Hermitian convention the closure Theorem 2.40 reads as follows. The algebra elements iT^a span $\mathfrak{g}$ over $\mathbb{R}$, and their bracket lies in $\mathfrak{g}$: $\left[iT^a, iT^b\right] = -\left[T^a, T^b\right] \in \mathfrak{g} = \mathrm{span}_{\mathbb{R}}\{iT^c\}$. Hence $\left[T^a, T^b\right]$ is i times a real combination of the T^c, which we write as

$$\boxed{\left[T^a, T^b\right] \;=\; i\, f^{abc}\, T^c} \tag{2.70}$$

with real coefficients f^{abc}, the *structure constants*, summed over c. That the f^{abc} are real is the content of the previous sentence; it can also be checked directly by taking the Hermitian conjugate of Eq. (2.70): the left side gives $\left[T^b, T^a\right] = -\left[T^a, T^b\right]$, while the right side gives $-i\,(f^{abc})^* T^c$, and consistency forces $(f^{abc})^* = f^{abc}$. Antisymmetry in the first two indices,

$$f^{abc} = -f^{bac}, \tag{2.71}$$

is immediate from $\left[T^a, T^b\right] = -\left[T^b, T^a\right]$.

The structure constants enjoy a stronger symmetry once we fix the normalization of the generators. The trace of a product of two Hermitian generators defines a symmetric, positive-definite bilinear form on the algebra; for a simple Lie algebra this form is unique up to scale, and we fix the scale in the defining representation by the canonical normalization

$$\boxed{\mathrm{tr}(T^a T^b) \;=\; \tfrac{1}{2}\,\delta^{ab}} \tag{2.72}$$

(the Dynkin index $T_F = \frac{1}{2}$ of Chapter B). With this normalization the structure constants become *totally antisymmetric* in all three indices.

Proposition 2.41 (Total antisymmetry of f^{abc})**.** *In a basis of Hermitian generators obeying Eq. (2.72), the structure constants defined by Eq. (2.70) satisfy*

$$f^{abc} \;=\; -2i\,\mathrm{tr}\Big(\,\big[T^a,T^b\big]\,T^c\Big), \tag{2.73}$$

and f^{abc} is totally antisymmetric: it changes sign under the interchange of any two indices and is invariant under cyclic permutations.

Proof. Multiply Eq. (2.70) on the right by T^d and take the trace, using Eq. (2.72):

$$\mathrm{tr}\Big(\,\big[T^a,T^b\big]\,T^d\Big) = i\,f^{abc}\,\mathrm{tr}(T^cT^d) = i\,f^{abc}\,\tfrac{1}{2}\delta^{cd} = \tfrac{i}{2}\,f^{abd}. \tag{2.74}$$

Solving for f^{abd} and renaming $d \to c$ gives Eq. (2.73). From this expression antisymmetry under $a \leftrightarrow b$ is Eq. (2.71) again (the commutator flips sign). For cyclic invariance, expand the commutator and use cyclicity of the trace, $\mathrm{tr}(ABC) = \mathrm{tr}(CAB) = \mathrm{tr}(BCA)$:

$$\begin{aligned} f^{abc} &= -2i\,\mathrm{tr}(T^aT^bT^c - T^bT^aT^c),\\ f^{bca} &= -2i\,\mathrm{tr}(T^bT^cT^a - T^cT^bT^a) = -2i\,\mathrm{tr}(T^aT^bT^c - T^bT^aT^c) = f^{abc}, \end{aligned} \tag{2.75}$$

where in the second line we cycled $\mathrm{tr}(T^bT^cT^a) = \mathrm{tr}(T^aT^bT^c)$ and $\mathrm{tr}(T^cT^bT^a) = \mathrm{tr}(T^aT^cT^b) = \mathrm{tr}(T^bT^aT^c)$. Thus f^{abc} is invariant under cyclic permutations and antisymmetric under the transposition $a \leftrightarrow b$. Since the cyclic permutations together with one transposition generate the full permutation group S_3 on three letters, and every transposition is conjugate to $a \leftrightarrow b$ under cyclic permutations, f^{abc} is antisymmetric under *every* transposition, i.e. totally antisymmetric. □

The structure constants are thus a totally antisymmetric real array, the same array that will appear as the self-coupling of the gauge field in the Yang–Mills Lagrangian of Chapter 25; the conventions Eq. (2.70) and Eq. (2.72) fixed here are exactly the ones that thread uses.

2.3.5 The Jacobi identity and the adjoint representation

The bracket is not an arbitrary antisymmetric product. Because it is built from the associative matrix product, it obeys one further constraint, the Jacobi identity, which is the precise statement that the algebra can represent itself.

Theorem 2.42 (Jacobi identity)**.** *For any X, Y, Z in a Lie algebra of matrices,*

$$\big[[X,Y],Z\big] + \big[[Y,Z],X\big] + \big[[Z,X],Y\big] \;=\; 0. \tag{2.76}$$

Equivalently, in terms of structure constants,

$$f^{abe}f^{ecd} + f^{bce}f^{ead} + f^{cae}f^{ebd} \;=\; 0. \tag{2.77}$$

Proof. Expand each double commutator using $[A,B]=AB-BA$, which is the only place associativity of matrix multiplication enters:

$$\begin{aligned}[[X,Y],Z] &= XYZ - YXZ - ZXY + ZYX,\\ [[Y,Z],X] &= YZX - ZYX - XYZ + XZY,\\ [[Z,X],Y] &= ZXY - XZY - YZX + YXZ.\end{aligned} \tag{2.78}$$

Adding the three lines, every one of the twelve triple products cancels against an identical product of opposite sign: XYZ in the first line cancels $-XYZ$ in the second, $-YXZ$ in the first cancels $+YXZ$ in the third, $-ZXY$ in the first cancels $+ZXY$ in the third, $+ZYX$ in the first cancels $-ZYX$ in the second, and the remaining four terms $YZX, XZY, -YZX, -XZY$ cancel pairwise. The sum is zero, which is Eq. (2.76). To obtain Eq. (2.77), set $X=T^a$, $Y=T^b$, $Z=T^c$ and use Eq. (2.70) twice. The first term is $\left[\left[T^a,T^b\right],T^c\right] = \left[if^{abe}T^e,T^c\right] = if^{abe}\,if^{ecd}T^d = -f^{abe}f^{ecd}\,T^d$; the other two follow by cyclic relabelling. Summing and dropping the overall factor $-T^d$ (the T^d are linearly independent) gives Eq. (2.77). □

The Jacobi identity acquires its meaning when rewritten as a statement about representations. Define, for each algebra element X, the linear operator ad_X that acts on the algebra itself by bracketing:

$$\mathrm{ad}_X : \mathfrak{g}\to\mathfrak{g}, \qquad \mathrm{ad}_X(Y) \;=\; [X,Y]\,. \tag{2.79}$$

By Theorem 2.40 the result lies in $\mathfrak{g}$, so ad_X is a genuine linear map of the vector space $\mathfrak{g}$ to itself, an element of the matrix algebra $\mathfrak{gl}(\mathfrak{g})$ of operators on $\mathfrak{g}$. The assignment $X\mapsto\mathrm{ad}_X$ is itself a representation of the Lie algebra.

Definition 2.43 (Adjoint representation of the algebra)**.** The *adjoint representation* of $\mathfrak{g}$ is the linear map $\mathrm{ad}:\mathfrak{g}\to\mathfrak{gl}(\mathfrak{g})$, $X\mapsto\mathrm{ad}_X$, of Eq. (2.79). Its dimension equals $\dim\mathfrak{g}$; for $\mathfrak{su}(n)$ it is the (n^2-1)-dimensional representation.

Proposition 2.44 (ad is a representation; this is the Jacobi identity)**.** *The adjoint map respects the bracket,*

$$\mathrm{ad}_{[X,Y]} \;=\; [\mathrm{ad}_X,\mathrm{ad}_Y] \quad \textit{(as operators on } \mathfrak{g}\textit{)}, \tag{2.80}$$

so ad *is a representation of* $\mathfrak{g}$ *in the sense of Theorem 2.7. The identity Eq. (2.80) is logically equivalent to the Jacobi identity Eq. (2.76).*

Proof. Apply both sides of Eq. (2.80) to an arbitrary $Z\in\mathfrak{g}$. The left side is $\mathrm{ad}_{[X,Y]}(Z)=[[X,Y],Z]$. The right side is

$$[\mathrm{ad}_X,\mathrm{ad}_Y](Z) = \mathrm{ad}_X\,\mathrm{ad}_Y(Z) - \mathrm{ad}_Y\,\mathrm{ad}_X(Z) = [X,[Y,Z]] - [Y,[X,Z]]\,. \tag{2.81}$$

Equality of the two for all Z reads $[[X,Y],Z] = [X,[Y,Z]] - [Y,[X,Z]]$. Rearranging and using antisymmetry, $[[X,Y],Z] - [X,[Y,Z]] + [Y,[X,Z]] = [[X,Y],Z] + [[Y,Z],X] + [[Z,X],Y] = 0$, which is exactly Eq. (2.76). Hence Eq. (2.80) holds if and only if the Jacobi identity holds. □

In the Hermitian-generator basis the adjoint representation has explicit matrices built from the structure constants. Acting on the basis, $\mathrm{ad}_{T^a}(T^b) = \left[T^a, T^b\right] = i f^{abc} T^c$, so reading off the coefficient of T^c and defining the matrix elements with the standard physics normalization,

$$\left(T^a_{\mathrm{adj}}\right)_{bc} \;=\; -\,i\, f^{abc}. \tag{2.82}$$

These are Hermitian: $(T^a_{\mathrm{adj}})^*_{cb} = (-if^{acb})^* = +if^{acb} = -if^{abc} = (T^a_{\mathrm{adj}})_{bc}$, using reality and total antisymmetry of f, and they satisfy the same algebra $\left[T^a_{\mathrm{adj}}, T^b_{\mathrm{adj}}\right] = i f^{abc} T^c_{\mathrm{adj}}$, which is once more Eq. (2.77). Thus the structure constants *are* the adjoint generators: a Lie algebra always represents itself, in dimension equal to its own. We will meet Eq. (2.82) again in the very next worked example, where the adjoint of $\mathfrak{su}(2)$ turns out to be the rotation generators of $\mathfrak{so}(3)$.

2.3.6 The exponentiated adjoint and the action of the group on its algebra

The adjoint representation of the *algebra* integrates to a representation of the *group*. A group element $g \in G$ acts on the algebra by conjugation,

$$\mathrm{Ad}_g : \mathfrak{g} \to \mathfrak{g}, \qquad \mathrm{Ad}_g(X) = g\, X\, g^{-1}, \tag{2.83}$$

which lands in $\mathfrak{g}$ because $\exp(t\, gXg^{-1}) = g \exp(tX) g^{-1} \in G$ for all t by Theorem 2.37(4), so $gXg^{-1} \in \mathfrak{g}$ by Theorem 2.39. The map $\mathrm{Ad} : G \to \mathrm{GL}(\mathfrak{g})$, $g \mapsto \mathrm{Ad}_g$, is a representation of the group on its own algebra, the *adjoint representation of the group*. Its relation to the algebra adjoint ad is the cleanest illustration of the exponential bridge.

Proposition 2.45 ($\mathrm{Ad} \circ \exp = \exp \circ \mathrm{ad}$)**.** *For all $X, Y \in \mathfrak{g}$,*

$$\mathrm{Ad}_{\exp(tX)}\, Y \;=\; \exp(t\ \mathrm{ad}_X)\, Y \;=\; Y + t\,[X,Y] + \tfrac{t^2}{2}\,[X,[X,Y]] + \cdots . \tag{2.84}$$

In words: conjugating by the group element $\exp(tX)$ acts on the algebra as the exponential of the operator ad_X. The group adjoint is the exponentiated algebra adjoint.

Proof. Let $F(t) = \mathrm{Ad}_{\exp(tX)}\, Y = \exp(tX)\, Y \exp(-tX)$. Differentiating with Theorem 2.37(1),

$$F'(t) = X \exp(tX)\, Y \exp(-tX) - \exp(tX)\, Y \exp(-tX)\, X = [X, F(t)] = \mathrm{ad}_X\ F(t), \tag{2.85}$$

since X commutes with $\exp(\pm tX)$ and may be moved through. This is a linear ODE for F in the (finite-dimensional) space $\mathfrak{g}$, with constant operator ad_X and initial value $F(0) = Y$; its unique solution is $F(t) = \exp(t\,\operatorname{ad}_X)Y$ by the same argument as Theorem 2.37(1). Expanding the operator exponential gives the explicit nested-commutator series. □

Theorem 2.45 is the first instance of a general principle: *differentiating a representation of the group at the identity yields a representation of the algebra, and exponentiating a representation of the algebra recovers (the identity component of) the representation of the group.* The differential of the group adjoint Ad is the algebra adjoint ad. This correspondence between group representations and algebra representations, of which $(\mathrm{Ad}, \mathrm{ad})$ is the example carried by the structure constants themselves, is what allows the entire classification problem to be moved down to the algebra — the strategy executed in full for $\mathfrak{su}(2)$ in the next section.

2.3.7 The Baker–Campbell–Hausdorff bridge

We have seen that the bracket controls the group commutator to leading order (Eq. (2.64)). The Baker–Campbell–Hausdorff (BCH) formula makes the sharper statement that the bracket controls the entire product of two exponentials: there is a single algebra element Z, built from X and Y using only brackets, with $\exp(X)\exp(Y) = \exp(Z)$. We derive its leading nontrivial term, which is all that the rest of the book needs and which already carries the qualitative message.

Theorem 2.46 (Leading BCH term)**.** *For matrices X, Y small enough that the logarithm series converges,*

$$\exp(X)\,\exp(Y) \;=\; \exp\Big(X + Y + \tfrac{1}{2}\,[X,Y] + \tfrac{1}{12}\,[X,[X,Y]] - \tfrac{1}{12}\,[Y,[X,Y]] + \cdots\Big), \tag{2.86}$$

where every term beyond $X+Y$ is a nested commutator. In particular, to second order,

$$\exp(X)\exp(Y) \;=\; \exp\Big(X + Y + \tfrac{1}{2}\,[X,Y] + O(\textit{order } 3)\Big). \tag{2.87}$$

Proof. We compute $Z = \log\big(\exp(X)\exp(Y)\big)$ to second order in the joint degree of X and Y. Multiply the two exponential series and keep terms of total degree ≤ 2:

$$\begin{aligned}\exp(X)\exp(Y) &= \Big(\mathbf{1} + X + \tfrac{1}{2}X^2\Big)\Big(\mathbf{1} + Y + \tfrac{1}{2}Y^2\Big) + \cdots \\ &= \mathbf{1} + (X+Y) + \Big(\tfrac{1}{2}X^2 + XY + \tfrac{1}{2}Y^2\Big) + \cdots \;\equiv\; \mathbf{1} + W. \end{aligned} \tag{2.88}$$

Here $W = (X+Y) + \big(\tfrac{1}{2}X^2 + XY + \tfrac{1}{2}Y^2\big) + \cdots$ collects everything beyond the identity, with a first-degree part $W_1 = X + Y$ and a second-degree part $W_2 = \tfrac{1}{2}X^2 + XY + \tfrac{1}{2}Y^2$. Now apply the logarithm series $\log(\mathbf{1} + W) = W -$

$\frac{1}{2}W^2 + \cdots$, keeping degree ≤ 2. Only W_1 contributes to W^2 at this order, so $W^2 = W_1^2 + \cdots = (X+Y)^2 + \cdots = X^2 + XY + YX + Y^2 + \cdots$. Therefore

$$\begin{aligned} Z &= W - \tfrac{1}{2}W^2 + \cdots = (X+Y) + \left(\tfrac{1}{2}X^2 + XY + \tfrac{1}{2}Y^2\right) - \tfrac{1}{2}(X^2 + XY + YX + Y^2) + \cdots \\ &= (X+Y) + \tfrac{1}{2}(XY - YX) + \cdots = X + Y + \tfrac{1}{2}[X,Y] + \cdots . \end{aligned} \tag{2.89}$$

The pure X^2 and Y^2 terms cancel between the two contributions, leaving precisely $\frac{1}{2}[X,Y]$ at second order. This establishes Eq. (2.87); the third-order terms in Eq. (2.86) are obtained by carrying the same computation one degree further, and one finds they assemble into the displayed nested commutators. The crucial structural fact — that *every* correction to $X+Y$ is a commutator, so that Z lies in the Lie algebra whenever X, Y do — is the theorem of Baker, Campbell, and Hausdorff in its full form; the closure under brackets proved in Theorem 2.40 is exactly what guarantees each such commutator stays in $\mathfrak{g}$. □

Physical Insight

Equation (2.87) is the quantitative meaning of "the algebra remembers the group to leading order." If the group were abelian, $[X,Y] = 0$ and $\exp(X)\exp(Y) = \exp(X+Y)$ exactly: exponentials would simply add their exponents, as for ordinary numbers. The first obstruction to this is the bracket, appearing at second order with the universal coefficient $\frac{1}{2}$. Every higher correction is built from brackets as well, so a group with a trivial bracket (an abelian Lie algebra) has, near the identity, the additive structure of a vector space, while all non-commutativity — and hence all of the interesting physics of non-abelian gauge theory in Chapter 25 — is generated by iterated brackets of the generators. The Lie algebra is therefore not a poor approximation to the group but a faithful one: the connected group is reconstructed from its algebra by Eq. (2.86), and the entire chapter's strategy of classifying representations at the level of the algebra is justified.

2.3.8 Worked example: $\mathfrak{su}(2)$ and $\mathfrak{so}(3)$ exponentiated

We close by carrying out the exponential map explicitly for the two algebras that dominate the rest of the chapter and the book. The computation produces closed forms we will reuse without comment when we solve $\mathfrak{su}(2)$ completely in Section 2.4, and it exhibits in miniature the relationship between a group and its double cover.

Worked Example 2.47 (Exponentiating the $\mathfrak{su}(2)$ and $\mathfrak{so}(3)$ generators)**.**

The $\mathfrak{su}(2)$ generators. By Eq. (2.61), $\mathfrak{su}(2)$ consists of traceless anti-Hermitian 2×2 matrices, the real span of $\{iT^a\}$ with Hermitian generators

$$T^a=\tfrac{1}{2}\sigma^a,\qquad \sigma^1=\begin{pmatrix}0&1\\1&0\end{pmatrix},\ \sigma^2=\begin{pmatrix}0&-i\\i&0\end{pmatrix},\ \sigma^3=\begin{pmatrix}1&0\\0&-1\end{pmatrix}. \tag{2.90}$$

The Pauli matrices obey $\sigma^a\sigma^b=\delta^{ab}\mathbf{1}+i\epsilon^{abc}\sigma^c$, from which both defining data of the generators follow at once. The normalization is $\operatorname{tr}(T^aT^b)=\frac{1}{4}\operatorname{tr}(\sigma^a\sigma^b)=\frac{1}{4}\cdot 2\delta^{ab}=\frac{1}{2}\delta^{ab}$, confirming Eq. (2.72). The bracket is

$$\left[T^a,T^b\right]=\tfrac{1}{4}\left[\sigma^a,\sigma^b\right]=\tfrac{1}{4}(2i\epsilon^{abc}\sigma^c)=i\,\epsilon^{abc}\,T^c, \tag{2.91}$$

so the structure constants of $\mathfrak{su}(2)$ are the totally antisymmetric Levi-Civita symbol, $f^{abc}=\epsilon^{abc}$, in accordance with Theorem 2.41.

Exponentiating $\mathfrak{su}(2)$. Take a unit vector $\hat n\in\mathbb{R}^3$ and an angle $\theta\in\mathbb{R}$, and form the group element $U=\exp(-i\theta\,\hat n\cdot\mathbf{T})=\exp(-i\tfrac{\theta}{2}\,\hat n\cdot\boldsymbol{\sigma})$, where $\hat n\cdot\boldsymbol{\sigma}=n^a\sigma^a$. The key simplification is that $\hat n\cdot\boldsymbol{\sigma}$ squares to the identity:

$$(\hat n\cdot\boldsymbol{\sigma})^2=n^an^b\,\sigma^a\sigma^b=n^an^b(\delta^{ab}\mathbf{1}+i\epsilon^{abc}\sigma^c)=|\hat n|^2\ \mathbf{1}=\mathbf{1}, \tag{2.92}$$

the antisymmetric piece vanishing because n^an^b is symmetric. Splitting the exponential series Eq. (2.60) into even and odd powers and using $(\hat n\cdot\boldsymbol{\sigma})^{2k}=\mathbf{1}$, $(\hat n\cdot\boldsymbol{\sigma})^{2k+1}=\hat n\cdot\boldsymbol{\sigma}$,

$$\begin{aligned}U=\exp\Big(-i\tfrac{\theta}{2}\,\hat n\cdot\boldsymbol{\sigma}\Big)&=\sum_{k=0}^{\infty}\frac{1}{(2k)!}\Big(-i\tfrac{\theta}{2}\Big)^{2k}\mathbf{1}+\sum_{k=0}^{\infty}\frac{1}{(2k+1)!}\Big(-i\tfrac{\theta}{2}\Big)^{2k+1}\hat n\cdot\boldsymbol{\sigma}\\&=\cos\frac{\theta}{2}\,\mathbf{1}-i\sin\frac{\theta}{2}\,\hat n\cdot\boldsymbol{\sigma}.\end{aligned} \tag{2.93}$$

This is the general element of SU(2) in axis–angle form. It is manifestly unitary, $U^\dagger U=(\cos\frac{\theta}{2}\,\mathbf{1}+i\sin\frac{\theta}{2}\,\hat n\cdot\boldsymbol{\sigma})(\cos\frac{\theta}{2}\,\mathbf{1}-i\sin\frac{\theta}{2}\,\hat n\cdot\boldsymbol{\sigma})=\cos^2\frac{\theta}{2}\,\mathbf{1}+\sin^2\frac{\theta}{2}\,(\hat n\cdot\boldsymbol{\sigma})^2=\mathbf{1}$, and unimodular, $\det U=\cos^2\frac{\theta}{2}+\sin^2\frac{\theta}{2}=1$ (the determinant of $a\mathbf{1}+i\,\hat n\cdot\boldsymbol{\sigma}\,b$ is a^2+b^2 for the Pauli matrices), so indeed $U\in\mathrm{SU}(2)$ as the bridge guarantees.

The $\mathfrak{so}(3)$ generators as the adjoint of $\mathfrak{su}(2)$. By Eq. (2.82) the adjoint representation of $\mathfrak{su}(2)$ has generators $(J^a)_{bc}=-if^{abc}=-i\epsilon^{abc}$, three Hermitian 3×3 matrices,

$$J^1=\begin{pmatrix}0&0&0\\0&0&-i\\0&i&0\end{pmatrix},\quad J^2=\begin{pmatrix}0&0&i\\0&0&0\\-i&0&0\end{pmatrix},\quad J^3=\begin{pmatrix}0&-i&0\\i&0&0\\0&0&0\end{pmatrix}, \tag{2.94}$$

satisfying the *same* algebra $\left[J^a,J^b\right]=i\epsilon^{abc}J^c$. These are exactly the generators of rotations of three-dimensional space, the Lie algebra $\mathfrak{so}(3)$ of Theorem 3.7: $\mathfrak{so}(3)=\mathfrak{su}(2)$ as Lie algebras, the adjoint of $\mathfrak{su}(2)$ being the defining representation

of SO(3). Acting on a vector $\mathbf{v} \in \mathbb{R}^3$ the generator realizes the cross product, $(\hat{n}\cdot\mathbf{J})\,\mathbf{v} = i\,\hat{n}\times\mathbf{v}$, since $\big((\hat{n}\cdot\mathbf{J})\mathbf{v}\big)_b = -i\epsilon^{abc}n^a v^c = i\,(\hat{n}\times\mathbf{v})_b$.

Exponentiating $\mathfrak{so}(3)$. Form $R = \exp(-i\theta\,\hat{n}\cdot\mathbf{J})$. Now the relevant identity is cubic rather than quadratic. Writing $B = \hat{n}\cdot\mathbf{J}$, the relation $(\hat{n}\cdot\mathbf{J})\mathbf{v} = i\,\hat{n}\times\mathbf{v}$ iterated gives $B^3\mathbf{v} = i\,\hat{n}\times\big(i\,\hat{n}\times(i\,\hat{n}\times\mathbf{v})\big) = -i\,\hat{n}\times\big(\hat{n}(\hat{n}\cdot\mathbf{v})-\mathbf{v}\big) = i\,\hat{n}\times\mathbf{v} = B\mathbf{v}$, so

$$B^3 = B, \qquad B = \hat{n}\cdot\mathbf{J}. \tag{2.95}$$

Splitting the series with $B^{2k+1} = B$ and $B^{2k} = B^2$ for $k \geq 1$,

$$\begin{aligned} R = \exp(-i\theta B) &= \mathbf{1} + B\sum_{k=0}^{\infty}\frac{(-i\theta)^{2k+1}}{(2k+1)!} + B^2\sum_{k=1}^{\infty}\frac{(-i\theta)^{2k}}{(2k)!} \\ &= \mathbf{1} - i\sin\theta\,B + (\cos\theta - 1)\,B^2, \end{aligned} \tag{2.96}$$

where $\sum_{k\geq 0}(-i\theta)^{2k+1}/(2k+1)! = \sinh(-i\theta) = -i\sin\theta$ and $\sum_{k\geq 1}(-i\theta)^{2k}/(2k)! = \cosh(-i\theta) - 1 = \cos\theta - 1$. Substituting $(B)_{bc} = -i\epsilon^{abc}n^a$ and $(B^2)_{bc} = \delta_{bc} - n_b n_c$ (which follows from $B^2\mathbf{v} = i\hat{n}\times(i\hat{n}\times\mathbf{v}) = -\big(\hat{n}(\hat{n}\cdot\mathbf{v}) - \mathbf{v}\big) = \mathbf{v} - \hat{n}(\hat{n}\cdot\mathbf{v})$),

$$R_{bc} = \cos\theta\,\delta_{bc} + (1-\cos\theta)\,n_b n_c - \sin\theta\,\epsilon_{bca}\,n_a, \tag{2.97}$$

which is the Rodrigues rotation formula: R is the rotation by angle θ about the axis $\hat{n}$. (The cross-term sign comes from the $-i\sin\theta\,B$ term: $-i\sin\theta\,(-i\epsilon^{abc}n^a) = -\sin\theta\,\epsilon^{abc}n^a = -\sin\theta\,\epsilon_{bca}n_a$, using the cyclic identity $\epsilon^{abc} = \epsilon_{bca}$, matching Eq. (2.97).) Thus exp carries $\mathfrak{so}(3)$ onto the rotation group SO(3), with θ the literal rotation angle.

The factor of two. Comparing Eq. (2.93) and Eq. (2.97), the same axis–angle data $(\hat{n},\theta)$ produces an SU(2) element through the *half*-angle $\theta/2$ but an SO(3) rotation through the full angle θ. The consequence is decisive. A full rotation $\theta = 2\pi$ returns the spatial rotation to the identity, $R(\hat{n},2\pi) = \mathbf{1}$ from Eq. (2.97), but sends the SU(2) element to

$$U(\hat{n},2\pi) = \cos\pi\,\mathbf{1} - i\sin\pi\,\hat{n}\cdot\boldsymbol{\sigma} = -\mathbf{1} \neq \mathbf{1}, \tag{2.98}$$

and only at $\theta = 4\pi$ does U return to $\mathbf{1}$. Both $U = \pm\mathbf{1}$ map to the single rotation $R = \mathbf{1}$, so the assignment $U \mapsto R$ is two-to-one. The map $\mathrm{SU}(2) \to \mathrm{SO}(3)$ defined by Ad — conjugation of the Pauli vector $\hat{n}\cdot\boldsymbol{\sigma}$ by U realizes the rotation R via Theorem 2.45 — is the two-to-one covering homomorphism with kernel $\{\pm\mathbf{1}\}$. This is the algebraic origin of the topological double cover $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$ recorded in Theorem 3.10, and the reason half-integer spin exists: representations of $\mathfrak{su}(2)$ that are single-valued on SU(2) but double-valued on SO(3) are physically admissible because the symmetry group acting on quantum states is the cover SU(2), not SO(3) itself. We take up that fact, and build every irreducible representation of $\mathfrak{su}(2)$ from these generators, in the next section.

With the Lie algebra, its bracket and structure constants, the Jacobi identity, the adjoint representations ad and Ad, and the exponential map all in hand — and with $\mathfrak{su}(2)$ and $\mathfrak{so}(3)$ exponentiated in closed form — we have the complete machinery for turning a continuous symmetry into a finite linear-algebra problem. The next section spends that machinery on its most important single application: solving $\mathfrak{su}(2)$ completely by the highest-weight and ladder construction, reading off the dimensions and Casimir spectrum of its irreducible representations, and settling the SU(2)-over-SO(3) relationship just glimpsed in Eq. (2.98) into the explanation of half-integer spin.

2.4 The Worked Spine: $\mathfrak{su}(2)$, Its Representations, and SU(2) over SO(3)

The previous section gave us the general machinery: a matrix Lie group is captured near the identity by its Lie algebra (Theorem 2.39), the bracket and its structure constants (Eq. (2.70)) encode the group multiplication to leading nontrivial order, and the exponential map (Eq. (2.60)) climbs back from the algebra to the group. That machinery is abstract until it is run, in full, on a concrete algebra; and there is exactly one algebra on which every later representation-theoretic move in this book is first rehearsed. It is $\mathfrak{su}(2)$: the smallest nonabelian compact simple Lie algebra, the rank-one case from which the entire theory of roots and weights is the patient generalization. We now solve it completely and by hand. Every irreducible representation will be built from scratch by the highest-weight/ladder construction; its dimension and Casimir eigenvalue will be derived rather than quoted; the low-spin matrices will be written out explicitly; and the relationship between the group SU(2) and the rotation group SO(3)—the relationship that forces the existence of half-integer spin—will be settled. The reader has met the angular-momentum ladder in nonrelativistic quantum mechanics; here we recast it as honest representation theory, deriving as theorems what there was assumed as the spectrum of $\mathbf{J}^2$ and J_3.

2.4.1 The algebra, the Casimir, and the ladder operators

Definition 2.48 (The Lie algebra $\mathfrak{su}(2)$)**.** The real Lie algebra $\mathfrak{su}(2)$ is the three-dimensional algebra spanned by Hermitian generators J^1, J^2, J^3 with brackets

$$\left[J^i, J^j\right] = i\,\epsilon^{ijk}\,J^k, \qquad i,j,k \in \{1,2,3\}, \tag{2.99}$$

ϵ^{ijk} the totally antisymmetric symbol with $\epsilon^{123} = +1$, and a sum over the repeated index k understood.

The structure constants of $\mathfrak{su}(2)$ in this basis are therefore $f^{ijk} = \epsilon^{ijk}$, fully antisymmetric, in keeping with the general normalization $\left[T^a, T^b\right] = i f^{abc} T^c$ fixed in the chapter introduction and tabulated in Chapter B. We choose the generators Hermitian so that the group elements $\exp(-i\theta_a J^a)$ are unitary; this is the convention under which physical symmetry operators act on Hilbert space. A *representation* of $\mathfrak{su}(2)$ on a finite-dimensional complex vector space V is, as in Theorem 2.39, a set of three operators on V—we use the same letters J^i, the context fixing whether the abstract element or its image is meant—satisfying Eq. (2.99). To classify the representations is to find every way these brackets can be realized by operators on a finite-dimensional space, up to the change of basis that identifies equivalent representations.

The first move is to build the operator that organizes the whole problem. Although no single generator commutes with the others—that is the content of Eq. (2.99)—a particular quadratic combination does.

Definition 2.49 (Casimir operator)**.** The *quadratic Casimir* of $\mathfrak{su}(2)$ is

$$\mathbf{J}^2 \;\equiv\; (J^1)^2 + (J^2)^2 + (J^3)^2. \tag{2.100}$$

Proposition 2.50 (The Casimir is central)**.** $\left[\mathbf{J}^2, J^i\right] = 0$ *for every* i.

Proof. It suffices to check $i = 3$; the other two follow by relabelling. Expand the commutator term by term, using the Leibniz identity $[AB, C] = A\,[B, C] + [A, C]\,B$ and the algebra Eq. (2.99) in the form $\left[J^1, J^3\right] = -iJ^2$, $\left[J^2, J^3\right] = +iJ^1$, $\left[J^3, J^3\right] = 0$:

$$\left[(J^1)^2, J^3\right] = J^1\left[J^1, J^3\right] + \left[J^1, J^3\right]J^1 = J^1(-iJ^2) + (-iJ^2)J^1 = -i(J^1J^2 + J^2J^1), \tag{2.101}$$

$$\left[(J^2)^2, J^3\right] = J^2\left[J^2, J^3\right] + \left[J^2, J^3\right]J^2 = J^2(iJ^1) + (iJ^1)J^2 = +i(J^2J^1 + J^1J^2), \tag{2.102}$$

$$\left[(J^3)^2, J^3\right] = 0. \tag{2.103}$$

The first two lines are negatives of one another, so their sum vanishes, and adding the third leaves $\left[\mathbf{J}^2, J^3\right] = 0$. □

The centrality of $\mathbf{J}^2$ is what makes it the lever of the construction. On an *irreducible* representation, an operator commuting with every generator commutes with the whole image of the algebra; by Schur's lemma (Theorem 2.21) it must then be a scalar multiple of the identity. Thus on each irreducible V the Casimir takes a single fixed value, $\mathbf{J}^2 = \lambda\,\mathbf{1}$, and labelling the irreducibles by λ will turn out to label them completely.

To resolve the representation we diagonalize as much as we can simultaneously. The operators $\mathbf{J}^2$ and J^3 commute (Theorem 2.50), and J^3 is Hermitian, so we

may choose a basis of common eigenvectors. The remaining two generators are repackaged not as Hermitian operators but as a raising/lowering pair, exactly as the harmonic oscillator's x and p are repackaged into $a^\dagger$ and a.

Definition 2.51 (Ladder operators)**.**

$$J_\pm \equiv J^1 \pm i\, J^2. \tag{2.104}$$

Because J^1, J^2 are Hermitian, $J_\pm^\dagger = J^1 \mp i J^2 = J_\mp$: the raising and lowering operators are mutual adjoints. Their algebra with J^3 and with each other is the engine of everything that follows, so we compute it in full.

Lemma 2.52 (Ladder algebra)**.**

$$\left[J^3, J_\pm\right] = \pm\, J_\pm, \tag{2.105}$$

$$[J_+, J_-] = 2\, J^3, \tag{2.106}$$

$$\mathbf{J}^2 = J^3(J^3 \pm 1) + J_\mp J_\pm. \tag{2.107}$$

Proof. For Eq. (2.105), use Eq. (2.99):

$$\left[J^3, J_\pm\right] = \left[J^3, J^1\right] \pm i \left[J^3, J^2\right] = iJ^2 \pm i(-iJ^1) = iJ^2 \pm J^1 = \pm(J^1 \pm iJ^2) = \pm J_\pm. \tag{2.108}$$

For Eq. (2.106),

$$[J_+, J_-] = \left[J^1 + iJ^2, J^1 - iJ^2\right] = -i\left[J^1, J^2\right] + i\left[J^2, J^1\right] = -2i\left[J^1, J^2\right] = -2i\,(iJ^3) = 2J^3. \tag{2.109}$$

For Eq. (2.107), compute the product $J_\mp J_\pm$ directly:

$$J_\mp J_\pm = (J^1 \mp iJ^2)(J^1 \pm iJ^2) = (J^1)^2 + (J^2)^2 \pm i\left[J^1, J^2\right] = (J^1)^2 + (J^2)^2 \mp J^3, \tag{2.110}$$

where the cross terms combined into the commutator and $\left[J^1, J^2\right] = iJ^3$ was used. Adding and subtracting $(J^3)^2$,

$$J_\mp J_\pm = \mathbf{J}^2 - (J^3)^2 \mp J^3 = \mathbf{J}^2 - J^3(J^3 \pm 1), \tag{2.111}$$

which rearranges to Eq. (2.107). □

Equation (2.105) is the decisive relation: it says that $J_\pm$ shifts the eigenvalue of J^3 by exactly ± 1. If $|m\rangle$ is an eigenvector of J^3 with eigenvalue m, then

$$J^3\left(J_\pm |m\rangle\right) = \left(J_\pm J^3 + \left[J^3, J_\pm\right]\right)|m\rangle = (m \pm 1)\, J_\pm |m\rangle\,, \tag{2.112}$$

so $J_\pm |m\rangle$ is either zero or an eigenvector with eigenvalue $m \pm 1$. The eigenvalue of J^3 is traditionally called the *weight* m; Eq. (2.112) is the statement that J_+ raises and J_- lowers the weight in unit steps. This is the abstract content of the angular-momentum ladder, here proved from the bracket alone rather than assumed.

2.4.2 The highest-weight construction

We can now state and prove the central classification theorem of the chapter. Everything later—the Lorentz representations of Chapter 3, the isospin and color multiplets, the Clebsch–Gordan series of the next section—is an application or a generalization of it.

Theorem 2.53 (Irreducible representations of $\mathfrak{su}(2)$)**.** *For each value $j \in \{0, \tfrac{1}{2}, 1, \tfrac{3}{2}, 2, \dots\}$ there is, up to equivalence, exactly one irreducible representation $D^{(j)}$ of $\mathfrak{su}(2)$, the* spin-j *representation, and these exhaust the finite-dimensional irreducibles. It has the following properties.*

1. *Its dimension is $2j+1$.*
2. *The Casimir acts as the scalar $\mathbf{J}^2 = j(j+1)\,\mathbf{1}$.*
3. *There is an orthonormal basis $\{|j,m\rangle : m = -j, -j+1, \dots, j-1, j\}$ of simultaneous eigenvectors,*

$$\mathbf{J}^2\,|j,m\rangle = j(j+1)\,|j,m\rangle\,, \qquad J^3\,|j,m\rangle = m\;|j,m\rangle\,, \tag{2.113}$$

   with the weights m spaced by unit steps and symmetric about zero.
4. *The ladder operators act by*

$$J_\pm\,|j,m\rangle = \sqrt{j(j+1) - m(m\pm 1)}\;\;|j,m\pm 1\rangle\,. \tag{2.114}$$

Proof. Let V be a finite-dimensional irreducible representation. By Theorem 2.50 and Schur's lemma (Theorem 2.21), $\mathbf{J}^2 = \lambda\,\mathbf{1}$ for a single number λ. Because J^3 is Hermitian on the finite-dimensional space V, it is diagonalizable with real eigenvalues; let the largest one be j (it exists, the spectrum being a finite set of reals), and let $|v\rangle$ be a corresponding unit eigenvector, $J^3\,|v\rangle = j\,|v\rangle$.

Step 1: the top of the ladder. Apply J_+. By Eq. (2.112), $J_+\,|v\rangle$ has weight $j+1$. But j was the largest weight, so no vector of weight $j+1$ exists; hence

$$J_+\,|v\rangle = 0. \tag{2.115}$$

We call $|v\rangle$ a *highest-weight vector*. Now evaluate the Casimir on it using the upper sign of Eq. (2.107):

$$\lambda\,|v\rangle = \mathbf{J}^2\,|v\rangle = \big(J^3(J^3+1) + J_-J_+\big)\,|v\rangle = \big(j(j+1) + 0\big)\,|v\rangle\,, \tag{2.116}$$

the last term vanishing by Eq. (2.115). Therefore

$$\lambda = j(j+1), \tag{2.117}$$

which fixes the Casimir eigenvalue in terms of the top weight and proves property (2) once we identify j as the spin label.

Step 2: descending the ladder. Define a chain of vectors by repeated lowering,

$$|v_0\rangle \equiv |v\rangle\,, \qquad |v_{n+1}\rangle \equiv J_-\,|v_n\rangle \quad (n = 0, 1, 2, \dots). \tag{2.118}$$

By Eq. (2.112), $|v_n\rangle$ (when nonzero) has weight $j - n$; distinct weights mean distinct eigenvectors of J^3, so the nonzero $|v_n\rangle$ are linearly independent. Since V is finite-dimensional, the chain must terminate: there is a smallest integer $N \geq 0$ with $|v_N\rangle \neq 0$ but $J_-\,|v_N\rangle = |v_{N+1}\rangle = 0$. The bottom vector $|v_N\rangle$ has weight $m_{\min} = j - N$ and is annihilated by J_-. Evaluate the Casimir on it, now with the lower sign of Eq. (2.107):

$$\lambda\,|v_N\rangle = \big(J^3(J^3 - 1) + J_+J_-\big)\,|v_N\rangle = m_{\min}(m_{\min} - 1)\,|v_N\rangle\,, \tag{2.119}$$

so $\lambda = m_{\min}(m_{\min} - 1)$. Combined with Eq. (2.117) this requires

$$m_{\min}(m_{\min} - 1) = j(j + 1). \tag{2.120}$$

This quadratic in $m_{\min}$ has the two roots $m_{\min} = -j$ and $m_{\min} = j + 1$. The second is excluded because $m_{\min} \leq j$, so

$$m_{\min} = -j. \tag{2.121}$$

Step 3: quantization of j and the dimension. The bottom weight is $j - N = -j$, hence $N = 2j$. But N is a nonnegative integer by construction, so

$$2j \in \{0, 1, 2, 3, \dots\}, \qquad \text{i.e.} \qquad j \in \left\{0, \tfrac{1}{2}, 1, \tfrac{3}{2}, \dots\right\}. \tag{2.122}$$

This is the entire reason spin is quantized in half-integer units, and it has come from nothing but the algebra Eq. (2.99) and the finiteness of the representation: the ladder must close on itself, and it can only do so after an integer number of unit steps that carry $+j$ to $-j$, a span of $2j$. The weights are then $m \in \{-j, -j+1, \dots, j\}$, a set of $N + 1 = 2j + 1$ values, and the corresponding vectors $|v_0\rangle, \dots, |v_N\rangle$ span a $(2j + 1)$-dimensional subspace $W \subseteq V$.

Step 4: W is the whole space, and the matrix elements. The subspace W is invariant under J^3 (it is spanned by J^3-eigenvectors) and under J_- (which maps each $|v_n\rangle$ to the next, or to zero). It is also invariant under J_+: applying J_+ to $|v_n\rangle$ gives a weight-$(j - n + 1)$ vector, which lies in W because W contains the unique-up-to-scale weight space at each weight. To see the uniqueness and pin the coefficients at once, normalize. Set $|j, j\rangle \equiv |v\rangle$ and define $|j, m\rangle$ as the unit-normalized lowering chain. The norm of $J_\pm\,|j, m\rangle$ follows from Eq. (2.107) and $J_\pm^\dagger = J_\mp$:

$$\big\|J_\pm\,|j, m\rangle\big\|^2 = \langle j, m|J_\mp J_\pm|j, m\rangle = \Big\langle j, m\Big|\mathbf{J}^2 - J^3(J^3 \pm 1)\Big|j, m\Big\rangle = j(j{+}1) - m(m{\pm}1). \tag{2.123}$$

The right-hand side is automatically ≥ 0 on the allowed weights, vanishing exactly at the ends $m = \pm j$ (consistent with $J_+ |j, j\rangle = 0$ and $J_- |j, -j\rangle = 0$), and choosing the phases so the square roots are positive gives Eq. (2.114), property (4). Because J_+ and J_- never leave W and J^3 acts diagonally on it, W is a nonzero invariant subspace; irreducibility of V forces $W = V$, so $\dim V = 2j + 1$, property (1), and the basis $\{|j, m\rangle\}$ is the one in property (3). Since Eqs. (2.113) and (2.114) determine the action of all generators completely in terms of j alone, any two irreducibles with the same top weight j are equivalent, and Eq. (2.122) shows every half-integer j is realized; this is uniqueness and exhaustiveness. □

Physical Insight

The construction never invoked Hilbert space, wavefunctions, or rotations—only three operators and one bracket. That is the lesson worth carrying forward: an irreducible representation is rigid. Once the highest weight is fixed, the dimension, the spectrum, the Casimir, and every matrix element are forced. The ladder is not a calculational trick borrowed from quantum mechanics; it is the structure of the algebra made visible. When we attack $\mathfrak{su}(3)$ and the higher-rank algebras later, the only thing that changes is that the single ladder becomes a lattice of ladders—one for each positive root—but the logic, "go up until you must stop, then descend and demand closure," is exactly the one proved here.

A picture helps fix the combinatorics of the weights. Each irreducible is a single string of equally spaced points on the m-axis, symmetric about the origin, with $J_\pm$ hopping along it; the half-integer strings sit on the half-integer lattice and the integer strings on the integer lattice.

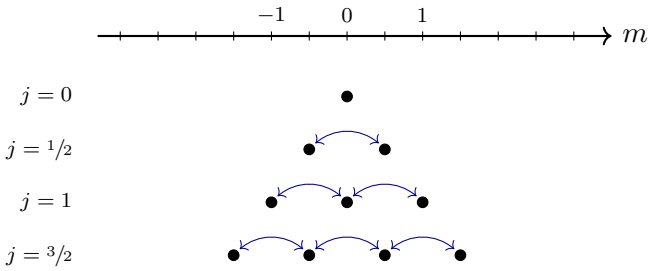

Figure 2.3: Weight diagrams of the first few $\mathfrak{su}(2)$ irreducibles. Each row is a single irreducible $D^{(j)}$; the dots are the weights $m \in \{-j, \ldots, j\}$, the arrows are the unit hops of $J_\pm$ from Eq. (2.114). Integer-j strings live on the integer lattice (and descend to genuine SO(3) representations), half-integer strings on the half-integer lattice (genuinely SU(2)). The string for $D^{(j)}$ has $2j + 1$ dots.

2.4.3 The fundamental and adjoint matrices

The theorem is a recipe; running it on the two smallest nontrivial spins produces the matrices that the rest of the book uses without further comment.

Spin $\frac{1}{2}$: the fundamental. For $j = \frac{1}{2}$ the space is two-dimensional, with weights $m = +\frac{1}{2}, -\frac{1}{2}$. In the ordered basis $\left(\left|\frac{1}{2}, \frac{1}{2}\right\rangle, \left|\frac{1}{2}, -\frac{1}{2}\right\rangle\right)$, Eq. (2.113) gives $J^3 = \frac{1}{2}\,\mathrm{diag}(1, -1)$, and Eq. (2.114) gives the single nonzero matrix element of each ladder operator: $J_+ \left|\frac{1}{2}, -\frac{1}{2}\right\rangle = \sqrt{\frac{3}{4} - (-\frac{1}{2})(\frac{1}{2})}\, \left|\frac{1}{2}, \frac{1}{2}\right\rangle = \left|\frac{1}{2}, \frac{1}{2}\right\rangle$ and $J_- \left|\frac{1}{2}, \frac{1}{2}\right\rangle = \left|\frac{1}{2}, -\frac{1}{2}\right\rangle$. Hence

$$J^3 = \tfrac{1}{2}\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \quad J_+ = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \quad J_- = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}. \tag{2.124}$$

Recombining $J^1 = \frac{1}{2}(J_+ + J_-)$ and $J^2 = \frac{1}{2i}(J_+ - J_-)$ reproduces the Pauli matrices:

$$J^i = \tfrac{1}{2}\,\sigma^i, \qquad \sigma^1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \; \sigma^2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \; \sigma^3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \tag{2.125}$$

The Pauli matrices satisfy $\sigma^i\sigma^j = \delta^{ij}\mathbf{1} + i\epsilon^{ijk}\sigma^k$, from which $\left[\frac{1}{2}\sigma^i, \frac{1}{2}\sigma^j\right] = \frac{1}{4}\left[\sigma^i, \sigma^j\right] = \frac{1}{4}(2i\epsilon^{ijk}\sigma^k) = i\epsilon^{ijk}(\frac{1}{2}\sigma^k)$, confirming Eq. (2.99). This spin-$\frac{1}{2}$ representation is the *fundamental* (or *defining*) representation of $\mathfrak{su}(2)$; the generators carry the standard normalization

$$\mathrm{tr}(J^i J^j) = \tfrac{1}{4}\,\mathrm{tr}(\sigma^i\sigma^j) = \tfrac{1}{4}\cdot 2\delta^{ij} = \tfrac{1}{2}\,\delta^{ij}, \tag{2.126}$$

matching the convention $\mathrm{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$ of the chapter introduction and Chapter B. This two-component object is the algebraic skeleton of the electron's spin; it is the representation QED will quantize when the electron enters as a Dirac field in Chapter 11, and it is one of the two $\mathfrak{su}(2)$ factors that Chapter 3 stacks to build the Lorentz group.

Spin 1: the adjoint. For $j = 1$ the space is three-dimensional with weights $m = 1, 0, -1$. The Casimir value is $j(j+1) = 2$. The ladder coefficients from Eq. (2.114) are $\sqrt{2 - m(m+1)}$: for $m = -1$ and $m = 0$ this is $\sqrt{2}$, and zero at the top. In the ordered basis $(|1,1\rangle, |1,0\rangle, |1,-1\rangle)$,

$$J^3 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix}, \quad J_+ = \begin{pmatrix} 0 & \sqrt{2} & 0 \\ 0 & 0 & \sqrt{2} \\ 0 & 0 & 0 \end{pmatrix}, \quad J_- = \begin{pmatrix} 0 & 0 & 0 \\ \sqrt{2} & 0 & 0 \\ 0 & \sqrt{2} & 0 \end{pmatrix}. \tag{2.127}$$

The name "adjoint" is earned because $\dim D^{(1)} = 3$ equals the dimension of $\mathfrak{su}(2)$ itself: the spin-1 representation is the action of the algebra on itself by the

bracket, $\mathrm{ad}_X(Y) = [X, Y]$, the adjoint representation of Section 2.3. We verify this identification, and the consistency of the whole apparatus, in the worked example.

Worked Example 2.54 (The spin-1 representation, by hand)**.** We build the spin-1 generators in two bases, check the $\mathfrak{su}(2) \cong \mathfrak{so}(3)$ brackets, and exponentiate to recover an ordinary rotation, closing the loop with the covering map of the next subsection.

(a) Cartesian (adjoint) form. The adjoint representation acts on the three-dimensional algebra; choosing the basis $\{J^1, J^2, J^3\}$ itself as the carrier space, the matrix of ad_{J^a} has entries

$$(\mathcal{J}^a)_{bc} = \text{coefficient of } J^b \text{ in } [J^a, J^c] = -i\,\epsilon^{abc}, \tag{2.128}$$

the last equality because $[J^a, J^c] = i\epsilon^{acd}J^d = i\epsilon^{acb}J^b = -i\epsilon^{abc}J^b$. Writing the three matrices out,

$$\mathcal{J}^1 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -i \\ 0 & i & 0 \end{pmatrix}, \quad \mathcal{J}^2 = \begin{pmatrix} 0 & 0 & i \\ 0 & 0 & 0 \\ -i & 0 & 0 \end{pmatrix}, \quad \mathcal{J}^3 = \begin{pmatrix} 0 & -i & 0 \\ i & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}. \tag{2.129}$$

These are Hermitian, and one checks the bracket directly. Multiplying the matrices Eq. (2.129) entry by entry,

$$\mathcal{J}^1\mathcal{J}^2 = \begin{pmatrix} 0 & 0 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \qquad \mathcal{J}^2\mathcal{J}^1 = \begin{pmatrix} 0 & -1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \tag{2.130}$$

so that

$$\left[\mathcal{J}^1, \mathcal{J}^2\right] = \mathcal{J}^1\mathcal{J}^2 - \mathcal{J}^2\mathcal{J}^1 = \begin{pmatrix} 0 & 1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} = i\,\mathcal{J}^3, \tag{2.131}$$

the last equality because $i\,\mathcal{J}^3 = i\begin{pmatrix} 0 & -i & 0 \\ i & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$. Cyclic relabelling gives $[\mathcal{J}^2, \mathcal{J}^3] = i\mathcal{J}^1$ and $[\mathcal{J}^3, \mathcal{J}^1] = i\mathcal{J}^2$, so Eq. (2.129) satisfies Eq. (2.99). The same conclusion follows in index form without writing out matrices: with $(\mathcal{J}^a)_{ce} = -i\epsilon^{ace}$,

$$\left[\mathcal{J}^a, \mathcal{J}^b\right]_{ce} = -\sum_d (\epsilon^{acd}\epsilon^{bde} - \epsilon^{bcd}\epsilon^{ade}) = \delta^{ac}\delta^{be} - \delta^{ae}\delta^{bc} = i\,\epsilon^{abf}\,(\mathcal{J}^f)_{ce}, \tag{2.132}$$

where the middle equality used $\epsilon^{acd}\epsilon^{bde} = \epsilon^{dac}\epsilon^{deb} = \delta^{ae}\delta^{cb} - \delta^{ab}\delta^{ce}$ (and the same with $a \leftrightarrow b$), and the last used $i\epsilon^{abf}(\mathcal{J}^f)_{ce} = \epsilon^{abf}\epsilon^{fce} = \delta^{ac}\delta^{be} - \delta^{ae}\delta^{bc}$. This is the very Levi-Civita identity that will produce the $\mathfrak{so}(3)$ algebra in Chapter 3. The Casimir is likewise computed in index form,

$$(\boldsymbol{\mathcal{J}}^2)_{ce} = \sum_a (\mathcal{J}^a\mathcal{J}^a)_{ce} = -\sum_{a,d} \epsilon^{acd}\epsilon^{ade} = -\sum_d (\delta^{cd}\delta^{de} - 3\,\delta^{ce}) = -(\delta^{ce} - 3\,\delta^{ce}) = 2\,\delta^{ce}, \tag{2.133}$$

so $\mathcal{J}^2 = 2\,\mathbf{1}_3$, confirming $j(j+1) = 2$ for $j = 1$.

(b) Equivalence to the spherical form. The matrices Eq. (2.127) and Eq. (2.129) are the same representation in different bases: $\mathcal{J}^3$ is brought to the diagonal form $\mathrm{diag}(1, 0, -1)$ by the unitary change of basis to the eigenvectors $|1, \pm 1\rangle = \mp\frac{1}{\sqrt{2}}(\hat{e}_1 \pm i\hat{e}_2)$, $|1, 0\rangle = \hat{e}_3$ (the spherical basis). Both therefore have Casimir 2 and weights $\{1, 0, -1\}$, and by the uniqueness in Theorem 2.53 they must be unitarily equivalent, as the explicit basis change confirms.

(c) Exponentiation. A rotation by angle θ about the third axis is $R_3(\theta) = \exp(-i\theta\,\mathcal{J}^3)$. Since $\mathcal{J}^3$ restricted to the 1–2 block is $\left(\begin{smallmatrix} 0 & -i \\ i & 0 \end{smallmatrix}\right) = \sigma^2$ with $(\sigma^2)^2 = \mathbf{1}_2$, the series splits into even and odd powers,

$$\exp(-i\theta\,\mathcal{J}^3) = \begin{pmatrix} \cos\theta & -\sin\theta & 0 \\ \sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{pmatrix}, \tag{2.134}$$

the ordinary 3×3 rotation of a vector about the z-axis. This is the "section's exp computation" the spin-1 representation must reproduce: the adjoint of $\mathfrak{su}(2)$ exponentiates to the rotation group acting on three-vectors. Where the spin-$\frac{1}{2}$ matrix $\exp(-i\theta\sigma^3/2) = \mathrm{diag}(e^{-i\theta/2}, e^{+i\theta/2})$ needs $\theta = 4\pi$ to return to the identity, the spin-1 matrix Eq. (2.134) returns at $\theta = 2\pi$. The factor of two between these two periods is the entire subject of the next subsection.

2.4.4 SU(2) over SO(3): the double cover and half-integer spin

We have classified representations of the *algebra* $\mathfrak{su}(2)$. The physics, however, asks for representations of a *group*—of the actual rotations a particle can undergo—and there are two candidate groups sharing the algebra $\mathfrak{su}(2) \cong \mathfrak{so}(3)$. One is SO(3), the rotations of three-dimensional space, 3×3 real orthogonal matrices of determinant one. The other is SU(2), the 2×2 complex unitary matrices of determinant one, in which the spin-$\frac{1}{2}$ matrices Eq. (2.125) naturally live. They are not the same group, and the precise way they differ is what determines which of our representations describe genuine particles and which the famous sign change under a 2π rotation.

Theorem 2.55 (The covering homomorphism)**.** *There is a surjective group homomorphism*

$$\varphi : \mathrm{SU}(2) \longrightarrow \mathrm{SO}(3) \tag{2.135}$$

whose kernel is $\{+\mathbf{1}, -\mathbf{1}\}$*. It is two-to-one:* $\varphi(U) = \varphi(-U)$ *for all* U*, and these are the only coincidences. Consequently* $\mathrm{SO}(3) \cong \mathrm{SU}(2)/\{\pm\mathbf{1}\}$*, and* SU(2) *is the (simply connected) double cover of* SO(3)*.*

Proof. The carrier of the action. The key is to find a copy of $\mathbb{R}^3$ on which SU(2) acts. Take the real vector space of traceless Hermitian 2×2 matrices. It is

three-dimensional, with the Pauli matrices Eq. (2.125) as a basis, so every such matrix is

$$X = \mathbf{x}\cdot\boldsymbol{\sigma} = x_1\sigma^1 + x_2\sigma^2 + x_3\sigma^3 = \begin{pmatrix} x_3 & x_1 - ix_2 \\ x_1 + ix_2 & -x_3 \end{pmatrix}, \qquad \mathbf{x}\in\mathbb{R}^3. \tag{2.136}$$

The determinant encodes the Euclidean length:

$$\det X = -x_3^2 - (x_1 - ix_2)(x_1 + ix_2) = -(x_1^2 + x_2^2 + x_3^2) = -|\mathbf{x}|^2. \tag{2.137}$$

The action. For $U\in\mathrm{SU}(2)$ define $X' = UXU^\dagger$. The map $X\mapsto X'$ is linear in X, and it stays inside the same space: X' is Hermitian because $(UXU^\dagger)^\dagger = UX^\dagger U^\dagger = UXU^\dagger$, and traceless because $\mathrm{tr}(UXU^\dagger) = \mathrm{tr}(U^\dagger UX) = \mathrm{tr}\,X = 0$ by cyclicity. So $X' = \mathbf{x}'\cdot\boldsymbol{\sigma}$ for some $\mathbf{x}'\in\mathbb{R}^3$, and since the map is linear in $\mathbf{x}$ there is a real 3×3 matrix $R(U)$ with $\mathbf{x}' = R(U)\,\mathbf{x}$.

It is a rotation. The determinant is preserved:

$$\det X' = \det(UXU^\dagger) = \det U\,\det X\,\det U^\dagger = \det X, \tag{2.138}$$

using $\det U = 1$ and $\det U^\dagger = \overline{\det U} = 1$. By Eq. (2.137) this says $|\mathbf{x}'|^2 = |\mathbf{x}|^2$ for all $\mathbf{x}$, so $R(U)$ is a linear isometry of $\mathbb{R}^3$: $R(U)\in\mathrm{O}(3)$, i.e. $R(U)^{\mathsf{T}}R(U) = \mathbf{1}$. To rule out the reflections (determinant -1) we use continuity. The group $\mathrm{SU}(2)$ is connected—indeed, writing $U = a\,\mathbf{1} + i\mathbf{b}\cdot\boldsymbol{\sigma}$ with $a^2 + |\mathbf{b}|^2 = 1$ identifies it with the unit three-sphere S^3, which is connected (and simply connected). The map $U\mapsto\det R(U)$ is continuous, takes values in the discrete set $\{+1,-1\}$, and equals $+1$ at $U = \mathbf{1}$ (where $R = \mathbf{1}$); a continuous function from a connected space into $\{\pm1\}$ is constant, so $\det R(U) = +1$ for all U. Hence $R(U)\in\mathrm{SO}(3)$, and we set $\varphi(U)\equiv R(U)$.

It is a homomorphism. For $U_1, U_2\in\mathrm{SU}(2)$, the action composes as $X\mapsto U_1U_2\,X\,(U_1U_2)^\dagger = U_1(U_2XU_2^\dagger)U_1^\dagger$, which is the action of U_2 followed by that of U_1. Translating to the vectors, $R(U_1U_2) = R(U_1)R(U_2)$, i.e. $\varphi(U_1U_2) = \varphi(U_1)\varphi(U_2)$.

The kernel. Suppose $\varphi(U) = \mathbf{1}$, i.e. $UXU^\dagger = X$ for every traceless Hermitian X, equivalently $U\sigma^i = \sigma^i U$ for $i = 1,2,3$. An operator commuting with all three Pauli matrices commutes with the entire algebra they generate, which acts irreducibly on $\mathbb{C}^2$ (the spin-$\frac{1}{2}$ representation is irreducible, having no proper invariant subspace); by Schur's lemma (Theorem 2.21) $U = c\,\mathbf{1}$ for a scalar c. The constraints $U\in\mathrm{SU}(2)$ then force $\det(c\,\mathbf{1}) = c^2 = 1$, so $c = \pm1$. Both $+\mathbf{1}$ and $-\mathbf{1}$ lie in $\mathrm{SU}(2)$ and both clearly act trivially (the minus signs cancel in $UXU^\dagger$), so

$$\ker\varphi = \{+\mathbf{1},\,-\mathbf{1}\}. \tag{2.139}$$

Surjectivity and the two-to-one count. We exhibit a preimage of every rotation. Consider

$$U(\theta,\hat{\mathbf{n}}) = \exp\!\Big(-\tfrac{i}{2}\,\theta\,\hat{\mathbf{n}}\cdot\boldsymbol{\sigma}\Big) = \cos\tfrac{\theta}{2}\,\mathbf{1} - i\sin\tfrac{\theta}{2}\,\hat{\mathbf{n}}\cdot\boldsymbol{\sigma}, \tag{2.140}$$

the second equality from $(\hat{\mathbf{n}}\cdot\boldsymbol{\sigma})^2 = \mathbf{1}$ summing the even/odd series as in the worked example. Take $\hat{\mathbf{n}} = \hat{e}_3$, so $U = \mathrm{diag}(e^{-i\theta/2}, e^{+i\theta/2})$, and compute its action on the basis. Using $\sigma^1, \sigma^2, \sigma^3$ and $U\sigma U^\dagger$:

$$\begin{aligned} U\sigma^3 U^\dagger &= \sigma^3, \\ U\sigma^1 U^\dagger &= \cos\theta\,\sigma^1 + \sin\theta\,\sigma^2, \\ U\sigma^2 U^\dagger &= -\sin\theta\,\sigma^1 + \cos\theta\,\sigma^2, \end{aligned} \tag{2.141}$$

the middle two obtained from $e^{-i\theta\sigma^3/2}\sigma^1 e^{+i\theta\sigma^3/2}$ by expanding and using $\sigma^3\sigma^1 = i\sigma^2$, $\sigma^3\sigma^2 = -i\sigma^1$. Reading off the coordinates, $R(U)$ is precisely the rotation by angle θ about the third axis,

$$\varphi(U(\theta,\hat{e}_3)) = \begin{pmatrix} \cos\theta & -\sin\theta & 0 \\ \sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{pmatrix}, \tag{2.142}$$

identical to the spin-1 exponential Eq. (2.134). Every rotation is a rotation about *some* axis through *some* angle, and by rotating the axis $\hat{\mathbf{n}}$ over the sphere and θ over $[0, 2\pi)$ the elements Eq. (2.140) cover all of SO(3); hence φ is surjective. Finally, given any $R \in \mathrm{SO}(3)$, the fiber $\varphi^{-1}(R)$ is a coset of the kernel Eq. (2.139), so it contains exactly two elements $\{U, -U\}$. The map is two-to-one and $\mathrm{SO}(3) \cong \mathrm{SU}(2)/\{\pm\mathbf{1}\}$. □

The two-to-one structure has a sharp consequence visible already in Eq. (2.140): a rotation by $\theta = 2\pi$ about any axis is the identity of SO(3), but its SU(2) preimage is

$$U(2\pi, \hat{\mathbf{n}}) = \cos\pi\,\mathbf{1} - i\sin\pi\,\hat{\mathbf{n}}\cdot\boldsymbol{\sigma} = -\mathbf{1} \neq +\mathbf{1}. \tag{2.143}$$

Only at $\theta = 4\pi$ does one return to $+\mathbf{1}$. Topologically, $\mathrm{SU}(2) = S^3$ is simply connected while $\mathrm{SO}(3) = S^3/\{\pm\mathbf{1}\} = \mathbb{RP}^3$ has fundamental group $\mathbb{Z}_2$: the loop in SO(3) traced by a full 2π rotation cannot be contracted, but traversing it *twice* can. This is the algebraic and topological content of the "belt trick" familiar from demonstrations of spin.

Theorem 2.56 (Which spins are genuine SO(3) representations)**.** *A spin-j representation $D^{(j)}$ of $\mathfrak{su}(2)$ descends to a single-valued representation of* SO(3) *if and only if j is an integer. For half-integer j, $D^{(j)}$ is a genuine (single-valued) representation of* SU(2) *but only a double-valued (projective) representation of* SO(3)*.*

Proof. A representation of the algebra exponentiates to a single-valued representation of SO(3) exactly when it is trivial on the kernel Eq. (2.139) of φ—i.e. when $D^{(j)}(-\mathbf{1}) = +\mathbf{1}$—because SO(3) is SU(2) modulo that kernel, so a function on SO(3) is the same as a function on SU(2) constant on the cosets $\{U, -U\}$. From Eq. (2.143), the group element $-\mathbf{1} \in \mathrm{SU}(2)$ is the 2π rotation about (say)

the third axis, $-\mathbf{1} = U(2\pi, \hat{e}_3) = \exp(-2\pi i J^3)$ in any representation. On the basis $|j, m\rangle$ this acts diagonally,

$$D^{(j)}(-\mathbf{1})\,|j, m\rangle = e^{-2\pi i\, m}\,|j, m\rangle = e^{-2\pi i\, j}\;|j, m\rangle\,, \tag{2.144}$$

where the second equality holds because the weights m all differ from j by integers, so $e^{-2\pi i m} = e^{-2\pi i j}$ for every m in the multiplet (this is also why the answer is a single scalar, as Schur demands). Now $e^{-2\pi i j} = +1$ if $j \in \mathbb{Z}$ and $e^{-2\pi i j} = -1$ if $j \in \mathbb{Z} + \frac{1}{2}$. Thus for integer j, $D^{(j)}(-\mathbf{1}) = +\mathbf{1}$ and the representation is single-valued on SO(3); for half-integer j, $D^{(j)}(-\mathbf{1}) = -\mathbf{1}$, so the two preimages U and $-U$ of a given rotation are represented by matrices differing by an overall sign—the representation assigns *two* matrices to each rotation and is double-valued (a projective representation with the $\mathbb{Z}_2$ phase) on SO(3), while remaining perfectly single-valued on SU(2). □

Physical Insight

This theorem is the reason the electron is described by SU(2) and not SO(3). A half-integer spin state is multiplied by -1 under a 2π rotation, a transformation that does nothing to the spatial coordinates. Such a sign is invisible in any single measurement—$|\psi|^2$ is unchanged—but it is real and observable in interference, and it is mandatory once one accepts that the rotation group acting on a quantum system need only be represented projectively (states being rays, not vectors). Nature uses the full SU(2): the spin-$\frac{1}{2}$ fundamental Eq. (2.125) is a legitimate building block, and the price of admission is that SU(2), not SO(3), is the true rotation group of quantum mechanics. The integer-spin representations lose nothing by this—they are single-valued either way—but the half-integer ones exist *only* because we passed to the cover.

Caution

"Double-valued representation" is shorthand, not a contradiction. A representation, by definition, is single-valued; the honest statement is that the half-integer $D^{(j)}$ are bona fide single-valued representations of SU(2) that fail to factor through φ, hence define only *projective* representations of SO(3). The clean resolution—always take the symmetry group to be the simply connected cover and demand ordinary (linear) representations of it—is the policy this book follows everywhere, and it is exactly the policy that Chapter 3 will apply to the Lorentz group, whose simply connected cover $\mathrm{SL}(2)\mathbb{C}$ plays the role SU(2) plays here.

With $\mathfrak{su}(2)$ now solved end to end—every irreducible constructed, dimensioned, and matrixed, and the group-level subtlety of half-integer spin settled—we

hold a complete catalogue $\{D^{(j)}\}_{j\in\frac{1}{2}\mathbb{Z}_{\geq 0}}$ and, more valuable than the catalogue, the highest-weight method that produced it. Two roads lead onward. The first asks what happens when two such systems are combined: the tensor product $D^{(j_1)}\otimes D^{(j_2)}$ is reducible, and decomposing it into irreducibles is the Clebsch–Gordan problem taken up in Section 2.5, where the same ladder reappears as the bookkeeping of the combined weights. The second asks how the method generalizes when the algebra has rank greater than one: the single ladder becomes a system of ladders indexed by roots, and the integer $2j$ becomes a set of integers, the Dynkin labels. Both roads start from the rank-one spine built here.

2.5 Tensor Products, Clebsch–Gordan, and Invariants

The previous section solved $\mathfrak{su}(2)$ completely: every irreducible representation is a spin-j multiplet of dimension $2j+1$, built by the highest-weight construction and labelled by the eigenvalue $j(j+1)$ of the Casimir (Theorem 2.53). That catalogue answers the question *"how can one system carry the symmetry?"* The physics, however, almost never presents one system. Two electrons each carry spin $\frac{1}{2}$; a quark carries colour while an antiquark carries the conjugate colour; a field and its derivative carry Lorentz indices that must be tied together into a scalar Lagrangian. In every such case we must combine two carriers of the symmetry into one composite carrier and ask how the composite decomposes into the irreducible atoms we have just classified. That operation is the *tensor product* of representations, and its decomposition into irreducibles is the *Clebsch–Gordan problem*. This section sets up the tensor product in general, solves the Clebsch–Gordan problem for $\mathfrak{su}(2)$ in full, and then isolates the single most important piece of the answer for field theory: the *singlet*, the invariant atom whose existence is exactly the statement that a particular combination of fields is symmetry-invariant. Every gauge-invariant interaction term in this book is, at bottom, a singlet picked out of a tensor product.

2.5.1 The tensor product of two representations

Let a group G act on two finite-dimensional complex vector spaces V_1 and V_2 through representations $\rho_1\colon G\to \mathrm{GL}(V_1)$ and $\rho_2\colon G\to\mathrm{GL}(V_2)$. The state space of the composite system is the tensor product $V_1\otimes V_2$, the vector space spanned by formal products $v_1\otimes v_2$ with $v_1\in V_1$, $v_2\in V_2$, bilinear in its two slots. If $\{e_i\}_{i=1}^{n_1}$ is a basis of V_1 and $\{f_a\}_{a=1}^{n_2}$ a basis of V_2, then $\{e_i\otimes f_a\}$ is a basis of $V_1\otimes V_2$, which therefore has dimension n_1n_2. The physical content is the familiar rule of quantum mechanics: the joint states of two independent systems are spanned by products of their individual states.

Definition 2.57 (Tensor product representation)**.** The *tensor product representation* $\rho_1 \otimes \rho_2$ of G on $V_1 \otimes V_2$ is defined on product vectors by

$$(\rho_1 \otimes \rho_2)(g)\,(v_1 \otimes v_2) \;=\; (\rho_1(g)\,v_1) \otimes (\rho_2(g)\,v_2), \tag{2.145}$$

and extended by linearity to all of $V_1 \otimes V_2$. The *same* group element g acts on both factors simultaneously.

That Eq. (2.145) is a representation is immediate from the homomorphism property of ρ_1 and ρ_2: for $g, h \in G$,

$$\begin{aligned}(\rho_1 \otimes \rho_2)(g)\,(\rho_1 \otimes \rho_2)(h)\,(v_1 \otimes v_2) &= (\rho_1(g)\rho_1(h)v_1) \otimes (\rho_2(g)\rho_2(h)v_2) \\ &= (\rho_1(gh)v_1) \otimes (\rho_2(gh)v_2) = (\rho_1 \otimes \rho_2)(gh)\,(v_1 \otimes v_2).\end{aligned} \tag{2.146}$$

In a product basis the matrix of $(\rho_1 \otimes \rho_2)(g)$ is the Kronecker product of the two factor matrices, $\big[(\rho_1 \otimes \rho_2)(g)\big]_{ia,jb} = \rho_1(g)_{ij}\,\rho_2(g)_{ab}$.

For a continuous symmetry the more useful object is the action of the Lie algebra, obtained by differentiating Eq. (2.145) along a one-parameter subgroup. Recall from the previous sections that a generator X of the algebra acts on a representation V through $\rho(e^{tX}) = \exp(t\,\rho_*(X))$, with $\rho_*(X) = \frac{d}{dt}\rho(e^{tX})\big|_{t=0}$. Apply this to the product. Writing $\rho_{1*}(X) \equiv X^{(1)}$ and $\rho_{2*}(X) \equiv X^{(2)}$ for the generators on the two factors, and differentiating the product $g(t) = e^{tX}$ acting through Eq. (2.145),

$$\frac{d}{dt}\Big[(e^{tX^{(1)}}v_1) \otimes (e^{tX^{(2)}}v_2)\Big]_{t=0} = (X^{(1)}v_1) \otimes v_2 \;+\; v_1 \otimes (X^{(2)}v_2), \tag{2.147}$$

by the Leibniz rule for the derivative of a product. Hence the generator on the tensor product is the *co-product*

$$(\rho_1 \otimes \rho_2)_*(X) \;=\; X^{(1)} \otimes \mathbf{1}_2 \;+\; \mathbf{1}_1 \otimes X^{(2)}, \tag{2.148}$$

where $\mathbf{1}_1, \mathbf{1}_2$ are the identities on V_1, V_2. This is the rule "angular momenta add": for $\mathfrak{su}(2)$, the total generator is $J^a = J^a_{(1)} \otimes \mathbf{1} + \mathbf{1} \otimes J^a_{(2)}$, the familiar $\mathbf{J} = \mathbf{J}_{(1)} + \mathbf{J}_{(2)}$ of the addition of angular momentum.

That Eq. (2.148) again satisfies the Lie bracket is a short check that exhibits why the cross terms cancel. Suppressing the identity factors and writing $X^{(1)}$ for $X^{(1)} \otimes \mathbf{1}$ (which commutes with every $Y^{(2)} = \mathbf{1} \otimes Y^{(2)}$ because they act on different factors),

$$\begin{aligned}\Big[X^{(1)} + X^{(2)}, Y^{(1)} + Y^{(2)}\Big] &= \Big[X^{(1)}, Y^{(1)}\Big] + \Big[X^{(2)}, Y^{(2)}\Big] + \Big[X^{(1)}, Y^{(2)}\Big] + \Big[X^{(2)}, Y^{(1)}\Big] \\ &= [X, Y]^{(1)} + [X, Y]^{(2)}\,,\end{aligned} \tag{2.149}$$

since the two mixed commutators vanish, the operators acting on independent factors. The co-product therefore defines a genuine representation of the algebra, with the same structure constants.

Physical Insight

The co-product is the algebraic heart of "conservation of total charge." Because $X^{(1)} \otimes \mathbf{1} + \mathbf{1} \otimes X^{(2)}$ generates the symmetry of the *whole* system, it is the additive total quantum number—total momentum, total spin, total isospin, total colour. Two particles that individually carry charges q_1 and q_2 carry total charge $q_1 + q_2$ for exactly the reason Eq. (2.148) is a sum. The Clebsch–Gordan problem below is the question of which total charges the composite can have.

The new feature, absent for a single system, is that a tensor product of two *irreducible* representations is generally *reducible*. The Kronecker product matrices in Eq. (2.145) do not in general act irreducibly on $V_1 \otimes V_2$; there are invariant subspaces. By complete reducibility for compact groups (Theorem 2.18) the product splits into a direct sum of irreducibles,

$$V_1 \otimes V_2 \;\cong\; \bigoplus_{\lambda} m_\lambda \, V_\lambda, \tag{2.150}$$

where V_λ runs over the irreducibles of G and the non-negative integer m_λ is the multiplicity with which V_λ appears. Computing the multiplicities m_λ *is* the Clebsch–Gordan decomposition. The change of basis that realizes Eq. (2.150) concretely—from the product basis $\{e_i \otimes f_a\}$ to a basis adapted to the irreducible blocks—is recorded in the Clebsch–Gordan coefficients of Section 2.5.3.

2.5.2 Weights add: the $\mathfrak{su}(2)$ Clebsch–Gordan series

For $\mathfrak{su}(2)$ the multiplicities in Eq. (2.150) are determined by a single elementary fact, which is the engine of all of representation theory beyond rank one: *under the tensor product, weights add.* The eigenvalue of J^3 (the weight) on a product state is the sum of the two individual eigenvalues, because J^3 acts through the co-product Eq. (2.148):

$$J^3 \left(|j_1\, m_1\rangle \otimes |j_2\, m_2\rangle \right) = (m_1 + m_2) \left(|j_1\, m_1\rangle \otimes |j_2\, m_2\rangle \right). \tag{2.151}$$

The product basis is therefore already a weight basis, with the product state $|j_1 m_1\rangle \otimes |j_2 m_2\rangle$ carrying weight $m = m_1 + m_2$. We can read off the decomposition by counting how many product states sit at each weight and matching that profile against the known weight content of the irreducibles—each spin-j multiplet contributes exactly one state at each weight $m \in \{-j, -j+1, \ldots, j\}$.

Theorem 2.58 ($\mathfrak{su}(2)$ Clebsch–Gordan series)**.** *For non-negative half-integers j_1, j_2, the tensor product of the spin-j_1 and spin-j_2 irreducibles of $\mathfrak{su}(2)$ decomposes, with unit multiplicity, as*

$$j_1 \otimes j_2 \;=\; \bigoplus_{j=|j_1-j_2|}^{j_1+j_2} j \;=\; (j_1+j_2) \oplus (j_1+j_2-1) \oplus \cdots \oplus |j_1-j_2|, \tag{2.152}$$

the spin j running in integer steps from $|j_1 - j_2|$ to $j_1 + j_2$. Each value of j in this range occurs exactly once; no value outside it occurs.

Proof. Assume without loss of generality $j_1 \geq j_2$. Let $N(m)$ be the number of product basis states $|j_1 m_1\rangle \otimes |j_2 m_2\rangle$ of total weight $m = m_1 + m_2$. Because m_1 ranges over $\{-j_1, \ldots, j_1\}$ and m_2 over $\{-j_2, \ldots, j_2\}$, the count $N(m)$ is the number of ways to write $m = m_1 + m_2$ with both constraints satisfied. The weight content is symmetric, $N(m) = N(-m)$, so it suffices to track $m \geq 0$. The maximum weight is $m = j_1 + j_2$, attained only by $m_1 = j_1, m_2 = j_2$, so $N(j_1 + j_2) = 1$. As m decreases by one, one more choice of (m_1, m_2) becomes available at each step—m_2 can be lowered while m_1 is raised to compensate, until m_2 hits its floor $-j_2$. Concretely, for m in the upper range,

$$N(m) = j_1 + j_2 - m + 1, \qquad j_1 - j_2 \leq m \leq j_1 + j_2, \tag{2.153}$$

which counts the admissible $m_2 \in \{m - j_1, \ldots, j_2\}$, i.e. $j_2 - (m - j_1) + 1$ values. Once m drops below $j_1 - j_2$, the constraint from j_2 saturates and the count plateaus at its maximum,

$$N(m) = 2j_2 + 1, \qquad -(j_1 - j_2) \leq m \leq j_1 - j_2, \tag{2.154}$$

the full width of the smaller multiplet. For $m > j_1 + j_2$ there are no states, $N(m) = 0$. The profile $N(m)$ is thus a symmetric trapezoid: it climbs linearly from 1 at the edge to $2j_2 + 1$ on the plateau, holds, and descends.

Now decompose this profile into irreducibles. Let n_j be the number of spin-j multiplets in the product. Since a spin-j multiplet contributes exactly one state to every weight m with $|m| \leq j$ and none with $|m| > j$, the count at weight $m \geq 0$ is the number of multiplets large enough to reach it,

$$N(m) = \sum_{j \geq m} n_j. \tag{2.155}$$

Inverting this telescoping sum gives the multiplicities directly,

$$n_j = N(j) - N(j+1). \tag{2.156}$$

On the descending edge $j_1 - j_2 \leq j \leq j_1 + j_2$ we use Eq. (2.153):

$$n_j = [(j_1 + j_2 - j + 1)] - [(j_1 + j_2 - (j+1) + 1)] = 1. \tag{2.157}$$

On the plateau $j < j_1 - j_2$ both $N(j)$ and $N(j+1)$ equal $2j_2 + 1$, so $n_j = 0$; and for $j > j_1 + j_2$ both counts vanish, so $n_j = 0$. Hence $n_j = 1$ precisely for $|j_1 - j_2| \leq j \leq j_1 + j_2$ and zero otherwise, which is Eq. (2.152). □

The decomposition must conserve dimension, and the check is a clean test of the arithmetic. The product space has dimension $(2j_1+1)(2j_2+1)$; the right-hand side of Eq. (2.152) has dimension

$$\sum_{j=|j_1-j_2|}^{j_1+j_2} (2j+1). \tag{2.158}$$

This is an arithmetic series with $(j_1+j_2)-|j_1-j_2|+1 = 2j_2+1$ terms (taking $j_1 \geq j_2$), first term $2|j_1-j_2|+1 = 2(j_1-j_2)+1$ and last term $2(j_1+j_2)+1$. The sum of an arithmetic series is the number of terms times the average of first and last,

$$\sum_{j=|j_1-j_2|}^{j_1+j_2} (2j+1) = (2j_2+1)\cdot\frac{[2(j_1-j_2)+1]+[2(j_1+j_2)+1]}{2} = (2j_2+1)(2j_1+1), \tag{2.159}$$

matching $\dim(V_{j_1}\otimes V_{j_2})$ exactly. Dimension is conserved.

The same series, read through characters

Theorem 2.58 can also be obtained from the character orthogonality of the earlier section (Theorem 2.27), and the two viewpoints illuminate each other. The character of the spin-j representation evaluated on a rotation by angle θ is the weight-generating polynomial

$$\chi_j(\theta) = \sum_{m=-j}^{j} e^{im\theta} = \frac{\sin((2j+1)\theta/2)}{\sin(\theta/2)}. \tag{2.160}$$

Because the character of a tensor product is the product of characters ($\mathrm{tr}(A\otimes B) = \mathrm{tr}\,A\ \mathrm{tr}\,B$ applied to Eq. (2.145)), the Clebsch–Gordan series is the statement that the product of two such Dirichlet kernels is the sum $\chi_{j_1}\chi_{j_2} = \sum_j \chi_j$ over the range Eq. (2.152). Multiplying the finite geometric sums, $\chi_{j_1}\chi_{j_2} = \sum_{m_1,m_2} e^{i(m_1+m_2)\theta}$, and regrouping the exponentials by total weight reproduces exactly the trapezoidal profile $N(m)$ of the proof—weight counting and character multiplication are the same computation in two notations.

2.5.3 Clebsch–Gordan coefficients

Theorem 2.58 tells us *which* total spins appear; the Clebsch–Gordan coefficients tell us *how* the coupled states are built from the product states. They are the entries of the unitary change of basis between the two natural bases of $V_{j_1}\otimes V_{j_2}$: the *product (uncoupled) basis* $\{|j_1m_1\rangle\otimes|j_2m_2\rangle\}$, in which $J^3_{(1)}$ and

$J^3_{(2)}$ are separately diagonal, and the *coupled basis* $\{|(j_1 j_2)\, j\, m\rangle\}$, in which the total Casimir $\mathbf{J}^2$ and J^3 are diagonal.

Definition 2.59 (Clebsch–Gordan coefficients)**.** The *Clebsch–Gordan coefficients* are the overlaps

$$\langle j_1\, m_1;\, j_2\, m_2 \,|\, j\, m\rangle \;\equiv\; \big(\langle j_1 m_1| \otimes \langle j_2 m_2|\big)\; |(j_1 j_2)\, j\, m\rangle\,, \tag{2.161}$$

defined so that the coupled states expand in the product basis as

$$|(j_1 j_2)\, j\, m\rangle \;=\; \sum_{m_1, m_2} \langle j_1\, m_1;\, j_2\, m_2 \,|\, j\, m\rangle \;\; |j_1 m_1\rangle \otimes |j_2 m_2\rangle\,. \tag{2.162}$$

Three structural facts fix these numbers almost completely. First, the *selection rule*: because weights add (Eq. (2.151)), the overlap vanishes unless $m = m_1 + m_2$. Second, the triangle condition $|j_1 - j_2| \le j \le j_1 + j_2$ of Theorem 2.58, outside which $|(j_1 j_2) j m\rangle$ does not exist. Third, *unitarity*: both bases are orthonormal, so the coefficients form a real orthogonal matrix once a phase convention is fixed, and they satisfy the completeness and orthogonality relations

$$\sum_{m_1, m_2} \langle j_1 m_1; j_2 m_2 | j\, m\rangle \, \langle j_1 m_1; j_2 m_2 | j'\, m'\rangle = \delta_{j j'}\, \delta_{m m'}, \tag{2.163}$$

$$\sum_{j, m} \langle j_1 m_1; j_2 m_2 | j\, m\rangle \, \langle j_1 m_1'; j_2 m_2' | j\, m\rangle = \delta_{m_1 m_1'}\, \delta_{m_2 m_2'}. \tag{2.164}$$

The remaining freedom is the phase of each coupled multiplet, fixed once and for all by the *Condon–Shortley convention*: the highest-weight overlap $\langle j_1\, j_1;\, j_2\, (j - j_1) \,|\, j\, j\rangle$ is taken real and positive. With that convention all Clebsch–Gordan coefficients are real, and the matrix is genuinely orthogonal.

The constructive route to the coefficients is the ladder algorithm, the direct extension of the highest-weight method of the previous section to the product space. It runs as follows. The unique product state of maximal weight, $|j_1 j_1\rangle \otimes |j_2 j_2\rangle$, must be the top of the largest multiplet, so $|(j_1 j_2)\,(j_1{+}j_2)\,(j_1{+}j_2)\rangle = |j_1 j_1\rangle \otimes |j_2 j_2\rangle$. Applying the total lowering operator $J^- = J^-_{(1)} \otimes \mathbf{1} + \mathbf{1} \otimes J^-_{(2)}$ repeatedly generates the whole spin-$(j_1{+}j_2)$ tower, using the action established in the previous section (Eq. (2.114)),

$$J^{\mp}\, |j\, m\rangle = \sqrt{(j \pm m)(j \mp m + 1)}\;\; |j\, m \mp 1\rangle\,. \tag{2.165}$$

At weight $m = j_1 + j_2 - 1$ the product space is two-dimensional; one combination is the descendant just computed, and the orthogonal combination (with Condon–Shortley sign) is the highest-weight state of the spin-$(j_1{+}j_2{-}1)$ multiplet. Lowering that generates its tower; proceeding down through each weight, peeling off one new highest-weight state at each level, produces every coupled state and hence every coefficient. The next subsection's worked example carries this algorithm out in complete detail for the smallest nontrivial case.

2.5.4 Invariant tensors and the singlet

Among the irreducibles, one is singled out for field theory: the trivial, one-dimensional representation $j = 0$, on which every group element acts as the identity. A vector in a copy of this representation inside some tensor product is called a *singlet*, and it is precisely an *invariant*: it is annihilated by every generator and therefore unchanged by every group transformation. The hunt for singlets inside tensor products is, almost verbatim, the hunt for symmetry-invariant combinations of fields.

Definition 2.60 (Singlet and invariant tensor)**.** A vector $|s\rangle \in V_1 \otimes \cdots \otimes V_k$ is a *singlet* (an invariant) if the total generator annihilates it, $(\rho_1 \otimes \cdots \otimes \rho_k)_*(X)\ |s\rangle = 0$ for every X in the algebra; equivalently $(\rho_1 \otimes \cdots \otimes \rho_k)(g)\,|s\rangle = |s\rangle$ for all $g \in G$. The component array of such a state, with one index for each factor, is an *invariant tensor*: a collection of numbers $T_{ia\ldots}$ unchanged when each index is rotated by the corresponding representation matrix.

The first question is when a singlet exists at all. For a product of two irreducibles the answer is immediate from the Clebsch–Gordan series and Schur's lemma.

Theorem 2.61 (The singlet in $j_1 \otimes j_2$)**.** *The tensor product $j_1 \otimes j_2$ of two $\mathfrak{su}(2)$ irreducibles contains a singlet if and only if $j_1 = j_2$, and then exactly one. Equivalently, an invariant bilinear pairing between V_{j_1} and V_{j_2} exists if and only if the two spins are equal, and is unique up to scale.*

Proof. By Theorem 2.58 the trivial representation $j = 0$ appears in $j_1 \otimes j_2$ iff 0 lies in the range $|j_1 - j_2| \le 0 \le j_1 + j_2$, i.e. iff $|j_1 - j_2| = 0$, i.e. $j_1 = j_2$; and the series has unit multiplicity, so it appears exactly once. The equivalence with the existence of an invariant pairing is Schur's lemma (Theorem 2.21): an invariant bilinear form on $V_{j_1} \otimes V_{j_2}$ is an intertwiner $V_{j_1} \to V_{j_2}^*$, and $V_{j_2}^*$ carries the representation conjugate to j_2, which for $\mathfrak{su}(2)$ is again spin j_2 (Theorem 2.63 below). A nonzero intertwiner between irreducibles exists iff they are isomorphic, i.e. $j_1 = j_2$, and is then unique up to a scalar. □

The fundamental case $j = \frac{1}{2}$ produces the invariant tensor that recurs throughout the book. The singlet in $\frac{1}{2} \otimes \frac{1}{2}$ is the antisymmetric combination (computed explicitly in Theorem 2.64 below), and the array of its coefficients is the two-index Levi–Civita symbol

$$\epsilon_{ab} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}_{ab}, \qquad \epsilon_{12} = -\epsilon_{21} = 1, \tag{2.166}$$

with $a, b \in \{1, 2\}$ labelling the two components of the doublet. That ϵ is an invariant tensor of SU(2) is the statement that contracting two doublets with it,

$\epsilon_{ab}\,\psi^a\chi^b = \psi^1\chi^2 - \psi^2\chi^1$, yields an SU(2)-invariant. The proof is one line at the group level: for $U \in \mathrm{SU}(2)$,

$$\epsilon_{ab}\,U^a{}_c\,U^b{}_d = (\det U)\,\epsilon_{cd} = \epsilon_{cd}, \tag{2.167}$$

because contracting the antisymmetric symbol with two columns of a matrix returns its determinant, and $\det U = 1$ for $U \in \mathrm{SU}(2)$. Infinitesimally, writing $U = \mathbf{1} + i\omega_a T^a + O(\omega^2)$ with $T^a = \sigma^a/2$, the invariance Eq. (2.167) becomes the generator condition

$$(T^a)^{\top}\epsilon + \epsilon\,T^a = 0 \quad\Longleftrightarrow\quad \epsilon\,\sigma^a\,\epsilon^{-1} = -(\sigma^a)^{\top}, \tag{2.168}$$

the familiar identity that $i\sigma^2 = \epsilon$ conjugates each Pauli matrix into minus its transpose, which one verifies directly on $\sigma^1, \sigma^2, \sigma^3$. This single tensor is the seed of SU(2) invariants: in the electroweak sector the Yukawa coupling of the Higgs doublet to a lepton doublet is written $\epsilon_{ab}H^aL^b$, and the antisymmetric contraction is exactly what makes the term gauge invariant.

Singlets are the gauge-invariant Lagrangian terms

This is the structural payoff of the section, and it underlies every interaction in QED and Yang–Mills theory. A term in a Lagrangian is admissible only if it is invariant under the symmetry group—a scalar, hence a singlet in the tensor product of the representations carried by the fields it contains. Building an invariant Lagrangian is therefore the combinatorial problem of finding all singlets in products of the field representations. For a Dirac mass term the relevant product is (fundamental) $\otimes$ (antifundamental), whose singlet is the contraction $\bar\psi\psi$; for the non-abelian field strength it is the singlet in the adjoint $\otimes$ adjoint product, realized by the Killing form δ^{ab} and giving $-\frac{1}{4}F^a_{\mu\nu}F^{a\,\mu\nu}$. The invariant tensors δ^{ab}, ϵ_{ab}, f^{abc}, and d^{abc} (Chapter B) are nothing but the realizations of singlets in the products that recur, and writing down a gauge theory amounts to contracting indices with them until everything is a singlet.

It is often useful to refine the decomposition by permutation symmetry. When the two factors are copies of the *same* representation, $V \otimes V$, the exchange of the two factors is itself a symmetry that commutes with the group action, so the product splits into its symmetric and antisymmetric parts,

$$V \otimes V \;=\; \mathrm{Sym}^2 V \;\oplus\; \Lambda^2 V, \tag{2.169}$$

of dimensions $\frac{1}{2}n(n+1)$ and $\frac{1}{2}n(n-1)$ for $n = \dim V$, and each summand is itself a subrepresentation. For $\mathfrak{su}(2)$ the spins in $j \otimes j$ alternate in exchange parity, the top spin $2j$ being symmetric and the parities alternating down the series; the singlet ($j' = 0$) therefore sits in the symmetric part when $2j$ is

even (integer j) and in the antisymmetric part when $2j$ is odd (half-integer j). For the doublet $j = \frac{1}{2}$ this reproduces what we found above: the singlet is *antisymmetric*, realized by ϵ_{ab}, while the triplet is the symmetric part. This symmetric/antisymmetric distinction of the invariant pairing is exactly the data that classifies a representation as real or pseudoreal, to which we turn next.

2.5.5 Conjugate representations and the real/pseudoreal/complex trichotomy

The proof of Theorem 2.61 invoked the conjugate representation, the last structural ingredient and the one that will distinguish a quark from an antiquark in the next section. Given a representation ρ, complex-conjugating the matrices produces another set of matrices acting on the conjugate space.

Definition 2.62 (Conjugate representation)**.** The *conjugate* (or complex-conjugate) representation $\bar{\rho}$ of ρ acts by $\bar{\rho}(g) = \rho(g)^*$, with Lie-algebra generators

$$\bar{T}^a = -\,(T^a)^*. \tag{2.170}$$

A representation carrying $\bar{\rho}$ on a copy $\bar{V}$ of the underlying space is denoted $\bar{V}$, and its weights are minus those of V.

The sign in Eq. (2.170) is forced by the convention $\rho(e^{-i\omega_a T^a}) = e^{-i\omega_a T^a}$ in the representation: conjugating $e^{-i\omega_a T^a}$ gives $e^{i\omega_a (T^a)^*} = e^{-i\omega_a (-(T^a)^*)}$, so the conjugate generator is $-(T^a)^*$. That $\bar{T}^a$ obeys the same algebra follows by conjugating the bracket: with real structure constants f^{abc},

$$\left[\bar{T}^a, \bar{T}^b\right] = \left[(T^a)^*, (T^b)^*\right] = \left(\left[T^a, T^b\right]\right)^* = \left(i f^{abc} T^c\right)^* = -i f^{abc} (T^c)^* = i f^{abc}\, \bar{T}^c, \tag{2.171}$$

so $\bar{\rho}$ is a bona fide representation with the same structure constants. Its J^3 weights are negated because $\bar{J}^3 = -(J^3)^* = -J^3$ (the Cartan generator is real and diagonal), which flips every weight; this is precisely why antiparticles carry opposite additive charges.

The decisive question is whether $\bar{\rho}$ is a *new* representation or merely ρ in disguise. There are exactly three possibilities, distinguished by whether, and how, an invariant bilinear form exists on V.

Theorem 2.63 (Real/pseudoreal/complex trichotomy)**.** *Let ρ be an irreducible representation of a compact group on a complex space V. Exactly one of the following holds.*

1. ***Complex:*** *ρ is not isomorphic to $\bar{\rho}$. There is no invariant bilinear form on V.*

2. ***Real (orthogonal):*** *$\rho \cong \bar{\rho}$ through an intertwiner that corresponds to a* symmetric *invariant bilinear form on V. The matrices can be brought to real form in a suitable basis.*

3. ***Pseudoreal (symplectic):*** *$\rho \cong \bar{\rho}$ through an intertwiner that corresponds to an* antisymmetric *invariant bilinear form on V. The matrices cannot be made real, but ρ and $\bar{\rho}$ are nonetheless isomorphic.*

Proof. A representation is isomorphic to its conjugate iff there is an invertible intertwiner C with $C\,\rho(g)\,C^{-1} = \rho(g)^* = \bar{\rho}(g)$ for all g, i.e. $C\,T^a = \bar{T}^a\,C = -(T^a)^*C$ at the algebra level. Such a C is the same data as a nondegenerate invariant bilinear form $B(u,v) = u^\top C\,v$ on V: invariance $B(\rho(g)u, \rho(g)v) = B(u,v)$ is exactly $\rho(g)^\top C\,\rho(g) = C$, which on differentiating reproduces the intertwining condition. If no such C exists, ρ is complex (case 1).

Suppose C exists, so V carries an invariant nondegenerate bilinear form B. Its transpose $B^\top$ is also an invariant bilinear form. By Schur's lemma (Theorem 2.21) the space of invariant bilinear forms on an irreducible V is at most one-dimensional—an invariant form is an intertwiner $V \to V^*$, unique up to scale when nonzero. Hence $B^\top = c\,B$ for some scalar c. Transposing once more, $B = (B^\top)^\top = c\,B^\top = c^2 B$, so $c^2 = 1$ and $c = \pm 1$. Thus B is either symmetric ($c = +1$, case 2) or antisymmetric ($c = -1$, case 3), and the two cases are mutually exclusive because the form is unique up to scale. A symmetric nondegenerate invariant form is, after a basis change, the standard inner product preserved by an orthogonal group, and the matrices are real in that basis; an antisymmetric one is a symplectic form, and no real basis exists because reality would force a symmetric invariant inner product. This exhausts the possibilities. □

The discriminator is computed by a single class function, the *Frobenius–Schur indicator*, which extracts c without finding C. Averaging the character over the group at squared arguments,

$$\nu(\rho) = \frac{1}{|G|}\sum_{g\in G} \chi_\rho(g^2) \quad (\text{sum} \to \text{Haar integral for a Lie group}), \tag{2.172}$$

returns $\nu = +1$ for real, $\nu = -1$ for pseudoreal, and $\nu = 0$ for complex representations; the value is exactly the scalar c of the proof when a form exists, and zero when none does.

For $\mathfrak{su}(2)$ the verdict is uniform and important: *every $\mathfrak{su}(2)$ irreducible is self-conjugate*, and the conjugating intertwiner is the rotation by π about the 2-axis,

$$C = e^{i\pi J^2}, \tag{2.173}$$

which sends $J^3 \to -J^3$ and so maps the spin-j weight ladder onto the reversed ladder of $\bar{\rho}$. Concretely on the doublet, $J^2 = \sigma^2/2$ gives $C = e^{i\pi\sigma^2/2} = i\sigma^2 = \epsilon$,

the very invariant tensor of Eq. (2.166); the intertwining relation Eq. (2.168), $\epsilon\,\sigma^a\epsilon^{-1} = -(\sigma^a)^*$ (using that the Hermitian σ^a satisfy $(\sigma^a)^\top = (\sigma^a)^*$), is exactly $CT^aC^{-1} = -(T^a)^* = \bar{T}^a$. Since ϵ is *antisymmetric*, the doublet is *pseudoreal* by Theorem 2.63: the spin-$\frac{1}{2}$ representation is equivalent to its conjugate, yet cannot be written with real matrices. More generally the invariant form on spin j is symmetric for integer j and antisymmetric for half-integer j—the very alternation found in Eq. (2.169)—so the Frobenius–Schur indicator is

$$\nu(j) = (-1)^{2j} = \begin{cases} +1, & j \text{ integer (real)}, \\ -1, & j \text{ half-integer (pseudoreal)}. \end{cases} \tag{2.174}$$

Caution

That spin $\frac{1}{2}$ is pseudoreal, not real, is a genuine subtlety with physical teeth. "Self-conjugate" is weaker than "real": the doublet equals its conjugate ($\mathbf{2} \cong \bar{\mathbf{2}}$ for SU(2), via ϵ), but no choice of basis makes the Pauli matrices real, because the invariant pairing is antisymmetric rather than symmetric. The contrast with SU(3) in the next section is exactly here: the fundamental $\mathbf{3}$ of SU(3) is genuinely *complex*, $\mathbf{3} \ncong \bar{\mathbf{3}}$, which is why a quark and an antiquark are distinct objects, whereas an SU(2) doublet and its conjugate are not.

2.5.6 Worked example: $\frac{1}{2} \otimes \frac{1}{2} = 0 \oplus 1$

We now carry out the Clebsch–Gordan construction in full for the smallest nontrivial product, the coupling of two spin-$\frac{1}{2}$ systems. This is the addition of two electron spins; the result organizes the two-electron spin states into the spin-singlet and spin-triplet that govern, for instance, the exchange splitting in atoms and the structure of the deuteron.

Worked Example 2.64 (Two spin-$\frac{1}{2}$: singlet and triplet)**.** Take $j_1 = j_2 = \frac{1}{2}$, writing $|\uparrow\rangle \equiv \left|\frac{1}{2}, +\frac{1}{2}\right\rangle$ and $|\downarrow\rangle \equiv \left|\frac{1}{2}, -\frac{1}{2}\right\rangle$ for each factor and abbreviating product states as $|\uparrow\downarrow\rangle \equiv |\uparrow\rangle \otimes |\downarrow\rangle$. The series Eq. (2.152) predicts $\frac{1}{2} \otimes \frac{1}{2} = 1 \oplus 0$, dimensions $4 = 3 + 1$. We construct both multiplets explicitly with the ladder algorithm.

Top of the triplet. The unique product state of maximal weight $m = 1$ is the top of the spin-1 multiplet,

$$|1, +1\rangle = |\uparrow\uparrow\rangle\,. \tag{2.175}$$

Lowering once. Apply $J^- = J^-_{(1)} \otimes \mathbf{1} + \mathbf{1} \otimes J^-_{(2)}$. On the left, Eq. (2.165) with $j = 1, m = 1$ gives $J^-\,|1,1\rangle = \sqrt{(1+1)(1-1+1)}\;|1,0\rangle = \sqrt{2}\;|1,0\rangle$. On the right, each single-spin lowering gives $J^-\,|\uparrow\rangle = \sqrt{(\frac{1}{2}+\frac{1}{2})(\frac{1}{2}-\frac{1}{2}+1)}\;|\downarrow\rangle = |\downarrow\rangle$,

so $J^-|\uparrow\uparrow\rangle = |\downarrow\uparrow\rangle + |\uparrow\downarrow\rangle$. Equating,

$$|1,0\rangle = \frac{1}{\sqrt{2}}\big(|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle\big). \tag{2.176}$$

Lowering again. With $j=1, m=0$, $J^-|1,0\rangle = \sqrt{(1)(2)}\,|1,-1\rangle = \sqrt{2}\,|1,-1\rangle$, while applying J^- to the right-hand combination gives $\frac{1}{\sqrt{2}}(|\downarrow\downarrow\rangle + |\downarrow\downarrow\rangle) = \sqrt{2}\,|\downarrow\downarrow\rangle$. Hence

$$|1,-1\rangle = |\downarrow\downarrow\rangle\,, \tag{2.177}$$

completing the symmetric spin-1 triplet.

The singlet. The weight-0 subspace is two-dimensional, spanned by $|\uparrow\downarrow\rangle$ and $|\downarrow\uparrow\rangle$. One direction is the triplet state $|1,0\rangle$ just found; the orthogonal direction, normalized and signed by the Condon–Shortley convention $\langle \frac{1}{2},+\frac{1}{2};\frac{1}{2},-\frac{1}{2}\,|\,0,0\rangle > 0$, is the spin-0 singlet,

$$|0,0\rangle = \frac{1}{\sqrt{2}}\big(|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle\big). \tag{2.178}$$

One checks it is a singlet directly: $J^3|0,0\rangle = 0$ since both terms have weight 0; $J^-|0,0\rangle = \frac{1}{\sqrt{2}}(|\downarrow\downarrow\rangle - |\downarrow\downarrow\rangle) = 0$; and $J^+|0,0\rangle = \frac{1}{\sqrt{2}}(|\uparrow\uparrow\rangle - |\uparrow\uparrow\rangle) = 0$. Annihilated by all three generators, it is invariant.

The coefficients and the ϵ tensor. Reading off the expansion coefficients gives the Clebsch–Gordan table

$$\langle \tfrac{1}{2}m_1;\tfrac{1}{2}m_2|1\,m\rangle: \quad \langle\uparrow\uparrow|1,1\rangle = 1,\ \langle\uparrow\downarrow|1,0\rangle = \langle\downarrow\uparrow|1,0\rangle = \tfrac{1}{\sqrt{2}},\ \langle\downarrow\downarrow|1,-1\rangle = 1, \tag{2.179}$$

$$\langle \tfrac{1}{2}m_1;\tfrac{1}{2}m_2|0\,0\rangle: \quad \langle\uparrow\downarrow|0,0\rangle = \tfrac{1}{\sqrt{2}}, \quad \langle\downarrow\uparrow|0,0\rangle = -\tfrac{1}{\sqrt{2}}. \tag{2.180}$$

The singlet is the antisymmetric combination, and writing $1\equiv\uparrow$, $2\equiv\downarrow$ for the doublet index its coefficient array is, up to the normalization $1/\sqrt{2}$, exactly the invariant tensor of Eq. (2.166),

$$|0,0\rangle = \frac{1}{\sqrt{2}}\,\epsilon_{ab}\,|a\rangle\otimes|b\rangle\,, \qquad \epsilon_{12} = -\epsilon_{21} = 1. \tag{2.181}$$

The triplet is the symmetric part of $\mathbf{2}\otimes\mathbf{2}$ and the singlet the antisymmetric part, in accord with Eq. (2.169) and the pseudoreality Eq. (2.174) of the doublet. This single computation—two spins giving one singlet and one triplet, with the singlet realized by ϵ—is the prototype reused for every later addition of angular momentum, isospin, or colour, and the spin-$\frac{1}{2}$ doublet here is the same electron spin that enters QED.

The weight-bookkeeping behind the whole construction is worth seeing at a glance. Figure 2.4 plots the four product states of $\frac{1}{2}\otimes\frac{1}{2}$ on the weight axis and regroups them into the triplet and the singlet: the trapezoidal weight profile

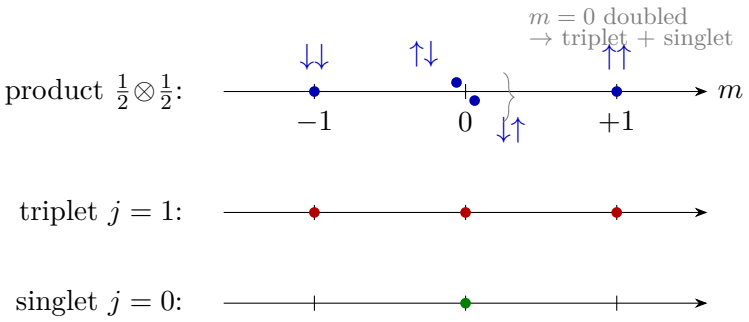

Figure 2.4: Weight addition for $\frac{1}{2}\otimes\frac{1}{2}$. The four product states (top) carry weights $m = m_1 + m_2 \in \{+1, 0, 0, -1\}$, the central weight appearing twice. Regrouping into irreducibles splits the doubled $m = 0$ level into the symmetric triplet ($j = 1$, weights $\{+1, 0, -1\}$) and the antisymmetric singlet ($j = 0$, weight $\{0\}$). The trapezoidal weight profile $N(m) = (1, 2, 1)$ is the $j_1 = j_2 = \frac{1}{2}$ case of the count in the proof of Theorem 2.58.

$N(m) = (1, 2, 1)$ at $m = (1, 0, -1)$ of the proof is laid out directly, with the doubled central weight $m = 0$ splitting into one triplet state and one singlet.

With the tensor product solved for $\mathfrak{su}(2)$ and the singlet identified as the carrier of invariance, the two ideas that propagate forward are now in hand. The first is the *weight-addition viewpoint*: a tensor product is decomposed by adding the weights of its factors and re-sorting the resulting multiset into the triangular weight patterns of irreducibles—a procedure that, recast as addition of weight *vectors* in the next section, decomposes products for any semisimple algebra through its weight diagrams. The second is the *singlet/invariant-tensor* construction, the algebraic statement of gauge invariance, which generalizes verbatim once the higher-rank weights and the conjugate representations are in place. Both are delivered to the Cartan–Weyl machinery of the following section, where the maximal commuting set of generators replaces the single J^3 and the entire structure is bootstrapped from the copies of $\mathfrak{su}(2)$ attached to each root.

2.6 Cartan–Weyl: Cartan Subalgebra, Roots, and the Highest-Weight Theorem

The solution of $\mathfrak{su}(2)$ in Section 2.4 was not a lucky accident of a small algebra; it was a method. We picked one generator, J_3, that could be diagonalized; we labelled states by its eigenvalue m; we found two more generators, $J_\pm = J_1 \pm iJ_2$, that did not commute with J_3 but instead *shifted* its eigenvalue by a fixed amount, $[J_3, J_\pm] = \pm J_\pm$; and we let those raising and lowering operators sweep out an entire irreducible representation from a single highest-weight state. The tensor-product bookkeeping of Section 2.5 added one more ingredient: weights

add when representations are multiplied, so the eigenvalue label is an additive quantum number living in a vector space. Cartan and Weyl observed that nothing in this procedure used the smallness of $\mathfrak{su}(2)$. For *any* semisimple Lie algebra one may diagonalize a maximal commuting set of generators, label states by the tuple of eigenvalues, and find that the remaining generators shift those eigenvalues by fixed vectors. The miracle that makes the general theory finite and computable is that each of those shift vectors comes with its own copy of $\mathfrak{su}(2)$ — so the entire structure of every simple Lie algebra is bootstrapped from the one example we have already solved completely. This section builds that machinery in full and ends by handing the rank-two instance to $\mathfrak{su}(3)$.

2.6.1 The Cartan subalgebra

We work with a compact semisimple Lie algebra $\mathfrak{g}$, the relevant case for the gauge groups of physics; $\mathfrak{su}(N)$ is the running example and the only one we will need concretely. In the physics convention fixed in the chapter introduction (Eq. (2.70)) the generators T^a are Hermitian, $\left[T^a, T^b\right] = if^{abc}T^c$, with the fundamental normalization $\mathrm{tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$. The trace form

$$\langle X, Y\rangle \;\equiv\; \mathrm{tr}(XY), \qquad X, Y \in \mathfrak{g}, \tag{2.182}$$

evaluated in the fundamental representation, is real, symmetric, and *positive definite* on the real span of the Hermitian generators, since $\langle X, X\rangle = \mathrm{tr}(X^2) = \mathrm{tr}(X^\dagger X) \geq 0$ with equality only for $X = 0$. It is moreover *invariant*, $\langle [Z, X]\,, Y\rangle + \langle X, [Z, Y]\rangle = 0$, by cyclicity of the trace. This nondegenerate invariant form is all we will need; it plays the role that the Killing form plays in the abstract theory, and for a compact algebra it is manifestly nondegenerate without invoking Cartan's criterion.

Definition 2.65 (Cartan subalgebra and rank)**.** A *Cartan subalgebra* (CSA) $\mathfrak{h} \subset \mathfrak{g}$ is a maximal abelian subalgebra consisting of elements that are simultaneously diagonalizable in every representation. Its dimension $r = \dim \mathfrak{h}$ is the *rank* of $\mathfrak{g}$.

For $\mathfrak{su}(2)$ the Cartan subalgebra is one-dimensional, spanned by J_3 alone: there is no second generator commuting with it, so $\mathfrak{su}(2)$ has rank one. For $\mathfrak{su}(N)$ one may take the $N-1$ diagonal traceless Hermitian matrices, so $\mathfrak{su}(N)$ has rank $N-1$; we will see this explicitly for $\mathfrak{su}(3)$ (rank two) in Section 2.7. That a maximal commuting set of Hermitian generators can be *simultaneously* diagonalized is exactly the spectral theorem for commuting Hermitian operators, so for compact $\mathfrak{g}$ the CSA exists and the diagonalizability clause in Theorem 2.65 is automatic. Choose once and for all a basis $H_1, \ldots, H_r$ of $\mathfrak{h}$, orthonormal in the trace form, $\langle H_i, H_j\rangle = \frac{1}{2}\delta_{ij}$.

2.6.2 Weights of a representation

Let ρ be a representation of $\mathfrak{g}$ on a vector space V. The operators $\rho(H_1), \dots, \rho(H_r)$ are commuting Hermitian operators, hence simultaneously diagonalizable: V decomposes into common eigenspaces.

Definition 2.66 (Weight)**.** A nonzero vector $|\mu\rangle \in V$ with

$$\rho(H_i)\,|\mu\rangle = \mu_i\,|\mu\rangle\,, \qquad i = 1, \dots, r, \tag{2.183}$$

is a *weight vector*; the real r-tuple $\mu = (\mu_1, \dots, \mu_r)$, viewed as a linear functional $\mu(H) = \sum_i \mu_i\, c_i$ on $H = \sum_i c_i H_i \in \mathfrak{h}$, is its *weight*. The number of independent weight vectors sharing a weight μ is the *multiplicity* of μ.

Weights live in the dual space $\mathfrak{h}^*$; the eigenvalues are real because the $\rho(H_i)$ are Hermitian. For $\mathfrak{su}(2)$ a weight is a single number, the eigenvalue m of J_3, and Theorem 2.53 is precisely the statement that the weights of the spin-j irreducible are $m = -j, -j+1, \dots, j$, each with multiplicity one. The content of Section 2.5 that weights add on tensor products is now transparent: if $|\mu\rangle \in V_1$ and $|\nu\rangle \in V_2$ then, because H_i acts on $V_1 \otimes V_2$ as $\rho_1(H_i) \otimes \mathbf{1} + \mathbf{1} \otimes \rho_2(H_i)$,

$$(\rho_1 \otimes \rho_2)(H_i)\,(|\mu\rangle \otimes |\nu\rangle) = (\mu_i + \nu_i)\;|\mu\rangle \otimes |\nu\rangle\,, \tag{2.184}$$

so the weights of a tensor product are the (multiset) sums of the weights of the factors. This additivity is the engine that drives every weight-diagram computation in higher rank.

2.6.3 The root-space decomposition of the algebra

The deepest application of weights is to the algebra acting on *itself*. The adjoint representation $\mathrm{ad}_X(Y) = [X, Y]$ makes $\mathfrak{g}$ a representation of itself (Theorem 2.39); its weights carry the entire structure of $\mathfrak{g}$. Restricting to the Cartan subalgebra, the operators $\mathrm{ad}_{H_1}, \dots, \mathrm{ad}_{H_r}$ commute — because $\mathrm{ad}_{[H_i,H_j]} = \big[\mathrm{ad}_{H_i}, \mathrm{ad}_{H_j}\big]$ and the H_i commute among themselves — and they are Hermitian with respect to the trace form, since $\langle \mathrm{ad}_H\, X, Y\rangle = -\langle X, \mathrm{ad}_H\, Y\rangle$ for H in the (real, Hermitian) compact form means ad_H is antisymmetric, hence $i\,\mathrm{ad}_H$ is symmetric and ad_H is diagonalizable with imaginary eigenvalues over $\mathbb{R}$, i.e. real eigenvalues once we pass to the complexified algebra. We therefore complexify: let $\mathfrak{g}_{\mathbb{C}} = \mathfrak{g} \otimes \mathbb{C}$. This is the same step that turned J_1, J_2 into $J_\pm = J_1 \pm i J_2$ — the ladder operators were never Hermitian; they lived in the complexification. In $\mathfrak{g}_{\mathbb{C}}$ the commuting operators ad_{H_i} are simultaneously diagonalizable.

Theorem 2.67 (Root-space decomposition)**.** *The complexified algebra decomposes as a direct sum of common eigenspaces of* $\mathrm{ad}_{\mathfrak{h}}$*,*

$$\mathfrak{g}_{\mathbb{C}} \;=\; \mathfrak{h}_{\mathbb{C}} \;\oplus\; \bigoplus_{\alpha \in \Phi} \mathfrak{g}_\alpha, \qquad \mathfrak{g}_\alpha = \big\{\, E \in \mathfrak{g}_{\mathbb{C}} : [H, E] = \alpha(H)\, E \;\; \forall H \in \mathfrak{h} \,\big\}, \tag{2.185}$$

where the roots α *run over a finite set* $\Phi \subset \mathfrak{h}^* \setminus \{0\}$ *of nonzero weights of the adjoint representation. The zero-eigenvalue space is exactly* $\mathfrak{h}_{\mathbb{C}}$*, and each root space* $\mathfrak{g}_\alpha$ *is one-dimensional.*

The phrase "roots are the weights of the adjoint representation" is the whole idea: a root α is just the weight of a generator $E_\alpha \in \mathfrak{g}_\alpha$ under the Cartan action,

$$[H_i, E_\alpha] = \alpha_i \, E_\alpha, \qquad i = 1, \ldots, r, \tag{2.186}$$

the direct analogue of $[J_3, J_\pm] = \pm J_\pm$ with $\alpha = \pm 1$. We prove the theorem in stages.

Diagonal action and the zero space. Simultaneous diagonalizability of $\mathrm{ad}_\mathfrak{h}$ was established above. Let E be a common eigenvector: $\mathrm{ad}_{H_i} E = c_i E$ for scalars c_i. Define $\alpha \in \mathfrak{h}^*$ by $\alpha(H_i) = c_i$ and extend linearly; then $[H, E] = \alpha(H)E$ for all $H \in \mathfrak{h}$, which is Eq. (2.186). The eigenvectors with $\alpha = 0$ are precisely the elements commuting with all of $\mathfrak{h}$, i.e. the centralizer of $\mathfrak{h}$ in $\mathfrak{g}_{\mathbb{C}}$. We claim this centralizer is $\mathfrak{h}_{\mathbb{C}}$ itself. Suppose X commutes with all of $\mathfrak{h}$ but $X \notin \mathfrak{h}_{\mathbb{C}}$; writing $X = H_0 + \sum_\alpha x_\alpha E_\alpha$ in the eigenbasis, $[H, X] = \sum_\alpha \alpha(H) x_\alpha E_\alpha$ must vanish for all H, forcing $x_\alpha = 0$ whenever $\alpha \neq 0$, so $X = H_0 \in \mathfrak{h}_{\mathbb{C}}$. Hence the centralizer is $\mathfrak{h}_{\mathbb{C}}$: the Cartan subalgebra is *self-centralizing*, which is the precise content of its maximality as an abelian subalgebra. This proves the zero space is exactly $\mathfrak{h}_{\mathbb{C}}$.

Conjugate roots and the reality of $E_\alpha^\dagger$. Taking the Hermitian conjugate of Eq. (2.186) and using $H_i^\dagger = H_i$ gives $\left[H_i, E_\alpha^\dagger\right] = -\alpha_i E_\alpha^\dagger$, so $E_\alpha^\dagger \in \mathfrak{g}_{-\alpha}$. Therefore $\alpha \in \Phi \Rightarrow -\alpha \in \Phi$, and we may always normalize the root vectors so that

$$E_{-\alpha} = E_\alpha^\dagger, \tag{2.187}$$

exactly as $J_- = J_+^\dagger$ in $\mathfrak{su}(2)$. The proof that each $\mathfrak{g}_\alpha$ is one-dimensional uses the $\mathfrak{su}(2)$ attached to α and is given in Section 2.6.4 once that structure is in place.

2.6.4 The form on weights and the $\mathfrak{su}(2)$ attached to each root

Because the trace form is nondegenerate on $\mathfrak{h}$, it sets up an isomorphism between $\mathfrak{h}$ and its dual $\mathfrak{h}^*$: to each linear functional $\lambda \in \mathfrak{h}^*$ corresponds a unique element $t_\lambda \in \mathfrak{h}_{\mathbb{C}}$ with

$$\lambda(H) = \langle t_\lambda, H \rangle \quad \text{for all } H \in \mathfrak{h}. \tag{2.188}$$

This lets us transport the form to weights and roots: define the (symmetric, real-valued on real weights) inner product

$$(\lambda, \mu) \;\equiv\; \langle t_\lambda, t_\mu \rangle = \lambda(t_\mu) = \mu(t_\lambda). \tag{2.189}$$

Concretely, in the orthonormal Cartan basis with $\langle H_i, H_j\rangle = \frac{1}{2}\delta_{ij}$ one has $t_\lambda = 2\sum_i \lambda(H_i)H_i$ and $(\lambda,\mu) = 2\sum_i \lambda(H_i)\mu(H_i)$; the constants will not matter because every formula below is invariant under rescaling the form.

Now fix a root α and pick generators $E_\alpha \in \mathfrak{g}_\alpha$, $E_{-\alpha} = E_\alpha^\dagger \in \mathfrak{g}_{-\alpha}$. Their commutator lies in $\mathfrak{h}_{\mathbb{C}}$, because for any $H \in \mathfrak{h}$,

$$[H,[E_\alpha,E_{-\alpha}]] = [[H,E_\alpha],E_{-\alpha}]+[E_\alpha,[H,E_{-\alpha}]] = \big(\alpha(H)-\alpha(H)\big)\,[E_\alpha,E_{-\alpha}] = 0, \tag{2.190}$$

so $[E_\alpha, E_{-\alpha}]$ commutes with all of $\mathfrak{h}$ and therefore, by self-centralizing, lies in $\mathfrak{h}_{\mathbb{C}}$. A short computation identifies it: for any $H \in \mathfrak{h}$, invariance of the trace form gives

$$\langle [E_\alpha,E_{-\alpha}],H\rangle = \langle E_\alpha,[E_{-\alpha},H]\rangle = \alpha(H)\,\langle E_\alpha,E_{-\alpha}\rangle, \tag{2.191}$$

using $[H,E_{-\alpha}] = -\alpha(H)E_{-\alpha}$. Comparing with Eq. (2.188), and normalizing the root vectors so that $\langle E_\alpha, E_{-\alpha}\rangle = 1$ (possible because the form pairs $\mathfrak{g}_\alpha$ nondegenerately with $\mathfrak{g}_{-\alpha}$),

$$[E_\alpha,E_{-\alpha}] = t_\alpha \in \mathfrak{h}_{\mathbb{C}}. \tag{2.192}$$

Finally $[t_\alpha, E_{\pm\alpha}] = \pm\alpha(t_\alpha)E_{\pm\alpha} = \pm(\alpha,\alpha)E_{\pm\alpha}$ from Eqs. (2.186) and (2.189). The three operators do not yet have the canonical $\mathfrak{su}(2)$ normalization, but rescaling fixes that. Define the *coroot*

$$\alpha^\vee \;\equiv\; \frac{2\,t_\alpha}{(\alpha,\alpha)} \in \mathfrak{h}_{\mathbb{C}}, \qquad e_\alpha \equiv E_\alpha, \quad f_\alpha \equiv \frac{2}{(\alpha,\alpha)}E_{-\alpha}, \quad h_\alpha \equiv \alpha^\vee. \tag{2.193}$$

Then, directly from Eqs. (2.186) and (2.192),

$$[h_\alpha,e_\alpha] = 2e_\alpha, \qquad [h_\alpha,f_\alpha] = -2f_\alpha, \qquad [e_\alpha,f_\alpha] = h_\alpha. \tag{2.194}$$

Proposition 2.68 (An $\mathfrak{su}(2)$ for every root)**.** *For each root α, the triple $\{e_\alpha, f_\alpha, h_\alpha\}$ spans a subalgebra $\mathfrak{su}(2)_\alpha \subset \mathfrak{g}_{\mathbb{C}}$ isomorphic to (the complexification of) $\mathfrak{su}(2)$, with h_α playing the role of $2J_3$, e_α of J_+, and f_α of J_-.*

The factor of 2 in $h_\alpha = 2J_3$ is the entire reason the theory is governed by *integers*: in the basis Eq. (2.194) the eigenvalues of h_α are $2m$, twice the magnetic quantum number, hence even or odd integers but always integers. This is the conventional normalization in which the structural numbers of Lie theory come out integral.

Root spaces are one-dimensional. We can now finish Theorem 2.67. Consider the subspace

$$V_\alpha = \mathbb{C}\,f_\alpha \;\oplus\; \mathbb{C}\,h_\alpha \;\oplus\; \bigoplus_{k\geq 1}\mathfrak{g}_{k\alpha}, \tag{2.195}$$

which is invariant under $\mathfrak{su}(2)_\alpha$ (acting by ad): e_α raises the h_α-eigenvalue by 2, f_α lowers it by 2, and h_α is diagonal. The h_α-eigenvalue on $\mathfrak{g}_{k\alpha}$ is $k\alpha(h_\alpha) = 2k$,

on h_α it is 0, and on f_α it is -2. As an $\mathfrak{su}(2)_\alpha$-representation V_α decomposes into irreducibles by Theorem 2.53; we read off constraints from its weight content. The weight -2 appears once (on f_α), and the weight 0 appears once (on h_α): every other zero-weight vector of $\mathfrak{g}_\mathbb{C}$ lies in $\mathfrak{h}_\mathbb{C}$ but is annihilated by both e_α and f_α — indeed for $H \in \mathfrak{h}$ with $\alpha(H) = 0$ one has $[e_\alpha, H] = -\alpha(H)e_\alpha = 0$ — so such vectors form $\mathfrak{su}(2)_\alpha$-singlets and do not belong to V_α. An $\mathfrak{su}(2)$ multiplet of spin j contains the weight 0 iff j is an integer, and then exactly once; it contains the weight -2 (i.e. $2m = -2$, $m = -1$) iff $j \geq 1$. Since V_α contains weight -2 exactly once and weight 0 exactly once, V_α must be a single irreducible of spin $j = 1$ — the adjoint of $\mathfrak{su}(2)_\alpha$, with weights $\{-2, 0, +2\}$. Consequently the only positive multiple of α that is a root is α itself ($\mathfrak{g}_{k\alpha} = 0$ for $k \geq 2$), and $\dim \mathfrak{g}_\alpha = 1$ (the weight $+2$ space). In particular 2α is never a root. This completes Theorem 2.67.

2.6.5 The root string and the master formula

The same $\mathfrak{su}(2)_\alpha$ now constrains how a root or weight may sit relative to α. This is the central quantization argument, generalizing the ladder of $\mathfrak{su}(2)$.

Theorem 2.69 (Root/weight strings)**.** *Let μ be any weight of any finite-dimensional representation (in particular μ may be a root, taking the representation to be the adjoint), and let α be a root. The set of weights of the form $\mu + j\alpha$, $j \in \mathbb{Z}$, that actually occur forms an unbroken string*

$$\mu - p\alpha,\ \mu - (p-1)\alpha,\ \ldots,\ \mu,\ \ldots,\ \mu + q\alpha, \qquad p, q \in \mathbb{Z}_{\geq 0}, \tag{2.196}$$

with no gaps, and the endpoints are tied to the geometry by the master formula

$$\boxed{\langle \mu, \alpha^\vee \rangle \equiv \frac{2(\mu,\alpha)}{(\alpha,\alpha)} = p - q \in \mathbb{Z}.} \tag{2.197}$$

Proof. Apply the operators $e_\alpha, f_\alpha, h_\alpha$ of $\mathfrak{su}(2)_\alpha$ to the weight vectors lying along the line $\mu + j\alpha$. The h_α-eigenvalue on a vector of weight $\mu + j\alpha$ is

$$(\mu + j\alpha)(h_\alpha) = \frac{2(\mu + j\alpha, \alpha)}{(\alpha,\alpha)} = \frac{2(\mu,\alpha)}{(\alpha,\alpha)} + 2j = \langle \mu, \alpha^\vee \rangle + 2j, \tag{2.198}$$

using Eq. (2.189) and $(\alpha,\alpha) = (\alpha,\alpha)$. Thus successive vectors along the string differ by 2 in h_α-eigenvalue, exactly the spacing of an $\mathfrak{su}(2)$ ladder. The span of the weight vectors on this line is an $\mathfrak{su}(2)_\alpha$-submodule (raising/lowering moves $j \to j \pm 1$ and stays on the line), so by Theorem 2.53 its h_α-weights run consecutively and symmetrically about 0: if the top occurs at $j = q$ and the bottom at $j = -p$, the corresponding h_α-eigenvalues $\langle \mu, \alpha^\vee \rangle + 2q$ and $\langle \mu, \alpha^\vee \rangle - 2p$ are $+2J$ and $-2J$ for the same J, hence sum to zero:

$$\big(\langle \mu, \alpha^\vee \rangle + 2q\big) + \big(\langle \mu, \alpha^\vee \rangle - 2p\big) = 0 \implies \langle \mu, \alpha^\vee \rangle = p - q. \tag{2.199}$$

The string is unbroken because an $\mathfrak{su}(2)$ irreducible has no missing internal weights (Theorem 2.53). The right-hand side is an integer, so $\langle \mu, \alpha^\vee \rangle \in \mathbb{Z}$. □

The integers $\langle \mu, \alpha^\vee \rangle$ are the *Cartan integers*. The master formula is the single most powerful constraint in the theory: it says that twice the projection of any weight onto any root, measured in units of that root's length-squared, is an integer determined by how far the weight can be lowered minus how far it can be raised along α. Applied with μ a root, it becomes a self-consistency condition on the root system itself, which we now exploit.

2.6.6 Root geometry: the allowed angles

Take two roots α, β that are not proportional. The master formula Eq. (2.197), applied once with $(\mu, \alpha) = (\beta, \alpha)$ and once with the roles swapped, gives two integers,

$$n_{\beta\alpha} \equiv \langle \beta, \alpha^\vee \rangle = \frac{2(\beta,\alpha)}{(\alpha,\alpha)} \in \mathbb{Z}, \qquad n_{\alpha\beta} \equiv \langle \alpha, \beta^\vee \rangle = \frac{2(\alpha,\beta)}{(\beta,\beta)} \in \mathbb{Z}. \tag{2.200}$$

Because the trace form is positive definite on the real span of the roots, the Cauchy–Schwarz angle θ between α and β is well defined through $(\alpha, \beta) = |\alpha|\,|\beta| \cos\theta$, where $|\alpha|^2 = (\alpha, \alpha)$. Multiplying the two integers,

$$n_{\alpha\beta}\, n_{\beta\alpha} = \frac{4(\alpha,\beta)^2}{(\alpha,\alpha)(\beta,\beta)} = 4\cos^2\theta. \tag{2.201}$$

Proposition 2.70 (Quantized root angles)**.** *For non-proportional roots α, β, the product $n_{\alpha\beta} n_{\beta\alpha} = 4\cos^2\theta$ is an integer in $\{0, 1, 2, 3\}$. Consequently the angle between two roots can only be $90°, 60°, 120°, 45°, 135°, 30°$, or $150°$, and whenever the roots are not orthogonal their squared-length ratio is fixed,*

$$\frac{|\beta|^2}{|\alpha|^2} = \frac{n_{\beta\alpha}}{n_{\alpha\beta}}. \tag{2.202}$$

Proof. The product is a product of two integers, hence an integer; it equals $4\cos^2\theta$, which lies in $[0, 4]$. The value 4 requires $\cos^2\theta = 1$, i.e. $\alpha \parallel \beta$, excluded. So $n_{\alpha\beta} n_{\beta\alpha} \in \{0, 1, 2, 3\}$. Solving $4\cos^2\theta \in \{0, 1, 2, 3\}$ gives $\cos^2\theta \in \{0, \frac{1}{4}, \frac{1}{2}, \frac{3}{4}\}$, hence $|\cos\theta| \in \{0, \frac{1}{2}, \frac{1}{\sqrt{2}}, \frac{\sqrt{3}}{2}\}$ and the listed angles. The length ratio follows by dividing the two definitions in Eq. (2.200), valid whenever both integers are nonzero. □

Figure 2.5 shows the four root systems this constraint allows in rank two; they are exactly the rank-two simple algebras plus the trivial product, and $\mathfrak{su}(3)$ is the case $\theta = 120°$ with equal lengths. The enumeration of these four is worked in full in Theorem 2.77.

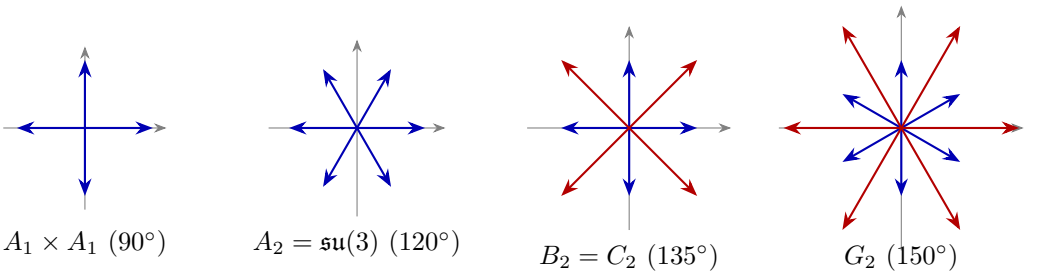

Figure 2.5: The four root systems allowed in rank two by Theorem 2.70, one for each value $4\cos^2\theta \in \{0, 1, 2, 3\}$ of the angle between a pair of simple roots. Short roots in blue, long roots in red. A_2 is the root system of $\mathfrak{su}(3)$, taken up in Section 2.7.

2.6.7 Simple roots and the Cartan matrix

The root system Φ contains every $\pm\alpha$, so it has a built-in redundancy; we extract a minimal generating set. Choose a generic linear functional (equivalently a hyperplane through the origin missing every root) and call a root *positive* if it lies on the chosen side; write $\alpha \succ 0$. Each root is then positive or negative, and $\Phi = \Phi^+ \sqcup (-\Phi^+)$.

Definition 2.71 (Simple roots)**.** A positive root is *simple* if it cannot be written as a sum of two positive roots. The set of simple roots is denoted $\Delta = \{\alpha_1, \dots, \alpha_r\}$.

The number of simple roots equals the rank r, and the simple roots are a basis of $\mathfrak{h}^*$: every positive root is a *non-negative integer* combination of simple roots (lower a positive root by simple roots until it is itself simple, the "height" decreasing at each step), and the simple roots are linearly independent because they all lie strictly on one side of the chosen hyperplane and pairwise satisfy the inequality of the next lemma, which forbids linear relations with positive coefficients. The key geometric fact is that simple roots meet only at obtuse or right angles.

Lemma 2.72 (Simple roots are non-acute)**.** *For distinct simple roots $\alpha_i \neq \alpha_j$, $(\alpha_i, \alpha_j) \leq 0$, hence the Cartan integer $\langle \alpha_i, \alpha_j^\vee \rangle \leq 0$.*

Proof. We first show $\alpha_i - \alpha_j$ is *not* a root. If it were a positive root $\gamma = \alpha_i - \alpha_j \succ 0$, then $\alpha_i = \gamma + \alpha_j$ would be a sum of two positive roots, contradicting the simplicity of α_i; if $\alpha_i - \alpha_j$ were a negative root, then $\alpha_j - \alpha_i \succ 0$ and $\alpha_j = (\alpha_j - \alpha_i) + \alpha_i$ would contradict the simplicity of α_j. So $\alpha_i - \alpha_j \notin \Phi$. Now consider the α_i-string through α_j from Theorem 2.69: since $\alpha_j - \alpha_i$ is not a root, the string cannot extend in the $-\alpha_i$ direction, so $p = 0$ and the master formula Eq. (2.197) gives $\langle \alpha_j, \alpha_i^\vee \rangle = p - q = -q \leq 0$. As (α_i, α_j) and $\langle \alpha_j, \alpha_i^\vee \rangle$ have the same sign (they differ by the positive factor $2/(\alpha_i, \alpha_i)$), $(\alpha_i, \alpha_j) \leq 0$. □

Definition 2.73 (Cartan matrix)**.** The *Cartan matrix* of $\mathfrak{g}$ is the $r \times r$ integer matrix

$$A_{ij} = \langle \alpha_i, \alpha_j^\vee \rangle = \frac{2(\alpha_i, \alpha_j)}{(\alpha_j, \alpha_j)}. \tag{2.203}$$

By the results above the Cartan matrix has a rigid shape: $A_{ii} = 2$ on the diagonal (each root makes angle 0 with itself, $\langle \alpha_i, \alpha_i^\vee \rangle = 2$); off-diagonal entries $A_{ij} \leq 0$ are non-positive integers (Theorem 2.72); and $A_{ij} = 0 \Leftrightarrow A_{ji} = 0$, since by Eq. (2.201) their product is $4\cos^2\theta_{ij}$ and one vanishes iff the angle is 90°. Moreover $A_{ij}A_{ji} = 4\cos^2\theta_{ij} \in \{0, 1, 2, 3\}$. The matrix A encodes the entire algebra: from it one reconstructs all roots (by repeatedly adding simple roots subject to the master formula), the full set of commutation relations (the Chevalley–Serre presentation), and every representation. The Cartan matrix need not be symmetric — the asymmetry records the length ratios of Eq. (2.202) — but it is symmetrizable, DA symmetric for the positive diagonal $D = \mathrm{diag}((\alpha_i, \alpha_i))$.

2.6.8 Dynkin diagrams

The Cartan matrix is conveniently drawn. To each simple root assign a node; join nodes i and j by $A_{ij}A_{ji} \in \{0, 1, 2, 3\}$ lines (no line for orthogonal roots), and when the roots have different lengths put an arrowhead on the multiple line pointing from the long root to the short root. This is the *Dynkin diagram*. It contains exactly the same information as the Cartan matrix — the number of lines fixes the angle and the length ratio, the arrow disambiguates which root is long — but it is read at a glance.

2.6.9 The highest-weight theorem

We can now state the higher-rank generalization of the $\mathfrak{su}(2)$ classification of irreducibles by their top spin. Choose the simple roots $\Delta = \{\alpha_i\}$ as above. A weight μ is *dominant integral* if every Cartan integer against a simple coroot is a non-negative integer,

$$\langle \mu, \alpha_i^\vee \rangle \in \mathbb{Z}_{\geq 0}, \qquad i = 1, \ldots, r. \tag{2.204}$$

Within a representation, call a weight vector $|\Lambda\rangle$ a *highest-weight vector* if it is annihilated by every raising operator of every simple root, $e_{\alpha_i}|\Lambda\rangle = 0$ for all i — the direct generalization of $J_+|j, j\rangle = 0$.

Theorem 2.74 (Highest weight)**.** *Every finite-dimensional irreducible representation of $\mathfrak{g}$ contains a unique (up to scale) highest-weight vector, whose weight Λ is dominant integral. Conversely, for every dominant integral weight Λ there is exactly one finite-dimensional irreducible representation with that highest weight,*

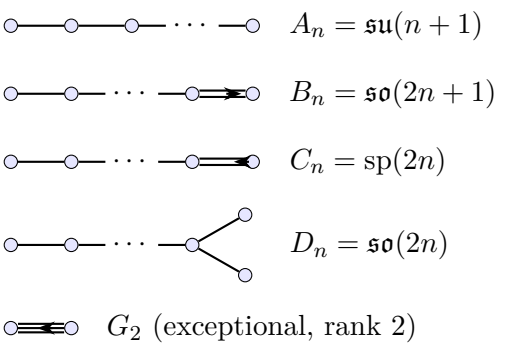

Figure 2.6: The connected Dynkin diagrams of the simple Lie algebras: the four infinite families A_n, B_n, C_n, D_n and the five exceptionals G_2, F_4, E_6, E_7, E_8. An arrow on a multiple bond points from the long root to the short root. The number of bonds between two nodes is $A_{ij}A_{ji} = 4\cos^2\theta_{ij}$.

and the assignment

$$\{\textit{finite-dimensional irreducibles of } \mathfrak{g}\} \longleftrightarrow \{\textit{dominant integral weights } \Lambda\} \tag{2.205}$$

is a bijection. The whole representation is generated from $|\Lambda\rangle$ *by repeated application of the lowering operators* f_{α_i}*, and every other weight has the form* $\Lambda - \sum_i k_i\alpha_i$ *with* $k_i \in \mathbb{Z}_{\geq 0}$.

Proof of the structural part. Order the weights by height $\mathrm{ht}(\mu) = \sum_i c_i$ where $\mu = \sum_i c_i\alpha_i$; in a finite-dimensional representation there are finitely many weights, so a maximal one Λ exists. A weight vector $|\Lambda\rangle$ of maximal height is annihilated by every e_{α_i}, since $e_{\alpha_i}|\Lambda\rangle$ would have weight $\Lambda + \alpha_i$ of greater height; thus $|\Lambda\rangle$ is a highest-weight vector. For each simple root, apply the $\mathfrak{su}(2)_{\alpha_i}$ analysis (Theorem 2.69) to the α_i-string through Λ: the string cannot rise ($q = 0$ since $\Lambda + \alpha_i$ is not a weight), so $\langle \Lambda, \alpha_i^\vee\rangle = p - q = p \geq 0$ and integral — hence Λ is dominant integral. Repeated lowering by the f_{α_i} generates an invariant subspace containing $|\Lambda\rangle$; by irreducibility it is the whole space, so every weight

is Λ minus a non-negative integer combination of simple roots, and Λ is the unique maximal weight (any other highest-weight vector would generate the same module from a weight $\leq \Lambda$ and $\geq \Lambda$, forcing equality). The remaining existence-and-uniqueness statement — that every dominant integral Λ is realized by a finite-dimensional irreducible, and only one — is proved by constructing the module as the irreducible quotient of the Verma module generated by a formal highest-weight vector and showing finite-dimensionality follows from dominance; we use this construction but do not reproduce it here, deferring the full argument to the references in Section 2.6 Further reading. The $\mathfrak{su}(2)$ case of the whole theorem is exactly Theorem 2.53, proved in full earlier. □

Caution

The honest scope of Theorem 2.74 is this: the structural half — that an irreducible *has* a unique dominant highest weight, is generated by lowering from it, and is determined by it — is proved above using only the $\mathfrak{su}(2)$ atom and finite-dimensionality. The *existence* half — that every dominant weight is actually attained by a finite-dimensional irreducible — requires the Verma-module construction and the Weyl dimension/character machinery, which we state and use but whose full proof we send to the literature. Every concrete representation we build in this book (the $\mathfrak{su}(3)$ multiplets of Section 2.7, the Lorentz fields of Chapter 3) is constructed explicitly by lowering, so existence is never assumed where we actually compute.

The dominant weights have a canonical basis. Define the *fundamental weights* $\omega_1, \ldots, \omega_r$ as the dual basis to the simple coroots,

$$\langle \omega_i, \alpha_j^\vee \rangle = \delta_{ij}. \tag{2.206}$$

Then every dominant integral weight is a non-negative integer combination

$$\Lambda = \sum_{i=1}^{r} a_i \, \omega_i, \qquad a_i = \langle \Lambda, \alpha_i^\vee \rangle \in \mathbb{Z}_{\geq 0}, \tag{2.207}$$

and the integers $(a_1, \ldots, a_r)$ are the *Dynkin labels* of the representation — the higher-rank replacement for the single label $2j$ of $\mathfrak{su}(2)$. The *fundamental representations* are those with a single $a_i = 1$; from them, by taking tensor products and projecting onto highest-weight components (Section 2.5), every irreducible is built. For $\mathfrak{su}(2)$, $r = 1$, the lone fundamental weight is $\omega_1 =$ the weight of the spin-$\frac{1}{2}$ doublet, and $\Lambda = 2j\,\omega_1$ recovers the familiar labelling.

2.6.10 The classification of simple Lie algebras

We have reduced the structure of a simple Lie algebra to a single combinatorial object — its Cartan matrix, equivalently its Dynkin diagram — subject to the

rigid constraints of Theorems 2.70 and 2.72: each pair of nodes carries $0, 1, 2$, or 3 bonds, and the matrix must be positive definite (the trace form is positive definite, so its restriction to the simple roots, of which the symmetrized Cartan matrix is the Gram matrix up to scale, must be too). The classification problem is therefore purely Euclidean: *which connected diagrams of unit vectors at the allowed angles have a positive-definite Gram matrix?* The answer is one of the cleanest results in mathematics.

Theorem 2.75 (Cartan–Killing classification)**.** *Every finite-dimensional simple complex Lie algebra is isomorphic to exactly one of:*

- *the four infinite families* A_n $(n \geq 1)$, B_n $(n \geq 2)$, C_n $(n \geq 3)$, D_n $(n \geq 4)$, *realized as*

$$A_n = \mathfrak{su}(n+1), \quad B_n = \mathfrak{so}(2n+1), \quad C_n = \mathrm{sp}(2n), \quad D_n = \mathfrak{so}(2n); \tag{2.208}$$

- *the five exceptional algebras* G_2, F_4, E_6, E_7, E_8, *of ranks* $2, 4, 6, 7, 8$.

Their Dynkin diagrams are precisely the connected diagrams of Fig. 2.6; equivalently, these are exactly the connected positive-definite diagrams allowed by the bond rules.

The honest scope: the *tools* for this theorem are all in hand — the bond rules from the master formula, the positive-definiteness of the trace form, and the reconstruction of the algebra from its Cartan matrix. The remaining step is a finite (if intricate) Euclidean enumeration: rule out diagrams with cycles, with too-high vertex degree, or with too many/too-long multiple bonds, by exhibiting a vector combination of zero or negative norm. We state the result and use it; the complete enumeration is in the references of the Further reading. The classical families are the algebras of the matrix groups physics already cares about: $A_{N-1} = \mathfrak{su}(N)$ is the gauge group of every Yang–Mills theory in Yang–Mills theory, with $A_1 = \mathfrak{su}(2)$ the rank-one atom of this whole development and $A_2 = \mathfrak{su}(3)$ the case taken up next. The exceptional algebras are not idle curiosities; E_6, E_7, E_8 are candidate grand-unified and string gauge groups returned to in Chapter 35, and the affine extensions of these same diagrams organize two-dimensional conformal field theory in Chapter 48.

2.6.11 Worked examples

Worked Example 2.76 (The A_2 root system and the Cartan matrix of $\mathfrak{su}(3)$)**.** We construct, from Theorem 2.70 alone, the rank-two root system with two simple roots at 120°, and read off its data. This is the root system of $\mathfrak{su}(3)$, and the construction is the template Section 2.7 fills in with explicit Gell-Mann matrices.

Take two simple roots α_1, α_2 of equal length, normalized to $(\alpha_i, \alpha_i) = 2$, meeting at $\theta = 120°$. Then $(\alpha_1, \alpha_2) = |\alpha_1||\alpha_2| \cos 120° = 2 \cdot (-\frac{1}{2}) = -1$, so the Cartan integers are

$$A_{12} = \frac{2(\alpha_1, \alpha_2)}{(\alpha_2, \alpha_2)} = \frac{2(-1)}{2} = -1, \qquad A_{21} = \frac{2(\alpha_2, \alpha_1)}{(\alpha_1, \alpha_1)} = -1, \tag{2.209}$$

giving the symmetric Cartan matrix

$$A = \begin{pmatrix} 2 & -1 \\ -1 & 2 \end{pmatrix}, \qquad \det A = 3 > 0, \tag{2.210}$$

which is positive definite, confirming A_2 is a genuine simple algebra. The product $A_{12}A_{21} = 1 = 4\cos^2 120°$ means the Dynkin diagram is two nodes joined by a single line, with no arrow (equal lengths): $\circ\!-\!\circ$.

Now generate the positive roots by adding simple roots subject to the master formula Eq. (2.197). Start with α_1 and ask whether $\alpha_1 + \alpha_2$ is a root, using the α_2-string through α_1. Since $\alpha_1 - \alpha_2$ is not a root (both simple, Theorem 2.72), the string has $p = 0$, so $q = -\langle \alpha_1, \alpha_2^\vee \rangle = -A_{12} = 1$: the string is $\alpha_1,\ \alpha_1 + \alpha_2$, and $\alpha_1 + \alpha_2$ *is* a root. Repeating in the α_1 direction through $\alpha_1 + \alpha_2$: the α_1-string downward already includes α_2 (one step down) so $p = 1$; and $\langle \alpha_1 + \alpha_2, \alpha_1^\vee \rangle = A_{11} + A_{21} = 2 - 1 = 1 = p - q$ gives $q = 0$, so $\alpha_1 + (\alpha_1 + \alpha_2) = 2\alpha_1 + \alpha_2$ is *not* a root. Likewise $\alpha_1 + 2\alpha_2$ is not a root. The positive roots are therefore

$$\Phi^+ = \{\alpha_1,\ \alpha_2,\ \alpha_1 + \alpha_2\}, \tag{2.211}$$

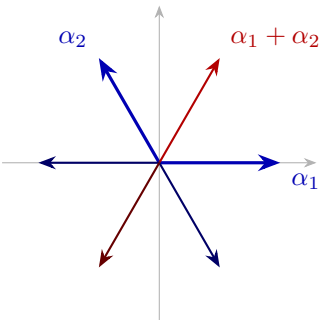
and with their negatives the full system has 6 roots, the hexagon of Fig. 2.7. Adding the $r = 2$ Cartan generators gives $\dim \mathfrak{su}(3) = 6 + 2 = 8$, the eight Gell-Mann generators, exactly as expected.

The fundamental weights solve Eq. (2.206), $\langle \omega_i, \alpha_j^\vee \rangle = \delta_{ij}$. Writing $\omega_i = \sum_k c_{ik}\alpha_k$ and using $\langle \alpha_k, \alpha_j^\vee \rangle = A_{kj}$ gives $\sum_k c_{ik}A_{kj} = \delta_{ij}$, i.e. $C = A^{-1}$ with

$$A^{-1} = \frac{1}{3}\begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}, \qquad \omega_1 = \tfrac{1}{3}(2\alpha_1 + \alpha_2), \quad \omega_2 = \tfrac{1}{3}(\alpha_1 + 2\alpha_2). \tag{2.212}$$

The fundamental representation with Dynkin labels $(1, 0)$ has highest weight ω_1 — this is the $\mathbf{3}$ of $\mathfrak{su}(3)$ — and $(0, 1)$ has highest weight ω_2 — the conjugate $\bar{\mathbf{3}}$. The adjoint, with highest root $\alpha_1 + \alpha_2$, has Dynkin labels $(1, 1)$ and dimension 8. All of this is the abstract skeleton; Section 2.7 clothes it in matrices and weight diagrams.

Worked Example 2.77 (All rank-two root systems)**.** We enumerate every rank-two simple root system directly from Theorem 2.70, confirming Fig. 2.5 and illustrating the classification in the smallest nontrivial case. Two simple roots



A_2 root system of $\mathfrak{su}(3)$

Figure 2.7: The six roots of $\mathfrak{su}(3)$ (A_2). The simple roots α_1, α_2 (heavy blue) sit at 120°; their sum $\alpha_1 + \alpha_2$ (red) is the highest root, and the remaining three are the negatives. Together with the two Cartan generators they give $\dim \mathfrak{su}(3) = 8$.

α_1, α_2 are characterized by the single Cartan-integer product $A_{12}A_{21} = 4\cos^2\theta \in \{0, 1, 2, 3\}$ (the value 4 being excluded as parallel). We treat each value.

Product 0 *($\theta = 90°$).* The simple roots are orthogonal, $A_{12} = A_{21} = 0$. The algebra is not simple: its Dynkin diagram is two disconnected nodes, $\mathfrak{su}(2) \oplus \mathfrak{su}(2) = A_1 \times A_1$. The root system is the four roots $\pm\alpha_1, \pm\alpha_2$ on perpendicular axes.

Product 1 *($\theta = 120°$).* Necessarily $A_{12} = A_{21} = -1$, so equal lengths, by Eq. (2.202). This is $A_2 = \mathfrak{su}(3)$ of Theorem 2.76, six roots forming a hexagon. Diagram $\circ\!-\!\circ$.

Product 2 *($\theta = 135°$).* Then $\{A_{12}, A_{21}\} = \{-1, -2\}$, so by Eq. (2.202) the roots have squared-length ratio 2: one short, one long. Generating roots as in Theorem 2.76, the α-strings now produce $\alpha_1, \alpha_2, \alpha_1 + \alpha_2, 2\alpha_1 + \alpha_2$ (with α_1 short), giving four positive roots and eight roots in all. This is $B_2 = \mathfrak{so}(5)$, equal as a root system to $C_2 = \mathrm{sp}(4)$ (the two differ only by which root is called long, i.e. the direction of the arrow). Diagram $\circ\Rightarrow\circ$.

Product 3 *($\theta = 150°$).* Then $\{A_{12}, A_{21}\} = \{-1, -3\}$, squared-length ratio 3. The strings now generate six positive roots, $\alpha_1, \alpha_2, \alpha_1 + \alpha_2, 2\alpha_1 + \alpha_2, 3\alpha_1 + \alpha_2, 3\alpha_1 + 2\alpha_2$ (with α_1 short), twelve roots total — the star-of-David configuration of G_2, the smallest exceptional algebra, $\dim G_2 = 12 + 2 = 14$. Diagram $\circ\Rrightarrow\circ$.

Thus the only rank-two simple root systems are A_2, $B_2 (= C_2)$, and G_2, with $A_1 \times A_1$ the lone (semisimple, non-simple) extra. The positive-definiteness check is automatic here since every 2×2 Cartan matrix $\left(\begin{smallmatrix} 2 & -a \\ -b & 2 \end{smallmatrix}\right)$ with $ab \leq 3$ has $\det = 4 - ab > 0$; rank three is where positive-definiteness first starts excluding diagrams, which is the seed of the full classification.

The machinery is now complete: a Cartan subalgebra to diagonalize, weights to label states, a root system carrying one $\mathfrak{su}(2)$ per root, the master formula

quantizing all geometry, simple roots and a Cartan matrix to package it, and the highest-weight theorem to enumerate representations. In the next section we stop working in the abstract and turn the crank on the first genuinely higher-rank case, $\mathfrak{su}(3)$ — building its weight diagrams, the fundamental **3** and $\bar{\mathbf{3}}$, the adjoint **8**, and the tensor-product decompositions that are the working language of QCD color and flavor.

2.7 su(3): The Physicist's Workhorse

The Cartan–Weyl construction of Section 2.6 is a machine that takes any semisimple Lie algebra apart into a maximal commuting set — the Cartan subalgebra — and a collection of ladder operators, each labelled by a root and each generating its own copy of $\mathfrak{su}(2)$. For $\mathfrak{su}(2)$ itself the machine is almost idle: the Cartan subalgebra is one-dimensional, there is a single pair of roots, and the whole of Section 2.4 is the result. The first time the construction has anything genuinely new to say is at rank two, and the first rank-two algebra a physicist meets is $\mathfrak{su}(3)$. It is not an academic example. $\mathfrak{su}(3)$ is the algebra of the color SU(3) gauge symmetry that binds quarks into hadrons, and, in a separate and approximate guise, the algebra of the flavor SU(3) that organized the particle zoo into the multiplets of the Eightfold Way before quarks were known to exist. The generators T^a, the structure constants f^{abc}, the triplet **3** and its distinct conjugate $\bar{\mathbf{3}}$, the octet **8**, and the invariants C_F, C_A, T_F that this section assembles are the literal alphabet of the Yang–Mills and QCD chapters in Part VII. We build them once, here, by running the Cartan–Weyl machine to completion on $\mathfrak{su}(3)$, so that when Yang–Mills theory begins in Chapter 25 the color bookkeeping is already in hand.

2.7.1 The algebra, the Cartan subalgebra, and the rank

The compact real algebra $\mathfrak{su}(3)$ is the space of traceless anti-Hermitian 3×3 matrices, with the matrix commutator as bracket. As always in this book we work with Hermitian generators T^a, related to the anti-Hermitian elements by a factor of i; the physical normalization is $\mathrm{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$ and the bracket is $\left[T^a, T^b\right] = i f^{abc} T^c$ (Chapter A). A Hermitian traceless 3×3 matrix has $3^2 - 1 = 8$ real parameters, so the algebra is eight-dimensional and carries eight generators. The standard basis is $T^a = \frac{1}{2}\lambda^a$, where the λ^a are the Gell-Mann matrices written out in Eq. (B.59) and shown there to satisfy $\mathrm{tr}(\lambda^a \lambda^b) = 2\delta^{ab}$ (Theorem B.17); the full set of structure constants f^{abc} and the symmetric symbols d^{abc} are computed by direct trace in Theorem B.18. We import that explicit matrix data rather than re-derive it, and concentrate here on what the Cartan–Weyl analysis makes of it.

The first question the machine asks is: how large a set of the T^a can be simultaneously diagonalized? Two of the Gell-Mann matrices are already diagonal,

$$H_1 \;=\; T^3 \;=\; \tfrac{1}{2}\,\mathrm{diag}(1,-1,0), \qquad H_2 \;=\; T^8 \;=\; \tfrac{1}{2\sqrt{3}}\,\mathrm{diag}(1,1,-2), \quad (2.213)$$

and they commute, $[H_1, H_2] = 0$, because diagonal matrices always do. No third generator commutes with both: a matrix commuting with H_1 and H_2, both of which have distinct diagonal entries in the generic combination, must itself be diagonal and traceless, and the diagonal traceless matrices form exactly the two-dimensional span of H_1, H_2. The Cartan subalgebra is therefore $\mathfrak{h} = \mathrm{span}\{H_1, H_2\}$, and the *rank* of $\mathfrak{su}(3)$ is two. This is the structural fact that makes $\mathfrak{su}(3)$ the first interesting case: with two commuting charges, states are labelled by a point in a two-dimensional plane, and the entire representation theory becomes genuinely geometric — weights are lattice points, roots are vectors, and the diagrams one draws are honest pictures rather than the points-on-a-line of $\mathfrak{su}(2)$.

2.7.2 The root system: the $\mathfrak{su}(3)$ hexagon

The remaining six generators are organized by the adjoint action of the Cartan subalgebra. Following Section 2.6, we look for ladder operators E_α — eigenvectors of ad_{H_1} and ad_{H_2} simultaneously — and the pair of eigenvalues $\alpha = (\alpha_1, \alpha_2)$ defined by

$$[H_i, E_\alpha] \;=\; \alpha_i\, E_\alpha, \qquad i = 1, 2, \quad (2.214)$$

is the root carried by E_α. The six off-diagonal directions of $\mathfrak{su}(3)$ combine into three conjugate pairs of ladder operators, each built from two Gell-Mann matrices supported on one off-diagonal block:

$$I_\pm = \tfrac{1}{2}(\lambda^1 \pm i\lambda^2), \qquad V_\pm = \tfrac{1}{2}(\lambda^4 \pm i\lambda^5), \qquad U_\pm = \tfrac{1}{2}(\lambda^6 \pm i\lambda^7). \quad (2.215)$$

In matrix-unit notation $I_+ = E_{12}$, $V_+ = E_{13}$, $U_+ = E_{23}$, where E_{ij} is the matrix with a single 1 in row i, column j; the lowering operators are the transposes. The eigenvalues (2.214) are now a one-line computation. For $I_+ = E_{12}$, using $[\mathrm{diag}(d_1, d_2, d_3), E_{ij}] = (d_i - d_j)E_{ij}$ together with the diagonals in (2.213),

$$[H_1, E_{12}] = (\tfrac{1}{2} - (-\tfrac{1}{2}))E_{12} = 1 \cdot E_{12}, \qquad [H_2, E_{12}] = (\tfrac{1}{2\sqrt{3}} - \tfrac{1}{2\sqrt{3}})E_{12} = 0, \quad (2.216)$$

so I_+ carries the root $\alpha_1 = (1, 0)$. The same arithmetic on E_{13} and E_{23} gives

$$V_+ = E_{13} : \; \Big(\tfrac{1}{2},\, \tfrac{1}{2\sqrt{3}} + \tfrac{1}{\sqrt{3}}\Big) = \Big(\tfrac{1}{2},\, \tfrac{\sqrt{3}}{2}\Big), \qquad U_+ = E_{23} : \; \Big(-\tfrac{1}{2},\, \tfrac{1}{2\sqrt{3}} + \tfrac{1}{\sqrt{3}}\Big) = \Big(-\tfrac{1}{2},\, \tfrac{\sqrt{3}}{2}\Big), \quad (2.217)$$

and the three lowering operators carry the opposite roots. The six roots of $\mathfrak{su}(3)$ are therefore

$$\pm(1, 0), \qquad \pm\Big(\tfrac{1}{2}, \tfrac{\sqrt{3}}{2}\Big), \qquad \pm\Big(\tfrac{1}{2}, -\tfrac{\sqrt{3}}{2}\Big), \quad (2.218)$$

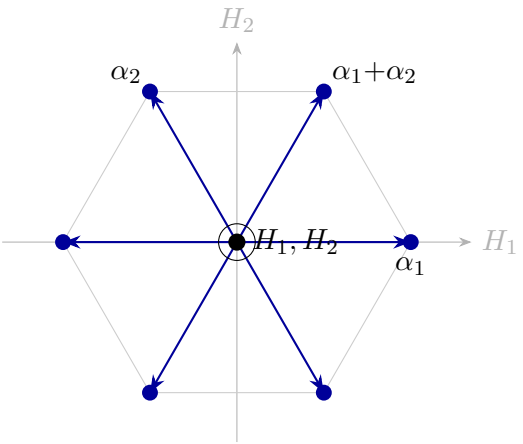


Figure 2.8: The root system of $\mathfrak{su}(3)$: six roots of equal length at the vertices of a regular hexagon in the orthonormal Cartan plane (H_1, H_2), together with the two-dimensional zero-root space (the Cartan subalgebra) at the centre. A choice of positive half-plane singles out the simple roots $\alpha_1 = (1, 0)$ and $\alpha_2 = (-\frac{1}{2}, \frac{\sqrt{3}}{2})$; their sum $\alpha_1 + \alpha_2$ is the third positive root, the highest root, and the highest weight of the adjoint representation $\mathbf{8}$.

and they are the great geometric punchline of rank two: each has length one in the (H_1, H_2) plane, and consecutive roots are separated by 60°. They sit at the vertices of a regular hexagon (Fig. 2.8). Every root α comes paired with $-\alpha$ and generates an $\mathfrak{su}(2)$: the trio (I_+, I_-, H_1) closes on the isospin $\mathfrak{su}(2)$, $(V_+, V_-, \cdot)$ and $(U_+, U_-, \cdot)$ on the V-spin and U-spin $\mathfrak{su}(2)$s. That every root reproduces the algebra we solved completely in Section 2.4 is the content of the Cartan–Weyl bootstrap, made concrete.

Notation Watch

The physics literature on the quark model uses coordinates (t_3, y) — isospin projection and hypercharge — with $t_3 = T^3$ and $y = \frac{1}{\sqrt{3}}\lambda^8$, so that $y = \frac{2}{\sqrt{3}}H_2$. In those coordinates the fundamental weights are $(\frac{1}{2}, \frac{1}{3}), (-\frac{1}{2}, \frac{1}{3}), (0, -\frac{2}{3})$, the familiar hypercharges of (u, d, s). The map from (H_1, H_2) to (t_3, y) stretches the vertical axis and shears the hexagon: lengths and angles are no longer the Killing-form lengths and angles, so the "hexagon" looks elongated. We draw all diagrams in the orthonormal (H_1, H_2) basis, where the geometry is the true root geometry, and convert to (t_3, y) only when comparing to hadron charge assignments. The same (t_3, y) plot appears in Fig. B.1.

Simple roots, the Cartan matrix, and the Dynkin diagram. To organize the hexagon we pick a positive half-plane — say, roots with $\alpha_1 > 0$, or $\alpha_1 = 0$ and $\alpha_2 > 0$ — giving the positive roots $\alpha_1 = (1, 0)$, $\alpha_2 = (-\frac{1}{2}, \frac{\sqrt{3}}{2})$, and $\alpha_1 + \alpha_2 = (\frac{1}{2}, \frac{\sqrt{3}}{2})$. A positive root is *simple* if it is not the sum of two positive roots; here α_1 and α_2 are simple and $\alpha_1 + \alpha_2$ is not. With the inner products $(\alpha_1, \alpha_1) = (\alpha_2, \alpha_2) = 1$ and $(\alpha_1, \alpha_2) = -\frac{1}{2}$, the Cartan matrix of Section 2.6 is

$$A_{ij} = \frac{2(\alpha_i, \alpha_j)}{(\alpha_j, \alpha_j)} = \begin{pmatrix} 2 & -1 \\ -1 & 2 \end{pmatrix}. \tag{2.219}$$

The off-diagonal entries $A_{12}A_{21} = 1$ mean the two simple roots meet at 120° and have equal length, which is the Dynkin diagram A_2: two nodes joined by a single line. This is the rank-two entry in the $A_n = \mathfrak{su}(n+1)$ family of the classification stated in Section 2.6.

Dual to the simple roots are the two *fundamental weights* ω_1, ω_2, defined by $2(\omega_i, \alpha_j)/(\alpha_j, \alpha_j) = \delta_{ij}$. Solving the linear system with (2.219) gives

$$\omega_1 = \left(\tfrac{1}{2}, \tfrac{1}{2\sqrt{3}}\right), \qquad \omega_2 = \left(0, \tfrac{1}{\sqrt{3}}\right), \tag{2.220}$$

and the highest-weight theorem (Theorem 2.74) tells us that every finite-dimensional irreducible representation of $\mathfrak{su}(3)$ is labelled by a pair of non-negative integers, its *Dynkin labels* (p, q), through the dominant highest weight $\Lambda = p\,\omega_1 + q\,\omega_2$. The whole representation theory of $\mathfrak{su}(3)$ is now indexed by the quadrant $p, q \geq 0$. We meet the four smallest members below.

2.7.3 The fundamental 3, the conjugate $\bar{\mathbf{3}}$, and why they differ

The defining representation acts on $\mathbb{C}^3$; its three basis vectors e_1, e_2, e_3 are simultaneous eigenvectors of H_1, H_2, and reading the diagonals of (2.213) gives their weights,

$$\mu_1 = \left(\tfrac{1}{2}, \tfrac{1}{2\sqrt{3}}\right), \quad \mu_2 = \left(-\tfrac{1}{2}, \tfrac{1}{2\sqrt{3}}\right), \quad \mu_3 = \left(0, -\tfrac{1}{\sqrt{3}}\right). \tag{2.221}$$

They sum to zero (the generators are traceless) and form an equilateral triangle. The highest of them is $\mu_1 = \omega_1$, so this is the irrep with Dynkin labels $(1, 0)$: the *fundamental* $\mathbf{3}$. A ladder operator moves a state by its root: I_+ sends $\mu_2 \to \mu_1$ (difference $\mu_1 - \mu_2 = (1, 0) = \alpha_1$), exactly as a raising operator should, and the three weights are connected into the triangle by the three positive roots.

The conjugate representation $\bar{\mathbf{3}}$ is built from generators $\bar{T}^a = -(T^a)^* = -(T^a)^\mathsf{T}$ (Hermiticity makes the conjugate and the negative-transpose coincide). These satisfy the same algebra, $\left[\bar{T}^a, \bar{T}^b\right] = i f^{abc} \bar{T}^c$, because complex-conjugating $\left[T^a, T^b\right] = i f^{abc} T^c$ flips the sign of the explicit i and the extra minus signs cancel.

Since the Cartan generators are real and diagonal, $\bar{H}_i = -H_i$, and the weights of $\bar{\mathbf{3}}$ are the negatives of (2.221),

$$-\mu_1 = \left(-\tfrac{1}{2}, -\tfrac{1}{2\sqrt{3}}\right), \quad -\mu_2 = \left(\tfrac{1}{2}, -\tfrac{1}{2\sqrt{3}}\right), \quad -\mu_3 = \left(0, \tfrac{1}{\sqrt{3}}\right), \tag{2.222}$$

with highest weight $-\mu_3 = \omega_2$, Dynkin labels $(0, 1)$.

Theorem 2.78 (The fundamental of $\mathfrak{su}(3)$ is complex)**.** *The representations* $\mathbf{3}$ *and* $\bar{\mathbf{3}}$ *are inequivalent. Equivalently,* $\mathbf{3}$ *is a* complex *representation: there is no change of basis taking the generators* T^a *to their conjugates* $-(T^a)^*$.

Proof. Two finite-dimensional representations of a semisimple Lie algebra are equivalent if and only if they have the same multiset of weights (a corollary of the highest-weight theorem, Theorem 2.74: the weight system is a complete invariant). The weight set of $\mathbf{3}$ is $\{\mu_1, \mu_2, \mu_3\}$, an equilateral triangle with its apex μ_3 pointing toward negative H_2; the weight set of $\bar{\mathbf{3}}$ is $\{-\mu_1, -\mu_2, -\mu_3\}$, the same triangle reflected through the origin, apex pointing toward positive H_2. A multiset of three points equals its own reflection through the origin only if the points are centrally symmetric, i.e. closed under $\mu \mapsto -\mu$; but $\mu_1 = (\frac{1}{2}, \frac{1}{2\sqrt{3}})$ and $-\mu_1$ are both required to lie in $\{\mu_1, \mu_2, \mu_3\}$, and $-\mu_1$ is none of the three. The weight sets differ, so the representations are inequivalent. □

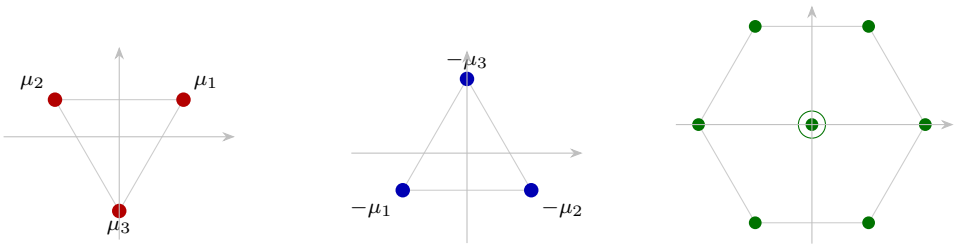
This is the first place the rank-one intuition fails. Every representation of $\mathfrak{su}(2)$ is real or pseudoreal — spin-j and its conjugate carry the same weights $\{-j, \dots, j\}$, a set symmetric about zero — so in $\mathfrak{su}(2)$ one never has to distinguish a representation from its conjugate. In $\mathfrak{su}(3)$ one must: a quark $q \sim \mathbf{3}$ and an antiquark $\bar{q} \sim \bar{\mathbf{3}}$ are genuinely different objects, and the physical distinction between matter and antimatter in QCD color is exactly the statement of Theorem 2.78.

2.7.4 The adjoint 8

The algebra acts on itself by the bracket, and this eight-dimensional adjoint representation is the octet $\mathbf{8}$. Its weights are read off the Cartan–Weyl decomposition directly: each ladder operator E_α is a weight vector of weight equal to its root α (that is precisely what (2.214) says, with ad_{H_i} the adjoint action), and each Cartan generator H_i has weight zero, since $[H_i, H_j] = 0$. The weight system of $\mathbf{8}$ is therefore

$$\underbrace{\{\pm(1,0),\ \pm(\tfrac{1}{2}, \tfrac{\sqrt{3}}{2}),\ \pm(\tfrac{1}{2}, -\tfrac{\sqrt{3}}{2})\}}_{\text{six roots}} \cup \underbrace{\{0,\ 0\}}_{H_1,\, H_2}, \tag{2.223}$$

the six hexagon vertices plus a doubly occupied centre (Fig. 2.9). Its highest weight is the highest root $\alpha_1 + \alpha_2 = \omega_1 + \omega_2$, Dynkin labels $(1, 1)$; for any simple



(a) $\mathbf{3} = (1,0)$ (b) $\bar{\mathbf{3}} = (0,1)$ (c) $\mathbf{8} = (1,1)$

Figure 2.9: Weight diagrams in the Cartan plane (H_1, H_2). The fundamental $\mathbf{3}$ and its conjugate $\bar{\mathbf{3}}$ are equilateral triangles of opposite orientation — the geometric image of Theorem 2.78, that the two are inequivalent. The adjoint $\mathbf{8}$ is the root hexagon with a doubly occupied centre (the circled point), the double occupancy being the rank, 2.

algebra the adjoint highest weight is the highest root, and the zero weight appears with multiplicity equal to the rank, which is why the centre of the octet diagram is doubly occupied. Physically $\mathbf{8}$ is the color content of the gluons: eight gauge bosons, one per generator, transforming in the adjoint — the fact that the gluon octet *is* the adjoint is the statement that gauge fields live in the Lie algebra, which Yang–Mills theory takes as its starting point in Chapter 25.

2.7.5 Tensor products by weight addition

The physically central products are decomposed by the rule established in Section 2.5: the weights of $R_1 \otimes R_2$ are the pairwise sums of the weights of the factors, and one peels off irreducibles by repeatedly identifying the highest remaining weight, attaching its full irrep, and subtracting that irrep's weight system. We carry this out for the two products on which the quark model and the color structure of QCD rest.

Worked Example 2.79 ($\mathbf{3} \otimes \bar{\mathbf{3}} = \mathbf{8} \oplus \mathbf{1}$: mesons and the color singlet)**.** We combine a fundamental (weights μ_i, Eq. (2.221)) with a conjugate (weights $-\mu_j$, Eq. (2.222)). The $3 \times 3 = 9$ product weights are the differences $\mu_i - \mu_j$. Split them by whether the indices agree.

Diagonal terms $i = j$. Each gives $\mu_i - \mu_i = 0$; there are three of them, so the zero weight occurs with multiplicity three.

Off-diagonal terms $i \neq j$. The six differences are

$$\mu_1 - \mu_2 = (1,0), \quad \mu_1 - \mu_3 = (\tfrac{1}{2}, \tfrac{\sqrt{3}}{2}), \quad \mu_2 - \mu_3 = (-\tfrac{1}{2}, \tfrac{\sqrt{3}}{2}), \tag{2.224}$$

together with their negatives $\mu_2 - \mu_1, \mu_3 - \mu_1, \mu_3 - \mu_2$. Comparing with (2.218), these are exactly the six roots of $\mathfrak{su}(3)$.

Assembling irreps. The full product weight system is {six roots} ∪ {0, 0, 0}. The highest weight present is the highest root $\alpha_1 + \alpha_2 = \mu_1 - \mu_3$, with Dynkin labels (1, 1): this is the adjoint **8**, whose weight system (2.223) is the six roots plus a *double* zero. Subtracting it leaves $3 - 2 = 1$ copy of the zero weight and nothing else — a single state at the origin, the trivial representation **1**. Therefore

$$\mathbf{3} \otimes \bar{\mathbf{3}} = \mathbf{8} \oplus \mathbf{1}, \tag{2.225}$$

and the dimensions check, $3 \times 3 = 9 = 8 + 1$. The singlet is the invariant: writing a fundamental index up, $q^i \sim \mathbf{3}$, and a conjugate index down, $\bar{q}_j \sim \bar{\mathbf{3}}$, the unique invariant bilinear is the trace $\bar{q}_i q^i = \delta^i_j\, \bar{q}_i q^j$, which is annihilated by every generator because δ^i_j is the invariant tensor of SU(3). It is the only piece of $q\bar{q}$ carrying no color, and the statement that physical hadrons are color singlets is the statement that only the **1** in (2.225) can appear as an asymptotic state. In flavor SU(3) the same decomposition is the meson nonet: a quark–antiquark pair makes an octet of mesons (the pions, kaons, and η) plus a flavor-singlet η'.

Physical Insight

Theorem 2.79 is the algebraic skeleton of two superficially different physical statements. In *color* SU(3) it says a quark and an antiquark can neutralize their color into the invariant **1**; confinement is the dynamical demand that asymptotic states sit in this singlet. In *flavor* SU(3) the very same $\mathbf{8} \oplus \mathbf{1}$ is the observed pattern of light mesons. One decomposition, two readings — which is exactly why the same algebra earned the name "the physicist's workhorse" twice over.

The second product is the two-quark combinatorics. Adding two fundamentals, the nine weights $\mu_i + \mu_j$ split into the six symmetric combinations $\{2\mu_1, 2\mu_2, 2\mu_3, \mu_1 + \mu_2, \mu_1 + \mu_3, \mu_2 + \mu_3\}$ and the three antisymmetric ones $\{\mu_1 + \mu_2, \mu_1 + \mu_3, \mu_2 + \mu_3\}$. The highest symmetric weight is $2\mu_1 = 2\omega_1$, Dynkin labels (2, 0): the sextet **6**. For the antisymmetric part, use $\mu_1 + \mu_2 + \mu_3 = 0$ to rewrite $\mu_1 + \mu_2 = -\mu_3$, $\mu_1 + \mu_3 = -\mu_2$, $\mu_2 + \mu_3 = -\mu_1$; these are precisely the weights (2.222) of $\bar{\mathbf{3}}$. Hence

$$\mathbf{3} \otimes \mathbf{3} = \mathbf{6} \oplus \bar{\mathbf{3}}, \tag{2.226}$$

with $3 \times 3 = 9 = 6 + 3$. The antisymmetric pair of quarks transforms as an antiquark in color — the group-theoretic root of the diquark and of the way three quarks build a baryon, since $\mathbf{3}\otimes\mathbf{3}\otimes\mathbf{3} \supset \bar{\mathbf{3}}\otimes\mathbf{3} \supset \mathbf{1}$ delivers the color-singlet baryon. (Iterating the same weight-addition on (2.226) gives $\mathbf{3} \otimes \mathbf{3} \otimes \mathbf{3} = \mathbf{10} \oplus \mathbf{8} \oplus \mathbf{8} \oplus \mathbf{1}$, the baryon decuplet, octets, and singlet of the Eightfold Way.)

2.7.6 Dimensions and the Young-tableau shortcut

Reading dimensions off weight diagrams works but does not scale. For $\mathfrak{su}(3)$ the highest-weight theorem is sharpened by the Weyl dimension formula into a

closed expression in the Dynkin labels (p, q),

$$\dim(p,q) = \tfrac{1}{2}\,(p+1)(q+1)(p+q+2), \tag{2.227}$$

which reproduces every dimension met above: $(1,0)$ and $(0,1)$ give 3; $(1,1)$ gives $\tfrac{1}{2}\cdot 2\cdot 2\cdot 4 = 8$; $(2,0)$ gives $\tfrac{1}{2}\cdot 3\cdot 1\cdot 4 = 6$; and $(3,0)$ gives $\tfrac{1}{2}\cdot 4\cdot 1\cdot 5 = 10$, the decuplet. Conjugation acts by $(p,q)\mapsto(q,p)$, which leaves (2.227) invariant — a representation and its conjugate always share a dimension, and $\mathbf{3}, \bar{\mathbf{3}}$ are the smallest pair where the two are nonetheless distinct.

For SU(N) generally the efficient bookkeeping is the *Young tableau*. A representation is encoded by a left-justified diagram of boxes whose row lengths weakly decrease, with at most $N-1$ rows (a full column of N boxes is a singlet and may be deleted). The fundamental $\mathbf{N}$ is a single box $\square$; the conjugate $\bar{\mathbf{N}}$ is a column of $N-1$ boxes (its weights complement the fundamental's to fill a column). Tensor products are computed by the Littlewood–Richardson rule for gluing tableaux, and the symmetric/antisymmetric split of two boxes,

$$\square \otimes \square = \underbrace{(\text{two boxes in a row})}_{\text{symmetric}} \;\oplus\; \underbrace{(\text{two boxes in a column})}_{\text{antisymmetric}}, \tag{2.228}$$

is exactly (2.226) for $N=3$: the row is the $\mathbf{6}$, the column (two of three boxes) is the $\bar{\mathbf{3}}$. The dimension of a tableau in SU(N) is the ratio

$$\dim_{\mathrm{SU}(N)}(\text{tableau}) = \frac{\prod_{\text{cells}}(N + \text{col} - \text{row})}{\prod_{\text{cells}}(\text{hook length})}, \tag{2.229}$$

where for a cell in row r, column c the numerator factor is $N + c - r$ and the hook length counts that cell plus the cells directly below and directly to its right. A single box gives $N/1 = N$; the two-box column gives, for $N=3$, numerator $(3)(3-1) = 6$ and hooks $(2)(1)$, so dim $= 3 = \bar{\mathbf{3}}$; the two-box row gives numerator $(3)(3+1) = 12$ and hooks $(2)(1)$, so dim $= 6 = \mathbf{6}$ — reproducing (2.226) dimensionally without ever drawing a weight. We use the tableau only as a shortcut here; the catalogued SU(N) tableau dimensions and product rules are collected in Chapter B.

2.7.7 The quadratic Casimir and the Dynkin index

Two invariants attach to every representation R and are the numbers that gauge theory actually consumes. The *Dynkin index* $T(R)$ is fixed by the trace normalization (Theorem B.2),

$$\mathrm{tr}(T_R^a\, T_R^b) = T(R)\,\delta^{ab}, \tag{2.230}$$

and the *quadratic Casimir* $C_2(R)$ by the value of the (basis-independent) operator $\sum_a T_R^a T_R^a$, which commutes with all generators and so, by Schur's lemma on an

irreducible R, is a multiple of the identity (Theorem B.4),

$$\sum_{a=1}^{8} T_R^a T_R^a = C_2(R)\,\mathbf{1}_R. \tag{2.231}$$

Taking the trace of (2.231) and using (2.230) on the left ties the two together for any R:

$$\dim(R)\,C_2(R) = \dim(G)\,T(R), \tag{2.232}$$

the master identity Theorem B.5, with $\dim(G) = 8$ for $\mathfrak{su}(3)$. We now compute both invariants for the fundamental and the adjoint and verify (2.232) in each case.

Worked Example 2.80 (C_2 and T for **3** and **8**)**.** *Fundamental.* The index is the normalization itself: with $T^a = \frac{1}{2}\lambda^a$ and $\mathrm{tr}(\lambda^a\lambda^b) = 2\delta^{ab}$ (Eq. (B.60)), one has $\mathrm{tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$, so

$$T(\mathbf{3}) = T_F = \tfrac{1}{2}. \tag{2.233}$$

For the Casimir, trace (2.231) over the three-dimensional space. The left side is $\sum_a \mathrm{tr}(T^aT^a) = 8\cdot\frac{1}{2} = 4$; the right side is $C_2(\mathbf{3})\ \mathrm{tr}\,\mathbf{1}_3 = 3\,C_2(\mathbf{3})$. Hence

$$C_2(\mathbf{3}) = C_F = \frac{4}{3}. \tag{2.234}$$

This is the $N = 3$ value of the general SU(N) result $C_F = (N^2-1)/2N$ (Eq. (B.70)): $(9-1)/6 = 4/3$. The master identity (2.232) reads $3\cdot\frac{4}{3} = 8\cdot\frac{1}{2}$, i.e. $4 = 4$. ✓

Adjoint. Here the generators are the structure constants, $(T^a_{\mathrm{adj}})_{bc} = -if^{abc}$, so the index and Casimir are both expressed through the contraction $f^{acd}f^{bcd}$. By Theorem B.28 this contraction is $f^{acd}f^{bcd} = C_A\,\delta^{ab}$ with $C_A = N = 3$ for $\mathfrak{su}(3)$. The Casimir of the adjoint follows from (2.231) by writing out the matrix product, summing the internal index e and the generator label a:

$$\begin{aligned}\left(\textstyle\sum_a T^a_{\mathrm{adj}}T^a_{\mathrm{adj}}\right)_{bc} &= \sum_{a,e}(T^a_{\mathrm{adj}})_{be}(T^a_{\mathrm{adj}})_{ec} = \sum_{a,e}(-if^{abe})(-if^{aec}) = -\sum_{a,e} f^{abe}f^{aec}\\ &= \sum_{a,e} f^{abe}f^{ace} = \sum_{a,e} f^{bae}f^{cae} = C_A\,\delta_{bc}.\end{aligned} \tag{2.235}$$

The fourth equality uses $f^{aec} = -f^{ace}$ to cancel the leading minus sign, and the fifth uses the antisymmetry $f^{abe} = -f^{bae}$, $f^{ace} = -f^{cae}$ (whose two sign flips cancel); the resulting sum $\sum_{a,e} f^{bae}f^{cae}$ is exactly the adjoint contraction $f^{acd}f^{bcd} = C_A\delta^{ab}$ of Theorem B.28, with the free pair (b,c) and summed pair (a,e). Hence $C_2(\mathbf{8}) = C_A = 3$. The index is read from the same contraction through (2.230):

$$\mathrm{tr}(T^a_{\mathrm{adj}}T^b_{\mathrm{adj}}) = \sum_{c,d}(T^a_{\mathrm{adj}})_{cd}(T^b_{\mathrm{adj}})_{dc} = \sum_{c,d}(-if^{acd})(-if^{bdc}) = -\sum_{c,d} f^{acd}f^{bdc} = \sum_{c,d} f^{acd}f^{bcd} = C \tag{2.236}$$

using $f^{bdc} = -f^{bcd}$ in the penultimate step, so $T(\mathbf{8}) = C_A = 3$. The adjoint is the case where index and Casimir coincide, which the master identity makes inevitable: since $\dim(\mathbf{8}) = \dim(G) = 8$, (2.232) collapses to $C_2(\mathbf{8}) = T(\mathbf{8})$, and indeed $8 \cdot 3 = 8 \cdot 3$. ✓

We record the $\mathfrak{su}(3)$ data the gauge-theory chapters will quote:

$$T_F = \tfrac{1}{2}, \qquad C_F = \tfrac{4}{3}, \qquad C_A = 3, \tag{2.237}$$

the $N = 3$ specialization of the SU(N) family $T_F = \frac{1}{2}$, $C_F = (N^2-1)/2N$, $C_A = N$ catalogued, with full proofs, in Chapter B. The numbers are not decorative. In the one-loop Yang–Mills β-function the combination $\frac{11}{3}C_A - \frac{4}{3}T_F n_f$ decides the sign of the running coupling; with $C_A = 3$ and $T_F = \frac{1}{2}$ it becomes $11 - \frac{2}{3}n_f$, positive for the six quark flavors of QCD, which is asymptotic freedom. The Casimir $C_F = \frac{4}{3}$ sets the strength with which a quark radiates gluons. Chapter 27 computes that β-function; the inputs are exactly (2.237).

With $\mathfrak{su}(3)$ the Cartan–Weyl programme of Chapter 2 has paid off into a complete, computable example of the higher-rank theory, and it hands forward the two pieces of machinery the rest of the book runs on. To Chapter 3 it hands the confidence that the root/weight method survives beyond rank one, the very technique by which the Lorentz algebra is unwound into $\mathfrak{su}(2) \oplus \mathfrak{su}(2)$. To Yang–Mills theory — the classical non-abelian Lagrangian of Chapter 25, its quantization in Chapter 26, and the asymptotic-freedom computation of Chapter 27 — it hands the literal alphabet: the Hermitian generators T^a and structure constants f^{abc}, the inequivalent color representations $\mathbf{3}$, $\bar{\mathbf{3}}$, and $\mathbf{8}$, and the invariants $C_F = \frac{4}{3}$, $C_A = 3$, $T_F = \frac{1}{2}$ of (2.237), so that the gauge-theory part of this book reads as growing out of these foundations rather than starting afresh.

Further reading

The physicist's route through this material, emphasizing $\mathfrak{su}(2)$, $\mathfrak{su}(3)$, roots, and weights with an eye to particle physics, is Georgi [218]; Zee [532] (the group-theory chapters) covers the same ground with the same motivations and many worked examples. For the representation-theoretic perspective developed rigorously—Schur, characters, the highest-weight theorem, and the full classification of simple Lie algebras whose proof we only scoped—see the mathematics texts Fulton and Harris [206] and Hall [248], the latter especially careful about the exponential map and the Lie group/Lie algebra correspondence used in Section 2.3. Nakahara [355] places Lie groups and algebras inside the broader differential-geometric setting that later chapters on gauge theory and topology will need. Weinberg [500] (chapter 2) gives the physical companion to Chapter 3: how these representations organize the states of a relativistic quantum theory, the form in which group theory will be used for the rest of the book.

Chapter 3

The Lorentz and Poincaré Groups

Chapter 2 ended on a promise. It built the language of groups and their representations, solved $\mathfrak{su}(2)$ completely, and argued—following Wigner—that an elementary particle is not an object with properties bolted on but *is* an irreducible unitary representation of the symmetry group of spacetime, its mass and spin the two invariant labels of that representation. This chapter redeems the promise for the group that relativity actually hands us. It asks one question and answers it exhaustively: *what can a relativistic particle be?* The premise is the principle of relativity, that the laws of physics look the same to every inertial observer; the transformations relating those observers form the Lorentz group, enlarged by spacetime translations to the Poincaré group, and a relativistic field or particle is forced to carry one of its representations. Determining those representations—finite-dimensional for fields, infinite-dimensional and unitary for particles—is the whole of the chapter.

We import freely from the foundations laid next door. The matrix-Lie-group machinery, the exponential map (Eq. (2.60)), and the linearization that trades a connected group for its Lie algebra are the tools of Section 2.3; the entire engine is the complete representation theory of $\mathfrak{su}(2)$, its spin-j irreducibles of dimension $2j+1$ (Theorem 2.53), Schur's lemma (Theorem 2.21), and the Clebsch–Gordan series (Section 2.5). Even the topological input we need—that a 2π rotation is a noncontractible loop, so that SU(2) double covers SO(3)—is the $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$ established there. Throughout we hold the global conventions fixed in Chapter A and mirrored in the chapter introduction: the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units $\hbar = c = 1$, and Hermitian generators normalized so that group elements are $\exp(-\frac{i}{2}\omega_{\mu\nu}M^{\mu\nu})$. The two-component spinor conventions and the chiral gamma-matrix basis introduced here are the ones collected in Chapter C.

The argument runs as a single road. We begin with the Lorentz group itself (Section 3.1), reading off its global shape—four disconnected components, non-compactness, and the $\mathbb{Z}_2$ fundamental group that will permit spinors—and

isolating the proper orthochronous component $\mathrm{SO}(1,3)^+$ as the piece whose representations we seek, with parity and time reversal standing outside it as discrete symmetries. Linearizing $\mathrm{SO}(1,3)^+$ produces the Lorentz Lie algebra and its six generators (Section 3.2); a single complex change of basis then splits the complexified algebra into two commuting copies of $\mathfrak{su}(2)$, and the spin classification of Chapter 2 delivers at once the (j_-, j_+) catalogue of fields—the scalar, the two Weyl spinors, the four-vector, the field strength (Section 3.3). We make those spinor labels concrete by building the double cover $\mathrm{SL}(2,\mathbb{C})$ and its Weyl, Dirac, and Majorana representations, and we show that parity is what forces the electron to be a Dirac, not a Weyl, field (Section 3.4).

These finite-dimensional representations describe fields, never states: being non-unitary, they cannot act on a Hilbert space of probabilities. The remedy is to restore the rest of the symmetry. Adjoining translations builds the Poincaré group and its algebra (Section 3.5), whose energy–momentum generators have continuous spectrum and therefore force the unitary representations to be infinite-dimensional. Two Casimir operators—the mass-squared P^2 and the Pauli–Lubański square W^2—survive to label them (Section 3.6), and Wigner's method of induced representations reduces the entire classification to the representation theory of a single small subgroup, the little group. Executing that program orbit by orbit (Section 3.7) yields the chapter's thesis: a relativistic particle is a unitary irreducible representation of the Poincaré group, one for each $(m > 0, s)$ and each massless helicity h—and the massless case, with its non-compact little group, forces gauge redundancy upon any covariant description of the photon. The cargo is then handed forward to the threads: the scalar of ϕ^4 theory, the electron of QED, and the photon and gluon of QED and Yang–Mills theory each leave this chapter knowing exactly what they are, ready to be quantized in Part III.

3.1 The Lorentz group: spacetime symmetry and its components

The chapter's guiding question — *what can a relativistic particle be?* — becomes a precise mathematical problem the moment we accept its premise: the laws of physics must look the same to all inertial observers, and the transformations relating those observers form a group. If a particle, or a field, is to be a physical object at all, the way it changes under a change of observer cannot be arbitrary; it must furnish a representation of that group, in the exact sense built abstractly in Chapter 2. The entire chapter is the determination of those representations. Before we can classify the representations of a group, however, we must know the group itself — not merely its multiplication law but its global shape: how many disconnected pieces it has, which piece is the one continuously connected to "no transformation at all," whether that piece is compact, and what its loops

look like. Each of these topological facts will turn out to control a piece of the physics — the existence of parity and time reversal as separate operations, the impossibility of finite-dimensional *unitary* representations, the existence of half-integer spin. This first section establishes those facts. We define the group, isolate the component whose representations we will spend the chapter classifying, and read off the topology that drives everything later.

We work throughout in natural units $\hbar = c = 1$ and with the mostly-minus Minkowski metric

$$\eta_{\mu\nu} = \eta^{\mu\nu} = \mathrm{diag}(+1, -1, -1, -1), \tag{3.1}$$

the particle-physics convention fixed in Chapter A and used in every chapter of this book where a sign matters. Greek indices $\mu, \nu, \ldots$ run over $0, 1, 2, 3$; Latin indices $i, j, \ldots$ run over the spatial values $1, 2, 3$; the Einstein summation convention is in force, and indices are raised and lowered with η. A point of spacetime is $x^\mu = (x^0, \mathbf{x}) = (t, \mathbf{x})$.

3.1.1 Minkowski space and the defining relation

Special relativity asserts that the geometry of spacetime is encoded not in a notion of separate spatial distance and elapsed time — both of which are observer-dependent — but in a single invariant, the spacetime interval between two events. For events separated by Δx^μ this interval is the quadratic form

$$\Delta s^2 \;=\; \eta_{\mu\nu}\,\Delta x^\mu \Delta x^\nu \;=\; (\Delta x^0)^2 - |\Delta \mathbf{x}|^2 \,. \tag{3.2}$$

Its sign classifies the separation as timelike ($\Delta s^2 > 0$), spacelike ($\Delta s^2 < 0$), or null ($\Delta s^2 = 0$), and these classifications are physical: they decide whether one event can causally influence another. The principle of relativity, in its kinematic form, is the statement that the admissible changes of inertial frame are exactly the coordinate transformations that leave Eq. (3.2) invariant. We restrict attention here to the *linear, homogeneous* such transformations — those fixing the origin; adjoining the spacetime translations to obtain the full Poincaré group is the business of a later section. A linear change of coordinates is a matrix Λ acting by

$$x^\mu \;\longmapsto\; x'^\mu = \Lambda^\mu{}_\nu \, x^\nu . \tag{3.3}$$

Definition 3.1 (Lorentz transformation and the Lorentz group)**.** A *Lorentz transformation* is a real 4×4 matrix $\Lambda = (\Lambda^\mu{}_\nu)$ that leaves the Minkowski interval Eq. (3.2) invariant, i.e. such that $\eta_{\mu\nu}\, x'^\mu x'^\nu = \eta_{\rho\sigma}\, x^\rho x^\sigma$ for every $x^\mu \in \mathbb{R}^4$. The set of all such matrices is the *Lorentz group* $\mathrm{O}(1,3)$.

The defining property translates into a single algebraic relation. Substituting Eq. (3.3) into the invariance condition gives $\eta_{\mu\nu}\Lambda^\mu{}_\rho \Lambda^\nu{}_\sigma \, x^\rho x^\sigma = \eta_{\rho\sigma}\, x^\rho x^\sigma$ for all

x. Because the quadratic form on each side is symmetric in ρ, σ and must agree for arbitrary x^ρ, the coefficient tensors must be equal:

$$\eta_{\mu\nu}\,\Lambda^{\mu}{}_{\rho}\,\Lambda^{\nu}{}_{\sigma} \;=\; \eta_{\rho\sigma}. \tag{3.4}$$

In matrix notation, writing Λ^{T} for the transpose $(\Lambda^{\mathsf{T}})_{\rho}{}^{\mu} = \Lambda^{\mu}{}_{\rho}$, this is the compact statement

$$\boxed{\Lambda^{\mathsf{T}}\,\eta\,\Lambda \;=\; \eta}\,. \tag{3.5}$$

Equation (3.5) is the defining relation of the Lorentz group, the exact analogue of the relation $R^{\mathsf{T}}\mathbf{1}\,R = \mathbf{1}$ defining the orthogonal group $\mathrm{O}(3)$, with the Euclidean metric $\mathbf{1}$ replaced by the Lorentzian η. Everything in this section is squeezed out of it.

That $\mathrm{O}(1,3)$ is a group is immediate from Eq. (3.5) and the general criterion for matrix groups in Chapter 2. The identity $\mathbf{1}$ satisfies it trivially. If Λ_1, Λ_2 both satisfy it, so does the product, since $(\Lambda_1\Lambda_2)^{\mathsf{T}}\eta(\Lambda_1\Lambda_2) = \Lambda_2^{\mathsf{T}}(\Lambda_1^{\mathsf{T}}\eta\,\Lambda_1)\Lambda_2 = \Lambda_2^{\mathsf{T}}\eta\,\Lambda_2 = \eta$. Taking determinants in Eq. (3.5) (anticipating the next subsection) shows $\det\Lambda \neq 0$, so Λ is invertible; and multiplying $\Lambda^{\mathsf{T}}\eta\Lambda = \eta$ on the left by $(\Lambda^{\mathsf{T}})^{-1}$ and on the right by Λ^{-1} gives $\eta = (\Lambda^{-1})^{\mathsf{T}}\eta\,\Lambda^{-1}$, so $\Lambda^{-1} \in \mathrm{O}(1,3)$ as well. Moreover $\mathrm{O}(1,3)$ is closed as a subset of the 16-dimensional space of real 4×4 matrices — it is the common zero set of the polynomial equations Eq. (3.4) — and the group operations are polynomial in the entries, so $\mathrm{O}(1,3)$ is a matrix Lie group in the sense of Chapter 2. What we do not yet know, and what the rest of the section is about, is its *global* structure.

3.1.2 Two invariant signs: the determinant and the time component

The defining relation forces two numbers built from Λ to take only the values ± 1 and to be "locally constant" across the group. These two discrete invariants are what break $\mathrm{O}(1,3)$ into pieces.

Proposition 3.2 (The two discrete invariants)**.** *Every* $\Lambda \in \mathrm{O}(1,3)$ *satisfies*

$$\det\Lambda = \pm 1, \tag{3.6}$$

$$(\Lambda^0{}_0)^2 = 1 + \sum_{i=1}^{3}(\Lambda^i{}_0)^2 \;\geq\; 1, \qquad \textit{so}\ \ \left|\Lambda^0{}_0\right| \geq 1. \tag{3.7}$$

Consequently $\det\Lambda \in \{+1,-1\}$ *and* $\Lambda^0{}_0 \in [1,\infty)\cup(-\infty,-1]$*; in particular* $\Lambda^0{}_0$ *never takes a value in the open interval* $(-1,1)$*.*

Proof. For Eq. (3.6), take the determinant of both sides of Eq. (3.5). Using $\det(ABC) = \det A\det B\det C$, $\det(\Lambda^{\mathsf{T}}) = \det\Lambda$, and $\det\eta = -1$,

$$(\det\Lambda)^2\,\det\eta = \det\eta \;\Longrightarrow\; (\det\Lambda)^2(-1) = -1 \;\Longrightarrow\; (\det\Lambda)^2 = 1, \tag{3.8}$$

hence $\det\Lambda = \pm 1$. In particular $\det\Lambda \neq 0$, justifying the invertibility claimed above.

For Eq. (3.7), evaluate the component form Eq. (3.4) at $\rho = \sigma = 0$. The right side is $\eta_{00} = +1$, and the left side is

$$\eta_{\mu\nu}\,\Lambda^{\mu}{}_{0}\,\Lambda^{\nu}{}_{0} = (\Lambda^{0}{}_{0})^{2} - \sum_{i=1}^{3}(\Lambda^{i}{}_{0})^{2}, \tag{3.9}$$

where the relative minus signs come from the spatial entries of η. Setting the two equal and rearranging gives exactly Eq. (3.7). The sum of squares on the right is ≥ 0, so $(\Lambda^{0}{}_{0})^{2} \geq 1$ and $|\Lambda^{0}{}_{0}| \geq 1$. □

The geometric content of Eq. (3.7) is worth naming. The first column $\Lambda^{\mu}{}_{0}$ of Λ is the image of the unit time vector $e_0 = (1, 0, 0, 0)$, i.e. the velocity-four-vector of the transformed time axis. The relation says this image is a *unit timelike* vector ($\eta_{\mu\nu}\Lambda^{\mu}{}_{0}\Lambda^{\nu}{}_{0} = 1 > 0$); a Lorentz transformation cannot tilt the time axis so far that it becomes spacelike. The two sheets $\Lambda^{0}{}_{0} \geq 1$ and $\Lambda^{0}{}_{0} \leq -1$ correspond to the transformed time axis pointing into the future or into the past light cone respectively. This is the kinematic root of the arrow of time being a discrete, not continuous, attribute of a Lorentz transformation.

We now record the names attached to the two signs.

Definition 3.3 (Proper/improper, orthochronous/non-orthochronous)**.** A Lorentz transformation Λ is called *proper* if $\det\Lambda = +1$ and *improper* if $\det\Lambda = -1$; it is called *orthochronous* if $\Lambda^{0}{}_{0} \geq 1$ and *non-orthochronous* if $\Lambda^{0}{}_{0} \leq -1$. The four sign combinations partition $\mathrm{O}(1,3)$ into four disjoint subsets,

$$L^{\uparrow}_{+}, \quad L^{\uparrow}_{-}, \quad L^{\downarrow}_{+}, \quad L^{\downarrow}_{-}, \tag{3.10}$$

where the subscript records $\mathrm{sgn}(\det\Lambda)$ and the arrow records $\mathrm{sgn}(\Lambda^{0}{}_{0})$ (up for orthochronous, down for non-orthochronous). The *proper orthochronous* subset is denoted $L^{\uparrow}_{+}$, also written $\mathrm{SO}(1,3)^{+}$.

These two signs are not merely labels assigned to a static set; their decisive feature is that the orthochronous sign is *multiplicative*, exactly as the determinant is. This is the technical heart of the section.

Lemma 3.4 (Conservation of the time sign under composition)**.** *For any* $\Lambda, \Lambda' \in \mathrm{O}(1,3)$*,*

$$\mathrm{sgn}\left((\Lambda\Lambda')^{0}{}_{0}\right) = \mathrm{sgn}(\Lambda^{0}{}_{0})\ \mathrm{sgn}(\Lambda'^{0}{}_{0}). \tag{3.11}$$

Moreover $(\Lambda^{-1})^{0}{}_{0} = \Lambda^{0}{}_{0}$*, so the inverse has the same time sign. Together with the multiplicativity of the determinant, this makes the two signs a homomorphism* $\mathrm{O}(1,3) \to \{\pm 1\} \times \{\pm 1\}$.

Proof. Write the matrix product in components:

$$(\Lambda\Lambda')^0{}_0 = \Lambda^0{}_\mu\,\Lambda'^\mu{}_0 = \Lambda^0{}_0\,\Lambda'^0{}_0 + \sum_{i=1}^{3}\Lambda^0{}_i\,\Lambda'^i{}_0. \tag{3.12}$$

The claim is that the cross term $\sum_i \Lambda^0{}_i\Lambda'^i{}_0$ is never large enough to overturn the sign of the leading term $\Lambda^0{}_0\Lambda'^0{}_0$. Introduce the two spatial vectors $\mathbf{a} = (\Lambda^0{}_1, \Lambda^0{}_2, \Lambda^0{}_3)$ and $\mathbf{b} = (\Lambda'^1{}_0, \Lambda'^2{}_0, \Lambda'^3{}_0)$, so that the cross term is the Euclidean dot product $\mathbf{a}\cdot\mathbf{b}$.

We need the Euclidean norms of $\mathbf{a}$ and $\mathbf{b}$. For $\mathbf{b}$, Eq. (3.7) applied to Λ' gives directly $|\mathbf{b}|^2 = \sum_i(\Lambda'^i{}_0)^2 = (\Lambda'^0{}_0)^2 - 1$. For $\mathbf{a}$ we need the analogue of Eq. (3.7) for the top *row* of Λ. This comes from the companion relation $\Lambda\,\eta\,\Lambda^{\mathsf T} = \eta$, which follows from Eq. (3.5): since $\Lambda^{\mathsf T}\eta\Lambda = \eta$ and $\eta^2 = \mathbf{1}$, we have $\Lambda^{-1} = \eta\,\Lambda^{\mathsf T}\eta$, and inserting this into $\Lambda\Lambda^{-1} = \mathbf{1}$ yields $\Lambda\,\eta\,\Lambda^{\mathsf T}\eta = \mathbf{1}$, i.e. $\Lambda\,\eta\,\Lambda^{\mathsf T} = \eta$. Its $(0,0)$ component reads $(\Lambda^0{}_0)^2 - \sum_i(\Lambda^0{}_i)^2 = 1$, so $|\mathbf{a}|^2 = (\Lambda^0{}_0)^2 - 1$.

By the Cauchy–Schwarz inequality $|\mathbf{a}\cdot\mathbf{b}| \le |\mathbf{a}|\;|\mathbf{b}| = \sqrt{\big((\Lambda^0{}_0)^2-1\big)\big((\Lambda'^0{}_0)^2-1\big)}$. Abbreviating $u = |\Lambda^0{}_0| \ge 1$ and $v = \left|\Lambda'^0{}_0\right| \ge 1$, the radicand is $(u^2-1)(v^2-1) = u^2v^2 - (u^2+v^2-1)$. Since $u^2, v^2 \ge 1$ we have $u^2+v^2-1 \ge 1 > 0$, hence $(u^2-1)(v^2-1) < u^2v^2$ and therefore

$$|\mathbf{a}\cdot\mathbf{b}| \;<\; uv \;=\; \left|\Lambda^0{}_0\,\Lambda'^0{}_0\right|. \tag{3.13}$$

The leading term in Eq. (3.12) therefore strictly dominates the cross term in magnitude, so the sum has the same sign as $\Lambda^0{}_0\Lambda'^0{}_0$, which is Eq. (3.11).

For the inverse, recall $\Lambda^{-1} = \eta\,\Lambda^{\mathsf T}\eta$. Because η is diagonal, the $(0,0)$ entry of the right side is $\eta_{00}(\Lambda^{\mathsf T})^0{}_0\eta_{00} = (+1)\,\Lambda^0{}_0\,(+1) = \Lambda^0{}_0$, so $(\Lambda^{-1})^0{}_0 = \Lambda^0{}_0$ as claimed. The determinant is multiplicative on any group of matrices and equal on Λ and Λ^{-1} up to the value ±1 here, so the pair $\big(\operatorname{sgn}\det\Lambda,\ \operatorname{sgn}\Lambda^0{}_0\big)$ is a group homomorphism into $\{\pm1\}^2$. □

Theorem 3.4 has an immediate structural payoff. The two signs being a homomorphism into $\{\pm1\}^2$ means the preimage of the identity element $(+1,+1)$ — namely $L_+^\uparrow = \mathrm{SO}(1,3)^+$, the proper orthochronous set — is a *subgroup*, indeed a normal subgroup, and the other three sets are its cosets.

Proposition 3.5 ($\mathrm{SO}(1,3)^+$ is a normal subgroup of index four)**.** *$L_+^\uparrow = \mathrm{SO}(1,3)^+$ is a normal subgroup of $\mathrm{O}(1,3)$, and the four sets Eq. (3.10) are its four cosets. The quotient $\mathrm{O}(1,3)/\mathrm{SO}(1,3)^+$ is the Klein four-group $\mathbb{Z}_2\times\mathbb{Z}_2$.*

Proof. $\mathrm{SO}(1,3)^+$ is the kernel of the homomorphism $\Phi : \mathrm{O}(1,3) \to \{\pm1\}\times\{\pm1\}$, $\Phi(\Lambda) = (\det\Lambda, \operatorname{sgn}\Lambda^0{}_0)$, of Theorem 3.4, hence a normal subgroup. By the first isomorphism theorem (Chapter 2) the cosets are the fibres of Φ, which are precisely the four sign-sectors, and $\mathrm{O}(1,3)/\mathrm{SO}(1,3)^+ \cong \operatorname{im}\Phi$. That the image is all of $\{\pm1\}^2$ — so the quotient is $\mathbb{Z}_2\times\mathbb{Z}_2$ and there are genuinely four nonempty sectors — is witnessed by the four representatives in Eq. (3.14) below. □

3.1.3 The discrete operations and the four components

The cosets are reached from $\mathrm{SO}(1,3)^+$ by two distinguished discrete transformations, which flip the two signs independently. *Parity* (space inversion) and *time reversal* are the matrices

$$P = \mathrm{diag}(+1,-1,-1,-1) = \eta, \qquad T = \mathrm{diag}(-1,+1,+1,+1) = -\eta, \tag{3.14}$$

together with their product $PT = -\mathbf{1} = \mathrm{diag}(-1,-1,-1,-1)$. Each manifestly satisfies Eq. (3.5) (for $P = \eta$, $P^{\mathsf{T}}\eta P = \eta\,\eta\,\eta = \eta$ since $\eta^2 = \mathbf{1}$; likewise for $T = -\eta$ and $PT = -\mathbf{1}$), so all three are genuine Lorentz transformations. Their invariants are read straight off the diagonals:

	det	$\Lambda^0{}_0$	sector
$\mathbf{1}$	$+1$	$+1$	$L^{\uparrow}_{+} = \mathrm{SO}(1,3)^+$
P	-1	$+1$	$L^{\uparrow}_{-}$
T	-1	-1	$L^{\downarrow}_{-}$
PT	$+1$	-1	$L^{\downarrow}_{+}$

(3.15)

Thus $\{\mathbf{1}, P, T, PT\}$ is a set of coset representatives, one in each sector, and every Lorentz transformation factors uniquely as one of these times an element of $\mathrm{SO}(1,3)^+$. The names matter physically: P and T are the discrete spacetime operations whose action on every field of the book — scalar, spinor, vector — is inherited from Eq. (3.14), and whose possible *violation* by the weak interaction is one of the central facts of the Standard Model. Here they enter purely as the topological connectors between the components, but we fix the conventions Eq. (3.14) once and for all, as flagged in the chapter program; all three benchmark theories inherit them.

We can now state precisely how the four sectors sit inside the group as a topological space. The key point is that the two sign invariants are not only locally constant algebraically; they are *continuous* functions on $\mathrm{O}(1,3)$, and a continuous function valued in $\{\pm 1\}$ cannot change without passing through forbidden values.

Theorem 3.6 (Four disconnected components)**.** *The Lorentz group* $\mathrm{O}(1,3)$ *has exactly four connected components, the four sets Eq. (3.10). The identity component is* $\mathrm{SO}(1,3)^+$*, and the other three are obtained from it by left multiplication by* P*,* T*, and* PT *respectively.*

Proof. The four sectors are mutually separated. The map $\Lambda \mapsto \det\Lambda$ is a polynomial in the entries of Λ, hence continuous on $\mathrm{O}(1,3)$, and takes only the values ± 1 by Eq. (3.6). The map $\Lambda \mapsto \Lambda^0{}_0$ is the projection onto a single matrix entry, also continuous, and by Eq. (3.7) it never takes a value in the open interval $(-1,1)$; therefore $\Lambda \mapsto \mathrm{sgn}\,\Lambda^0{}_0$ is continuous on $\mathrm{O}(1,3)$ (its only possible discontinuity would be at a zero crossing, which is excluded). A continuous map into the

discrete two-point set $\{\pm 1\}$ is constant on each connected component. Hence both signs are constant on each component, so each component lies entirely within one of the four sectors; equivalently, no continuous path in $\mathrm{O}(1,3)$ can join two different sectors. The four sectors are therefore unions of components, pairwise disjoint and open-and-closed in $\mathrm{O}(1,3)$.

Each sector is itself connected. It suffices to prove this for $\mathrm{SO}(1,3)^+$, since left multiplication by the fixed invertible matrix P, T, or PT is a homeomorphism of $\mathrm{O}(1,3)$ carrying $\mathrm{SO}(1,3)^+$ onto the other three sectors and preserving connectedness; this is established as Theorem 3.7 below. Granting it, each sector is connected, so the four sectors are exactly the four connected components, and the one containing $\mathbf{1}$ is $\mathrm{SO}(1,3)^+$. □

It remains to prove that $\mathrm{SO}(1,3)^+$ is connected. We do this with an argument that will also be the prototype for the Wigner classification later in the chapter: a group that acts transitively on a connected space, with connected stabilizer, is itself connected.

Proposition 3.7 ($\mathrm{SO}(1,3)^+$ is path-connected)**.** *$\mathrm{SO}(1,3)^+$ is path-connected; in particular it is the connected component of the identity in $\mathrm{O}(1,3)$.*

Proof. Consider the action of $\mathrm{SO}(1,3)^+$ on the *forward unit hyperboloid*

$$H^+ = \{\, p^\mu \in \mathbb{R}^4 : \eta_{\mu\nu} p^\mu p^\nu = 1,\ p^0 > 0 \,\}, \tag{3.16}$$

the upper sheet of the two-sheeted hyperboloid of unit future-pointing timelike vectors (H^+ is the set of four-velocities, and after rescaling the mass shell of a particle of unit mass). As a graph $p^0 = \sqrt{1+|\mathbf{p}|^2}$ over $\mathbf{p} \in \mathbb{R}^3$, H^+ is homeomorphic to $\mathbb{R}^3$, hence connected.

The action is transitive. Take any $p \in H^+$. We exhibit a proper orthochronous Λ with $\Lambda\, e_0 = p$, where $e_0 = (1,0,0,0)$. If $\mathbf{p} = 0$ then $p = e_0$ and $\Lambda = \mathbf{1}$ works. Otherwise write $|\mathbf{p}| = \sinh\zeta$ with $\zeta > 0$ (so $p^0 = \cosh\zeta$, consistent with $p \in H^+$), let $\hat{\mathbf{n}} = \mathbf{p}/|\mathbf{p}|$ be the unit spatial direction, and define the boost of rapidity ζ along $\hat{\mathbf{n}}$,

$$B(\zeta\hat{\mathbf{n}})^0{}_0 = \cosh\zeta, \quad B^0{}_i = B^i{}_0 = \hat{n}_i \sinh\zeta, \quad B^i{}_j = \delta_{ij} + (\cosh\zeta - 1)\hat{n}_i\hat{n}_j. \tag{3.17}$$

A direct check (carried out for the special case $\hat{\mathbf{n}} = \hat{\mathbf{x}}$ in Theorem 3.8, and reducing to it after a spatial rotation) shows $B(\zeta\hat{\mathbf{n}}) \in \mathrm{SO}(1,3)^+$ and $B(\zeta\hat{\mathbf{n}})\, e_0 = (\cosh\zeta, \sinh\zeta\, \hat{\mathbf{n}}) = p$. Hence the action is transitive.

The stabilizer of e_0 is connected. If $\Lambda \in \mathrm{SO}(1,3)^+$ fixes e_0, then its first column is $\Lambda^\mu{}_0 = \delta^\mu_0$. The defining relation $\Lambda\eta\Lambda^{\mathsf{T}} = \eta$ at $(0,i)$ then forces $\Lambda^0{}_i = 0$ as well, so Λ is block diagonal, $\Lambda = \mathrm{diag}(1, R)$ with R a real 3×3 matrix. The remaining content of the defining relation is $R^{\mathsf{T}}R = \mathbf{1}$, i.e. $R \in \mathrm{O}(3)$, and $\det\Lambda = \det R = +1$ selects $R \in \mathrm{SO}(3)$. The stabilizer is therefore a copy of the

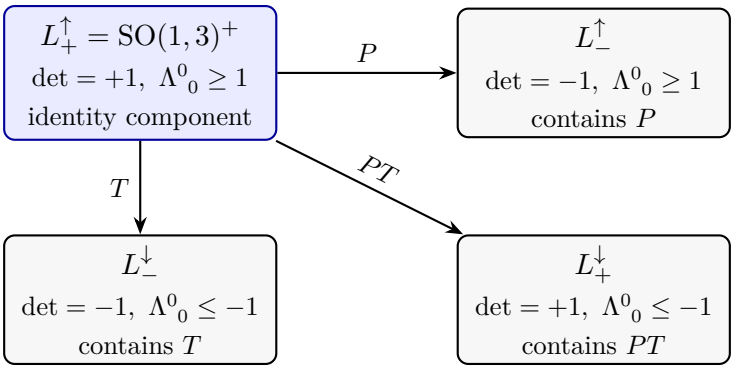


Figure 3.1: The four connected components of the Lorentz group $\mathrm{O}(1,3)$, labelled by the two invariant signs $\det\Lambda = \pm 1$ and $\operatorname{sgn}\Lambda^0{}_0 = \pm 1$. Only the proper orthochronous component $\mathrm{SO}(1,3)^+$ contains the identity and is a subgroup; the discrete operations $P = \mathrm{diag}(+,-,-,-)$, $T = \mathrm{diag}(-,+,+,+)$, and $PT = -\mathbf{1}$ map it onto the other three. The representation theory of this chapter is the representation theory of $\mathrm{SO}(1,3)^+$; P and T are imposed afterwards as discrete symmetries.

rotation group $\mathrm{SO}(3)$, which is path-connected (Chapter 2: every rotation is exp of an antisymmetric generator, and the segment $s \mapsto \exp(s\,\omega)$, $s \in [0,1]$, joins it to the identity).

Connectedness of the total group. The orbit map $\pi : \mathrm{SO}(1,3)^+ \to H^+$, $\pi(\Lambda) = \Lambda e_0$, identifies H^+ with the homogeneous space $\mathrm{SO}(1,3)^+/\mathrm{SO}(3)$ and, for a closed subgroup of a Lie group, is a locally trivial fibre bundle (Chapter 2); in particular it has the path-lifting property. Now let $\Lambda \in \mathrm{SO}(1,3)^+$ be arbitrary. Since H^+ is path-connected, choose a path γ in H^+ from $\pi(\Lambda) = \Lambda e_0$ to $\pi(\mathbf{1}) = e_0$; lift it through π to a path in $\mathrm{SO}(1,3)^+$ starting at Λ and ending at some h with $\pi(h) = e_0$, i.e. $h \in \mathrm{SO}(3)$. Since $\mathrm{SO}(3)$ is path-connected, join h to $\mathbf{1}$ by a path inside $\mathrm{SO}(3) \subset \mathrm{SO}(1,3)^+$. Concatenating, Λ is joined to $\mathbf{1}$ by a path in $\mathrm{SO}(1,3)^+$. As Λ was arbitrary, $\mathrm{SO}(1,3)^+$ is path-connected. □

Theorem 3.7 completes the proof of Theorem 3.6: $\mathrm{O}(1,3)$ has exactly four connected components, the proper orthochronous one $\mathrm{SO}(1,3)^+$ is the identity component, and P, T, PT are the discrete operations that connect it to the other three. The geometry is summarized in Fig. 3.1.

There is a strategic conclusion to draw before we go on. Because P and T are disconnected from the identity, no continuous (let alone infinitesimal) symmetry argument can produce them; they are extra, optional structure. The representations we can build by exponentiating infinitesimal generators — the program of the next sections — are representations of the *identity component* $\mathrm{SO}(1,3)^+$ alone. Whether a given field or particle also carries a representation of P or T is a separate question, answered theory by theory (the neutrino's

answer differs from the electron's). This is why we single out $\mathrm{SO}(1,3)^+$ as "the connected piece whose representations we seek": it is the largest part of the symmetry group reachable from the identity, and hence the part forced on us by relativity together with the requirement of a continuous symmetry.

3.1.4 A worked transformation: boosts, rotations, and rapidity

Before extracting the topology of $\mathrm{SO}(1,3)^+$ we make the abstract definition concrete by exhibiting its two basic kinds of element and verifying the defining relation by hand. This also pins down the parametrization that will make the non-compactness transparent.

Worked Example 3.8 (A boost and a rotation, checked against $\Lambda^{\mathsf{T}}\eta\Lambda = \eta$)**.**

The boost. The standard boost along the x^1-axis with rapidity $\zeta \in \mathbb{R}$ is

$$B_1(\zeta) = \begin{pmatrix} \cosh\zeta & \sinh\zeta & 0 & 0 \\ \sinh\zeta & \cosh\zeta & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}. \tag{3.18}$$

The rapidity is related to the relative velocity $\beta = v/c$ and Lorentz factor $\gamma = (1-\beta^2)^{-1/2}$ by $\cosh\zeta = \gamma$, $\sinh\zeta = \gamma\beta$, $\tanh\zeta = \beta$; the familiar form of the boost is recovered by this substitution. We verify $B_1^{\mathsf{T}}\eta B_1 = \eta$. Only the upper-left 2×2 block is nontrivial, so it suffices to check that block. With $\eta_2 = \mathrm{diag}(+1,-1)$ and $b = \left(\begin{smallmatrix} \cosh\zeta & \sinh\zeta \\ \sinh\zeta & \cosh\zeta \end{smallmatrix}\right)$ (which is symmetric, $b^{\mathsf{T}} = b$),

$$b^{\mathsf{T}}\eta_2 b = b\,\eta_2\,b = \begin{pmatrix} \cosh\zeta & \sinh\zeta \\ \sinh\zeta & \cosh\zeta \end{pmatrix}\begin{pmatrix} \cosh\zeta & \sinh\zeta \\ -\sinh\zeta & -\cosh\zeta \end{pmatrix} = \begin{pmatrix} \cosh^2\zeta - \sinh^2\zeta & 0 \\ 0 & \sinh^2\zeta - \cosh^2\zeta \end{pmatrix} \tag{3.19}$$

using $\cosh^2\zeta - \sinh^2\zeta = 1$. Thus $B_1(\zeta) \in \mathrm{O}(1,3)$. Its invariants are $\det B_1 = \cosh^2\zeta - \sinh^2\zeta = 1$ and ${B_1}^0{}_0 = \cosh\zeta \geq 1$, so $B_1(\zeta) \in \mathrm{SO}(1,3)^+$ for every ζ, as the topology demands. Acting on the time axis, $B_1(\zeta)\,e_0 = (\cosh\zeta, \sinh\zeta, 0, 0)$, a point of the hyperboloid H^+ of Eq. (3.16), confirming the construction used in Theorem 3.7.

Rapidity adds. Composing two boosts along the same axis,

$$B_1(\zeta_1)B_1(\zeta_2)^0{}_0 = \cosh\zeta_1\cosh\zeta_2 + \sinh\zeta_1\sinh\zeta_2 = \cosh(\zeta_1+\zeta_2), \tag{3.20}$$

and similarly for the other entries, so $B_1(\zeta_1)B_1(\zeta_2) = B_1(\zeta_1+\zeta_2)$. *Collinear boosts add their rapidities*; the map $\zeta \mapsto B_1(\zeta)$ is a group isomorphism from $(\mathbb{R},+)$ onto the one-parameter subgroup of x^1-boosts. The nonlinear velocity-addition law $\beta = (\beta_1+\beta_2)/(1+\beta_1\beta_2)$ is just $\tanh(\zeta_1+\zeta_2)$ rewritten, and $\operatorname{sgn} B^0{}_0 = +1$ is preserved under the addition, in concrete agreement with Theorem 3.4.

The rotation. A rotation by angle θ about the x^3-axis is

$$R_3(\theta) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos\theta & -\sin\theta & 0 \\ 0 & \sin\theta & \cos\theta & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \tag{3.21}$$

which leaves x^0 untouched and rotates (x^1, x^2). Here ${R_3}^0{}_0 = 1$ and $\det R_3 = +1$, so again $R_3(\theta) \in \mathrm{SO}(1,3)^+$, and the defining relation reduces to the Euclidean orthogonality of the spatial block, $\left(\begin{smallmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{smallmatrix}\right)$, which is manifest. Unlike the boost, the rotation is *periodic*: $R_3(\theta)$ has det and ${\Lambda^0}_0$ bounded, all entries lying in $[-1, 1]$, and $R_3(\theta + 2\pi) = R_3(\theta)$. The contrast between the unbounded $\cosh\zeta$ of the boost and the bounded $\cos\theta$ of the rotation is precisely the contrast between the non-compact and compact directions of the group, to which we now turn.

3.1.5 Non-compactness

The boost of Theorem 3.8 already contains the decisive topological fact that separates the Lorentz group from the rotation group and forces the entire representation-theoretic story that follows.

Proposition 3.9 ($\mathrm{SO}(1,3)^+$ is non-compact)**.** *The group* $\mathrm{SO}(1,3)^+$ *is not compact.*

Proof. View $\mathrm{SO}(1,3)^+$ as a subset of the space $M_4(\mathbb{R}) \cong \mathbb{R}^{16}$ of real 4×4 matrices with its usual topology. By the Heine–Borel theorem a subset of a finite-dimensional Euclidean space is compact if and only if it is closed and bounded. The one-parameter family of boosts $\{B_1(\zeta) : \zeta \in \mathbb{R}\} \subset \mathrm{SO}(1,3)^+$ from Eq. (3.18) has matrix entries $\cosh\zeta$ and $\sinh\zeta$, which tend to $+\infty$ as $\zeta \to \infty$. Hence the operator norm of $B_1(\zeta)$ is unbounded over the group, so $\mathrm{SO}(1,3)^+$ is an unbounded subset of $\mathbb{R}^{16}$ and therefore not compact. □

The physical reading is that the boost parameter — the rapidity ζ — ranges over the entire real line $\mathbb{R}$, with no largest value, reflecting the fact that one can boost to a frame of arbitrarily large relative velocity (approaching but never reaching c, since $\beta = \tanh\zeta \to 1$). The rotations, by contrast, form a compact subgroup $\mathrm{SO}(3)$ with the angle running over a circle. The Lorentz group is thus a product, in a sense made precise by the polar decomposition below, of a compact rotational factor and a non-compact boost factor.

This single fact will reverberate through the rest of the chapter, so it is worth saying now why it matters, even though the payoff comes later.

Physical Insight: why non-compactness forbids finite-dimensional unitary representations

A continuous unitary representation of a non-compact group on a *finite*-dimensional Hilbert space cannot be faithful and nontrivial on the non-compact directions. The reason is structural: the boost generators, being non-compact, must be represented by operators whose one-parameter groups $e^{i\zeta K}$ are unbounded unless K is represented trivially, whereas a unitary operator on a finite-dimensional space has all eigenvalues of modulus one and is therefore bounded. Concretely, the finite-dimensional representations we construct in Section 3.2 and the sections following it will represent boosts by Hermitian, *non*-unitary matrices like $e^{\zeta K}$ with real exponent — exactly right for transforming *field components*, which need not have a Lorentz-invariant inner product. The unitary representations, which describe *particle states* and must preserve probabilities, are forced to be infinite-dimensional; building them is the content of Wigner's classification later in the chapter. The split between "fields" (finite-dimensional, non-unitary) and "states" (infinite-dimensional, unitary) traces directly to the non-compactness proved here.

3.1.6 The fundamental group: a first look at the double cover

The last topological invariant we need is the fundamental group $\pi_1(\mathrm{SO}(1,3)^+)$, which counts the inequivalent classes of loops based at the identity. Its value is the single most consequential topological fact about the Lorentz group, because a nontrivial π_1 is exactly what permits *double-valued* representations — spinors — and hence half-integer spin.

Theorem 3.10 (Fundamental group of the Lorentz group)**.** $\mathrm{SO}(1,3)^+$ *is connected but not simply connected; its fundamental group is*

$$\pi_1(\mathrm{SO}(1,3)^+) = \mathbb{Z}_2. \tag{3.22}$$

We give here the topological reduction that makes the result transparent and computes it modulo the single input $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$ established in Chapter 2; the *constructive* proof, which exhibits the connected double cover explicitly as the group $\mathrm{SL}(2,\mathbb{C})$ and is what we actually use to build spinors, is given in Section 3.4.

Proof via deformation retraction onto $\mathrm{SO}(3)$. The mechanism is the polar (Cartan) decomposition of the Lorentz group: every $\Lambda \in \mathrm{SO}(1,3)^+$ factors *uniquely* as a pure boost times a rotation,

$$\Lambda = B\,R, \qquad B = e^{\boldsymbol{\zeta}\cdot\mathbf{K}} \text{ (symmetric, positive)}, \quad R \in \mathrm{SO}(3) \text{ (block-diagonal)}, \tag{3.23}$$

where $\boldsymbol{\zeta} \in \mathbb{R}^3$ is the boost rapidity-vector and $\mathbf{K}$ are the boost generators constructed in Section 3.2. The decomposition is the Lorentzian analogue of writing an invertible matrix as positive-symmetric times orthogonal; existence and uniqueness follow from the polar decomposition of the restriction of Λ to its action on H^+, with the boost factor recovered as the unique positive square root. The factorization gives a homeomorphism

$$\mathrm{SO}(1,3)^+ \;\cong\; \mathbb{R}^3 \times \mathrm{SO}(3) \tag{3.24}$$

as topological spaces (*not* as groups): the boost factor is parametrized by $\boldsymbol{\zeta} \in \mathbb{R}^3$, which is contractible, and the rotation factor by SO(3). Contracting the Euclidean $\mathbb{R}^3$ to a point — explicitly, the deformation $r_s(\boldsymbol{\zeta}, R) = (s\,\boldsymbol{\zeta}, R)$ for s running from 1 to 0 — is a deformation retraction of $\mathrm{SO}(1,3)^+$ onto its maximal compact subgroup SO(3). A deformation retraction preserves the fundamental group, so

$$\pi_1(\mathrm{SO}(1,3)^+) \;\cong\; \pi_1(\mathrm{SO}(3)) \;=\; \mathbb{Z}_2, \tag{3.25}$$

the last equality being the result, proved in Chapter 2, that a 2π rotation is a noncontractible loop in SO(3) while a 4π rotation is contractible (the "belt trick" / plate trick). This establishes Eq. (3.22). □

The factor of $\mathbb{R}^3$ in Eq. (3.24) confirms once more the non-compactness of Theorem 3.9: $\mathrm{SO}(1,3)^+$ retracts onto a compact core SO(3) but is itself the product of that core with three unbounded boost directions. And the surviving $\mathbb{Z}_2$ in π_1 is the seed of everything spinorial. A group with $\pi_1 = \mathbb{Z}_2$ possesses a unique connected double cover, and the genuine, single-valued representations of that double cover include extra "half-integer" ones that descend only to *projective* (double-valued) representations of $\mathrm{SO}(1,3)^+$ itself. Those are the spinor representations; the electron of QED is one of them. We will identify the double cover concretely as $\mathrm{SL}(2,\mathbb{C})$, and use it as the actual engine of the representation theory, in Section 3.4.

We have now isolated the object whose representations are the relativistic fields and particles: the proper orthochronous Lorentz group $\mathrm{SO}(1,3)^+$, the identity component of O(1, 3), a non-compact, doubly-connected matrix Lie group, with the discrete operations P and T standing outside it as separate symmetries to be imposed by hand. Connectedness is what now lets us trade the group for its infinitesimal version: every element of $\mathrm{SO}(1,3)^+$ is reached from the identity along a continuous path, so the group is generated by the tangent vectors to such paths at the identity. The next section takes that derivative — linearizing the defining relation $\Lambda^{\mathsf{T}}\eta\Lambda = \eta$ at $\Lambda = \mathbf{1}$ to extract the six generators $M^{\mu\nu}$ and their commutation relations, the Lorentz Lie algebra from which the entire classification of fields will be assembled.

3.2 The Lorentz Lie algebra

The previous section singled out the proper orthochronous Lorentz group $\mathrm{SO}(1,3)^+$ as the connected component of the identity: the largest piece of the full transformation group that can be reached from the identity by a continuous path, and therefore the piece on which the methods of Chapter 2 can act. A connected matrix Lie group is, however, an awkward object to classify directly. Its representation theory is much easier to attack through its *tangent space at the identity*, the Lie algebra, because a representation of a connected, simply-connected group is in one-to-one correspondence with a representation of its algebra, and even when the group is only connected (as $\mathrm{SO}(1,3)^+$ is, being doubly connected rather than simply connected) the algebra captures every local fact and very nearly every global one. The strategy of this section is the standard linearization of Section 2.3: sit at the identity element $\Lambda = \mathbf{1}$, move an infinitesimal amount, and read off the constraints that the defining relation imposes on the allowed directions of motion. Those directions are the generators; their commutators are the structure constants; and the structure constants are the entire content we will spend the next section decoding.

We work throughout in the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$ and natural units fixed in the chapter introduction. The starting point is the defining relation of the Lorentz group, which we recall from the previous section: a real 4×4 matrix Λ with components $\Lambda^{\mu}{}_{\nu}$ is a Lorentz transformation iff it preserves the Minkowski form, $\eta_{\rho\sigma}\,\Lambda^{\rho}{}_{\mu}\,\Lambda^{\sigma}{}_{\nu} = \eta_{\mu\nu}$, which in matrix form is the relation $\Lambda^{\mathsf{T}}\eta\,\Lambda = \eta$ of Eq. (3.5). Everything in this section is the systematic exploitation of Eq. (3.5) in a neighborhood of $\Lambda = \mathbf{1}$.

3.2.1 Infinitesimal transformations and the antisymmetry constraint

A curve through the identity in $\mathrm{SO}(1,3)^+$ is a one-parameter family $\Lambda(t)$ with $\Lambda(0) = \mathbf{1}$. Its tangent at $t = 0$ is the object we want, so we write the most general infinitesimal transformation as

$$\Lambda^{\mu}{}_{\nu} = \delta^{\mu}{}_{\nu} + \omega^{\mu}{}_{\nu} + \mathcal{O}(\omega^2), \tag{3.26}$$

where the entries of $\omega^{\mu}{}_{\nu}$ are first-order small and otherwise arbitrary; they parametrize the directions one may move away from the identity. Not every ω is allowed, however: Λ must still satisfy Eq. (3.5). Substituting Eq. (3.26) into the defining relation and keeping only terms through first order,

$$\begin{aligned} \eta_{\mu\nu} &= \eta_{\rho\sigma}\,(\delta^{\rho}{}_{\mu} + \omega^{\rho}{}_{\mu})\,(\delta^{\sigma}{}_{\nu} + \omega^{\sigma}{}_{\nu}) \\ &= \eta_{\rho\sigma}\,\delta^{\rho}{}_{\mu}\,\delta^{\sigma}{}_{\nu} + \eta_{\rho\sigma}\,\omega^{\rho}{}_{\mu}\,\delta^{\sigma}{}_{\nu} + \eta_{\rho\sigma}\,\delta^{\rho}{}_{\mu}\,\omega^{\sigma}{}_{\nu} + \mathcal{O}(\omega^2) \\ &= \eta_{\mu\nu} + \eta_{\sigma\nu}\,\omega^{\sigma}{}_{\mu} + \eta_{\rho\mu}\,\omega^{\rho}{}_{\nu} + \mathcal{O}(\omega^2). \end{aligned} \tag{3.27}$$

The zeroth-order term reproduces $\eta_{\mu\nu}$, so the first-order terms must cancel among themselves. It is convenient to lower the free index on ω by defining $\omega_{\mu\nu} \equiv \eta_{\mu\rho}\,\omega^{\rho}{}_{\nu}$; the surviving condition in Eq. (3.27) is then $\omega_{\nu\mu} + \omega_{\mu\nu} = 0$, that is,

$$\omega_{\mu\nu} = -\,\omega_{\nu\mu}. \tag{3.28}$$

The infinitesimal Lorentz parameters form an antisymmetric rank-two tensor. An antisymmetric 4×4 matrix has $\frac{1}{2} \cdot 4 \cdot 3 = 6$ independent entries, so the Lorentz group is six-dimensional: three of the parameters will turn out to generate rotations and three to generate boosts. This is the linear-algebraic origin of the fact, anticipated in the previous section, that $\mathrm{SO}(1,3)^{+}$ is a six-parameter group.

3.2.2 The six generators $M^{\mu\nu}$

To extract a basis of generators we exhibit the six independent components of $\omega_{\mu\nu}$ explicitly. Because the index pair $(\mu\nu)$ ranges over an antisymmetric tensor, we may write $\omega^{\mu}{}_{\nu}$ as a linear combination of six fixed basis matrices, one for each independent component, with $\omega_{\mu\nu}$ supplying the coefficients. The conventional way to package this—and the one that makes the generators carry the same index structure as the parameters—is to write the finite group element as an exponential, in the manner of the exponential map Eq. (2.60), and to define the generators as the coefficients in the expansion. We set

$$\Lambda = \exp\!\Big(-\tfrac{i}{2}\,\omega_{\rho\sigma}\,M^{\rho\sigma}\Big), \qquad \Lambda^{\mu}{}_{\nu} = \delta^{\mu}{}_{\nu} - \tfrac{i}{2}\,\omega_{\rho\sigma}\,(M^{\rho\sigma})^{\mu}{}_{\nu} + \mathcal{O}(\omega^{2}), \tag{3.29}$$

where the second expression is the first-order expansion. Here $M^{\rho\sigma}$ is a set of six 4×4 matrices labelled by the antisymmetric pair $\rho\sigma$ (so $M^{\rho\sigma} = -M^{\sigma\rho}$, matching the antisymmetry of $\omega_{\rho\sigma}$), and $(M^{\rho\sigma})^{\mu}{}_{\nu}$ denotes the (μ,ν) entry of the matrix $M^{\rho\sigma}$. The factor of $-\frac{i}{2}$ is pure convention: the i makes the generators Hermitian in the unitary representations we eventually want (so that Λ there is unitary), and the $\frac{1}{2}$ compensates the double-counting that comes from summing the antisymmetric pair $\rho\sigma$ over all ordered values rather than over $\rho < \sigma$.

Comparing the two expansions Eq. (3.26) and Eq. (3.29) gives

$$\omega^{\mu}{}_{\nu} = -\tfrac{i}{2}\,\omega_{\rho\sigma}\,(M^{\rho\sigma})^{\mu}{}_{\nu}, \tag{3.30}$$

and this identity, valid for arbitrary antisymmetric $\omega_{\rho\sigma}$, determines the generator matrices. To solve it we re-express the left-hand side in terms of $\omega_{\rho\sigma}$ as well. Raising one index, $\omega^{\mu}{}_{\nu} = \eta^{\mu\alpha}\omega_{\alpha\nu}$, and writing $\omega_{\alpha\nu}$ through its antisymmetry as the manifestly antisymmetric combination

$$\omega_{\alpha\nu} = \tfrac{1}{2}\,\omega_{\rho\sigma}\big(\delta^{\rho}{}_{\alpha}\,\delta^{\sigma}{}_{\nu} - \delta^{\sigma}{}_{\alpha}\,\delta^{\rho}{}_{\nu}\big), \tag{3.31}$$

we obtain

$$\omega^{\mu}{}_{\nu} = \eta^{\mu\alpha}\,\tfrac{1}{2}\,\omega_{\rho\sigma}\big(\delta^{\rho}{}_{\alpha}\,\delta^{\sigma}{}_{\nu} - \delta^{\sigma}{}_{\alpha}\,\delta^{\rho}{}_{\nu}\big) = \tfrac{1}{2}\,\omega_{\rho\sigma}\big(\eta^{\mu\rho}\,\delta^{\sigma}{}_{\nu} - \eta^{\mu\sigma}\,\delta^{\rho}{}_{\nu}\big). \tag{3.32}$$

Setting Eq. (3.32) equal to the right-hand side of Eq. (3.30) and using that $\omega_{\rho\sigma}$ is an arbitrary antisymmetric tensor—so its coefficient, already antisymmetric in $\rho \leftrightarrow \sigma$ on both sides, may be equated—gives $-\frac{i}{2}(M^{\rho\sigma})^{\mu}{}_{\nu} = \frac{1}{2}(\eta^{\mu\rho}\delta^{\sigma}{}_{\nu} - \eta^{\mu\sigma}\delta^{\rho}{}_{\nu})$. Solving for the generator and using the symmetry $\eta^{\mu\rho} = \eta^{\rho\mu}$,

$$\boxed{(M^{\rho\sigma})^{\mu}{}_{\nu} = i(\eta^{\rho\mu}\,\delta^{\sigma}{}_{\nu} - \eta^{\sigma\mu}\,\delta^{\rho}{}_{\nu}).} \tag{3.33}$$

This is the explicit defining representation of the six Lorentz generators. We record its salient features. The matrix $M^{\rho\sigma}$ is antisymmetric in its label pair, $(M^{\rho\sigma})^{\mu}{}_{\nu} = -(M^{\sigma\rho})^{\mu}{}_{\nu}$, as required. Each generator has exactly two nonzero entries: $M^{\rho\sigma}$ acts in the ρ–σ plane and annihilates the two orthogonal directions. And the position of the metric controls a crucial sign difference between the two types of plane—a 0–i plane (one timelike direction) versus an i–j plane (two spacelike directions)—which is exactly the sign that will distinguish boosts from rotations below.

Definition 3.11 (Lorentz generators)**.** The six *Lorentz generators* in the defining (vector) representation are the antisymmetric set of matrices $M^{\rho\sigma}$, $\rho, \sigma \in \{0, 1, 2, 3\}$, with components given by Eq. (3.33). A finite proper orthochronous Lorentz transformation is recovered as $\Lambda = \exp\!\big(-\frac{i}{2}\omega_{\rho\sigma}M^{\rho\sigma}\big)$ for a real antisymmetric parameter tensor $\omega_{\rho\sigma}$.

3.2.3 The covariant commutation relations

The Lie algebra is the set of commutators of the generators. Because Eq. (3.33) gives the generators as explicit matrices, we can compute the commutator directly by matrix multiplication—no abstraction required—and the result, being expressed entirely through η and M, will then hold in *every* representation, not just the defining one. This is the central structural fact of the chapter.

Proposition 3.12 (The Lorentz algebra $\mathfrak{so}(1,3)$)**.** *The Lorentz generators satisfy*

$$[M^{\mu\nu}, M^{\rho\sigma}] = i(\eta^{\nu\rho}M^{\mu\sigma} - \eta^{\mu\rho}M^{\nu\sigma} - \eta^{\nu\sigma}M^{\mu\rho} + \eta^{\mu\sigma}M^{\nu\rho}). \tag{3.34}$$

Proof. We compute the matrix product $(M^{\mu\nu}M^{\rho\sigma})^{\alpha}{}_{\beta}$ by inserting an intermediate index γ and using Eq. (3.33) twice:

$$\begin{aligned}(M^{\mu\nu}M^{\rho\sigma})^{\alpha}{}_{\beta} &= (M^{\mu\nu})^{\alpha}{}_{\gamma}\,(M^{\rho\sigma})^{\gamma}{}_{\beta} \\ &= i(\eta^{\mu\alpha}\delta^{\nu}{}_{\gamma} - \eta^{\nu\alpha}\delta^{\mu}{}_{\gamma})\; i(\eta^{\rho\gamma}\delta^{\sigma}{}_{\beta} - \eta^{\sigma\gamma}\delta^{\rho}{}_{\beta}) \\ &= -(\eta^{\mu\alpha}\delta^{\nu}{}_{\gamma} - \eta^{\nu\alpha}\delta^{\mu}{}_{\gamma})(\eta^{\rho\gamma}\delta^{\sigma}{}_{\beta} - \eta^{\sigma\gamma}\delta^{\rho}{}_{\beta}).\end{aligned} \tag{3.35}$$

The sum over γ collapses each Kronecker delta against a metric, e.g. $\delta^{\nu}{}_{\gamma}\eta^{\rho\gamma} = \eta^{\rho\nu}$, giving the four terms

$$(M^{\mu\nu}M^{\rho\sigma})^{\alpha}{}_{\beta} = -\Big[\eta^{\mu\alpha}\eta^{\rho\nu}\delta^{\sigma}{}_{\beta} - \eta^{\mu\alpha}\eta^{\sigma\nu}\delta^{\rho}{}_{\beta} - \eta^{\nu\alpha}\eta^{\rho\mu}\delta^{\sigma}{}_{\beta} + \eta^{\nu\alpha}\eta^{\sigma\mu}\delta^{\rho}{}_{\beta}\Big]. \tag{3.36}$$

The opposite ordering $(M^{\rho\sigma}M^{\mu\nu})^{\alpha}{}_{\beta}$ follows from Eq. (3.36) by the simultaneous swap $(\mu\nu) \leftrightarrow (\rho\sigma)$:

$$(M^{\rho\sigma}M^{\mu\nu})^{\alpha}{}_{\beta} = -\Big[\eta^{\rho\alpha}\eta^{\mu\sigma}\delta^{\nu}{}_{\beta} - \eta^{\rho\alpha}\eta^{\nu\sigma}\delta^{\mu}{}_{\beta} - \eta^{\sigma\alpha}\eta^{\mu\rho}\delta^{\nu}{}_{\beta} + \eta^{\sigma\alpha}\eta^{\nu\rho}\delta^{\mu}{}_{\beta}\Big]. \tag{3.37}$$

Subtracting Eq. (3.37) from Eq. (3.36) and using the symmetry of the metric throughout, the commutator is the eight-term expression

$$\begin{aligned}[M^{\mu\nu}, M^{\rho\sigma}]^{\alpha}{}_{\beta} = -\Big[\ &\eta^{\mu\alpha}\eta^{\nu\rho}\delta^{\sigma}{}_{\beta} - \eta^{\mu\alpha}\eta^{\nu\sigma}\delta^{\rho}{}_{\beta} - \eta^{\nu\alpha}\eta^{\mu\rho}\delta^{\sigma}{}_{\beta} + \eta^{\nu\alpha}\eta^{\mu\sigma}\delta^{\rho}{}_{\beta} \\ &- \eta^{\rho\alpha}\eta^{\mu\sigma}\delta^{\nu}{}_{\beta} + \eta^{\rho\alpha}\eta^{\nu\sigma}\delta^{\mu}{}_{\beta} + \eta^{\sigma\alpha}\eta^{\mu\rho}\delta^{\nu}{}_{\beta} - \eta^{\sigma\alpha}\eta^{\nu\rho}\delta^{\mu}{}_{\beta}\Big].\end{aligned} \tag{3.38}$$

It remains to recognize the right-hand side as a combination of single generators. From Eq. (3.33), the matrix entry of a generator times the imaginary unit is $i\,(M^{ab})^{\alpha}{}_{\beta} = -(\eta^{a\alpha}\delta^{b}{}_{\beta} - \eta^{b\alpha}\delta^{a}{}_{\beta})$. Expanding the claimed right-hand side of Eq. (3.34) in this way,

$$\begin{aligned}i(\eta^{\nu\rho}M^{\mu\sigma} - \eta^{\mu\rho}M^{\nu\sigma} - \eta^{\nu\sigma}M^{\mu\rho} + \eta^{\mu\sigma}M^{\nu\rho})^{\alpha}{}_{\beta} = -\Big[\ &\eta^{\nu\rho}(\eta^{\mu\alpha}\delta^{\sigma}{}_{\beta} - \eta^{\sigma\alpha}\delta^{\mu}{}_{\beta}) \\ &- \eta^{\mu\rho}(\eta^{\nu\alpha}\delta^{\sigma}{}_{\beta} - \eta^{\sigma\alpha}\delta^{\nu}{}_{\beta}) \\ &- \eta^{\nu\sigma}(\eta^{\mu\alpha}\delta^{\rho}{}_{\beta} - \eta^{\rho\alpha}\delta^{\mu}{}_{\beta}) \\ &+ \eta^{\mu\sigma}(\eta^{\nu\alpha}\delta^{\rho}{}_{\beta} - \eta^{\rho\alpha}\delta^{\nu}{}_{\beta})\Big].\end{aligned} \tag{3.39}$$

Multiplying out the eight products in Eq. (3.39) and comparing with Eq. (3.38) term by term, each of the eight terms matches exactly: for instance the term $-\eta^{\mu\alpha}\eta^{\nu\rho}\delta^{\sigma}{}_{\beta}$ appears in both, the term $+\eta^{\sigma\alpha}\eta^{\nu\rho}\delta^{\mu}{}_{\beta}$ in Eq. (3.39) matches $-(-\eta^{\sigma\alpha}\eta^{\nu\rho}\delta^{\mu}{}_{\beta})$ in Eq. (3.38), and so on through all eight. The two expressions are identical, which establishes Eq. (3.34). □

A few remarks fix the meaning of Eq. (3.34). First, the right-hand side is again a Lorentz generator, so the commutator closes: the $M^{\mu\nu}$ span a six-dimensional Lie algebra, denoted $\mathfrak{so}(1,3)$, with the metric components $\eta^{\mu\nu}$ playing the role of (part of) the structure constants in the sense of Chapter 2. Second, every appearance of η on the right is what carries the indefinite signature of spacetime into the algebra; had we worked with the Euclidean metric δ we would have obtained the compact rotation algebra $\mathfrak{so}(4)$ instead, and the entire representation theory would have been different. Third—and this is the feature we will pursue—Eq. (3.34) is manifestly covariant but it mixes the timelike index 0 and the spacelike indices $1, 2, 3$ on an equal footing, which hides the physical content. The next step is to split it.

3.2.4 Rotations, boosts, and the J–K algebra

The covariant algebra Eq. (3.34) treats all six generators symmetrically, but physically they are of two kinds: the three that rotate space among itself, and the three that mix time with a spatial direction. We make this split explicit. The three generators with both indices spatial, M^{jk} with $j,k \in \{1,2,3\}$, are antisymmetric in j,k and so encode three independent matrices; we package them, exactly as orbital angular momentum is packaged in nonrelativistic quantum mechanics, by contracting with the Levi-Civita symbol. The three with a timelike index, M^{0i}, are the remaining three.

Definition 3.13 (Rotation and boost generators)**.** The *rotation generators* J_i and *boost generators* K_i, $i \in \{1,2,3\}$, are

$$J_i \;\equiv\; \tfrac{1}{2}\,\epsilon_{ijk}\,M^{jk}, \qquad K_i \;\equiv\; M^{0i}. \tag{3.40}$$

The definition of J_i is invertible: contracting with ϵ and using $\epsilon_{ijk}\epsilon_{iab} = \delta_{ja}\delta_{kb} - \delta_{jb}\delta_{ka}$ gives $\epsilon_{ijk}J_i = \frac{1}{2}\epsilon_{ijk}\epsilon_{iab}M^{ab} = \frac{1}{2}(M^{jk} - M^{kj}) = M^{jk}$, so

$$M^{jk} = \epsilon_{ijk}\,J_i, \qquad M^{0i} = K_i. \tag{3.41}$$

Throughout this reduction we use that in the mostly-minus convention the spatial metric components are $\eta^{ij} = -\delta^{ij}$, while $\eta^{00} = +1$ and $\eta^{0i} = 0$. The single relative minus sign between η^{00} and η^{ij} is the whole story; we now watch it propagate through the three families of commutators.

Proposition 3.14 (The J–K algebra)**.** *The rotation and boost generators obey*

$$[J_i, J_j] = i\,\epsilon_{ijk}\,J_k, \tag{3.42}$$
$$[J_i, K_j] = i\,\epsilon_{ijk}\,K_k, \tag{3.43}$$
$$[K_i, K_j] = -\,i\,\epsilon_{ijk}\,J_k. \tag{3.44}$$

Proof. We evaluate the three cases in turn from the covariant relation Eq. (3.34), substituting $\eta^{ij} = -\delta^{ij}$ wherever both indices are spatial and dropping any term containing a single $\eta^{0i} = 0$.

(i) Rotation–rotation. Using Eq. (3.40),

$$[J_i, J_j] = \tfrac{1}{4}\,\epsilon_{iab}\,\epsilon_{jcd}\,\Big[M^{ab}, M^{cd}\Big]. \tag{3.45}$$

With all four indices a,b,c,d spatial, every metric in Eq. (3.34) is of the form $\eta^{ab} = -\delta^{ab}$, so

$$\Big[M^{ab}, M^{cd}\Big] = i(-\delta^{bc}M^{ad} + \delta^{ac}M^{bd} + \delta^{bd}M^{ac} - \delta^{ad}M^{bc}). \tag{3.46}$$

The four terms contribute equally after the contraction with $\epsilon_{iab}\epsilon_{jcd}$, because M^{ab} and the ϵ's are each antisymmetric: relabelling dummy indices turns each term into the first. Taking four times the first term,

$$[J_i, J_j] = \tfrac{1}{4} \cdot 4 \cdot (-i)\, \epsilon_{iab}\, \epsilon_{jcd}\, \delta^{bc} M^{ad} = -\, i\, \epsilon_{iab}\, \epsilon_{jbd}\, M^{ad}. \tag{3.47}$$

Now $\epsilon_{iab}\epsilon_{jbd} = -\epsilon_{iab}\epsilon_{jdb} = -(\delta_{ij}\delta_{ad} - \delta_{id}\delta_{aj})$, so

$$[J_i, J_j] = i\,(\delta_{ij}\delta_{ad} - \delta_{id}\delta_{aj}) M^{ad} = i\,\delta_{ij}\, M^{aa} - i\, M^{ji}. \tag{3.48}$$

The first term vanishes because $M^{aa} = 0$ by antisymmetry; in the second, $-iM^{ji} = +iM^{ij} = i\,\epsilon_{ijk} J_k$ by Eq. (3.41). Hence $[J_i, J_j] = i\,\epsilon_{ijk} J_k$, which is Eq. (3.42). This is precisely the angular-momentum algebra $\mathfrak{su}(2)$ of Chapter 2: the rotation subgroup of the Lorentz group is the rotation group of space, and the J_i are its generators.

(ii) Rotation–boost. Here

$$[J_i, K_j] = \tfrac{1}{2}\, \epsilon_{iab} \left[M^{ab}, M^{0j} \right], \tag{3.49}$$

with a, b spatial and one timelike index on the second factor. From Eq. (3.34) with $(\mu\nu\rho\sigma) = (a\, b\, 0\, j)$,

$$\left[M^{ab}, M^{0j} \right] = i(\eta^{b0} M^{aj} - \eta^{a0} M^{bj} - \eta^{bj} M^{a0} + \eta^{aj} M^{b0}). \tag{3.50}$$

The first two terms vanish since $\eta^{a0} = \eta^{b0} = 0$. In the remaining two, $\eta^{bj} = -\delta^{bj}$, $\eta^{aj} = -\delta^{aj}$, and $M^{a0} = -M^{0a} = -K_a$, so

$$\left[M^{ab}, M^{0j} \right] = i(\delta^{bj} M^{a0} - \delta^{aj} M^{b0}) = i(-\delta^{bj} K_a + \delta^{aj} K_b). \tag{3.51}$$

Therefore

$$[J_i, K_j] = \tfrac{i}{2}\, \epsilon_{iab}(-\delta^{bj} K_a + \delta^{aj} K_b) = \tfrac{i}{2}(-\epsilon_{iaj} K_a + \epsilon_{ijb} K_b) = \tfrac{i}{2}(\epsilon_{ija} K_a + \epsilon_{ijb} K_b) = i\,\epsilon_{ijk} K_k, \tag{3.52}$$

where we used $-\epsilon_{iaj} = \epsilon_{ija}$. This is Eq. (3.43): under rotations, the three boost generators transform as the components of an ordinary spatial vector—as they must, since $\mathbf{K}$ points along the boost direction.

(iii) Boost–boost. Finally

$$[K_i, K_j] = \left[M^{0i}, M^{0j} \right]. \tag{3.53}$$

Applying Eq. (3.34) with $(\mu\nu\rho\sigma) = (0\, i\, 0\, j)$,

$$\left[M^{0i}, M^{0j} \right] = i(\eta^{i0} M^{0j} - \eta^{00} M^{ij} - \eta^{ij} M^{00} + \eta^{0j} M^{i0}). \tag{3.54}$$

The terms with η^{i0} and η^{0j} vanish, and $M^{00} = 0$. Only the second term survives, and here is the decisive point: it carries the timelike metric component $\eta^{00} = +1$, not a spatial $-\delta$. Thus

$$[K_i, K_j] = -\,i\,\eta^{00}\,M^{ij} = -\,i\,M^{ij} = -\,i\,\epsilon_{ijk}\,J_k, \tag{3.55}$$

using Eq. (3.41) in the last step. This is Eq. (3.44). □

The sign in Eq. (3.44) deserves to be stated plainly, because it is the hinge on which the rest of the chapter turns. Trace it back through the proof: it came from $\eta^{00} = +1$ in the boost–boost commutator, whereas the corresponding sign in the rotation–rotation commutator came from $\eta^{ij} = -\delta^{ij}$. The lone relative minus sign of the mostly-minus metric, sitting between the time and space components, has reappeared as the lone minus sign in $[K_i, K_j] = -i\epsilon_{ijk}J_k$. Had spacetime been Euclidean, $\mathfrak{so}(4)$, this sign would have been $+i$ and boosts would close into a second, independent rotation algebra; the Lorentzian signature instead makes the commutator of two boosts produce a rotation *with the wrong sign*.

Physical Insight

The minus sign is not a bookkeeping curiosity; it is the geometric statement that boosts do not form a closed subgroup the way rotations do. Two successive rotations about different axes compose into a single rotation (the J's close: Eq. (3.42)). Two successive boosts in different directions do *not* compose into a boost—their composition contains a rotation, the Wigner rotation responsible for Thomas precession—and the algebraic fingerprint of this fact is exactly the appearance of J on the right of Eq. (3.44). Geometrically, the rotations sweep out a compact sphere of directions while the boosts run off to infinite rapidity along non-compact hyperbolas; the next subsection makes this compact-versus-non-compact contrast fully explicit at the level of finite transformations.

3.2.5 Finite rotations and boosts

To connect the generators back to the transformations they generate, we feed the split Eq. (3.40) into the exponential map of Theorem 3.11. Restrict the antisymmetric parameter tensor first to its purely spatial part, writing $\omega_{jk} = \epsilon_{jkl}\,\theta_l$ with $\boldsymbol{\theta} = (\theta_1, \theta_2, \theta_3)$ and setting the mixed components ω_{0i} to zero. Then

$$-\tfrac{i}{2}\,\omega_{\rho\sigma}M^{\rho\sigma} = -\tfrac{i}{2}\,\omega_{jk}M^{jk} = -\tfrac{i}{2}\,\epsilon_{jkl}\theta_l\,M^{jk} = -\,i\,\theta_l\big(\tfrac{1}{2}\epsilon_{ljk}M^{jk}\big) = -\,i\,\boldsymbol{\theta}\cdot\mathbf{J}, \tag{3.56}$$

so that finite rotations are

$$R(\boldsymbol{\theta}) = \exp\!\big(-\,i\,\boldsymbol{\theta}\cdot\mathbf{J}\big). \tag{3.57}$$

Restricting instead to the mixed components, write $\omega_{0i} = \eta_i$ with $\boldsymbol{\eta} = (\eta_1, \eta_2, \eta_3)$ the *rapidity*, and set $\omega_{jk} = 0$. Using the antisymmetry $\omega_{i0} = -\eta_i$ together with $M^{i0} = -M^{0i}$,

$$-\tfrac{i}{2}\,\omega_{\rho\sigma}M^{\rho\sigma} = -\tfrac{i}{2}(\omega_{0i}M^{0i}+\omega_{i0}M^{i0}) = -\tfrac{i}{2}(\eta_i M^{0i}+(-\eta_i)(-M^{0i})) = -\,i\,\eta_i M^{0i} = -\,i\,\boldsymbol{\eta}\cdot\mathbf{K}, \tag{3.58}$$

so that finite boosts are

$$B(\boldsymbol{\eta}) = \exp\!\big(-\,i\,\boldsymbol{\eta}\cdot\mathbf{K}\big). \tag{3.59}$$

Every element of $\mathrm{SO}(1,3)^+$ can be written, in a neighborhood of the identity and in fact globally by the polar decomposition, as a product of a rotation Eq. (3.57) and a boost Eq. (3.59).

Notation Watch

The symbol η does double duty in this section: $\eta_{\mu\nu}$ (always with two spacetime indices) is the Minkowski metric, while $\boldsymbol{\eta}$ (boldface, three-component) is the rapidity vector parametrizing a boost in Eq. (3.59). The two never share an index structure, so no ambiguity arises, but the coincidence of letters is standard and worth flagging once. The rapidity is additive for collinear boosts—unlike the velocity—which is precisely why it, and not v, is the natural exponential parameter. The single-boost worked example of Section 3.1 wrote the rapidity as a scalar ζ (in $B_1(\zeta)$); it is the same parameter, $\boldsymbol{\eta} = \eta\,\hat{\mathbf{n}}$ being its vector form along the boost axis $\hat{\mathbf{n}}$. Likewise, the boost factor of the polar decomposition Eq. (3.23) was written there as $e^{\boldsymbol{\eta}\cdot\mathbf{K}}$ with a *real, symmetric* exponent and no explicit i; that is consistent with the present $B(\boldsymbol{\eta}) = \exp(-i\boldsymbol{\eta}\cdot\mathbf{K})$ because, in the Hermitian-generator convention Eq. (3.33) adopted here, the matrices $-i\mathbf{K} = -iM^{0i}$ are exactly real and symmetric (see Theorem 3.15), so $\exp(-i\boldsymbol{\eta}\cdot\mathbf{K}) = \exp(\boldsymbol{\eta}\cdot(-i\mathbf{K}))$ displays the boost as the exponential of a real symmetric generator. We use the i-convention Eq. (3.33) uniformly, since it is the one in which $\mathbf{J}$ is Hermitian and the $\mathfrak{su}(2)\oplus\mathfrak{su}(2)$ split of the next section is cleanest.

The two finite transformations Eqs. (3.57) and (3.59) look symmetric, but the metric makes them behave very differently. The following worked example computes both explicitly in the defining representation and exposes the contrast that drives the next section.

Worked Example 3.15 (A boost and a rotation, exponentiated)**.** We construct K_1 and J_3 as explicit 4×4 matrices from Eq. (3.33) and exponentiate them.

The boost generator. With $\rho\sigma = 01$, Eq. (3.33) gives $(K_1)^{\mu}{}_{\nu} = (M^{01})^{\mu}{}_{\nu} = i(\eta^{0\mu}\delta^{1}{}_{\nu} - \eta^{1\mu}\delta^{0}{}_{\nu})$. Only $\eta^{00} = 1$ and $\eta^{11} = -1$ are nonzero among the relevant components, so the only nonvanishing entries are $(K_1)^{0}{}_{1} = i\,\eta^{00} = i$ and $(K_1)^{1}{}_{0} =$

$-i\,\eta^{11} = i$. Ordering the rows and columns as $(0,1,2,3)$,

$$K_1 = \begin{pmatrix} 0 & i & 0 & 0 \\ i & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}. \tag{3.60}$$

To exponentiate, form $-i\,\eta_1 K_1$, which restricted to the 0–1 block is $\eta_1\,S$ with $S = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$. Since $S^2 = \mathbf{1}_2$, the exponential series splits into even and odd powers,

$$\exp(\eta_1 S) = \mathbf{1}_2 \cosh\eta_1 + S \sinh\eta_1 = \begin{pmatrix} \cosh\eta_1 & \sinh\eta_1 \\ \sinh\eta_1 & \cosh\eta_1 \end{pmatrix}, \tag{3.61}$$

so the finite boost Eq. (3.59) along the x^1-axis is

$$B(\eta_1 \hat{\mathbf{e}}_1) = \exp(-i\eta_1 K_1) = \begin{pmatrix} \cosh\eta_1 & \sinh\eta_1 & 0 & 0 \\ \sinh\eta_1 & \cosh\eta_1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}. \tag{3.62}$$

This is the familiar Lorentz boost $x^{0\prime} = x^0 \cosh\eta_1 + x^1 \sinh\eta_1$, $x^{1\prime} = x^0 \sinh\eta_1 + x^1 \cosh\eta_1$, with the rapidity related to the velocity by $\tanh\eta_1 = v$ (so $\cosh\eta_1 = \gamma$). The matrix entries grow without bound as $\eta_1 \to \infty$: the boost orbit is a non-compact hyperbola, $(\cosh\eta_1)^2 - (\sinh\eta_1)^2 = 1$.

The rotation generator. With $\rho\sigma = 12$, $(J_3)^\mu{}_\nu = (M^{12})^\mu{}_\nu = i(\eta^{1\mu}\delta^2{}_\nu - \eta^{2\mu}\delta^1{}_\nu)$, whose only nonzero entries are $(J_3)^1{}_2 = i\,\eta^{11} = -i$ and $(J_3)^2{}_1 = -i\,\eta^{22} = i$. In the 1–2 block this is $\left(\begin{smallmatrix} 0 & -i \\ i & 0 \end{smallmatrix}\right)$, the Pauli matrix σ_2, which satisfies $\sigma_2^2 = \mathbf{1}_2$. The same even/odd split now yields trigonometric, not hyperbolic, functions,

$$R(\theta_3 \hat{\mathbf{e}}_3) = \exp(-i\theta_3 J_3) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos\theta_3 & -\sin\theta_3 & 0 \\ 0 & \sin\theta_3 & \cos\theta_3 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \tag{3.63}$$

the ordinary rotation by angle θ_3 in the x^1–x^2 plane, periodic in θ_3 with period 2π: the rotation orbit is a compact circle.

The lesson. Inspect the generators as matrices. The rotation generator J_3 is Hermitian, $J_3^\dagger = J_3$, so $R = \exp(-i\theta_3 J_3)$ is unitary. The boost generator K_1 is *anti*-Hermitian, $K_1^\dagger = -K_1$, so $B = \exp(-i\eta_1 K_1)$ is *not* unitary—indeed it is symmetric and real, with eigenvalues $e^{\pm\eta_1}$ running off to infinity. In this finite-dimensional defining representation the boosts cannot be represented unitarily. This is no accident of the choice of representation: it is forced by the algebra. The sign in $[K_i, K_j] = -i\epsilon_{ijk}J_k$ means that one cannot make all six generators Hermitian at once in any finite-dimensional representation, because doing so would require the boosts to generate a compact subgroup, contradicting the non-compact hyperbolic orbits we have just exhibited.

Caution

The generators $M^{\mu\nu}$ are not Hermitian matrices in the naive sense in the defining representation, and one should not expect them to be: only the three rotation generators are Hermitian, while the three boost generators are anti-Hermitian. The defining four-vector representation is therefore a perfectly good *finite-dimensional* representation of the Lorentz algebra, but it is *not* a unitary one. This is the generic situation for finite-dimensional representations of a non-compact group, and it is exactly why fields (which carry finite-dimensional representations) and states (which must carry unitary ones) are governed by different parts of the representation theory—a division the chapter introduction flagged and that the Poincaré analysis later in the chapter resolves.

We have linearized $\mathrm{SO}(1,3)^+$ completely. The six generators $M^{\mu\nu}$ obey the covariant algebra Eq. (3.34); split into rotations and boosts they obey the J–K algebra Eqs. (3.42) to (3.44); and the finite transformations are the exponentials Eqs. (3.57) and (3.59). The one feature that does not fit the comfortable pattern of Chapter 2 is the minus sign in $[K_i, K_j] = -i\epsilon_{ijk}J_k$, which—as Theorem 3.15 showed concretely—blocks any finite-dimensional unitary representation and prevents the J's and K's from organizing into two ordinary, independent angular-momentum algebras. The next section turns this apparent obstruction into the central tool of the chapter: by complexifying the algebra and forming the combinations $\mathbf{J} \pm i\mathbf{K}$, the troublesome sign is absorbed, the boosts and rotations decouple into two commuting copies of $\mathfrak{su}(2)$, and the entire finite-dimensional representation theory of the Lorentz group falls out of the spin classification already in hand.

3.3 $\mathfrak{su}(2) \oplus \mathfrak{su}(2)$ and the (j_-, j_+) classification of fields

The previous section linearised $\mathrm{SO}(1,3)^+$ and split its six generators into the three rotations J_i and the three boosts K_i, ending with the algebra

$$[J_i, J_j] = i\,\epsilon_{ijk}J_k, \qquad [J_i, K_j] = i\,\epsilon_{ijk}K_k, \qquad [K_i, K_j] = -\,i\,\epsilon_{ijk}J_k, \tag{3.64}$$

established in Eqs. (3.42) to (3.44) of Section 3.2. (Throughout this chapter the metric is mostly-minus, $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, and $\hbar = c = 1$; ϵ_{ijk} is the flat three-dimensional Levi-Civita symbol with $\epsilon_{123} = +1$.) The first two relations are reassuring: the J_i close among themselves into the familiar rotation algebra $\mathfrak{su}(2)$, and the K_i transform as a vector under rotations, exactly as a boost direction should. The third relation is the source of every difficulty and every richness in the representation theory that follows. Its minus sign says that the commutator of two boosts is a *rotation*, and it is the algebraic fingerprint of the

noncompactness of $\mathrm{SO}(1,3)^+$: boosting in two different planes and undoing the boosts does not return you to the identity but leaves a residual rotation, while the rapidity that parametrises a boost runs over all of $\mathbb{R}$ rather than a compact circle.

That same minus sign blocks the most naive hope. One might wish that J_i and K_i each closed into its own copy of $\mathfrak{su}(2)$, so that the entire representation theory would reduce twice over to the $\mathfrak{su}(2)$ theory already built in Chapter 2. They do not: $[K_i, K_j]$ produces a J, not a K, so the boosts alone do not close. The remedy is to allow ourselves complex coefficients. We complexify the algebra, and inside the complexification we will discover that two genuinely decoupled $\mathfrak{su}(2)$'s have been hiding all along. This is the central structural fact of the chapter, and from it the entire catalogue of relativistic fields — scalar, the two Weyl spinors, the four-vector, the field strength — drops out mechanically.

3.3.1 Complexifying the algebra: the two hidden $\mathfrak{su}(2)$'s

The obstruction in Eq. (3.64) is that J and K are coupled by real structure constants in a way that cannot be diagonalised over $\mathbb{R}$. Over $\mathbb{C}$ it can. Consider the complex linear combinations that follow.

Definition 3.16 (Self-dual and anti-self-dual generators)**.** On the complexification of the Lorentz algebra — the complex span of $\{J_i, K_i\}$ with complex coefficients — define

$$N_i^{\pm} \;=\; \tfrac{1}{2}(J_i \pm i\,K_i), \qquad i = 1,2,3. \tag{3.65}$$

We also write $\vec{A} \equiv \vec{N}^{+} = \tfrac{1}{2}(\vec{J} + i\vec{K})$ and $\vec{B} \equiv \vec{N}^{-} = \tfrac{1}{2}(\vec{J} - i\vec{K})$ for the two triples; these are the names carried into the spinor section. The relations invert to

$$J_i = N_i^{+} + N_i^{-}, \qquad K_i = -\,i\,(N_i^{+} - N_i^{-}). \tag{3.66}$$

These six combinations are not elements of the real Lorentz algebra $\mathfrak{so}(1,3)$ — they involve i times a real generator — but they are perfectly good elements of its complexification $\mathfrak{so}(1,3)_{\mathbb{C}}$, and that is all we need to organise the representation theory. We compute their brackets directly from Eq. (3.64). The computation is short and worth doing in full because the cancellations are the whole point.

For the bracket of two N^{+}'s, expand bilinearly,

$$\begin{aligned}\left[N_i^{+}, N_j^{+}\right] &= \tfrac{1}{4}\left[J_i + iK_i,\; J_j + iK_j\right] \\ &= \tfrac{1}{4}\Big([J_i, J_j] + i\,[J_i, K_j] + i\,[K_i, J_j] + i^2\,[K_i, K_j]\Big).\end{aligned} \tag{3.67}$$

Insert Eq. (3.64), using $[K_i, J_j] = -\,[J_j, K_i] = -i\,\epsilon_{jik}K_k = +\,i\,\epsilon_{ijk}K_k$ for the third term and $-\,[K_i, K_j] = +\,i\,\epsilon_{ijk}J_k$ for the fourth:

$$\left[N_i^{+}, N_j^{+}\right] = \tfrac{1}{4}\Big(i\epsilon_{ijk}J_k + i\,(i\epsilon_{ijk}K_k) + i\,(i\epsilon_{ijk}K_k) + i\epsilon_{ijk}J_k\Big)$$

$$= \tfrac{1}{4}\Big(2i\,\epsilon_{ijk}J_k - 2\,\epsilon_{ijk}K_k\Big) = \tfrac{1}{4}\,(2i\,\epsilon_{ijk})\,(J_k + iK_k) = i\,\epsilon_{ijk}\,N_k^+. \quad (3.68)$$

The identical manipulation with $i \to -i$ throughout gives the N^- bracket; carrying it out,

$$\begin{aligned}\Big[N_i^-, N_j^-\Big] &= \tfrac{1}{4}\Big([J_i, J_j] - i\,[J_i, K_j] - i\,[K_i, J_j] + i^2\,[K_i, K_j]\Big) \\ &= \tfrac{1}{4}\Big(i\epsilon_{ijk}J_k + \epsilon_{ijk}K_k + \epsilon_{ijk}K_k + i\epsilon_{ijk}J_k\Big) = \tfrac{1}{4}(2i\epsilon_{ijk})\,(J_k - iK_k) = i\,\epsilon_{ijk}\,N_k^-.\end{aligned} \quad (3.69)$$

Finally the cross bracket, where the cancellation is the decisive one:

$$\begin{aligned}\Big[N_i^+, N_j^-\Big] &= \tfrac{1}{4}\,[J_i + iK_i,\; J_j - iK_j\,] \\ &= \tfrac{1}{4}\Big([J_i, J_j] - i\,[J_i, K_j] + i\,[K_i, J_j] + [K_i, K_j]\Big) \\ &= \tfrac{1}{4}\Big(i\epsilon_{ijk}J_k - i(i\epsilon_{ijk}K_k) + i(i\epsilon_{ijk}K_k) - i\epsilon_{ijk}J_k\Big) = 0.\end{aligned} \quad (3.70)$$

The J-terms cancel against each other and the K-terms cancel against each other. We have proved the following.

Theorem 3.17 (Decoupling of the complexified Lorentz algebra)**.** *The generators $N_i^\pm$ of Theorem 3.16 satisfy*

$$\Big[N_i^+, N_j^+\Big] = i\,\epsilon_{ijk}N_k^+, \qquad \Big[N_i^-, N_j^-\Big] = i\,\epsilon_{ijk}N_k^-, \qquad \Big[N_i^+, N_j^-\Big] = 0. \quad (3.71)$$

Hence the complexified Lorentz algebra is a direct sum of two commuting copies of the complexified $\mathfrak{su}(2)$,

$$\mathfrak{so}(1,3)_{\mathbb{C}} \;\cong\; \mathfrak{su}(2)_{\mathbb{C}} \oplus \mathfrak{su}(2)_{\mathbb{C}}, \quad (3.72)$$

the first copy spanned by $\{N_i^+\} = \{\vec{A}\}$ and the second by $\{N_i^-\} = \{\vec{B}\}$.

Proof. The brackets Eq. (3.71) were computed above. The six elements $N_i^\pm$ are related to the six real generators J_i, K_i by the invertible complex-linear change of basis Eq. (3.65), so they span the same complex vector space $\mathfrak{so}(1,3)_{\mathbb{C}}$. The first two relations say each triple closes into the $\mathfrak{su}(2)$ bracket; the third says the two triples commute. A Lie algebra that is the vector-space direct sum of two subalgebras which commute elementwise is, by definition, their Lie-algebra direct sum. Each summand has the structure constants of $\mathfrak{su}(2)$ over $\mathbb{C}$, i.e. is $\mathfrak{su}(2)_{\mathbb{C}} \cong \mathfrak{sl}(2,\mathbb{C})$. □

Two remarks fix the meaning of this isomorphism, because it is easy to over-read.

Notation Watch

The decomposition Eq. (3.72) holds for the *complexified* algebra. The real Lorentz algebra $\mathfrak{so}(1,3)$ is *not* a direct sum of two real $\mathfrak{su}(2)$'s: the $N_i^{\pm}$ are not real generators, and there is no real change of basis achieving the split. (Indeed $\mathfrak{su}(2) \oplus \mathfrak{su}(2)$ is the real algebra of the compact group SO(4), which is a *different* real form of the same complexification — the precise sense in which "SO(1,3) is the analytic continuation of SO(4)."") What survives over $\mathbb{R}$ is a reality structure: complex conjugation of Eq. (3.65) swaps $N_i^+ \leftrightarrow N_i^-$, equivalently $\vec{A} \leftrightarrow \vec{B}$, because it flips the sign of the i multiplying the real K_i while leaving the real J_i alone. This swap of the two factors is the algebraic seed of the relation between the two Weyl spinors under complex conjugation and parity, taken up in Section 3.4. The $\pm$ labels are attached to $\frac{1}{2}(J \pm iK)$ once and for all by Theorem 3.16; some texts use the opposite sign, so when comparing formulas one must check which combination is being called "+."

Physical Insight

Physically, $\vec{A} = \vec{N}^+$ and $\vec{B} = \vec{N}^-$ measure two independent "angular momenta" built from rotations and boosts together. Because they commute and each generates an $\mathfrak{su}(2)$, a relativistic field carries *two* half-integer charges, not one. The single spin of nonrelativistic quantum mechanics is the diagonal combination $\vec{J} = \vec{A} + \vec{B}$ that survives when boosts are forgotten; relativity refines it into a pair. The two charges are what we will come to call left- and right-handed (chirality), and a theory that treats them asymmetrically is a chiral theory — the structural origin of parity violation in the weak interaction lives in this very decoupling.

3.3.2 The (j_-, j_+) classification

Theorem 3.17 reduces the representation theory of the Lorentz algebra to a problem we have already solved. We import two facts from Chapter 2. First, the finite-dimensional irreducible representations of $\mathfrak{su}(2)$ are labelled by a single nonnegative half-integer, the spin $j \in \{0, \frac{1}{2}, 1, \frac{3}{2}, \dots\}$, with the spin-$j$ representation D^j acting on a space of dimension $2j+1$ on which the Casimir $\mathbf{J}^2 = \sum_i J_i J_i$ takes the value $j(j+1)$ (Theorem 2.53). This classification is unchanged when we pass to the complexification $\mathfrak{su}(2)_{\mathbb{C}} = \mathfrak{sl}(2,\mathbb{C})$: a complex-linear representation of $\mathfrak{sl}(2,\mathbb{C})$ on a finite-dimensional complex space is the same data as a representation of the real $\mathfrak{su}(2)$, because $\mathfrak{su}(2)$ spans $\mathfrak{sl}(2,\mathbb{C})$ over $\mathbb{C}$ and a Lie-algebra homomorphism out of it extends uniquely complex-linearly. Second, we need the rule by which representations of a direct sum are built from those of the summands, which rests on Schur's lemma (Theorem 2.21).

Lemma 3.18 (Irreps of a direct sum are external tensor products)**.** *Let $\mathfrak{g} = \mathfrak{g}_1 \oplus \mathfrak{g}_2$ be a direct sum of Lie algebras and let (ρ, V) be a finite-dimensional irreducible complex representation. Then there exist irreducible representations (ρ_1, V_1) of $\mathfrak{g}_1$ and (ρ_2, V_2) of $\mathfrak{g}_2$ such that $V \cong V_1 \otimes V_2$ with*

$$\rho(X_1 \oplus X_2) = \rho_1(X_1) \otimes \mathbf{1}_{V_2} + \mathbf{1}_{V_1} \otimes \rho_2(X_2), \qquad X_i \in \mathfrak{g}_i. \tag{3.73}$$

Conversely every such external tensor product of irreducibles is an irreducible representation of $\mathfrak{g}$, and these exhaust the irreducibles up to isomorphism.

Proof. Because $[\mathfrak{g}_1, \mathfrak{g}_2] = 0$ inside $\mathfrak{g}$, the operators $\rho(X_1)$ commute with all $\rho(X_2)$. Restrict the representation to $\mathfrak{g}_1$; as a $\mathfrak{g}_1$-module V decomposes into isotypic components, each a sum of copies of a fixed irreducible $\mathfrak{g}_1$-module. Fix one irreducible $\mathfrak{g}_1$-module V_1 that actually occurs, and form the multiplicity space $M = \mathrm{Hom}_{\mathfrak{g}_1}(V_1, V)$, the space of $\mathfrak{g}_1$-intertwiners from V_1 into V. The evaluation map

$$V_1 \otimes M \longrightarrow V, \qquad v \otimes f \mapsto f(v), \tag{3.74}$$

is a $\mathfrak{g}_1$-module map onto the V_1-isotypic component of V; it is injective because the f's are linearly independent intertwiners, hence an isomorphism onto that component. Now each $\rho(X_2)$ commutes with $\mathfrak{g}_1$, so it preserves the $\mathfrak{g}_1$-isotypic decomposition and maps the V_1-component into itself. By Schur's lemma (Theorem 2.21) a $\mathfrak{g}_1$-endomorphism of the isotypic component $V_1 \otimes M$ acts as $\mathbf{1}_{V_1} \otimes \sigma(X_2)$ for a unique operator $\sigma(X_2)$ on M, since it must act as a scalar (in fact the identity, being a module map) on the irreducible factor V_1 and arbitrarily on M. The assignment $X_2 \mapsto \sigma(X_2)$ is a representation of $\mathfrak{g}_2$ on M. The subspace $V_1 \otimes M$ is thus invariant under all of $\mathfrak{g} = \mathfrak{g}_1 \oplus \mathfrak{g}_2$; since V is irreducible and $V_1 \otimes M$ is nonzero and invariant, $V = V_1 \otimes M$. Finally, irreducibility of V forces M to be an irreducible $\mathfrak{g}_2$-module V_2: any proper invariant $W \subsetneq M$ would give the proper invariant subspace $V_1 \otimes W$ of V. The converse — that $V_1 \otimes V_2$ is irreducible for irreducible factors, and that these exhaust the list — follows by reversing the argument: an invariant subspace of $V_1 \otimes V_2$, restricted to either tensor factor, would yield a proper invariant subspace there. □

Combining the lemma with the $\mathfrak{su}(2)$ classification gives the result that organises the entire chapter.

Theorem 3.19 (The (j_-, j_+) classification of Lorentz representations)**.** *The finite-dimensional irreducible representations of the (complexified) Lorentz algebra are in one-to-one correspondence with ordered pairs*

$$(j_-, j_+), \qquad j_-, j_+ \in \{0, \tfrac{1}{2}, 1, \tfrac{3}{2}, \dots\}. \tag{3.75}$$

The representation $D^{(j_-, j_+)}$ acts on $V_{j_-} \otimes V_{j_+}$, where the first factor (generators $\vec{A} = \vec{N}^+$) carries the spin-j_- irreducible and the second factor (generators $\vec{B} = \vec{N}^-$) carries the spin-j_+ irreducible. Its dimension is

$$\dim D^{(j_-, j_+)} = (2j_- + 1)(2j_+ + 1). \tag{3.76}$$

Proof. By Theorem 3.17 the complexified Lorentz algebra is $\mathfrak{su}(2)_{\mathbb{C}} \oplus \mathfrak{su}(2)_{\mathbb{C}}$, with the first summand spanned by $\vec{A} = \vec{N}^+$ and the second by $\vec{B} = \vec{N}^-$. By Theorem 3.18 its finite-dimensional irreducibles are the external tensor products $D^{j_-} \boxtimes D^{j_+}$ of irreducibles of the two factors, and by Theorem 2.53 each factor's irreducibles are the spin representations labelled by a half-integer. The dimension is the product $(2j_- + 1)(2j_+ + 1)$. A finite-dimensional representation of the real algebra $\mathfrak{so}(1,3)$ on a complex vector space is the same as a complex-linear representation of its complexification, so the same list classifies the (complex) representations of the real Lorentz algebra. □

The convention deserves one sentence of explanation, since the two factors are on an equal footing and the choice of which to call "first" is a convention that propagates through the rest of the chapter. We assign j_- to the $\vec{A} = \vec{N}^+ = \frac{1}{2}(\vec{J} + i\vec{K})$ factor. With this choice, the smallest nontrivial representation in which only $\vec{A}$ acts is $(\frac{1}{2}, 0)$, and Section 3.4 will identify it with the *left-handed* Weyl spinor of the standard physics convention — the spinor whose boost generator is $\vec{K} = -i\vec{\sigma}/2$. The opposite assignment merely relabels every representation by the reflection $(j_-, j_+) \mapsto (j_+, j_-)$ and is just as consistent; we fix ours to match the spinor labelling used universally below.

The single most useful corollary tells us how an ordinary spin — the quantity measured in the rest frame, generated by the rotation subgroup — sits inside (j_-, j_+). The rotation generator is the *diagonal* sum $\vec{J} = \vec{A} + \vec{B} = \vec{N}^+ + \vec{N}^-$, so as a representation of the rotation $\mathfrak{su}(2)$ alone, $D^{(j_-,j_+)}$ is the tensor product of a spin-j_- and a spin-j_+ representation. Its decomposition is exactly the Clebsch–Gordan series (Section 2.5):

$$D^{(j_-,j_+)}\Big|_{\text{rotations}} \cong \bigoplus_{j=|j_- - j_+|}^{j_- + j_+} D^j, \tag{3.77}$$

so the rotational spins present in the field are $j = |j_- - j_+|, |j_- - j_+| + 1, \dots, j_- + j_+$, each once. Counting dimensions, $\sum_{j=|j_- - j_+|}^{j_- + j_+} (2j + 1) = (2j_- + 1)(2j_+ + 1)$, consistent with Eq. (3.76). This is the bridge between the abstract pair (j_-, j_+) and the physical content, "what spins does this field describe."

3.3.3 The catalogue of low-spin fields

We now read off the smallest representations. They are not a random list: they are precisely the fields out of which every Lagrangian in this book is built, and naming them here fixes the objects that the rest of Part I and the benchmark theories will quantise.

$(0,0)$ — **the scalar.** The trivial representation, $j_- = j_+ = 0$, of dimension 1. Both $\vec{A}$ and $\vec{B}$ act as zero, so $J_i = K_i = 0$: the single component is unchanged by

every Lorentz transformation. A field carrying this representation is a Lorentz scalar $\phi(x)$, transforming as $\phi'(x') = \phi(x)$. This is the representation of ϕ^4 theory: the real scalar field of $\mathcal{L} = \frac{1}{2}(\partial\phi)^2 - \frac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4$, whose classical theory is built in Chapter 6 and which is quantised in Chapter 9. The rest-frame spin from Eq. (3.77) is $j = 0$, as it must be for a scalar particle.

$(\frac{1}{2}, 0)$ and $(0, \frac{1}{2})$ — the two Weyl spinors. Each has dimension $(2\cdot\frac{1}{2}+1)(1) = 2$, and by Eq. (3.77) each carries rotational spin $j = \frac{1}{2}$: these are two-component spin-$\frac{1}{2}$ objects. In $(\frac{1}{2}, 0)$ the first factor $\vec{A} = \vec{N}^+$ acts as the spin-$\frac{1}{2}$ generator $\vec{\sigma}/2$ and the second $\vec{B} = \vec{N}^-$ acts trivially; in $(0, \frac{1}{2})$ it is the reverse. Reading off the physical generators from Eq. (3.66),

$$(\tfrac{1}{2}, 0): \quad \vec{J} = \tfrac{1}{2}\vec{\sigma}, \quad \vec{K} = -\tfrac{i}{2}\vec{\sigma}; \qquad\qquad (0, \tfrac{1}{2}): \quad \vec{J} = \tfrac{1}{2}\vec{\sigma}, \quad \vec{K} = +\tfrac{i}{2}\vec{\sigma}, \tag{3.78}$$

since for $(\frac{1}{2}, 0)$ we have $\vec{A} = \vec{\sigma}/2, \vec{B} = 0$, hence $\vec{J} = \vec{A} = \vec{\sigma}/2$ and $\vec{K} = -i(\vec{A} - \vec{B}) = -i\vec{\sigma}/2$, and the signs flip for $(0, \frac{1}{2})$. The two representations are inequivalent — no Lorentz transformation turns one into the other, because they differ in the sign of the boost generator — but they are exchanged by the reality structure (complex conjugation) and, as we will see, by parity. We call $(\frac{1}{2}, 0)$ the *left-handed* Weyl spinor and $(0, \frac{1}{2})$ the *right-handed* Weyl spinor; this assignment, and the concrete realisation through $\mathrm{SL}(2, \mathbb{C})$ with undotted and dotted two-component indices, is the business of Section 3.4. For now the content is purely algebraic: there are exactly two distinct two-component spinor representations because there are two factors in Eq. (3.72), and the boost generators act on them with opposite signs.

$(\frac{1}{2}, \frac{1}{2})$ — the four-vector. Dimension $2 \cdot 2 = 4$. By Eq. (3.77) the rotational content is $j = 0 \oplus 1$: a scalar (one component) plus a three-vector (three components), which is exactly how the four components of a Lorentz vector $V^\mu = (V^0, \mathbf{V})$ look to a nonrelativistic observer — a time component that is a rotational scalar and a spatial part that is a rotational vector. We prove in Theorem 3.20 below that $(\frac{1}{2}, \frac{1}{2})$ is genuinely the vector representation V^μ, by constructing the explicit intertwiner between a four-vector index μ and a pair of spinor indices. This representation underlies the gauge potential A_μ of QED and Yang–Mills theory: A_μ transforms as a four-vector (up to the gauge ambiguity dissected in Chapters 8 and 25), i.e. it lives in $(\frac{1}{2}, \frac{1}{2})$.

$(1, 0) \oplus (0, 1)$ — the field strength. Each of $(1, 0)$ and $(0, 1)$ has dimension 3; their sum has dimension 6, the number of independent components of an antisymmetric rank-two tensor $F_{\mu\nu} = -F_{\nu\mu}$ in four dimensions. By Eq. (3.77) the spin content of $(1, 0)$ alone is $j = 1$, and likewise for $(0, 1)$. We show in Theorem 3.21 that the antisymmetric tensor representation decomposes precisely

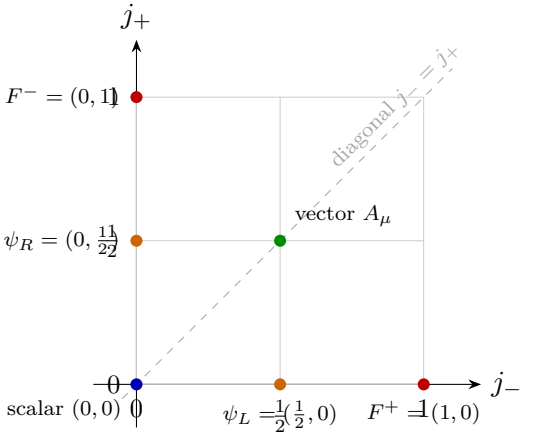

Figure 3.2: The lattice of finite-dimensional irreducible Lorentz representations (j_-, j_+), with j_- (the spin of $\vec{A} = \vec{N}^+$) horizontal and j_+ (the spin of $\vec{B} = \vec{N}^-$) vertical. The diagonal $j_- = j_+$ carries the tensor (bosonic) fields with integer rest-frame spin: $(0,0)$ the scalar, $(\frac{1}{2}, \frac{1}{2})$ the four-vector A_μ. Off-diagonal points carry half-integer spin (Weyl spinors $\psi_L = (\frac{1}{2}, 0)$, $\psi_R = (0, \frac{1}{2})$) or the self-dual/anti-self-dual field strengths $F^\pm = (1,0), (0,1)$. Complex conjugation, and (Section 3.4) parity, reflect the lattice across the diagonal, $(j_-, j_+) \mapsto (j_+, j_-)$.

as $(1,0) \oplus (0,1)$, the two pieces being the self-dual and anti-self-dual parts of $F_{\mu\nu}$, equivalently the combinations $\mathbf{E} \pm i\mathbf{B}$ of the electric and magnetic fields. This is the representation of the electromagnetic and Yang–Mills field strengths.

The pattern visible in Fig. 3.2 is worth naming. Representations on the diagonal $j_- = j_+$ contain integer spins only and describe *tensor* (bosonic) fields; representations with $j_- + j_+$ half-odd-integer contain half-integer spins and describe *spinor* (fermionic) fields. The reflection across the diagonal, $(j_-, j_+) \mapsto (j_+, j_-)$, is the complex-conjugation/parity operation flagged in the notation watch above; a representation fixed by it ($j_- = j_+$, or a reducible sum like $(1,0) \oplus (0,1)$) admits real, parity-even field content, while a single off-diagonal representation does not — the deep reason a single Weyl field is intrinsically chiral.

Worked Example 3.20 (The $(\frac{1}{2}, \frac{1}{2})$ representation is the four-vector)**.** We show explicitly that $(\frac{1}{2}, \frac{1}{2})$ is the four-vector representation by constructing an invertible intertwiner between the four-vector index μ and the pair of two-component spinor indices carried by $(\frac{1}{2}, 0) \otimes (0, \frac{1}{2})$, and verifying that it commutes with the Lorentz action.

Setup. A vector in $(\frac{1}{2}, \frac{1}{2}) = (\frac{1}{2}, 0) \otimes (0, \frac{1}{2})$ carries one index $a \in \{1,2\}$ transforming under the first factor $(\vec{A})$ and one index $\dot{b} \in \{1,2\}$ transforming under the second $(\vec{B})$; write its components $v_{a\dot{b}}$, a 2×2 array. (The dot distinguishes the second-factor index from the first; the full index calculus is set

up in Section 3.4.) Introduce the four Hermitian 2×2 matrices

$$\sigma^\mu_{a\dot{b}} = (\mathbf{1}, \sigma^1, \sigma^2, \sigma^3), \qquad \sigma^1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \ \sigma^2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \ \sigma^3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \tag{3.79}$$

the unit matrix together with the three Pauli matrices, and define the map from four-vectors to 2×2 matrices

$$v^\mu \ \longmapsto \ \underline{v}_{a\dot{b}} \ := \ v_\mu \, \sigma^\mu_{a\dot{b}} \ = \ v^0 \, \mathbf{1} - \sum_{i=1}^{3} v^i \, \sigma^i, \tag{3.80}$$

where $v_\mu = \eta_{\mu\nu} v^\nu = (v^0, -\mathbf{v})$ in the mostly-minus metric.

It is a real-linear bijection onto Hermitian matrices. Writing out Eq. (3.80),

$$\underline{v} = \begin{pmatrix} v^0 - v^3 & -v^1 + iv^2 \\ -v^1 - iv^2 & v^0 + v^3 \end{pmatrix}. \tag{3.81}$$

Every 2×2 Hermitian matrix has exactly four real parameters (two real diagonal entries and one complex off-diagonal entry), and reading Eq. (3.81) off entry by entry recovers $v^0, \ldots, v^3$ uniquely. Hence Eq. (3.80) is a real-linear isomorphism from $\mathbb{R}^{1,3}$ onto the four-real-dimensional space of Hermitian 2×2 matrices.

The intertwining property, infinitesimally. An infinitesimal element of the first factor $(\frac{1}{2}, 0)$ acts on the undotted index by the matrix $\delta M = -\frac{i}{2}\vec{\theta} \cdot \vec{\sigma} - \frac{1}{2}\vec{\eta} \cdot \vec{\sigma}$, read off from the generators Eq. (3.78) ($\delta M = -i\vec{\theta} \cdot \vec{J} - i\vec{\eta} \cdot \vec{K}$ with $\vec{J} = \vec{\sigma}/2$, $\vec{K} = -i\vec{\sigma}/2$). The dotted index, transforming in the complex-conjugate factor, is acted on from the right by $\delta M^\dagger = +\frac{i}{2}\vec{\theta} \cdot \vec{\sigma} - \frac{1}{2}\vec{\eta} \cdot \vec{\sigma}$. The induced change of the matrix $\underline{v}$ is therefore

$$\delta \underline{v} = \delta M \, \underline{v} + \underline{v} \, \delta M^\dagger. \tag{3.82}$$

We evaluate the rotation and boost parts separately. For a rotation ($\vec{\eta} = 0$) the $\vec{\theta}$-terms combine into a commutator,

$$\begin{aligned} \delta \underline{v}\big|_{\text{rot}} &= -\tfrac{i}{2} \, \theta^a \, [\sigma^a, \underline{v}] = -\tfrac{i}{2} \, \theta^a \big(-v^k \left[\sigma^a, \sigma^k\right]\big) = -\tfrac{i}{2} \, \theta^a \big(-v^k \, 2i\epsilon^{akl} \sigma^l\big) \\ &= -\, \theta^a v^k \epsilon^{akl} \sigma^l = -(\vec{\theta} \times \mathbf{v})^l \sigma^l, \end{aligned} \tag{3.83}$$

using $\left[\sigma^a, \sigma^k\right] = 2i\epsilon^{akl}\sigma^l$ and $\epsilon^{akl}\theta^a v^k = (\vec{\theta} \times \mathbf{v})^l$. This is precisely $-\delta v^l \sigma^l$ for the ordinary rotation $\delta \mathbf{v} = \vec{\theta} \times \mathbf{v}$, $\delta v^0 = 0$ of a four-vector. For a boost ($\vec{\theta} = 0$) the $\vec{\eta}$-terms combine into an anticommutator,

$$\begin{aligned} \delta \underline{v}\big|_{\text{boost}} &= -\tfrac{1}{2} \, \eta^a \, \{\sigma^a, \underline{v}\} = -\tfrac{1}{2} \, \eta^a \big(2v^0 \sigma^a - v^k \left\{\sigma^a, \sigma^k\right\}\big) \\ &= -\tfrac{1}{2} \, \eta^a \big(2v^0 \sigma^a - 2v^a\big) = (\vec{\eta} \cdot \mathbf{v}) \, \mathbf{1} - v^0 \, \eta^a \sigma^a, \end{aligned} \tag{3.84}$$

using $\left\{\sigma^a, \sigma^k\right\} = 2\delta^{ak}\mathbf{1}$. This is exactly $\delta v^0 \, \mathbf{1} - \delta v^a \sigma^a$ for the four-vector boost $\delta v^0 = \vec{\eta} \cdot \mathbf{v}$, $\delta \mathbf{v} = v^0 \vec{\eta}$. In both cases Eq. (3.82) reproduces the four-vector

transformation of v^μ, so the map Eq. (3.80) intertwines the spinor-pair action $(\frac{1}{2},0)\otimes(0,\frac{1}{2})$ with the vector action. Being also a bijection, it is an isomorphism of representations: $(\frac{1}{2},\frac{1}{2}) \cong$ the four-vector.

The invariant is the determinant. As a bonus the construction exposes the Minkowski norm. Computing the determinant of Eq. (3.81),

$$\det \underline{v} = (v^0-v^3)(v^0+v^3)-(-v^1+iv^2)(-v^1-iv^2) = (v^0)^2-(v^3)^2-(v^1)^2-(v^2)^2 = v_\mu v^\mu. \tag{3.85}$$

The finite version of the transformation is $\underline{v} \mapsto A\,\underline{v}\,A^\dagger$ with $A \in \mathrm{SL}(2,\mathbb{C})$ the exponential of δM; it preserves Hermiticity and, since $\det A = 1$, the determinant, hence the norm $v\cdot v$. That the resulting map on v^μ is exactly the proper orthochronous Lorentz group, two-to-one, is the double-cover statement built in Theorem 3.23; here we needed only the infinitesimal intertwining, which already pins down the representation.

Worked Example 3.21 (The antisymmetric tensor is $(1,0)\oplus(0,1)$)**.** An antisymmetric rank-two tensor $F_{\mu\nu} = -F_{\nu\mu}$ has six independent components; we show it carries the reducible representation $(1,0)\oplus(0,1)$ and identify the two irreducible pieces.

Decomposition by symmetry of the two factors. An antisymmetric tensor is the antisymmetric square $\Lambda^2 V$ of the vector representation $V = (\frac{1}{2},\frac{1}{2})$. Using Theorem 3.18 the full tensor square is

$$V\otimes V = \left((\tfrac{1}{2},0)\otimes(0,\tfrac{1}{2})\right)^{\otimes 2} = (\tfrac{1}{2}\otimes\tfrac{1}{2})_{\vec{A}} \otimes (\tfrac{1}{2}\otimes\tfrac{1}{2})_{\vec{B}}, \tag{3.86}$$

where each parenthesis is a tensor product of two spin-$\frac{1}{2}$ representations of one $\mathfrak{su}(2)$ factor. By the $\mathfrak{su}(2)$ Clebsch–Gordan rule (Section 2.5), $\frac{1}{2}\otimes\frac{1}{2} = 1\oplus 0$ in each factor, with the spin-1 triplet *symmetric* and the spin-0 singlet *antisymmetric* under exchange of the two copies. The overall exchange symmetry of a term is the product of the symmetries in the two factors, so

$$V\otimes V = \underbrace{(1,1)}_{\text{sym}\otimes\text{sym}} \oplus \underbrace{(0,0)}_{\text{asym}\otimes\text{asym}} \oplus \underbrace{(1,0)}_{\text{sym}\otimes\text{asym}} \oplus \underbrace{(0,1)}_{\text{asym}\otimes\text{sym}}, \tag{3.87}$$

of dimensions $9+1+3+3 = 16$. The symmetric square $\mathrm{Sym}^2 V$ (dimension 10) is $(1,1)\oplus(0,0)$ — a traceless symmetric tensor plus a trace — while the antisymmetric square is

$$\Lambda^2 V = (1,0)\oplus(0,1), \qquad \dim = 3+3 = 6, \tag{3.88}$$

matching the six components of $F_{\mu\nu}$. This proves the decomposition.

Identifying the pieces as $\mathbf{E}\pm i\mathbf{B}$. Write the electric and magnetic fields as $E^i = F^{i0}$ and $B^i = -\frac{1}{2}\epsilon^{ijk}F_{jk}$, the standard repackaging of the six components

of $F_{\mu\nu}$. Under the Lorentz group both rotate as ordinary three-vectors, $\vec{J}$ acting as the spin-1 generator. Under an infinitesimal boost of rapidity $\vec{\eta}$ they mix as

$$\delta\mathbf{E} = \vec{\eta} \times \mathbf{B}, \qquad \delta\mathbf{B} = -\vec{\eta} \times \mathbf{E}, \tag{3.89}$$

which follows from $F_{\mu\nu}$ being a Lorentz two-tensor acted on by the boost matrix of Theorem 3.15. Forming the complex combinations $\mathbf{F}^{\pm} = \mathbf{E} \pm i\mathbf{B}$, the boost Eq. (3.89) becomes a single closed transformation,

$$\delta\mathbf{F}^{+} = \vec{\eta} \times \mathbf{B} - i\,\vec{\eta} \times \mathbf{E} = -\,i\,\vec{\eta} \times (\mathbf{E} + i\mathbf{B}) = -\,i\,\vec{\eta} \times \mathbf{F}^{+}, \tag{3.90}$$

and likewise $\delta\mathbf{F}^{-} = +i\,\vec{\eta} \times \mathbf{F}^{-}$: the boost acts on $\mathbf{F}^{\pm}$ as $\mp i$ times a rotation, i.e. $\vec{K} = \mp i\vec{J}$ on $\mathbf{F}^{\pm}$. Substituting into Eq. (3.65), on $\mathbf{F}^{+}$ we get $\vec{N}^{-} = \frac{1}{2}(\vec{J} - i\vec{K}) = \frac{1}{2}(\vec{J} - i(-i\vec{J})) = 0$ and $\vec{N}^{+} = \frac{1}{2}(\vec{J} + i\vec{K}) = \vec{J}$, a spin-1 representation of the first factor only: this is $(1, 0)$. On $\mathbf{F}^{-}$ the signs reverse, $\vec{N}^{+} = 0$, $\vec{N}^{-} = \vec{J}$, which is $(0, 1)$. Hence

$$\mathbf{F}^{+} = \mathbf{E} + i\mathbf{B} \;\in\; (1, 0), \qquad \mathbf{F}^{-} = \mathbf{E} - i\mathbf{B} \;\in\; (0, 1). \tag{3.91}$$

The Lorentz-invariant projectors are the Hodge dual. The splitting Eq. (3.91) can be written covariantly. Define the dual tensor

$$\widetilde{F}_{\mu\nu} = \tfrac{1}{2}\,\epsilon_{\mu\nu\rho\sigma} F^{\rho\sigma}, \tag{3.92}$$

with the totally antisymmetric symbol normalised by $\epsilon_{0123} = +1$ (the convention of Chapter A). In Lorentzian signature the dual squares to minus the identity on two-forms,

$$\widetilde{(\widetilde{F})}_{\mu\nu} = \tfrac{1}{4}\,\epsilon_{\mu\nu\rho\sigma}\epsilon^{\rho\sigma\alpha\beta} F_{\alpha\beta} = -\,F_{\mu\nu}, \tag{3.93}$$

where we used $\epsilon_{\mu\nu\rho\sigma}\epsilon^{\rho\sigma\alpha\beta} = -2(\delta^{\alpha}_{\mu}\delta^{\beta}_{\nu} - \delta^{\beta}_{\mu}\delta^{\alpha}_{\nu})$, the extra minus sign relative to Euclidean signature coming from $\det\eta = -1$. Because the dual map is built from the invariant tensors ϵ and η it commutes with Lorentz transformations, and because $\widetilde{(\,\cdot\,)}^{2} = -1$ its eigenvalues are $\pm i$. Its eigenprojections,

$$F^{\pm}_{\mu\nu} = \tfrac{1}{2}(F_{\mu\nu} \mp i\,\widetilde{F}_{\mu\nu}), \qquad \text{satisfying} \qquad \widetilde{F^{\pm}}_{\mu\nu} = \pm\,i\,F^{\pm}_{\mu\nu}, \tag{3.94}$$

are the Lorentz-invariant *self-dual* and *anti-self-dual* parts, each a three-complex-dimensional space, and a short component check identifies them with $\mathbf{F}^{\pm} = \mathbf{E} \pm i\mathbf{B}$ of Eq. (3.91). Reality of the physical $F_{\mu\nu} = F^{+}_{\mu\nu} + F^{-}_{\mu\nu}$ ties the two halves: complex conjugation sends $\mathbf{E} + i\mathbf{B} \mapsto \mathbf{E} - i\mathbf{B}$, i.e. $(1, 0) \leftrightarrow (0, 1)$, exactly the diagonal reflection of Fig. 3.2. A single real antisymmetric tensor field — the electromagnetic field strength of QED, the Yang–Mills field strength $F^{a}_{\mu\nu}$ of Yang–Mills theory — therefore carries the *reducible but parity-symmetric* representation $(1, 0) \oplus (0, 1)$.

3.3.4 Why none of these are unitary

There is a price for the elegance of the (j_-, j_+) classification, and stating it now prevents a serious confusion later. The finite-dimensional representations we have just catalogued describe *fields*; they do not describe *quantum states*. A quantum state lives in a Hilbert space, and a symmetry must act on it by unitary operators so that probabilities are preserved. The representations above are, with the single exception of the trivial $(0,0)$, never unitary. The obstruction is exactly the noncompactness traced to the minus sign in Eq. (3.64).

Theorem 3.22 (No nontrivial finite-dimensional unitary representation)**.** *Let $D^{(j_-,j_+)}$ be a finite-dimensional irreducible representation of the Lorentz algebra with $(j_-, j_+) \neq (0,0)$. There is no positive-definite Hermitian inner product on its representation space with respect to which every Lorentz transformation acts unitarily; equivalently, the boost generators cannot all be represented by Hermitian operators.*

Proof. On $V = V_{j_-} \otimes V_{j_+}$ equip each factor with the standard $\mathfrak{su}(2)$-invariant inner product, so that the angular-momentum operators $\vec{A} = \vec{N}^+$ on V_{j_-} and $\vec{B} = \vec{N}^-$ on V_{j_+} are Hermitian (this is the unitarity of the compact group's representations, Theorem 2.53). With respect to this product the rotation generator $J_i = N_i^+ + N_i^-$ is Hermitian, but the boost generator

$$K_i = -\,i\,(N_i^+ - N_i^-) \tag{3.95}$$

from Eq. (3.66) is *anti*-Hermitian, being $-i$ times the Hermitian operator $N_i^+ - N_i^-$. An anti-Hermitian operator is normal, hence diagonalisable, and its eigenvalues are purely imaginary.

Now suppose, for contradiction, that some positive-definite inner product $\langle \cdot, \cdot \rangle_1$ made the whole representation unitary. Then each boost generator K_i, which generates the one-parameter subgroup $e^{-i\eta K_i}$, would have to be Hermitian with respect to $\langle \cdot, \cdot \rangle_1$, hence would have *real* eigenvalues. But the eigenvalues of a fixed linear operator are the roots of its characteristic polynomial and do not depend on any choice of inner product. They would therefore have to be simultaneously purely imaginary and real, that is, all zero. A diagonalisable operator whose eigenvalues all vanish is the zero operator, so $K_i = 0$ for every i. Then Eq. (3.66) forces $N_i^+ = N_i^-$ for all i, and the vanishing cross-commutator $\left[N_i^+, N_j^-\right] = 0$ collapses to $\left[N_i^+, N_j^+\right] = 0$; comparing with $\left[N_i^+, N_j^+\right] = i\epsilon_{ijk} N_k^+$ forces $N_k^+ = 0$, whence $J_i = K_i = 0$ and the representation is trivial, $(j_-, j_+) = (0,0)$, contrary to hypothesis. □

Physical Insight

The result is not a technicality; it is the structural fact that splits the rest of the chapter in two. *Fields* transform in the finite-dimensional, non-unitary (j_-, j_+) representations — and there is no contradiction, because a classical or quantum field is not a probability amplitude and need not preserve a norm. *One-particle states*, by contrast, transform in genuinely unitary representations, which by the theorem must be infinite-dimensional; the Lorentz group acts unitarily only on function spaces, never on a finite tuple of indices. Constructing those infinite-dimensional unitary representations is the work of Wigner's classification, which we reach after adjoining translations to form the Poincaré group (Sections 3.5 and 3.7). The mass and spin of a particle are the labels of *that* classification; the pair (j_-, j_+) is the label of the field that creates it.

With the catalogue in hand, the abstract pieces now demand a concrete realisation. The two two-component representations $(\tfrac{1}{2}, 0)$ and $(0, \tfrac{1}{2})$ have so far been distinguished only by which factor acts and by the opposite sign of their boost generators in Eq. (3.78); we have not yet written down the matrices $A \in \mathrm{SL}(2,\mathbb{C})$ that implement them, nor explained why the reflection $(j_-, j_+) \mapsto (j_+, j_-)$ that exchanges them should be physically realised by *parity*. The next section builds $\mathrm{SL}(2,\mathbb{C})$ as the universal double cover of $\mathrm{SO}(1,3)^+$, gives the two Weyl spinors their explicit transformation laws with dotted and undotted indices, and shows how demanding parity invariance glues $(\tfrac{1}{2}, 0) \oplus (0, \tfrac{1}{2})$ into the Dirac representation that carries the electron of QED.

3.4 Spinors: Weyl, Dirac, Majorana, and the SL(2,ℂ) double cover

The classification of Section 3.3 handed us, among the finite-dimensional irreducible representations labelled by a pair of half-integers (j_-, j_+), two objects that are equally simple and yet stubbornly abstract: the representations $(\tfrac{1}{2}, 0)$ and $(0, \tfrac{1}{2})$. They are the smallest faithful representations of the Lorentz algebra that are not the trivial scalar, and the decomposition $\mathfrak{so}(1,3)_{\mathbb{C}} \cong \mathfrak{su}(2) \oplus \mathfrak{su}(2)$ told us they exist and what their dimensions are. But that argument worked entirely at the level of the complexified *algebra*; it never produced an honest matrix group acting on an honest two-dimensional space, and it left untouched two physical questions that the algebra alone cannot answer. First, what *group* do these representations represent — is there a Lie group whose representation theory contains $(\tfrac{1}{2}, 0)$ and $(0, \tfrac{1}{2})$, and how is it related to the rotation–boost group $\mathrm{SO}^+(1,3)$ we started from? Second, how does *parity*, which is a symmetry of the full Lorentz group $\mathrm{O}(1,3)$ but lies *outside* the identity component, act on

these labels? The answer to the first question is the group $\mathrm{SL}(2,\mathbb{C})$, the universal double cover of $\mathrm{SO}^+(1,3)$; the answer to the second is that parity exchanges the two labels, which is exactly why the electron — a parity-respecting spin-$\frac{1}{2}$ particle — cannot be a single Weyl spinor but must be the reducible Dirac pair $(\frac{1}{2},0)\oplus(0,\frac{1}{2})$. This section makes both statements precise and proves them in full, realising the spinor representations concretely and, along the way, discharging the topological claim $\pi_1(\mathrm{SO}^+(1,3)) = \mathbb{Z}_2$ that we left open in Section 3.1.

The whole construction rests on a single, almost magical, change of viewpoint: a real four-vector can be repackaged as a 2×2 Hermitian matrix in such a way that its Minkowski length becomes a determinant. We start there.

3.4.1 The Pauli map: four-vectors as Hermitian matrices

Let σ^i $(i=1,2,3)$ be the Pauli matrices and write $\sigma^\mu = (\mathbf{1},\vec{\sigma}) = (\mathbf{1},\sigma^1,\sigma^2,\sigma^3)$, a four-tuple of 2×2 matrices indexed by a spacetime index μ. To a four-vector $x^\mu = (x^0,\vec{x})$ we associate the matrix

$$X \;\equiv\; x_\mu\,\sigma^\mu \;=\; x^0\,\mathbf{1} - \vec{x}\cdot\vec{\sigma} \;=\; \begin{pmatrix} x^0 - x^3 & -x^1 + ix^2 \\ -x^1 - ix^2 & x^0 + x^3 \end{pmatrix}, \tag{3.96}$$

where we used the mostly-minus metric $\eta = \mathrm{diag}(+,-,-,-)$ so that $x_\mu = (x^0,-\vec{x})$. The map $x \mapsto X$ is a real-linear isomorphism from $\mathbb{R}^{1,3}$ onto the four-real-dimensional space $\mathcal{H}_2$ of Hermitian 2×2 matrices: it is linear and invertible (the inverse is $x^\mu = \frac{1}{2}\,\mathrm{tr}(\bar{\sigma}^\mu X)$, with $\bar{\sigma}^\mu$ defined in Eq. (3.106) below), and X is Hermitian precisely because the x^μ are real and the σ^μ are Hermitian.

The point of the repackaging is the determinant. Reading off the entries of Eq. (3.96),

$$\det X \;=\; (x^0{-}x^3)(x^0{+}x^3) - (-x^1{+}ix^2)(-x^1{-}ix^2) \;=\; (x^0)^2 - (x^3)^2 - (x^1)^2 - (x^2)^2 \;=\; x\cdot x. \tag{3.97}$$

The Minkowski square of x *is* the determinant of its matrix avatar. This is the hinge on which everything turns: any operation on matrices that preserves both Hermiticity and the determinant will, transported back through the isomorphism, act on $\mathbb{R}^{1,3}$ as a linear transformation preserving $x\cdot x$ — that is, as a Lorentz transformation.

There is exactly such an operation. For any matrix $A \in \mathrm{SL}(2,\mathbb{C})$ — the group of complex 2×2 matrices with $\det A = 1$ — consider

$$X \;\longmapsto\; X' \;=\; A\,X\,A^\dagger. \tag{3.98}$$

This sends Hermitian matrices to Hermitian matrices, since $(AXA^\dagger)^\dagger = AX^\dagger A^\dagger = AXA^\dagger$ when $X^\dagger = X$. And it preserves the determinant, because $\det(AXA^\dagger) = \det A\,\det X\,\overline{\det A} = |\det A|^2 \det X = \det X$, using $\det A = 1$. By Eq. (3.97), the four-vector x' defined by $X' = x'_\mu\sigma^\mu$ satisfies $x'\cdot x' = x\cdot x$. The transformation

$x \mapsto x'$ is real-linear (because Eq. (3.98) is, and the isomorphism is real-linear), so it is a genuine element of $\mathrm{O}(1,3)$. We have produced a map

$$\Lambda : \mathrm{SL}(2,\mathbb{C}) \longrightarrow \mathrm{O}(1,3), \qquad A\,X\,A^{\dagger} \;=\; \big(\Lambda(A)\,x\big)_{\mu}\,\sigma^{\mu}. \tag{3.99}$$

The next subsection establishes exactly which Lorentz transformations are reached and how many matrices A produce each one.

3.4.2 $\mathrm{SL}(2,\mathbb{C})$ double covers $\mathrm{SO}^{+}(1,3)$

This is the central structural theorem of the section, and the concrete spinorial counterpart of the abstract $\mathrm{SU}(2) \to \mathrm{SO}(3)$ double cover that Chapter 2 built as a template. We state it in full and prove every clause.

Theorem 3.23 (The spinor double cover)**.** *The map Λ of Eq. (3.99) is a surjective group homomorphism from $\mathrm{SL}(2,\mathbb{C})$ onto the proper orthochronous Lorentz group $\mathrm{SO}^{+}(1,3)$, with kernel $\{+\mathbf{1}, -\mathbf{1}\}$. It is therefore exactly two-to-one. Moreover $\mathrm{SL}(2,\mathbb{C})$ is connected and simply connected, so it is the universal cover of $\mathrm{SO}^{+}(1,3)$ and consequently*

$$\pi_1\big(\mathrm{SO}^{+}(1,3)\big) \;\cong\; \ker\Lambda \;\cong\; \mathbb{Z}_2. \tag{3.100}$$

Proof. Homomorphism. For $A, B \in \mathrm{SL}(2,\mathbb{C})$ we compute the action of the product directly from Eq. (3.99): $(AB)X(AB)^{\dagger} = A\,(BXB^{\dagger})\,A^{\dagger}$. The inner factor $BXB^{\dagger}$ is the matrix avatar of $\Lambda(B)x$, and applying $A(\cdot)A^{\dagger}$ to it produces the avatar of $\Lambda(A)(\Lambda(B)x)$. Hence $\Lambda(AB) = \Lambda(A)\Lambda(B)$.

Kernel. Suppose $\Lambda(A) = \mathbf{1}$, i.e. $AXA^{\dagger} = X$ for every Hermitian X. Choosing $X = \mathbf{1}$ gives $AA^{\dagger} = \mathbf{1}$, so A is unitary. Then $AXA^{\dagger} = AXA^{-1} = X$ for all Hermitian X; since every complex 2×2 matrix is a complex linear combination of Hermitian matrices (write $M = \frac{1}{2}(M + M^{\dagger}) + i\cdot\frac{1}{2i}(M - M^{\dagger})$, both summands Hermitian), A commutes with *every* 2×2 matrix. By Schur's lemma (Chapter 2) $A = c\,\mathbf{1}$ for some scalar c, and $\det A = 1$ forces $c^2 = 1$, so $c = \pm 1$. Thus $\ker\Lambda = \{\pm\mathbf{1}\}$, and because the kernel has two elements, Λ is exactly two-to-one onto its image.

Image lands in $\mathrm{SO}^{+}(1,3)$. The group $\mathrm{SL}(2,\mathbb{C})$ is connected: any A can be joined to $\mathbf{1}$ by a path inside $\mathrm{SL}(2,\mathbb{C})$, as the explicit polar decomposition below makes manifest. A continuous homomorphism carries a connected group into a connected subgroup, so $\Lambda(\mathrm{SL}(2,\mathbb{C}))$ lies in the connected component of the identity of $\mathrm{O}(1,3)$, which is precisely $\mathrm{SO}^{+}(1,3)$ (the transformations of determinant $+1$ that preserve the direction of time). In particular every $\Lambda(A)$ is proper and orthochronous; no parity or time reversal can arise from Eq. (3.98).

Surjectivity onto $\mathrm{SO}^{+}(1,3)$. The differential of Λ at the identity is an isomorphism of Lie algebras. Concretely, write $A = \mathbf{1} + \frac{1}{2}\,\zeta_j\,\sigma^{j} + \cdots$ with complex parameters $\zeta_j = -i\theta_j - \eta_j$; tracelessness of $\frac{1}{2}\zeta_j\sigma^{j}$ is automatic and is exactly

the linearised condition $\det A = 1$, so the six real parameters $(\vec{\theta}, \vec{\eta})$ parametrise the tangent space $\mathfrak{sl}(2) = \mathfrak{su}(2) \oplus i\,\mathfrak{su}(2)$ at $\mathbf{1}$. Substituting into Eq. (3.98) and keeping first order reproduces, as the explicit computation of Section 3.4.3 will show, an infinitesimal rotation by $\vec{\theta}$ and boost by rapidity $\vec{\eta}$ — the full six-dimensional Lorentz algebra of Section 3.2. Hence $d\Lambda$ is a linear isomorphism $\mathfrak{sl}(2)(\mathbb{C})_{\mathbb{R}} \xrightarrow{\sim} \mathfrak{so}(1,3)$ of six-dimensional real Lie algebras, so the image of Λ contains an open neighbourhood of the identity in $\mathrm{SO}^+(1,3)$. A connected Lie group is generated by any neighbourhood of its identity (every element is a finite product of elements near $\mathbf{1}$, since the union of all powers of a symmetric identity-neighbourhood is open, closed, and nonempty, hence everything), so Λ is onto $\mathrm{SO}^+(1,3)$.

Simple connectedness and π_1. Polar decomposition realises every $A \in \mathrm{SL}(2,\mathbb{C})$ uniquely as $A = PU$ with $P = (AA^\dagger)^{1/2}$ a positive-definite Hermitian matrix and $U = P^{-1}A$ unitary. Taking determinants, $\det P \det U = 1$ with $\det P > 0$ real and $|\det U| = 1$; the only solution is $\det P = 1$, $\det U = 1$, so $U \in \mathrm{SU}(2)$ and P is a positive Hermitian matrix of unit determinant. The set of such P is the image of the traceless Hermitian matrices under the exponential $P = \exp(\frac{1}{2}\vec{\eta}\cdot\vec{\sigma})$ and is homeomorphic to $\mathbb{R}^3$ (parametrised freely by $\vec{\eta}$), hence contractible; and $\mathrm{SU}(2) \cong S^3$ is simply connected (Chapter 2). Therefore, as a topological space,

$$\mathrm{SL}(2,\mathbb{C}) \;\cong\; \mathbb{R}^3 \times S^3, \tag{3.101}$$

which is connected and simply connected. A connected double cover of $\mathrm{SO}^+(1,3)$ by a simply connected group is its universal cover, and for a covering of connected groups the fibre over the identity — here $\ker\Lambda = \{\pm\mathbf{1}\}$ — is isomorphic to the fundamental group of the base. This proves Eq. (3.100), discharging the claim deferred from Section 3.1. □

Physical Insight

The two sheets are not a bookkeeping nuisance; they are the reason spinors exist. A rotation by 2π about a fixed axis is the *identity* in $\mathrm{SO}^+(1,3)$, but the path tracing it lifts to a path in $\mathrm{SU}(2) \subset \mathrm{SL}(2,\mathbb{C})$ from $+\mathbf{1}$ to $-\mathbf{1}$: a 2π rotation sends $A \to -A$, and only a 4π rotation returns to $+\mathbf{1}$. Any object that transforms under A rather than under $\Lambda(A)$ — a spinor — therefore picks up a sign under a full rotation. The non-trivial loop generating $\mathbb{Z}_2 = \pi_1(\mathrm{SO}^+(1,3))$ is exactly the 2π rotation, and the spinor's minus sign is the holonomy of the double cover around that loop. This single $\mathbb{Z}_2$ is what the spin–statistics connection of Chapter 11 will trade for the antisymmetry of fermionic wavefunctions.

3.4.3 Weyl spinors and their transformation laws

Theorem 3.23 tells us that $\mathrm{SL}(2,\mathbb{C})$ is the group whose representations we should be cataloguing, and it comes equipped with an obvious two-dimensional one: its own defining action on $\mathbb{C}^2$.

Definition 3.24 (Left- and right-handed Weyl spinors)**.** A *left-handed Weyl spinor* is a pair $\psi_L \in \mathbb{C}^2$ transforming in the defining (fundamental) representation of $\mathrm{SL}(2,\mathbb{C})$,

$$\psi_L \;\longrightarrow\; A\,\psi_L, \qquad A \in \mathrm{SL}(2,\mathbb{C}). \tag{3.102}$$

A *right-handed Weyl spinor* is $\psi_R \in \mathbb{C}^2$ transforming in the conjugate-inverse-transpose, or anti-fundamental, representation,

$$\psi_R \;\longrightarrow\; (A^\dagger)^{-1}\psi_R. \tag{3.103}$$

To see that these are the abstract $(\tfrac12,0)$ and $(0,\tfrac12)$ we read off their generators. Parametrise a general element near the identity, exactly as in the surjectivity argument, by a rotation angle $\vec\theta$ and a rapidity $\vec\eta$:

$$A(\vec\theta,\vec\eta) \;=\; \exp\!\Big(-\tfrac{i}{2}\,\vec\theta\cdot\vec\sigma - \tfrac12\,\vec\eta\cdot\vec\sigma\Big). \tag{3.104}$$

Then Eqs. (3.102) and (3.103) become, using $(A^\dagger)^{-1} = \exp(-\frac{i}{2}\vec\theta\cdot\vec\sigma + \frac12\vec\eta\cdot\vec\sigma)$ (the rapidity term is anti-Hermitian-conjugated and flips sign while the rotation term, being anti-Hermitian, does not),

$$\psi_L \to \exp\!\Big(\tfrac{(-i\vec\theta-\vec\eta)\cdot\vec\sigma}{2}\Big)\psi_L, \qquad \psi_R \to \exp\!\Big(\tfrac{(-i\vec\theta+\vec\eta)\cdot\vec\sigma}{2}\Big)\psi_R. \tag{3.105}$$

Both spinors carry the *same* rotation generator $\vec J = \vec\sigma/2$, the spin-$\frac12$ generator of $\mathfrak{su}(2)$ from Chapter 2; they differ only in the sign of the boost generator, $\vec K = \pm i\vec\sigma/2$. In terms of the commuting combinations $\vec A = \frac12(\vec J + i\vec K)$ and $\vec B = \frac12(\vec J - i\vec K)$ introduced in Section 3.3, the left spinor has $\vec A = \vec\sigma/2,\ \vec B = 0$ and the right spinor has $\vec A = 0,\ \vec B = \vec\sigma/2$. Thus ψ_L realises $(\tfrac12,0)$ and ψ_R realises $(0,\tfrac12)$, concretely and explicitly. This is the realisation promised in the section opening.

We should check that the parametrisation Eq. (3.104) is the one consistent with Eq. (3.98); verifying it on a boost both confirms the claim and shows where the second set of Pauli matrices, $\bar\sigma^\mu$, comes from.

Worked Example 3.25 (A boost from $\mathrm{SL}(2,\mathbb{C})$, and the appearance of $\bar\sigma^\mu$)**.** Take a pure boost along $\hat z$ with rapidity η, so $\vec\theta = 0$, $\vec\eta = \eta\,\hat z$, and from Eq. (3.104),

$$A = \exp(-\tfrac{\eta}{2}\sigma^3) = \mathrm{diag}(e^{-\eta/2},\, e^{+\eta/2}), \qquad A^\dagger = A.$$

With $X = x^0\mathbf{1} - \vec{x}\cdot\vec{\sigma}$ from Eq. (3.96), the congruence Eq. (3.98) acts only on the diagonal entries, which carry $x^0 \mp x^3$:

$$(AXA^\dagger)_{11} = e^{-\eta}(x^0 - x^3), \qquad (AXA^\dagger)_{22} = e^{+\eta}(x^0 + x^3),$$

while the off-diagonal entries (carrying x^1, x^2) are multiplied by $e^{-\eta/2}e^{+\eta/2} = 1$ and are unchanged. Writing $X' = x'^0\mathbf{1} - \vec{x}'\cdot\vec{\sigma}$ and matching, $x'^0 - x'^3 = e^{-\eta}(x^0 - x^3)$ and $x'^0 + x'^3 = e^{+\eta}(x^0 + x^3)$. Adding and subtracting,

$$x'^0 = x^0\cosh\eta + x^3\sinh\eta, \qquad x'^3 = x^0\sinh\eta + x^3\cosh\eta, \qquad x'^1 = x^1,\ x'^2 = x^2,$$

which is exactly a boost of rapidity η along $\hat{z}$. So Eq. (3.104) is the correct dictionary, and $\psi_L \to A\psi_L$ is genuinely a left Weyl spinor under this boost.

The same computation reveals the natural objects for forming Lorentz invariants and covariants. Define

$$\bar{\sigma}^\mu \;=\; (\mathbf{1}, -\vec{\sigma}) \;=\; (\mathbf{1}, -\sigma^1, -\sigma^2, -\sigma^3), \tag{3.106}$$

the spatial sign-flipped partner of $\sigma^\mu = (\mathbf{1}, \vec{\sigma})$. Consider the bilinear $j^\mu = \psi_L^\dagger\,\bar{\sigma}^\mu\,\psi_L$. Under Eq. (3.102) it becomes $\psi_L^\dagger A^\dagger\,\bar{\sigma}^\mu\,A\,\psi_L$, so it is a four-vector iff $A^\dagger\bar{\sigma}^\mu A = \Lambda^\mu{}_\nu\,\bar{\sigma}^\nu$. For the boost at hand, $A^\dagger\bar{\sigma}^0 A = A^2 = \mathrm{diag}(e^{-\eta}, e^{\eta}) = \cosh\eta\,\mathbf{1} - \sinh\eta\,\sigma^3 = \cosh\eta\,\bar{\sigma}^0 + \sinh\eta\,\bar{\sigma}^3$, since $\bar{\sigma}^3 = -\sigma^3$. The right-hand side is $\Lambda^0{}_0\,\bar{\sigma}^0 + \Lambda^0{}_3\,\bar{\sigma}^3$ with precisely the boost matrix entries found above. Hence $\psi_L^\dagger\bar{\sigma}^\mu\psi_L$ transforms as a contravariant four-vector. By the mirror argument $\psi_R^\dagger\,\sigma^\mu\,\psi_R$ is also a four-vector, with σ^μ and $\bar{\sigma}^\mu$ trading places. These two bilinears are the kinetic-term building blocks of the Weyl Lagrangians quantised in Chapter 11.

There is one more invariant we will need constantly. The defining and anti-fundamental representations are not independent: $\mathrm{SL}(2,\mathbb{C})$ leaves invariant the antisymmetric symbol

$$\varepsilon = i\sigma^2 = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \qquad \varepsilon^{-1} = -i\sigma^2 = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}, \tag{3.107}$$

which plays for spinor indices the role the metric $\eta_{\mu\nu}$ plays for vector indices. The key identity is that for *any* 2×2 matrix A,

$$A^{\mathsf{T}}\,\varepsilon\,A = (\det A)\,\varepsilon, \tag{3.108}$$

which one checks by direct multiplication (both sides are antisymmetric 2×2 matrices, so each is a multiple of ε, and comparing the $(1,2)$ entries gives the cofactor expansion $\det A$). For $A \in \mathrm{SL}(2,\mathbb{C})$ this reads $A^{\mathsf{T}}\varepsilon A = \varepsilon$, the precise statement that ε is an invariant bilinear form: the combination $\psi_L^{\mathsf{T}}\varepsilon\,\chi_L = \psi_L^1\chi_L^2 - \psi_L^2\chi_L^1$ of two left spinors is Lorentz invariant. Rearranging $A^\dagger\varepsilon A^* = \varepsilon$

(which is Eq. (3.108) conjugated, using $\varepsilon^* = \varepsilon$) — left-multiplying by $(A^\dagger)^{-1}$ and right-multiplying by ε^{-1} — gives the equally important

$$\varepsilon\, A^*\, \varepsilon^{-1} = (A^\dagger)^{-1}. \tag{3.109}$$

This says that $\varepsilon\, \psi_L^*$ transforms with $(A^\dagger)^{-1}$ — that is, as a *right*-handed Weyl spinor. The complex conjugate of a left spinor, dressed with ε, is a right spinor; this is the algebraic seed of both the Majorana condition (Section 3.4.6) and charge conjugation (Chapter 11).

3.4.4 The Dirac spinor and the Clifford algebra

A left and a right Weyl spinor can always be stacked into a single four-component object on which the Lorentz group acts reducibly. Doing so is not merely notational: it is forced by parity (next subsection), and it is the natural arena for the Clifford algebra of gamma matrices.

Definition 3.26 (Dirac spinor)**.** A *Dirac spinor* is the four-component column

$$\psi = \begin{pmatrix} \psi_L \\ \psi_R \end{pmatrix} \in \mathbb{C}^4, \tag{3.110}$$

carrying the reducible representation $(\tfrac{1}{2}, 0) \oplus (0, \tfrac{1}{2})$ of $\mathrm{SL}(2,\mathbb{C})$, with each block transforming by Eq. (3.105).

The reason this stacking is so productive is that the two-component matrices σ^μ and $\bar\sigma^\mu$ assemble into a set of four 4×4 matrices satisfying a single clean relation. Define, in the *Weyl* (chiral) basis,

$$\gamma^\mu = \begin{pmatrix} 0 & \sigma^\mu \\ \bar\sigma^\mu & 0 \end{pmatrix}, \qquad \sigma^\mu = (\mathbf{1}, \vec\sigma), \quad \bar\sigma^\mu = (\mathbf{1}, -\vec\sigma). \tag{3.111}$$

These obey the Clifford (Dirac) algebra

$$\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}\, \mathbf{1}_4, \tag{3.112}$$

the master relation of Chapter C (Appendix C), whose full set of trace and contraction identities we collect there and use here only without full proof. We can verify Eq. (3.112) directly from Eq. (3.111): the anticommutator is block-diagonal,

$$\{\gamma^\mu, \gamma^\nu\} = \begin{pmatrix} \sigma^\mu\bar\sigma^\nu + \sigma^\nu\bar\sigma^\mu & 0 \\ 0 & \bar\sigma^\mu\sigma^\nu + \bar\sigma^\nu\sigma^\mu \end{pmatrix},$$

and the two-component blocks satisfy $\sigma^\mu\bar\sigma^\nu + \sigma^\nu\bar\sigma^\mu = 2\eta^{\mu\nu}\mathbf{1}$. The latter is checked case by case: for $\mu = \nu = 0$ it is $2\mathbf{1} = 2\eta^{00}\mathbf{1}$; for $\mu = \nu = i$ it is

$2\sigma^i(-\sigma^i) = -2\mathbf{1} = 2\eta^{ii}\mathbf{1}$ (no sum); and for $\mu = 0, \nu = i$ it is $(-\sigma^i)+\sigma^i = 0 = 2\eta^{0i}$. The same holds for the lower block. The Weyl basis thus *solves* the Clifford algebra, and conversely any solution of Eq. (3.112) in 4×4 matrices is unitarily equivalent to it.

In this basis the chirality matrix is diagonal:

$$\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3 = \begin{pmatrix} -\mathbf{1} & 0 \\ 0 & +\mathbf{1} \end{pmatrix}, \qquad P_L = \tfrac{1-\gamma^5}{2} = \begin{pmatrix} \mathbf{1} & 0 \\ 0 & 0 \end{pmatrix}, \quad P_R = \tfrac{1+\gamma^5}{2} = \begin{pmatrix} 0 & 0 \\ 0 & \mathbf{1} \end{pmatrix}. \tag{3.113}$$

The projectors P_L, P_R extract the upper and lower blocks, so $P_L\psi = (\psi_L, 0)^{\mathsf{T}}$ and $P_R\psi = (0, \psi_R)^{\mathsf{T}}$ — chirality is literally the choice of Weyl component, which is why Eq. (3.110) writes ψ_L above ψ_R.

The Lorentz generators on a Dirac spinor are built from the gammas as

$$S^{\mu\nu} = \frac{i}{4}\,[\gamma^\mu, \gamma^\nu]\,, \tag{3.114}$$

and the Lorentz transformation of the spinor is $\psi \to \exp(-\frac{i}{2}\omega_{\mu\nu}S^{\mu\nu})\psi$, with $\omega_{\mu\nu}$ the antisymmetric parameter encoding $(\vec{\theta}, \vec{\eta})$. Two facts must be established: that Eq. (3.114) *is* a representation of the Lorentz algebra, and that it is the *reducible* representation $(\frac{1}{2}, 0) \oplus (0, \frac{1}{2})$ and no other. The first is a computation we owe the reader in full; the second follows by inspection of the blocks.

Worked Example 3.27 ($S^{\mu\nu} = \frac{i}{4}\,[\gamma^\mu, \gamma^\nu]$ satisfies the Lorentz algebra)**.** We show that the matrices Eq. (3.114) reproduce the Lorentz commutation relations of Section 3.2,

$$[S^{\mu\nu}, S^{\rho\sigma}] = i\big(\eta^{\nu\rho}S^{\mu\sigma} - \eta^{\mu\rho}S^{\nu\sigma} - \eta^{\nu\sigma}S^{\mu\rho} + \eta^{\mu\sigma}S^{\nu\rho}\big), \tag{3.115}$$

using only the Clifford relation Eq. (3.112). First rewrite $S^{\mu\nu}$ without the commutator. Since $[\gamma^\mu, \gamma^\nu] = 2\gamma^\mu\gamma^\nu - \{\gamma^\mu, \gamma^\nu\} = 2\gamma^\mu\gamma^\nu - 2\eta^{\mu\nu}$,

$$S^{\mu\nu} = \frac{i}{2}\big(\gamma^\mu\gamma^\nu - \eta^{\mu\nu}\big), \qquad \text{equivalently} \qquad \gamma^\mu\gamma^\nu = -2i\,S^{\mu\nu} + \eta^{\mu\nu}. \tag{3.116}$$

Step 1 (the gamma is a vector operator). We first compute $[S^{\mu\nu}, \gamma^\rho]$. Only the $\gamma^\mu\gamma^\nu$ piece of Eq. (3.116) contributes, so $[S^{\mu\nu}, \gamma^\rho] = \frac{i}{2}\,[\gamma^\mu\gamma^\nu, \gamma^\rho]$. Move γ^ρ through using $\gamma^\nu\gamma^\rho = 2\eta^{\nu\rho} - \gamma^\rho\gamma^\nu$ and $\gamma^\rho\gamma^\mu = 2\eta^{\rho\mu} - \gamma^\mu\gamma^\rho$:

$$\begin{aligned} \gamma^\mu\gamma^\nu\gamma^\rho &= \gamma^\mu\big(2\eta^{\nu\rho} - \gamma^\rho\gamma^\nu\big) = 2\eta^{\nu\rho}\gamma^\mu - \gamma^\mu\gamma^\rho\gamma^\nu, \\ \gamma^\rho\gamma^\mu\gamma^\nu &= \big(2\eta^{\rho\mu} - \gamma^\mu\gamma^\rho\big)\gamma^\nu = 2\eta^{\rho\mu}\gamma^\nu - \gamma^\mu\gamma^\rho\gamma^\nu, \end{aligned}$$

so that $[\gamma^\mu\gamma^\nu, \gamma^\rho] = 2\eta^{\nu\rho}\gamma^\mu - 2\eta^{\mu\rho}\gamma^\nu$, and therefore

$$[S^{\mu\nu}, \gamma^\rho] = i\big(\eta^{\nu\rho}\gamma^\mu - \eta^{\mu\rho}\gamma^\nu\big). \tag{3.117}$$

This is precisely the statement that γ^ρ transforms as a four-vector under the action generated by $S^{\mu\nu}$.

Step 2 (close the algebra). Now use Eq. (3.116) to write $S^{\rho\sigma}$ in terms of $\gamma^\rho\gamma^\sigma$ and apply the Leibniz rule for the commutator together with Eq. (3.117):

$$\begin{aligned}[S^{\mu\nu}, S^{\rho\sigma}] &= \frac{i}{2}\,[S^{\mu\nu}, \gamma^\rho\gamma^\sigma] = \frac{i}{2}\Big([S^{\mu\nu}, \gamma^\rho]\,\gamma^\sigma + \gamma^\rho\,[S^{\mu\nu}, \gamma^\sigma]\Big) \\ &= \frac{i}{2}\Big(i(\eta^{\nu\rho}\gamma^\mu - \eta^{\mu\rho}\gamma^\nu)\gamma^\sigma + \gamma^\rho\, i(\eta^{\nu\sigma}\gamma^\mu - \eta^{\mu\sigma}\gamma^\nu)\Big) \\ &= -\frac{1}{2}\Big(\eta^{\nu\rho}\gamma^\mu\gamma^\sigma - \eta^{\mu\rho}\gamma^\nu\gamma^\sigma + \eta^{\nu\sigma}\gamma^\rho\gamma^\mu - \eta^{\mu\sigma}\gamma^\rho\gamma^\nu\Big).\end{aligned}$$

Replace each product $\gamma^\alpha\gamma^\beta = -2iS^{\alpha\beta} + \eta^{\alpha\beta}$ from Eq. (3.116). The four pure-metric terms are $\eta^{\nu\rho}\eta^{\mu\sigma} - \eta^{\mu\rho}\eta^{\nu\sigma} + \eta^{\nu\sigma}\eta^{\rho\mu} - \eta^{\mu\sigma}\eta^{\rho\nu}$, which cancel in pairs ($\eta^{\nu\rho}\eta^{\mu\sigma} = \eta^{\mu\sigma}\eta^{\rho\nu}$ and $\eta^{\mu\rho}\eta^{\nu\sigma} = \eta^{\nu\sigma}\eta^{\rho\mu}$). The S-terms give

$$\begin{aligned}[S^{\mu\nu}, S^{\rho\sigma}] &= -\frac{1}{2}(-2i)\Big(\eta^{\nu\rho}S^{\mu\sigma} - \eta^{\mu\rho}S^{\nu\sigma} + \eta^{\nu\sigma}S^{\rho\mu} - \eta^{\mu\sigma}S^{\rho\nu}\Big) \\ &= i\Big(\eta^{\nu\rho}S^{\mu\sigma} - \eta^{\mu\rho}S^{\nu\sigma} - \eta^{\nu\sigma}S^{\mu\rho} + \eta^{\mu\sigma}S^{\nu\rho}\Big),\end{aligned}$$

where in the last step we used the antisymmetry $S^{\rho\mu} = -S^{\mu\rho}$, $S^{\rho\nu} = -S^{\nu\rho}$. This is Eq. (3.115) verbatim. The Dirac matrices therefore furnish an honest representation of the Lorentz algebra of Section 3.2.

That this representation is $(\tfrac12, 0) \oplus (0, \tfrac12)$ is now visible by inspection, since Eq. (3.114) is block-diagonal. Using Eq. (3.111), the commutator $[\gamma^\mu, \gamma^\nu]$ has vanishing off-diagonal blocks, so $S^{\mu\nu} = \mathrm{diag}(S_L^{\mu\nu}, S_R^{\mu\nu})$ acts independently on ψ_L and ψ_R. Evaluating the blocks, the rotation generators $J^k = \frac12\epsilon^{kij}S^{ij}$ come out to $\vec\sigma/2$ on *both* blocks, while the boost generators $K^k = S^{0k}$ are $-\frac{i}{2}\vec\sigma$ on the upper (ψ_L) block and $+\frac{i}{2}\vec\sigma$ on the lower (ψ_R) block. For the upper block, for instance, $S_L^{ij} = \frac{i}{4}(\sigma^i\bar\sigma^j - \sigma^j\bar\sigma^i) = \frac{i}{4}(\sigma^i(-\sigma^j) - \sigma^j(-\sigma^i)) = -\frac{i}{4}\,[\sigma^i, \sigma^j] = \frac12\epsilon^{ijk}\sigma^k$, whence $J_L^k = \frac12\sigma^k$, and $S_L^{0k} = \frac{i}{4}(\sigma^0\bar\sigma^k - \sigma^k\bar\sigma^0) = \frac{i}{4}(-\sigma^k - \sigma^k) = -\frac{i}{2}\sigma^k$. Exponentiating, the upper block of $\exp(-\frac{i}{2}\omega_{\mu\nu}S^{\mu\nu})$ is exactly the left-spinor law Eq. (3.105) and the lower block the right-spinor law. The Dirac representation is precisely the Weyl pair — nothing more, nothing less — which is the decomposition $(\tfrac12, 0) \oplus (0, \tfrac12)$ we set out to prove.

3.4.5 Parity and the necessity of the Dirac spinor

Everything so far lives inside the identity component $\mathrm{SO}^+(1,3)$, reached by $\mathrm{SL}(2,\mathbb{C})$. Parity $P : (x^0, \vec x) \mapsto (x^0, -\vec x)$ has $\det = -1$ and lies in a *disconnected* sheet of $\mathrm{O}(1,3)$, so it is not of the form $\Lambda(A)$ for any A. Its effect on representations is nonetheless completely fixed by its effect on the generators.

Proposition 3.28 (Parity exchanges the representation labels)**.** *Under parity the rotation generators are unchanged and the boost generators reverse sign,*

$$P: \quad \vec{J} \mapsto \vec{J}, \qquad \vec{K} \mapsto -\vec{K}. \tag{3.118}$$

Consequently the commuting $\mathfrak{su}(2)$ *generators of Section 3.3 are interchanged,* $\vec{A} \leftrightarrow \vec{B}$*, and parity maps the irreducible representation* (j_-, j_+) *to* (j_+, j_-)*. In particular it exchanges the two Weyl spinors,* $(\frac{1}{2}, 0) \leftrightarrow (0, \frac{1}{2})$*.*

Proof. Rotations are spatial and survive parity unchanged: $\vec{J}$ generates rotations of $\vec{x}$, and conjugating by P leaves a rotation a rotation, $P\, e^{-i\vec{\theta}\cdot\vec{J}} P^{-1} = e^{-i\vec{\theta}\cdot\vec{J}}$, so $\vec{J} \mapsto \vec{J}$. A boost, on the other hand, mixes x^0 with $\vec{x}$; conjugating a boost of rapidity $\vec{\eta}$ by P reverses the spatial direction and hence the boost, $P\, e^{-i\vec{\eta}\cdot\vec{K}} P^{-1} = e^{+i\vec{\eta}\cdot\vec{K}}$, giving $\vec{K} \mapsto -\vec{K}$. This is Eq. (3.118). (Equivalently and more compactly, parity acts on the generators $M^{\mu\nu}$ of Section 3.2 by $M^{\mu\nu} \mapsto P^{\mu}{}_{\rho} P^{\nu}{}_{\sigma} M^{\rho\sigma}$ with $P = \mathrm{diag}(+,-,-,-)$; the purely spatial $M^{ij} = \epsilon^{ijk} J_k$ pick up two sign flips and are unchanged, while the mixed $M^{0i} = K^i$ pick up one and flip sign.)

Now recall the decoupling combinations of Section 3.3, $\vec{A} = \frac{1}{2}(\vec{J} + i\vec{K})$ and $\vec{B} = \frac{1}{2}(\vec{J} - i\vec{K})$, the two commuting $\mathfrak{su}(2)$ factors labelled by spins (j_-, j_+). Applying Eq. (3.118),

$$\vec{A} = \tfrac{1}{2}(\vec{J} + i\vec{K}) \xmapsto{P} \tfrac{1}{2}(\vec{J} - i\vec{K}) = \vec{B}, \qquad \vec{B} \xmapsto{P} \vec{A}.$$

Parity swaps the two $\mathfrak{su}(2)$ factors. A representation in which the first factor carries spin j_- and the second j_+ is therefore carried, after parity, into the representation with the spins exchanged: $(j_-, j_+) \mapsto (j_+, j_-)$. Setting $(j_-, j_+) = (\frac{1}{2}, 0)$ gives $(0, \frac{1}{2})$, and vice versa. □

Figure 3.3 displays the action as a reflection of the (j_-, j_+) lattice across its diagonal. The physical consequence is immediate and decisive. A field that is to describe a spin-$\frac{1}{2}$ particle in a parity-respecting theory — and electromagnetism, the binding force of the electron, conserves parity — must transform into itself (up to a fixed unitary) under P. A single left Weyl spinor cannot: parity would map it to a right Weyl spinor, an object that does not live in the representation we started with. The smallest parity-invariant representation containing spin $\frac{1}{2}$ is therefore the *reducible* sum

$$(\tfrac{1}{2}, 0) \oplus (0, \tfrac{1}{2}), \tag{3.119}$$

on which parity acts by exchanging the two summands — concretely, by $\psi \mapsto \gamma^0 \psi$, since $\gamma^0 = \left(\begin{smallmatrix} 0 & \mathbf{1} \\ \mathbf{1} & 0 \end{smallmatrix}\right)$ in the Weyl basis swaps ψ_L and ψ_R. This is the Dirac spinor of Theorem 3.26. *Parity forces the Dirac representation.* The electron of QED is a Dirac field for exactly this reason; the neutrino, which participates only in the parity-violating weak interaction, can be (and in the minimal Standard Model is) a single Weyl spinor.

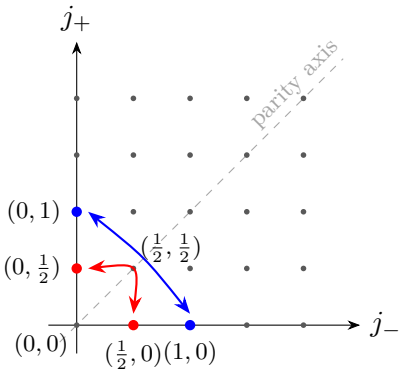

Figure 3.3: The lattice of finite-dimensional Lorentz representations (j_-, j_+). Parity reflects the lattice across the diagonal $j_- = j_+$, exchanging $(j_-, j_+) \leftrightarrow (j_+, j_-)$ (Theorem 3.28). The two Weyl spinors $(\frac{1}{2}, 0)$ (red) and $(0, \frac{1}{2})$ (red) are swapped, as are $(1, 0)$ and $(0, 1)$ (blue, the self-dual and anti-self-dual parts of the field strength). Only diagonal representations (j, j) — the scalar $(0, 0)$ and the vector $(\frac{1}{2}, \frac{1}{2})$ — are parity-invariant by themselves.

Physical Insight

The arithmetic of Theorem 3.28 also explains the rest of the field content of Section 3.3 at a glance. The scalar $(0, 0)$ and the four-vector $(\frac{1}{2}, \frac{1}{2})$ sit *on* the diagonal of Fig. 3.3 and are individually parity-invariant — consistent with a single scalar field and a single vector potential being perfectly good parity-even objects. The field strength $F_{\mu\nu}$, an antisymmetric tensor, sits at $(1, 0) \oplus (0, 1)$: its self-dual and anti-self-dual parts $(1, 0)$ and $(0, 1)$ are individually *off*-diagonal and are swapped by parity, which is the representation-theoretic statement that parity exchanges $\vec{E} \pm i\vec{B}$, i.e. sends $\vec{E} \to \vec{E}$, $\vec{B} \to -\vec{B}$. Parity is not an afterthought bolted onto the classification; it is a reflection symmetry of the whole lattice.

3.4.6 The Majorana condition

The Dirac spinor Eq. (3.110) carries four complex components, twice the count of a Weyl spinor. We saw in Eq. (3.109) that complex conjugation, dressed with ε, turns a left spinor into a right one. This opens the possibility of a *reality* constraint that ties the right block to the conjugate of the left block, halving the degrees of freedom while keeping a four-component, parity-friendly object.

Definition 3.29 (Majorana spinor)**.** A Dirac spinor satisfies the *Majorana condition* if its right-handed part is the ε-conjugate of its left-handed part,

$$\psi_R = \varepsilon\, \psi_L^* = i\sigma^2\, \psi_L^*. \tag{3.120}$$

A spinor obeying Eq. (3.120) is called a *Majorana spinor*; it is built from a single Weyl spinor ψ_L and carries two complex (four real) degrees of freedom, half those of a Dirac spinor.

The condition Eq. (3.120) is Lorentz covariant: this is exactly what Eq. (3.109) guarantees. Under a Lorentz transformation $\psi_L \to A\psi_L$, the left side of Eq. (3.120) transforms as $\psi_R \to (A^\dagger)^{-1}\psi_R$, while the right side transforms as $\varepsilon\psi_L^* \to \varepsilon A^*\psi_L^* = (\varepsilon A^*\varepsilon^{-1})\,\varepsilon\psi_L^* = (A^\dagger)^{-1}\varepsilon\psi_L^*$. Both sides transform identically, so a spinor satisfying the constraint in one frame satisfies it in all frames. The constraint is thus a Lorentz-invariant statement, and the Majorana spinor is a bona fide field, not a frame-dependent artifact.

Two remarks fix its meaning. First, the Majorana condition is the spinor analogue of the reality condition $\phi = \phi^*$ that distinguishes a real scalar from a complex one: it is the maximal reality constraint compatible with Lorentz invariance for a spin-$\frac{1}{2}$ field. Second, because $\varepsilon\psi_L^*$ is precisely the combination that will define the charge-conjugate field in Chapter 11, Eq. (3.120) states that a Majorana spinor equals its own charge conjugate; physically, the corresponding particle is its own antiparticle. Whether nature realises this for the neutrino is an open experimental question, pursued through the search for neutrinoless double beta decay; we flag it here only to mark that the algebraic possibility is forced on us by Eq. (3.109) and will be quantised in Chapter 11.

Notation Watch

The two-component sign conventions adopted here — $\sigma^\mu = (\mathbf{1}, \vec{\sigma})$, $\bar{\sigma}^\mu = (\mathbf{1}, -\vec{\sigma})$ of Eq. (3.106), the invariant $\varepsilon = i\sigma^2$ of Eq. (3.107), and the chiral gamma basis Eq. (3.111) with $\gamma^5 = \mathrm{diag}(-\mathbf{1}, +\mathbf{1})$ — are the ones used throughout this book and collected in Chapter C. They match the four-component spinor of Chapter 11 and the two-component (van der Waerden) notation revisited in the amplitudes chapters Chapter 58. References differ in the sign of γ^5 and in whether ψ_L sits above or below ψ_R in Eq. (3.110); we fix both choices once, here.

We now have the complete finite-dimensional dictionary: every field of the theory is a definite (j_-, j_+), the spin-$\frac{1}{2}$ entries are realised concretely as Weyl, Dirac, and Majorana spinors carried by the double cover $\mathrm{SL}(2,\mathbb{C})$, and parity organises them by reflection. What is still missing is the rest of the symmetry: these representations describe how fields respond to rotations and boosts *at a point*, but a relativistic theory must also be invariant under spacetime translations. Adjoining translations to the Lorentz group enlarges it to the Poincaré group, the actual symmetry algebra of relativistic quantum field theory, and turns the finite-dimensional (field) picture into the infinite-dimensional unitary (state) picture; that enlargement, and the semidirect-product structure $\mathbb{R}^{1,3} \rtimes \mathrm{SO}^+(1,3)$ it produces, is the business of Section 3.5.

3.5 The Poincaré group and algebra

The finite-dimensional classification just completed answers a sharp question: it lists every way a single multiplet of field components can transform linearly under the proper orthochronous Lorentz group $\mathrm{SO}^+(1,3)$, and it labels those ways by the pair (j_-, j_+) of half-integers. Scalars, Weyl spinors, the Dirac bispinor, the four-vector — the entire field content of the theories in this book sits somewhere in that list. Yet the list describes *fields*, the local carriers of the dynamics, and not the *states* of the quantum theory, the vectors in the physical Hilbert space whose inner products are probabilities. For states the relevant representations must be *unitary*, so that probability is conserved under symmetry transformations; and we have already seen that $\mathrm{SO}^+(1,3)$, being noncompact, has *no* nontrivial finite-dimensional unitary representation (Theorem 3.22). Something is missing.

What is missing is the rest of the symmetry group of Minkowski spacetime. The Lorentz group rotates and boosts about a fixed origin; but the laws of physics do not single out an origin of spacetime any more than they single out a rest frame. Spacetime is *homogeneous*: a translation $x \mapsto x + a$ is as good a symmetry as a rotation. Adjoining these translations to the Lorentz group produces the full isometry group of Minkowski space — the *Poincaré group* — and the generators of the translations are precisely the energy and momentum operators P^μ. Their spectrum, as we will see at the end of this section, is forced to be continuous, and that single fact is what makes the unitary representations infinite-dimensional: they are spaces of states labelled by momentum, not finite multiplets of field components. The Poincaré group, not the Lorentz group alone, is therefore the actual symmetry algebra of relativistic quantum field theory. This section builds it: the group, its semidirect-product structure, and its complete Lie algebra. (Throughout we keep the conventions fixed for this chapter: the metric is mostly-minus, $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, and $\hbar = c = 1$.)

3.5.1 Spacetime translations and the inhomogeneous Lorentz group

A Lorentz transformation acts on a spacetime point by the linear map $x^\mu \mapsto \Lambda^\mu{}_\nu x^\nu$, with $\Lambda \in \mathrm{SO}^+(1,3)$ preserving the quadratic form $\eta_{\mu\nu}x^\mu x^\nu$ and fixing the origin $x = 0$. The most general transformation that preserves the *interval* between any two points — the genuine isometry of Minkowski space — need not fix the origin. It is the affine map

$$x^\mu \longmapsto x'^\mu = \Lambda^\mu{}_\nu\, x^\nu + a^\mu, \qquad \Lambda \in \mathrm{SO}^+(1,3), \quad a \in \mathbb{R}^{1,3}, \tag{3.121}$$

the composition of a Lorentz transformation with a rigid translation by the constant four-vector a^μ. That this preserves intervals is immediate: for two points x, y, $x' - y' = \Lambda(x - y)$, so $\eta_{\mu\nu}(x'-y')^\mu(x'-y')^\nu = \eta_{\mu\nu}(x-y)^\mu(x-y)^\nu$.

Conversely, any interval-preserving map of Minkowski space onto itself is of this form; the translation part is $a^\mu = x'^\mu(0)$, the image of the origin, and the linear part is then forced to be Lorentz. We package the data as an ordered pair.

Definition 3.30 (Poincaré group)**.** The *Poincaré group* (the inhomogeneous Lorentz group) is the set

$$\mathrm{ISO}^+(1,3) \;=\; \{\,(\Lambda, a) : \Lambda \in \mathrm{SO}^+(1,3),\; a \in \mathbb{R}^{1,3}\,\} \tag{3.122}$$

of pairs, each acting on Minkowski space by Eq. (3.121), with the group operation defined by composition of these actions.

The composition law is fixed by demanding that the action Eq. (3.121) be a genuine left action: applying (Λ_2, a_2) and then (Λ_1, a_1) must equal applying their product. Track a point through both:

$$\begin{aligned} x \;&\xmapsto{(\Lambda_2,a_2)}\; \Lambda_2 x + a_2 \;\xmapsto{(\Lambda_1,a_1)}\; \Lambda_1(\Lambda_2 x + a_2) + a_1 \\ &=\; (\Lambda_1\Lambda_2)\, x + (a_1 + \Lambda_1 a_2). \end{aligned} \tag{3.123}$$

The right-hand side is the action Eq. (3.121) of the single pair $(\Lambda_1\Lambda_2,\; a_1 + \Lambda_1 a_2)$. Hence the group law is

$$\boxed{(\Lambda_1, a_1)\,(\Lambda_2, a_2) \;=\; (\Lambda_1\Lambda_2,\; a_1 + \Lambda_1 a_2).} \tag{3.124}$$

The structure is not a direct product: the translation parts do not simply add, because the second translation a_2 is first rotated by Λ_1 before being combined with a_1. This entanglement of the two factors — the rotation acting on the translation — is the whole content of what follows, and it is exactly what will produce the nonzero commutator $[M^{\mu\nu}, P^\rho]$ at the level of the algebra.

From Eq. (3.124) the unit element is $(\mathbf{1}, 0)$, and the inverse is found by solving $(\Lambda, a)(\Lambda', a') = (\mathbf{1}, 0)$: the Lorentz part gives $\Lambda' = \Lambda^{-1}$, and the translation part $a + \Lambda a' = 0$ gives $a' = -\Lambda^{-1} a$. Thus

$$(\Lambda, a)^{-1} \;=\; (\Lambda^{-1},\, -\Lambda^{-1} a), \tag{3.125}$$

which one checks also satisfies $(\Lambda, a)^{-1}(\Lambda, a) = (\mathbf{1}, 0)$. Associativity follows from associativity of matrix multiplication together with the linearity of Λ acting on a; we verify it once, since the same algebra recurs below:

$$\begin{aligned} \big[(\Lambda_1, a_1)(\Lambda_2, a_2)\big](\Lambda_3, a_3) &= (\Lambda_1\Lambda_2,\; a_1 + \Lambda_1 a_2)(\Lambda_3, a_3) \\ &= \big(\Lambda_1\Lambda_2\Lambda_3,\; a_1 + \Lambda_1 a_2 + \Lambda_1\Lambda_2 a_3\big), \end{aligned} \tag{3.126}$$

while grouping the other way,

$$(\Lambda_1, a_1)\big[(\Lambda_2, a_2)(\Lambda_3, a_3)\big] = (\Lambda_1, a_1)(\Lambda_2\Lambda_3,\; a_2 + \Lambda_2 a_3)$$

$$= (\Lambda_1\Lambda_2\Lambda_3,\ a_1 + \Lambda_1(a_2 + \Lambda_2 a_3)), \tag{3.127}$$

and the two translation parts agree because $\Lambda_1(a_2+\Lambda_2 a_3) = \Lambda_1 a_2 + \Lambda_1\Lambda_2 a_3$. The Poincaré group is therefore a genuine group; because both factors are smooth manifolds and the operations are smooth, it is a ten-dimensional Lie group — six Lorentz parameters and four translation parameters.

3.5.2 The semidirect-product structure

The composition law Eq. (3.124) is the defining instance of a construction introduced abstractly in Chapter 2: the *semidirect product*. We recall it here in the concrete setting we need, because the structure dictates the form of the algebra.

Two subgroups sit inside the Poincaré group. The *translations*

$$T \;=\; \{\, (\mathbf{1}, a) : a \in \mathbb{R}^{1,3} \,\} \tag{3.128}$$

form a copy of the additive group $\mathbb{R}^{1,3}$, since by Eq. (3.124) $(\mathbf{1}, a)(\mathbf{1}, b) = (\mathbf{1}, a+b)$; this subgroup is abelian. The *Lorentz transformations*

$$L \;=\; \{\, (\Lambda, 0) : \Lambda \in \mathrm{SO}^+(1,3) \,\} \tag{3.129}$$

form a copy of $\mathrm{SO}^+(1,3)$, with $(\Lambda_1, 0)(\Lambda_2, 0) = (\Lambda_1\Lambda_2, 0)$. Every Poincaré element factorizes *uniquely* as a translation followed by a Lorentz transformation,

$$(\Lambda, a) \;=\; (\mathbf{1}, a)\,(\Lambda, 0), \tag{3.130}$$

which is immediate from Eq. (3.124) since the right-hand side is $(\mathbf{1}\cdot\Lambda,\ a + \mathbf{1}\cdot 0) = (\Lambda, a)$. So as a set the group is the product $T \times L \cong \mathbb{R}^{1,3} \times \mathrm{SO}^+(1,3)$; what is nontrivial is how the two factors fail to commute.

The decisive structural fact is that the translation subgroup is *normal*: it is stable under conjugation by the whole group. Conjugating a pure translation $(\mathbf{1}, b)$ by an arbitrary element (Λ, a),

$$\begin{aligned}(\Lambda, a)\,(\mathbf{1}, b)\,(\Lambda, a)^{-1} &= (\Lambda,\ a + \Lambda b)\,(\Lambda^{-1},\ -\Lambda^{-1}a) \\ &= (\Lambda\Lambda^{-1},\ a + \Lambda b + \Lambda(-\Lambda^{-1}a)) \\ &= (\mathbf{1},\ a + \Lambda b - a) \;=\; (\mathbf{1},\ \Lambda b),\end{aligned} \tag{3.131}$$

where we used Eq. (3.125) for the inverse and Eq. (3.124) twice. The result $(\mathbf{1}, \Lambda b)$ is again a pure translation, so $T \trianglelefteq \mathrm{ISO}^+(1,3)$ is normal. The Lorentz subgroup L is *not* normal — conjugating $(\Lambda', 0)$ by a translation produces a translation part — which is the asymmetry built into the semidirect, as opposed to direct, product.

Eq. (3.131) does more than establish normality: it tells us exactly *how* the Lorentz factor acts on the normal factor. Conjugation by $(\Lambda, 0)$ sends the translation b to Λb — the Lorentz group acts on the space of translations by its defining four-vector representation. This is the data of a semidirect product.

Definition 3.31 (Semidirect product)**.** Let N and H be groups and let $\phi : H \to \mathrm{Aut}(N)$ be a homomorphism from H into the automorphisms of N, written $\phi_h(n)$. The *(outer) semidirect product* $N \rtimes_\phi H$ is the set $N \times H$ with the product

$$(n_1, h_1)(n_2, h_2) \;=\; (n_1\, \phi_{h_1}(n_2),\; h_1 h_2). \tag{3.132}$$

In it $N \cong \{(n, e)\}$ is normal, $H \cong \{(e, h)\}$ is a subgroup, $N \cap H = \{e\}$, and NH is the whole group; conjugation realizes the action, $(e, h)(n, e)(e, h)^{-1} = (\phi_h(n), e)$.

Theorem 3.32 (Poincaré as a semidirect product)**.** *The Poincaré group is the semidirect product*

$$\mathrm{ISO}^+(1,3) \;=\; \mathbb{R}^{1,3} \rtimes \mathrm{SO}^+(1,3), \tag{3.133}$$

where $\mathrm{SO}^+(1,3)$ *acts on the translation group* $\mathbb{R}^{1,3}$ *through its defining representation,* $\phi_\Lambda(b) = \Lambda b$*.*

Proof. Take $N = \mathbb{R}^{1,3}$ (written additively, with neutral element 0), $H = \mathrm{SO}^+(1,3)$, and $\phi_\Lambda(b) = \Lambda b$. That ϕ is a homomorphism into $\mathrm{Aut}(\mathbb{R}^{1,3})$ is clear: Λ acts linearly, so it is an additive automorphism, and $\phi_{\Lambda_1\Lambda_2} = \phi_{\Lambda_1} \circ \phi_{\Lambda_2}$ because $(\Lambda_1\Lambda_2)b = \Lambda_1(\Lambda_2 b)$. With these choices the abstract product Eq. (3.132) reads $(a_1, \Lambda_1)(a_2, \Lambda_2) = (a_1 + \Lambda_1 a_2,\, \Lambda_1\Lambda_2)$, which is exactly Eq. (3.124) after writing the pair in the order (Λ, a). The identification of the normal factor with the translations and of the conjugation action with ϕ is the content of Eq. (3.131). Hence the two groups coincide. □

Physical Insight

A semidirect product is the precise algebraic statement of "a symmetry that moves you around space, sitting inside a larger symmetry that also rotates the directions you can move in." Translations form the normal, abelian backbone; the Lorentz group is a non-normal factor that *stirs* that backbone by rotating and boosting the translation vectors. The same pattern — an abelian normal subgroup acted on by a nonabelian factor — recurs throughout physics: the Euclidean group $\mathbb{R}^3 \rtimes \mathrm{SO}(3)$ of nonrelativistic space, and the gauge groups of spontaneously broken theories. The nonabelian commutator that this structure forces between "momentum" and "rotation" is below.

3.5.3 The Lie algebra: generators and the translation block

We now linearize. By the Lie-group/Lie-algebra correspondence of Chapter 2, the ten-dimensional Poincaré group has a ten-dimensional Lie algebra, spanned by the infinitesimal generators of its one-parameter subgroups. We are interested in unitary representations on the Hilbert space of states, so we write the generators

as the Hermitian operators that represent the group there, $(\Lambda, a) \mapsto U(\Lambda, a)$ with U unitary and $U(\Lambda_1, a_1)U(\Lambda_2, a_2) = U((\Lambda_1, a_1)(\Lambda_2, a_2))$.

For the Lorentz factor we keep the convention fixed in Eq. (3.29): a Lorentz transformation $\Lambda^\mu{}_\nu = \delta^\mu_\nu + \omega^\mu{}_\nu$ with antisymmetric parameter $\omega_{\mu\nu} = -\omega_{\nu\mu}$ is represented by

$$U(\Lambda, 0) \;=\; \exp\!\Big(-\tfrac{i}{2}\,\omega_{\mu\nu} M^{\mu\nu}\Big), \qquad M^{\mu\nu} = -M^{\nu\mu}, \tag{3.134}$$

with the six Hermitian generators $M^{\mu\nu}$ obeying the Lorentz algebra established in Section 3.2,

$$[M^{\mu\nu}, M^{\rho\sigma}] \;=\; i(\eta^{\nu\rho} M^{\mu\sigma} - \eta^{\mu\rho} M^{\nu\sigma} - \eta^{\nu\sigma} M^{\mu\rho} + \eta^{\mu\sigma} M^{\nu\rho}). \tag{3.135}$$

For the translations we introduce four Hermitian generators P^μ, the *energy–momentum operators*, through

$$U(\mathbf{1}, a) \;=\; \exp\!\big(i\, a^\mu P_\mu\big) \;=\; \exp\!\big(i\, a \cdot P\big), \qquad a \cdot P \equiv a^\mu P_\mu = \eta_{\mu\nu} a^\mu P^\nu. \tag{3.136}$$

The sign and the factor of i are the standard quantum-mechanical convention: $P^0 = H$ is the Hamiltonian, generating time translations $U(\mathbf{1}, a^0) = e^{iHa^0}$, and P^i the momentum, with eigenvalues that will turn out to be the physical four-momenta. We read off the four-vector index on P^μ as a label for now; that it genuinely *is* a four-vector is the theorem of Section 3.5.4.

The first commutator is the easiest and follows directly from the abelian multiplication of translations. Since $(\mathbf{1}, a)(\mathbf{1}, b) = (\mathbf{1}, a + b) = (\mathbf{1}, b)(\mathbf{1}, a)$, the representing operators commute, $U(\mathbf{1}, a)U(\mathbf{1}, b) = U(\mathbf{1}, a + b) = U(\mathbf{1}, b)U(\mathbf{1}, a)$. Expanding both sides to second order in the parameters, $(1 + ia \cdot P - \frac{1}{2}(a \cdot P)^2 + \dots)(1 + ib \cdot P + \dots)$, the terms linear in each parameter cancel against the reversed product, and the surviving condition is $a_\mu b_\nu\, P^\mu P^\nu = a_\mu b_\nu\, P^\nu P^\mu$ for all a, b, i.e. $P^\mu P^\nu = P^\nu P^\mu$. Hence

$$\boxed{[P^\mu, P^\nu] \;=\; 0.} \tag{3.137}$$

The four energy–momentum operators commute: energy and the three momenta can be simultaneously diagonalized, and their common eigenvalues will label states. This is the algebraic shadow of the homogeneity of spacetime — translating first in one direction and then another gives the same result either way.

3.5.4 P^μ is a four-vector: the $[M, P]$ commutator

The remaining nontrivial commutator, $[M^{\mu\nu}, P^\rho]$, is forced entirely by the semidirect structure Eq. (3.131): it encodes the fact that conjugating a translation by a Lorentz transformation rotates the translation vector. We derive it cleanly by representing that conjugation statement and then linearizing.

Lift Eq. (3.131) with $a = 0$ to the representation. Because U is a homomorphism, $U(\Lambda,0)U(\mathbf{1},b)U(\Lambda,0)^{-1} = U((\Lambda,0)(\mathbf{1},b)(\Lambda,0)^{-1}) = U(\mathbf{1},\Lambda b)$. Writing the translations through Eq. (3.136),

$$U(\Lambda)\, e^{\,i\, b^\mu P_\mu}\, U(\Lambda)^{-1} \;=\; e^{\,i\,(\Lambda b)^\mu P_\mu}, \qquad U(\Lambda) \equiv U(\Lambda,0). \tag{3.138}$$

The exponent on the left is $i\, b^\mu\, U(\Lambda) P_\mu U(\Lambda)^{-1}$, since conjugation distributes over the power series of the exponential; the exponent on the right is $i\,(\Lambda b)^\mu P_\mu = i\,\Lambda^\mu{}_\nu b^\nu P_\mu = i\, b^\nu(\Lambda^\mu{}_\nu P_\mu)$. These hold for every b, so matching the coefficient of b^ν gives the finite transformation law of the momentum operator,

$$U(\Lambda)\, P_\nu\, U(\Lambda)^{-1} \;=\; \Lambda^\mu{}_\nu\, P_\mu. \tag{3.139}$$

This is precisely the statement that P_μ transforms as a covariant four-vector under the Lorentz group: conjugation by $U(\Lambda)$ acts on the index of P exactly as Λ acts on the index of a coordinate. (Raising the index with η and using $\eta^{\rho\nu}\Lambda^\mu{}_\nu\eta_{\mu\sigma} = (\Lambda^{-1})^\rho{}_\sigma$, the same law reads $U(\Lambda)P^\rho U(\Lambda)^{-1} = (\Lambda^{-1})^\rho{}_\sigma P^\sigma$, the contravariant form.)

Now linearize. Put $\Lambda^\mu{}_\nu = \delta^\mu_\nu + \omega^\mu{}_\nu$ with ω infinitesimal, and expand both sides of Eq. (3.139) to first order in ω. On the left, with $U(\Lambda) = 1 - \frac{i}{2}\omega_{\rho\sigma}M^{\rho\sigma} + \dots$ from Eq. (3.134) and $U(\Lambda)^{-1} = 1 + \frac{i}{2}\omega_{\rho\sigma}M^{\rho\sigma} + \dots$,

$$U(\Lambda)\, P_\nu\, U(\Lambda)^{-1} \;=\; P_\nu - \tfrac{i}{2}\,\omega_{\rho\sigma}\,[M^{\rho\sigma}, P_\nu] + O(\omega^2). \tag{3.140}$$

On the right,

$$\Lambda^\mu{}_\nu P_\mu = (\delta^\mu_\nu + \omega^\mu{}_\nu)P_\mu = P_\nu + \omega^\mu{}_\nu P_\mu. \tag{3.141}$$

We rewrite the inhomogeneous term to expose the antisymmetric parameter $\omega_{\rho\sigma}$. Lowering with the metric, $\omega^\mu{}_\nu = \eta^{\mu\alpha}\omega_{\alpha\nu}$, so $\omega^\mu{}_\nu P_\mu = \eta^{\mu\alpha}\omega_{\alpha\nu}P_\mu = \omega_{\alpha\nu}P^\alpha = \omega_{\rho\nu}P^\rho$ after renaming $\alpha \to \rho$. To match the structure $\omega_{\rho\sigma}(\cdots)$ on the left, insert δ^σ_ν and antisymmetrize in $\rho\sigma$, which is legitimate because $\omega_{\rho\sigma}$ is antisymmetric:

$$\omega_{\rho\nu}P^\rho \;=\; \omega_{\rho\sigma}\,\delta^\sigma_\nu\,P^\rho \;=\; \tfrac{1}{2}\,\omega_{\rho\sigma}\big(\delta^\sigma_\nu P^\rho - \delta^\rho_\nu P^\sigma\big). \tag{3.142}$$

Equating Eq. (3.140) with Eq. (3.142) and cancelling P_ν,

$$-\tfrac{i}{2}\,\omega_{\rho\sigma}\,[M^{\rho\sigma}, P_\nu] \;=\; \tfrac{1}{2}\,\omega_{\rho\sigma}\big(\delta^\sigma_\nu P^\rho - \delta^\rho_\nu P^\sigma\big). \tag{3.143}$$

The parameter $\omega_{\rho\sigma}$ is an arbitrary antisymmetric array and both sides are already antisymmetric in $\rho\sigma$, so the coefficients must match: $-i\,[M^{\rho\sigma}, P_\nu] = \delta^\sigma_\nu P^\rho - \delta^\rho_\nu P^\sigma$. Dividing by $-i$ (so that $1/(-i) = i$),

$$[M^{\rho\sigma}, P_\nu] \;=\; i\big(\delta^\sigma_\nu P^\rho - \delta^\rho_\nu P^\sigma\big). \tag{3.144}$$

Finally raise the index $\nu \to \lambda$ with $\eta^{\lambda\nu}$, using $\eta^{\lambda\nu}\delta^\sigma_\nu = \eta^{\lambda\sigma}$ and likewise for ρ, and rename $(\rho,\sigma,\lambda) \to (\mu,\nu,\rho)$:

$$\boxed{\;[M^{\mu\nu}, P^\rho] \;=\; i\big(\eta^{\nu\rho}P^\mu - \eta^{\mu\rho}P^\nu\big).\;} \tag{3.145}$$

This is the second nontrivial relation of the Poincaré algebra. It has the identical index structure to the action of $M^{\mu\nu}$ on the single index of any four-vector operator V^ρ — which is the invariant way of saying that P^ρ *is* a four-vector under the Lorentz generators, not merely a quartet of operators that happen to be labelled by a spacetime index.

It is worth confirming Eq. (3.145) against the nonrelativistic expectation in a concrete component, because a sign slip here propagates through the whole representation theory. Take $\mu\nu = 12$, so that $M^{12} = J^3$ is the generator of rotations about the third axis, and $\rho = 1$:

$$\left[J^3, P^1\right] = \left[M^{12}, P^1\right] = i(\eta^{21}P^1 - \eta^{11}P^2) = i(0 - (-1)P^2) = i\,P^2, \quad (3.146)$$

using $\eta^{11} = -1$. Lowering both spatial indices ($P^1 = -P_1$, $P^2 = -P_2$) this is $[J^3, P_1] = iP_2$, the familiar $[J_i, P_j] = i\epsilon_{ijk}P_k$ of elementary quantum mechanics. The relativistic relation Eq. (3.145) contains the nonrelativistic angular-momentum algebra as its rotation sub-block, and in addition tells us how boosts ($M^{0i} = K^i$) mix energy and momentum — for $\mu\nu = 0i$ and $\rho = 0$, $[K^i, P^0] = i(\eta^{i0}P^0 - \eta^{00}P^i) = -iP^i$, the statement that a boost generator does not commute with the Hamiltonian, exactly as it must since boosting changes the energy.

3.5.5 The full Poincaré algebra

Assembling Eqs. (3.135), (3.137) and (3.145) gives the complete Lie algebra of the Poincaré group, $\mathfrak{iso}(1,3)$, the symmetry algebra of every relativistic quantum field theory in this book:

$$[P^\mu, P^\nu] = 0, \quad (3.147)$$

$$[M^{\mu\nu}, P^\rho] = i(\eta^{\nu\rho}P^\mu - \eta^{\mu\rho}P^\nu), \quad (3.148)$$

$$[M^{\mu\nu}, M^{\rho\sigma}] = i(\eta^{\nu\rho}M^{\mu\sigma} - \eta^{\mu\rho}M^{\nu\sigma} - \eta^{\nu\sigma}M^{\mu\rho} + \eta^{\mu\sigma}M^{\nu\rho}). \quad (3.149)$$

Three structural features deserve to be named. First, the translations Eq. (3.147) form an abelian ideal: $[P, P] = 0$ and, by Eq. (3.148), $[M, P] \sim P$ closes back into the translations. An abelian normal subalgebra of this kind is exactly the infinitesimal counterpart of the normal subgroup T found in Eq. (3.131); it is the reason the Poincaré algebra is not semisimple, which in turn is why its representation theory (next section) cannot be read off the Cartan classification and instead requires Wigner's separate method. Second, Eq. (3.149) alone is the Lorentz subalgebra, closed in itself: setting all P^μ to zero recovers the homogeneous theory of Section 3.2. Third, the cross relation Eq. (3.148) is the only place the two factors talk to each other, and it says nothing more than "P is a four-vector": the entire nontriviality of gluing translations to Lorentz transformations is concentrated in that one line.

Notation Watch

The signs in Eqs. (3.148) and (3.149) are tied to the three conventions fixed above: the mostly-minus metric $\eta = \mathrm{diag}(+,-,-,-)$, the Lorentz exponential $U(\Lambda,0) = \exp(-\frac{i}{2}\omega_{\mu\nu}M^{\mu\nu})$ of Eq. (3.134), and the translation exponential $U(\mathbf{1},a) = \exp(+i\,a^\mu P_\mu)$ of Eq. (3.136). References that adopt mostly-plus, or the opposite sign in either exponent, will display $[M,M]$ or $[M,P]$ with flipped signs; the physical content — the rotation sub-block $[J_i,P_j] = i\epsilon_{ijk}P_k$ and $[J_i,J_j] = i\epsilon_{ijk}J_k$ — is convention-independent and is what we checked componentwise above.

To see the algebra realized in a setting where every commutator can be computed by hand, and to make contact with the fields that will carry it, we work out the action of the generators on functions of spacetime.

Worked Example 3.33 (The generators as differential operators on a scalar field)**.** A scalar field φ transforms under a Poincaré element by being dragged along with the spacetime point, $(U(\Lambda,a)\varphi)(x) = \varphi((\Lambda,a)^{-1}x) = \varphi(\Lambda^{-1}(x-a))$, the value at the new point equalling the old value at the pre-image. We extract the generators by linearizing this action and verify that they satisfy Eqs. (3.147) and (3.148) directly.

Translations. For $\Lambda = \mathbf{1}$ and infinitesimal a, $\varphi(x-a) = \varphi(x) - a^\mu\partial_\mu\varphi(x) + O(a^2)$. Matching against $U(\mathbf{1},a)\varphi = (1 + i\,a^\mu P_\mu)\varphi + O(a^2)$ from Eq. (3.136) gives $i\,a^\mu P_\mu\varphi = -a^\mu\partial_\mu\varphi$, so

$$P_\mu = i\,\partial_\mu, \qquad \text{equivalently} \qquad P^\mu = i\,\partial^\mu. \tag{3.150}$$

On a plane wave $\varphi = e^{-ip\cdot x}$ this gives $P_\mu\, e^{-ip\cdot x} = i\partial_\mu e^{-ip\cdot x} = p_\mu\, e^{-ip\cdot x}$, so the eigenvalue of P_μ is the four-momentum p_μ and that of $P^0 = H$ is the energy p^0, confirming the physical identification. The commutator Eq. (3.147) is now immediate: $[P^\mu,P^\nu] = -\,[\partial^\mu,\partial^\nu] = 0$, since partial derivatives commute.

Lorentz transformations. For $a = 0$ and $\Lambda^{-1\mu}{}_\nu = \delta^\mu_\nu - \omega^\mu{}_\nu$, the pre-image is $(\Lambda^{-1}x)^\mu = x^\mu - \omega^\mu{}_\nu x^\nu$, so $\varphi(\Lambda^{-1}x) = \varphi(x) - \omega^\mu{}_\nu x^\nu\partial_\mu\varphi + O(\omega^2)$. Writing the inhomogeneous piece as in Eq. (3.142), $\omega^\mu{}_\nu x^\nu\partial_\mu = \omega_{\rho\sigma}x^\sigma\partial^\rho = \frac{1}{2}\omega_{\rho\sigma}(x^\sigma\partial^\rho - x^\rho\partial^\sigma)$, and matching against $U(\Lambda,0)\varphi = (1 - \frac{i}{2}\omega_{\rho\sigma}M^{\rho\sigma})\varphi$ gives

$$M^{\mu\nu} = i(x^\mu\partial^\nu - x^\nu\partial^\mu). \tag{3.151}$$

This is the orbital angular-momentum operator promoted to spacetime; for a field carrying internal indices there would be an additional spin piece, but the scalar has none.

Verification of $[M^{\mu\nu},P^\rho]$. Using Eqs. (3.150) and (3.151) and the elementary relation $[x^\mu,\partial^\rho] = -\eta^{\mu\rho}$ (from $\partial^\rho x^\mu = \eta^{\rho\alpha}\partial_\alpha x^\mu = \eta^{\rho\alpha}\delta^\mu_\alpha = \eta^{\rho\mu}$),

$$[M^{\mu\nu},P^\rho] = [\,i(x^\mu\partial^\nu - x^\nu\partial^\mu)\,,\,i\,\partial^\rho\,] = -\,[x^\mu\partial^\nu - x^\nu\partial^\mu,\partial^\rho]$$

$$= -\Big([x^\mu, \partial^\rho]\,\partial^\nu - [x^\nu, \partial^\rho]\,\partial^\mu\Big) = -(-\eta^{\mu\rho}\partial^\nu + \eta^{\nu\rho}\partial^\mu)$$
$$= \eta^{\mu\rho}\partial^\nu - \eta^{\nu\rho}\partial^\mu, \tag{3.152}$$

where the $x^\mu\,[\partial^\nu, \partial^\rho]$ terms vanished. Substituting $\partial^\mu = -iP^\mu$ from Eq. (3.150),

$$[M^{\mu\nu}, P^\rho] = \eta^{\mu\rho}(-iP^\nu) - \eta^{\nu\rho}(-iP^\mu) = i(\eta^{\nu\rho}P^\mu - \eta^{\mu\rho}P^\nu), \tag{3.153}$$

in exact agreement with Eq. (3.148). A parallel computation reproduces Eq. (3.149); the differential realization Eqs. (3.150) and (3.151) thus furnishes an explicit, faithful representation of the entire Poincaré algebra on functions of spacetime, the representation that every classical field carries before its internal spin indices are switched on.

3.5.6 Unitary representations are infinite-dimensional

We close by drawing the structural conclusion that motivated adjoining translations in the first place, and that sets the agenda for the rest of the chapter. The physical states of a quantum theory live in a Hilbert space on which the symmetry acts by *unitary* operators; the generators P^μ and $M^{\mu\nu}$ are then Hermitian. We claim that any such representation, if it is nontrivial, is necessarily infinite-dimensional.

Theorem 3.34 (Nontrivial unitary Poincaré representations are infinite-dimensional)**.** *Let U be a unitary representation of* $\mathrm{ISO}^+(1,3)$ *on a Hilbert space $\mathcal{H}$ in which the energy–momentum operators P^μ are not all zero. Then* $\dim \mathcal{H} = \infty$.

Proof. Suppose, for contradiction, that $\dim \mathcal{H} = N < \infty$. The operators P^μ are Hermitian (because U is unitary and Eq. (3.136) holds) and mutually commuting by Eq. (3.147). On a finite-dimensional space a commuting family of Hermitian operators is simultaneously diagonalizable, so $\mathcal{H}$ has a basis of joint eigenvectors $|p, \ldots\rangle$ with $P^\mu\,|p, \ldots\rangle = p^\mu\,|p, \ldots\rangle$, and the set of eigenvalues $\mathrm{Spec} = \{p^\mu\} \subset \mathbb{R}^{1,3}$ is *finite*, of size at most N.

Now use Lorentz covariance. For any $\Lambda \in \mathrm{SO}^+(1,3)$ and any joint eigenvector $|p\rangle$, the finite transformation law Eq. (3.139) in its contravariant form gives, for the rotated state $|p'\rangle \equiv U(\Lambda)\,|p\rangle$,

$$P^\mu\,|p'\rangle = P^\mu U(\Lambda)\,|p\rangle = U(\Lambda)\,\big(U(\Lambda)^{-1}P^\mu U(\Lambda)\big)\,|p\rangle = U(\Lambda)\,\Lambda^\mu{}_\nu P^\nu\,|p\rangle = (\Lambda p)^\mu\;|p'\rangle\,. \tag{3.154}$$

So $|p'\rangle$ is again a joint eigenvector, with eigenvalue Λp. The spectrum Spec is therefore invariant under the action of the entire Lorentz group: if $p \in \mathrm{Spec}$ then $\Lambda p \in \mathrm{Spec}$ for every Λ. But the orbit of any nonzero four-vector p under $\mathrm{SO}^+(1,3)$ is an entire mass hyperboloid (when $p^2 = \eta_{\mu\nu}p^\mu p^\nu \neq 0$) or an entire light-cone sheet (when $p^2 = 0$, $p \neq 0$) — in every case an uncountably infinite set, since boosts move p continuously along the hyperboloid. A finite set cannot

contain an infinite one, so Spec can contain no nonzero vector; the only Lorentz-invariant finite subset of $\mathbb{R}^{1,3}$ is $\{0\}$. Hence $p^\mu = 0$ on all of $\mathcal{H}$, i.e. $P^\mu = 0$, contradicting the hypothesis. Therefore no nontrivial unitary representation is finite-dimensional. □

Physical Insight

This theorem is the precise sense in which *fields are not states*. The finite-dimensional representations classified earlier in this chapter — the scalar, the Weyl and Dirac spinors, the vector — are non-unitary, and they describe the local field operators: finite multiplets of components that mix under Lorentz transformations at a point. The states of the theory, by contrast, fill out infinite-dimensional unitary representations, organized by a *continuous* label — the momentum p^μ ranging over a Lorentz orbit — together with whatever discrete data distinguishes states of the same momentum. A one-particle state is not a point in a small matrix multiplet; it is a wavefunction on a mass shell. The tension between the two kinds of representation, finite-dimensional for fields and infinite-dimensional for states, is resolved by the field operators of later chapters, which are built precisely to intertwine them.

The proof has done more than establish a dimension count: it has shown that the *orbit* of p^μ under the Lorentz group — the mass hyperboloid or light-cone — is the natural arena, and that classifying the unitary representations means classifying these orbits together with the residual structure that survives at a fixed momentum. Two questions are thereby forced upon us. First, which Lorentz-invariant quantities distinguish the orbits and the representations built on them — that is, what are the *Casimir operators* of the Poincaré algebra Eqs. (3.147) to (3.149)? Second, what is the residual symmetry that fixes a chosen momentum p^μ — the *little group* — and how do its representations complete the classification? The next section constructs the two Casimirs, P^2 and the square of the Pauli–Lubański vector W^2, proves their invariance, and through them sets Wigner's method of induced representations in motion, reducing the entire problem to the pair (mass, little-group representation) — the data that, we will find, *is* the definition of a relativistic particle.

3.6 Casimir operators: mass and spin

The previous section closed the algebraic part of the story: adjoining translations to the Lorentz group produced the Poincaré algebra $\mathfrak{iso}(1,3)$, whose full set of commutators we recorded in Eqs. (3.147) to (3.149). That algebra is the symmetry algebra of every relativistic quantum theory in this book. What we have *not* yet done is the thing the whole chapter was built to do: classify the

unitary irreducible representations of this algebra, the representations that can act on a quantum-mechanical Hilbert space of states. The finite-dimensional representations classified in Sections 3.3 and 3.4 are non-unitary (the boosts are represented by non-Hermitian matrices, as Section 3.3.4 showed) and describe *fields*; the unitary representations describe *states*, and they are necessarily infinite-dimensional because the Lorentz group is non-compact. The Cartan machinery of Chapter 2 does not apply directly, because $\mathfrak{iso}(1,3)$ is not semisimple — the translations form an abelian ideal. The replacement, due to Wigner, rests on two operators that commute with everything in the algebra. By Theorem 2.21 such an operator acts as a single scalar on each irreducible representation, so its eigenvalue is a label that tells the representations apart. These are the *Casimir operators*, and this section constructs both of them, proves they are invariants, and then turns them into a complete classification scheme by reducing the problem to the representation theory of a single small subgroup — the little group. The orbit-by-orbit execution of that scheme is the business of Section 3.7; here we build the apparatus.

Throughout we use the conventions fixed earlier in the chapter: the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units $\hbar = c = 1$, the Hermitian Lorentz generators $M^{\mu\nu} = -M^{\nu\mu}$ of Theorem 3.11 and the translation generators P^μ, and the totally antisymmetric Levi–Civita symbol normalized to $\epsilon_{0123} = +1$, so that with all indices raised $\epsilon^{0123} = -1$ (collected in Chapter A). We will lean repeatedly on the three relations

$$[P^\mu, P^\nu] = 0, \tag{3.155}$$

$$[M^{\mu\nu}, P^\rho] = i(\eta^{\nu\rho}P^\mu - \eta^{\mu\rho}P^\nu), \tag{3.156}$$

$$[M^{\mu\nu}, M^{\rho\sigma}] = i(\eta^{\nu\rho}M^{\mu\sigma} - \eta^{\mu\rho}M^{\nu\sigma} - \eta^{\nu\sigma}M^{\mu\rho} + \eta^{\mu\sigma}M^{\nu\rho}), \tag{3.157}$$

which are Eqs. (3.147) to (3.149) of Section 3.5.5, recalled here for convenience.

3.6.1 The first Casimir: P^2 and mass

The simplest invariant is built from the translations alone. Because the four momenta commute among themselves by Eq. (3.155), their Lorentz-invariant contraction is a natural candidate for an operator that commutes with the whole algebra.

Definition 3.35 (First Casimir)**.** The *first Casimir operator* of the Poincaré algebra is the mass-squared operator

$$C_1 \;\equiv\; P^2 \;=\; P^\mu P_\mu \;=\; \eta_{\mu\nu}\,P^\mu P^\nu. \tag{3.158}$$

Proposition 3.36 (P^2 is a Casimir)**.** *The operator P^2 commutes with every generator of the Poincaré algebra:* $\left[P^2, P^\lambda\right] = 0$ *and* $\left[P^2, M^{\rho\sigma}\right] = 0$.

Proof. The first identity is immediate from Eq. (3.155): since each P^μ commutes with P^λ,

$$\left[P^2, P^\lambda\right] = \left[P^\mu P_\mu, P^\lambda\right] = \left[P^\mu, P^\lambda\right] P_\mu + P^\mu \left[P_\mu, P^\lambda\right] = 0. \tag{3.159}$$

For the second, we use the derivation property of the commutator together with Eq. (3.156). Lowering the free index in Eq. (3.156) gives $[M^{\rho\sigma}, P_\mu] = i(\delta^\sigma{}_\mu P^\rho - \delta^\rho{}_\mu P^\sigma)$, so

$$\begin{aligned}\left[M^{\rho\sigma}, P^2\right] &= [M^{\rho\sigma}, P^\mu]\, P_\mu + P^\mu\, [M^{\rho\sigma}, P_\mu] \\ &= i(\eta^{\sigma\mu} P^\rho - \eta^{\rho\mu} P^\sigma) P_\mu + i\, P^\mu (\delta^\sigma{}_\mu P^\rho - \delta^\rho{}_\mu P^\sigma) \\ &= i(P^\rho P^\sigma - P^\sigma P^\rho) + i(P^\sigma P^\rho - P^\rho P^\sigma) = 0,\end{aligned} \tag{3.160}$$

where in the last line we contracted the metrics ($\eta^{\sigma\mu} P_\mu = P^\sigma$, etc.) and then used $[P^\rho, P^\sigma] = 0$ to see each parenthesis vanish separately. Hence P^2 commutes with all ten generators. □

By Theorem 2.21, an operator that commutes with every element of an irreducible representation is a multiple of the identity. On a given unitary irreducible representation, therefore, P^2 takes a single fixed value, which we write as

$$P^2 = m^2\, \mathbf{1}. \tag{3.161}$$

The real number m^2 is the first invariant label of the representation. For physical one-particle states it is non-negative and $m \geq 0$ is the *mass* of the particle; on shell $p^2 = m^2$ is exactly the relativistic mass-shell condition, recovered here not as an equation of motion but as the statement that mass is a Casimir eigenvalue. The representations with $m^2 < 0$ (tachyonic) and the degenerate case $m^2 = 0$ are not excluded by the algebra and will be handled, with the physical verdict on each, in Section 3.7.1.

Physical Insight

That mass is a Casimir eigenvalue, not a parameter we are free to vary within a single particle species, is the representation-theoretic content of the statement "a particle has a definite mass." A superposition of states with different m^2 is not a state in any single irreducible representation; it is a state in a reducible one, and decomposing it is exactly what diagonalizing the mass matrix accomplishes in theories with mixing. The mass shell is the orbit of the momentum operator, and we will see in Section 3.6.3 that the entire representation is built by sweeping a single internal multiplet over that orbit.

3.6.2 The Pauli–Lubanski vector and the second Casimir

One invariant is not enough. The momentum-squared distinguishes representations by mass, but it says nothing about the internal degrees of freedom — the spin — that a particle of fixed mass can carry. A second invariant must be built from the Lorentz generators $M^{\mu\nu}$. The naive contraction $M^{\mu\nu}M_{\mu\nu}$ is Lorentz invariant but does *not* commute with the translations, so it is not a Casimir of the full Poincaré algebra. The correct object, which entangles the spin generators with the momentum in precisely the way that survives translations, is the Pauli–Lubanski vector.

Definition 3.37 (Pauli–Lubanski vector)**.** The *Pauli–Lubanski (pseudo)vector* is

$$W^{\mu} \;\equiv\; -\tfrac{1}{2}\,\epsilon^{\mu\nu\rho\sigma}\,P_{\nu}M_{\rho\sigma}. \tag{3.162}$$

The ordering of P_ν and $M_{\rho\sigma}$ in Eq. (3.162) is immaterial. Their commutator is $[P_\nu, M_{\rho\sigma}] = -\,[M_{\rho\sigma}, P_\nu] = -i(\eta_{\nu\sigma}P_\rho - \eta_{\nu\rho}P_\sigma)$, and contracting it with $\epsilon^{\mu\nu\rho\sigma}$ gives zero, because ϵ is antisymmetric in $(\nu\sigma)$ and in $(\nu\rho)$ while the two terms are symmetric in exactly those pairs. Thus $\epsilon^{\mu\nu\rho\sigma}P_\nu M_{\rho\sigma} = \epsilon^{\mu\nu\rho\sigma}M_{\rho\sigma}P_\nu$, and W^μ is unambiguous. Lowering the free index and relabelling dummies, Eq. (3.162) is identical to the form $W_\mu = -\frac{1}{2}\epsilon_{\mu\nu\rho\sigma}M^{\nu\rho}P^\sigma$ used in Section 3.7.

The Pauli–Lubanski vector has three defining properties, which together make W^2 a Casimir.

Proposition 3.38 (Properties of W^μ)**.** *The Pauli–Lubanski vector satisfies*

$$\left[W^{\mu}, P^{\lambda}\right] = 0, \tag{3.163}$$

$$W^{\mu}P_{\mu} = 0. \tag{3.164}$$

Moreover W^μ is a Lorentz four-vector operator:

$$[M^{\rho\sigma}, W^{\mu}] = i(\eta^{\sigma\mu}W^{\rho} - \eta^{\rho\mu}W^{\sigma}). \tag{3.165}$$

Proof. (i) $\left[W^{\mu}, P^{\lambda}\right] = 0$. Since P_ν commutes with P^λ, only the $M_{\rho\sigma}$ factor contributes:

$$\left[W^{\mu}, P^{\lambda}\right] = -\tfrac{1}{2}\,\epsilon^{\mu\nu\rho\sigma}\,P_{\nu}\,\left[M_{\rho\sigma}, P^{\lambda}\right]. \tag{3.166}$$

Lowering both Lorentz indices in Eq. (3.156) gives $\left[M_{\rho\sigma}, P^{\lambda}\right] = i(\delta^{\lambda}{}_{\sigma}P_\rho - \delta^{\lambda}{}_{\rho}P_\sigma)$, whence

$$\begin{aligned}\left[W^{\mu}, P^{\lambda}\right] &= -\tfrac{i}{2}\,\epsilon^{\mu\nu\rho\sigma}\left(\delta^{\lambda}{}_{\sigma}P_{\nu}P_{\rho} - \delta^{\lambda}{}_{\rho}P_{\nu}P_{\sigma}\right)\\ &= -\tfrac{i}{2}\Big(\epsilon^{\mu\nu\rho\lambda}P_{\nu}P_{\rho} - \epsilon^{\mu\nu\lambda\sigma}P_{\nu}P_{\sigma}\Big) = 0.\end{aligned} \tag{3.167}$$

In the first term $\epsilon^{\mu\nu\rho\lambda}$ is antisymmetric in $(\nu\rho)$ while $P_\nu P_\rho$ is symmetric (the momenta commute), so the contraction vanishes; the second term vanishes by the same argument in $(\nu\sigma)$. This proves Eq. (3.163).

(ii) $W^\mu P_\mu = 0$. Write $W^\mu P_\mu = -\frac{1}{2}\epsilon^{\mu\nu\rho\sigma} P_\nu M_{\rho\sigma} P_\mu$ and move P_μ to the left past $M_{\rho\sigma}$:

$$M_{\rho\sigma} P_\mu = P_\mu M_{\rho\sigma} + [M_{\rho\sigma}, P_\mu], \qquad [M_{\rho\sigma}, P_\mu] = i(\eta_{\mu\sigma} P_\rho - \eta_{\mu\rho} P_\sigma). \tag{3.168}$$

The first piece gives $-\frac{1}{2}\epsilon^{\mu\nu\rho\sigma} P_\nu P_\mu M_{\rho\sigma} = 0$, because ϵ is antisymmetric in $(\mu\nu)$ and $P_\nu P_\mu$ is symmetric. The second piece gives

$$-\tfrac{i}{2}\,\epsilon^{\mu\nu\rho\sigma} P_\nu (\eta_{\mu\sigma} P_\rho - \eta_{\mu\rho} P_\sigma) = -\tfrac{i}{2}\Big(\epsilon^{\mu\nu\rho}{}_{\mu}\, P_\nu P_\rho - \epsilon^{\mu\nu}{}_{\mu}{}^{\sigma} P_\nu P_\sigma\Big) = 0, \tag{3.169}$$

since each surviving symbol carries the index μ in two slots (one raised, one lowered by the metric) and is therefore antisymmetric under the exchange of those slots while the metric contracting them is symmetric. Hence Eq. (3.164) holds: W is orthogonal to P, leaving it with at most three independent components on a momentum eigenstate.

(iii) W^μ *is a four-vector.* This is the statement Eq. (3.165). We prove it by a structural argument that we isolate as a lemma, because it recurs whenever a covariant operator is assembled by contracting tensor operators with invariant symbols. □

Lemma 3.39 (Invariant symbols and tensor operators)**.** *Call a collection of operators* $T^{\mu_1\cdots\mu_n}$ *a* tensor operator *if each index transforms in the vector representation under the Lorentz generators, i.e. if for every index slot*

$$\Big[M^{ab}, T^{\cdots c\cdots}\Big] = i(\eta^{bc}\, T^{\cdots a\cdots} - \eta^{ac}\, T^{\cdots b\cdots}), \tag{3.170}$$

the replacement acting on the displayed slot and summed over all slots. Then:

1. *the momentum* P^μ *is a tensor operator (Eq. (3.156)), and the Lorentz generator* $M^{\rho\sigma}$ *is a tensor operator (Eq. (3.157));*
2. *the product of two tensor operators is a tensor operator with the union of their indices;*
3. *a constant tensor* $C^{\mu_1\cdots\mu_n}$ *that is* Lorentz invariant*, meaning*

$$\sum_{k=1}^{n} \omega^{\mu_k}{}_{\alpha}\, C^{\mu_1\cdots\alpha\cdots\mu_k} = 0 \qquad \text{for every antisymmetric } \omega_{ab}, \tag{3.171}$$

contracts a tensor operator into a tensor operator on the uncontracted indices. The metric $\eta^{\mu\nu}$ *and the Levi–Civita symbol* $\epsilon^{\mu\nu\rho\sigma}$ *are both Lorentz invariant in this sense.*

Proof. Statement (1) for P is Eq. (3.156) read as Eq. (3.170) with one index. For $M^{\rho\sigma}$, applying the single-index rule Eq. (3.170) to each of the two indices of $M^{\rho\sigma}$ and using $M^{ab} = -M^{ba}$ reproduces exactly Eq. (3.157); this is the computation already carried out around Eq. (3.34), now reinterpreted as "M transforms as an antisymmetric two-tensor." Statement (2) is the Leibniz rule for the commutator: $\big[M^{ab}, TS\big] = \big[M^{ab}, T\big]\, S + T\, \big[M^{ab}, S\big]$, and each term on the right is the vector action on the indices of T and of S respectively, so the sum is the vector action on all indices of TS.

For statement (3), recall the defining multilinear property of the determinant: for any 4×4 matrix Λ,

$$\Lambda^{\mu}{}_{a}\Lambda^{\nu}{}_{b}\Lambda^{\rho}{}_{c}\Lambda^{\sigma}{}_{d}\,\epsilon^{abcd} = (\det\Lambda)\,\epsilon^{\mu\nu\rho\sigma}. \tag{3.172}$$

Setting $\Lambda^{\mu}{}_{a} = \delta^{\mu}{}_{a} + \omega^{\mu}{}_{a}$ and expanding both sides to first order in ω, with $\det(\mathbf{1}+\omega) = 1 + \omega^{\alpha}{}_{\alpha} + O(\omega^2)$, the linear terms give

$$\omega^{\mu}{}_{\alpha}\epsilon^{\alpha\nu\rho\sigma} + \omega^{\nu}{}_{\alpha}\epsilon^{\mu\alpha\rho\sigma} + \omega^{\rho}{}_{\alpha}\epsilon^{\mu\nu\alpha\sigma} + \omega^{\sigma}{}_{\alpha}\epsilon^{\mu\nu\rho\alpha} = \big(\omega^{\alpha}{}_{\alpha}\big)\,\epsilon^{\mu\nu\rho\sigma}. \tag{3.173}$$

For ω in the Lorentz algebra the trace vanishes: $\omega^{\alpha}{}_{\alpha} = \eta^{\alpha\beta}\omega_{\beta\alpha} = 0$, the contraction of the symmetric η with the antisymmetric ω. Hence the left side of Eq. (3.173) is zero, which is precisely Eq. (3.171) for $C = \epsilon$. The same differentiation of the defining relation $\Lambda^{\mu}{}_{a}\Lambda^{\nu}{}_{b}\,\eta^{ab} = \eta^{\mu\nu}$ gives $\omega^{\mu}{}_{\alpha}\eta^{\alpha\nu} + \omega^{\nu}{}_{\alpha}\eta^{\mu\alpha} = \omega^{\mu\nu} + \omega^{\nu\mu} = 0$, so η is invariant too.

Finally, given an invariant C and a tensor operator T, form the contraction $U^{\cdots} = C^{\cdots}{}_{\nu_1\cdots\nu_k}\,T^{\cdots\nu_1\cdots\nu_k}$. Taking the commutator with M^{ab}, only T responds, and by Eq. (3.170) it produces the vector action on each of its indices. The actions on the *contracted* indices can be moved onto C at the cost of a sign, by the invariance identity Eq. (3.171) rewritten with the algebra index ab in place of the generic ω; these telescope and cancel, leaving exactly the vector action on the *free* indices. Thus U is a tensor operator. □

Equation (3.165) now follows in one line. By Theorem 3.39, the product $P_\nu M_{\rho\sigma}$ is a tensor operator with three lower indices, and $\epsilon^{\mu\nu\rho\sigma}$ is an invariant symbol; contracting ν, ρ, σ leaves the single free index μ, so $W^{\mu} = -\frac{1}{2}\epsilon^{\mu\nu\rho\sigma}P_\nu M_{\rho\sigma}$ is a vector operator, which is the content of Eq. (3.165). (The explicit index computation, expanding $\big[M^{ab}, P_\nu M_{\rho\sigma}\big]$ with Eqs. (3.156) and (3.157) and resumming, reproduces the same result; the lemma packages that algebra once and for all.) An independent check at the level of components is provided in Theorem 3.45 of the next section, where W^{μ} is evaluated in the rest frame and found to be the angular momentum.

With these properties in hand the second invariant is immediate.

Definition 3.40 (Second Casimir)**.** The *second Casimir operator* is the Lorentz square of the Pauli–Lubanski vector,

$$C_2 \;\equiv\; W^2 \;=\; W^{\mu}W_{\mu}. \tag{3.174}$$

Proposition 3.41 (W^2 is a Casimir)**.** $\left[W^2, P^\lambda\right] = 0$ *and* $\left[W^2, M^{\rho\sigma}\right] = 0$.

Proof. For the translations, Eq. (3.163) gives

$$\left[W^2, P^\lambda\right] = \left[W^\mu, P^\lambda\right] W_\mu + W^\mu \left[W_\mu, P^\lambda\right] = 0. \tag{3.175}$$

For the Lorentz generators, W^2 is a scalar contraction of the vector operator W^μ with the invariant metric, so it is invariant; explicitly, using Eq. (3.165) and its lowered form $[M^{\rho\sigma}, W_\mu] = i(\delta^\sigma{}_\mu W^\rho - \delta^\rho{}_\mu W^\sigma)$,

$$\begin{aligned}\left[M^{\rho\sigma}, W^2\right] &= \left[M^{\rho\sigma}, W^\mu\right] W_\mu + W^\mu \left[M^{\rho\sigma}, W_\mu\right] \\ &= i(\eta^{\sigma\mu} W^\rho - \eta^{\rho\mu} W^\sigma) W_\mu + i\, W^\mu (\delta^\sigma{}_\mu W^\rho - \delta^\rho{}_\mu W^\sigma) \\ &= i(W^\rho W^\sigma - W^\sigma W^\rho) + i(W^\sigma W^\rho - W^\rho W^\sigma) = 0. \end{aligned} \tag{3.176}$$

The two contributions cancel term by term, irrespective of whether the components of W commute among themselves; this is the algebraic signature of a Lorentz scalar. □

Again by Theorem 2.21, W^2 is a fixed scalar on each unitary irreducible representation. Its eigenvalue is the second invariant label; we will see in Section 3.7.2 that for $m > 0$ it equals $-m^2 s(s+1)$ with s the spin, and in Section 3.7.3 that for $m = 0$ it degenerates and helicity takes over. Before that, one further computation exposes *why* W^2 encodes spin: the components of W close, on a mass shell, into the angular-momentum algebra.

Worked Example 3.42 (The Pauli–Lubanski algebra and the emergence of spin)**.** We compute the commutator of two Pauli–Lubanski components and show it reduces, on a fixed momentum, to an $\mathfrak{su}(2)$. Start from Eq. (3.162) and use that P_α commutes with W^μ by Eq. (3.163), so only the $M_{\beta\gamma}$ factor responds:

$$[W^\mu, W^\nu] = -\tfrac{1}{2}\, \epsilon^{\nu\alpha\beta\gamma} P_\alpha \left[W^\mu, M_{\beta\gamma}\right]. \tag{3.177}$$

Because W^μ is a vector operator, Eq. (3.165) (lowered on the second pair) gives $[W^\mu, M_{\beta\gamma}] = -\left[M_{\beta\gamma}, W^\mu\right] = i(\delta^\mu{}_\beta W_\gamma - \delta^\mu{}_\gamma W_\beta)$. Substituting,

$$\begin{aligned}[W^\mu, W^\nu] &= -\tfrac{i}{2}\, \epsilon^{\nu\alpha\beta\gamma} P_\alpha (\delta^\mu{}_\beta W_\gamma - \delta^\mu{}_\gamma W_\beta) \\ &= -\tfrac{i}{2}\left(\epsilon^{\nu\alpha\mu\gamma} P_\alpha W_\gamma - \epsilon^{\nu\alpha\beta\mu} P_\alpha W_\beta\right) = -i\, \epsilon^{\nu\alpha\mu\gamma} P_\alpha W_\gamma, \end{aligned} \tag{3.178}$$

where the two terms combined after relabelling $\beta \to \gamma$ in the second and using $\epsilon^{\nu\alpha\gamma\mu} = -\epsilon^{\nu\alpha\mu\gamma}$. Renaming $\alpha \to \sigma$, $\gamma \to \rho$ and reordering the (commuting) W and P, the index string $\epsilon^{\nu\sigma\mu\rho}$ is brought to standard order by an odd permutation, $\epsilon^{\nu\sigma\mu\rho} = -\epsilon^{\mu\nu\rho\sigma}$, giving the covariant Pauli–Lubanski algebra

$$[W^\mu, W^\nu] = i\, \epsilon^{\mu\nu\rho\sigma} W_\rho P_\sigma. \tag{3.179}$$

Now specialize to a state of definite timelike momentum and pass to its rest frame, $P^\sigma \to (m, \mathbf{0})$, so that only $\sigma = 0$ contributes on the right:

$$\left[W^i, W^j\right] = i\, m\, \epsilon^{ijk0}\, W_k = i\, m\, \epsilon^{ijk}\, W^k, \tag{3.180}$$

using $\epsilon^{ijk0} = -\epsilon^{0ijk} = \epsilon^{ijk}_{(3)}$ (the three-dimensional symbol, since $\epsilon^{0123} = -1$) and $W_k = -W^k$. Defining the rest-frame spin $S^i \equiv W^i/m$, this reads $[S^i, S^j] = i\epsilon^{ijk}S^k$: *the spatial Pauli–Lubanski components, divided by the mass, satisfy exactly the angular-momentum algebra* $\mathfrak{su}(2)$ *of Chapter 2.* The Casimir $W^2 = -m^2\mathbf{S}^2$ is then $-m^2$ times the $\mathfrak{su}(2)$ Casimir, and on the spin-s irreducible representation $\mathbf{S}^2 = s(s+1)$. This is the algebraic reason a massive particle's internal states form a spin multiplet, and it identifies the relevant subgroup — the rotations that fix the rest momentum — as the object whose representations we must classify. The full extraction of $W^2 = -m^2 s(s+1)$ in components is carried out in Theorem 3.45.

3.6.3 The little group and Wigner's induced representations

We now have two invariant labels, (m^2, w^2), where w^2 is the eigenvalue of W^2. The remaining task is to construct the representation space itself and to see exactly what additional data, beyond these two numbers, specify it. The construction is Wigner's method of *induced representations*: build the entire Hilbert space by acting with the group on a single, carefully chosen multiplet of states sitting over one standard momentum. The structure that organizes this is a subgroup of the Lorentz group called the little group.

States and the momentum orbit. Because the four momenta commute, Eq. (3.155), we may diagonalize them simultaneously. A basis of the one-particle Hilbert space is

$$P^\mu\ |p, \sigma\rangle = p^\mu\ |p, \sigma\rangle\,, \tag{3.181}$$

where p^μ is the momentum eigenvalue and σ is a discrete label distinguishing states of the same momentum — the internal degeneracy we are trying to characterize. The first Casimir fixes $p^2 = m^2$ on the representation, so every accessible momentum lies on the mass shell. How a Lorentz transformation acts on these states follows from P^μ being a four-vector operator. The finite form of Eq. (3.156), established in Eq. (3.139), is $U(\Lambda)^{-1}P^\mu U(\Lambda) = \Lambda^\mu{}_\nu P^\nu$, equivalently $U(\Lambda)\, P^\mu\, U(\Lambda)^{-1} = (\Lambda^{-1})^\mu{}_\nu P^\nu$. Acting on a momentum eigenstate,

$$P^\mu \left(U(\Lambda)\,|p,\sigma\rangle\right) = U(\Lambda)\left(U(\Lambda)^{-1}P^\mu U(\Lambda)\right)|p,\sigma\rangle = U(\Lambda)\,\Lambda^\mu{}_\nu P^\nu\,|p,\sigma\rangle = (\Lambda p)^\mu\left(U(\Lambda)\,|p,\sigma\rangle\right). \tag{3.182}$$

Thus $U(\Lambda)\,|p,\sigma\rangle$ is a momentum eigenstate with eigenvalue Λp: *Lorentz transformations move momenta along the mass shell.* This intertwining property —

inherited unchanged by Section 3.7.1 — means that within a single irreducible representation the momenta sweep out exactly one Lorentz orbit, and $U(\Lambda)$ can change the internal label σ but cannot leave the orbit. The whole representation is therefore determined by (i) which orbit, and (ii) how the residual symmetry acts on σ at one point of the orbit.

Standard momentum and the little group. Choose, once and for all, a convenient reference point k^μ on the orbit — the *standard momentum* (for example $k = (m, \mathbf{0})$ on the massive shell, or $k = (\omega, 0, 0, \omega)$ on the light cone). Every other momentum p on the orbit is reached from k by some Lorentz transformation. The transformations that leave k alone form the key subgroup.

Definition 3.43 (Little group)**.** The *little group* of the standard momentum k is the stabilizer

$$G_k \;\equiv\; \{\, \Lambda \in \mathrm{SO}(1,3)^+ \;:\; \Lambda^\mu{}_\nu k^\nu = k^\mu \,\}, \tag{3.183}$$

the subgroup of proper orthochronous Lorentz transformations that fix k.

The little group is the precise carrier of spin. Its elements act on the standard momentum trivially, so they map the fibre of states $\{|k,\sigma\rangle\}$ over k to itself, and the way they shuffle the labels σ is a genuine finite-dimensional problem — a representation of G_k.

The induced construction. Pick for each momentum p on the orbit a specific "standard boost" $L(p)$, a Lorentz transformation with

$$L(p)^\mu{}_\nu\, k^\nu = p^\mu, \qquad L(k) = \mathbf{1}, \tag{3.184}$$

chosen smoothly in p (a choice of representatives for the cosets $\mathrm{SO}(1,3)^+/G_k$, which is the orbit). *Define* the states over a general momentum by boosting the fibre over k:

$$|p,\sigma\rangle \;\equiv\; U\big(L(p)\big)\;|k,\sigma\rangle\,. \tag{3.185}$$

We use the *covariant* normalization throughout, in which this factor-free definition is the right one and the resulting inner product is the Lorentz-invariant $\langle p',\sigma'|p,\sigma\rangle = (2\pi)^3 2E_{\mathbf{p}}\,\delta^3(\mathbf{p}-\mathbf{p}')\delta_{\sigma'\sigma}$ recorded below; the alternative non-covariant convention and the explicit energy factor it introduces are discussed honestly at the end of the subsection. The whole Hilbert space is thereby generated from the single fibre over k and a choice of boosts; nothing has been assumed about how $U(\Lambda)$ acts except on that one fibre.

Now compute the action of an arbitrary Lorentz transformation Λ on a general state. Using $U(\Lambda)U(L(p)) = U(\Lambda L(p))$ and inserting $\mathbf{1} = U(L(\Lambda p))U(L(\Lambda p))^{-1}$,

$$U(\Lambda)\,|p,\sigma\rangle = U\big(L(\Lambda p)\big)\,\underbrace{U\big(L(\Lambda p)^{-1}\,\Lambda\,L(p)\big)}_{W(\Lambda,p)}\,|k,\sigma\rangle\,. \tag{3.186}$$

The element $W(\Lambda, p) \equiv L(\Lambda p)^{-1} \Lambda\, L(p)$ is in the little group:

$$W(\Lambda, p)\, k = L(\Lambda p)^{-1}\, \Lambda\, L(p)\, k = L(\Lambda p)^{-1}\, \Lambda\, p = L(\Lambda p)^{-1} (\Lambda p) = k, \tag{3.187}$$

since by construction $L(\Lambda p)$ carries k to Λp. This $W(\Lambda, p) \in G_k$ is the *Wigner rotation*: the net little-group element produced by boosting up from k to p, transforming by Λ, and boosting back down from Λp to k. Because it fixes k, it acts only on the internal labels of the fibre,

$$U\big(W(\Lambda, p)\big)\, |k, \sigma\rangle = \sum_{\sigma'} D_{\sigma'\sigma}\big(W(\Lambda, p)\big)\ |k, \sigma'\rangle\,, \tag{3.188}$$

where the matrices $D(W)$ form a representation of G_k. Substituting back into Eq. (3.186) and recognizing $U(L(\Lambda p))\, |k, \sigma'\rangle = |\Lambda p, \sigma'\rangle$ from Eq. (3.185),

$$\boxed{U(\Lambda)\, |p, \sigma\rangle = \sum_{\sigma'} D_{\sigma'\sigma}\big(W(\Lambda, p)\big)\ |\Lambda p, \sigma'\rangle\,.} \tag{3.189}$$

This is the master formula — the covariant-normalization form, carrying no extra energy factor, exactly as it is reused in Eq. (3.199). It says the full, infinite-dimensional Poincaré representation is completely determined by the finite-dimensional little-group representation D: the momentum index is carried along the orbit by the geometric action $p \mapsto \Lambda p$, and *all* the nontrivial internal dynamics is the Wigner-rotation matrix $D(W(\Lambda, p))$.

That the matrices D genuinely form a representation is forced by associativity. From the definition of W one checks the composition law (a cocycle identity)

$$W(\Lambda_1 \Lambda_2,\, p) = W(\Lambda_1,\, \Lambda_2 p)\, W(\Lambda_2,\, p), \tag{3.190}$$

obtained by substituting the definitions and cancelling the intermediate $L(\Lambda_2 p)^{-1} L(\Lambda_2 p) = \mathbf{1}$. Applying Eq. (3.189) twice and demanding consistency with $U(\Lambda_1)U(\Lambda_2) = U(\Lambda_1\Lambda_2)$ then requires $D(W(\Lambda_1, \Lambda_2 p))D(W(\Lambda_2, p)) = D(W(\Lambda_1\Lambda_2, p))$, which is exactly Eq. (3.190): D is a homomorphism on G_k.

Theorem 3.44 (Wigner's classification, induced form)**.** *Let U be a unitary representation of the Poincaré group on a one-particle Hilbert space, built by induction from the standard momentum k as in Eqs. (3.185) and (3.189). Then U is irreducible if and only if the little-group representation D on the fibre over k is irreducible. Consequently the unitary irreducible representations of the Poincaré group are classified by*

> (the choice of momentum orbit, equivalently the value of P^2 and the sign of p^0) together with a unitary irreducible representation D of the little group G_k.

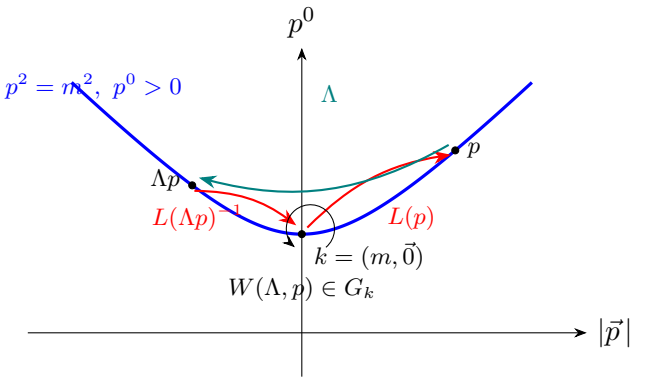

Figure 3.4: Wigner's induced construction on the massive shell. States over a general momentum p are defined by boosting the fibre over the standard momentum k with $L(p)$. A Lorentz transformation Λ moves $p \mapsto \Lambda p$ along the orbit; following the boost up from k, the transformation, and the boost back down, $W(\Lambda, p) = L(\Lambda p)^{-1} \Lambda L(p)$ returns to k and so lies in the little group G_k. All internal (spin) structure is the little-group matrix $D(W)$.

Proof sketch. The momentum operators act diagonally and transitively over the orbit, by Eq. (3.182): any two momenta are connected by some $U(\Lambda)$, so a nonzero Poincaré-invariant subspace must contain states of *every* momentum in the orbit, obtained by boosting. Restricted to the fibre over k, such a subspace is invariant under $U(G_k)$ — the little group maps the k-fibre to itself. Hence an invariant subspace of the whole representation is in one-to-one correspondence with a D-invariant subspace of the fibre: the representation is irreducible exactly when D is. The map (orbit, D) $\mapsto U$ is, conversely, surjective onto the irreducibles, because every irreducible U singles out an orbit (its momentum support) and an irreducible little-group action on the fibre. This is the content of Mackey's theory of induced representations for a semidirect product with abelian normal subgroup, of which $\mathbb{R}^{1,3} \rtimes \mathrm{SO}(1,3)^+$ is the case at hand. □

The classification has thus been reduced, completely, to a finite problem repeated once per orbit: find the little group, and list its unitary irreducible representations. The two Casimirs are the invariant fingerprints of the result — $P^2 = m^2$ names the orbit, and W^2 (on the massive orbit, $-m^2 s(s+1)$) names the little-group irrep — so the abstract pair (m^2, w^2) and the concrete pair (orbit, D) carry the same information.

Measure, normalization, and unitarity — stated honestly. The construction above is exact at the level of the group action, but a few analytic points must be named rather than glossed, because they are where the formal manipulation meets the demands of a genuine Hilbert space. The states

Eq. (3.181) are momentum eigenstates and hence not normalizable; they are continuum-normalized distributions, and the rigorous object is the Hilbert space $L^2(\mathcal{O}_m, d\tilde{p}) \otimes V_D$ of square-integrable, V_D-valued functions on the orbit $\mathcal{O}_m$, with V_D the little-group representation space. The natural measure on the mass shell is the Lorentz-invariant one,

$$d\tilde{p} \;=\; \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}}, \qquad E_{\mathbf{p}} = \sqrt{\mathbf{p}^2 + m^2} = p^0. \tag{3.191}$$

Its invariance is the identity

$$\int \frac{d^3p}{2E_{\mathbf{p}}}\, f(p) = \int d^4p\; \delta(p^2 - m^2)\, \theta(p^0)\, f(p), \tag{3.192}$$

obtained by performing the p^0 integral against $\delta(p^2 - m^2) = \delta\big((p^0)^2 - \mathbf{p}^2 - m^2\big) = \frac{1}{2E_{\mathbf{p}}}\delta(p^0 - E_{\mathbf{p}})$ on the forward sheet; the right-hand side is manifestly Lorentz invariant (each factor is), so the left-hand side is too. In the covariant convention adopted at Eq. (3.185) the states then satisfy the invariant normalization

$$\langle p', \sigma' | p, \sigma \rangle = (2\pi)^3\, 2E_{\mathbf{p}}\, \delta^3(\mathbf{p} - \mathbf{p}')\, \delta_{\sigma'\sigma}. \tag{3.193}$$

Two facts make the representation Eq. (3.189) unitary on this space. First, the measure Eq. (3.191) is invariant under $p \mapsto \Lambda p$, so the geometric part of the action preserves the L^2 inner product with the weight $2E_{\mathbf{p}}$ of Eq. (3.193) — this invariance is exactly why the covariant transformation law Eq. (3.189) carries *no* extra energy factor. Second, the internal part is the Wigner matrix $D(W)$, and *the whole construction is unitary if and only if D is a unitary representation of the little group.* This is the reason the classification demands *unitary* irreps of G_k, not arbitrary ones: only those give a unitary — hence physically admissible — Poincaré representation.

It is worth naming the alternative convention, since the discrepancy is a perennial source of sign-and-factor confusion. Rescaling to the non-covariant states $|p, \sigma\rangle_0 \equiv \big[(2\pi)^3 2E_{\mathbf{p}}\big]^{-1/2} |p, \sigma\rangle$ replaces Eq. (3.193) by the flat normalization $\langle p', \sigma' | p, \sigma \rangle_0 = \delta^3(\mathbf{p} - \mathbf{p}')\delta_{\sigma'\sigma}$, at the price of an explicit factor in the transformation law,

$$U(\Lambda)\, |p, \sigma\rangle_0 = \sqrt{\frac{E_{\Lambda\mathbf{p}}}{E_{\mathbf{p}}}} \sum_{\sigma'} D_{\sigma'\sigma}(W(\Lambda, p))\; |\Lambda p, \sigma'\rangle_0 \,, \tag{3.194}$$

the square root being precisely the Jacobian of $p \mapsto \Lambda p$ that the invariant measure absorbed above. The two conventions are unitarily equivalent and describe the same representation; we use the covariant one throughout, including in Section 3.7. Finally, the construction depends on the arbitrary choice of standard boost $L(p)$ (a section of $\mathrm{SO}(1,3)^+ \to \mathcal{O}_m$): a different section $L'(p) = L(p)\, h(p)$ with $h(p) \in G_k$ changes D by a p-dependent conjugation $D \mapsto D(h)^{-1} D\, D(h)$, which

is a unitary equivalence. The *equivalence class* of D — and therefore the physical content, the spin or helicity — is independent of this choice. We will make the standard choices explicit, orbit by orbit, in the next section.

This reduces the entire classification to a checklist: for each Lorentz orbit on momentum space, identify the little group G_k as a stabilizer, and read off its unitary irreducible representations. The forward timelike orbit will give the rotation group and its spins; the forward null orbit will give the Euclidean group of the plane and its helicities — and, as the degeneracy of that non-compact little group, the seed of gauge redundancy. Those orbits, together with the negative-energy, vacuum, and spacelike cases, are precisely what Section 3.7 now works out one by one, delivering the chapter's final answer to what a relativistic particle can be. The two invariants built here, $P^2 = m^2$ and W^2, are the labels that survive into dynamics: they fix the one-particle asymptotic states that enter the LSZ reduction of Chapter 14 for all three benchmark theories — the spin-0 scalar of ϕ^4 theory, the spin-$\frac{1}{2}$ electron of QED, and the massless helicity-1 photon and gluon of QED and Yang–Mills theory.

3.7 Wigner's classification: what a relativistic particle can be

The previous section reduced an enormous problem to a finite one. We constructed the two Poincaré Casimirs — the mass-squared operator P^2 and the Pauli–Lubanski square W^2 — proved that they commute with every generator, and set up Wigner's method of induced representations: a unitary irreducible representation of the Poincaré group is fixed by the value of P^2 on the orbit it lives on, together with an irreducible representation of the *little group*, the subgroup of the Lorentz group that fixes a chosen standard momentum on that orbit (Section 3.6). The classification of *all* one-particle states therefore amounts to one finite task repeated orbit by orbit: list the orbits of the Lorentz group on momentum space, identify the little group of each, and classify its unitary irreducible representations. That is the work of this section. When it is done we will have the complete catalogue of what a relativistic particle can be — the chapter's thesis — and, as a byproduct that will reshape everything that follows, we will see the massless case force the existence of gauge redundancy.

3.7.1 The orbits: where a momentum can live

A one-particle state is, before anything else, an eigenstate of the four-momentum operator P^μ with some eigenvalue p^μ. Acting with a Lorentz transformation $U(\Lambda)$ sends $|p, \sigma\rangle$ to a state of momentum Λp (this is the defining intertwining property of the unitary representation, Section 3.6). Hence within a single irreducible representation the accessible momenta form exactly one *Lorentz orbit*: a set

of the form $\{\Lambda p : \Lambda \in \mathrm{SO}(1,3)^{\uparrow}\}$. Because $p^2 = \eta_{\mu\nu}p^\mu p^\nu$ and the sign of p^0 are Lorentz invariants (the latter on account of the orthochronous restriction, Section 3.1.2), the orbits are precisely the level sets of these invariants. Writing $m^2 \equiv p^2$, the possibilities are:

(I) $m^2 > 0$, $p^0 > 0$: the *forward mass hyperboloid*. Standard momentum $k = (m, 0, 0, 0)$ — the rest frame.

(II) $m^2 > 0$, $p^0 < 0$: the backward mass hyperboloid. Standard momentum $k = (-m, 0, 0, 0)$.

(III) $m^2 = 0$, $p^0 > 0$: the *forward light cone* (minus its apex). Standard momentum $k = (\omega, 0, 0, \omega)$, any fixed $\omega > 0$.

(IV) $m^2 = 0$, $p^0 < 0$: the backward light cone. Standard momentum $k = (-\omega, 0, 0, \omega)$.

(V) $p^\mu = 0$: the single point at the origin. The vacuum.

(VI) $m^2 < 0$: the spacelike (single-sheeted) hyperboloid. Standard momentum $k = (0, 0, 0, \kappa)$, $\kappa > 0$. Tachyons.

Figure 3.5 shows the six families in the $(p^0, |\vec{p}\,|)$ half-plane. They exhaust momentum space: every p^μ has a definite $(p^2, \operatorname{sgn} p^0)$ and so lies in exactly one. The classification problem now splits into six independent sub-problems, one per orbit, and three of them we can dispose of immediately on physical grounds before doing any group theory.

The vacuum orbit (V) is trivial: the little group is the whole Lorentz group, and the physical vacuum is the unique Lorentz-invariant state, the one-dimensional trivial representation. It is a "particle" only in the degenerate sense of carrying no momentum and no spin.

The tachyonic orbit (VI) has little group $\mathrm{SO}(2,1)$, the stabilizer of a spacelike vector. This is a *non-compact* group; its nontrivial unitary representations are all infinite-dimensional, so a tachyon would carry an infinite tower of internal states. Worse, the orbit contains momenta with p^0 of either sign connected by orthochronous transformations only through the spacelike region, and a field built on it has spacelike-separated excitations that fail to commute — microcausality is lost. Tachyons therefore do not describe stable propagating particles. (When a "tachyonic mass" $m^2 < 0$ appears in a Lagrangian it signals that one is expanding about an unstable point of the potential; the cure is to find the true vacuum, the mechanism behind spontaneous symmetry breaking, taken up in Part VIII — it is never an honest one-particle state.) We set (VI) aside.

The backward orbits (II) and (IV) have $p^0 < 0$: they would be negative-energy states. In the quantum theory these are not discarded but *reinterpreted*: the

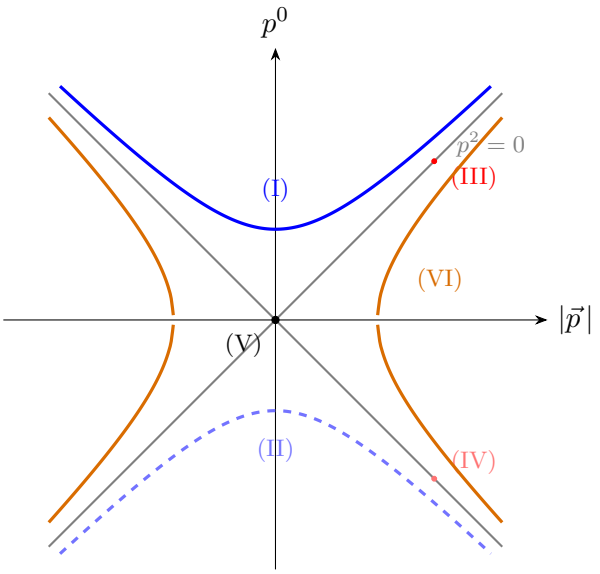

Figure 3.5: The Lorentz orbits in momentum space, drawn in the $(p^0, |\vec{p}\,|)$ half-plane (each point off the axis is a full SO(3) shell). The forward (I) and backward (II) mass hyperboloids carry the massive particles and antiparticles; the forward (III) and backward (IV) light cones carry the massless ones; the origin (V) is the vacuum; the spacelike hyperboloid (VI) would carry tachyons and is excluded. The light cone $p^2 = 0$ separates the timelike interior from the spacelike exterior.

construction of local fields will require, alongside each positive-energy particle, an equal-mass partner built from the backward orbit, the antiparticle, with the relabelling restoring positive energy. The little-group analysis of (II) and (IV) is identical to that of (I) and (III) — same stabilizer, same standard-momentum group — so the representation content is the same and we lose nothing by analyzing only the forward orbits here. The pairing of (I) with (II) and of (III) with (IV) is exactly the particle/antiparticle doubling that the spin–statistics and CPT discussion of Chapter 11 will make precise.

Two orbits remain to be worked in full: the massive forward hyperboloid (I) and the massless forward cone (III). They are genuinely different because their little groups are different — one compact, one not — and that single distinction is the origin of the deepest dichotomy in particle physics: massive particles carry *spin*, massless particles carry *helicity*, and only the massless case forces gauge redundancy.

3.7.2 The massive case: little group SU(2) and spin

Fix the standard momentum of orbit (I) at the rest frame value

$$k^\mu = (m, 0, 0, 0), \qquad m > 0. \tag{3.195}$$

The little group G_k is the set of $\Lambda \in \mathrm{SO}(1,3)^\uparrow$ with $\Lambda k = k$. A Lorentz transformation fixes the timelike vector $(m, 0, 0, 0)$ iff it leaves the time axis pointwise fixed, i.e. iff it acts only on the three spatial axes as a rotation:

$$G_k = \mathrm{SO}(3). \tag{3.196}$$

This is the heart of the massive case: *in the rest frame, the residual symmetry is exactly the rotation group*, the same SO(3) whose representation theory we already possess. The unitary representations of the little group are therefore the unitary representations of SO(3), or — because a quantum state is defined only up to phase and we have the option of representing the double cover — of its universal cover SU(2). Which one nature uses is not ours to choose a priori; both are admissible, and we have already classified them: the irreducible unitary representations of SU(2) are labelled by a spin

$$s \in \{0, \tfrac{1}{2}, 1, \tfrac{3}{2}, 2, \dots\}, \tag{3.197}$$

of dimension $2s+1$, spanned by the eigenstates $|s, s_3\rangle$ of J_3 with $s_3 \in \{-s, -s+1, \dots, s\}$ (Theorem 2.53). The integer-s representations are genuine representations of SO(3); the half-integer ones are faithful only on SU(2), the double cover whose existence we traced to the $\mathbb{Z}_2$ topology of the Lorentz group in Section 3.4.2. That a half-integer-spin state changes sign under a 2π rotation is not a paradox but the defining signature of the spinor representations built there.

Putting the pieces together through Wigner's induction, a massive one-particle representation is labelled by (m, s) and is spanned by states $|p, s_3\rangle$ where p ranges over the forward hyperboloid $p^2 = m^2,\ p^0 > 0$ and s_3 over the $2s+1$ values for fixed s. The boost $L(p)$ that carries k to p defines the states off the rest frame,

$$|p, s_3\rangle \equiv U(L(p))\ |k, s_3\rangle\,, \tag{3.198}$$

and a general Lorentz transformation acts by

$$U(\Lambda)\ |p, s_3\rangle = \sum_{s_3'} D^{(s)}_{s_3' s_3}(\mathcal{W}(\Lambda, p))\ |\Lambda p,\ s_3'\rangle\,, \qquad \mathcal{W}(\Lambda, p) \equiv L(\Lambda p)^{-1}\,\Lambda\,L(p) \in \mathrm{SU}(2), \tag{3.199}$$

where $D^{(s)}$ is the spin-s Wigner matrix and $\mathcal{W}$ is the *Wigner rotation*: the little-group element produced by going to p, transforming, and returning. The momentum index transforms by the orbit action; all the spin information is

carried by the finite-dimensional unitary matrix $D^{(s)}(\mathcal{W})$. The representation is manifestly unitary because $D^{(s)}$ is unitary, and it is irreducible because SU(2) acts irreducibly on each fixed-p fibre and the boosts move between fibres transitively. This is a complete, finite description of an infinite-dimensional Hilbert space: $2s+1$ numbers attached to each point of a three-dimensional hyperboloid.

It remains to connect this labelling to the invariant we built for exactly this purpose, the Pauli–Lubanski square, and confirm that "spin s" is the value of a Casimir and not merely a bookkeeping choice.

Worked Example 3.45 (W^2 **in the rest frame:** $W^2 = -m^2 s(s+1)$**).** Recall the Pauli–Lubanski vector from Section 3.6,

$$W_\mu = -\tfrac{1}{2}\,\varepsilon_{\mu\nu\rho\sigma}\,J^{\nu\rho}P^\sigma, \qquad \varepsilon_{0123} = +1, \tag{3.200}$$

with $J^{\nu\rho}$ the Lorentz generators and P^σ the translation generators. We evaluate $W^2 = W^\mu W_\mu$ directly on a rest-frame state, where $P^\sigma \to k^\sigma = m\,\delta^\sigma{}_0$ by Eq. (3.195). Substituting,

$$W_\mu = -\tfrac{1}{2}\,m\,\varepsilon_{\mu\nu\rho 0}\,J^{\nu\rho}. \tag{3.201}$$

The symbol $\varepsilon_{\mu\nu\rho 0}$ is nonzero only when μ,ν,ρ are the three *spatial* indices, so first $W_0 = 0$ (its index would have to be spatial). For a spatial index i,

$$W_i = -\tfrac{1}{2}\,m\,\varepsilon_{ijk0}\,J^{jk} = -\tfrac{1}{2}\,m\,(-\varepsilon_{ijk})\,J^{jk} = \tfrac{1}{2}\,m\,\varepsilon_{ijk}\,J^{jk}, \tag{3.202}$$

where $\varepsilon_{ijk0} = -\varepsilon_{0ijk} = -\varepsilon_{ijk}$ (one transposition moving the index 0 past three slots gives $(-1)^3$) and ε_{ijk} is the ordinary three-dimensional Levi-Civita symbol. Now $\frac{1}{2}\varepsilon_{ijk}J^{jk}$ is precisely the rotation generator J^i, the angular momentum, so

$$W_0 = 0, \qquad W_i = m\,J^i. \tag{3.203}$$

In the rest frame the Pauli–Lubanski vector *is* the angular momentum, rescaled by the mass — the precise sense in which W^μ generalizes spin covariantly. Contracting with the mostly-minus metric, and remembering $W^0 = W_0$, $W^i = -W_i$,

$$W^2 = W^\mu W_\mu = (W_0)^2 - \sum_{i=1}^{3}(W_i)^2 = 0 - m^2\sum_i (J^i)^2 = -m^2\,\mathbf{J}^2. \tag{3.204}$$

On the spin-s irreducible representation of the little group $\mathbf{J}^2 = s(s+1)$ (Theorem 2.53), so

$$\boxed{W^2 = -m^2\,s(s+1)\,.} \tag{3.205}$$

Because W^2 commutes with every Poincaré generator, this value is frame-independent: although we computed it in the rest frame, it holds on every state of the representation. The pair of Casimir eigenvalues $(P^2, W^2) = (m^2, -m^2 s(s+1))$ is the invariant fingerprint of the massive irrep, confirming that (m, s) are good labels and that "spin" is genuinely a Casimir of the Poincaré algebra, not an artefact of a frame.

The massive catalogue is now closed. For each $m > 0$ and each $s \in \{0, \frac{1}{2}, 1, \dots\}$ there is exactly one unitary irreducible representation, with $2s+1$ spin states. The scalar ($s = 0$) will be the quantum of ϕ^4 theory; the $s = \frac{1}{2}$ representation will be the electron of QED. Their field-theoretic homes are fixed in Section 3.7.5.

3.7.3 The massless case: little group ISO(2) and helicity

For a massless particle there is no rest frame: the orbit (III) is the light cone, and the standard momentum cannot be brought to $(m, 0, 0, 0)$. We choose instead a fixed null momentum along the z-axis,

$$k^\mu = (\omega, 0, 0, \omega), \qquad \omega > 0, \tag{3.206}$$

and ask which Lorentz transformations fix it. The answer is structurally richer than SO(3), and the difference is the whole story.

The little-group algebra. We work infinitesimally. Write the Lorentz generators as the rotations J_i and boosts K_i obeying the algebra established in Section 3.6,

$$[J_i, J_j] = i\varepsilon_{ijk} J_k, \qquad [J_i, K_j] = i\varepsilon_{ijk} K_k, \qquad [K_i, K_j] = -i\varepsilon_{ijk} J_k. \tag{3.207}$$

A generator X belongs to the little group iff its action annihilates k, i.e. iff the matrix $X^\mu{}_\nu$ satisfies $X^\mu{}_\nu k^\nu = 0$. The rotation about z obviously qualifies: J_3 fixes the z-axis and hence k. To find the rest, act with the elementary generators on $k = (\omega, 0, 0, \omega)$, using the explicit 4×4 matrices (boosts mix p^0 with a spatial component symmetrically, rotations mix two spatial components antisymmetrically). The boost K_1 sends $k \mapsto (0, \omega, 0, 0)$ (it raises a p^1 component from p^0), while the rotation J_2 sends $k \mapsto (0, \omega, 0, 0)$ as well (it rotates the z-component into x); their difference therefore annihilates k. The same in the y-direction relates K_2 and J_1. Define

$$A \equiv K_1 - J_2, \qquad B \equiv K_2 + J_1. \tag{3.208}$$

By construction $Ak = Bk = 0$: together with J_3 these are the three independent generators of the little group. Their algebra follows from Eq. (3.207) by direct computation. For $[J_3, A]$,

$$[J_3, A] = [J_3, K_1] - [J_3, J_2] = i\,\varepsilon_{312} K_2 - i\,\varepsilon_{321} J_1 = iK_2 + iJ_1 = iB, \tag{3.209}$$

using $\varepsilon_{312} = +1$, $\varepsilon_{321} = -1$. Likewise

$$[J_3, B] = [J_3, K_2] + [J_3, J_1] = i\,\varepsilon_{321} K_1 + i\,\varepsilon_{312} J_2 = -iK_1 + iJ_2 = -iA. \tag{3.210}$$

Finally

$$\begin{aligned}[A,B] &= [K_1 - J_2,\, K_2 + J_1] \\ &= [K_1,K_2] + [K_1,J_1] - [J_2,K_2] - [J_2,J_1] \\ &= (-i\,\varepsilon_{123}J_3) + 0 - 0 - (i\,\varepsilon_{213}J_3) \\ &= -iJ_3 + iJ_3 = 0,\end{aligned} \tag{3.211}$$

where the middle two brackets vanish because $[K_1, J_1] \propto \varepsilon_{11k} = 0$ and $[J_2, K_2] \propto \varepsilon_{22k} = 0$. Collecting,

$$[A,B] = 0, \qquad [J_3,A] = iB, \qquad [J_3,B] = -iA. \tag{3.212}$$

This is the Lie algebra $\mathfrak{iso}(2)$ of $\mathrm{ISO}(2) \cong E(2)$, the group of rigid motions of the Euclidean plane: A and B are the two commuting "translations," and J_3 is the "rotation" that mixes them like x and y. The massless little group is the symmetry group of a two-dimensional flat space — which is itself a miniature Poincaré group, with A, B playing the role of momenta and J_3 the role of angular momentum.

Representations and the continuous-spin trap. We now classify the unitary irreducible representations of ISO(2). The strategy mirrors Wigner's own method one dimension down. The translations commute, so we may diagonalize them simultaneously,

$$A\,|a,b\rangle = a\,|a,b\rangle\,, \qquad B\,|a,b\rangle = b\,|a,b\rangle\,. \tag{3.213}$$

The "rotation" J_3 acts on the eigenvalue pair (a, b) as a rotation of the plane — this is exactly content of $[J_3, A] = iB$, $[J_3, B] = -iA$ — so it preserves the invariant $A^2 + B^2$, the single Casimir of $\mathfrak{iso}(2)$. Set

$$A^2 + B^2 = \rho^2, \qquad \rho \geq 0. \tag{3.214}$$

Two cases arise, and the physical consequence of the distinction is enormous.

If $\rho > 0$, then (a, b) lives on a circle of radius ρ, and acting with finite J_3 rotations sweeps out the whole circle: the representation contains a continuum of states $|a, b\rangle$ parametrized by the angle on that circle, and a particle in it would carry a continuous internal degree of freedom together with an infinite tower of J_3 eigenvalues. These are the *continuous-spin* (or infinite-spin) representations. They are mathematically perfectly good unitary irreps of the Poincaré group, but they are not realized by any known particle, and there are strong reasons to expect they cannot be: ρ is a dimensionful continuous label, so such a particle would have a continuum of polarization states, giving, for instance, a divergent specific heat for any thermal gas of such particles and a thermodynamics incompatible

with observation. No local, finite-component field describes them. We therefore impose, as the physical selection rule that defines an ordinary massless particle,

$$\rho = 0 \quad \Longleftrightarrow \quad A\,|\psi\rangle = B\,|\psi\rangle = 0 \ \text{ on all physical states.} \tag{3.215}$$

(That $A^2 + B^2 = 0$ forces $A = B = 0$ follows because A, B are Hermitian: $\langle\psi|\, A^2 + B^2\,|\psi\rangle = \|A\psi\|^2 + \|B\psi\|^2 = 0$ makes each norm vanish.)

Caution

The vanishing of A and B is a *physical* restriction, not a theorem: continuous-spin representations exist and are unitary. What we have shown is that an ordinary massless particle — one with a finite number of polarization states and a local field description — is exactly the $\rho = 0$ case. The infinite-spin representations remain a live, if exotic, theoretical possibility; that they are absent from nature is an empirical input, dated and honest, not a consequence of Poincaré invariance alone.

Helicity. With $A = B = 0$ the little group collapses to the single remaining generator J_3. Its representations are one-dimensional — a massless particle of the ordinary type has *no internal multiplet at all*, only a single state per momentum — labelled by the eigenvalue

$$J_3\,|k\rangle = h\,|k\rangle\,, \tag{3.216}$$

the *helicity*. Because J_3 generates rotations about the direction of motion $\hat{k} = \hat{z}$, helicity is the projection of angular momentum onto the momentum, $h = \mathbf{J}\cdot\hat{p}$ — a Lorentz-invariant statement for a massless particle precisely because no boost can overtake it and flip $\hat{p}$. Evaluating the Casimirs on this representation, $P^2 = 0$ trivially and, since W^μ is built from $J^{\nu\rho}P^\sigma$ and reduces on the little group to a multiple of the momentum, $W^\mu = h\,P^\mu$; hence $W^2 = h^2P^2 = 0$. Both Casimirs vanish: the massless irreps are *not* distinguished by W^2 but by the single number h, which is why helicity, not spin, is the right label here.

Quantization of helicity. The allowed values of h are fixed by the same topology that gave us half-integer spin. A rotation by 2π about $\hat{z}$ is the identity in SO(3) but equals the nontrivial central element $-\mathbf{1}$ in its double cover; consistency of the representation under the closed loop of 2π rotations requires $e^{-2\pi i h} = \pm 1$, the sign being fixed once and for all by whether the state lies in a genuine SO(3) representation or in the double cover. This is exactly the $\mathbb{Z}_2 = \pi_1(\mathrm{SO}(1,3)^\uparrow)$ we identified in Sections 3.1.6 and 3.4.2: the universal cover $\mathrm{SL}(2,\mathbb{C})$ is a double cover, and its center acts on physical states by ± 1. Hence

$$h \in \left\{0,\ \pm\tfrac{1}{2},\ \pm 1,\ \pm\tfrac{3}{2},\ \ldots\right\}, \tag{3.217}$$

quantized in half-integers for precisely the reason spin is. Helicity quantization is not an independent postulate; it is the $\mathbb{Z}_2$ topology of the Lorentz group read off on the light cone.

The discrete operations and the pairing of $\pm h$. A given irreducible representation has a *single* helicity h; the positive- and negative-helicity states are, group-theoretically, different representations. Whether a particle carries both is decided by the discrete spacetime symmetries, which lie outside the connected component $\mathrm{SO}(1,3)^{\uparrow}$ (Section 3.1.3). Under parity P, the momentum reverses, $\vec{p} \to -\vec{p}$, while angular momentum, an axial vector, does not, $\mathbf{J} \to \mathbf{J}$; therefore helicity flips,

$$P: \quad h \longmapsto -h. \tag{3.218}$$

A parity-invariant massless theory must therefore contain *both* helicities $\pm h$: they are exchanged by P and so cannot be split apart without breaking it. The photon ($h = \pm 1$) and the graviton ($h = \pm 2$) accordingly come with two states each. The neutrinos of the Standard Model, by contrast, are described — in the idealization of exact masslessness — by single-helicity Weyl representations, and the theory is correspondingly *not* parity invariant: this is the chiral structure that Chapter 11's Weyl spinors realize at field level. Either way, the count is fixed: an ordinary massless particle is either one state (a single helicity, parity violated) or two (the pair $\pm h$, parity respected) — never the $2s+1$ of the massive case.

Physical Insight

The compactness of the little group is destiny. For $m > 0$ the little group $\mathrm{SU}(2)$ is compact, its irreps are finite-dimensional, and a massive particle of spin s carries the full $2s+1$-fold multiplet — a spin-1 massive vector has *three* polarizations. For $m = 0$ the little group $\mathrm{ISO}(2)$ is non-compact; demanding a finite number of states forces $A = B = 0$ and leaves only the abelian J_3, so a massless particle carries at most *two* helicity states regardless of how large $|h|$ is. The disappearing polarizations as $m \to 0$ — three becoming two for a vector — are not a smooth limit but a change in the little group itself, and the "lost" longitudinal state is exactly what gauge invariance will have to account for.

3.7.4 Helicity one cannot be a four-vector: the seed of gauge invariance

We have learned that a massless helicity-± 1 particle — the photon, the gluon — carries exactly two physical states. We will eventually want to describe it with a field that transforms simply under the Lorentz group, and the natural candidate

is a four-vector field $A^\mu(x)$, transforming in the $(\frac{1}{2},\frac{1}{2})$ representation built in Section 3.3.3. But A^μ has *four* components, and as an SO(3) representation $(\frac{1}{2},\frac{1}{2})$ decomposes as $\mathbf{4} = \mathbf{3} \oplus \mathbf{1}$, i.e. spin-1 plus spin-0. There is a mismatch between four field components and two physical helicity states, and the resolution of that mismatch is forced on us by the little group. It is the origin of gauge invariance.

To see it cleanly, track what the little group does to the polarization vectors directly.

Worked Example 3.46 (The little group shifts polarizations by k^μ: gauge redundancy is forced)**.** For the standard null momentum $k^\mu = (\omega, 0, 0, \omega)$ of Eq. (3.206), a one-photon state is created by a four-vector field contracted with a polarization vector $\varepsilon^\mu(k)$. The two physical (transverse) polarizations corresponding to helicity ± 1 are

$$\varepsilon^\mu_\pm(k) = \tfrac{1}{\sqrt{2}}\,(0,\ 1,\ \pm i,\ 0), \tag{3.219}$$

the same circular-polarization combinations familiar from classical electromagnetism, chosen so that a rotation by θ about $\hat{z}$ multiplies $\varepsilon_\pm$ by $e^{\mp i\theta}$, confirming helicity ± 1. Now apply a little-group "translation," the generator $A = K_1 - J_2$ of Eq. (3.208), to ε_+. Acting on a four-vector V, the boost contributes $K_1 : V^1 \to V^1 + \alpha V^0$, $V^0 \to V^0 + \alpha V^1$, and the rotation $J_2 : V^1 \to V^1 + \alpha V^3$, $V^3 \to V^3 - \alpha V^1$ at first order in the parameter α. On $\varepsilon_+ = \frac{1}{\sqrt{2}}(0,1,i,0)$, only the $V^1 = 1/\sqrt{2}$ component sources anything:

$$A\,\varepsilon_+ = K_1\,\varepsilon_+ - J_2\,\varepsilon_+ = \tfrac{1}{\sqrt{2}}(1,0,0,0) - \tfrac{1}{\sqrt{2}}(0,0,0,-1) = \tfrac{1}{\sqrt{2}}(1,0,0,1) = \frac{1}{\sqrt{2}\,\omega}\,k^\mu. \tag{3.220}$$

The action of the little group on the polarization vector is *not* homogeneous: it shifts ε^μ_+ by a multiple of the momentum k^μ itself. Exponentiating, a finite little-group element W acts as

$$\varepsilon^\mu_\pm(k) \ \longmapsto\ \varepsilon^\mu_\pm(k) + \beta(W)\,k^\mu, \tag{3.221}$$

with β a real parameter determined by W. The transverse polarizations do *not* transform among themselves as the components of a genuine four-vector would; the inhomogeneous k^μ term is unavoidable, a direct consequence of the non-compact translations A, B in $\mathfrak{iso}(2)$.

There are only two ways to live with Eq. (3.221). Either ε^μ is not a Lorentz four-vector — but then the field built from it is not Lorentz covariant, and manifest relativistic invariance is lost. Or we keep the covariant four-vector field A^μ and *declare the shift Eq. (3.221) to be a redundancy of description*: two polarization vectors differing by a multiple of k^μ describe the same physical state,

$$\varepsilon^\mu(k) \ \sim\ \varepsilon^\mu(k) + \beta\,k^\mu. \tag{3.222}$$

This is exactly a gauge transformation. In position space $\varepsilon^\mu(k)e^{-ik\cdot x}$ is the plane-wave content of $A^\mu(x)$, and adding $\beta k^\mu e^{-ik\cdot x}$ is adding $\partial^\mu\chi$ for $\chi \propto e^{-ik\cdot x}$: the equivalence Eq. (3.222) is the momentum-space form of

$$A^\mu(x) \;\sim\; A^\mu(x) + \partial^\mu\chi(x). \tag{3.223}$$

The bookkeeping now closes perfectly. The four components of A^μ are reduced by one through the equivalence Eq. (3.222) (the freedom to add k^μ) and by one more through the masslessness constraint that removes the would-be time-like/longitudinal mode ($k\cdot\varepsilon = 0$ together with the shift), leaving $4 - 2 = 2$ physical degrees of freedom — exactly the two helicities. Gauge invariance is not an aesthetic principle imposed from outside; it is the price of writing a massless helicity-1 particle, which intrinsically has two states, inside a Lorentz-covariant four-component field.

This is the chapter's most consequential conclusion, so it is worth stating plainly. A massive spin-1 particle has three states and is described, without redundancy, by a constrained four-vector (the Proca field, with $\partial_\mu A^\mu = 0$ eliminating the fourth component). A massless helicity-1 particle has only two states, and *no* unconstrained or simply-constrained four-vector field can carry exactly two Lorentz-covariant states: the little group forces the inhomogeneous transformation Eq. (3.221), and the only Lorentz-covariant way to absorb it is to gauge it away. Every gauge theory in this book — the electromagnetism of QED, the Yang–Mills theory of Yang–Mills theory — is, at bottom, a response to this single representation-theoretic fact. The full development is owed to later chapters: the classical gauge principle in Chapter 8, the quantization of the photon with its physical-state problem in Chapter 13, and the non-abelian generalization in Chapter 25. What Theorem 3.46 establishes is that those chapters are not introducing a new postulate but discharging a debt incurred here, on the light cone, by Wigner's classification.

3.7.5 The catalogue: fields to particles

We can now lay the two halves of the chapter side by side. Sections 3.3 and 3.4 classified the finite-dimensional — and therefore non-unitary — representations of the Lorentz algebra by a pair (j_-, j_+) of $\mathfrak{su}(2)$ spins; these are the *fields*, the local objects that carry Lorentz indices and out of which Lagrangians are built. The present section classified the infinite-dimensional unitary representations of the Poincaré group by (m, s) or by $m = 0$ and helicity h; these are the *states*, the actual particles in the Hilbert space. Table 3.1 is the dictionary between them, and it is the destination the whole chapter has been travelling toward.

Three features of the table deserve emphasis, because they encode the tension that drives the rest of the book. First, the scalar is the clean case: one field component, one particle state, no mismatch — which is why ϕ^4 is the workhorse

Field	(j_-, j_+)	**Particle (unitary irrep)**	**Theory / chapter**
Scalar ϕ	$(0,0)$	$m \geq 0$, spin/helicity 0	ϕ^4 theory (Chapter 9
Weyl ψ_L, ψ_R	$(\frac{1}{2},0)$, $(0,\frac{1}{2})$	$m = 0$, helicity $\mp\frac{1}{2}$	chiral fermions (Cha
Dirac Ψ	$(\frac{1}{2},0)\oplus(0,\frac{1}{2})$	$m > 0$, spin $\frac{1}{2}$ (2 states)	QED, electron (Chap
Vector A^μ	$(\frac{1}{2},\frac{1}{2})$	$m = 0$, helicity ±1 (2 states, *gauge*)	QED / Yang–Mills (

Table 3.1: The dictionary between field representations (finite-dimensional, non-unitary, Section 3.3) and particle representations (infinite-dimensional, unitary, this section). The left column transforms under the Lorentz algebra by (j_-, j_+); the right column is the one-particle Hilbert space content, labelled by mass and by spin (massive) or helicity (massless). The vector field carries gauge redundancy precisely because its two physical helicity states cannot fill its four covariant components, as shown in Theorem 3.46.

on which every technique is first tried. Second, the Dirac field bundles the two Weyl representations together precisely so that parity can act (it exchanges $(\frac{1}{2},0) \leftrightarrow (0,\frac{1}{2})$, the field-level image of the helicity flip $h \to -h$), and a massive Dirac particle's two states are the spin-$\frac{1}{2}$ doublet of the massive little group SU(2). Third, the vector is the case where field and particle counts genuinely disagree, and the entry "gauge" in its row is the residue of Theorem 3.46: a four-component covariant field for a two-state particle is necessarily redundant. The systematic study of *fields* as classical objects begins in Part II; their *quantization* into the particle states catalogued here begins in Part III.

This completes the chapter's central argument. We began by asking what a relativistic particle can be, and we have answered it exhaustively: a one-particle state is a unitary irreducible representation of the Poincaré group, and there is precisely one for every $(m > 0,\ s)$ with $s \in \{0, \frac{1}{2}, 1, \dots\}$, one for every massless helicity $h \in \{0, \pm\frac{1}{2}, \pm1, \dots\}$, and the vacuum — the rest excluded by causality or unobserved. The threads now collect their cargo from this catalogue and carry it forward into dynamics: the scalar of ϕ^4 theory is quantized in Chapter 9, the spin-$\frac{1}{2}$ electron of QED in Chapter 11, and the massless helicity-1 photon and gluon of QED and Yang–Mills theory in Chapters 13 and 25 — where the gauge redundancy seeded in Theorem 3.46, and first met classically in Chapter 8, is finally confronted head on.

Further reading

The definitive physical treatment of the unitary representations of the Poincaré group, and the source of the field-versus-particle organizing principle used through-

out this chapter, is Weinberg [500] (chapter 2); it is the natural companion to everything here. The classification itself is Wigner's, in the founding paper [509], with the finite-dimensional field representations and the relativistic wave equations laid out in Bargmann and Wigner [50]. The standard textbook accounts of the Lorentz algebra, the (j_-, j_+) classification, and the spinor formalism are Peskin and Schroeder [396], Schwartz [432], and Srednicki [454] (the last especially careful with the two-component dotted/undotted calculus); Zee [532] gives the same material with the group-theoretic motivation foregrounded. For the topology underlying the double cover and $\pi_1(\mathrm{SO}(1,3)^+) = \mathbb{Z}_2$—covering spaces, $\mathrm{SL}(2,\mathbb{C})$, and the spin groups—see Nakahara [355] and, for the representation-theoretic backbone, Fulton and Harris [206] and Hall [248]. Readers wanting the axiomatic setting in which Poincaré covariance, spin, and statistics are tied together rigorously should consult Streater and Wightman [458] and Haag [246].

Chapter 4

Functional Methods

Quantum field theory is, at bottom, a theory of *functions of functions*. The action that defines a theory assigns a number to each field configuration; the amplitude for one configuration to evolve into another is a sum over all configurations interpolating between them; the correlation functions that encode every observable are functional derivatives of a single generating object. To speak this language fluently one needs a calculus whose variables are not points in $\mathbb{R}^n$ but entire fields, an integration theory over the infinite-dimensional space of such fields, and a Legendre-transform technology that converts between a description in terms of sources and a description in terms of the fields they produce. This chapter builds that toolbox. It is the second of the two foundational machineries Part I lays down: Chapters 2 and 3 supplied the symmetry-and-representation language, and the present chapter supplies the variational and functional-integral language, leaving only the analytic machinery of Chapter 5 before the field theory of Part II can begin.

The chapter is deliberately staged from the rigorous to the formal, and it is honest at every step about which is which. We begin on solid ground in Section 4.1, where the functional derivative is defined precisely in the Gâteaux and Fréchet senses, its computational rules are established, the functional Taylor expansion is set up, and the Euler–Lagrange equation is derived as the exact stationarity condition of an action functional with its boundary terms tracked honestly rather than discarded. We then descend to finite dimensions in Section 4.2, where everything can be proved: the real and complex Gaussian integral formulas with their determinant prefactors and source terms, and Wick's theorem as a purely combinatorial statement about moments of a Gaussian measure, the two-point function being the inverse of the quadratic form. These finite-dimensional identities are the templates for every Gaussian manipulation in the rest of the book; we prove them once, in full, so that the field-theoretic versions later can be read as their formal continuum limits rather than as new postulates.

With the finite-dimensional theory secured, Section 4.3 confronts the cen-

tral object directly. The functional integral is constructed as a limit of finite-dimensional integrals over a lattice discretization; we exhibit exactly where that limit is a theorem (the Euclidean Gaussian case, where the measure genuinely exists) and exactly where it is a formal device (the oscillatory Minkowski case, whose convergence is a question deferred to the $i\epsilon$ and Wick-rotation analysis of Chapter 5). This section is the chapter's rigor summary: it states precisely which path-integral results in this book are theorems and which are controlled formal limits, so that no later chapter has to pretend the continuum measure is something it is not. The remaining sections then develop the formalism that makes the integral useful regardless of its measure-theoretic status.

Section 4.4 introduces the generating functional $Z[J]$, its logarithm $W[J] = \log Z[J]$, and the hierarchy of correlation functions they produce; the linked-cluster (cumulant) theorem, proved here in finite dimensions, identifies W as the generator of *connected* correlators. Section 4.5 performs the Legendre transform of W to obtain the effective action $\Gamma[\phi]$, establishing the convex-analysis facts it rests on (involution, the $\Gamma'' W'' = 1$ identity), showing that Γ generates the one-particle-irreducible vertices, and that Γ reduces to the classical action S at tree level. Finally Section 4.6 develops Laplace and steepest-descent asymptotics in finite dimensions with controlled error, organizes the resulting expansion as a series in $\hbar$ (the loop expansion), and identifies the functional determinant of the second variation as the one-loop Gaussian-fluctuation prefactor, so that the one-loop effective action is $\frac{i}{2}\log\det$ of the second variation.

Throughout, a zero-dimensional ϕ^4 "field theory" – a single ordinary integral with a quartic weight – serves as the carried model computation. It is not yet ϕ^4 theory proper, which is not defined as a Lagrangian field theory until Chapter 6; rather it is the testbed in which Z, W, Γ, the loop expansion, and the asymptotic (and Borel-summable) character of the perturbative series can all be exhibited *exactly*, with no functional-analytic difficulty, before any of them is asked to survive the continuum limit. The genuine field-theoretic versions – the free propagator, Wick's theorem for fields, and the field-theory generating functional – are assembled in Chapter 10, which imports this chapter's finite-dimensional results wholesale. We are stocking a toolbox; we name on the box exactly which later chapters each tool is for.

4.1 The Calculus of Functionals

Classical mechanics is dynamics on a finite-dimensional configuration space: a particle is a point $q \in \mathbb{R}^n$, its history is a path $t \mapsto q(t)$, and the action $S(q)$ is an ordinary — if multivariable — function whose stationary points are the trajectories. Field theory replaces the point q by an entire field configuration ϕ, a function on spacetime. The configuration space is now the space of all such functions, which is infinite-dimensional, and the action becomes a machine that

eats a whole field and returns a number. To do dynamics on this space — to write "$\delta S = 0$", to expand around a classical solution, to define a generating functional and differentiate it — we need a calculus on the space of field configurations: a notion of derivative for maps whose argument is a function. That calculus is the subject of this section. We build it carefully, because every later manipulation in this book, from the Euler–Lagrange equations to the loop expansion of the effective action, is an application of the rules established here.

The guiding principle is conservative: infinite-dimensional calculus should reduce to ordinary calculus the moment we discretise spacetime onto a finite lattice of points. Every definition below is engineered so that this reduction is transparent, and we will point it out as we go. The one genuinely new object is the *functional derivative*, whose "components" are labelled by a continuous index x rather than a discrete index i, and whose Kronecker delta is therefore a Dirac delta. We use the delta function at the naive level throughout this section; its rigorous incarnation as a tempered distribution, and the function spaces on which all of this is genuinely well defined, are the business of Chapter 5. Here we keep the analysis honest by stating the hypotheses each result needs and flagging where the naive manipulation hides a distributional subtlety.

4.1.1 Functionals

We must first say precisely what kind of object we are differentiating. Fix a domain $\Omega \subseteq \mathbb{R}^4$ — either a bounded region with smooth boundary $\partial\Omega$, or all of Minkowski space $\mathbb{R}^{1,3}$ — and a real vector space V of field configurations on it. For concreteness V may be taken as the smooth fields $\phi : \Omega \to \mathbb{R}$ that, together with all their derivatives, decay rapidly at infinity (the Schwartz space $\mathcal{S}(\mathbb{R}^4)$ when $\Omega = \mathbb{R}^4$) or vanish appropriately on $\partial\Omega$; the precise choice is dictated by the boundary conditions of the problem and is discussed where it matters. The only structure we need now is that V is a real topological vector space, so that "$\phi + \varepsilon\eta$" makes sense for $\phi, \eta \in V$ and $\varepsilon \in \mathbb{R}$, and so that we have a notion of one field being close to another.

Definition 4.1 (Functional)**.** A *functional* on V is a map $F : U \to \mathbb{R}$ (or $\to \mathbb{C}$) defined on an open subset $U \subseteq V$, assigning to each field configuration $\phi \in U$ a single number $F[\phi]$. We write the argument in square brackets, $F[\phi]$, to signal that the input is an entire function and not the value of ϕ at one point.

The square-bracket notation is not decorative: $F[\phi]$ depends on *all* the values $\{\phi(x) : x \in \Omega\}$ at once, in general nonlocally. Three families of examples recur constantly and are worth fixing now, because the entire computational apparatus of the section is calibrated against them.

Example 4.2 (The building-block functionals)**.**

1. **Local functionals.** Given a smooth function $g : \mathbb{R} \to \mathbb{R}$, set

$$F[\phi] = \int_\Omega \mathrm{d}^4x \; g(\phi(x)). \tag{4.1}$$

   More generally the integrand may depend on ϕ and finitely many of its derivatives, $F[\phi] = \int_\Omega \mathrm{d}^4x \; \mathcal{L}(\phi(x), \partial_\mu\phi(x))$; this is the *action functional*, the central object of the chapter.

2. **Bilocal functionals.** Given a kernel $K(x, y)$,

$$F[\phi] = \int_\Omega\int_\Omega \mathrm{d}^4x \, \mathrm{d}^4y \; \phi(x)\, K(x, y)\, \phi(y). \tag{4.2}$$

   Such quadratic forms are the integrands of every Gaussian integral in the next section, with K the inverse propagator.

3. **The evaluation (point) functional.** For a fixed $y \in \Omega$,

$$E_y[\phi] = \phi(y) = \int_\Omega \mathrm{d}^4x \; \delta^4(x - y)\, \phi(x). \tag{4.3}$$

   This trivial-looking functional, which simply reads off the field's value at one point, is what forces the Dirac delta into the formalism; the rewriting on the right, legitimate at the naive level, anticipates exactly that.

Physical Insight

The discretised picture makes the abstraction concrete. Replace Ω by a finite lattice of N points x_i with cell volume Δ, so a field configuration is the finite list of numbers $\phi_i \equiv \phi(x_i) \in \mathbb{R}^N$ and an integral becomes a sum, $\int_\Omega \mathrm{d}^4x \, (\cdots) \to \Delta \sum_i (\cdots)$. A functional $F[\phi]$ is then literally an ordinary function $F(\phi_1, \ldots, \phi_N)$ of N real variables. The local functional (4.1) becomes $\Delta \sum_i g(\phi_i)$, the bilocal (4.2) becomes $\Delta^2 \sum_{ij} \phi_i K_{ij} \phi_j$, and the evaluation functional (4.3) just picks out one component. Functional calculus is multivariable calculus in the limit $N \to \infty$, $\Delta \to 0$; we keep returning to this dictionary to sanity-check every formula.

4.1.2 The functional derivative

To differentiate a functional we mimic the directional derivative of multivariable calculus. There, $\partial_v f(q) = \frac{d}{d\varepsilon} f(q + \varepsilon v)\big|_0$ measures the rate of change of f as we move from q in the direction v. For a functional, the "direction" is itself a field $\eta \in V$, and we move along the straight line $\phi + \varepsilon\eta$ in configuration space.

Definition 4.3 (First variation / Gateaux derivative)**.** Let F be a functional and $\phi \in U$. The *first variation* of F at ϕ in the direction $\eta \in V$ is

$$\delta F[\phi;\eta] \;\equiv\; \frac{d}{d\varepsilon}\, F[\phi+\varepsilon\eta]\Big|_{\varepsilon=0} \;=\; \lim_{\varepsilon\to 0} \frac{F[\phi+\varepsilon\eta]-F[\phi]}{\varepsilon}, \tag{4.4}$$

whenever the limit exists. This is the *Gateaux derivative* of F at ϕ.

By construction $\delta F[\phi;\eta]$ is the ordinary derivative at the origin of the one-real-variable function $\varepsilon \mapsto F[\phi+\varepsilon\eta]$; all the familiar one-dimensional differentiation rules apply to it before we do anything field-theoretic. The map $\eta \mapsto \delta F[\phi;\eta]$ is in good cases linear and continuous — it then is a continuous linear functional on V, i.e. a distribution. When such a distribution can be represented by integration against a function (or distribution) $\frac{\delta F}{\delta\phi(x)}$, that representative is what we call the functional derivative.

Definition 4.4 (Functional derivative)**.** Suppose the first variation (4.4) exists for all $\eta \in V$, is linear and continuous in η, and can be written in the integral form

$$\delta F[\phi;\eta] \;=\; \int_\Omega \mathrm{d}^4x\, \frac{\delta F}{\delta\phi(x)}\, \eta(x) \tag{4.5}$$

for some locally integrable kernel (or distribution) $\dfrac{\delta F}{\delta\phi(x)}$. That kernel is the *functional derivative* of F with respect to ϕ at the point x. It depends on the base configuration ϕ and is itself, for each fixed ϕ, a function of x.

Two points of interpretation. First, $\dfrac{\delta F}{\delta\phi(x)}$ is the continuum analogue of the gradient component $\partial f/\partial\phi_i$: in the discretised picture, (4.5) reads $\delta F = \Delta \sum_i \frac{\delta F}{\delta\phi(x_i)}\,\eta_i$, and comparing with the chain rule $\delta F = \sum_i \frac{\partial F}{\partial\phi_i}\,\eta_i$ identifies

$$\frac{\delta F}{\delta\phi(x_i)} \;=\; \frac{1}{\Delta}\,\frac{\partial F}{\partial\phi_i}. \tag{4.6}$$

The factor $1/\Delta$ (units of inverse volume) is the seed of the Dirac delta that will appear in place of the Kronecker delta. Second, the representation (4.5) is a genuine restriction: not every continuous linear functional of η is an integral against an ordinary function (the evaluation functional already needs a delta function), but in the cases we meet — local and bilocal functionals, and the actions built from them — the kernel exists, possibly as a distribution, and is what we compute.

Uniqueness of the kernel. For the definition to be meaningful, the kernel representing a given first variation must be unique. It is, and the proof is the foundational lemma of the entire variational calculus.

Lemma 4.5 (Fundamental lemma of the calculus of variations)**.** *Let f be a continuous function on Ω. If*

$$\int_\Omega \mathrm{d}^4x\, f(x)\,\eta(x) = 0 \qquad \text{for every smooth } \eta \text{ with compact support in the interior of } \Omega, \tag{4.7}$$

then $f \equiv 0$ on Ω.

Proof. Suppose not. Then $f(x_0) \neq 0$ for some interior point x_0; without loss of generality $f(x_0) > 0$. By continuity there is a closed ball $\bar{B}_r(x_0)$ of radius $r > 0$ contained in the interior of Ω on which $f(x) \geq \tfrac{1}{2} f(x_0) > 0$. Choose a *bump function*: a smooth $\eta \geq 0$ supported in $B_r(x_0)$ with $\eta(x_0) > 0$, for instance the standard mollifier

$$\eta(x) = \begin{cases} \exp\!\Big(-\dfrac{r^2}{r^2 - |x - x_0|^2}\Big), & |x - x_0| < r, \\ 0, & |x - x_0| \geq r, \end{cases} \tag{4.8}$$

which is smooth (all derivatives vanish as $|x - x_0| \to r^-$), nonnegative, compactly supported, and strictly positive at x_0. With this choice the integrand $f\eta \geq 0$ everywhere and is strictly positive on a neighbourhood of x_0, so $\int_\Omega f\eta > 0$, contradicting (4.7). Hence no such x_0 exists and $f \equiv 0$. $\square$

Theorem 4.6 (Uniqueness of the functional derivative)**.** *If two continuous kernels $K_1(x)$ and $K_2(x)$ both represent the first variation of F at ϕ in the sense of (4.5) for all admissible η, then $K_1 = K_2$. The functional derivative, when it exists as a continuous function, is unique.*

Proof. Subtracting the two representations gives $\int_\Omega \mathrm{d}^4x\, [K_1(x) - K_2(x)]\,\eta(x) = 0$ for all test functions η. By Theorem 4.5 the continuous difference $K_1 - K_2$ vanishes identically. $\square$

When the kernel is only a distribution the same conclusion holds with "equal as distributions," which is the appropriate statement once Chapter 5 puts the delta function on a rigorous footing; the bump-function argument above is exactly the seed of the distributional uniqueness theorem proved there.

The delta-function kernel. The functional derivative of the field with respect to itself is the basic input to all subsequent computations. Apply the definition to the evaluation functional (4.3), $E_y[\phi] = \phi(y)$. Its first variation is immediate,

$$\delta E_y[\phi;\eta] = \frac{d}{d\varepsilon}\,\big(\phi(y) + \varepsilon\,\eta(y)\big)\Big|_{0} = \eta(y) = \int_\Omega \mathrm{d}^4x\; \delta^4(x - y)\,\eta(x), \tag{4.9}$$

where the last step is the defining property of the delta function. Comparing with (4.5) we read off the kernel,

$$\boxed{\frac{\delta\phi(y)}{\delta\phi(x)} = \delta^4(x-y).} \tag{4.10}$$

This is the continuum statement that the components of a field are independent coordinates: varying ϕ at x has no effect on its value at any other point y, and unit effect at $y = x$. It is the exact analogue of $\partial\phi_i/\partial\phi_j = \delta_{ij}$, with the Dirac delta replacing the Kronecker delta precisely as the correspondence (4.6) demands: $\delta_{ij}/\Delta \to \delta^4(x-y)$ as the lattice is refined. Every functional derivative we compute is, at bottom, repeated use of (4.10) together with the rules of the next subsection.

Gateaux versus Frechet. The first variation (4.4) is a *directional* derivative: it probes F one direction η at a time. The stronger notion is the *Frechet derivative*, a single bounded linear map $DF[\phi]$ approximating the increment uniformly in the direction,

$$F[\phi+\eta] - F[\phi] - DF[\phi]\,\eta = o(\|\eta\|) \quad \text{as } \|\eta\| \to 0, \tag{4.11}$$

with the remainder controlled uniformly over all η in a norm ball. The relation between the two is exactly as in finite dimensions:

- If F is Frechet differentiable at ϕ, then the Gateaux derivative exists and equals it, $\delta F[\phi;\eta] = DF[\phi]\,\eta$; the functional derivative (4.5) is then the integral kernel of the bounded operator $DF[\phi]$.
- The converse can fail: a functional may have a directional derivative in every direction without being Frechet differentiable (as already in finite dimensions). But if the Gateaux derivative $\delta F[\phi;\eta]$ exists in a neighbourhood of ϕ, is linear in η, and depends *continuously* on the base point ϕ, then F is Frechet differentiable and the two coincide.

For the functionals of physics — polynomials in the field and its derivatives, integrated against smooth kernels — this continuity holds, and we use "functional derivative" for the common value without further comment. We compute everything via the workable Gateaux definition (4.4) and rely on the equivalence to know the result is the honest derivative.

4.1.3 Computational rules

The first variation is an ordinary derivative in ε, so the rules of single-variable calculus transfer to functionals essentially for free. We prove each one from (4.4) rather than assert it, then read off its consequence for the kernel via (4.5).

Proposition 4.7 (Linearity, product rule, chain rule)**.** *Let F, G be functionals differentiable at ϕ, and a, b constants. Then*

$$\frac{\delta(aF + bG)}{\delta\phi(x)} = a\,\frac{\delta F}{\delta\phi(x)} + b\,\frac{\delta G}{\delta\phi(x)}, \tag{4.12}$$

$$\frac{\delta(FG)}{\delta\phi(x)} = \frac{\delta F}{\delta\phi(x)}\,G[\phi] + F[\phi]\,\frac{\delta G}{\delta\phi(x)}, \tag{4.13}$$

and, for an ordinary smooth function $h : \mathbb{R} \to \mathbb{R}$ composed with a real-valued functional, $\frac{\delta\, h(F)}{\delta\phi(x)} = h'(F[\phi])\,\frac{\delta F}{\delta\phi(x)}$. If $F[\phi] = G[\psi]$ where $\psi = \psi[\phi]$ is itself a field-valued functional, the chain rule reads

$$\frac{\delta F}{\delta\phi(x)} = \int_\Omega \mathrm{d}^4 y\; \frac{\delta G}{\delta\psi(y)}\,\frac{\delta\psi(y)}{\delta\phi(x)}. \tag{4.14}$$

Proof. Linearity is immediate: $\frac{d}{d\varepsilon}(aF + bG)[\phi + \varepsilon\eta]|_0 = a\,\delta F[\phi;\eta] + b\,\delta G[\phi;\eta]$, and matching to (4.5) gives (4.12).

Product rule. Define the one-variable functions $f(\varepsilon) = F[\phi + \varepsilon\eta]$ and $g(\varepsilon) = G[\phi + \varepsilon\eta]$, so $(FG)[\phi + \varepsilon\eta] = f(\varepsilon)g(\varepsilon)$. The ordinary product rule in ε gives

$$\delta(FG)[\phi;\eta] = \frac{d}{d\varepsilon}(fg)\Big|_0 = f'(0)g(0) + f(0)g'(0) = \delta F[\phi;\eta]\,G[\phi] + F[\phi]\,\delta G[\phi;\eta]. \tag{4.15}$$

Substituting the kernel representation (4.5) for each first variation,

$$\int_\Omega \mathrm{d}^4 x\,\frac{\delta(FG)}{\delta\phi(x)}\eta(x) = \int_\Omega \mathrm{d}^4 x\Big[\frac{\delta F}{\delta\phi(x)}G[\phi] + F[\phi]\frac{\delta G}{\delta\phi(x)}\Big]\eta(x), \tag{4.16}$$

and since this holds for every η, Theorem 4.5 forces the integrands to agree, which is (4.13). The composition rule with h is the same argument run with the single-variable chain rule: $\frac{d}{d\varepsilon}h(f(\varepsilon))|_0 = h'(f(0))f'(0) = h'(F[\phi])\,\delta F[\phi;\eta]$.

Chain rule for field-valued ψ. Now $F[\phi + \varepsilon\eta] = G[\psi[\phi + \varepsilon\eta]]$. Write $\psi_\varepsilon \equiv \psi[\phi + \varepsilon\eta]$ and differentiate at $\varepsilon = 0$. The inner variation is, by definition of the functional derivative of ψ,

$$\frac{d}{d\varepsilon}\psi_\varepsilon(y)\Big|_0 = \int_\Omega \mathrm{d}^4 x\,\frac{\delta\psi(y)}{\delta\phi(x)}\,\eta(x), \tag{4.17}$$

i.e. the curve $\varepsilon \mapsto \psi_\varepsilon$ in configuration space leaves $\psi[\phi]$ at $\varepsilon = 0$ with this "velocity" field. Applying the Gateaux derivative of G in that velocity direction,

$$\begin{aligned}\delta F[\phi;\eta] &= \frac{d}{d\varepsilon}G[\psi_\varepsilon]\Big|_0 = \int_\Omega \mathrm{d}^4 y\,\frac{\delta G}{\delta\psi(y)}\,\frac{d}{d\varepsilon}\psi_\varepsilon(y)\Big|_0 \\ &= \int_\Omega \mathrm{d}^4 y\,\frac{\delta G}{\delta\psi(y)}\int_\Omega \mathrm{d}^4 x\,\frac{\delta\psi(y)}{\delta\phi(x)}\,\eta(x) = \int_\Omega \mathrm{d}^4 x\,\Big[\int_\Omega \mathrm{d}^4 y\,\frac{\delta G}{\delta\psi(y)}\,\frac{\delta\psi(y)}{\delta\phi(x)}\Big]\eta(x).\end{aligned} \tag{4.18}$$

The bracketed quantity is, by Theorem 4.6, the functional derivative $\delta F/\delta\phi(x)$, which is (4.14). The intermediate spacetime point y is summed over precisely as the intermediate index is summed in the matrix chain rule $\partial F/\partial\phi_i = \sum_j (\partial G/\partial\psi_j)(\partial\psi_j/\partial\phi_i)$; the integral $\int \mathrm{d}^4y$ is the continuum $\sum_j$. □

These three rules, together with the delta-kernel (4.10), suffice to differentiate every functional we encounter. We now apply them to the building blocks of Theorem 4.2, since these results are used verbatim throughout the book.

Worked Example 4.8 (Functional derivatives of the building blocks)**.** We compute $\delta F/\delta\phi(z)$ for each functional of Theorem 4.2.

(a) Ultralocal density. For $F[\phi] = \int_\Omega \mathrm{d}^4x\, g(\phi(x))$, the first variation is

$$\delta F[\phi;\eta] = \frac{d}{d\varepsilon}\int_\Omega \mathrm{d}^4x\, g(\phi(x)+\varepsilon\eta(x))\Big|_0 = \int_\Omega \mathrm{d}^4x\, g'(\phi(x))\,\eta(x), \tag{4.19}$$

where we differentiated under the integral and used the ordinary chain rule on g. Comparison with (4.5) gives

$$\frac{\delta F}{\delta\phi(z)} = g'(\phi(z)). \tag{4.20}$$

The functional derivative of an ultralocal functional is itself ultralocal: it is just g' evaluated at the same point. As a check, take $g(\phi) = \tfrac12\phi^2$, so $F = \tfrac12\int\phi^2$ and $\delta F/\delta\phi(z) = \phi(z)$, the field itself.

(b) A density with one derivative. The kinetic term $F[\phi] = \tfrac12\int_\Omega \mathrm{d}^4x\,(\partial_\mu\phi)(\partial^\mu\phi)$ introduces the only genuinely new step, an integration by parts. Its first variation is

$$\begin{aligned}\delta F[\phi;\eta] &= \frac{d}{d\varepsilon}\tfrac12\int_\Omega \mathrm{d}^4x\,\partial_\mu(\phi+\varepsilon\eta)\,\partial^\mu(\phi+\varepsilon\eta)\Big|_0 = \int_\Omega \mathrm{d}^4x\,(\partial_\mu\phi)(\partial^\mu\eta)\\ &= \int_\Omega \mathrm{d}^4x\,\partial_\mu[(\partial^\mu\phi)\eta] - \int_\Omega \mathrm{d}^4x\,(\partial_\mu\partial^\mu\phi)\,\eta = -\int_\Omega \mathrm{d}^4x\,(\Box\phi)\,\eta + \oint_{\partial\Omega}\mathrm{d}S_\mu\,(\partial^\mu\phi)\,\eta,\end{aligned} \tag{4.21}$$

where $\Box \equiv \partial_\mu\partial^\mu = \partial_0^2 - \nabla^2$ is the d'Alembertian in the mostly-minus metric, and the boundary integral comes from the divergence theorem applied to $\partial_\mu[(\partial^\mu\phi)\eta]$. For test functions η supported in the interior (or fields decaying at infinity) the boundary term vanishes, and

$$\frac{\delta F}{\delta\phi(z)} = -\Box\,\phi(z). \tag{4.22}$$

The boundary term is not optional bookkeeping — it is the connection where boundary conditions enter the variational principle, and we track it explicitly when we turn to the action in Section 4.1.5.

(c) Bilocal form. For $F[\phi] = \int\!\int \mathrm{d}^4x\,\mathrm{d}^4y\,\phi(x)K(x,y)\phi(y)$, linearity of the first variation across the two factors gives, using (4.10) on each,

$$\begin{aligned}\delta F[\phi;\eta] &= \iint \mathrm{d}^4x\,\mathrm{d}^4y\,\big[\eta(x)K(x,y)\phi(y) + \phi(x)K(x,y)\eta(y)\big] \\ &= \int_\Omega \mathrm{d}^4z\,\eta(z)\int_\Omega \mathrm{d}^4y\,\big[K(z,y)+K(y,z)\big]\phi(y),\end{aligned} \tag{4.23}$$

where the second line relabels the integration variable in each term to z. Hence

$$\frac{\delta F}{\delta\phi(z)} = \int_\Omega \mathrm{d}^4y\,\big[K(z,y)+K(y,z)\big]\phi(y) \xrightarrow{\;K\text{ symmetric}\;} 2\int_\Omega \mathrm{d}^4y\,K(z,y)\phi(y). \tag{4.24}$$

This is the continuum gradient of a quadratic form, $\partial_i(\phi^{\mathsf{T}}K\phi) = (K+K^{\mathsf{T}})_{ij}\phi_j$, with the matrix index j promoted to the spacetime integral $\int \mathrm{d}^4y$. It is exactly the combination that, set to zero in the next section, yields the linear field equation $K\phi = 0$, and whose kernel is the quadratic operator of the Gaussian integral.

4.1.4 The functional Taylor expansion

Single derivatives let us locate stationary configurations; to expand a functional *around* one — the central operation of the entire perturbative and semiclassical apparatus — we need the full Taylor series. We obtain it, and the higher functional derivatives that are its coefficients, by reducing to the ordinary Taylor expansion in the single variable ε.

Higher functional derivatives are defined by iterating Theorem 4.4. The second functional derivative $\dfrac{\delta^2 F}{\delta\phi(x_1)\delta\phi(x_2)}$ is the functional derivative, with respect to $\phi(x_2)$, of the function $x_1 \mapsto \delta F/\delta\phi(x_1)$; in terms of first variations it is read off from the double variation

$$\frac{d}{d\varepsilon_1}\frac{d}{d\varepsilon_2}F[\phi+\varepsilon_1\eta_1+\varepsilon_2\eta_2]\Big|_{\varepsilon_1=\varepsilon_2=0} = \iint \mathrm{d}^4x_1\,\mathrm{d}^4x_2\,\frac{\delta^2 F}{\delta\phi(x_1)\,\delta\phi(x_2)}\,\eta_1(x_1)\,\eta_2(x_2), \tag{4.25}$$

and in general the n-th derivative is the symmetric kernel appearing when n independent variations are taken,

$$\frac{\mathrm{d}^n}{\mathrm{d}\varepsilon_1\cdots\mathrm{d}\varepsilon_n}F\Big[\phi+\sum_a \varepsilon_a\eta_a\Big]\Big|_{\varepsilon=0} = \int\cdots\int \prod_{a=1}^{n}\mathrm{d}^4x_a\,\frac{\delta^n F}{\delta\phi(x_1)\cdots\delta\phi(x_n)}\prod_{a=1}^{n}\eta_a(x_a). \tag{4.26}$$

Proposition 4.9 (Symmetry of the higher kernels)**.** *Whenever the mixed variations exist and are continuous, the n-th functional derivative is symmetric under any permutation of its arguments $x_1,\dots,x_n$:*

$$\frac{\delta^n F}{\delta\phi(x_{\sigma(1)})\cdots\delta\phi(x_{\sigma(n)})} = \frac{\delta^n F}{\delta\phi(x_1)\cdots\delta\phi(x_n)} \qquad \text{for every permutation } \sigma. \tag{4.27}$$

Proof. It suffices to prove symmetry under interchange of two adjacent arguments, since transpositions of neighbours generate the full permutation group. Consider the two-parameter real function $g(\varepsilon_i, \varepsilon_j) = F[\phi + \varepsilon_i \eta_i + \varepsilon_j \eta_j + \cdots]$, the dots denoting any other fixed variations held at their values. The left-hand sides of (4.25) computed in the two orders are $\partial_{\varepsilon_i}\partial_{\varepsilon_j} g$ and $\partial_{\varepsilon_j}\partial_{\varepsilon_i} g$. By the equality of mixed partial derivatives (Clairaut–Schwarz) for the ordinary smooth function g of two real variables, these are equal. Since they equal the kernel integrated against $\eta_i \otimes \eta_j$ in the two orders, and this holds for all test functions η_i, η_j, Theorem 4.5 applied in each variable forces the kernels themselves to be equal, which is (4.27) for the transposition (ij). □

This symmetry is the functional shadow of the symmetry of the Hessian matrix $\partial_i \partial_j F = \partial_j \partial_i F$, and it is the reason the Taylor coefficients below can be treated as symmetric multilinear kernels — equivalently, as symmetric tensors with continuous indices. We now assemble the series.

Theorem 4.10 (Functional Taylor expansion)**.** *Let F be a functional with continuous functional derivatives to all orders in a neighbourhood of ϕ. Then for η small enough that the line $\phi + \varepsilon\eta$, $\varepsilon \in [0, 1]$, stays in that neighbourhood,*

$$F[\phi + \eta] = \sum_{n=0}^{\infty} \frac{1}{n!} \int \cdots \int \prod_{a=1}^{n} \mathrm{d}^4 x_a \, \frac{\delta^n F}{\delta\phi(x_1) \cdots \delta\phi(x_n)}\bigg|_{\phi} \eta(x_1) \cdots \eta(x_n), \tag{4.28}$$

whenever the series converges, with the understanding that it is at least the asymptotic expansion of $F[\phi + \eta]$ in powers of η.

Proof. Fix ϕ and η and define the single-variable function $g(\varepsilon) \equiv F[\phi + \varepsilon\eta]$. Its ordinary Maclaurin expansion is

$$g(1) = \sum_{n=0}^{\infty} \frac{1}{n!} g^{(n)}(0), \qquad g^{(n)}(0) = \frac{\mathrm{d}^n}{\mathrm{d}\varepsilon^n} F[\phi + \varepsilon\eta]\Big|_0. \tag{4.29}$$

The n-th derivative is the special case of (4.26) with all directions equal, $\eta_1 = \cdots = \eta_n = \eta$ (set $\varepsilon_a = \varepsilon$ and use $\frac{d}{d\varepsilon} = \sum_a \partial_{\varepsilon_a}$ on the diagonal, which produces $n!$ identical cross terms only after the symmetric kernel collapses them — here they are automatically accounted because we take all η_a equal):

$$g^{(n)}(0) = \int \cdots \int \prod_{a=1}^{n} \mathrm{d}^4 x_a \, \frac{\delta^n F}{\delta\phi(x_1) \cdots \delta\phi(x_n)}\bigg|_{\phi} \eta(x_1) \cdots \eta(x_n). \tag{4.30}$$

Substituting into $g(1) = \sum_n g^{(n)}(0)/n!$ and recognising $g(1) = F[\phi + \eta]$ yields (4.28). Convergence is governed by the radius of convergence of the scalar series $\sum g^{(n)}(0)/n!$; for the polynomial functionals of field theory the series in η *terminates* (a degree-k polynomial functional has $\delta^n F = 0$ for $n > k$), so (4.28) is an exact finite sum and convergence is not at issue. For non-polynomial F it is the Taylor expansion of g about $\varepsilon = 0$ evaluated at $\varepsilon = 1$, valid with its usual remainder. □

The first three terms of (4.28) are the ones we use constantly, so we display them with names:

$$F[\phi+\eta] = \underbrace{F[\phi]}_{\text{value}} + \underbrace{\int \mathrm{d}^4x\, \frac{\delta F}{\delta\phi(x)}\,\eta(x)}_{\text{first variation } \delta F} + \underbrace{\frac{1}{2}\iint \mathrm{d}^4x\,\mathrm{d}^4y\,\eta(x)\,\frac{\delta^2 F}{\delta\phi(x)\delta\phi(y)}\,\eta(y)}_{\text{second variation } \frac{1}{2}\delta^2 F} + \cdots \tag{4.31}$$

The linear term vanishes precisely at a stationary configuration (the topic of the next subsection); there the leading nontrivial term is the second variation, the *quadratic form*

$$\delta^2 F[\phi;\eta] = \iint \mathrm{d}^4x\,\mathrm{d}^4y\;\eta(x)\,\frac{\delta^2 F}{\delta\phi(x)\delta\phi(y)}\bigg|_{\phi}\,\eta(y), \tag{4.32}$$

whose kernel $\dfrac{\delta^2 F}{\delta\phi(x)\delta\phi(y)}$ is the continuum Hessian. By Theorem 4.9 it is a symmetric kernel, hence a symmetric operator on the space of variations; this is the object whose determinant and inverse the Gaussian integration of the next section is built to compute. The whole point of expanding around a stationary configuration is that (4.32) becomes the leading term, and a Gaussian.

4.1.5 The Euler–Lagrange equation as a stationarity condition

We can now state and prove the central result of classical field dynamics in the language just built. An action functional assigns to each field history a number, and the physical histories are its stationary points: those configurations from which the action does not change to first order under any allowed variation. "Stationary" is "$\delta S/\delta\phi = 0$," and computing that functional derivative honestly — with its boundary term — yields the Euler–Lagrange equation.

Theorem 4.11 (Euler–Lagrange equation and the variational boundary term)**.** *Let*

$$S[\phi] = \int_\Omega \mathrm{d}^4x\;\mathcal{L}(\phi(x), \partial_\mu\phi(x)) \tag{4.33}$$

be a local action with $\mathcal{L}$ a smooth function of the field and its first derivatives. Then the first variation of S in the direction η is

$$\delta S[\phi;\eta] = \int_\Omega \mathrm{d}^4x\,\Big[\frac{\partial\mathcal{L}}{\partial\phi} - \partial_\mu\Big(\frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi)}\Big)\Big]\,\eta + \oint_{\partial\Omega} \mathrm{d}S_\mu\;\frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi)}\,\eta, \tag{4.34}$$

so the functional derivative, valid wherever the boundary term is annihilated, is the Euler–Lagrange combination

$$\frac{\delta S}{\delta\phi(x)} = \frac{\partial\mathcal{L}}{\partial\phi} - \partial_\mu\Big(\frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi)}\Big). \tag{4.35}$$

If S is stationary, $\delta S[\phi;\eta]=0$ for all admissible variations η, and the boundary term vanishes (by either of the conditions below), then ϕ satisfies the Euler–Lagrange equation

$$\boxed{\frac{\partial \mathcal{L}}{\partial \phi}-\partial_\mu\Big(\frac{\partial \mathcal{L}}{\partial(\partial_\mu\phi)}\Big)=0.} \tag{4.36}$$

Proof. Form $S[\phi+\varepsilon\eta]=\int_\Omega \mathrm{d}^4x\,\mathcal{L}(\phi+\varepsilon\eta,\partial_\mu\phi+\varepsilon\partial_\mu\eta)$ and differentiate at $\varepsilon=0$, using the ordinary chain rule on $\mathcal{L}$ as a function of its two slots ϕ and $\partial_\mu\phi$ (the latter varying because $\partial_\mu(\phi+\varepsilon\eta)=\partial_\mu\phi+\varepsilon\,\partial_\mu\eta$):

$$\delta S[\phi;\eta]=\int_\Omega \mathrm{d}^4x\,\Big[\frac{\partial \mathcal{L}}{\partial \phi}\,\eta+\frac{\partial \mathcal{L}}{\partial(\partial_\mu\phi)}\,\partial_\mu\eta\Big]. \tag{4.37}$$

The second term carries the derivative on η; to expose the kernel we move that derivative off η by the Leibniz identity

$$\frac{\partial \mathcal{L}}{\partial(\partial_\mu\phi)}\,\partial_\mu\eta=\partial_\mu\Big[\frac{\partial \mathcal{L}}{\partial(\partial_\mu\phi)}\,\eta\Big]-\partial_\mu\Big(\frac{\partial \mathcal{L}}{\partial(\partial_\mu\phi)}\Big)\,\eta. \tag{4.38}$$

Substituting (4.38) into (4.37) and applying the four-dimensional divergence theorem to the total-derivative piece, $\int_\Omega \mathrm{d}^4x\,\partial_\mu V^\mu=\oint_{\partial\Omega}\mathrm{d}S_\mu\,V^\mu$ with $V^\mu=\frac{\partial \mathcal{L}}{\partial(\partial_\mu\phi)}\eta$, gives exactly (4.34). The bracket multiplying η in the bulk integral is, by Theorem 4.4, the functional derivative (4.35), provided the boundary term does not contribute — which holds under either standard condition:

1. *Fixed (Dirichlet) data.* If the field's values are prescribed on $\partial\Omega$, then admissible variations are those that respect this prescription, $\eta|_{\partial\Omega}=0$, and the boundary integrand $\frac{\partial \mathcal{L}}{\partial(\partial_\mu\phi)}\eta$ vanishes pointwise on $\partial\Omega$. This is the case in the action principle "with fixed endpoints": in mechanics one holds $q(t_1),q(t_2)$ fixed; in field theory one holds the field fixed on the boundary of the spacetime region. It is also the case for $\Omega=\mathbb{R}^4$ with variations of compact support, or fields and variations decaying fast enough that the surface integral at infinity vanishes.

2. *Natural (Neumann-type) boundary conditions.* If the field is *not* fixed on $\partial\Omega$, stationarity for arbitrary η — including those nonzero on the boundary — forces *both* the bulk Euler–Lagrange equation (4.36) *and* the vanishing of the boundary integrand, $\frac{\partial \mathcal{L}}{\partial(\partial_\mu\phi)}n_\mu=0$ on $\partial\Omega$, with n_μ the outward normal. These are the natural boundary conditions; the variational principle generates them automatically rather than having them imposed by hand.

In either case the boundary term is annihilated, and stationarity reduces to $\int_\Omega \mathrm{d}^4x\,[\partial\mathcal{L}/\partial\phi-\partial_\mu(\partial\mathcal{L}/\partial(\partial_\mu\phi))]\,\eta=0$ for all admissible η. By the fundamental lemma Theorem 4.5 the bracket vanishes identically, which is (4.36). □

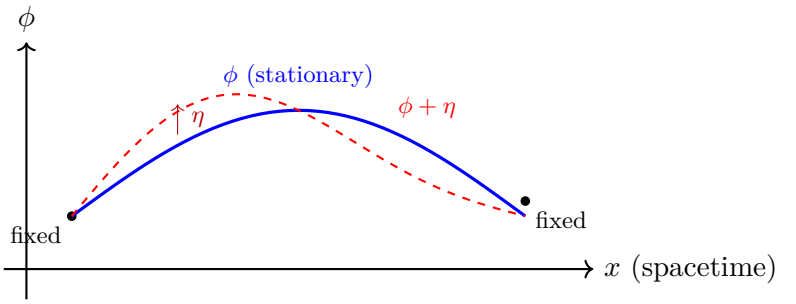

Figure 4.1: The variational setup behind Theorem 4.11, drawn with one spacetime direction. The stationary configuration ϕ (solid) and a nearby varied one $\phi + \eta$ (dashed) share the same data on the boundary, so the variation η vanishes there ($\eta|_{\partial\Omega} = 0$); this is condition 1 of the proof, which kills the surface term in (4.34). Stationarity demands $\delta S = 0$ for *every* such η, and the fundamental lemma then forces the Euler–Lagrange equation pointwise in the bulk.

Caution

The boundary term in (4.34) is the single most frequently dropped — and most frequently legitimately dropped — object in field theory, but it is never *automatically* zero. Whether it vanishes is a statement about boundary conditions, not about the action, and it is exactly the place where physics beyond the bulk equations of motion lives: it determines which boundary terms one is free to add to an action without changing the dynamics (they shift the surface integral, not the Euler–Lagrange equation), it underlies the Gibbons–Hawking term in gravity, and it governs the consistency of an action principle on a manifold with boundary. When this book "integrates by parts and drops the surface term," it is invoking one of the two conditions above; we state which one whenever the distinction could matter.

It remains to compute the second variation of a generic local action, since that quadratic operator is precisely what the next section will integrate. We do so as a worked computation, both to exhibit the second functional derivative of an action explicitly and to hand off the operator cleanly.

Worked Example 4.12 (First and second variation of a generic local action)**.** Take the canonical local action of a single scalar field,

$$S[\phi] = \int_\Omega \mathrm{d}^4x \left[\tfrac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) - V(\phi)\right], \tag{4.39}$$

with V a smooth potential. We compute its first and second variations from scratch.

First variation. With $\mathcal{L} = \frac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) - V(\phi)$ we have $\partial\mathcal{L}/\partial(\partial_\mu\phi) = \partial^\mu\phi$ and $\partial\mathcal{L}/\partial\phi = -V'(\phi)$. Substituting into the general result (4.34),

$$\delta S[\phi;\eta] = -\int_\Omega \mathrm{d}^4x\,\left[\Box\phi + V'(\phi)\right]\eta + \oint_{\partial\Omega}\mathrm{d}S_\mu\,(\partial^\mu\phi)\,\eta, \tag{4.40}$$

so that, dropping the surface term under the conditions of Theorem 4.11,

$$\frac{\delta S}{\delta\phi(x)} = -\left[\Box\phi(x) + V'(\phi(x))\right], \qquad \text{stationary} \iff \Box\phi + V'(\phi) = 0. \tag{4.41}$$

This is the classical equation of motion for the field (4.39); we have built the operator $\delta S/\delta\phi$ but deliberately do not specialise V here. The genuine $\lambda\phi^4$ stage — the choice $V = \frac{1}{2}m^2\phi^2 + \frac{\lambda}{4!}\phi^4$ giving the equation of motion $(\Box + m^2)\phi = -\frac{\lambda}{3!}\phi^3$ of ϕ^4 theory — is owned by Chapter 6, which opens the classical dynamics chapter; here we only construct the $\delta/\delta\phi$ machinery it will be applied with.

Second variation. Differentiate once more. The cleanest route is to expand $S[\phi+\eta]$ directly to second order in η and read off the quadratic piece per (4.31). Inserting $\phi \to \phi + \eta$ into (4.39) and using $(\partial(\phi+\eta))^2 = (\partial\phi)^2 + 2(\partial_\mu\phi)(\partial^\mu\eta) + (\partial_\mu\eta)(\partial^\mu\eta)$ and the Taylor expansion $V(\phi+\eta) = V(\phi) + V'(\phi)\eta + \frac{1}{2}V''(\phi)\eta^2 + \cdots$, the part quadratic in η is

$$\tfrac{1}{2}\,\delta^2 S[\phi;\eta] = \int_\Omega \mathrm{d}^4x\,\Big[\tfrac{1}{2}(\partial_\mu\eta)(\partial^\mu\eta) - \tfrac{1}{2}V''(\phi)\,\eta^2\Big]. \tag{4.42}$$

Integrate the kinetic piece by parts exactly as in (4.21), discarding the surface term (the variation η already vanishes on $\partial\Omega$ by the same boundary condition that fixed the first variation):

$$\delta^2 S[\phi;\eta] = \int_\Omega \mathrm{d}^4x\,\eta(x)\,\big[-\Box - V''(\phi(x))\big]\,\eta(x). \tag{4.43}$$

Comparing with the definition (4.32) of the second variation as a bilinear form $\int\!\!\int \eta(x)\,\frac{\delta^2 S}{\delta\phi(x)\delta\phi(y)}\,\eta(y)$, we read off the second functional derivative as a kernel,

$$\left.\frac{\delta^2 S}{\delta\phi(x)\,\delta\phi(y)}\right|_\phi = \big[-\Box_x - V''(\phi(x))\big]\,\delta^4(x-y). \tag{4.44}$$

The delta function expresses that, at the level of two derivatives, the action of (4.39) is still local: differentiating twice produces a differential operator acting at a single point, not a genuinely bilocal smearing. The operator

$$\mathcal{K}_\phi \;\equiv\; -\Box - V''(\phi) \tag{4.45}$$

is the *second-variation operator* (or fluctuation operator) about the configuration ϕ. It is symmetric, as Theorem 4.9 guarantees, since $\delta^4(x-y)$ and $-\Box_x$ are each symmetric under $x \leftrightarrow y$ when paired between two copies of η. For the

free field $V = \frac{1}{2}m^2\phi^2$ it is the field-independent operator $\mathcal{K} = -(\Box + m^2)$, the inverse propagator whose Gaussian integral is computed next; for an interacting potential it acquires the background-dependent piece $-V''(\phi)$ evaluated on the configuration about which we expand.

The computation just completed is the bridge to the next section. We have shown that expanding any local action to second order about a configuration ϕ produces, as the leading nontrivial term, the quadratic form $\frac{1}{2}\int \eta\, \mathcal{K}_\phi\, \eta$ built from the symmetric second-variation operator $\mathcal{K}_\phi = -\Box - V''(\phi)$ of (4.45). When ϕ is a stationary configuration — a solution of the Euler–Lagrange equation (4.36), so that the first-order term vanishes — this Gaussian integrand is precisely what controls the leading fluctuations about the classical solution. The next section develops the one integral that can be done exactly, the multidimensional Gaussian $\int \mathrm{d}^n\eta\, \exp(-\frac{1}{2}\eta^{\mathsf{T}}\mathcal{K}\eta)$, and so learns to integrate exactly the quadratic form $\mathcal{K}_\phi$ we have just constructed — the operation on which every usable formula of quantum field theory is a formal limit.

4.2 Gaussian Integration in Finite Dimensions

The previous section closed by handing us a quadratic form. Expanding an action functional about a stationary configuration ϕ_{cl}, the functional Taylor expansion of Section 4.1 gave

$$S[\phi_{\mathrm{cl}} + \eta] = S[\phi_{\mathrm{cl}}] + \frac{1}{2}\iint d^dx\, d^dy\, \eta(x)\, \frac{\delta^2 S}{\delta\phi(x)\,\delta\phi(y)}\bigg|_{\phi_{\mathrm{cl}}} \eta(y) + \cdots , \tag{4.46}$$

with the linear term absent precisely because ϕ_{cl} solves the Euler–Lagrange equation. The object that controls the leading behaviour of the theory near a classical solution is therefore the *second variation*: a symmetric bilinear form on the space of fluctuations η. Every program that follows in this book—the path integral, perturbation theory, the loop expansion, the effective action—rests on giving meaning to a "sum over fluctuations" weighted by the exponential of such a form, $\exp(-\frac{1}{2}\,\eta\cdot K\eta)$ in Euclidean signature or $\exp(\frac{i}{2}\,\eta\cdot K\eta)$ in Lorentzian. That sum is an integral over infinitely many variables, and there is exactly one such integral that mathematics permits us to do in closed form: the Gaussian. It is no exaggeration that every usable formula in quantum field theory is, in the end, a Gaussian integral—either an exact one, or one treated by expanding a non-Gaussian weight around a Gaussian and integrating term by term.

For this reason we now stop and develop the Gaussian integral in finite dimensions to complete rigor, because the field-theoretic object of the next section will be *defined* as a limit of these. We work throughout with a real symmetric *positive-definite* matrix A, i.e. a quadratic form $x^{\mathsf{T}}Ax$ that is strictly positive for $x \neq 0$; this is the Euclidean case, where the integrals converge

absolutely as ordinary Riemann integrals and no regularization is needed. The oscillatory Lorentzian weight, where A is merely real symmetric and the integral converges only conditionally, is handled by the $i\epsilon$ prescription and analytic continuation developed in Chapter 5; we flag the distinction where it matters but do not need it here. We assume the linear algebra of symmetric positive-definite matrices—orthogonal diagonalization, the relation between the determinant and the product of eigenvalues, and that $A > 0$ has a unique positive inverse A^{-1}—as a prerequisite.

4.2.1 The one-dimensional Gaussian

Everything multidimensional is bootstrapped from a single one-dimensional integral, so we begin there and carry the constant precisely.

Lemma 4.13 (The basic Gaussian integral)**.** *For any real $a > 0$ and any real j,*

$$\int_{-\infty}^{\infty} dx\, e^{-\frac{1}{2}ax^2+jx} \;=\; \sqrt{\frac{2\pi}{a}}\; e^{j^2/2a}. \tag{4.47}$$

Proof. Take first $j = 0$ and call the integral $I = \int_{-\infty}^{\infty} dx\, e^{-\frac{1}{2}ax^2}$. The integrand is positive and decays faster than any power, so I is a finite positive number, and we may evaluate I^2 as a two-dimensional integral over the plane and pass to polar coordinates:

$$\begin{aligned} I^2 &= \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy\; e^{-\frac{1}{2}a(x^2+y^2)} = \int_0^{2\pi} d\theta \int_0^{\infty} r\, dr\; e^{-\frac{1}{2}ar^2} \\ &= 2\pi \int_0^{\infty} r\, dr\; e^{-\frac{1}{2}ar^2} = 2\pi \left[-\frac{1}{a}\, e^{-\frac{1}{2}ar^2} \right]_0^{\infty} = \frac{2\pi}{a}. \end{aligned} \tag{4.48}$$

The substitution $u = \frac{1}{2}ar^2$, $du = a\, r\, dr$ makes the radial integral elementary, as shown. Since $I > 0$ we conclude $I = \sqrt{2\pi/a}$.

For general j complete the square in the exponent,

$$-\frac{1}{2}ax^2 + jx = -\frac{a}{2}\left(x - \frac{j}{a}\right)^2 + \frac{j^2}{2a}, \tag{4.49}$$

and translate the integration variable $x \to x + j/a$, which leaves the measure dx and the infinite limits unchanged. The integral factorizes into the constant $e^{j^2/2a}$ times the $j = 0$ integral $\sqrt{2\pi/a}$, giving (4.47). □

The exponent $j^2/2a$ is the first appearance of the structure that will dominate the whole section: the value of a sourced Gaussian is the exponential of a quadratic in the source, with the coefficient $1/a$ being the *inverse* of the quadratic form. We now lift this to n variables.

4.2.2 The multidimensional Gaussian and the determinant prefactor

Let A be a real symmetric $n\times n$ matrix with $A>0$, and write $x=(x_1,\dots,x_n)^{\mathsf T}\in\mathbb{R}^n$, $x^{\mathsf T}Ax=\sum_{i,j}x_iA_{ij}x_j$, and $d^nx=dx_1\cdots dx_n$.

Proposition 4.14 (Source-free n-dimensional Gaussian)**.** *For real symmetric $A>0$,*

$$\int_{\mathbb{R}^n} d^nx\, e^{-\frac{1}{2}x^{\mathsf T}Ax} \;=\; \frac{(2\pi)^{n/2}}{\sqrt{\det A}}\,. \tag{4.50}$$

Proof. Because A is real and symmetric, the spectral theorem provides an orthogonal matrix O ($O^{\mathsf T}O=\mathbf{1}$, hence $|\det O|=1$) that diagonalizes it:

$$A=O^{\mathsf T}D\,O,\qquad D=\operatorname{diag}(a_1,\dots,a_n), \tag{4.51}$$

and positive-definiteness means every eigenvalue $a_i>0$. Change variables to the principal axes by $y=Ox$, equivalently $x=O^{\mathsf T}y$. The Jacobian of a linear change of variables is the absolute value of its determinant, $d^nx=|\det O^{\mathsf T}|\,d^ny=d^ny$, and the domain $\mathbb{R}^n$ is preserved. In the new variables the quadratic form is diagonal,

$$x^{\mathsf T}Ax=(O^{\mathsf T}y)^{\mathsf T}\,O^{\mathsf T}DO\,(O^{\mathsf T}y)=y^{\mathsf T}(OO^{\mathsf T})D(OO^{\mathsf T})y=y^{\mathsf T}Dy=\sum_{i=1}^{n}a_i\,y_i^2, \tag{4.52}$$

using $OO^{\mathsf T}=\mathbf{1}$. The integral therefore factorizes into n independent one-dimensional integrals, each evaluated by Theorem 4.13 at $j=0$:

$$\int_{\mathbb{R}^n} d^nx\, e^{-\frac{1}{2}x^{\mathsf T}Ax}=\prod_{i=1}^{n}\int_{-\infty}^{\infty}dy_i\, e^{-\frac{1}{2}a_iy_i^2}=\prod_{i=1}^{n}\sqrt{\frac{2\pi}{a_i}}=\frac{(2\pi)^{n/2}}{\sqrt{\prod_i a_i}}. \tag{4.53}$$

Finally $\det A=\det(O^{\mathsf T}DO)=\det D=\prod_i a_i$ because $\det O^{\mathsf T}\det O=1$, so $\prod_i a_i=\det A$ and (4.50) follows. □

The result deserves a pause. The integral has produced a pure number times $(\det A)^{-1/2}$. In field theory A becomes a differential operator—typically the operator K appearing in the second variation (4.46)—and this prefactor becomes its *functional determinant*, the source of the entire one-loop contribution to the effective action. The single inverse square root of a determinant computed here is, quite literally, the seed of every one-loop calculation in the book.

4.2.3 The source term and completing the square

The structurally decisive formula adds a linear source $J\in\mathbb{R}^n$. It is the finite-dimensional ancestor of the generating functional $Z[J]$.

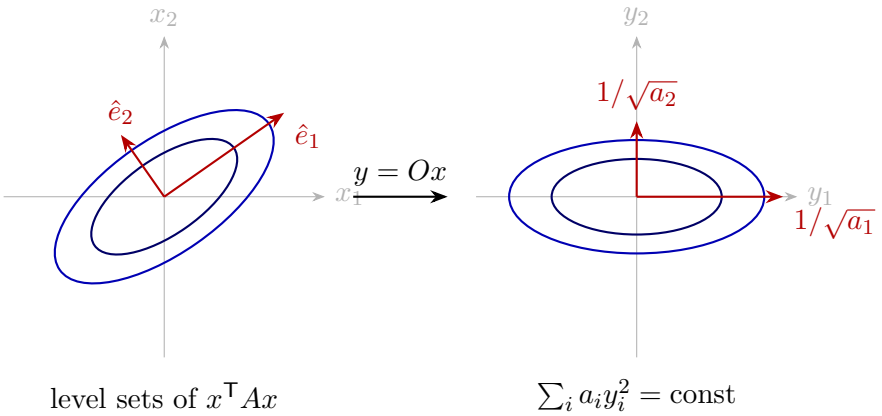

Figure 4.2: The orthogonal change of variables $y = Ox$ underlying Theorem 4.14. The level sets of $x^{\mathsf{T}}Ax$ are ellipsoids; rotating to the principal axes $\hat{e}_i$ (eigenvectors of A) makes the form a sum of squares with weights a_i (the eigenvalues), along which the Gaussian factorizes. The rotation preserves the volume element, $d^n x = d^n y$, so the only surviving geometric data is $\prod_i a_i = \det A$.

Theorem 4.15 (The sourced Gaussian integral)**.** *For real symmetric $A > 0$ and any $J \in \mathbb{R}^n$,*

$$Z(J) \;\equiv\; \int_{\mathbb{R}^n} d^n x\, e^{-\frac{1}{2}x^{\mathsf{T}}Ax + J^{\mathsf{T}}x} \;=\; \frac{(2\pi)^{n/2}}{\sqrt{\det A}}\, \exp\Big(\tfrac{1}{2}\, J^{\mathsf{T}} A^{-1} J\Big). \tag{4.54}$$

Proof. Complete the square. Since A is invertible we may shift $x = y + A^{-1}J$, a translation that leaves $d^n x = d^n y$ and the domain unchanged. Using $A^{\mathsf{T}} = A$ and $(A^{-1})^{\mathsf{T}} = A^{-1}$, expand

$$\begin{aligned} -\frac{1}{2}x^{\mathsf{T}}Ax + J^{\mathsf{T}}x &= -\frac{1}{2}(y + A^{-1}J)^{\mathsf{T}}A(y + A^{-1}J) + J^{\mathsf{T}}(y + A^{-1}J) \\ &= -\frac{1}{2}\Big(y^{\mathsf{T}}Ay + y^{\mathsf{T}}J + J^{\mathsf{T}}y + J^{\mathsf{T}}A^{-1}J\Big) + J^{\mathsf{T}}y + J^{\mathsf{T}}A^{-1}J, \end{aligned} \tag{4.55}$$

where we used $A\,A^{-1}J = J$ and $(A^{-1}J)^{\mathsf{T}}A = J^{\mathsf{T}}A^{-1}A = J^{\mathsf{T}}$. Each of $y^{\mathsf{T}}J$ and $J^{\mathsf{T}}y$ is the same scalar, so $-\frac{1}{2}y^{\mathsf{T}}J - \frac{1}{2}J^{\mathsf{T}}y = -J^{\mathsf{T}}y$, which cancels the $+J^{\mathsf{T}}y$; and $-\frac{1}{2}J^{\mathsf{T}}A^{-1}J + J^{\mathsf{T}}A^{-1}J = +\frac{1}{2}J^{\mathsf{T}}A^{-1}J$. The exponent collapses to

$$-\frac{1}{2}x^{\mathsf{T}}Ax + J^{\mathsf{T}}x = -\frac{1}{2}y^{\mathsf{T}}Ay + \frac{1}{2}J^{\mathsf{T}}A^{-1}J. \tag{4.56}$$

The second term is x-independent and comes out of the integral; the first reproduces the source-free integral (4.50). Hence $Z(J) = e^{\frac{1}{2}J^{\mathsf{T}}A^{-1}J}\,(2\pi)^{n/2}(\det A)^{-1/2}$, which is (4.54). □

Two features of (4.54) will be used relentlessly. First, the J-dependence is entirely in the exponential of a quadratic form whose kernel is A^{-1}, *not* A: the object that appears in correlators is always the inverse of the operator in the action. Second, the J-independent prefactor $Z(0) = (2\pi)^{n/2}(\det A)^{-1/2}$ drops out of every normalized average, so it is convenient to factor it off once and for all.

Definition 4.16 (Gaussian average)**.** For a polynomially-bounded function $f : \mathbb{R}^n \to \mathbb{C}$ define its *Gaussian average* with respect to $A > 0$ by

$$\langle f \rangle \;\equiv\; \frac{\displaystyle\int_{\mathbb{R}^n} d^n x\; f(x)\, e^{-\frac{1}{2}x^{\mathsf{T}}Ax}}{\displaystyle\int_{\mathbb{R}^n} d^n x\; e^{-\frac{1}{2}x^{\mathsf{T}}Ax}}\,. \tag{4.57}$$

Dividing (4.54) by $Z(0)$ gives the *normalized generating function*

$$\frac{Z(J)}{Z(0)} \;=\; \langle e^{J^{\mathsf{T}}x} \rangle \;=\; \exp\!\Big(\tfrac{1}{2}\, J^{\mathsf{T}} A^{-1} J\Big), \tag{4.58}$$

the central identity from which all moments will be read off by differentiation.

4.2.4 The complex Gaussian

Charged fields, and later (by formal analogy) fermions, are integrated against a *Hermitian* quadratic form in complex variables. The result differs from the real case in a way worth isolating now: the determinant appears to the first inverse power, not the inverse square root.

Let $z = (z_1, \dots, z_n)^{\mathsf{T}} \in \mathbb{C}^n$ with conjugate $\bar z$ and $z^\dagger = \bar z^{\mathsf{T}}$, and let A be a Hermitian positive-definite matrix, $A^\dagger = A > 0$ (real positive eigenvalues). We integrate over the underlying real plane with the measure

$$d^{2n}z \;\equiv\; \prod_{i=1}^{n} \frac{d(\operatorname{Re} z_i)\, d(\operatorname{Im} z_i)}{\pi}, \tag{4.59}$$

the factor $1/\pi$ per complex variable chosen so that the normalization comes out clean.

Theorem 4.17 (The complex (Hermitian) Gaussian)**.** *For Hermitian $A > 0$ and any $w \in \mathbb{C}^n$,*

$$\int d^{2n}z\; e^{-z^\dagger A z + w^\dagger z + z^\dagger w} \;=\; \frac{1}{\det A}\; \exp(w^\dagger A^{-1} w). \tag{4.60}$$

In particular the source-free integral equals $(\det A)^{-1}$.

Proof. Take first $w = 0$. Diagonalize the Hermitian matrix by a unitary U ($U^\dagger U = \mathbf{1}$), $A = U^\dagger D U$ with $D = \mathrm{diag}(a_1, \dots, a_n)$ and each $a_i > 0$, and change variables $z = U^\dagger \zeta$. As a real-linear map on $\mathbb{R}^{2n}$, multiplication by the unitary $U^\dagger$ has Jacobian determinant $|\det U^\dagger|^2 = 1$ (each complex eigenvalue $e^{i\theta}$ of a unitary contributes a 2×2 rotation block of unit determinant), so the measure (4.59) is invariant, $d^{2n}z = d^{2n}\zeta$. The form becomes diagonal, $z^\dagger A z = \zeta^\dagger D \zeta = \sum_i a_i |\zeta_i|^2$, and the integral factorizes. Writing $\zeta_i = u_i + i v_i$, each factor is a real two-dimensional Gaussian,

$$\int \frac{du_i\, dv_i}{\pi}\, e^{-a_i(u_i^2+v_i^2)} = \frac{1}{\pi} \cdot \frac{\pi}{a_i} = \frac{1}{a_i}, \tag{4.61}$$

using (4.48) with $a \to 2a_i$ in each of the two real directions (or directly the polar evaluation). The product gives $\prod_i a_i^{-1} = (\det D)^{-1} = (\det A)^{-1}$, since $\det A = \det D$ for a unitary similarity. This proves the $w = 0$ case.

For general w, complete the square exactly as in the real case but now respecting Hermiticity. Shift $z = \zeta + A^{-1}w$, so that $z^\dagger = \zeta^\dagger + w^\dagger A^{-1}$ because A^{-1} is Hermitian. Then

$$\begin{aligned} -z^\dagger A z + w^\dagger z + z^\dagger w &= -(\zeta^\dagger + w^\dagger A^{-1}) A (\zeta + A^{-1}w) + w^\dagger(\zeta + A^{-1}w) + (\zeta^\dagger + w^\dagger A^{-1})w \\ &= -\zeta^\dagger A \zeta - \zeta^\dagger w - w^\dagger \zeta - w^\dagger A^{-1} w + w^\dagger \zeta + w^\dagger A^{-1} w + \zeta^\dagger w + w^\dagger A^{-1} w \\ &= -\zeta^\dagger A \zeta + w^\dagger A^{-1} w, \end{aligned} \tag{4.62}$$

where the cross terms $\zeta^\dagger w$ and $w^\dagger \zeta$ cancel pairwise. The constant $w^\dagger A^{-1} w$ exits the integral and the remaining ζ-integral is the $w = 0$ result, giving (4.60). □

Notation Watch

The contrast between $(\det A)^{-1/2}$ for one real field (Theorem 4.15) and $(\det A)^{-1}$ for one complex field (Theorem 4.17) is exactly the statement that a complex field is "two real fields," so its determinant prefactor is squared relative to a single real degree of freedom. The same Hermitian-form integral, but with the integration variables promoted to anticommuting Grassmann numbers, will instead yield $\det A$ in the numerator—the inverse of the bosonic answer. That sign in the exponent of the determinant is the bookkeeping origin of the closed fermion loop's minus sign; we build Grassmann/Berezin integration from scratch and prove the $+\det A$ rule in Chapter 12, and merely note the analogy here.

4.2.5 Moments and Wick's theorem

We now harvest the moments of the real Gaussian. The two-point function comes out first, and most cleanly, directly from the definition.

Proposition 4.18 (The two-point function is the inverse form)**.** *For the Gaussian average* (4.57) *with respect to* $A > 0$*,*

$$\langle x_i \rangle = 0, \qquad \langle x_i\, x_j \rangle = (A^{-1})_{ij}. \tag{4.63}$$

Proof. We use the only fact about the measure we shall ever need: it is a total derivative when differentiated, so boundary terms vanish. Concretely, for any polynomially-bounded $g(x)$ the Gaussian weight $\rho(x) = e^{-\frac{1}{2}x^{\mathsf{T}}Ax}$ decays faster than any polynomial grows, so

$$\int_{\mathbb{R}^n} d^n x\, \frac{\partial}{\partial x_\ell}\Big[\, g(x)\, \rho(x) \,\Big] = 0, \tag{4.64}$$

the integral of an exact derivative over all of $\mathbb{R}^n$. Since $\partial_{x_\ell}\rho = -(Ax)_\ell\, \rho = -\sum_p A_{\ell p} x_p\, \rho$, expanding (4.64) gives the *Schwinger–Dyson relation*

$$\Big\langle \frac{\partial g}{\partial x_\ell} \Big\rangle = \sum_p A_{\ell p}\, \langle x_p\, g \rangle. \tag{4.65}$$

Take $g = 1$: the left side vanishes, so $\sum_p A_{\ell p}\langle x_p\rangle = 0$ for every ℓ; as A is invertible, $\langle x_p\rangle = 0$. Take $g = x_j$: the left side is $\langle \delta_{\ell j}\rangle = \delta_{\ell j}$, so $\delta_{\ell j} = \sum_p A_{\ell p}\langle x_p x_j\rangle$, i.e. $A\,\langle x x_j\rangle = e_j$ componentwise. Multiplying by A^{-1} yields $\langle x_i x_j\rangle = (A^{-1})_{ij}$. □

This is the result the whole section was built to reach: *the two-point function is the inverse of the quadratic form in the action.* The matrix A^{-1} is the finite-dimensional propagator. With this in hand, all higher moments are fixed combinatorially.

Theorem 4.19 (Wick's theorem in finite dimensions)**.** *Let* $A > 0$ *be real symmetric and write* $G \equiv A^{-1}$ *for the propagator. Then all odd moments vanish, and the* $2k$*-point moment is the sum over perfect pairings of its indices:*

$$\langle x_{i_1} x_{i_2} \cdots x_{i_{2k}} \rangle \;=\; \sum_{\text{pairings } P}\; \prod_{(a,b)\in P} G_{i_a i_b} \;=\; \sum_{\text{pairings } P}\; \prod_{(a,b)\in P} (A^{-1})_{i_a i_b}, \tag{4.66}$$

where a pairing *(perfect matching) of* $\{1, 2, \ldots, 2k\}$ *is a partition into* k *unordered pairs, and the number of such pairings is* $(2k-1)!! = (2k)!/(2^k k!)$*.*

Proof. We give the generating-function proof, which makes the combinatorics explicit, and then note the equivalent inductive proof from (4.65).

Differentiate the normalized generating function (4.58). Each factor of x_i inside the average is produced by a derivative with respect to the source:

$$\frac{\partial}{\partial J_i}\, \langle e^{J^{\mathsf{T}}x} \rangle = \langle x_i\, e^{J^{\mathsf{T}}x} \rangle, \tag{4.67}$$

the interchange of derivative and integral being justified by the uniform Gaussian decay. Applying m such derivatives and then setting $J = 0$ removes the exponential and leaves the moment,

$$\langle x_{i_1} \cdots x_{i_m} \rangle = \frac{\partial}{\partial J_{i_1}} \cdots \frac{\partial}{\partial J_{i_m}} \exp\Big(\tfrac{1}{2}\, J^{\mathsf{T}} A^{-1} J\Big)\Big|_{J=0}. \tag{4.68}$$

Write $Q(J) = \frac{1}{2}\sum_{a,b} J_a G_{ab} J_b$ with $G = A^{-1}$ symmetric, and expand $e^{Q} = \sum_{r\geq 0} Q^r/r!$. Each power Q^r is a homogeneous polynomial of degree $2r$ in J. A polynomial term of degree D has a nonvanishing m-fold derivative at $J = 0$ only when $D = m$: if $D < m$ some derivative kills it, and if $D > m$ a factor of J survives and is set to zero. Hence:

Odd moments vanish. If m is odd, no power Q^r has degree m (all degrees $2r$ are even), so (4.68) is zero.

Even moments. Set $m = 2k$; only the term $r = k$ survives,

$$Q^k = \frac{1}{2^k}\Big(\sum_{a,b} J_a G_{ab} J_b\Big)^k = \frac{1}{2^k} \sum_{a_1,b_1,\ldots,a_k,b_k} \Big(\prod_{s=1}^{k} G_{a_s b_s}\Big)\, J_{a_1} J_{b_1} \cdots J_{a_k} J_{b_k}, \tag{4.69}$$

so that

$$\langle x_{i_1} \cdots x_{i_{2k}} \rangle = \frac{1}{2^k k!} \sum_{a_1,b_1,\ldots,a_k,b_k} \Big(\prod_{s=1}^{k} G_{a_s b_s}\Big) \frac{\partial}{\partial J_{i_1}} \cdots \frac{\partial}{\partial J_{i_{2k}}} (J_{a_1} J_{b_1} \cdots J_{a_k} J_{b_k}). \tag{4.70}$$

The derivative of a product of $2k$ first-order monomials $J_{c_1} \cdots J_{c_{2k}}$ (here the c's are the list $a_1, b_1, \ldots, a_k, b_k$) by $2k$ distinct derivatives is

$$\frac{\partial}{\partial J_{i_1}} \cdots \frac{\partial}{\partial J_{i_{2k}}} (J_{c_1} \cdots J_{c_{2k}}) = \sum_{\sigma \in S_{2k}} \prod_{t=1}^{2k} \delta_{i_t,\, c_{\sigma(t)}}, \tag{4.71}$$

the sum over all $(2k)!$ bijections matching the derivative slots i_t to the factor slots $c_{\sigma(t)}$: each derivative removes exactly one J, and every assignment of which derivative removes which factor contributes one term.

Inserting (4.71) into (4.70) and performing the free sums over the dummy indices a_s, b_s, each permutation σ assigns the external indices $i_1, \ldots, i_{2k}$ to the $2k$ slots of the k propagator factors $G_{a_s b_s}$, producing a product of k factors of G, one for each pair of slots (a_s, b_s). Thus the result is a sum over the $(2k)!$ permutations of $\prod_s G_{(\text{index in slot } a_s)(\text{index in slot } b_s)}$. This overcounts the distinct *pairings* of $\{i_1, \ldots, i_{2k}\}$: a given pairing arises from

- the $k!$ orderings of which pair occupies which factor s, and
- the 2^k swaps $a_s \leftrightarrow b_s$ within each factor, all equal because G is symmetric, $G_{ab} = G_{ba}$,

giving $2^k k!$ permutations per pairing. These $2^k k!$ copies are exactly cancelled by the prefactor $1/(2^k k!)$ in (4.70). What remains is one term per distinct pairing, $\prod_{(a,b)\in P} G_{i_a i_b}$, summed over all pairings P, which is (4.66). The count of pairings is the number of permutations modulo this symmetry, $(2k)!/(2^k k!) = (2k-1)!!$. □

Remark 4.20 (The inductive form: Wick's recursion). The same theorem follows from the Schwinger–Dyson relation (4.65) by induction on the number of insertions, a route worth recording because it is exactly how Wick's theorem is organized for fields in Chapter 10. Put $g = x_{i_2}\cdots x_{i_m}$ in (4.65). Its derivative by x_ℓ hits each factor in turn, $\partial_{x_\ell} g = \sum_{r=2}^{m} \delta_{\ell,i_r}\, x_{i_2}\cdots \widehat{x_{i_r}} \cdots x_{i_m}$ (the hat denoting omission), so

$$\sum_{r=2}^{m} \delta_{\ell,i_r} \,\langle x_{i_2}\cdots \widehat{x_{i_r}} \cdots x_{i_m}\rangle = \sum_{p} A_{\ell p}\,\langle x_p\, x_{i_2}\cdots x_{i_m}\rangle. \tag{4.72}$$

Contracting with $(A^{-1})_{i_1\ell}$ and summing over ℓ turns the right side into $\langle x_{i_1} x_{i_2}\cdots x_{i_m}\rangle$ and gives the recursion

$$\langle x_{i_1} x_{i_2}\cdots x_{i_m}\rangle = \sum_{r=2}^{m} (A^{-1})_{i_1 i_r}\,\langle x_{i_2}\cdots \widehat{x_{i_r}} \cdots x_{i_m}\rangle. \tag{4.73}$$

In words: the first variable x_{i_1} must be contracted with one of the remaining $m-1$ variables, contributing a propagator $(A^{-1})_{i_1 i_r}$ times the average of what is left. Starting from $\langle 1\rangle = 1$ and $\langle x_i\rangle = 0$, this recursion manifestly generates the sum over all pairings: it pairs i_1 with every partner and recurses on the rest, and it forces every odd moment to zero (an odd recursion always bottoms out on a single unpaired $\langle x_i\rangle = 0$). For $m = 2$ it reproduces $\langle x_{i_1} x_{i_2}\rangle = (A^{-1})_{i_1 i_2}$ of Theorem 4.18.

It is worth writing the lowest nontrivial case in full, since its pattern is the one that recurs for fields. The four-point function has $(4-1)!! = 3$ pairings:

$$\langle x_i x_j x_k x_l\rangle = (A^{-1})_{ij}(A^{-1})_{kl} + (A^{-1})_{ik}(A^{-1})_{jl} + (A^{-1})_{il}(A^{-1})_{jk}. \tag{4.74}$$

Physical Insight

Wick's theorem says that a Gaussian random vector has *no genuine higher correlation*: every moment is built from the single two-point datum A^{-1} by the purely combinatorial rule of pairing. This is the precise sense in which the Gaussian is the "free" or "non-interacting" distribution—all structure resides in the propagator, and all the diagrams one will ever draw for a free field are just the perfect matchings counted here. Interactions, when we add them, are exactly the failure of (4.66): the deviation of the true

moments from their Gaussian (pairing) values.

4.2.6 The carried toy: the zero-dimensional ϕ^4 model

To see the whole apparatus at work on the model we will return to repeatedly, we set up the simplest interacting theory imaginable: a field theory in zero spacetime dimensions, where the "field" is a single real number x and the "functional integral" is one ordinary integral. This is a self-contained model computation, not the formal ϕ^4 theory of Chapter 6 onward; it is a rigorous laboratory in which every statement of the preceding subsections becomes an honest, convergent integral. The genuine free scalar propagator and Wick's theorem *for fields*—where A^{-1} becomes the Feynman propagator and the indices become spacetime points—are built in Chapter 10; here we exercise only the zero-dimensional shadow.

Worked Example 4.21 (The zero-dimensional ϕ^4 partition function)**.** Define, for a coupling $\lambda \geq 0$ and source $J \in \mathbb{R}$, the partition function

$$Z(\lambda, J) \;=\; \int_{-\infty}^{\infty} dx \;\exp\Big(-\tfrac{1}{2}x^2 - \tfrac{\lambda}{4!}x^4 + Jx\Big). \tag{4.75}$$

Convergence and status. For $\lambda > 0$ the quartic term $-\frac{\lambda}{4!}x^4$ dominates the exponent at large $|x|$ and the integrand decays like $e^{-\lambda x^4/4!}$, so the integral converges absolutely for *every* real J and defines a smooth function of J; at $\lambda = 0$ it reduces to the convergent Gaussian. (For $\lambda < 0$ the integral diverges—the would-be "vacuum" is unstable—which is the zero-dimensional face of the statement that the ϕ^4 perturbation series is asymptotic, not convergent; we set that question up in Section 4.3 and treat asymptotic series in Chapter 5.) Thus (4.75) is, in contrast to the field-theoretic integral of the next section, an ordinary integral about which everything is rigorous.

The free value. At $\lambda = 0$ this is the one-dimensional sourced Gaussian of Theorem 4.13 with $a = 1$, $j = J$:

$$Z(0, J) = \int_{-\infty}^{\infty} dx\; e^{-\frac{1}{2}x^2 + Jx} = \sqrt{2\pi}\; e^{J^2/2}, \qquad Z(0,0) = \sqrt{2\pi}. \tag{4.76}$$

The quadratic form is the 1×1 matrix $A = 1$, so the propagator is $A^{-1} = 1$. The normalized generating function is $Z(0, J)/Z(0, 0) = e^{J^2/2}$, the $n = 1$ instance of (4.58).

Free moments by Wick. With $G = A^{-1} = 1$, Theorem 4.19 gives the free moments as plain pairing counts,

$$\langle x^{2k}\rangle_0 = (2k-1)!! \cdot (A^{-1})^k = (2k-1)!!, \qquad \langle x^{2k+1}\rangle_0 = 0, \tag{4.77}$$

where $\langle\,\cdot\,\rangle_0$ is the average (4.57) at $\lambda = 0$. One can verify the first two directly from (4.76): differentiating $e^{J^2/2}$ twice and four times and setting $J = 0$ gives $\langle x^2\rangle_0 = 1$ and $\langle x^4\rangle_0 = 3$, matching $1!! = 1$ and $3!! = 3$.

Enumerating the contractions of $\langle x^4\rangle_0$. The quartic interaction will be expanded as a power series in λ, and each term is a free average of a power of x; the lowest is $\langle x^4\rangle_0$. By (4.74) with all indices equal and $A^{-1} = 1$, the three pairings of the four factors $x\,x\,x\,x$ are

$$\underbrace{(12)(34)}_{1} \;+\; \underbrace{(13)(24)}_{1} \;+\; \underbrace{(14)(23)}_{1} \;=\; 3, \tag{4.78}$$

each contributing $(A^{-1})^2 = 1$. The number $3 = 3!!$ is precisely the combinatorial weight that will reappear as the symmetry factor of the one-vertex ("figure-eight" tadpole) diagram of the ϕ^4 theory: writing the first correction to the free energy,

$$\frac{Z(\lambda,0)}{Z(0,0)} = \left\langle e^{-\frac{\lambda}{4!}x^4}\right\rangle_0 = 1 - \frac{\lambda}{4!}\,\langle x^4\rangle_0 + O(\lambda^2) = 1 - \frac{\lambda}{4!}\cdot 3 + O(\lambda^2) = 1 - \frac{\lambda}{8} + O(\lambda^2), \tag{4.79}$$

where the coefficient $3/4! = 1/8$ is the $4!$ of the vertex partly cancelled by the 3 ways of contracting—the zero-dimensional avatar of a Feynman symmetry factor. We stop the expansion here: it is the *setup* that this section owes. The status of the series (4.79) as λ-power series—convergent or merely asymptotic—and its diagrammatic organization belong to the following sections and to Chapter 15, where symmetry factors are done with full care.

We have now extracted, from one convergent integral and its sources, the complete finite-dimensional kit: the Gaussian value with its $(\det A)^{-1/2}$ prefactor (4.54), its complex/Hermitian counterpart (4.60), the normalized generating function (4.58), the identification of the two-point function with the inverse form A^{-1} (4.63), and Wick's pairing theorem (4.66). Every one of these statements was a theorem about an ordinary integral over $\mathbb{R}^n$. The next section takes the only remaining step that separates this from quantum field theory: it lets $n \to \infty$, replacing the matrix A by the differential operator of the second variation (4.46) and the sum over $\mathbb{R}^n$ by a sum over field configurations, and asks—carefully, and with the honesty the chapter's scope demands—which of these clean finite-dimensional theorems survive the limit as theorems and which survive only as disciplined formal definitions.

4.3 From Finite to Infinite: The Functional Integral and Its Status

The previous section closed by handing us a complete, fully rigorous kit of finite-dimensional theorems: the sourced Gaussian value with its $(\det A)^{-1/2}$

prefactor (4.54), the identification of the two-point function with the inverse form A^{-1} (4.63), and Wick's pairing theorem (4.66). Each was a theorem about an honest integral over $\mathbb{R}^n$. What separates that finite-dimensional calculus from quantum field theory is a single, enormous step: $n \to \infty$. A field configuration is not a finite list of numbers but a function on spacetime—an element of an infinite-dimensional space—and the "sum over configurations" weighted by e^{iS} or e^{-S_E} is an integral over that space. The purpose of this section is to take that step *explicitly*, by the only honest route: discretize spacetime so that the field becomes a finite vector and the integral becomes one of the finite-dimensional Gaussians we have already proved, and then remove the discretization. We will find that the algebra goes through cleanly and reproduces the formulas one writes in practice—but that the limit itself is a theorem in some cases and only a disciplined formal definition in others. The chapter's scope demands that we say, precisely and without bluffing, which is which. By the end we will have a field generating functional $Z[J]$, an explicit formula for the free propagator as the inverse of the quadratic operator, and an Assessment of Current Status of the standing of the symbol $\int \mathcal{D}\phi$.

4.3.1 Lattice discretization of a field on a finite box

The infinity in $\int \mathcal{D}\phi$ is of two distinct kinds, and it pays to separate them. The first is the *ultraviolet* infinity: a field has independent values at every point of a continuum, uncountably many degrees of freedom in any region. The second is the *infrared* infinity: spacetime is unbounded, so even after coarse-graining there are infinitely many regions. We tame both at once by working in a finite box with a finite mesh, leaving a genuinely finite-dimensional integral to which Section 4.2 applies verbatim.

We work in Euclidean signature throughout this construction—the case in which the weight e^{-S_E} is a decaying exponential rather than an oscillatory phase, so the finite-dimensional integrals converge absolutely and the limit has a chance of being a genuine measure. The passage from the physical Lorentzian theory to this Euclidean one is the Wick rotation $t \to -i\tau$ introduced in Chapter 5 and carried out for fields in Chapter 10; we return to the oscillatory Minkowski integral in Section 4.3.3 and treat it as what it is, a formal object made meaningful by analytic continuation from here. We carry the running example, the real scalar of ϕ^4 theory (Chapter 6), with Euclidean action

$$S_E[\phi] = \int d^d x \left[\tfrac{1}{2} (\partial_\mu \phi)(\partial_\mu \phi) + \tfrac{1}{2} m^2 \phi^2 + \tfrac{\lambda}{4!} \phi^4 \right], \tag{4.80}$$

where the index μ is now summed with the Euclidean (Kronecker) metric, all signs in the quadratic part are positive, and d is the Euclidean spacetime dimension ($d = 4$ for the physical theory, but we keep d general because the rigor verdict will depend on it).

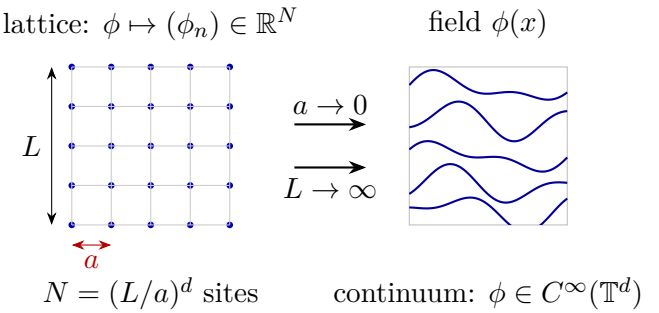

Figure 4.3: The discretize-then-continuum strategy of this section. A field on a box of side L is sampled on a mesh of spacing a, becoming a finite vector $(\phi_n) \in \mathbb{R}^N$ with $N = (L/a)^d$; the functional integral becomes the finite-dimensional Gaussian of Section 4.2. The continuum field theory is the limit $a \to 0$ (ultraviolet, infinitely many degrees of freedom per unit volume) and $L \to \infty$ (infrared, infinite volume). Whether this limit exists as a *theorem* or only as a *formal* prescription is the subject of Section 4.3.4.

The box and the mesh. Replace $\mathbb{R}^d$ by a cubic box of side L with periodic boundary conditions—topologically a torus $\mathbb{T}^d$, which removes boundary effects and makes Fourier analysis a finite sum. Introduce a lattice spacing a dividing L, so that the sites are

$$x_n = a\,n, \qquad n \in \Lambda \equiv \{0, 1, \dots, \mathcal{N}-1\}^d, \qquad \mathcal{N} = \frac{L}{a}, \tag{4.81}$$

with site indices read modulo $\mathcal{N}$ in each direction (periodicity). There are

$$N = \mathcal{N}^d = (L/a)^d \tag{4.82}$$

sites in all, a finite number. A field configuration is now specified by its values at the sites, i.e. by the finite vector

$$\phi \;\longmapsto\; (\phi_n)_{n\in\Lambda} \in \mathbb{R}^N, \qquad \phi_n \equiv \phi(x_n). \tag{4.83}$$

This is the substitution "field $\to$ finite vector" that the construction demands; everything else follows by translating each piece of S_E and of the measure into this finite data.

The action becomes a quadratic-plus-interaction form. Each ingredient of (4.80) has a canonical lattice counterpart. The spacetime integral becomes a Riemann sum weighted by the cell volume,

$$\int d^d x \;\longrightarrow\; a^d \sum_{n\in\Lambda} . \tag{4.84}$$

The gradient becomes a finite difference. Writing $\hat{\mu}$ for the unit lattice vector in direction μ, the forward difference

$$(\partial_\mu \phi)(x_n) \;\longrightarrow\; \frac{\phi_{n+\hat{\mu}} - \phi_n}{a} \tag{4.85}$$

reproduces the derivative to $O(a)$. The potential terms are local and simply sample the field at each site. Assembling these, the lattice action is

$$S_E^{\mathrm{lat}}[\phi] = a^d \sum_{n \in \Lambda} \left[\frac{1}{2} \sum_{\mu=1}^{d} \Big(\frac{\phi_{n+\hat{\mu}} - \phi_n}{a} \Big)^2 + \frac{1}{2} m^2 \phi_n^2 + \frac{\lambda}{4!} \phi_n^4 \right]. \tag{4.86}$$

The first two terms are quadratic in the vector (ϕ_n) and the last is the interaction; this is exactly the "quadratic + interaction form" structure of the finite-dimensional theory. To expose the quadratic form, expand the square and use periodicity to relabel the shifted sums (a discrete summation by parts: the cross term $\sum_n \phi_n \phi_{n+\hat{\mu}}$ is unchanged under $n \to n - \hat{\mu}$ because the sum runs over the whole torus). Then

$$\begin{aligned} a^d \sum_n \frac{1}{2} \sum_\mu \frac{(\phi_{n+\hat{\mu}} - \phi_n)^2}{a^2} &= \frac{a^d}{2a^2} \sum_n \sum_\mu \left(\phi_{n+\hat{\mu}}^2 + \phi_n^2 - 2\phi_n \phi_{n+\hat{\mu}} \right) \\ &= -\frac{a^d}{2a^2} \sum_n \sum_\mu \phi_n \left(\phi_{n+\hat{\mu}} + \phi_{n-\hat{\mu}} - 2\phi_n \right) \\ &= -\frac{a^d}{2} \sum_n \phi_n \, (\Delta_{\mathrm{lat}} \phi)_n, \end{aligned} \tag{4.87}$$

where the *lattice Laplacian* is

$$(\Delta_{\mathrm{lat}} \phi)_n \equiv \frac{1}{a^2} \sum_{\mu=1}^{d} \left(\phi_{n+\hat{\mu}} + \phi_{n-\hat{\mu}} - 2\phi_n \right). \tag{4.88}$$

Therefore the quadratic part of (4.86) is $\frac{1}{2} \sum_{n,n'} \phi_n K_{nn'} \phi_{n'}$ with the real symmetric $N \times N$ matrix

$$K_{nn'} = a^d \left[(-\Delta_{\mathrm{lat}} + m^2) \right]_{nn'}, \tag{4.89}$$

which is precisely the discretized quadratic operator $-\Delta + m^2$ of the second variation (4.46), dressed by the cell volume a^d. It is positive definite: for any nonzero ϕ, $\sum_{n,n'} \phi_n K_{nn'} \phi_{n'} = a^d \sum_n \left[\frac{1}{2} \sum_\mu \big(\frac{\phi_{n+\hat{\mu}} - \phi_n}{a} \big)^2 \cdot 2 + m^2 \phi_n^2 \right] \geq a^d m^2 \sum_n \phi_n^2 > 0$, so $K > 0$ and all of Section 4.2 applies.

The measure becomes a product of Lebesgue measures. The remaining ingredient is the "sum over configurations." On the lattice this is the ordinary Lebesgue integral over the value at each site,

$$\mathcal{D}\phi \;\longrightarrow\; \prod_{n \in \Lambda} d\phi_n, \tag{4.90}$$

a product of N copies of $d\phi$, i.e. Lebesgue measure on $\mathbb{R}^N$. The source term $\int d^dx\, J\phi$ becomes $a^d \sum_n J_n\phi_n$ with $J_n \equiv J(x_n)$. We have arrived at a completely well-defined finite-dimensional integral.

Definition 4.22 (The regularized (lattice) functional integral)**.** The *lattice-regularized generating functional* of the scalar theory on the box $\mathbb{T}_L^d$ with spacing a is the ordinary N-dimensional integral

$$Z_a^L[J] \;\equiv\; \int_{\mathbb{R}^N} \Big(\prod_{n\in\Lambda} d\phi_n\Big)\, \exp\Big(-S_E^{\text{lat}}[\phi] + a^d \sum_n J_n\phi_n\Big). \tag{4.91}$$

The (still purely formal) continuum functional integral is the symbol

$$Z[J] \;\equiv\; \int \mathcal{D}\phi\; e^{-S_E[\phi] + \int d^dx\, J\phi}, \tag{4.92}$$

whose precise meaning—when it has one—is the double limit $\lim_{a\to 0,\, L\to\infty} Z_a^L[J]$ (after the field- and coupling-renormalizations of Chapter 22 are inserted), and whose meaning otherwise is exactly (4.91) at fixed regulators.

Physical Insight

The lattice is not an approximation scheme bolted on after the fact; for the interacting continuum theory it is, as far as anyone can prove, the *definition*. The symbol $\int \mathcal{D}\phi$ has no content independent of some regulator that renders it a finite-dimensional integral. When we manipulate $\int \mathcal{D}\phi\, e^{-S}$ in later chapters as though it were an integral—shifting variables, completing the square, differentiating under the sign—each such move is legitimate because it is a move on (4.91), where it is an ordinary theorem of calculus, that survives the limit. The honest reading of every path integral in this book is "the $a \to 0$, $L \to \infty$ limit of this lattice expression, when it exists."

4.3.2 The free generating functional and the continuum propagator

Set $\lambda = 0$. Then $S_E^{\text{lat}} = \frac{1}{2}\phi^{\mathsf{T}} K \phi$ is purely quadratic and (4.91) is *exactly* the sourced Gaussian of Theorem 4.15 with matrix $A = K$ and source vector $\tilde{J}_n = a^d J_n$ (the cell volume is part of the source because the source term carries the measure factor a^d). The theorem applies with no modification and gives, at once,

$$Z_{a,0}^L[J] = \frac{(2\pi)^{N/2}}{\sqrt{\det K}}\, \exp\Big(\tfrac{1}{2}\, \tilde{J}^{\mathsf{T}} K^{-1} \tilde{J}\Big) = Z_{a,0}^L[0]\, \exp\Big(\tfrac{1}{2} \sum_{n,n'} a^d J_n\, (K^{-1})_{nn'}\, a^d J_{n'}\Big). \tag{4.93}$$

This is the central point of fidelity: *the discretized free generating functional is literally the finite-dimensional Gaussian result.* Nothing has been added or guessed; we have only renamed the variables of Theorem 4.15. By Theorem 4.18 the lattice two-point function is the inverse matrix,

$$\langle \phi_n \, \phi_{n'} \rangle = (K^{-1})_{nn'}, \tag{4.94}$$

and all higher correlators are its Wick pairings (4.66). Everything now reduces to one computation: the continuum limit of the matrix K^{-1}. We carry it in full, because the result—that the continuum propagator is the kernel of the inverse of the quadratic operator—is the single most-used fact in the rest of the book.

Diagonalizing by the discrete Fourier transform. The lattice operator $-\Delta_{\text{lat}} + m^2$ is translation invariant on the torus and is therefore diagonalized by plane waves. The momenta compatible with the period-L boundary condition are quantized, and the spacing a truncates them to a *Brillouin zone*:

$$p_\mu = \frac{2\pi}{L}\, k_\mu, \qquad k_\mu \in \Big\{ -\tfrac{\mathcal{N}}{2}, \dots, \tfrac{\mathcal{N}}{2} - 1 \Big\}, \qquad \text{so} \qquad p_\mu \in \Big[-\frac{\pi}{a}, \frac{\pi}{a} \Big), \tag{4.95}$$

exactly N momenta in all—as many as there are sites, as it must be. The normalized plane waves $u_n^{(p)} = N^{-1/2} e^{ip\cdot x_n}$ form an orthonormal basis of $\mathbb{C}^N$. Acting on one of them, the lattice Laplacian (4.88) returns the same wave times a number,

$$\begin{aligned} (-\Delta_{\text{lat}} u^{(p)})_n &= -\frac{1}{a^2} \sum_\mu \big(e^{ip_\mu a} + e^{-ip_\mu a} - 2 \big) u_n^{(p)} = \frac{1}{a^2} \sum_\mu \big(2 - 2\cos p_\mu a \big)\, u_n^{(p)} \\ &= \underbrace{\Big[\sum_{\mu=1}^{d} \frac{4}{a^2} \sin^2 \frac{p_\mu a}{2} \Big]}_{\equiv\ \hat{p}^{\,2}} \, u_n^{(p)}, \end{aligned} \tag{4.96}$$

using $2 - 2\cos\theta = 4\sin^2(\theta/2)$. The quantity $\hat{p}^{\,2}$ is the *lattice momentum squared*; it agrees with $p^2 = \sum_\mu p_\mu^2$ when $|p_\mu| a \ll 1$ and bends over to a finite maximum at the zone boundary. Thus the eigenvalues of $K = a^d(-\Delta_{\text{lat}} + m^2)$ are $a^d(\hat{p}^{\,2} + m^2)$, and the inverse matrix in position space is the spectral sum

$$(K^{-1})_{nn'} = \sum_p u_n^{(p)} \, \frac{1}{a^d(\hat{p}^{\,2} + m^2)} \, (u_{n'}^{(p)})^* = \frac{1}{Na^d} \sum_p \frac{e^{ip\cdot(x_n - x_{n'})}}{\hat{p}^{\,2} + m^2}. \tag{4.97}$$

Because $Na^d = (L/a)^d a^d = L^d$, the prefactor is simply L^{-d}, the inverse volume, and the lattice propagator is

$$G_a^L(x_n, x_{n'}) \equiv (K^{-1})_{nn'} = \frac{1}{L^d} \sum_p \frac{e^{ip\cdot(x_n - x_{n'})}}{\hat{p}^{\,2} + m^2}. \tag{4.98}$$

The two limits. Take infinite volume first, $L \to \infty$ at fixed a. The momenta (4.95) have spacing $\Delta p_\mu = 2\pi/L \to 0$ and fill the Brillouin zone densely; the Riemann-sum rule $\frac{1}{L^d}\sum_p \to \int_{\mathrm{BZ}} \frac{d^d p}{(2\pi)^d}$ (each momentum cell has volume $(2\pi/L)^d$) converts the sum to an integral,

$$G_a(x-y) = \int_{-\pi/a}^{\pi/a} \frac{d^d p}{(2\pi)^d}\, \frac{e^{ip\cdot(x-y)}}{\hat{p}^{\,2} + m^2}. \tag{4.99}$$

Now take the continuum, $a \to 0$. The integrand converges pointwise: $\hat{p}^{\,2} = \sum_\mu \frac{4}{a^2}\sin^2(p_\mu a/2) \to \sum_\mu p_\mu^2 = p^2$ as $a \to 0$ (Taylor: $\sin(p_\mu a/2) = p_\mu a/2 + O(a^3)$), and the integration domain opens up to all of $\mathbb{R}^d$. The result is the *Euclidean propagator*,

$$\boxed{G(x-y) = \int \frac{d^d p}{(2\pi)^d}\, \frac{e^{ip\cdot(x-y)}}{p^2 + m^2}} \tag{4.100}$$

which is exactly the kernel of the inverse operator $(-\Delta + m^2)^{-1}$: applying $-\Delta + m^2$ in x brings down $p^2 + m^2$ inside the integral, cancelling the denominator and leaving $\int \frac{d^d p}{(2\pi)^d} e^{ip(x-y)} = \delta^d(x-y)$, i.e.

$$(-\Delta_x + m^2)\, G(x-y) = \delta^d(x-y). \tag{4.101}$$

We have therefore *derived*, by an explicit lattice-to-continuum limit, the statement that in field theory the two-point function is the inverse of the quadratic operator in the action—the infinite-dimensional incarnation of Theorem 4.18, with the matrix index i replaced by the spacetime point x and the matrix inverse replaced by the Green's function. Feeding (4.100) back into (4.93), and using $a^d \sum_n \to \int d^d x$ to turn the source pairing into a double spacetime integral, gives the free continuum generating functional

$$\frac{Z[J]}{Z[0]} = \exp\Big(\tfrac{1}{2}\iint d^d x\, d^d y\; J(x)\, G(x-y)\, J(y)\Big), \qquad G = (-\Delta + m^2)^{-1}, \tag{4.102}$$

the field-theoretic analogue of the normalized Gaussian generating function (4.58). This is the object whose functional derivatives the next section differentiates to extract correlators.

The prefactor and the functional determinant. The source-independent prefactor of (4.93) is $Z^L_{a,0}[0] = (2\pi)^{N/2}(\det K)^{-1/2}$. As $a \to 0$ the number of sites $N \to \infty$ and $\det K = \prod_p a^d(\hat{p}^{\,2} + m^2)$ runs off to a meaningless value: this is the *functional determinant* $\det(-\Delta + m^2)$, and it is divergent. The continuum symbol $(\det(-\Delta + m^2))^{-1/2}$ is therefore the most formal part of the whole construction. Two things rescue it in practice. First, the prefactor is J-independent and cancels in every normalized correlator, which is why the next section divides it out at the start. Second, physical quantities depend only on *ratios* of such

determinants—e.g. the determinant in a background field divided by the free one—and these ratios are finite after renormalization; this is the content of the one-loop effective action computed in Section 4.6 and made systematic with zeta-function or heat-kernel regularization there. We flag the divergence now and discharge it there.

4.3.3 The Minkowski integral and the oscillatory obstruction

The physical theory lives in Lorentzian signature, where the weight is the phase e^{iS} rather than the decaying e^{-S_E}. Repeating the lattice construction with the mostly-minus action $S[\phi] = \int d^dx\,[\frac{1}{2}(\partial\phi)^2 - \frac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4]$ gives, in the free case, the quadratic form $\frac{i}{2}\phi^{\mathsf{T}}K_M\phi$ with $K_M = a^d\,[-(\Box + m^2)]$ (an integration by parts turns $\frac{i}{2}\phi(-\Box - m^2)\phi$ into iS). Formally completing the square as in the one-dimensional oscillatory integral $\int dx\, e^{\frac{i}{2}ax^2+ijx} = \sqrt{2\pi i/a}\; e^{-ij^2/2a}$—the analytic continuation $a \to ia$ of Theorem 4.13, justified by the $i\epsilon$ device of Chapter 5—one obtains

$$\frac{Z[J]}{Z[0]} = \exp\Big(-\tfrac{1}{2}\iint d^dx\, d^dy\; J(x)\, D_F(x-y)\, J(y)\Big), \tag{4.103}$$

with the Feynman propagator

$$D_F(x-y) = \int \frac{d^dp}{(2\pi)^d}\,\frac{i\,e^{-ip\cdot(x-y)}}{p^2 - m^2 + i\epsilon}, \qquad (\Box_x + m^2)\, D_F(x-y) = -i\,\delta^d(x-y). \tag{4.104}$$

The $+i\epsilon$ is not optional decoration. The naive Lorentzian quadratic operator $\Box + m^2$ is *not invertible*: it annihilates every on-shell mode $p^2 = m^2$, so it has a kernel and "$(\Box + m^2)^{-1}$" is ill-defined until the singular denominator is displaced off the real axis. The $+i\epsilon$ is the unique displacement that selects the boundary condition making D_F the *time-ordered* two-point function—the propagator that emerges automatically because the (formal) Lorentzian path integral, like its rigorous Euclidean continuation, weights configurations in a way that orders operators in time. We state this here for the free field; the systematic proof that the path integral computes vacuum expectation values of time-ordered products, and the derivation of (4.104) by Wick rotation from (4.100) ($p_E^0 = -ip^0$, $p_E^2 = -p^2 + i\epsilon$), are carried out in Chapter 10 and used in Chapter 15. The deeper point for the present section is that the Minkowski integral is the place where rigor genuinely breaks: a bounded oscillatory "measure" $e^{iS}\mathcal{D}\phi$ has infinite total variation and is not a measure at all even in finite dimensions (the integral $\int e^{iax^2}dx$ converges only conditionally, as an improper Riemann integral). The honest object is the Euclidean one of Section 4.3.2; the Minkowski formulas are its analytic continuation.

4.3.4 The rigor summary: what is a theorem and what is formal

We can now state plainly, as precision requires, the standing of the symbol $\int \mathcal{D}\phi$. There are three distinct verdicts.

(i) The Euclidean, super-renormalizable, low-dimensional case is a theorem. In low enough Euclidean dimension the double limit of Theorem 4.22 exists and defines a genuine probability measure on a space of (distributional) field configurations, with all moments finite and Euclidean-invariant. This is the achievement of *constructive quantum field theory*: the $P(\phi)_2$ theories (polynomial self-interactions of a scalar in $d = 2$) and ϕ^4_3 (the quartic scalar in $d = 3$) were constructed rigorously, the lattice (or continuum cutoff) removed, and the limiting correlation functions shown to satisfy the axioms below. In these cases "$\int \mathcal{D}\phi\, e^{-S_E}$" is not a figure of speech: it is an integral against an honest measure, and the manipulations of this chapter are theorems. The constructive machinery itself lies beyond our scope; we record it without full proof and point to the lattice formulation of Chapter 43 and to the further reading for the constructions.

(ii) The Minkowski/oscillatory integral is formal. As just discussed, $e^{iS}\mathcal{D}\phi$ is not a measure; the Lorentzian functional integral acquires meaning only through Wick rotation to case (i) and analytic continuation back. We use it freely and productively, but as a generating device for a perturbation series and as the continuation of a Euclidean object, never as an integral in the measure-theoretic sense.

(iii) The $d = 4$ interacting case is, as of the mid-2020s, formal. The physically central theories—ϕ^4 in four dimensions in particular—are not known to exist as nontrivial continuum quantum field theories. The accumulated evidence has now become a theorem: ϕ^4_4 is *trivial*, meaning that any continuum limit of the lattice theory (4.91) with $a \to 0$ forces the renormalized coupling to zero, so the only survivor is the free theory. Triviality for $d > 4$ was established by Aizenman and Fröhlich [10, 202], and the marginal physical case $d = 4$ (together with the four-dimensional critical Ising model) was settled rigorously by Aizenman and Duminil-Copin in 2021 [11]. Four-dimensional Yang–Mills with a mass gap is the subject of one of the Clay Millennium Problems and is open. For these theories the path integral is a formal perturbative definition—an asymptotic series generated by the manipulations we are developing—together with the lattice at finite a as a non-perturbative regulator; it is not (yet) a constructed measure. This is the honest status, and it is the contract Chapter 10 inherits and that the renormalization program of Part V works within.

Behind verdicts (ii)–(iii) sits a single, elementary mathematical fact that explains why the difficulty is structural rather than a failure of cleverness: there

is no infinite-dimensional analogue of Lebesgue measure. The phrase $\mathcal{D}\phi$, taken literally as "$\prod_x d\phi(x)$," would be a translation-invariant measure on an infinite-dimensional space, and no such object exists. We prove this now, in complete elementary detail, so that the reader *sees* why $\int \mathcal{D}\phi$ cannot be a measure on its own.

Theorem 4.23 (No translation-invariant Lebesgue measure in infinite dimensions)**.** *Let H be an infinite-dimensional separable Hilbert space (e.g. the L^2 space of field configurations). There is no nonzero Borel measure μ on H that is both* translation invariant*—$\mu(v+E)=\mu(E)$ for every Borel set E and every $v\in H$—and* locally finite*, in the sense of assigning finite measure to every bounded set. Equivalently, any translation-invariant Borel measure on H that is finite on some ball is identically zero.*

Proof. Suppose μ is translation invariant and locally finite; we show $\mu\equiv 0$. Since H is infinite dimensional it contains an orthonormal sequence $\{e_k\}_{k=1}^{\infty}$. Any two distinct members are at distance

$$\|e_k-e_l\|^2=\|e_k\|^2+\|e_l\|^2-2\langle e_k,e_l\rangle=1+1-0=2,\qquad k\neq l, \tag{4.105}$$

so $\|e_k-e_l\|=\sqrt{2}$. Consider the open balls $B(e_k,r)$ of radius $r=\frac{1}{2}$ centred at these points. They are pairwise disjoint: if some z lay in both $B(e_k,r)$ and $B(e_l,r)$ then by the triangle inequality $\sqrt{2}=\|e_k-e_l\|\le\|e_k-z\|+\|z-e_l\|<r+r=1<\sqrt{2}$, a contradiction. Each $B(e_k,r)$ is a translate of the fixed ball $B(0,r)$ by the vector e_k, so by translation invariance they all have the *same* measure,

$$\mu\big(B(e_k,r)\big)=\mu\big(B(0,r)\big)\equiv c,\qquad \text{for every } k. \tag{4.106}$$

Moreover every $B(e_k,r)$ is contained in the single bounded ball $B(0,1+r)$, because $\|e_k\|=1$ implies any point within r of e_k is within $1+r$ of the origin. Countable additivity over the disjoint family then gives

$$\mu\big(B(0,1+r)\big)\;\ge\;\sum_{k=1}^{\infty}\mu\big(B(e_k,r)\big)\;=\;\sum_{k=1}^{\infty}c. \tag{4.107}$$

Local finiteness says the left-hand side is finite. A sum of infinitely many copies of a fixed nonnegative number c is finite only if $c=0$. Hence $\mu(B(0,\frac{1}{2}))=c=0$, and by translation invariance *every* ball of radius $\frac{1}{2}$ has measure zero. Finally, H is separable, so it has a countable dense subset $\{x_j\}$, and the balls $\{B(x_j,\frac{1}{2})\}_j$ cover H (every point is within $\frac{1}{2}$ of some x_j). Countable subadditivity gives

$$\mu(H)\le\sum_{j=1}^{\infty}\mu\big(B(x_j,\tfrac{1}{2})\big)=\sum_{j=1}^{\infty}0=0, \tag{4.108}$$

so $\mu(H)=0$ and μ is the zero measure. □

Caution

Theorem 4.23 is the precise reason $\int \mathcal{D}\phi$ is *not* an integral against a measure $\mathcal{D}\phi$. The flat, translation-invariant "$\prod_x d\phi(x)$" one is tempted to write down cannot exist on the infinite-dimensional configuration space: it would have to assign the same value to the infinitely many disjoint unit balls packed into a bounded region, and no nonzero locally finite measure can do that. What *does* exist on such spaces is the *Gaussian measure*—the rigorous object underlying (4.102)—which is not translation invariant: shifting a configuration changes its Gaussian weight, and that weight (the $e^{-\frac{1}{2}\phi K\phi}$ of the free action) is exactly what provides the missing decay. The interacting measure, when it exists (case (i)), is built by reweighting the Gaussian one by $e^{-S_{\text{int}}}$. So the meaningful decomposition is never "measure = flat × weight"; it is "measure = Gaussian reference measure, possibly reweighted." The symbol $\mathcal{D}\phi$ in isolation is shorthand for the lattice product (4.90) awaiting a limit, nothing more.

Notation Watch

Throughout the book the symbol $\int \mathcal{D}\phi\, e^{iS[\phi]}$ (or its Euclidean $\int \mathcal{D}\phi\, e^{-S_E[\phi]}$) is used as a complete unit. Read it as: "the $a \to 0$, $L \to \infty$ limit of the finite-dimensional integral (4.91), with renormalizations inserted, when that limit exists; and otherwise as that finite-dimensional integral at fixed regulators, generating an asymptotic perturbation series." No separate meaning is ever attached to $\mathcal{D}\phi$ by itself. This is why every later "derivation from the path integral" is legitimate: it is a manipulation valid at finite N that commutes with the limit.

4.3.5 The Euclidean route and Osterwalder–Schrader reconstruction

It is worth naming, without full proof, what a rigorous construction would have to accomplish, because it organizes the entire constructive program and clarifies the status of the perturbative manipulations that follow. The strategy of case (i)—and the only known route to a rigorous interacting QFT—is the *Euclidean route*: construct the Euclidean correlation functions (the moments of the limiting measure of Theorem 4.22), verify that they satisfy a short list of axioms, and then *reconstruct* the physical Lorentzian theory from them by analytic continuation.

Theorem 4.24 (Osterwalder–Schrader reconstruction)**.** *Suppose a family of Euclidean n-point functions $\{S_n(x_1, \dots, x_n)\}_{n\geq 0}$ satisfies (OS0) suitable temperedness/growth bounds, (OS1) Euclidean invariance under the rotations and*

translations of $\mathbb{R}^d$, (OS2) symmetry under permutations of the points, (OS3) reflection positivity*—a positivity condition under reflection in a hyperplane that is the Euclidean shadow of unitarity—and (OS4) a clustering property at large separation. Then the S_n are the analytic continuations to imaginary time of the Wightman correlation functions of a unique relativistic quantum field theory in Minkowski signature, satisfying the Wightman axioms; in particular reflection positivity (OS3) is what guarantees a Hilbert space with positive-definite inner product and a unitary time evolution.*

This is the precise sense in which the Euclidean lattice integral (4.91), if its continuum limit can be controlled, *would* make the path integral rigorous: the limit supplies the S_n, the lattice construction manifestly delivers (OS1)–(OS2) and, with a reflection-positive discretization, (OS3), and Theorem 4.24 converts them into an honest operator theory. We prove neither the reconstruction theorem nor any specific construction here—they are the province of constructive field theory and the lattice chapter, Chapter 43, and we cite them for further reading rather than reproving them—but the reader should carry away the logical shape: *Euclidean measure (rigorous in low d) $\to$ OS axioms $\to$ Lorentzian QFT*. The perturbative path integral of the rest of this Part is, in effect, an algorithm for computing the would-be S_n order by order in the coupling, valid whether or not the underlying measure has been constructed.

4.3.6 The carried toy: the one case where the path integral is an honest integral

The zero-dimensional ϕ^4 model of Theorem 4.21 is the unique member of the family that escapes every difficulty catalogued above, and that makes it the perfect place to see the rigorous-versus-formal contrast in sharp relief. In $d = 0$ there is a single spacetime point, the "field" is one real number, and the "functional integral" is one ordinary integral—there is no ultraviolet limit to take (a never appears), no infrared limit (L never appears), no infinite-dimensional space, and hence no obstruction from Theorem 4.23. The lattice count (4.82) reads $N = (L/a)^0 = 1$: the regulator is already absent.

Worked Example 4.25 (The $d = 0$ path integral converges, but its perturbation series does not)**.** We continue ϕ^4 theory from Theorem 4.21. The partition function (4.75) at zero source,

$$Z(\lambda) = \int_{-\infty}^{\infty} dx\, e^{-\frac{1}{2}x^2 - \frac{\lambda}{4!}x^4}, \tag{4.109}$$

is, for every $\lambda > 0$, an absolutely convergent integral defining a smooth (indeed real-analytic in $\lambda > 0$) function: the integrand is dominated by $e^{-x^2/2}$ for all $\lambda \geq 0$, so the integral exists and may be differentiated under the sign in λ any number of times. By the three-part verdict of Section 4.3.4 this is the whole

content of "the path integral exists rigorously" in $d = 0$: (4.109) *is* the measure $e^{-S}\,dx$ on $\mathbb{R}^1$, with no limit pending. None of cases (ii)–(iii) can arise.

Now contrast its *perturbation series*. Expanding the interaction and integrating term by term using the free moments (4.77), $\langle x^{4k}\rangle_0 = (4k-1)!!$,

$$\frac{Z(\lambda)}{Z(0)} = \Big\langle e^{-\frac{\lambda}{4!}x^4}\Big\rangle_0 = \sum_{k=0}^{\infty}\frac{1}{k!}\Big(-\frac{\lambda}{4!}\Big)^k\langle x^{4k}\rangle_0 = \sum_{k=0}^{\infty} a_k\,(-\lambda)^k, \qquad a_k = \frac{(4k-1)!!}{(4!)^k\,k!}. \tag{4.110}$$

This is the perturbative "Feynman expansion" of the toy: a_k is the sum of symmetry-weighted vacuum diagrams at order k. We show its radius of convergence is *zero*. Using $(4k+3)!! = (4k+3)(4k+1)(4k-1)!!$ for consecutive odd factors,

$$\frac{a_{k+1}}{a_k} = \frac{(4(k+1)-1)!!}{(4k-1)!!}\cdot\frac{(4!)^k\,k!}{(4!)^{k+1}\,(k+1)!} = \frac{(4k+3)(4k+1)}{4!\,(k+1)} \xrightarrow[k\to\infty]{} \infty, \tag{4.111}$$

since the numerator grows like $16k^2$ while the denominator grows like $24k$, so the ratio behaves as $\frac{2}{3}k \to \infty$. By the ratio test the series (4.110) converges only at $\lambda = 0$: its radius of convergence is 0. The terms eventually grow factorially, the universal hallmark of an *asymptotic* series.

The lesson is exactly the chapter's: the object $Z(\lambda)$ is rigorous and finite, yet the series of Feynman diagrams that "computes" it does not converge to it—it is asymptotic, faithful only as $\lambda \to 0^+$ term by term. The divergence is not a defect of the integral but of the expansion: interchanging the (convergent) x-integral with the (divergent) λ-sum is illegitimate, which one can see directly from the fact that at $\lambda < 0$ the integral (4.109) diverges outright, so no power series in λ with positive radius could represent a function analytic in a disc about $\lambda = 0$. This is the zero-dimensional shadow of the status verdicts: even where the path integral is a perfectly honest integral, its perturbative definition is only a formal (asymptotic) series. Its resummation—the recovery of $Z(\lambda)$ from the divergent coefficients a_k by Borel summation—is set up without full proof in Chapter 5, and the diagrammatic reading of the a_k as symmetry factors is completed in Chapter 15. The constructive analogues for $d \le 3$ and the lattice definition for general d are the further-reading endpoint of this thread and the business of Chapter 43.

We have now done what this section set out to do. The functional integral has been built honestly—discretize on a box, recognize the finite-dimensional Gaussian, take the continuum and infinite-volume limits—and the free generating functional (4.102) together with the propagator-as-inverse-operator (4.100) have been derived, not asserted. Its standing has been stated without evasion: a theorem in low-d Euclidean signature, a Wick-rotated formal object in Minkowski, and a perturbatively defined formal object (with the lattice as its non-perturbative

regulator) for the physical four-dimensional interacting theories, with the non-existence of a flat infinite-dimensional measure (Theorem 4.23) as the structural reason. This $Z[J]$—and the precise contract attached to it—is the object the rest of the chapter organizes; the next section takes it as given and asks how to extract from it the physically irreducible data, the connected correlators generated by $W[J] = \log Z[J]$.

4.4 Generating Functionals and Connected Correlators

The previous section handed us the generating functional $Z[J]$ and, with it, a careful accounting of which of its manipulations are theorems and which are disciplined formal limits (Section 4.3). A generating functional is a bookkeeping device: it packs an entire hierarchy of correlation functions into a single object whose functional derivatives, evaluated at vanishing source, peel the correlators off one at a time. But $Z[J]$ packs them in a redundant way. Its derivatives produce *all* correlators, including the disconnected ones that are mere products of lower correlators and carry no new dynamical information. The central discovery of this section is that the redundancy is removed in one stroke by taking a logarithm: $W[J] = \log Z[J]$ generates exactly the *connected* correlators, the irreducible data of the theory, with every disconnected piece automatically subtracted. This is the *linked-cluster* (cumulant) theorem, and we prove it in full in the rigorous finite-dimensional setting before transcribing it to fields. Along the way we identify the first derivative $\frac{\delta W[J]}{\delta J}$ as the source-dependent expectation value of the field — the *classical field* $\phi_c[J]$ — and the second derivative as the connected two-point function, i.e. the covariance. These two objects are precisely the input the Legendre transform of the next section consumes, so the present section both completes the statistical structure of $Z[J]$ and prepares its Legendre conjugate.

Throughout we work primarily in the Euclidean convention, where $Z[J] = \int \mathcal{D}\phi\, e^{-S_E[\phi]+\int J\phi}$ is a genuine (formal limit of) absolutely convergent integral and $W = \log Z$ is real; the Minkowski bookkeeping, which differs only by tracked factors of i, is recorded in Section 4.4.2. The finite-dimensional model that makes every statement a theorem is the one fixed in Section 4.2: a measure $d\mu(x) = e^{-S(x)}\, d^N x$ on $\mathbb{R}^N$ with S bounded below and growing fast enough that all moments exist.

4.4.1 Full correlators as derivatives of Z

We begin with the unnormalized generating functional of the finite-dimensional model,

$$Z[J] \;=\; \int_{\mathbb{R}^N} d^N x\; e^{-S(x)+J\cdot x}, \qquad J\cdot x = \sum_{i=1}^{N} J_i x_i, \tag{4.112}$$

which is nothing but the moment generating function of the measure $d\mu$. From the derivative dictionary established in Section 4.2 — that each $\partial/\partial J_i$ acting under the integral brings down a factor of x_i — repeated differentiation produces the moments,

$$\left.\frac{\partial^n Z[J]}{\partial J_{i_1}\cdots\partial J_{i_n}}\right|_{J=0} \;=\; \int d^N x\; x_{i_1}\cdots x_{i_n}\, e^{-S(x)} \;=\; Z[0]\,\langle x_{i_1}\cdots x_{i_n}\rangle. \tag{4.113}$$

Here the (normalized) expectation value of any function f is $\langle f\rangle \equiv Z[0]^{-1}\int f\, e^{-S}\, d^N x$. Dividing (4.113) by $Z[0]$ defines the *full* (or *complete*) n-point functions as the normalized derivatives of Z. The normalization matters: $Z[0] = \int e^{-S}$ is the partition function, and in the field theory it is the sum of all vacuum diagrams, which must be divided out for any correlator to be finite and physical. It is convenient to absorb it once and for all into a normalized functional.

Definition 4.26 (Full correlators)**.** Let $\widehat{Z}[J] \equiv Z[J]/Z[0]$, so $\widehat{Z}[0] = 1$. In the field theory, with continuous index x replacing the discrete i, the *full n-point correlation function* is

$$\begin{aligned} G^{(n)}(x_1,\ldots,x_n) \;&\equiv\; \langle\phi(x_1)\cdots\phi(x_n)\rangle \\ &=\; \frac{1}{Z[0]}\,\frac{\delta^n Z[J]}{\delta J(x_1)\cdots\delta J(x_n)}\bigg|_{J=0} \;=\; \frac{\delta^n \widehat{Z}[J]}{\delta J(x_1)\cdots\delta J(x_n)}\bigg|_{J=0}. \end{aligned} \tag{4.114}$$

The functional Taylor expansion of $\widehat{Z}[J]$ in powers of the source therefore has the full correlators as its coefficients,

$$\widehat{Z}[J] \;=\; \sum_{n=0}^{\infty}\frac{1}{n!}\int d^d x_1\cdots d^d x_n\; G^{(n)}(x_1,\ldots,x_n)\, J(x_1)\cdots J(x_n). \tag{4.115}$$

In the Euclidean field theory the bracket $\langle\cdot\rangle$ is the path-integral average; on Minkowski continuation it becomes the vacuum expectation value of a *time-ordered* product, $\langle 0|\,\mathcal{T}\,\phi(x_1)\cdots\phi(x_n)\,|0\rangle$, because the path integral builds correlators in time order automatically — a point established for the free theory in Section 4.3 and carried forward to Feynman rules in Chapter 15. The functional (4.115) is honest but wasteful: as we now show, most of the information in $G^{(n)}$ is already contained in the lower correlators.

4.4.2 The connected generating functional W

The waste is visible already in the free Gaussian theory. There Wick's theorem (Section 4.2) gives $G^{(4)}$ as a sum of three products of two-point functions; the four-point function contains *nothing* the propagator does not already contain. We want a generating functional whose derivatives strip away these factorized pieces and retain only the genuinely new, "connected" part at each order. The remarkable fact is that the operation that does this is the logarithm.

Definition 4.27 (Connected generating functional and connected correlators)**.** The *connected generating functional* is

$$W[J] \;\equiv\; \log Z[J] \qquad \text{(Euclidean)}, \tag{4.116}$$

and the *connected n-point functions* are its functional derivatives,

$$G_c^{(n)}(x_1,\dots,x_n) \;\equiv\; \left.\frac{\delta^n W[J]}{\delta J(x_1)\cdots\delta J(x_n)}\right|_{J=0}, \qquad n \geq 1. \tag{4.117}$$

Two remarks fix the conventions. First, W and $\widehat{W} \equiv \log \widehat{Z} = W - \log Z[0]$ differ only by the additive constant $\log Z[0]$, which is killed by any derivative with $n \geq 1$; the connected correlators (4.117) are therefore insensitive to the vacuum normalization, exactly as they should be. The constant $W[0] = \log Z[0]$ is itself meaningful — it is (minus) the free energy, the sum of connected vacuum diagrams — but it never contaminates the $n \geq 1$ correlators. Second, the *logarithm is the whole content*: the claim, proved in Section 4.4.3, is that the coefficients of $W[J]$ are precisely the connected parts of the coefficients of log-free $Z[J]$.

Notation Watch

Minkowski factors of i. In Minkowski signature the generating functional carries the phase e^{iS}, $Z[J] = \int \mathcal{D}\phi\, e^{i(S[\phi]+\int J\phi)}$, and the standard definition is

$$W[J] \;\equiv\; -\,i \log Z[J]. \tag{4.118}$$

Each $\delta/\delta J(x)$ now brings down $i\phi(x)$, so the full correlator carries $G^{(n)} = (-i)^n Z[0]^{-1}\delta^n Z/\delta J^n|_0$ and, after the same algebra as below, the connected correlator is $G_c^{(n)} = (-i)^{\,n-1}\,\delta^n W/\delta J(x_1)\cdots\delta J(x_n)\big|_0$. The single residual factor $(-i)^{n-1}$ is bookkeeping; the combinatorial statement of this section — which W generates which graphs — is identical in both signatures. We use $W = \log Z$ (Euclidean) for every proof and translate at the end.

Before proving the theorem we extract its two lowest consequences, which are the connections this section is responsible for. Differentiating $W = \log Z$ once,

$$\frac{\delta W[J]}{\delta J(x)} \;=\; \frac{1}{Z[J]}\,\frac{\delta Z[J]}{\delta J(x)} \;=\; \frac{\int \mathcal{D}\phi\;\phi(x)\,e^{-S+\int J\phi}}{\int \mathcal{D}\phi\; e^{-S+\int J\phi}} \;=\; \big\langle \phi(x) \big\rangle_J \;\equiv\; \phi_c(x;J). \tag{4.119}$$

The first derivative of W is the expectation value of the field *in the presence of the source* — the source-dependent mean, which we name the *classical field* $\phi_c[J]$. At $J = 0$ it is the genuine one-point function (the vacuum condensate), which vanishes in a $\mathbb{Z}_2$-symmetric vacuum but need not in general. Differentiating once

more,

$$\frac{\delta^2 W[J]}{\delta J(x)\,\delta J(y)} = \frac{\delta}{\delta J(y)}\left[\frac{1}{Z}\frac{\delta Z}{\delta J(x)}\right] = \frac{1}{Z}\frac{\delta^2 Z}{\delta J(x)\,\delta J(y)} - \frac{1}{Z^2}\frac{\delta Z}{\delta J(x)}\frac{\delta Z}{\delta J(y)}$$
$$= \big\langle \phi(x)\phi(y)\big\rangle_J - \big\langle \phi(x)\big\rangle_J \big\langle \phi(y)\big\rangle_J . \tag{4.120}$$

The second derivative of W is the *covariance* of the field — the connected two-point function at arbitrary source. At $J = 0$,

$$G_c^{(2)}(x,y) \;=\; \langle \phi(x)\phi(y)\rangle - \langle \phi(x)\rangle\langle \phi(y)\rangle, \tag{4.121}$$

which in a symmetric vacuum ($\langle\phi\rangle = 0$) is just the full propagator. This is the bridge to the free theory: at $\lambda = 0$ the bracket is Gaussian and (4.121) reduces to the Feynman propagator $D_F(x-y)$ of Chapters 9 and 10. The connected two-point function *is* the propagator, dressed by interactions; the logarithm has already subtracted the disconnected $\langle\phi\rangle\langle\phi\rangle$ piece in (4.120).

4.4.3 The linked-cluster theorem

We now prove, in the finite-dimensional setting where it is a theorem and not a formal manipulation, that the derivatives of $W = \log Z$ are exactly the connected parts of the derivatives of Z. The statement is purely combinatorial: it is the moment-cumulant relation of probability theory, and its diagrammatic shadow is the statement that "log of all diagrams = connected diagrams."

To state it cleanly, fix a finite index set and let $S = \{i_1, \dots, i_n\}$ label the external legs (repetitions allowed; the i_a need not be distinct). For a subset $B \subseteq S$ write $\partial_B \equiv \prod_{i\in B} \partial/\partial J_i$, and for a partition π of S into nonempty disjoint blocks B write $|\pi|$ for the number of blocks. Define the connected correlator over a block by $\langle x_B\rangle_c \equiv \partial_B W\big|_{J=0}$.

Theorem 4.28 (Linked-cluster / cumulant theorem)**.** *With $Z[J] = \int e^{-S(x)+J\cdot x} d^N x$ and $W[J] = \log Z[J]$, for every finite multiset S of indices,*

$$\partial_S Z \;=\; Z \sum_{\pi \vdash S} \prod_{B\in\pi} \partial_B W, \tag{4.122}$$

where the sum runs over all set partitions π of S. Consequently, dividing by $Z[0]$ and setting $J = 0$, the full correlators are sums over partitions of products of connected correlators,

$$\big\langle x_{i_1}\cdots x_{i_n}\big\rangle \;=\; \sum_{\pi\vdash\{i_1,\dots,i_n\}} \prod_{B\in\pi} \big\langle x_B\big\rangle_c . \tag{4.123}$$

Proof. We prove (4.122) by induction on $|S|$; (4.123) then follows by setting $J = 0$, dividing by $Z[0] = Z|_{J=0}$, and using $\partial_S Z|_0 / Z[0] = \langle x_S\rangle$ from (4.113) and $\partial_B W|_0 = \langle x_B\rangle_c$ from (4.117).

Base case. For $S = \{i\}$ there is a single partition, the one block $\{i\}$, and the definition $W = \log Z$ gives $\partial_i Z = (\partial_i \log Z)\, Z = Z\, \partial_i W$, which is (4.122).

Inductive step. Assume (4.122) for a set S, and adjoin a new index $j \notin S$. Apply ∂_j to both sides and use the product rule on the right, together with $\partial_j Z = (\partial_j W) Z$:

$$\begin{aligned}
\partial_j \partial_S Z &= \partial_j \left(Z \sum_{\pi \vdash S} \prod_{B \in \pi} \partial_B W \right) \\
&= (\partial_j Z) \sum_{\pi \vdash S} \prod_{B \in \pi} \partial_B W \;+\; Z \sum_{\pi \vdash S} \partial_j \left(\prod_{B \in \pi} \partial_B W \right) \\
&= Z\, (\partial_j W) \sum_{\pi \vdash S} \prod_{B \in \pi} \partial_B W \;+\; Z \sum_{\pi \vdash S} \sum_{B \in \pi} \left(\partial_{B \cup \{j\}} W \right) \prod_{B' \in \pi,\, B' \neq B} \partial_{B'} W .
\end{aligned} \tag{4.124}$$

Read the two terms as a sum over partitions of $S \cup \{j\}$. In the first term, the factor $\partial_j W$ adjoins the *singleton* block $\{j\}$ to a partition π of S; this generates exactly those partitions of $S \cup \{j\}$ in which j sits alone. In the second term, the operator ∂_j has merged j into one existing block B, turning $\partial_B W$ into $\partial_{B \cup \{j\}} W$; ranging over $\pi \vdash S$ and over the blocks $B \in \pi$ generates exactly those partitions of $S \cup \{j\}$ in which j joins a nonsingleton placement, i.e. shares its block with at least one element of S. Every partition π' of $S \cup \{j\}$ falls into precisely one of these two cases — either $\{j\} \in \pi'$ or not — and is produced exactly once. Hence

$$\partial_j \partial_S Z \;=\; Z \sum_{\pi' \vdash S \cup \{j\}} \prod_{B \in \pi'} \partial_B W, \tag{4.125}$$

which is (4.122) for $S \cup \{j\}$. This closes the induction. □

Theorem 4.28 is the rigorous core. It says that the full correlators are recovered from the connected ones by summing over all ways of partitioning the external legs into connected clusters — each cluster a connected correlator, the partition encoding how the legs group. Equivalently, inverting the relation (done explicitly in Section 4.4.4), the connected correlator $G_c^{(n)}$ is the full $G^{(n)}$ with all partitioned products of lower correlators subtracted off. The logarithm performs this subtraction to all orders at once.

Physical Insight

The content of Theorem 4.28 is the exponential formula: a structure built from labelled pieces, in which a configuration is an arbitrary disjoint collection of "connected" pieces, has a generating function that is the exponential of the generating function of the connected pieces alone. Here the configuration is a correlator, the connected pieces are the $\langle x_B \rangle_c$, and

$Z = e^W$ is precisely the exponential. The same identity appears as the cumulant expansion in statistics (where W is the cumulant generating function), as the cluster expansion in statistical mechanics (where W is the free energy and the connected pieces are clusters), and — in the next subsection — as the diagrammatic statement that the logarithm of the sum of all Feynman diagrams is the sum of the connected ones.

Diagrammatic restatement. In perturbation theory each correlator is a sum of Feynman diagrams with external legs at $x_1, \dots, x_n$, vertices from the interaction, and propagators from the free covariance (the rules are derived in Chapter 15; we anticipate only their gross structure). A general diagram need not be connected: it decomposes uniquely into connected components. Summing over all diagrams contributing to $Z[J]$ is the same as summing over all ways of choosing a multiset of connected diagrams and juxtaposing them. If $\mathcal{C}$ denotes the sum of all distinct connected diagrams (each weighted by its symmetry factor), then a configuration containing k copies of connected pieces is counted with a $1/k!$ for the interchange of identical copies, and summing k from 0 to ∞ assembles the exponential series,

$$\begin{aligned} Z[J] \;&=\; \sum_{k=0}^{\infty} \frac{1}{k!}\, \mathcal{C}^{\,k} \;=\; e^{\mathcal{C}}, \\ \Longrightarrow \qquad W[J] \;&=\; \log Z[J] \;=\; \mathcal{C} \;=\; (\text{sum of connected diagrams}). \end{aligned} \tag{4.126}$$

This is the same statement as (4.122), now read on graphs: a partition of the external legs into blocks is the decomposition of a diagram into its connected components. In particular the disconnected vacuum diagrams that plague $Z[0]$ exponentiate into $W[0] = \log Z[0]$ and cancel out of every $n \geq 1$ connected correlator — the diagrammatic face of the normalization remark after Theorem 4.27. The finer field-theoretic taxonomy (connected vs. *amputated* vs. *one-particle irreducible*) and the precise symmetry-factor accounting belong to Chapter 15; here we have established the first and most basic layer, connectedness, and proved it cleanly in the finite-dimensional model.

4.4.4 Low-order connected–full relations

We now make (4.123) explicit at low order and invert it, both to exhibit the combinatorics concretely and because the $n = 2$ and $n = 4$ relations are quoted constantly later. Write $\langle \cdots \rangle$ for full correlators and $\langle \cdots \rangle_c$ for connected ones, and label external points by their indices. The partitions of an n-element set number the Bell numbers $B_n = 1, 1, 2, 5, 15, \dots$, and each partition contributes one product term.

For $n = 1$ there is one partition, so moment and cumulant coincide:

$$\langle x_1 \rangle \;=\; \langle x_1 \rangle_c . \tag{4.127}$$

For $n = 2$ the two partitions $\{12\}$ and $\{1\}\{2\}$ give

$$\langle x_1 x_2 \rangle \;=\; \langle x_1 x_2 \rangle_c \;+\; \langle x_1 \rangle_c \langle x_2 \rangle_c , \tag{4.128}$$

which inverts immediately (using (4.127)) to the connected two-point function as the covariance,

$$\boxed{\langle x_1 x_2 \rangle_c \;=\; \langle x_1 x_2 \rangle - \langle x_1 \rangle \langle x_2 \rangle} \tag{4.129}$$

in agreement with the direct computation (4.121). For $n = 3$ the $B_3 = 5$ partitions ($\{123\}$; three of type $\{ij\}\{k\}$; and $\{1\}\{2\}\{3\}$) give

$$\langle x_1 x_2 x_3 \rangle = \langle x_1 x_2 x_3 \rangle_c + \big[\langle x_1 x_2 \rangle_c \langle x_3 \rangle_c + 2 \text{ perms} \big] + \langle x_1 \rangle_c \langle x_2 \rangle_c \langle x_3 \rangle_c , \tag{4.130}$$

the bracket denoting the sum over the three ways to choose the singleton.

The case $n = 4$ is the one that recurs throughout perturbation theory, so we carry it in full. The $B_4 = 15$ partitions of $\{1, 2, 3, 4\}$ fall into five types: one block of four (1 partition); a block of three and a singleton (4 partitions, one for each choice of singleton); two blocks of two (3 partitions); a block of two and two singletons (6 partitions); and four singletons (1 partition). Summing one product per partition,

$$\begin{aligned} \langle x_1 x_2 x_3 x_4 \rangle = {} & \langle x_1 x_2 x_3 x_4 \rangle_c \\ & + \big[\langle x_1 x_2 x_3 \rangle_c \langle x_4 \rangle_c + 3 \text{ perms} \big] \\ & + \big[\langle x_1 x_2 \rangle_c \langle x_3 x_4 \rangle_c + \langle x_1 x_3 \rangle_c \langle x_2 x_4 \rangle_c + \langle x_1 x_4 \rangle_c \langle x_2 x_3 \rangle_c \big] \\ & + \big[\langle x_1 x_2 \rangle_c \langle x_3 \rangle_c \langle x_4 \rangle_c + 5 \text{ perms} \big] + \langle x_1 \rangle_c \langle x_2 \rangle_c \langle x_3 \rangle_c \langle x_4 \rangle_c . \end{aligned} \tag{4.131}$$

The five term-types use $1 + 4 + 3 + 6 + 1 = 15$ partitions, as required. To obtain the connected four-point function we solve (4.131) for $\langle x_1 x_2 x_3 x_4 \rangle_c$. In the physically central case of a symmetric vacuum, all one-point functions vanish, $\langle x_i \rangle = \langle x_i \rangle_c = 0$, which kills every term containing a singleton cumulant; by (4.129) the surviving two-point cumulants equal the full two-point functions. What remains is the clean relation

$$\boxed{\langle x_1 x_2 x_3 x_4 \rangle_c = \langle x_1 x_2 x_3 x_4 \rangle - \langle x_1 x_2 \rangle \langle x_3 x_4 \rangle - \langle x_1 x_3 \rangle \langle x_2 x_4 \rangle - \langle x_1 x_4 \rangle \langle x_2 x_3 \rangle} \tag{4.132}$$

The three subtracted products are exactly the three disconnected pairings of the four legs — the Wick contractions that the free theory produces and that carry no interaction information. The connected four-point function is what is left after removing them, and at leading order in $\lambda\phi^4$ it is the single connected "X" graph joining all four legs at one vertex. Figure 4.4 draws the decomposition. For a generic (non-symmetric) vacuum one simply retains the singleton terms; the inversion is mechanical, and we have written it once at $n = 2$ and $n = 4$ to display the pattern.

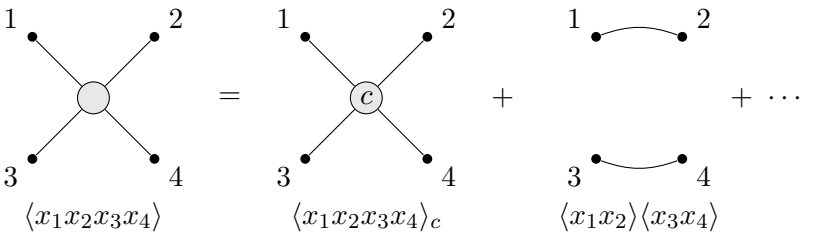

Figure 4.4: The full four-point function as connected part plus disconnected pairings, (4.132) (symmetric vacuum). The connected blob c is the new information at fourth order; the three disconnected pairings $\langle x_1x_2\rangle\langle x_3x_4\rangle$, $\langle x_1x_3\rangle\langle x_2x_4\rangle$, $\langle x_1x_4\rangle\langle x_2x_3\rangle$ are the Wick products already fixed by the two-point function. Taking $W = \log Z$ removes the latter automatically.

4.4.5 The classical field and the bridge to the Legendre transform

We return to the first derivative (4.119) and develop it into the object the next section needs. The classical field

$$\phi_c(x;J) \;=\; \frac{\delta W[J]}{\delta J(x)} \;=\; \langle\phi(x)\rangle_J \tag{4.133}$$

is the expectation value of $\phi(x)$ computed in the source-tilted measure $\propto e^{-S+\int J\phi}$. It is not the operator field and not, in general, a solution of the classical equation of motion; it is the quantum-averaged field profile that the source J sustains. The terminology "classical" is justified in the next section, where ϕ_c turns out to extremize the effective action $\Gamma[\phi_c]$ in exactly the way the true classical field extremizes S. The verification that $\phi_c = \langle\phi\rangle_J$ was already given in (4.119); the point to record is that ϕ_c is a functional of J, and that this functional is invertible precisely when the map is monotone — which is governed by the second derivative.

That second derivative we computed in (4.120): at arbitrary source,

$$\frac{\delta\phi_c(x;J)}{\delta J(y)} = \frac{\delta^2 W[J]}{\delta J(x)\,\delta J(y)} = \langle\phi(x)\phi(y)\rangle_J - \langle\phi(x)\rangle_J\langle\phi(y)\rangle_J \;\equiv\; G_c^{(2)}(x,y;J). \tag{4.134}$$

Two facts follow that are the entire input to the Legendre transform. First, the right-hand side is a covariance, hence (in the Euclidean theory) a positive semi-definite kernel: for any test function f,

$$\int f(x)\,G_c^{(2)}(x,y;J)\,f(y) = \big\langle\big(\textstyle\int f\,\phi - \langle\int f\,\phi\rangle_J\big)^2\big\rangle_J \;\geq\; 0. \tag{4.135}$$

Thus $W[J]$ is a convex functional of J — its Hessian $\delta^2 W/\delta J\,\delta J$ is positive semi-definite — which is exactly the property the Legendre transform requires for

its conjugate to be well defined and the transform to be an involution. Second, (4.134) identifies the Hessian of W as the Jacobian of the map $J \mapsto \phi_c$. When this Jacobian is invertible the map can be inverted to give $J = J[\phi_c]$, and its inverse kernel — the functional inverse of $G_c^{(2)}$ — will turn out to be the second derivative of the effective action. The relation between Γ'' and W'' as mutual inverses, $\int \Gamma'' W'' = \mathbf{1}$, is the technical heart of the next section; the present section has supplied its two ingredients, the conjugate variable $\phi_c = \delta W/\delta J$ and the positive-definite covariance $\delta^2 W/\delta J\,\delta J = G_c^{(2)}$.

Worked Example 4.29 (Connected correlators of the zero-dimensional ϕ^4 model)**.** We advance the carried zero-dimensional ϕ^4 toy of Section 4.2 — the $N = 1$ instance of (4.112) — by computing $W(J) = \log Z(J)$ to first order in the coupling and reading off its connected correlators, watching the disconnected pieces drop out. With $m^2 = 1$ for arithmetic cleanliness (so the free covariance, the propagator, equals 1) the model is

$$Z(J) \;=\; \int_{-\infty}^{\infty} dx\; \exp\Big(-\tfrac{1}{2}x^2 - \tfrac{\lambda}{4!}\,x^4 + Jx \Big), \qquad \lambda > 0. \tag{4.136}$$

This is an ordinary, absolutely convergent integral — a genuine 0-dimensional "field theory" — so every step is rigorous and the linked-cluster theorem (Theorem 4.28) applies verbatim with the single index dropped.

Source trick. Pull the quartic out of the integral by replacing $x \to \partial_J$ acting on the free generating function. With $Z_0(J) = \int dx\, e^{-x^2/2 + Jx} = \sqrt{2\pi}\, e^{J^2/2}$,

$$Z(J) = e^{-\frac{\lambda}{4!}\partial_J^4} Z_0(J) = \sqrt{2\pi}\, e^{J^2/2}\Big[1 - \tfrac{\lambda}{4!}\, e^{-J^2/2}\, \partial_J^4\, e^{J^2/2} + O(\lambda^2)\Big]. \tag{4.137}$$

We need $\partial_J^4 e^{J^2/2}$. Differentiating $f = e^{J^2/2}$ repeatedly, $\partial_J f = Jf$, $\partial_J^2 f = (1 + J^2)f$, $\partial_J^3 f = (3J + J^3)f$, and

$$\partial_J^4 e^{J^2/2} = (3 + 6J^2 + J^4)\, e^{J^2/2} \;\Longrightarrow\; e^{-J^2/2}\partial_J^4 e^{J^2/2} = J^4 + 6J^2 + 3. \tag{4.138}$$

Therefore, to first order in λ,

$$Z(J) = \sqrt{2\pi}\, e^{J^2/2}\Big[1 - \tfrac{\lambda}{24}(J^4 + 6J^2 + 3) + O(\lambda^2)\Big]. \tag{4.139}$$

Take the logarithm. Using $\log(1 - u) = -u + O(u^2)$ with $u = O(\lambda)$,

$$W(J) = \log Z(J) = \underbrace{\log\sqrt{2\pi}}_{\text{const}} + \tfrac{1}{2}J^2 - \tfrac{\lambda}{24}(J^4 + 6J^2 + 3) + O(\lambda^2). \tag{4.140}$$

The logarithm has linearized what was a ratio: there is no longer any denominator $Z(0) = \sqrt{2\pi}\,(1 - \lambda/8 + \cdots)$ to expand, because log converted the division by $Z(0)$ into the subtraction of the constant $W(0) = \log\sqrt{2\pi} - \lambda/8 + \cdots$. This is the cancellation of disconnected vacuum pieces in action.

Read off the connected correlators as derivatives of W at $J=0$, per (4.117). The model is $\mathbb{Z}_2$-symmetric, so odd derivatives vanish; the nonzero ones through $O(\lambda)$ are

$$\langle x^2\rangle_c = W''(0) = \frac{d^2}{dJ^2}\Big[\tfrac{1}{2}J^2 - \tfrac{\lambda}{24}\cdot 6J^2\Big]_{J=0} = 1 - \frac{\lambda}{2} + O(\lambda^2), \tag{4.141}$$

$$\langle x^4\rangle_c = W^{(4)}(0) = -\frac{\lambda}{24}\frac{d^4}{dJ^4}J^4\Big|_{J=0} = -\frac{\lambda}{24}\cdot 24 = -\lambda + O(\lambda^2). \tag{4.142}$$

The connected two-point function is the propagator 1 corrected at one loop by $-\lambda/2$; the connected four-point function is, at leading order, simply $-\lambda$ — the bare vertex (the 0-dimensional avatar of the $-i\lambda$ that ϕ^4 theory meets in Chapter 15). Nothing disconnected appears in W by construction.

Cross-check against the full correlators and the inversion (4.132). Compute the full moments directly from (4.136), normalizing by $Z(0)$ and using the Gaussian moments $\langle x^2\rangle_0 = 1$, $\langle x^4\rangle_0 = 3$, $\langle x^6\rangle_0 = 15$, $\langle x^8\rangle_0 = 105$. With $Z(0)/\sqrt{2\pi} = 1 - \frac{\lambda}{24}\cdot 3 = 1 - \lambda/8$,

$$\langle x^2\rangle = \frac{\langle x^2\rangle_0 - \frac{\lambda}{24}\langle x^6\rangle_0}{1-\lambda/8} = \frac{1-\frac{15\lambda}{24}}{1-\lambda/8} = \Big(1-\tfrac{15\lambda}{24}\Big)\Big(1+\tfrac{\lambda}{8}\Big) + O(\lambda^2) = 1 - \frac{\lambda}{2} + O(\lambda^2), \tag{4.143}$$

$$\langle x^4\rangle = \frac{\langle x^4\rangle_0 - \frac{\lambda}{24}\langle x^8\rangle_0}{1-\lambda/8} = \frac{3-\frac{105\lambda}{24}}{1-\lambda/8} = \Big(3-\tfrac{105\lambda}{24}\Big)\Big(1+\tfrac{\lambda}{8}\Big) + O(\lambda^2) = 3 - 4\lambda + O(\lambda^2). \tag{4.144}$$

The full two-point function agrees with the connected one, (4.141), because $\langle x\rangle = 0$. For the four-point function the inversion (4.132) with all points equal reads $\langle x^4\rangle_c = \langle x^4\rangle - 3\langle x^2\rangle^2$, and indeed

$$\langle x^4\rangle - 3\langle x^2\rangle^2 = (3-4\lambda) - 3\Big(1-\tfrac{\lambda}{2}\Big)^2 = (3-4\lambda) - 3(1-\lambda) + O(\lambda^2) = -\lambda + O(\lambda^2), \tag{4.145}$$

exactly $W^{(4)}(0)$ from (4.142). The arithmetic displays the combinatorics of Fig. 4.4 concretely: the full $\langle x^4\rangle = 3 - 4\lambda$ splits into the connected vertex $-\lambda$ and the three disconnected pairings $3\langle x^2\rangle^2 = 3 - 3\lambda$, the "3" being the three Wick contractions of the free theory and the -3λ their propagator corrections. The logarithm subtracts the whole $3-3\lambda$ in one operation, leaving the connected $-\lambda$. This is the linked-cluster theorem made completely explicit in the simplest model that has any interactions at all.

Handoff

We have organized $Z[J]$ into its irreducible content: $W[J] = \log Z[J]$ (or $-i\log Z$ in Minkowski) generates exactly the connected correlators, a fact proved as

the linked-cluster theorem (4.123) and made explicit through the $n = 2$ and $n = 4$ relations and the zero-dimensional ϕ^4 computation. The two derivatives we singled out — the classical field $\phi_c[J] = \delta W/\delta J$, the source-dependent expectation value, and the connected propagator $\delta^2 W/\delta J\,\delta J = G_c^{(2)}$, a positive-definite covariance making W convex — are precisely the data a Legendre transform consumes. The next section trades the independent variable J for its conjugate ϕ_c and builds the effective action $\Gamma[\phi_c]$, whose second derivative we will prove is the functional inverse of $G_c^{(2)}$.

4.5 The Legendre Transform and the Effective Action

The previous section handed us three objects and one promise. The objects are the connected generating functional $W[J] = \log Z[J]$ (Theorem 4.27), its first derivative the *classical field*

$$\phi_c(x;J) \;=\; \frac{\delta W[J]}{\delta J(x)} \;=\; \langle \phi(x) \rangle_J, \tag{4.146}$$

and its second derivative, the connected two-point function at arbitrary source,

$$\frac{\delta \phi_c(x;J)}{\delta J(y)} = \frac{\delta^2 W[J]}{\delta J(x)\,\delta J(y)} = G_c^{(2)}(x,y;J), \tag{4.147}$$

a positive semi-definite covariance (Eqs. (4.134) and (4.135)). The promise, recorded at the end of Section 4.4.5, is that the inverse of this covariance is the second derivative of a new functional — the *effective action* $\Gamma[\phi_c]$ — obtained from $W[J]$ by trading the source J for its conjugate variable ϕ_c. That trade is the Legendre transform. It is the same operation that, in classical mechanics, passes from the Lagrangian $L(q,\dot q)$ to the Hamiltonian $H(q,p)$ by trading $\dot q$ for $p = \partial L/\partial \dot q$, and in thermodynamics passes from the energy to the free energies by trading extensive for intensive variables. Here it trades the external source for the field it sustains, and the functional it produces is the central object of the chapter: $\Gamma[\phi_c]$ is the quantum-corrected action whose stationary points are the true field configurations of the interacting theory, whose Hessian is the full inverse propagator, and whose higher derivatives are the one-particle-irreducible vertices from which every connected amplitude is assembled as a tree. We build it in four steps: the Legendre transform reviewed rigorously in finite dimensions; the definition of Γ and the conjugate relation $\delta\Gamma/\delta\phi_c = J$; the reciprocity identity $\Gamma'' W'' = \mathbf{1}$ and its consequence that Γ generates the one-particle-irreducible (1PI) vertices; and the tree-level identity $\Gamma = S$ that names Γ "the effective action."

4.5.1 The Legendre transform of a convex function

We first establish the transform where it is a theorem of ordinary calculus: on $\mathbb{R}^N$, for the smooth strictly convex functions to which the finite-dimensional

W of Theorem 4.28 belongs. The functional statements we need follow by the dictionary "index $i \to$ spacetime point x, sum $\to$ integral" that has organized the whole chapter; we make the transcription explicit at the end. Throughout, a function $f\colon \mathbb{R}^N \to \mathbb{R}$ is *convex* if its Hessian $f''_{ij} = \partial^2 f/\partial J_i \partial J_j$ is positive semi-definite everywhere, and *strictly convex* if f'' is positive definite; the latter is the case for W, whose Hessian (4.147) is the covariance of a non-degenerate distribution and hence strictly positive (Eq. (4.135)).

Definition 4.30 (Legendre transform)**.** Let $f\colon \mathbb{R}^N \to \mathbb{R}$ be convex. Its *Legendre transform* (or *convex conjugate*) is the function $f^\star\colon \mathbb{R}^N \to \mathbb{R} \cup \{+\infty\}$

$$f^\star(\xi) \;\equiv\; \sup_{J \in \mathbb{R}^N} \Big(\xi \cdot J - f(J) \Big), \qquad \xi \cdot J = \sum_{i=1}^{N} \xi_i J_i. \tag{4.148}$$

The variable ξ is *conjugate* to J.

The geometric content of (4.148) is worth stating before the algebra, because it makes every subsequent property obvious. Fix the slope ξ and slide the hyperplane $J \mapsto \xi \cdot J - c$ of that slope downward (increasing c) until it last touches the graph of f from below; the value of c at that contact is $f^\star(\xi)$. The transform thus records, for each slope ξ, how far below the origin the supporting hyperplane of that slope sits (Fig. 4.5). Because f is convex its graph lies above all its tangents, so for a smooth f the supremum is attained where the tangent plane has slope ξ, i.e. where $\nabla f(J) = \xi$. This single picture contains the conjugate relations, Fenchel's inequality, and the involution; we now extract them.

Theorem 4.31 (Conjugate relations, Fenchel–Young, and involution)**.** *Let $f \in C^2(\mathbb{R}^N)$ be strictly convex with ∇f a bijection of $\mathbb{R}^N$ onto its image. Then:*

(i) (Fenchel–Young inequality.) *For all J, ξ,*

$$f(J) + f^\star(\xi) \;\geq\; \xi \cdot J, \tag{4.149}$$

with equality if and only if $\xi = \nabla f(J)$.

(ii) (Conjugate variables.) *The supremum in (4.148) is attained at the unique $J = J^\star(\xi)$ solving $\nabla f(J) = \xi$, and there*

$$f^\star(\xi) = \xi \cdot J^\star(\xi) - f\big(J^\star(\xi)\big), \qquad \nabla f^\star(\xi) = J^\star(\xi). \tag{4.150}$$

Thus $\xi = \nabla f(J) \iff J = \nabla f^\star(\xi)$: the gradient maps of f and $f^\star$ are mutual inverses.

(iii) (Convexity of the conjugate and involution.) *$f^\star$ is convex, and $f^{\star\star} = f$.*

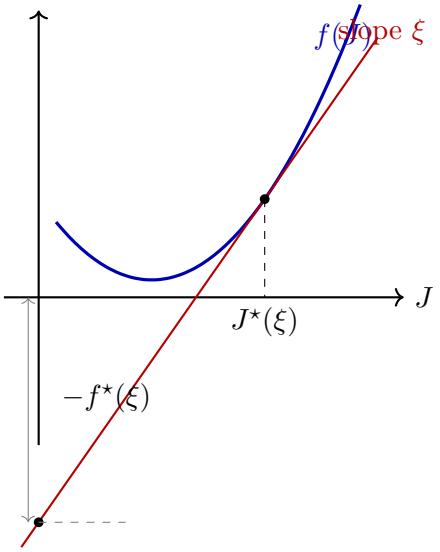

Figure 4.5: The Legendre transform geometrically. For a fixed slope ξ the supporting line $J \mapsto \xi J - c$ touches the convex graph of f from below at the point $J^\star(\xi)$ where $f' = \xi$; its intercept with the vertical axis is $-f^\star(\xi)$. As ξ ranges over all slopes the family of supporting lines reconstructs f from below, which is the geometric statement of the involution $f^{\star\star} = f$.

Proof. (i). Fix J, ξ. By definition $f^\star(\xi) \geq \xi \cdot J' - f(J')$ for every J'; taking $J' = J$ gives $f^\star(\xi) \geq \xi \cdot J - f(J)$, which is (4.149). Equality holds iff J itself realizes the supremum.

(ii). The objective $g_\xi(J) \equiv \xi \cdot J - f(J)$ has gradient $\nabla g_\xi = \xi - \nabla f(J)$ and Hessian $-f''(J) \prec 0$ (negative definite, since f is strictly convex). A function with everywhere negative-definite Hessian is strictly concave, so any critical point is the unique global maximum. The critical-point equation $\nabla g_\xi = 0$ reads $\nabla f(J) = \xi$, which by hypothesis has the unique solution $J^\star(\xi)$. Hence the supremum is attained there and equals $\xi \cdot J^\star(\xi) - f(J^\star(\xi))$, the first equation of (4.150). For the gradient of $f^\star$, differentiate this expression in ξ, treating $J^\star = J^\star(\xi)$ as a function of ξ and using the chain rule:

$$\frac{\partial f^\star}{\partial \xi_i} = J_i^\star + \sum_j \xi_j \frac{\partial J_j^\star}{\partial \xi_i} - \sum_j \frac{\partial f}{\partial J_j}\Big|_{J^\star} \frac{\partial J_j^\star}{\partial \xi_i}. \tag{4.151}$$

At $J^\star$ one has $\partial f / \partial J_j = \xi_j$, so the last two sums cancel term by term, leaving $\partial f^\star / \partial \xi_i = J_i^\star$, i.e. $\nabla f^\star(\xi) = J^\star(\xi)$. This is the second equation of (4.150). The cancellation in (4.151) is the engine of the whole construction; it is the reason a Legendre transform of a function of J is a clean function of ξ alone, with no leftover dependence on the stationary point $J^\star(\xi)$. It is the envelope theorem: the derivative of an optimized objective with respect to a parameter is the partial

derivative of the objective, the implicit variation of the optimizer contributing nothing because the objective is stationary there.

(iii). Convexity of $f^\star$ is immediate from (4.148): for each fixed J the map $\xi \mapsto \xi \cdot J - f(J)$ is affine (hence convex), and a pointwise supremum of convex functions is convex. For the involution, apply (4.150) to $f^\star$ in place of f. By (ii), $\nabla f^\star$ is the inverse map of ∇f; in particular it is a bijection, so $f^{\star\star}$ is defined and, by the conjugate relation read backwards,

$$f^{\star\star}(J) = \sup_{\xi} \big(J \cdot \xi - f^\star(\xi) \big) = J \cdot \xi^\star(J) - f^\star(\xi^\star(J)), \tag{4.152}$$

where $\xi^\star(J)$ is the maximizer, characterized by $\nabla f^\star(\xi) = J$. By (ii) this last equation says $J = J^\star(\xi)$, i.e. $\xi^\star(J) = \nabla f(J)$. Substituting the value of $f^\star$ from (4.150) at $\xi = \xi^\star(J)$,

$$f^{\star\star}(J) = J \cdot \xi^\star(J) - \big[\xi^\star(J) \cdot J - f(J) \big] = f(J), \tag{4.153}$$

the cross terms cancelling identically. Hence $f^{\star\star} = f$. □

The transform is therefore an involution on smooth strictly convex functions: applied twice it returns the original. This symmetry is what makes W and Γ equal partners rather than one being primary; either determines the other, and the relation is the same in both directions. The remaining structural fact is what the transform does to second derivatives. It is the identity the previous section promised, and it is the technical heart of everything that follows.

Proposition 4.32 (Reciprocity of Hessians)**.** *Under the hypotheses of Theorem 4.31, the Hessians of f and $f^\star$ are matrix inverses of one another at conjugate points. Writing $f''(J)_{ij} = \partial^2 f / \partial J_i \partial J_j$ and $f^{\star\prime\prime}(\xi)_{ij} = \partial^2 f^\star / \partial \xi_i \partial \xi_j$, with $\xi = \nabla f(J)$,*

$$\sum_k f''(J)_{ik}\, f^{\star\prime\prime}(\xi)_{kj} \;=\; \delta_{ij}, \qquad \text{i.e.} \qquad f^{\star\prime\prime}(\xi) = \big[f''(J) \big]^{-1}. \tag{4.154}$$

Proof. We have two mutually inverse maps from Theorem 4.31(ii): the gradient $\nabla f \colon J \mapsto \xi$ and the gradient $\nabla f^\star \colon \xi \mapsto J$. Their Jacobians are exactly the Hessians:

$$\frac{\partial \xi_i}{\partial J_k} = \frac{\partial}{\partial J_k} \frac{\partial f}{\partial J_i} = f''(J)_{ik}, \qquad \frac{\partial J_k}{\partial \xi_j} = \frac{\partial}{\partial \xi_j} \frac{\partial f^\star}{\partial \xi_k} = f^{\star\prime\prime}(\xi)_{kj}. \tag{4.155}$$

Because the maps are inverse, $\xi(J(\xi)) = \xi$, so by the chain rule the product of their Jacobians is the identity:

$$\delta_{ij} = \frac{\partial \xi_i}{\partial \xi_j} = \sum_k \frac{\partial \xi_i}{\partial J_k} \frac{\partial J_k}{\partial \xi_j} = \sum_k f''(J)_{ik}\, f^{\star\prime\prime}(\xi)_{kj}. \tag{4.156}$$

This is (4.154). Equivalently, it is the inverse-function theorem applied to ∇f: the Jacobian of the inverse map is the inverse of the Jacobian. □

Three remarks transcribe these results to the functional setting and prepare the application. First, the dictionary is literal: a functional $W[J]$ of a field $J(x)$ has a "gradient" $\delta W/\delta J(x)$ and a "Hessian" $\delta^2 W/\delta J(x)\delta J(y)$, the latter a two-point kernel; (4.154) becomes the statement that two kernels are inverse in the convolution sense, $\int dz\, A(x,z)B(z,y) = \delta(x-y)$. Second, the bijectivity hypothesis on ∇f is, functionally, the invertibility of the map $J \mapsto \phi_c$, which the previous section tied to the positive-definiteness of the covariance (4.147); we assume it holds on the domain of interest, i.e. that the source uniquely determines the classical field and vice versa. Third, the strict convexity of W established in Eq. (4.135) is exactly the hypothesis of Theorem 4.31: W is a legitimate input to the Legendre transform, its conjugate is well defined, convex, and involutive, and the reciprocity (4.154) holds. We may now define the effective action.

4.5.2 The effective action and the conjugate relation

Definition 4.33 (Effective action)**.** The *effective action* is the Legendre transform of the connected generating functional with respect to the source,

$$\Gamma[\phi_c] \;\equiv\; W^\star[\phi_c] \;=\; \sup_J \Big(\int d^d x\, J(x)\,\phi_c(x) - W[J] \Big) \;=\; \int d^d x\, J(x)\,\phi_c(x) - W[J]\Big|_{J=J[\phi_c]}, \tag{4.157}$$

where $J[\phi_c]$ is the source that produces the prescribed classical field, i.e. the solution of $\phi_c(x) = \delta W/\delta J(x)$ read as an equation for J.

The defining property is the conjugate relation, which Theorem 4.31(ii) delivers directly. Differentiating (4.157) with respect to $\phi_c(y)$ and using the envelope cancellation (4.151) verbatim — now with the continuous index — the implicit variation of $J[\phi_c]$ drops out and

$$\boxed{\frac{\delta \Gamma[\phi_c]}{\delta \phi_c(x)} \;=\; J(x)\,.} \tag{4.158}$$

Let us see the cancellation once in the functional notation, since it is the relation on which the entire interpretation rests. Writing $J = J[\phi_c]$ for the stationary source,

$$\begin{aligned} \frac{\delta \Gamma}{\delta \phi_c(x)} &= J(x) + \int d^d y\, \phi_c(y)\, \frac{\delta J(y)}{\delta \phi_c(x)} - \int d^d y\, \frac{\delta W}{\delta J(y)}\, \frac{\delta J(y)}{\delta \phi_c(x)} \\ &= J(x) + \int d^d y\, \big[\phi_c(y) - \phi_c(y)\big]\, \frac{\delta J(y)}{\delta \phi_c(x)} = J(x), \end{aligned} \tag{4.159}$$

where the second line used $\delta W/\delta J(y) = \phi_c(y)$ from (4.146). The relation (4.158) is the precise sense in which Γ is dual to W: where the first derivative of W returns the field sustained by a source, the first derivative of Γ returns the source

required to sustain a field. Setting the external source to zero, $J = 0$, the physical configurations of the theory are the stationary points of the effective action,

$$\left.\frac{\delta\Gamma[\phi_c]}{\delta\phi_c(x)}\right|_{J=0} = 0, \tag{4.160}$$

the quantum-mechanical replacement for the classical equation of motion $\delta S/\delta\phi = 0$. This is why ϕ_c earned the name "classical field" in Section 4.4.5: it extremizes Γ exactly as the genuine classical field extremizes S, with Γ playing the role of an action that has absorbed all quantum fluctuations. The solution of (4.160) is the true vacuum expectation value $\langle\phi\rangle$, equation of state and all radiative corrections included.

Notation Watch: Euclidean versus Minkowski sign of the effective action

We work in Euclidean signature ($W = \log Z$, Theorem 4.27), where W is genuinely convex (4.135) and the Legendre theory of Section 4.5.1 applies as stated; this is the convention of the previous section and of the effective-potential and Wilsonian-flow chapters that consume this object (Chapters 23 and 29). In Minkowski signature the generating functional carries e^{iS} and one sets $W = -i\log Z$ (Section 4.4.2); the standard field-theory effective action is then written with the opposite overall sign,

$$\Gamma[\phi_c] = W[J] - \int d^dx\, J\,\phi_c, \qquad \frac{\delta\Gamma}{\delta\phi_c(x)} = -J(x), \tag{4.161}$$

the flip being part of the same factor-of-i bookkeeping that turned $\log Z$ into $-i\log Z$. Every structural statement below — the reciprocity, the 1PI generation, the tree-level identity — holds in both conventions; only signs and factors of i differ, and we flag them where they matter. We use the Euclidean form (4.157) for all proofs.

We can now redeem the reciprocity promise. The effective action is $W^\star$, so Theorem 4.32 applies with $f = W$, $f^\star = \Gamma$, $\xi = \phi_c$. The finite-dimensional identity (4.154) becomes, in the functional setting, an identity of two-point kernels.

Theorem 4.34 (The Hessian of Γ is the inverse propagator)**.** *At conjugate points ($\phi_c = \delta W/\delta J$), the second functional derivative of Γ is the kernel inverse of the connected two-point function,*

$$\int d^dz\, \frac{\delta^2 W[J]}{\delta J(x)\,\delta J(z)}\,\frac{\delta^2\Gamma[\phi_c]}{\delta\phi_c(z)\,\delta\phi_c(y)} = \delta^{(d)}(x-y). \tag{4.162}$$

Equivalently, with $G_c^{(2)} = \delta^2 W/\delta J\,\delta J$ the full connected propagator and $\Gamma^{(2)} \equiv$

$\delta^2\Gamma/\delta\phi_c\,\delta\phi_c$,

$$\Gamma^{(2)} = \left(G_c^{(2)}\right)^{-1}. \tag{4.163}$$

Proof. Differentiate the conjugate relation (4.158), $\delta\Gamma/\delta\phi_c(z) = J(z)$, with respect to $\phi_c(y)$, and likewise $\phi_c = \delta W/\delta J$ with respect to J. The two maps $J \mapsto \phi_c$ and $\phi_c \mapsto J$ are functional inverses, so by the chain rule, exactly as in (4.156) but with the index sum replaced by an integral over the intermediate point z,

$$\delta^{(d)}(x-y) = \frac{\delta\phi_c(x)}{\delta\phi_c(y)} = \int d^dz\, \frac{\delta\phi_c(x)}{\delta J(z)}\,\frac{\delta J(z)}{\delta\phi_c(y)} = \int d^dz\, \frac{\delta^2 W}{\delta J(x)\delta J(z)}\,\frac{\delta^2\Gamma}{\delta\phi_c(z)\delta\phi_c(y)}, \tag{4.164}$$

using (4.146) for $\delta\phi_c/\delta J = W''$ and (4.158) for $\delta J/\delta\phi_c = \Gamma''$. This is (4.162); (4.163) is the same statement in operator notation. □

Theorem 4.34 is the first concrete payoff. In a symmetric vacuum the connected two-point function $G_c^{(2)}$ *is* the full propagator of the interacting theory (Eq. (4.121)); its inverse is therefore the full inverse propagator. The theorem says that this full inverse propagator is nothing but the second derivative of Γ. At the free level we can check it against objects already in hand. For the free scalar, W is Gaussian and $G_c^{(2)}$ reduces to the Euclidean propagator $(-\partial^2 + m^2)^{-1}$ (Chapters 9 and 10); its inverse kernel is the operator $-\partial^2 + m^2$, which is exactly $\delta^2 S/\delta\phi\,\delta\phi$ for the free action. Thus at the free level $\Gamma^{(2)} = S^{(2)}$ — the second derivative of Γ equals the second derivative of the classical action. This is the $n = 2$ instance of a general fact proved below, that $\Gamma = S$ at tree level. In Minkowski signature the same computation, carried with the factors of i of (4.161) and the Feynman propagator $i/(p^2 - m^2 + i\epsilon)$, gives $\Gamma^{(2)}(p) = p^2 - m^2$, again equal to the momentum-space inverse free propagator $S^{(2)}$; the interacting $\Gamma^{(2)}(p) = p^2 - m^2 - \Pi(p^2)$ then defines the self-energy Π, the object ϕ^4 theory computes at one loop in Chapters 21 and 22.

Physical Insight

The Legendre transform exchanges "cause" and "effect." The functional $W[J]$ answers "given a source, what field response do I get, and how do connected clusters of the field correlate?" Its conjugate $\Gamma[\phi_c]$ answers the inverse question: "to hold the field at a prescribed profile ϕ_c, what source must I apply?" — and at zero source this is the equation of state of the vacuum. Because the two questions are inverse, their second derivatives are inverse kernels: the response function (propagator) and the stiffness (inverse propagator) are reciprocal, just as compliance and elastic modulus are in a material. The interacting vacuum behaves like a polarizable medium, and Γ'' measures its stiffness against being displaced.

4.5.3 Γ generates the one-particle-irreducible vertices

The reciprocity identity is the $n = 2$ member of an infinite family. Differentiating it repeatedly expresses every connected correlator $W^{(n)} = \delta^n W/\delta J^n$ in terms of the derivatives of Γ,

$$\Gamma^{(n)}(x_1, \ldots, x_n) \;\equiv\; \left.\frac{\delta^n \Gamma[\phi_c]}{\delta\phi_c(x_1)\cdots\delta\phi_c(x_n)}\right|_{\phi_c=\bar\phi}, \tag{4.165}$$

evaluated at the stationary configuration $\bar\phi$ (the solution of (4.160); $\bar\phi = 0$ in a symmetric vacuum). These $\Gamma^{(n)}$ are the *proper vertices*. The central structural theorem of this section is that they are precisely the *one-particle-irreducible* (1PI) vertices — the amputated correlation functions that cannot be disconnected by cutting a single internal line — and that the full connected correlators are reconstructed from them by summing *tree* graphs. We prove this by carrying the differentiation to fourth order, where the pattern becomes unambiguous, working in one variable (the zero-dimensional reduction) for algebraic transparency and quoting the index-carrying multivariate form alongside; the multivariate proof is identical with sums over intermediate points reinstated.

Write $W' = \phi_c$, $\Gamma' = J$ (the conjugate relations), and abbreviate $W^{(n)}$, $\Gamma^{(n)}$ for the J- and ϕ_c-derivatives respectively. The reciprocity (4.163) reads

$$W''\,\Gamma'' = 1, \qquad \text{so} \qquad W'' = \frac{1}{\Gamma''}. \tag{4.166}$$

Treat Γ'' as a function of ϕ_c and recall $d\phi_c/dJ = W''$. Differentiate (4.166) with respect to J:

$$W''' = \frac{d}{dJ}\frac{1}{\Gamma''} = -\frac{1}{(\Gamma'')^2}\,\frac{d\Gamma''}{d\phi_c}\,\frac{d\phi_c}{dJ} = -\frac{\Gamma'''}{(\Gamma'')^2}\,W'' = -\frac{\Gamma'''}{(\Gamma'')^3} = -\,(W'')^3\,\Gamma'''. \tag{4.167}$$

The connected three-point function is minus the proper three-vertex Γ''' dressed with three full propagators W'', one on each external leg. In the multivariate (functional) form, with all factors understood as kernels contracted over the suppressed intermediate points,

$$W^{(3)}_{ijk} = -\sum_{abc} W_{ia} W_{jb} W_{kc}\,\Gamma^{(3)}_{abc}. \tag{4.168}$$

Differentiate (4.167) once more, again using $d/dJ = W''\,d/d\phi_c$ on the ϕ_c-dependent factors Γ''' and Γ'':

$$\begin{aligned} W'''' &= \frac{d}{dJ}\Big[-(W'')^3\Gamma'''\Big] = -3(W'')^2\,W'''\,\Gamma''' - (W'')^3\,\frac{d\Gamma'''}{d\phi_c}\,W'' \\ &= -3(W'')^2\big[-(W'')^3\Gamma'''\big]\Gamma''' - (W'')^4\,\Gamma'''' \end{aligned}$$

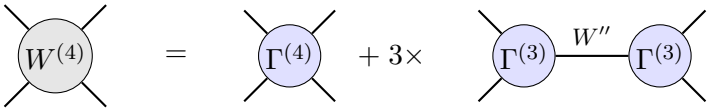

Figure 4.6: The tree expansion (4.169) of the connected four-point function. The proper vertices $\Gamma^{(n)}$ (1PI, light blobs) are joined by full propagators W'' into tree graphs; external legs also carry a W''. The single internal line in the second topology makes it one-particle-reducible, and the factor 3 is the sum over s, t, u channels. No closed loops appear: Γ generates the skeleton, and W is built from it by trees.

$$= -(W'')^4\,\Gamma'''' + 3\,(W'')^5\,(\Gamma''')^2. \tag{4.169}$$

This is the decomposition we were after. The connected four-point function is the sum of two topologically distinct contributions: a *single* proper four-vertex Γ'''' with four external propagators, and a *pair* of proper three-vertices Γ''' joined by one *internal* propagator (the fifth W'') and carrying four external propagators, the factor 3 counting the three ways of partitioning the four external legs into two pairs — the s, t, u channels. Figure 4.6 draws the two topologies. Crucially, the second graph is a *tree*: it has no closed loop, and it is one-particle-reducible (cutting the single internal W'' line disconnects it). All such reducibility in $W^{(4)}$ is exhibited explicitly, built from the irreducible pieces Γ'''. The proper vertex Γ'''' is, by contrast, what remains after every such reducible tree has been stripped: it is one-particle-irreducible by construction.

The pattern of (4.167)–(4.169) continues to all orders and is the content of the following theorem, whose inductive proof is the systematic version of the two differentiations just performed.

Theorem 4.35 (Γ generates the 1PI vertices)**.** *Each connected n-point function $W^{(n)}$ ($n \geq 3$) is the sum over all* tree *graphs whose vertices are the proper vertices $\Gamma^{(k)}$ ($3 \leq k \leq n$), whose internal and external lines are full propagators $W'' = (\Gamma'')^{-1}$, weighted by the symmetry factor of the tree and an overall sign $(-1)^{(\#\,\text{vertices})-1}$. Equivalently, the proper vertices $\Gamma^{(n)}$ are the amputated one-particle-irreducible n-point functions: those connected, amputated diagrams that remain connected after any single internal line is cut.*

Proof (induction on n). The base cases $n = 2, 3, 4$ are (4.163), (4.167), (4.169). For the inductive step, suppose $W^{(n)}$ is given by the stated tree sum. Differentiate with respect to J once more, using the operator identity

$$\frac{d}{dJ} = \sum_a \frac{\delta\phi_c(a)}{\delta J}\,\frac{\delta}{\delta\phi_c(a)} = \int W''\,\frac{\delta}{\delta\phi_c}, \tag{4.170}$$

which converts a J-derivative into a ϕ_c-derivative preceded by attachment of one full propagator W''. Acting on the tree sum for $W^{(n)}$, the new derivative either

(i) lands on one of the proper vertices $\Gamma^{(k)}$, raising it to $\Gamma^{(k+1)}$ and attaching the new external leg through the inserted W'', or (ii) lands on one of the propagator lines $W'' = (\Gamma'')^{-1}$, and since $\frac{d}{dJ}(\Gamma'')^{-1} = -(\Gamma'')^{-1}\Gamma'''(\Gamma'')^{-1}W''$ this splits the line into two propagators joined by a new proper three-vertex Γ''', again attaching the new leg through a W''. Case (i) grows an existing vertex; case (ii) inserts a new trivalent vertex onto an existing line. Both operations preserve the tree topology (no loop is ever created, since each step adds exactly one new external leg through one new propagator and either one or zero new vertices, keeping the relation $\#\text{lines} = \#\text{vertices} + \#\text{external} - 1$ that characterizes a tree), and together they generate *exactly* all trees with $n+1$ external legs from all trees with n legs, each with the correct symmetry factor and the sign incremented by one factor of -1 whenever case (ii) adds a vertex. This is the stated tree sum at order $n+1$. The irreducibility characterization follows: a graph contributing to $W^{(n)}$ that is one-particle-reducible is, by definition, cut by some internal line into two connected pieces; in the tree sum that internal line is one of the propagators W'' joining two sub-trees, so the reducible content is precisely the part of the sum with at least one internal line, leaving the single-vertex term $\Gamma^{(n)}$ (no internal line) as the irreducible remainder. □

Physical Insight

Theorem 4.35 is the organizing principle behind the entire diagrammatic expansion to come. It says the connected correlators contain no information beyond the proper vertices: W is reconstructed from Γ by drawing trees. All the genuinely new structure at each order — everything that is not just two simpler processes glued by a propagator — lives in the 1PI vertices $\Gamma^{(n)}$. This is why renormalization is organized around 1PI quantities (Chapters 21 and 22): one need only render the finitely many divergent *proper* vertices finite, and the reducible trees take care of themselves. It is also why Γ, not W, is the natural carrier of the quantum dynamics: it is the irreducible skeleton from which the flesh is hung.

4.5.4 $\Gamma = S$ at tree level and the loop expansion

We have called Γ the effective action and the quantum-corrected classical action; both names are justified by a single computation. Reinstate $\hbar$ as a bookkeeping parameter multiplying the action in the exponent — the loop-counting parameter of the next section — so that the Euclidean generating functional reads

$$Z[J] = \int \mathcal{D}\phi \, \exp\Big[-\tfrac{1}{\hbar}\big(S[\phi] - \textstyle\int J\phi\big)\Big], \qquad W[J] = \hbar \log Z[J]. \tag{4.171}$$

The normalization $W = \hbar \log Z$ keeps $\phi_c = \delta W/\delta J = \langle\phi\rangle_J$ finite as $\hbar \to 0$. In that limit the integral (4.171) is dominated by its saddle point, the configuration

ϕ_J extremizing the exponent,

$$\left.\frac{\delta S}{\delta \phi}\right|_{\phi_J} = J, \tag{4.172}$$

which is the classical equation of motion in the presence of the source. The leading-order Laplace evaluation (Section 4.2; the systematic asymptotic expansion is the business of Section 4.6) gives

$$W[J] = -\big(S[\phi_J] - \textstyle\int J\phi_J\big) + O(\hbar) = \sup_{\phi}\Big(\textstyle\int J\phi - S[\phi]\Big) + O(\hbar) = S^\star[J] + O(\hbar). \tag{4.173}$$

The supremum is over field configurations because, S being bounded below and convex near the relevant configurations, (4.172) locates its maximum; the result is precisely the Legendre transform $S^\star$ of the classical action. Now apply the effective action's own definition, $\Gamma = W^\star$, and the involution Theorem 4.31(iii):

$$\Gamma[\phi_c] = W^\star[\phi_c] = \big(S^\star\big)^\star[\phi_c] + O(\hbar) = S^{\star\star}[\phi_c] + O(\hbar) = S[\phi_c] + O(\hbar). \tag{4.174}$$

Theorem 4.36 (Tree-level identity)**.** *To leading order in the loop-counting parameter, the effective action equals the classical action,*

$$\Gamma[\phi_c] = S[\phi_c] + O(\hbar). \tag{4.175}$$

The quantum corrections begin at order $\hbar$ (one loop).

The proof is (4.173)–(4.174): W is the Legendre transform of S at leading order, and Γ is the Legendre transform of W, so by the involution Γ returns to S. The two Legendre transforms undo each other, and the tree-level effective action is simply the classical action. This is the cleanest possible statement of why Γ deserves to be called *the* effective action: it begins life, at $\hbar^0$, as the action S itself, and the loop expansion dresses it order by order in $\hbar$ with quantum corrections, $\Gamma = S + \hbar\,\Gamma_1 + \hbar^2\,\Gamma_2 + \cdots$. The $n = 2$ shadow of (4.175) is the free-level identity $\Gamma^{(2)} = S^{(2)}$ verified after Theorem 4.34; the full statement upgrades it to every vertex.

That the corrections are organized by powers of $\hbar$ as a *loop* expansion is the content of the next section, but the counting is already visible. A connected graph with V vertices and I internal lines carries, from (4.171), a factor $\hbar^{-1}$ per vertex and $\hbar$ per propagator, hence $\hbar^{I-V}$; with the topological identity $L = I - V + 1$ for the number of independent loops, this is $\hbar^{L-1}$. The tree graphs ($L = 0$) carry $\hbar^{-1}$ and assemble, through Theorem 4.35, into $\Gamma = S$ at $O(\hbar^0)$ after the overall normalization of (4.171); each additional loop costs one power of $\hbar$. Thus the loop expansion of Γ is literally its expansion in $\hbar$, with the classical action as the zeroth term.

Physical Insight

For spacetime-constant field configurations $\phi_c(x) = \varphi$, the effective action reduces to a single function, the *effective potential*: in Euclidean signature $\Gamma[\varphi] = \left(\int d^d x\right) V_{\text{eff}}(\varphi)$, the volume factor emerging because nothing depends on position. By Theorem 4.36 its leading term is the classical potential, $V_{\text{eff}}(\varphi) = V(\varphi) + O(\hbar)$, and the stationarity condition (4.160) becomes $V'_{\text{eff}}(\varphi) = 0$: the vacuum sits at the minimum of the quantum-corrected potential, not the classical one. This is the engine of spontaneous symmetry breaking, where the one-loop term can shift, tilt, or even create the minimum. We compute V_{eff} for the real scalar and read off its consequences in Chapter 29; the convexity of Γ guaranteed by Theorem 4.31(iii) is, in that context, the exact statement of the Maxwell construction that flattens V_{eff} between degenerate vacua.

4.5.5 The carried toy: the effective action of the zero-dimensional ϕ^4 model

We close by carrying ϕ^4 theory one step further, computing Γ for the zero-dimensional model and watching the 1PI structure assemble with no integrals to obscure it. We continue directly from Theorem 4.29, which gave $W(J) = \log Z(J)$ for the $N = 1$ model with $m^2 = 1$ to first order in the coupling.

Worked Example 4.37 (Effective action of the zero-dimensional ϕ^4 model)**.** Recall from (4.140) the connected generating functional of the model $Z(J) = \int dx\, \exp(-\frac{1}{2}x^2 - \frac{\lambda}{4!}x^4 + Jx)$, namely (dropping the additive constant, which no derivative sees)

$$W(J) = \tfrac{1}{2}J^2 - \frac{\lambda}{24}(J^4 + 6J^2) + O(\lambda^2). \tag{4.176}$$

The classical field is the first derivative,

$$\phi_c = W'(J) = J - \frac{\lambda}{6}J^3 - \frac{\lambda}{2}J + O(\lambda^2) = \Big(1 - \frac{\lambda}{2}\Big)J - \frac{\lambda}{6}J^3 + O(\lambda^2). \tag{4.177}$$

To build $\Gamma(\phi_c)$ we need the inverse map $J(\phi_c)$, which by the conjugate relation (4.158) equals $\Gamma'(\phi_c)$. Invert (4.177) perturbatively, writing $J = \phi_c + \lambda J_1 + O(\lambda^2)$ and matching:

$$\phi_c = \Big(1 - \tfrac{\lambda}{2}\Big)(\phi_c + \lambda J_1) - \tfrac{\lambda}{6}\phi_c^3 + O(\lambda^2) = \phi_c + \lambda\Big(J_1 - \tfrac{1}{2}\phi_c - \tfrac{1}{6}\phi_c^3\Big) + O(\lambda^2), \tag{4.178}$$

so the $O(\lambda)$ term must vanish, giving $J_1 = \frac{1}{2}\phi_c + \frac{1}{6}\phi_c^3$ and

$$\Gamma'(\phi_c) = J(\phi_c) = \phi_c + \lambda\Big(\tfrac{1}{2}\phi_c + \tfrac{1}{6}\phi_c^3\Big) + O(\lambda^2). \tag{4.179}$$

Integrate in ϕ_c (the constant of integration is irrelevant):

$$\Gamma(\phi_c) = \tfrac{1}{2}\phi_c^2 + \frac{\lambda}{24}\phi_c^4 + \frac{\lambda}{4}\phi_c^2 + O(\lambda^2). \tag{4.180}$$

The first two terms are exactly the classical action $S(\phi_c) = \frac{1}{2}\phi_c^2 + \frac{\lambda}{4!}\phi_c^4$ with $m^2 = 1$, confirming Theorem 4.36: $\Gamma = S$ plus a correction that starts at one loop. That correction is the term $\frac{\lambda}{4}\phi_c^2$, and it is precisely the one-loop functional determinant of the next section reduced to zero dimensions. Indeed the one-loop formula $\Gamma = S + \frac{1}{2}\log S''(\phi_c)$, which Section 4.6 derives in general, gives here

$$\tfrac{1}{2}\log S''(\phi_c) = \tfrac{1}{2}\log\left(1 + \tfrac{\lambda}{2}\phi_c^2\right) = \frac{\lambda}{4}\phi_c^2 + O(\lambda^2), \tag{4.181}$$

matching (4.180) term by term: the "functional determinant" is the single logarithm $\log S''$, and its $O(\lambda)$ piece is the toy's one-loop mass renormalization.

Reciprocity check. From (4.180), the proper two-point "vertex" is $\Gamma''(0) = 1 + \frac{\lambda}{2} + O(\lambda^2)$, while the connected two-point function computed in (4.141) is $W''(0) = \langle x^2\rangle_c = 1 - \frac{\lambda}{2} + O(\lambda^2)$. Their product is

$$\Gamma''(0)\,W''(0) = \left(1 + \tfrac{\lambda}{2}\right)\left(1 - \tfrac{\lambda}{2}\right) + O(\lambda^2) = 1 + O(\lambda^2), \tag{4.182}$$

verifying $\Gamma''W'' = 1$ (Eq. (4.163)) to the order computed.

1PI structure. The proper four-vertex is, from (4.180),

$$\Gamma^{(4)}(0) = \frac{d^4}{d\phi_c^4}\Big[\frac{\lambda}{24}\phi_c^4\Big] = \lambda + O(\lambda^2), \tag{4.183}$$

the classical coupling itself — the zero-dimensional 1PI vertex is the bare λ at tree level (the Euclidean avatar of the Minkowski Feynman-rule vertex $-i\lambda$ that ϕ^4 theory meets in Chapter 15). The model is $\mathbb{Z}_2$-symmetric, so $\Gamma^{(3)} = 0$ and the tree formula (4.169) collapses to its first term,

$$W^{(4)}(0) = -\Gamma^{(4)}(0)\,\big(W''(0)\big)^4 = -\lambda\cdot(1)^4 + O(\lambda^2) = -\lambda + O(\lambda^2), \tag{4.184}$$

which is exactly the connected four-point function $\langle x^4\rangle_c = -\lambda$ found independently in (4.142). The 1PI structure is thus completely explicit: the connected $W^{(4)}$ is the single proper vertex $\Gamma^{(4)} = \lambda$ with its four legs amputated — in zero dimensions "amputation" is just stripping four factors of the full propagator $W''(0) = 1 + O(\lambda)$ — and there is no reducible piece because $\Gamma^{(3)}$ vanishes. The same arithmetic in a theory with a cubic coupling would populate the second topology of Fig. 4.6.

This completes the toolbox's central construction. We have built $\Gamma[\phi_c]$ as the Legendre transform of $W[J]$, proved it convex and involutive with the source

as conjugate variable ($\delta\Gamma/\delta\phi_c = J$), shown its Hessian to be the full inverse propagator ($\Gamma'' W'' = \mathbf{1}$), identified its higher derivatives as the 1PI vertices from which all connected amplitudes assemble as trees, and established that it reduces to the classical action S at tree level, with quantum corrections organized in powers of $\hbar$. The tree-level identity $\Gamma = S$ already exposed, in (4.173), the object the final section needs: the leading-order evaluation of the functional integral by its saddle point. Section 4.6 makes that evaluation systematic — the Laplace expansion with controlled error, transcribed to the functional integral as the loop expansion, with the one-loop term emerging as the functional determinant $\frac{1}{2}\log\det S''$ whose zero-dimensional shadow we just met in (4.181). The effective action built here is the stationary-action functional that Chapter 23 flows under the Wilsonian renormalization group and that Chapter 29 evaluates as the effective potential governing spontaneous symmetry breaking.

4.6 Saddle Points, Functional Determinants, and the Loop Expansion

The previous section handed us the effective action $\Gamma[\phi_c]$, the Legendre transform of $W[J]$, together with the single most important fact about it: at lowest order it is the classical action, $\Gamma[\phi_c] = S[\phi_c]$, and its second variation $\delta^2\Gamma/\delta\phi_c^2$ is the inverse of the connected two-point function (Section 4.5). What we did not yet do is *compute* Γ beyond that leading statement. To do so we must finally confront the integral that defines $W[J]$ and learn to evaluate it. We have no hope of doing the functional integral exactly outside the Gaussian case of Section 4.2; what we can do is evaluate it *asymptotically*, dominated by the configurations that extremize the exponent. This is the method of steepest descent, and transcribing it to the functional integral is the single most productive idea in perturbative quantum field theory. It produces the loop expansion, exposes it as an expansion in powers of $\hbar$ about the classical limit, and identifies its first quantum correction as a functional determinant of the second-variation operator $\delta^2 S/\delta\phi\,\delta\phi$ already isolated in Section 4.1.

We build the method honestly: first in one finite-dimensional integral, with the error term controlled; then in n dimensions, where the Gaussian prefactor becomes a determinant of the Hessian; then we organize the corrections as connected vacuum graphs and read off the loop-counting rule. Only then do we restore $\hbar$, transcribe everything to the functional integral, and write down the one-loop effective action. We close by carrying the zero-dimensional ϕ^4 toy of ϕ^4 theory to its asymptotic loop series and proving that this series has zero radius of convergence — the first appearance of a theme (the divergence of perturbation theory) that Chapter 5 and Chapter 42 develop in earnest.

4.6.1 Laplace's method in one dimension

Consider the one-parameter family of integrals

$$I(\lambda) = \int_a^b g(x)\, e^{-\lambda f(x)}\, \mathrm{d}x, \qquad \lambda \to +\infty, \tag{4.185}$$

with $-\infty \le a < b \le +\infty$. The idea is elementary and physical: as λ grows, $e^{-\lambda f}$ becomes overwhelmingly concentrated near the point where f is smallest, so the integral is controlled by the value of g there and by the local curvature of f. The content of the method is to make "overwhelmingly" quantitative and to bound the error.

Theorem 4.38 (Laplace's method, one dimension)**.** *Let $f, g \in C^\infty$ on $[a,b]$. Suppose f attains its global minimum over $[a,b]$ at a single interior point $x_0 \in (a,b)$, that this minimum is nondegenerate, $f'(x_0) = 0$ and $f''(x_0) > 0$, and that the integral (4.185) converges absolutely for some $\lambda = \lambda_0$. Then as $\lambda \to +\infty$,*

$$I(\lambda) = e^{-\lambda f(x_0)} \sqrt{\frac{2\pi}{\lambda f''(x_0)}} \left[g(x_0) + \frac{c_1}{\lambda} + \frac{c_2}{\lambda^2} + \cdots \right], \tag{4.186}$$

an asymptotic expansion in $1/\lambda$ whose leading term carries a relative error $O(1/\lambda)$. The coefficients c_k are universal polynomials in the derivatives of f and g at x_0; c_1 is computed in Theorem 4.39.

Proof. Write $\phi(x) \equiv f(x) - f(x_0) \ge 0$, so that $\phi(x_0) = 0$ and $\phi(x) > 0$ for $x \neq x_0$; pull the constant $e^{-\lambda f(x_0)}$ out front. It remains to show

$$J(\lambda) \equiv \int_a^b g(x)\, e^{-\lambda \phi(x)}\, \mathrm{d}x = \sqrt{\frac{2\pi}{\lambda f''(x_0)}} \left[g(x_0) + O(1/\lambda) \right]. \tag{4.187}$$

Step 1: localization. Fix $\delta > 0$ small enough that $[x_0 - \delta, x_0 + \delta] \subset (a,b)$ and $f'' > 0$ throughout this interval (possible since f'' is continuous and $f''(x_0) > 0$). Split $J = J_{\mathrm{in}} + J_{\mathrm{out}}$ over $|x - x_0| < \delta$ and $|x - x_0| \ge \delta$. On the outer region ϕ is bounded below by a positive constant, $\eta \equiv \inf_{|x-x_0|\ge\delta} \phi(x) > 0$, because x_0 is the *unique* global minimum. For $\lambda > \lambda_0$ we estimate, using $\phi \ge \eta$ on the outer region and absolute convergence at λ_0,

$$|J_{\mathrm{out}}| \le \int_{|x-x_0|\ge\delta} |g|\, e^{-(\lambda-\lambda_0)\phi}\, e^{-\lambda_0 \phi}\, \mathrm{d}x \le e^{-(\lambda-\lambda_0)\eta} \int_a^b |g|\, e^{-\lambda_0 \phi}\, \mathrm{d}x = C\, e^{-(\lambda-\lambda_0)\eta}, \tag{4.188}$$

with $C < \infty$ independent of λ. The outer contribution is therefore exponentially small in λ — smaller than every power λ^{-k} — and contributes nothing to the asymptotic series.

Step 2: rescaling the core. On the inner interval Taylor's theorem with remainder gives

$$\phi(x) = \tfrac{1}{2} f''(x_0)(x-x_0)^2 + \rho(x), \qquad |\rho(x)| \le M\,|x-x_0|^3, \tag{4.189}$$

where $M = \frac{1}{6}\sup_{|x-x_0|\le\delta}|f'''| < \infty$. Substitute $x = x_0 + u/\sqrt{\lambda}$, so $\mathrm{d}x = \lambda^{-1/2}\mathrm{d}u$ and the inner region becomes $|u| \le \delta\sqrt{\lambda}$:

$$J_{\mathrm{in}} = \frac{1}{\sqrt{\lambda}} \int_{|u|\le\delta\sqrt{\lambda}} g\Big(x_0 + \tfrac{u}{\sqrt{\lambda}}\Big) \exp\Big(-\tfrac{1}{2} f''(x_0)\,u^2 - \lambda\,\rho(x_0 + \tfrac{u}{\sqrt{\lambda}})\Big)\,\mathrm{d}u. \tag{4.190}$$

The remainder in the exponent obeys $|\lambda\,\rho| \le M|u|^3/\sqrt{\lambda}$, so it vanishes pointwise as $\lambda\to\infty$; likewise $g(x_0+u/\sqrt{\lambda}) \to g(x_0)$. We need a λ-independent integrable majorant to pass the limit inside. Shrink δ if necessary so that $M\delta \le \frac{1}{4}f''(x_0)$. Then for $|u| \le \delta\sqrt{\lambda}$ we have $|u|^3/\sqrt{\lambda} = |u|^2\cdot(|u|/\sqrt{\lambda}) \le \delta\,u^2$, hence $|\lambda\rho| \le M\delta\,u^2 \le \frac{1}{4}f''(x_0)u^2$, and the integrand is bounded in modulus by

$$\Big(\sup_{[x_0-\delta,x_0+\delta]}|g|\Big)\, e^{-\frac{1}{2}f''(x_0)u^2 + \frac{1}{4}f''(x_0)u^2} = \Big(\sup|g|\Big)\, e^{-\frac{1}{4}f''(x_0)u^2}, \tag{4.191}$$

which is integrable over $\mathbb{R}$ and independent of λ. By dominated convergence,

$$\sqrt{\lambda}\,J_{\mathrm{in}} \xrightarrow{\lambda\to\infty} g(x_0)\int_{-\infty}^{\infty} e^{-\frac{1}{2}f''(x_0)u^2}\,\mathrm{d}u = g(x_0)\sqrt{\frac{2\pi}{f''(x_0)}}, \tag{4.192}$$

which is (4.187) at leading order. Combining with the exponentially small J_{out} proves the leading term of (4.186).

Step 3: the full series. To extract the subleading coefficients, do not take the limit but instead expand the two λ-dependent factors in (4.190) in powers of $\lambda^{-1/2}$:

$$g\Big(x_0+\tfrac{u}{\sqrt{\lambda}}\Big) = \sum_{m\ge 0}\frac{g^{(m)}(x_0)}{m!}\,\frac{u^m}{\lambda^{m/2}}, \qquad e^{-\lambda\rho} = \exp\Big(-\sum_{j\ge 3}\frac{f^{(j)}(x_0)}{j!}\,\frac{u^j}{\lambda^{(j-2)/2}}\Big). \tag{4.193}$$

Each factor is a power series in $\lambda^{-1/2}$ with coefficients that are polynomials in u. Multiplying out and integrating term by term against the Gaussian weight $e^{-\frac{1}{2}f''(x_0)u^2}$, every *odd* power of u integrates to zero by parity, so only integer powers of $1/\lambda$ survive — this is why (4.186) is a series in $1/\lambda$ rather than $1/\sqrt{\lambda}$. Extending each truncated u-integral from $|u| \le \delta\sqrt{\lambda}$ to all of $\mathbb{R}$ costs only an exponentially small error of the type (4.188), and the Gaussian moments $\int u^{2k}e^{-\frac{1}{2}f''u^2}\mathrm{d}u = (2k-1)!!\,(f'')^{-k}\sqrt{2\pi/f''}$ are finite. Truncating (4.193) after the terms that produce λ^{-N} leaves a remainder bounded, by the same dominated-convergence estimate applied to the first omitted monomial, by $O(\lambda^{-N-1})$. This is precisely the statement that (4.186) is a genuine asymptotic expansion. $\square$

The mechanism in Step 3 is worth naming, because it recurs verbatim in the field theory. The quadratic part of f supplies a Gaussian measure; the cubic and higher derivatives of f are *interaction vertices*; the factor g is an *insertion*; and the asymptotic series is generated by Wick-contracting the vertices and insertions against the Gaussian. The bookkeeping device — expand the exponential of the non-Gaussian part, contract with Gaussian moments — is the entire content of perturbation theory, stripped of spacetime.

Worked Example 4.39 (The first Laplace correction)**.** We compute c_1 in (4.186) for $g \equiv 1$, the case relevant to a partition function. Abbreviate $A \equiv f''(x_0)$, $B \equiv f'''(x_0)$, $C \equiv f''''(x_0)$. Only the contributions of order $1/\lambda$ are kept. From (4.193) with $g \equiv 1$, the exponent of the non-Gaussian factor is $-\lambda\rho = -\frac{B}{6}\frac{u^3}{\sqrt{\lambda}} - \frac{C}{24}\frac{u^4}{\lambda} + \cdots$. Expanding $e^{-\lambda\rho}$ and retaining all terms of order λ^{-1} in the integrand,

$$e^{-\lambda\rho} = 1 - \frac{C}{24}\frac{u^4}{\lambda} + \frac{1}{2}\Big(\frac{B}{6}\Big)^2\frac{u^6}{\lambda} + O(\lambda^{-3/2}), \tag{4.194}$$

where the u^6 term is the square of the cubic vertex (the cross term $u^3 \cdot u^4$ is odd and the linear u^3 term is odd, so both vanish on integration). Writing $\langle u^{2k}\rangle \equiv (2k-1)!!\,A^{-k}$ for the normalized Gaussian moments, the bracket in (4.186) equals $1 + \lambda^{-1}c_1 + \cdots$ with

$$c_1 = -\frac{C}{24}\langle u^4\rangle + \frac{B^2}{72}\langle u^6\rangle = -\frac{C}{24}\frac{3}{A^2} + \frac{B^2}{72}\frac{15}{A^3} = -\frac{f''''(x_0)}{8\,f''(x_0)^2} + \frac{5\,f'''(x_0)^2}{24\,f''(x_0)^3}. \tag{4.195}$$

The two terms are exactly the two connected vacuum diagrams at this order: the quartic "figure-eight" (one C vertex, two propagators A^{-1}) and the cubic "sunset" (two B vertices, three propagators). We will meet them again, now drawn as Feynman graphs, in Section 4.6.2.

4.6.2 Steepest descent in n dimensions and the determinant prefactor

The step that matters for field theory is the passage from one integration variable to many, because the functional integral is the limit of an n-dimensional integral as $n \to \infty$. Consider

$$I(\lambda) = \int_{\mathbb{R}^n} g(\mathbf{x})\, e^{-\lambda f(\mathbf{x})}\, \mathrm{d}^n x, \tag{4.196}$$

with f attaining a unique, nondegenerate global minimum at $\mathbf{x}_0$: the gradient vanishes, $\nabla f(\mathbf{x}_0) = 0$, and the Hessian $H_{ij} \equiv \partial_i\partial_j f(\mathbf{x}_0)$ is positive definite. This is the finite-dimensional ancestor of the saddle-point condition $\delta S/\delta\phi = 0$ and of the second-variation operator $\delta^2 S/\delta\phi\,\delta\phi$.

Theorem 4.40 (Laplace's method, n dimensions)**.** *Under the hypotheses above, with f, g smooth and the integral absolutely convergent for some λ_0, as $\lambda \to +\infty$*

$$I(\lambda) = e^{-\lambda f(\mathbf{x}_0)} \left(\frac{2\pi}{\lambda}\right)^{n/2} \frac{1}{\sqrt{\det H}} \left[g(\mathbf{x}_0) + O(1/\lambda)\right]. \tag{4.197}$$

Proof. The localization argument of Theorem 4.38 carries over unchanged: outside any ball $|\mathbf{x} - \mathbf{x}_0| \geq \delta$ the exponent exceeds its minimum by a fixed positive amount and the contribution is exponentially small. For the core, diagonalize the Hessian. Since H is real symmetric positive definite, there is an orthogonal O with $O^{\mathsf{T}} H O = \operatorname{diag}(\omega_1, \dots, \omega_n)$, all $\omega_i > 0$. Change variables $\mathbf{x} - \mathbf{x}_0 = O\,\mathbf{y}$ (Jacobian 1, since $\det O = \pm 1$), then rescale $y_i = u_i/\sqrt{\lambda}$. The quadratic part of the exponent becomes $\frac{1}{2}\sum_i \omega_i u_i^2$, the measure becomes $\lambda^{-n/2}\prod_i \mathrm{d}u_i$, and exactly as in one dimension the cubic and higher terms are suppressed by powers of $\lambda^{-1/2}$. Dominated convergence gives, at leading order,

$$I(\lambda) \sim e^{-\lambda f(\mathbf{x}_0)}\, \lambda^{-n/2}\, g(\mathbf{x}_0) \prod_{i=1}^{n} \int_{-\infty}^{\infty} e^{-\frac{1}{2}\omega_i u_i^2}\, \mathrm{d}u_i = e^{-\lambda f(\mathbf{x}_0)}\, \lambda^{-n/2}\, g(\mathbf{x}_0) \prod_{i=1}^{n} \sqrt{\frac{2\pi}{\omega_i}}. \tag{4.198}$$

Now $\prod_i \omega_i = \det H$, so $\prod_i \sqrt{2\pi/\omega_i} = (2\pi)^{n/2} (\det H)^{-1/2}$, which is (4.197). □

Equation (4.197) is the formula on which everything below rests. The exponential is the value of the integrand at the saddle; the power of λ counts the dimensions; and the Gaussian fluctuations around the saddle produce the prefactor $(\det H)^{-1/2}$, the determinant of the Hessian. When we let the integral become functional, H becomes the second-variation operator $\delta^2 S/\delta\phi\,\delta\phi$ and $(\det H)^{-1/2}$ becomes a *functional determinant*. The whole one-loop apparatus is contained, in embryo, in this prefactor.

Corrections as connected vacuum graphs. To organize the subleading terms, set $g \equiv 1$ and write the exponent as its quadratic part plus everything else,

$$f(\mathbf{x}) = f(\mathbf{x}_0) + \tfrac{1}{2}(\mathbf{x}-\mathbf{x}_0)^{\mathsf{T}} H (\mathbf{x}-\mathbf{x}_0) + V(\mathbf{x}-\mathbf{x}_0), \qquad V = \sum_{r \geq 3} \frac{1}{r!} f_{i_1 \cdots i_r}\, \xi^{i_1} \cdots \xi^{i_r}, \tag{4.199}$$

where $\xi \equiv \mathbf{x} - \mathbf{x}_0$ and $f_{i_1 \cdots i_r}$ are the higher derivatives of f at $\mathbf{x}_0$. Factoring out the saddle and the Gaussian, define the normalized Gaussian average

$$\langle\, \mathcal{O} \,\rangle \equiv \frac{\displaystyle\int \mathrm{d}^n\xi\, \mathcal{O}\, e^{-\frac{\lambda}{2}\xi^{\mathsf{T}} H \xi}}{\displaystyle\int \mathrm{d}^n\xi\, e^{-\frac{\lambda}{2}\xi^{\mathsf{T}} H \xi}}, \qquad \left\langle \xi^i \xi^j \right\rangle = \frac{1}{\lambda}\,(H^{-1})^{ij}. \tag{4.200}$$

The key fact, the finite-dimensional avatar of the propagator, is the second line: each contraction of two fluctuation variables carries one inverse power of λ. Then

$$I(\lambda) = e^{-\lambda f(\mathbf{x}_0)} \left(\tfrac{2\pi}{\lambda}\right)^{n/2} (\det H)^{-1/2} \left\langle e^{-\lambda V(\xi)} \right\rangle, \tag{4.201}$$

and $\langle e^{-\lambda V} \rangle$ is evaluated by expanding the exponential and Wick-contracting, exactly as in Theorem 4.39. By the linked-cluster theorem — which states that the logarithm of a sum of all Wick contractions equals the sum over *connected* contractions, proved for the generating functional in Section 4.4.3 — the logarithm collects only connected vacuum graphs:

$$\log \left\langle e^{-\lambda V} \right\rangle = \sum_{\Gamma \text{ connected vacuum}} \frac{1}{\sigma(\Gamma)} \, \lambda^{V(\Gamma) - I(\Gamma)} \, (\text{amplitude}), \tag{4.202}$$

with $V(\Gamma)$ the number of vertices, $I(\Gamma)$ the number of internal lines (contractions), and $\sigma(\Gamma)$ the symmetry factor. Each vertex of (4.199) carries one factor of λ (it comes from $-\lambda V$); each internal line carries λ^{-1} by (4.200); hence the power λ^{V-I}.

The loop-counting relation. The exponent $V - I$ is not arbitrary: it is fixed by the topology of the graph. For a connected graph the number of independent loops — the first Betti number L — obeys

$$\boxed{L = I - V + 1}. \tag{4.203}$$

Proof. Pick a spanning tree of the connected graph: a maximal subset of internal lines containing no loop and touching every vertex. A tree on V vertices has exactly $V - 1$ lines. Each of the remaining $I - (V - 1)$ internal lines, when added back, closes exactly one independent loop, and these are a basis for the loop space; hence $L = I - (V - 1) = I - V + 1$. □

There is a second reading of (4.203) that we will use constantly once momenta appear: each internal line carries an integration variable (a loop momentum), each vertex imposes one conservation constraint, and one such constraint is redundant (it fixes only the overall external balance), leaving $I - (V - 1) = L$ free integrations — one per loop. Either way, combining (4.203) with the power λ^{V-I} gives

$$\lambda^{V(\Gamma) - I(\Gamma)} = \lambda^{-(L(\Gamma) - 1)} = \lambda^{1 - L(\Gamma)}. \tag{4.204}$$

A connected vacuum graph with L loops is suppressed by $\lambda^{-(L-1)}$ relative to the Gaussian (one-loop) term. The leading Gaussian factor $(\det H)^{-1/2}$ is itself the $L = 1$ contribution; the figure-eight and sunset of Theorem 4.39 have $L = 2$ and contribute the $1/\lambda$ correction; and so on. The small parameter that orders the whole expansion is $1/\lambda$, and it counts loops. Figure 4.7 shows the two-loop graphs.

figure-eight: $V=1,\ I=2,\ L=2$ sunset: $V=2,\ I=3,\ L=2$

Figure 4.7: The two connected two-loop vacuum graphs that produce the first correction c_1/λ in Laplace's method, Theorem 4.39. Each obeys $L=I-V+1=2$, so each is suppressed by one power of $1/\lambda$ relative to the Gaussian determinant. These are the finite-dimensional ancestors of the two-loop vacuum diagrams of ϕ^4 theory.

4.6.3 Restoring $\hbar$: the saddle expansion is the loop expansion

We now transcribe the finite-dimensional method to the functional integral and identify the expansion parameter physically. The generating functional of Section 4.5, with $\hbar$ restored to the exponent, is

$$Z[J]=e^{iW[J]/\hbar}=\int \mathcal{D}\phi\ \exp\Big[\tfrac{i}{\hbar}\Big(S[\phi]+\textstyle\int J\phi\Big)\Big]. \tag{4.205}$$

The integral (4.205) is the formal $n\to\infty$ limit of (4.196) with the identification $\lambda\leftrightarrow 1/\hbar$ and a rotation of the contour that turns the oscillatory $e^{iS/\hbar}$ into the convergent steepest-descent $e^{-(\,\cdot\,)/\hbar}$; the rotation is the Wick rotation, defined and justified in Chapter 10, and at the level of asymptotics it does not affect the combinatorics. With that identification, $\hbar\to 0$ is exactly the $\lambda\to\infty$ limit, and *the steepest-descent expansion in $1/\lambda$ becomes an expansion in powers of $\hbar$.*

The saddle point is the stationary configuration of the exponent,

$$\frac{\delta}{\delta\phi}\Big(S[\phi]+\textstyle\int J\phi\Big)\Big|_{\phi=\phi_J}=0 \quad\Longleftrightarrow\quad \frac{\delta S}{\delta\phi(x)}\Big|_{\phi_J}+J(x)=0, \tag{4.206}$$

which is nothing but the classical equation of motion in the presence of the source J. The leading term of W is the action at this saddle, $W[J]=S[\phi_J]+\int J\phi_J+O(\hbar)$, reproducing the tree-level identification $\Gamma=S$ of Section 4.5. The classical solution *is* the $\hbar\to 0$ limit; quantum corrections are the fluctuations around it.

To count $\hbar$ in the corrections, write $\phi=\phi_J+\sqrt{\hbar}\,\eta$ and expand the exponent. The shift by the factor $\sqrt{\hbar}$ is chosen precisely so the quadratic fluctuation term is $\hbar$-independent. Using the saddle condition (4.206) to kill the linear term,

$$\begin{aligned}\frac{1}{\hbar}\Big(S[\phi]+\textstyle\int J\phi\Big)=\frac{1}{\hbar}\Big(S[\phi_J]+\int J\phi_J\Big)+\tfrac12\textstyle\int\eta\,\frac{\delta^2 S}{\delta\phi\,\delta\phi}\Big|_{\phi_J}\eta\\ +\sqrt{\hbar}\,\frac{1}{3!}\int S^{(3)}[\phi_J]\,\eta^3+\hbar\,\frac{1}{4!}\int S^{(4)}[\phi_J]\,\eta^4+\cdots,\end{aligned} \tag{4.207}$$

where $S^{(r)}[\phi_J] \equiv \delta^r S/\delta\phi^r|_{\phi_J}$ and the schematic $\int \eta^r$ denotes the r-fold spacetime integral against $S^{(r)}$. A vertex with r legs thus carries a factor $\hbar^{r/2-1}$: cubic vertices come with $\sqrt{\hbar}$, quartic with $\hbar$, and so on. The Gaussian contraction $\langle \eta\,\eta \rangle$ is now $\hbar$-independent (the $\hbar$ was scaled out by the $\sqrt{\hbar}$ in $\phi = \phi_J + \sqrt{\hbar}\eta$).

For a connected vacuum graph with V vertices and I internal lines, the total power of $\hbar$ from the vertices is $\sum_v (\frac{r_v}{2} - 1)$. Because every internal line joins two vertex-legs, $\sum_v r_v = 2I$, so the total is $I - V = L - 1$ by the loop relation (4.203). We have proved the central combinatorial fact:

Proposition 4.41 (Loop expansion = $\hbar$ expansion)**.** *In the saddle-point evaluation of (4.205), a connected vacuum graph with L loops contributes at order $\hbar^{L-1}$ to $\log Z$ and at order $\hbar^L$ to $W[J] = -i\hbar \log Z$. Equivalently, if one keeps $S/\hbar$ without rescaling the field, each propagator carries $\hbar$ and each vertex carries $\hbar^{-1}$, so a connected graph carries $\hbar^{I-V} = \hbar^{L-1}$; the overall factor $\hbar$ in $W = -i\hbar \log Z$ raises this to $\hbar^L$. The expansion of W (and of Γ) in powers of $\hbar$ is therefore an expansion in the number of loops.*

The two counting routes in Theorem 4.41 agree because they differ only by the field redefinition $\phi = \phi_J + \sqrt{\hbar}\,\eta$, whose Jacobian is a field-independent constant absorbed into the normalization of $\mathcal{D}\phi$. The physical reading is the content of the insight box at the end of this section: $\hbar$ is the size of quantum fluctuations, and counting loops is counting powers of $\hbar$, i.e. counting how far one has moved from the classical limit.

4.6.4 The one-loop effective action and the functional determinant

We can now extract the first quantum correction to the effective action. Keep only the terms through order $\hbar$ in Theorem 4.41. From (4.207), dropping the interaction vertices (which start at order $\hbar$ in $\log Z$ through two loops), the fluctuation integral is purely Gaussian:

$$Z[J] = \exp\Big[\tfrac{i}{\hbar}\big(S[\phi_J] + \textstyle\int J\phi_J\big)\Big] \int \mathcal{D}\eta\, \exp\Big[\tfrac{i}{2}\textstyle\int \eta\, \frac{\delta^2 S}{\delta\phi\,\delta\phi}\Big|_{\phi_J} \eta\Big]\,(1 + O(\hbar)). \tag{4.208}$$

The fluctuation integral is the infinite-dimensional Gaussian of Section 4.2. With the operator

$$\mathcal{O}_J(x,y) \equiv \frac{\delta^2 S}{\delta\phi(x)\,\delta\phi(y)}\Big|_{\phi=\phi_J}, \tag{4.209}$$

the Gaussian formula $\int \mathcal{D}\eta\, \exp(\frac{i}{2}\int \eta\, \mathcal{O}_J\, \eta) = \mathcal{N}\,(\det \mathcal{O}_J)^{-1/2}$, where $\mathcal{N}$ is the field-independent normalization, gives

$$W[J] = S[\phi_J] + \int J\phi_J + \frac{i\hbar}{2} \log\det \mathcal{O}_J + O(\hbar^2), \tag{4.210}$$

using $W = -i\hbar \log Z$ and $\log(\det \mathcal{O}_J)^{-1/2} = -\frac{1}{2}\log\det \mathcal{O}_J$, with $\mathcal{N}$ absorbed into the (physically irrelevant) additive normalization of W.

To convert this into a statement about Γ rather than W, we use the background-field reading of the Legendre transform. The cleanest route is to choose the source so that the classical field is a prescribed background $\bar\phi$, i.e. set $\phi_c = \bar\phi$ and shift $\phi = \bar\phi + \eta$ from the start. Then $\Gamma[\bar\phi]$ is the generating functional of one-particle-irreducible (1PI) vacuum graphs computed in the presence of $\bar\phi$ (Section 4.5): the linear-in-η term is removed by the very definition of the Legendre transform (it is cancelled against J), and disconnected and one-particle-reducible pieces drop out. At one loop there is a single 1PI vacuum graph — the closed loop of the fluctuation η in the quadratic potential $S^{(2)}[\bar\phi]$ — and it is exactly the Gaussian determinant. Hence

$$\boxed{\Gamma[\bar\phi] = S[\bar\phi] + \frac{i\hbar}{2}\log\det\left(\frac{\delta^2 S}{\delta\phi\,\delta\phi}\Big|_{\bar\phi}\right) + O(\hbar^2)} \tag{4.211}$$

With $\hbar = 1$ this is the formula promised by this section: $\Gamma = S + \frac{i}{2}\log\det S'' +$ higher loops. The tree term $S[\bar\phi]$ is the classical action; the one-loop term is the logarithm of the functional determinant of the second-variation operator; the two-loop and higher terms are the sums of connected 1PI vacuum graphs with $L \geq 2$, each carrying $\hbar^{L-1}$ more than the tree.

What the functional determinant means, and why it diverges. The object $\det \mathcal{O}_J$ is defined as the product of eigenvalues of the operator (4.209). If $\mathcal{O}_J$ has a discrete spectrum $\{\lambda_n\}$ (as it does, for example, on a compact Euclidean spacetime, or after putting the theory in a box), then

$$\log\det \mathcal{O}_J = \operatorname{Tr}\log \mathcal{O}_J = \sum_n \log\lambda_n. \tag{4.212}$$

This is a formal expression: in field theory the spectrum is unbounded above, $\lambda_n \to \infty$, so the sum $\sum_n \log\lambda_n$ diverges. The divergence is the ultraviolet divergence of the one-loop vacuum energy, seen here in its cleanest guise — it is the statement that summing the zero-point energies $\frac{1}{2}\hbar\omega$ of infinitely many fluctuation modes gives infinity. It is a genuine divergence of the unrenormalized expression, not a flaw in the derivation, and it is cured by the renormalization program of Part VI; in the regulated, renormalized theory (4.211) delivers finite, physical one-loop corrections such as the Coleman–Weinberg effective potential of Chapter 29.

To make (4.212) a well-defined finite object before renormalization one introduces a *regularized determinant*. Two standard definitions, equivalent where both apply, are

- the *zeta-function determinant*: from the spectral zeta function $\zeta_{\mathcal{O}}(s) \equiv \sum_n \lambda_n^{-s}$, analytically continued from the region $\mathrm{Re}\, s$ large where it converges, one defines $\log\det \mathcal{O} \equiv -\zeta'_{\mathcal{O}}(0)$, which is finite because $\zeta_{\mathcal{O}}(s)$ is analytic at $s = 0$ for the elliptic operators of interest;
- the *heat-kernel* (proper-time) representation: $\log\det \mathcal{O} = -\int_0^\infty \frac{\mathrm{d}t}{t}\ \mathrm{Tr}\ e^{-t\mathcal{O}}$, regulated by a short-time cutoff $t \geq \epsilon^2$ whose divergences as $\epsilon \to 0$ are local and absorbed into counterterms.

We *state* these here so that (4.211) is not left dangling on a divergent symbol; the constructions are carried out in full, including the analytic continuation of $\zeta_{\mathcal{O}}$ and the small-t heat-kernel (Seeley–DeWitt) expansion, in Chapter E. The one-loop effective potential of ϕ^4 and the running it encodes are computed there and in Chapters 23 and 29; the genuine ϕ^4 theory loop integrals begin at Chapter 14.

Physical Insight

The loop expansion is the semiclassical expansion. Restoring $\hbar$ in $e^{iS/\hbar}$ shows that $\hbar$ multiplies the fluctuations and $1/\hbar$ multiplies the classical action; the stationary-phase (saddle) point is the classical trajectory, and each additional loop is one more power of $\hbar$ — one step further from classical mechanics into the quantum. The effective action $\Gamma[\bar{\phi}]$ is the object that makes this precise: it is the quantity whose own stationarity, $\delta\Gamma/\delta\bar{\phi} = 0$ at $J = 0$, gives the *full quantum* equations of motion for the field expectation value, just as $\delta S/\delta\phi = 0$ gives the classical ones. In this sense Γ is the "quantum-corrected action": replace S by Γ and treat the resulting variational problem classically, and you have resummed all the quantum fluctuations into the equations of motion. The one-loop term $\frac{i}{2}\hbar \log\det S''$ is the leading such correction — the back-reaction of the zero-point fluctuations of every mode on the dynamics of the background.

4.6.5 The zero-dimensional ϕ^4 integral as an asymptotic series

We close by carrying ϕ^4 theory to the point this section makes possible. Strip spacetime down to a single point, so the field is one real number $\phi \equiv x$ and the functional integral is one ordinary integral. With the Euclidean ϕ^4 action, $S_E = \frac{1}{2}\phi^2 + \frac{\lambda}{4!}\phi^4$ (mass set to one), the partition function is

$$Z(\lambda) = \int_{-\infty}^{\infty} \mathrm{d}x\ \exp\Big(-\tfrac{1}{2}x^2 - \tfrac{\lambda}{4!}\,x^4\Big), \qquad \lambda \geq 0, \tag{4.213}$$

the interacting continuation of the Gaussian ($\lambda = 0$) integral of Section 4.2. It converges for every $\lambda \geq 0$ (and, as an analytic function, for all complex λ with $\mathrm{Re}\,\lambda > 0$), so $Z(\lambda)$ is a perfectly well-defined, finite number for each such λ. The question is what its perturbative (loop) expansion in λ looks like.

Worked Example 4.42 (The asymptotic loop series of the zero-dimensional toy)**.** *The coefficients.* Expand the interaction and integrate term by term, using the Gaussian moments $\int_{-\infty}^{\infty} x^{2k} e^{-x^2/2}\,\mathrm{d}x = \sqrt{2\pi}\,(2k-1)!! = \sqrt{2\pi}\,(2k)!/(2^k k!)$:

$$Z(\lambda) = \sum_{n=0}^{\infty} \frac{1}{n!}\Big(-\frac{\lambda}{4!}\Big)^n \int_{-\infty}^{\infty} x^{4n} e^{-x^2/2}\,\mathrm{d}x = \sqrt{2\pi}\sum_{n=0}^{\infty} a_n\,\lambda^n, \qquad a_n = \frac{(-1)^n\,(4n)!}{n!\,(2n)!\,96^{\,n}}, \tag{4.214}$$

where $96 = 24\cdot 4$ collects the $4!$ from the vertex and the 2^{2n} from the double factorial. The first few coefficients are

$$a_0 = 1, \quad a_1 = -\tfrac{1}{8}, \quad a_2 = \tfrac{35}{384}, \quad a_3 = -\tfrac{385}{3072}, \quad \dots \tag{4.215}$$

The term of order λ^n is the sum of all vacuum diagrams built from n quartic vertices: by (4.203), n quartic vertices ($V = n$, hence $I = 2n$ lines) give $L = n+1$ loops, so successive powers of λ are successive loop orders. The coefficient $a_1 = -\frac{1}{8}$ is precisely the figure-eight of Fig. 4.7 with its symmetry factor; the loop expansion of this toy is literally the series (4.214).

The radius of convergence is zero. Form the ratio of consecutive coefficients exactly,

$$\left|\frac{a_{n+1}}{a_n}\right| = \frac{(4n+1)(4n+2)(4n+3)(4n+4)}{(n+1)(2n+1)(2n+2)\cdot 96} \xrightarrow{\;n\to\infty\;} \frac{256\,n^4}{384\,n^3} = \frac{2}{3}\,n \;\to\; \infty. \tag{4.216}$$

For any fixed $\lambda \neq 0$ the terms $a_n\lambda^n$ eventually grow without bound, so the series diverges: its radius of convergence is 0. Sharpening (4.216) with Stirling's formula gives the large-order behavior

$$a_n \;\sim\; \frac{(-1)^n}{\pi\sqrt{2}}\left(\frac{2}{3}\right)^n \frac{(n-1)!}{1}, \qquad n\to\infty, \tag{4.217}$$

the hallmark factorial growth $a_n \sim n!\,(2/3)^n$ of a perturbative series. The series (4.214) is therefore *asymptotic* to $Z(\lambda)$ as $\lambda \to 0^+$ — each partial sum approximates Z with an error smaller than the first omitted term — but it does not converge to it.

There is a second, entirely physical, argument for the zero radius of convergence, due to Dyson, that we record because it generalizes verbatim to the real theory. Suppose the series converged in some disk $|\lambda| < r$. Then it would converge for small *negative* λ as well. But for any $\lambda < 0$ the integrand of (4.213) behaves like $e^{+|\lambda| x^4/4!}$ at large $|x|$ and the integral *diverges*: the would-be ground state is unstable because the potential is unbounded below. A function that fails to exist on one side of the origin cannot have a convergent Taylor series centered there. The divergence of perturbation theory is thus not a technical accident but a reflection of the nonanalyticity of the theory at zero coupling —

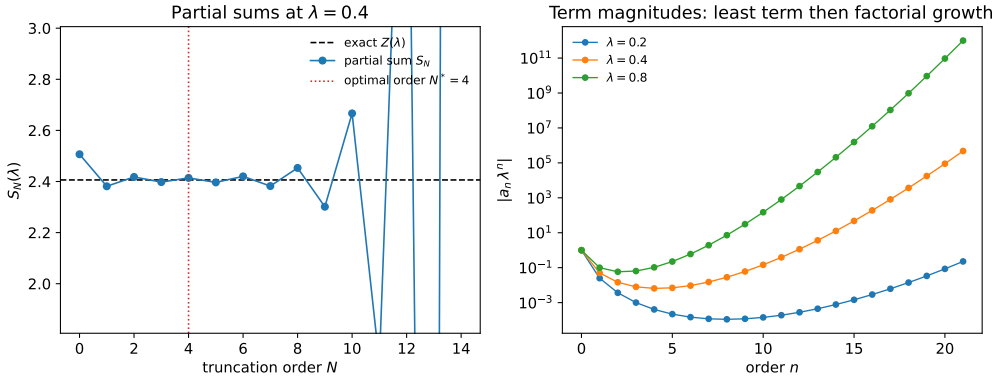

Figure 4.8: The asymptotic loop series of the zero-dimensional ϕ^4 integral (4.213). *Left:* partial sums $S_N(\lambda) = \sqrt{2\pi}\sum_{n\le N} a_n\lambda^n$ at $\lambda = 0.4$ converge toward the exact $Z(\lambda)$ (dashed) up to the optimal truncation N^*, then diverge. *Right:* the magnitudes $|a_n\lambda^n|$ shrink to a least term near N^* and thereafter grow factorially, the universal signature of an asymptotic series. The sign-alternating factorial growth (4.217) with ratio 2/3 places the leading Borel singularity at $t = -3/2$, on the negative real axis and so off the positive integration contour — exactly the configuration that makes this series Borel summable.

the same nonanalyticity that, in four dimensions, is organized by instantons and renormalons in Chapter 42.

Figure 4.8 shows both faces of the asymptotic series: the partial sums chase the exact value, achieve their best accuracy at an optimal truncation order $N^* \sim 1/(\text{const}\cdot\lambda)$, and then diverge as the factorially growing terms take over.

That the series is Borel summable — that one can recover the exact $Z(\lambda)$ from its divergent coefficients by forming the Borel transform $B(t) = \sum_n (a_n/n!)\, t^n$, which by (4.217) has finite radius 3/2, continuing it, and evaluating $Z(\lambda) = \int_0^\infty e^{-t} B(\lambda t)\, \mathrm{d}t$ — is a statement we can make here but not yet justify. The notions of asymptotic series and Borel summation are developed without full proof in Chapter 5, and the obstruction to Borel summability in genuine field theories (Borel-plane singularities from instantons and renormalons) is the subject of Chapter 42.

This completes the functional toolbox. We now hold the variational derivative and the second variation (Section 4.1), the exact Gaussian integral and its determinant (Section 4.2), the generating functionals $Z[J]$ and $W[J]$ and the effective action $\Gamma[\phi_c]$ (Section 4.5), and now the saddle-point/loop expansion with its one-loop functional determinant. Chapter 6 puts the variational calculus to work on classical field dynamics; Chapter 10 builds the scalar path integral and turns the loop expansion derived here into the working perturbation theory of quantum fields; and Chapters 23 and 29 take the effective action and its

potential to the renormalization group and to spontaneous symmetry breaking.

Further reading

The functional and path-integral methods of this chapter are developed, with the physicist's emphasis, in Zee [532], Peskin and Schroeder [396], Schwartz [432], and Srednicki [454]; Weinberg [500] gives the formalism with unusual care about what the generating functionals do and do not assume. Coleman [129] is the classic source for the effective action, the loop expansion, and the saddle-point organization of perturbation theory. For the convex-analysis foundation of the Legendre transform and the effective action as a true convex envelope, and for the asymptotic and Borel-summation theory of the loop series, see Zinn-Justin [534]. The honest status of the continuum measure – which path-integral statements are theorems and which are formal – is the subject of constructive field theory, surveyed in Glimm and Jaffe [225], with the axiomatic backdrop in Streater and Wightman [458].

Chapter 5

Analysis Tools: Distributions, Complex Analysis, Asymptotics

This is the last toolbox laid down before field theory begins. The previous chapters of Part I supplied two of the three languages the rest of the book speaks. Chapters 2 and 3 built the symmetry-and-representation language – finite and Lie groups, the Lorentz and Poincaré algebras, Wigner's classification of what a relativistic particle can be – and Chapter 4 built the functional-calculus machinery – variations, functional derivatives, Gaussian and generating functionals, the Legendre transform. What is still missing is the *analytic* language: the precise theory of the singular, the complex, and the divergent. That is what this chapter supplies, and with it Part I is complete and Part II can begin. We assume the reader's complex analysis through Cauchy's theorem and the residue theorem, together with elementary Fourier analysis and Gaussian integration. These are *reviewed for deployment, not rebuilt*: we restate exactly the residue and Jordan-lemma machinery we will lean on, in our notation, and then use it. Everything past that line – distribution theory, the $i\varepsilon$ prescription, the legality of Wick rotation, dispersion relations, and the asymptotic/Borel circle of ideas – is *built* here from the ground up.

The chapter exists to resolve two difficulties that are not optional decorations on quantum field theory but structural features of it, unavoidable the moment one writes down a propagator or a perturbative amplitude. The first is that the central objects of the theory – propagators, vertex functions, scattering amplitudes – are *not ordinary functions*. A free propagator has a pole exactly where energy and momentum sit on the mass shell, the place one most wants to evaluate it; the time-ordered two-point function is a boundary value of an analytic function, well defined only once a rule is given for going around that pole. That rule is the $i\varepsilon$ prescription, and an amplitude is meaningful only relative to it. The second difficulty is that the central computational engine of the theory – perturbation theory in a coupling – produces power series with

zero radius of convergence. The number of Feynman diagrams grows factorially with the order, and the resulting series diverges for every nonzero coupling. A perturbative "answer" is therefore not the sum of a convergent series; it is an asymptotic expansion, and extracting a number from it requires a theory of what such an expansion means. Both difficulties must be given precise meaning before a single field is quantized, or every later computation rests on undefined symbols.

These two threads – singular objects and divergent series – are in fact one argument, and the single word that unifies them is *analytic structure*. The chapter is organized so that each section hands the next link of one chain. Singular distributions – the delta function, the Cauchy principal value, the boundary values $1/(x \pm i\varepsilon)$ – are introduced first (Section 5.1) and shown by the Sokhotski–Plemelj formula to encode, in one identity, both a principal value and a delta function: the analytic content of an $i\varepsilon$. The Fourier transform on tempered distributions (Section 5.2) turns these objects into momentum space, where the $1/(x \pm i\varepsilon)$ structure becomes a *pole* in a complex energy variable. Poles are then handled by contour integration (Section 5.3): the retarded, advanced, and Feynman propagators are revealed to be one and the same integrand evaluated on three different contours, three prescriptions for going around the same two poles. The Feynman pole placement is exactly what makes one contour deformation legal, and that deformation is the *Wick rotation* (Section 5.4) connecting Minkowski and Euclidean signature – the prototype of analytic continuation as a computational tool. Continuation in the *external* invariants, rather than the loop variables, is the subject of Section 5.5: there analyticity in the upper half of a complex energy plane is shown to be, read physically, nothing but *causality*, and from causality one derives the Kramers–Kronig and subtracted dispersion relations and the sum rules they imply. Finally, the analytic functions these methods produce are approximated in practice by the divergent perturbative series of the second difficulty; Section 5.6 develops the asymptotic-series technology – optimal truncation, Watson's lemma, Laplace and steepest-descent – that controls them term by term, and Section 5.7 develops Borel summation, which reconstructs the function from the series when it can, and exposes the nonperturbative ambiguity when it cannot. Singular distribution $\to$ pole $\to$ contour $\to$ continuation $\to$ causality $\to$ dispersion relation $\to$ asymptotic series $\to$ Borel sum: one chain, seven sections.

A brief word on scope and rigor. The bulk of this chapter is proved in full and stands on its own: the construction of the distribution spaces and the universal differentiability of distributions, the Sokhotski–Plemelj formula, the Fourier transform on $\mathcal{S}'$ and the transform dictionary, the residue/Jordan-lemma evaluation of the propagator contours, the legality of the Wick rotation traced directly to the Feynman pole placement, the Kramers–Kronig relations, Watson's lemma, and the steepest-descent expansion are all established here with every step shown. A smaller set of results is given as precise statements with explicit forward pointers to where the book discharges them: the Källén–Lehmann

spectral representation, whose nonperturbative positivity underlies the analytic assumptions used here, is stated now and proved in Chapter 9; the optical theorem, whose imaginary part feeds the dispersion relations, is stated now and proved in Chapter 14; and the deepest questions – whether the full perturbative series of a realistic four-dimensional QFT is Borel summable, the renormalon obstruction in asymptotically free theories, and the resurgence/transseries program – are flagged as genuinely open and dated to the mid-2020s, not papered over. The reader should know which sentences are theorems and which are signposts.

A word on the threads, and a word on what the worked computations are doing. no earlier model is formally advanced in this chapter: the ϕ^4, QED, and Yang–Mills models are not defined until Part II, so there is no Lagrangian here to continue. What the chapter does instead is *plant the exact analytic objects* those threads will later need, as self-contained model calculations. The momentum-space scalar propagator $i/(p^2 - m^2 + i\varepsilon)$ assembled here is, verbatim, the internal line that ϕ^4 theory will quantize in Chapter 9 and feed into the path integral in Chapter 10; the Wick rotation made legal here is the one every loop integral in Chapter 19 performs before reaching the master integrals of Chapter D; the dispersion-relation and optical-theorem machinery is the analytic backbone of the unitarity methods in Chapter 60; and the Borel-summation and saddle-point analysis is exactly the language in which the semiclassical expansion of Chapter 10 and the instanton physics of Chapter 42 are later phrased. The conventions in force throughout match the book-wide canon collected in Appendix A (Chapter A): the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units $\hbar = c = 1$, the Fourier convention with $e^{-ip\cdot x}$ and a $(2\pi)^{-4}$ per momentum integral, and the Feynman $i\varepsilon$. We are stocking a toolbox, and we name on the box exactly which later chapters each tool is for.

5.1 Distributions and the $i\epsilon$ prescription

The chapter introduction made a promise that this section must now redeem. The central objects of quantum field theory — propagators, vertex functions, amplitudes — are not functions in the sense of the calculus. The free Feynman propagator in momentum space, $i/(p^2 - m^2 + i\epsilon)$, is singular on the entire mass shell $p^2 = m^2$; in position space it oscillates without decaying and cannot be evaluated pointwise on the light cone; and the small imaginary part $i\epsilon$, which the textbook reader is taught to "send to zero at the end," is doing genuine analytic work that no naive limit of functions can reproduce. We met this already at the naive level in Chapter 4, where the functional derivative produced a Dirac delta as its "Kronecker delta" and we agreed to postpone the question of what that object really is. The postponement ends here. The right framework is L. Schwartz's theory of *distributions*: one enlarges the class of admissible objects from functions to continuous linear functionals on a space of very well-behaved

test functions, recovering ordinary functions as a special case but admitting also δ, its derivatives, the principal value $\mathrm{PV}\,1/x$, and — the result this section is built toward — the boundary values $1/(x \pm i\epsilon)$. Once these live in a vector space on which differentiation is always defined and limits have a precise meaning, the statement "the propagator is a distribution" stops being folklore and becomes a theorem we can compute with. Throughout we use the Fourier and sign conventions fixed in Chapter A; the Fourier transform itself is built on the present foundation in Section 5.2.

5.1.1 Test functions: $\mathcal{D}$ and $\mathcal{S}$

The strategy is to define a singular object not by its values — it has none — but by how it *acts*, by the numbers it returns when integrated against a smooth, rapidly-decaying probe. Everything therefore rests on a good choice of probe. Two spaces of probes are standard, and we will need both.

Definition 5.1 (Test function spaces)**.** Let $\mathbb{R}^n$ be the underlying space.

1. The space of *compactly supported test functions* is
$$\mathcal{D}(\mathbb{R}^n) = C_c^\infty(\mathbb{R}^n) = \{\, \varphi \in C^\infty(\mathbb{R}^n) : \ \operatorname{supp}\varphi \text{ is compact} \,\}, \tag{5.1}$$
the infinitely differentiable functions that vanish outside some bounded set.

2. The *Schwartz space* of *rapidly decreasing functions* is
$$\mathcal{S}(\mathbb{R}^n) = \Big\{ \varphi \in C^\infty(\mathbb{R}^n) : \ \|\varphi\|_{\alpha,\beta} := \sup_{x\in\mathbb{R}^n} \big|x^\alpha\, \partial^\beta \varphi(x)\big| < \infty \ \text{ for all } \alpha, \beta \Big\}, \tag{5.2}$$
the smooth functions all of whose derivatives decay faster than any inverse power of $|x|$. The countable family of *seminorms* $\|\cdot\|_{\alpha,\beta}$ defines the topology of $\mathcal{S}$.

Here $\alpha = (\alpha_1, \dots, \alpha_n)$ is a multi-index, $x^\alpha = x_1^{\alpha_1} \cdots x_n^{\alpha_n}$, $\partial^\beta = \partial_1^{\beta_1} \cdots \partial_n^{\beta_n}$, and $|\alpha| = \sum_i \alpha_i$. The condition in Eq. (5.2) says that multiplying any derivative of φ by any polynomial still leaves a bounded function: φ and all its derivatives die off at infinity faster than $|x|^{-N}$ for every N. The Gaussian $e^{-|x|^2}$ is the prototype and lives in $\mathcal{S}$ but not in $\mathcal{D}$ (it never exactly vanishes). The standard bump
$$\varphi_0(x) = \begin{cases} \exp\!\big(-1/(1-|x|^2)\big), & |x| < 1, \\ 0, & |x| \geq 1, \end{cases} \tag{5.3}$$
lives in $\mathcal{D}$: it is smooth (all derivatives vanish as $|x| \uparrow 1$ because the essential singularity of $e^{-1/t}$ at $t = 0^+$ is flatter than any power) and is supported in the closed unit ball. Such bumps exist in abundance; their existence is what makes the

whole theory nonvacuous. Since compact support forces faster-than-polynomial decay trivially, we have the inclusion

$$\mathcal{D}(\mathbb{R}^n) \subset \mathcal{S}(\mathbb{R}^n) \subset C^\infty(\mathbb{R}^n), \tag{5.4}$$

and the smaller the space of probes, the larger the space of objects that can be tested against them.

Physical Insight

Why *two* spaces? The compactly supported $\mathcal{D}$ is the more permissive probe, and its dual $\mathcal{D}'$ accordingly contains the most objects — including wildly growing ones like e^{x^2}, read as a functional. But Schwartz space is closed under the Fourier transform (a Gaussian maps to a Gaussian, and rapid decay in x is exactly smoothness in p and vice versa), whereas $\mathcal{D}$ is *not*: a compactly supported function has an entire, hence non-compactly-supported, Fourier transform. Since QFT lives and breathes in momentum space, the Fourier-friendly pair $\mathcal{S}$ and its dual $\mathcal{S}'$ are the ones we will marry to the Fourier transform in Section 5.2. We develop both here because $\mathcal{D}$ gives the cleanest definitions and $\mathcal{S}$ gives the objects we actually need.

5.1.2 Distributions and tempered distributions

A distribution is a rule that assigns a number to each test function, linearly and continuously. Linearity is obvious; continuity is what excludes pathologies and must be stated with care, because the test-function spaces are not normed but are topologized by families of seminorms.

Definition 5.2 (Distributions and tempered distributions)**.** A *distribution* is a continuous linear functional $T : \mathcal{D}(\mathbb{R}^n) \to \mathbb{C}$. The space of distributions is denoted $\mathcal{D}'(\mathbb{R}^n)$. A *tempered distribution* is a continuous linear functional $T : \mathcal{S}(\mathbb{R}^n) \to \mathbb{C}$; their space is $\mathcal{S}'(\mathbb{R}^n)$. We write the action of T on a test function as a pairing, $\langle T, \varphi\rangle \in \mathbb{C}$, linear in φ.

Concretely, continuity is the following sequential criterion, which is all we will ever use.

Proposition 5.3 (Continuity criteria)**.** *A linear functional T on $\mathcal{S}(\mathbb{R}^n)$ is a tempered distribution if and only if there exist a constant $C \geq 0$ and an integer $N \geq 0$ such that*

$$\big|\langle T, \varphi\rangle\big| \;\leq\; C \max_{|\alpha|,|\beta|\leq N} \|\varphi\|_{\alpha,\beta} \qquad \text{for all } \varphi \in \mathcal{S}(\mathbb{R}^n). \tag{5.5}$$

Equivalently, $\langle T, \varphi_k\rangle \to 0$ whenever $\|\varphi_k\|_{\alpha,\beta} \to 0$ for every α, β. For $T \in \mathcal{D}'$ the analogous statement holds with the seminorms taken over a fixed compact set containing the supports.

The estimate Eq. (5.5) is the working definition of "tempered": the functional is controlled by *finitely many* seminorms, so it grows at most polynomially. We verify this bound for every functional we introduce; doing so is what certifies membership in $\mathcal{S}'$.

The simplest distributions are the functions themselves. Any locally integrable function f that grows at most polynomially, $|f(x)| \le C(1+|x|)^M$, defines a *regular* tempered distribution T_f by integration,

$$\langle T_f, \varphi \rangle = \int_{\mathbb{R}^n} f(x)\,\varphi(x)\,\mathrm{d}^n x, \tag{5.6}$$

the integral converging absolutely because φ decays faster than f grows. The map $f \mapsto T_f$ is injective (if $\int f\varphi = 0$ for all φ then $f = 0$ almost everywhere), so we may and do identify f with T_f and write $\langle f, \varphi\rangle$ for the integral. This is the precise sense in which distributions *enlarge* the functions rather than replacing them: every reasonable function is a distribution, and the new objects are the ones — like δ — that are *not* of the form T_f for any function f.

We will also need a notion of limit. Because a distribution is known through its pairings, the natural convergence is pairing-by-pairing.

Definition 5.4 (Weak / distributional convergence)**.** A sequence (or net) T_k in $\mathcal{S}'$ *converges weakly* (equivalently, in $\mathcal{S}'$, or in the sense of distributions) to $T \in \mathcal{S}'$ if

$$\langle T_k, \varphi\rangle \;\longrightarrow\; \langle T, \varphi\rangle \qquad \text{for every } \varphi \in \mathcal{S}(\mathbb{R}^n). \tag{5.7}$$

The same definition with $\mathcal{S}$ replaced by $\mathcal{D}$ gives convergence in $\mathcal{D}'$.

This is exactly the topology in which "$i\epsilon \to 0^+$" will be made precise: the family $1/(x+i\epsilon)$, indexed by $\epsilon > 0$, is a net of regular distributions, and its $\epsilon \downarrow 0$ limit is taken in the weak sense of Eq. (5.7), never pointwise.

5.1.3 The Dirac delta, multiplication, and the distributional derivative

Definition 5.5 (Dirac delta)**.** The *Dirac delta* at the origin is the tempered distribution $\delta \in \mathcal{S}'(\mathbb{R}^n)$ defined by evaluation,

$$\langle \delta, \varphi\rangle = \varphi(0), \tag{5.8}$$

and δ_a, the delta at a, by $\langle \delta_a, \varphi\rangle = \varphi(a)$.

That $\delta \in \mathcal{S}'$ is immediate from Theorem 5.3: $|\langle\delta,\varphi\rangle| = |\varphi(0)| \le \sup|\varphi| = \|\varphi\|_{0,0}$, the bound Eq. (5.5) with $C = 1$, $N = 0$. It is *not* a regular distribution: no locally integrable f satisfies $\int f\varphi = \varphi(0)$ for all φ, as one sees by taking bumps φ concentrated away from the origin (forcing $f = 0$ a.e.) and yet demanding

$\varphi(0) \neq 0$. The delta is the cleanest example of a genuinely new object, and the physicist's "function that is zero everywhere but infinite at the origin with unit integral" is just an evocative but incoherent paraphrase of Eq. (5.8).

Two operations on functions extend to distributions *by duality*: one defines the operation on T so that, on regular distributions, it agrees with the ordinary operation under the integral sign. This single principle generates the entire calculus of distributions.

Multiplication by a smooth function. If $T = T_f$ is regular and g is smooth with all derivatives polynomially bounded (so that $g\varphi \in \mathcal{S}$ whenever $\varphi \in \mathcal{S}$), then $\langle gT_f, \varphi\rangle = \int gf\varphi = \int f(g\varphi) = \langle T_f, g\varphi\rangle$. We *define* the product gT for any $T \in \mathcal{S}'$ by this last expression:

$$\langle gT, \varphi\rangle := \langle T, g\varphi\rangle. \tag{5.9}$$

It is a tempered distribution because $\varphi \mapsto g\varphi$ is continuous on $\mathcal{S}$. In particular $\langle g\,\delta, \varphi\rangle = \langle \delta, g\varphi\rangle = g(0)\varphi(0)$, i.e.

$$g(x)\,\delta(x) = g(0)\,\delta(x), \qquad \text{whence} \qquad x\,\delta(x) = 0. \tag{5.10}$$

Note the sharp limitation: *multiplication of two distributions is not defined in general.* There is no consistent meaning for $\delta(x)^2$, and the ultraviolet divergences of QFT are, at root, the failure of products of propagators (themselves distributions) to be distributions — a point we return to when renormalization is built (Chapter 21).

The distributional derivative. Let $f \in C^1$ define a regular distribution. For $\varphi \in \mathcal{D}$ (compact support, so no boundary terms) or $\varphi \in \mathcal{S}$ (rapid decay, so boundary terms vanish at infinity), integration by parts gives, with $\partial_j = \partial/\partial x_j$,

$$\langle \partial_j f, \varphi\rangle = \int (\partial_j f)\,\varphi\,\mathrm{d}^n x = -\int f\,(\partial_j \varphi)\,\mathrm{d}^n x = -\langle f, \partial_j \varphi\rangle. \tag{5.11}$$

The right-hand side makes sense for *any* distribution, since $\partial_j\varphi$ is again a test function. We therefore define the derivative of any $T \in \mathcal{S}'$ (or $\mathcal{D}'$) by

$$\langle \partial_j T, \varphi\rangle := -\langle T, \partial_j \varphi\rangle, \qquad \text{and more generally} \qquad \langle \partial^\alpha T, \varphi\rangle = (-1)^{|\alpha|}\langle T, \partial^\alpha \varphi\rangle. \tag{5.12}$$

This definition has a remarkable consequence, the single structural fact that makes distributions so powerful in field theory.

Theorem 5.6 (Distributions are infinitely differentiable)**.** *Every $T \in \mathcal{D}'(\mathbb{R}^n)$ has derivatives $\partial^\alpha T \in \mathcal{D}'(\mathbb{R}^n)$ of all orders, given by Eq. (5.12); the same holds for every $T \in \mathcal{S}'(\mathbb{R}^n)$ with derivatives in $\mathcal{S}'$. Moreover, mixed partials commute, $\partial_i\partial_j T = \partial_j\partial_i T$.*

Proof. Fix $T \in \mathcal{S}'$ and a multi-index α. The map $\varphi \mapsto (-1)^{|\alpha|}\langle T, \partial^\alpha \varphi\rangle$ is linear. It is continuous: differentiation $\varphi \mapsto \partial^\alpha \varphi$ is continuous on $\mathcal{S}$ because $\|\partial^\alpha \varphi\|_{\gamma,\beta} = \|\varphi\|_{\gamma,\beta+\alpha}$ is itself one of the defining seminorms, so if T obeys the bound Eq. (5.5) with data (C, N) then $\partial^\alpha T$ obeys it with $(C, N + |\alpha|)$. Hence $\partial^\alpha T \in \mathcal{S}'$. Commutativity of mixed partials is inherited from the test functions, where it is the equality of smooth mixed partials of φ: $\langle \partial_i \partial_j T, \varphi\rangle = \langle T, \partial_j \partial_i \varphi\rangle = \langle T, \partial_i \partial_j \varphi\rangle = \langle \partial_j \partial_i T, \varphi\rangle$. The argument for $\mathcal{D}'$ is identical with seminorms restricted to compact sets. □

The content is worth pausing on. An ordinary function need not be differentiable, or even continuous; but *as a distribution* it is differentiable infinitely often, the derivative simply being moved onto the always-smooth test function. The step function, the absolute value, the propagator's discontinuity across the light cone — all are differentiable in $\mathcal{D}'$. The price, and it is the right price, is that the derivative may be a more singular object than the original.

Worked Example 5.7 (The derivatives of the delta)**.** We establish that $\delta' \in \mathcal{S}'(\mathbb{R})$ acts by $\langle \delta', \varphi\rangle = -\varphi'(0)$ and check the definition against an explicit regularization, exactly the kind of regularize-then-remove manoeuvre that the $i\epsilon$ prescription will formalize.

From the definition. Applying Eq. (5.12) with $T = \delta$,

$$\langle \delta', \varphi\rangle = -\langle \delta, \varphi'\rangle = -\varphi'(0), \qquad \text{and} \qquad \langle \delta^{(k)}, \varphi\rangle = (-1)^k \varphi^{(k)}(0). \tag{5.13}$$

This is a tempered distribution: $|\langle \delta', \varphi\rangle| = |\varphi'(0)| \le \|\varphi\|_{0,1}$, the bound Eq. (5.5) with $N = 1$. So δ' has *order one*, one notch more singular than δ.

Justification by regularization. Represent δ as the weak limit of the smooth, normalized Lorentzians

$$\eta_\epsilon(x) = \frac{1}{\pi}\,\frac{\epsilon}{x^2 + \epsilon^2}, \qquad \int_{-\infty}^{\infty} \eta_\epsilon(x)\,\mathrm{d}x = 1, \tag{5.14}$$

which we prove converge to δ in Eq. (5.28) below. Each η_ϵ is a genuine smooth function, so its derivative is the ordinary one, and integration by parts (the boundary terms vanish because η_ϵ and φ decay) gives

$$\langle \eta_\epsilon', \varphi\rangle = \int_{-\infty}^{\infty} \eta_\epsilon'(x)\,\varphi(x)\,\mathrm{d}x = -\int_{-\infty}^{\infty} \eta_\epsilon(x)\,\varphi'(x)\,\mathrm{d}x \xrightarrow[\epsilon \to 0^+]{} -\varphi'(0). \tag{5.15}$$

The limit is $-\varphi'(0)$ because $\eta_\epsilon \to \delta$ weakly applied to the test function $\varphi' \in \mathcal{S}$. Thus $\eta_\epsilon' \to \delta'$ in $\mathcal{S}'$, and the abstract definition Eq. (5.13) agrees with the regularized object in the weak limit. This is the template for the whole section: a singular distribution is the weak limit of a one-parameter family of honest functions, and operations on it are operations on the family, taken under the limit.

5.1.4 The Cauchy principal value

The function $1/x$ is not locally integrable at the origin, so the naive prescription Eq. (5.6) fails: $\int \varphi(x)/x\,\mathrm{d}x$ diverges for a generic φ with $\varphi(0) \neq 0$. The cure is to excise a symmetric neighborhood of the singularity and let it shrink, so that the divergent contributions from $x > 0$ and $x < 0$ cancel before they can blow up.

Definition 5.8 (Cauchy principal value)**.** The *principal value* of $1/x$ is the functional

$$\left\langle \mathrm{PV}\tfrac{1}{x},\ \varphi \right\rangle = \mathrm{PV}\int_{-\infty}^{\infty} \frac{\varphi(x)}{x}\,\mathrm{d}x := \lim_{\delta\to 0^+} \int_{|x|\geq\delta} \frac{\varphi(x)}{x}\,\mathrm{d}x, \qquad \varphi \in \mathcal{S}(\mathbb{R}). \tag{5.16}$$

That the symmetric limit exists, and defines a tempered distribution, is not automatic and must be shown; the symmetric exclusion is doing real work.

Worked Example 5.9 ($\mathrm{PV}\,1/x$ is a well-defined tempered distribution)**.** We prove the limit Eq. (5.16) exists for every $\varphi \in \mathcal{S}(\mathbb{R})$ and obeys the continuity bound Eq. (5.5).

Existence. Split the excised integral at $|x| = 1$ and combine the contributions from $\pm x$ on the inner region. On $\delta \leq |x| \leq 1$, pairing x with $-x$,

$$\int_{\delta\leq|x|\leq 1} \frac{\varphi(x)}{x}\,\mathrm{d}x = \int_{\delta}^{1} \frac{\varphi(x) - \varphi(-x)}{x}\,\mathrm{d}x. \tag{5.17}$$

The integrand is the heart of the matter. By the mean value theorem (or by Taylor with remainder), $\varphi(x) - \varphi(-x) = 2x\,\varphi'(\xi_x)$ for some $\xi_x \in (-x, x)$, so

$$\frac{\varphi(x) - \varphi(-x)}{x} \xrightarrow[x\to 0^+]{} 2\varphi'(0), \qquad \left|\frac{\varphi(x) - \varphi(-x)}{x}\right| \leq 2 \sup_{|t|\leq 1} |\varphi'(t)| \leq 2\,\|\varphi\|_{0,1}\,. \tag{5.18}$$

The integrand is therefore bounded on $(0, 1]$ and extends continuously to $x = 0$, so $\int_\delta^1$ converges to $\int_0^1$ as $\delta \to 0^+$: the inner limit exists. The outer piece $\int_{|x|\geq 1} \varphi(x)/x\,\mathrm{d}x$ is independent of δ and converges absolutely, since $|\varphi(x)/x| \leq |\varphi(x)|$ there and φ is integrable. Hence the full limit Eq. (5.16) exists.

Temperedness. Bound the two pieces. From Eq. (5.18),

$$\left|\int_0^1 \frac{\varphi(x) - \varphi(-x)}{x}\,\mathrm{d}x\right| \leq 2\,\|\varphi\|_{0,1}\,. \tag{5.19}$$

For the tail, insert and remove a factor x^2 and use that $(1 + x^2)\varphi$ is bounded by a seminorm:

$$\left|\int_{|x|\geq 1} \frac{\varphi(x)}{x}\,\mathrm{d}x\right| \leq \int_{|x|\geq 1} \frac{|(1+x^2)\varphi(x)|}{|x|\,(1+x^2)}\,\mathrm{d}x \leq (\|\varphi\|_{0,0} + \|\varphi\|_{2,0}) \int_{|x|\geq 1} \frac{\mathrm{d}x}{|x|(1+x^2)}. \tag{5.20}$$

The remaining integral is a finite number ($2\int_1^\infty \mathrm{d}x/(x+x^3) = \ln 2$). Adding the two estimates,

$$\left|\langle \mathrm{PV}\tfrac{1}{x}, \varphi\rangle\right| \le 2\,\|\varphi\|_{0,1} + (\ln 2)(\|\varphi\|_{0,0} + \|\varphi\|_{2,0}) \le C \max_{|\alpha|,|\beta|\le 2} \|\varphi\|_{\alpha,\beta}\,, \tag{5.21}$$

which is the bound Eq. (5.5) with $N = 2$. Therefore $\mathrm{PV}\,1/x \in \mathcal{S}'(\mathbb{R})$, of order at most one (the only derivative of φ that entered is the first).

The principal value is exactly the odd part of $1/x$ tamed: the even singularity would survive the symmetric limit and diverge, but $1/x$ is odd, and the symmetric excision lets the antisymmetry cancel the pole. This is the structural fact that the Sokhotski–Plemelj formula now turns into an identity between boundary values.

5.1.5 The Sokhotski–Plemelj formula

We can now prove the first load-bearing result of the chapter. The objects $1/(x \pm i\epsilon)$ are, for each fixed $\epsilon > 0$, perfectly ordinary smooth bounded functions of the real variable x (the denominator never vanishes); each is a regular tempered distribution. The claim is that their $\epsilon \downarrow 0$ limits exist in $\mathcal{S}'$ and split cleanly into the principal value and a delta.

Theorem 5.10 (Sokhotski–Plemelj)**.** *As $\epsilon \to 0^+$, the following limits hold in $\mathcal{S}'(\mathbb{R})$:*

$$\frac{1}{x \pm i\epsilon} \xrightarrow[\epsilon\to 0^+]{} \mathrm{PV}\frac{1}{x} \;\mp\; i\pi\,\delta(x). \tag{5.22}$$

Explicitly, for every $\varphi \in \mathcal{S}(\mathbb{R})$,

$$\lim_{\epsilon\to 0^+} \int_{-\infty}^{\infty} \frac{\varphi(x)}{x \pm i\epsilon}\,\mathrm{d}x = \mathrm{PV}\int_{-\infty}^{\infty} \frac{\varphi(x)}{x}\,\mathrm{d}x \;\mp\; i\pi\,\varphi(0). \tag{5.23}$$

Proof. Take the upper sign throughout; the lower sign follows by complex conjugation, since $1/(x - i\epsilon) = \overline{1/(x + i\epsilon)}$ for real x. Rationalize the denominator by multiplying by the conjugate,

$$\frac{1}{x + i\epsilon} = \frac{x - i\epsilon}{(x + i\epsilon)(x - i\epsilon)} = \frac{x}{x^2 + \epsilon^2} \;-\; i\,\frac{\epsilon}{x^2 + \epsilon^2}, \tag{5.24}$$

a clean separation into a real part (odd in x) and an imaginary part (even in x). We treat the two parts as separate weak limits and add the results.

Imaginary part: a nascent delta. The imaginary part is $-i$ times $\epsilon/(x^2+\epsilon^2) = \pi\,\eta_\epsilon(x)$, the normalized Lorentzian of Eq. (5.14). First, its mass is fixed for every ϵ: with $x = \epsilon u$,

$$\int_{-\infty}^{\infty} \frac{\epsilon}{x^2 + \epsilon^2}\,\mathrm{d}x = \int_{-\infty}^{\infty} \frac{\mathrm{d}u}{1 + u^2} = \big[\arctan u\big]_{-\infty}^{\infty} = \pi. \tag{5.25}$$

Now pair against φ and subtract the expected answer, using Eq. (5.25) to write $\pi\varphi(0) = \int \frac{\epsilon}{x^2+\epsilon^2}\varphi(0)\,\mathrm{d}x$:

$$\int_{-\infty}^{\infty} \frac{\epsilon}{x^2+\epsilon^2}\,\varphi(x)\,\mathrm{d}x - \pi\,\varphi(0) = \int_{-\infty}^{\infty} \frac{\epsilon}{x^2+\epsilon^2}\,\big[\varphi(x)-\varphi(0)\big]\,\mathrm{d}x. \tag{5.26}$$

Substitute $x = \epsilon u$ again ($\mathrm{d}x = \epsilon\,\mathrm{d}u$, and $\epsilon\cdot\epsilon/(\epsilon^2u^2+\epsilon^2) = 1/(1+u^2)$):

$$\int_{-\infty}^{\infty} \frac{\epsilon}{x^2+\epsilon^2}\,\big[\varphi(x)-\varphi(0)\big]\,\mathrm{d}x = \int_{-\infty}^{\infty} \frac{\varphi(\epsilon u)-\varphi(0)}{1+u^2}\,\mathrm{d}u. \tag{5.27}$$

The integrand converges pointwise to 0 as $\epsilon \to 0^+$ (because φ is continuous, $\varphi(\epsilon u)\to\varphi(0)$ for each fixed u), and it is dominated by the fixed integrable function $2\,\|\varphi\|_{0,0}/(1+u^2)$ since $|\varphi(\epsilon u)-\varphi(0)| \le 2\sup|\varphi|$. By dominated convergence the integral tends to 0. Therefore

$$\int_{-\infty}^{\infty} \frac{\epsilon}{x^2+\epsilon^2}\,\varphi(x)\,\mathrm{d}x \xrightarrow[\epsilon\to0^+]{} \pi\,\varphi(0), \qquad \text{i.e.} \qquad \frac{\epsilon}{x^2+\epsilon^2} \xrightarrow{\mathcal{S}'} \pi\,\delta(x). \tag{5.28}$$

This also discharges the promise made in Theorem 5.7: $\eta_\epsilon = \frac{1}{\pi}\frac{\epsilon}{x^2+\epsilon^2} \to \delta$ weakly. The imaginary part of Eq. (5.24) thus contributes $-i\pi\,\varphi(0)$ in the limit.

Real part: the principal value. We show that, against any $\varphi \in \mathcal{S}$,

$$\int_{-\infty}^{\infty} \frac{x}{x^2+\epsilon^2}\,\varphi(x)\,\mathrm{d}x \xrightarrow[\epsilon\to0^+]{} \mathrm{PV}\int_{-\infty}^{\infty} \frac{\varphi(x)}{x}\,\mathrm{d}x. \tag{5.29}$$

Split the real integral at $|x| = 1$, exactly as in Theorem 5.9. On $|x| \le 1$, the function $x/(x^2+\epsilon^2)$ is odd, so the constant part of φ integrates to zero for every ϵ:

$$\int_{-1}^{1} \frac{x}{x^2+\epsilon^2}\,\varphi(0)\,\mathrm{d}x = 0. \tag{5.30}$$

Write $\varphi(x) = \varphi(0) + x\,\psi(x)$, where Hadamard's lemma gives the explicit smooth remainder

$$\psi(x) = \int_0^1 \varphi'(tx)\,\mathrm{d}t, \qquad \psi \in C^\infty, \quad \psi(0) = \varphi'(0). \tag{5.31}$$

Then, using Eq. (5.30),

$$\int_{-1}^{1} \frac{x}{x^2+\epsilon^2}\,\varphi(x)\,\mathrm{d}x = \int_{-1}^{1} \frac{x^2}{x^2+\epsilon^2}\,\psi(x)\,\mathrm{d}x. \tag{5.32}$$

As $\epsilon\to0^+$ the factor $x^2/(x^2+\epsilon^2)$ increases to 1 for $x \neq 0$ and is bounded by 1; since ψ is bounded on $[-1,1]$, dominated convergence gives $\int_{-1}^{1}\frac{x^2}{x^2+\epsilon^2}\psi\,\mathrm{d}x \to \int_{-1}^{1}\psi(x)\,\mathrm{d}x$. On the other side, the principal value over the same region is, by the identical decomposition (the $\varphi(0)/x$ term vanishes in the symmetric limit because it is odd),

$$\mathrm{PV}\int_{-1}^{1}\frac{\varphi(x)}{x}\,\mathrm{d}x = \lim_{\delta\to0^+}\int_{\delta\le|x|\le1}\frac{\varphi(0)+x\psi(x)}{x}\,\mathrm{d}x = \int_{-1}^{1}\psi(x)\,\mathrm{d}x. \tag{5.33}$$

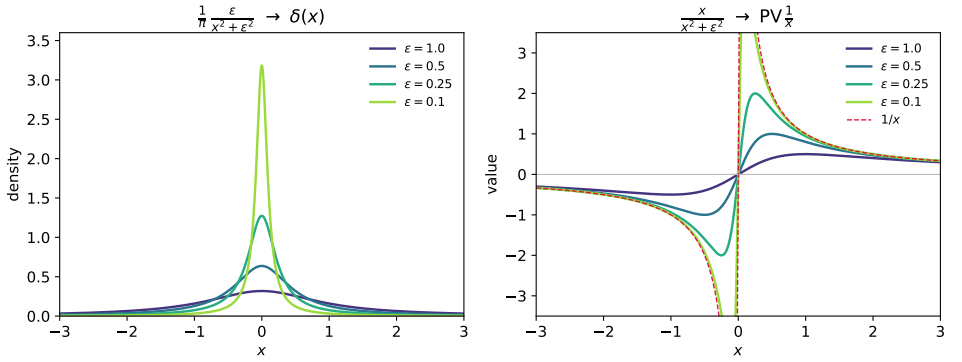

Figure 5.1: The Sokhotski–Plemelj decomposition $1/(x - i\epsilon) = x/(x^2 + \epsilon^2) + i\,\epsilon/(x^2 + \epsilon^2)$. Left: the imaginary part is the normalized Lorentzian $\frac{1}{\pi}\frac{\epsilon}{x^2+\epsilon^2}$, a nascent delta of fixed unit mass that concentrates at the origin as $\epsilon \to 0^+$ (Eq. (5.28)). Right: the real part $x/(x^2 + \epsilon^2)$ (odd in x) regularizes the pole of $1/x$ (dashed) at the origin and reproduces it elsewhere, converging weakly to $\mathrm{PV}\,1/x$ (Eq. (5.29)).

The inner contributions match. For the tail $|x| \geq 1$, the integrand $x\varphi(x)/(x^2+\epsilon^2)$ converges pointwise to $\varphi(x)/x$ and is dominated by the integrable $|\varphi(x)|/|x| \leq |\varphi(x)|$ uniformly in $\epsilon \leq 1$ (since $x^2 + \epsilon^2 \geq x^2$ there), so dominated convergence gives $\int_{|x|\geq 1} \to \int_{|x|\geq 1} \varphi(x)/x\,\mathrm{d}x$, which is the (absolutely convergent) tail of the principal value. Adding inner and tail establishes Eq. (5.29).

Assembly. Combining the real and imaginary limits in Eq. (5.24),

$$\int_{-\infty}^{\infty} \frac{\varphi(x)}{x + i\epsilon}\,\mathrm{d}x \xrightarrow[\epsilon\to 0^+]{} \mathrm{PV}\int_{-\infty}^{\infty} \frac{\varphi(x)}{x}\,\mathrm{d}x \;-\; i\pi\,\varphi(0), \tag{5.34}$$

which is Eq. (5.23) with the upper sign. Conjugation flips the sign of the imaginary part and fixes the (real) principal value, giving the lower sign and completing the proof. □

Figure 5.1 shows the two halves of Eq. (5.24) in action: the even Lorentzian narrowing into the delta, and the odd $x/(x^2 + \epsilon^2)$ flattening onto $1/x$ away from the origin while staying finite at it.

Physical Insight

The sign of the $i\epsilon$ chooses which way an infinitesimal contour skirts the pole, and the $\mp i\pi\delta$ records the half-residue picked up in passing. This is the seed of every contour prescription in the book. The same formula, read in energy, separates a real *dispersive* part (PV) from an imaginary *absorptive* part (δ); read on the propagator's mass shell it is the statement that the real part of $i/(p^2 - m^2 + i\epsilon)$ is a delta enforcing $p^2 = m^2$, i.e.

on-shell particle production. The Feynman prescription's $+i\epsilon$ is precisely the choice in Eq. (5.22); the link between this analytic choice and causality is developed when the propagator is constructed in Chapter 9, and its physical face — the optical theorem — in Chapter 14.

Caution

The decomposition Eq. (5.22) is an identity *between distributions*, valid only under an integral against a test function. Reading it pointwise — "$1/(x+i\epsilon)$ equals $1/x$ except at the origin where it is $-i\pi\delta$" — is meaningless: δ has no values, and $1/x$ is not locally integrable. Every manipulation of $i\epsilon$ factors in this book is, at bottom, an application of Theorem 5.10 inside a (momentum) integral, and is legitimate exactly to the extent that such an integral is present.

5.1.6 Order, support, and the structure of tempered distributions

We have repeatedly read off how many derivatives of φ a functional needs: δ needed none, δ' one, $\mathrm{PV}\,1/x$ one. This is a genuine invariant.

Definition 5.11 (Order and support)**.** A distribution T has *finite order* if the bound Eq. (5.5) (restricted to a fixed compact set, for $T \in \mathcal{D}'$) holds for some N; the least such N is the *order* $\operatorname{ord} T$. The *support* $\operatorname{supp} T$ is the complement of the largest open set U on which T vanishes, where T *vanishes on* U means $\langle T, \varphi\rangle = 0$ for every test function φ with $\operatorname{supp}\varphi \subset U$.

Thus $\operatorname{ord}\delta = 0$, $\operatorname{ord}\delta^{(k)} = k$, $\operatorname{ord}(\mathrm{PV}\,1/x) = 1$; and $\operatorname{supp}\delta = \{0\} = \operatorname{supp}\delta^{(k)}$, while $\operatorname{supp}(\mathrm{PV}\,1/x) = \mathbb{R}$. A regular distribution T_f has order 0 and support equal to the (essential) support of f. Distributions supported at a single point are completely classified — they are exactly the finite linear combinations of δ and its derivatives there — a fact we will invoke when local counterterms are characterized in Chapter 21.

The examples are not accidental in their tameness. Every tempered distribution, however singular it looks, is a finite number of derivatives of an ordinary, mildly-growing *function* — which is why distribution theory is exactly the right enlargement of the functions and no larger. We state this at the level the book uses it (the proof is a standard application of the Fourier characterization of $\mathcal{S}'$ developed in Section 5.2, and we do not need its details).

Theorem 5.12 (Structure of tempered distributions)**.** *Every $T \in \mathcal{S}'(\mathbb{R}^n)$ has finite order, and there exist a multi-index α and a continuous function $F : \mathbb{R}^n \to \mathbb{C}$*

of polynomial growth, $|F(x)| \le C(1+|x|)^M$*, such that*

$$T = \partial^\alpha F \qquad \textit{(distributional derivative).} \tag{5.35}$$

That is, the tempered distributions are precisely the finite-order distributional derivatives of polynomially bounded continuous functions.

The theorem dignifies every singular object we have met: $\delta = \theta'$ is one derivative of the bounded Heaviside step θ (a fact we verify directly once the step's distributional derivative is computed in Section 5.2), and $\mathrm{PV}\,1/x = (\ln|x|)'$ is one derivative of the locally integrable, polynomially-bounded $\ln|x|$ — as one checks by integration by parts against a test function, using oddness exactly as in Eq. (5.17). The propagators of QFT will be no worse: distributions of finite order, derivatives of honest functions, manipulated only inside integrals.

With the singular objects of daily QFT now precisely defined — δ, its derivatives, $\mathrm{PV}\,1/x$, and the boundary values $1/(x \pm i\epsilon)$ — and with weak convergence as the meaning of every limit, we have the vector space $\mathcal{S}'$ on which differentiation is unconditional and the $i\epsilon$ rule is a theorem rather than a slogan. The Sokhotski–Plemelj formula already hints that these objects are most transparent in momentum language: an $i\epsilon$ turned into a δ, a pole into an on-shell condition. To exploit that, we need to carry the Fourier transform from Schwartz functions onto all of $\mathcal{S}'$ by the same duality that built the derivative here — the task of Section 5.2.

5.2 Tempered distributions and the Fourier transform

The previous section gave singular objects a rigorous home: the delta, its derivatives, the principal value, and the boundary values $1/(x \pm i\epsilon)$ are all distributions, and the Sokhotski–Plemelj identity Theorem 5.10 showed that an $i\epsilon$ in a denominator is precisely a packaging of a principal value together with a delta. That identity already contains, in miniature, the entire analytic content of a propagator. What it does not yet contain is the *momentum-space* face of the same object. Every propagator the reader will meet—the scalar $i/(p^2 - m^2 + i\epsilon)$, the photon, the Dirac $i(\not{p} + m)/(p^2 - m^2 + i\epsilon)$—is written in momentum space, and every loop integral is an integral over momenta. The bridge between the position-space distributions of Section 5.1 (the previous section) and these momentum-space expressions is the Fourier transform. We therefore now do for the Fourier transform what Section 5.1 did for differentiation: we extend it from nice functions, where it is elementary, to distributions, where it is indispensable.

The extension is not automatic. The Fourier transform trades smoothness for decay and decay for smoothness, so a test space adapted to it must control *both* at once; the compactly supported test functions of the previous section will not

do, for a sharp reason we make precise below. The right space is Schwartz space, and the distributions it supports are the *tempered* distributions—exactly the class to which every propagator, vertex function, and correlation function in this book belongs. Once we have the transform on this class, the rules that physicists use daily ($\partial_\mu \leftrightarrow$ momentum, product$\leftrightarrow$ convolution, translation$\leftrightarrow$phase) become theorems, and the handful of transforms that underlie every Feynman computation ($\hat{\delta} = 1$, $\widehat{1} = (2\pi)^n \delta$, the self-dual Gaussian, the transform of the step function) become one-line consequences. We close by writing the Feynman propagator as the tempered distribution it is, reading its $i\epsilon$ through Sokhotski–Plemelj, and handing the resulting momentum integral to the contour calculus of the next section.

5.2.1 Why a new test space: Schwartz functions

The test functions of the previous section were the smooth, compactly supported functions $\mathcal{D} = C_c^\infty(\mathbb{R}^n)$. They are an excellent probe for *local* questions, but they are catastrophically ill-suited to the Fourier transform, and the reason is structural rather than technical.

Proposition 5.13 (Compact support is not Fourier-stable)**.** *If $\varphi \in C_c^\infty(\mathbb{R}^n)$ is not identically zero, then its Fourier transform $\hat{\varphi}$ extends to an entire analytic function on $\mathbb{C}^n$ and therefore cannot have compact support.*

Proof. Write $\hat{\varphi}(k) = \int_{\mathbb{R}^n} d^n x\, e^{ik\cdot x}\varphi(x)$ with φ supported in a ball of radius R. For complex $k = u + iv$ the integrand is $e^{iu\cdot x}e^{-v\cdot x}\varphi(x)$, bounded in modulus by $e^{R|v|}\,|\varphi(x)|$ on the compact support, so the integral converges for every $k \in \mathbb{C}^n$ and may be differentiated under the integral sign in each complex variable; $\hat{\varphi}$ is entire. An entire function that vanishes on an open set vanishes identically (it is determined by its Taylor series at any point), and an entire function of one variable with compact support would vanish on the complement of a compact set, hence everywhere; the same holds variable by variable. Thus $\hat{\varphi} \equiv 0$, contradicting the inversion formula $\varphi = \mathcal{F}^{-1}\hat{\varphi}$ unless $\varphi \equiv 0$. □

So the Fourier transform pushes us out of $\mathcal{D}$ immediately. The cure is to ask of test functions not compact support but *rapid decay*, symmetrically in position and momentum: a function should decay faster than any inverse polynomial, and so should all its derivatives. This is exactly the property that the derivative$\leftrightarrow$multiplication rule of the Fourier transform preserves, which is why the resulting space is the natural one.

This is exactly the Schwartz space introduced in the previous section, and we use it without redefinition. We recall (Theorem 5.1) that $\mathcal{S}(\mathbb{R}^n)$ consists of the $f \in C^\infty(\mathbb{R}^n)$ for which every seminorm

$$\|f\|_{\alpha,\beta} \;:=\; \sup_{x\in\mathbb{R}^n} \left| x^\alpha\, \partial^\beta f(x) \right| \tag{5.36}$$

is finite for all multi-indices $\alpha, \beta \in \mathbb{N}_0^n$ (here $x^\alpha = x_1^{\alpha_1} \cdots x_n^{\alpha_n}$ and $\partial^\beta = \partial_1^{\beta_1} \cdots \partial_n^{\beta_n}$): every derivative decays faster than every inverse power, so smoothness and decay are controlled on an equal footing. Convergence $f_j \to f$ in $\mathcal{S}$ means $\|f_j - f\|_{\alpha,\beta} \to 0$ for every α, β. The Gaussian $e^{-|x|^2/2}$ is the prototype, and the previous section recorded the strict inclusions $C_c^\infty(\mathbb{R}^n) \subset \mathcal{S}(\mathbb{R}^n) \subset C^\infty(\mathbb{R}^n)$ (Eq. (5.4)). The one new structural remark we need is its consequence for the dual spaces: because $\mathcal{D} \subset \mathcal{S}$, every continuous linear functional on $\mathcal{S}$ restricts to one on $\mathcal{D}$, so the tempered distributions form a *subclass* of the distributions of the previous section, $\mathcal{S}'(\mathbb{R}^n) \subset \mathcal{D}'(\mathbb{R}^n)$ — the price of demanding continuity against the larger probe space $\mathcal{S}$ is that the functional may grow no faster than a polynomial.

The objects we transform are therefore the tempered distributions $\mathcal{S}'(\mathbb{R}^n)$ already defined in Theorem 5.2: the continuous linear functionals $T\colon \mathcal{S}(\mathbb{R}^n) \to \mathbb{C}$, where continuity is the bound of Theorem 5.3, namely the existence of a constant C and an integer N with $|\langle T, \varphi\rangle| \le C \max_{|\alpha|,|\beta|\le N} \|\varphi\|_{\alpha,\beta}$ for all $\varphi \in \mathcal{S}$. We restate the membership criterion here only because the entire Fourier construction below is one long verification of it: every transform we build is shown to obey this bound.

The word "tempered" refers to temperate (at most polynomial) growth, and the examples make the point. Every polynomially bounded locally integrable function g—in particular every bounded function, every L^1 or L^2 function, the constant 1, and any polynomial—defines a tempered distribution by $\langle g, \varphi\rangle = \int g\varphi$, the integral converging because φ kills any polynomial growth. The delta δ, its derivatives $\partial^\beta \delta$, the principal value $\mathrm{PV}(1/x)$, and the boundary values $1/(x \pm i\epsilon)$ from Section 5.1 are all tempered (each is bounded by finitely many Schwartz seminorms, as the previous section's estimates show). What is *not* tempered is anything growing faster than every polynomial: e^x on $\mathbb{R}$ is not a tempered distribution, because pairing it against a Schwartz function need not converge and, more to the point, its "Fourier transform" would be a delta displaced into the complex plane, outside $\mathcal{S}'$. The restriction to temperate growth is exactly the price of a well-defined Fourier transform, and it is a price QFT is always willing to pay: fields, propagators, and amplitudes are tempered.

5.2.2 The Fourier transform on Schwartz space

We fix the convention once, in line with the book's standing choice (Appendix A, Chapter A); every (2π) and every sign below follows from it.

Notation Watch

Throughout the book the Fourier transform and its inverse are

$$\hat{f}(k) \equiv (\mathcal{F}f)(k) = \int_{\mathbb{R}^n} d^n x\, e^{ik\cdot x}\, f(x), \qquad f(x) = \int_{\mathbb{R}^n} \frac{d^n k}{(2\pi)^n}\, e^{-ik\cdot x}\, \hat{f}(k), \tag{5.37}$$

so that *all* factors of $(2\pi)^{-1}$ sit on the momentum-integral (inverse) side, and the forward transform carries the sign $e^{+ik\cdot x}$. This is the spacetime convention of Chapter A read with the *Euclidean* dot product $k\cdot x = \sum_j k_j x_j$; for the Minkowski spacetime transform one replaces $k\cdot x$ by the metric pairing $k\cdot x = k^0 x^0 - \mathbf{k}\cdot\mathbf{x}$, which is the same formula after a relabelling of signs (a linear change of variables of unit Jacobian, since $|\det \eta| = 1$) and changes none of the results of this subsection. We write n for the dimension in the abstract development and specialize to $n = 4$ for the propagator.

Because $f \in \mathcal{S} \subset L^1$, the integral in Eq. (5.37) converges absolutely and $\hat{f}$ is a bounded continuous function. The first task is to show that $\hat{f}$ is again Schwartz, and the engine is the pair of rules that turn calculus in x into algebra in k. They follow from a single integration by parts and a single differentiation under the integral sign.

The transform dictionary. For $f \in \mathcal{S}$ and any index j, integrate $\int e^{ik\cdot x}\partial_{x_j} f\, d^n x$ by parts (boundary terms vanish by rapid decay) and differentiate $\hat{f}$ under the integral; one finds

$$\widehat{\partial_{x_j} f}(k) = -\,i\,k_j\,\hat{f}(k), \tag{5.38}$$

$$\widehat{x_j f}\,(k) = -\,i\,\partial_{k_j}\hat{f}(k). \tag{5.39}$$

Differentiation in position becomes multiplication by momentum, and multiplication by position becomes differentiation in momentum. Iterating, $\widehat{\partial^\beta f} = (-ik)^\beta \hat{f}$ and $\widehat{x^\alpha f} = (-i\partial_k)^\alpha \hat{f}$, where $(-ik)^\beta = \prod_j (-ik_j)^{\beta_j}$. Two further rules round out the dictionary, each a one-line change of variables in Eq. (5.37): for the translate $(\tau_a f)(x) := f(x-a)$ and the modulated function $e^{ib\cdot x} f(x)$,

$$\widehat{\tau_a f}(k) = e^{\,ik\cdot a}\,\hat{f}(k), \qquad \widehat{e^{\,ib\cdot x} f}(k) = \hat{f}(k+b), \tag{5.40}$$

so *translation becomes a phase and a phase becomes a translation*; and for the rescaling $f(\lambda x)$ with $\lambda > 0$,

$$\widehat{f(\lambda\,\cdot)}(k) = \lambda^{-n}\,\hat{f}(k/\lambda), \tag{5.41}$$

the contraction in position dilating into momentum. Finally the two rules that the interacting theory lives on. Recall the convolution $(f*g)(x) = \int f(y)\, g(x-y)\, d^n y$;

for $f, g \in \mathcal{S}$ a direct application of Fubini's theorem to Eq. (5.37) gives the *convolution theorem* and its dual,

$$\widehat{f * g} = \hat{f}\,\hat{g}, \tag{5.42}$$

$$\widehat{f\,g} = \tfrac{1}{(2\pi)^n}\,\hat{f} * \hat{g}. \tag{5.43}$$

The first is immediate: $\widehat{f*g}(k) = \int d^n y\, f(y) e^{iky} \int d^n z\, g(z) e^{ikz} = \hat{f}(k)\hat{g}(k)$ after writing $z = x - y$. The second follows by inserting the inverse transform of f and using Eq. (5.40); the $(2\pi)^{-n}$ is the price of the convention's asymmetric placement of 2π's. *Convolution becomes pointwise product, and pointwise product becomes convolution*—the statement that interactions, which are pointwise products of fields, become momentum-space convolutions, i.e. the momentum-conserving integrals at vertices. On $\mathcal{S}$ both sides are unambiguous because the product and convolution of Schwartz functions are again Schwartz; on $\mathcal{S}'$ they hold only when one factor is regular enough to make the operation legal, a caveat we return to in Section 5.2.5.

Equipped with the dictionary, the central structural fact is now within reach.

Theorem 5.14 ($\mathcal{F}$ is a continuous bijection of $\mathcal{S}$)**.** *The Fourier transform Eq. (5.37) maps $\mathcal{S}(\mathbb{R}^n)$ into itself, continuously, and is a bijection whose inverse is the second formula in Eq. (5.37). Explicitly, $(\mathcal{F}^{-1}g)(x) = (2\pi)^{-n}\hat{g}(-x)$, so $\mathcal{F}^4 = (2\pi)^{2n}\,(\text{parity})^2 = (2\pi)^{2n}\,\mathrm{id}$ after the appropriate rescaling.*

Proof. Step 1: $\hat{f} \in \mathcal{S}$. For any multi-indices α, β, combine Eqs. (5.38) and (5.39):

$$k^\alpha\, \partial_k^\beta\, \hat{f}(k) \;=\; k^\alpha\, \widehat{(ix)^\beta f}(k) \;=\; (+i)^{|\beta|}(+i)^{|\alpha|}\, \widehat{\partial_x^\alpha (x^\beta f)}(k), \tag{5.44}$$

where in the last step we used Eq. (5.38) in reverse, turning the factor k^α into the transform of ∂_x^α of the argument. The function $\partial_x^\alpha(x^\beta f)$ is a finite sum of terms $x^{\beta'}\partial_x^{\alpha'} f$, each in $\mathcal{S} \subset L^1$; hence its Fourier transform is bounded, with

$$\left\|\hat{f}\right\|_{\alpha,\beta} = \sup_k \left|k^\alpha \partial_k^\beta \hat{f}(k)\right| \le \int_{\mathbb{R}^n} \left|\partial_x^\alpha (x^\beta f)\right| d^n x \le C_{\alpha,\beta} \sum_{\alpha' \le \alpha,\, \beta' \le \beta} \|f\|_{\beta',\alpha'}\ , \tag{5.45}$$

the last inequality because the L^1 norm of a Schwartz function is controlled by finitely many of its sup-seminorms (multiply and divide by $(1+|x|^2)^n$, whose reciprocal is integrable). Every Schwartz seminorm of $\hat{f}$ is finite, so $\hat{f} \in \mathcal{S}$; and Eq. (5.45) is exactly the estimate stating that $\mathcal{F}\colon \mathcal{S} \to \mathcal{S}$ is *continuous*.

Step 2: the multiplication formula. For $f, g \in \mathcal{S}$, Fubini's theorem applied to the absolutely convergent double integral gives the symmetric identity that lets one "move the hat":

$$\int_{\mathbb{R}^n} \hat{f}(x)\, g(x)\, d^n x = \iint e^{ix\cdot y} f(y) g(x)\, d^n y\, d^n x = \int_{\mathbb{R}^n} f(y)\, \hat{g}(y)\, d^n y. \tag{5.46}$$

This is Theorem 5.15 below; it is the seed of the duality definition in the next subsection.

Step 3: inversion. We must show $f = \mathcal{F}^{-1}\mathcal{F}f$, i.e. $f(x) = \int \frac{d^n k}{(2\pi)^n} e^{-ik\cdot x}\hat{f}(k)$. Regulate the k-integral with a Gaussian and write $\hat{f}$ out:

$$I_\epsilon(x) := \int \frac{d^n k}{(2\pi)^n}\, e^{-ik\cdot x}\, e^{-\epsilon|k|^2/2}\, \hat{f}(k) = \int_{\mathbb{R}^n} d^n y\, f(y) \underbrace{\int \frac{d^n k}{(2\pi)^n}\, e^{\,ik\cdot(y-x)-\epsilon|k|^2/2}}_{=\,G_\epsilon(y-x)}. \tag{5.47}$$

The inner k-integral is the Gaussian transform computed in Theorem 5.16 below: with the normalization there, $G_\epsilon(b) = (2\pi\epsilon)^{-n/2} e^{-|b|^2/2\epsilon}$, a Gaussian of total mass $\int G_\epsilon = 1$ and width $\sqrt{\epsilon}$. Thus $I_\epsilon = f * G_\epsilon$ is the convolution of f with an approximate identity, so $I_\epsilon(x) \to f(x)$ pointwise (indeed uniformly) as $\epsilon \to 0^+$, because f is continuous and G_ϵ concentrates at the origin. On the other hand, since $\hat{f} \in \mathcal{S} \subset L^1$, dominated convergence gives $I_\epsilon(x) \to \int \frac{d^n k}{(2\pi)^n} e^{-ik\cdot x}\hat{f}(k)$. Equating the two limits proves the inversion formula. Inversion makes $\mathcal{F}$ injective (it has a left inverse) and surjective (it has a right inverse), hence a bijection; the explicit form $\mathcal{F}^{-1}g = (2\pi)^{-n}\hat{g}(-\cdot)$ is read directly from Eq. (5.37). □

Lemma 5.15 (Multiplication formula / Parseval on $\mathcal{S}$)**.** *For all $f, g \in \mathcal{S}(\mathbb{R}^n)$, $\int \hat{f}\, g = \int f\, \hat{g}$, and consequently the Plancherel identity $\int |f|^2 = (2\pi)^{-n} \int \left|\hat{f}\right|^2$ holds.*

Proof. The first identity is Eq. (5.46). For Plancherel apply it with $g = \overline{\mathcal{F}^{-1}\bar{f}}$ and use inversion; the constant $(2\pi)^{-n}$ is again the convention's bookkeeping. We will not need Plancherel until the spectral discussions of later chapters, but record it here for completeness. □

The Gaussian computation that powers inversion is worth isolating, both because the result is used constantly and because the contour shift that appears in it is the first instance of the analytic-continuation move that organizes the whole chapter.

Worked Example 5.16 (The Gaussian is its own transform)**.** We evaluate $\hat{g}(k) = \int_{\mathbb{R}^n} d^n x\, e^{ik\cdot x}\, e^{-a|x|^2/2}$ for a constant a with $\operatorname{Re} a > 0$. The integrand factorizes over coordinates, so it suffices to do the one-dimensional integral

$$\mathcal{I}(\kappa) = \int_{-\infty}^{\infty} dx\, e^{\,i\kappa x - \frac{a}{2}x^2}. \tag{5.48}$$

Complete the square in the exponent: $i\kappa x - \frac{a}{2}x^2 = -\frac{a}{2}\left(x - \frac{i\kappa}{a}\right)^2 - \frac{\kappa^2}{2a}$. Hence

$$\mathcal{I}(\kappa) = e^{-\kappa^2/2a} \int_{-\infty}^{\infty} dx\, e^{-\frac{a}{2}\,(x - i\kappa/a)^2}. \tag{5.49}$$

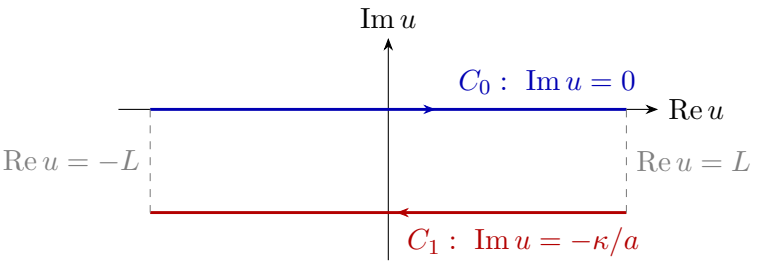

Figure 5.2: The contour shift in Theorem 5.16. The integrand $e^{-au^2/2}$ is entire; on the closed rectangle Cauchy's theorem holds, and the dashed vertical sides vanish as $L \to \infty$ because $\operatorname{Re} a > 0$. Hence the integral over the displaced line C_1 equals the integral over the real axis C_0. This is the prototype of every contour shift in the chapter; the oscillatory case a purely imaginary (the Minkowski path integral) is handled by the same move regularized by an $i\epsilon$, taken up in Section 5.3 (the next section).

The remaining integral runs over the horizontal line $\{x - i\kappa/a : x \in \mathbb{R}\}$, displaced from the real axis into the complex u-plane by the constant imaginary amount $-i\kappa/a$. We claim it equals the integral over the real axis. The function $u \mapsto e^{-au^2/2}$ is entire (no poles to cross), and on the rectangle with horizontal sides the real axis and the shifted line, closed by two vertical segments at $\operatorname{Re} u = \pm L$, Cauchy's theorem gives a vanishing contour integral. The two vertical contributions are bounded by $|\kappa/a| \cdot \sup e^{-a\operatorname{Re}(u^2)/2} \sim e^{-aL^2/2} \to 0$ as $L \to \infty$, because $\operatorname{Re} a > 0$ makes the Gaussian decay dominate the bounded imaginary excursion (Fig. 5.2). The shifted integral therefore equals the real one, $\int_{\mathbb{R}} e^{-au^2/2}\,du = \sqrt{2\pi/a}$ (the standard real Gaussian, analytically continued in a from the positive axis, with the principal branch of the square root). Collecting,

$$\mathcal{I}(\kappa) = \sqrt{\tfrac{2\pi}{a}}\, e^{-\kappa^2/2a}, \qquad \Longrightarrow \qquad \boxed{\hat{g}(k) = \left(\tfrac{2\pi}{a}\right)^{n/2} e^{-|k|^2/2a}} \tag{5.50}$$

In particular the choice $a = 1$ gives $\widehat{e^{-|x|^2/2}} = (2\pi)^{n/2} e^{-|k|^2/2}$: the Gaussian is its own Fourier transform up to the convention's normalization, the unique fixed point (up to scale) of $\mathcal{F}$. Setting $a = \epsilon$ and reading Eq. (5.50) as an inverse transform reproduces the nascent-delta kernel G_ϵ of Eq. (5.47): $\int \frac{dk}{(2\pi)} e^{ikb - \epsilon k^2/2} = (2\pi\epsilon)^{-1/2} e^{-b^2/2\epsilon}$ per coordinate.

5.2.3 Extension to tempered distributions by duality

We now have everything needed to define the Fourier transform of a distribution. The guiding principle is the multiplication formula Theorem 5.15: for an ordinary function f that is itself a tempered distribution, the identity $\int \hat{f}\,\varphi = \int f\,\hat{\varphi}$ says

that "pairing $\hat{f}$ against φ" equals "pairing f against $\hat{\varphi}$." The right-hand side makes sense for *any* tempered distribution in place of f, because $\hat{\varphi} \in \mathcal{S}$ whenever $\varphi \in \mathcal{S}$ (Theorem 5.14). We therefore promote the identity to a definition.

Definition 5.17 (Fourier transform of a tempered distribution)**.** For $T \in \mathcal{S}'(\mathbb{R}^n)$, its Fourier transform $\hat{T} = \mathcal{F}T$ is the tempered distribution defined by

$$\langle \hat{T}, \varphi \rangle := \langle T, \hat{\varphi} \rangle, \qquad \text{for all } \varphi \in \mathcal{S}(\mathbb{R}^n). \tag{5.51}$$

Theorem 5.18 (The transform is a bijection of $\mathcal{S}'$)**.** *Equation (5.51) defines $\hat{T}$ as an element of $\mathcal{S}'$; the map $\mathcal{F}\colon \mathcal{S}' \to \mathcal{S}'$ is a bijection with inverse $\langle \mathcal{F}^{-1}S, \varphi \rangle = \langle S, \mathcal{F}^{-1}\varphi \rangle$; and it agrees with the classical transform Eq. (5.37) on every $f \in \mathcal{S}$ (and more generally on every L^1 or L^2 function), so no notational clash arises.*

Proof. Well-defined and tempered. The right-hand side of Eq. (5.51) is finite because $\hat{\varphi} \in \mathcal{S}$ and $T \in \mathcal{S}'$. It is linear in φ. For continuity, if $\varphi_j \to \varphi$ in $\mathcal{S}$ then $\hat{\varphi}_j \to \hat{\varphi}$ in $\mathcal{S}$ by the continuity half of Theorem 5.14 (Eq. (5.45)), whence $\langle T, \hat{\varphi}_j \rangle \to \langle T, \hat{\varphi} \rangle$ by continuity of T; so $\langle \hat{T}, \varphi_j \rangle \to \langle \hat{T}, \varphi \rangle$ and $\hat{T} \in \mathcal{S}'$. *Bijection.* Define $\mathcal{F}^{-1}$ on $\mathcal{S}'$ by the displayed transpose formula. For $\varphi \in \mathcal{S}$, $\langle \mathcal{F}^{-1}\hat{T}, \varphi \rangle = \langle \hat{T}, \mathcal{F}^{-1}\varphi \rangle = \langle T, \mathcal{F}\mathcal{F}^{-1}\varphi \rangle = \langle T, \varphi \rangle$ using inversion on $\mathcal{S}$; likewise $\mathcal{F}\mathcal{F}^{-1} = \mathrm{id}$, so $\mathcal{F}$ is bijective on $\mathcal{S}'$ with the stated inverse. *Consistency.* If $T = f \in \mathcal{S}$ (or $f \in L^1$), then for every φ, $\langle \hat{T}, \varphi \rangle = \langle f, \hat{\varphi} \rangle = \int f \hat{\varphi} = \int \hat{f}\, \varphi = \langle \hat{f}, \varphi \rangle$, the middle equality being exactly Theorem 5.15; thus the distributional transform coincides with the function-theoretic one. □

The entire dictionary Eqs. (5.38) to (5.41) transfers verbatim to $\mathcal{S}'$, because each rule is the transpose of the corresponding rule on $\mathcal{S}$. For instance, the derivative rule on distributions reads

$$\begin{aligned} \langle \widehat{\partial_j T}, \varphi \rangle &= \langle \partial_j T, \hat{\varphi} \rangle = -\langle T, \partial_j \hat{\varphi} \rangle = -i \, \langle T, \widehat{x_j \varphi} \rangle \\ &= -i \, \langle \hat{T}, x_j \varphi \rangle = \langle -i k_j \, \hat{T}, \varphi \rangle \quad \Longrightarrow \quad \widehat{\partial_j T} = -i k_j \, \hat{T}, \end{aligned} \tag{5.52}$$

where we used the multiplication rule Eq. (5.39) on the test function in the form $\partial_j \hat{\varphi} = i \, \widehat{x_j \varphi}$, then the duality Eq. (5.51) to move the hat back onto T, and where k_j denotes the coordinate of the momentum space on which $\hat{T}$ lives. The distributional derivative $\partial_j T$ was defined in Section 5.1 (the previous section); the chain of pairings just pushes Eq. (5.38) through the duality. The convolution theorem Eq. (5.42) survives in the legal cases: if $\psi \in \mathcal{S}$ and $T \in \mathcal{S}'$, the convolution $T * \psi$ is a smooth, polynomially bounded function (hence tempered) and $\widehat{T * \psi} = \hat{\psi}\, \hat{T}$, the product now of a Schwartz function with a tempered distribution—a product that *is* defined precisely because one factor is smooth. We flag for emphasis, and develop in Section 5.2.5, that the unrestricted product of two tempered distributions is *not* defined; the convolution theorem is the safe face of a generally dangerous operation.

5.2.4 The catalogue every propagator uses

We can now compute, in two or three lines apiece, the transforms that every momentum-space computation in this book silently invokes. Each follows by feeding Eq. (5.51) a test function and using inversion.

The delta and the constant. The delta is the easiest: for any $\varphi \in \mathcal{S}$,

$$\langle \hat{\delta}, \varphi \rangle = \langle \delta, \hat{\varphi} \rangle = \hat{\varphi}(0) = \int_{\mathbb{R}^n} d^n x \, e^{i0\cdot x} \varphi(x) = \int \varphi = \langle 1, \varphi \rangle, \qquad \Longrightarrow \qquad \boxed{\hat{\delta} = 1} \tag{5.53}$$

The delta, the perfectly localized object, transforms to the constant 1, the perfectly delocalized one—the uncertainty principle in its starkest form. The reciprocal statement, the transform of the constant, is the single most-used Fourier identity in field theory, since it is the origin of every momentum-conserving $(2\pi)^n \delta^{(n)}$ at a vertex.

Worked Example 5.19 ($\widehat{1} = (2\pi)^n \delta$)**.** Apply Eq. (5.51) to $T = 1$:

$$\langle \hat{1}, \varphi \rangle = \langle 1, \hat{\varphi} \rangle = \int_{\mathbb{R}^n} d^n k \; \hat{\varphi}(k). \tag{5.54}$$

Now read the inverse transform Eq. (5.37) at $x = 0$: $\varphi(0) = \int \frac{d^n k}{(2\pi)^n} \hat{\varphi}(k)$, i.e. $\int d^n k \, \hat{\varphi}(k) = (2\pi)^n \varphi(0)$. Therefore $\langle \hat{1}, \varphi \rangle = (2\pi)^n \varphi(0) = (2\pi)^n \langle \delta, \varphi \rangle$ for every φ, which is the assertion

$$\boxed{\widehat{1} = (2\pi)^n \, \delta} \tag{5.55}$$

It is illuminating to see this as the width-to-zero limit of the Gaussian, the computation the spec of this chapter calls for and the one that makes the $(2\pi)^n$ tangible. The constant is the pointwise limit $1 = \lim_{a \to 0^+} e^{-a|x|^2/2}$, and this limit also holds in $\mathcal{S}'$ (dominated convergence in each pairing). Since $\mathcal{F}$ is continuous on $\mathcal{S}'$, we may transform inside the limit and use Eq. (5.50):

$$\widehat{1} = \lim_{a \to 0^+} \widehat{e^{-a|x|^2/2}} = \lim_{a \to 0^+} \left(\tfrac{2\pi}{a}\right)^{n/2} e^{-|k|^2/2a} = (2\pi)^n \lim_{a \to 0^+} \underbrace{\tfrac{1}{(2\pi a)^{n/2}} e^{-|k|^2/2a}}_{\text{unit-mass Gaussian}} = (2\pi)^n \delta(k). \tag{5.56}$$

The bracketed factor is a Gaussian of total integral 1 and width $\sqrt{a} \to 0$: a nascent delta. The leftover $(2\pi)^n$ is exactly the normalization factor of Eq. (5.55), now seen to be the volume factor the convention parks on the inverse transform. This is the identity that, in four spacetime dimensions, produces the $(2\pi)^4 \delta^{(4)}(\sum p)$ enforcing energy–momentum conservation at every interaction vertex (Chapters 9 and 13).

The Gaussian, again. The transform Eq. (5.50) is already a $\mathcal{S}'$ statement when read for $\operatorname{Re} a > 0$, and it is the workhorse of every Euclidean (Wick-rotated) propagator and every saddle-point evaluation later in the chapter. We record only that the purely imaginary case $a = -i\beta$ (the oscillatory Fresnel integral of the Minkowski path integral) is obtained from Eq. (5.50) by analytic continuation $a \to -i\beta + 0^+$, the limit existing as a tempered distribution; the $+0^+$ is the very $i\epsilon$ that the next two sections install as a contour prescription.

Step and sign: the appearance of PV and δ together. The last entry is the one that ties the Fourier transform back to Sokhotski–Plemelj and forward to the propagator. We work in one dimension and write the variable as ω in momentum space, anticipating its role as an energy.

Worked Example 5.20 (Transform of the Heaviside step and the sign)**.** Let $\theta(t)$ be the Heaviside step ($\theta = 1$ for $t > 0$, 0 for $t < 0$). It is bounded, hence tempered. Its forward transform $\int_0^\infty e^{i\omega t}\,dt$ does not converge as an ordinary integral, but it converges as a distribution, and the clean way to see the answer is to insert the convergence factor that defines θ as the limit of an integrable function: $\theta(t) = \lim_{\eta\to 0^+} \theta(t)e^{-\eta t}$ in $\mathcal{S}'$. For $\eta > 0$,

$$\widehat{\theta\, e^{-\eta t}}(\omega) = \int_0^\infty e^{\,i\omega t - \eta t}\,dt = \frac{1}{\eta - i\omega} = \frac{i}{\omega + i\eta}. \tag{5.57}$$

Taking $\eta \to 0^+$ inside the pairing and applying Sokhotski–Plemelj Theorem 5.10, $\dfrac{1}{\omega + i\eta} \to \mathrm{PV}\,\dfrac{1}{\omega} - i\pi\delta(\omega)$, we obtain

$$\boxed{\hat\theta(\omega) = i\Big(\mathrm{PV}\,\tfrac{1}{\omega} - i\pi\delta(\omega)\Big) = \pi\,\delta(\omega) + i\,\mathrm{PV}\,\frac{1}{\omega}} \tag{5.58}$$

The transform of the step splits into a delta and a principal value—the same two pieces that Sokhotski–Plemelj extracted from $1/(\omega + i\eta)$ in the previous section, now arising as the real (even) and imaginary (odd) parts of a causal object's spectrum. The sign function follows at once. Since $\operatorname{sgn}(t) = 2\theta(t) - 1$, linearity together with Eq. (5.55) (here $\widehat{1} = 2\pi\delta$ in $n = 1$) gives

$$\widehat{\operatorname{sgn}}(\omega) = 2\hat\theta(\omega) - \widehat{1} = 2\pi\delta(\omega) + 2i\,\mathrm{PV}\,\tfrac{1}{\omega} - 2\pi\delta(\omega) = 2i\,\mathrm{PV}\,\frac{1}{\omega}. \tag{5.59}$$

The delta pieces cancel: the sign function, being odd and unbounded only as a constant at infinity, has a purely imaginary, purely principal-value transform. Inverting Eq. (5.59) also records the companion fact $\widehat{\mathrm{PV}(1/t)} = i\pi\,\operatorname{sgn}(\omega)$, the transform of the principal value, which reappears in the dispersion relations of a later section.

Physical Insight

The decomposition $\hat{\theta} = \pi\delta + i\,\mathrm{PV}(1/\omega)$ is the spectral signature of *causality*. The step function $\theta(t)$ is what multiplies a field commutator to build a *retarded* (cause-precedes-effect) Green function. Its transform having a δ part (an on-shell, real, dissipative piece) and a PV part (an off-shell, reactive piece) tied together is, read at the level of response functions, the Kramers–Kronig relation between absorption and dispersion. The same PV/δ pairing, repackaged as $1/(\omega \pm i\eta)$, is what distinguishes the retarded, advanced, and Feynman propagators in the next section. Here is the chapter's through-line in one formula: a singular distribution has become a pole, and the side on which the pole sits will become a contour prescription.

5.2.5 Why products of distributions are dangerous

The Fourier dictionary turns pointwise products into convolutions (Eq. (5.43)). In the interacting theory the central objects are products of propagators *at the same spacetime point*, and these are products of distributions. It is essential to understand, before any field is quantized, that such products are in general *undefined*, because this single fact is the structural origin of the ultraviolet divergences that renormalization exists to treat.

The obstruction is already visible for the delta. There is no consistent way to assign a value to $\delta(x)^2$: approximating δ by nascent deltas δ_ϵ of width ϵ, the candidate $\delta_\epsilon(x)^2$ has integral $\sim 1/\epsilon \to \infty$, so no limit exists in $\mathcal{D}'$. More sharply, a theorem of L. Schwartz states that there is no associative, commutative bilinear product on $\mathcal{D}'(\mathbb{R})$ that restricts to the ordinary product on continuous functions and respects differentiation by the Leibniz rule: the distributions cannot be made into such an algebra. The product of two distributions is therefore a *partial* operation, legal only when the singularities of the two factors do not collide.

The precise criterion, which we state at the level we will need and not reprove here, is Hörmander's. To each distribution u one attaches its *wavefront set* $\mathrm{WF}(u) \subset (\mathbb{R}^n \times (\mathbb{R}^n \setminus \{0\}))$, a refinement of the singular support that records not only *where* u is singular but *in which momentum directions* that singularity points (the directions in which $\hat{u}$ fails to decay rapidly when u is localized near the point). For the delta on $\mathbb{R}$, $\mathrm{WF}(\delta) = \{(0,\xi) : \xi \neq 0\}$: singular at the origin, in *all* momentum directions.

Proposition 5.21 (Hörmander's product criterion)**.** *Let $u, v \in \mathcal{D}'(\mathbb{R}^n)$. If their wavefront sets satisfy the transversality condition*

$$(x,\xi) \in \mathrm{WF}(u) \implies (x,-\xi) \notin \mathrm{WF}(v) \qquad \text{for all } x,\ \xi \neq 0, \tag{5.60}$$

then the product uv is well-defined as a distribution, independent of the approximating sequences, and $\mathrm{WF}(uv)$ *is contained in the natural sum of the two wavefront sets. If the condition fails—if some singular point carries opposite momentum directions in u and in v, so that the convolution $\hat{u} * \hat{v}$ of Eq. (5.43) diverges—the product is not defined by any limiting procedure.*

The square $\delta \cdot \delta$ violates Eq. (5.60) at the origin, where $(0, \xi)$ and $(0, -\xi)$ both lie in $\mathrm{WF}(\delta)$: hence δ^2 is meaningless, in agreement with the divergent estimate above. By contrast $\theta \cdot \delta$ at points away from the origin is fine, and a smooth function times any distribution is always legal because a smooth factor has empty wavefront set.

Physical Insight

This is the mathematical reason quantum field theory needs renormalization, stated before we have written down a single loop. A propagator is a distribution whose wavefront set sits on the light cone; a Feynman diagram with a loop multiplies two or more propagators that share spacetime arguments, and at coincident points their wavefront sets point in opposite directions along the cone—exactly the collision Eq. (5.60) forbids. The product of propagators at a vertex is therefore an ill-defined distribution, and the divergent loop integral is the symptom. Renormalization is, from this vantage, the systematic procedure for *extending* these ill-defined products to genuine distributions by subtracting their coincident-point ambiguity—the Epstein–Glaser viewpoint. We take this up properly in Chapter 21, where the superficial degree of divergence is precisely a measure of how badly Eq. (5.60) fails.

5.2.6 The Feynman propagator as a tempered distribution

We have assembled enough to give the central object of the chapter its precise status. In four-dimensional Minkowski spacetime, with the metric pairing of Chapter A and $n = 4$, the *Feynman propagator* of a free scalar of mass m is the tempered distribution $D_F \in \mathcal{S}'(\mathbb{R}^{1,3})$ whose Fourier transform is the locally integrable function

Definition 5.22 (Momentum-space Feynman propagator)**.**

$$\widehat{D_F}(p) \;=\; \frac{i}{p^2 - m^2 + i\epsilon}, \qquad D_F(x) = \int \frac{d^4p}{(2\pi)^4}\, \frac{i\, e^{-ip\cdot x}}{p^2 - m^2 + i\epsilon}, \tag{5.61}$$

with $p^2 = p_\mu p^\mu = (p^0)^2 - |\mathbf{p}|^2$ and $\epsilon \to 0^+$ understood after pairing against test functions.

Three points justify every word of this definition with the machinery just built. First, *it is a legitimate tempered distribution.* For fixed $\epsilon > 0$ the denominator $p^2 - m^2 + i\epsilon$ never vanishes (its imaginary part is ϵ), so $\widehat{D_F}$ is a smooth, polynomially bounded—indeed bounded by $1/\epsilon$—function of p, manifestly an element of $\mathcal{S}'$. By Theorem 5.18 its inverse transform D_F is then a well-defined tempered distribution on position space, and the $\epsilon \to 0^+$ limit exists in $\mathcal{S}'$ because the boundary value $1/(p^2 - m^2 + i\epsilon)$ does, exactly as in the previous section. The propagator is not a function—it is singular on the mass shell $p^2 = m^2$ and along the light cone in x—but it *is* a distribution, and the slogan "the propagator is a distribution" is now a theorem.

Second, *the $i\epsilon$ is read through Sokhotski–Plemelj.* Treating $p^2 - m^2$ as the real variable in Theorem 5.10,

$$\frac{i}{p^2 - m^2 + i\epsilon} \;=\; i\,\mathrm{PV}\,\frac{1}{p^2 - m^2} \;+\; \pi\,\delta(p^2 - m^2), \tag{5.62}$$

so the propagator carries a principal-value part (the off-shell, virtual propagation) and a $\delta(p^2 - m^2)$ part (the on-shell, real-particle content) welded together in exactly the proportion the step function displayed in Eq. (5.58). The same analytic anatomy—a pole plus a delta, a PV plus an on-shell piece—runs from $\theta(t)$ through $1/(x \pm i\epsilon)$ to the propagator: this is one object wearing three costumes.

Third, *this is the object the threads will need.* The momentum-space form Eq. (5.61) is precisely the scalar propagator of ϕ^4 theory, to be derived from the free path integral and the mode expansion in Chapter 9, and its photon analogue underlies QED in Chapter 13; no thread is formally advanced in this foundations chapter, but the analytic object every thread later manipulates has now been built and certified. What remains is purely computational and is the business of the next section: the position-space content of Eq. (5.61) is locked inside the energy integral $\int dp^0\, e^{-ip^0x^0}/(p^2 - m^2 + i\epsilon)$, whose integrand has two poles in the complex p^0 plane displaced off the real axis by the $i\epsilon$. To turn the distribution into a number one must choose how a contour passes those poles—and the retarded, advanced, and Feynman propagators are nothing but the three such choices. The contour calculus that makes those choices, and evaluates the integral, is where we go now.

5.3 Contour integration and the propagator prescriptions

The previous section handed us the Feynman propagator as a *distribution* in momentum space,

$$\widetilde{D}_F(p) = \frac{i}{p^2 - m^2 + i\varepsilon}, \tag{5.63}$$

the object Eq. (5.61), with the $i\varepsilon$ understood as the boundary-value prescription that makes the singular denominator a well-defined tempered distribution through the Sokhotski–Plemelj identity Eq. (5.22). That is a complete *definition*, but it is not yet a number. To extract a number—the propagator in position space, the amplitude for a particle to get from one event to another—we must perform the Fourier integral $\int d^4p\, e^{-ip\cdot x}\, \widetilde{D}_F(p)/(2\pi)^4$, and the heart of that integral is the contour integral over the energy variable p^0. The purpose of this section is to make the $i\varepsilon$ *operational*: to show that it is precisely an instruction about how a contour in the complex p^0-plane is to step around two poles, and that the celebrated retarded, advanced, and Feynman propagators are not three different functions handed down from on high but three choices of that single instruction, applied to one and the same integrand.

We proceed in three movements. First we recall—reviewing, not rebuilding, since complex analysis through the residue theorem is a prerequisite—exactly the residue calculus we will deploy, and we prove in full the one estimate that is genuinely a working tool rather than a memory: Jordan's lemma, which controls the arc that closes a Fourier contour at infinity. Second, we locate the poles of Eq. (5.63) in the complex p^0-plane and read off how the $i\varepsilon$ displaces them. Third, in a single self-contained worked computation, we evaluate the energy integral three times—retarded, advanced, Feynman—from the same integrand, and watch the contour decide which poles it encloses. The Feynman case will deliver exactly the time-ordered combination $\theta(t)e^{-iE_{\mathbf{p}}t} + \theta(-t)e^{+iE_{\mathbf{p}}t}$ that Chapter 9 will recognize as the vacuum expectation value $\langle 0|\mathcal{T}\phi\phi|0\rangle$, and that ϕ^4 theory (from Chapter 9) and QED (from Chapter 13) will quantize. No thread is formally advanced here—the interacting field theories are not defined until Part II—so the computation stands on its own as the model calculation that *plants* the analytic object those threads later need.

5.3.1 The residue calculus, reviewed for deployment

We assume the reader has met holomorphic functions, contour integrals, and the residue theorem; we restate them only to fix notation and to isolate the one fact we must prove. Throughout, $z = x + iy$ is a complex variable, a *contour* is a piecewise-C^1 curve, and "positively oriented" means counterclockwise. The residue of a meromorphic f at an isolated singularity z_0 is the coefficient a_{-1} in its Laurent expansion $f(z) = \sum_n a_n (z - z_0)^n$ about z_0, written $\operatorname{Res}_{z=z_0} f$. For a *simple* pole the only case we need below,

$$\operatorname{Res}_{z=z_0} f = \lim_{z\to z_0} (z-z_0)\, f(z), \qquad \text{and if } f = \frac{g}{h} \text{ with } h(z_0) = 0,\ h'(z_0) \neq 0,\ \operatorname{Res}_{z=z_0} \frac{g}{h} = \frac{g}{h'} \tag{5.64}$$

Proposition 5.23 (Cauchy's theorem and the residue theorem; reviewed, not proved)**.** *Let $D \subset \mathbb{C}$ be open and simply connected, and let f be holomorphic on*

D except at finitely many isolated singularities. Let γ be a positively oriented simple closed contour in D enclosing the singularities $z_1, \dots, z_n$ and no others. Then

$$\oint_\gamma f(z)\,dz = 2\pi i \sum_{k=1}^{n} \operatorname{Res}_{z=z_k} f. \tag{5.65}$$

In particular, if f is holomorphic everywhere inside γ (no singularities enclosed), the integral vanishes (Cauchy's integral theorem). A clockwise *(negatively oriented) closed contour gives instead $-2\pi i \sum_k \operatorname{Res}_{z=z_k} f$.*

These are standard and are reviewed here only to be used; the proofs belong to a complex-analysis course and are not reproduced. What is *not* merely a quoted fact, and what we therefore prove in full, is the lemma that licenses the entire method we are about to use: when we evaluate a Fourier-type integral $\int_{-\infty}^{\infty} e^{ikx} f(k)\,dk$ by closing the real axis into a large semicircle and applying Eq. (5.65), we must know that the contribution of the semicircular arc vanishes as its radius grows. For an integrand decaying as fast as $1/k^2$—which is the case for the propagator denominator $1/(k^2 - \dots)$—this is immediate, since the integrand falls as R^{-2} while the arc length grows only as R. But many integrals in this book carry only a single power, $f(k) \sim 1/k$ (the Fourier transforms of the sign and Heaviside distributions from §2 are exactly of this type, and so are individual terms in spectral representations), and there the cruder estimate fails: $R^{-1} \cdot R = O(1)$. The oscillatory factor e^{ikx} must be made to do the work. That is Jordan's lemma.

5.3.2 Jordan's lemma

Lemma 5.24 (Jordan's lemma)**.** *Let C_R^+ denote the semicircular arc $z = Re^{i\theta}$, $\theta \in [0, \pi]$, in the upper half-plane, and suppose f is continuous on C_R^+ for all large R with*

$$M_R \equiv \max_{0 \le \theta \le \pi} \left| f(Re^{i\theta}) \right| \longrightarrow 0 \qquad \text{as } R \to \infty. \tag{5.66}$$

Then for every real $a > 0$,

$$\lim_{R \to \infty} \int_{C_R^+} e^{iaz} f(z)\,dz = 0. \tag{5.67}$$

The mirror statement holds in the lower half-plane: if C_R^- is the arc $\theta \in [-\pi, 0]$ and $M_R \to 0$ there, then $\int_{C_R^-} e^{iaz} f(z)\,dz \to 0$ for every $a < 0$.

Proof. Parametrize C_R^+ by $z = Re^{i\theta}$, $dz = iRe^{i\theta}\,d\theta$, so that $|dz| = R\,d\theta$. The exponent is

$$iaz = iaR(\cos\theta + i\sin\theta) = iaR\cos\theta - aR\sin\theta, \tag{5.68}$$

whose modulus factor is $|e^{iaz}| = e^{-aR\sin\theta}$. Bounding the integrand by its modulus,

$$\left|\int_{C_R^+} e^{iaz} f(z)\,dz\right| \le \int_0^\pi e^{-aR\sin\theta}\,|f(Re^{i\theta})|\,R\,d\theta \le M_R\,R\int_0^\pi e^{-aR\sin\theta}\,d\theta. \quad (5.69)$$

The integrand $e^{-aR\sin\theta}$ is symmetric about $\theta=\pi/2$, since $\sin\theta=\sin(\pi-\theta)$, so

$$\int_0^\pi e^{-aR\sin\theta}\,d\theta = 2\int_0^{\pi/2} e^{-aR\sin\theta}\,d\theta. \quad (5.70)$$

Now we use the elementary *Jordan inequality*: on $[0,\pi/2]$ the sine lies above its chord,

$$\sin\theta \ge \frac{2\theta}{\pi}, \qquad 0\le\theta\le\frac{\pi}{2}. \quad (5.71)$$

This is geometrically the statement that the concave function $\sin\theta$, which agrees with the straight line $2\theta/\pi$ at the endpoints $\theta=0$ and $\theta=\pi/2$, lies above that line between them; analytically, $g(\theta)\equiv\sin\theta-2\theta/\pi$ satisfies $g(0)=g(\pi/2)=0$ and $g''(\theta)=-\sin\theta\le 0$, so g is concave and hence nonnegative on the interval. Because $a>0$ and $R>0$, the exponential is decreasing in its argument, so Eq. (5.71) gives the pointwise bound $e^{-aR\sin\theta}\le e^{-2aR\theta/\pi}$ on $[0,\pi/2]$. Therefore

$$2\int_0^{\pi/2} e^{-aR\sin\theta}\,d\theta \le 2\int_0^{\pi/2} e^{-2aR\theta/\pi}\,d\theta = 2\cdot\frac{\pi}{2aR}\Big(1-e^{-aR}\Big) = \frac{\pi}{aR}\Big(1-e^{-aR}\Big) \le \frac{\pi}{aR}. \quad (5.72)$$

Combining Eqs. (5.69), (5.70) and (5.72),

$$\left|\int_{C_R^+} e^{iaz} f(z)\,dz\right| \le M_R\,R\cdot\frac{\pi}{aR} = \frac{\pi}{a}\,M_R \xrightarrow[R\to\infty]{} 0, \quad (5.73)$$

since $M_R\to 0$ by hypothesis. The factors of R have cancelled exactly: this is the whole content of the lemma, that the linear growth of the arc length is defeated by the integrated exponential suppression even though f alone need only vanish. The lower-half-plane statement follows by the substitution $\theta\to-\theta$, which sends $\sin\theta\to-\sin\theta$ and therefore requires $a<0$ to keep the exponent $-|a|R|\sin\theta|$ negative. □

The hypothesis $a>0\Leftrightarrow$ close upward, $a<0\Leftrightarrow$ close downward is the crucial bookkeeping, and it is worth stating as the operational rule that we will invoke without further comment for the rest of the book.

Proposition 5.25 (Closure rule for Fourier-type integrals)**.** *Let f be meromorphic with finitely many poles, none on the real axis, and with $M_R\to 0$ on large*

semicircles in at least one half-plane. Then for real b,

$$\int_{-\infty}^{\infty} e^{ibk} f(k)\,dk = \begin{cases} 2\pi i \displaystyle\sum_{\text{poles in UHP}} \operatorname{Res} f, & b > 0 \quad (\textit{close in the upper half-plane}), \\ -2\pi i \displaystyle\sum_{\text{poles in LHP}} \operatorname{Res} f, & b < 0 \quad (\textit{close in the lower half-plane}). \end{cases} \tag{5.74}$$

Proof. For $b > 0$, close the real-axis integral with the arc C_R^+. The closed contour $[-R, R] \cup C_R^+$ is positively oriented and, for R larger than the modulus of every pole, encloses exactly the poles in the upper half-plane, so Eq. (5.65) gives $\int_{-R}^{R} + \int_{C_R^+} = 2\pi i \sum_{\text{UHP}} \operatorname{Res} f$. By Jordan's lemma Theorem 5.24 with $a = b > 0$ the arc term vanishes as $R \to \infty$, leaving the first line. For $b < 0$ close downward with C_R^-; this closed contour is *clockwise* (it runs $-R \to R$ along the real axis and then back through the lower arc), hence carries the sign $-2\pi i$, and Jordan's lemma with $a = b < 0$ kills the arc, giving the second line. □

The sign of the exponent's coefficient b dictates the closure: this is the single most-used fact in every propagator and amplitude computation in this book, and it is what turns the abstract $i\varepsilon$ into the concrete $\theta(\pm t)$ that physically encodes the direction of time. We now apply it.

5.3.3 Pole structure of the momentum-space propagator

Fix the spatial momentum $\mathbf{p}$ and regard the Feynman denominator in Eq. (5.63) as a function of the complex energy p^0. With the mostly-minus metric, $p^2 = (p^0)^2 - \mathbf{p}^2$, so writing

$$E_{\mathbf{p}} \equiv \sqrt{\mathbf{p}^2 + m^2} \; > 0 \tag{5.75}$$

for the on-shell energy, the denominator becomes

$$p^2 - m^2 + i\varepsilon = (p^0)^2 - (\mathbf{p}^2 + m^2) + i\varepsilon = (p^0)^2 - E_{\mathbf{p}}^2 + i\varepsilon. \tag{5.76}$$

This is a quadratic in p^0 with roots at $p^0 = \pm\sqrt{E_{\mathbf{p}}^2 - i\varepsilon}$. Since ε is a positive infinitesimal we may expand the square root to first order, $\sqrt{E_{\mathbf{p}}^2 - i\varepsilon} = E_{\mathbf{p}}\sqrt{1 - i\varepsilon/E_{\mathbf{p}}^2} = E_{\mathbf{p}} - i\varepsilon/(2E_{\mathbf{p}}) + O(\varepsilon^2)$. Absorbing the positive constant $1/(2E_{\mathbf{p}})$ into the redefinition of the infinitesimal (a standard and harmless abuse: only the *sign* of ε carries meaning, never its magnitude, and a positive multiple of a positive infinitesimal is again a positive infinitesimal), the two roots are

$$p_+^0 = +E_{\mathbf{p}} - i\varepsilon \qquad \text{and} \qquad p_-^0 = -E_{\mathbf{p}} + i\varepsilon, \tag{5.77}$$

and the denominator factorizes as

$$(p^0)^2 - E_{\mathbf{p}}^2 + i\varepsilon = (p^0 - E_{\mathbf{p}} + i\varepsilon)(p^0 + E_{\mathbf{p}} - i\varepsilon). \tag{5.78}$$

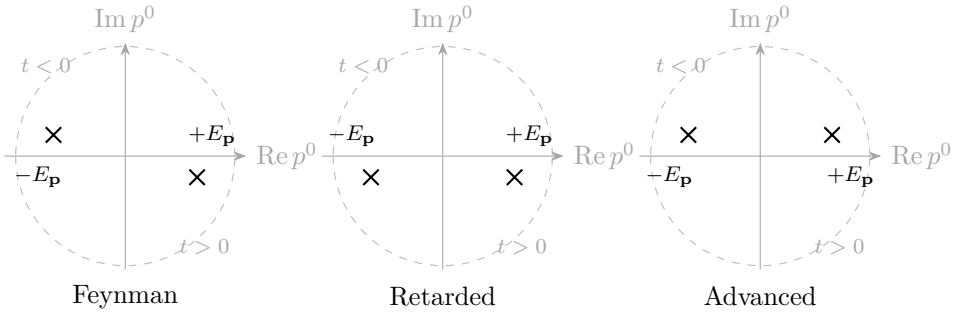

Figure 5.3: The three propagator prescriptions as pole placements in the complex p^0-plane, for fixed spatial momentum $\mathbf{p}$, together with the semicircular arcs that close the energy integral. The exponential $e^{-ip^0 t}$ forces closure *downward* for $t > 0$ and *upward* for $t < 0$ (Theorem 5.25). The Feynman prescription straddles the axis ($+E_{\mathbf{p}}$ below, $-E_{\mathbf{p}}$ above); the retarded keeps both poles below, so the upward $t < 0$ contour encloses nothing and the propagator vanishes for $t < 0$; the advanced keeps both above, vanishing for $t > 0$.

The reader can verify the factorization by multiplying out: the cross terms in ε cancel and the ε^2 term is dropped, leaving $(p^0)^2 - E_{\mathbf{p}}^2 + i\varepsilon(p^0 + E_{\mathbf{p}}) - i\varepsilon(p^0 - E_{\mathbf{p}}) = (p^0)^2 - E_{\mathbf{p}}^2 + 2i\varepsilon E_{\mathbf{p}}$, which is $(p^0)^2 - E_{\mathbf{p}}^2 + i\varepsilon$ after the same rescaling of the infinitesimal.

The content of Eq. (5.77) is the geometric statement around which the whole section turns: *the Feynman $i\varepsilon$ pushes the positive-energy pole $+E_{\mathbf{p}}$ infinitesimally below the real axis and the negative-energy pole $-E_{\mathbf{p}}$ infinitesimally above it.* The two poles straddle the real p^0-axis on opposite sides. This asymmetric placement is the algebraic fingerprint of time-ordering, as the worked computation will show. It is also exactly the placement that will permit the real p^0-contour to be rotated onto the imaginary axis without crossing a pole—the Wick rotation that Section 5.4 builds in the next section—because a contour swung from the positive real axis up to the positive imaginary axis sweeps through the first quadrant, which the Feynman prescription has kept clear of poles.

The retarded and advanced prescriptions correspond to placing *both* poles on the same side of the real axis. Concretely they replace $p^0 \to p^0 + i\varepsilon$ (retarded) or $p^0 \to p^0 - i\varepsilon$ (advanced) uniformly in the energy argument, i.e. they use the denominators

$$\text{retarded:}\quad (p^0 + i\varepsilon)^2 - E_{\mathbf{p}}^2, \qquad \text{advanced:}\quad (p^0 - i\varepsilon)^2 - E_{\mathbf{p}}^2. \tag{5.79}$$

For the retarded denominator the roots are $p^0 = -i\varepsilon \pm E_{\mathbf{p}}$, i.e. *both* poles sit just below the real axis at $\pm E_{\mathbf{p}} - i\varepsilon$; for the advanced denominator both sit just above, at $\pm E_{\mathbf{p}} + i\varepsilon$. Figure 5.3 collects the three pole layouts together with the contours that close them.

5.3.4 The three propagators from one integrand

We now compute. The position-space propagator is the four-dimensional Fourier transform of Eq. (5.63), in the book's fixed convention (Chapter A),

$$D_F(x) = \int \frac{d^4p}{(2\pi)^4}\, e^{-ip\cdot x}\, \frac{i}{p^2 - m^2 + i\varepsilon} = \int \frac{d^3p}{(2\pi)^3}\, e^{i\mathbf{p}\cdot\mathbf{x}} \underbrace{\int_{-\infty}^{\infty} \frac{dp^0}{2\pi}\, \frac{i\, e^{-ip^0 t}}{(p^0)^2 - E_{\mathbf{p}}^2 + i\varepsilon}}_{\equiv\, I_F(t)}, \tag{5.80}$$

where we used $p\cdot x = p^0 t - \mathbf{p}\cdot\mathbf{x}$ with $t \equiv x^0$, and the spatial part has been separated out cleanly. Every physical and analytic feature of the propagator lives in the inner one-dimensional energy integral $I_F(t)$; the spatial integral is a spectator that merely reattaches the $\mathbf{x}$-dependence. The worked example below evaluates I_F and its retarded and advanced cousins from the identical integrand, the only difference being the placement of the two poles fixed in Section 5.3.3.

Worked Example 5.26 (The three energy integrals)**.** We evaluate the energy integral

$$I(t) = \int_{-\infty}^{\infty} \frac{dp^0}{2\pi}\, \frac{i\, e^{-ip^0 t}}{(p^0)^2 - E_{\mathbf{p}}^2} \tag{5.81}$$

for each of the three pole prescriptions of Fig. 5.3, recovering the Feynman, retarded, and advanced propagators in turn.

Setting up the closure. The exponent is $-ip^0 t$, so in the notation of the closure rule Theorem 5.25 the coefficient of ip^0 is $b = -t$. Hence:

- for $t > 0$ we have $b < 0$ and must close *downward*, in the lower half-plane, picking up $-2\pi i$ times the residues there;
- for $t < 0$ we have $b > 0$ and must close *upward*, in the upper half-plane, picking up $+2\pi i$ times the residues there.

The integrand decays as $|p^0|^{-2}$ on the arcs, so the arc contribution vanishes by the elementary estimate (and a fortiori by Jordan's lemma Theorem 5.24); the closure is legitimate in every case below.

Two residues, computed once. Writing the denominator in factored form $(p^0 - E_{\mathbf{p}})(p^0 + E_{\mathbf{p}})$ (the $i\varepsilon$ only moves the poles; it does not change the residues, which we evaluate at the limiting locations $\pm E_{\mathbf{p}}$), the residues of the integrand $i\, e^{-ip^0 t}/[(p^0 - E_{\mathbf{p}})(p^0 + E_{\mathbf{p}})]$ at the two poles are, by Eq. (5.64),

$$\mathrm{Res}_{p^0 = +E_{\mathbf{p}}} = \frac{i\, e^{-iE_{\mathbf{p}}t}}{(E_{\mathbf{p}} + E_{\mathbf{p}})} = \frac{i\, e^{-iE_{\mathbf{p}}t}}{2E_{\mathbf{p}}}, \tag{5.82}$$

$$\mathrm{Res}_{p^0 = -E_{\mathbf{p}}} = \frac{i\, e^{+iE_{\mathbf{p}}t}}{(-E_{\mathbf{p}} - E_{\mathbf{p}})} = -\frac{i\, e^{+iE_{\mathbf{p}}t}}{2E_{\mathbf{p}}}. \tag{5.83}$$

These two numbers, assembled according to which poles each contour encloses, produce all three propagators.

Feynman ($+E_{\mathbf{p}}$ below, $-E_{\mathbf{p}}$ above). For $t > 0$ close downward; the lower half-plane contains only the pole at $p^0 = +E_{\mathbf{p}} - i\varepsilon$. The contour is clockwise, so

$$I_F(t>0) = \frac{1}{2\pi}\,(-2\pi i)\,\mathrm{Res}_{p^0=+E_{\mathbf{p}}} = \frac{1}{2\pi}\,(-2\pi i)\,\frac{i\,e^{-iE_{\mathbf{p}}t}}{2E_{\mathbf{p}}} = \frac{e^{-iE_{\mathbf{p}}t}}{2E_{\mathbf{p}}}, \tag{5.84}$$

using $(-2\pi i)(i) = 2\pi$. For $t < 0$ close upward; the upper half-plane contains only the pole at $p^0 = -E_{\mathbf{p}} + i\varepsilon$. The contour is counterclockwise, so

$$I_F(t<0) = \frac{1}{2\pi}\,(+2\pi i)\,\mathrm{Res}_{p^0=-E_{\mathbf{p}}} = \frac{1}{2\pi}\,(2\pi i)\left(-\frac{i\,e^{+iE_{\mathbf{p}}t}}{2E_{\mathbf{p}}}\right) = \frac{e^{+iE_{\mathbf{p}}t}}{2E_{\mathbf{p}}}, \tag{5.85}$$

using $(2\pi i)(-i) = 2\pi$. Combining the two cases with Heaviside step functions,

$$\boxed{I_F(t) = \frac{1}{2E_{\mathbf{p}}}\Big[\theta(t)\,e^{-iE_{\mathbf{p}}t} + \theta(-t)\,e^{+iE_{\mathbf{p}}t}\Big].} \tag{5.86}$$

Retarded (both poles below). For $t > 0$ close downward; now *both* poles lie in the lower half-plane, so the clockwise contour encloses both:

$$\begin{aligned} I_R(t>0) &= \frac{1}{2\pi}\,(-2\pi i)\Big(\mathrm{Res}_{+E_{\mathbf{p}}} + \mathrm{Res}_{-E_{\mathbf{p}}}\Big) = (-i)\left(\frac{i\,e^{-iE_{\mathbf{p}}t}}{2E_{\mathbf{p}}} - \frac{i\,e^{+iE_{\mathbf{p}}t}}{2E_{\mathbf{p}}}\right) \\ &= \frac{1}{2E_{\mathbf{p}}}\big(e^{-iE_{\mathbf{p}}t} - e^{+iE_{\mathbf{p}}t}\big) = -\frac{i\,\sin(E_{\mathbf{p}}t)}{E_{\mathbf{p}}}, \end{aligned} \tag{5.87}$$

where we used $e^{-i\phi} - e^{+i\phi} = -2i\sin\phi$. For $t < 0$ close upward; the upper half-plane now contains *no* poles, so by Cauchy's theorem $I_R(t<0) = 0$. Thus

$$\boxed{I_R(t) = -\theta(t)\,\frac{\sin(E_{\mathbf{p}}t)}{E_{\mathbf{p}}}\,i \;=\; -\,\frac{i\,\theta(t)}{E_{\mathbf{p}}}\,\sin(E_{\mathbf{p}}t).} \tag{5.88}$$

The retarded propagator vanishes identically for $t < 0$: it has *support* only in the forward light-cone in time, which is exactly the causal requirement that an effect cannot precede its source. The two poles sitting on the same (lower) side is what makes the $t < 0$ contour enclose nothing.

Advanced (both poles above). The computation mirrors the retarded one. For $t < 0$ close upward, enclosing both poles counterclockwise:

$$I_A(t<0) = \frac{1}{2\pi}\,(+2\pi i)\Big(\mathrm{Res}_{+E_{\mathbf{p}}} + \mathrm{Res}_{-E_{\mathbf{p}}}\Big) = (i)\left(\frac{i\,e^{-iE_{\mathbf{p}}t}}{2E_{\mathbf{p}}} - \frac{i\,e^{+iE_{\mathbf{p}}t}}{2E_{\mathbf{p}}}\right)$$

$$= -\frac{1}{2E_{\mathbf{p}}}(e^{-iE_{\mathbf{p}}t} - e^{+iE_{\mathbf{p}}t}) = \frac{i\,\sin(E_{\mathbf{p}}t)}{E_{\mathbf{p}}}, \tag{5.89}$$

while for $t > 0$ the downward contour encloses no poles and $I_A(t > 0) = 0$. Hence

$$\boxed{I_A(t) = +\frac{i\,\theta(-t)}{E_{\mathbf{p}}}\,\sin(E_{\mathbf{p}}t),} \tag{5.90}$$

supported only in the backward time-cone $t < 0$, as the name advertises. Comparing Eqs. (5.88) and (5.90) one sees $I_A(t) = I_R(-t)$, the time-reversal of the retarded propagator, exactly as the mirror-image pole placements in Fig. 5.3 demand.

It is worth pausing on what the worked example demonstrates, because it is the conceptual payload of the section. One integrand—the manifestly meromorphic $i\,e^{-ip^0t}/[(p^0)^2 - E_{\mathbf{p}}^2]$—produced three physically distinct propagators, and the *only* input that distinguished them was an infinitesimal displacement of two poles off the real axis. The $i\varepsilon$ is not a regulator one bolts on and forgets; it is the entire physical content, dictating which residues a closed contour sees and therefore which combinations of $e^{\pm iE_{\mathbf{p}}t}$ appear and with what step-function support. Causality (the vanishing of D_R for $t < 0$), and the particle/antiparticle bookkeeping of the Feynman propagator, are read off the geometry of Fig. 5.3.

Physical Insight: the $i\varepsilon$ *is* the boundary condition

A Green's function of a differential operator is only determined once boundary conditions are imposed; for the wave operator $\Box + m^2$ the homogeneous solutions are precisely the on-shell modes $e^{\mp iE_{\mathbf{p}}t}$, so a Green's function is ambiguous up to their addition. In the frequency domain that ambiguity is exactly the freedom to slide poles across the real axis. The retarded prescription chooses "no signal before the source," the advanced "no signal after," and the Feynman prescription chooses the mixed boundary condition—positive frequencies forward in time, negative frequencies backward—that, as Chapter 9 will show, is what the vacuum of a relativistic quantum field actually realizes. There is one analytic object, the propagator-as-distribution; the three names are three boundary conditions, and the $i\varepsilon$ is how a boundary condition is written in the integrand.

5.3.5 The Feynman propagator and time ordering

The Feynman result Eq. (5.86) deserves to be examined on its own, because it is the object the rest of the book is built to compute. Reattaching the spatial

integral from Eq. (5.80),

$$D_F(x) = \int \frac{d^3p}{(2\pi)^3}\,\frac{1}{2E_{\mathbf{p}}}\,e^{i\mathbf{p}\cdot\mathbf{x}}\Big[\theta(t)\,e^{-iE_{\mathbf{p}}t} + \theta(-t)\,e^{+iE_{\mathbf{p}}t}\Big]. \tag{5.91}$$

Read the bracket. For $t > 0$ the propagator carries the *positive-frequency* factor $e^{-iE_{\mathbf{p}}t}$: a disturbance created at the earlier time propagates forward with the energy of a particle of mass m. For $t < 0$ it carries $e^{+iE_{\mathbf{p}}t} = e^{-iE_{\mathbf{p}}|t|}$, again a positive-energy phase but running in the opposite time sense—the contribution one will later interpret as an antiparticle propagating forward, or equivalently a particle propagating backward. The combination is precisely the *time-ordered* structure

$$I_F(t) = \frac{1}{2E_{\mathbf{p}}}\Big[\theta(t)\,e^{-iE_{\mathbf{p}}t} + \theta(-t)\,e^{+iE_{\mathbf{p}}t}\Big], \tag{5.92}$$

where the step functions place the larger-time factor on the left in each term. In Chapter 9 this exact object will be identified, mode by mode, with the vacuum two-point function $\langle 0|\mathcal{T}\phi(x)\phi(0)|0\rangle$ of the free scalar field, the time-ordering symbol $\mathcal{T}$ being the field-theoretic origin of the very $\theta(\pm t)$ we have just produced by contour choice. We have, in other words, computed $\langle 0|\mathcal{T}\phi\phi|0\rangle$ before we have a field ϕ: the analytic structure determines the answer, and quantization in Part III will only supply its operator interpretation. This is why the present calculation is the model computation that "plants" the object the threads need rather than itself advancing a thread.

Historical Note: Stückelberg, Feynman, and the two-sided propagator

The recognition that a single causal-looking propagator could carry positive frequencies forward and negative frequencies backward in time—unifying particle and antiparticle into one analytic object—is due to Stückelberg in the late 1930s and to Feynman in his 1949 spacetime approach to quantum electrodynamics. The $i\varepsilon$ that selects this combination is sometimes still called the Feynman prescription for that reason. The retarded Green's function, by contrast, is the classical object familiar from electrodynamics, where causality is imposed by hand through the choice of boundary condition; the quantum theory makes the Feynman combination, not the retarded one, the natural propagator inside the path integral, for reasons that become transparent once the generating functional is built in Chapters 9 and 10.

5.3.6 Poles versus branch points: a preview of cuts

Every singularity we have met in this section is a *pole*: an isolated point where the function blows up like $(z - z_0)^{-n}$, around which the function is single-valued

and the residue theorem applies verbatim. The propagator $1/(p^2 - m^2 + i\varepsilon)$ is meromorphic in p^0, with the two simple poles of Eq. (5.77) and nothing else. This is the entire reason the contour technology of this section works so cleanly: closing the contour reduces an integral to a finite sum of residues.

The integrals produced by *loops*, which the book will meet from Chapter 19 onward, are not so simple. A one-loop diagram in ϕ^4 or QED produces, after the loop momentum is integrated, functions such as $\log(m^2 - p^2 - i\varepsilon)$ or $\sqrt{1 - 4m^2/s}$, whose singularities are *branch points*, not poles. We must distinguish the two carefully, since the cut structure they generate is the analytic shadow of physical thresholds and the engine of the dispersion relations of Section 5.5.

Definition 5.27 (Branch point and branch cut)**.** A point z_0 is a *branch point* of a function f if f is not single-valued in any punctured neighborhood of z_0: continuing f analytically once around a small loop encircling z_0 returns a *different* value. To work with a single-valued branch one removes a curve emanating from z_0—a *branch cut*—across which f jumps by the discontinuity $\operatorname{disc} f(z) \equiv f(z + i0) - f(z - i0)$, the difference of the boundary values from the two sides.

The contrast with a pole is sharp and worth stating explicitly. Encircle a simple pole of $g(z) = 1/(z - z_0)$ once and the function returns to its starting value; the integral around it is the nonzero number $2\pi i$, but the function is single-valued. Encircle the branch point of $h(z) = \log(z - z_0)$ once and the function does *not* return: it shifts by $2\pi i$, because log is genuinely multivalued. A pole contributes a residue; a branch cut contributes an integral of the discontinuity along the cut. The simplest field-theoretic example, which Chapter 19 computes in full, is the scalar one-loop "bubble," whose value is proportional to a function with a branch point at the two-particle threshold $s = 4m^2$ in the Mandelstam invariant $s = (p_1 + p_2)^2$; below threshold the function is real, above threshold it develops an imaginary part—the discontinuity across the cut—which the optical theorem ties to the physical production rate of the two-particle intermediate state. The same analytic continuation that we used here innocuously, to move a contour past poles, becomes in Section 5.5 the deep statement that the propagator and amplitudes are boundary values of functions analytic in their invariants, with poles at stable particles and cuts at multiparticle thresholds, the whole structure dictated by causality.

For the present chapter the lesson is one of bookkeeping discipline: *before* closing a contour one must know whether the singularities inside are poles, to be summed by residues, or branch points, around which the contour must instead be deformed onto the cut. In this section there were only poles, and the residue theorem sufficed; from Chapter 19 the cuts arrive, and the residue theorem must be supplemented by the discontinuity calculus previewed here.

The worked computation has established the operational meaning of the $i\varepsilon$

as a contour instruction, and Fig. 5.3 shows that the Feynman prescription is the one placement that leaves the first and third quadrants of the p^0-plane free of poles. That clearance is not an accident of bookkeeping; it is precisely what will permit the real p^0-contour to be rotated onto the imaginary axis without crossing a singularity—and a contour that may be moved freely so long as it crosses no pole is the seed of analytic continuation. The next section promotes this freedom to a principle and carries out the rotation in earnest, establishing the Wick rotation that links Minkowski and Euclidean signature and identifying the Feynman $i\varepsilon$ as exactly the ingredient that makes the rotation legal.

5.4 Analytic continuation and Wick rotation

The previous section ended with a freedom and a puzzle. The freedom is that the energy integral defining a propagator may be evaluated along any contour in the complex p^0 plane that begins and ends at the same places and does not cross a pole; deforming the contour changes nothing. The puzzle is that this freedom looks like a mere convenience for doing residue arithmetic, when in fact it is an instance of something far larger. Once an integral is recognized as the boundary value of an analytic function, the integral is no longer tied to the real axis at all: it can be slid, rotated, and re-expressed wherever the analyticity permits, and two expressions that look completely different—a Minkowski integral oscillating along the real p^0 axis and a Euclidean integral decaying along the imaginary axis—turn out to be the same number. This section promotes contour deformation to the principle of *analytic continuation*, and then spends that principle on the single most-used continuation in the book: the *Wick rotation* that links Lorentzian and Euclidean signature. We will prove that the Feynman $i\epsilon$ is exactly the prescription that makes the rotation legal, and we will introduce the Schwinger proper-time representation, which turns the indefinite, conditionally convergent Minkowski denominators into manifestly convergent Euclidean Gaussians.

5.4.1 The principle of analytic continuation

We assume, as a reviewed prerequisite, the basic structure theory of holomorphic functions: a function analytic on an open set has a convergent power series about every point of that set, and conversely. The one statement we need to isolate, because everything in this section rests on it, is the rigidity of analytic functions.

Theorem 5.28 (Identity theorem)**.** *Let f and g be analytic on a connected open set $U \subseteq \mathbb{C}$, and suppose $f = g$ on a subset $S \subseteq U$ that has a limit point in U (for instance, S contains a line segment, an open subdomain, or any sequence converging to an interior point). Then $f = g$ everywhere on U.*

Proof. Set $h = f - g$, analytic on U and vanishing on S. Let $z_\star \in U$ be a limit

point of S. Expanding h in its power series about $z_\star$, suppose h is not identically zero near $z_\star$; then there is a smallest n with $h^{(n)}(z_\star) \neq 0$, so $h(z) = (z - z_\star)^n\, u(z)$ with u analytic and $u(z_\star) \neq 0$. By continuity $u \neq 0$ in a punctured neighbourhood of $z_\star$, so h has no zeros there other than $z_\star$ itself—contradicting that $z_\star$ is a limit of zeros of h. Hence h vanishes to all orders at $z_\star$ and is identically zero on a neighbourhood. The set on which h vanishes to all orders is therefore open; it is also closed in U (an intersection of the closed sets $\{h^{(k)} = 0\}$); since U is connected and the set is nonempty, it is all of U. □

The identity theorem has one consequence we use relentlessly: *analytic continuation, when it exists, is unique.* If a function is defined and analytic on a domain D_1, and one wishes to extend it to a larger connected domain $D_2 \supset D_1$ as an analytic function, then *any* such extension must agree with any other on D_1, hence—by Theorem 5.28—everywhere on D_2. There is at most one analytic continuation. This turns "find a formula that agrees with the original where the original makes sense, and is analytic on a larger region" into a rigorous and unambiguous operation: the new formula *is* the old function, merely viewed where its first definition broke down.

In quantum field theory the objects we continue are almost never bare functions; they are integrals depending on an external parameter. The pattern is the following.

Proposition 5.29 (Continuation of a parameter integral)**.** *Suppose $F(z) = \int_\Omega \kappa(x, z)\, dx$ converges absolutely and uniformly on compact subsets of an open set $D_1 \subseteq \mathbb{C}$, with $z \mapsto \kappa(x, z)$ analytic for each x. Then F is analytic on D_1. If G is analytic on a larger connected $D_2 \supset D_1$ and $G = F$ on D_1, then G is the unique analytic continuation of F, and one is entitled to* use *G*'s formula as the value of the original integral *for all $z \in D_2$—even at points z where the original integral $\int_\Omega \kappa(x, z)\, dx$ no longer converges.*

Proof. Analyticity of F on D_1 is Morera's theorem combined with Fubini: for any closed contour γ in a compact subset of D_1, uniform convergence lets us exchange $\oint_\gamma dz$ with $\int_\Omega dx$, and $\oint_\gamma \kappa(x, z)\, dz = 0$ for each x by Cauchy's theorem, so $\oint_\gamma F = 0$ and F is analytic. Uniqueness of the continuation is Theorem 5.28. □

The clause that matters is the last one. The Euler integral $\Gamma(z) = \int_0^\infty t^{z-1} e^{-t}\, dt$ converges only for $\operatorname{Re} z > 0$, yet the gamma function is defined and analytic on all of $\mathbb{C}$ except the nonpositive integers; the recursion $\Gamma(z) = \Gamma(z+1)/z$ is the continuation, and Theorem 5.29 is the licence to read off $\Gamma(-\tfrac{1}{2})$ from it even though the defining integral diverges there. Dimensional regularization (Chapter D) is the same move performed on the spacetime dimension d: a loop integral convergent only for d in some strip is *defined*, for all other d, as its unique analytic continuation. And the Wick rotation we now build is this principle applied to the contour of the energy integral.

5.4.2 The Wick rotation

Minkowski-space calculations carry oscillatory weights—e^{iS} in the path integral, $e^{-ip\cdot x}$ in Fourier transforms, and propagator denominators $p^2 - m^2$ that change sign and vanish on the mass shell. None of these is absolutely convergent without the $i\epsilon$ regulator, and the oscillations make both analytic estimates and numerical work treacherous. The Wick rotation trades the Lorentzian signature for a Euclidean one in which every weight becomes a real, decaying Gaussian. We first fix the rotation as a change of variables; the next subsection proves it is legal.

Definition 5.30 (Wick rotation)**.** The *Wick rotation* continues the time coordinate and the energy into the complex plane by

$$x^0 = t \;\longrightarrow\; -i\,\tau, \qquad p^0 \;\longrightarrow\; i\,p_E^4, \tag{5.93}$$

with $\tau \in \mathbb{R}$ the *Euclidean time* and $p_E^4 \in \mathbb{R}$ the *Euclidean energy*. Spatial components are unchanged, $x^i = x_E^i$, $p^i = p_E^i$. The Euclidean four-vectors are $x_E = (\tau, \mathbf{x})$, $p_E = (p_E^4, \mathbf{p})$, contracted with the positive-definite metric $\delta_{\mu\nu} = \mathrm{diag}(+,+,+,+)$.

Throughout, p_E^2 denotes the Euclidean square $p_E^2 = (p_E^4)^2 + \mathbf{p}^2 \geq 0$, in contrast to the Minkowski $p^2 = (p^0)^2 - \mathbf{p}^2$.

Notation Watch

Two unrelated objects in this section are both spelled with an epsilon. The *regulator* $i\epsilon$ in the Feynman propagator is the infinitesimal positive quantity sent to 0^+ at the end; it sets the analytic structure. The dimensional-regularization parameter in $d = 4 - 2\varepsilon$, which appears only in the worked example below, is written ε and is a finite continuation variable. They are never the same symbol and never interact; keep them visually distinct.

The two substitutions in Eq. (5.93) are consistent with the Fourier kernel and with the metric. Under them the Minkowski square continues to minus the Euclidean square,

$$p^2 = (p^0)^2 - \mathbf{p}^2 \;\longrightarrow\; (ip_E^4)^2 - \mathbf{p}^2 = -\big[(p_E^4)^2 + \mathbf{p}^2\big] = -\,p_E^2, \tag{5.94}$$

and the phase of a plane wave becomes a real exponent, $p\cdot x = p^0 x^0 - \mathbf{p}\cdot\mathbf{x} \to (ip_E^4)(-i\tau) - \mathbf{p}\cdot\mathbf{x} = p_E^4\tau - \mathbf{p}\cdot\mathbf{x}$.

The deepest consequence is for the action, and it is what makes the rotation the backbone of the Euclidean path integral of Chapter 10. For the carried scalar theory with Lagrangian density $\mathcal{L} = \tfrac{1}{2}(\partial_t\phi)^2 - \tfrac{1}{2}(\nabla\phi)^2 - \tfrac{1}{2}m^2\phi^2 - V(\phi)$, the Minkowski action is $S = \int dt\, d^3x\, \mathcal{L}$. Substituting $t = -i\tau$, so that $\partial_t = i\,\partial_\tau$

and the temporal kinetic term flips sign, $(\partial_t\phi)^2 \to -(\partial_\tau\phi)^2$, while the measure becomes $dt\, d^3x = -i\, d\tau\, d^3x = -i\, d^4x_E$, one finds

$$\begin{aligned} iS &= i\int(-i\, d^4x_E)\left[-\tfrac{1}{2}(\partial_\tau\phi)^2 - \tfrac{1}{2}(\nabla\phi)^2 - \tfrac{1}{2}m^2\phi^2 - V(\phi)\right] \\ &= -\int d^4x_E\left[\tfrac{1}{2}(\partial_\tau\phi)^2 + \tfrac{1}{2}(\nabla\phi)^2 + \tfrac{1}{2}m^2\phi^2 + V(\phi)\right] \;\equiv\; -S_E, \end{aligned} \tag{5.95}$$

so that the oscillatory weight becomes a real, bounded, decaying one,

$$e^{iS} \;\longrightarrow\; e^{-S_E}, \qquad S_E = \int d^4x_E\Big[\tfrac{1}{2}(\partial_\mu\phi)(\partial_\mu\phi) + \tfrac{1}{2}m^2\phi^2 + V(\phi)\Big] \geq 0, \tag{5.96}$$

with all indices in S_E summed with the Euclidean metric. The Euclidean action is bounded below; e^{-S_E} is a genuine probability weight. This is exactly the S_E frozen for ϕ^4 theory, whose quartic version $V = \frac{\lambda}{4!}\phi^4$ gives the Euclidean action used in Chapter 10; the present rotation is the operation that chapter invokes by name.

Physical Insight

A Lorentzian path integral is an interference problem: e^{iS} assigns each history a unit-modulus phase, and observables emerge from delicate cancellation. A Euclidean path integral is a statistics problem: e^{-S_E} assigns each history a positive Boltzmann weight, and observables are expectation values in an ordinary probability measure. The Wick rotation says these are two analytic faces of one object. Everything hard about oscillatory integrals—conditional convergence, sign problems, the meaning of "$\int e^{iS}$"—is bought off by paying the price of working at imaginary time and continuing back at the end.

5.4.3 Why the rotation is legal: the $i\epsilon$ does the work

A change of variables in a one-dimensional integral is only as good as the contour deformation that justifies it. Replacing $\int dp^0$ along the real axis by $\int dp^4_E$ along the imaginary axis is the deformation $\theta : 0 \to \pi/2$ of the ray $p^0 = |p^0|e^{i\theta}$, swinging the contour counterclockwise through the first and third quadrants. This is legitimate precisely when (i) the integrand has no poles in the swept quadrants and (ii) the contributions from the connecting arcs at infinity vanish. The content of the legality theorem is that the *Feynman* prescription, and only it, places the propagator poles out of the way of this particular rotation. We import the pole positions established in the previous section.

The pole structure is read off from the Feynman denominator. Setting $p^2 - m^2 + i\epsilon = 0$ at fixed real spatial momentum $\mathbf{p}$ gives $(p^0)^2 = \mathbf{p}^2 + m^2 - i\epsilon =$

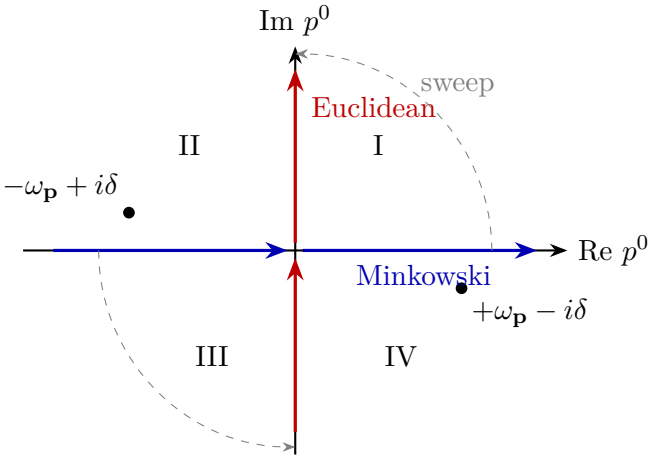

Figure 5.4: The complex p^0 plane for the Feynman propagator. The poles sit in quadrants II ($-\omega_{\mathbf{p}} + i\delta$) and IV ($+\omega_{\mathbf{p}} - i\delta$), with $\delta = \epsilon/2\omega_{\mathbf{p}} \to 0^+$. Wick rotation swings the integration contour counterclockwise from the real axis (Minkowski, blue) to the imaginary axis (Euclidean, red) through the pole-free quadrants I and III; the quarter-circle arcs at infinity (gray) contribute nothing, and no pole is crossed.

$\omega_{\mathbf{p}}^2 - i\epsilon$, with $\omega_{\mathbf{p}} = \sqrt{\mathbf{p}^2 + m^2} > 0$, so to first order in ϵ,

$$p^0 = \pm\sqrt{\omega_{\mathbf{p}}^2 - i\epsilon} = \pm\Big(\omega_{\mathbf{p}} - \tfrac{i\epsilon}{2\omega_{\mathbf{p}}}\Big) + O(\epsilon^2) = \pm(\omega_{\mathbf{p}} - i\delta), \qquad \delta = \frac{\epsilon}{2\omega_{\mathbf{p}}} > 0. \tag{5.97}$$

The pole at $+\omega_{\mathbf{p}} - i\delta$ lies in the fourth quadrant (positive real part, negative imaginary part); the pole at $-\omega_{\mathbf{p}} + i\delta$ lies in the second quadrant. This is precisely the placement derived in Eq. (5.77), and it is what distinguishes the Feynman prescription from the retarded ($i\epsilon\,\mathrm{sgn}\,p^0$, both poles below the axis) and advanced (both above) choices. Quadrants I and III—the regions the rotation sweeps—are free of poles. Figure 5.4 shows the geometry.

Theorem 5.31 (Legality of the Wick rotation)**.** *Let $f(p^0)$ be meromorphic in p^0 at fixed real $\mathbf{p}$, with all poles confined to the open second and fourth quadrants (the Feynman placement (5.97)), and suppose there are constants $C > 0$ and $\eta > 0$ such that $|f(p^0)| \le C\,|p^0|^{-1-\eta}$ for all sufficiently large $|p^0|$ with $\arg p^0 \in [0, \frac{\pi}{2}] \cup [\pi, \frac{3\pi}{2}]$. Then the Minkowski and Euclidean energy integrals agree:*

$$\int_{-\infty}^{\infty} dp^0\, f(p^0) \;=\; i\int_{-\infty}^{\infty} dp_E^4\, f(i\,p_E^4). \tag{5.98}$$

Proof. Work first in the first quadrant. Consider the closed, positively oriented contour Γ_R consisting of: the segment C_1 along the real axis from 0 to R; the quarter-circle arc C_2, $p^0 = Re^{i\theta}$ with $\theta : 0 \to \frac{\pi}{2}$; and the segment C_3 down the

imaginary axis from iR to 0. Since all poles of f lie in quadrant II or IV, Γ_R encloses none, and Cauchy's theorem gives

$$\int_{C_1} f\,dp^0 + \int_{C_2} f\,dp^0 + \int_{C_3} f\,dp^0 = 0. \tag{5.99}$$

On the arc, the ML estimate together with the decay hypothesis bounds the length $\frac{\pi}{2}R$ times the maximum of $|f|$:

$$\left|\int_{C_2} f\,dp^0\right| \le \frac{\pi}{2}R \cdot CR^{-1-\eta} = \frac{\pi C}{2}\,R^{-\eta} \xrightarrow[R\to\infty]{} 0. \tag{5.100}$$

On C_3 parametrize $p^0 = ir$ with r running from R down to 0, so $dp^0 = i\,dr$ and $\int_{C_3} f\,dp^0 = \int_R^0 f(ir)\,i\,dr = -i\int_0^R f(ir)\,dr$. Inserting this and (5.100) into (5.99) and letting $R \to \infty$,

$$\int_0^\infty f(p^0)\,dp^0 = i\int_0^\infty f(ir)\,dr. \tag{5.101}$$

The third quadrant is treated identically with the closed contour built from the negative real axis ($-R \to 0$), the arc $\theta : \pi \to \frac{3\pi}{2}$, and the negative imaginary axis; the arc again vanishes and the same parametrization gives

$$\int_{-\infty}^0 f(p^0)\,dp^0 = i\int_{-\infty}^0 f(ir)\,dr. \tag{5.102}$$

Adding (5.101) and (5.102) and renaming the dummy variable $r = p_E^4$ yields (5.98). □

Two remarks fix the meaning. First, the decay hypothesis $|f| \lesssim |p^0|^{-1-\eta}$ holds for a single Feynman propagator ($f \sim (p^0)^{-2}$, so $\eta = 1$) and a fortiori for any product of propagators, which is the only case we ever rotate; when an integrand grows—a loop integral that is genuinely divergent—the arcs do not vanish in $d = 4$, and the rotation is justified instead in $d = 4 - 2\varepsilon$ dimensions, where the integral is made convergent first (Chapter D). Second, and this is the whole point of the section heading: had we used the retarded or advanced prescription, both poles would sit in the lower (or upper) half-plane, one of them *inside* a swept quadrant, and Eq. (5.99) would pick up a residue; the rotation would change the answer. The Feynman $i\epsilon$ is not one acceptable choice among several—it is the unique pole placement for which Lorentzian and Euclidean integrals are literally equal. This is the precise sense in which the $i\epsilon$ "makes the rotation legal."

Caution

The rotation $p^0 \to ip_E^4$ in momentum space and $t \to -i\tau$ in position space turn the same way only because energy and time are conjugate; do not rotate one clockwise and the other counterclockwise. A sign error here

flips e^{-S_E} to a divergent e^{+S_E} and is among the most common slips in the subject. The fixed convention is Eq. (5.93), matching Chapter 10.

5.4.4 The Schwinger proper-time representation

The Wick rotation makes denominators convergent, but it is paired with a second device that converts those denominators into Gaussians, at which point the Euclidean integrals of Chapter 19 and Chapter D can actually be done. That device is the Schwinger, or proper-time, representation: it writes a denominator as an integral of an exponential over an auxiliary "time" $s \geq 0$, exchanging $1/A$ for $\int ds\, e^{\pm isA}$. The $i\epsilon$ resurfaces here in a new guise—now as the regulator that guarantees convergence at the upper limit $s \to \infty$.

Proposition 5.32 (Schwinger representation)**.** *For real A and $\epsilon > 0$,*

$$\frac{1}{A + i\epsilon} = -\,i \int_0^\infty ds\; e^{\,is\,(A+i\epsilon)}, \tag{5.103}$$

the integral converging absolutely because the $i\epsilon$ supplies a damping factor $e^{-\epsilon s}$. Applied to the Feynman propagator denominator ($A = p^2 - m^2$) this is the compact and manifestly convergent identity

$$\frac{i}{p^2 - m^2 + i\epsilon} = \int_0^\infty ds\; e^{\,is\,(p^2 - m^2 + i\epsilon)}. \tag{5.104}$$

In Euclidean signature, where the denominator $A = p_E^2 + m^2 > 0$ is strictly positive, no regulator is needed and the representation is the elementary Laplace identity

$$\frac{1}{A} = \int_0^\infty ds\; e^{-sA}, \qquad A > 0, \tag{5.105}$$

together with its powered version, for $n > 0$,

$$\frac{1}{A^{\,n}} = \frac{1}{\Gamma(n)} \int_0^\infty ds\; s^{\,n-1} e^{-sA}. \tag{5.106}$$

Proof. For (5.103), the integrand is $e^{is(A+i\epsilon)} = e^{isA}\, e^{-\epsilon s}$, whose modulus is $e^{-\epsilon s}$; hence the integral converges absolutely for $\epsilon > 0$. Integrating directly,

$$\int_0^\infty ds\; e^{\,is(A+i\epsilon)} = \left[\frac{e^{\,is(A+i\epsilon)}}{i(A+i\epsilon)}\right]_0^\infty = \frac{0 - 1}{i(A+i\epsilon)} = \frac{-1}{i(A+i\epsilon)} = \frac{i}{A+i\epsilon}, \tag{5.107}$$

where the upper endpoint vanishes precisely because $|e^{is(A+i\epsilon)}| = e^{-\epsilon s} \to 0$, and we used $-1/i = i$. Multiplying (5.107) by $-i$ gives (5.103); and (5.104) is (5.107) evaluated at $A = p^2 - m^2$. For the Euclidean identity (5.105), $A > 0$ makes $\int_0^\infty e^{-sA}\, ds = [-e^{-sA}/A]_0^\infty = 1/A$ with no regulator. The powered form (5.106) follows by substituting $s \to s/A$ in the definition $\Gamma(n) = \int_0^\infty u^{n-1} e^{-u}\, du$, which gives $\Gamma(n) = A^n \int_0^\infty s^{n-1} e^{-sA}\, ds$. □

The structure to internalize is the parallel between the two regulators. In the Lorentzian form (5.104) the exponent $is(p^2 - m^2) - \epsilon s$ has a real part $-\epsilon s$ that comes *entirely* from the Feynman $i\epsilon$; without it the integral over s would be a pure phase $e^{is(p^2-m^2)}$ and would not converge at $s \to \infty$. After Wick rotation $p^2 \to -p_E^2$, the same exponent becomes $-s(p_E^2 + m^2)$, a real decaying Gaussian-in-the-making whose convergence is automatic. The $i\epsilon$ is the Lorentzian shadow of Euclidean positivity: it is exactly the infinitesimal needed to push the Minkowski integral onto the convergent side, and once one has rotated to Euclidean signature it has done its job and is dropped. This is why every practical loop calculation in the book rotates first and parametrizes second.

5.4.5 A worked Wick rotation: the scalar bubble integral

We now run the entire machine on the representative one-loop scalar integral that recurs throughout Chapter 19 and is tabulated in Chapter D. It is the simplest integral that is only conditionally defined in Minkowski space yet perfectly convergent (away from $d = 4$) in Euclidean space, so it shows the payoff cleanly.

Worked Example 5.33 (Wick rotation of $\int d^4p\,/(p^2 - m^2 + i\epsilon)^2$)**.** Consider

$$I = \int \frac{d^4p}{(2\pi)^4} \frac{1}{(p^2 - m^2 + i\epsilon)^2}. \tag{5.108}$$

The integrand is the square of a Feynman propagator denominator; by (5.97) it has *double* poles in p^0 at $\pm(\omega_{\mathbf{p}} - i\delta)$, both in quadrants II and IV. At fixed $\mathbf{p}$ it falls as $(p^0)^{-4}$, so the hypotheses of Theorem 5.31 hold with room to spare, and the p^0 contour may be rotated to the imaginary axis.

Step 1: rotate. Apply Eq. (5.93) to the energy integration inside the four-dimensional measure. With $p^0 = ip_E^4$ we have $dp^0 = i\,dp_E^4$, hence $d^4p = i\,d^4p_E$, while by (5.94) $p^2 - m^2 + i\epsilon \to -(p_E^2 + m^2)$, the regulator now superfluous because the denominator no longer vanishes. The squared denominator becomes $(p_E^2 + m^2)^2$, and so

$$I = \int \frac{i\,d^4p_E}{(2\pi)^4} \frac{1}{(p_E^2 + m^2)^2} = i \int \frac{d^4p_E}{(2\pi)^4} \frac{1}{(p_E^2 + m^2)^2}. \tag{5.109}$$

The conditionally convergent Minkowski oscillation has become a positive, rotationally symmetric Euclidean integrand. Only the overall factor of i records that we ever left Lorentzian signature.

Step 2: regulate the dimension. In $d = 4$ the Euclidean integral (5.109) diverges logarithmically at large p_E ($\int d^4p_E/p_E^4$). We therefore continue the dimension to $d = 4 - 2\varepsilon$, as licensed by Theorem 5.29 and detailed in Chapter D, and compute

$$I_E(d) \equiv \int \frac{d^dp_E}{(2\pi)^d} \frac{1}{(p_E^2 + m^2)^2}. \tag{5.110}$$

Step 3: Schwinger-parametrize and Gaussian-integrate. Apply the powered Euclidean representation (5.106) with $n = 2$ and $A = p_E^2 + m^2$, so that $\frac{1}{(p_E^2+m^2)^2} = \int_0^\infty ds\, s\, e^{-s(p_E^2+m^2)}$. Inserting this and exchanging the orders of integration (legitimate by absolute convergence, the momentum integral being Gaussian for each $s > 0$),

$$I_E(d) = \int_0^\infty ds\, s\, e^{-sm^2} \int \frac{d^d p_E}{(2\pi)^d}\, e^{-s\, p_E^2}. \tag{5.111}$$

The inner integral is the d-dimensional Gaussian transform established in Eq. (5.50); with all d components decoupling, $\int d^d p_E\, e^{-sp_E^2} = (\pi/s)^{d/2}$, so

$$\int \frac{d^d p_E}{(2\pi)^d}\, e^{-s\, p_E^2} = \frac{1}{(2\pi)^d}\Big(\frac{\pi}{s}\Big)^{d/2} = \frac{1}{(4\pi)^{d/2}}\, s^{-d/2}. \tag{5.112}$$

Substituting (5.112) into (5.111) collapses the problem to a single proper-time integral,

$$I_E(d) = \frac{1}{(4\pi)^{d/2}} \int_0^\infty ds\, s^{\,1-d/2}\, e^{-sm^2} = \frac{1}{(4\pi)^{d/2}}\, \Gamma\Big(2 - \tfrac{d}{2}\Big)\, (m^2)^{\frac{d}{2}-2}, \tag{5.113}$$

where the last equality is $\int_0^\infty s^{a-1} e^{-sm^2}\, ds = \Gamma(a)(m^2)^{-a}$ with $a = 2 - \frac{d}{2}$.

Step 4: restore the rotation factor and read off the divergence. Combining (5.109) with (5.113),

$$\boxed{I = \frac{i}{(4\pi)^{d/2}}\, \Gamma\Big(2 - \tfrac{d}{2}\Big)\, (m^2)^{\frac{d}{2}-2}} \xrightarrow{d=4-2\varepsilon} \frac{i}{(4\pi)^2}\Big[\frac{1}{\varepsilon} - \gamma_E + \ln\frac{4\pi}{m^2} + O(\varepsilon)\Big], \tag{5.114}$$

the expansion using $\Gamma(\varepsilon) = \frac{1}{\varepsilon} - \gamma_E + O(\varepsilon)$ and $(m^2)^{-\varepsilon} = 1 - \varepsilon \ln m^2 + \cdots$ (with the usual $\mu^{2\varepsilon}$ restoring dimensions, supplied in Chapter D). The logarithmic divergence of the original $d = 4$ integral has become the simple pole $\Gamma(2 - d/2) = \Gamma(\varepsilon) \sim 1/\varepsilon$, which is exactly what the renormalization machinery of Chapter 19 subtracts.

Three threads tie together in Theorem 5.33, and it is worth naming them. The pole placement of Eq. (5.77) told us *which way* to rotate; the legality theorem Theorem 5.31 told us we were *allowed* to; the Schwinger identity Theorem 5.32 and the Gaussian of Eq. (5.50) did the *work*. The general one-loop master integral $\int d^d p_E/(p_E^2 + \Delta)^n$, of which (5.110) is the case $n = 2$, $\Delta = m^2$, is obtained by the identical steps and is recorded in Chapter D; every loop computation in QED (Chapter 19) and ϕ^4 theory proceeds by rotating to Euclidean signature, combining denominators, Schwinger- or Feynman-parametrizing, and reducing to this single Gaussian.

With the Wick rotation established, the correlators and amplitudes of the book are seen to be Euclidean analytic functions of their external invariants, continued

back to Lorentzian signature at the end. The location of the singularities that this continuation cannot avoid—the poles and branch cuts that survive on the real-momentum axis—is not a defect of the continuation but a physical datum: it encodes the spectrum and the thresholds of the theory. The next section reads that analytic structure physically, showing that analyticity in the external invariants is the imprint of causality, and turns it into the working dispersion relations that reconstruct an amplitude from its discontinuity.

5.5 Analyticity as physics: causality and dispersion relations

The previous section, Section 5.4, established analyticity as a *technical* fact: contour deformation promoted to a principle, the Wick rotation made legal by the Feynman $i\epsilon$, Euclidean correlation functions read as the boundary values of objects holomorphic in a domain of complexified momenta. In Euclidean signature that holomorphy is almost featureless — the Euclidean propagator $1/(p_E^2 + m^2)$ has no singularity for real p_E at all — and it is tempting to regard analyticity as nothing more than a convenience that lets one rotate integrals into a region where they converge. The purpose of this section is to overturn that impression. Read in Minkowski signature, the singularities of an amplitude are not blemishes to be rotated away; they *are* the physics. A pole on the real axis is a stable particle; a branch cut is the opening of a decay or scattering channel; the location of the nearest singularity sets the range of a force. And the very fact that the amplitude is the boundary value of an analytic function turns out to be the mathematical shadow of a single physical principle: *causality* — no effect before its cause.

This is the most economical idea in the analytic toolkit. We will prove that a response which respects causality, in the sharp sense that it vanishes before the stimulus that produced it, has a Fourier transform that is holomorphic in an entire half-plane of complex frequency. From holomorphy plus a mild bound at infinity, Cauchy's theorem then squeezes out a rigid constraint: the real and imaginary parts of the response are not independent functions but are determined by each other through a principal-value integral — the Kramers–Kronig relations. The same machinery, applied to a scattering amplitude regarded as a function of a Mandelstam invariant, becomes a *dispersion relation*: a formula that reconstructs the whole amplitude from the discontinuity across its cuts, with the discontinuity itself fixed — via the Sokhotski–Plemelj identity of Theorem 5.10 — to be twice the imaginary part, the *absorptive* part. We close by stating, at the level of precise definitions awaiting their proofs, the two results that this circle of ideas exists to serve: the Källén–Lehmann spectral representation of the two-point function and the optical theorem $2\,\mathrm{Im}\,\mathcal{M} \sim \sigma_{\mathrm{tot}}$. The worked computation that ends the section — reconstructing a model two-point function with a single threshold from

its discontinuity — is self-contained, but it is not idle: it builds, with all algebra shown, exactly the analytic object that QED's vacuum polarization $\Pi(q^2)$ will be in Chapter 19, and the dispersive logic that organizes the unitarity methods of Chapter 60.

5.5.1 Causality as a support condition

The cleanest setting in which to see analyticity emerge from causality is linear response. Suppose a system in equilibrium is poked by an external force $f(t)$ and responds with some observable $x(t)$. For small forces the response is linear and time-translation invariant, so the most general possibility is a convolution

$$x(t) = \int_{-\infty}^{\infty} G_R(t - t')\, f(t')\, \mathrm{d}t', \tag{5.115}$$

in which the *response function* (or retarded Green's function) G_R encodes everything about the system's dynamics. The kernel $G_R(\tau)$ is the response measured at a time τ after a sharp unit kick. Causality is the statement that the system cannot respond before it is kicked:

Definition 5.34 (Causal (retarded) response)**.** A response function G_R is *causal* if

$$G_R(\tau) = 0 \qquad \text{for all } \tau < 0. \tag{5.116}$$

Equivalently, $\operatorname{supp} G_R \subseteq [0, \infty)$.

This is a *support condition* — a statement about where the function is allowed to be nonzero — and it is the entire physical input. Everything that follows is its analytic consequence. We work with the Fourier transform in the frequency variable ω, adopting for this subsection the response-theory convention

$$\widehat{G}(\omega) = \int_{-\infty}^{\infty} G_R(\tau)\, e^{i\omega\tau}\, \mathrm{d}\tau \overset{(5.116)}{=} \int_{0}^{\infty} G_R(\tau)\, e^{i\omega\tau}\, \mathrm{d}\tau, \tag{5.117}$$

where the second equality is the only place the support condition enters. (The sign in the exponent is the standard one for retarded functions; it is the time-component of the book's spacetime convention of Chapter 3 restricted to one dimension, and it is what makes the half-plane below come out to be the *upper* one. We flag the clash with the spatial Fourier sign in Section 5.5.1.) The transform variable will now be allowed to become complex, $\omega = \operatorname{Re}\omega + i \operatorname{Im}\omega$.

Theorem 5.35 (Causality forces upper-half-plane analyticity)**.** *Let $G_R \in L^1(0, \infty)$ satisfy the support condition (5.116). Then the function $\widehat{G}(\omega)$ defined by (5.117) is holomorphic in the open upper-half plane*

$$\mathbb{C}_+ = \{\omega \in \mathbb{C} : \operatorname{Im}\omega > 0\}, \tag{5.118}$$

and is bounded there by $|\widehat{G}(\omega)| \le \|G_R\|_{L^1}$. *If moreover* G_R *is bounded with at most exponential growth* $|G_R(\tau)| \le Ce^{\gamma\tau}$, *the same conclusions hold in the shifted half-plane* $\operatorname{Im}\omega > \gamma$.

Proof. Write $\omega = \sigma + i\eta$ with $\eta = \operatorname{Im}\omega > 0$. Inside the integral (5.117) the exponential factorizes,

$$e^{i\omega\tau} = e^{i\sigma\tau}\, e^{-\eta\tau}, \tag{5.119}$$

and here the support condition does its work: because τ ranges only over $[0,\infty)$, the factor $e^{-\eta\tau}$ is a *decaying* exponential, never a growing one. The integrand is therefore dominated in modulus by an integrable function independent of the real part σ,

$$\bigl|G_R(\tau)\, e^{i\omega\tau}\bigr| = |G_R(\tau)|\, e^{-\eta\tau} \le |G_R(\tau)| \in L^1(0,\infty). \tag{5.120}$$

This already gives absolute convergence of (5.117) throughout $\mathbb{C}_+$ and the bound

$$|\widehat{G}(\omega)| \le \int_0^\infty |G_R(\tau)|\, e^{-\eta\tau}\, \mathrm{d}\tau \le \int_0^\infty |G_R(\tau)|\, \mathrm{d}\tau = \|G_R\|_{L^1}. \tag{5.121}$$

It remains to show holomorphy. We verify it by Morera's theorem, which sidesteps any need to differentiate under the integral sign. Let Δ be any closed triangle contained in $\mathbb{C}_+$; then $\eta \ge \eta_0 > 0$ on Δ for some η_0, and the bound (5.120) sharpens to the uniform, τ-integrable majorant $|G_R(\tau)|\, e^{-\eta_0\tau}$. The function $\omega \mapsto e^{i\omega\tau}$ is entire, so for each fixed τ its contour integral around $\partial\Delta$ vanishes by Cauchy's theorem. The uniform integrable bound licenses Fubini's theorem to exchange the two integrations,

$$\oint_{\partial\Delta} \widehat{G}(\omega)\, \mathrm{d}\omega = \oint_{\partial\Delta} \left(\int_0^\infty G_R(\tau)\, e^{i\omega\tau}\, \mathrm{d}\tau \right) \mathrm{d}\omega = \int_0^\infty G_R(\tau) \left(\oint_{\partial\Delta} e^{i\omega\tau}\, \mathrm{d}\omega \right) \mathrm{d}\tau = 0. \tag{5.122}$$

Since the integral of $\widehat{G}$ around every triangle in $\mathbb{C}_+$ vanishes and $\widehat{G}$ is continuous there (again by dominated convergence applied to (5.117)), Morera's theorem makes $\widehat{G}$ holomorphic on $\mathbb{C}_+$. The exponential-growth refinement is identical with $e^{-\eta\tau}$ replaced by $e^{-(\eta-\gamma)\tau}$, integrable precisely when $\eta > \gamma$. □

The logic is worth restating in one sentence, because the same sentence will recur in every later appearance of analyticity. *The support of the function in time controls the half-plane of analyticity in frequency:* support in $\tau > 0$ buys analyticity for $\operatorname{Im}\omega > 0$. The exponent $e^{i\omega\tau}$ converts the geometric fact "τ is positive" into the analytic fact "$e^{i\omega\tau}$ decays upward," and decay is exactly what convergence and holomorphy require.

Physical Insight

The half-plane is not arbitrary. A retarded function lives on $\tau > 0$ and is analytic *above*; an advanced function lives on $\tau < 0$ and is analytic *below*; the Feynman propagator, which is neither purely retarded nor advanced, is the boundary value of a function analytic in neither half-plane alone but built — via the $i\epsilon$ of Section 5.4 — to have its positive- and negative-frequency parts each propagate causally. The single phrase "analytic in the upper-half plane" is thus a precise, checkable encoding of "the future does not influence the past."

The converse of Theorem 5.35 is also true, and it is the deeper half of the equivalence; we state it without proof, as it is not needed downstream and its proof is a genuine excursion into Hardy-space theory.

Theorem 5.36 (Titchmarsh)**.** *Let $g \in L^2(\mathbb{R})$. The following are equivalent:* (i) *g is the boundary value of a function holomorphic and uniformly square-integrable on the upper-half plane (a function in the Hardy space $H^2(\mathbb{C}_+)$);* (ii) *the inverse Fourier transform of g is supported in $[0, \infty)$, i.e. g is causal;* (iii) *the real and imaginary parts of g on the real axis are Hilbert transforms of one another — the Kramers–Kronig relations of Theorem 5.37 below. This is the Paley–Wiener/Titchmarsh circle of theorems; Theorem 5.35 proves the implication* (ii)⇒(i) *that we actually use.*

Notation Watch

In this section the temporal transform carries $e^{+i\omega\tau}$ (Eq. (5.117)), so that causal functions are analytic in the *upper* ω-plane. The book's standing spacetime convention (Chapter 3) is $f(x) = \int \frac{d^4p}{(2\pi)^4} e^{-ip\cdot x} \tilde{f}(p)$ with $p \cdot x = p^0 t - \mathbf{p} \cdot \mathbf{x}$; the time-component there is $e^{-ip^0 t}$. The two agree once one identifies $\omega = p^0$ and remembers that the response kernel is integrated against the *source at earlier times*, which flips the sign relative to the field expansion. When we pass to amplitudes as functions of $s = p^2$ in Section 5.5.5, the relevant analyticity is in s and this sign bookkeeping no longer intrudes.

5.5.2 The Kramers–Kronig relations

Analyticity in a half-plane, together with a decay bound, is enough to make the real and imaginary parts of a response function rigidly interdependent. The mechanism is Cauchy's formula evaluated on the boundary of the half-plane, and the technical heart is the Sokhotski–Plemelj identity, which tells us precisely what happens when a Cauchy kernel is pushed onto the contour of integration.

Assume henceforth that $\widehat{G}$ is holomorphic in $\mathbb{C}_+$ (guaranteed by Theorem 5.35) and that it *decays* on large semicircles in the closed upper-half plane: $|\widehat{G}(\omega)| \to 0$ as $|\omega| \to \infty$ with $\operatorname{Im}\omega \geq 0$. (Physically $\widehat{G}$ is a susceptibility, and the system cannot respond to an infinitely fast drive, so $\widehat{G} \to 0$ at high frequency; we lift this assumption in Section 5.5.3.) Fix a real frequency ω and approach it from inside the half-plane, writing the interior point as $\omega + i\epsilon$ with $\epsilon \to 0^+$. Cauchy's integral formula on the contour Γ_R consisting of the real axis from $-R$ to R closed by the semicircle of radius R in $\mathbb{C}_+$ gives, since $\widehat{G}$ is holomorphic inside,

$$\widehat{G}(\omega + i\epsilon) = \frac{1}{2\pi i} \oint_{\Gamma_R} \frac{\widehat{G}(\omega')}{\omega' - \omega - i\epsilon}\, \mathrm{d}\omega'. \tag{5.123}$$

The semicircular arc contributes a term bounded by $\max_{\text{arc}} |\widehat{G}| \cdot \pi R/R = \pi \max_{\text{arc}} |\widehat{G}| \to 0$ as $R \to \infty$, by the decay assumption (this is Jordan's lemma in its elementary form, the $1/R$ from the denominator beating the πR arclength once $\widehat{G} \to 0$). Sending $R \to \infty$ leaves only the real-axis integral,

$$\widehat{G}(\omega + i\epsilon) = \frac{1}{2\pi i} \int_{-\infty}^{\infty} \frac{\widehat{G}(\omega')}{\omega' - \omega - i\epsilon}\, \mathrm{d}\omega'. \tag{5.124}$$

Now take $\epsilon \to 0^+$. The boundary value of $\widehat{G}$ on the left is its physical real-frequency value $\widehat{G}(\omega)$. On the right the Cauchy kernel hits the real axis, and this is exactly the situation the Sokhotski–Plemelj identity (Theorem 5.10) governs:

$$\frac{1}{\omega' - \omega - i\epsilon} \xrightarrow{\epsilon \to 0^+} \operatorname{PV} \frac{1}{\omega' - \omega} + i\pi\, \delta(\omega' - \omega). \tag{5.125}$$

Inserting (5.125) into (5.124) and doing the delta-function integral,

$$\widehat{G}(\omega) = \frac{1}{2\pi i} \operatorname{PV} \int_{-\infty}^{\infty} \frac{\widehat{G}(\omega')}{\omega' - \omega}\, \mathrm{d}\omega' + \frac{1}{2\pi i}\, i\pi\, \widehat{G}(\omega) = \frac{1}{2\pi i} \operatorname{PV} \int_{-\infty}^{\infty} \frac{\widehat{G}(\omega')}{\omega' - \omega}\, \mathrm{d}\omega' + \tfrac{1}{2}\widehat{G}(\omega). \tag{5.126}$$

The term $\frac{1}{2}\widehat{G}(\omega)$ — the contribution of the boundary pole, geometrically the half of a residue picked up by an indentation that skirts the singularity (Fig. 5.5) — moves to the left, and multiplying through by 2 yields the master relation

$$\boxed{\widehat{G}(\omega) = \frac{1}{i\pi} \operatorname{PV} \int_{-\infty}^{\infty} \frac{\widehat{G}(\omega')}{\omega' - \omega}\, \mathrm{d}\omega'.} \tag{5.127}$$

This says $\widehat{G}$ is, up to the factor $1/i$, its own Hilbert transform — a statement that has bite only because the real and imaginary parts can now be separated.

Write $\widehat{G} = \operatorname{Re}\widehat{G} + i \operatorname{Im}\widehat{G}$ on the real axis and take the real and imaginary parts of (5.127). Because $1/i = -i$, the real part of the left side equals the imaginary part of the integral and vice versa:

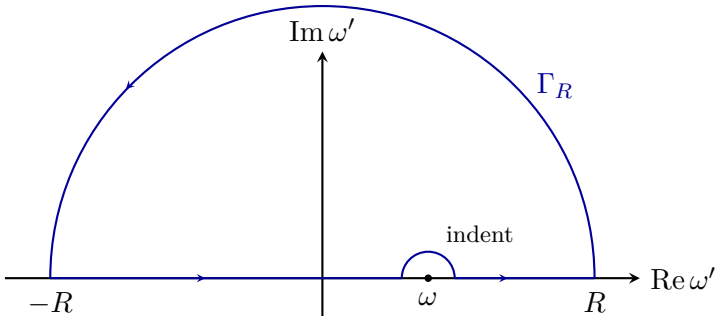

Figure 5.5: The contour behind the Kramers–Kronig relation (5.127). Because the causal response $\widehat{G}$ is holomorphic in the upper-half plane (Theorem 5.35) and decays on the large arc, the closed contour Γ_R encloses no singularity. Pushing the evaluation point onto the real axis produces the simple pole at $\omega' = \omega$; the small semicircular indentation skirting it contributes half a residue, the $\frac{1}{2}\widehat{G}(\omega)$ of (5.126), equivalently the $i\pi\delta$ of Sokhotski–Plemelj (5.125).

Theorem 5.37 (Kramers–Kronig relations)**.** *For a causal response function $\widehat{G}$ holomorphic in $\mathbb{C}_+$ and vanishing at infinity there,*

$$\operatorname{Re}\widehat{G}(\omega) = \frac{1}{\pi}\,\mathrm{PV}\int_{-\infty}^{\infty} \frac{\operatorname{Im}\widehat{G}(\omega')}{\omega' - \omega}\,\mathrm{d}\omega', \tag{5.128}$$

$$\operatorname{Im}\widehat{G}(\omega) = -\frac{1}{\pi}\,\mathrm{PV}\int_{-\infty}^{\infty} \frac{\operatorname{Re}\widehat{G}(\omega')}{\omega' - \omega}\,\mathrm{d}\omega'. \tag{5.129}$$

The real and imaginary parts are Hilbert transforms of each other: knowing one on the whole real axis determines the other completely.

The physical content is striking. The imaginary part of a susceptibility is the *dissipative* response — the part of the system's reaction that is out of phase with the drive and therefore absorbs energy from it. The real part is the *reactive* (dispersive) response, in phase with the drive. Theorem 5.37 says these cannot be chosen independently: a medium that absorbs at some frequencies is *obliged*, by causality alone, to be dispersive at others. In optics, with $\widehat{G}$ the complex refractive index, this is the statement that the frequency dependence of the refractive index (the cause of a prism's rainbow) is fixed by the absorption spectrum, and conversely.

For a *real* response kernel $G_R(\tau) \in \mathbb{R}$ — the physical case, since $x(t)$ and $f(t)$ in (5.115) are real — there is an extra symmetry that folds these integrals onto positive frequencies. Conjugating (5.117) and using G_R real,

$$\widehat{G}(\omega)^* = \int_0^\infty G_R(\tau)\, e^{-i\omega^*\tau}\,\mathrm{d}\tau = \widehat{G}(-\omega^*), \qquad \text{so on the real axis} \quad \operatorname{Re}\widehat{G}(-\omega) = \operatorname{Re}\widehat{G}(\omega), \quad \text{I} \tag{5.130}$$

The real part is even and the imaginary part odd. Splitting the integral (5.128) at the origin and substituting $\omega' \to -\omega'$ on the negative half,

$$\int_{-\infty}^{0} \frac{\operatorname{Im}\widehat{G}(\omega')}{\omega'-\omega}\,\mathrm{d}\omega' \overset{\omega'\to-\omega'}{=} \int_{0}^{\infty} \frac{-\operatorname{Im}\widehat{G}(\omega')}{-\omega'-\omega}\,\mathrm{d}\omega' = \int_{0}^{\infty} \frac{\operatorname{Im}\widehat{G}(\omega')}{\omega'+\omega}\,\mathrm{d}\omega', \tag{5.131}$$

so that the two halves combine over the common denominator $(\omega'-\omega)^{-1}+(\omega'+\omega)^{-1} = 2\omega'/(\omega'^2-\omega^2)$, giving the form in which the relations are usually quoted:

$$\operatorname{Re}\widehat{G}(\omega) = \frac{2}{\pi}\,\mathrm{PV}\int_{0}^{\infty} \frac{\omega'\,\operatorname{Im}\widehat{G}(\omega')}{\omega'^2-\omega^2}\,\mathrm{d}\omega', \tag{5.132}$$

$$\operatorname{Im}\widehat{G}(\omega) = -\frac{2\omega}{\pi}\,\mathrm{PV}\int_{0}^{\infty} \frac{\operatorname{Re}\widehat{G}(\omega')}{\omega'^2-\omega^2}\,\mathrm{d}\omega'. \tag{5.133}$$

These are the Kramers–Kronig relations as they appear in optics and many-body theory. We have proved them from nothing but the support condition (5.116) and a decay bound.

5.5.3 Subtractions: the price of slow decay

The derivation above leaned on $\widehat{G}\to 0$ at large $|\omega|$ so that the arc in (5.123) would drop. Many functions of interest — and essentially every amplitude in field theory — do not decay; they approach a constant or grow. The cure is standard and carries a name that will reappear, with the same arithmetic, at the centre of renormalization: *subtraction*.

Suppose $\widehat{G}$ is holomorphic in $\mathbb{C}_+$ but tends to a nonzero constant, or more generally grows slower than linearly, so that the arc contribution in (5.123) does not vanish. Choose a reference point ω_0 on the real axis where $\widehat{G}(\omega_0)$ is known (typically a low frequency, or threshold, where the response is measured or where it is real). The *once-subtracted* function

$$\widehat{G}_1(\omega) \equiv \frac{\widehat{G}(\omega)-\widehat{G}(\omega_0)}{\omega-\omega_0} \tag{5.134}$$

is still holomorphic in $\mathbb{C}_+$ — the apparent pole at $\omega=\omega_0$ is removable because the numerator vanishes there — and it decays one power faster than $\widehat{G}$, fast enough that the arc now drops. Applying the unsubtracted master relation (5.127) to $\widehat{G}_1$ and multiplying back through by $(\omega-\omega_0)$ gives the once-subtracted dispersion relation

$$\widehat{G}(\omega) = \widehat{G}(\omega_0) + \frac{\omega-\omega_0}{i\pi}\,\mathrm{PV}\int_{-\infty}^{\infty} \frac{\widehat{G}(\omega')}{(\omega'-\omega)(\omega'-\omega_0)}\,\mathrm{d}\omega'. \tag{5.135}$$

The extra factor $(\omega'-\omega_0)^{-1}$ in the integrand improves its convergence at large ω' by one power; the price is the appearance of one undetermined constant,

$\widehat{G}(\omega_0)$, which the dispersion integral does *not* fix and which must be supplied from outside — a measurement, a symmetry, or a renormalization condition. If $\widehat{G}$ grows linearly, one subtraction is not enough and one subtracts twice, at the cost of two constants:

$$\widehat{G}(\omega) = \widehat{G}(\omega_0) + (\omega-\omega_0)\,\widehat{G}'(\omega_0) + \frac{(\omega-\omega_0)^2}{i\pi}\,\mathrm{PV}\!\int_{-\infty}^{\infty} \frac{\widehat{G}(\omega')}{(\omega'-\omega)(\omega'-\omega_0)^2}\,\mathrm{d}\omega'. \tag{5.136}$$

The pattern is clear: each power of high-energy growth that the function exhibits costs one subtraction, hence one undetermined constant, which is fixed by one piece of low-energy data. The number of subtractions needed is set by the behaviour at infinity; the constants are the data that the dispersion relation cannot generate from the discontinuity alone.

Physical Insight

The arithmetic "one power of growth = one subtraction = one undetermined constant fixed by data" is the same arithmetic that will organize renormalization. There, the superficial degree of divergence of a diagram (Chapter 21) counts the powers of large loop momentum, hence the number of subtractions needed to render the amplitude finite, hence the number of counterterms whose finite parts are fixed by renormalization conditions (Chapter 22). A dispersion relation and a renormalized amplitude are the same analytic function written two ways: as an integral over its discontinuity plus a polynomial of undetermined constants. We have met the bookkeeping of renormalization here, in its gentlest form, before any field is quantized.

5.5.4 The discontinuity across a cut is twice the imaginary part

We now pass from the frequency variable of linear response to the natural variable of relativistic amplitudes, a Mandelstam invariant we call s (for the two-point function below it is $s = p^2$, the squared momentum flowing through). An amplitude $\Pi(s)$ is, generically, a function holomorphic in the complex s-plane except for singularities forced on it by physical processes: a pole at $s = m^2$ where an intermediate state can go on shell as a single stable particle, and a *branch cut* running along the real axis from a threshold s_{th} (the squared invariant mass of the lightest multiparticle state into which the system can decay or scatter) to $+\infty$, where a continuum of intermediate states opens up. The cut is the analytic signature of those open channels.

The key structural fact is that the size of the jump across the cut is not free: it is fixed to be twice the imaginary part of the boundary value. The reason is a reflection symmetry inherited from reality.

Theorem 5.38 (Discontinuity equals twice the imaginary part)**.** *Let* Π *be holomorphic in the cut plane* $\mathbb{C}\setminus[s_{\rm th},\infty)$ *and real on the segment of the real axis below threshold,* $\Pi(s)\in\mathbb{R}$ *for* $s<s_{\rm th}$*. Then* Π *obeys the Schwarz reflection principle* $\Pi(s^*)=\Pi(s)^*$*, and the discontinuity across the cut is*

$$\operatorname{disc}\Pi(s)\equiv\lim_{\epsilon\to0^+}\big[\Pi(s+i\epsilon)-\Pi(s-i\epsilon)\big]=2i\,\operatorname{Im}\Pi(s+i\epsilon),\qquad s>s_{\rm th}. \tag{5.137}$$

Proof. The function $h(s)\equiv\Pi(s^*)^*$ is holomorphic wherever Π is (composition with the antiholomorphic conjugation done twice is holomorphic), and on the lower-threshold segment it agrees with Π because Π is real there: for $s<s_{\rm th}$ real, $h(s)=\Pi(s)^*=\Pi(s)$. Two functions holomorphic on the (connected) cut plane that agree on a segment agree everywhere there, by the identity theorem (Section 5.4). Hence $\Pi(s^*)^*=\Pi(s)$, i.e. $\Pi(s^*)=\Pi(s)^*$ throughout. Apply this with $s\to s+i\epsilon$, whose conjugate is $s-i\epsilon$:

$$\Pi(s-i\epsilon)=\Pi\big((s+i\epsilon)^*\big)=\Pi(s+i\epsilon)^*. \tag{5.138}$$

Therefore the jump is

$$\Pi(s+i\epsilon)-\Pi(s-i\epsilon)=\Pi(s+i\epsilon)-\Pi(s+i\epsilon)^*=2i\,\operatorname{Im}\Pi(s+i\epsilon), \tag{5.139}$$

which is (5.137). □

This little theorem is the hinge of the whole subject. It says that the *imaginary part* of an amplitude on the upper lip of its cut — a quantity that, by the optical theorem of Section 5.5.6, is a sum of physical probabilities and is therefore directly measurable — is exactly one half of the analytic discontinuity that a contour integral around the cut would pick up. The Sokhotski–Plemelj identity (Theorem 5.10) is the same statement at the level of the elementary kernel: writing a propagator denominator as $1/(s'-s\mp i\epsilon)$, the two sign choices straddle the cut, and their difference,

$$\frac{1}{s'-s-i\epsilon}-\frac{1}{s'-s+i\epsilon}=2\pi i\,\delta(s'-s), \tag{5.140}$$

is the discontinuity of $1/(s'-s)$ regarded as a function of s across its (point) singularity. Every cut in field theory is, microscopically, a coherent sum of such elementary $i\epsilon$ discontinuities, one for each intermediate particle put on shell.

Physical Insight

The physical reading of (5.137) is that *an amplitude acquires an imaginary part exactly when an intermediate state can go on shell.* Below threshold there is no real process the intermediate state can undergo, the propagators stay off the real-axis poles, and Π is real. Above threshold the intermediate

particles can be produced as real, on-shell quanta; the propagator denominators hit their poles, Sokhotski–Plemelj converts $1/(p^2 - m^2 + i\epsilon)$ into a $-i\pi\delta(p^2 - m^2)$ that enforces the on-shell condition, and the amplitude develops an absorptive (imaginary) part. "Absorptive" is literal: it is the part of forward scattering that removes flux from the beam into open channels.

5.5.5 Dispersion relations: reconstructing an amplitude from its cut

With Theorem 5.38 in hand, the dispersion relation for an amplitude writes itself. Suppose $\Pi(s)$ is holomorphic in the cut plane, real below threshold, and bounded at infinity well enough that the following arc drops. By Cauchy's formula, for s off the cut,

$$\Pi(s) = \frac{1}{2\pi i} \oint_C \frac{\Pi(s')}{s' - s}\, \mathrm{d}s', \tag{5.141}$$

where C is a small counterclockwise circle around s. Now *deform* C outward (Fig. 5.6). The integrand is holomorphic everywhere except at the cut $[s_{\mathrm{th}}, \infty)$ and on the arc at infinity, so the circle around s can be blown up until it becomes a large circle at radius R minus a contour that wraps tightly around the cut (the deformation sweeps across no singularity except the explicit pole at $s' = s$, which is what we are computing). If $\Pi(s') \to 0$ as $|s'| \to \infty$, the large circle drops, and what remains is the integral down the upper lip of the cut and back along the lower lip:

$$\Pi(s) = \frac{1}{2\pi i} \int_{s_{\mathrm{th}}}^{\infty} \frac{\Pi(s' + i\epsilon) - \Pi(s' - i\epsilon)}{s' - s}\, \mathrm{d}s' = \frac{1}{2\pi i} \int_{s_{\mathrm{th}}}^{\infty} \frac{\operatorname{disc}\Pi(s')}{s' - s}\, \mathrm{d}s'. \tag{5.142}$$

Inserting the discontinuity (5.137) converts this into an integral over the imaginary part alone:

$$\boxed{\Pi(s) = \frac{1}{\pi} \int_{s_{\mathrm{th}}}^{\infty} \frac{\operatorname{Im}\Pi(s')}{s' - s}\, \mathrm{d}s'.} \tag{5.143}$$

The amplitude everywhere in the cut plane is reconstructed from its imaginary part on the cut — from its absorptive part, hence (looking ahead) from total cross sections.

When Π does not vanish at infinity the large circle does not drop, and we subtract exactly as in Section 5.5.3, now most conveniently at $s = 0$. The once-subtracted dispersion relation reads

$$\Pi(s) = \Pi(0) + \frac{s}{\pi} \int_{s_{\mathrm{th}}}^{\infty} \frac{\operatorname{Im}\Pi(s')}{s'\,(s' - s)}\, \mathrm{d}s', \tag{5.144}$$

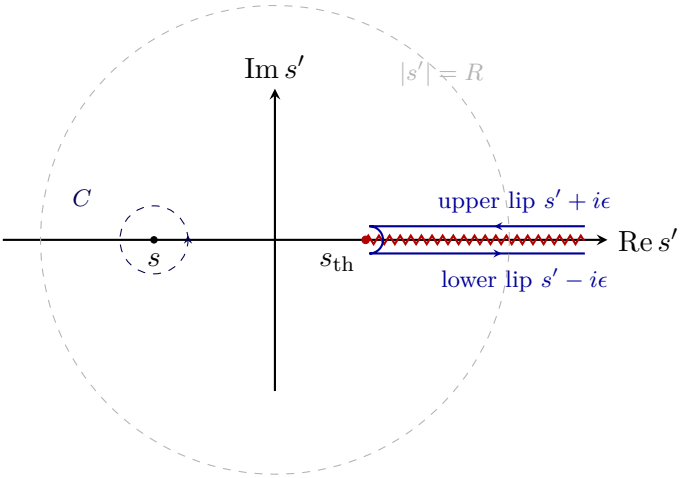

Figure 5.6: The contour deformation behind the dispersion relation (5.143). Cauchy's formula on the small circle C around s equals the same integrand wrapped around all other singularities. The only other singularity is the branch cut $[s_{\text{th}}, \infty)$ (zigzag); deforming C out to the large circle $|s'| = R$ and collapsing onto the cut leaves an integral down the upper lip and back along the lower lip, whose integrand is the discontinuity $\operatorname{disc}\Pi = 2i\,\operatorname{Im}\Pi$ of (5.137). If $\Pi \to 0$ on the large circle it drops; otherwise it must be tamed by subtractions (5.144).

the extra $1/s'$ in the integrand again buying one power of convergence at the cost of the single constant $\Pi(0)$. A twice-subtracted version,

$$\Pi(s) = \Pi(0) + s\,\Pi'(0) + \frac{s^2}{\pi}\int_{s_{\text{th}}}^{\infty} \frac{\operatorname{Im}\Pi(s')}{s'^2\,(s'-s)}\,\mathrm{d}s', \tag{5.145}$$

costs two constants, $\Pi(0)$ and $\Pi'(0)$. These are the workhorse formulas of Chapters 19 and 60.

5.5.6 Two results stated, awaiting their proofs

The dispersive machinery exists to serve two structural results of quantum field theory. Neither can be proved before fields are quantized, so we state them precisely here, with forward pointers to the chapters that discharge them, and note how each is an instance of what we have just built.

The Källén–Lehmann spectral representation. For an interacting scalar field ϕ with a single stable particle of mass m, the exact (Heisenberg-picture) two-point function has a Fourier transform of the form

$$\Delta(p^2) = \int_0^{\infty} \mathrm{d}\mu^2\,\rho(\mu^2)\,\frac{i}{p^2 - \mu^2 + i\epsilon}, \qquad \rho(\mu^2) \geq 0, \tag{5.146}$$

with a nonnegative *spectral density* ρ that consists of a delta function $Z\,\delta(\mu^2 - m^2)$ at the one-particle mass (the residue $0 \le Z \le 1$ being the field-strength renormalization) plus a continuum supported above the multiparticle threshold $\mu^2 \ge (2m)^2$. Comparing (5.146) with the dispersion relation (5.143) shows they are the *same statement*: the spectral density is the discontinuity of the propagator, $\rho(\mu^2) = \frac{1}{\pi}\operatorname{Im}\Delta(\mu^2)$, and the representation (5.146) is precisely the reconstruction of Δ from its cut. The nonnegativity $\rho \ge 0$ is the new physical input — it follows from inserting a complete set of states and is the spectral shadow of unitarity. The full construction, including the proof that $\rho \ge 0$ and the identification of Z, is carried out in Chapter 9 (free case) and completed for the interacting field alongside LSZ in Chapter 14.

The optical theorem. Unitarity of the S-matrix, $\mathbf{S}^\dagger\mathbf{S} = 1$ written as $\mathbf{S} = 1 + i\mathcal{T}$, forces $-i(\mathcal{T} - \mathcal{T}^\dagger) = \mathcal{T}^\dagger\mathcal{T}$, whose diagonal matrix element relates the imaginary part of a forward amplitude to a sum over all states the initial state can scatter into:

$$2\,\operatorname{Im}\mathcal{M}(i \to i) = \sum_X \int \mathrm{d}\Pi_X\, \left|\mathcal{M}(i \to X)\right|^2, \tag{5.147}$$

the sum running over all kinematically allowed final states X with their Lorentz-invariant phase space $\mathrm{d}\Pi_X$. For a two-particle initial state at centre-of-mass energy squared s, the right-hand side is proportional to the total cross section, giving the form usually quoted,

$$\operatorname{Im}\mathcal{M}(s, t=0) = 2\,E_{\mathrm{cm}}\,p_{\mathrm{cm}}\,\sigma_{\mathrm{tot}}(s) \xrightarrow{\;s\to\infty\;} s\,\sigma_{\mathrm{tot}}(s). \tag{5.148}$$

This is the promised physical meaning of the imaginary part that the dispersion integrals (5.143)–(5.145) integrate over: $\operatorname{Im}\Pi$ is not an abstract analytic datum but a sum of squared physical amplitudes, hence a total rate. A dispersion relation thus reconstructs the full amplitude — real and imaginary parts at all s — from cross-section data alone, up to the subtraction constants. The derivation of (5.147) from unitarity is given in Chapter 14, its diagrammatic incarnation (Cutkosky's cutting rules, which compute $\operatorname{disc}\Pi$ diagram by diagram by putting internal lines on shell exactly as in (5.140)) in Chapter 60.

5.5.7 Worked computation: a two-point function from its discontinuity

We now make the whole circle of ideas concrete on a model that is not a toy: it is, up to spin and charge factors supplied in Chapter 19, the vacuum polarization of QED. Consider the one-loop "bubble" two-point function built from two propagators of a particle of mass m,

$$\Pi(s) = \frac{g^2}{2}\int \frac{\mathrm{d}^4k}{(2\pi)^4}\,\frac{1}{(k^2 - m^2 + i\epsilon)\,((k+q)^2 - m^2 + i\epsilon)}, \qquad s = q^2, \tag{5.149}$$

with g a coupling of mass dimension making Π dimensionless. We do *not* evaluate the loop integral directly here — that is the business of Chapter 19, with the dimensional regularization of Chapter 5's companion machinery. Instead we exploit analyticity: we compute only the *discontinuity*, which is elementary, and then *reconstruct* the whole function by a dispersion relation. This is the strategy the worked example is built to teach, because it is how hard amplitudes are actually obtained when the direct integral is intractable.

Worked Example 5.39 (Reconstructing the bubble from its cut)**. Step 1: locate the cut.** The integrand of (5.149) develops a singularity in s when both internal lines can be simultaneously on shell with positive energy — when the external momentum q can create a real pair. The lightest such intermediate state is two quanta of mass m, with invariant mass squared $(2m)^2$. Hence the cut runs along

$$s \in [s_{\rm th}, \infty), \qquad s_{\rm th} = 4m^2, \tag{5.150}$$

and $\Pi(s)$ is real and analytic for $s < 4m^2$, in particular at $s = 0$.

Step 2: the discontinuity from on-shell phase space. By Theorem 5.38, the discontinuity is $2i\,\mathrm{Im}\,\Pi$, and by the optical-theorem logic (5.147) the imaginary part is the two-body phase space of the on-shell pair weighted by the (here constant) production amplitude. Put the two lines on shell with the Sokhotski–Plemelj replacement (5.140), $1/(k^2 - m^2 + i\epsilon) \to -i\pi\,\delta(k^2 - m^2)$ for each line, keeping positive energies. The resulting integral is the standard two-body Lorentz-invariant phase space,

$$\mathrm{Im}\,\Pi(s) = \frac{g^2}{2}\cdot\frac{1}{8\pi}\,\beta(s)\,\theta(s-4m^2) = \frac{g^2}{16\pi}\,\beta(s)\,\theta(s-4m^2), \qquad \beta(s) \equiv \sqrt{1-\frac{4m^2}{s}}, \tag{5.151}$$

where $\beta(s)$ is the velocity of each produced quantum in the centre-of-mass frame and the factor $1/8\pi$ is the two-body phase-space volume $\int \mathrm{d}\Pi_2 = \beta/8\pi$ (derived in Chapter 16; we quote only the kinematic number, which is all the example needs). The key qualitative facts are visible immediately: $\mathrm{Im}\,\Pi$ vanishes as $\beta \to 0$ at threshold ($s \to 4m^2$, the pair produced at rest, vanishing phase space) and approaches the constant $g^2/16\pi$ as $s \to \infty$ ($\beta \to 1$). Because $\mathrm{Im}\,\Pi$ tends to a nonzero constant, the unsubtracted integral (5.143) would diverge logarithmically: *one subtraction is mandatory.*

Step 3: the once-subtracted dispersion relation. Subtracting at $s = 0$ (allowed, since Π is analytic there), Eq. (5.144) gives

$$\Pi(s) - \Pi(0) = \frac{s}{\pi}\int_{4m^2}^{\infty} \frac{\mathrm{Im}\,\Pi(s')}{s'\,(s'-s)}\,\mathrm{d}s' = \frac{g^2}{16\pi^2}\,s\int_{4m^2}^{\infty}\frac{\beta(s')}{s'\,(s'-s)}\,\mathrm{d}s'. \tag{5.152}$$

We now evaluate the integral in closed form. The natural variable is β itself: set $v = \beta(s') = \sqrt{1-4m^2/s'}$, so $s' = 4m^2/(1-v^2)$ and $\mathrm{d}s' = 4m^2\cdot 2v\,(1-v^2)^{-2}\,\mathrm{d}v$,

with $v:0\to 1$ as $s':4m^2\to\infty$. A short reduction, using $s'-s=[4m^2-s(1-v^2)]/(1-v^2)$, collapses the integrand to a rational function of v:

$$\frac{\beta(s')\,\mathrm{d}s'}{s'\,(s'-s)}=\frac{v\cdot 4m^2\,\dfrac{2v}{(1-v^2)^2}\,\mathrm{d}v}{\dfrac{4m^2}{1-v^2}\cdot\dfrac{4m^2-s(1-v^2)}{1-v^2}}=\frac{2v^2}{4m^2-s(1-v^2)}\,\mathrm{d}v=\frac{2v^2}{(4m^2-s)+s\,v^2}\,\mathrm{d}v. \tag{5.153}$$

Thus

$$K(s)\equiv\int_{4m^2}^{\infty}\frac{\beta(s')}{s'(s'-s)}\,\mathrm{d}s'=\int_0^1\frac{2v^2}{(4m^2-s)+s\,v^2}\,\mathrm{d}v=\frac{2}{s}\int_0^1\left[1-\frac{4m^2-s}{(4m^2-s)+s\,v^2}\right]\mathrm{d}v, \tag{5.154}$$

where we split $sv^2=[(4m^2-s)+sv^2]-(4m^2-s)$ in the numerator. For $0<s<4m^2$ the constant $4m^2-s>0$, and writing $b\equiv\sqrt{4m^2/s-1}=\sqrt{(4m^2-s)/s}>0$ the remaining elementary integral is an arctangent,

$$\int_0^1\frac{\mathrm{d}v}{(4m^2-s)+s\,v^2}=\frac{1}{s}\int_0^1\frac{\mathrm{d}v}{b^2+v^2}=\frac{1}{s\,b}\arctan\frac{1}{b}, \tag{5.155}$$

so that, assembling (5.154) with $4m^2-s=s\,b^2$,

$$K(s)=\frac{2}{s}\Big[\,1-s\,b^2\cdot\frac{1}{s\,b}\arctan\frac{1}{b}\,\Big]=\frac{2}{s}\Big[\,1-b\arctan\frac{1}{b}\,\Big]. \tag{5.156}$$

Multiplying by the prefactor in (5.152), the once-subtracted dispersion relation delivers the two-point function below threshold in closed form,

$$\boxed{\Pi(s)-\Pi(0)=\frac{g^2}{8\pi^2}\left[1-\sqrt{\frac{4m^2}{s}-1}\,\arctan\frac{1}{\sqrt{\frac{4m^2}{s}-1}}\right],\qquad 0<s<4m^2.} \tag{5.157}$$

Step 4: continue across the cut and recover the input. The expression (5.157) is real and analytic for $0<s<4m^2$. Continue it to $s>4m^2$ by following $s\to s+i\epsilon$, the physical prescription. There $b=\sqrt{4m^2/s-1}$ becomes imaginary; with the $+i\epsilon$ branch it continues to $b\to -i\,\beta$ with $\beta=\sqrt{1-4m^2/s}\in(0,1)$. Using $\arctan(z)=\frac{1}{2i}\ln\frac{1+iz}{1-iz}$, one finds $b\arctan(1/b)\to\beta\,\mathrm{artanh}(1/\beta)=\frac{\beta}{2}\ln\frac{1+\beta}{1-\beta}-i\,\frac{\pi\beta}{2}$, so that

$$\Pi(s)-\Pi(0)=\frac{g^2}{8\pi^2}\left[1-\frac{\beta}{2}\ln\frac{1+\beta}{1-\beta}\right]+i\,\frac{g^2}{16\pi}\,\beta,\qquad s>4m^2. \tag{5.158}$$

The imaginary part of the reconstructed function is $\dfrac{g^2}{16\pi}\beta$ — *exactly the input* (5.151) we started from. The dispersion relation has reproduced its own discontinuity, the internal consistency check guaranteed by Theorem 5.38: the

analytic function built from a given imaginary part has that imaginary part. The real part, the genuinely new output, is the logarithm $-\frac{g^2}{16\pi^2}\beta \ln\frac{1+\beta}{1-\beta}$ that one would otherwise have to extract from the full loop integral. Figure 5.7 plots both parts: the imaginary part switches on at $s = 4m^2$ with the square-root threshold behaviour of β, while the real part is smooth and develops a logarithmic shoulder there.

Step 5: read off the lessons. Three features of (5.157)–(5.158) are permanent. First, the branch point sits exactly at the physical threshold $s = 4m^2$ for producing the two-particle intermediate state: *singularities are kinematics*. Second, the single subtraction constant $\Pi(0)$ is undetermined by the dispersion integral; it is fixed by a renormalization condition, and the choice $\Pi(0)$ as the value at zero momentum is precisely the on-shell-like scheme used for QED vacuum polarization in Chapters 19 and 20, where this same $\Pi(0)$ subtraction is what renders the photon self-energy finite and defines the renormalized charge. Third, the logarithm $\ln\frac{1+\beta}{1-\beta}$ — with its imaginary part above threshold and its real, smooth behaviour below — is the universal one-loop bubble function; the QED computation of Chapter 19 differs only by spin-dependent numerator factors and the replacement of the scalar pair by an e^+e^- pair, and yields the running of the fine-structure constant of Chapter 24 through this very logarithm.

We have closed the loop promised at the start: a support condition in time (causality) became analyticity in a half-plane; analyticity plus a growth bound became the Kramers–Kronig and dispersion relations; and a single elementary discontinuity, fixed by Sokhotski–Plemelj to be twice an imaginary part, was enough to reconstruct an entire nontrivial two-point function, with the only freedom an undetermined subtraction constant that anticipates renormalization. The lesson is that an analytic amplitude is *rigid*: it is completely fixed by the locations and strengths of its singularities. There is, however, a sting in the tail. Perturbation theory does not hand us this rigid analytic function directly; it hands us a power series in the coupling that *approximates* it — and, as the zero-dimensional computation of Section 4.6 already warned and Chapter 42 will confirm, that series has zero radius of convergence. To make sense of the approximation we must understand what it means for a divergent series to represent an analytic function, and how to extract numbers from it. That is the asymptotic-analysis toolkit — asymptotic series, Watson's lemma, and the method of steepest descent — to which the next section turns.

5.6 Asymptotic series, Watson's lemma, and steepest descent

The dispersion relations of the previous section (Section 5.5) reconstruct an analytic amplitude from its discontinuity, exhibiting it as a genuine, well-defined

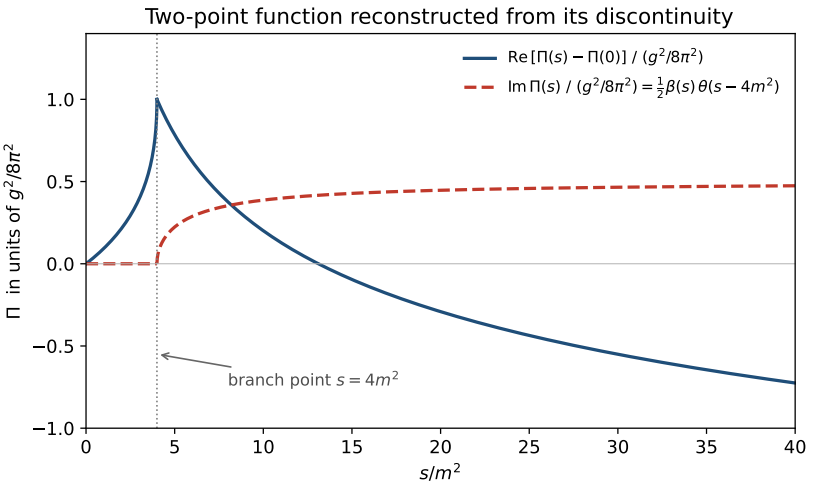

Figure 5.7: The model two-point function $\Pi(s)$ of Theorem 5.39, reconstructed from its discontinuity by the once-subtracted dispersion relation (5.152). The imaginary part (dashed) vanishes below the threshold $s = 4m^2$, switches on there as the phase-space factor $\beta(s) = \sqrt{1 - 4m^2/s}$, and saturates at high energy. The real part (solid), the new output of the dispersion integral, is everywhere smooth and carries the logarithmic shoulder (5.158) at threshold. This is, up to spin factors, the vacuum-polarization function $\Pi(q^2)$ of QED computed in Chapter 19. Both parts are in units of $g^2/8\pi^2$; the imaginary curve shows $\frac{1}{2}\beta$ in those units.

analytic function of the external invariants. Yet the only systematic way we will ever have to *compute* such an amplitude is perturbation theory: an expansion in a small coupling, generated diagram by diagram. The uncomfortable fact, foreshadowed already in the zero-dimensional toy of Section 4.6.5 and made unavoidable by Dyson's argument below, is that this expansion does not converge. For any fixed nonzero coupling the successive terms eventually grow without bound; the series has zero radius of convergence. A naive reading would conclude that perturbation theory is meaningless. The correct reading, which this section establishes, is that the perturbative series is *asymptotic*: it is a precisely defined object that approximates the true amplitude with an error controlled by its own terms, and from which physical numbers are extracted by stopping at the right place. To make this precise we need three things, developed in turn: the Poincaré definition of an asymptotic expansion and the phenomenon of optimal truncation; Watson's lemma, which reads off the asymptotics of a Laplace-type integral from the small-time behaviour of its integrand and exposes the factorial growth of the coefficients; and the method of steepest descent, which evaluates the oscillatory and exponential integrals — propagators, partition functions, semiclassical path integrals — that generate these series in the first place. The whole apparatus is the analytic engine of every saddle-point evaluation in the book, from the

loop expansion (Chapter 10) to instantons (Chapter 42); here we build it on self-contained model integrals that plant exactly the objects those later chapters consume.

5.6.1 Asymptotic (Poincaré) series

The first task is to say precisely what it means for a divergent series to "represent" a function. The definition is due to Poincaré, and its entire content is to reverse the order of two limits.

Definition 5.40 (Asymptotic expansion)**.** Let f be defined on a punctured neighbourhood of $g = 0$ (for definiteness, on an interval $0 < g < g_0$, or in a sector of the complex g-plane). A formal power series $\sum_{n=0}^{\infty} a_n g^n$ is an *asymptotic expansion* of f as $g \to 0^+$, written

$$f(g) \sim \sum_{n=0}^{\infty} a_n g^n \qquad (g \to 0^+), \tag{5.159}$$

if for every fixed integer $N \geq 0$ the remainder after $N+1$ terms is of higher order than the last term retained:

$$R_N(g) \equiv f(g) - \sum_{n=0}^{N} a_n g^n = o(g^N) \quad \text{as } g \to 0^+, \quad \text{equivalently} \quad R_N(g) = O(g^{N+1}). \tag{5.160}$$

The two estimates in (5.160) are equivalent whenever, as in every case we meet, the next term $a_{N+1} g^{N+1}$ is itself the leading part of R_N; we use the sharper $O(g^{N+1})$ form throughout. The crucial point is what Theorem 5.40 does *not* require: nothing whatsoever is said about the limit $N \to \infty$ at fixed g. A *convergent* series demands that, holding g fixed, the partial sums tend to $f(g)$ as $N \to \infty$. An *asymptotic* series demands that, holding N fixed, the error shrinks faster than g^N as $g \to 0$. These are independent conditions. A convergent power series with a positive radius of convergence is automatically asymptotic (its tail is $O(g^{N+1})$), but the converse fails spectacularly: a series can be asymptotic to a function and yet diverge for every $g \neq 0$. That is precisely the situation in quantum field theory, and the cleanest model exhibiting it is the following.

The canonical model: the Euler–Stieltjes integral. Consider the function defined for $g > 0$ by the convergent integral

$$E(g) \equiv \int_0^{\infty} \frac{e^{-t}}{1 + gt}\, \mathrm{d}t. \tag{5.161}$$

Because $0 < 1/(1+gt) \leq 1$ on the domain of integration, the integral is bounded by $\int_0^{\infty} e^{-t} \mathrm{d}t = 1$ and converges absolutely for every $g \geq 0$; E is a smooth,

finite, decreasing function with $E(0) = 1$. (It is, up to a substitution, the exponential integral; here we need only the elementary bounds.) Now generate its perturbative expansion in the naive way, by expanding the geometric factor under the integral sign,

$$\frac{1}{1+gt} = \sum_{n=0}^{N} (-gt)^n + \frac{(-gt)^{N+1}}{1+gt}, \tag{5.162}$$

an *exact* algebraic identity (the finite geometric sum plus its remainder), valid for all $t \geq 0$ and $g \geq 0$. Multiplying by e^{-t} and integrating term by term using the elementary moment $\int_0^\infty t^n e^{-t}\,\mathrm{d}t = n!$, we obtain

$$E(g) = \sum_{n=0}^{N} (-1)^n\, n!\, g^n + R_N(g), \qquad R_N(g) = (-1)^{N+1} g^{N+1} \int_0^\infty \frac{t^{N+1} e^{-t}}{1+gt}\,\mathrm{d}t. \tag{5.163}$$

The series is forced upon us: its coefficients are $a_n = (-1)^n\, n!$. They grow factorially, so by the ratio test the radius of convergence is

$$\lim_{n\to\infty} \left| \frac{a_n g^n}{a_{n+1} g^{n+1}} \right| = \lim_{n\to\infty} \frac{1}{(n+1)\,|g|} = 0, \tag{5.164}$$

i.e. the series $\sum (-1)^n n!\, g^n$ *diverges for every* $g \neq 0$. Nonetheless it is asymptotic to E. To see this we do not discard the remainder but bound it. Since $1 + gt \geq 1$ for $g, t \geq 0$,

$$|R_N(g)| = g^{N+1} \int_0^\infty \frac{t^{N+1} e^{-t}}{1+gt}\,\mathrm{d}t \leq g^{N+1} \int_0^\infty t^{N+1} e^{-t}\,\mathrm{d}t = (N+1)!\, g^{N+1}. \tag{5.165}$$

The error after summing through $a_N g^N$ is bounded by $(N+1)!\, g^{N+1}$ — exactly the magnitude of the *first omitted term*. Thus $R_N(g) = O(g^{N+1})$ for each fixed N, which is Theorem 5.40: the divergent series (5.163) is the asymptotic expansion of the perfectly good function (5.161). This single example contains, in miniature, the entire situation of perturbative QFT: a finite analytic observable, a factorially divergent series that nonetheless represents it, and a remainder bounded by its own first dropped term. The factorial $(N+1)!$ in (5.165) is the same factorial that Watson's lemma will trace, in Section 5.6.2, to the $n!$ moments of the Laplace measure.

The coefficients are unique; the function is not. Two facts about asymptotic series are decisive for everything that follows, and they pull in opposite directions.

Proposition 5.41 (Uniqueness of asymptotic coefficients)**.** *If f admits an asymptotic expansion (5.159), its coefficients are determined by f through the*

iterated limits

$$a_0 = \lim_{g\to 0^+} f(g), \qquad a_N = \lim_{g\to 0^+} \frac{1}{g^N}\Big(f(g) - \sum_{n=0}^{N-1} a_n g^n\Big). \tag{5.166}$$

In particular a given function has at most one asymptotic power series.

Proof. By (5.160) with N replaced by $N-1$, $f(g)-\sum_{n=0}^{N-1} a_n g^n = a_N g^N + o(g^N)$. Dividing by g^N and letting $g \to 0^+$ kills the $o(g^N)$ term and isolates a_N, which proves (5.166) by induction on N starting from $a_0 = \lim f$. Each a_N is thereby fixed by f alone. □

The reverse statement is the one that creates the central problem of the chapter. The map from functions to asymptotic series is *not injective*. Consider $h(g) = e^{-1/g}$ for $g > 0$ (and $h(0) = 0$). Every derivative of h at the origin vanishes: by induction $h^{(k)}(g) = P_k(1/g)\, e^{-1/g}$ for a polynomial P_k, and $g^{-m} e^{-1/g} \to 0$ as $g \to 0^+$ for every m (set $u = 1/g \to \infty$ and use $u^m e^{-u} \to 0$). Hence

$$e^{-1/g} \sim 0 + 0\cdot g + 0\cdot g^2 + \cdots \qquad (g \to 0^+)\,: \tag{5.167}$$

the function $e^{-1/g}$ has the *zero* asymptotic series, indistinguishable order by order from the constant function 0. Consequently, if $f \sim \sum a_n g^n$ then $f + c\, e^{-1/g}$ has the very same asymptotic series for any constant c. The coefficients $\{a_n\}$ remember f only up to an additive term that is smaller than every power of g — a contribution "beyond all orders" in perturbation theory. This exponentially small ambiguity is not a defect of the definition; it is a true feature of the objects. In QFT the missing piece $e^{-1/g}$ is no abstraction: with g a coupling it is the weight $e^{-S_{\text{inst}}/g}$ of an instanton (Chapter 42), a genuine non-perturbative contribution to which the perturbative series is, by construction, blind. The question of whether and how the function can nevertheless be recovered from its coefficients is exactly what Borel summation answers in Section 5.7.

Optimal truncation and the irreducible error. If the series diverges, one cannot sum it; one truncates it. The art is to truncate at the order that minimises the error. Take the Euler model, where by (5.165) the error after N terms is no larger than the first omitted term, $|R_N(g)| \lesssim (N+1)!\, g^{N+1}$, and (since the terms alternate in sign and the remainder integral is positive) is in fact bracketed between the first two omitted terms. The size of the term of order n is $b_n(g) \equiv n!\, g^n$. As n increases at fixed g the terms first *decrease*, then reach a minimum, then *increase* factorially. The turning point is where consecutive terms are equal in magnitude,

$$\frac{b_{n+1}}{b_n} = (n+1)\, g \approx 1 \quad \Longrightarrow \quad N^*(g) \approx \frac{1}{g}, \tag{5.168}$$

the *optimal truncation order*: sum up to the least term and stop. The accuracy achievable there is the size of that least term. Using Stirling's formula $N! \sim \sqrt{2\pi N}\,(N/e)^N$ (derived in Theorem 5.45) at $N = N^* = 1/g$,

$$b_{N^*}(g) = N^*!\, g^{N^*} \sim \sqrt{2\pi N^*}\left(\frac{N^*}{e}\right)^{N^*} g^{N^*} = \sqrt{\frac{2\pi}{g}}\left(\frac{1}{eg}\right)^{1/g} g^{1/g} = \sqrt{\frac{2\pi}{g}}\; e^{-1/g}. \tag{5.169}$$

The best the divergent series can do is to reproduce $E(g)$ with an error of order $e^{-1/g}$ — precisely the size of the invisible term (5.167). This is no coincidence: the irreducible error of optimal truncation and the ambiguity in reconstructing f from its coefficients are the same exponentially small object, seen from two sides. Optimal truncation is how perturbative QED achieves its astonishing accuracy: with $g \sim \alpha/\pi \approx 2 \times 10^{-3}$, the least term sits near $N^* \sim 1/g \sim 400$, far beyond any order ever computed, so in practice every accessible term still lies on the decreasing part of the curve and adding terms keeps improving the answer. The divergence is real but operationally invisible at the couplings of nature. Figure 4.8 already displayed this behaviour for the zero-dimensional ϕ^4 partition function; we record the quantitative law here.

Worked Example 5.42 (Optimal truncation of the Euler series)**.** We make (5.168)–(5.169) sharp for $E(g)$ at a definite coupling and exhibit the alternating bracket. Take $g = \frac{1}{5}$. The terms $b_n = (-1)^n n!\, 5^{-n}$ have magnitudes

$$|b_0| = 1,\ |b_1| = 0.2,\ |b_2| = 0.08,\ |b_3| = 0.048,\ |b_4| = 0.0384,\ |b_5| = 0.0384,\ |b_6| = 0.046, \ldots \tag{5.170}$$

The magnitudes decrease to a least term at $n = 4, 5$ (equal, since $b_{n+1}/b_n = (n+1)/5 = 1$ at $n = 4$, confirming $N^* = 1/g = 5$) and increase thereafter. Because the partial sums of an alternating series with the remainder of one sign bracket the true value, summing through $n = 4$ and through $n = 5$ traps $E(\frac{1}{5})$ between consecutive partial sums:

$$S_4 = 1 - 0.2 + 0.08 - 0.048 + 0.0384 = 0.8704, \qquad S_5 = S_4 - 0.0384 = 0.8320, \tag{5.171}$$

so $0.8320 < E(\frac{1}{5}) < 0.8704$, an uncertainty of 0.0384 — exactly the least term. The midpoint 0.8512 estimates $E(\frac{1}{5})$ with error below 0.02, and the predicted irreducible scale $\sqrt{2\pi/g}\, e^{-1/g} = \sqrt{10\pi}\, e^{-5} \approx 5.6 \times 0.0067 \approx 0.038$ matches the least term (5.169) to the accuracy of the estimate. No truncation of the divergent series can do better than this $O(e^{-1/g})$ window; to cross it one needs the non-perturbative information of Section 5.7.

5.6.2 Watson's lemma

Where do the factorially growing coefficients of a perturbative series come from? The generic source is a *Laplace integral* — an integral over a positive variable

with an exponential weight $e^{-t/g}$ (or e^{-xt} with $x = 1/g \to \infty$). Such integrals are ubiquitous: every Schwinger proper-time representation of a propagator (Eq. (5.104)) is of this form, and after Wick rotation so is every Euclidean partition function. Watson's lemma is the theorem that converts the *small-t* behaviour of the integrand directly into the *small-g* asymptotic expansion of the integral, and in doing so makes the origin of the factorials completely transparent.

The mechanism is a single elementary moment. With $x = 1/g$,

$$\int_0^\infty e^{-t/g}\, t^{\,n}\, \mathrm{d}t = \int_0^\infty e^{-xt}\, t^{\,n}\, \mathrm{d}t = \frac{n!}{x^{\,n+1}} = n!\; g^{\,n+1}, \tag{5.172}$$

the substitution $s = xt$ reducing it to $x^{-(n+1)} \int_0^\infty s^n e^{-s} \mathrm{d}s = x^{-(n+1)}\, \Gamma(n+1)$. More generally, for any exponent $\beta > -1$,

$$\int_0^\infty e^{-t/g}\, t^{\,\beta}\, \mathrm{d}t = \Gamma(\beta+1)\, g^{\,\beta+1}. \tag{5.173}$$

The factorial in (5.172) is the seed: a term $a_n t^n$ in the integrand contributes $a_n\, n!\, g^{n+1}$ to the integral, and summing such contributions produces a series whose coefficients carry an explicit $n!$. The factorial divergence of perturbation theory is, at bottom, the factorial in the moments of the exponential measure.

Theorem 5.43 (Watson's lemma)**.** *Let $\phi : [0,\infty) \to \mathbb{C}$ be measurable, and suppose:*

(i) ϕ has an asymptotic expansion at the origin in (possibly non-integer) powers,

$$\phi(t) \sim \sum_{n=0}^{\infty} a_n\, t^{\,\alpha+\beta n} \qquad (t \to 0^+), \qquad \alpha > -1,\ \beta > 0, \tag{5.174}$$

meaning that for each N, $\phi(t) - \sum_{n=0}^{N} a_n t^{\alpha+\beta n} = O(t^{\alpha+\beta(N+1)})$ as $t \to 0^+$;

(ii) ϕ does not grow too fast at infinity: there are constants C, b with $|\phi(t)| \le C\, e^{bt}$ for all $t \ge T_0$.

Then the Laplace integral $F(g) \equiv \int_0^\infty e^{-t/g}\, \phi(t)\, \mathrm{d}t$ converges for $0 < g < 1/b$ and admits the asymptotic expansion

$$F(g) \sim \sum_{n=0}^{\infty} a_n\, \Gamma(\alpha+\beta n+1)\; g^{\,\alpha+\beta n+1} \qquad (g \to 0^+). \tag{5.175}$$

Proof. Convergence. For $0 < g < 1/b$ the weight $e^{-t/g}$ beats the growth bound (ii): on $[T_0,\infty)$, $|e^{-t/g}\phi(t)| \le C\, e^{-(1/g-b)t}$ is integrable, while on $[0,T_0]$ the integrand is bounded by hypothesis (i) (ϕ is $O(t^\alpha)$ with $\alpha > -1$ near 0, hence integrable). So $F(g)$ is finite.

Splitting. Fix N. By hypothesis (i) there are constants $\delta > 0$ and K_N such that, on the core interval $[0, \delta]$,

$$\Big|\phi(t) - \sum_{n=0}^{N} a_n t^{\alpha+\beta n}\Big| \le K_N\, t^{\alpha+\beta(N+1)}, \qquad 0 \le t \le \delta. \tag{5.176}$$

Write $F(g) = \int_0^\delta + \int_\delta^\infty$. We treat the tail, the principal terms, and the core remainder separately.

Step 1: the tail is exponentially small. On $[\delta, \infty)$, splitting off the growth at T_0 and using (ii),

$$\Big|\int_\delta^\infty e^{-t/g}\phi(t)\,\mathrm{d}t\Big| \le e^{-\delta/2g}\int_\delta^\infty e^{-t/2g}|\phi(t)|\,\mathrm{d}t \le e^{-\delta/2g}\,C', \tag{5.177}$$

where we factored $e^{-t/g} = e^{-\delta/2g}\,e^{-(t/g-\delta/2g)}$ and, for g small enough that $1/2g > b$, bounded the remaining integral by a g-independent constant C' (the integral $\int_\delta^\infty e^{-t/2g}|\phi|\,\mathrm{d}t$ is largest at the smallest admissible g and is dominated by $\int_\delta^\infty e^{-(1/2g-b)t}C\,\mathrm{d}t$, uniformly bounded for g below a fixed threshold). The factor $e^{-\delta/2g}$ is smaller than every power g^M, so the tail contributes nothing to the asymptotic series.

Step 2: the principal terms. For each $n \le N$, the integral of $a_n t^{\alpha+\beta n}$ over $[0, \delta]$ differs from the integral over $[0, \infty)$ by a tail of the same exponentially small type as (5.177). Hence, by (5.173),

$$\int_0^\delta e^{-t/g}\,a_n t^{\alpha+\beta n}\,\mathrm{d}t = a_n\,\Gamma(\alpha+\beta n+1)\,g^{\alpha+\beta n+1} + O(e^{-\delta/2g}). \tag{5.178}$$

Summed over $n = 0, \dots, N$ this produces exactly the first $N+1$ terms of (5.175), up to exponentially small corrections.

Step 3: the core remainder is the right order. Using the bound (5.176) and again (5.173),

$$\Big|\int_0^\delta e^{-t/g}\Big(\phi(t) - \sum_{n=0}^{N} a_n t^{\alpha+\beta n}\Big)\mathrm{d}t\Big| \le K_N\int_0^\infty e^{-t/g}\,t^{\alpha+\beta(N+1)}\,\mathrm{d}t = K_N\,\Gamma\big(\alpha+\beta(N+1)+1\big)\,g^{\alpha+\beta(} \tag{5.179}$$

where extending the upper limit from δ to ∞ only enlarges the (positive) integral. This is $O(g^{\alpha+\beta(N+1)+1})$, i.e. higher order than the last term $n = N$ retained in (5.175).

Assembling the three steps, $F(g) - \sum_{n=0}^{N} a_n\Gamma(\alpha+\beta n+1)g^{\alpha+\beta n+1} = O(g^{\alpha+\beta(N+1)+1}) + O(e^{-\delta/2g})$, which is $o(g^{\alpha+\beta N+1})$. Since N was arbitrary, this is precisely Theorem 5.40 for the series (5.175). □

Watson's lemma is exactly the rigorous content of "expand the integrand and integrate term by term": the term-by-term integration is legitimate *as*

an asymptotic statement even when the resulting series diverges, because each truncation carries the controlled remainder (5.179). Applied to the Euler integral (5.161) it reproduces (5.163) instantly: there $\phi(t) = e^{-t}/(1+gt)$ is not quite of the pure form, but writing $E(g) = \int_0^\infty e^{-t}(1+gt)^{-1}\mathrm{d}t$ and expanding $(1+gt)^{-1} = \sum(-gt)^n$ is the same manoeuvre, with the moment $\int_0^\infty e^{-t}t^n\mathrm{d}t = n! = \Gamma(n+1)$ playing the role of (5.172). The general lesson is structural: *the more singular (the higher the powers in) the small-t behaviour of ϕ, the faster the coefficients $a_n\Gamma(\alpha+\beta n+1)$ grow*, because Γ grows factorially in its argument. Large orders of perturbation theory are governed by the integrand near the endpoint of integration — a principle that, in the path integral, becomes the statement that large orders are governed by the configurations nearest the saddle, which is the bridge to instantons.

5.6.3 Laplace's method and the method of steepest descent

Watson's lemma handles integrals already in Laplace form. The integrals that actually arise — amplitudes, partition functions, the path integral itself — are not: they carry an exponent $e^{\lambda f(z)}$ with f a nontrivial function of an integration variable that may range over the real line or a contour in the complex plane, and the large parameter λ (a large mass, an inverse coupling, $1/\hbar$) sits in the exponent. The method that evaluates them asymptotically is *Laplace's method* when f is real and *steepest descent* when f is complex; *stationary phase* is the purely oscillatory limit. The strategy is always the same: the integral is dominated by the neighbourhood of the point where the exponent is stationary, and the local quadratic behaviour there produces a Gaussian whose width and orientation supply the prefactor.

The real-variable case was established in full in Chapter 4 as the engine of the loop expansion: Theorem 4.38 proves that for f, g smooth with a unique nondegenerate interior minimum x_0 of f,

$$\int_a^b g(x)\, e^{-\lambda f(x)}\,\mathrm{d}x = e^{-\lambda f(x_0)}\sqrt{\frac{2\pi}{\lambda f''(x_0)}}\left[g(x_0) + \frac{c_1}{\lambda} + O(\lambda^{-2})\right] \qquad (\lambda \to +\infty), \tag{5.180}$$

with the subleading coefficient $c_1 = -\frac{f''''(x_0)}{8f''(x_0)^2} + \frac{5f'''(x_0)^2}{24f''(x_0)^3}$ computed in Theorem 4.39, and Theorem 4.40 extends this to n dimensions with the Gaussian fluctuation prefactor $(\det H)^{-1/2}$, H the Hessian of f at the saddle. We *import* these results rather than reprove them. What Chapter 4 deliberately deferred — the honest treatment of the contour rotation that turns the oscillatory e^{iS} into the convergent e^{-S_E} — is exactly the complex story we now build.

Why one must go into the complex plane. Consider the prototype

$$I(\lambda) = \int_C g(z)\, e^{\lambda f(z)}\,\mathrm{d}z, \tag{5.181}$$

with f, g holomorphic in a domain containing the contour C, and $\lambda \to +\infty$. Two features distinguish this from the real case. First, f is complex, so "minimise f" is meaningless; the natural object is the modulus $|e^{\lambda f}| = e^{\lambda \operatorname{Re} f}$, governed by the real part $u \equiv \operatorname{Re} f$. Second, u is harmonic ($\nabla^2 u = 0$, since f is holomorphic and the Cauchy–Riemann equations give $\partial_x^2 u = -\partial_y^2 u$), and a nonconstant harmonic function has *no* interior maxima or minima — only *saddles*, by the maximum principle. There is therefore no peak to sit on; the best one can do is find a saddle of u and route the contour through it along the direction in which u *descends fastest in both directions*, so that the saddle is a local maximum *along the contour*. This is the geometric content of the name.

Saddle, steepest-descent direction, constant phase. A saddle point is a zero of the derivative,

$$f'(z_0) = 0, \tag{5.182}$$

and we assume it nondegenerate, $f''(z_0) \neq 0$. Write the holomorphic increment to quadratic order,

$$f(z) = f(z_0) + \tfrac{1}{2} f''(z_0)\,(z - z_0)^2 + O\big((z - z_0)^3\big). \tag{5.183}$$

Set $f''(z_0) = |f''(z_0)|\, e^{i\theta}$ and parametrise the displacement by its direction, $z - z_0 = \rho\, e^{i\varphi}$ with $\rho \geq 0$. Then the quadratic term is

$$\tfrac{1}{2} f''(z_0)(z - z_0)^2 = \tfrac{1}{2} |f''(z_0)|\, \rho^2\, e^{i(\theta + 2\varphi)}. \tag{5.184}$$

Along the contour we want this term to be *real and negative*, for two reasons at once: real, so that the integrand does not oscillate near the saddle (the *constant-phase* or *stationary-phase* condition, $\operatorname{Im} f = \text{const}$, which is what makes the Gaussian approximation legitimate rather than a delicate cancellation of oscillations); and negative, so that $e^{\lambda f}$ *decays* away from the saddle (the *steepest-descent* condition). Both are secured by

$$\theta + 2\varphi = \pi \quad \Longrightarrow \quad \varphi = \frac{\pi - \theta}{2} \ \ (\text{or } \varphi + \pi), \tag{5.185}$$

which fixes the two opposite directions (the contour passes straight through) of steepest descent. That "constant phase" and "steepest descent" coincide is not luck but the Cauchy–Riemann structure: with $f = u + iv$, the curves $v = \text{const}$ and $u = \text{const}$ are orthogonal families, and the gradient of u (the direction of steepest change of u) is tangent to the curves $v = \text{const}$. So the path along which $|e^{\lambda f}|$ falls off fastest is automatically a path on which $\operatorname{Im} f$ is constant. Figure 5.8 draws this for the oscillatory prototype $f = iz^2$.

Reduction to a real Laplace integral. With the steepest-descent contour located, the evaluation is mechanical. Deform C to a contour C' that passes through z_0 in the direction (5.185); the deformation is legitimate by Cauchy's theorem provided the integrand is holomorphic in the swept region and the arcs at infinity give no contribution — precisely the contour-deformation discipline established in Section 5.3, applied here to a saddle rather than a pole. On C' parametrise $z = z_0 + s\,e^{i\varphi}$ with s real (arc length, signed), so $\mathrm{d}z = e^{i\varphi}\mathrm{d}s$ and, by construction (5.185),

$$f(z) = f(z_0) - \tfrac{1}{2}|f''(z_0)|\,s^2 + O(s^3), \qquad e^{\lambda f(z)} = e^{\lambda f(z_0)}\,e^{-\frac{\lambda}{2}|f''(z_0)|\,s^2}\big[1 + O(s^3)\big]. \tag{5.186}$$

The integral has become a real Laplace integral of exactly the type (5.180), with the exponent $-\frac{1}{2}|f''(z_0)|s^2$ playing the role of $-f(s)$ and an overall constant phase $e^{i\varphi}$ from the measure:

$$I(\lambda) = e^{i\varphi}\,e^{\lambda f(z_0)} \int_{-\infty}^{\infty} \big[g(z_0) + O(s)\big]\, e^{-\frac{\lambda}{2}|f''(z_0)|s^2}\,\mathrm{d}s\,\big[1 + O(\lambda^{-1})\big]. \tag{5.187}$$

The leading Gaussian integral is $\int_{-\infty}^{\infty} e^{-\frac{\lambda}{2}|f''|s^2}\mathrm{d}s = \sqrt{2\pi/(\lambda|f''(z_0)|)}$. Restoring $e^{i\varphi} = e^{i(\pi-\theta)/2}$ and noting $|f''(z_0)| = f''(z_0)e^{-i\theta}$, the direction phase and the modulus combine into a single clean branch,

$$e^{i\varphi}\sqrt{\frac{2\pi}{\lambda|f''(z_0)|}} = \sqrt{\frac{2\pi}{\lambda\,|f''(z_0)|}}\;e^{i(\pi-\theta)/2} = \sqrt{\frac{2\pi}{-\lambda\,f''(z_0)}}, \tag{5.188}$$

where the square root on the right is the one whose phase is $(\pi-\theta)/2$, i.e. the branch selected by the steepest-descent direction. We have proved:

Theorem 5.44 (Method of steepest descent, leading order)**.** *Let f, g be holomorphic near a contour C, let z_0 be a simple saddle, $f'(z_0) = 0$, $f''(z_0) \neq 0$, dominating* $\operatorname{Re} f$ *on C, and suppose C may be deformed to the steepest-descent contour through z_0 without crossing singularities and with negligible contribution from infinity. Then*

$$\boxed{I(\lambda) = \int_C g(z)\,e^{\lambda f(z)}\,\mathrm{d}z = g(z_0)\sqrt{\frac{2\pi}{-\lambda\,f''(z_0)}}\;e^{\lambda f(z_0)}\Big[1 + O(\lambda^{-1})\Big] \quad (\lambda \to +\infty),} \tag{5.189}$$

with the branch of the square root fixed by the steepest-descent direction (5.185). The full asymptotic series in $1/\lambda$ has the same form as the real case: writing $f(z) = f(z_0) + \frac{1}{2}f''(z_0)w^2$ locally and expanding g and the cubic-and-higher part of f in powers of w, term-by-term Gaussian integration gives

$$I(\lambda) = \sqrt{\frac{2\pi}{-\lambda f''(z_0)}}\;e^{\lambda f(z_0)}\Big[g(z_0) + \frac{1}{\lambda}\Big(-\frac{g''(z_0)}{2f''(z_0)} + \frac{g'(z_0)f'''(z_0)}{2f''(z_0)^2} + g(z_0)\Big(\frac{f''''(z_0)}{8f''(z_0)^2} - \frac{5f'''(z_0)^2}{24f''(z_0)^3}\Big)\Big) + \tag{5.190}$$

Proof. The leading order is (5.187)–(5.188). For the series, the localization and dominated-convergence estimates that justify replacing the deformed contour by the full real s-line, expanding, and integrating term by term are identical to those proved in Theorem 4.38 (Step 3 there); the only change is the complex prefactor $e^{i\varphi}$ and the use of the holomorphic Taylor expansion (5.183) in place of the real one. With $g \equiv \text{const}$ the bracket reduces to $1+\lambda^{-1}c_1$ with $c_1 = \frac{f''''}{8f''^2}\cdot(-1)+\frac{5f'''^2}{24f''^3}$ evaluated with the sign convention $e^{+\lambda f}$ here versus $e^{-\lambda f}$ in (5.180) (which flips $f \to -f$, hence the displayed signs); this is exactly the negative of Eq. (4.195), as the change $e^{-\lambda f} \to e^{+\lambda f}$ demands. The g' and g'' terms come from expanding the insertion $g(z_0 + e^{i\varphi}s)$ to second order and keeping the even moment. □

Caution

Steepest descent is only as good as the global contour analysis. Equation (5.189) is the contribution of *one* saddle; when the original contour deforms onto several saddles, one sums their contributions, and the dominant one is the saddle of largest $\operatorname{Re} f(z_0)$. When two saddles have equal $\operatorname{Re} f$, their contributions can interfere — this is the Stokes phenomenon, and the abrupt switching-on of a subdominant exponential as a parameter varies is a Stokes line. Honestly tracking which saddles contribute on which side of a Stokes line is the analytic heart of resurgence (Section 5.7, Chapter 42); the naive single-saddle formula is the first term of a structure that can be much richer.

Stationary phase and the Fresnel $e^{\pm i\pi/4}$. The purely oscillatory case — the one relevant to the Minkowski path integral e^{iS} before Wick rotation — is the special instance $\operatorname{Re} f \equiv 0$ on the original contour. Take $f(x) = i\psi(x)$ with ψ real on the real axis and a nondegenerate stationary point $\psi'(x_0) = 0$, $\psi''(x_0) \neq 0$, and consider

$$I(\lambda) = \int_{-\infty}^{\infty} g(x)\, e^{i\lambda\psi(x)}\, \mathrm{d}x. \tag{5.191}$$

Here $\operatorname{Re} f = 0$ everywhere on the real axis, so there is no decay at all: the integrand has constant modulus and converges only by oscillation. The saddle is at x_0, where $f''(x_0) = i\psi''(x_0)$, so $\theta = \arg(i\psi'') = \pm\pi/2$ according to the sign of $\psi''(x_0)$. The steepest-descent direction (5.185) is then $\varphi = (\pi \mp \pi/2)/2 = \pm\pi/4$: one must rotate the contour off the real axis by 45° into the complex plane to find the path on which the oscillation becomes a Gaussian decay (this is precisely the rotation drawn in Fig. 5.8). Applying Theorem 5.44 with $\lambda f'' = i\lambda\psi''$ and $-\lambda f'' = -i\lambda\psi'' = \lambda|\psi''|e^{\mp i\pi/2}$,

$$I(\lambda) = g(x_0)\sqrt{\frac{2\pi}{\lambda|\psi''(x_0)|}}\, e^{\pm i\pi/4}\, e^{i\lambda\psi(x_0)}\,[1 + O(\lambda^{-1})], \qquad \pm = \operatorname{sgn}\psi''(x_0). \tag{5.192}$$

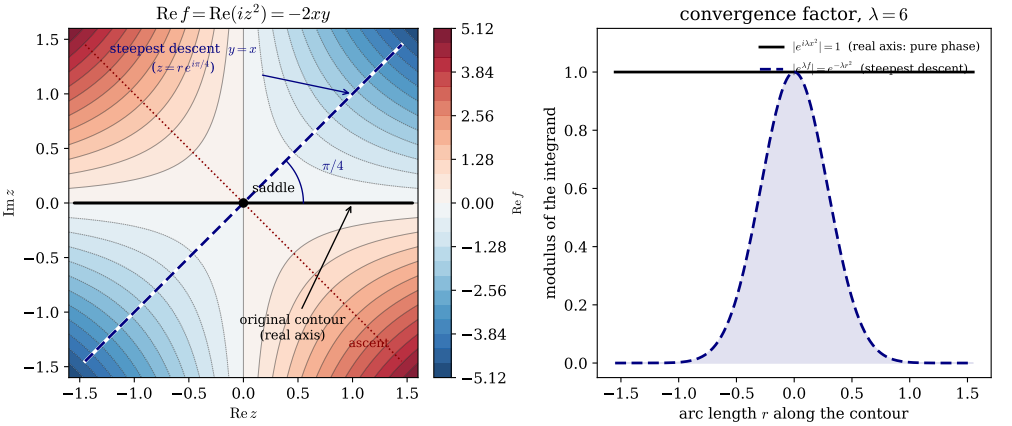

Figure 5.8: Steepest descent and stationary phase for the oscillatory prototype $I(\lambda) = \int g(z)\, e^{i\lambda z^2} \mathrm{d}z$, exponent $f(z) = iz^2$ with a saddle at the origin. *Left:* filled contours of $\mathrm{Re}\, f = \mathrm{Re}(iz^2) = -2xy$; the level sets $\mathrm{Im}\, f = \text{const}$ are the hyperbolas $xy = \text{const}$. The real axis (the original contour, black) is a constant-phase curve on which $\mathrm{Re}\, f \equiv 0$, so the integrand merely oscillates. Rotating by $\varphi = \pi/4$ onto the diagonal $y = x$ (navy dashed) reaches the steepest-descent ray $z = r\, e^{i\pi/4}$, where $iz^2 = -r^2$ is real and negative; the orthogonal diagonal $y = -x$ is the steepest-ascent direction. *Right:* along the real axis the modulus $|e^{i\lambda x^2}| = 1$ never decays, whereas along the rotated contour $|e^{\lambda f}| = e^{-\lambda r^2}$ is a genuine Gaussian. The 45° rotation is the geometric origin of the Fresnel phase $e^{i\pi/4}$ in (5.192).

The extra phase $e^{\pm i\pi/4} = \sqrt{\pm i}$ is the celebrated Fresnel factor; it is nothing but the branch (5.188) of the Gaussian, $\sqrt{2\pi/(-i\lambda\psi'')} = \sqrt{2\pi/(\lambda|\psi''|)}\, e^{\pm i\pi/4}$. In the semiclassical path integral the accumulation of these $\pi/4$ phases along a trajectory is the Maslov index; it is the seed, planted here in one dimension, of the phase conventions that Chapter 10 will need when the saddle is a classical field configuration. The leading factor $\lambda^{-1/2}$ per stationary point is, in d dimensions, $\lambda^{-d/2}(\det)^{-1/2}$ by the same diagonalization as Theorem 4.40.

5.6.4 Stirling's formula from the saddle point

The Gamma function provides the canonical worked output of the whole machinery: its asymptotics are pure Laplace's method, its integral representation is exactly of the form (5.181), and the answer — Stirling's series — is the formula we have already used twice above (in (5.169) and in the loop-counting of Chapter 4). We now derive it in full, leading term and first correction, directly from the saddle point.

Worked Example 5.45 (Stirling's series for Γ)**.** Start from the Euler integral,

valid for $\operatorname{Re} z > 0$,

$$\Gamma(z+1) = \int_0^\infty t^{\,z}\, e^{-t}\, \mathrm{d}t = \int_0^\infty \exp\!\big(z \ln t - t\big)\, \mathrm{d}t. \tag{5.193}$$

The exponent $z \ln t - t$ is *not* yet in Laplace form with a large parameter multiplying a fixed function, because z multiplies only part of it. The standard rescaling cures this: substitute $t = z\,\tau$, so $\mathrm{d}t = z\,\mathrm{d}\tau$, $t^z = z^z \tau^z$, $e^{-t} = e^{-z\tau}$, and

$$\Gamma(z+1) = z^{\,z+1} \int_0^\infty \exp\!\big(-z\,\varphi(\tau)\big)\, \mathrm{d}\tau, \qquad \varphi(\tau) \equiv \tau - \ln \tau. \tag{5.194}$$

Now z multiplies the entire fixed function φ, and we may take $z \to +\infty$ by Laplace's method. The exponent φ has a unique minimum on $(0,\infty)$:

$$\varphi'(\tau) = 1 - \frac{1}{\tau} = 0 \;\Rightarrow\; \tau_0 = 1, \qquad \varphi(1) = 1, \qquad \varphi''(\tau) = \frac{1}{\tau^2} \;\Rightarrow\; \varphi''(1) = 1 > 0, \tag{5.195}$$

so $\tau_0 = 1$ is a nondegenerate minimum, exactly the hypothesis of Theorem 4.38. The leading term follows immediately from (5.180) with $g \equiv 1$, $\lambda = z$, $f = \varphi$:

$$\Gamma(z{+}1) = z^{z+1}\, e^{-z\varphi(1)} \sqrt{\frac{2\pi}{z\,\varphi''(1)}}\,[1{+}O(1/z)] = z^{z+1}\, e^{-z} \sqrt{\frac{2\pi}{z}}\,[1{+}\cdots] = \sqrt{2\pi z}\,\left(\frac{z}{e}\right)^{\!z}[1{+}\cdots]. \tag{5.196}$$

This is Stirling's formula. For integer $z = n$ it reads $n! \sim \sqrt{2\pi n}\,(n/e)^n$; for $\Gamma(n) = (n-1)!$ the same calculation with $z \to z-1$ in the prefactor gives the equivalent form $\Gamma(z) \sim \sqrt{2\pi/z}\,(z/e)^z$ quoted in the section blueprint, the two differing only by the factor z that distinguishes $\Gamma(z+1) = z\,\Gamma(z)$.

The first correction. For the $1/z$ term we invoke the universal Laplace coefficient $c_1 = -\frac{\varphi''''(1)}{8\varphi''(1)^2} + \frac{5\varphi'''(1)^2}{24\varphi''(1)^3}$ of Eq. (4.195) with $f = \varphi$. The derivatives at $\tau_0 = 1$ are

$$\varphi''(1) = 1, \qquad \varphi'''(\tau) = -\frac{2}{\tau^3} \Rightarrow \varphi'''(1) = -2, \qquad \varphi''''(\tau) = \frac{6}{\tau^4} \Rightarrow \varphi''''(1) = 6, \tag{5.197}$$

so that

$$c_1 = -\frac{6}{8\cdot 1^2} + \frac{5\cdot(-2)^2}{24\cdot 1^3} = -\frac{3}{4} + \frac{20}{24} = -\frac{3}{4} + \frac{5}{6} = \frac{-9+10}{12} = \frac{1}{12}. \tag{5.198}$$

The expansion parameter is $1/\lambda = 1/z$, so the bracket in (5.196) is $1 + \frac{1}{12z} + O(z^{-2})$, giving the first two terms of Stirling's series:

$$\boxed{\Gamma(z+1) = \sqrt{2\pi z}\,\left(\frac{z}{e}\right)^{\!z}\left(1 + \frac{1}{12z} + \frac{1}{288 z^2} - \cdots\right)} \tag{5.199}$$

where we have appended the next coefficient $1/288$ (obtainable by carrying the expansion one order further, exactly as c_1 was obtained) for completeness. Two

checks confirm the result. Numerically, at $z = 10$: $\sqrt{20\pi}\,(10/e)^{10} = 3598695.6\ldots$, and multiplying by $(1 + \frac{1}{120} + \frac{1}{28800}) = 1.008368$ gives 3628810, against the exact $10! = 3628800$ — agreement to seven figures from two correction terms. Structurally, the series (5.199) is itself *asymptotic, not convergent*: its coefficients eventually grow factorially (the Stirling coefficients are essentially Bernoulli numbers, $B_{2k} \sim (2k)!$), so it is a textbook instance of the Poincaré series of Theorem 5.40 — to be summed only up to its least term, with an irreducible error of the $O(e^{-2\pi z})$ type. Stirling's formula is thus not merely an application of the method; it is a complete miniature of the entire section.

5.6.5 Dyson's argument: why the QFT series must be asymptotic

We have built the tools that generate and tame asymptotic series. It remains to state, at the level of principle, why the perturbation series of a genuine quantum field theory is one of them — why it cannot possibly converge. The argument is Dyson's, first made for quantum electrodynamics in 1952, and we already met its arithmetic in the zero-dimensional toy of Section 4.6.5. Its virtue is that it requires no computation of any diagram: it is a statement about the analytic structure of the theory as a function of the coupling.

The physical observables of QED (or of ϕ^4) are computed as power series in the coupling — in $\alpha = e^2/4\pi$ for QED, in λ for ϕ^4. Suppose, for contradiction, that such a series converged in some disk of positive radius about the origin in the complex coupling plane. A convergent power series defines an analytic function throughout its disk of convergence, in particular along the negative real axis: the theory at small *negative* coupling would then be the analytic continuation of the theory at small positive coupling, a well-defined physical world. But consider what negative coupling means.

- For ϕ^4 with $\lambda < 0$, the potential $\frac{\lambda}{4!}\phi^4$ is unbounded *below*: arbitrarily large field configurations have arbitrarily negative energy. The would-be vacuum is unstable; there is no ground state, and the partition function (the $\int e^{-S_E}$ of Eq. (4.75), generalised to the field theory) diverges. The theory simply does not exist for $\lambda < 0$.

- For QED with $e^2 < 0$, the Coulomb interaction reverses sign: like charges *attract* and unlike charges *repel*. The vacuum becomes catastrophically unstable to the spontaneous creation of widely separated regions of like charge, whose negative interaction energy can overcompensate the rest mass of the produced pairs. Again there is no stable ground state.

In both cases the theory fails to exist for any negative coupling, however small. But an analytic function cannot fail to exist on one side of a point where it is analytic: if the series converged in a disk, the theory would exist in that

whole disk, negative axis included. The only way to reconcile a perfectly good theory at $\lambda > 0$ (or $\alpha > 0$) with a non-existent one at $\lambda < 0$ is for the coupling origin to be a *singular point* — a point of non-analyticity — of every physical quantity. A function nonanalytic at the origin has *zero radius of convergence* for its Taylor series there. The perturbation series therefore cannot converge; it can at best be *asymptotic*, in exactly the Poincaré sense of Theorem 5.40.

This argument fixes more than the mere fact of divergence; it predicts its rate. The same instability that forbids convergence is, quantitatively, a configuration that tunnels out of the false vacuum, and the amplitude for that tunnelling is the exponentially small $e^{-A/\lambda}$ weight of an instanton. Reading the singularity at $\lambda = 0$ through this instanton lens (as Chapter 42 does in detail) predicts that the perturbative coefficients grow factorially,

$$a_n \;\sim\; C\,(-A)^{-n}\,n! \qquad (n \to \infty), \tag{5.200}$$

with A the instanton action — precisely the behaviour we computed directly for the zero-dimensional toy in Eq. (4.217) (there $A^{-1} = 2/3$), and precisely the behaviour that makes the series divergent and Watson's lemma the natural language for it. The constant A is the location of the nearest singularity in the Borel plane, the object Section 5.7 is about to define.

This leaves us in a sharp position. We possess, in the perturbative coefficients $\{a_n\}$, a complete and computable summary of a definite analytic observable; yet the series $\sum a_n g^n$ they form has zero radius of convergence and so cannot be summed in any ordinary sense, while the coefficients themselves — by Theorem 5.41 and the flat-function ambiguity (5.167) — determine the underlying function only up to an exponentially small remainder. The natural question is whether that remainder can be pinned down: can the original function be reconstructed from its divergent asymptotic coefficients, and if so, exactly when? The answer, and the obstruction to it posed by the very Borel-plane singularities at $g = -A$ that Dyson's argument has just located, is the Borel summation developed in Section 5.7.

5.7 Divergent series and Borel summation

The previous section left us with a sharp and uncomfortable question. We showed that the perturbative expansions of quantum field theory are at best *asymptotic*: by Dyson's argument (Section 5.6.5 and Eq. (5.200)) the radius of convergence is zero, and Watson's lemma (Theorem 5.43) exposed *why*—the coefficients grow like $n!$, so the would-be power series $\sum a_n g^n$ diverges for every nonzero coupling g. Optimal truncation salvaged a finite, exponentially accurate *number* from such a series, but it did not give us back a *function*. The asymptotic series knows the function only up to an irreducible error of order $e^{-\text{const}/g}$, and many distinct functions share the same asymptotic series (the standard witness is $e^{-1/g}$, whose

every Taylor coefficient at $g = 0^+$ vanishes). So: can a function be recovered *exactly* from its divergent asymptotic coefficients, and if so, under what conditions is the recovery unique?

The affirmative answer, when it exists, is *Borel summation*. The idea is disarmingly simple. The series diverges because its coefficients carry an extra $n!$; divide it out, sum the resulting (now convergent) series to a genuine function $B(t)$ in an auxiliary *Borel plane*, and then reinstate the $n!$ by a Laplace integral $\int_0^\infty e^{-t} t^n \, dt = n!$. The divergence has been laundered through an integral transform. The deep content—and the reason this section closes the analytic toolbox rather than merely decorating it—is that the entire question of *when* the procedure reconstructs the original function, and *when* it fails, is governed by the analytic structure of $B(t)$: by where its singularities sit in the Borel plane. Singularities off the integration ray cost nothing; singularities *on* it make the answer ambiguous by an exponentially small, purely imaginary amount. Those obstructing singularities are not pathologies of toy models—in real quantum field theory they are the fingerprints of instantons and of the running coupling (renormalons), and their organization is the subject of the modern *resurgence* program. We develop the machinery rigorously, prove the prototype reconstruction in full, exhibit the ambiguity by direct computation, and then state honestly what is and is not known about the field-theoretic case as of the mid-2020s.

5.7.1 The Borel transform and the Borel sum

We begin with the formal manipulation and then make it precise.

Definition 5.46 (Borel transform)**.** Let $\hat{f}(g) = \sum_{n=0}^{\infty} a_n g^n$ be a formal power series. Its *Borel transform* is the formal power series in the auxiliary variable t obtained by dividing each coefficient by $n!$,

$$B(t) \;:=\; \sum_{n=0}^{\infty} \frac{a_n}{n!}\, t^n. \tag{5.201}$$

If the original coefficients grow factorially, $|a_n| \le A\, \sigma^n \, n!$ for some constants A, σ—precisely the growth Watson's lemma attached to a QFT amplitude—then $|a_n/n!| \le A\sigma^n$, so Eq. (5.201) converges in the disk $|t| < 1/\sigma$ and defines an honest analytic function near the origin of the Borel plane. The $n!$ in the denominator is doing exactly the job we asked of it: it converts a series of zero radius of convergence into one of *finite* radius. The function $B(t)$ is the first genuine object the divergent series has produced.

To undo the division we use the elementary Laplace identity $\int_0^\infty e^{-t}\, t^n \, dt = \Gamma(n+1) = n!$. Substituting $B(gt) = \sum_n (a_n/n!)(gt)^n$ under the integral and integrating term by term reinstates each coefficient:

$$\int_0^\infty e^{-t}\, B(gt)\, dt \;=\; \sum_{n=0}^{\infty} \frac{a_n}{n!}\, g^n \int_0^\infty e^{-t}\, t^n \, dt \;=\; \sum_{n=0}^{\infty} a_n\, g^n \;=\; \hat{f}(g). \tag{5.202}$$

The interchange of sum and integral in Eq. (5.202) is legitimate *inside the disk of convergence* $|g| < 1/\sigma$ of $\hat{f}$, where the series converges anyway and Borel summation tells us nothing new. The entire utility of the construction is that the *integral* on the left may exist and define an analytic function even where the *series* on the right diverges, provided B continues analytically from its disk along the positive real axis and does not grow too fast there. This motivates the operative definition.

Definition 5.47 (Borel sum)**.** A formal power series $\hat{f}(g) = \sum_n a_n g^n$ is *Borel summable* (in the direction of the positive real axis) if (i) its Borel transform Eq. (5.201) has a nonzero radius of convergence, (ii) $B(t)$ admits analytic continuation to an open neighbourhood of the half-line $[0, \infty)$, and (iii) the continuation grows at most exponentially there, $|B(t)| \le K e^{|t|/R}$ for some $K, R > 0$. The *Borel sum* is then the function

$$\mathcal{B}\hat{f}(g) \;:=\; \int_0^\infty e^{-t}\, B(gt)\, dt \;=\; \frac{1}{g}\int_0^\infty e^{-s/g}\, B(s)\, ds, \tag{5.203}$$

the two forms related by the substitution $s = gt$. The integral converges absolutely for $0 < g < R$ and, more generally, for complex g with $\mathrm{Re}(1/g) > 1/R$.

The second form in Eq. (5.203) displays the structure most clearly: the Borel sum is a Laplace transform of B evaluated at $1/g$, and the convergence condition $\mathrm{Re}(1/g) > 1/R$ is exactly what tames the exponential growth $e^{|s|/R}$ against the kernel $e^{-s/g}$. We have purchased a function from a divergent series at the price of an analytic-continuation requirement on B. The rest of the section is, in essence, the study of when that requirement can be met.

Physical Insight

The Borel sum is an instruction to read the divergent series as data about a *different* function—B, living in the Borel plane—and then to perform a single, ordinary integral. All the difficulty of resummation has been relocated to a question of complex analysis: the analytic continuation and singularity structure of $B(t)$. This is the same move that organized the whole chapter: singular distributions became poles, poles became contour prescriptions, contour prescriptions became analytic continuations. Borel summation is that doctrine applied one last time, now to the perturbative series itself.

Directional and lateral Borel sums

The integration ray in Eq. (5.203) need not be the positive real axis. If B continues along the ray $\arg t = \theta$ with the same exponential bound, we may

define the *directional Borel sum*

$$\mathcal{B}_\theta \hat{f}(g) \;=\; \frac{1}{g}\int_0^{e^{i\theta}\infty} e^{-s/g}\, B(s)\, ds, \tag{5.204}$$

the contour running from the origin to infinity along $\arg s = \theta$. When B is analytic in a sector containing several such rays the answer is independent of θ by Cauchy's theorem, and the series is unambiguously summable. The interesting and physically generic case is when a singularity of B sits *on* the positive axis, $\theta = 0$. Then the two one-sided limits

$$\mathcal{B}_{0^\pm} \hat{f}(g) \;=\; \lim_{\theta \to 0^\pm} \mathcal{B}_\theta \hat{f}(g), \tag{5.205}$$

the *lateral* Borel sums obtained by skirting the singularity above ($\theta \to 0^+$) or below ($\theta \to 0^-$), need not agree. Their disagreement is the analytic statement of a nonperturbative ambiguity, and we compute it exactly in Theorem 5.51.

5.7.2 When the Borel sum reproduces the function: the Nevanlinna–Sokal theorem

Definition 5.47 produces *a* function from a divergent series, but it does not by itself guarantee that this function is *the* one we started from. We need a converse: a theorem stating that, under stated hypotheses on the original function f, its asymptotic series is Borel summable and its Borel sum equals f—and, crucially, that f is the *unique* function with that asymptotic series obeying the hypotheses. The sharpest such statement is due to Sokal, building on a 1919 theorem of F. Nevanlinna; it improves Watson's classical Borel-summability criterion by replacing a sector by a disk and is the standard working tool.

Theorem 5.48 (Nevanlinna–Sokal)**.** *Let $R > 0$ and let f be analytic in the open disk*

$$C_R \;=\; \Big\{ z \in \mathbb{C} \;:\; \operatorname{Re} \tfrac{1}{z} > \tfrac{1}{R} \Big\} \;=\; \Big\{ z : \; |z - \tfrac{R}{2}| < \tfrac{R}{2} \Big\}, \tag{5.206}$$

the open disk of radius $R/2$ centred at $R/2$, tangent to the imaginary axis at the origin. Suppose f obeys, uniformly in $z \in C_R$*, the asymptotic estimates*

$$\Big| f(z) - \sum_{n=0}^{N-1} a_n z^n \Big| \;\le\; A\, \sigma^N\, N!\, |z|^N \qquad \text{for all } N \ge 0, \tag{5.207}$$

with constants A, σ independent of N and z. Then:

1. *the Borel transform $B(t) = \sum_n a_n t^n/n!$ converges for $|t| < 1/\sigma$ and continues analytically to the strip $S_\sigma = \{t : \operatorname{dist}(t, [0,\infty)) < 1/\sigma\}$ about the positive real axis;*

2. *on S_σ the continuation obeys the exponential bound $|B(t)| \le K\, e^{|t|/R}$ for some $K > 0$;*

3. *f is recovered by its Borel sum: for every $z \in C_R$,*

$$f(z) \;=\; \frac{1}{z}\int_0^\infty e^{-t/z}\, B(t)\, dt, \tag{5.208}$$

the integral converging absolutely.

Conversely, these properties pin f down: any two functions analytic in C_R and satisfying Eq. (5.207) with the same *coefficients a_n coincide throughout C_R.*

The geometry of the disk Eq. (5.206) is the whole point and deserves a word, since it is where Sokal's version is stronger than Watson's. The equivalence of the two descriptions in Eq. (5.206) is immediate algebra: writing $z = x + iy$,

$$\operatorname{Re}\tfrac{1}{z} = \frac{x}{x^2+y^2} > \tfrac{1}{R} \iff x^2 + y^2 < Rx \iff \left(x - \tfrac{R}{2}\right)^2 + y^2 < \left(\tfrac{R}{2}\right)^2, \tag{5.209}$$

a disk tangent to the imaginary axis at the origin. The reason it must be a disk and not merely a sector $|\arg z| < \pi/2 + \delta$ is sharp: a sector of opening just greater than π is exactly the regime in which uniqueness can fail—there one can add a function like $e^{-c/z}$, which is analytic and asymptotically zero in the sector but does not vanish, and the asymptotic series no longer determines the function. Requiring analyticity and the remainder bound on the full disk C_R, which approaches the boundary tangentially rather than along straight rays, removes exactly that freedom and restores uniqueness. The improvement from Watson's theorem is precisely this passage from a sector to a tangent disk; it is what makes the criterion usable, because the disk condition is the one that QFT amplitudes plausibly satisfy.

Remark 5.49 (Why we state rather than reprove the hard direction). The forward implications (i)–(iii) are a direct computation: the bound Eq. (5.207) at order N controls a_n through Cauchy's estimates on C_R, which yields both the radius of convergence of B and the exponential bound, and Eq. (5.208) then follows by the same term-by-term Laplace identity as in Eq. (5.202) together with a remainder estimate. The uniqueness (converse) direction is the substantive part and rests on a Phragmén–Lindelöf argument in the Borel plane; we use it without full proof and record the precise reference [363, 449]. What matters for the book is the *shape* of the statement, which we will invoke verbatim: a factorially-bounded remainder, *uniform on a tangent disk*, is necessary and sufficient for the asymptotic series to reconstruct its function by Borel summation. The corresponding analyticity-in-g statement for honest field theories is exactly what is not known in general (Section 5.7.5).

We now make the entire circle of ideas concrete on the series that every later chapter's perturbative expansion resembles.

Worked Example 5.50 (Borel summation of the prototype factorial series)**.** Consider the divergent series

$$\hat{f}(g) \;=\; \sum_{n=0}^{\infty} (-1)^n\, n!\, g^{n+1} \;=\; g - 1!\, g^2 + 2!\, g^3 - 3!\, g^4 + \cdots, \tag{5.210}$$

the *Euler series*, the cleanest model of an alternating factorially divergent expansion. By the ratio test its radius of convergence is 0: for any $g \neq 0$ the terms eventually grow without bound. We Borel-sum it and show that (a) the procedure reproduces Eq. (5.210) coefficient by coefficient, and (b) it returns a definite finite function, the exponential integral.

Step 1: the Borel transform. It is convenient to strip the overall factor g and Borel-transform the bracket $\hat{E}(g) = \hat{f}(g)/g = \sum_{n\geq 0} (-1)^n n!\, g^n$, whose coefficients are $a_n = (-1)^n n!$. Dividing by $n!$ collapses the factorial entirely,

$$B(t) \;=\; \sum_{n=0}^{\infty} \frac{(-1)^n n!}{n!}\, t^n \;=\; \sum_{n=0}^{\infty} (-t)^n \;=\; \frac{1}{1+t}, \qquad |t| < 1. \tag{5.211}$$

The Borel transform is a single pole at $t = -1$. This location—on the *negative* real axis, off the integration ray—is the reason the Euler series is unambiguously Borel summable, as we now see.

Step 2: the Borel integral. The function Eq. (5.211) continues analytically to all of $\mathbb{C} \setminus \{-1\}$, in particular along the whole positive axis, where it is bounded by 1; the exponential-bound hypothesis of Theorem 5.47 holds trivially with $R = \infty$. Hence for every $g > 0$,

$$\mathcal{B}\hat{E}(g) \;=\; \int_0^{\infty} e^{-t}\, B(gt)\, dt \;=\; \int_0^{\infty} \frac{e^{-t}}{1+gt}\, dt, \tag{5.212}$$

a perfectly finite, positive number for each $g > 0$. The full prototype is $\mathcal{B}\hat{f}(g) = g\, \mathcal{B}\hat{E}(g) = \int_0^{\infty} g\, e^{-t}/(1+gt)\, dt$.

Step 3: identification with the exponential integral. Substitute $u = 1 + gt$, so $t = (u-1)/g$ and $dt = du/g$, with $u : 1 \to \infty$:

$$\int_0^{\infty} \frac{e^{-t}}{1+gt}\, dt = \frac{e^{1/g}}{g} \int_1^{\infty} \frac{e^{-u/g}}{u}\, du = \frac{e^{1/g}}{g} \int_{1/g}^{\infty} \frac{e^{-v}}{v}\, dv = \frac{e^{1/g}}{g}\, E_1\!\left(\tfrac{1}{g}\right), \tag{5.213}$$

where in the middle step $v = u/g$ and $E_1(x) = \int_x^{\infty} e^{-v} v^{-1}\, dv$ is the standard exponential integral. Therefore the Borel sum of the prototype series is the explicit function

$$\mathcal{B}\hat{f}(g) \;=\; g \cdot \frac{e^{1/g}}{g}\, E_1\!\left(\tfrac{1}{g}\right) \;=\; e^{1/g}\, E_1\!\left(\tfrac{1}{g}\right), \tag{5.214}$$

finite and analytic for all $g > 0$. The divergent series has been replaced by a genuine closed-form function.

Step 4: it really is the asymptotic series of Eq. (5.214). Expand the geometric kernel in Eq. (5.212) to finite order with exact remainder,

$$\frac{1}{1+gt} = \sum_{n=0}^{N-1} (-gt)^n + \frac{(-gt)^N}{1+gt}, \tag{5.215}$$

and integrate against e^{-t} using $\int_0^\infty e^{-t} t^n \, dt = n!$:

$$\mathcal{B}\hat{E}(g) = \sum_{n=0}^{N-1} (-1)^n n! \, g^n + R_N(g), \qquad R_N(g) = (-1)^N g^N \int_0^\infty \frac{e^{-t} t^N}{1+gt} \, dt. \tag{5.216}$$

For $g > 0$ and $t > 0$ the denominator satisfies $1 + gt > 1$, so $0 < 1/(1+gt) < 1$ and the remainder is bounded by

$$|R_N(g)| \;\le\; g^N \int_0^\infty e^{-t} t^N \, dt \;=\; N! \, g^N. \tag{5.217}$$

Two conclusions follow. First, the partial sums of Eq. (5.216) *are* the prototype series Eq. (5.210) (after restoring the factor g): Borel summation has reproduced every coefficient. Second, the bound Eq. (5.217) is exactly a Poincaré asymptotic estimate with the tell-tale $N!$ growth, so the explicit function Eq. (5.214) has Eq. (5.210) as its asymptotic series and no more—and, by the uniqueness clause of Theorem 5.48, it is the *only* such function. Finally, the error $N! \, g^N$ is minimized over N near $N_* \sim 1/g$, where Stirling gives $N_*! \, g^{N_*} \sim \sqrt{2\pi/g} \, e^{-1/g}$: optimal truncation (Eq. (5.168)) recovers the function only up to an error of order $e^{-1/g}$, while Borel summation recovers it exactly. The gap between the two is the nonperturbative information that the bare series cannot hold and the Borel integral can.

The Euler example is benign because its Borel singularity lies at $t = -1$, away from the integration ray. The defining feature of *realistic* perturbation theory is that the singularities land on the positive axis, and that is where the analysis becomes physics.

5.7.3 Singularities in the Borel plane and nonperturbative ambiguity

Suppose the coefficients do not alternate—the generic situation when the large order is dominated by a single sign, as for a series whose terms count configurations of fixed sign. The cleanest model is $a_n = n!$, giving the Borel transform

$$B(t) = \sum_{n \ge 0} \frac{n!}{n!} t^n = \sum_{n \ge 0} t^n = \frac{1}{1-t}, \tag{5.218}$$

with a pole now at $t = +1$, squarely *on* the integration ray. The Borel integral $\int_0^\infty e^{-t}/(1-gt)\,dt$ runs straight through the singularity at $t = 1/g$ and is not defined as it stands. Something must be specified to give it meaning, and whatever we specify will leave a residue of arbitrariness. This is the analytic origin of the nonperturbative ambiguity of perturbation theory, and the next worked example computes it exactly. Figure 5.9 contrasts the two situations.

Figure 5.9: Singularity structure in the Borel t-plane. Left: the Euler series of Theorem 5.50 has its only singularity at $t = -1$, off the integration ray $\theta = 0$; the Borel sum is unambiguous. Right: a same-sign factorial series has a singularity at $t_0 = 1/g_0 > 0$ on the ray. The two lateral sums $\mathcal{B}_{0\pm}$ skirt it above and below and differ by the exponentially small, purely imaginary amount computed in Theorem 5.51.

Worked Example 5.51 (A Borel-plane pole and its two-fold ambiguity)**.** Model a single nonperturbative singularity by the Borel transform

$$B(t) = \frac{t_0}{t_0 - t}, \qquad t_0 = \frac{1}{g_0} > 0, \tag{5.219}$$

a simple pole at $t = t_0$ on the positive axis (normalized so $B(0) = 1$). We compute the two lateral Borel sums of Theorem 5.47 and show their difference is purely imaginary and exponentially small in $1/g$.

Step 1: lateral contours. Using the directional form Eq. (5.204), the lateral sums skirt the pole above ($\theta \to 0^+$) and below ($\theta \to 0^-$):

$$\mathcal{B}_{0\pm}(g) = \frac{1}{g}\int_{\mathcal{C}_\pm} e^{-t/g}\,\frac{t_0}{t_0 - t}\,dt, \tag{5.220}$$

where $\mathcal{C}_+$ ($\mathcal{C}_-$) runs from 0 to $+\infty$ passing infinitesimally above (below) t_0. Both integrals exist because the kernel $e^{-t/g}$ enforces convergence at infinity for $g > 0$ and the contour avoids the pole.

Step 2: the difference is a residue. The two contours agree everywhere except in a neighbourhood of t_0. Subtracting, $\mathcal{B}_{0+} - \mathcal{B}_{0-}$ is $1/g$ times the integral over the

closed loop that goes out along $\mathcal{C}_+$ (above) and back along $\mathcal{C}_-$ (below)—a loop encircling t_0 once *clockwise*. By the residue theorem,

$$\mathcal{B}_{0^+}(g) - \mathcal{B}_{0^-}(g) = \frac{1}{g}\,(-2\pi i)\,\mathrm{Res}_{t=t_0}\Big[e^{-t/g}\,\frac{t_0}{t_0 - t}\Big]. \tag{5.221}$$

Near t_0 we have $t_0/(t_0-t) = -t_0/(t-t_0)$, a simple pole of residue $-t_0$; multiplying by the regular factor $e^{-t/g}$ evaluated at $t = t_0$ gives

$$\mathrm{Res}_{t=t_0}\Big[e^{-t/g}\frac{t_0}{t_0 - t}\Big] = -t_0\, e^{-t_0/g}. \tag{5.222}$$

Substituting Eq. (5.222) into Eq. (5.221),

$$\boxed{\mathcal{B}_{0^+}(g) - \mathcal{B}_{0^-}(g) = \frac{2\pi i\, t_0}{g}\; e^{-t_0/g} = \frac{2\pi i}{g_0\, g}\; e^{-1/(g_0 g)}.} \tag{5.223}$$

Step 3: read off the ambiguity. The two prescriptions share the same real part—the Cauchy principal value, well defined by the Sokhotski–Plemelj theorem proved in Theorem 5.10—and differ only by the imaginary term Eq. (5.223). Concretely, writing the common real part as $\mathrm{Re}\;\mathcal{B}_0(g) = \frac{1}{g}\,\mathrm{PV}\!\int_0^\infty e^{-t/g}\,\frac{t_0}{t_0 - t}\,dt$, the lateral sums are

$$\mathcal{B}_{0^\pm}(g) = \mathrm{Re}\;\mathcal{B}_0(g)\;\pm\;\frac{i\pi t_0}{g}\,e^{-t_0/g}, \tag{5.224}$$

the same split into principal value plus $\pm i\pi\,\delta$-contribution that Sokhotski–Plemelj attaches to $1/(t_0 - t \mp i0)$. The ambiguity in the resummed function is the imaginary piece

$$\mathrm{Im}\;\mathcal{B}_{0^\pm}(g) = \pm\frac{\pi t_0}{g}\,e^{-t_0/g} = \pm\frac{\pi}{g_0 g}\,e^{-1/(g_0 g)}, \tag{5.225}$$

smaller than every power of g as $g \to 0^+$ and therefore invisible to the perturbative series, which sees only the real Taylor coefficients. A singularity on the positive Borel axis converts the divergent series into a function defined only up to an exponentially small, purely imaginary nonperturbative ambiguity.

Three features of Theorem 5.51 carry directly into field theory. First, the obstruction is *local* in the Borel plane: it is governed entirely by the nearest singularity to the origin on the positive axis, whose position t_0 sets the size $e^{-t_0/g}$ of the ambiguity. Second, the ambiguity is purely *imaginary* for real coupling, even though the physical quantity (a cross section, an energy level) is real—a paradox resolved only when the ambiguity is cancelled against another imaginary contribution from elsewhere in the nonperturbative expansion. Third, the position t_0 of the singularity is not arbitrary: in honest theories it is fixed by a physical action or by the running of the coupling, which is what we turn to now.

5.7.4 Physical identification: instanton and renormalon singularities

Where do the Borel singularities of a real quantum field theory sit, and what puts them there? The large-order behaviour of perturbation theory—the very $n!$ that Watson's lemma exposed—is controlled by the singularity of $B(t)$ nearest the origin, through the elementary correspondence between a power-law branch point of B and factorial growth of its Taylor coefficients: if $B(t) \sim (1 - t/t_0)^{-\gamma}$ near t_0, then $a_n = n!\,[t^n]B(t) \sim n!\,t_0^{-n}\,n^{\gamma-1}/\Gamma(\gamma)$, so that

$$a_n \;\sim\; \frac{n!}{t_0^{n}}\, n^{\gamma-1} \qquad (n \to \infty). \tag{5.226}$$

Reading Eq. (5.226) backwards: the *rate* of the factorial divergence measured in perturbation theory *is* the location t_0 of the leading Borel singularity. Two distinct mechanisms generate such singularities, and they are physically very different.

Instanton singularities. The first source is semiclassical. In the path-integral evaluation of a perturbative coefficient (ϕ^4 theory and QED, once they are quantized in Part II onward), the $n!$ growth arises because the number of Feynman diagrams at order n grows factorially, and Lipatov's method [324] shows that this combinatorial growth is captured by a nontrivial saddle point of the action—an *instanton*, a finite-action solution of the Euclidean equations of motion. Such a saddle, of action S_{inst}, places a Borel singularity at

$$t_0 \;=\; S_{\mathrm{inst}} \tag{5.227}$$

in the conventions where the coupling sits as $e^{-S/g}$ in the Borel kernel, so that the associated nonperturbative ambiguity $e^{-t_0/g} = e^{-S_{\mathrm{inst}}/g}$ of Theorem 5.51 is exactly the weight of one instanton. The factorial divergence of perturbation theory and the existence of instantons are thus two faces of one analytic fact. We construct instantons explicitly, compute S_{inst} for Yang–Mills (Yang–Mills theory), and exhibit the θ-vacuum in Chapter 42; the present section establishes *why* they must appear as Borel singularities before they are constructed.

Renormalon singularities. The second source has no semiclassical avatar and was identified by 't Hooft [465]. Even in a theory or observable with no relevant instanton, factorial growth arises from a single chain of diagrams—a string of bubble insertions on a propagator—once one integrates the *running* coupling over loop momenta. A subintegral of the schematic form $\int dk^2\,\alpha(k^2)\,(k^2/Q^2)^p$ with $\alpha(k^2) \propto 1/\ln(k^2/\Lambda^2)$ produces, upon expansion in the coupling at the external scale, coefficients growing like $n!\,(b_0/p)^{-n}$, hence a Borel singularity at $t_0 \propto p/b_0$ set by the one-loop coefficient b_0 of the beta function rather than by

any action. These are the *renormalons*. The region of small loop momentum produces *infrared renormalons*, which sit on the positive Borel axis and therefore generate genuine ambiguities of the kind computed above; the region of large loop momentum produces *ultraviolet renormalons* on the negative axis, which do not. The crucial physical statement, which we can only flag here and develop with the operator product expansion and the running coupling later, is that the infrared-renormalon ambiguity is not a defect of the theory: it is exactly cancelled by the ambiguity in defining the nonperturbative power corrections (vacuum condensates) of the operator product expansion, so that the sum of perturbative and power-suppressed pieces is unambiguous. The renormalon and its cancellation belong to the renormalization and running-coupling development; we forward-reference the running coupling and Λ_{QCD} of Chapter 27 and the Callan–Symanzik machinery of Chapter 24, where b_0 is computed, and the modern review [60].

Caution

Borel summability is not a property a quantum field theory enjoys by default. The benign Euler series of Theorem 5.50 is Borel summable precisely because its singularity lies off the positive axis; the same-sign factorial series of Eq. (5.218), the infrared renormalon, and the instanton–anti-instanton sector all put singularities *on* the positive axis and are therefore Borel summable only after a lateral prescription is chosen, at the cost of the ambiguity Eq. (5.225). Stating that "the QFT perturbation series is Borel summable" without specifying the direction and without exhibiting the cancellation of the resulting ambiguity is, in general, a false statement of closure. What is rigorously established (Borel summability of specific super-renormalizable models and of quantum-mechanical examples) and what is conjectural (full four-dimensional gauge theory) must be kept apart; see Section 5.7.5.

5.7.5 Resurgence and transseries: the mid-2020s frontier

The picture that has emerged is that perturbation theory is one sector of a larger object. The imaginary ambiguity Eq. (5.225) of the lateral Borel sum cannot be the final word, because physical answers are real and unambiguous; the resolution is that the perturbative series is accompanied by *additional* sectors—one-instanton, two-instanton, and so on—each itself an asymptotic series with its own Borel ambiguity, and these ambiguities cancel among the sectors. The bookkeeping device that makes this precise is the *transseries*: instead of a single power series one writes

$$f(g) \;\sim\; \sum_{k\geq 0} e^{-k\,S/g}\, g^{-k\beta_k} \sum_{n\geq 0} a_n^{(k)}\, g^n, \tag{5.228}$$

a double expansion in powers of g *and* in the nonperturbative exponentials $e^{-S/g}$, with $k = 0$ the ordinary perturbative series. The content of *resurgence*, the theory founded by Écalle [169], is that these sectors are not independent: the late-order coefficients $a_n^{(0)}$ of the perturbative series *re-surge*, encoding through Eq. (5.226) the data of the very instanton sectors $k \geq 1$ whose ambiguities cancel theirs. The lateral Borel ambiguity of the $k = 0$ sector, $\pm i\pi$ times an $e^{-S/g}$-weighted residue, is cancelled by the explicitly imaginary ambiguity of the $k = 1$ sector, leaving a real, prescription-independent *median* resummation. Écalle's alien calculus and the associated bridge equations make the cancellation an exact and computable statement.

This is the correct modern framework for everything this chapter has been building toward, and it is also, honestly stated, an active research frontier rather than a closed theory. As of the mid-2020s, resurgence is established rigorously and used quantitatively in quantum mechanics (the double well and periodic potentials), matrix models, topological string theory, and a growing list of integrable and two-dimensional field theories; in those settings the transseries Eq. (5.228) is constructed and the cancellation of ambiguities is demonstrated. For full four-dimensional gauge theory the program is *conjectural and incomplete*: the relevant Borel singularities (instanton and renormalon) are identified, the structure Eq. (5.228) is expected, but a constructive proof that the trans-series reproduces the theory, with all ambiguities cancelling, does not exist. We will meet the first concrete ingredients—explicit instantons and their action—in Chapter 42, and the renormalon side in the renormalization and running-coupling chapters; the synthesis into a complete resurgent description of QCD remains open. The honest register here matches the one set at the start of the chapter: the analytic objects are exact and in hand, while their full assembly into a nonperturbative definition of the gauge theories is a problem of the current era [25, 159].

Historical Note

The taming of divergent series has a long arc. Euler summed $\sum(-1)^n n!\, g^{n+1}$ to the exponential integral by exactly the manipulation of Theorem 5.50 a century before it was justified; Borel's $n!$-dividing transform and its Laplace inverse date to the 1890s, and Hardy's *Divergent Series* [250] codified the classical theory. F. Nevanlinna's 1919 uniqueness theorem [363] lay essentially unused by physicists until Sokal [449] sharpened it to the tangent-disk form of Theorem 5.48 and made it the working criterion. Dyson's 1952 argument [168] that QED perturbation theory must diverge (Section 5.6.5), Lipatov's 1977 instanton calculus of large orders [324], and 't Hooft's 1979 identification of renormalons [465] turned the abstract theory into physics. Écalle's *Les fonctions résurgentes*

[169] supplied the language that, four decades on, organizes the subject.

With Borel summation in place, the analytic toolbox of Part I is complete. Every propagator the next part writes down is a boundary value fixed by the $i\epsilon$ prescription and the Sokhotski–Plemelj theorem of Section 5.1.5; every Euclidean computation is licensed by the Wick rotation; every dispersive and unitarity argument rests on the analyticity in external invariants of Section 5.5; and every perturbative series those chapters generate is now understood as an asymptotic expansion to be read, at best, through Borel resummation, with its instanton and renormalon singularities already named. We are ready to leave the foundations and begin classical field theory in Part II, where the threads ϕ^4, QED, and Yang–Mills are at last defined and the analytic machinery stocked here is put to work.

Further reading

The functional-analytic theory of distributions is developed in Reed and Simon [416] and, with the physicist's emphasis on generalized functions and their transforms, in Gel'fand and Shilov [214]; the definitive modern treatment, including the wavefront-set technology behind the products of distributions deferred to renormalization, is Hörmander [270]. The axiomatic role of tempered distributions and analyticity in quantum field theory proper is the subject of Streater and Wightman [458]. The analytic-S-matrix program – causality, analyticity in invariants, and dispersion relations as physical principles – is laid out in Eden et al. [170]. For the asymptotic and divergent-series machinery, Bender and Orszag [59] is the standard working reference for Watson's lemma and steepest descent, while the divergence of QFT perturbation theory traces to Dyson [168]; the large-order behaviour, Borel summation, and the renormalon story are collected in Le Guillou and Zinn-Justin [318] and developed in depth in Zinn-Justin [534]. The use of all of these tools in context appears throughout Weinberg [500], Peskin and Schroeder [396], and Schwartz [432].

Part II

Classical Field Theory

Chapter 6

Lagrangian and Hamiltonian Field Theory

Part I built the stage. In Chapter 3 we asked what a relativistic field is even *allowed* to be, and the answer came from representation theory: a field must transform in some finite-dimensional representation of the Lorentz group, and the classification of those representations (predicted Theorem 3.19, Section 3.3) handed us the entire kinematic vocabulary of the subject—scalars, Weyl and Dirac spinors, vectors—before a single equation of motion was written. In Chapter 4 we built the analytic machinery for objects that depend on a continuum of variables: the functional derivative, the action functional, the fundamental lemma of the calculus of variations, and the Legendre transform (predicted Section 4.1.2, Section 4.5.1). What Part I conspicuously did not supply was *motion*. We know the alphabet; we have not yet written a sentence. A scalar field at rest and a scalar field in violent oscillation are the same kinematic object; nothing said so far distinguishes them, because nothing so far is dynamical.

This chapter supplies the dynamics, and it does so from a single organizing principle. Just as the entire mechanics of a finite collection of particles flows from Hamilton's principle—trajectories are the ones that make an action stationary—so the entire classical dynamics of fields flows from *stationary action* applied to a system with a continuum of degrees of freedom, one (or a few) at every point of spacetime. From that one postulate we will extract the equations of motion, the conserved energy and momentum, the canonical bracket structure, and the obstructions (constraints) that appear whenever the action is built with redundancy. Everything in this chapter is purely classical. The fields here are c-number functions on spacetime (with a flagged exception for the anticommuting Dirac field, whose Grassmann nature we note but do not yet exploit); there are no operators, no Hilbert space, no $\hbar$ doing any work. This is deliberate. The cleanest route to understanding quantization, which occupies Part III and beyond, is to first hold in hand—completely, with no loose ends—the classical

theory that quantization acts upon.

In the arc set out in Chapter 1, quantum field theory is the reconciliation of special relativity with quantum mechanics: the framework in which a fixed, finite number of particles is no longer a consistent assumption and fields become the fundamental dynamical entities. That reconciliation has two halves. One half is relativistic and classical—a Lorentz-invariant dynamics for fields—and the other is quantum. This chapter completes the first half. We build relativistic classical field theory to a finish, so that when Part III promotes Poisson brackets to commutators there is a definite, fully understood structure being promoted, and the only genuinely new ingredient is the quantum one.

The chapter also introduces the book's standing cast. Three classical field theories recur from here to the research frontier, and all three make their first appearance in these pages with their Lagrangians, equations of motion, Hamiltonians, and stress tensors derived once and imported everywhere after. The real scalar field becomes ϕ^4 theory the instant we add the quartic self-interaction $-\frac{\lambda}{4!}\phi^4$, and we carry its full classical layer in this chapter—action, the equation of motion $(\Box + m^2)\phi = -\frac{\lambda}{3!}\phi^3$, Hamiltonian, Poisson brackets, and stress tensor. The Dirac field, the protagonist of QED, appears with its first-order Lagrangian and the Dirac equation. The Maxwell field appears with $-\frac{1}{4}F_{\mu\nu}F^{\mu\nu}$, the inhomogeneous equations $\partial_\mu F^{\mu\nu} = J^\nu$, and the gauge redundancy that will dominate so much of the later book. These are not toy illustrations; they are the actual theories the rest of the book quantizes, renormalizes, and pushes to the frontier.

Conventions are those fixed for the whole book and collected in Chapter A: the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units $\hbar = c = 1$, and the Fourier and index conventions stated there; the gamma-matrix algebra and the $\bar{\psi} = \psi^\dagger\gamma^0$ convention used for the Dirac field live in Chapter C. The forward map is equally definite. The chapter ends by extracting, from invariance of the action under spacetime translations, the canonical stress–energy tensor and the conserved four-momentum; Chapter 7 generalizes that single computation into the full Noether correspondence between continuous symmetries and conserved currents, and repairs the canonical tensor into the symmetric, gauge-invariant Belinfante form. The canonical momenta and equal-time Poisson brackets assembled here are, object for object, exactly what Chapter 9 promotes to canonical commutators when the scalar field is quantized. Read this way, the chapter is the hinge on which the book turns from kinematics to dynamics, and from classical to quantum.

6.1 From Particles to Fields: The Action Functional

Part I built a stage and left it empty. Chapter 3 classified what a relativistic field is *allowed* to be — the catalogue of Lorentz/Poincaré representations: scalar, Weyl and Dirac spinor, vector — and Chapter 4 assembled the variational

calculus, the notion of a functional and its derivative, that we will need to put those objects in motion. What neither chapter supplied is dynamics: a rule that selects, out of all conceivable histories of a field, the ones nature actually realizes. This chapter supplies that rule, and it does so with a single organizing principle, stationary action, applied to systems carrying a continuum of degrees of freedom. The present section builds the object that the principle acts on. We first show, by taking a concrete mechanical system — a lattice of masses joined by springs — to its continuum limit, that a field is nothing more exotic than a mechanical system with one degree of freedom at every point of space, and that the energetics of such a system organize themselves into a *Lagrangian density*. We then abstract from the example to the general definition, fix the three structural requirements that every Lagrangian density in this book obeys — locality, Lorentz invariance, and dependence on at most first derivatives — and justify each one rather than decree it. The section closes by putting the book's first protagonist on stage: the free real scalar field, whose Lagrangian is the seed of ϕ^4 theory.

Everything here is purely classical. The fields are c-number functions on spacetime; there is no Hilbert space, no operator, no $\hbar$. This is deliberate. The cleanest route to understanding quantization (Part III) is to hold the classical theory it quantizes completely in hand first, and the classical theory is interesting and structured in its own right.

6.1.1 A mechanical system with infinitely many degrees of freedom

The conceptual leap from particle mechanics to field theory is the leap from finitely many degrees of freedom to a continuum of them. The honest way to take that leap is to watch it happen in an example where every step is ordinary mechanics. We therefore start not with a field but with a long chain of identical masses connected by springs, write down its Lagrangian as taught in any course on classical mechanics, and ask what becomes of that Lagrangian when the masses are packed infinitely densely. A field, and the density whose integral is its action, will fall out.

Consider N point masses m arranged along a line at equilibrium spacing a, the n-th mass tethered to its neighbours by identical springs of stiffness κ. Let $q_n(t)$ be the longitudinal displacement of the n-th mass from its equilibrium position $x_n = na$ (Fig. 6.1). The kinetic energy is the usual sum $\sum_n \frac{1}{2} m \dot{q}_n^2$. The potential energy is stored in the springs; the spring between masses n and $n+1$ is stretched by $q_{n+1} - q_n$, so it holds energy $\frac{1}{2}\kappa\,(q_{n+1} - q_n)^2$. The Lagrangian of the chain is therefore

$$L \;=\; \sum_n \Big[\tfrac{1}{2}\, m\, \dot{q}_n^2 \;-\; \tfrac{1}{2}\, \kappa\, (q_{n+1} - q_n)^2 \Big]. \tag{6.1}$$

This is a system of N coupled oscillators: N degrees of freedom, one displacement

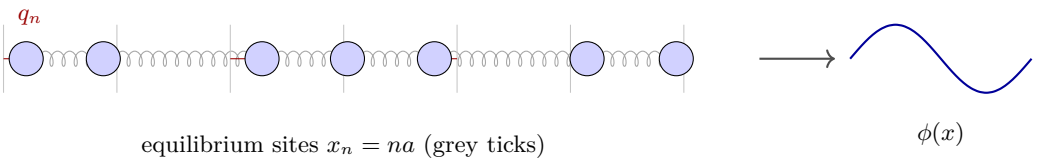

Figure 6.1: From a chain to a field. A line of masses m at equilibrium spacing a (grey ticks), each displaced by q_n (red) and coupled to its neighbours by springs of stiffness κ. As $a \to 0$ at fixed mass density $\mu = m/a$ and fixed elastic modulus $Y = \kappa a$, the discrete displacements $q_n(t)$ become a smooth field $\phi(x,t)$, the finite difference $q_{n+1} - q_n$ becomes $a\,\partial_x\phi$, and the sum over sites becomes an integral. The chain's N degrees of freedom become one degree of freedom at each point of space.

per site. Nothing about Eq. (6.1) is unfamiliar; it is the standard model problem whose normal modes are lattice phonons.

We now take the continuum limit. Hold fixed two macroscopic quantities as $a \to 0$ and $N \to \infty$ with $L_{\text{tot}} = Na$ fixed: the linear *mass density* $\mu \equiv m/a$ and the elastic *modulus* $Y \equiv \kappa a$ (the one-dimensional analogue of Young's modulus). Both are intensive: they describe the material, not the discretization. Introduce a smooth field $\phi(x,t)$ that interpolates the displacements, $\phi(x_n,t) = q_n(t)$. For neighbouring sites Taylor expansion gives

$$q_{n+1} - q_n \;=\; \phi(x_n + a, t) - \phi(x_n, t) \;=\; a\,\frac{\partial\phi}{\partial x}\Big|_{x_n} + O(a^2), \tag{6.2}$$

so the finite difference is $a\,\partial_x\phi$ to leading order. Rewrite Eq. (6.1) by inserting one factor of a per term and grouping it with the sum, which is what turns $\sum_n a\,(\cdots)$ into a Riemann sum for $\int dx\,(\cdots)$:

$$L \;=\; \sum_n a\left[\tfrac{1}{2}\,\frac{m}{a}\,\dot{q}_n^2 \;-\; \tfrac{1}{2}\,\kappa a\left(\frac{q_{n+1}-q_n}{a}\right)^2\right] \;=\; \sum_n a\left[\tfrac{1}{2}\,\mu\,\dot{\phi}^2 \;-\; \tfrac{1}{2}\,Y\,(\partial_x\phi)^2\right] + O(a), \tag{6.3}$$

where in the second equality we used $m/a = \mu$, $\kappa a = Y$, the interpolation $\dot{q}_n = \dot{\phi}(x_n)$, and Eq. (6.2). The error term collects the $O(a^2)$ remainder of the Taylor expansion, which carries an extra power of a relative to the kept terms and vanishes in the limit. Taking $a \to 0$, the Riemann sum becomes an integral and the Lagrangian becomes a *spatial integral of a density*:

$$L \;=\; \int dx\,\mathcal{L}, \qquad \mathcal{L}(x,t) \;=\; \tfrac{1}{2}\,\mu\,\dot{\phi}^2 \;-\; \tfrac{1}{2}\,Y\,(\partial_x\phi)^2. \tag{6.4}$$

This $\mathcal{L}$ is the *Lagrangian density*, and it is the central object of the rest of this chapter. Three of its features were forced on us by the derivation and are worth naming, because they survive the abstraction to come.

First, the appearance of a degree of freedom at every point. The label n that indexed the masses has become the continuous label x; the configuration of the system at one instant is no longer a list of N numbers but the entire function $x \mapsto \phi(x,t)$. A field is, precisely, a mechanical system whose degrees of freedom are indexed by the points of space — uncountably many of them, one real number per point. This is the sense in which field theory *is* mechanics with infinitely many degrees of freedom, and it is the reason the variational principle of Chapter 4 will transcribe to fields with only cosmetic change.

Second, the appearance of $(\partial_x\phi)^2$. The gradient term is not put in by hand; it is the continuum residue of the spring coupling $\frac{1}{2}\kappa(q_{n+1}-q_n)^2$ between neighbours. Because the potential energy of a spring depends only on the *difference* of adjacent displacements — a uniform displacement $q_n \to q_n + \text{const}$ stretches no spring and costs no energy — the leading continuum cost of a nonuniform configuration is quadratic in the first spatial derivative. The squared gradient is the field-theoretic statement that it costs energy to bend the field but not to slide it rigidly. This term is the origin of every $(\partial\phi)^2$ in the book.

Third, the kinetic term $\frac{1}{2}\mu\dot{\phi}^2$ is the obvious continuum sum of the site kinetic energies $\frac{1}{2}m\dot{q}_n^2$, with m/a collected into the density μ. Kinetic energy depends on the *time* derivative of the field, potential energy on its *space* derivatives; the Lagrangian density is their difference, exactly as $L = T - V$ in particle mechanics.

The relativistic idealization

The density Eq. (6.4) is not yet Lorentz invariant, and it should not be: a lattice of masses is a Galilean mechanical system with a preferred rest frame, the frame of the material. To expose its near-relativistic structure, factor out the density,

$$\mathcal{L} = \tfrac{1}{2}\,\mu\Big[\dot{\phi}^2 - v^2(\partial_x\phi)^2\Big], \qquad v^2 \equiv \frac{Y}{\mu} = \frac{\kappa a^2}{m}. \tag{6.5}$$

The combination v has dimensions of speed; a plane wave $\phi \sim e^{i(kx-\omega t)}$ inserted into the Euler–Lagrange equation of Eq. (6.5) (the equation of motion derived in general in the next section) obeys $\omega^2 = v^2k^2$, so v is the speed at which long-wavelength disturbances propagate down the chain — the speed of sound in this elastic medium. The density Eq. (6.5) is invariant under the boosts of an "acoustic" Lorentz group built with v in place of c.

A genuinely relativistic field is the idealization in which the propagation speed of the medium is the universal speed of light, $v = c$, which in natural units ($\hbar = c = 1$, Chapter A) means $v = 1$. Setting $v = 1$ and absorbing the constant μ by the canonical rescaling $\phi \to \phi/\sqrt{\mu}$ (a field redefinition that leaves the dynamics unchanged, since L is quadratic and homogeneous in ϕ) collapses Eq. (6.5) to

$$\mathcal{L} = \tfrac{1}{2}\,\dot{\phi}^2 - \tfrac{1}{2}\,(\partial_x\phi)^2. \tag{6.6}$$

In one space and one time dimension, with the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-)$ of Chapter A, the two terms are exactly the two pieces of a Lorentz scalar:

$$\partial_\mu\phi\,\partial^\mu\phi = (\partial_0\phi)^2 - (\partial_1\phi)^2 = \dot\phi^2 - (\partial_x\phi)^2, \quad \text{so} \quad \mathcal{L} = \tfrac{1}{2}\,\partial_\mu\phi\,\partial^\mu\phi. \tag{6.7}$$

The same construction in three space dimensions — a cubic lattice of masses with springs along each axis — produces, by the identical Taylor-and-collect argument applied independently to each direction, the kinetic term $\frac{1}{2}\dot\phi^2$ and a gradient term $\frac{1}{2}\sum_{i=1}^{3}(\partial_i\phi)^2 = \frac{1}{2}(\nabla\phi)^2$, whose difference is again $\frac{1}{2}\partial_\mu\phi\,\partial^\mu\phi$ with $\mu = 0,1,2,3$. We have manufactured, from balls and springs, the kinetic part of the free scalar field theory.

Physical Insight

The squared gradient is the price of inhomogeneity, and the relativistic theory is the one in which that price is the same in every frame. The lattice "knows" a rest frame — the frame in which the masses sit still — and its sound speed v is generically far below c. Promoting $v \to c$ is not a cosmetic relabeling but a genuine physical postulate: it asserts that the field's excitations are causal at the universal speed, i.e. that the field is a relativistic, not a material, degree of freedom. This is why Lorentz invariance must be *imposed* as a requirement on field Lagrangians (Section 6.1.4) rather than discovered — the mechanical model that motivates the structure does not, on its own, supply it.

The mass term

The free scalar field carries one more term, the mass term, and the mechanical model produces it too once we add one ingredient. Suppose that in addition to the springs between neighbours, each mass is tethered to its own equilibrium point by an on-site spring of stiffness κ' — physically, a restoring force that resists *absolute* displacement, not just relative displacement. This adds $-\sum_n \frac{1}{2}\kappa' q_n^2$ to the potential energy. Collecting a factor of a as before, $\sum_n \frac{1}{2}\kappa' q_n^2 = \sum_n a\,\frac{1}{2}(\kappa'/a)\phi^2 \to \int dx\,\frac{1}{2}(\kappa'/a)\phi^2$, so after the same rescaling $\phi \to \phi/\sqrt{\mu}$ and $v = 1$ the density acquires a term $-\frac{1}{2}m^2\phi^2$ with

$$m^2 \equiv \frac{\kappa'}{\mu\, a}. \tag{6.8}$$

The dispersion relation now reads $\omega^2 = k^2 + m^2$: a plane wave of wavenumber k oscillates at frequency $\omega = \sqrt{k^2+m^2}$, so even the longest-wavelength mode $k \to 0$ has a nonzero frequency $\omega \to m$. The on-site spring opens a *gap* in the spectrum, and m is the size of that gap. This is the first appearance of the deepest single fact about the mass term: in a relativistic field theory the mass is

the energy of the field's lowest excitation, the gap below which no propagating mode exists, and equivalently the inverse of the length scale $1/m$ over which static disturbances of the field decay. We will meet $1/m$ again as the Compton wavelength, as the range of a force, and as the correlation length of the quantum theory; all are the same length, first seen here as the reciprocal of an on-site spring constant.

6.1.2 What a classical field is

The example has done its work. We now state, once and cleanly, what a classical field is in this book, importing the representation-theoretic content from Chapter 3 rather than rebuilding it.

Definition 6.1 (Classical field)**.** Let M be Minkowski spacetime with coordinates $x^\mu = (x^0, \mathbf{x})$ and metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$ (Chapter A), and let (R, V) be a finite-dimensional representation of the Lorentz group $\mathrm{O}(1,3)$ (or of its Poincaré extension), as classified in Section 3.3. A *classical field of type* R is a smooth assignment

$$x \longmapsto \phi_a(x) \in V, \qquad a = 1, \dots, \dim V, \tag{6.9}$$

of an element of the representation space V to each spacetime point, transforming under a Lorentz transformation $x' = \Lambda x$ as

$$\phi'_a(x') \;=\; R(\Lambda)_a{}^b \, \phi_b(x). \tag{6.10}$$

The index a runs over the components of V; for a multi-field theory the collection $\{\phi_a\}$ may assemble several irreducible representations, and a then runs over all of them.

The cases that recur throughout the book are exactly those catalogued in Section 3.3.3, and we name them here only to fix the notation; their transformation laws and the proof that the list is complete belong to Chapter 3.

A *scalar field* $\phi(x)$ carries the trivial representation, $R(\Lambda) = 1$, so Eq. (6.10) reads $\phi'(x') = \phi(x)$: the value of the field is unchanged, merely re-evaluated at the transformed point. This is the simplest field and the protagonist of this chapter.

A *Dirac spinor field* $\psi_a(x)$, $a = 1, \dots, 4$, carries the representation $(\tfrac{1}{2}, 0) \oplus (0, \tfrac{1}{2})$, with $R(\Lambda) = S(\Lambda)$ the spinor representation built from the gamma matrices of Chapter C; it describes the electron of QED.

A *vector field* $A^\mu(x)$ carries the $(\tfrac{1}{2}, \tfrac{1}{2})$ representation, transforming as $A'^\mu(x') = \Lambda^\mu{}_\nu A^\nu(x)$; it describes the photon of QED and, in its non-abelian generalization, the gluon of Yang–Mills theory.

These are introduced as the recurring cast of the whole book. Their classical Lagrangians, equations of motion, Hamiltonians, and stress tensors are derived once, in this chapter, and imported everywhere afterward. For the remainder of this section the scalar suffices.

6.1.3 The action functional

In particle mechanics the dynamics of $q(t)$ is encoded in the action $S = \int dt\, L(q, \dot{q}, t)$, a number assigned to each trajectory, made stationary by the physical path (Chapter 4). For a field the trajectory is replaced by a field configuration $\phi_a(x)$ over a region of spacetime, and the time integral by an integral over that region. We have just seen, in Eq. (6.4), that the natural field Lagrangian is itself a spatial integral of a density; combining the two integrals, the action of a field theory is a single integral over spacetime of a Lagrangian *density*.

Definition 6.2 (Lagrangian density and action)**.** Let $\{\phi_a\}$ be a collection of classical fields. A *Lagrangian density* is a function

$$\mathcal{L}(\phi_a(x),\, \partial_\mu \phi_a(x),\, x) \tag{6.11}$$

of the fields, their first spacetime derivatives, and (at most) the point x explicitly. The *action* of the field configuration over a spacetime region $\Omega \subseteq M$ is the functional

$$S[\phi_a] \;=\; \int_\Omega d^4x\; \mathcal{L}(\phi_a,\, \partial_\mu \phi_a,\, x), \qquad d^4x \equiv dx^0\, dx^1\, dx^2\, dx^3, \tag{6.12}$$

where the notion of a functional and its variation are those of Section 4.1.1. When Ω is unspecified it is understood to be all of M, with the fields assumed to fall off fast enough at infinity for the integral to converge.

The functional $S[\phi_a]$ assigns a real number to each field configuration; the dynamics, derived in the next section, is the statement that the physically realized configurations are those at which S is stationary against all variations vanishing on the boundary of Ω. Before we can vary it, however, we must pin down the form of $\mathcal{L}$. Theorem 6.2 already encodes two strong assumptions — that $\mathcal{L}$ depends on the fields at a single point and on no derivative higher than the first — which we have so far merely read off the balls-and-springs example. We now elevate them to principles and justify them.

6.1.4 The three structural requirements

Not every functional of ϕ_a is an admissible action. Three requirements constrain the Lagrangian density of every theory in this book. They are not arbitrary aesthetics; each is the formal expression of a physical demand, and we give the demand together with the constraint it imposes.

Locality

> *The Lagrangian density at x depends on the fields and their derivatives evaluated at the single point x, not on their values elsewhere.*

This is the assumption that produced the *density* in Eq. (6.4): each term in the chain's Lagrangian involved a single site or a pair of infinitesimally separated sites, and in the continuum that became a function of ϕ and $\partial_\mu\phi$ at one point. A nonlocal alternative — a Lagrangian containing, say, $\int d^4y\,\phi(x)\,K(x-y)\,\phi(y)$ with K of finite range — is mathematically conceivable, but it would let the field at x feel the field at a finite distance instantaneously across the term, in tension with the causal structure of relativity: influences should propagate through the field, point to neighbouring point, not jump across gaps. Locality is the demand that all interaction be mediated by the field itself, contact-like at each point, with finite-range effects arising only *dynamically*, by the field carrying influence from point to point at speeds bounded by c. Every fundamental Lagrangian we write is local in this sense; apparent nonlocality (as in an effective theory where a heavy field has been integrated out) is always the shadow of an underlying local description, expandable in local operators with more and more derivatives. We will return to this point when we discuss effective field theory; for now locality is a standing assumption, built into Theorem 6.2 by allowing only pointwise dependence.

Lorentz invariance

> *The action is a Lorentz scalar: S takes the same value in every inertial frame. Because the spacetime measure d^4x is itself invariant, this holds if and only if the Lagrangian density $\mathcal{L}$ is a Lorentz scalar.*

The physical content is the principle of relativity: the laws of motion, which are the stationarity conditions of S, must be the same in every inertial frame, and the cleanest way to guarantee this is to make the object they descend from, S, frame-independent. The requirement splits into a statement about the measure and a statement about the integrand, and the first half is a short computation worth doing once.

Proposition 6.3 (The spacetime measure is Lorentz invariant)**.** *Under a Lorentz transformation $x'^\mu = \Lambda^\mu{}_\nu x^\nu$ with $\Lambda \in \mathrm{O}(1,3)$, the four-volume element is unchanged: $d^4x' = d^4x$.*

Proof. A change of variables in a multiple integral rescales the volume element by the absolute value of the Jacobian determinant,

$$d^4x' = \left|\det\Big(\frac{\partial x'^\mu}{\partial x^\nu}\Big)\right| d^4x = |\det\Lambda|\; d^4x, \tag{6.13}$$

since $\partial x'^\mu/\partial x^\nu = \Lambda^\mu{}_\nu$ for a linear transformation. It remains to show $|\det\Lambda| = 1$. By definition a Lorentz transformation preserves the metric, $\Lambda^\mu{}_\rho\,\eta_{\mu\nu}\,\Lambda^\nu{}_\sigma = \eta_{\rho\sigma}$,

which in matrix form is $\Lambda^{\mathsf{T}}\eta\,\Lambda = \eta$. Taking determinants of both sides and using $\det(ABC) = \det A \det B \det C$ and $\det \Lambda^{\mathsf{T}} = \det \Lambda$,

$$(\det \Lambda)^2 \, \det \eta = \det \eta. \tag{6.14}$$

Since $\det \eta = -1 \neq 0$, it cancels, leaving $(\det \Lambda)^2 = 1$, hence $\det \Lambda = \pm 1$ and $|\det \Lambda| = 1$. Substituting into Eq. (6.13) gives $d^4x' = d^4x$. □

The two signs $\det \Lambda = \pm 1$ distinguish the proper Lorentz transformations ($\det \Lambda = +1$, continuously connected to the identity — rotations and boosts) from the improper ones ($\det \Lambda = -1$, involving a reflection such as parity or time reversal), a distinction analyzed in Chapter 3. For the invariance of the measure only the absolute value matters, and both branches give $|\det \Lambda| = 1$. Translations, the remaining Poincaré generators, shift $x^\mu \to x^\mu + a^\mu$ with unit Jacobian trivially, so d^4x is invariant under the full Poincaré group.

Proposition 6.4 (Invariance of the action)**.** *With d^4x Lorentz invariant by Theorem 6.3, the action $S = \int d^4x\, \mathcal{L}$ is Lorentz invariant if and only if the Lagrangian density transforms as a Lorentz scalar, $\mathcal{L}'(x') = \mathcal{L}(x)$.*

Proof. Under $x' = \Lambda x$ the transformed action is $S' = \int d^4x'\, \mathcal{L}'(x')$. Changing the integration variable back to x via Theorem 6.3, $d^4x' = d^4x$, gives $S' = \int d^4x\, \mathcal{L}'(x'(x))$. This equals $S = \int d^4x\, \mathcal{L}(x)$ for every region and every configuration precisely when the integrands agree, $\mathcal{L}'(x') = \mathcal{L}(x)$, which is the defining transformation law of a Lorentz scalar. Conversely, if $\mathcal{L}$ is a scalar the two integrals are equal term by term, so $S' = S$. □

In practice Theorem 6.4 is a constructive recipe: to build a Lorentz-invariant action one assembles $\mathcal{L}$ out of Lorentz scalars formed from the fields and their derivatives. For a scalar field the available scalars are ϕ, $\partial_\mu\phi\,\partial^\mu\phi$, ϕ^2, ϕ^4, and so on — any expression in which every Lorentz index is contracted. For a Dirac field the invariants are bilinears such as $\bar\psi\psi$ and $\bar\psi\, i\partial\!\!\!/\psi$ (built with the gamma matrices of Chapter C); for a vector field, contractions such as $F_{\mu\nu}F^{\mu\nu}$. The transformation law Eq. (6.10) guarantees that any fully contracted polynomial in the fields and their derivatives is a scalar, hence an admissible contribution to $\mathcal{L}$. This is how every Lagrangian in the book is written down: list the fields, list the scalars one can build from them up to the required dimension, and take a linear combination.

Dependence on at most first derivatives

> *The Lagrangian density depends on the fields and their* first *derivatives only — not on $\partial_\mu\partial_\nu\phi$ or anything higher.*

This is the requirement that the example handed us for free — the spring energy produced $(\partial_x\phi)^2$, never $(\partial_x^2\phi)^2$ — but unlike locality and Lorentz invariance it is not a matter of taste or even of relativity. It is forced by the demand that the theory have a stable ground state and a well-posed initial-value problem. A Lagrangian with first derivatives only yields second-order equations of motion (as we derive in the next section), whose solution is fixed by two pieces of initial data per degree of freedom, ϕ and $\dot\phi$ — exactly the Cauchy data of mechanics. A Lagrangian containing genuine higher derivatives yields higher-order equations needing more initial data, and the price of those extra data is catastrophic: the Hamiltonian is unbounded below. This is the content of Ostrogradsky's theorem, which we now state and demonstrate in its simplest nontrivial instance, because the instability is the honest reason for the first-derivative rule and deserves to be seen, not merely asserted.

Worked Example 6.5 (The Ostrogradsky instability)**.** We work in ordinary mechanics, one degree of freedom; the field case is the same statement at every point of space. Consider a Lagrangian that depends on the acceleration, $L(q,\dot q,\ddot q)$, and is *nondegenerate*, meaning $\partial^2 L/\partial\ddot q^2 \neq 0$ so that $\ddot q$ genuinely appears. The Euler–Lagrange equation generalizes to

$$\frac{\partial L}{\partial q} - \frac{d}{dt}\frac{\partial L}{\partial \dot q} + \frac{d^2}{dt^2}\frac{\partial L}{\partial \ddot q} = 0, \tag{6.15}$$

a *fourth*-order differential equation: its solution requires four initial data $(q,\dot q,\ddot q,\dddot q)$, twice the usual two. Ostrogradsky's prescription handles such a system canonically by treating q and $\dot q$ as two independent coordinates,

$$Q_1 \equiv q, \qquad Q_2 \equiv \dot q, \tag{6.16}$$

with two conjugate momenta dictated by the higher-derivative Legendre transform,

$$P_1 \equiv \frac{\partial L}{\partial \dot q} - \frac{d}{dt}\frac{\partial L}{\partial \ddot q}, \qquad P_2 \equiv \frac{\partial L}{\partial \ddot q}. \tag{6.17}$$

Nondegeneracy, $\partial^2 L/\partial\ddot q^2 \neq 0$, is exactly the condition that the second relation can be inverted to express the acceleration as a function $\ddot q = \mathcal{A}(Q_1,Q_2,P_2)$ of the phase-space variables. The Hamiltonian is the higher-derivative Legendre transform,

$$H = P_1\dot q + P_2\ddot q - L = P_1\,Q_2 + P_2\,\mathcal{A}(Q_1,Q_2,P_2) - L(Q_1,Q_2,\mathcal{A}). \tag{6.18}$$

The decisive feature is the very first term: H is *linear* in the momentum P_1, which appears nowhere else in Eq. (6.18) (the remaining terms depend only on Q_1,Q_2,P_2). A function linear in P_1 with a nonzero coefficient Q_2 takes arbitrarily large positive *and* arbitrarily large negative values as $P_1 \to \pm\infty$. The Hamiltonian is therefore unbounded below: there is no state of lowest energy.

To see that this is a genuine instability and not a coordinate artifact, take the explicit nondegenerate example

$$L = \tfrac{1}{2}\,\ddot{q}^{\,2} - \tfrac{1}{2}\,\omega^2 \dot{q}^{\,2}, \tag{6.19}$$

a free higher-derivative oscillator. Here $\partial^2 L/\partial \ddot{q}^2 = 1 \neq 0$, the momenta Eq. (6.17) are $P_1 = -\omega^2 \dot{q} - \dddot{q} = -\omega^2 Q_2 - \dddot{q}$ and $P_2 = \ddot{q}$, so $\mathcal{A} = P_2$, and Eq. (6.18) becomes

$$H = P_1 Q_2 + \tfrac{1}{2} P_2^2 + \tfrac{1}{2}\omega^2 Q_2^2. \tag{6.20}$$

Along the direction $P_1 \to -\infty$ at fixed positive Q_2, $H \to -\infty$ without bound. The equation of motion Eq. (6.15) reads $\ddddot{q} + \omega^2 \ddot{q} = 0$, with general solution $q(t) = c_1 + c_2 t + c_3 \cos\omega t + c_4 \sin\omega t$: alongside the ordinary oscillation at frequency ω there is a mode (the $c_2 t$ piece, and in interacting versions a second oscillator with the *wrong*-sign kinetic energy, a "ghost") that carries negative energy. Coupling such a system to any normal positive-energy degree of freedom lets the total energy run away — the negative-energy mode is excited without bound while the positive-energy mode is excited to compensate, conserving energy while both amplitudes diverge. This runaway is fatal classically and worse quantum-mechanically.

The lesson of Theorem 6.5 is the justification for Theorem 6.2: restricting $\mathcal{L}$ to first derivatives is the condition that the Ostrogradsky construction never runs, so that the Hamiltonian is bounded below and a stable vacuum can exist. We state the result at the level we will use it.

Proposition 6.6 (Ostrogradsky)**.** *A nondegenerate Lagrangian depending on time derivatives of order higher than the first has a canonical Hamiltonian that is linear in at least one canonical momentum, and is therefore unbounded below. Consequently the Lagrangian densities of stable, local field theories are taken to depend on the fields and their first derivatives only; higher-derivative terms, when they appear in effective descriptions, are treated perturbatively as small corrections rather than as defining a new propagating degree of freedom.*

The full statement and proof of Ostrogradsky's theorem for arbitrary order are a direct generalization of the worked computation above and add no new idea; the linearity in the lowest Ostrogradsky momentum is generic, and the parenthetical qualification about effective theories is the standard escape hatch, made precise when we organize derivative expansions in the renormalization chapters. For all the fundamental Lagrangians of this book — scalar, Dirac, Maxwell, Yang–Mills — the first-derivative rule holds exactly.

Caution

The first-derivative rule constrains the Lagrangian *density*, not the action. Adding a total derivative $\partial_\mu K^\mu$ to $\mathcal{L}$ changes S only by a boundary term and so contains no new dynamics, even though $\partial_\mu K^\mu$ may involve second derivatives of the fields when K^μ depends on $\partial\phi$; such terms are harmless precisely because they integrate to the boundary and drop out of the bulk equations of motion. The honest statement is that the *bulk* dynamics depends on $\mathcal{L}$ only up to total derivatives, and within that equivalence class one may always choose a representative with at most first derivatives. The careful treatment of these boundary terms is the technical heart of the next section.

6.1.5 The first protagonist: the free real scalar field

We now write down the Lagrangian that the rest of the book will quantize, perturb, and renormalize. Following the structural requirements, we want the simplest local, Lorentz-invariant Lagrangian for a single real scalar field $\phi(x)$, built from at most first derivatives. The Lorentz scalars available at lowest order are the kinetic invariant $\partial_\mu\phi\,\partial^\mu\phi$ and the field invariants $\phi^2, \phi^4, \ldots$; reflection symmetry $\phi \to -\phi$ (the $\mathbb{Z}_2$ symmetry that becomes the organizing symmetry of ϕ^4 theory in Chapter 7) forbids odd powers. Keeping the kinetic term and the quadratic potential — the two pieces the balls-and-springs limit handed us in Eq. (6.7) and Eq. (6.8) — gives the *free real scalar Lagrangian*:

$$\boxed{\mathcal{L} = \tfrac{1}{2}\,(\partial_\mu\phi)(\partial^\mu\phi) - \tfrac{1}{2}\,m^2\phi^2} \tag{6.21}$$

in the mostly-minus metric, with $\partial_\mu\phi\,\partial^\mu\phi = \dot\phi^2 - (\nabla\phi)^2$. The relative minus sign between kinetic and mass terms is the $L = T - V$ of mechanics: $\frac{1}{2}\dot\phi^2$ is kinetic energy density, while $\frac{1}{2}(\nabla\phi)^2 + \frac{1}{2}m^2\phi^2$ is potential energy density (gradient cost plus on-site cost), and the Lagrangian density is their difference. The coefficient $\frac{1}{2}$ is the conventional normalization for a real field, fixed by the requirement that the kinetic term be canonically normalized; it is the canonical normalization of ϕ^4 theory, and we adopt it without alteration here and everywhere the scalar appears.

Notation Watch

Equation (6.21) is the $\lambda \to 0$ (free) limit of the ϕ^4 Lagrangian. The full interacting Lagrangian adds the quartic self-interaction $-\frac{\lambda}{4!}\phi^4$, introduced in the next section once the variational machinery is in place; the present section deliberately stops at the free theory so that the equation of motion derived next is the Klein–Gordon equation in its purest form. Throughout

the book, the scalar field is denoted ϕ, the mass m, and the quartic coupling λ with its $1/4!$ normalization.

Dimensional analysis

Before leaving the scalar we fix its mass dimension, a number used constantly in later chapters to decide which interactions are renormalizable and which operators are relevant or irrelevant. The action is dimensionless in natural units, because it appears in the quantum theory only through $e^{iS/\hbar}$ and $\hbar = 1$ (Chapter A); writing $[\,\cdot\,]$ for the mass dimension (the power of mass, with length counted as mass^{-1} since $\hbar = c = 1$), this is the statement

$$[S] = 0. \tag{6.22}$$

In d spacetime dimensions the measure carries $[d^d x] = -d$ (it is a d-fold product of lengths), so from $S = \int d^d x\, \mathcal{L}$ and $[S] = 0$ the Lagrangian density must carry $[\mathcal{L}] = d$. In the physical case $d = 4$,

$$[\mathcal{L}] = 4. \tag{6.23}$$

Now read the dimension of ϕ off the kinetic term. Each derivative carries one power of mass, $[\partial_\mu] = 1$, so $[\partial_\mu \phi\, \partial^\mu \phi] = 2 + 2[\phi]$, and demanding this equal $[\mathcal{L}] = 4$ gives $2 + 2[\phi] = 4$, hence

$$[\phi] = 1 \qquad \text{(a scalar field has the dimension of mass, in } d = 4\text{)}. \tag{6.24}$$

The mass term is a consistency check: $[m^2\phi^2] = 2[m] + 2[\phi] = 2 + 2 = 4 = [\mathcal{L}]$, confirming that the parameter m in Eq. (6.21) indeed has $[m] = 1$, the dimension of a mass, as its name promised. The same accounting in general d gives $[\phi] = (d-2)/2$, a formula we will need when continuing to $d = 4 - 2\varepsilon$ in dimensional regularization; the quartic coupling then has $[\lambda] = 4 - d = 2\varepsilon$, the fact that makes ϕ^4 marginally renormalizable in four dimensions. We record these here only to note that the dimensional bookkeeping of the entire renormalization program starts from Eq. (6.24).

We have built the stage's first piece of machinery. A classical field is a mechanical system with one degree of freedom per point of space (Theorem 6.1); its dynamics is to be extracted from an action $S = \int d^4x\, \mathcal{L}$ (Theorem 6.2) whose density is local, a Lorentz scalar, and a function of the fields and their first derivatives alone — three requirements we have justified rather than imposed. The free real scalar Lagrangian Eq. (6.21) is the first concrete protagonist, written in the canonical normalization of ϕ^4 theory. What we do not yet have is its equation of motion. The action is a number assigned to each history; the physical history is the one that makes it stationary. Carrying out that variation

— handling the boundary term with the care the Theorem 6.5 caution demanded, and reading off the Euler–Lagrange field equations — is the work of the next section, where the free scalar's stationarity condition turns out to be the Klein–Gordon equation and the engine that generates every equation of motion in the book is built.

6.2 Stationary Action and the Euler–Lagrange Field Equations

The previous section built the object whose stationarity is to generate all of classical dynamics: the action functional

$$S[\phi] \;=\; \int_{\Omega} \mathrm{d}^4x \; \mathcal{L}(\phi_a(x),\, \partial_\mu \phi_a(x),\, x), \tag{6.25}$$

a number assigned to each field configuration ϕ_a on a spacetime region Ω, built from a local Lagrangian density $\mathcal{L}$ that depends on the fields and their first derivatives (Section 6.1). Here the index $a = 1, \dots, N$ runs over the components of whatever multiplet of fields the theory contains — a single real scalar has $N = 1$, the Dirac field will have several complex components, the electromagnetic field four — and the explicit x-dependence in $\mathcal{L}$ is retained for generality, though every fundamental Lagrangian in this book turns out to have none (translation invariance, the subject of Chapter 7). Mechanics taught us that the physical trajectory of a system is the one that makes its action stationary against small variations with fixed endpoints. We now carry that principle, intact, to the continuum: the physical field configuration is the one for which S is stationary against small variations of ϕ_a that vanish on the boundary $\partial\Omega$. This single demand, written out, is the engine of the entire chapter — indeed of the entire book. Every equation of motion that follows, for the scalar, the Dirac field, the Maxwell field, and every interacting theory built from them, is a special case of the covariant Euler–Lagrange equation derived below.

6.2.1 The variational problem and admissible variations

We must first say precisely what "small variation with fixed endpoints" means for a field. Fix a configuration ϕ_a and a second smooth function $\eta_a(x)$ on Ω, and form the one-parameter family

$$\phi_a(x;\, s) \;=\; \phi_a(x) \;+\; s\,\eta_a(x), \qquad s \in \mathbb{R}. \tag{6.26}$$

The function η_a encodes the direction of the variation and s its magnitude; the *variation* of the field is

$$\delta\phi_a(x) \;\equiv\; \frac{\partial}{\partial s}\,\phi_a(x;s)\Big|_{s=0} = \eta_a(x). \tag{6.27}$$

The boundary condition of mechanics — endpoints held fixed — becomes, in the field setting, the requirement that the variation vanish on the boundary of the integration region:

$$\delta\phi_a(x) \;=\; 0 \qquad \text{for all } x \in \partial\Omega. \tag{6.28}$$

A variation η_a satisfying Eq. (6.28) (and otherwise smooth) we call *admissible*. It is worth pausing on what $\partial\Omega$ is. The natural region Ω for a dynamical problem is a spacetime slab bounded by two equal-time hypersurfaces $t = t_1$ and $t = t_2$ together with a timelike "wall" at large spatial radius. On the two temporal faces, Eq. (6.28) is the direct analogue of holding the initial and final configurations fixed — exactly the endpoint condition of Hamilton's principle in mechanics. On the spatial wall, Eq. (6.28) is guaranteed in practice by the standing physical assumption that fields (and hence their variations) fall off to zero at spatial infinity, so that the system carries finite energy; we take this fall-off as part of the definition of an admissible configuration. The two faces play genuinely different roles — one is the boundary of a finite control interval, the other is a decay condition — but both contribute to $\partial\Omega$, and both will be needed when we drop the boundary term below.

Definition 6.7 (Stationary action)**.** A configuration ϕ_a is a *stationary point* of the action Eq. (6.25) if, for every admissible variation η_a,

$$\frac{\mathrm{d}}{\mathrm{d}s}\, S[\phi_a + s\,\eta_a]\Big|_{s=0} \;=\; 0. \tag{6.29}$$

We write this condition as $\delta S = 0$ and call Eq. (6.29) the *principle of stationary action*.

Physical Insight

The classical principle is one of *stationary*, not least, action. For the systems of this book the stationary configuration is rarely a minimum — the relativistic free particle maximizes its proper time along the physical worldline, so its action $S = -m\int d\tau$ is a local minimum, while field actions are typically saddle points. What is universal is that the first-order change vanishes: the physical configuration is one from which the action does not change to linear order in any allowed deformation. This is also exactly the feature that survives quantization. In the path integral of Chapter 10 every configuration contributes with weight e^{iS}, and the stationary configurations are those of stationary phase — the points where neighbouring histories interfere constructively rather than wash out. The classical equation of motion is thus the leading term of an $\hbar \to 0$ stationary-phase expansion, which is the precise sense in which classical field theory is the skeleton of the quantum theory.

6.2.2 Derivation of the covariant Euler–Lagrange equations

We now evaluate the stationarity condition Eq. (6.29) explicitly and read off the differential equation it imposes. The result is the central theorem of the chapter.

Theorem 6.8 (Covariant Euler–Lagrange field equations)**.** *Let $\mathcal{L}(\phi_a, \partial_\mu \phi_a, x)$ be a Lagrangian density that is differentiable in its arguments, and let S be the action Eq. (6.25) on a region Ω. A smooth configuration ϕ_a is a stationary point of S against all admissible variations (Theorem 6.7) if and only if it satisfies, at every interior point of Ω and for each component a,*

$$\boxed{\partial_\mu \left(\frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)} \right) - \frac{\partial \mathcal{L}}{\partial \phi_a} = 0} \tag{6.30}$$

with the repeated index μ summed over the four spacetime directions.

Proof. Insert the family Eq. (6.26) into the action and differentiate under the integral sign with respect to the parameter s. Because Ω is fixed and $\mathcal{L}$ is differentiable, the s-derivative passes through the integral and acts on the integrand by the chain rule:

$$\frac{\mathrm{d}}{\mathrm{d}s} S[\phi + s\eta]\Big|_{s=0} = \int_\Omega \mathrm{d}^4 x \left[\frac{\partial \mathcal{L}}{\partial \phi_a} \frac{\partial \phi_a}{\partial s} + \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)} \frac{\partial(\partial_\mu \phi_a)}{\partial s} \right]_{s=0}, \tag{6.31}$$

where a sum over both a and μ is understood. The first factor in each term is evaluated on the unperturbed configuration ϕ_a. For the derivative factors, Eq. (6.27) gives $\partial \phi_a / \partial s = \eta_a = \delta \phi_a$, and the corresponding statement for the field gradient follows because the spacetime derivative ∂_μ and the parameter derivative ∂_s act on independent variables and therefore commute:

$$\frac{\partial}{\partial s} (\partial_\mu \phi_a(x; s))\Big|_{s=0} = \partial_\mu \left(\frac{\partial \phi_a(x; s)}{\partial s}\Big|_{s=0} \right) = \partial_\mu (\delta \phi_a). \tag{6.32}$$

This identity — that the variation of the derivative is the derivative of the variation, $\delta(\partial_\mu \phi_a) = \partial_\mu(\delta \phi_a)$ — is the field-theoretic content of "δ commutes with ∂_μ" and holds simply because $\delta \phi_a(x)$ is the difference of two field configurations evaluated at the *same* point x. Substituting both results,

$$\delta S = \int_\Omega \mathrm{d}^4 x \left[\frac{\partial \mathcal{L}}{\partial \phi_a} \delta \phi_a + \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)} \partial_\mu (\delta \phi_a) \right]. \tag{6.33}$$

The two terms are not yet in a common form: the first multiplies $\delta \phi_a$, the second multiplies its gradient. To extract a single overall factor of $\delta \phi_a$ we integrate the second term by parts, using the Leibniz rule in the guise

$$\frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)} \partial_\mu (\delta \phi_a) = \partial_\mu \left(\frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)} \delta \phi_a \right) - \partial_\mu \left(\frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)} \right) \delta \phi_a. \tag{6.34}$$

Inserting Eq. (6.34) into Eq. (6.33) and grouping, the variation splits into a "bulk" piece proportional to $\delta\phi_a$ and a total-divergence "boundary" piece:

$$\delta S \;=\; \underbrace{\int_\Omega \mathrm{d}^4x \,\left[\frac{\partial\mathcal{L}}{\partial\phi_a} - \partial_\mu\!\left(\frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi_a)}\right)\right]\delta\phi_a}_{\text{bulk}} \;+\; \underbrace{\int_\Omega \mathrm{d}^4x\;\partial_\mu\!\left(\frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi_a)}\,\delta\phi_a\right)}_{\text{boundary}}. \tag{6.35}$$

The boundary piece is the integral of a four-divergence $\partial_\mu V^\mu$ with $V^\mu \equiv (\partial\mathcal{L}/\partial(\partial_\mu\phi_a))\,\delta\phi_a$. By the divergence theorem applied to the region Ω,

$$\int_\Omega \mathrm{d}^4x\;\partial_\mu V^\mu \;=\; \oint_{\partial\Omega} \mathrm{d}\Sigma_\mu\, V^\mu \;=\; \oint_{\partial\Omega} \mathrm{d}\Sigma_\mu\,\frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi_a)}\,\delta\phi_a, \tag{6.36}$$

where $\mathrm{d}\Sigma_\mu$ is the outward-directed surface element on $\partial\Omega$. This is the step where the boundary condition earns its keep. Because every admissible variation satisfies $\delta\phi_a = 0$ on all of $\partial\Omega$ by Eq. (6.28), the integrand of Eq. (6.36) vanishes identically on the boundary, and the entire boundary piece is zero. Hence the variation reduces to the bulk integral alone,

$$\delta S \;=\; \int_\Omega \mathrm{d}^4x\,\left[\frac{\partial\mathcal{L}}{\partial\phi_a} - \partial_\mu\!\left(\frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi_a)}\right)\right]\delta\phi_a. \tag{6.37}$$

Stationarity demands that this vanish for *every* admissible $\eta_a = \delta\phi_a$. The bracket multiplying $\delta\phi_a$ is a fixed continuous function of x (it is built from the configuration ϕ_a and its derivatives, which are given), and $\delta\phi_a$ ranges over all smooth functions vanishing on $\partial\Omega$. The fundamental lemma of the calculus of variations (Section 4.1.2) states precisely that if the integral of a continuous function against every such test function vanishes, then the function itself vanishes at every interior point. Applying it component by component — choosing variations supported near any chosen interior point and in any single component a — forces the bracket to vanish for each a:

$$\frac{\partial\mathcal{L}}{\partial\phi_a} - \partial_\mu\!\left(\frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi_a)}\right) = 0, \tag{6.38}$$

which is Eq. (6.30) up to an overall sign. Conversely, if Eq. (6.30) holds then the bulk integrand vanishes identically and $\delta S = 0$ for every admissible variation. The two conditions are therefore equivalent. □

A few structural remarks fix the meaning of Eq. (6.30) before we use it. There is one equation for each field component a, so a multiplet of N fields obeys N coupled equations. Each is manifestly Lorentz covariant: $\partial/\partial\phi_a$ is a scalar operation, while $\partial/\partial(\partial_\mu\phi_a)$ carries an upper index μ that is contracted with the divergence ∂_μ, so the whole left-hand side transforms as a scalar (for a scalar field) or, more generally, in the same representation as ϕ_a itself. Because $\mathcal{L}$

depends on first derivatives, the term $\partial_\mu(\partial\mathcal{L}/\partial(\partial_\mu\phi_a))$ contains *second* derivatives of the fields: the Euler–Lagrange equations are second-order partial differential equations, exactly as the Newtonian intuition "$\ddot{q} =$ force" would predict. That second-order structure is why specifying a field and its time derivative on one hypersurface determines the evolution — the Cauchy data that the Hamiltonian formulation of Section 6.4 will repackage into canonical pairs.

6.2.3 The functional-derivative restatement

The content of Theorem 6.8 can be compressed into a single statement about the functional derivative of S. Recall from Section 4.1.2 that the functional derivative $\delta S/\delta\phi_a(x)$ is defined as the coefficient of $\delta\phi_a(x)$ in the first-order change of S, i.e. by the relation $\delta S = \int \mathrm{d}^4x\,(\delta S/\delta\phi_a(x))\,\delta\phi_a(x)$ holding for all admissible variations. Comparing with Eq. (6.37) reads off the functional derivative of the action directly:

$$\frac{\delta S}{\delta\phi_a(x)} \;=\; \frac{\partial\mathcal{L}}{\partial\phi_a} - \partial_\mu\!\left(\frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi_a)}\right), \tag{6.39}$$

all quantities evaluated at the point x. The principle of stationary action is then the statement that the physical configuration is a zero of this functional derivative,

$$\frac{\delta S}{\delta\phi_a(x)} \;=\; 0 \qquad \text{for all } x, \tag{6.40}$$

which is identical in form to the finite-dimensional condition "$\partial S/\partial q_i = 0$ at a critical point," now with the discrete index i replaced by the continuous label (a, x). This is the most useful packaging of the equations of motion for later chapters: the generating functionals of Chapter 10 are differentiated by exactly this $\delta/\delta\phi_a(x)$, and the classical equation of motion will reappear as the saddle-point condition $\delta S/\delta\phi = -J$ in the presence of a source J.

6.2.4 Total-derivative ambiguity of the Lagrangian

The action does not determine the Lagrangian density uniquely. Two Lagrangians that differ by a total spacetime divergence,

$$\mathcal{L}' \;=\; \mathcal{L} \;+\; \partial_\mu K^\mu, \tag{6.41}$$

with $K^\mu = K^\mu(\phi_a, x)$ any differentiable function of the fields and position, yield *the same equations of motion*. The quickest argument is the one already assembled in the proof. The extra term contributes to the action a pure boundary integral,

$$\int_\Omega \mathrm{d}^4x\;\partial_\mu K^\mu \;=\; \oint_{\partial\Omega} \mathrm{d}\Sigma_\mu\, K^\mu, \tag{6.42}$$

which depends only on the values of the fields on $\partial\Omega$. But those boundary values are held fixed under admissible variations, so the boundary integral is a constant

along the family Eq. (6.26) and its variation vanishes: $\delta\int_\Omega \partial_\mu K^\mu = 0$. Therefore $\delta S' = \delta S$ for every admissible variation, and S' and S have identical stationary points. Adding a total derivative to the Lagrangian is invisible to the dynamics.

This freedom is not a mere curiosity; it is a structural feature we will exploit and must guard against in equal measure. On the constructive side, it lets us drop total derivatives freely when simplifying a Lagrangian, and it underlies the freedom to integrate by parts inside an action — a manipulation used constantly from Chapter 7 onward. On the cautionary side, it means that quantities computed *from* the Lagrangian rather than from the equations of motion need not be unique. The canonical stress–energy tensor derived at the end of this chapter (Section 6.6) inherits exactly this ambiguity — it is defined only up to an "improvement" term — and the proper treatment of boundary terms becomes essential the moment we consider variations that do *not* vanish on $\partial\Omega$, as in the derivation of Noether currents (Chapter 7) and in gauge theories where surface terms carry physical charge. The following worked example verifies the invariance Eq. (6.41) by direct computation, exhibiting in detail why the Euler–Lagrange operator annihilates any total divergence.

Worked Example 6.9 (A total divergence is annihilated by the Euler–Lagrange operator)**.** Define the *Euler–Lagrange operator* acting on any density $f(\phi_a, \partial_\mu\phi_a, x)$ by

$$E_a[f] \;\equiv\; \frac{\partial f}{\partial \phi_a} - \partial_\mu\!\left(\frac{\partial f}{\partial(\partial_\mu \phi_a)}\right), \tag{6.43}$$

so that the equation of motion Eq. (6.30) reads $E_a[\mathcal{L}] = 0$. We show that for $K^\nu = K^\nu(\phi_b, x)$ depending on the fields and position but not on field derivatives,

$$E_a\big[\partial_\nu K^\nu\big] \;=\; 0 \qquad \text{identically (for every configuration).} \tag{6.44}$$

This is stronger than the boundary argument above: it shows the cancellation happens algebraically in the field equations themselves, with no appeal to boundary conditions.

Setup. Write the total divergence out with the chain rule. Since K^ν depends on x both through the fields $\phi_b(x)$ and explicitly,

$$F \;\equiv\; \partial_\nu K^\nu \;=\; \frac{\partial K^\nu}{\partial \phi_b}\,\partial_\nu\phi_b \;+\; \left.\frac{\partial K^\nu}{\partial x^\nu}\right|_{\phi}, \tag{6.45}$$

where $|_\phi$ denotes the partial derivative at fixed fields (the explicit x-dependence) and sums over b and ν are understood. Note that F depends on the fields ϕ_b and on the first derivatives $\partial_\nu\phi_b$, so it is a legitimate argument of the operator Eq. (6.43).

First piece, $\partial F/\partial\phi_a$. Differentiating Eq. (6.45) with respect to ϕ_a at fixed field derivatives,

$$\frac{\partial F}{\partial \phi_a} \;=\; \frac{\partial^2 K^\nu}{\partial\phi_a\partial\phi_b}\,\partial_\nu\phi_b \;+\; \left.\frac{\partial^2 K^\nu}{\partial\phi_a\partial x^\nu}\right|_{\phi}. \tag{6.46}$$

Only the field-dependent coefficients are differentiated; the factor $\partial_\nu \phi_b$ is an independent variable and is untouched.

Second piece, $\partial F/\partial(\partial_\mu \phi_a)$. The only place a field derivative appears in Eq. (6.45) is the explicit factor $\partial_\nu \phi_b$ in the first term. Differentiating,

$$\frac{\partial F}{\partial(\partial_\mu \phi_a)} \;=\; \frac{\partial K^\nu}{\partial \phi_b}\,\frac{\partial(\partial_\nu \phi_b)}{\partial(\partial_\mu \phi_a)} \;=\; \frac{\partial K^\nu}{\partial \phi_b}\,\delta^\mu_\nu\,\delta_{ab} \;=\; \frac{\partial K^\mu}{\partial \phi_a}, \tag{6.47}$$

using that distinct components and distinct derivative directions are independent variables, $\partial(\partial_\nu \phi_b)/\partial(\partial_\mu \phi_a) = \delta^\mu_\nu \delta_{ab}$. Now take the spacetime divergence of Eq. (6.47). The function $\partial K^\mu/\partial \phi_a$ depends on x through the fields and explicitly, so the chain rule gives

$$\partial_\mu\!\left(\frac{\partial F}{\partial(\partial_\mu \phi_a)}\right) \;=\; \partial_\mu\!\left(\frac{\partial K^\mu}{\partial \phi_a}\right) \;=\; \frac{\partial^2 K^\mu}{\partial \phi_a \partial \phi_b}\,\partial_\mu \phi_b \;+\; \frac{\partial^2 K^\mu}{\partial \phi_a \partial x^\mu}\Big|_\phi . \tag{6.48}$$

Subtraction. Form $E_a[F] = \partial F/\partial \phi_a - \partial_\mu(\partial F/\partial(\partial_\mu \phi_a))$ by subtracting Eq. (6.48) from Eq. (6.46):

$$E_a[F] \;=\; \left(\frac{\partial^2 K^\nu}{\partial \phi_a \partial \phi_b}\,\partial_\nu \phi_b + \frac{\partial^2 K^\nu}{\partial \phi_a \partial x^\nu}\Big|_\phi\right) - \left(\frac{\partial^2 K^\mu}{\partial \phi_a \partial \phi_b}\,\partial_\mu \phi_b + \frac{\partial^2 K^\mu}{\partial \phi_a \partial x^\mu}\Big|_\phi\right). \tag{6.49}$$

The two summed indices μ and ν are dummies; relabelling $\nu \to \mu$ in the first parenthesis makes the two parentheses term-by-term identical, so they cancel exactly:

$$E_a\big[\partial_\nu K^\nu\big] \;=\; 0. \tag{6.50}$$

The cancellation hinges only on the equality of mixed partial derivatives of K^ν (Schwarz's theorem), and holds off-shell, for every field configuration. This confirms from the inside that shifting $\mathcal{L} \to \mathcal{L} + \partial_\mu K^\mu$ leaves $E_a[\mathcal{L}]$ — and hence the equation of motion — untouched, in complete agreement with the boundary argument of Eq. (6.42).

6.2.5 The free scalar: the Klein–Gordon equation

We now turn the machine on its first concrete target, the simplest relativistic field: a single real scalar ϕ. The unique Lorentz-invariant Lagrangian built from ϕ and its first derivatives, quadratic in the field (hence "free") and containing the canonical kinetic term, is

$$\mathcal{L}_0 \;=\; \tfrac{1}{2}\,(\partial_\mu \phi)(\partial^\mu \phi) \;-\; \tfrac{1}{2}\,m^2 \phi^2 \;=\; \tfrac{1}{2}\,\eta^{\rho\sigma}(\partial_\rho \phi)(\partial_\sigma \phi) - \tfrac{1}{2} m^2 \phi^2, \tag{6.51}$$

with m a real constant of mass dimension one (in natural units) that will turn out to be the mass of the associated particle. The mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$ is in force, so the kinetic term $\tfrac{1}{2}(\partial_\mu \phi)(\partial^\mu \phi) = \tfrac{1}{2}\dot{\phi}^2 - \tfrac{1}{2}(\nabla \phi)^2$

has the "kinetic minus gradient" form of a mechanical energy density, the sign that makes the energy bounded below (Section 6.6). To apply Eq. (6.30) we need the two partial derivatives of $\mathcal{L}_0$.

The field-derivative is immediate, since only the mass term depends on ϕ undifferentiated:

$$\frac{\partial \mathcal{L}_0}{\partial \phi} \;=\; -m^2 \phi. \tag{6.52}$$

The gradient-derivative requires care with the two factors in the kinetic term, which must be treated as a function of the independent variables $\partial_\mu \phi$. Writing the kinetic term as $\frac{1}{2}\eta^{\rho\sigma}(\partial_\rho\phi)(\partial_\sigma\phi)$ and differentiating with the product rule,

$$\begin{aligned} \frac{\partial \mathcal{L}_0}{\partial(\partial_\mu\phi)} &= \tfrac{1}{2}\,\eta^{\rho\sigma}\left[\frac{\partial(\partial_\rho\phi)}{\partial(\partial_\mu\phi)}\,\partial_\sigma\phi + \partial_\rho\phi\,\frac{\partial(\partial_\sigma\phi)}{\partial(\partial_\mu\phi)}\right] = \tfrac{1}{2}\,\eta^{\rho\sigma}\left[\delta^\mu_\rho\,\partial_\sigma\phi + \partial_\rho\phi\,\delta^\mu_\sigma\right] \\ &= \tfrac{1}{2}\left(\eta^{\mu\sigma}\partial_\sigma\phi + \eta^{\rho\mu}\partial_\rho\phi\right) = \tfrac{1}{2}\left(\partial^\mu\phi + \partial^\mu\phi\right) = \partial^\mu\phi. \end{aligned} \tag{6.53}$$

The two terms are equal because the metric is symmetric, and they combine to cancel the $\frac{1}{2}$ — a small calculation worth doing once explicitly, because the same pattern (the kinetic normalization $\frac{1}{2}$ existing precisely to undo the factor of two from the two identical factors) recurs for every field in the book. Now assemble the Euler–Lagrange equation. Taking the divergence of Eq. (6.53) gives $\partial_\mu(\partial^\mu\phi) = \partial_\mu\partial^\mu\phi \equiv \Box\phi$, the d'Alembertian, and Eq. (6.30) reads

$$\partial_\mu\left(\frac{\partial \mathcal{L}_0}{\partial(\partial_\mu\phi)}\right) - \frac{\partial \mathcal{L}_0}{\partial\phi} \;=\; \Box\phi - (-m^2\phi) \;=\; \Box\phi + m^2\phi \;=\; 0, \tag{6.54}$$

that is,

$$\boxed{\left(\Box + m^2\right)\phi \;=\; 0} \tag{6.55}$$

the *Klein–Gordon equation*. With the mostly-minus convention, $\Box = \partial_\mu\partial^\mu = \partial_t^2 - \nabla^2$, so Eq. (6.55) is the wave equation with a mass term. Its plane-wave solutions $\phi \sim e^{-ip\cdot x}$ require $p_\mu p^\mu = p^2 = m^2$, the relativistic mass-shell condition — the first sign that the parameter m in Eq. (6.51) is a physical mass, and the seed of the particle interpretation built in Chapter 9. The Klein–Gordon equation is the free equation of motion that all of ϕ^4 theory perturbs around.

6.2.6 Scalar ϕ^4 theory: the interacting scalar and its equation of motion

We now introduce the first of the book's three carried protagonists. ϕ^4 *theory* is the self-interacting real scalar field, the universal pedagogical workhorse that we will follow from this classical Lagrangian through quantization, its first scattering amplitude, renormalization, and finally a nontrivial renormalization-group fixed point. Its standard Lagrangian, in the symbols adds a single quartic

self-interaction term to the free scalar Eq. (6.51):

$$\boxed{\mathcal{L} \;=\; \tfrac{1}{2}\,(\partial_\mu\phi)(\partial^\mu\phi) \;-\; \tfrac{1}{2}\,m^2\phi^2 \;-\; \frac{\lambda}{4!}\,\phi^4\,, \qquad \phi \text{ real},\ \lambda > 0.} \tag{6.56}$$

The coupling λ is dimensionless in four spacetime dimensions (a fact whose significance for renormalizability is taken up in Chapter 21), and the conventional factor $1/4!$ is chosen so that the Feynman rule for the four-point vertex will come out as the clean $-i\lambda$ of Chapter 15; the same $4! = 24$ that looks arbitrary here is exactly the number of ways to attach four identical lines to a vertex, and it cancels neatly in the equation of motion, as we now see. The condition $\lambda > 0$ ensures the potential $V(\phi) = \frac{1}{2}m^2\phi^2 + \frac{\lambda}{4!}\phi^4$ is bounded below, so that the energy of Section 6.6 is bounded below and the theory has a stable vacuum. The quartic term is the minimal interaction consistent with the discrete symmetry $\phi \to -\phi$ (the $\mathbb{Z}_2$ symmetry whose consequences Chapter 7 draws out); a cubic term ϕ^3 would break it and render the potential unbounded below.

The following worked example derives the exact classical equation of motion for Eq. (6.56) by direct application of the Euler–Lagrange machine, completing the Chapter 6 classical foundation of ϕ^4 theory.

Worked Example 6.10 (The classical ϕ^4 equation of motion)**.** We apply Eq. (6.30) to the Lagrangian Eq. (6.56). The kinetic part is identical to the free scalar, so its derivatives are quoted from Eqs. (6.52) and (6.53); only the potential changes the field-derivative.

Gradient-derivative. The interaction $-\frac{\lambda}{4!}\phi^4$ contains no field derivatives, so it does not contribute to $\partial\mathcal{L}/\partial(\partial_\mu\phi)$, and the result is unchanged from the free case:

$$\frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi)} \;=\; \partial^\mu\phi, \qquad \partial_\mu\!\left(\frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi)}\right) \;=\; \Box\phi. \tag{6.57}$$

Field-derivative. Differentiating Eq. (6.56) with respect to ϕ at fixed gradient,

$$\frac{\partial\mathcal{L}}{\partial\phi} \;=\; -m^2\phi \;-\; \frac{\lambda}{4!}\,\frac{\partial(\phi^4)}{\partial\phi} \;=\; -m^2\phi \;-\; \frac{\lambda}{4!}\,4\phi^3 \;=\; -m^2\phi \;-\; \frac{\lambda}{3!}\,\phi^3, \tag{6.58}$$

where the factor $4/4! = 4/24 = 1/6 = 1/3!$ is the promised cancellation: differentiating the quartic brings down the four, and $4!/4 = 3!$.

Assemble. The Euler–Lagrange equation $\partial_\mu(\partial\mathcal{L}/\partial(\partial_\mu\phi)) - \partial\mathcal{L}/\partial\phi = 0$ becomes

$$\Box\phi \;-\; \left(-m^2\phi - \frac{\lambda}{3!}\phi^3\right) \;=\; \Box\phi + m^2\phi + \frac{\lambda}{3!}\phi^3 \;=\; 0, \tag{6.59}$$

which rearranges to the carried equation of motion of ϕ^4 theory,

$$\boxed{(\Box + m^2)\,\phi \;=\; -\,\frac{\lambda}{3!}\,\phi^3\,.} \tag{6.60}$$

The structure is transparent and sets the template for every interacting equation of motion to come: the free Klein–Gordon operator $(\Box + m^2)$ on the left, and on the right a source term $-\frac{\lambda}{3!}\phi^3$ built from the field itself — the field acting as its own source through the self-interaction. The free equation Eq. (6.55) is recovered exactly in the limit $\lambda \to 0$. This nonlinearity is precisely what makes the theory interacting and nontrivial: it has no general closed-form solution, and the perturbative expansion in powers of λ that organizes its quantum treatment (Chapters 14 and 15) is, at its root, the iterative solution of Eq. (6.60) treating the right-hand side as a small correction.

Caution

The equations of motion are insensitive to total-derivative terms and to boundary data *only* because admissible variations vanish on $\partial\Omega$. The instant one considers variations that do not vanish there — which is exactly the situation in the derivation of Noether's theorem, where the variation is generated by a symmetry transformation and need not respect any boundary condition — the boundary term in Eq. (6.35) no longer drops and carries genuine physical information (it becomes the conserved current). Likewise, the total-derivative ambiguity Eq. (6.41) that is harmless for the equations of motion is *not* harmless for the canonical stress–energy tensor, which is read off from the Lagrangian rather than from the field equations. Keep the boundary term in view: it is dropped here only under a stated hypothesis, and later chapters lift that hypothesis deliberately.

With the Euler–Lagrange equations established as a general machine, the functional-derivative restatement in hand, the total-derivative ambiguity understood, and ϕ^4 theory advanced to its exact classical equation of motion $(\Box + m^2)\phi = -\frac{\lambda}{3!}\phi^3$, we are ready to stress-test the machine on the two protagonists whose Lagrangians hide structural surprises. The next section assembles the rest of the cast — the Dirac field, whose action is first-order in derivatives, and the Maxwell field, whose action carries a gauge redundancy — deriving their equations of motion from the same principle and surfacing the two features that the Hamiltonian sections must then confront.

6.3 The Cast Assembled: Dirac and Maxwell Lagrangians

The previous section forged a single tool. From $\delta S = 0$ we extracted the covariant Euler–Lagrange equation for a field ϕ,

$$\partial_\mu \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi)} - \frac{\partial \mathcal{L}}{\partial \phi} = 0, \tag{6.61}$$

and tested it on the real scalar, recovering the Klein–Gordon equation and, with the quartic term, the classical equation of motion of ϕ^4 theory (Section 6.2). One protagonist is now in hand. This section assembles the rest of the cast. We turn the same crank (6.61) on the two remaining fields that recur throughout the book — the Dirac spinor and the Maxwell potential — and on the way meet a third, the complex scalar, whose global phase symmetry is the seed from which the entire gauge principle of Chapter 8 will grow.

The point of doing all three here, side by side, is not merely to collect equations of motion. It is to expose two *structural* features that the scalar did not display and that the Hamiltonian sections to come must confront head-on. The Dirac action turns out to be *first order* in derivatives: its Lagrangian is, up to a total derivative, already its own canonical one-form, so the Legendre transform that defines the Hamiltonian will be degenerate before we even begin. The Maxwell action turns out to be *gauge redundant*: distinct potentials describe the same physics, so the Euler–Lagrange operator has a kernel and cannot be inverted. Both surprises are visible at the purely classical level, and both are flagged here so that Section 6.4 and Chapter 13 know exactly what they inherit. Everything in this section is classical — c-number fields, and (flagged where it matters) anticommuting fields — with no operators and no Hilbert space.

6.3.1 The complex scalar and its global $U(1)$

Before the spinor, a gentle generalization of the scalar we already understand. Instead of one real field we take a single *complex* field $\phi(x)$, equivalently two real fields packaged as $\phi = (\phi_1 + i\phi_2)/\sqrt{2}$. The natural Lorentz-invariant, $U(1)$-symmetric Lagrangian with the right (mass) dimension is

$$\mathcal{L} = (\partial_\mu \phi^*)(\partial^\mu \phi) - m^2\, \phi^* \phi, \tag{6.62}$$

with $\phi^*\phi = |\phi|^2 \geq 0$. The relative coefficients are fixed by the same logic as for the real scalar: the kinetic term must be real and have the canonical normalization that makes the field's quantum a particle of mass m, and the only Lorentz scalar quadratic in ϕ without derivatives is $|\phi|^2$.

Notation Watch

Within this chapter the symbol ϕ does double duty. In ϕ^4 theory (Section 6.2) it is a *real* field; here in Section 6.3.1 it is *complex*. The two never appear in the same computation, and the complex case is always signalled by the presence of ϕ^*. We never write ϕ^* for the real field.

To extract the equations of motion we must vary (6.62). The cleanest route is the one used for every complex or charged field in this book, so it is worth stating once with care. The Lagrangian (6.62) depends on the two real fields

ϕ_1, ϕ_2; stationarity of the action requires $\delta S = 0$ under independent variations of *both*. But the map

$$(\phi_1, \phi_2) \longleftrightarrow (\phi, \phi^*), \qquad \phi = \tfrac{1}{\sqrt{2}}(\phi_1 + i\phi_2), \quad \phi^* = \tfrac{1}{\sqrt{2}}(\phi_1 - i\phi_2), \tag{6.63}$$

is an invertible linear change of variables (with constant, nonsingular coefficients). Requiring $\delta S = 0$ for all independent $\delta\phi_1, \delta\phi_2$ is therefore exactly equivalent to requiring $\delta S = 0$ for all independent $\delta\phi, \delta\phi^*$. We may thus treat ϕ and ϕ^* as two independent fields and apply the Euler–Lagrange equation (6.61) to each separately. This is not a trick or an approximation; it is a legitimate, invertible relabelling of the real degrees of freedom, and the same observation will license treating ψ and $\bar{\psi}$ as independent for the Dirac field below.

Varying ϕ^* in (6.62): the Lagrangian depends on $\partial_\mu\phi^*$ through $(\partial_\mu\phi^*)(\partial^\mu\phi)$ and on ϕ^* through $-m^2\phi^*\phi$, so

$$\frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi^*)} = \partial^\mu\phi, \qquad \frac{\partial\mathcal{L}}{\partial\phi^*} = -m^2\phi, \tag{6.64}$$

and (6.61) gives

$$\partial_\mu\partial^\mu\phi + m^2\phi = (\Box + m^2)\phi = 0. \tag{6.65}$$

Varying ϕ instead yields the complex conjugate equation $(\Box + m^2)\phi^* = 0$, as it must, since the action is real. The complex scalar is thus two Klein–Gordon fields of equal mass — exactly what the decomposition (6.63) promised, since ϕ_1 and ϕ_2 each satisfy $(\Box + m^2)\phi_i = 0$.

What distinguishes (6.62) from a pair of unrelated real scalars is a symmetry the real case did not possess. The Lagrangian is invariant under the rigid (spacetime-independent) phase rotation

$$\phi(x) \longrightarrow e^{i\alpha}\phi(x), \qquad \phi^*(x) \longrightarrow e^{-i\alpha}\phi^*(x), \qquad \alpha \in \mathbb{R} \text{ constant}, \tag{6.66}$$

because every term in (6.62) pairs one ϕ with one ϕ^*, so the phases cancel: $\phi^*\phi \to e^{-i\alpha}e^{i\alpha}\phi^*\phi = \phi^*\phi$, and likewise for the kinetic term, since α is constant and passes through ∂_μ. The transformations (6.66) form the group $U(1)$, and the invariance is a *global continuous internal symmetry*. By the machinery of the next chapter this symmetry implies a conserved Noether current $j^\mu = i(\phi^*\partial^\mu\phi - \phi\,\partial^\mu\phi^*)$ and a conserved charge; we state this here only to place the marker and defer the systematic derivation to Chapter 7.

Physical Insight

The invariance (6.66) is rigid: the *same* phase α is applied at every spacetime point. A natural and far-reaching question — what if we demand invariance under a phase $\alpha(x)$ that varies from point to point? — breaks (6.62) immediately, because $\partial_\mu(e^{i\alpha(x)}\phi) = e^{i\alpha(x)}(\partial_\mu + i\,\partial_\mu\alpha)\phi$

produces an unwanted $\partial_\mu \alpha$ term. Repairing the kinetic term so that local phase rotations *are* a symmetry forces the introduction of a new vector field that transforms to cancel $\partial_\mu \alpha$ — and that field is the photon. This is the gauge principle, and (6.66) is its seed. We do not pursue it now; it is the central business of Chapter 8.

6.3.2 The Dirac Lagrangian and equation of motion

We now meet the field whose quanta are spin-$\frac{1}{2}$ particles — the electron of QED. From Chapter 3 we import the Dirac spinor $\psi(x)$, a four-component object transforming in the $(\frac{1}{2}, 0) \oplus (0, \frac{1}{2})$ representation of the Lorentz group (Section 3.3.3), and from Chapter C the gamma-matrix algebra

$$\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}\mathbf{1}, \qquad \bar{\psi} \equiv \psi^\dagger \gamma^0, \tag{6.67}$$

together with the conjugation conventions fixed there (Theorem C.1). The Dirac adjoint $\bar{\psi}$, rather than $\psi^\dagger$, is the object that combines with ψ into Lorentz scalars, because γ^0 supplies precisely the factor that turns the non-unitary spinor representation into one under which $\bar{\psi}\,\Gamma\,\psi$ transforms correctly for each gamma-matrix structure Γ.

The unique Lorentz-invariant Lagrangian that is first order in derivatives, bilinear in the spinor, and yields a sensible (mass-m) wave equation is the *Dirac Lagrangian*

$$\mathcal{L} = \bar{\psi}\,(i\gamma^\mu \partial_\mu - m)\,\psi = \bar{\psi}\,(i\partial\!\!\!/ - m)\,\psi, \tag{6.68}$$

where $\partial\!\!\!/ \equiv \gamma^\mu \partial_\mu$. Each term is a Lorentz scalar: $\bar{\psi}\psi$ is the scalar bilinear, and $\bar{\psi}\gamma^\mu\psi$ is a four-vector contracted with the four-vector ∂_μ. The factor of i makes the kinetic term Hermitian up to a total derivative (we verify this below), and the relative sign and coefficient of the mass term are fixed by demanding that (6.68) reproduce the Dirac equation with the standard mass.

Caution

The classical Dirac field is *Grassmann-valued*: its components anticommute, $\psi_a(x)\psi_b(y) = -\psi_b(y)\psi_a(x)$. This is not optional decoration; it is what the spin–statistics connection (Chapter 11) will force on the quantum theory, and keeping it classically is what makes the classical limit consistent. In the variations below it changes intermediate *signs* but never the final equation of motion, because each term in (6.68) is bilinear: an even number of Grassmann fields, so reordering two of them costs two sign flips that cancel. We carry out the variation in the order that keeps the bookkeeping transparent and note the one place a sign must be tracked.

Worked Example 6.11 (The Dirac equation from the Dirac Lagrangian)**.** We vary the action $S = \int d^4x\, \bar\psi(i\partial\!\!\!/ - m)\psi$ treating ψ and $\bar\psi$ as independent fields, the justification being the same invertible relabelling (6.63) that licensed independent ϕ, ϕ^* variation: the real and imaginary parts of the components of ψ are the independent real fields, and $(\psi, \bar\psi)$ is a constant invertible linear repackaging of them.

Variation with respect to $\bar\psi$. The Lagrangian (6.68) contains $\bar\psi$ undifferentiated — every derivative falls on ψ. Hence

$$\frac{\partial \mathcal{L}}{\partial(\partial_\mu \bar\psi)} = 0, \qquad \frac{\partial \mathcal{L}}{\partial \bar\psi} = (i\partial\!\!\!/ - m)\psi, \tag{6.69}$$

and the Euler–Lagrange equation (6.61), applied to $\bar\psi$, reduces to its second term:

$$\boxed{(i\partial\!\!\!/ - m)\,\psi = 0} \qquad \Longleftrightarrow \qquad (i\gamma^\mu \partial_\mu - m)\psi = 0. \tag{6.70}$$

This is the Dirac equation. Because $\bar\psi$ appears without derivatives, no integration by parts is needed: the equation of motion drops out algebraically. That the *adjoint* field is the convenient variable to vary — it sits to the left, undifferentiated — is the first hint of the first-order structure we dissect below.

Variation with respect to ψ. Now the derivative is in play. Writing the variation explicitly,

$$\delta S = \int d^4x\; \bar\psi\,(i\gamma^\mu \partial_\mu - m)\,\delta\psi = \int d^4x\; \big[\, i\,\bar\psi\gamma^\mu\, \partial_\mu(\delta\psi) - m\,\bar\psi\,\delta\psi\,\big]. \tag{6.71}$$

Integrate the derivative term by parts, discarding the boundary term (the variation $\delta\psi$ vanishes on the boundary of the integration region, exactly as in Section 6.2):

$$\int d^4x\; i\,\bar\psi\gamma^\mu\,\partial_\mu(\delta\psi) = -\int d^4x\; i\,(\partial_\mu\bar\psi)\gamma^\mu\,\delta\psi \;+\; \underbrace{\oint d\Sigma_\mu\; i\,\bar\psi\gamma^\mu\,\delta\psi}_{=\,0}\,. \tag{6.72}$$

Collecting the coefficient of $\delta\psi$ (which is itself Grassmann-odd; the integration by parts and the factoring of $\delta\psi$ to the right are precisely where the even-bilinear remark in the Caution guarantees no stray sign survives) gives

$$\delta S = \int d^4x\; \big[\, -i\,(\partial_\mu\bar\psi)\gamma^\mu - m\,\bar\psi\,\big]\,\delta\psi = 0 \quad \text{for all } \delta\psi, \tag{6.73}$$

hence

$$\boxed{i\,(\partial_\mu\bar\psi)\gamma^\mu + m\,\bar\psi = 0} \qquad \Longleftrightarrow \qquad i\,\partial_\mu\bar\psi\,\gamma^\mu + m\,\bar\psi = 0, \tag{6.74}$$

the *Dirac adjoint equation*, often written $\bar\psi\,(i\overleftarrow{\partial\!\!\!/} + m) = 0$ with the arrow indicating that the derivative acts to the left.

The two equations (6.70) and (6.74) are not independent statements but Dirac conjugates of one another, and checking this consistency is a sharp test of the gamma-matrix conventions. Take the Hermitian conjugate of (6.70). Using $(\gamma^\mu)^\dagger = \gamma^0\gamma^\mu\gamma^0$ (the defining relation that makes $\bar\psi$ the right adjoint, Chapter C),

$$[(i\gamma^\mu\partial_\mu - m)\psi]^\dagger = -i\,\partial_\mu\psi^\dagger\,(\gamma^\mu)^\dagger - m\,\psi^\dagger = -i\,\partial_\mu\psi^\dagger\,\gamma^0\gamma^\mu\gamma^0 - m\,\psi^\dagger = 0. \quad (6.75)$$

Multiply on the right by γ^0 and use $(\gamma^0)^2 = \mathbf{1}$ together with $\bar\psi = \psi^\dagger\gamma^0$:

$$-i\,\partial_\mu(\psi^\dagger\gamma^0)\,\gamma^\mu - m\,\psi^\dagger\gamma^0 = -i\,\partial_\mu\bar\psi\,\gamma^\mu - m\,\bar\psi = 0, \quad (6.76)$$

which is exactly -1 times (6.74). The two variations are consistent, and the reality (Hermiticity) of the action is confirmed: varying ψ and varying $\bar\psi$ give conjugate content, not new content.

The first structural surprise: the Dirac action is first order

The scalar Lagrangian was *quadratic* in derivatives — a term $\frac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi)$ with two factors of velocity — and this is what made its Legendre transform routine: the canonical momentum $\pi = \partial\mathcal{L}/\partial\dot\phi = \dot\phi$ was a genuine, invertible function of the velocity. The Dirac Lagrangian (6.68) is *linear* in derivatives. Isolating the time derivative,

$$\mathcal{L} = i\,\bar\psi\gamma^0\partial_0\psi + i\,\bar\psi\gamma^i\partial_i\psi - m\,\bar\psi\psi = i\,\psi^\dagger\dot\psi + (\text{no further } \dot\psi,\ \text{no } \dot{\bar\psi}), \quad (6.77)$$

where we used $\bar\psi\gamma^0 = \psi^\dagger\gamma^0\gamma^0 = \psi^\dagger$. The entire dependence on the velocity $\dot\psi$ sits in the single term $i\,\psi^\dagger\dot\psi$, which is *linear* in $\dot\psi$, and there is no dependence on $\dot{\bar\psi}$ at all.

This is structurally the form $p\,\dot q$ — a canonical one-form (a symplectic potential) $\theta = p\,\dot q$ — rather than a kinetic energy $\frac{1}{2}p^2$. Reading off the momentum conjugate to ψ,

$$\pi_\psi = \frac{\partial\mathcal{L}}{\partial\dot\psi} = i\,\psi^\dagger, \quad (6.78)$$

we find that the momentum is *not* an independent quantity expressing the velocity — it is simply the field $\psi^\dagger$ itself, with no velocity appearing anywhere. The relation $\pi_\psi - i\psi^\dagger = 0$ is a *constraint* on phase space, not a definition that can be inverted to solve for $\dot\psi$. The Legendre transform is therefore degenerate from the outset, and the naive Hamiltonian $\mathcal{H} = \pi_\psi\dot\psi - \mathcal{L}$ has its velocity dependence cancel identically. We flag this now and resolve it properly in Section 6.4: the Dirac field's phase space must be handled as a *constrained* system, and the constraint (6.78) is the classical origin of the anticommutator structure that quantization (Chapter 11) will impose.

6.3.3 The Maxwell Lagrangian and equation of motion

The last protagonist is the electromagnetic field, carried as the photon of QED. From Chapter 3 the gauge potential $A_\mu(x)$ is a Lorentz four-vector field, transforming in the $(\frac{1}{2},\frac{1}{2})$ representation (Section 3.3.3). The gauge-invariant object built from it is the antisymmetric *field-strength tensor*

$$F_{\mu\nu} \equiv \partial_\mu A_\nu - \partial_\nu A_\mu, \tag{6.79}$$

whose components reproduce the electric and magnetic fields ($F^{0i} = -E^i$, $F^{ij} = -\epsilon^{ijk}B^k$ in our conventions, Chapter A). The unique Lorentz-invariant, parity-even Lagrangian quadratic in F and yielding second-order linear field equations is the *Maxwell Lagrangian*

$$\mathcal{L} = -\tfrac{1}{4}\, F_{\mu\nu}F^{\mu\nu}. \tag{6.80}$$

The overall normalization $-\frac{1}{4}$ is the standard one that gives the canonically normalized kinetic term for the propagating photon polarizations and the conventional Maxwell equations; the sign makes the energy density positive (the time-derivative, "electric" part enters $\mathcal{L}$ with a $+\frac{1}{2}E^2$). We now derive its equation of motion, carrying every index contraction explicitly because the antisymmetrization at the heart of it is exactly the step where sign and factor errors breed.

Worked Example 6.12 (The inhomogeneous Maxwell equations from $\mathcal{L} = -\frac{1}{4}F^2$)**.** The dynamical field is A_μ, so the Euler–Lagrange equation (6.61) reads, with β the free index,

$$\partial_\alpha \frac{\partial \mathcal{L}}{\partial(\partial_\alpha A_\beta)} - \frac{\partial \mathcal{L}}{\partial A_\beta} = 0. \tag{6.81}$$

The Lagrangian (6.80) contains A_μ only through its derivatives, so $\partial\mathcal{L}/\partial A_\beta = 0$ and the whole equation lives in the first term. We must compute $\partial\mathcal{L}/\partial(\partial_\alpha A_\beta)$.

Step 1: differentiate the square. Write $\mathcal{L} = -\frac{1}{4}\, F_{\mu\nu}F^{\mu\nu}$ and differentiate, using the chain rule and the symmetry $F_{\mu\nu}F^{\mu\nu}$ being a sum over both indices:

$$\frac{\partial \mathcal{L}}{\partial(\partial_\alpha A_\beta)} = -\tfrac{1}{4}\,\frac{\partial(F_{\mu\nu}F^{\mu\nu})}{\partial(\partial_\alpha A_\beta)} = -\tfrac{1}{4}\cdot 2\, F^{\mu\nu}\,\frac{\partial F_{\mu\nu}}{\partial(\partial_\alpha A_\beta)} = -\tfrac{1}{2}\, F^{\mu\nu}\,\frac{\partial F_{\mu\nu}}{\partial(\partial_\alpha A_\beta)}, \tag{6.82}$$

where the factor of 2 arises because both F's in the product depend on ∂A (equivalently, $\partial F^{\mu\nu}/\partial(\partial_\alpha A_\beta)$ and $\partial F_{\mu\nu}/\partial(\partial_\alpha A_\beta)$ contribute equally after raising/lowering with the metric).

Step 2: differentiate the field strength. From (6.79), $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$, and treating each $\partial_\alpha A_\beta$ as an independent variable,

$$\frac{\partial(\partial_\mu A_\nu)}{\partial(\partial_\alpha A_\beta)} = \delta_\mu{}^\alpha\,\delta_\nu{}^\beta \quad\Longrightarrow\quad \frac{\partial F_{\mu\nu}}{\partial(\partial_\alpha A_\beta)} = \delta_\mu{}^\alpha\delta_\nu{}^\beta - \delta_\nu{}^\alpha\delta_\mu{}^\beta. \tag{6.83}$$

This is the antisymmetrization: differentiating F, which is itself an antisymmetrized derivative of A, returns an antisymmetrized pair of Kronecker deltas.

Step 3: contract. Insert (6.83) and contract the deltas against $F^{\mu\nu}$:

$$\frac{\partial \mathcal{L}}{\partial(\partial_\alpha A_\beta)} = -\tfrac{1}{2}\,F^{\mu\nu}(\delta_\mu{}^\alpha\delta_\nu{}^\beta - \delta_\nu{}^\alpha\delta_\mu{}^\beta) = -\tfrac{1}{2}(F^{\alpha\beta} - F^{\beta\alpha}) = -\tfrac{1}{2}(F^{\alpha\beta} + F^{\alpha\beta}) = -F^{\alpha\beta}, \tag{6.84}$$

where the last step used the antisymmetry $F^{\beta\alpha} = -F^{\alpha\beta}$. The two terms of the antisymmetrized delta combine to cancel the $\frac{1}{2}$ exactly — the factor and the antisymmetrization conspire to give the clean result $\partial\mathcal{L}/\partial(\partial_\alpha A_\beta) = -F^{\alpha\beta}$.

Step 4: assemble. With $\partial\mathcal{L}/\partial A_\beta = 0$, the Euler–Lagrange equation (6.81) becomes

$$\partial_\alpha(-F^{\alpha\beta}) = 0 \quad\Longrightarrow\quad \boxed{\partial_\mu F^{\mu\nu} = 0}. \tag{6.85}$$

These are the source-free inhomogeneous Maxwell equations. If we add a coupling to an external conserved current, $\mathcal{L} \to \mathcal{L} - A_\mu J^\mu$, the only change is $\partial\mathcal{L}/\partial A_\beta = -J^\beta$, and (6.81) gives

$$\partial_\alpha(-F^{\alpha\beta}) - (-J^\beta) = 0 \quad\Longrightarrow\quad \boxed{\partial_\mu F^{\mu\nu} = J^\nu}, \tag{6.86}$$

the inhomogeneous Maxwell equations with a source: $\nu = 0$ is Gauss's law $\nabla\cdot\mathbf{E} = \rho$, and $\nu = i$ is the Ampère–Maxwell law. Consistency demands $\partial_\nu J^\nu = 0$: contracting (6.86) with ∂_ν gives $\partial_\nu\partial_\mu F^{\mu\nu} = 0$ automatically, because $\partial_\nu\partial_\mu$ is symmetric while $F^{\mu\nu}$ is antisymmetric, so the current's conservation is not an extra assumption but a built-in requirement of the field equation.

The Bianchi identity: the homogeneous equations for free

The two equations (6.86) are only half of Maxwell's system. The other half — $\nabla\cdot\mathbf{B} = 0$ and Faraday's law $\nabla\times\mathbf{E} + \partial_t\mathbf{B} = 0$ — are *not* equations of motion at all. They follow identically, off-shell, from the mere fact that F is built as $F = dA$, i.e. from the definition (6.79). Form the totally antisymmetrized derivative

$$\partial_\lambda F_{\mu\nu} + \partial_\mu F_{\nu\lambda} + \partial_\nu F_{\lambda\mu}. \tag{6.87}$$

Substitute $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ into each term:

$$\begin{aligned}
\partial_\lambda F_{\mu\nu} &= \partial_\lambda\partial_\mu A_\nu - \partial_\lambda\partial_\nu A_\mu,\\
\partial_\mu F_{\nu\lambda} &= \partial_\mu\partial_\nu A_\lambda - \partial_\mu\partial_\lambda A_\nu,\\
\partial_\nu F_{\lambda\mu} &= \partial_\nu\partial_\lambda A_\mu - \partial_\nu\partial_\mu A_\lambda.
\end{aligned} \tag{6.88}$$

Adding the three lines, the six terms cancel in pairs, each pair related by the commuting of partial derivatives $\partial_a\partial_b = \partial_b\partial_a$. Hence

$$\boxed{\partial_\lambda F_{\mu\nu} + \partial_\mu F_{\nu\lambda} + \partial_\nu F_{\lambda\mu} = 0}, \tag{6.89}$$

the *Bianchi identity*, holding for any A_μ whatsoever, on-shell or off. It is an identity, not a dynamical law: it encodes that $\mathbf{E}$ and $\mathbf{B}$ descend from a single potential. In differential-form language (6.89) is just $dF = d(dA) = 0$, the statement $d^2 = 0$. The split is conceptually clean: the homogeneous Maxwell equations are kinematics (they say $F = dA$), the inhomogeneous ones are dynamics (they come from $\delta S = 0$).

The second structural surprise: gauge redundancy and a degenerate operator

We turn to the feature that will reverberate through the entire book. The combination (6.79) is invariant under shifting the potential by the gradient of an arbitrary scalar function $\chi(x)$:

$$A_\mu(x) \longrightarrow A_\mu(x) + \partial_\mu \chi(x). \tag{6.90}$$

The verification is immediate and worth seeing in full:

$$F_{\mu\nu} \longrightarrow \partial_\mu(A_\nu + \partial_\nu\chi) - \partial_\nu(A_\mu + \partial_\mu\chi) = F_{\mu\nu} + (\partial_\mu\partial_\nu\chi - \partial_\nu\partial_\mu\chi) = F_{\mu\nu}, \tag{6.91}$$

the added piece vanishing because partial derivatives commute. Since $F_{\mu\nu}$ is unchanged, so is $\mathcal{L} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu}$: the transformation (6.90) is an *exact* symmetry of the Maxwell action, for *every* function $\chi(x)$. This is a redundancy, not a physical symmetry: it does not relate distinct physical states but rather identifies many potentials A_μ as descriptions of the *same* electromagnetic field. The physical content is $F_{\mu\nu}$; the potential carries a surplus of unphysical, longitudinal information.

This redundancy has a sharp algebraic fingerprint: the Euler–Lagrange operator is *non-invertible*. Expand the left-hand side of the source-free equation (6.85) in terms of the potential,

$$\partial_\mu F^{\mu\nu} = \partial_\mu(\partial^\mu A^\nu - \partial^\nu A^\mu) = \Box A^\nu - \partial^\nu(\partial_\mu A^\mu) = (\eta^{\nu\mu}\Box - \partial^\nu\partial^\mu)A_\mu \equiv M^{\nu\mu}A_\mu, \tag{6.92}$$

which defines the second-order differential operator $M^{\nu\mu} = \eta^{\nu\mu}\Box - \partial^\nu\partial^\mu$. In momentum space, with $A_\mu(x) \propto e^{-ik\cdot x}$ so that $\partial_\mu \to -ik_\mu$, this operator becomes the matrix

$$M^{\nu\mu}(k) = -(\eta^{\nu\mu}k^2 - k^\nu k^\mu). \tag{6.93}$$

Now test it on a pure-gauge configuration. A gauge transformation (6.90) with $\chi \propto e^{-ik\cdot x}$ shifts A_μ by $\partial_\mu\chi \propto -ik_\mu\chi$ — that is, by a vector *proportional to* k_μ (a "longitudinal" mode). Acting on k_μ,

$$M^{\nu\mu}(k)\,k_\mu = -(\eta^{\nu\mu}k^2 - k^\nu k^\mu)k_\mu = -(k^\nu k^2 - k^\nu k^2) = 0. \tag{6.94}$$

The operator *annihilates* every pure-gauge mode. Its kernel is non-empty, so $M^{\nu\mu}$ is not invertible: there is no matrix $G_{\nu\rho}$ with $M^{\nu\mu}G_{\mu\rho} = \delta^\nu{}_\rho$. The equation

(6.94) is, of course, the same statement as gauge invariance (6.90): the directions in field space along which the operator does nothing are exactly the directions a gauge transformation moves you, the directions along which the action is flat (Fig. 6.2).

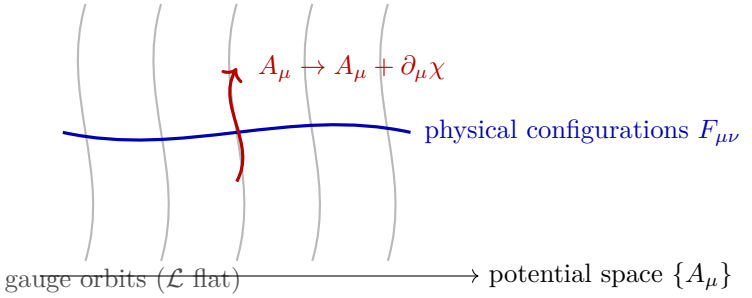

Figure 6.2: Gauge redundancy as flatness of the action. Each grey fibre is a gauge orbit, the set of potentials $A_\mu + \partial_\mu \chi$ related by (6.90); the Maxwell Lagrangian is constant along it, so the Euler–Lagrange operator $M^{\nu\mu}$ has no curvature in the fibre direction and annihilates it, equation (6.94). Only the transverse, physical data — the field strength $F_{\mu\nu}$ — carry dynamics. Inverting $M^{\nu\mu}$ (to define a propagator) requires first picking one representative per orbit: gauge fixing.

Physical Insight

Non-invertibility of $M^{\nu\mu}$ is not a technical nuisance to be patched; it is the classical seed of every gauge subtlety in this book. To define a photon propagator one must invert the kinetic operator, and one cannot invert an operator with a kernel. The cure — choosing one representative from each gauge orbit, i.e. *gauge fixing* — is forced on us already at the classical level and becomes unavoidable at quantization (Chapter 13, and in the non-abelian case the Faddeev–Popov construction of Chapter 26). Equivalently, in the Hamiltonian language of the next section, the same redundancy appears as a *constraint*: the momentum conjugate to A_0 vanishes identically, $\pi^0 = \partial\mathcal{L}/\partial\dot{A}_0 = -F^{00} = 0$, exactly as the Dirac momentum (6.78) was constrained. Two fields, two constraints, one moral: the naive Legendre transform fails whenever the Lagrangian is degenerate.

The cast is now complete. We have, derived from first principles and on equal footing, the real scalar (Section 6.2), the complex scalar with its global $U(1)$ (6.66), the Dirac field with its first-order action (6.77), and the Maxwell field with its gauge redundancy (6.90). These are the protagonists of the entire book, and their classical Lagrangians and equations of motion are fixed here once and for all. Two of them — the first-order Dirac action and the degenerate Maxwell action — arrive carrying constraints that the ordinary Legendre transform cannot

digest. It is to that transform, and to the constrained phase space these two surprises demand, that Section 6.4 now turns; the gauge principle that will weld the complex-scalar phase symmetry and the Maxwell field into a single structure waits for Chapter 8 and QED proper.

6.4 The Hamiltonian Formulation of Fields

The previous two sections gave us the dynamics of fields in their most economical form: a single scalar functional, the action, whose stationarity encodes the entire content of the equations of motion. From it we read off the Klein–Gordon equation for the scalar, the Dirac equation for the spinor, and Maxwell's equations for the vector, each as an Euler–Lagrange condition (Section 6.2). The Lagrangian picture is supremely well suited to relativity, because the action is a Lorentz scalar and the symmetry of a theory is visible at a glance. But it is not the picture in which one quantizes. Quantization—the business of Part III—needs a notion of *state at an instant*, of the data one specifies on a spatial slice and then propagates forward, and of the algebra obeyed by the basic observables on that slice. That is the Hamiltonian picture. It trades the manifest covariance of the action for a phase space: a configuration variable and its conjugate momentum at each point of space, evolving under a Hamiltonian, with a Poisson bracket that measures how observables fail to commute under canonical flow.

This section performs that trade for fields. We define the canonical momentum density by a Legendre transform in the time derivative, build the Hamiltonian, derive Hamilton's field equations from the variational principle and check that they reproduce the Euler–Lagrange equations on the sector where the transform is honest, and then install the equal-time Poisson-bracket algebra. The payoff is twofold. First, we obtain for the real scalar—and hence for ϕ^4 theory—the exact classical objects that Chapter 9 will promote to operators and canonical commutators: the Hamiltonian density and the bracket $\{\phi(\mathbf{x}), \pi(\mathbf{y})\}_{\mathrm{P}} = \delta^3(\mathbf{x}-\mathbf{y})$. Second, we discover that the construction is not automatic. The Legendre transform presupposes that the momenta can be solved for the velocities, and for two of our three protagonists—the first-order Dirac field and the gauge-degenerate Maxwell field—that presupposition fails. Isolating exactly where and how it fails is the work of Section 6.5; here we lay the regular-case machinery cleanly enough that the failure, when it comes, is unmistakable.

6.4.1 The field Legendre transform and the canonical momentum density

In point-particle mechanics one passes from $L(q, \dot{q})$ to $H(q, p)$ by defining the conjugate momentum $p = \partial L/\partial \dot{q}$ and Legendre-transforming in $\dot{q}$, replacing the velocity by the momentum as an independent coordinate (Section 4.5.1). A

classical field theory is a mechanical system with a continuous label: instead of finitely many coordinates $q_i(t)$ we have a field value $\phi_a(\mathbf{x}, t)$ at every point $\mathbf{x}$ of space, the spatial position playing the role of the index i. The Legendre transform is taken in the time derivative $\dot{\phi}_a \equiv \partial_0 \phi_a$ alone—time is singled out the moment we choose a frame in which to define "an instant"—while the spatial gradients $\partial_i \phi_a$ are spectators, carried along as part of the configuration.

Throughout, the dynamics derives from a local Lagrangian density

$$\mathcal{L} = \mathcal{L}(\phi_a,\, \partial_0 \phi_a,\, \partial_i \phi_a), \tag{6.95}$$

a function of the fields, their time derivatives, and their spatial gradients, with the index a running over all field components in play (for several real scalars, the four components of A^μ, the spinor components of ψ, and so on). We isolate the time derivative because the Hamiltonian formalism does.

Definition 6.13 (Canonical momentum density)**.** The *canonical momentum density conjugate to* ϕ_a is

$$\pi^a(x) \;\equiv\; \frac{\partial \mathcal{L}}{\partial(\partial_0 \phi_a)} \;=\; \frac{\partial \mathcal{L}}{\partial \dot{\phi}_a}\,, \tag{6.96}$$

the partial derivative of the Lagrangian density with respect to the velocity $\dot{\phi}_a$ at the spacetime point x, taken at fixed ϕ_a and fixed spatial gradients $\partial_i \phi_a$.

The object $\pi^a(x)$ is a *density*: it carries the same mass dimension as $\mathcal{L}/\dot{\phi}_a$, and the quantity with the dimensions of a momentum is $\int \mathrm{d}^3x\, \pi^a$. The placement of the field index is a bookkeeping choice; we write π^a with an upper index to pair against ϕ_a and will lower or raise it freely when there is no ambiguity, since for the cases at hand the field-space metric is trivial.

For the Legendre transform to be invertible we must be able to read Eq. (6.96) backwards—to solve it for the velocities $\dot{\phi}_a$ as functions of $(\phi_b, \partial_i \phi_b, \pi^b)$. By the implicit function theorem this is possible, locally, precisely when the Jacobian of the map $\dot{\phi}_a \mapsto \pi^a$ is nonsingular.

Definition 6.14 (Regular and singular Lagrangians)**.** The *velocity Hessian* of $\mathcal{L}$ is the matrix in field-component space

$$W_{ab} \;\equiv\; \frac{\partial^2 \mathcal{L}}{\partial \dot{\phi}_a \partial \dot{\phi}_b}\,. \tag{6.97}$$

The Lagrangian is *regular* (or non-singular) at a configuration if $\det W_{ab} \neq 0$ there, and *singular* if $\det W_{ab} = 0$. On the regular sector the relation Eq. (6.96) can be inverted to give $\dot{\phi}_a = \dot{\phi}_a(\phi, \partial_i \phi, \pi)$.

Caution

Regularity is exactly the hypothesis that will fail for two of our three protagonists. The Dirac Lagrangian is *first order* in derivatives, so $\mathcal{L}$ is linear in $\dot{\psi}$ and $W_{ab} = 0$ identically; the Maxwell Lagrangian contains no $\dot{A}_0$ at all, so the momentum conjugate to A_0 vanishes identically and W_{ab} has a zero eigenvalue. In both cases Eq. (6.96) cannot be solved for all the velocities; it instead imposes *constraints* relating the π's and ϕ's. The whole of Section 6.5 is devoted to that situation. For the remainder of *this* section we assume a regular Lagrangian, which the real scalar—and ϕ^4 theory—satisfies.

With invertibility in hand we define the Hamiltonian by the field Legendre transform.

Definition 6.15 (Hamiltonian density and Hamiltonian)**.** For a regular Lagrangian the *Hamiltonian density* is

$$\mathcal{H} \;\equiv\; \pi^a\,\dot{\phi}_a - \mathcal{L}\,, \tag{6.98}$$

expressed as a function of $(\phi_a, \partial_i\phi_a, \pi^a)$ by using the inverse relation $\dot{\phi}_a = \dot{\phi}_a(\phi, \partial_i\phi, \pi)$ to eliminate every velocity. The *Hamiltonian* is its spatial integral over a constant-time slice,

$$H[\phi, \pi] \;=\; \int \mathrm{d}^3x\; \mathcal{H}(\phi_a(\mathbf{x}),\, \partial_i\phi_a(\mathbf{x}),\, \pi^a(\mathbf{x}))\,, \tag{6.99}$$

a functional of the field configuration and the momentum configuration on that slice.

Two points deserve emphasis before we differentiate anything. First, $\mathcal{H}$ is built to have *no explicit dependence on the velocities*: every $\dot{\phi}_a$ has been traded for a π^a. This is the entire purpose of the Legendre transform, and it is what makes the variation in the next subsection collapse so cleanly. Second, H lives on a Cauchy slice. The pair $(\phi_a(\mathbf{x}), \pi^a(\mathbf{x}))$ specified at one instant constitutes a point in the field-theoretic phase space, and the Hamiltonian is a number assigned to each such point. Whereas the action is a functional of an entire spacetime history, the Hamiltonian is a functional of instantaneous data—which is exactly the form one needs to speak of a state and its evolution.

6.4.2 Hamilton's field equations

We now show that the single first-order-in-time system of Hamilton's equations is equivalent, on the regular sector, to the second-order Euler–Lagrange equations. The derivation is a variation of H carried with all the algebra in view; the key step is the cancellation that the Legendre transform was designed to produce.

Recall (Section 4.1.2) that for a local functional $F[\phi,\pi]=\int \mathrm{d}^3x\, f(\phi_a,\partial_i\phi_a,\pi^a)$ the functional derivatives are the coefficients in

$$\delta F=\int \mathrm{d}^3x\left[\frac{\delta F}{\delta\phi_a}\,\delta\phi_a+\frac{\delta F}{\delta\pi^a}\,\delta\pi^a\right], \tag{6.100}$$

where, after any integration by parts that moves derivatives off the variations, the boundary terms are discarded under the standing assumption that variations have compact spatial support (or fall off fast enough that surface integrals at spatial infinity vanish). For a density depending on the field and its first gradient this gives the explicit rule

$$\frac{\delta F}{\delta\phi_a}=\frac{\partial f}{\partial\phi_a}-\partial_i\!\left(\frac{\partial f}{\partial(\partial_i\phi_a)}\right), \qquad \frac{\delta F}{\delta\pi^a}=\frac{\partial f}{\partial\pi^a}, \tag{6.101}$$

the second being simpler because $\mathcal{H}$ for our cases contains no spatial derivatives of π^a.

Varying the Hamiltonian. Take the differential of Eq. (6.98) treating $\mathcal{H}$ momentarily as a function of all of $\phi_a,\partial_i\phi_a,\pi^a$ *and* the velocities $\dot\phi_a$, before imposing the inverse relation. Using the definition $\mathcal{H}=\pi^a\dot\phi_a-\mathcal{L}$ and the chain rule,

$$\delta\mathcal{H}=\dot\phi_a\,\delta\pi^a+\pi^a\,\delta\dot\phi_a-\frac{\partial\mathcal{L}}{\partial\phi_a}\,\delta\phi_a-\frac{\partial\mathcal{L}}{\partial(\partial_i\phi_a)}\,\delta(\partial_i\phi_a)-\frac{\partial\mathcal{L}}{\partial\dot\phi_a}\,\delta\dot\phi_a\,. \tag{6.102}$$

The defining relation $\pi^a=\partial\mathcal{L}/\partial\dot\phi_a$ from Eq. (6.96) makes the second and last terms cancel identically:

$$\pi^a\,\delta\dot\phi_a-\frac{\partial\mathcal{L}}{\partial\dot\phi_a}\,\delta\dot\phi_a=0\,. \tag{6.103}$$

This is the heart of the Legendre transform: the velocity variation drops out, and $\mathcal{H}$ is genuinely a function of $(\phi_a,\partial_i\phi_a,\pi^a)$ with no residual $\dot\phi_a$ dependence. What survives is

$$\delta\mathcal{H}=\dot\phi_a\,\delta\pi^a-\frac{\partial\mathcal{L}}{\partial\phi_a}\,\delta\phi_a-\frac{\partial\mathcal{L}}{\partial(\partial_i\phi_a)}\,\delta(\partial_i\phi_a)\,. \tag{6.104}$$

Now integrate over the slice to form $\delta H=\int\mathrm{d}^3x\,\delta\mathcal{H}$ and integrate the last term by parts, $-\partial\mathcal{L}/\partial(\partial_i\phi_a)\,\partial_i(\delta\phi_a)\to+\partial_i(\partial\mathcal{L}/\partial(\partial_i\phi_a))\,\delta\phi_a$, dropping the surface term:

$$\delta H=\int\mathrm{d}^3x\left[\dot\phi_a\,\delta\pi^a+\left(-\frac{\partial\mathcal{L}}{\partial\phi_a}+\partial_i\frac{\partial\mathcal{L}}{\partial(\partial_i\phi_a)}\right)\delta\phi_a\right]. \tag{6.105}$$

Comparing Eq. (6.105) term by term with the definition Eq. (6.100) of the functional derivatives, we read off

$$\frac{\delta H}{\delta\pi^a}=\dot\phi_a\,, \qquad \frac{\delta H}{\delta\phi_a}=-\frac{\partial\mathcal{L}}{\partial\phi_a}+\partial_i\frac{\partial\mathcal{L}}{\partial(\partial_i\phi_a)}\,. \tag{6.106}$$

Closing the loop with the Euler–Lagrange equation. The first relation in Eq. (6.106) is already the first half of Hamilton's equations. For the second half we invoke the Euler–Lagrange equation of Section 6.2, written with its time and space derivatives split apart:

$$\partial_\mu \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)} - \frac{\partial \mathcal{L}}{\partial \phi_a} = \partial_0 \frac{\partial \mathcal{L}}{\partial \dot{\phi}_a} + \partial_i \frac{\partial \mathcal{L}}{\partial(\partial_i \phi_a)} - \frac{\partial \mathcal{L}}{\partial \phi_a} = 0 \,. \tag{6.107}$$

The first term is $\partial_0 \pi^a = \dot{\pi}^a$ by Eq. (6.96). Solving Eq. (6.107) for it,

$$\dot{\pi}^a = \frac{\partial \mathcal{L}}{\partial \phi_a} - \partial_i \frac{\partial \mathcal{L}}{\partial(\partial_i \phi_a)} \,, \tag{6.108}$$

and recognizing the right-hand side as the negative of $\delta H / \delta \phi_a$ from Eq. (6.106), we obtain the companion equation. Collecting the two:

Theorem 6.16 (Hamilton's field equations)**.** *For a regular Lagrangian, the field configuration $(\phi_a(\mathbf{x}, t), \pi^a(\mathbf{x}, t))$ extremizes the action if and only if it satisfies the first-order system*

$$\dot{\phi}_a = \frac{\delta H}{\delta \pi^a} \,, \qquad \dot{\pi}^a = -\frac{\delta H}{\delta \phi_a} \,. \tag{6.109}$$

These are equivalent to the Euler–Lagrange equations Eq. (6.107) of Section 6.2: the first member is the inverse Legendre relation $\dot{\phi}_a = \dot{\phi}_a(\phi, \partial_i \phi, \pi)$, and the second member is the Euler–Lagrange equation rewritten with $\dot{\pi}^a = \partial_0(\partial \mathcal{L} / \partial \dot{\phi}_a)$.

Proof. The forward direction was just carried: Eq. (6.106) gives $\dot{\phi}_a = \delta H / \delta \pi^a$ directly from the Legendre structure, and Eq. (6.108) converts the Euler–Lagrange equation into $\dot{\pi}^a = -\delta H / \delta \phi_a$. Conversely, suppose Eq. (6.109) holds. The first equation reproduces the defining relation between velocity and momentum (it is $\delta H / \delta \pi^a = \dot{\phi}_a$, which by Eq. (6.106) is an identity of the Legendre transform), so $\pi^a = \partial \mathcal{L} / \partial \dot{\phi}_a$ is consistent. Differentiating that in time gives $\dot{\pi}^a = \partial_0(\partial \mathcal{L} / \partial \dot{\phi}_a)$; substituting into the second Hamilton equation and using the expression Eq. (6.106) for $\delta H / \delta \phi_a$ yields $\partial_0(\partial \mathcal{L} / \partial \dot{\phi}_a) = \partial \mathcal{L} / \partial \phi_a - \partial_i(\partial \mathcal{L} / \partial(\partial_i \phi_a))$, which rearranges to the Euler–Lagrange equation Eq. (6.107). The two formulations are therefore logically equivalent on the regular sector. □

Physical Insight

The two pictures repackage the same content. The Lagrangian description is one second-order equation per field component—the configuration ϕ_a and its acceleration. The Hamiltonian description is two first-order equations—the configuration ϕ_a and its conjugate momentum π^a, each evolving by a first derivative. The doubling of the number of variables is exactly compensated by the halving of the order, and the phase-space pair (ϕ_a, π^a)

is the natural arena because it is the data one must specify on a slice to fix the future. It is also the data one quantizes: in Chapter 9 the slice pair (ϕ, π) becomes a conjugate operator pair, and Eq. (6.109) becomes the Heisenberg equation of motion.

6.4.3 The equal-time Poisson bracket

The Hamiltonian formalism becomes a calculus once we install a bracket on functionals of the phase-space data. As in mechanics, the Poisson bracket is the antisymmetric pairing built from the symplectic structure of phase space; for fields it is defined through functional derivatives on a fixed time slice.

Definition 6.17 (Equal-time Poisson bracket)**.** Let $F[\phi, \pi]$ and $G[\phi, \pi]$ be functionals of the phase-space data on a constant-time slice. Their *equal-time Poisson bracket* is

$$\{F, G\}_{\mathrm{P}} \equiv \int \mathrm{d}^3 z \left[\frac{\delta F}{\delta \phi_a(\mathbf{z})} \frac{\delta G}{\delta \pi^a(\mathbf{z})} - \frac{\delta F}{\delta \pi^a(\mathbf{z})} \frac{\delta G}{\delta \phi_a(\mathbf{z})} \right], \tag{6.110}$$

with summation over the repeated field index a and the integration running over the slice. The bracket is bilinear, antisymmetric ($\{F, G\}_{\mathrm{P}} = -\{G, F\}_{\mathrm{P}}$), satisfies the Leibniz rule $\{FG, K\}_{\mathrm{P}} = F\{G, K\}_{\mathrm{P}} + \{F, K\}_{\mathrm{P}} G$, and obeys the Jacobi identity $\{F, \{G, K\}_{\mathrm{P}}\}_{\mathrm{P}} + \{G, \{K, F\}_{\mathrm{P}}\}_{\mathrm{P}} + \{K, \{F, G\}_{\mathrm{P}}\}_{\mathrm{P}} = 0$, inherited from the corresponding properties of partial derivatives.

The basic objects of the theory are the fields and momenta evaluated at a point, which we treat as functionals via $\phi_a(\mathbf{x}) = \int \mathrm{d}^3 z\, \delta^3(\mathbf{x} - \mathbf{z})\, \phi_a(\mathbf{z})$. Their functional derivatives are sharp:

$$\frac{\delta \phi_a(\mathbf{x})}{\delta \phi_b(\mathbf{z})} = \delta_a{}^b\, \delta^3(\mathbf{x} - \mathbf{z}), \qquad \frac{\delta \pi^a(\mathbf{x})}{\delta \pi^b(\mathbf{z})} = \delta^a{}_b\, \delta^3(\mathbf{x} - \mathbf{z}), \tag{6.111}$$

with $\delta \phi_a(\mathbf{x})/\delta \pi^b(\mathbf{z}) = 0$ and $\delta \pi^a(\mathbf{x})/\delta \phi_b(\mathbf{z}) = 0$ because ϕ and π are independent coordinates on phase space. Substituting these into the definition Eq. (6.110) gives the fundamental algebra.

Theorem 6.18 (Canonical Poisson brackets)**.** *The equal-time Poisson brackets of the basic phase-space variables are*

$$\Big\{\phi_a(\mathbf{x}), \pi^b(\mathbf{y})\Big\}_P = \delta_a{}^b\, \delta^3(\mathbf{x} - \mathbf{y}), \qquad \{\phi_a(\mathbf{x}), \phi_b(\mathbf{y})\}_P = 0, \qquad \Big\{\pi^a(\mathbf{x}), \pi^b(\mathbf{y})\Big\}_P = 0, \tag{6.112}$$

all evaluated at equal times $x^0 = y^0$.

Proof. For the mixed bracket, set $F = \phi_a(\mathbf{x})$ and $G = \pi^b(\mathbf{y})$ in Eq. (6.110). The second term vanishes because $\delta\phi_a/\delta\pi = 0$, and the first uses Eq. (6.111):

$$\big\{\phi_a(\mathbf{x}), \pi^b(\mathbf{y})\big\}_{\mathrm{P}} = \int \mathrm{d}^3 z \, \frac{\delta\phi_a(\mathbf{x})}{\delta\phi_c(\mathbf{z})} \, \frac{\delta\pi^b(\mathbf{y})}{\delta\pi^c(\mathbf{z})} = \int \mathrm{d}^3 z \; \delta_a{}^c \, \delta^3(\mathbf{x}-\mathbf{z}) \, \delta^b{}_c \, \delta^3(\mathbf{y}-\mathbf{z}) = \delta_a{}^b \, \delta^3(\mathbf{x}-\mathbf{y}). \tag{6.113}$$

For $\{\phi_a(\mathbf{x}), \phi_b(\mathbf{y})\}_{\mathrm{P}}$ both terms in Eq. (6.110) contain a factor $\delta\phi/\delta\pi = 0$, and likewise for $\big\{\pi^a, \pi^b\big\}_{\mathrm{P}}$ both contain $\delta\pi/\delta\phi = 0$; both brackets vanish. □

These three relations are the classical skeleton of canonical quantization. In Chapter 9 the prescription $\{\,\cdot\,,\,\cdot\,\}_{\mathrm{P}} \to -i\,[\,\cdot\,,\,\cdot\,]$ turns Eq. (6.112) into the equal-time commutator $\big[\hat{\phi}_a(\mathbf{x}), \hat{\pi}^b(\mathbf{y})\big] = i\,\delta_a{}^b\,\delta^3(\mathbf{x}-\mathbf{y})$ of the free scalar field—the foundational commutation relation of the entire quantum theory. The Dirac case will, by contrast, demand anticommutators, because its fields are Grassmann-valued and its bracket is graded; that subtlety is opened classically in Section 6.5 and discharged at quantization in Chapter 11.

Hamilton's equations and time evolution in bracket form. The bracket also packages the dynamics. Specializing $G = H$ in Eq. (6.110) with $F = \phi_a(\mathbf{x})$ and using Eq. (6.106),

$$\{\phi_a(\mathbf{x}), H\}_{\mathrm{P}} = \int \mathrm{d}^3 z \, \frac{\delta\phi_a(\mathbf{x})}{\delta\phi_b(\mathbf{z})} \, \frac{\delta H}{\delta\pi^b(\mathbf{z})} = \frac{\delta H}{\delta\pi^a(\mathbf{x})} = \dot{\phi}_a(\mathbf{x}), \tag{6.114}$$

and similarly $\{\pi^a(\mathbf{x}), H\}_{\mathrm{P}} = -\delta H/\delta\phi_a(\mathbf{x}) = \dot{\pi}^a(\mathbf{x})$. So Hamilton's equations Eq. (6.109) read

$$\dot{\phi}_a = \{\phi_a, H\}_{\mathrm{P}}\,, \qquad \dot{\pi}^a = \{\pi^a, H\}_{\mathrm{P}}\,. \tag{6.115}$$

This is no accident of the basic variables: the same statement holds for any observable.

Theorem 6.19 (The Hamiltonian generates time evolution)**.** *Let $F[\phi, \pi; t]$ be any (possibly explicitly time-dependent) local functional of the phase-space data. Along a solution of Hamilton's equations its total time derivative is*

$$\frac{dF}{dt} = \{F, H\}_{P} + \frac{\partial F}{\partial t}\,, \tag{6.116}$$

where $\partial F/\partial t$ is the explicit time dependence at fixed (ϕ, π). In particular a functional with no explicit time dependence is conserved if and only if it Poisson-commutes with H.

Proof. Write $F = \int \mathrm{d}^3 x \, f(\phi_a, \partial_i\phi_a, \pi^a; t)$. The total time derivative collects the change through the time dependence of the fields and the explicit dependence:

$$\frac{dF}{dt} = \int \mathrm{d}^3 x \left[\frac{\delta F}{\delta\phi_a(\mathbf{x})}\,\dot{\phi}_a(\mathbf{x}) + \frac{\delta F}{\delta\pi^a(\mathbf{x})}\,\dot{\pi}^a(\mathbf{x})\right] + \frac{\partial F}{\partial t}\,, \tag{6.117}$$

where the chain rule with functional derivatives already accounts for the gradient dependence after integration by parts (Eq. (6.101)). Now insert Hamilton's equations Eq. (6.109), $\dot{\phi}_a = \delta H/\delta\pi^a$ and $\dot{\pi}^a = -\delta H/\delta\phi_a$:

$$\frac{dF}{dt} = \int \mathrm{d}^3x \left[\frac{\delta F}{\delta\phi_a}\frac{\delta H}{\delta\pi^a} - \frac{\delta F}{\delta\pi^a}\frac{\delta H}{\delta\phi_a}\right] + \frac{\partial F}{\partial t} = \{F, H\}_{\mathrm{P}} + \frac{\partial F}{\partial t}\,, \tag{6.118}$$

the bracket integral being exactly Eq. (6.110). If $\partial F/\partial t = 0$ then $dF/dt = \{F, H\}_{\mathrm{P}}$, which vanishes iff $\{F, H\}_{\mathrm{P}} = 0$. □

Equation (6.116) is the classical template for the Heisenberg equation $dF/dt = i\,[H, F] + \partial F/\partial t$ of Chapter 9, and it is the engine that will let Chapter 7 express every conserved charge as the generator, through the bracket, of its symmetry: charges generate transformations precisely because $\{Q, \cdot\,\}_{\mathrm{P}}$ acts as the corresponding infinitesimal flow on phase space, with the Hamiltonian being the charge that generates time translation.

6.4.4 Worked example: the scalar field and ϕ^4 theory

We now carry the entire construction explicitly for the real scalar, producing the phase-space data that Chapter 9 quantizes. This continues ϕ^4 theory from Section 6.2.

Worked Example 6.20 (Hamiltonian and brackets of the real scalar)**.** Recall the real scalar Lagrangian density (Section 6.2),

$$\mathcal{L} = \tfrac{1}{2}\,\partial_\mu\phi\,\partial^\mu\phi - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4 = \tfrac{1}{2}\dot{\phi}^2 - \tfrac{1}{2}(\nabla\phi)^2 - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4, \tag{6.119}$$

where in the second form we used the mostly-minus metric (Chapter A) to write $\partial_\mu\phi\,\partial^\mu\phi = \dot{\phi}^2 - (\nabla\phi)^2$, with $(\nabla\phi)^2 = \partial_i\phi\,\partial_i\phi \geq 0$ the squared spatial gradient. We carry out the four steps: momentum, Hamiltonian, equations of motion, and brackets.

Step 1: canonical momentum. By Eq. (6.96),

$$\pi = \frac{\partial\mathcal{L}}{\partial\dot{\phi}} = \dot{\phi}\,. \tag{6.120}$$

The velocity Hessian is $W = \partial^2\mathcal{L}/\partial\dot{\phi}^2 = 1 \neq 0$, so the scalar is regular and Eq. (6.120) inverts trivially to $\dot{\phi} = \pi$.

Step 2: Hamiltonian density. Substituting into Eq. (6.98),

$$\begin{aligned}\mathcal{H} &= \pi\dot{\phi} - \mathcal{L} = \dot{\phi}^2 - \left[\tfrac{1}{2}\dot{\phi}^2 - \tfrac{1}{2}(\nabla\phi)^2 - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4\right] \\ &= \tfrac{1}{2}\dot{\phi}^2 + \tfrac{1}{2}(\nabla\phi)^2 + \tfrac{1}{2}m^2\phi^2 + \frac{\lambda}{4!}\phi^4\,,\end{aligned} \tag{6.121}$$

and eliminating the velocity with $\dot\phi = \pi$,

$$\boxed{\mathcal{H} = \tfrac{1}{2}\pi^2 + \tfrac{1}{2}(\nabla\phi)^2 + \tfrac{1}{2}m^2\phi^2 + \frac{\lambda}{4!}\phi^4} \qquad H = \int \mathrm{d}^3x\, \mathcal{H}\,. \tag{6.122}$$

Every term is manifestly non-negative for $\lambda \geq 0$: the kinetic energy $\frac{1}{2}\pi^2$, the gradient ("shear") energy $\frac{1}{2}(\nabla\phi)^2$, the mass ("rest") energy $\frac{1}{2}m^2\phi^2$, and the self-interaction $\frac{\lambda}{4!}\phi^4$. The Hamiltonian is bounded below, with minimum at $\phi = \pi = 0$—the classical vacuum—which is the property that makes the quantized theory of Chapter 9 have a stable ground state.

Step 3: equations of motion from Hamilton's equations. The first Hamilton equation reproduces the momentum relation,

$$\dot\phi = \frac{\delta H}{\delta \pi} = \pi\,. \tag{6.123}$$

For the second we need $\delta H/\delta\phi$. Only the gradient, mass, and quartic terms depend on ϕ; applying the rule Eq. (6.101) to the density Eq. (6.122), with $\partial\mathcal{H}/\partial(\partial_i\phi) = \partial_i\phi$,

$$\frac{\delta H}{\delta\phi} = \frac{\partial\mathcal{H}}{\partial\phi} - \partial_i\frac{\partial\mathcal{H}}{\partial(\partial_i\phi)} = (m^2\phi + \tfrac{\lambda}{3!}\phi^3) - \partial_i(\partial_i\phi) = -\nabla^2\phi + m^2\phi + \frac{\lambda}{3!}\phi^3\,, \tag{6.124}$$

where $\partial(\frac{\lambda}{4!}\phi^4)/\partial\phi = \frac{4\lambda}{4!}\phi^3 = \frac{\lambda}{3!}\phi^3$. Hence the second Hamilton equation reads

$$\dot\pi = -\frac{\delta H}{\delta\phi} = \nabla^2\phi - m^2\phi - \frac{\lambda}{3!}\phi^3\,. \tag{6.125}$$

Differentiating $\dot\phi = \pi$ once more in time gives $\ddot\phi = \dot\pi$, so

$$\ddot\phi - \nabla^2\phi + m^2\phi = -\frac{\lambda}{3!}\phi^3 \quad\Longleftrightarrow\quad (\Box + m^2)\phi = -\frac{\lambda}{3!}\phi^3\,, \tag{6.126}$$

using $\Box = \partial_0^2 - \nabla^2 = \ddot{} - \nabla^2$. This is exactly the ϕ^4 equation of motion derived in Section 6.2, recovered here from the Hamiltonian side—a concrete check of Theorem 6.16.

Step 4: the same equations from the Poisson bracket. Using Eq. (6.115) with the fundamental brackets Eq. (6.112), the dynamics follows without any new computation. The bracket with H of the field is

$$\dot\phi(\mathbf{x}) = \{\phi(\mathbf{x}), H\}_{\mathrm{P}} = \int \mathrm{d}^3z\, \frac{\delta\phi(\mathbf{x})}{\delta\phi(\mathbf{z})}\frac{\delta H}{\delta\pi(\mathbf{z})} = \frac{\delta H}{\delta\pi(\mathbf{x})} = \pi(\mathbf{x}), \tag{6.127}$$

and of the momentum,

$$\dot\pi(\mathbf{x}) = \{\pi(\mathbf{x}), H\}_{\mathrm{P}} = -\int \mathrm{d}^3z\, \frac{\delta\pi(\mathbf{x})}{\delta\pi(\mathbf{z})}\frac{\delta H}{\delta\phi(\mathbf{z})} = -\frac{\delta H}{\delta\phi(\mathbf{x})} = \nabla^2\phi - m^2\phi - \frac{\lambda}{3!}\phi^3, \tag{6.128}$$

where the second line reuses Eq. (6.124). Eliminating π reproduces Eq. (6.126). The equation of motion is thus generated by the Poisson action of H, exactly as Theorem 6.19 promises.

The frozen ϕ^4 theory data. The objects this worked example delivers—the canonical momentum $\pi = \dot{\phi}$, the Hamiltonian density Eq. (6.122), and the equal-time bracket $\{\phi(\mathbf{x}), \pi(\mathbf{y})\}_{\mathrm{P}} = \delta^3(\mathbf{x} - \mathbf{y})$—are precisely the classical inputs that Chapter 9 promotes to operators to build the free scalar Fock space (set $\lambda = 0$) and that Chapters 14 and 15 perturb in λ for the first interacting amplitude.

It is worth pausing on the structure of H for the free theory. With $\lambda = 0$ the Hamiltonian Eq. (6.122) is quadratic, and the equations of motion Eq. (6.126) reduce to the linear Klein–Gordon equation $(\Box + m^2)\phi = 0$. A quadratic Hamiltonian with positive-definite kinetic and potential parts is, point by point in Fourier space, a collection of decoupled harmonic oscillators—one for each spatial momentum $\mathbf{k}$, with frequency $\omega_{\mathbf{k}} = \sqrt{\mathbf{k}^2 + m^2}$. That observation is the bridge to Chapter 9: quantizing the field is quantizing this continuum of oscillators, and the canonical bracket Eq. (6.112) is what makes each oscillator's position and momentum conjugate. The quartic term $\frac{\lambda}{4!}\phi^4$ couples the oscillators, which is why the interacting theory cannot be solved exactly and must be treated perturbatively.

6.4.5 Time translation as a canonical flow

We close by recording the conceptual statement that Theorem 6.19 encodes, because Chapter 7 builds directly on it. The map that advances every observable by an infinitesimal time δt,

$$F \;\longmapsto\; F + \delta t \,\frac{dF}{dt} = F + \delta t\, \{F, H\}_{\mathrm{P}} \qquad (\text{for } \partial_t F = 0), \tag{6.129}$$

is generated by the Hamiltonian through the Poisson bracket. In the language we will make systematic in the next chapter, H is the *conserved charge of time-translation symmetry*, and "conserved charge generates its symmetry via the bracket" is the classical content of Noether's theorem. Spatial translations will be generated by the field momentum P^i, rotations by the angular momentum, and so on; each is a particular phase-space functional whose bracket reproduces the corresponding infinitesimal transformation. The Hamiltonian is simply the time-translation member of this family, distinguished only because time is the direction along which we have chosen to evolve.

This completes the phase-space description of the regular scalar: a configuration–momentum pair on each slice, a Hamiltonian bounded below, first-order Hamilton equations equivalent to the Klein–Gordon/ϕ^4 dynamics, and a canonical bracket algebra ready to be quantized. Two of our three protagonists, however, refuse this clean passage. The Dirac field is first order in time, so its velocity Hessian

vanishes and Eq. (6.96) cannot be inverted; the Maxwell field has no $\dot{A}_0$ in its Lagrangian, so the momentum conjugate to A_0 vanishes identically. In both cases the Legendre transform returns not the velocities but *constraints* relating the phase-space variables. Identifying those primary constraints, and constructing the Hamiltonian on the surface they define, is the subject of Section 6.5.

6.5 Singular Lagrangians and Primary Constraints

The Hamiltonian construction of Section 6.4 rested on a step we performed without comment for the real scalar and which, we noted at the close of that section, cannot be performed at all for two of the three protagonists of this book. To pass from the Lagrangian to the Hamiltonian we defined the canonical momentum $\pi_a = \partial\mathcal{L}/\partial\dot{\phi}_a$ and then *solved* this relation for the velocities $\dot{\phi}_a$ as functions of the momenta, so that the Hamiltonian $\mathcal{H} = \pi_a\dot{\phi}_a - \mathcal{L}$ could be written on phase space, with no velocity left in sight. For the scalar that inversion was trivial: $\pi = \dot{\phi}$, so $\dot{\phi} = \pi$ and the substitution is immediate. But the Dirac Lagrangian is *linear* in the velocities $\dot{\psi}$, and the Maxwell Lagrangian contains *no* time derivative of A_0 at all. In neither case can $\dot{\phi}_a$ be recovered from π_a. The definition of the momentum, instead of being a relation to be inverted, becomes a *constraint*: an identity tying the momenta to the fields that holds before any equation of motion is imposed.

This is not a pathology to be regretted; it is the classical fingerprint of two of the deepest features of relativistic field theory. The Dirac constraint is the classical shadow of the spin-statistics connection — it forces the fermionic bracket to be an *anti*bracket, hence anticommutators on quantization. The Maxwell constraint is the classical shadow of gauge redundancy — A_0 is not a dynamical variable but a Lagrange multiplier, and the consistency of its (absent) dynamics is Gauss's law. Our task in this section is the honest classical groundwork: to define precisely what a degenerate Lagrangian is, to identify the primary constraints of the Dirac and Maxwell systems, to compute their constrained Hamiltonians with every term shown, and to name — at the level of precise statement, with the full machinery deferred — the systematic theory (the Dirac–Bergmann algorithm) that organizes the rest. We draw a sharp line between what is a classical fact, settled here, and what is genuinely a quantization choice, handed to Chapter 13 (the photon) and Chapter 26 (non-abelian gauge fields).

6.5.1 Degenerate Lagrangians and the Hessian criterion

We work with a collection of fields $\phi_a(x)$, the index a running over both field species and any internal/spinor components, with first-order Lagrangian density

$\mathcal{L}(\phi_a, \partial_\mu \phi_a)$. The canonical momentum conjugate to ϕ_a is

$$\pi^a(x) \;=\; \frac{\partial \mathcal{L}}{\partial \dot{\phi}_a(x)}, \qquad \dot{\phi}_a \equiv \partial_0 \phi_a, \tag{6.130}$$

exactly as in Section 6.4. Whether (6.130) can be solved for the velocities is a question about a single matrix. Differentiating (6.130) once more with respect to a velocity,

$$\frac{\partial \pi^a}{\partial \dot{\phi}_b} \;=\; \frac{\partial^2 \mathcal{L}}{\partial \dot{\phi}_a \, \partial \dot{\phi}_b} \;\equiv\; W_{ab}, \tag{6.131}$$

defines the *Hessian* of the Lagrangian with respect to the velocities. By the implicit function theorem, the relations (6.130) can be inverted for $\dot{\phi}_b = \dot{\phi}_b(\phi, \pi)$ in a neighbourhood precisely when W_{ab} is invertible. This dichotomy is the organizing definition of the section.

Definition 6.21 (Regular and singular Lagrangians)**.** The Lagrangian $\mathcal{L}$ is *regular* (or *non-degenerate*) if its velocity Hessian (6.131) is everywhere invertible, $\det W_{ab} \neq 0$; then every velocity is a function of the canonical data and the Legendre transform to the Hamiltonian is well defined. It is *singular* (or *degenerate*) if $\det W_{ab} = 0$. In the singular case the momenta (6.130) are not all independent functions of the velocities: there exist relations

$$\chi_m(\phi, \pi) \;\approx\; 0, \qquad m = 1, \dots, M, \tag{6.132}$$

satisfied identically by the momenta as defined, without using any equation of motion.

Definition 6.22 (Primary constraint)**.** A relation of the form (6.132) that follows directly from the definition (6.130) of the momenta — i.e. that holds on the image of the map $(\phi, \dot{\phi}) \mapsto (\phi, \pi)$ *before* the equations of motion are imposed — is a *primary constraint*. The number of independent primary constraints equals the number of null eigenvectors of W_{ab}.

The symbol "$\approx$" is Dirac's *weak equality*: $\chi_m \approx 0$ means χ_m vanishes on the constraint surface in phase space carved out by all the constraints, but is *not* identically zero as a function on the unconstrained phase space, so it may have nonzero Poisson brackets with the canonical variables. The distinction matters: one may set $\chi_m = 0$ only *after* all brackets have been evaluated, never inside a bracket. We will keep this discipline scrupulously below.

The kernel of W_{ab} counts the constraints because each null eigenvector v^a (with $W_{ab} v^b = 0$) is a direction in velocity space along which $\mathcal{L}$ is at most linear; the corresponding combination $v_a \pi^a$ of momenta is then independent of all velocities, hence a function of the fields alone — precisely a relation of the form (6.132). The real scalar of ϕ^4 theory has $W = \partial^2[\tfrac{1}{2}\dot{\phi}^2 - \cdots]/\partial\dot{\phi}^2 = 1 \neq 0$: regular, no constraints, which is why Section 6.4 proceeded without incident. The two theories we now confront are at the opposite extreme.

Physical Insight

Degeneracy is never accidental in a theory that anyone writes down on purpose. It is the phase-space signature of structure: a first-order (Dirac) kinetic term means the field and its momentum are not independent — half of phase space is redundant — and a gauge symmetry (Maxwell) means some "coordinates" are pure redundancy with no conjugate dynamics at all. The constraint analysis is how the canonical formalism discovers, on its own, the spin-statistics and gauge structure that we built into the Lagrangian.

6.5.2 The Dirac field: a momentum that is a constraint

We continue QED at the classical level. The free Dirac Lagrangian density fixed in Section 6.3 is

$$\mathcal{L}_{\mathrm{D}} \;=\; \bar{\psi}\,(i\partial\!\!\!/ - m)\,\psi \;=\; i\,\bar{\psi}\,\gamma^0\dot{\psi} + i\,\bar{\psi}\,\gamma^i\partial_i\psi - m\,\bar{\psi}\psi, \tag{6.133}$$

where $\bar{\psi} = \psi^\dagger\gamma^0$ and the gamma algebra $\{\gamma^\mu,\gamma^\nu\} = 2\eta^{\mu\nu}$ is the canon of Chapter C; the spinor field ψ and its components are *anticommuting* (Grassmann-valued) classical fields, the c-number-but-odd objects whose calculus is built from scratch in Chapter 12. The sum over $i = 1,2,3$ is the only place a spatial derivative enters; the single time derivative sits in the first term, and using $\bar{\psi}\gamma^0 = \psi^\dagger(\gamma^0)^2 = \psi^\dagger$ that term is simply $i\,\psi^\dagger\dot{\psi}$. The Lagrangian is therefore *linear* in $\dot{\psi}$ and contains no $\dot{\bar{\psi}}$ whatsoever. This is the maximally degenerate case, and the constraint structure can be read off by inspection.

Worked Example 6.23 (Dirac momenta, Hessian, and Hamiltonian)**.** We compute the canonical momenta of (6.133), exhibit the primary constraints, and Legendre-transform to the Hamiltonian, carrying every step.

Momenta. Treat ψ and $\psi^\dagger$ as independent fields (equivalently ψ and $\bar{\psi}$). For the anticommuting field we use the left derivative, with the overall sign convention fixed in Chapter 12; the result, on which all references agree, is

$$\pi_\psi = \frac{\partial\mathcal{L}_{\mathrm{D}}}{\partial\dot{\psi}} = \frac{\partial}{\partial\dot{\psi}}(i\,\psi^\dagger\dot{\psi}) = i\,\psi^\dagger, \qquad \pi_{\psi^\dagger} = \frac{\partial\mathcal{L}_{\mathrm{D}}}{\partial\dot{\psi}^\dagger} = 0, \tag{6.134}$$

the second because $\dot{\psi}^\dagger$ does not appear in (6.133) at all. Neither equation can be solved for a velocity. Both are primary constraints:

$$\chi_1 \equiv \pi_\psi - i\,\psi^\dagger \approx 0, \qquad \chi_2 \equiv \pi_{\psi^\dagger} \approx 0. \tag{6.135}$$

The momentum conjugate to ψ is *fixed in terms of the field* $\psi^\dagger$; no new phase-space information lives in π_ψ.

Hessian. The velocities are $(\dot\psi, \dot\psi^\dagger)$. Since $\mathcal{L}_\mathrm{D}$ is linear in $\dot\psi$ and independent of $\dot\psi^\dagger$, every second velocity-derivative (6.131) vanishes,

$$W = \frac{\partial^2 \mathcal{L}_\mathrm{D}}{\partial(\dot\psi, \dot\psi^\dagger)^2} = 0, \tag{6.136}$$

the identically-zero matrix. It is as singular as a Hessian can be; correspondingly the number of primary constraints, two per spinor component, saturates the count in Theorem 6.22.

Hamiltonian. The canonical Hamiltonian density is the Legendre transform $\mathcal{H}_\mathrm{D} = \pi_\psi\dot\psi + \dot\psi^\dagger\pi_{\psi^\dagger} - \mathcal{L}_\mathrm{D}$. The second term drops by (6.134). Substituting $\pi_\psi\dot\psi = i\,\psi^\dagger\dot\psi$ and (6.133),

$$\mathcal{H}_\mathrm{D} = \underbrace{i\,\psi^\dagger\dot\psi}_{\pi_\psi\dot\psi} - \underbrace{\left(i\,\psi^\dagger\dot\psi + i\,\bar\psi\gamma^i\partial_i\psi - m\,\bar\psi\psi\right)}_{\mathcal{L}_\mathrm{D}} = -\,i\,\bar\psi\gamma^i\partial_i\psi + m\,\bar\psi\psi. \tag{6.137}$$

The velocity term cancels identically — the hallmark of a Lagrangian linear in $\dot\psi$ — leaving a Hamiltonian density with *no* velocity in it:

$$\boxed{\mathcal{H}_\mathrm{D} = \bar\psi\left(-i\,\gamma^i\partial_i + m\right)\psi} \tag{6.138}$$

Writing $\bar\psi = \psi^\dagger\gamma^0$ and introducing the Dirac matrices $\alpha^i \equiv \gamma^0\gamma^i$, $\beta \equiv \gamma^0$ of nonrelativistic notation (Chapter C), (6.138) reads $\mathcal{H}_\mathrm{D} = \psi^\dagger(-i\,\alpha^i\partial_i + \beta m)\psi = \psi^\dagger(\boldsymbol{\alpha}\cdot\mathbf{p} + \beta m)\psi$ with $\mathbf{p} = -i\nabla$: exactly the single-particle Dirac Hamiltonian of relativistic quantum mechanics, now read as a classical field-energy density. That the field-theoretic $\mathcal{H}_\mathrm{D}$ reproduces the first-quantized Dirac Hamiltonian is the consistency check that the Legendre transform, constraints and all, has been done correctly.

The classical content is now exact and complete: the Dirac field carries the two second-class primary constraints (6.135), and its energy is (6.138). What remains — that the bracket of χ_1 with χ_2 is invertible, so that these constraints must be solved by passing to a modified bracket whose fermionic version is an *anti*bracket — is the quantization story, and we name it precisely in Section 6.5.4 before deferring its execution.

6.5.3 The Maxwell field: a non-dynamical potential and Gauss's law

We now open QED's gauge sector at the classical level. The Maxwell Lagrangian density fixed in Section 6.3 is

$$\mathcal{L}_\mathrm{M} = -\tfrac{1}{4}\,F_{\mu\nu}F^{\mu\nu}, \qquad F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu, \tag{6.139}$$

with the four-potential A_μ as the fundamental field. We use the mostly-minus metric of Chapter A and the standard identification of the electric and magnetic fields,

$$E^i = F^{i0} = -\dot{A}^i - \partial_i A^0, \qquad B^i = -\tfrac{1}{2}\epsilon^{ijk}F_{jk} = (\nabla \times \mathbf{A})^i, \tag{6.140}$$

so that $-\frac{1}{4}F_{\mu\nu}F^{\mu\nu} = \frac{1}{2}(\mathbf{E}^2 - \mathbf{B}^2)$. The asymmetry that creates the constraint is already visible: $F_{\mu\nu}$ is antisymmetric, so $F_{00} = 0$, so $\dot{A}_0$ — the time derivative of the time component — cannot appear in $\mathcal{L}_{\mathrm{M}}$. The potential A_0 has no kinetic term.

Worked Example 6.24 (Maxwell momenta and the constrained Hamiltonian)**.** We compute the four canonical momenta conjugate to A_μ, identify the primary constraint, and Legendre-transform to the Hamiltonian, performing the integration by parts in full.

Momenta. With $\mathcal{L}_{\mathrm{M}} = -\frac{1}{4}F_{\rho\sigma}F^{\rho\sigma}$, the derivative with respect to a velocity $\partial_0 A_\mu$ is the standard

$$\pi^\mu = \frac{\partial \mathcal{L}_{\mathrm{M}}}{\partial(\partial_0 A_\mu)} = -F^{0\mu}, \tag{6.141}$$

which follows because $\partial(-\frac{1}{4}F_{\rho\sigma}F^{\rho\sigma})/\partial(\partial_\alpha A_\beta) = -F^{\alpha\beta}$ (each of the two factors of F contributes $-\frac{1}{2}F^{\alpha\beta}$ after the antisymmetric index pairing). Splitting the index μ into time and space:

$$\pi^0 = -F^{00} = 0, \tag{6.142}$$

$$\pi^i = -F^{0i} = F^{i0} = E^i. \tag{6.143}$$

Equation (6.142) is the primary constraint: the momentum conjugate to A_0 vanishes *identically*, before any field equation, simply because $\dot{A}_0$ never appeared. Equation (6.143) says the momenta conjugate to the spatial potentials are the components of the electric field — the genuinely dynamical half of phase space. So the primary constraint is

$$\chi \equiv \pi^0 \approx 0. \tag{6.144}$$

The velocity Hessian (6.131), restricted to the four velocities $\dot{A}_\mu$, has the single null direction $\mu = 0$ (since $\mathcal{L}_{\mathrm{M}}$ is independent of $\dot{A}_0$), confirming exactly one primary constraint per spacetime point, in agreement with Theorem 6.22.

Hamiltonian. The canonical Hamiltonian density is $\mathcal{H}_{\mathrm{M}} = \pi^\mu \dot{A}_\mu - \mathcal{L}_{\mathrm{M}}$, and because $\pi^0 = 0$ the sum reduces to $\pi^i \dot{A}_i$. We must express the velocity $\dot{A}_i$ through the momentum. From (6.143) and $E^i = -\dot{A}^i - \partial_i A^0$, together with $\dot{A}_i = -\dot{A}^i$ (lowering a spatial index flips the sign in mostly-minus),

$$\pi^i = E^i = -\dot{A}^i - \partial_i A^0 \quad \Longrightarrow \quad \dot{A}_i = -\dot{A}^i = \pi^i + \partial_i A^0. \tag{6.145}$$

Hence the kinetic pairing is

$$\pi^i \dot{A}_i = \pi^i(\pi^i + \partial_i A^0) = \mathbf{E}^2 + \mathbf{E} \cdot \nabla A^0, \tag{6.146}$$

using $\pi^i = E^i$. Subtracting $\mathcal{L}_{\mathrm{M}} = \tfrac{1}{2}(\mathbf{E}^2 - \mathbf{B}^2)$,

$$\mathcal{H}_{\mathrm{M}} = \mathbf{E}^2 + \mathbf{E}\cdot\nabla A^0 - \tfrac{1}{2}\mathbf{E}^2 + \tfrac{1}{2}\mathbf{B}^2 = \tfrac{1}{2}(\mathbf{E}^2 + \mathbf{B}^2) + \mathbf{E}\cdot\nabla A^0. \tag{6.147}$$

The first two terms are the familiar field-energy density of electromagnetism. The third is the term the constraint analysis cares about. Integrate it by parts over space inside $H_{\mathrm{M}} = \int d^3x\, \mathcal{H}_{\mathrm{M}}$, moving the gradient off A^0:

$$\int d^3x\; \mathbf{E}\cdot\nabla A^0 = \int d^3x\; \Big[\nabla\cdot(A^0\,\mathbf{E}) - A^0\,(\nabla\cdot\mathbf{E})\Big] = \oint_{\partial} A^0\,\mathbf{E}\cdot d\mathbf{S} - \int d^3x\; A^0\,(\nabla\cdot\mathbf{E}). \tag{6.148}$$

For fields decaying at spatial infinity the surface integral vanishes, and we record the Hamiltonian in the form that exhibits its structure:

$$\boxed{H_{\mathrm{M}} = \int d^3x\; \Big[\,\tfrac{1}{2}(\mathbf{E}^2 + \mathbf{B}^2) - A^0\,(\nabla\cdot\mathbf{E})\,\Big]} \tag{6.149}$$

with $\mathbf{E} = \boldsymbol{\pi}$ and $\mathbf{B} = \nabla\times\mathbf{A}$ understood as phase-space functions of (A_i, π^i). The potential A_0 has disappeared from any time derivative and now appears in H_{M} *linearly and undifferentiated*, multiplying the quantity $\nabla\cdot\mathbf{E}$. This is the unmistakable signature of a Lagrange multiplier.

The shape of (6.149) is no accident: A_0 is not a degree of freedom but a multiplier enforcing a constraint, and that constraint is Gauss's law. We show this directly, as the dynamical consequence of preserving the primary constraint.

Worked Example 6.25 (Gauss's law as a secondary constraint from A_0)**.** We require the primary constraint $\pi^0 \approx 0$ to remain true under time evolution and read off Gauss's law; then we re-derive it as the Euler–Lagrange equation obtained by varying A_0, confirming the Lagrange-multiplier interpretation.

Consistency of the primary constraint. The time evolution of any phase-space functional is generated by the Hamiltonian through the equal-time Poisson bracket of Section 6.4; for the canonical pair (A_μ, π^ν) with $\{A_\mu(\mathbf{x}), \pi^\nu(\mathbf{y})\}_{\mathrm{P}} = \delta_\mu^{\ \nu}\,\delta^3(\mathbf{x}-\mathbf{y})$ this gives Hamilton's equation $\dot\pi^0 = \{\pi^0, H_{\mathrm{M}}\}_{\mathrm{P}} = -\,\delta H_{\mathrm{M}}/\delta A_0$. Differentiating (6.149) with respect to A_0 — only the last term depends on it, undifferentiated —

$$\dot\pi^0 = -\frac{\delta H_{\mathrm{M}}}{\delta A_0} = -(-\nabla\cdot\mathbf{E}) = \nabla\cdot\mathbf{E}. \tag{6.150}$$

A constraint is worthless unless it is preserved by the dynamics it constrains: we must have $\dot\pi^0 \approx 0$, for otherwise the system would immediately leave the surface $\pi^0 = 0$. Demanding this *consistency condition* yields a brand-new relation among the canonical variables,

$$\boxed{\nabla\cdot\mathbf{E} \approx 0} \tag{6.151}$$

which is Gauss's law (in vacuum). Because it was *not* present in the definition of the momenta but emerged from requiring time-consistency of a primary

constraint, it is called a *secondary* constraint. It is the first nontrivial output of the iterative algorithm sketched in Section 6.5.4.

The same law from varying A_0. The Lagrange-multiplier reading is confirmed by the Euler–Lagrange equation for A_0 derived from (6.139). Since $\mathcal{L}_{\mathrm{M}}$ depends on A_0 only through its spatial gradient $\partial_i A_0$ inside $F_{i0} = \partial_i A_0 - \partial_0 A_i$,

$$0 = \frac{\partial \mathcal{L}_{\mathrm{M}}}{\partial A_0} - \partial_\mu \frac{\partial \mathcal{L}_{\mathrm{M}}}{\partial(\partial_\mu A_0)} = 0 - \partial_i(-F^{i0}) = \partial_i E^i = \nabla \cdot \mathbf{E}, \tag{6.152}$$

where we used $\partial \mathcal{L}_{\mathrm{M}}/\partial(\partial_\mu A_0) = -F^{\mu 0}$ and $F^{00} = 0$. The field equation produced by A_0 contains *no* second time derivative of any field: it is not an evolution equation but a constraint on the initial data, $\nabla \cdot \mathbf{E} = 0$, exactly (6.151). A variable whose Euler–Lagrange equation is a constraint rather than an evolution law is, by definition, a Lagrange multiplier. The Hamiltonian (6.149) displays this plainly: varying the undifferentiated A_0 in H_{M} enforces $\nabla \cdot \mathbf{E} = 0$, just as varying a multiplier λ in $\lambda\, g(q,p)$ enforces $g = 0$.

Caution

Gauss's law (6.151) is a constraint on a *spatial slice*, not an equation of motion. It restricts which $(\mathbf{A}, \mathbf{E})$ qualify as legitimate initial data; the genuine time evolution is carried by the remaining Hamilton equations for A_i and π^i. Conflating the two — treating $\nabla \cdot \mathbf{E} = 0$ as something the dynamics "produces" rather than something it "preserves" — is the most common error in the canonical treatment of electromagnetism. The constraint is a property of every instant, guaranteed for all later times by the consistency computation above.

6.5.4 The Dirac–Bergmann algorithm: statement and the bridge to quantization

The two computations above are special cases of a single systematic procedure, due to Dirac and Bergmann, for converting any singular Lagrangian into a consistent Hamiltonian system. We state the procedure precisely — this is knowledge the reader needs to classify our two theories — while deferring the parts that are genuinely quantization choices. The algorithm proceeds in four stages, summarized in Fig. 6.3.

1. **Primary constraints.** Compute the momenta (6.130). The relations that cannot be solved for velocities are the primary constraints $\chi_m \approx 0$ of Theorem 6.22. (Dirac: χ_1, χ_2 of (6.135). Maxwell: $\pi^0 \approx 0$.)

2. **Total Hamiltonian.** Because the primary constraints carry no dynamics of their own, they enter evolution with arbitrary multipliers $u^m(x)$. The

generator of time evolution is the *total Hamiltonian*

$$H_{\mathrm{T}} = H_{\mathrm{c}} + \int d^3x\, u^m(x)\, \chi_m(x), \tag{6.153}$$

where $H_{\mathrm{c}} = \int d^3x\, \mathcal{H}$ is the canonical Hamiltonian of (6.138) or (6.149). The multipliers are to be fixed (or left free) by the next stage.

3. **Consistency and secondary constraints.** Each constraint must be preserved: $\dot{\chi}_m = \{\chi_m, H_{\mathrm{T}}\}_{\mathrm{P}} \approx 0$. For each m this equation either (a) is satisfied identically, (b) fixes one of the multipliers u^n, or (c) yields a new relation independent of the χ_m — a *secondary constraint*. One iterates, demanding consistency of the new constraints too, until no further independent relations appear. (Maxwell: consistency of $\pi^0 \approx 0$ produced the secondary constraint $\nabla \cdot \mathbf{E} \approx 0$, exactly as in Theorem 6.25; its own consistency $\partial_t(\nabla \cdot \mathbf{E}) \approx 0$ is automatic, so the chain terminates.)

4. **Classification: first and second class.** Collect all constraints, primary and secondary, into one set $\{\Phi_A\}$. A constraint Φ_A is *first class* if it has weakly vanishing Poisson bracket with *every* constraint, $\{\Phi_A, \Phi_B\}_{\mathrm{P}} \approx 0$ for all B; otherwise it is *second class*. The matrix $C_{AB} = \{\Phi_A, \Phi_B\}_{\mathrm{P}}$ is, after removing first-class members, invertible on the second-class sector.

Definition 6.26 (First- and second-class constraints)**.** With $\{\Phi_A\}$ the full set of constraints and $C_{AB} = \{\Phi_A, \Phi_B\}_{\mathrm{P}}$: the *first-class* constraints are those whose brackets with all Φ_B vanish weakly; they generate gauge transformations and signal redundant variables. The *second-class* constraints are the remainder, on which the antisymmetric matrix C_{AB} is nonsingular; they reduce phase space genuinely and are handled by replacing the Poisson bracket with the *Dirac bracket*

$$\{f, g\}_{\mathrm{D}} = \{f, g\}_{\mathrm{P}} - \{f, \Phi_A\}_{\mathrm{P}}\, \left(C^{-1}\right)^{AB}\, \{\Phi_B, g\}_{\mathrm{P}}\,, \tag{6.154}$$

where A, B run only over the second-class set. The Dirac bracket has the defining property $\{\Phi_A, g\}_{\mathrm{D}} = 0$ for every second-class Φ_A and every g, so the second-class constraints become strong identities and may be solved and eliminated; here $\{\,\cdot\,,\,\cdot\,\}_{\mathrm{D}}$ denotes the Dirac bracket, with C^{-1} the inverse of the second-class constraint matrix.

This vocabulary classifies our two protagonists cleanly, and the classification is the whole point of doing the analysis classically before quantizing.

Proposition 6.27 (Constraint type of the Dirac and Maxwell systems)**.** (i) *The Dirac primary constraints* (6.135) *are* second class*: their mutual bracket is nonsingular,* $\{\chi_{1\alpha}(\mathbf{x}), \chi_{2\beta}(\mathbf{y})\}_P = -i\,\delta_{\alpha\beta}\,\delta^3(\mathbf{x}-\mathbf{y})$ *on spinor indices* α, β*. There is no gauge freedom; the constraints reduce phase space by half and must be imposed through the Dirac bracket* (6.154)*.* (ii) *The Maxwell constraints* $\pi^0 \approx 0$

and $\nabla\cdot\mathbf{E}\approx 0$ *are both* first class*:* $\{\pi^0,\nabla\cdot\mathbf{E}\}_P=0$ *because* π^0 *commutes with the spatial momenta* $\pi^i=E^i$*, and each commutes with itself trivially. They generate the* $U(1)$ *gauge transformations* $A_\mu\to A_\mu+\partial_\mu\lambda$ *and signal two redundant field components per point.*

Proof. (i) Using the only nonvanishing canonical bracket of the Dirac sector, $\{\psi_\alpha(\mathbf{x}),\pi_{\psi\,\beta}(\mathbf{y})\}_{\mathrm{P}}=\delta_{\alpha\beta}\,\delta^3(\mathbf{x}-\mathbf{y})$, evaluate $\{\chi_{1\alpha},\chi_{2\beta}\}_{\mathrm{P}}$ with $\chi_{1\alpha}=\pi_{\psi\,\alpha}-i\,\psi^\dagger_\alpha$ and $\chi_{2\beta}=\pi_{\psi^\dagger\beta}$. The bracket $\left\{\pi_{\psi\,\alpha},\pi_{\psi^\dagger\beta}\right\}_{\mathrm{P}}=0$, while $\left\{-i\,\psi^\dagger_\alpha,\pi_{\psi^\dagger\beta}\right\}_{\mathrm{P}}=-i\,\delta_{\alpha\beta}\,\delta^3(\mathbf{x}-\mathbf{y})$ since $\pi_{\psi^\dagger}$ is conjugate to $\psi^\dagger$. Hence $\{\chi_{1\alpha},\chi_{2\beta}\}_{\mathrm{P}}=-i\,\delta_{\alpha\beta}\,\delta^3(\mathbf{x}-\mathbf{y})$, a nonsingular kernel: the constraint matrix is invertible, so the constraints are second class. *(ii)* The constraint π^0 has vanishing bracket with A_i and with π^i (distinct canonical sectors), so it commutes with $\nabla\cdot\mathbf{E}=\partial_i\pi^i$; $\nabla\cdot\mathbf{E}$ commutes with itself; and both are weakly preserved by H_{T} as shown in Theorem 6.25. All mutual brackets vanish, so both are first class. That the first-class $\nabla\cdot\mathbf{E}$ generates gauge transformations is the content of Chapter 8 and Chapter 13. □

Theorem 6.27 draws the line this section exists to draw. The dichotomy is real and classical: the Dirac field carries second-class constraints, the Maxwell field carries first-class constraints. Everything up to and including this classification is settled here, with full proofs. What lies on the far side of the line is genuinely a quantization choice, and it splits exactly along the first/second-class divide.

Notation Watch

Two distinct objects deferred to two distinct places must not be confused. (1) For the *second-class* Dirac system, the resolution is the Dirac bracket (6.154); computing it for χ_1,χ_2 gives $\left\{\psi_\alpha(\mathbf{x}),\psi^\dagger_\beta(\mathbf{y})\right\}_{\mathrm{D}}=-i\,\delta_{\alpha\beta}\,\delta^3(\mathbf{x}-\mathbf{y})$, an object *symmetric* under exchange in the bracket sense, which upon quantization $\{\,\cdot,\cdot\,\}_{\mathrm{D}}\to-i\{\,\cdot,\cdot\,\}$ becomes the anticommutator $\left\{\psi,\psi^\dagger\right\}$ — the classical origin of Fermi statistics. We carry this out in Chapter 11 (canonical quantization of the Dirac field) with the Grassmann calculus of Chapter 12. (2) For the *first-class* Maxwell system, no Dirac bracket is available — the constraint matrix C_{AB} is singular — and one must instead *fix the gauge*, restricting the redundant variables by hand before quantizing. The two implementations, Gupta–Bleuler (an indefinite-metric physical-state condition) and Faddeev–Popov gauge fixing, are the subject of Chapter 13 for the abelian photon and Chapter 26 for the non-abelian generalization. Nothing in this section presumes either choice; we have only certified, classically, which machinery each theory will need.

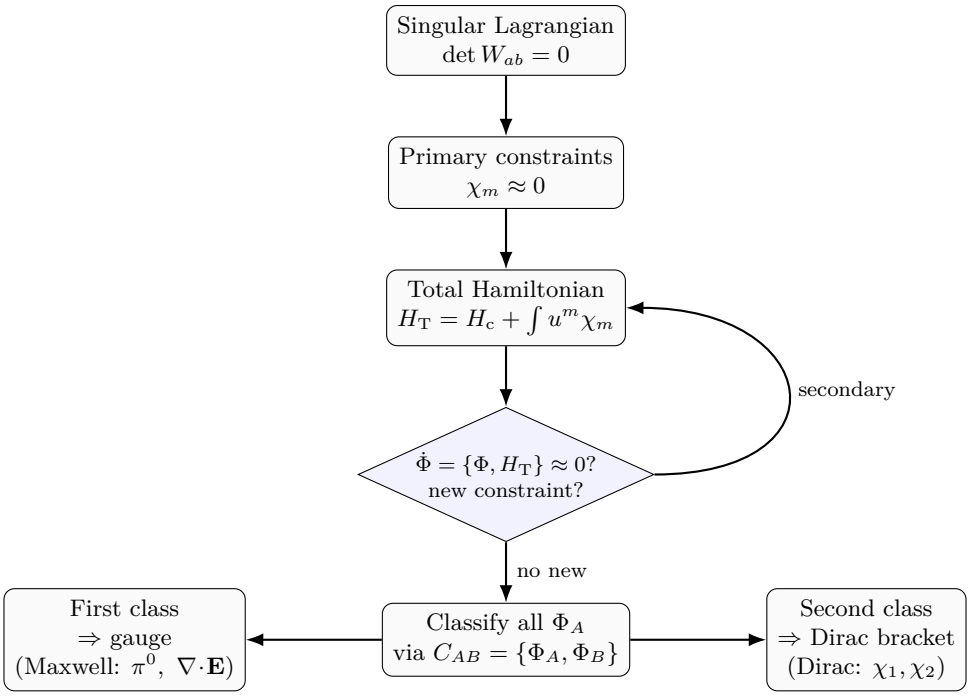

Figure 6.3: The Dirac–Bergmann algorithm. Degeneracy of the velocity Hessian produces primary constraints; demanding their time-consistency under the total Hamiltonian either fixes multipliers or generates secondary constraints (the loop); the closed set is then split into first-class (gauge-generating: Maxwell) and second-class (phase-space-reducing: Dirac) constraints. The classical analysis of this chapter carries every box; the resolution of each branch — the Dirac bracket for fermions and the quantization of the gauge branch — is the quantum work of Chapter 11, Chapter 13, and Chapter 26.

Handoff

We have isolated the purely classical core of every later gauge and fermion subtlety: the Dirac field's first-order kinetic term makes its momentum a second-class constraint $\pi_\psi \approx i\psi^\dagger$ with the constrained energy (6.138), while the Maxwell field's gauge degeneracy makes A_0 a non-dynamical Lagrange multiplier whose consistency is Gauss's law (6.151), both first class. These are facts of the classical theory, proved here in full, and they are exactly the facts Chapter 13 and Chapter 26 require before they may quantize. With the Hamiltonian densities of all three protagonists now in hand — scalar, Dirac (6.138), and Maxwell (6.149) — the final section turns to the deeper question of where the Hamiltonian density *comes from*: it is the T^{00} component of the conserved current of spacetime translations, the stress–energy tensor, to which we now build.

6.6 The Stress–Energy Tensor and Conserved Energy–Momentum

The Hamiltonian formulation of the preceding sections handed us a definite energy for a classical field: the number $H = \int d^3x\, \mathcal{H}$, built from the canonical momenta $\pi_a = \frac{\partial \mathcal{L}}{\partial \dot{\phi}_a}$ assembled in Section 6.4. That construction was unapologetically non-covariant. We singled out a time coordinate, performed a Legendre transform in $\dot{\phi}_a$ alone, and obtained a scalar H that lives on a fixed time slice. Energy, however, is the time component of a four-vector; in a relativistic theory it cannot be the whole story. Boost the slice and the energy mixes with momentum, exactly as p^0 mixes with $\mathbf{p}$ for a particle. There must be a covariant object whose 00 component is the energy density $\mathcal{H}$, whose $0i$ components are the momentum density, and which is conserved in a way that reduces, on a constant-time slice, to "energy in = energy out." That object is the *stress–energy tensor*, and the principle that produces it is the invariance of the action under rigid displacements of spacetime. Constructing it closes the loop opened in Section 6.2: the same Lagrangian that gave us equations of motion, through its symmetries, gives us the conserved quantities those equations respect.

We build the tensor directly from translation invariance, treating it as the first concrete instance of the Noether construction that Chapter 7 will erect in full generality. Doing the spacetime-translation case by hand first is deliberate: when the general theorem arrives, the reader will recognize it as the abstraction of a computation already understood in the marrow.

6.6.1 Translation invariance and the canonical current

Throughout, $\phi_a(x)$ denotes a collection of classical fields, the index a running over all components of all species in the theory (the four real components of a complex doublet, the four Dirac components ψ_α together with the four of $\bar{\psi}$, the four vector components A_μ, and so on). A repeated a is summed. The dynamics follow from

$$S = \int d^4x\, \mathcal{L}(\phi_a, \partial_\mu \phi_a), \tag{6.155}$$

where the crucial structural fact is that $\mathcal{L}$ depends on the spacetime point x *only* through the fields and their derivatives—there is no explicit factor of x^μ multiplying anything. This is precisely the statement that the laws of motion are the same at every point of spacetime: a field configuration and its rigidly translated copy obey identical equations. We now extract the conserved current encoded in that homogeneity.

Consider an infinitesimal constant translation of the spacetime argument,

$$x^\mu \;\longrightarrow\; x'^\mu = x^\mu + a^\mu, \qquad a^\mu = \text{const, infinitesimal.} \tag{6.156}$$

A translation carries a field configuration to a new one whose value at the shifted point equals the old value at the old point, $\phi'_a(x') = \phi_a(x)$. Re-expressed at a fixed coordinate x, the new configuration is the old one evaluated a step back, $\phi'_a(x) = \phi_a(x - a)$. To first order in a,

$$\delta\phi_a(x) \;\equiv\; \phi'_a(x) - \phi_a(x) = -\,a^\nu\,\partial_\nu\phi_a(x). \tag{6.157}$$

This is the variation of the fields induced by the symmetry; it is what we feed into the action.

We need two independent expressions for the resulting change $\delta\mathcal{L}$ in the Lagrangian density, one a kinematic identity true for any field configuration, the other valid only on solutions. Their equality is the conservation law.

The identity (off shell). Because $\mathcal{L}$ has no explicit x-dependence, shifting the fields by Eq. (6.157) shifts $\mathcal{L}$ as the corresponding total derivative. Compute the variation by the chain rule,

$$\delta\mathcal{L} = \frac{\partial\mathcal{L}}{\partial\phi_a}\,\delta\phi_a + \frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi_a)}\,\partial_\mu(\delta\phi_a), \tag{6.158}$$

where we used $\delta(\partial_\mu\phi_a) = \partial_\mu(\delta\phi_a)$, the variation commuting with the derivative. Substituting Eq. (6.157),

$$\delta\mathcal{L} = -a^\nu\left[\frac{\partial\mathcal{L}}{\partial\phi_a}\,\partial_\nu\phi_a + \frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi_a)}\,\partial_\mu\partial_\nu\phi_a\right] = -a^\nu\,\partial_\nu\mathcal{L}. \tag{6.159}$$

The bracket is exactly the chain-rule expansion of the total derivative $\partial_\nu\mathcal{L}$, legitimate *only* because $\mathcal{L}$ carries no explicit x^ν; any explicit dependence would have left an uncancelled $\partial_\nu\mathcal{L}\big|_{\text{expl}}$. Equation Eq. (6.159) holds for every field configuration, solution or not. Rewrite it as a four-divergence,

$$\delta\mathcal{L} = -a^\nu\,\partial_\nu\mathcal{L} = -\,\partial_\mu(a^\nu\,\delta^\mu{}_\nu\,\mathcal{L}), \tag{6.160}$$

using $\partial_\nu = \delta^\mu{}_\nu\partial_\mu$ and the constancy of a^ν.

The dynamical expression (on shell). Now suppose ϕ_a solves the Euler–Lagrange equations of Section 6.2,

$$\frac{\partial\mathcal{L}}{\partial\phi_a} - \partial_\mu\frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi_a)} = 0. \tag{6.161}$$

Return to the general chain-rule form Eq. (6.158), valid for *any* variation, and trade $\partial\mathcal{L}/\partial\phi_a$ for the divergence of the momentum using Eq. (6.161):

$$\delta\mathcal{L} = \left(\partial_\mu\frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi_a)}\right)\delta\phi_a + \frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi_a)}\,\partial_\mu(\delta\phi_a) = \partial_\mu\left(\frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi_a)}\,\delta\phi_a\right), \tag{6.162}$$

the last step the Leibniz rule run backwards. This is again a pure four-divergence, but its content is now dynamical: it used the equations of motion.

Equating the two. On a solution both Eq. (6.160) and Eq. (6.162) hold, so their difference vanishes:

$$\partial_\mu \left(\frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)} \, \delta\phi_a + a^\nu \, \delta^\mu{}_\nu \, \mathcal{L} \right) = 0. \tag{6.163}$$

Insert $\delta\phi_a = -a^\nu \partial_\nu \phi_a$ from Eq. (6.157) and pull out the arbitrary constant a^ν:

$$a^\nu \, \partial_\mu \left[\frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)} \, \partial_\nu \phi_a - \delta^\mu{}_\nu \, \mathcal{L} \right] = 0. \tag{6.164}$$

Since the four numbers a^ν are independent, each of the four currents in brackets is separately conserved. Raising the free index with $\eta^{\nu\rho}$, we have proved the central object of this section.

Definition 6.28 (Canonical stress–energy tensor)**.** For a theory with Lagrangian density $\mathcal{L}(\phi_a, \partial_\mu \phi_a)$ free of explicit spacetime dependence, the *canonical stress–energy tensor* (also called the canonical energy–momentum tensor) is

$$\boxed{T^{\mu\nu} = \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)} \, \partial^\nu \phi_a - \eta^{\mu\nu} \mathcal{L}} \tag{6.165}$$

with an implicit sum over the field index a. It is the Noether current of the four constant spacetime translations: the free index ν labels which translation (one for time, three for space), while μ is the current's spacetime index.

The structure is worth reading aloud. The first term is "conjugate momentum density times the gradient of the field along direction ν"—the field-theoretic analogue of $p\,\dot{q}$. The second subtracts off $\eta^{\mu\nu}\mathcal{L}$, exactly the subtraction a Legendre transform performs. Setting $\mu = \nu = 0$ will reproduce $\pi_a \dot{\phi}_a - \mathcal{L} = \mathcal{H}$, which is the promised identification and the reason the same letter "$\mathcal{H}$" was chosen for the energy density in Section 6.4.

6.6.2 On-shell conservation, by direct computation

The derivation above already establishes $\partial_\mu T^{\mu\nu} = 0$ as a by-product of equating Eq. (6.160) and Eq. (6.162). It is nonetheless instructive—and a useful independent check that no sign slipped—to verify the conservation law by brute differentiation of Eq. (6.165), substituting the equations of motion at the one place they are needed. This is the template the general Noether theorem will follow.

Theorem 6.29 (Conservation of the canonical stress tensor)**.** *Let ϕ_a satisfy the Euler–Lagrange equations Eq. (6.161). Then the canonical stress–energy tensor Eq. (6.165) is conserved on every index,*

$$\partial_\mu T^{\mu\nu} = 0. \tag{6.166}$$

Proof. Differentiate Eq. (6.165) and apply the product rule to the first term:

$$\partial_\mu T^{\mu\nu} = \left(\partial_\mu \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)}\right) \partial^\nu \phi_a + \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)}\, \partial_\mu \partial^\nu \phi_a - \partial^\nu \mathcal{L}. \tag{6.167}$$

In the first term, the divergence of the canonical momentum is exactly what the Euler–Lagrange equation Eq. (6.161) equates to $\partial \mathcal{L}/\partial \phi_a$; this is the single, decisive use of the equations of motion. Substituting,

$$\partial_\mu T^{\mu\nu} = \frac{\partial \mathcal{L}}{\partial \phi_a}\, \partial^\nu \phi_a + \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)}\, \partial_\mu \partial^\nu \phi_a - \partial^\nu \mathcal{L}. \tag{6.168}$$

The remaining task is purely kinematic: expand the last term by the chain rule. Since $\mathcal{L}$ has no explicit x-dependence,

$$\partial^\nu \mathcal{L} = \eta^{\nu\rho} \partial_\rho \mathcal{L} = \eta^{\nu\rho} \left[\frac{\partial \mathcal{L}}{\partial \phi_a}\, \partial_\rho \phi_a + \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)}\, \partial_\rho \partial_\mu \phi_a \right] = \frac{\partial \mathcal{L}}{\partial \phi_a}\, \partial^\nu \phi_a + \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)}\, \partial^\nu \partial_\mu \phi_a. \tag{6.169}$$

The first piece of Eq. (6.169) cancels the first term of Eq. (6.168); the second piece cancels the second term, because partial derivatives commute, $\partial_\mu \partial^\nu \phi_a = \partial^\nu \partial_\mu \phi_a$. Every term has paired off, and

$$\partial_\mu T^{\mu\nu} = 0. \tag{6.170}$$

□

The proof exposes the anatomy of every conservation law to come. Two ingredients combine: a kinematic identity that holds because the Lagrangian is translation-homogeneous (the expansion of $\partial^\nu \mathcal{L}$), and a single substitution of the equations of motion (the divergence of the canonical momentum). Chapter 7 will show that this is the universal shape of Noether's theorem—one identity from the symmetry, one substitution of the dynamics—with spacetime translations merely the first and most concrete example.

6.6.3 Charges: the conserved four-momentum

A conserved current yields a conserved charge by integrating its time component over a spatial slice. Here there are four currents, indexed by ν, so there are four charges, and they assemble into a four-vector.

Definition 6.30 (Four-momentum of the field)**.** The total energy–momentum carried by a field configuration is

$$P^\nu = \int d^3x\, T^{0\nu}(t, \mathbf{x}). \tag{6.171}$$

Proposition 6.31 (Conservation of P^ν)**.** *If the fields and their conjugate momenta fall off fast enough at spatial infinity that surface terms vanish, then P^ν is independent of time, $dP^\nu/dt = 0$.*

Proof. Differentiate Eq. (6.171) under the integral and split the conservation law Eq. (6.166) into its time and space parts, $\partial_\mu T^{\mu\nu} = \partial_0 T^{0\nu} + \partial_i T^{i\nu} = 0$:

$$\frac{dP^\nu}{dt} = \int d^3x\, \partial_0 T^{0\nu} = -\int d^3x\, \partial_i T^{i\nu} = -\oint_{S_\infty} dS_i\, T^{i\nu} = 0, \tag{6.172}$$

the third equality the divergence theorem in three dimensions, the last the assumed decay at infinity. The same computation is the field-theoretic restatement of "the rate of change of the charge inside a region equals minus the flux of the current through its boundary," with $T^{i\nu}$ the flux of the ν-th charge. □

Now identify the components. The time–time component, with $\partial^0 = \partial_0$ and $\eta^{00} = +1$, is

$$T^{00} = \frac{\partial \mathcal{L}}{\partial(\partial_0 \phi_a)}\, \partial^0 \phi_a - \eta^{00}\mathcal{L} = \pi_a\, \dot{\phi}_a - \mathcal{L} = \mathcal{H}, \tag{6.173}$$

precisely the Hamiltonian density of Section 6.4, since $\pi_a = \partial\mathcal{L}/\partial\dot{\phi}_a$ is the canonical momentum and $\dot{\phi}_a = \partial^0\phi_a$. Therefore the conserved charge for time translations is the Hamiltonian itself,

$$P^0 = \int d^3x\, T^{00} = \int d^3x\, \mathcal{H} = H. \tag{6.174}$$

This is the loop the chapter set out to close: *energy is the Noether charge of time translation, and the covariant tensor Eq. (6.165) reproduces the Hamiltonian density built non-covariantly two sections ago.* The spatial charges are the field momentum,

$$P^i = \int d^3x\, T^{0i} = \int d^3x\, \pi_a\, \partial^i \phi_a = -\int d^3x\, \pi_a\, \partial_i \phi_a, \tag{6.175}$$

using $\partial^i = -\partial_i$. The conserved $P^\mu = (H, \mathbf{P})$ is the classical precursor of the momentum operator that Chapter 9 promotes to the generator of translations on Fock space; its very existence is the statement that a free or self-interacting field, like an isolated mechanical system, carries a definite total energy and momentum that the equations of motion preserve.

Physical Insight

The four-by-four array $T^{\mu\nu}$ records the entire flow of energy and momentum through spacetime. Read the first index μ as "which face of an infinitesimal box" (the 0-face is a snapshot in time, the i-face is a wall in space) and the second index ν as "which component of four-momentum." Then T^{00} is energy per unit volume, T^{0i} is the density of the i-momentum (equivalently, by symmetry of the improved tensor, the flux of energy in direction i—the Poynting vector for the electromagnetic field), T^{i0} is the flux of energy through the i-wall, and T^{ij} is the flux of j-momentum through the i-

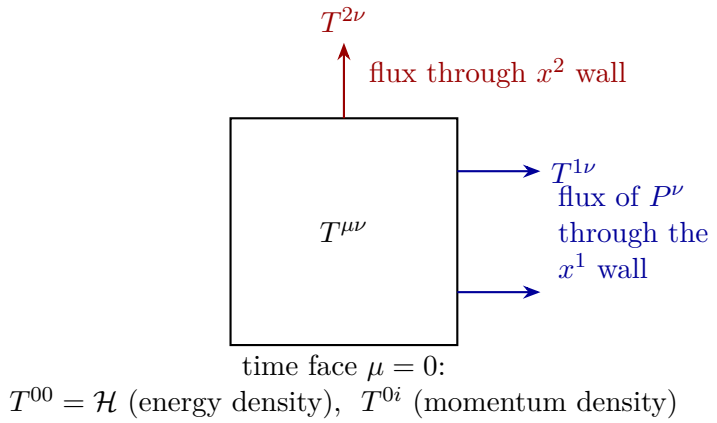

Figure 6.4: The stress–energy tensor as flux bookkeeping. The component $T^{\mu\nu}$ is the flow of the ν-th component of four-momentum across a surface of constant x^μ. The conservation law $\partial_\mu T^{\mu\nu} = 0$ states that for each fixed ν the change in the charge $\int T^{0\nu}$ inside a region equals minus the flux $T^{i\nu}$ through its walls.

wall, i.e. the mechanical stress—pressure on the diagonal, shear off it. Conservation $\partial_\mu T^{\mu\nu} = 0$ is the bookkeeping that none of it is created or destroyed, only transported.

6.6.4 Scalar ϕ^4 theory: the scalar stress tensor in full

We now make the abstract formula concrete on the field that will accompany us through the whole book. The classical $\lambda\phi^4$ theory introduced in Section 6.3 has Lagrangian density

$$\mathcal{L} = \tfrac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4, \qquad \phi \text{ real},\ \lambda > 0, \tag{6.176}$$

whose Euler–Lagrange equation is $(\Box + m^2)\phi = -\frac{\lambda}{3!}\phi^3$. We continue ϕ^4 theory from the equation of motion of Section 6.2 and the Hamiltonian density of Section 6.4.

Worked Example 6.32 (Stress–energy tensor of $\lambda\phi^4$, and the check $T^{00} = \mathcal{H}$)**.** There is a single field, so the index a is trivial. The only derivative-dependence is in the kinetic term; differentiating Eq. (6.176),

$$\frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi)} = \partial^\mu\phi. \tag{6.177}$$

Inserting this and Eq. (6.176) into the master formula Eq. (6.165) gives the

canonical stress tensor of the scalar,

$$T^{\mu\nu} = \partial^\mu\phi\,\partial^\nu\phi - \eta^{\mu\nu}\left[\tfrac{1}{2}(\partial_\alpha\phi)(\partial^\alpha\phi) - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4\right]. \tag{6.178}$$

A scalar field carries no internal spacetime indices, so the only index structure available is $\partial^\mu\phi\,\partial^\nu\phi$ and $\eta^{\mu\nu}$ times scalars; consequently Eq. (6.178) is automatically *symmetric*, $T^{\mu\nu} = T^{\nu\mu}$, and manifestly built from ϕ alone (no gauge ambiguity). The scalar is the lucky case where the canonical tensor already has every property one could want—a fact that throws the defects of the Dirac and Maxwell tensors below into sharp relief.

Energy density. Set $\mu = \nu = 0$. With $\partial^0\phi = \dot\phi$ and the spatial split $(\partial_\alpha\phi)(\partial^\alpha\phi) = \dot\phi^2 - (\nabla\phi)^2$,

$$\begin{aligned} T^{00} &= \dot\phi^2 - \left[\tfrac{1}{2}\dot\phi^2 - \tfrac{1}{2}(\nabla\phi)^2 - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4\right] \\ &= \tfrac{1}{2}\dot\phi^2 + \tfrac{1}{2}(\nabla\phi)^2 + \tfrac{1}{2}m^2\phi^2 + \frac{\lambda}{4!}\phi^4. \end{aligned} \tag{6.179}$$

With the canonical momentum $\pi = \dot\phi$ of Section 6.4, this is verbatim the Hamiltonian density

$$\mathcal{H} = \tfrac{1}{2}\pi^2 + \tfrac{1}{2}(\nabla\phi)^2 + \tfrac{1}{2}m^2\phi^2 + \frac{\lambda}{4!}\phi^4 \tag{6.180}$$

obtained there by Legendre transform. The general identity Eq. (6.173) is confirmed in the concrete case: every term—kinetic, gradient, mass, quartic—matches, and the energy density is manifestly non-negative, as a sensible energy must be.

Momentum density. Set $\mu = 0$, $\nu = i$. The metric term drops because $\eta^{0i} = 0$:

$$T^{0i} = \partial^0\phi\,\partial^i\phi = \dot\phi\,\partial^i\phi = -\dot\phi\,\partial_i\phi. \tag{6.181}$$

The field-momentum density is $\mathcal{P}^i = T^{0i} = -\dot\phi\,\partial_i\phi$, so that the conserved spatial momentum of the configuration is $P^i = -\int d^3x\,\dot\phi\,\partial_i\phi$, in agreement with the general expression Eq. (6.175) at $\pi = \dot\phi$. Physically a travelling wave $\phi \propto \cos(k\cdot x)$ has $\dot\phi$ and $\nabla\phi$ in step, so $\mathcal{P}^i$ points along $\mathbf{k}$: the field transports momentum in its direction of propagation.

Trace and broken scale invariance. Contracting Eq. (6.178) with $\eta_{\mu\nu}$, and using $\eta_{\mu\nu}\eta^{\mu\nu} = 4$ in four dimensions,

$$T^\mu{}_\mu = (\partial_\alpha\phi)(\partial^\alpha\phi) - 4\left[\tfrac{1}{2}(\partial_\alpha\phi)(\partial^\alpha\phi) - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4\right] = -(\partial_\alpha\phi)(\partial^\alpha\phi) + 2m^2\phi^2 + \frac{\lambda}{3!}\phi^4. \tag{6.182}$$

This off-shell expression simplifies decisively on a solution. Multiply the equation of motion, written as $\Box\phi = -m^2\phi - \frac{\lambda}{3!}\phi^3$, by ϕ and combine it with the identity

$\phi\,\Box\phi = \partial_\alpha(\phi\,\partial^\alpha\phi) - (\partial_\alpha\phi)(\partial^\alpha\phi)$ to isolate the kinetic scalar,

$$(\partial_\alpha\phi)(\partial^\alpha\phi) = \partial_\alpha(\phi\,\partial^\alpha\phi) - \phi\,\Box\phi = \partial_\alpha(\phi\,\partial^\alpha\phi) + m^2\phi^2 + \frac{\lambda}{3!}\phi^4. \tag{6.183}$$

Substituting Eq. (6.183) into the trace Eq. (6.182), the two quartic terms cancel and a single mass term survives:

$$T^\mu{}_\mu \overset{\text{on shell}}{=} -\Big[\partial_\alpha(\phi\,\partial^\alpha\phi) + m^2\phi^2 + \frac{\lambda}{3!}\phi^4\Big] + 2m^2\phi^2 + \frac{\lambda}{3!}\phi^4 = m^2\phi^2 - \partial_\alpha(\phi\,\partial^\alpha\phi). \tag{6.184}$$

The result is sharper than Eq. (6.182) alone suggested: up to the total derivative $-\partial_\alpha(\phi\,\partial^\alpha\phi)$, the on-shell trace is *purely* $m^2\phi^2$, and the quartic has dropped out entirely. This is the classical statement that $\lambda\phi^4$ in four dimensions is a *marginal* interaction. The coupling λ is dimensionless, so $\int d^4x\,\frac{\lambda}{4!}\phi^4$ is invariant under the rescaling $x \to e^{-\omega}x$, $\phi(x) \to e^{\omega}\phi(e^{\omega}x)$ in which ϕ carries its canonical mass dimension one; the quartic alone therefore does not obstruct scale invariance. The single obstruction is the mass term: $\int d^4x\,\frac{1}{2}m^2\phi^2$ fails to be scale invariant precisely because m is dimensionful, and it is exactly $m^2\phi^2$ that remains in Eq. (6.184). A traceless stress tensor is the local signature of invariance under those rescalings; the massless theory ($m = 0$) has, once the improvement discussed below removes the total-derivative remnant, a traceless tensor and is classically scale—indeed conformally—invariant, while a nonzero m breaks it. The fingerprint $T^\mu{}_\mu \propto m^2\phi^2$ is the seed of the dilatation current that Chapter 7 will construct; and the fact that the classically harmless coupling λ nonetheless breaks scale invariance *quantum* mechanically—through the running of λ and the attendant trace anomaly—is one of the deepest threads the book follows downstream.

6.6.5 Two defects of the canonical tensor

The scalar lulled us: its canonical $T^{\mu\nu}$ was symmetric and built only from the field. That is an accident of spin zero. The two other protagonists of the book expose what the construction generically produces, and the failures point straight at the repairs that Chapter 7 will carry out.

Dirac: non-symmetric. The free Dirac Lagrangian of Section 6.3 is

$$\mathcal{L}_D = \bar\psi\,(i\partial\!\!\!/ - m)\,\psi = \bar\psi\,(i\gamma^\mu\partial_\mu - m)\,\psi, \tag{6.185}$$

with ψ and $\bar\psi = \psi^\dagger\gamma^0$ treated as independent fields (the gamma conventions are those of Chapter C). Only ψ is differentiated, so $\partial\mathcal{L}_D/\partial(\partial_\mu\bar\psi) = 0$ and

$$\frac{\partial\mathcal{L}_D}{\partial(\partial_\mu\psi)} = \bar\psi\,i\gamma^\mu. \tag{6.186}$$

The master formula Eq. (6.165) then gives

$$T_D^{\mu\nu} = i\,\bar\psi\,\gamma^\mu\partial^\nu\psi - \eta^{\mu\nu}\mathcal{L}_D. \tag{6.187}$$

On shell the Dirac equation $(i\partial\!\!\!/ - m)\psi = 0$ makes the Lagrangian Eq. (6.185) vanish identically, so the metric term drops and

$$T_D^{\mu\nu} \overset{\text{on shell}}{=} i\,\bar\psi\,\gamma^\mu\partial^\nu\psi. \tag{6.188}$$

This is patently *not* symmetric under $\mu \leftrightarrow \nu$: the index μ sits on a gamma matrix while ν sits on a derivative, and $i\bar\psi\gamma^\mu\partial^\nu\psi \neq i\bar\psi\gamma^\nu\partial^\mu\psi$ in general. Its antisymmetric part $T_D^{[\mu\nu]} = \frac{i}{2}\bar\psi(\gamma^\mu\partial^\nu - \gamma^\nu\partial^\mu)\psi$ is non-vanishing, and—as the angular-momentum analysis below shows—it is exactly the divergence of the electron's intrinsic spin current. Spin-$\frac{1}{2}$ matter cannot have a symmetric canonical stress tensor; the asymmetry *is* the spin.

Maxwell: non-symmetric and non-gauge-invariant. The free Maxwell Lagrangian of Section 6.3 is

$$\mathcal{L}_{\text{Max}} = -\tfrac{1}{4}F_{\alpha\beta}F^{\alpha\beta}, \qquad F_{\alpha\beta} = \partial_\alpha A_\beta - \partial_\beta A_\alpha, \tag{6.189}$$

the dynamical fields being the four components A_ρ. Differentiating with respect to $\partial_\mu A_\rho$ and using $\partial F_{\alpha\beta}/\partial(\partial_\mu A_\rho) = \delta^\mu{}_\alpha\delta^\rho{}_\beta - \delta^\mu{}_\beta\delta^\rho{}_\alpha$,

$$\frac{\partial\mathcal{L}_{\text{Max}}}{\partial(\partial_\mu A_\rho)} = -\tfrac{1}{4}\cdot 2\,F^{\alpha\beta}(\delta^\mu{}_\alpha\delta^\rho{}_\beta - \delta^\mu{}_\beta\delta^\rho{}_\alpha) = -\tfrac{1}{2}(F^{\mu\rho} - F^{\rho\mu}) = -F^{\mu\rho}. \tag{6.190}$$

The master formula Eq. (6.165) then yields the canonical electromagnetic stress tensor

$$\boxed{T^{\mu\nu}_{\text{can}} = -F^{\mu\rho}\,\partial^\nu A_\rho + \tfrac{1}{4}\,\eta^{\mu\nu}F_{\alpha\beta}F^{\alpha\beta}} \tag{6.191}$$

and it suffers *both* diseases at once. First, it is not symmetric: the term $-F^{\mu\rho}\partial^\nu A_\rho$ has no symmetry between μ (on the field strength) and ν (on the derivative). Second, and worse, it is not gauge invariant: it contains the bare potential A_ρ and its undifferentiated gradient $\partial^\nu A_\rho$, not the gauge-invariant F. Under $A_\rho \to A_\rho + \partial_\rho\chi$,

$$T^{\mu\nu}_{\text{can}} \;\longrightarrow\; T^{\mu\nu}_{\text{can}} - F^{\mu\rho}\,\partial^\nu\partial_\rho\chi, \tag{6.192}$$

which does not vanish. A physically meaningful energy density cannot depend on a choice of gauge; Eq. (6.191) as it stands is unacceptable as the energy of the electromagnetic field. (One quickly checks that its $T^{00} = -F^{0\rho}\partial^0 A_\rho + \frac{1}{4}F^2$ is neither the familiar $\frac{1}{2}(\mathbf{E}^2 + \mathbf{B}^2)$ nor even gauge invariant.)

Caution

The non-symmetry and non-gauge-invariance of $T^{\mu\nu}_{\text{can}}$ are defects of the *canonical* construction, not of the physics. The conserved charges $P^\nu = \int d^3x\, T^{0\nu}$ are perfectly correct—they are the true energy and momentum—because a current is only fixed up to the addition of an identically conserved "improvement" term that integrates to zero. What is wrong is the local distribution of energy and momentum, $T^{\mu\nu}(x)$ itself, which the canonical recipe gets gauge-dependent and asymmetric. The cure is to add such an improvement term.

6.6.6 The improvement program, and angular momentum

Both defects are repaired by adding to $T^{\mu\nu}$ a term of the form $\partial_\rho K^{\rho\mu\nu}$ with K antisymmetric in its first two indices, $K^{\rho\mu\nu} = -K^{\mu\rho\nu}$. Antisymmetry guarantees two things at once: the addition is identically conserved in μ, $\partial_\mu\partial_\rho K^{\rho\mu\nu} = 0$, so $\partial_\mu T^{\mu\nu} = 0$ is preserved; and it leaves the charges untouched, since $\int d^3x\, \partial_\rho K^{\rho 0\nu} = \int d^3x\, \partial_i K^{i0\nu}$ is a spatial surface integral that vanishes at infinity (the $\rho = 0$ term drops by antisymmetry $K^{00\nu} = 0$). One is therefore free to choose K to mend the tensor without disturbing P^ν. For electromagnetism the choice $K^{\rho\mu\nu} = F^{\mu\rho}A^\nu$ does the job: on shell, where $\partial_\rho F^{\rho\mu} = 0$,

$$T^{\mu\nu}_{\text{can}} + \partial_\rho\big(F^{\mu\rho}A^\nu\big) = -F^{\mu\rho}\big(\partial^\nu A_\rho - \partial_\rho A^\nu\big) + \tfrac{1}{4}\eta^{\mu\nu}F^2 = -F^{\mu\rho}F^{\nu}{}_{\rho} + \tfrac{1}{4}\eta^{\mu\nu}F_{\alpha\beta}F^{\alpha\beta}, \tag{6.193}$$

which is at once symmetric in $\mu\nu$ and built entirely from the gauge-invariant F; its $T^{00} = \frac{1}{2}(\mathbf{E}^2 + \mathbf{B}^2)$ and $T^{0i} = (\mathbf{E}\times\mathbf{B})^i$ are the textbook electromagnetic energy density and Poynting vector. We display Eq. (6.193) only as a preview of where the story lands; the *systematic* construction—the Belinfante–Rosenfeld procedure that produces the right K for any field of any spin from its behaviour under Lorentz transformations—belongs to Chapter 7, where it falls out naturally once Noether's theorem is in hand.

The deeper reason a symmetric tensor is the correct target is angular momentum. Lorentz invariance furnishes its own Noether current, the angular-momentum current, which (anticipating the full derivation in Chapter 7) has the schematic form

$$M^{\mu\,\nu\rho} = \underbrace{x^\nu T^{\mu\rho} - x^\rho T^{\mu\nu}}_{\text{orbital}} + \underbrace{S^{\mu\,\nu\rho}}_{\text{spin}}, \tag{6.194}$$

antisymmetric in $\nu\rho$, with $S^{\mu\nu\rho}$ the contribution from the intrinsic transformation of the fields (zero for a scalar, nonzero for the spinor and the vector). Taking its divergence on shell, and using $\partial_\mu T^{\mu\nu} = 0$,

$$\partial_\mu M^{\mu\,\nu\rho} = T^{\nu\rho} - T^{\rho\nu} + \partial_\mu S^{\mu\,\nu\rho}. \tag{6.195}$$

Conservation of total angular momentum, $\partial_\mu M^{\mu\nu\rho} = 0$, therefore forces the antisymmetric part of the stress tensor to be tied to the divergence of the spin current, $T^{\nu\rho} - T^{\rho\nu} = -\partial_\mu S^{\mu\nu\rho}$. This is the precise sense in which the Dirac asymmetry Eq. (6.188) "is" the electron's spin. It also shows that the very improvement term K that symmetrizes $T^{\mu\nu}$ is built from $S^{\mu\nu\rho}$: symmetrizing the stress tensor is the act of absorbing the spin current into the orbital part, so that for the improved tensor the orbital expression $x^\nu T^{\mu\rho} - x^\rho T^{\mu\nu}$ alone is conserved. The full statement and proof of Eqs. (6.194) and (6.195), and the Belinfante construction of the symmetric, gauge-invariant tensor, are the first order of business in Chapter 7.

With energy and momentum identified as the Noether charges of translation, and with the canonical tensor's two defects diagnosed and their cure named, the classical dynamics of fields is complete. Chapter 7 promotes the single computation of this section into Noether's theorem for every continuous symmetry—internal as well as spacetime—and discharges the deferred items: the symmetric Belinfante stress tensor, the angular-momentum current in full, and, for ϕ^4 theory, the $\mathbb{Z}_2$ symmetry $\phi \to -\phi$ and the broken scale current foreshadowed by the non-zero trace Eq. (6.182). The conserved $P^\mu = (H, \mathbf{P})$ assembled here is, in turn, exactly the object that Chapter 9 will promote from a number to the operator generating spacetime translations on the quantum Hilbert space.

Further reading

The variational and canonical structure of classical field theory is treated in every comprehensive text on the subject; the presentations closest in spirit and convention to this chapter are [396, 432, 454], with [500] giving the most careful account of the relationship between Poincaré invariance and the field content, and [532] the most physically motivated overview. The classical-mechanics roots—Hamilton's principle, the Legendre transform, and the passage from discrete to continuous systems—are developed at length in [230] and, with characteristic economy and the field-theoretic stress tensor included, in [312]. The theory of singular Lagrangians and constrained Hamiltonian dynamics that we only open here is presented in its original form, and still most readably, in [152].

Chapter 7

Symmetries and Conservation Laws

Chapter 6 closed by extracting, from the invariance of the action under a rigid spacetime translation, the canonical stress–energy tensor and the conserved four-momentum it carries. That single computation was a special case of a general correspondence, and this chapter is its systematic development. The thesis is the one that organizes all of field theory: a continuous symmetry of the action is not merely an aesthetic feature but a *conservation law in disguise*, and the dictionary translating between the two—Emmy Noether's first theorem [369]—is local, constructive, and exact. Give the theorem a transformation and it returns a current whose divergence vanishes on shell; integrate that current over a spatial slice and it returns a charge that does not change in time. Energy, momentum, angular momentum, electric charge, and the internal quantum numbers that label particles into multiplets are all, without exception, outputs of this one machine fed different inputs.

We build the machine from the variational calculus assembled in Chapter 4 and the Euler–Lagrange equations and canonical structures of Chapter 6, and we phrase every field transformation in the representation-theoretic language of Chapter 3—fields carry a finite-dimensional representation of the Lorentz group, and the generators T^a of any internal symmetry obey the Lie-algebra conventions of Chapter 2. The opening section is careful bookkeeping: it separates the intrinsic variation of a field from the total variation that also moves the coordinate, derives the master identity for the first variation of the action, and fixes the precise notion of a continuous *quasi*-symmetry (invariance up to a boundary term). With those two ingredients in hand—the off-shell quasi-symmetry condition and the on-shell boundary reduction of the master identity—the second section proves the first theorem by setting the two against each other, defines the conserved current and charge, establishes the charge's time- and slice-independence, and isolates the improvement ambiguity that will be put to work twice later in the

chapter.

The remaining sections turn the crank. Switching off the coordinate piece gives the internal symmetries: the U(1) current of a complex scalar, the non-abelian currents of a multiplet, the proof that the charges generate the field transformation and close into the symmetry's Lie algebra, and—kept throughout as the instructive foil—the discrete $\mathbb{Z}_2$ of ϕ^4 theory, which yields no current but a sharp selection rule forbidding odd-point amplitudes. Switching the coordinate piece back on gives the spacetime symmetries: translations reproduce the canonical stress tensor of Chapter 6, Lorentz invariance delivers the angular-momentum current and exposes the spin current, and the ten Poincaré charges emerge as the classical precursors of the operators Chapter 9 will quantize. That construction surfaces a defect—the canonical tensor is generically neither symmetric nor (for gauge fields) gauge invariant—and the improvement freedom is spent repairing it into the symmetric, gauge-invariant Belinfante–Rosenfeld tensor [57, 419], the flat-space seed of the gravitational source.

The chapter then sharpens the global/local distinction with Noether's *second* theorem: when a symmetry parameter is allowed to vary from point to point, the would-be current is on-shell a pure superpotential divergence, its charge a boundary flux, and the genuine conserved charges of a theory are seen to come from its global symmetries while a local symmetry contributes only off-shell identities and a redundancy—precisely the logic Chapter 8 will run forward to derive electromagnetism from the gauge principle. A final section carries ϕ^4 theory to its symmetry layer, treating scale and conformal invariance: the dilatation current, the trace of the stress tensor as the diagnostic of scale breaking, the conformally improved traceless tensor, and the classical trace identity $\Theta^{\mu}_{\mathrm{c}\,\mu} = m^2\phi^2$ whose quantum deformation into the trace anomaly is the handoff to the renormalization group of Chapters 23 and 24 and the conformal-field-theory machinery of Chapters 47 and 52. Throughout, the conventions are those fixed for the whole book—the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$ and natural units $\hbar = c = 1$ collected in Chapter A, with the gamma-matrix algebra of Chapter C used wherever the Dirac field appears.

7.1 What Is a Symmetry? Variations, Invariance, and Quasi-Symmetry

The previous chapter handed us a complete classical apparatus: an action functional $S[\phi] = \int_\Omega \mathrm{d}^4x\, \mathcal{L}(\phi_a, \partial_\mu\phi_a, x)$ (6.25), the Euler–Lagrange equations $E_a[\mathcal{L}] = 0$ that its stationarity imposes (Theorem 6.8), the canonical momenta $\pi^a = \partial\mathcal{L}/\partial\dot{\phi}_a$ (6.96), and—worked out by hand for the single case of spacetime translations—a first conserved current, the canonical stress–energy tensor of Theorem 6.28. That last computation was the appetizer. It showed, in one concrete instance, that the *symmetries* of an action are not decorative facts

about a theory but the source of its conservation laws: invariance under rigid time translation produced the conserved energy, invariance under rigid space translation the conserved momentum. The thesis of this chapter is that this is completely general. Every continuous global symmetry of a classical field theory comes with an exact accounting identity—a locally conserved current and a time-independent charge—and the machine that manufactures the current from the symmetry is Noether's first theorem, proved in full in Section 7.2.

Before we can state that theorem, we must say with precision what is meant by "a symmetry," and we must set up the variational bookkeeping the proof will consume. Both tasks are subtler than the translation example let on. There, the transformation acted on the field and on the spacetime point at once, and we slipped between "the field changes" and "the point changes" without comment because for a rigid translation the two descriptions collapse into one. In general they do not, and Noether's theorem in its full reach—covering not just internal symmetries that leave the coordinates untouched but the Lorentz rotations and boosts that move them—demands that we keep the two kinds of change rigorously apart. This section builds that distinction (the *intrinsic* versus *total* variation), derives from it the single master identity for the first variation of a general transformation that every later section reuses, and pins down the precise sense in which a transformation can be called a symmetry: invariance of the action not necessarily on the nose but up to a boundary term, the notion of *quasi-symmetry*. Along the way we separate three things that are easy to conflate—symmetries of the action, symmetries of the equations of motion, and discrete transformations—only the first of which Noether's first theorem converts into a current.

7.1.1 Two notions of variation

A general transformation of a field theory acts on two things simultaneously: it moves each spacetime point, and it changes the value the field takes. Write the coordinate change as

$$x^\mu \longrightarrow x'^\mu = x^\mu + \delta x^\mu, \tag{7.1}$$

with δx^μ an infinitesimal displacement (constant for a translation, linear in x for a Lorentz rotation, and so on), and the field change as a new configuration ϕ'_a whose value at the new point x' is some prescribed function of the old data. The complete specification of a transformation is the pair $(\delta x^\mu,\ \phi'_a)$. The difficulty is that there are two inequivalent ways to measure "how much the field changed," and the literature's sign errors almost all trace to confusing them.

The first compares the new field with the old at the *same coordinate value*:

$$\delta\phi_a(x) \equiv \phi'_a(x) - \phi_a(x). \tag{7.2}$$

This is the *intrinsic* variation (also called the local, or form, variation): it asks how the functional *shape* of the field has changed at a fixed label x, holding the

coordinate fixed and comparing two functions of it. It is exactly the variation $\delta\phi_a$ that Theorem 6.8 was built on, where the coordinates never moved at all ($\delta x = 0$), and it is the object the Euler–Lagrange derivation requires, because only at a fixed point can one subtract two field values and call the difference a variation.

The second comparison follows the point as it moves and compares the new field at the new point with the old field at the old point:

$$\bar{\delta}\phi_a(x) \;\equiv\; \phi'_a(x') - \phi_a(x). \tag{7.3}$$

This is the *total* variation: it measures the change experienced by an observer carried along by the transformation, the full change in the field including the effect of the coordinate transport. For a translation $x' = x + a$ that carries a configuration rigidly, demanding the moved field agree with the original—$\phi'_a(x') = \phi_a(x)$, the defining property of a rigid displacement—means $\bar{\delta}\phi_a = 0$ even though $\delta\phi_a \neq 0$; the field looks unchanged to the comoving observer precisely because the whole profile slid along with the frame.

Definition 7.1 (Intrinsic and total variation)**.** For a transformation $(\delta x^\mu, \phi'_a)$ acting on a field theory, the *intrinsic* (same-point) variation is $\delta\phi_a(x) \equiv \phi'_a(x) - \phi_a(x)$ and the *total* variation is $\bar{\delta}\phi_a(x) \equiv \phi'_a(x') - \phi_a(x)$, both taken to first order in the infinitesimal parameters of the transformation.

The two are related by a single term, the coordinate transport. Expand the total variation by moving the evaluation point of the *new* field from x' back to x:

$$\phi'_a(x') \;=\; \phi'_a(x + \delta x) \;=\; \phi'_a(x) + \delta x^\mu\, \partial_\mu \phi'_a(x) + O(\delta^2). \tag{7.4}$$

In the second term we may replace $\partial_\mu \phi'_a$ by $\partial_\mu \phi_a$, since their difference $\partial_\mu(\delta\phi_a)$ is already first order and the prefactor δx^μ is too, making the discrepancy second order. Subtracting $\phi_a(x)$ from both sides of Eq. (7.4) and using the two definitions,

$$\boxed{\bar{\delta}\phi_a \;=\; \delta\phi_a \;+\; \delta x^\mu\, \partial_\mu \phi_a} \tag{7.5}$$

to first order. The total change equals the intrinsic change at fixed coordinate plus the change $\delta x^\mu \partial_\mu \phi_a$ accumulated by sliding the evaluation point through the field's own gradient. Equation Eq. (7.5) is the hinge of all later bookkeeping: it lets us translate between the comoving description (natural for stating what a symmetry *does*—"the field is a scalar, so it is carried unchanged") and the fixed-point description (mandatory for varying the action). For an internal transformation, which by definition leaves the coordinates alone ($\delta x^\mu = 0$), the two variations coincide, $\bar{\delta}\phi_a = \delta\phi_a$; the distinction has teeth only for spacetime symmetries.

A property that will be used constantly: the intrinsic variation commutes with the spacetime derivative, while the total variation does not. For the intrinsic

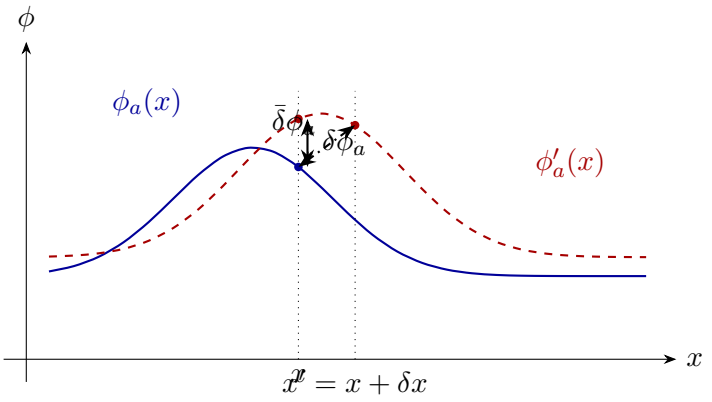

Figure 7.1: The two variations of a field. The solid curve is the original profile ϕ_a, the dashed curve the transformed profile ϕ'_a. The *intrinsic* variation $\delta\phi_a = \phi'_a(x) - \phi_a(x)$ compares the two profiles at the same coordinate x (vertical double arrow). The *total* variation $\bar{\delta}\phi_a = \phi'_a(x') - \phi_a(x)$ also accounts for the displacement of the evaluation point to $x' = x + \delta x$ (slanted dash-dotted arrow). The difference between them is the transport term $\delta x^\mu \partial_\mu \phi_a$ of Eq. (7.5).

variation,

$$\delta(\partial_\mu \phi_a) = \partial_\mu \phi'_a(x) - \partial_\mu \phi_a(x) = \partial_\mu(\phi'_a(x) - \phi_a(x)) = \partial_\mu(\delta\phi_a), \tag{7.6}$$

because δ subtracts two functions at the same argument, and the derivative of a difference is the difference of derivatives. This is the same fact already used in Eq. (6.32) to derive the Euler–Lagrange equations. The total variation enjoys no such identity: from Eq. (7.5),

$$\bar{\delta}(\partial_\mu \phi_a) = \partial_\mu(\delta\phi_a) + \delta x^\nu \, \partial_\nu \partial_\mu \phi_a = \partial_\mu(\bar{\delta}\phi_a) - (\partial_\mu \delta x^\nu)\, \partial_\nu \phi_a, \tag{7.7}$$

where the last form follows by differentiating Eq. (7.5) and rearranging. The obstruction is the term $(\partial_\mu \delta x^\nu)\partial_\nu \phi_a$, which vanishes only when the coordinate displacement is constant. This is precisely why one varies the action through the intrinsic variation $\delta\phi_a$ and never directly through $\bar{\delta}\phi_a$: the integration by parts that produced the Euler–Lagrange operator relied on δ passing freely through ∂_μ, a privilege $\bar{\delta}$ does not hold.

Worked Example 7.2 (The two variations for a scalar under translation and Lorentz rotation)**.** We exercise Eq. (7.5) on the two transformations that matter most, taking a single real scalar field ϕ, for which the comoving prescription is the simplest possible: a scalar is carried unchanged by the flow, $\phi'(x') = \phi(x)$, i.e. $\bar{\delta}\phi = 0$.

Translation. Let $\delta x^\mu = a^\mu$ with a^μ a constant infinitesimal. With $\bar{\delta}\phi = 0$, the relation Eq. (7.5) gives the intrinsic variation immediately,

$$\delta\phi = \bar{\delta}\phi - \delta x^\mu \partial_\mu \phi = -a^\mu \partial_\mu \phi, \tag{7.8}$$

which is exactly the field variation Eq. (6.157) that drove the stress-tensor construction of the previous chapter. The intrinsic variation is nonzero—at a fixed coordinate the field value genuinely changes—while the total variation vanishes. Check the commutation claims directly: $\delta(\partial_\mu\phi) = \partial_\mu(\delta\phi) = -a^\nu\partial_\nu\partial_\mu\phi$ is symmetric and consistent, whereas $\bar\delta(\partial_\mu\phi) = \partial_\mu\bar\delta\phi - (\partial_\mu\delta x^\nu)\partial_\nu\phi = 0$ here only because $\partial_\mu a^\nu = 0$; the constancy of the translation is what makes both descriptions tidy.

Lorentz rotation. Let $\delta x^\mu = \omega^\mu{}_\nu x^\nu$ with $\omega_{\mu\nu} = -\omega_{\nu\mu}$ the infinitesimal antisymmetric parameter of an $\mathrm{SO}(1,3)$ transformation (the antisymmetry is the condition that the metric be preserved, $\delta(\eta_{\mu\nu}x^\mu x^\nu) = 0$; the parametrization is fixed in Chapter 3). A scalar still rides along unchanged, $\bar\delta\phi = 0$, so

$$\delta\phi = -\delta x^\mu\partial_\mu\phi = -\omega^\mu{}_\nu x^\nu\,\partial_\mu\phi = +\tfrac{1}{2}\,\omega_{\mu\nu}(x^\mu\partial^\nu - x^\nu\partial^\mu)\phi, \tag{7.9}$$

the last equality obtained by writing $\omega^\mu{}_\nu x^\nu\partial_\mu = \omega_{\mu\nu}x^\nu\partial^\mu$ and antisymmetrizing in $(\mu\nu)$ against the antisymmetric $\omega_{\mu\nu}$. The differential operator in brackets is the orbital angular-momentum generator the reader will recognize from Chapter 3; here it has fallen out purely from the relation between the two variations. Now the non-commutation of $\bar\delta$ is real and instructive: from Eq. (7.7) with $\partial_\mu\delta x^\nu = \omega^\nu{}_\mu \neq 0$,

$$\bar\delta(\partial_\mu\phi) = -\omega^\nu{}_\mu\,\partial_\nu\phi \neq 0. \tag{7.10}$$

The total variation of the field is zero, but the total variation of its gradient is *not*: the gradient of a scalar is a vector, and a vector is rotated by the transformation even though the scalar is not. This is the precise content of "$\bar\delta$ does not commute with ∂_μ," and it is why the gradient must be varied through δ, not $\bar\delta$, when we attack the action.

7.1.2 The first variation of the action: the master identity

We now compute how the action responds to a completely general infinitesimal transformation $(\delta x^\mu, \delta\phi_a)$, with no assumption yet that the transformation is a symmetry of anything. The result is a single identity—valid for every field configuration, on shell or off—that the entire chapter consumes: Noether's first theorem reads a conservation law off it, the energy–momentum and angular-momentum currents of Section 7.4 are special cases, and the second theorem of Section 7.6 pushes it one step further.

The transformation deforms both the integrand and the region of integration, so the varied action is

$$S' \;=\; \int_{\Omega'} \mathrm{d}^4x'\;\mathcal{L}(\phi'_a(x'),\,\partial'_\mu\phi'_a(x'),\,x'), \tag{7.11}$$

where Ω' is the image of Ω under Eq. (7.1) and $\partial'_\mu = \partial/\partial x'^\mu$. To compare with S we pull everything back to the original coordinates. The change of variables

$x' = x + \delta x$ carries a Jacobian: from $\partial x'^{\mu}/\partial x^{\nu} = \delta^{\mu}{}_{\nu} + \partial_{\nu}(\delta x^{\mu})$, the determinant is

$$\mathrm{d}^4x' = \left|\det \tfrac{\partial x'^{\mu}}{\partial x^{\nu}}\right| \mathrm{d}^4x = \left(1 + \partial_{\mu}(\delta x^{\mu})\right) \mathrm{d}^4x + O(\delta^2), \tag{7.12}$$

using $\det(\mathbf{1} + M) = 1 + \operatorname{tr} M + O(M^2)$ with $\operatorname{tr} M = \partial_{\mu}(\delta x^{\mu})$. The integrand, re-expressed at the running point, differs from the old one by the *total* variation of the Lagrangian density,

$$\bar{\delta}\mathcal{L} \;\equiv\; \mathcal{L}(\phi'_a(x'), \partial'_{\mu}\phi'_a(x'), x') - \mathcal{L}(\phi_a(x), \partial_{\mu}\phi_a(x), x), \tag{7.13}$$

since $\mathcal{L}$ is itself a (composite) field and Theorem 7.1 applies to it verbatim. Assembling Eq. (7.12) and Eq. (7.13) and keeping only first order,

$$\delta S \;=\; S' - S \;=\; \int_{\Omega} \mathrm{d}^4x \,\Big[\, \bar{\delta}\mathcal{L} + \mathcal{L}\,\partial_{\mu}(\delta x^{\mu}) \,\Big]. \tag{7.14}$$

Now convert the total variation of $\mathcal{L}$ to the intrinsic one using Eq. (7.5) applied to $\mathcal{L}$, namely $\bar{\delta}\mathcal{L} = \delta\mathcal{L} + \delta x^{\mu}\partial_{\mu}\mathcal{L}$ (here $\partial_{\mu}\mathcal{L}$ is the *total* spacetime derivative of $\mathcal{L}$, which collects any explicit x-dependence as well as the dependence carried through the fields). The two δx terms combine into a perfect divergence,

$$\bar{\delta}\mathcal{L} + \mathcal{L}\,\partial_{\mu}(\delta x^{\mu}) = \delta\mathcal{L} + \delta x^{\mu}\partial_{\mu}\mathcal{L} + \mathcal{L}\,\partial_{\mu}(\delta x^{\mu}) = \delta\mathcal{L} + \partial_{\mu}\big(\mathcal{L}\,\delta x^{\mu}\big), \tag{7.15}$$

by the Leibniz rule. The remaining piece, the intrinsic variation $\delta\mathcal{L}$, is computed at fixed x exactly as in the Euler–Lagrange derivation—and crucially carries *no* explicit $\partial_{\mu}\mathcal{L}|_{\text{expl}}$ term, because δ holds the coordinate fixed and the explicit x-dependence cancels in the same-point difference. By the chain rule and the commutation property Eq. (7.6),

$$\delta\mathcal{L} = \frac{\partial\mathcal{L}}{\partial\phi_a}\,\delta\phi_a + \frac{\partial\mathcal{L}}{\partial(\partial_{\mu}\phi_a)}\,\partial_{\mu}(\delta\phi_a). \tag{7.16}$$

Introduce the covariant canonical momentum

$$\pi_a{}^{\mu} \;\equiv\; \frac{\partial\mathcal{L}}{\partial(\partial_{\mu}\phi_a)}, \qquad \pi_a{}^{0} = \pi^a \text{ of Eq. (6.96)}, \tag{7.17}$$

a one-index generalization of the canonical momentum whose time component reproduces the Ch. 6 object. Then the standard split—trading $\partial\mathcal{L}/\partial\phi_a$ for the Euler–Lagrange operator $E_a[\mathcal{L}] = \partial\mathcal{L}/\partial\phi_a - \partial_{\mu}\pi_a{}^{\mu}$ of Eq. (6.43) and collecting the leftover into a divergence—gives

$$\delta\mathcal{L} = \Big(\frac{\partial\mathcal{L}}{\partial\phi_a} - \partial_{\mu}\pi_a{}^{\mu}\Big)\delta\phi_a + \partial_{\mu}\big(\pi_a{}^{\mu}\,\delta\phi_a\big) = E_a[\mathcal{L}]\,\delta\phi_a + \partial_{\mu}\big(\pi_a{}^{\mu}\,\delta\phi_a\big). \tag{7.18}$$

Substituting Eq. (7.18) into Eq. (7.15) and that into Eq. (7.14) collapses everything into one statement.

Proposition 7.3 (Master variation of the action)**.** *Under an arbitrary infinitesimal transformation* $(\delta x^\mu, \delta\phi_a)$*, with* $\delta\phi_a$ *the intrinsic variation* (7.2)*, the first variation of the action* (6.25) *is, for* every *field configuration,*

$$\boxed{\delta S = \int_\Omega \mathrm{d}^4x \left\{ E_a[\mathcal{L}]\,\delta\phi_a + \partial_\mu\big(\,\pi_a{}^\mu\,\delta\phi_a + \mathcal{L}\,\delta x^\mu\,\big)\right\}} \tag{7.19}$$

where $E_a[\mathcal{L}] = \partial\mathcal{L}/\partial\phi_a - \partial_\mu\pi_a{}^\mu$ *is the Euler–Lagrange operator* (6.43) *and* $\pi_a{}^\mu = \partial\mathcal{L}/\partial(\partial_\mu\phi_a)$ (7.17)*. On shell, where* $E_a[\mathcal{L}] = 0$*, the variation reduces to a pure boundary term,*

$$\delta S\big|_{\text{on-shell}} = \int_\Omega \mathrm{d}^4x\;\partial_\mu K^\mu, \qquad K^\mu \equiv \pi_a{}^\mu\,\delta\phi_a + \mathcal{L}\,\delta x^\mu. \tag{7.20}$$

The structure of Eq. (7.19) repays study, because every result downstream is a way of reading it. It splits the response of the action into two physically distinct pieces. The *bulk* term $E_a[\mathcal{L}]\,\delta\phi_a$ is the dynamical content: it is what the principle of stationary action sets to zero, and it carries no information about the transformation beyond the direction $\delta\phi_a$. The *boundary* term $\partial_\mu K^\mu$ is pure surface flux; it survives even on solutions and is the seat of every conservation law in this chapter. Two limits recover earlier results and confirm the bookkeeping. If we hold the coordinates fixed ($\delta x = 0$) and demand stationarity against arbitrary $\delta\phi_a$ vanishing on $\partial\Omega$, the boundary term drops and Eq. (7.19) is the Euler–Lagrange derivation of Theorem 6.8. If instead we put the field on shell, Eq. (7.20) says the on-shell action is a boundary functional—the same fact that, in mechanics, makes Hamilton's principal function a function of the endpoints alone.

It is worth recording the boundary current K^μ in the variables of the comoving observer, because that is the form in which the spacetime-symmetry currents will appear. Substitute $\delta\phi_a = \bar\delta\phi_a - \delta x^\nu\partial_\nu\phi_a$ from Eq. (7.5) into the definition in Eq. (7.20):

$$\begin{aligned} K^\mu &= \pi_a{}^\mu\big(\bar\delta\phi_a - \delta x^\nu\partial_\nu\phi_a\big) + \mathcal{L}\,\delta x^\mu \\ &= \pi_a{}^\mu\,\bar\delta\phi_a - \big(\pi_a{}^\mu\,\partial_\nu\phi_a - \delta^\mu{}_\nu\mathcal{L}\big)\,\delta x^\nu = \pi_a{}^\mu\,\bar\delta\phi_a - T^\mu{}_\nu\,\delta x^\nu, \end{aligned} \tag{7.21}$$

where in the last step the combination $\pi_a{}^\mu\partial_\nu\phi_a - \delta^\mu{}_\nu\mathcal{L}$ is exactly the canonical stress–energy tensor $T^\mu{}_\nu$ of Theorem 6.28. The boundary current of a general transformation thus organizes itself automatically into two recognizable blocks: the momentum $\pi_a{}^\mu$ contracted with the comoving field change, plus the canonical stress tensor contracted with the coordinate displacement. We are one short step from Noether's theorem—but only one, and we take it deliberately in the next section rather than here, after the notion of symmetry has been made precise.

7.1.3 Symmetry, quasi-symmetry, and the boundary term

Nothing so far has assumed the transformation does anything special to the action; Theorem 7.3 is an identity for any $(\delta x, \delta\phi)$. A transformation earns the name *symmetry* when it leaves the action's content untouched. The naive demand $\delta S = 0$ is, however, slightly too strong, and getting the definition exactly right is what makes Noether's theorem both true and useful.

The physical requirement is that the transformation leave the *dynamics* invariant: it must map every solution of the equations of motion to another solution. From Eq. (7.19) this is guaranteed if the transformation changes the action by at most a surface term for *every* configuration—not only on shell—because a surface term cannot affect which configurations make the bulk variation vanish. Concretely, two Lagrangians differing by a total divergence yield identical Euler–Lagrange equations: $E_a[\partial_\nu F^\nu] = 0$ identically, as established in Eq. (6.44). A transformation that shifts $\mathcal{L}$ by a total divergence therefore shifts S by a boundary integral that the equations of motion never see. This is the content we want to legislate.

Definition 7.4 (Continuous symmetry and quasi-symmetry)**.** A continuous (infinitesimal) transformation $(\delta x^\mu, \delta\phi_a)$ is a *quasi-symmetry* of the action (6.25) if there exists a local current $\Lambda^\mu(\phi_a, \partial_\mu\phi_a, x)$, built from the fields and a finite number of their derivatives, such that the integrand of the first variation is a total divergence *off shell*:

$$\delta\mathcal{L} + \partial_\mu(\mathcal{L}\,\delta x^\mu) = \partial_\mu\Lambda^\mu \qquad \text{for every field configuration.} \tag{7.22}$$

Equivalently, $\delta S = \int_\Omega \mathrm{d}^4x\,\partial_\mu\Lambda^\mu$ is a boundary integral for all configurations. If Eq. (7.22) holds with $\Lambda^\mu \equiv 0$—the action being invariant on the nose, $\delta\mathcal{L} + \partial_\mu(\mathcal{L}\,\delta x^\mu) = 0$—the transformation is a *strict* (or manifest) symmetry. Otherwise it is a quasi-symmetry *proper*, invariant only up to the boundary term Λ^μ.

The condition Eq. (7.22) is demanded off shell, for every configuration, and this is the crux. It is what distinguishes a symmetry of the *action* from the weaker notion, discussed below, of a symmetry of the equations of motion. The current Λ^μ is not part of the data of the transformation; it is determined (up to an identically conserved piece) by working out the left-hand side and recognizing it as a divergence. When it cannot be so recognized—when $\delta\mathcal{L} + \partial_\mu(\mathcal{L}\,\delta x^\mu)$ fails to be a total derivative for some configuration—the transformation is not a symmetry of the action at all, and the first theorem yields nothing.

Physical Insight

Why tolerate the boundary term Λ^μ at all—why not insist on strict invariance? Because the action's job is to produce equations of motion, and it does that only through the bulk variation; the surface term is

invisible to the dynamics. Insisting on strict invariance would discard genuine symmetries on a technicality. The cleanest examples are the supersymmetry transformations of Chapter 48, under which the Lagrangian shifts by a total derivative that *cannot* be removed, and the Galilean boosts of nonrelativistic field theory, whose Noether charge picks up the famous boundary contribution. Even the spacetime translations of Ch. 6 are, in the fixed-coordinate description, quasi-symmetries with nonzero Λ^μ, as the next worked example shows. The boundary term is not a blemish to be tolerated; it is part of the symmetry, and Noether's theorem will absorb it cleanly into the conserved current.

Worked Example 7.5 (Translation: strict symmetry or quasi-symmetry, depending on the bookkeeping)**.** Consider a Lagrangian with no explicit x-dependence, $\mathcal{L} = \mathcal{L}(\phi_a, \partial_\mu \phi_a)$, and the constant translation $x'^\mu = x^\mu + a^\mu$. We compute δS in two equivalent bookkeepings and find the same physics described once as a strict symmetry and once as a quasi-symmetry—a concrete demonstration that the strict/quasi split is partly a matter of how one apportions the change between δx and $\delta\phi$.

Coordinate-inclusive description ($\delta x^\mu = a^\mu$, $\bar\delta\phi_a = 0$). A translation carries every field rigidly, so the comoving change vanishes, $\bar\delta\phi_a = 0$, and likewise $\bar\delta\mathcal{L} = 0$ because $\mathcal{L}$ is a scalar built from the fields with no explicit x. Since $\partial_\mu(\delta x^\mu) = \partial_\mu a^\mu = 0$, the integrand of Eq. (7.14) is $\bar\delta\mathcal{L} + \mathcal{L}\,\partial_\mu(\delta x^\mu) = 0$. The action is invariant on the nose: translation is a *strict* symmetry, $\Lambda^\mu = 0$.

Fixed-coordinate description ($\delta x^\mu = 0$, $\delta\phi_a = -a^\nu \partial_\nu \phi_a$). Now we refuse to move the coordinates and absorb the entire transformation into the intrinsic field variation Eq. (7.8). The intrinsic variation of the Lagrangian is, by the chain rule Eq. (7.16),

$$\delta\mathcal{L} = \frac{\partial\mathcal{L}}{\partial\phi_a}\delta\phi_a + \pi_a{}^\mu\,\partial_\mu(\delta\phi_a) = -a^\nu\Big[\frac{\partial\mathcal{L}}{\partial\phi_a}\partial_\nu\phi_a + \pi_a{}^\mu\,\partial_\mu\partial_\nu\phi_a\Big] = -a^\nu\,\partial_\nu\mathcal{L}, \tag{7.23}$$

the bracket being precisely the chain-rule expansion of $\partial_\nu\mathcal{L}$, legitimate because $\mathcal{L}$ has no explicit coordinate dependence. With $\delta x = 0$ the quasi-symmetry condition Eq. (7.22) reads $\delta\mathcal{L} = \partial_\mu\Lambda^\mu$, and Eq. (7.23) is exactly such a divergence:

$$\delta\mathcal{L} = -a^\nu\partial_\nu\mathcal{L} = \partial_\mu(-a^\mu\mathcal{L}) \implies \Lambda^\mu = -a^\mu\mathcal{L} \neq 0. \tag{7.24}$$

In this bookkeeping translation is a *quasi-symmetry proper*, with boundary current $\Lambda^\mu = -a^\mu\mathcal{L}$. The two descriptions agree on the only invariant fact—that δS is a boundary integral—but disagree on whether Λ^μ vanishes, because they apportion the transformation differently between coordinate and field. The lesson for the next section is sharp: the boundary term Λ^μ cannot be discarded. Were one to drop it, the conserved current produced by Noether's theorem would be

$\pi_a{}^\mu \delta\phi_a$ alone—missing exactly the $-\eta^{\mu\nu}\mathcal{L}$ piece of the canonical stress tensor Eq. (6.165). The $\Lambda^\mu = -a^\mu\mathcal{L}$ here *is* that missing piece, as one sees by comparing with Eq. (7.21). The boundary term is not optional accounting; it is half of the energy.

There remains a distinction that the word "symmetry" invites one to blur: the difference between a symmetry of the action and a symmetry of the equations of motion. A transformation is a *symmetry of the equations of motion* if it maps solutions to solutions—if whenever ϕ_a satisfies $E_a[\mathcal{L}] = 0$, so does the transformed field. Every quasi-symmetry of the action is automatically a symmetry of the equations of motion, by the argument above: changing $\mathcal{L}$ by a total divergence leaves $E_a[\mathcal{L}]$ untouched. The converse fails, and the failure is exactly the class of transformations Noether's first theorem cannot reach.

Example 7.6 (A symmetry of the equations of motion that is not a symmetry of the action)**.** Take the free massless real scalar, $\mathcal{L} = \frac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi)$, with linear equation of motion $\Box\phi = 0$, and the rigid field rescaling $\phi \to \phi' = e^\alpha\phi$, i.e. $\delta\phi = \alpha\,\phi$ at fixed coordinates ($\delta x = 0$). Linearity makes this a symmetry of the equation of motion: if $\Box\phi = 0$ then $\Box(e^\alpha\phi) = 0$, so solutions map to solutions for any α. But it is *not* a symmetry of the action. The Lagrangian is quadratic, so it rescales homogeneously, $\mathcal{L} \to e^{2\alpha}\mathcal{L}$, and

$$\delta\mathcal{L} = 2\alpha\,\mathcal{L} = \alpha\,(\partial_\mu\phi)(\partial^\mu\phi), \tag{7.25}$$

which is *not* a total divergence for a generic configuration: its value at a point is the local kinetic density, a quantity that cannot be written as $\partial_\mu\Lambda^\mu$ with Λ^μ local, since integrating it over a finite region gives a configuration-dependent number rather than a pure surface flux. The quasi-symmetry condition Eq. (7.22) fails, so Theorem 7.3 yields no conserved current. Rescaling the field is a symmetry of the dynamics with no accompanying conservation law—the clearest illustration that Noether's first theorem is a theorem about symmetries of the *action*, not of the equations of motion. (The genuine *spacetime* dilatation symmetry of the massless theory, which transforms the coordinates as well and *does* leave the action invariant up to a boundary term, is a separate transformation; it carries a real conserved dilatation current, constructed in Section 7.7.5 when we close ϕ^4 theory.)

Caution

The phrase "ϕ^4 theory is scale invariant when $m = 0$" is true but must be read carefully. What is scale invariant is the full *dilatation* transformation, which rescales the spacetime coordinates $x \to e^{-\alpha}x$ *together* with the field $\phi \to e^\alpha\phi$, and which leaves the action invariant up to a boundary term. The field rescaling alone, with coordinates frozen, is Theorem 7.6: a

symmetry of the equation of motion but *not* of the action, and hence *not* a source of any Noether current. Conflating the two is a standard route to a spurious "conservation law."

7.1.4 Continuous families, generators, and the discrete foil

Noether's first theorem is a statement about *continuous* symmetries, and we close the section by saying precisely what that means and why the qualifier is indispensable. A continuous symmetry is not a single transformation but a smooth family of them, connected to the identity by a parameter that can be made arbitrarily small. It is the existence of this infinitesimal neighborhood—the very thing Theorem 7.3 expanded in—that makes a conservation law possible.

Definition 7.7 (One- and multi-parameter symmetry families and their generators)**.** A *one-parameter family* of transformations is a smooth map $s \mapsto (\delta x^\mu_s, \phi_a^{(s)})$ with $s \in \mathbb{R}$ reducing to the identity at $s = 0$. Its *generator* is the pair of first-order data

$$\delta x^\mu = \frac{dx'^\mu}{ds}\Big|_{s=0}, \qquad \delta\phi_a = \frac{\partial \phi_a^{(s)}}{\partial s}\Big|_{s=0}, \tag{7.26}$$

read off the linear term $x'^\mu = x^\mu + s\,\delta x^\mu + O(s^2)$, $\phi_a^{(s)} = \phi_a + s\,\delta\phi_a + O(s^2)$. A *multi-parameter* (Lie) family carries r independent parameters α^A, $A = 1, \dots, r$, with infinitesimal data

$$\delta x^\mu = \alpha^A\, X^\mu_A(x), \qquad \delta\phi_a = \alpha^A\, \Phi_{A,a}(\phi, \partial\phi, x), \tag{7.27}$$

one generator $(X^\mu_A, \Phi_{A,a})$ for each parameter. The family is a (quasi-)symmetry when Theorem 7.4 holds for each α^A independently, producing a boundary current Λ^μ_A for every generator.

When the transformations close under composition—the result of doing one and then another is again a member of the family—the generators close into a Lie algebra, $[\,\delta_A, \delta_B\,] = f_{AB}{}^C\,\delta_C$, with the structure constants $f_{AB}{}^C$ of Chapter 2. This is what makes the symmetries of a field theory a *group*, and it is the reason the conserved charges of an internal symmetry will be found in Section 7.3 to satisfy that same algebra under the Poisson bracket—the charges *generate* the very transformation they conserve. For now the only point we need is structural: a continuous symmetry supplies, through Eq. (7.27), exactly r independent infinitesimal directions, and Noether's first theorem will return exactly r independent conserved currents—one per parameter. The counting "one current per continuous parameter" is built into the very definition of the family.

The qualifier "continuous" is not a convenience; it is load-bearing. The entire machine of Theorem 7.3 rests on expanding the action to *first order* in an

infinitesimal parameter. A transformation that admits no such expansion—one not connected to the identity, with no neighborhood to linearize in—never enters the master identity, and Noether's first theorem is simply silent about it. Such are the *discrete* symmetries.

Example 7.8 (The $\mathbb{Z}_2$ of ϕ^4 theory yields no Noether current)**.** The standard Lagrangian of ϕ^4 theory,

$$\mathcal{L} = \tfrac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4, \tag{7.28}$$

is invariant under the reflection $\phi \to -\phi$: every term contains an even power of ϕ, so $\mathcal{L}(-\phi, -\partial_\mu\phi) = \mathcal{L}(\phi, \partial_\mu\phi)$ exactly. This $\mathbb{Z}_2$ is a genuine symmetry of the action—indeed a strict one, $\delta\mathcal{L} = 0$—and it has powerful consequences: it forbids every correlation function with an odd number of fields, and its spontaneous breaking in Chapter 31 is the prototype of the Higgs mechanism. But it is a group of two elements, $\{\phi \to \phi,\ \phi \to -\phi\}$, with *no* element infinitesimally close to the identity: there is no smooth family $\phi \to e^{\alpha} \cdot (\text{reflection})\phi$ interpolating to it, because -1 is not connected to $+1$ within the real numbers acting on a single real field. There is no generator (7.26) to feed into the master identity Eq. (7.19), and hence no conserved current and no conserved charge. Noether's first theorem cannot see the $\mathbb{Z}_2$. We will return to this reflection in Section 7.3 precisely as the foil that marks the boundary of the theorem's reach—the symmetry that organizes the theory's selection rules without contributing to its conserved currents.

The same verdict applies to the discrete spacetime operations—parity P, time reversal T, and the internal charge conjugation C—each of which is a reflection with no infinitesimal version. They are indispensable to the structure of quantum field theory, governing selection rules and culminating in the CPT theorem of Chapter 12, but none is a continuous symmetry and none produces a Noether current. The dividing line is clean: continuous symmetries give conservation laws through the first theorem; discrete symmetries give selection rules through their action on states and amplitudes. This chapter is about the former; the latter are taken up where they belong.

With the variational bookkeeping in place—the intrinsic and total variations and their relation (7.5), the master identity (7.19) for the first variation of the action, and the precise definition (7.4) of a continuous (quasi-)symmetry—we have assembled exactly the two ingredients Noether's theorem needs. On one side stands the off-shell quasi-symmetry condition, $\delta\mathcal{L} + \partial_\mu(\mathcal{L}\,\delta x^\mu) = \partial_\mu\Lambda^\mu$; on the other, the on-shell reduction of the master identity to the pure boundary term $\partial_\mu K^\mu$. Setting these two expressions for the same quantity against each other—one true off shell, the other true on shell—forces a local current to be conserved. That single confrontation is the whole of Noether's first theorem, and it is the business of Section 7.2.

7.2 Noether's First Theorem

The previous section assembled the two ingredients this one consumes, and did so deliberately holding back the final step. On one side it produced the *master variation identity* (Theorem 7.3): for an arbitrary infinitesimal transformation $(\delta x^\mu, \delta\phi_a)$ of an arbitrary field configuration, the first variation of the action splits into a bulk term carrying the Euler–Lagrange operator and a pure boundary divergence. On the other it pinned down what it means for such a transformation to deserve the name *symmetry*: not that the Lagrangian density be numerically unchanged, but the weaker and more useful demand that the action change by at most a surface term *off shell*—the notion of quasi-symmetry (Theorem 7.4). The master identity is an algebraic statement true for every configuration; the symmetry condition is a hypothesis we may or may not impose. The content of Noether's first theorem is what happens when both are in force at once together with the equations of motion: the symmetry says one combination is a pure divergence, the dynamics says another combination vanishes, and what is squeezed out between them is the vanishing of a single local current. The argument is short—it is essentially one substitution—but its consequences organize the rest of the book, so we state every hypothesis, prove every step, read off the conserved current and the conserved charge, and chart precisely how much freedom the construction leaves.

We carry the conventions of the chapter: mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units, and a (possibly multi-component) classical field ϕ_a with first-order Lagrangian density $\mathcal{L}(\phi_a, \partial_\mu\phi_a, x)$ on a spacetime region Ω, the index a running over all internal and spacetime components the theory carries, repeated indices summed. Two objects from the previous section recur on every line below, and we recall them rather than redefine them. The first is the covariant canonical momentum $\pi_a{}^\mu \equiv \partial\mathcal{L}/\partial(\partial_\mu\phi_a)$ of Eq. (7.17), the one-index four-vector whose time component $\pi_a{}^0$ is the canonical momentum of Theorem 6.13. The second is the relation between the intrinsic (fixed-point) variation $\delta\phi_a$ and the total (comoving) variation $\bar{\delta}\phi_a$,

$$\bar{\delta}\phi_a = \delta\phi_a + \delta x^\mu\, \partial_\mu\phi_a, \tag{7.29}$$

which is Eq. (7.5); the single property that drives the whole derivation is that the intrinsic variation, being taken at fixed x, commutes with the partial derivative, $\delta(\partial_\mu\phi_a) = \partial_\mu(\delta\phi_a)$ (Eq. (7.6)), whereas the total variation does not.

7.2.1 From the master identity to a conservation law

The master variation of Theorem 7.3 was stated as an integrated identity for δS. For the theorem we want its *local*, pre-integration form, which is already contained in the steps that produced it. Recall from the previous section that

the intrinsic variation of the Lagrangian, after one integration by parts, reads

$$\delta\mathcal{L} = E_a[\mathcal{L}]\,\delta\phi_a + \partial_\mu(\pi_a{}^\mu\,\delta\phi_a), \qquad E_a[\mathcal{L}] \equiv \frac{\partial\mathcal{L}}{\partial\phi_a} - \partial_\mu\pi_a{}^\mu, \tag{7.30}$$

which is Eq. (7.18) with $E_a[\mathcal{L}]$ the Euler–Lagrange operator of Theorem 6.8. Adding $\partial_\mu(\mathcal{L}\,\delta x^\mu)$ to both sides and using the recombination $\delta\mathcal{L} + \partial_\mu(\mathcal{L}\,\delta x^\mu) = \bar{\delta}\mathcal{L} + \mathcal{L}\,\partial_\mu(\delta x^\mu)$ of Eq. (7.15), the left-hand side becomes exactly the quantity that the quasi-symmetry condition controls, while the right-hand side organizes itself into an Euler–Lagrange piece and a single divergence:

$$\delta\mathcal{L} + \partial_\mu(\mathcal{L}\,\delta x^\mu) \;=\; E_a[\mathcal{L}]\,\delta\phi_a + \partial_\mu K^\mu, \qquad K^\mu \equiv \pi_a{}^\mu\,\delta\phi_a + \mathcal{L}\,\delta x^\mu. \tag{7.31}$$

Here K^μ is the on-shell boundary current already introduced in Eq. (7.20). Equation Eq. (7.31) is the local master identity. It is an off-shell statement, true for every field configuration, solution or not, and nothing in it has yet used either the symmetry of the action or the equations of motion. It is the neutral substrate; the theorem is what one reads off it after imposing those two hypotheses.

The candidate conserved object is the divergence-carrying current K^μ, corrected by the boundary current that quasi-symmetry permits.

Definition 7.9 (Noether current)**.** Let the transformation $(\delta x^\mu, \delta\phi_a)$ be a quasi-symmetry of the action with boundary current Λ^μ as in Theorem 7.4, i.e. $\delta\mathcal{L} + \partial_\mu(\mathcal{L}\,\delta x^\mu) = \partial_\mu\Lambda^\mu$ off shell. The associated *Noether current* is

$$\boxed{J^\mu \;\equiv\; K^\mu - \Lambda^\mu \;=\; \pi_a{}^\mu\,\delta\phi_a + \mathcal{L}\,\delta x^\mu - \Lambda^\mu} \tag{7.32}$$

where $\delta\phi_a$ is the intrinsic field variation (7.2).

Theorem 7.10 (Noether's first theorem)**.** *If the transformation $(\delta x^\mu, \delta\phi_a)$ is a quasi-symmetry of the action (6.25), then on every solution of the Euler–Lagrange equations (6.30) the Noether current (7.32) is locally conserved,*

$$\partial_\mu J^\mu = 0. \tag{7.33}$$

Proof. Start from the local master identity Eq. (7.31), valid off shell for any configuration,

$$\delta\mathcal{L} + \partial_\mu(\mathcal{L}\,\delta x^\mu) = E_a[\mathcal{L}]\,\delta\phi_a + \partial_\mu K^\mu. \tag{7.34}$$

Now impose the first hypothesis. The quasi-symmetry condition Eq. (7.22) states that the entire left-hand side is itself a total divergence, $\delta\mathcal{L} + \partial_\mu(\mathcal{L}\,\delta x^\mu) = \partial_\mu\Lambda^\mu$, again as an identity in the fields. Substituting this for the left-hand side of Eq. (7.34),

$$\partial_\mu\Lambda^\mu = E_a[\mathcal{L}]\,\delta\phi_a + \partial_\mu K^\mu. \tag{7.35}$$

Move the divergence of Λ^μ across and combine the two divergences, which by linearity is the divergence of $K^\mu - \Lambda^\mu = J^\mu$:

$$\partial_\mu(K^\mu - \Lambda^\mu) = -E_a[\mathcal{L}]\,\delta\phi_a, \qquad \text{i.e.} \qquad \boxed{\partial_\mu J^\mu = -E_a[\mathcal{L}]\,\delta\phi_a} \tag{7.36}$$

This is still an off-shell identity: the divergence of the Noether current equals, at every point and for every configuration, minus the Euler–Lagrange operator contracted with the intrinsic field variation. Now impose the second hypothesis. On a solution of the equations of motion the Euler–Lagrange operator vanishes identically, $E_a[\mathcal{L}] = 0$ (Theorem 6.8), so the right-hand side of Eq. (7.36) is zero and $\partial_\mu J^\mu = 0$ on shell. □

The proof exhibits the anatomy promised at the close of the previous section: *one identity from the symmetry, one substitution of the dynamics.* The quasi-symmetry condition collapses the left-hand side of the master identity to $\partial_\mu \Lambda^\mu$; the equations of motion annihilate the Euler–Lagrange term; what survives is the vanishing of a divergence. The off-shell form Eq. (7.36) deserves to be kept in its own right, not discarded as a stepping stone. It says that the failure of the Noether current to be conserved is measured precisely by the equations of motion—the current is conserved exactly to the extent that the field obeys its dynamics. In the quantum theory this same off-shell relation, with $E_a[\mathcal{L}]$ becoming an operator insertion, is the seed of the Ward–Takahashi identities: the classical equations-of-motion term turns into contact terms inside correlation functions, and the would-be conservation law acquires calculable anomalies and contact corrections. The classical statement Eq. (7.36) is the skeleton on which all of that is later hung.

Physical Insight

Noether's theorem is an accounting identity, not a force law. It does not assert that something is conserved *because* a particular interaction balances another; it asserts that the bookkeeping of a continuous symmetry, combined with *any* dynamics derived from a symmetric action, manufactures a quantity whose total time derivative is a pure spatial flux. The deep content is the correspondence itself: each independent continuous direction in which the action is invariant supplies exactly one locally conserved current. This is the sense in which, in field theory, symmetry rather than force is the organizing principle—forces are the incidental content of a particular Lagrangian, while the conservation laws are dictated by its symmetries alone.

It is illuminating to rewrite Eq. (7.32) so that the contributions of field space and of spacetime appear separately, because that is the form in which internal and spacetime symmetries will specialize. Substitute the inverse of Eq. (7.29), $\delta\phi_a = \bar{\delta}\phi_a - \delta x^\nu \partial_\nu \phi_a$, into the field term of K^μ:

$$\begin{aligned} J^\mu &= \pi_a{}^\mu \big(\bar{\delta}\phi_a - \delta x^\nu \partial_\nu \phi_a\big) + \mathcal{L}\, \delta^\mu{}_\nu\, \delta x^\nu - \Lambda^\mu \\ &= \pi_a{}^\mu\, \bar{\delta}\phi_a - \underbrace{\big(\pi_a{}^\mu\, \partial_\nu \phi_a - \delta^\mu{}_\nu\, \mathcal{L}\big)}_{= T^\mu{}_\nu}\, \delta x^\nu - \Lambda^\mu . \end{aligned} \tag{7.37}$$

The underbraced combination is exactly the canonical stress–energy tensor $T^{\mu}{}_{\nu}$ of Theorem 6.28; this is the same regrouping already recorded for the boundary current in Eq. (7.21). Naming the *coordinate piece*

$$F^{\mu} \;\equiv\; T^{\mu}{}_{\nu}\,\delta x^{\nu} = \left(\pi_a{}^{\mu}\,\partial_{\nu}\phi_a - \delta^{\mu}{}_{\nu}\,\mathcal{L}\right)\delta x^{\nu}, \tag{7.38}$$

the current takes the three-piece form anticipated in the chapter blueprint,

$$\boxed{J^{\mu} = \pi_a{}^{\mu}\,\bar{\delta}\phi_a - F^{\mu} - \Lambda^{\mu}} \tag{7.39}$$

whose three terms are, respectively, the response of the field measured by the comoving observer ($\pi_a{}^{\mu}\,\bar{\delta}\phi_a$), the response to the displacement of the spacetime point itself ($-F^{\mu}$, built from the canonical stress tensor), and the boundary term that quasi-symmetry permits ($-\Lambda^{\mu}$). The two great families of symmetries are the two ways of switching pieces on and off. *Internal* symmetries leave the coordinates fixed, $\delta x^{\mu} = 0$, so F^{μ} vanishes and the current is carried by the field piece; these are the subject of the next section. *Spacetime* symmetries move the coordinates and are carried largely by F^{μ}; these come later. Both are special cases of the single formula Eq. (7.39).

The most concrete check is the one symmetry already worked out by hand in the previous chapter. We run it through the general machine, both to verify signs and to set the template for the spacetime symmetries to come.

Worked Example 7.11 (Spacetime translations recover the canonical stress tensor and the four-momentum)**.** Take the rigid translation $x'^{\mu} = x^{\mu} + a^{\mu}$ with constant infinitesimal a^{μ}, in a theory whose Lagrangian carries no explicit coordinate dependence. The generators are $\delta x^{\mu} = a^{\mu}$ and, since a translated configuration carries its value rigidly to the new point, $\phi'_a(x') = \phi_a(x)$, i.e. the comoving change vanishes, $\bar{\delta}\phi_a = 0$. That this is a strict symmetry, $\Lambda^{\mu} = 0$, was established in the coordinate-inclusive bookkeeping of Theorem 7.5: with $\bar{\delta}\mathcal{L} = 0$ and $\partial_{\mu}(\delta x^{\mu}) = 0$ the invariance condition holds on the nose. We need only read off the current. Using the three-piece form Eq. (7.39) with $\bar{\delta}\phi_a = 0$, $\Lambda^{\mu} = 0$, and $\delta x^{\nu} = a^{\nu}$,

$$J^{\mu} = \pi_a{}^{\mu}\cdot 0 - T^{\mu}{}_{\nu}\,a^{\nu} - 0 = -\,a^{\nu}\,T^{\mu}{}_{\nu}. \tag{7.40}$$

The four components a^{ν} are independent parameters, so by the multi-parameter statement proved below (Theorem 7.17) each coefficient is separately conserved: stripping the arbitrary constant $-a^{\nu}$, the conserved current of the ν-th translation is $T^{\mu}{}_{\nu}$ itself, and Eq. (7.33) reads

$$\partial_{\mu}T^{\mu}{}_{\nu} = 0 \qquad (\nu = 0, 1, 2, 3), \tag{7.41}$$

in exact agreement with the direct computation Theorem 6.29. The associated charges are the components of the four-momentum: integrating the time component of $-a^{\nu}T^{\mu}{}_{\nu}$ over a constant-time slice and stripping $-a^{\nu}$,

$$P_{\nu} = \int_{\mathbb{R}^3} \mathrm{d}^3x\; T^{0}{}_{\nu}, \tag{7.42}$$

which is the four-momentum of Theorem 6.30, conserved by Theorem 6.31. The general theorem and the previous chapter's hand computation agree on every sign. The lesson to carry forward is structural: the canonical stress tensor is nothing other than the Noether current of spacetime translation, and energy and momentum are its charges—a statement we will sharpen, and repair, when the coordinate piece F^μ is developed in full.

7.2.2 The conserved charge and its time-independence

A locally conserved current is a statement about densities and fluxes at each point. To extract from it a single conserved *number*—the charge—one integrates the time component over a spatial slice. The local law $\partial_\mu J^\mu = 0$ then becomes the global law that this number does not change in time, provided the current does not leak out through the boundary at spatial infinity. The fall-off that guarantees no such leakage is a genuine physical hypothesis, not a formality, and we state it explicitly.

Definition 7.12 (Noether charge)**.** The *Noether charge* associated with a conserved current J^μ is the integral of its time component over a constant-time slice,

$$Q(t) = \int_{\mathbb{R}^3} \mathrm{d}^3x \; J^0(t, \mathbf{x}). \tag{7.43}$$

Theorem 7.13 (Conservation of the Noether charge)**.** *Let J^μ satisfy $\partial_\mu J^\mu = 0$, let $J^0(t,\cdot) \in L^1(\mathbb{R}^3)$ so that $Q(t)$ is finite, and assume the spatial fall-off*

$$\lim_{R\to\infty} R^2 \sup_{|\mathbf{x}|=R} \left|J^i(t,\mathbf{x})\right| = 0 \qquad \text{for each fixed } t, \tag{7.44}$$

i.e. the spatial current decays faster than $1/R^2$, so that its flux through the sphere of radius R vanishes as $R \to \infty$. Then the charge is time-independent,

$$\frac{dQ}{dt} = 0. \tag{7.45}$$

Proof. Differentiate Eq. (7.43) under the integral sign—legitimate because J^0 and its time derivative are integrable—and use the conservation law to trade the time derivative of the charge density for the spatial divergence of the current. Splitting the four-divergence into temporal and spatial parts, $\partial_\mu J^\mu = \partial_0 J^0 + \partial_i J^i = 0$, gives $\partial_0 J^0 = -\partial_i J^i$, so

$$\frac{dQ}{dt} = \int_{\mathbb{R}^3} \mathrm{d}^3x \; \partial_0 J^0 = -\int_{\mathbb{R}^3} \mathrm{d}^3x \; \partial_i J^i. \tag{7.46}$$

The integrand is now a three-dimensional divergence. Integrate it over the ball B_R of radius R and apply the divergence theorem,

$$\int_{B_R} \mathrm{d}^3x \; \partial_i J^i = \oint_{S_R} \mathrm{d}S \; \hat{n}_i \, J^i, \tag{7.47}$$

where $S_R = \partial B_R$ is the sphere of radius R with outward unit normal $\hat{n}_i$ and scalar area element $\mathrm{d}S$. The magnitude of the surface integral is bounded by the area $4\pi R^2$ times the supremum of $|J^i|$ on the sphere,

$$\left| \oint_{S_R} \mathrm{d}S \, \hat{n}_i \, J^i \right| \leq 4\pi R^2 \sup_{|\mathbf{x}|=R} |J^i| \xrightarrow[R\to\infty]{} 0 \tag{7.48}$$

by the fall-off hypothesis Eq. (7.44). Therefore the spatial integral in Eq. (7.46) is the $R \to \infty$ limit of $\int_{B_R} \mathrm{d}^3x \, \partial_i J^i$, which equals the limit of the surface integral, which is zero. Hence $\mathrm{d}Q/\mathrm{d}t = 0$. □

The physical reading is the familiar continuity equation. Writing $\partial_0 J^0 = -\nabla \mathbf{J}$, the time component J^0 is a charge density and the spatial part $\mathbf{J}$ is its current; charge is neither created nor destroyed locally but only transported, and the fall-off Eq. (7.44) says none of it escapes through the sphere at infinity. The hypothesis is not idle: in a theory with long-range fields, or with charged matter that reaches null or spatial infinity, the flux integral need not vanish, and then the naively defined charge is genuinely not conserved. We will meet exactly this subtlety for the electric charge of electrodynamics, where the Gauss-law constraint ties the total charge to the flux of the field at infinity. For the symmetries treated in this chapter the fields are taken to decay, and Eq. (7.44) holds.

Caution

The conservation of Q requires the spatial fall-off Eq. (7.44) *in addition to* the local conservation $\partial_\mu J^\mu = 0$. A current can be perfectly conserved as a local density and yet carry a time-dependent charge if probability or charge flows in from infinity. The two statements—local conservation and global conservation—are logically distinct, joined only by the boundary condition. Sloppily identifying "$\partial_\mu J^\mu = 0$" with "Q is conserved" is a standard error; the bridge between them is the divergence theorem plus a fall-off assumption that must be checked.

There is a sharper, manifestly covariant statement hiding inside Theorem 7.13. The charge is not merely independent of the coordinate time t; it is the same number computed on *any* spacelike slice, and is therefore a Lorentz scalar when J^μ transforms as a four-vector. This is the form in which the charge enters the relativistic theory and the charge algebra of the next section, so we record it.

Proposition 7.14 (Slice-independence of the charge)**.** *Define the charge on a spacelike Cauchy slice Σ as the flux*

$$Q[\Sigma] = \int_\Sigma \mathrm{d}\Sigma_\mu \, J^\mu, \tag{7.49}$$

where $\mathrm{d}\Sigma_\mu = n_\mu \, \mathrm{d}S$ with n_μ the future-pointing unit normal and $\mathrm{d}S$ the induced volume element. If $\partial_\mu J^\mu = 0$ and J^μ obeys the spatial fall-off Eq. (7.44), then

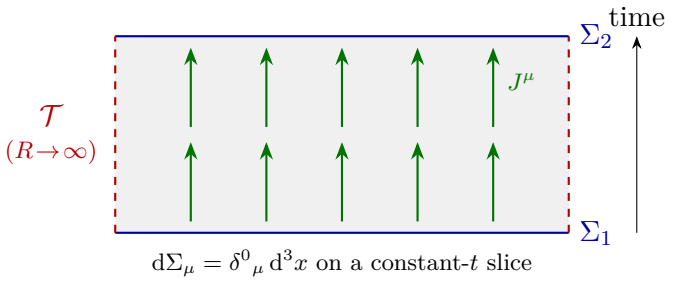

Figure 7.2: Slice-independence of the Noether charge (Theorem 7.14). The current J^μ has vanishing four-divergence inside the region V bounded below by the spacelike slice Σ_1, above by Σ_2, and laterally by the wall $\mathcal{T}$ pushed to spatial infinity. The four-dimensional divergence theorem equates the flux out through Σ_2 with the flux in through Σ_1, while the wall flux vanishes by the fall-off Eq. (7.44). The charge $Q[\Sigma] = \int_\Sigma \mathrm{d}\Sigma_\mu J^\mu$ is therefore the same on every slice; on a constant-time slice it reduces to $\int \mathrm{d}^3x\, J^0$.

$Q[\Sigma]$ is independent of the slice Σ. On a constant-time slice $\mathrm{d}\Sigma_\mu = \delta^0{}_\mu\,\mathrm{d}^3x$ and Eq. (7.49) reduces to Eq. (7.43).

Proof. Let Σ_1 and Σ_2 be two spacelike slices with Σ_2 to the future of Σ_1, and let V be the four-dimensional region between them, closed off at large spatial radius by a timelike "wall" $\mathcal{T}$ at $|\mathbf{x}| = R$ (Fig. 7.2). The four-dimensional divergence theorem applied to J^μ over V gives

$$\int_V \mathrm{d}^4x\, \partial_\mu J^\mu = \oint_{\partial V} \mathrm{d}\Sigma_\mu\, J^\mu = \int_{\Sigma_2} \mathrm{d}\Sigma_\mu\, J^\mu - \int_{\Sigma_1} \mathrm{d}\Sigma_\mu\, J^\mu + \int_{\mathcal{T}} \mathrm{d}\Sigma_\mu\, J^\mu, \tag{7.50}$$

the relative sign between the two slice contributions arising because the outward normal of V points to the future on Σ_2 but to the past on Σ_1. The left-hand side vanishes by $\partial_\mu J^\mu = 0$. The wall contribution involves the spatial components J^i integrated over a cylinder of radius R, whose lateral area grows like R^2 while $|J^i|$ decays faster than R^{-2} by Eq. (7.44); sending $R \to \infty$ kills it. What remains is

$$\int_{\Sigma_2} \mathrm{d}\Sigma_\mu\, J^\mu = \int_{\Sigma_1} \mathrm{d}\Sigma_\mu\, J^\mu, \qquad \text{i.e.} \qquad Q[\Sigma_2] = Q[\Sigma_1]. \tag{7.51}$$

Two arbitrary spacelike slices can always be joined by such a region (subdividing the construction if they happen to intersect), so $Q[\Sigma]$ takes the same value on every slice. The reduction to Eq. (7.43) on a constant-time slice is immediate from $\mathrm{d}\Sigma_\mu = \delta^0{}_\mu\,\mathrm{d}^3x$. □

7.2.3 The improvement ambiguity

The conservation law and the charge are physical, but the current that carries them is not unique. One may add to any conserved current a piece that is conserved identically—without using the equations of motion—and the charge is unchanged provided that piece, too, decays at infinity. The canonical such piece is the divergence of an antisymmetric tensor, and this freedom, far from being a defect, is exactly what later lets us repair the canonical stress tensor into a symmetric, gauge-invariant object.

Proposition 7.15 (Improvement of the Noether current)**.** *Let J^μ be a conserved current and let $B^{\mu\nu} = -B^{\nu\mu}$ be any antisymmetric tensor field (a "superpotential"). Then the improved current*

$$J'^\mu = J^\mu + \partial_\nu B^{\mu\nu} \tag{7.52}$$

is also conserved, $\partial_\mu J'^\mu = 0$, and, provided B^{0i} obeys the spatial fall-off Eq. (7.44), carries the same charge, $Q' = Q$.

Proof. For the conservation, take the divergence of the added term,

$$\partial_\mu \partial_\nu B^{\mu\nu} = 0, \tag{7.53}$$

which vanishes *identically*—with no recourse to the equations of motion—because the double derivative $\partial_\mu \partial_\nu$ is symmetric in $\mu \leftrightarrow \nu$ while $B^{\mu\nu}$ is antisymmetric. Concretely, relabelling the summed indices, $\partial_\mu \partial_\nu B^{\mu\nu} = \partial_\nu \partial_\mu B^{\nu\mu} = -\partial_\mu \partial_\nu B^{\mu\nu}$, so the quantity equals its own negative and is zero. Hence $\partial_\mu J'^\mu = \partial_\mu J^\mu + 0 = 0$. For the charge, integrate the time component of the added term over a constant-time slice,

$$Q' - Q = \int_{\mathbb{R}^3} \mathrm{d}^3x \; \partial_\nu B^{0\nu} = \int_{\mathbb{R}^3} \mathrm{d}^3x \; (\partial_0 B^{00} + \partial_i B^{0i}). \tag{7.54}$$

The first term vanishes because $B^{00} = 0$ by antisymmetry. The second is a pure spatial divergence, and the divergence theorem converts it to a surface integral at infinity,

$$Q' - Q = \int_{\mathbb{R}^3} \mathrm{d}^3x \; \partial_i B^{0i} = \lim_{R\to\infty} \oint_{S_R} \mathrm{d}S \; \hat{n}_i \, B^{0i} = 0, \tag{7.55}$$

the last equality by the assumed fall-off of B^{0i} (the same argument as in Theorem 7.13). Therefore $Q' = Q$. □

The identity Eq. (7.53) is the precise reason the improvement is "automatic": $\partial_\nu B^{\mu\nu}$ is a current whose conservation requires no dynamics at all, only the antisymmetry of B. The freedom is not academic. The canonical stress tensor $T^\mu{}_\nu$ extracted in Theorem 7.11 is, for fields of nonzero spin, generally neither

symmetric in its two indices nor gauge invariant—both defects already flagged in Section 6.6.6. A later section will exploit exactly the ambiguity Eq. (7.52), adding a specific antisymmetric superpotential built from the spin current, to repair $T^{\mu\nu}$ into the symmetric, gauge-invariant Belinfante tensor that ultimately sources gravity—all without disturbing the conserved energy and momentum. Theorem 7.15 is the licence for that repair: it guarantees in advance that the total four-momentum cannot see the improvement.

Worked Example 7.16 (An improvement that moves the charge density but not the charge)**.** We make the abstract freedom concrete and confirm that it relocates charge in space without changing the total. Take any conserved current J^μ and improve it with a superpotential built from a smooth scalar profile $\chi(x)$ of compact spatial support (or rapid decay) and a constant four-vector c^ν,

$$B^{\mu\nu} = \chi\,(\delta^\mu{}_0\, c^\nu - \delta^\nu{}_0\, c^\mu), \tag{7.56}$$

manifestly antisymmetric. The improved current is $J'^\mu = J^\mu + \partial_\nu B^{\mu\nu}$, and its time component differs from J^0 by

$$J'^0 - J^0 = \partial_\nu B^{0\nu} = \partial_\nu\big[\chi\,(c^\nu - \delta^\nu{}_0\, c^0)\big] = \partial_i(\chi\, c^i), \tag{7.57}$$

a total spatial divergence (the $\nu = 0$ term cancels, $c^0 - c^0 = 0$). This is genuinely nonzero pointwise: wherever χ has a gradient, J'^0 assigns a different charge density than J^0 does—the two distribute the same total charge differently across space. Yet the total is untouched,

$$Q' - Q = \int_{\mathbb{R}^3} \mathrm{d}^3x\; \partial_i(\chi\, c^i) = \oint_{S_\infty} \mathrm{d}S\; \hat{n}_i\, \chi\, c^i = 0, \tag{7.58}$$

because χ vanishes at infinity. The lesson is exactly the one the improvement freedom is meant to teach: "where the charge sits" is convention-dependent, an artifact of the chosen current, while "how much charge there is" is physical. Only the integrated, slice-independent quantity Q of Theorem 7.14 is an observable; the current and its local density carry a genuine gauge freedom.

7.2.4 Several parameters: one current per generator

Realistic symmetries have more than one continuous parameter—a non-abelian internal group, or the ten-parameter Poincaré group. Such a symmetry produces not a single current but a multiplet, one conserved current for each independent generator. This is an immediate consequence of the linearity of the whole construction in the infinitesimal parameters, but it is the form in which currents actually appear in every theory of interest, so we state and prove it.

Recall from Theorem 7.7 that an r-parameter family is specified by constant parameters ω^A $(A = 1, \dots, r)$ and one generator per parameter,

$$\delta x^\mu = \omega^A X^\mu_A(x), \qquad \delta\phi_a = \omega^A \Phi_{a,A}(x, \phi) \tag{7.59}$$

(this is Eq. (7.27), with $\Phi_{a,A}$ now understood as the *total* field variation $\bar{\delta}$ per generator, so that the field piece of the current is read directly from it).

Theorem 7.17 (Multi-parameter Noether theorem)**.** *Suppose the transformation Eq. (7.59) is a quasi-symmetry for each of its r independent constant parameters ω^A, with boundary current $\Lambda^\mu = \omega^A \Lambda^\mu_A$. Then there are r independently conserved currents*

$$J^\mu_A = \pi_a{}^\mu \, \Phi_{a,A} - T^\mu{}_\nu \, X^\nu_A - \Lambda^\mu_A, \qquad \partial_\mu J^\mu_A = 0 \quad (A = 1, \dots, r), \tag{7.60}$$

each with its own conserved charge $Q_A = \int_{\mathbb{R}^3} \mathrm{d}^3x \, J^0_A$, and the full current is their linear combination $J^\mu = \omega^A J^\mu_A$.

Proof. Every ingredient of the three-piece current Eq. (7.39) is homogeneous of first order in the parameters: the comoving field variation is $\bar{\delta}\phi_a = \omega^A \Phi_{a,A}$, the coordinate variation is $\delta x^\nu = \omega^A X^\nu_A$, and the boundary current is $\Lambda^\mu = \omega^A \Lambda^\mu_A$ by hypothesis. Substituting these into Eq. (7.39) and Eq. (7.38),

$$J^\mu = \pi_a{}^\mu \, \omega^A \Phi_{a,A} - T^\mu{}_\nu \, \omega^A X^\nu_A - \omega^A \Lambda^\mu_A = \omega^A \, J^\mu_A, \tag{7.61}$$

with J^μ_A as in Eq. (7.60). By Theorem 7.10 the full current is conserved on shell, $\partial_\mu J^\mu = 0$, i.e. $\omega^A \, \partial_\mu J^\mu_A = 0$. Because the parameters ω^A are arbitrary and independent, the coefficient of each must vanish separately,

$$\partial_\mu J^\mu_A = 0 \qquad \text{for each } A. \tag{7.62}$$

Integrating each time component over a slice and invoking Theorem 7.13 gives r separately conserved charges Q_A. □

The translation worked example Theorem 7.11 is the case $r = 4$ with $X^\nu_A = \delta^\nu{}_A$, $\Phi_{a,A} = 0$, $\Lambda^\mu_A = 0$, for which Eq. (7.60) returns $J^\mu{}_\nu = -T^\mu{}_\nu$: four currents, four charges P_ν. The same counting will deliver three rotation currents and three boost currents from the Lorentz subgroup, and, in the next section, one current for each generator of an internal symmetry group G—that is, $\dim \mathfrak{g}$ currents for the Lie algebra $\mathfrak{g}$ of Theorem 7.7. That the number of conserved currents equals the dimension of the symmetry group is the structural fact that makes "one conserved quantity per continuous symmetry parameter" precise. It is also the hinge of what comes next: when the generators close into a Lie algebra, $[\delta_A, \delta_B] = f_{AB}{}^C \delta_C$, the charges Q_A will be found to represent that same algebra under the Poisson bracket, so that they not only *count* the symmetries but *generate* them.

The abstract machine is now complete: the Noether current Eq. (7.39) with its field, coordinate, and boundary pieces; its on-shell conservation Eq. (7.33) and the sharper off-shell relation Eq. (7.36); the time-independent, slice-independent charge Eq. (7.43); the improvement freedom Eq. (7.52) that leaves the charge

invariant; and the one-current-per-generator counting Eq. (7.60). Everything downstream is this machine fed a concrete transformation. The next section switches off the coordinate piece, $\delta x^\mu = 0$, and turns the crank on internal symmetries—abelian U(1) and non-abelian multiplets—extracting their currents and charges and proving that the charges close into the symmetry's Lie algebra and generate the field transformations they conserve, with the discrete $\mathbb{Z}_2$ of ϕ^4 theory kept as the explicit foil. A later section switches the coordinate piece on and reads off energy, momentum, and angular momentum, where the improvement freedom of Theorem 7.15 finally earns its keep in the construction of the Belinfante tensor.

7.3 Internal Symmetries, Currents, and the Charge Algebra

The previous section built the abstract machine and proved it: every continuous quasi-symmetry of the action yields a locally conserved current Eq. (7.39), and integrating its time component over a slice produces a time-independent charge Eq. (7.43). The current came in three pieces—the field response $\Pi_a^\mu\,\delta\phi_a$, the coordinate response $-F^\mu$, and the boundary term $-\Lambda^\mu$—and we promised to feed the machine concrete transformations. We begin with the simplest and most pervasive class: *internal symmetries*, transformations that mix the field components among themselves while leaving spacetime untouched. They are the symmetries that fix electric charge, isospin, baryon number, and colour, and they are where the conserved charges reveal their deepest structural property—that they do not merely sit there being conserved, but close into the symmetry's Lie algebra and generate the transformation that produced them. We extract the abelian U(1) current of a complex scalar, then the non-abelian currents of a multiplet in a representation, and prove the two central facts about their charges. We close by carrying ϕ^4 theory to its symmetry layer: its $\mathbb{Z}_2$ reflection $\phi \to -\phi$, a *discrete* symmetry that produces no Noether current at all, yet still rules the theory through selection rules—the sharp foil that shows exactly what continuity buys.

7.3.1 Internal symmetries and the field response

Definition 7.18 (Internal symmetry)**.** An *internal* (or *global, field-space*) symmetry is a quasi-symmetry of the action whose coordinate generators vanish, $X_A^\mu = 0$ in Eq. (7.27), so that points are not moved, $\delta x^\mu = 0$, and the transformation acts only on the field values,

$$\phi_a(x) \;\longmapsto\; \phi'_a(x) = \phi_a(x) + \delta\phi_a(x), \qquad \delta\phi_a = \alpha^c\,\delta^c\phi_a, \tag{7.63}$$

with constant parameters α^c and prescribed field-space generators $\delta^c\phi_a$ that depend on the fields at the same point x. The parameters being constant (independent of x) is what makes the symmetry *global*; the local case, where $\alpha^c = \alpha^c(x)$, is the gauge logic taken up in Chapter 8.

For such a symmetry the three-piece current Eq. (7.39) simplifies dramatically. Setting $\delta x^\mu = 0$ switches off the canonical-stress-tensor piece $F^\mu = T^\mu{}_\nu\,\delta x^\nu$; and for a *strict* symmetry of the Lagrangian—one for which $\delta_0\mathcal{L} = 0$ rather than merely $\delta_0\mathcal{L} = \partial_\mu\Lambda^\mu$—the boundary current vanishes too, $\Lambda^\mu = 0$. We will encounter only strict internal symmetries in this section (the boundary term Λ^μ earns its keep for spacetime symmetries, where the Lagrangian density is a scalar that genuinely shifts), so the master current collapses to its first piece alone,

$$J^{c\,\mu} \;=\; \Pi^\mu_a\,\delta^c\phi_a, \qquad \Pi^\mu_a \equiv \frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi_a)}, \tag{7.64}$$

one current $J^{c\,\mu}$ per generator c, exactly as the multi-parameter theorem Theorem 7.17 demands with $X^\nu_A = 0$ and $\Lambda^\mu_A = 0$. The associated charges are

$$Q^c \;=\; \int_{\mathbb{R}^3} \mathrm{d}^3x\; J^{c\,0} \;=\; \int_{\mathbb{R}^3} \mathrm{d}^3x\; \Pi^0_a\,\delta^c\phi_a \;=\; \int_{\mathbb{R}^3} \mathrm{d}^3x\; \pi_a\,\delta^c\phi_a, \tag{7.65}$$

where in the last step we used $\Pi^0_a = \partial\mathcal{L}/\partial\dot\phi_a = \pi_a$, the canonical momentum density of Theorem 6.13. Equation Eq. (7.65) is the master formula of this section: *the internal charge is the spatial integral of the canonical momentum contracted with the field-space generator.* Its right-hand side is a functional purely of the phase-space data (ϕ_a, π_a) on a slice, which is exactly what we need to compute its Poisson brackets. Everything below is the working-out of Eq. (7.64) and Eq. (7.65) in concrete representations, followed by the proof that the Q^c realize the symmetry algebra.

7.3.2 The abelian case: U(1) of a complex scalar

The cleanest abelian internal symmetry is the phase rotation of a complex scalar field. Let $\Phi(x)$ be a single complex scalar, equivalently a pair of real fields packaged as $\Phi = (\phi_1 + i\phi_2)/\sqrt{2}$, with the Lagrangian

$$\mathcal{L} \;=\; (\partial_\mu\Phi)^*(\partial^\mu\Phi) \;-\; V(\Phi^*\Phi), \tag{7.66}$$

where V is any real function of the real, non-negative combination $\Phi^*\Phi = |\Phi|^2$ (for instance $V = m^2\Phi^*\Phi + \lambda(\Phi^*\Phi)^2$, but we need no specific form). The point of writing V as a function of $|\Phi|^2$ alone is that it makes the symmetry manifest: under a constant phase rotation

$$\Phi \;\longmapsto\; \Phi' = e^{-i\alpha}\,\Phi, \qquad \Phi^* \;\longmapsto\; \Phi'^* = e^{+i\alpha}\,\Phi^*, \tag{7.67}$$

the combination $\Phi^*\Phi$ is invariant and the kinetic term $(\partial_\mu\Phi)^*(\partial^\mu\Phi)$ is invariant because the constant phases $e^{\pm i\alpha}$ pass through the derivative and cancel. So Eq. (7.66) is strictly invariant, $\delta_0\mathcal{L} = 0$, and Eq. (7.67) is a one-parameter family of internal symmetries: the group U(1). (We have chosen the sign of the exponent in Eq. (7.67) as $e^{-i\alpha}$; the opposite choice flips the overall sign of the current below and corresponds to calling the antiparticle positive. Nothing physical depends on it, but we fix it now and keep it.) Infinitesimally,

$$\delta\Phi = -i\alpha\,\Phi, \qquad \delta\Phi^* = +i\alpha\,\Phi^*, \tag{7.68}$$

so the per-generator field variations (the coefficient of the single parameter α) are $\delta\Phi = -i\Phi$ and $\delta\Phi^* = +i\Phi^*$.

To apply Eq. (7.64) we treat Φ and Φ^* as the two independent fields and read off their conjugate momentum densities from Eq. (7.66):

$$\Pi^\mu_\Phi = \frac{\partial\mathcal{L}}{\partial(\partial_\mu\Phi)} = (\partial^\mu\Phi)^* = \partial^\mu\Phi^*, \qquad \Pi^\mu_{\Phi^*} = \frac{\partial\mathcal{L}}{\partial(\partial_\mu\Phi^*)} = \partial^\mu\Phi. \tag{7.69}$$

Substituting these and Eq. (7.68) into the internal-current formula Eq. (7.64) (summing the two field components Φ and Φ^*),

$$\begin{aligned} J^\mu &= \Pi^\mu_\Phi\,(\delta\Phi) + \Pi^\mu_{\Phi^*}\,(\delta\Phi^*) = (\partial^\mu\Phi^*)(-i\Phi) + (\partial^\mu\Phi)(+i\Phi^*) \\ &= i\big(\Phi^*\,\partial^\mu\Phi - \Phi\,\partial^\mu\Phi^*\big) \;=\; i\big(\Phi^*\,\partial^\mu\Phi - (\partial^\mu\Phi^*)\,\Phi\big). \end{aligned} \tag{7.70}$$

This is the conserved U(1) current of the complex scalar. It is real ($J^\mu = (J^\mu)^*$, as a Noether current of a real Lagrangian must be), and it is exactly the structure announced in the chapter blueprint: $J^\mu = i\big[\Pi^\mu_\Phi\,\Phi - \text{c.c.}\big]$ up to the overall sign fixed by the convention Eq. (7.67). A common shorthand uses the antisymmetric double-derivative $A\overleftrightarrow{\partial^\mu}B \equiv A\,\partial^\mu B - (\partial^\mu A)B$, in which $J^\mu = i\,\Phi^*\overleftrightarrow{\partial^\mu}\Phi$. That $\partial_\mu J^\mu = 0$ on shell is guaranteed by Noether's theorem Theorem 7.10; one can also see it directly, since $\partial_\mu J^\mu = i(\Phi^*\Box\Phi - \Phi\,\Box\Phi^*)$, and the equations of motion $\Box\Phi = -V'(\Phi^*\Phi)\,\Phi$ and its conjugate make the two terms cancel because V' is real.

The conserved charge is the spatial integral of J^0,

$$Q = \int_{\mathbb{R}^3} \mathrm{d}^3x\; i(\Phi^*\dot\Phi - \dot\Phi^*\,\Phi), \tag{7.71}$$

where $\dot\Phi = \partial^0\Phi$. We recognize the integrand as $i(\Phi^*\pi_{\Phi^*} - \Phi\,\pi_\Phi)$ once we use the canonical momenta $\pi_\Phi = \Pi^0_\Phi = \dot\Phi^*$ and $\pi_{\Phi^*} = \Pi^0_{\Phi^*} = \dot\Phi$ from Eq. (7.69). The physical meaning of Q becomes transparent only after quantization: in Chapter 9 the complex field's mode expansion will split into a particle annihilation operator and an antiparticle creation operator, and Q will become the number operator $N_a - N_b$, the particle number minus the antiparticle number. Classically it is already the conserved "amount of Φ minus amount of Φ^*"—the prototype of every additive quantum number in physics.

Physical Insight

A U(1) phase symmetry is invisible in the value of $|\Phi|^2$ but visible in the *flow* of phase. The conserved current Eq. (7.70) measures the rate at which the field winds in the complex plane: where the phase $\arg\Phi$ advances coherently, the charge flows. This is why the same current reappears as electric current once the phase is gauged in Chapter 8—electric charge is, structurally, the bookkeeping of an unobservable phase, and its conservation is the statement that the phase has no physical zero.

Worked Example 7.19 (The U(1) charge generates the phase rotation)**.** We verify directly, before proving the general statement, that the charge Eq. (7.71) reproduces the infinitesimal transformation Eq. (7.68) under the Poisson bracket. The relevant canonical brackets, inherited from Eq. (6.112) applied to the independent pairs (Φ, π_Φ) and (Φ^*, π_{Φ^*}), are

$$\{\Phi(\mathbf{x}), \pi_\Phi(\mathbf{y})\}_{\mathrm{P}} = \delta^3(\mathbf{x}-\mathbf{y}), \qquad \{\Phi^*(\mathbf{x}), \pi_{\Phi^*}(\mathbf{y})\}_{\mathrm{P}} = \delta^3(\mathbf{x}-\mathbf{y}), \tag{7.72}$$

with all mixed brackets (Φ with π_{Φ^*}, Φ with Φ^*, etc.) vanishing because the two pairs are independent coordinates on phase space. Write the charge Eq. (7.71) in terms of momenta as $Q = i\int \mathrm{d}^3z\,(\Phi^*(\mathbf{z})\,\pi_{\Phi^*}(\mathbf{z}) - \Phi(\mathbf{z})\,\pi_\Phi(\mathbf{z}))$. Its functional derivatives are

$$\frac{\delta Q}{\delta \pi_\Phi(\mathbf{z})} = -i\,\Phi(\mathbf{z}), \qquad \frac{\delta Q}{\delta \pi_{\Phi^*}(\mathbf{z})} = +i\,\Phi^*(\mathbf{z}). \tag{7.73}$$

Then, using the bracket definition Eq. (6.110) with $F = \Phi(\mathbf{x})$ (so $\delta F/\delta\phi = \delta^3$ on the Φ slot only),

$$\{\Phi(\mathbf{x}), Q\}_{\mathrm{P}} = \int \mathrm{d}^3z\,\frac{\delta\Phi(\mathbf{x})}{\delta\Phi(\mathbf{z})}\,\frac{\delta Q}{\delta\pi_\Phi(\mathbf{z})} = \int \mathrm{d}^3z\,\delta^3(\mathbf{x}-\mathbf{z})\,(-i\,\Phi(\mathbf{z})) = -i\,\Phi(\mathbf{x}). \tag{7.74}$$

This is precisely $\delta\Phi$ of Eq. (7.68) (per unit parameter): $\{\Phi, Q\}_{\mathrm{P}} = \delta\Phi$. An identical computation gives $\{\Phi^*, Q\}_{\mathrm{P}} = +i\,\Phi^* = \delta\Phi^*$. The charge *is* the generator of the phase rotation: bracketing any field with Q rotates its phase. We will now prove this is no accident of the abelian case.

7.3.3 The non-abelian case: a multiplet in a representation

Promote the single field to a multiplet ϕ_i, $i = 1, \dots, N$, transforming in a representation of a compact Lie group G with Lie algebra $\mathfrak{g}$ (Theorem 2.39). The infinitesimal action of the group on the multiplet is, in the Hermitian-generator convention of Eq. (2.70),

$$\phi_i \longmapsto \phi_i' = \left(e^{-i\alpha^a T^a}\right)_{ij}\phi_j, \qquad \delta\phi_i = -i\,\alpha^a (T^a)_{ij}\,\phi_j, \tag{7.75}$$

where $a = 1, \dots, \dim \mathfrak{g}$ labels the generators, the T^a are the Hermitian representation matrices obeying

$$\left[T^a, T^b\right] = i f^{abc}\, T^c \tag{7.76}$$

with the real, totally antisymmetric structure constants f^{abc} of Eq. (2.70), and α^a are the constant group parameters. The per-generator field variation, the coefficient of α^a, is

$$\delta^a \phi_i \;=\; -i\,(T^a)_{ij}\,\phi_j \;\equiv\; (t^a)_{ij}\,\phi_j, \qquad t^a \equiv -i\,T^a. \tag{7.77}$$

The matrices $t^a = -iT^a$ are the generators in their "real" form: stripping the i from the Hermitian convention, they satisfy the structure relation without the i,

$$\left[t^a, t^b\right] = (-i)^2 \left[T^a, T^b\right] = -\,i f^{abc}\, T^c = f^{abc}\,(-iT^c) = f^{abc}\, t^c. \tag{7.78}$$

For a real multiplet—N real fields rotated into one another, as in an SO(N) vector—the t^a are real antisymmetric matrices and Eq. (7.75) keeps the ϕ_i real; for a complex multiplet (the U(1) case above is N complex with the single generator $T = 1$, $t = -i$) the same formulas hold with the components understood as complex. We carry the algebra in the index form Eq. (7.77), which covers both.

For the Lagrangian we take any density built from invariant contractions of the multiplet, the canonical example being

$$\mathcal{L} = \tfrac{1}{2}\,\partial_\mu \phi_i\, \partial^\mu \phi_i - V(\phi_i \phi_i), \tag{7.79}$$

invariant because $\phi_i \phi_i$ and $\partial_\mu \phi_i\, \partial^\mu \phi_i$ are unchanged under $\phi \to e^{-i\alpha\cdot T}\phi$ when the T^a are Hermitian (so $e^{-i\alpha\cdot T}$ is orthogonal/unitary and preserves the contraction). The conjugate momentum density is $\Pi_i^\mu = \partial^\mu \phi_i$, so $\pi_i = \dot{\phi}_i$. Feeding Eq. (7.77) into the internal-current master formula Eq. (7.64) gives one current per generator,

$$J^{a\,\mu} = \Pi_i^\mu\, \delta^a \phi_i = \partial^\mu \phi_i\, (t^a)_{ij}\, \phi_j = -i\,\partial^\mu \phi_i\, (T^a)_{ij}\, \phi_j, \tag{7.80}$$

and the corresponding charges, from Eq. (7.65),

$$Q^a = \int_{\mathbb{R}^3} \mathrm{d}^3x\; \pi_i\, (t^a)_{ij}\, \phi_j = -i \int_{\mathbb{R}^3} \mathrm{d}^3x\; \pi_i\, (T^a)_{ij}\, \phi_j. \tag{7.81}$$

Each $J^{a\mu}$ is separately conserved by Theorem 7.17, and each Q^a is separately time-independent by Theorem 7.13. There are $\dim \mathfrak{g}$ of them—as many conserved charges as the group has dimensions, the counting promised at the end of Section 7.2.4. What distinguishes the non-abelian case from the abelian one is what happens when we bracket these charges with one another.

7.3.4 The charges generate the transformation

We first prove that each charge generates, through the Poisson bracket, exactly the field transformation it descended from. This is the classical statement of which the quantum statement $\delta\hat{\phi} = i\alpha^a[\hat{Q}^a, \hat{\phi}]$ will be the operator translate.

Theorem 7.20 (Charges generate the field transformation)**.** *For the internal symmetry Eq. (7.75) with charges Eq. (7.81), the equal-time Poisson bracket of a charge with the field reproduces the field-space generator,*

$$\{\phi_k(\mathbf{x}), Q^a\}_P = \delta^a\phi_k(\mathbf{x}) = (t^a)_{kj}\,\phi_j(\mathbf{x}). \tag{7.82}$$

Consequently the finite transformation Eq. (7.75) is generated by exponentiating the bracket: $\phi'_k = (e^{-\alpha^a\{\cdot, Q^a\}_P})\phi_k$ *in the sense of the formal series.*

Proof. Write the charge Eq. (7.81) as $Q^a = \int \mathrm{d}^3z\,\pi_l(\mathbf{z})\,(t^a)_{lj}\,\phi_j(\mathbf{z})$. Its functional derivative with respect to the momentum is

$$\frac{\delta Q^a}{\delta\pi^c(\mathbf{z})} = (t^a)_{cj}\,\phi_j(\mathbf{z}), \tag{7.83}$$

and its derivative with respect to ϕ will not contribute because $\delta\phi_k/\delta\pi = 0$. Inserting $F = \phi_k(\mathbf{x})$ and $G = Q^a$ into the bracket definition Eq. (6.110) and using the sharp functional derivative $\delta\phi_k(\mathbf{x})/\delta\phi_c(\mathbf{z}) = \delta_{kc}\,\delta^3(\mathbf{x}-\mathbf{z})$,

$$\{\phi_k(\mathbf{x}), Q^a\}_{\mathrm{P}} = \int \mathrm{d}^3z\,\frac{\delta\phi_k(\mathbf{x})}{\delta\phi_c(\mathbf{z})}\,\frac{\delta Q^a}{\delta\pi^c(\mathbf{z})} = \int \mathrm{d}^3z\,\delta_{kc}\,\delta^3(\mathbf{x}-\mathbf{z})\,(t^a)_{cj}\,\phi_j(\mathbf{z}) = (t^a)_{kj}\,\phi_j(\mathbf{x}). \tag{7.84}$$

The right-hand side is $\delta^a\phi_k(\mathbf{x})$ by Eq. (7.77). The finite statement follows because $\{\cdot, Q^a\}_{\mathrm{P}}$ acts on ϕ as the constant matrix t^a, so its n-fold iteration is $(t^a)^n$, and the formal exponential sums to $e^{-\alpha^a T^a\cdot}$ acting on the multiplet, which is Eq. (7.75). □

The bracket order in Eq. (7.82) matters and is fixed by consistency with the dynamics. In Eq. (6.115) the Hamiltonian generated time evolution through $\dot{F} = \{F, H\}_{\mathrm{P}}$, with the evolving quantity on the *left*. The same convention here—generated object on the left, generator on the right—makes Q^a the spatial-symmetry analogue of H: just as H generates the flow in time, Q^a generates the flow along the a-th internal direction. We will use this uniform convention throughout, so that in Section 7.3's sequel the momentum P^μ and angular momentum $J^{\mu\nu}$ generate spacetime translations and rotations by the identical rule.

Notation Watch

Some texts write the generator on the left, $\delta^a\phi = \{Q^a, \phi\}_{\mathrm{P}}$. Because the Poisson bracket is antisymmetric, $\{Q^a, \phi\}_{\mathrm{P}} = -\{\phi, Q^a\}_{\mathrm{P}}$, that convention flips the sign of the field-space generator (equivalently, it accompanies the opposite sign for the charge). The physics—which field-space rotation a given charge induces—is identical; only the placement of a minus sign moves. We keep the object-on-the-left convention Eq. (7.82) to match Eq. (6.115).

7.3.5 The charge algebra

The deepest fact about the charges is that they do not merely each generate their own transformation; the brackets of the charges among themselves reproduce the commutators of the generators. The charges *represent* the Lie algebra.

Theorem 7.21 (Classical charge algebra)**.** *The Noether charges Eq. (7.81) of the internal symmetry Eq. (7.75) satisfy the equal-time Poisson-bracket algebra*

$$\boxed{\left\{Q^a, Q^b\right\}_P = f^{abc}\, Q^c} \tag{7.85}$$

with the same structure constants f^{abc} that define the Lie algebra $\mathfrak{g}$ in Eq. (7.76). The map $a \mapsto Q^a$ is therefore a homomorphism from $\mathfrak{g}$ into the Poisson-bracket algebra of phase-space functions.

Proof. Write both charges in the real-generator form, $Q^a = \int \mathrm{d}^3z\, \pi_p(\mathbf{z})\,(t^a)_{pq}\,\phi_q(\mathbf{z})$ and likewise for Q^b. Each is bilinear in the phase-space variables, so its functional derivatives are linear:

$$\frac{\delta Q^a}{\delta\phi_c(\mathbf{z})} = \pi_p(\mathbf{z})\,(t^a)_{pc}, \qquad \frac{\delta Q^a}{\delta\pi^c(\mathbf{z})} = (t^a)_{cq}\,\phi_q(\mathbf{z}). \tag{7.86}$$

Insert these into the bracket definition Eq. (6.110):

$$\begin{aligned}
\left\{Q^a, Q^b\right\}_{\mathrm{P}} &= \int \mathrm{d}^3z \left[\frac{\delta Q^a}{\delta\phi_c(\mathbf{z})}\frac{\delta Q^b}{\delta\pi^c(\mathbf{z})} - \frac{\delta Q^a}{\delta\pi^c(\mathbf{z})}\frac{\delta Q^b}{\delta\phi_c(\mathbf{z})}\right] \\
&= \int \mathrm{d}^3z \left[\pi_p\,(t^a)_{pc}\,(t^b)_{cq}\,\phi_q - (t^a)_{cq}\,\phi_q\,\pi_p\,(t^b)_{pc}\right] \\
&= \int \mathrm{d}^3z\; \pi_p \left[(t^a)_{pc}(t^b)_{cq} - (t^b)_{pc}(t^a)_{cq}\right]\phi_q \\
&= \int \mathrm{d}^3z\; \pi_p \left[t^a, t^b\right]_{pq}\phi_q .
\end{aligned} \tag{7.87}$$

In the second line both products are ordinary numbers (the fields and momenta commute as classical functions), so the second term could be reordered to

expose the matrix product $(t^b)_{pc}(t^a)_{cq} = (t^b t^a)_{pq}$, leaving the matrix commutator $[t^a, t^b]_{pq} = (t^a t^b - t^b t^a)_{pq}$ in the last line. Now use the structure relation Eq. (7.78), $[t^a, t^b] = f^{abc} t^c$:

$$\left\{Q^a, Q^b\right\}_{\mathrm{P}} = \int \mathrm{d}^3 z \; \pi_p \, f^{abc} \, (t^c)_{pq} \, \phi_q = f^{abc} \int \mathrm{d}^3 z \; \pi_p \, (t^c)_{pq} \, \phi_q = f^{abc} \, Q^c, \quad (7.88)$$

the last integral being Q^c by Eq. (7.81). This is Eq. (7.85). □

It is worth seeing why the sign in Eq. (7.85) comes out as $+f^{abc}$ and not $-f^{abc}$, because the result is convention-sensitive and the conventions were fixed precisely to make it clean. Had we written the field transformation with the opposite phase, $\delta\phi = +i\alpha^a T^a \phi$, the generators would be $t^a = +iT^a$, the structure relation Eq. (7.78) would read $[t^a, t^b] = -f^{abc} t^c$, and the same computation would yield $\left\{Q^a, Q^b\right\}_{\mathrm{P}} = -f^{abc} Q^c$—an *anti*-homomorphism. Our choice $e^{-i\alpha\cdot T}$ in Eq. (7.75) is exactly the one that makes $Q \mapsto \{\cdot, Q\}_{\mathrm{P}}$ a genuine homomorphism, so that the classical charges represent $\mathfrak{g}$ the right way up. The same choice is what made $\{\phi, Q^a\}_{\mathrm{P}} = +\delta^a \phi$ in Theorem 7.20; the two signs are locked together, and we fixed them once and for all in Eq. (7.75).

Physical Insight

Equation (7.85) is the classical seed of the entire operator structure of internal symmetry in the quantum theory. Under canonical quantization $\{\cdot,\cdot\}_{\mathrm{P}} \to -i\,[\cdot,\cdot]$ (Chapter 9), the charge algebra becomes $\left[\hat{Q}^a, \hat{Q}^b\right] = i f^{abc} \hat{Q}^c$—the Hermitian generators Eq. (7.76) realized as operators on the Hilbert space. The conserved charges are not just labels on states; they are the very operators whose simultaneous eigenvalues (for a maximal commuting set, the Cartan subalgebra) are the quantum numbers—isospin and its third component, colour weights, hypercharge—that organize the particle spectrum. Multiplets of particles are multiplets of $\mathfrak{g}$ because the charges close into $\mathfrak{g}$.

A consistency check ties the two theorems together. The charges generate transformations (Theorem 7.20), and the commutator of two infinitesimal transformations must itself be a transformation—the one labelled by the commutator of the generators. Computing the commutator of two field-space rotations directly from Eq. (7.77),

$$[\delta^a, \delta^b]\phi_k = (t^a t^b - t^b t^a)_{kj} \, \phi_j = [t^a, t^b]_{kj} \, \phi_j = f^{abc} \, (t^c)_{kj} \, \phi_j = f^{abc} \, \delta^c \phi_k, \quad (7.89)$$

and this must equal what the bracketed charges generate. Indeed, using the Jacobi identity of the Poisson bracket (Theorem 6.17) and Theorem 7.20 twice, one finds $[\delta^a, \delta^b]\phi_k = \left\{\phi_k, \left\{Q^a, Q^b\right\}_{\mathrm{P}}\right\}_{\mathrm{P}}$, so that $\left\{\phi_k, \left\{Q^a, Q^b\right\}_{\mathrm{P}}\right\}_{\mathrm{P}} = f^{abc} \, \delta^c \phi_k =$

$\{\phi_k, f^{abc}Q^c\}_{\mathrm{P}}$ for every field, which forces $\{Q^a, Q^b\}_{\mathrm{P}} = f^{abc}Q^c$ up to a quantity bracketing trivially with all fields. Classically that quantity is an irrelevant constant (a possible *central extension*); for the linearly realized internal symmetries here it vanishes, as the explicit computation Eq. (7.87) confirmed. The two routes—direct phase-space computation and abstract Jacobi argument—agree, and they will agree again for the Poincaré charges of the next section, where the central term is likewise absent.

7.3.6 Discrete symmetries: Scalar ϕ^4 theory's $\mathbb{Z}_2$

Everything so far rested on *continuity*: the Noether construction differentiates the transformation with respect to its parameter, and a current exists because there is a parameter to differentiate. We now carry ϕ^4 theory to its symmetry layer and meet the opposite case—a symmetry with no parameter at all—to see exactly what is lost and what survives. Recall the frozen real-scalar Lagrangian of Eq. (6.56),

$$\mathcal{L} = \tfrac{1}{2}\,\partial_\mu\phi\,\partial^\mu\phi - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4, \tag{7.90}$$

with a single *real* field ϕ. There is no continuous phase to rotate: a real field has no complex structure to support a U(1). What it does have is a reflection.

Definition 7.22 (The $\mathbb{Z}_2$ reflection of ϕ^4 theory)**.** The transformation $\phi(x) \mapsto -\phi(x)$, leaving spacetime fixed, is a symmetry of Eq. (7.90): every term contains ϕ to an even power ($\partial_\mu\phi\,\partial^\mu\phi$, ϕ^2, ϕ^4), so $\mathcal{L}[-\phi] = \mathcal{L}[\phi]$ and the action is invariant. The transformation squares to the identity, $(-1)^2 = 1$, and together with the identity forms the two-element group $\mathbb{Z}_2 = \{1, -1\}$.

This invariance is exactly what selected the Lagrangian Eq. (7.90) in the first place: when Eq. (6.56) was assembled, the reflection symmetry was imposed to forbid the odd terms ϕ, ϕ^3 that Lorentz invariance and dimensional analysis would otherwise permit. The $\mathbb{Z}_2$ is therefore not an accident of the model but a defining constraint on it. The question is what conserved quantity, if any, it produces.

Proposition 7.23 (A discrete symmetry produces no Noether current)**.** *The reflection $\phi \to -\phi$ of Theorem 7.22 yields no conserved Noether current.*

Proof. The Noether construction of Theorem 7.10 takes as input an infinitesimal transformation $\delta\phi = \alpha\,\delta^c\phi$ obtained by differentiating a one-parameter family ϕ_s at $s = 0$, $\delta^c\phi = \frac{d\phi_s}{ds}\big|_{s=0}$, with $\phi_0 = \phi$ the identity. The current Eq. (7.64) is built from this derivative, $J^\mu = \Pi^\mu_a\,\delta^c\phi$. For a continuous symmetry such a family exists by definition; for the reflection it does not. The symmetry group $\mathbb{Z}_2 = \{1, -1\}$ is a zero-dimensional manifold: it consists of two isolated points, and there is no continuous path within it from the identity 1 to the reflection

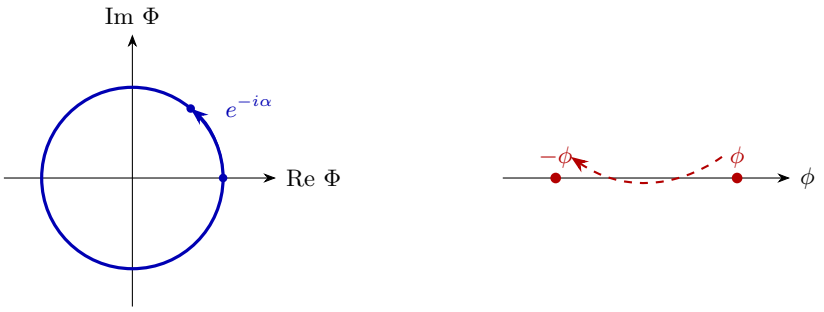

Figure 7.3: Internal symmetry as motion in field space. A U(1) phase rotation (left) moves the complex field Φ along a continuous orbit—a circle—so the transformation can be done infinitesimally, differentiated, and fed to Noether's theorem, producing a conserved current and charge. The $\mathbb{Z}_2$ reflection of ϕ^4 theory (right) maps the real field ϕ to the single isolated point $-\phi$; the group is zero-dimensional and there is no continuous path from the identity, so there is nothing to differentiate and no Noether current. The discrete symmetry still constrains the theory through selection rules.

-1. Concretely, any attempt to interpolate, $\phi_s = (1-2s)\phi$ with $\phi_0 = \phi$ and $\phi_1 = -\phi$, passes through configurations ϕ_s that are *not* symmetries of the action—$\mathcal{L}[(1-2s)\phi] \neq \mathcal{L}[\phi]$ for $0 < s < 1$, since the quartic term scales as $(1-2s)^4$. There is no s-derivative of a *symmetry* family to feed the construction, hence no infinitesimal generator $\delta^c\phi$, hence no current. The hypothesis of Noether's first theorem—a one-parameter family of symmetries—is simply not met. □

So discreteness costs us the current and the charge: there is no locally conserved J^μ, no time-independent Q, no generator in the Poisson algebra. What survives is a global constraint on the theory's correlation functions, sharper in some ways than a conservation law. The cleanest classical statement is a *selection rule*.

Worked Example 7.24 (The $\mathbb{Z}_2$ selection rule, classically)**.** Couple the field to an external source $J(x)$ and consider the sourced field equation derived from Eq. (7.90),

$$(\Box + m^2)\,\phi + \frac{\lambda}{3!}\,\phi^3 = J, \tag{7.91}$$

whose left-hand side is the variational derivative $-\delta S/\delta\phi$ and which reduces to the ϕ^4 equation of motion Eq. (6.60) when $J = 0$. The left-hand side is *odd* under $\phi \to -\phi$: each of $\Box\phi$, $m^2\phi$, and ϕ^3 flips sign. Therefore the solution $\phi = \phi[J]$, with the standard (Feynman) boundary conditions that pick a unique solution,

obeys

$$\phi[-J] = -\phi[J], \tag{7.92}$$

because replacing $J \to -J$ and $\phi \to -\phi$ leaves Eq. (7.91) unchanged. The classical field is an *odd functional of the source*. Expanding it perturbatively in powers of J—which is the tree-level expansion whose terms are the connected correlation functions, made precise by the generating functional of Chapter 10—

$$\phi[J](x) = \int G_2(x, y_1)\, J(y_1) + \frac{1}{3!} \int G_4(x, y_1, y_2, y_3)\, J(y_1) J(y_2) J(y_3) + \cdots , \tag{7.93}$$

the oddness Eq. (7.92) forces every *even* power of J to be absent: only $J^1, J^3, J^5, \ldots$ appear. The coefficient of J^n is the $(n{+}1)$-point function G_{n+1}, so the surviving functions have $n+1$ *even*, i.e. all G_{odd} vanish:

$$\boxed{G_{2k+1} = 0 \quad \text{for all } k} \tag{7.94}$$

Every correlation function with an odd number of fields vanishes identically. Equivalently, every interaction vertex of Eq. (7.90) has an even number of legs (ϕ^2 and ϕ^4, never ϕ or ϕ^3), so any process connects an even number of external ϕ quanta: an amplitude with an odd number of external ϕ lines is zero. This is the classical shadow of the quantum statement, sharpened in Chapter 10 (the generating functional) and put to work in Chapter 14 (the first amplitude $\phi\phi \to \phi\phi$), that the $\mathbb{Z}_2$ forbids odd-point amplitudes.

The contrast is now complete and instructive. A *continuous* internal symmetry gives a local conservation law $\partial_\mu J^\mu = 0$, a time-independent charge Q, a generator in the Poisson algebra, and—when non-abelian—a charge algebra Eq. (7.85) that organizes the spectrum into multiplets. A *discrete* internal symmetry gives none of these analytic structures, but it gives a selection rule Eq. (7.94): an exact statement that whole classes of processes have vanishing amplitude. Both are genuine consequences of invariance; they differ because Noether's theorem is a theorem about derivatives, and only a continuous family has a derivative to take. The $\mathbb{Z}_2$ of ϕ^4 theory is the carried example of the discrete case, and Eq. (7.94) is the constraint it imposes on every later stage of the thread—a constraint we will invoke without re-deriving each time a ϕ^4 amplitude is computed.

Physical Insight

The deep distinction is not "continuous versus discrete" as a taxonomy but *what each kind of symmetry produces*. Continuity is exactly the structure needed to convert a global invariance into a *local* statement at every point—a current whose divergence vanishes there. Discreteness cannot do that; the best it can do is constrain *global* objects, the correlation functions, all at once. This is why the parade of conserved currents in the

Standard Model—electric charge, colour, hypercharge—are all continuous symmetries, while the discrete symmetries (parity, charge conjugation, the residual $\mathbb{Z}_2$'s that stabilize dark-matter candidates) act as selection rules and superselection labels rather than as conserved flows.

With the internal symmetries dispatched—abelian and non-abelian currents extracted from the single formula Eq. (7.64), their charges shown to generate the transformation Eq. (7.82) and to close into the Lie algebra Eq. (7.85), and the discrete $\mathbb{Z}_2$ of ϕ^4 theory separated off as a selection rule—we have established the charge-as-generator picture in its cleanest setting, where the field-space generators t^a are constant matrices. The next section switches the coordinate piece F^μ back on and applies the same machine to spacetime symmetries: translations will deliver the four-momentum P^μ and Lorentz transformations the angular-momentum current $J^{\mu\nu}$, and the brackets proved here—charge generates transformation, charges close into an algebra—will recur verbatim, now realizing the Poincaré algebra with P^μ and $J^{\mu\nu}$ as its generators.

7.4 Spacetime Symmetries: The Canonical Stress Tensor and Angular Momentum

The previous two sections built the machine and ran it once on field space. Noether's first theorem (Theorem 7.10) attached to every continuous quasi-symmetry a locally conserved current $J^\mu = \Pi^\mu_a\,\delta\phi_a - F^\mu - \Lambda^\mu$ (Eq. (7.39)), and the charge built from it (Theorem 7.12) was shown to be time-independent, slice-independent, and—for internal symmetries—to close into the symmetry's Lie algebra under Poisson brackets and to generate the field transformation it came from. Internal symmetries are, however, the case in which the coordinate piece $F^\mu = T^\mu{}_\nu\,\delta x^\nu$ is switched off, because they leave the spacetime point fixed: $\delta x^\mu = 0$. We now turn the machine on the opposite extreme, the symmetries that move the point itself—the Poincaré transformations of spacetime—where the current is carried *almost entirely* by F^μ, and where the field-space piece $\Pi^\mu_a\,\delta\phi_a$ survives only for fields of nonzero spin. The payoff is the identification of the deepest conserved quantities a relativistic field theory possesses: energy, momentum, and angular momentum become the Noether charges of translations and Lorentz rotations, and the charge-as-generator dictionary of the last section promotes them into the ten generators of the Poincaré algebra (Eqs. (3.147) to (3.149)). Along the way the construction hands us, for free, the two structural defects that the next section must repair: the canonical stress tensor is generically not symmetric, and for gauge fields not even gauge invariant.

7.4.1 Translations revisited: the canonical stress tensor as a Noether current

The four rigid translations $x'^{\mu} = x^{\mu} + a^{\mu}$ were already fed through the general theorem in Theorem 7.11, where they reproduced the canonical stress–energy tensor of Theorem 6.28. We consolidate that result here as the first of the two spacetime cases, because it fixes the notation and the sign conventions that the Lorentz analysis will lean on, and because the four-momentum it produces is one of the section's owed results.

A translation carries a field configuration bodily to the shifted point, so a field of *any* spin transforms as a scalar under it: the comoving value is unchanged, $\phi'_a(x') = \phi_a(x)$, hence the total variation vanishes, $\delta\phi_a = 0$, while the coordinate generators are $\delta x^{\mu} = a^{\mu}$ with a^{μ} four independent constants. Because $\mathcal{L}$ carries no explicit coordinate dependence, the translation is a strict symmetry, $\Lambda^{\mu} = 0$ (the cancellation $\delta_0\mathcal{L} + \partial_\mu(\mathcal{L}\,\delta x^{\mu}) = -a^{\nu}\partial_\nu\mathcal{L} + a^{\mu}\partial_\mu\mathcal{L} = 0$ was carried out in Theorem 7.11). The three-piece current Eq. (7.39) therefore collapses onto its coordinate part,

$$J^{\mu} = \Pi^{\mu}_{a}\cdot 0 - F^{\mu} - 0 = -T^{\mu}{}_{\nu}\,a^{\nu}, \tag{7.95}$$

and since the four parameters a^{ν} are independent, the multi-parameter theorem (Theorem 7.17) extracts four separately conserved currents, the columns of the canonical stress tensor,

$$T^{\mu\nu} = \Pi^{\mu}_{a}\,\partial^{\nu}\phi_a - \eta^{\mu\nu}\mathcal{L}, \qquad \partial_\mu T^{\mu\nu} = 0, \tag{7.96}$$

exactly Eq. (6.165). The associated Noether charges are the spatial integrals of the time components,

$$\boxed{P^{\nu} = \int \mathrm{d}^3x\; T^{0\nu}(t,\mathbf{x})} \tag{7.97}$$

which is the four-momentum of Eq. (6.171); its time component $P^0 = \int \mathrm{d}^3x\, T^{00} = H$ is the energy and its spatial components $P^i = \int \mathrm{d}^3x\, T^{0i}$ the field momentum. The generic conservation theorem (Theorem 7.13) and slice-independence (Theorem 7.14) specialize to these and reproduce the direct results of Theorem 6.31. In the language of the charge-as-generator dictionary of the previous section, the four P^{ν} are the generators of spacetime translations, and they are the relativistic upgrade of the Hamiltonian: where nonrelativistic mechanics had a single time-translation generator H, Lorentz invariance forces three more, the components of $\mathbf{P}$, into the same multiplet.

We pause to record the one consistency check the thread obligation asks for, and no more: the carried scalar reproduces, through the general machine, the stress tensor computed by hand in the previous chapter.

Worked Example 7.25 (ϕ^4 theory: the canonical stress tensor from the general theorem)**.** Take the frozen scalar Lagrangian Eq. (6.176),

$$\mathcal{L} = \tfrac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4,$$

the single field carrying no spacetime index, so the multiplet index a is trivial and the field-space variation $\delta\phi$ vanishes under translation. The conjugate-momentum density is $\Pi^\mu = \partial\mathcal{L}/\partial(\partial_\mu\phi) = \partial^\mu\phi$, the only derivative dependence sitting in the kinetic term. Inserting this and $\mathcal{L}$ into Eq. (7.96) gives

$$T^{\mu\nu} = \partial^\mu\phi\,\partial^\nu\phi - \eta^{\mu\nu}\left[\tfrac{1}{2}(\partial_\alpha\phi)(\partial^\alpha\phi) - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4\right], \tag{7.98}$$

which is verbatim Eq. (6.178). The result is automatically symmetric, $T^{\mu\nu} = T^{\nu\mu}$, because a scalar offers no index structure beyond $\partial^\mu\phi\,\partial^\nu\phi$ and $\eta^{\mu\nu}$ times scalars; and it is manifestly built from ϕ alone, so there is no gauge ambiguity. The scalar is the case in which the canonical construction already delivers a flawless tensor. As the Lorentz analysis below makes precise, the reason is that a spin-zero field has *no spin current*: the field-space piece $\Pi^\mu_a\,\delta\phi_a$ that would source the antisymmetric part of T is identically zero. The substantive symmetry layer of ϕ^4 theory—the $\mathbb{Z}_2$ reflection and the classically exact scale invariance of the massless theory—is taken up in Section 7.7; here the scalar serves only to confirm that the general machine and the hand computation agree.

7.4.2 Lorentz invariance and the angular-momentum current

The remaining six Poincaré generators are the Lorentz transformations, and they are the genuinely new content of this section, because the field-space piece of the Noether current no longer vanishes: under a Lorentz transformation a field of nonzero spin is not merely carried to a new point but is *rotated in field space* according to the representation it carries. This rotation is the source of intrinsic spin, and reading it off cleanly is the whole task.

We need both pieces of the transformation, the coordinate piece and the field piece. The coordinate piece is fixed by Chapter 3: an infinitesimal Lorentz transformation acts on spacetime by

$$\delta x^\mu = \omega^\mu{}_\nu\, x^\nu = \tfrac{1}{2}\,\omega_{\alpha\beta}(\eta^{\mu\alpha}x^\beta - \eta^{\mu\beta}x^\alpha), \qquad \omega_{\alpha\beta} = -\omega_{\beta\alpha}, \tag{7.99}$$

the antisymmetry of the six parameters $\omega_{\alpha\beta}$ being exactly the condition $\delta(\eta_{\mu\nu}x^\mu x^\nu) = 0$ that the transformation preserve the interval. The second equality writes $\omega^\mu{}_\nu x^\nu$ in manifestly antisymmetric form against the pair $(\alpha\beta)$; it identifies the coordinate generators

$$X^\mu_{\alpha\beta} = \eta^{\mu\alpha}x^\beta - \eta^{\mu\beta}x^\alpha, \qquad \delta x^\mu = \tfrac{1}{2}\,\omega_{\alpha\beta}\,X^\mu_{\alpha\beta}, \tag{7.100}$$

antisymmetric in $\alpha\beta$ as the parameters demand.

The field piece is fixed by the field's Lorentz representation, the classification of Section 3.3. A multiplet ϕ_a transforming in a representation with Hermitian generators $\Sigma^{\alpha\beta}$ (matrices acting on the multiplet index a, satisfying the Lorentz algebra Eq. (3.34)) is carried by a finite Lorentz transformation to

$$\phi'_a(x') = S(\Lambda)_a{}^b\,\phi_b(x), \qquad S(\Lambda) = \exp\Big(-\tfrac{i}{2}\,\omega_{\alpha\beta}\,\Sigma^{\alpha\beta}\Big), \tag{7.101}$$

in exact parallel with the defining-representation rule $\Lambda = \exp(-\frac{i}{2}\omega_{\alpha\beta}M^{\alpha\beta})$ of Theorem 3.11. The *total* variation in the sense of Eq. (7.39)—the difference between the new field at the new point and the old field at the old point—is the linearized representation rotation, with no derivative term,

$$\delta\phi_a = (S(\Lambda)_a{}^b - \delta_a^b)\phi_b = -\tfrac{i}{2}\,\omega_{\alpha\beta}\,(\Sigma^{\alpha\beta})_a{}^b\,\phi_b, \qquad \Phi_{a,\alpha\beta} = -i\,(\Sigma^{\alpha\beta})_a{}^b\,\phi_b, \tag{7.102}$$

the second equality reading off the field-space generators $\Phi_{a,\alpha\beta}$ in the notation of the multi-parameter theorem (Theorem 7.17). The representation content is the entire input: $\Sigma^{\alpha\beta} = 0$ for a scalar, $\Sigma^{\alpha\beta} = \frac{1}{2}\sigma^{\alpha\beta}$ with $\sigma^{\alpha\beta} = \frac{i}{2}[\gamma^\alpha, \gamma^\beta]$ for a Dirac spinor, and $(\Sigma^{\alpha\beta})^\mu{}_\nu = (M^{\alpha\beta})^\mu{}_\nu = i(\eta^{\alpha\mu}\delta^\beta{}_\nu - \eta^{\beta\mu}\delta^\alpha{}_\nu)$ of Eq. (3.33) for a vector field.

Before turning the crank we must check that a Lorentz transformation is a strict symmetry, $K^\mu = 0$, so that no boundary term contaminates the current. Because $\mathcal{L}$ is, by construction, a Lorentz scalar, it transforms as $\mathcal{L}'(x') = \mathcal{L}(x)$, i.e. its total variation vanishes, $\delta\mathcal{L} = 0$, equivalently $\delta_0\mathcal{L} = \delta\mathcal{L} - \delta x^\mu\partial_\mu\mathcal{L} = -\delta x^\mu\partial_\mu\mathcal{L}$. The invariance condition (Theorem 7.4) is then

$$\delta_0\mathcal{L} + \partial_\mu(\mathcal{L}\,\delta x^\mu) = -\delta x^\mu\partial_\mu\mathcal{L} + (\partial_\mu\delta x^\mu)\mathcal{L} + \delta x^\mu\partial_\mu\mathcal{L} = \mathcal{L}\,\partial_\mu\delta x^\mu = 0, \tag{7.103}$$

the final equality because $\partial_\mu\delta x^\mu = \partial_\mu(\omega^\mu{}_\nu x^\nu) = \omega^\mu{}_\mu = 0$ is the trace of an antisymmetric matrix. Hence $\partial_\mu K^\mu = 0$ and we may take $K^\mu = 0$: Lorentz transformations, like translations, are strict symmetries of any Poincaré-invariant action.

With $K^\mu = 0$, the multi-parameter Noether current Eq. (7.60), one current per generator pair $(\alpha\beta)$, is

$$J^\mu_{\alpha\beta} = \Pi^\mu_a\,\Phi_{a,\alpha\beta} - T^\mu{}_\nu\,X^\nu_{\alpha\beta} = -i\,\Pi^\mu_a\,(\Sigma^{\alpha\beta})_a{}^b\,\phi_b - T^\mu{}_\nu(\eta^{\nu\alpha}x^\beta - \eta^{\nu\beta}x^\alpha). \tag{7.104}$$

Contracting the stress tensor against the coordinate generators gives $T^\mu{}_\nu(\eta^{\nu\alpha}x^\beta - \eta^{\nu\beta}x^\alpha) = T^{\mu\alpha}x^\beta - T^{\mu\beta}x^\alpha$, so

$$J^\mu_{\alpha\beta} = x^\alpha T^{\mu\beta} - x^\beta T^{\mu\alpha} - i\,\Pi^\mu_a\,(\Sigma^{\alpha\beta})_a{}^b\,\phi_b. \tag{7.105}$$

This is the angular-momentum current. We give it the name and the index ordering fixed in the previous chapter (Eq. (6.194)), $M^{\mu\,\alpha\beta} \equiv J^\mu_{\alpha\beta}$, and isolate its two pieces.

Definition 7.26 (Spin current)**.** For a field multiplet ϕ_a in a Lorentz representation with generators $\Sigma^{\nu\rho}$, the *intrinsic spin current* is the field-space piece of the Lorentz Noether current,

$$\boxed{S^{\mu\,\nu\rho} = -\,i\,\Pi^{\mu}_{a}\,(\Sigma^{\nu\rho})_{a}{}^{b}\,\phi_b = -\,i\,\frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi_a)}\,(\Sigma^{\nu\rho})_{a}{}^{b}\,\phi_b} \tag{7.106}$$

antisymmetric in $\nu\rho$ because $\Sigma^{\nu\rho}$ is. It vanishes identically for a scalar ($\Sigma = 0$) and is nonzero precisely when the field carries spin.

Theorem 7.27 (The Lorentz Noether current and its conservation)**.** *On solutions of the Euler–Lagrange equations, the angular-momentum current*

$$M^{\mu\,\nu\rho} = \underbrace{x^{\nu}T^{\mu\rho} - x^{\rho}T^{\mu\nu}}_{\text{orbital}} + \underbrace{S^{\mu\,\nu\rho}}_{\text{spin}} \tag{7.107}$$

is the conserved Noether current of Lorentz invariance,

$$\partial_\mu M^{\mu\,\nu\rho} = 0, \tag{7.108}$$

antisymmetric in the pair $\nu\rho$, with orbital part built from the canonical stress tensor Eq. (7.96) and spin part the spin current Eq. (7.106).

Proof. Equation Eq. (7.107) is Eq. (7.105) with $(\alpha\beta)$ renamed $(\nu\rho)$ and the spin current Eq. (7.106) substituted; the orbital term $x^{\alpha}T^{\mu\beta} - x^{\beta}T^{\mu\alpha} = x^{\nu}T^{\mu\rho} - x^{\rho}T^{\mu\nu}$ on relabelling. Antisymmetry in $\nu\rho$ is manifest term by term. Conservation is the content of Noether's first theorem (Theorem 7.10) applied to the Lorentz quasi-symmetry, which we have just shown is a *strict* symmetry ($K^{\mu} = 0$, Eq. (7.103)): the current Eq. (7.105) is of the form Eq. (7.60), and the theorem gives $\partial_\mu M^{\mu\,\nu\rho} = 0$ for each independent pair $(\nu\rho)$. We verify it independently—and expose its structural content—in Theorem 7.28 below. □

This reproduces and now proves the schematic statement Eq. (6.194) that the previous chapter could only anticipate, and it makes the spin term fully explicit: $S^{\mu\nu\rho}$ is dictated, with no freedom, by the field's behaviour under the Lorentz generators in its representation. The orbital part $x^{\nu}T^{\mu\rho} - x^{\rho}T^{\mu\nu}$ is the field-theoretic "$\mathbf{r}\times\mathbf{p}$"—position x wedged against the momentum-flux columns of the stress tensor—and the spin part is the irreducible remainder that survives even at a point, the angular momentum a field carries by virtue of what it *is* rather than where it sits.

7.4.3 The non-symmetry of the canonical tensor and the spin current

Conservation of the angular-momentum current is not an independent fact: combined with conservation of the stress tensor it pins down the antisymmetric

part of $T^{\mu\nu}$ exactly. This is the precise diagnosis, promised in Section 6.6.6, of why the canonical tensor of a spinning field cannot be symmetric.

Theorem 7.28 (Antisymmetry of T equals minus the divergence of the spin current)**.** *Given $\partial_\mu T^{\mu\nu} = 0$, the angular-momentum current Eq. (7.107) is conserved if and only if the antisymmetric part of the canonical stress tensor equals minus the divergence of the spin current,*

$$\boxed{T^{\nu\rho} - T^{\rho\nu} = -\,\partial_\mu S^{\mu\,\nu\rho}} \tag{7.109}$$

equivalently $2\,T^{[\nu\rho]} = -\,\partial_\mu S^{\mu\,\nu\rho}$.

Proof. Differentiate the orbital part of Eq. (7.107) directly, using the product rule and $\partial_\mu x^\nu = \delta^\nu_\mu$:

$$\begin{aligned}\partial_\mu\big(x^\nu T^{\mu\rho} - x^\rho T^{\mu\nu}\big) &= (\partial_\mu x^\nu)\,T^{\mu\rho} + x^\nu\,\partial_\mu T^{\mu\rho} - (\partial_\mu x^\rho)\,T^{\mu\nu} - x^\rho\,\partial_\mu T^{\mu\nu} \\ &= \delta^\nu_\mu\,T^{\mu\rho} - \delta^\rho_\mu\,T^{\mu\nu} = T^{\nu\rho} - T^{\rho\nu},\end{aligned} \tag{7.110}$$

the two terms with $\partial_\mu T^{\mu\cdot}$ dropping out by conservation of the stress tensor Eq. (7.96). Adding the divergence of the spin part,

$$\partial_\mu M^{\mu\,\nu\rho} = \big(T^{\nu\rho} - T^{\rho\nu}\big) + \partial_\mu S^{\mu\,\nu\rho}, \tag{7.111}$$

which reproduces Eq. (6.195). The left-hand side vanishes if and only if the two terms on the right cancel, i.e. if and only if Eq. (7.109) holds. Since Lorentz invariance guarantees $\partial_\mu M^{\mu\nu\rho} = 0$ (Theorem 7.27), the identity Eq. (7.109) holds on shell as a consequence. □

The theorem is the whole story of the canonical tensor's non-symmetry in one line. The antisymmetric part of $T^{\mu\nu}$ is not arbitrary: it is exactly the divergence of the object that carries intrinsic spin. A scalar has $S^{\mu\nu\rho} = 0$, so Eq. (7.109) forces $T^{\nu\rho} = T^{\rho\nu}$—the canonical scalar tensor is automatically symmetric, as Theorem 7.25 found. A spinning field has $S^{\mu\nu\rho} \neq 0$, and its canonical $T^{\mu\nu}$ is symmetric only where the spin current happens to be divergence-free, which it generically is not. The asymmetry *is* the spin, made quantitative.

It is worth proving Eq. (7.109) a second way, directly from the invariance of the Lagrangian, because the argument exposes where the stress tensor's antisymmetry comes from at the level of $\mathcal{L}$ itself, and because the off-shell identity it produces is the classical seed of the rotational Ward identity. Invariance of $\mathcal{L}$ as a Lorentz scalar is the statement that, when the multiplet index and the spacetime indices of its arguments are rotated together by the generator labelled $(\nu\rho)$, the density does not change. Treating ϕ_a and $\psi_{\mu a} \equiv \partial_\mu \phi_a$ as independent arguments, ϕ_a rotates by $\Sigma^{\nu\rho}$ on its multiplet index while $\psi_{\mu a}$ rotates by $\Sigma^{\nu\rho}$ on its multiplet

index *and* by the vector generator $(M^{\nu\rho})_\mu{}^\sigma$ of Eq. (3.33) on its derivative index. Setting the resulting first-order change of $\mathcal{L}$ to zero gives the algebraic identity

$$\frac{\partial \mathcal{L}}{\partial \phi_a}\,(\Sigma^{\nu\rho})_a{}^b\,\phi_b + \Pi^\mu_a\,(\Sigma^{\nu\rho})_a{}^b\,\partial_\mu\phi_b + \Pi^\mu_a\,(M^{\nu\rho})_\mu{}^\sigma\,\partial_\sigma\phi_a = 0, \tag{7.112}$$

true for every configuration, on shell or off—the Lorentz analogue of the translation homogeneity used in Theorem 6.29. Evaluate the third term with the explicit vector generator $(M^{\nu\rho})_\mu{}^\sigma = i(\delta^\nu_\mu\,\eta^{\rho\sigma} - \delta^\rho_\mu\,\eta^{\nu\sigma})$:

$$\Pi^\mu_a\,(M^{\nu\rho})_\mu{}^\sigma\,\partial_\sigma\phi_a = i(\Pi^\nu_a\,\partial^\rho\phi_a - \Pi^\rho_a\,\partial^\nu\phi_a). \tag{7.113}$$

Now $\Pi^\nu_a\,\partial^\rho\phi_a = T^{\nu\rho} + \eta^{\nu\rho}\mathcal{L}$ from the definition Eq. (7.96), and the $\eta\mathcal{L}$ pieces cancel in the antisymmetric difference, so Eq. (7.113) equals $i(T^{\nu\rho} - T^{\rho\nu})$. The first two terms of Eq. (7.112), on shell where $\partial_\mu\Pi^\mu_a = \partial\mathcal{L}/\partial\phi_a$, are precisely $i\,\partial_\mu S^{\mu\nu\rho}$:

$$\partial_\mu S^{\mu\,\nu\rho} = -i\,\partial_\mu(\Pi^\mu_a(\Sigma^{\nu\rho})_a{}^b\phi_b) = -i\Big[\tfrac{\partial\mathcal{L}}{\partial\phi_a}(\Sigma^{\nu\rho})_a{}^b\phi_b + \Pi^\mu_a(\Sigma^{\nu\rho})_a{}^b\partial_\mu\phi_b\Big]. \tag{7.114}$$

Multiplying Eq. (7.112) through by i and substituting both pieces gives $i\,\partial_\mu S^{\mu\nu\rho} + i(T^{\nu\rho} - T^{\rho\nu}) = 0$, that is Eq. (7.109) once more. The two derivations meet: the kinematic non-symmetry forced by Lorentz invariance of $\mathcal{L}$ (Eq. (7.112)) is the same as the dynamical non-symmetry forced by conservation of M^μ (Theorem 7.28).

Worked Example 7.29 (The Dirac spin current and the asymmetry of $T_D^{\mu\nu}$)**.** We make the spin current concrete on the electron, computing $S^{\mu\nu\rho}$ for the free Dirac field and verifying that its divergence accounts exactly for the asymmetry of the canonical tensor found in Eq. (6.188). The Dirac Lagrangian is $\mathcal{L}_D = \bar\psi(i\partial\!\!\!/ - m)\psi$ (Eq. (6.68)), with ψ and $\bar\psi$ independent and only ψ differentiated, so from Eq. (6.78) the conjugate momenta are

$$\Pi^\mu_\psi = \frac{\partial\mathcal{L}_D}{\partial(\partial_\mu\psi)} = i\,\bar\psi\gamma^\mu, \qquad \Pi^\mu_{\bar\psi} = 0. \tag{7.115}$$

The spinor carries the representation $\Sigma^{\nu\rho} = \frac{1}{2}\sigma^{\nu\rho}$, with $\sigma^{\nu\rho} = \frac{i}{2}\,[\gamma^\nu, \gamma^\rho]$ the spin matrix $S^{\nu\rho} = \frac{i}{4}\,[\gamma^\nu, \gamma^\rho]$ of Eq. (3.114) written as $S^{\nu\rho} = \frac{1}{2}\sigma^{\nu\rho}$. Only the ψ contribution survives in Eq. (7.106) (the $\bar\psi$ term is killed by $\Pi^\mu_{\bar\psi} = 0$), so

$$S^{\mu\,\nu\rho} = -i\,\Pi^\mu_\psi\,\Sigma^{\nu\rho}\psi = -i\,(i\bar\psi\gamma^\mu)\,\tfrac{1}{2}\sigma^{\nu\rho}\,\psi = \tfrac{1}{2}\,\bar\psi\,\gamma^\mu\sigma^{\nu\rho}\,\psi. \tag{7.116}$$

This is the intrinsic angular-momentum current of the electron; its time component $S^{0\,ij} = \frac{1}{2}\bar\psi\gamma^0\sigma^{ij}\psi = \frac{1}{2}\psi^\dagger\sigma^{ij}\psi$ integrates to the familiar spin operator $\frac{1}{2}\boldsymbol{\Sigma}$ when quantized.

Now verify Eq. (7.109). Differentiate Eq. (7.116), distributing the derivative onto $\bar\psi$ and ψ,

$$\partial_\mu S^{\mu\,\nu\rho} = \tfrac{1}{2}\big[(\partial_\mu\bar\psi)\gamma^\mu\sigma^{\nu\rho}\psi + \bar\psi\,\gamma^\mu\sigma^{\nu\rho}(\partial_\mu\psi)\big]. \tag{7.117}$$

Use the Dirac equations $i\not{\partial}\psi = m\psi$ and $i\partial_\mu\bar\psi\,\gamma^\mu = -m\bar\psi$, i.e. $\gamma^\mu\partial_\mu\psi = -im\psi$ and $(\partial_\mu\bar\psi)\gamma^\mu = im\bar\psi$. The first term becomes $\frac{1}{2}(im\bar\psi)\sigma^{\nu\rho}\psi$. In the second term commute γ^μ past $\sigma^{\nu\rho}$ to expose $\gamma^\mu\partial_\mu\psi$: writing $\gamma^\mu\sigma^{\nu\rho} = \sigma^{\nu\rho}\gamma^\mu + [\gamma^\mu, \sigma^{\nu\rho}]$,

$$\bar\psi\,\gamma^\mu\sigma^{\nu\rho}\partial_\mu\psi = \bar\psi\,\sigma^{\nu\rho}(\gamma^\mu\partial_\mu\psi) + \bar\psi\,[\gamma^\mu, \sigma^{\nu\rho}]\partial_\mu\psi = -im\,\bar\psi\sigma^{\nu\rho}\psi + \bar\psi\,[\gamma^\mu, \sigma^{\nu\rho}]\partial_\mu\psi. \tag{7.118}$$

The two mass terms cancel, leaving the commutator term alone,

$$\partial_\mu S^{\mu\,\nu\rho} = \tfrac{1}{2}\,\bar\psi\,[\gamma^\mu, \sigma^{\nu\rho}]\,\partial_\mu\psi. \tag{7.119}$$

The gamma-matrix identity $[\gamma^\mu, \sigma^{\nu\rho}] = 2i(\eta^{\mu\nu}\gamma^\rho - \eta^{\mu\rho}\gamma^\nu)$ (Chapter C) collapses the commutator,

$$\partial_\mu S^{\mu\,\nu\rho} = \tfrac{1}{2}\,\bar\psi\,2i(\eta^{\mu\nu}\gamma^\rho - \eta^{\mu\rho}\gamma^\nu)\,\partial_\mu\psi = i\,\bar\psi(\gamma^\rho\partial^\nu - \gamma^\nu\partial^\rho)\psi. \tag{7.120}$$

On the other side, the on-shell canonical Dirac tensor is $T_D^{\mu\nu} = i\bar\psi\gamma^\mu\partial^\nu\psi$ (Eq. (6.188)), so its antisymmetric part is

$$T_D^{\nu\rho} - T_D^{\rho\nu} = i\bar\psi\gamma^\nu\partial^\rho\psi - i\bar\psi\gamma^\rho\partial^\nu\psi = i\,\bar\psi(\gamma^\nu\partial^\rho - \gamma^\rho\partial^\nu)\psi. \tag{7.121}$$

Comparing Eq. (7.120) with Eq. (7.121), $\partial_\mu S^{\mu\nu\rho} = -(T_D^{\nu\rho} - T_D^{\rho\nu})$ exactly, confirming the master identity Eq. (7.109) for the Dirac field by direct computation. The electron's stress tensor is asymmetric, and the asymmetry is precisely the divergence of its spin current—the statement made concrete.

Remark 7.30 (Maxwell, and the cue for the next section). The same construction applied to the vector field, with $\Sigma^{\nu\rho}$ the generators Eq. (3.33) acting on the index of A_σ, gives a spin current $S^{\mu\nu\rho} = -F^{\mu\nu}A^\rho + F^{\mu\rho}A^\nu$, and Eq. (7.109) again ties it to the asymmetry of the canonical electromagnetic tensor Eq. (6.191). Here a second disease compounds the first: that spin current is built from the bare potential A^σ and is not gauge invariant, so the canonical Maxwell tensor is neither symmetric nor gauge invariant, as Eq. (6.192) showed. Both defects are repaired at once by the Belinfante construction of Section 7.5, which uses exactly the spin current of Eq. (7.106) as the seed of the improvement superpotential.

7.4.4 The angular-momentum charges and the Poincaré generators

A conserved current means a conserved charge. The six conserved charges of Lorentz invariance are the spatial integrals of the time components of $M^{\mu\nu\rho}$, exactly as the four-momentum was built from $T^{0\nu}$.

Definition 7.31 (Angular-momentum charges)**.** The conserved *angular-momentum tensor* is

$$J^{\nu\rho} = \int \mathrm{d}^3x\; M^{0\,\nu\rho}(t, \mathbf{x}) = \int \mathrm{d}^3x\,\Big[(x^\nu T^{0\rho} - x^\rho T^{0\nu}) + S^{0\,\nu\rho}\Big], \tag{7.122}$$

antisymmetric in $\nu\rho$, hence six independent numbers. By Theorem 7.13 applied to each of the six currents, $dJ^{\nu\rho}/dt = 0$.

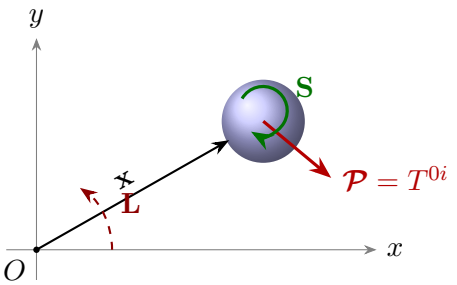

Figure 7.4: The two contributions to the conserved angular momentum Eq. (7.123). A localized field configuration at position $\mathbf{x}$ carries momentum density $\boldsymbol{\mathcal{P}} = T^{0i}$; its moment about the origin O is the orbital angular momentum $\mathbf{L} = \int \mathbf{x} \times \boldsymbol{\mathcal{P}}$. Independently, the field's Lorentz representation endows it with an intrinsic spin density S^{0jk}, integrating to the spin $\mathbf{S}$, which survives even for a configuration at rest at the origin. Total angular momentum is $\mathbf{J} = \mathbf{L} + \mathbf{S}$.

The six charges split, by the now-familiar rotation/boost decomposition of Theorem 3.13, into the three spatial-spatial components and the three time-space components. The spatial components are the total angular momentum: defining $J_i = \frac{1}{2}\epsilon_{ijk}J^{jk}$ in parallel with Eq. (3.40),

$$J^{jk} = \int \mathrm{d}^3x\, (x^j T^{0k} - x^k T^{0j}) + \int \mathrm{d}^3x\, S^{0\,jk} = L^{jk} + \Sigma^{jk}_{\text{spin}}, \tag{7.123}$$

the first integral the *orbital* angular momentum L^{jk}—the moment $\mathbf{x} \times \boldsymbol{\mathcal{P}}$ of the momentum density $\mathcal{P}^k = T^{0k}$—and the second the *spin* angular momentum $\Sigma^{jk}_{\text{spin}} = \int \mathrm{d}^3x\, S^{0jk}$, the integrated intrinsic current. This is the field-theoretic origin of the textbook decomposition $\mathbf{J} = \mathbf{L} + \mathbf{S}$: orbital angular momentum is the moment of the energy–momentum flow, spin is the irreducible piece that a localized field configuration carries even when it is not orbiting anything. For the electron, $\Sigma^{jk}_{\text{spin}} = \frac{1}{2}\int \mathrm{d}^3x\, \psi^\dagger \sigma^{jk}\psi$ is the spin-$\frac{1}{2}$ that quantization will sharpen into eigenvalues $\pm\frac{1}{2}$ (Fig. 7.4).

The time-space components are the boost charges,

$$J^{0i} = \int \mathrm{d}^3x\, (x^0 T^{0i} - x^i T^{00}) + \int \mathrm{d}^3x\, S^{0\,0i} = t\,P^i - \int \mathrm{d}^3x\, x^i\, T^{00} + \int \mathrm{d}^3x\, S^{0\,0i}, \tag{7.124}$$

where $x^0 = t$ is constant on the slice and pulls out of the integral against T^{0i} to give tP^i. The statement $dJ^{0i}/dt = 0$ is the relativistic conservation of the center of energy: differentiating, $P^i = d/dt \int \mathrm{d}^3x\, x^i T^{00}$ (the spin piece is time-independent on its own), i.e. the center of energy $X^i_{\text{cm}} = (1/P^0)\int x^i T^{00}$ moves uniformly with velocity P^i/P^0, the field-theoretic analogue of the free-particle relation between momentum and center-of-mass motion.

These ten charges—the four P^ν of Eq. (7.97) and the six $J^{\nu\rho}$ of Eq. (7.122)—are the complete set of conserved quantities supplied by Poincaré invariance, and

they are the classical precursors of the ten generators of the Poincaré algebra. The charge-as-generator dictionary established for internal symmetries in the previous section carries over verbatim: each charge generates, through the Poisson bracket of Section 7.3, the transformation it came from, and the brackets of the charges among themselves close into the Lie algebra of the symmetry. For the Poincaré group that algebra is

$$\begin{aligned} \{P^\mu, P^\nu\}_{\mathrm{P}} &= 0, \\ \{J^{\mu\nu}, P^\rho\}_{\mathrm{P}} &= \eta^{\nu\rho} P^\mu - \eta^{\mu\rho} P^\nu, \\ \{J^{\mu\nu}, J^{\rho\sigma}\}_{\mathrm{P}} &= \eta^{\nu\rho} J^{\mu\sigma} - \eta^{\mu\rho} J^{\nu\sigma} - \eta^{\nu\sigma} J^{\mu\rho} + \eta^{\mu\sigma} J^{\nu\rho}, \end{aligned} \tag{7.125}$$

the same structure as the operator algebra Eqs. (3.147) to (3.149), with the Poisson bracket standing in for $-i$ times the commutator. The last line is the Lorentz subalgebra Eq. (3.34) carried by the charges; the middle line says P^ρ transforms as a four-vector under Lorentz, exactly as its index advertises; the first line says translations commute. Energy, momentum, and angular momentum have thus become Noether charges that *generate* the spacetime symmetries from which they sprang—the classical skeleton that Chapter 9 will quantize into the operators P^μ and $J^{\mu\nu}$ acting on the Hilbert space, where the eigenvalues of P^2 and of the spin Casimir built from $J^{\mu\nu}$ will label particles by mass and spin.

Physical Insight

The split of $\mathbf{J}$ into $\mathbf{L}+\mathbf{S}$ is not a convention but a representation-theoretic fact: orbital angular momentum is the moment of the momentum density and depends on where you put the origin, while spin is the intrinsic Lorentz quantum number of the field and is origin-independent. A scalar has only $\mathbf{L}$; a spinor and a vector carry $\mathbf{S}$ in addition. The same generator $J^{\mu\nu}$ that rotates spacetime coordinates simultaneously rotates the field's components, and it is the second action—the representation matrices $\Sigma^{\mu\nu}$—that is the entire content of "spin." This is why the classification of particles by spin is, at bottom, the classification of the unitary representations of the Poincaré group.

We have now extracted from Poincaré invariance the full complement of spacetime conserved quantities and, with them, the canonical stress tensor in its proper role as the Noether current of translations. But that tensor arrived with the two defects this section has made precise and quantitative: by Theorem 7.28 it is generically non-symmetric, its antisymmetric part fixed to $-\partial_\mu S^{\mu\nu\rho}$ by the very spin current Eq. (7.106) we computed, and for gauge fields (Theorem 7.30) it is not even gauge invariant. Both the asymmetry and the spin current that drives it are the raw material for the repair. The next section takes the spin current $S^{\mu\nu\rho}$ and builds from it the antisymmetric superpotential whose divergence—an improvement of the type licensed by Theorem 7.15, harmless to the charges

P^ν—turns the canonical tensor into the symmetric, gauge-invariant Belinfante–Rosenfeld tensor, the object that will later couple to gravity.

7.5 The Belinfante–Rosenfeld Symmetric Stress Tensor

The previous section handed us two Noether currents born of spacetime symmetry and a single algebraic identity binding them. Translations gave the canonical stress tensor $T^{\mu\nu}$, conserved on the index μ, whose charges $P^\nu = \int d^3x\, T^{0\nu}$ are the energy and three-momentum. Lorentz transformations gave the angular-momentum current, which splits into an *orbital* part built from $T^{\mu\nu}$ and an *intrinsic* part—the spin current $S^{\lambda\mu\nu}$—encoding how the field components rotate among themselves. Demanding that the total angular momentum be conserved then forced a relation between the two: the antisymmetric part of $T^{\mu\nu}$ is exactly the divergence of the spin current. That relation is the lever of this section. The canonical $T^{\mu\nu}$ is in general neither symmetric (we saw the Dirac and Maxwell tensors fail this in Section 6.6.5) nor, for gauge fields, gauge invariant. Both defects are cosmetic in the sense that they leave the charges P^ν untouched, but they are fatal for the one job a stress tensor must ultimately do: source gravity, which couples to a *symmetric* tensor. We now repair $T^{\mu\nu}$ once and for all, by adding to it a divergence-free superpotential built from the very spin current the asymmetry produced. The result, due to Belinfante and Rosenfeld, is the canonical object of the rest of the book.

7.5.1 What an improvement may and may not change

Any current is ambiguous up to the addition of an identically conserved piece. For the stress tensor the useful form of that ambiguity is the addition of a divergence,

$$\Theta^{\mu\nu} = T^{\mu\nu} + \partial_\rho B^{\rho\mu\nu}, \qquad B^{\rho\mu\nu} = -B^{\mu\rho\nu}, \tag{7.126}$$

where the object $B^{\rho\mu\nu}$—the *superpotential*—is required to be antisymmetric in its first two indices. This single antisymmetry buys both of the properties an improvement must have, before we have even said what B is.

First, $\Theta^{\mu\nu}$ is conserved on μ whenever $T^{\mu\nu}$ is. Taking the divergence of Eq. (7.126),

$$\partial_\mu \Theta^{\mu\nu} = \partial_\mu T^{\mu\nu} + \partial_\mu \partial_\rho B^{\rho\mu\nu} = 0 + 0, \tag{7.127}$$

because $\partial_\mu \partial_\rho$ is symmetric in $\mu \leftrightarrow \rho$ while $B^{\rho\mu\nu}$ is antisymmetric in exactly that pair, so the contraction vanishes identically—off shell, as a matter of calculus, with no use of the equations of motion. The improvement can never spoil conservation.

Second, $\Theta^{\mu\nu}$ carries the same charges as $T^{\mu\nu}$. The added energy–momentum is

$$\Delta P^{\nu} = \int d^3x\, \partial_\rho B^{\rho 0\nu} = \int d^3x\, (\partial_0 B^{00\nu} + \partial_i B^{i0\nu}) = \int d^3x\, \partial_i B^{i0\nu}, \tag{7.128}$$

where the time-derivative term dropped because $B^{00\nu} = -B^{00\nu} = 0$ by the antisymmetry of the first two indices. What survives is a pure spatial divergence, and by Gauss's theorem

$$\Delta P^{\nu} = \oint_{S^2_\infty} dS_i\, B^{i0\nu} = 0 \tag{7.129}$$

for any field configuration that falls off at spatial infinity, as physical configurations must. The local distribution of energy and momentum is reshuffled by the improvement; the integrated energy and momentum are not. This is the precise sense, promised in Section 6.6.5, in which the defects of $T^{\mu\nu}$ are cosmetic: they live entirely in a superpotential that integrates to zero.

The freedom in Eq. (7.126) is therefore exactly the freedom to redistribute energy and momentum without changing the totals. We now spend that freedom to make $\Theta^{\mu\nu}$ symmetric.

7.5.2 Constructing the superpotential from the spin current

Everything we need from the previous section is the antisymmetric-part relation. With the spin current written $S^{\lambda\mu\nu}$—index λ the conserved-current (divergence) index, the last pair antisymmetric,

$$S^{\lambda\mu\nu} = -S^{\lambda\nu\mu}, \tag{7.130}$$

—the conservation of the total angular-momentum current $J^{\lambda\mu\nu} = x^\mu T^{\lambda\nu} - x^\nu T^{\lambda\mu} + S^{\lambda\mu\nu}$, defined in Eq. (7.107) and proved conserved in Theorem 7.27, was shown in Theorem 7.28 to force the antisymmetric-part relation

$$\partial_\lambda S^{\lambda\mu\nu} = T^{\nu\mu} - T^{\mu\nu}, \qquad \text{equivalently} \qquad T^{\mu\nu} - T^{\nu\mu} = -\,\partial_\rho S^{\rho\mu\nu}, \tag{7.131}$$

which is Eq. (7.109) written with the current index displayed first. The antisymmetric part of the canonical stress tensor is the divergence of the spin current: a non-symmetric $T^{\mu\nu}$ is the signature of a field that carries spin. Our task is to cancel this antisymmetric part with a $\partial_\rho B^{\rho\mu\nu}$ of exactly the right form.

Subtract Eq. (7.126) from its transpose:

$$\Theta^{\mu\nu} - \Theta^{\nu\mu} = (T^{\mu\nu} - T^{\nu\mu}) + \partial_\rho (B^{\rho\mu\nu} - B^{\rho\nu\mu}) = \partial_\rho \big[B^{\rho\mu\nu} - B^{\rho\nu\mu} - S^{\rho\mu\nu}\big], \tag{7.132}$$

where the second equality used Eq. (7.131). The bracket vanishes—and $\Theta^{\mu\nu}$ is symmetric—if the superpotential satisfies the algebraic condition

$$B^{\rho\mu\nu} - B^{\rho\nu\mu} = S^{\rho\mu\nu}. \tag{7.133}$$

We must therefore find a $B^{\rho\mu\nu}$ that is (i) antisymmetric in its first two indices, $B^{\rho\mu\nu} = -B^{\mu\rho\nu}$, and (ii) antisymmetrizes in its last two indices to the spin current, Eq. (7.133). Rather than guess, we solve these two linear conditions. The only object linear in S available is the spin current itself, and because S is already antisymmetric in its *last* pair, its three cyclic orderings $S^{\rho\mu\nu}$, $S^{\mu\nu\rho}$, $S^{\nu\rho\mu}$ exhaust the independent index placements. Make the ansatz

$$B^{\rho\mu\nu} = a\,S^{\rho\mu\nu} + b\,S^{\mu\nu\rho} + c\,S^{\nu\rho\mu}, \tag{7.134}$$

and impose the two conditions in turn. Condition (ii), $B^{\rho\mu\nu} - B^{\rho\nu\mu} = S^{\rho\mu\nu}$, after reducing every term to the cyclic basis with $S^{\cdots} = -S^{\cdots}$ on its last pair (so $S^{\rho\nu\mu} = -S^{\rho\mu\nu}$, $S^{\nu\mu\rho} = -S^{\nu\rho\mu}$, $S^{\mu\rho\nu} = -S^{\mu\nu\rho}$), reads $2a\,S^{\rho\mu\nu} + 2b\,S^{\mu\nu\rho} + 2c\,S^{\nu\rho\mu} = S^{\rho\mu\nu}$ once the b and c contributions to the antisymmetrization are tracked; carrying this out gives $a = \tfrac{1}{2}$ together with $b + c$ unconstrained by (ii) alone. Condition (i), $B^{\rho\mu\nu} = -B^{\mu\rho\nu}$, supplies the second equation and fixes the antisymmetric combination of b and c, yielding $b = \tfrac{1}{2}$, $c = -\tfrac{1}{2}$. The system has the unique solution within this ansatz,

$$\boxed{B^{\rho\mu\nu} = \tfrac{1}{2}\big(S^{\rho\mu\nu} + S^{\mu\nu\rho} - S^{\nu\rho\mu}\big)} \tag{7.135}$$

the *Belinfante–Rosenfeld superpotential*, and with it the *Belinfante–Rosenfeld stress tensor* $\Theta^{\mu\nu} = T^{\mu\nu} + \partial_\rho B^{\rho\mu\nu}$. (The improvement is not unique in the absolute sense—one may always add to $B^{\rho\mu\nu}$ any tensor antisymmetric in $\rho\mu$ that is also symmetric in $\mu\nu$, since such a piece changes neither the conservation nor the symmetrization; Eq. (7.135) is the minimal choice built purely from the spin current, and it is the one the gravitational coupling will select.)

Definition 7.32 (Belinfante–Rosenfeld tensor)**.** Given a canonical stress tensor $T^{\mu\nu}$ and the canonical spin current $S^{\lambda\mu\nu}$ of the same theory, antisymmetric in its last pair, the Belinfante–Rosenfeld stress tensor is

$$\Theta^{\mu\nu} = T^{\mu\nu} + \partial_\rho B^{\rho\mu\nu}, \qquad B^{\rho\mu\nu} = \tfrac{1}{2}\big(S^{\rho\mu\nu} + S^{\mu\nu\rho} - S^{\nu\rho\mu}\big). \tag{7.136}$$

It remains to verify that Eq. (7.135) has the two required properties. The verification is pure index bookkeeping, using only the antisymmetry Eq. (7.130) of S in its last pair, and we carry it out in full.

Property (i): antisymmetry in the first two indices. Swap $\rho \leftrightarrow \mu$ in Eq. (7.135):

$$B^{\mu\rho\nu} = \tfrac{1}{2}\big(S^{\mu\rho\nu} + S^{\rho\nu\mu} - S^{\nu\mu\rho}\big). \tag{7.137}$$

Now reduce each term to the basis appearing in Eq. (7.135) using Eq. (7.130), which lets us flip the last pair at the cost of a sign: $S^{\mu\rho\nu} = -S^{\mu\nu\rho}$, $S^{\rho\nu\mu} = -S^{\rho\mu\nu}$, $S^{\nu\mu\rho} = -S^{\nu\rho\mu}$. Substituting,

$$B^{\mu\rho\nu} = \tfrac{1}{2}\big(-S^{\mu\nu\rho} - S^{\rho\mu\nu} + S^{\nu\rho\mu}\big) = -\tfrac{1}{2}\big(S^{\rho\mu\nu} + S^{\mu\nu\rho} - S^{\nu\rho\mu}\big) = -B^{\rho\mu\nu}. \tag{7.138}$$

So $B^{\rho\mu\nu} = -B^{\mu\rho\nu}$, and by the work of Section 7.5.1 the tensor $\Theta^{\mu\nu}$ is automatically conserved and shares the charges of $T^{\mu\nu}$.

Property (ii): the symmetrization condition. Swap $\mu \leftrightarrow \nu$ in Eq. (7.135):

$$B^{\rho\nu\mu} = \tfrac{1}{2}(S^{\rho\nu\mu} + S^{\nu\mu\rho} - S^{\mu\rho\nu}) = \tfrac{1}{2}(-S^{\rho\mu\nu} - S^{\nu\rho\mu} + S^{\mu\nu\rho}), \tag{7.139}$$

again using Eq. (7.130) term by term. Subtracting from Eq. (7.135),

$$\begin{aligned} B^{\rho\mu\nu} - B^{\rho\nu\mu} &= \tfrac{1}{2}(S^{\rho\mu\nu} + S^{\mu\nu\rho} - S^{\nu\rho\mu}) - \tfrac{1}{2}(-S^{\rho\mu\nu} - S^{\nu\rho\mu} + S^{\mu\nu\rho}) \\ &= \tfrac{1}{2}(2\,S^{\rho\mu\nu}) = S^{\rho\mu\nu}, \end{aligned} \tag{7.140}$$

where the $S^{\mu\nu\rho}$ terms cancelled and the two $-S^{\nu\rho\mu}$ and $+S^{\nu\rho\mu}$ likewise cancelled. This is precisely Eq. (7.133). Both requirements hold, so we have proved the central result of the section.

Theorem 7.33 (Properties of the Belinfante–Rosenfeld tensor)**.** *Let $T^{\mu\nu}$ be the canonical stress tensor and $S^{\lambda\mu\nu}$ the canonical spin current of a Poincaré-invariant field theory, related by the angular-momentum identity Eq. (7.131). Then the tensor $\Theta^{\mu\nu}$ of Eq. (7.136) is*

1. conserved*: $\partial_\mu \Theta^{\mu\nu} = 0$ on shell;*
2. symmetric*: $\Theta^{\mu\nu} = \Theta^{\nu\mu}$;*
3. charge-equivalent to $T^{\mu\nu}$*: $P^\nu = \displaystyle\int d^3x\, \Theta^{0\nu} = \int d^3x\, T^{0\nu}$.*

Proof. Properties 1 and 3 follow from the antisymmetry $B^{\rho\mu\nu} = -B^{\mu\rho\nu}$ established in Eq. (7.138), by the general arguments Eq. (7.127) and Eqs. (7.128) and (7.129) respectively. For property 2, the symmetrization condition Eq. (7.140) makes the bracket in Eq. (7.132) vanish identically, so $\Theta^{\mu\nu} - \Theta^{\nu\mu} = 0$. □

Physical Insight

The asymmetry of the canonical tensor and the existence of the spin current are not two facts but one: Eq. (7.131) says the antisymmetric part of $T^{\mu\nu}$ *is* the divergence of the spin current. The Belinfante construction does not destroy the spin information—it relocates it. The piece $\partial_\rho B^{\rho\mu\nu}$ transfers the intrinsic spin from a separate current into the orbital motion of a symmetric stress tensor, so that after improvement the entire angular momentum can be written in the purely orbital form $J^{\mu\nu\rho}_\Theta = x^\nu \Theta^{\mu\rho} - x^\rho \Theta^{\mu\nu}$. One checks directly that this is conserved precisely because Θ is symmetric: $\partial_\mu J^{\mu\nu\rho}_\Theta = \Theta^{\nu\rho} - \Theta^{\rho\nu} + x^\nu \partial_\mu \Theta^{\mu\rho} - x^\rho \partial_\mu \Theta^{\mu\nu} = 0$. Symmetry of the stress tensor and conservation of angular momentum are the same statement.

Physical Insight

Why insist on symmetry at all, when the charges are unchanged? Because the stress tensor will eventually be promoted from a Noether current to the *source of gravity*. In general relativity the Einstein equations read $G_{\mu\nu} = 8\pi G\,\Theta_{\mu\nu}$, and the left-hand side $G_{\mu\nu}$ is manifestly symmetric, built from the metric. A non-symmetric source would be inconsistent. Equivalently, the gravitational coupling is obtained by varying the matter action with respect to the metric, $\Theta_{\mu\nu} \propto -(2/\sqrt{-g})\,\delta S_{\text{matter}}/\delta g^{\mu\nu}$, and this *Hilbert* stress tensor is automatically symmetric and gauge invariant because $g^{\mu\nu}$ is. The Belinfante tensor is the flat-space shadow of that variation: the systematic curved-space construction (deferred to Chapter 64) reproduces Eq. (7.136) on a flat background. This is the deep reason the symmetric tensor, not the canonical one, is "the" stress tensor.

7.5.3 The electromagnetic field: from canonical mess to gauge-invariant tensor

The Maxwell field is the worked example that the whole construction was built for, and the one that anticipates the field-strength-as-curvature viewpoint of Chapter 8. In Section 6.6.5 we found its canonical stress tensor to be simultaneously asymmetric and gauge dependent; we now show the Belinfante recipe cures both at a stroke, producing the symmetric, gauge-invariant tensor whose components are the textbook energy density and Poynting vector. This continues the classical electromagnetic thread that Chapter 8 will quantize.

Worked Example 7.34 (The Belinfante tensor of Maxwell theory)**.** The free Maxwell Lagrangian is $\mathcal{L}_{\text{Max}} = -\frac{1}{4}F_{\alpha\beta}F^{\alpha\beta}$ with $F_{\alpha\beta} = \partial_\alpha A_\beta - \partial_\beta A_\alpha$ (Eq. (6.80)). From Eq. (6.190) the canonical momentum conjugate to A_ρ is

$$\pi^{\mu\rho} \equiv \frac{\partial \mathcal{L}_{\text{Max}}}{\partial(\partial_\mu A_\rho)} = -F^{\mu\rho}, \tag{7.141}$$

and from Eq. (6.191) the canonical stress tensor is

$$T^{\mu\nu}_{\text{can}} = -F^{\mu\rho}\,\partial^\nu A_\rho + \tfrac{1}{4}\,\eta^{\mu\nu}F_{\alpha\beta}F^{\alpha\beta}. \tag{7.142}$$

The spin current. Under an infinitesimal Lorentz transformation the vector potential transforms in the vector representation, $\delta A_\rho = \omega_\rho{}^\sigma A_\sigma$ with $\omega_{\rho\sigma} = -\omega_{\sigma\rho}$; the corresponding spin matrix has the index structure $(\Sigma^{\mu\nu})_\rho{}^\sigma = \delta^\mu_\rho\,\eta^{\nu\sigma} - \delta^\nu_\rho\,\eta^{\mu\sigma}$ inherited from the Lorentz generators of Chapter 3 acting on a vector index. The canonical spin current, $S^{\lambda\mu\nu} = \pi^{\lambda\rho}(\Sigma^{\mu\nu})_\rho{}^\sigma A_\sigma$, then evaluates to

$$S^{\lambda\mu\nu} = \pi^{\lambda\mu}A^\nu - \pi^{\lambda\nu}A^\mu = -F^{\lambda\mu}A^\nu + F^{\lambda\nu}A^\mu = F^{\lambda\nu}A^\mu - F^{\lambda\mu}A^\nu, \tag{7.143}$$

which is manifestly antisymmetric in the pair $\mu\nu$, as a spin current must be. As a check that this is the genuine partner of $T^{\mu\nu}_{\rm can}$, it satisfies the identity Eq. (7.131). On shell ($\partial_\lambda F^{\lambda\nu}=0$) its divergence is

$$\partial_\lambda S^{\lambda\mu\nu} = F^{\lambda\nu}\partial_\lambda A^\mu - F^{\lambda\mu}\partial_\lambda A^\nu = F^{\lambda\nu}F_\lambda{}^\mu - F^{\lambda\mu}F_\lambda{}^\nu + (F^{\lambda\nu}\partial^\mu A_\lambda - F^{\lambda\mu}\partial^\nu A_\lambda), \tag{7.144}$$

where we wrote $\partial_\lambda A^\mu = F_\lambda{}^\mu + \partial^\mu A_\lambda$ using $F_\lambda{}^\mu = \partial_\lambda A^\mu - \partial^\mu A_\lambda$. The first two terms cancel: $F^{\lambda\nu}F_\lambda{}^\mu = \eta_{\lambda\sigma}F^{\sigma\nu}F^{\lambda\mu}$ is symmetric under $\mu\leftrightarrow\nu$ (relabel $\lambda\leftrightarrow\sigma$ and use the symmetry of η), so it equals $F^{\lambda\mu}F_\lambda{}^\nu$. The remaining bracket is $-(T^{\mu\nu}_{\rm can}-T^{\nu\mu}_{\rm can})$ read off from Eq. (7.142) (the $\frac{1}{4}\eta F^2$ term is symmetric and drops), so $\partial_\lambda S^{\lambda\mu\nu} = T^{\nu\mu}_{\rm can} - T^{\mu\nu}_{\rm can}$, which is exactly Eq. (7.131). The spin current and the canonical tensor are the matched pair the theorem requires.

The superpotential. Insert Eq. (7.143) into the master formula Eq. (7.135). The three permutations are

$$\begin{aligned} S^{\rho\mu\nu} &= F^{\rho\nu}A^\mu - F^{\rho\mu}A^\nu,\\ S^{\mu\nu\rho} &= F^{\mu\rho}A^\nu - F^{\mu\nu}A^\rho,\\ S^{\nu\rho\mu} &= F^{\nu\mu}A^\rho - F^{\nu\rho}A^\mu. \end{aligned} \tag{7.145}$$

Forming $S^{\rho\mu\nu}+S^{\mu\nu\rho}-S^{\nu\rho\mu}$ and collecting by the free factor A:

$$\begin{aligned} A^\mu:&\quad F^{\rho\nu}+F^{\nu\rho}=0,\\ A^\nu:&\quad -F^{\rho\mu}+F^{\mu\rho}=-2F^{\rho\mu},\\ A^\rho:&\quad -F^{\mu\nu}-F^{\nu\mu}=0, \end{aligned} \tag{7.146}$$

using $F^{\nu\rho}=-F^{\rho\nu}$ throughout. Only the A^ν term survives, so

$$B^{\rho\mu\nu} = \tfrac{1}{2}\big(-2F^{\rho\mu}A^\nu\big) = -F^{\rho\mu}A^\nu = F^{\mu\rho}A^\nu. \tag{7.147}$$

This is the superpotential anticipated in Eq. (6.193); the construction has now *derived* it from the spin current rather than guessing it.

The improved tensor. Compute the divergence of Eq. (7.147):

$$\partial_\rho B^{\rho\mu\nu} = \partial_\rho(F^{\mu\rho}A^\nu) = (\partial_\rho F^{\mu\rho})A^\nu + F^{\mu\rho}\,\partial_\rho A^\nu. \tag{7.148}$$

Here we use the field equations: in the source-free theory the Maxwell equation is $\partial_\rho F^{\mu\rho}=0$, so the first term—the only piece containing the bare, non-gauge-invariant potential A^ν undifferentiated—vanishes on shell. This is the step at which gauge invariance is restored: the offending term is killed by the equations of motion. The improvement reduces to $\partial_\rho B^{\rho\mu\nu} = F^{\mu\rho}\partial_\rho A^\nu$, and

$$\begin{aligned} \Theta^{\mu\nu}_{\rm Max} &= T^{\mu\nu}_{\rm can} + F^{\mu\rho}\partial_\rho A^\nu = -F^{\mu\rho}\partial^\nu A_\rho + \tfrac{1}{4}\eta^{\mu\nu}F^2 + F^{\mu\rho}\partial_\rho A^\nu\\ &= -F^{\mu\rho}(\partial^\nu A_\rho - \partial_\rho A^\nu) + \tfrac{1}{4}\eta^{\mu\nu}F_{\alpha\beta}F^{\alpha\beta}\\ &= -F^{\mu\rho}\,F^\nu{}_\rho + \tfrac{1}{4}\eta^{\mu\nu}F_{\alpha\beta}F^{\alpha\beta}, \end{aligned} \tag{7.149}$$

where the second line factored out $F^{\mu\rho}$ and the third recognized $\partial^\nu A_\rho - \partial_\rho A^\nu = F^\nu{}_\rho$. The boxed result,

$$\boxed{\Theta^{\mu\nu}_{\text{Max}} = -F^{\mu\alpha}F^\nu{}_\alpha + \tfrac{1}{4}\eta^{\mu\nu}F_{\alpha\beta}F^{\alpha\beta}}, \tag{7.150}$$

is at once *symmetric* in $\mu\nu$ (the first term because $F^{\mu\alpha}F^\nu{}_\alpha = \eta_{\alpha\beta}F^{\mu\alpha}F^{\nu\beta}$ is, by the same relabeling used above, symmetric; the second manifestly) and *gauge invariant* (built entirely from the field strength F, with no bare A). Both diseases of Eq. (7.142) are cured.

Reading off the physics. It remains to confirm that Eq. (7.150) is the familiar electromagnetic energy and momentum. With the mostly-minus metric, the field strength encodes $F^{0i} = -E^i$ and $F^{ij} = -\epsilon^{ijk}B^k$, and the Lorentz scalar is $F_{\alpha\beta}F^{\alpha\beta} = 2(B^2 - E^2)$. For the energy density set $\mu = \nu = 0$:

$$\Theta^{00}_{\text{Max}} = -F^{0\alpha}F^0{}_\alpha + \tfrac{1}{4}F^2 = -F^{0i}F^0{}_i + \tfrac{1}{4}\cdot 2(B^2 - E^2). \tag{7.151}$$

Now $F^0{}_i = \eta_{ij}F^{0j} = -F^{0i} = E^i$, so $-F^{0i}F^0{}_i = -(-E^i)(E^i) = E^2$, and

$$\Theta^{00}_{\text{Max}} = E^2 + \tfrac{1}{2}(B^2 - E^2) = \tfrac{1}{2}(E^2 + B^2), \tag{7.152}$$

the standard electromagnetic energy density, manifestly non-negative. For the momentum density set $\mu = 0, \nu = i$; the metric term drops ($\eta^{0i} = 0$):

$$\Theta^{0i}_{\text{Max}} = -F^{0\alpha}F^i{}_\alpha = -F^{0j}F^i{}_j = -(-E^j)(-\epsilon^{ijk}B^k) = -\epsilon^{ijk}E^jB^k = (\mathbf{E}\times\mathbf{B})^i, \tag{7.153}$$

using $F^i{}_j = \eta_{jk}F^{ik} = -F^{ij} = \epsilon^{ijk}B^k$ and that the $\alpha = 0$ term vanishes since $F^i{}_0 = -F^{i0} = F^{0i} = -E^i$ pairs with $F^{00} = 0$. (The full contraction is $-F^{0\alpha}F^i{}_\alpha = -F^{00}F^i{}_0 - F^{0j}F^i{}_j$, and the first term is zero.) This is the Poynting vector, the electromagnetic momentum density and energy flux. The Belinfante tensor of electromagnetism is exactly the object one writes down in classical field theory on physical grounds—but here it has been *derived*, with its symmetry and gauge invariance guaranteed by the general theorem rather than imposed by hand.

Caution

The cancellation in Eq. (7.148) uses the *source-free* equation $\partial_\rho F^{\mu\rho} = 0$. In the presence of charged matter the Maxwell equation reads $\partial_\rho F^{\mu\rho} = -J^\mu$, and the term $(\partial_\rho F^{\mu\rho})A^\nu = -J^\mu A^\nu$ no longer vanishes; the electromagnetic field's stress tensor is then not separately conserved, only the total (matter + field) stress tensor is, with the difference accounting for the work done by the field on the charges. This is the classical statement of energy–momentum exchange, and it is the correct behavior: an isolated subsystem need not conserve its own energy. The minimal-coupling structure that

organizes this exchange is the subject of Chapter 8.

With a symmetric, conserved, gauge-invariant stress tensor in hand, two roads open. Its trace $\Theta^{\mu}{}_{\mu}$ is now a clean, gauge-invariant diagnostic of scale invariance—vanishing for the massless theory and signalling the breaking of dilatation symmetry otherwise—and the same improvement-by-superpotential technique, applied to the dilatation current rather than the spin current, will furnish the further *conformal* improvement that makes the traceless tensor manifest; that analysis is taken up when we carry ϕ^4 theory to its symmetry layer later in this chapter. And the symmetric $\Theta^{\mu\nu}$ is the object that couples to the metric, the flat-space seed of the gravitational source whose curved-spacetime construction is deferred to Chapter 64. Before either, the next section turns to a sharper question the improvement freedom has quietly raised—what happens when a symmetry's parameter is allowed to vary from point to point—and answers it with Noether's second theorem.

7.6 Noether's Second Theorem: Global versus Local Symmetry

Every symmetry we have exploited so far has been *rigid*: a single constant parameter rotates the field at every point of spacetime in lockstep. Noether's first theorem (Theorem 7.10) attached to each such parameter a conserved current and, on integration over a spatial slice, a time-independent charge. The internal charges closed into the symmetry's Lie algebra; the spacetime charges were energy, momentum, and angular momentum; and the Belinfante construction of the preceding section repaired the stress tensor that carries them. The machinery is by now routine, and it is tempting to apply it on autopilot to the largest symmetry a field theory can have—a symmetry whose parameter is an arbitrary function of position. That is exactly the stress test this section performs, and the outcome is not more of the same. When the parameter is allowed to vary from point to point, the Noether procedure does not manufacture a new tower of conserved charges. Instead it manufactures an *identity*: a relation among the equations of motion that holds whether or not those equations are satisfied. The associated current, far from carrying independent physical content, collapses on shell into a total derivative and so into a boundary integral that registers no bulk charge at all. This is Noether's *second* theorem, and reading it correctly is what separates a genuine global symmetry—which constrains dynamics and yields real conserved quantities—from a local "symmetry," which is not a symmetry of the physics but a redundancy in how we have chosen to describe it. That distinction is the entire conceptual content of the gauge principle, and pinning it down here is what prepares the explicit construction of electromagnetism from a local phase

in Chapter 8.

7.6.1 Local symmetries and the variational identity

We work with the conventions fixed for this chapter: mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units, and a Lagrangian density $\mathcal{L}(\phi_a, \partial_\mu \phi_a)$ depending on a multiplet of fields ϕ_a and their first derivatives, with no explicit coordinate dependence. It is convenient to package the dynamics in the *Euler–Lagrange operator*, the same combination whose vanishing is the equation of motion proved in Theorem 6.8,

$$\mathcal{E}_a[\phi] \;\equiv\; \partial_\mu\!\left(\frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)}\right) - \frac{\partial \mathcal{L}}{\partial \phi_a}, \qquad \mathcal{E}_a[\phi] = 0 \iff \phi_a \text{ solves Eq. (6.30).} \tag{7.154}$$

A field configuration is said to be *on shell* when $\mathcal{E}_a[\phi] = 0$ and *off shell* otherwise; the whole force of what follows is the distinction between identities that require $\mathcal{E}_a = 0$ and identities that do not.

The basic bookkeeping of the variational calculus is the rewriting of an arbitrary variation of the Lagrangian as an Euler–Lagrange term plus a total derivative. For *any* infinitesimal field variation $\delta\phi_a$,

$$\delta\mathcal{L} \;=\; \frac{\partial \mathcal{L}}{\partial \phi_a}\,\delta\phi_a + \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)}\,\partial_\mu \delta\phi_a \;=\; -\,\mathcal{E}_a[\phi]\,\delta\phi_a + \partial_\mu \Theta^\mu, \qquad \Theta^\mu \equiv \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)}\,\delta\phi_a, \tag{7.155}$$

where the second equality is obtained by adding and subtracting $\partial_\mu\!\left(\frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)}\right)\delta\phi_a$ and recognizing Eq. (7.154). This is purely algebraic: it holds for every $\delta\phi_a$, on shell or off, and it is the single most important formula in Noether theory. Recall how the first theorem reads it: for a *rigid* symmetry, $\delta\phi_a = \delta\alpha\, R_a(\phi)$ with $\delta\alpha$ a constant and $\delta\mathcal{L} = \delta\alpha\, \partial_\mu K^\mu$ a total derivative, the master identity Eq. (7.155) becomes $\partial_\mu(\Theta^\mu - \delta\alpha\, K^\mu) = -\mathcal{E}_a\,\delta\phi_a$, so that the current $j^\mu = \Theta^\mu/\delta\alpha - K^\mu$ is conserved *on shell*.

We now relax the rigidity. The defining feature of a *local* (or *gauge*) symmetry is that the symmetry transformation is parameterized by a function $\varepsilon(x)$ that may be chosen freely at each spacetime point, and that the action is invariant for *every* such choice.

Definition 7.35 (Local symmetry)**.** A transformation of the fields of the form

$$\delta_\varepsilon \phi_a \;=\; \varepsilon(x)\, R_a(\phi) + \big(\partial_\mu \varepsilon(x)\big)\, R_a^\mu(\phi), \tag{7.156}$$

with R_a and R_a^μ local functions of the fields (and possibly their derivatives), is a *local symmetry* of the action $S = \int \mathrm{d}^4x\, \mathcal{L}$ if $\delta_\varepsilon S = 0$ for every smooth, compactly supported parameter $\varepsilon(x)$. Equivalently—since a compactly supported ε generates no boundary contribution—the Lagrangian changes at most by a total derivative, $\delta_\varepsilon \mathcal{L} = \partial_\mu K^\mu[\varepsilon]$, for arbitrary $\varepsilon(x)$.

Two remarks fix the scope. First, Eq. (7.156) is the general first-order local transformation linear in ε; allowing R_a^μ to depend on fields covers the gauged matter we care about, and the extension to higher derivatives of ε (needed only for theories such as gravity, treated later) is a mechanical iteration of the integration by parts below. Second, the constant-ε specialization of Eq. (7.156) is $\delta\phi_a = \varepsilon\, R_a$: this is an ordinary rigid transformation, the *global subgroup* sitting inside the local symmetry. The pivotal question of this section is precisely how much of the conservation content lives in this global subgroup and how much is genuinely new.

7.6.2 The second theorem and its proof

Theorem 7.36 (Noether's second theorem)**.** *Let the action $S = \int \mathrm{d}^4x\, \mathcal{L}$ possess the local symmetry Eq. (7.156) of Theorem 7.35. Then the Euler–Lagrange expressions Eq. (7.154) satisfy the off-shell differential identity*

$$\boxed{\mathcal{E}_a[\phi]\, R_a(\phi) \;-\; \partial_\mu\big(\mathcal{E}_a[\phi]\, R_a^\mu(\phi)\big) \;=\; 0} \tag{7.157}$$

holding identically in ϕ—for every field configuration, whether or not it solves the equations of motion. Equivalently, writing $W^\mu \equiv \mathcal{E}_a R_a^\mu$, the combination $\mathcal{E}_a R_a$ is the divergence of W^μ.

Proof. Invariance of the action under Eq. (7.156) for an arbitrary compactly supported $\varepsilon(x)$ reads $\delta_\varepsilon S = 0$. Evaluate the variation with the master identity Eq. (7.155), in which the total-derivative term $\int \mathrm{d}^4x\, \partial_\mu \Theta^\mu$ vanishes because Θ^μ is supported where ε and $\partial\varepsilon$ are, i.e. in a compact region with no boundary contribution. Hence

$$0 \;=\; \delta_\varepsilon S \;=\; -\int \mathrm{d}^4x\; \mathcal{E}_a[\phi]\, \delta_\varepsilon \phi_a \;=\; -\int \mathrm{d}^4x\; \mathcal{E}_a\big(\varepsilon\, R_a + \partial_\mu \varepsilon\, R_a^\mu\big). \tag{7.158}$$

The crucial step is to move the derivative off ε in the second term by integrating by parts. Because ε has compact support the boundary term again vanishes, and

$$\int \mathrm{d}^4x\; \mathcal{E}_a\, R_a^\mu\, \partial_\mu \varepsilon \;=\; -\int \mathrm{d}^4x\; \varepsilon\, \partial_\mu\big(\mathcal{E}_a\, R_a^\mu\big). \tag{7.159}$$

Substituting Eq. (7.159) into Eq. (7.158) collects the entire integrand against a single factor of ε:

$$0 \;=\; -\int \mathrm{d}^4x\; \varepsilon(x) \Big[\, \mathcal{E}_a\, R_a - \partial_\mu\big(\mathcal{E}_a\, R_a^\mu\big) \Big]. \tag{7.160}$$

This must hold for *every* smooth compactly supported $\varepsilon(x)$. The fundamental lemma of the calculus of variations then forces the bracket to vanish at every point: if a continuous function integrated against all test functions ε gives zero, the function is identically zero. This is exactly Eq. (7.157). No equation of motion was imposed anywhere in the derivation—$\mathcal{E}_a$ was never set to zero—so the identity is off shell. □

The contrast with the first theorem is sharp and worth stating in words. Noether's first theorem takes a rigid symmetry and produces a statement that is empty off shell and becomes the conservation law $\partial_\mu j^\mu = 0$ only *after* the equations of motion are imposed; its content is dynamical. Noether's second theorem takes a local symmetry and produces a statement that holds *before* any equation of motion is imposed; its content is kinematical—a built-in redundancy among the $\mathcal{E}_a$ themselves. The price of demanding invariance under an infinite-dimensional group of transformations, one parameter per spacetime point, is that the equations of motion are not all independent: Eq. (7.157) is a linear relation among them (and their derivatives) that the Lagrangian satisfies automatically. Such relations are the field-theoretic generalization of the Bianchi identities of electromagnetism and gravity, as the worked example below makes concrete.

Physical Insight

A rigid symmetry is a property of *solutions*: it maps one solution to another and thereby pairs each parameter with a quantity that is constant in time. A local symmetry is a property of the *theory itself*: it says that the map "initial data $\mapsto$ solution" is not injective, because field configurations related by a local transformation are physically identical. The first kind of symmetry adds information (a conservation law); the second kind subtracts it (a redundancy). It is a genuine misnomer, entrenched by history, to call both "symmetries"—and the second theorem is the precise theorem that tells them apart.

7.6.3 The naive current and its on-shell triviality

If a local symmetry yields no new conservation law, what becomes of the Noether current one would naively write down by feeding Eq. (7.156) into the first-theorem recipe? Tracking it explicitly is the most instructive way to see the redundancy at work. Because a local symmetry leaves the Lagrangian invariant up to a total derivative, $\delta_\varepsilon \mathcal{L} = \partial_\mu K^\mu[\varepsilon]$, the master identity Eq. (7.155) gives, for the local variation with general $\varepsilon(x)$,

$$\partial_\mu j^\mu \;=\; \mathcal{E}_a[\phi]\,\delta_\varepsilon\phi_a, \qquad j^\mu \;\equiv\; \Theta^\mu - K^\mu \;=\; \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)}\,\delta_\varepsilon\phi_a - K^\mu[\varepsilon]. \tag{7.161}$$

This is the same current the first theorem would assign; on shell ($\mathcal{E}_a = 0$) it is conserved, $\partial_\mu j^\mu = 0$, exactly as advertised. The new feature is what the second theorem says about the right-hand side. Using Eq. (7.156) and the identity Eq. (7.157) in the form $\mathcal{E}_a R_a = \partial_\mu W^\mu$ with $W^\mu = \mathcal{E}_a R_a^\mu$,

$$\mathcal{E}_a\,\delta_\varepsilon\phi_a \;=\; \varepsilon\,\mathcal{E}_a R_a + \partial_\mu\varepsilon\,\mathcal{E}_a R_a^\mu \;=\; \varepsilon\,\partial_\mu W^\mu + (\partial_\mu\varepsilon)\,W^\mu \;=\; \partial_\mu(\varepsilon\,W^\mu). \tag{7.162}$$

Comparing with Eq. (7.161), the naive current obeys $\partial_\mu(j^\mu - \varepsilon\, W^\mu) = 0$ as an *off-shell identity*. We record this as a corollary, because it already exhibits the central pathology.

Corollary 7.37 (Trivial conservation)**.** *For a local symmetry the current j^μ of Eq. (7.161) satisfies, off shell,*

$$\partial_\mu(j^\mu - \varepsilon\, W^\mu) = 0, \qquad W^\mu = \mathcal{E}_a R_a^\mu. \tag{7.163}$$

The term $\varepsilon\, W^\mu$ is proportional to the equations of motion and therefore vanishes on shell. Thus the on-shell conservation $\partial_\mu j^\mu = 0$ carries no information beyond the equations of motion themselves: it is an algebraic consequence of $\mathcal{E}_a = 0$, not an independent constraint extracted from a symmetry.

The combination $V^\mu \equiv j^\mu - \varepsilon W^\mu$ is conserved *identically*—for all field configurations and all $\varepsilon(x)$, with no equation of motion imposed. An identically conserved current is a much weaker object than a dynamically conserved one: in fact it is always a total curl, and hence integrates to a pure boundary term. We isolate this elementary but decisive fact as a lemma.

Lemma 7.38 (An identically conserved current is a superpotential divergence)**.** *Let $V^\mu(x)$ be a smooth vector field on $\mathbb{R}^4$ (more generally on any region star-shaped about the origin) satisfying $\partial_\mu V^\mu = 0$ everywhere. Then there exists an antisymmetric tensor $k^{\mu\nu} = -k^{\nu\mu}$ with $V^\mu = \partial_\nu k^{\mu\nu}$. An explicit choice is*

$$k^{\mu\nu}(x) \;=\; \int_0^1 \mathrm{d}t\; t^{\,2}\,\big[\, x^\nu V^\mu(tx) - x^\mu V^\nu(tx)\,\big]. \tag{7.164}$$

Proof. Antisymmetry of Eq. (7.164) is manifest. Differentiate, using $\partial_\nu[\, f(tx)\,] = t\,(\partial_\nu f)(tx)$ and the contractions $\partial_\nu x^\nu = 4$, $\partial_\nu x^\mu = \delta^\mu_\nu$:

$$\begin{aligned}\partial_\nu k^{\mu\nu} &= \int_0^1 \mathrm{d}t\; t^2\Big[\partial_\nu(x^\nu V^\mu(tx)) - \partial_\nu(x^\mu V^\nu(tx))\Big] \\ &= \int_0^1 \mathrm{d}t\; t^2\Big[\,4\,V^\mu(tx) + t\,x^\nu(\partial_\nu V^\mu)(tx) - V^\mu(tx) - t\,x^\mu(\partial_\nu V^\nu)(tx)\,\Big].\end{aligned} \tag{7.165}$$

The last term vanishes by hypothesis, $\partial_\nu V^\nu = 0$. In the second term recognize the total t-derivative along the ray, $\frac{\mathrm{d}}{\mathrm{d}t}V^\mu(tx) = x^\nu(\partial_\nu V^\mu)(tx)$, so that $t\,x^\nu(\partial_\nu V^\mu)(tx) = t\,\frac{\mathrm{d}}{\mathrm{d}t}V^\mu(tx)$. Hence

$$\partial_\nu k^{\mu\nu} = \int_0^1 \mathrm{d}t\,\Big[\,3\,t^2\,V^\mu(tx) + t^3\,\tfrac{\mathrm{d}}{\mathrm{d}t}V^\mu(tx)\Big] = \int_0^1 \mathrm{d}t\;\tfrac{\mathrm{d}}{\mathrm{d}t}\big[\,t^3\,V^\mu(tx)\,\big] = V^\mu(x), \tag{7.166}$$

where the bracket assembles into an exact t-derivative and the endpoint $t = 1$ gives $V^\mu(x)$ while $t = 0$ contributes nothing. This is the claim. □

Applying the lemma to $V^\mu = j^\mu - \varepsilon W^\mu$ from Theorem 7.37 and then setting ε to the constant parameter of the global subgroup yields the structural statement that decides the physics.

Proposition 7.39 (On-shell triviality of the gauge current)**.** *Let j^μ_{glob} denote the Noether current Eq. (7.161) of the global subgroup, obtained by taking $\varepsilon \equiv 1$ (constant), so that $\delta\phi_a = R_a$. Then there is an antisymmetric superpotential $k^{\mu\nu} = -k^{\nu\mu}$ such that,* on shell,

$$j^\mu_{\text{glob}} \overset{\mathcal{E}=0}{=} \partial_\nu k^{\mu\nu}. \tag{7.167}$$

Consequently the associated charge reduces to a surface integral over the boundary of the spatial slice,

$$Q = \int_\Sigma \mathrm{d}^3x\, j^0_{\text{glob}} = \int_\Sigma \mathrm{d}^3x\, \partial_i k^{0i} = \oint_{\partial\Sigma} \mathrm{d}S_i\, k^{0i}, \tag{7.168}$$

and is fixed entirely by the fields at spatial infinity. The current is thus improvable to zero*: subtracting the identically conserved superpotential term $\partial_\nu k^{\mu\nu}$ sets it to zero on shell, removing it as a source of independent charge.*

Proof. By Theorem 7.37 with $\varepsilon \equiv 1$, the current $V^\mu = j^\mu_{\text{glob}} - W^\mu$ is identically conserved, $\partial_\mu V^\mu = 0$ off shell. Theorem 7.38 then supplies an antisymmetric $k^{\mu\nu}$ with $V^\mu = \partial_\nu k^{\mu\nu}$, i.e. $j^\mu_{\text{glob}} = \partial_\nu k^{\mu\nu} + W^\mu$ identically. On shell $W^\mu = \mathcal{E}_a R^\mu_a = 0$, leaving Eq. (7.167). Integrating its time component over a spatial slice Σ and using $\partial_\nu k^{0\nu} = \partial_i k^{0i}$ (the $\nu = 0$ piece vanishes by antisymmetry, $k^{00} = 0$) gives Eq. (7.168) by the divergence theorem. □

This is the precise sense in which a local symmetry yields "no new charge." A genuine global symmetry produces a charge $Q = \int_\Sigma \mathrm{d}^3x\, j^0$ that is a bulk integral of a density—a count of particles, a net flavor, an energy—whose conservation in time is a nontrivial dynamical statement. The would-be charge of a local symmetry is, by Theorem 7.39, a flux through the boundary: it is determined by boundary data and does not register any independent property of the interior. In the absence of charged matter at infinity it is simply zero. The infinite family of local transformations, one per spacetime point, collapses on shell to no physical conserved quantity whatsoever; only the constant mode—the global subgroup—can survive, and it survives only when the matter content makes its action nontrivial. We turn that abstract chain into explicit formulas.

7.6.4 The gauged example: electromagnetism

Worked Example 7.40 (Maxwell theory: the gauge current is a curl)**.** Take the free electromagnetic Lagrangian of the recurring cast,

$$\mathcal{L} = -\tfrac{1}{4} F_{\mu\nu}F^{\mu\nu}, \qquad F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu, \tag{7.169}$$

with the gauge field A_ρ playing the role of the field multiplet ϕ_a (the field index a is the Lorentz index ρ). The local symmetry is the gauge transformation $\delta_\varepsilon A_\rho = \partial_\rho \varepsilon$, which in the notation of Eq. (7.156) means

$$R_\rho = 0, \qquad R_\rho^\mu = \delta_\rho^\mu, \tag{7.170}$$

since $\delta_\varepsilon A_\rho = (\partial_\mu \varepsilon)\, \delta_\rho^\mu$. It is a symmetry because $\delta_\varepsilon F_{\mu\nu} = \partial_\mu \partial_\nu \varepsilon - \partial_\nu \partial_\mu \varepsilon = 0$, so $\delta_\varepsilon \mathcal{L} = 0$ exactly and $K^\mu = 0$.

Euler–Lagrange operator. From Eq. (7.169), $\partial \mathcal{L}/\partial(\partial_\mu A_\rho) = -F^{\mu\rho}$ and $\partial \mathcal{L}/\partial A_\rho = 0$, so Eq. (7.154) gives

$$\mathcal{E}^\rho = \partial_\mu\big(-F^{\mu\rho}\big) = -\partial_\mu F^{\mu\rho}, \qquad \mathcal{E}^\rho = 0 \iff \partial_\mu F^{\mu\rho} = 0, \tag{7.171}$$

the sourceless Maxwell equations.

Second theorem as a Bianchi identity. With Eq. (7.170), the identity Eq. (7.157) reads $\mathcal{E}^\rho R_\rho - \partial_\mu(\mathcal{E}^\rho R_\rho^\mu) = 0 - \partial_\mu(\mathcal{E}^\rho \delta_\rho^\mu) = -\partial_\mu \mathcal{E}^\mu$, so the second theorem asserts

$$\partial_\mu \mathcal{E}^\mu = \partial_\mu \partial_\nu F^{\nu\mu} \equiv 0, \tag{7.172}$$

which is true identically because $\partial_\mu \partial_\nu$ is symmetric while $F^{\nu\mu}$ is antisymmetric. This is the off-shell redundancy in flesh: the four Maxwell equations $\mathcal{E}^\rho = 0$ are not independent; their divergence vanishes automatically, so they encode only three independent dynamical equations together with a constraint. Here $W^\mu = \mathcal{E}^\rho R_\rho^\mu = \mathcal{E}^\mu = -\partial_\nu F^{\nu\mu}$.

The naive current. With $K^\mu = 0$ and $\delta_\varepsilon A_\rho = \partial_\rho \varepsilon$, Eq. (7.161) gives

$$j^\mu = \frac{\partial \mathcal{L}}{\partial(\partial_\mu A_\rho)}\, \delta_\varepsilon A_\rho = -F^{\mu\rho}\, \partial_\rho \varepsilon. \tag{7.173}$$

Its divergence is $\partial_\mu j^\mu = -(\partial_\mu F^{\mu\rho})\partial_\rho \varepsilon - F^{\mu\rho}\partial_\mu \partial_\rho \varepsilon$; the second term vanishes (antisymmetric $F^{\mu\rho}$ against symmetric $\partial_\mu \partial_\rho$), leaving $\partial_\mu j^\mu = -(\partial_\mu F^{\mu\rho})\partial_\rho \varepsilon = (\partial_\rho \varepsilon)\, W^\rho$, in exact agreement with Eq. (7.162). On shell it is conserved, but only because $\partial_\mu F^{\mu\rho} = 0$ already—no new content.

The current is a total derivative. Rewrite Eq. (7.173) by moving the derivative onto ε:

$$j^\mu = -F^{\mu\rho}\partial_\rho \varepsilon = -\partial_\rho\big(\varepsilon\, F^{\mu\rho}\big) + \varepsilon\, \partial_\rho F^{\mu\rho} \overset{\mathcal{E}=0}{=} \partial_\rho\big(\varepsilon\, F^{\rho\mu}\big) \equiv \partial_\rho k^{\rho\mu}, \tag{7.174}$$

where on shell $\partial_\rho F^{\mu\rho} = 0$ and the superpotential

$$k^{\rho\mu} = \varepsilon\, F^{\rho\mu} = -k^{\mu\rho} \tag{7.175}$$

is antisymmetric—precisely the structure guaranteed in general by Theorem 7.39, now exhibited as an explicit local expression rather than the homotopy integral of Theorem 7.38.

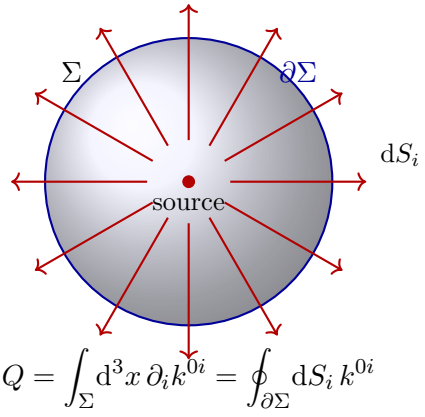

Figure 7.5: The would-be charge of a local symmetry is a boundary flux. Because the on-shell current is a spatial divergence, $j^0 = \partial_i k^{0i}$ with k^{0i} antisymmetric, no charge is stored in the bulk of the slice Σ; the charge Eq. (7.168) is the flux of k^{0i} through $\partial\Sigma$. In Maxwell theory $k^{0i} = \varepsilon\, F^{0i}$ and this is Gauss's law: the electric flux through the boundary equals the enclosed charge.

The charge is a flux. The charge is therefore a surface integral. With $F^{i0} = E^i$ the components of the electric field,

$$Q = \int_\Sigma \mathrm{d}^3x\, j^0 = \int_\Sigma \mathrm{d}^3x\, \partial_i(\varepsilon\, F^{i0}) = \oint_{\partial\Sigma} \mathrm{d}S_i\, \varepsilon\, F^{i0} = \oint_{\partial\Sigma} \varepsilon\, \mathbf{E}\cdot\mathrm{d}\mathbf{S}. \tag{7.176}$$

For the constant mode $\varepsilon = 1$ this is $\oint \mathbf{E}\cdot\mathrm{d}\mathbf{S}$—the flux of the electric field through the boundary, which by Gauss's law equals the total electric charge enclosed. The "Noether charge" of the gauge symmetry is not a new conserved quantity at all; it is the electric flux, fixed entirely by the boundary, and it is the physical charge only because Gauss's law ties the boundary flux to the enclosed source. Pure Maxwell theory has no charged field, so $\delta_\varepsilon A_\rho = \partial_\rho \varepsilon$ acts trivially on a constant ε and the bulk charge is simply zero.

Figure 7.5 renders the geometry of Eq. (7.176): a would-be conserved density that is a total spatial divergence stores nothing in the bulk, so the charge collects entirely on the bounding surface.

7.6.5 Where the genuine charge lives: global versus local in scalar QED

The Maxwell example is the clean skeleton, but it is almost too clean: with no charged matter, even the global subgroup is trivial. To see the global subgroup carry a real charge while its local extension adds nothing, we couple a charged scalar—the system in which the genuine $U(1)$ charge and its gauge redundancy sit side by side.

Worked Example 7.41 (Scalar electrodynamics: a real global charge inside a gauge redundancy)**.** Consider a complex scalar of charge q minimally coupled to the photon, with the chapter's gauge-coupling convention $D_\mu = \partial_\mu - iqA_\mu$,

$$\mathcal{L} = (D_\mu\phi)^*(D^\mu\phi) - m^2\phi^*\phi - \tfrac{1}{4}F_{\mu\nu}F^{\mu\nu}, \qquad D_\mu\phi = \partial_\mu\phi - iqA_\mu\phi. \tag{7.177}$$

The local symmetry is $\phi \to e^{iq\alpha(x)}\phi$ together with $A_\mu \to A_\mu + \partial_\mu\alpha$, whose infinitesimal form is

$$\delta_\alpha\phi = iq\,\alpha\,\phi, \qquad \delta_\alpha\phi^* = -iq\,\alpha\,\phi^*, \qquad \delta_\alpha A_\mu = \partial_\mu\alpha. \tag{7.178}$$

One checks $\delta_\alpha(D_\mu\phi) = iq\,\alpha\,D_\mu\phi$, so each term in Eq. (7.177) is invariant and the action has the local symmetry for arbitrary $\alpha(x)$.

The global subgroup carries a bulk charge. Restrict to constant α. Then $\delta A_\mu = 0$ and only the phase rotation of ϕ survives—this is the rigid internal $U(1)$ of Theorem 7.10. With $\partial\mathcal{L}/\partial(\partial_\mu\phi) = (D^\mu\phi)^*$ and $\partial\mathcal{L}/\partial(\partial_\mu\phi^*) = D^\mu\phi$, the first-theorem current ($K^\mu = 0$, α scaled out) is

$$j^\mu = \frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi)}\frac{\delta\phi}{\alpha} + \frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi^*)}\frac{\delta\phi^*}{\alpha} = iq\big[(D^\mu\phi)^*\phi - (D^\mu\phi)\phi^*\big] = iq\big[\phi\,(D^\mu\phi)^* - \phi^*\,D^\mu\phi\big]. \tag{7.179}$$

This is a genuine bulk current: its density j^0 is built from the matter fields and their momenta, and $Q = \int_\Sigma \mathrm{d}^3x\, j^0$ counts the net charge of the scalar quanta—a real, nonzero, dynamically conserved number, not a boundary artifact. The global $U(1)$ is an honest symmetry and yields an honest charge.

The local extension adds only a constraint. Now allow $\alpha(x)$ to vary. The full set of Euler–Lagrange equations includes the photon equation, obtained by varying Eq. (7.177) in A_ν,

$$\partial_\mu F^{\mu\nu} = J^\nu, \qquad J^\nu = iq\big[\phi\,(D^\nu\phi)^* - \phi^*\,D^\nu\phi\big], \tag{7.180}$$

i.e. the matter current Eq. (7.179) is exactly the source of the photon. Noether's second theorem for the gauge parameter A_ν-sector reproduces the Bianchi identity Eq. (7.172); taking the divergence of Eq. (7.180) then gives $\partial_\nu J^\nu = \partial_\nu\partial_\mu F^{\mu\nu} \equiv 0$. Conservation of the matter current is thereby *enforced as an identity* by the gauge structure, rather than supplied as new information. The local symmetry's own would-be charge is, by Theorem 7.39 and Eq. (7.176), again the flux $\oint \mathbf{E}\cdot\mathrm{d}\mathbf{S}$; by Eq. (7.180) this flux equals $\int_\Sigma J^0 = Q$. The local symmetry contributes no charge of its own—it only ties the already-existing global charge Q to the electric flux through the boundary (Gauss's law) and elevates current conservation from a dynamical theorem to a kinematic identity.

The lesson generalizes verbatim to the non-abelian and gravitational cases treated later: the genuine conserved charges of a theory come from its *global* symmetry group, while the local symmetry contributes Bianchi-type identities, a Gauss-law constraint, and a charge that is always a boundary flux. The reader should hold one caution.

Caution

"The gauge current carries no charge" does not mean gauge symmetry is physically vacuous. On the contrary, demanding it is enormously restrictive: it fixes the matter–photon coupling to be minimal, forces the photon to be massless, and renders the equations of motion mutually consistent through the Bianchi identity. What the second theorem denies is only that a *local* parameter yields an *independent conserved charge*. The physical content of a gauge symmetry is the redundancy it certifies—and, downstream, the constraints it imposes on which Lagrangians and which states are admissible—not a Noether charge.

Physical Insight

The cleanest one-line summary is operational. Count the independent conserved charges by counting the *constant* modes of your symmetry parameters: a rigid symmetry has one parameter and gives one charge; a local symmetry has one parameter *per point*, but all the non-constant modes are redundancy, and the single constant mode gives at most the one charge of the global subgroup—realized, when matter is present, as a boundary flux. Symmetry is the organizing principle of field theory, but only *global* symmetry is the bookkeeping of conserved quantities; local "symmetry" is the bookkeeping of description.

With the global–local distinction now sharp—a global symmetry supplies a conserved charge, a local symmetry supplies an off-shell identity and a redundancy—we have isolated exactly the structure that the gauge principle will turn into a construction. Chapter 8 runs the logic forward: starting from the genuine global phase symmetry of a charged field Eq. (7.179) and *demanding* that it be promoted to a local one, the connection A_μ, minimal coupling $D_\mu = \partial_\mu - iqA_\mu$, and the field strength $F_{\mu\nu}$ as its curvature are forced upon us, deriving electromagnetism from a redundancy. The same redundancy viewpoint, now read as a constraint that must be gauge-fixed before quantization, is what organizes the Faddeev–Popov and BRST treatment of Yang–Mills theory in Chapter 25 and Chapter 26.

7.7 Scale, Conformal Symmetry, and the Trace of the Stress Tensor

The Belinfante tensor $\Theta^{\mu\nu}$ assembled in the previous section is the repaired, symmetric, gauge-invariant stress–energy tensor: conserved on every index, $\partial_\mu \Theta^{\mu\nu} = 0$, and symmetric, $\Theta^{\mu\nu} = \Theta^{\nu\mu}$, with the asymmetry of the canonical tensor absorbed by a superpotential improvement $\Theta^{\mu\nu} = T^{\mu\nu} + \partial_\rho B^{\rho\mu\nu}$, $B^{\rho\mu\nu} =$

$-B^{\mu\rho\nu}$, that leaves the charges $P^\nu = \int d^3x\, \Theta^{0\nu}$ untouched (Theorem 7.33). Two of the three numbers that classify a Poincaré current have now been wrung from this single object: its conservation gives energy–momentum, its symmetry gives angular momentum. There is a third number it carries, one we have so far only glanced at through the non-zero trace of the scalar's canonical tensor in Eq. (6.182): the trace $\Theta^\mu{}_\mu$. This section shows that the trace is the exact local measure of a further would-be symmetry — invariance under rescaling of all lengths — and that for a special class of theories the same superpotential technology that symmetrized $\Theta^{\mu\nu}$ can also make it *traceless*, at which point the theory is invariant not merely under dilatations but under the full conformal group. We derive the dilatation current and the identity $\partial_\mu D^\mu = \Theta^\mu{}_\mu$, build the improved traceless scalar tensor explicitly, exhibit the special-conformal currents, and close the classical layer of ϕ^4 theory: massless ϕ^4 in four dimensions is classically scale and conformally invariant, the mass term is the unique relevant operator that breaks it, and the quartic coupling sits exactly at the marginal boundary. The quantum fate of this symmetry — its generic destruction by renormalization — is flagged and deferred.

7.7.1 Dilatations and the scaling dimension of a field

A *dilatation* (or scale transformation) rescales all spacetime coordinates by a common positive factor,

$$x^\mu \;\longrightarrow\; x'^\mu = \lambda\, x^\mu, \qquad \lambda = e^\omega > 0, \tag{7.181}$$

and acts on the dynamical field according to how the field is built from lengths. The defining postulate is that a field ϕ carries a definite *scaling dimension* Δ, meaning it transforms as

$$\phi(x) \;\longrightarrow\; \phi'(x') = \lambda^{-\Delta}\, \phi(x), \tag{7.182}$$

so that the rescaled field, read at the rescaled point, is the old field diminished by $\lambda^{-\Delta}$. The exponent Δ is not free: it is fixed by demanding that the kinetic term be left invariant, as we determine below. Writing $\lambda = e^\omega$ and expanding to first order in the infinitesimal parameter ω, the coordinate shift and the *total* field variation (the change including the displacement of the argument) are

$$\delta x^\mu = \omega\, x^\mu, \qquad \delta\phi \;\equiv\; \phi'(x') - \phi(x) = -\omega\, \Delta\, \phi. \tag{7.183}$$

The *intrinsic* (form) variation $\delta_0\phi = \delta\phi - \delta x^\nu \partial_\nu \phi$, the change at a fixed coordinate, is then

$$\delta_0\phi = -\omega\, (\Delta + x^\nu \partial_\nu)\, \phi, \tag{7.184}$$

which displays the two ways a dilatation moves a field: it dilutes its value (the Δ piece) and it advects it along the radial flow $x^\nu\partial_\nu$ (the orbital piece).

Definition 7.42 (Scaling dimension)**.** The *scaling dimension* (or classical, "engineering," mass dimension) Δ of a field ϕ is the exponent in Eq. (7.182). In natural units it coincides with the mass dimension $[\phi]$ assigned by requiring the action $S = \int d^d x\, \mathcal{L}$ to be dimensionless: since $[d^d x] = -d$ and a kinetic Lagrangian must have $[\mathcal{L}] = d$, a canonically normalized scalar with kinetic term $\frac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi)$ has

$$2\Delta + 2 = d \quad \Longrightarrow \quad \Delta = \frac{d-2}{2}, \tag{7.185}$$

which equals 1 in $d = 4$. A spin-$\frac{1}{2}$ field has $\Delta = (d-1)/2$ and a gauge potential $\Delta = (d-2)/2$ as well; only the scalar is needed here.

Equation Eq. (7.185) is the first concrete payoff: it *fixes* the scaling dimension of the scalar field. The number $\Delta = 1$ (in $d = 4$) is not a choice; it is forced by the demand that the kinetic term, the one piece of the Lagrangian present in every scalar theory, be invariant under Eq. (7.181)–Eq. (7.182). We will see in a moment that every other term in the Lagrangian then either respects this scaling or breaks it, and that the breaking is governed entirely by the mass dimensions of the couplings.

7.7.2 The dilatation current and the trace of the stress tensor

We now feed the dilatation Eq. (7.183) into Noether's first theorem. The master current of Eq. (7.32), written in its three-piece form Eq. (7.39), is $J^\mu = \Pi^\mu_a\, \delta\phi_a - T^\mu{}_\nu\, \delta x^\nu - \Lambda^\mu$, with $\Pi^\mu \equiv \partial\mathcal{L}/\partial(\partial_\mu\phi)$ and $T^\mu{}_\nu$ the canonical stress tensor of Theorem 6.28. For the scalar there is no internal index and, crucially, the canonical tensor already coincides with the Belinfante tensor, $T^{\mu\nu} = \Theta^{\mu\nu}$, because spin zero has no spin current to absorb (Eq. (6.178)). Taking $\Lambda^\mu = 0$ for now and inserting $\delta\phi = -\omega\Delta\phi$, $\delta x^\nu = \omega x^\nu$, $\Pi^\mu = \partial^\mu\phi$, the Noether current per unit parameter ω is

$$J^\mu = -\big[\, \Delta\, \phi\, \partial^\mu\phi + x_\nu\, \Theta^{\mu\nu} \,\big]. \tag{7.186}$$

A conserved current is fixed only up to an overall sign and an additive identically-conserved term; we fix the sign by convention and *define* the dilatation current as

$$\boxed{\; D^\mu \;=\; x_\nu\, \Theta^{\mu\nu} \;+\; V^\mu, \qquad V^\mu \;\equiv\; \Delta\, \phi\, \partial^\mu\phi \;} \tag{7.187}$$

the sum of an *orbital* piece $x_\nu\Theta^{\mu\nu}$, built from the stress tensor exactly as the orbital angular-momentum current was, and a *field virial* V^μ, which records the intrinsic scaling weight Δ of the field and has no analogue in the translation or rotation currents. The virial is the genuinely new ingredient of scale symmetry.

Its divergence is immediate. Using $\partial_\mu x_\nu = \eta_{\mu\nu}$ and the conservation of the Belinfante tensor,

$$\partial_\mu(x_\nu\Theta^{\mu\nu}) = (\partial_\mu x_\nu)\Theta^{\mu\nu} + x_\nu\, \partial_\mu\Theta^{\mu\nu} = \eta_{\mu\nu}\Theta^{\mu\nu} + 0 = \Theta^\mu{}_\mu, \tag{7.188}$$

so that

$$\boxed{\partial_\mu D^\mu \;=\; \Theta^\mu{}_\mu \;+\; \partial_\mu V^\mu\,.} \tag{7.189}$$

This is the central kinematic identity of scale symmetry, and it already tells the whole story in outline: the orbital part of the dilatation current is conserved *up to the trace of the stress tensor*. Whether the full D^μ is conserved hinges on whether the trace term and the virial divergence cancel. The next two results show that they do — for a special class of theories, and only after an improvement that absorbs the virial into the stress tensor itself.

Theorem 7.43 (Scale current and the trace)**.** *Let a Poincaré-invariant theory possess a symmetric, conserved stress tensor $\Theta^{\mu\nu}$. If its trace can be written as a total divergence of a field virial, $\Theta^\mu{}_\mu = -\partial_\mu V^\mu$ on shell, then the dilatation current Eq. (7.187) is conserved, $\partial_\mu D^\mu = 0$, and the theory is scale invariant. Conversely, scale invariance requires the trace of the stress tensor to be a total derivative on shell.*

Proof. The forward statement is Eq. (7.189) read in reverse: if $\Theta^\mu{}_\mu + \partial_\mu V^\mu = 0$ then $\partial_\mu D^\mu = 0$. For the converse, suppose the action is invariant under Eq. (7.181)–Eq. (7.182). Noether's theorem then produces a conserved D^μ of the form Eq. (7.187) (with $V^\mu = \Delta\,\Pi^\mu_a \phi_a$ in the general case), and $\partial_\mu D^\mu = 0$ combined with Eq. (7.189) forces $\Theta^\mu{}_\mu = -\partial_\mu V^\mu$. □

The cleanest situation arises when the field virial is itself the divergence of a local tensor, $V^\mu = \partial_\nu \sigma^{\nu\mu}$. For the scalar this holds identically:

$$V^\mu = \Delta\,\phi\,\partial^\mu\phi = \frac{\Delta}{2}\,\partial^\mu(\phi^2) = \partial_\nu\Big(\tfrac{\Delta}{2}\,\eta^{\nu\mu}\phi^2\Big), \qquad \sigma^{\nu\mu} = \tfrac{\Delta}{2}\,\eta^{\nu\mu}\phi^2. \tag{7.190}$$

When the virial is a total derivative the theory is not merely scale invariant but, as we show in Section 7.7.4, fully *conformally* invariant, and — the point of the next subsection — the stress tensor can be improved to a manifestly traceless object that makes both facts transparent. Before that, a worked computation pins down what happens for the massless free scalar without any improvement, to expose precisely how the virial rescues conservation.

Worked Example 7.44 (The virial cancellation for the massless free scalar)**.** Take the massless free scalar in d dimensions, $\mathcal{L}_0 = \frac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi)$, with equation of motion $\Box\phi = 0$. Its (canonical = Belinfante) stress tensor is $\Theta^{\mu\nu} = \partial^\mu\phi\,\partial^\nu\phi - \eta^{\mu\nu}\frac{1}{2}(\partial_\alpha\phi)(\partial^\alpha\phi)$, whose trace is

$$\Theta^\mu{}_\mu = (\partial_\alpha\phi)(\partial^\alpha\phi) - \frac{d}{2}(\partial_\alpha\phi)(\partial^\alpha\phi) = \frac{2-d}{2}\,(\partial_\alpha\phi)(\partial^\alpha\phi), \tag{7.191}$$

which is *not zero* in $d = 4$: the bare stress tensor of the massless scalar has trace $-(\partial\phi)^2$. Were D^μ equal to its orbital part alone, scale symmetry would

already be broken. The virial $V^\mu = \Delta\,\phi\,\partial^\mu\phi$ saves it. With $\Delta = (d-2)/2$ from Eq. (7.185),

$$\partial_\mu V^\mu = \Delta\big[(\partial_\mu\phi)(\partial^\mu\phi) + \phi\,\Box\phi\big] \xrightarrow{\Box\phi=0} \frac{d-2}{2}\,(\partial_\alpha\phi)(\partial^\alpha\phi), \tag{7.192}$$

the term $\phi\,\Box\phi$ vanishing on shell. Adding to Eq. (7.191),

$$\partial_\mu D^\mu = \Theta^\mu{}_\mu + \partial_\mu V^\mu = \frac{2-d}{2}(\partial\phi)^2 + \frac{d-2}{2}(\partial\phi)^2 = 0. \tag{7.193}$$

The cancellation is exact and dimension-independent: the orbital trace $\frac{2-d}{2}(\partial\phi)^2$ and the virial divergence $\frac{d-2}{2}(\partial\phi)^2$ are equal and opposite *for the canonical value* $\Delta = (d-2)/2$ of the scaling dimension. This is the precise sense in which Eq. (7.185) is forced: had we assigned the scalar any other scaling dimension, the dilatation current would fail to be conserved. Scale invariance of the massless scalar and the value $\Delta = (d-2)/2$ are one and the same statement.

7.7.3 The improved, traceless stress tensor

The cancellation just witnessed is correct but unsatisfying: it splits the dilatation current into two pieces whose conservation is an accident of arithmetic, and it leaves the stress tensor with a non-zero trace even when the theory is scale invariant. The remedy is to push the virial *into* the stress tensor. Because V^μ is a total derivative Eq. (7.190), it can be absorbed by a superpotential improvement of exactly the kind that symmetrized the Belinfante tensor, but now chosen to cancel the trace rather than the antisymmetric part. The result is the celebrated improved scalar stress tensor.

Definition 7.45 (Conformally improved scalar stress tensor)**.** For a real scalar in d dimensions, the *conformally improved* (or "new improved") stress tensor is the Belinfante tensor corrected by a symmetric, identically-conserved improvement term,

$$\boxed{\Theta^{\mu\nu}_{\rm c} \;=\; \Theta^{\mu\nu} \;+\; \xi_d\,(\eta^{\mu\nu}\Box - \partial^\mu\partial^\nu)\,\phi^2, \qquad \xi_d = \frac{d-2}{4(d-1)}\,,} \tag{7.194}$$

with $\xi_4 = \frac{1}{6}$ in four dimensions.

Three properties make $\Theta^{\mu\nu}_{\rm c}$ a legitimate replacement for $\Theta^{\mu\nu}$, and the algebra below verifies each in turn.

(i) It is symmetric. The improvement term involves $\eta^{\mu\nu}$ and the symmetric $\partial^\mu\partial^\nu$, so $\Theta^{\mu\nu}_{\rm c} = \Theta^{\nu\mu}_{\rm c}$ inherits the symmetry of $\Theta^{\mu\nu}$.

(ii) It is identically conserved. The improvement adds nothing to the divergence, off shell:

$$\partial_\mu\Big[\xi_d(\eta^{\mu\nu}\Box - \partial^\mu\partial^\nu)\phi^2\Big] = \xi_d(\partial^\nu\Box - \Box\partial^\nu)\phi^2 = 0, \tag{7.195}$$

since $\partial_\mu \eta^{\mu\nu}\Box = \partial^\nu \Box$ and $\partial_\mu \partial^\mu \partial^\nu = \Box \partial^\nu$, and partial derivatives commute. Thus $\partial_\mu \Theta^{\mu\nu}_{\mathrm{c}} = \partial_\mu \Theta^{\mu\nu} = 0$. The improvement term has the superpotential form $\partial_\rho B^{\rho\mu\nu}$ with $B^{\rho\mu\nu} = \xi_d(\eta^{\mu\nu}\partial^\rho - \eta^{\rho\nu}\partial^\mu)\phi^2$ antisymmetric in its first two indices, which is the structural reason Eq. (7.195) holds.

(iii) It carries the same energy and momentum. The charges are unchanged because the added density is a spatial total derivative on each time slice. For $\nu = 0$, $\xi_d(\eta^{00}\Box - \partial^0\partial^0)\phi^2 = \xi_d(\Box - \partial_0^2)\phi^2 = \xi_d \nabla^2 \phi^2$, and for $\nu = i$, $\xi_d(\eta^{0i}\Box - \partial^0\partial^i)\phi^2 = -\xi_d\, \partial^0\partial^i\phi^2 = \partial_j(\cdots)$; in both cases $\int d^3x$ of the addition vanishes by Gauss's theorem for fields decaying at spatial infinity. Hence $P^\nu = \int d^3x\, \Theta^{0\nu}_{\mathrm{c}} = \int d^3x\, \Theta^{0\nu}$.

The point of the particular coefficient ξ_d is that it makes the trace as small as the dimensionful couplings allow. The trace of the improvement term is

$$\eta_{\mu\nu}\, \xi_d(\eta^{\mu\nu}\Box - \partial^\mu\partial^\nu)\phi^2 = \xi_d\,(d-1)\,\Box\phi^2, \tag{7.196}$$

using $\eta_{\mu\nu}\eta^{\mu\nu} = d$ and $\eta_{\mu\nu}\partial^\mu\partial^\nu = \Box$. The free parameter ξ_d is fixed by demanding that the gradient term in the total trace cancel, which we now carry out for the full interacting scalar of ϕ^4 theory.

Worked Example 7.46 (The classical trace identity of $\lambda\phi^4$)**.** We compute $\Theta^{\mu}_{\mathrm{c}\,\mu}$ for the frozen ϕ^4 Lagrangian Eq. (6.56), $\mathcal{L} = \frac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) - \frac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4$, in general dimension d, then specialize to $d = 4$.

Trace of the Belinfante tensor. With $\Theta^{\mu\nu} = \partial^\mu\phi\,\partial^\nu\phi - \eta^{\mu\nu}\mathcal{L}$,

$$\begin{aligned}
\Theta^{\mu}{}_{\mu} &= (\partial_\alpha\phi)(\partial^\alpha\phi) - d\,\mathcal{L} \\
&= (\partial\phi)^2 - d\Big[\tfrac{1}{2}(\partial\phi)^2 - \tfrac{1}{2}m^2\phi^2 - \tfrac{\lambda}{4!}\phi^4\Big] \\
&= \Big(1 - \tfrac{d}{2}\Big)(\partial\phi)^2 + \tfrac{d}{2}\,m^2\phi^2 + \tfrac{d}{4!}\,\lambda\phi^4,
\end{aligned} \tag{7.197}$$

where $(\partial\phi)^2 \equiv (\partial_\alpha\phi)(\partial^\alpha\phi)$.

The improvement contribution, on shell. From Eq. (7.196) the improvement adds $\xi_d(d-1)\Box\phi^2$. Expanding $\Box\phi^2 = 2(\partial_\alpha\phi)(\partial^\alpha\phi) + 2\phi\,\Box\phi$ and substituting the equation of motion Eq. (6.60), $\Box\phi = -m^2\phi - \frac{\lambda}{3!}\phi^3$,

$$\Box\phi^2 = 2(\partial\phi)^2 + 2\phi\Big(-m^2\phi - \tfrac{\lambda}{3!}\phi^3\Big) = 2(\partial\phi)^2 - 2m^2\phi^2 - \tfrac{\lambda}{3}\phi^4. \tag{7.198}$$

Hence

$$\xi_d(d-1)\,\Box\phi^2 = \frac{d-2}{4}\Big[\,2(\partial\phi)^2 - 2m^2\phi^2 - \tfrac{\lambda}{3}\phi^4\Big] = \frac{d-2}{2}(\partial\phi)^2 - \frac{d-2}{2}m^2\phi^2 - \frac{(d-2)\lambda}{12}\phi^4, \tag{7.199}$$

where $\xi_d(d-1) = \frac{d-2}{4(d-1)}(d-1) = \frac{d-2}{4}$.

Assemble. Adding Eq. (7.197) and Eq. (7.199),

$$\Theta^{\mu}_{\mathrm{c}\,\mu} = \underbrace{\Big[\Big(1-\tfrac{d}{2}\Big) + \tfrac{d-2}{2}\Big]}_{=0}(\partial\phi)^2 + \underbrace{\Big[\tfrac{d}{2} - \tfrac{d-2}{2}\Big]}_{=1} m^2\phi^2 + \underbrace{\Big[\tfrac{d}{4!} - \tfrac{(d-2)}{12}\Big]}_{=\frac{4-d}{24}}\lambda\phi^4. \tag{7.200}$$

The gradient term cancels for *every* d — this is precisely what the choice $\xi_d = \frac{d-2}{4(d-1)}$ engineers — leaving the clean classical trace identity

$$\boxed{\Theta^{\mu}_{\mathrm{c}\,\mu} \;=\; m^2\,\phi^2 \;+\; \frac{4-d}{24}\,\lambda\,\phi^4\,.} \tag{7.201}$$

In four dimensions the quartic term drops out identically and

$$\boxed{\Theta^{\mu}_{\mathrm{c}\,\mu}\big|_{d=4} \;=\; m^2\,\phi^2\,.} \tag{7.202}$$

The result Eq. (7.201) is the trace identity the section set out to establish, and its structure is worth reading carefully because it is the classical skeleton of the whole theory of the renormalization group. Each term in the trace is a Lagrangian operator multiplied by a number, and that number is exactly the *mass dimension of the coupling* in front of the operator. The mass term $\frac{1}{2}m^2\phi^2$ has a coupling $\frac{1}{2}m^2$ of dimension $[m^2] = 2$, and indeed $2 \times \frac{1}{2}m^2\phi^2 = m^2\phi^2$ appears in the trace. The quartic $\frac{\lambda}{4!}\phi^4$ has a coupling of dimension

$$[\lambda] = d - 4\,[\phi] = d - 4\cdot\frac{d-2}{2} = 4 - d, \tag{7.203}$$

and indeed $(4-d) \times \frac{\lambda}{4!}\phi^4 = \frac{4-d}{24}\lambda\phi^4$ appears. The general pattern, valid for any local scalar Lagrangian written as a sum of monomials with couplings g_i, is the classical trace formula

$$\Theta^{\mu}_{\mathrm{c}\,\mu} = \sum_i [g_i]\, g_i\, \mathcal{O}_i, \tag{7.204}$$

the trace being sourced exactly by the dimensionful couplings, each weighted by its own mass dimension. *Scale-noninvariance is the dimensionful couplings, nothing more.* A theory built only from dimensionless (marginal) couplings has a classically traceless stress tensor and is classically scale invariant; every dimensionful coupling contributes a term to the trace and breaks the symmetry.

Physical Insight

A traceless symmetric stress tensor is the local certificate of scale invariance, just as a symmetric one is the certificate of angular-momentum conservation and a conserved one of energy–momentum conservation. The three avatars of $\Theta^{\mu\nu}$ — conserved, symmetric, traceless — are the three pillars of conformal symmetry. The trace $\Theta^{\mu}{}_{\mu}$ is the single function whose vanishing upgrades a Poincaré-invariant theory to a scale-invariant one; Eq. (7.201) measures exactly how far the classical ϕ^4 theory falls short, and pins the shortfall on the mass and (away from $d = 4$) on the dimensionful quartic.

Notation Watch

We reserve $\Theta^{\mu\nu}$ for the symmetric, conserved Belinfante tensor of Theorem 7.33 and $\Theta_{\rm c}^{\mu\nu}$ for the conformally improved tensor Eq. (7.194); the two differ by the identically-conserved improvement term and carry the same charges. Some texts (Callan–Coleman–Jackiw) write the improvement with the opposite global sign as $-\frac{d-2}{4(d-1)}(\partial^\mu\partial^\nu-\eta^{\mu\nu}\Box)\phi^2$, which is identical to ours; others fold the coefficient into a non-minimal curvature coupling $\xi_d R\phi^2$ in a gravitational background. The number $\xi_4=\frac{1}{6}$ is the same in all conventions and is the conformal coupling of a scalar to gravity.

7.7.4 Special conformal transformations and the conformal algebra

Tracelessness buys far more than scale invariance. We show that a symmetric, conserved, traceless stress tensor automatically supplies a conserved current for every *conformal* transformation — the largest group of spacetime transformations under which a local field theory can be invariant — and that this group is generated by precisely $\frac{1}{2}(d+1)(d+2)$ currents, all of them packaged in the single object $\Theta_{\rm c}^{\mu\nu}$.

The organizing device is to contract the stress tensor with an arbitrary vector field $\xi_\nu(x)$ and form the current $J^\mu_\xi=\Theta_{\rm c}^{\mu\nu}\xi_\nu$. Its divergence, using conservation and the symmetry of the tensor to keep only the symmetric part of $\partial_\mu\xi_\nu$, is

$$\partial_\mu J^\mu_\xi=(\partial_\mu\Theta_{\rm c}^{\mu\nu})\xi_\nu+\Theta_{\rm c}^{\mu\nu}\partial_\mu\xi_\nu=\Theta_{\rm c}^{\mu\nu}\,\partial_\mu\xi_\nu=\tfrac{1}{2}\,\Theta_{\rm c}^{\mu\nu}(\partial_\mu\xi_\nu+\partial_\nu\xi_\mu). \tag{7.205}$$

The current is conserved whenever the symmetric derivative $\partial_\mu\xi_\nu+\partial_\nu\xi_\mu$ is annihilated by contraction with $\Theta_{\rm c}^{\mu\nu}$. For a generic conserved symmetric tensor this requires $\partial_\mu\xi_\nu+\partial_\nu\xi_\mu=0$, the Killing equation, whose solutions are exactly the $\frac{1}{2}d(d+1)$ Poincaré generators (translations $\xi^\mu=a^\mu$ and Lorentz rotations $\xi^\mu=\omega^\mu{}_\nu x^\nu$ with ω antisymmetric). A traceless tensor relaxes the requirement dramatically: contraction with $\Theta_{\rm c}^{\mu\nu}$ kills any pure $\eta_{\mu\nu}$ piece, so it suffices that $\partial_\mu\xi_\nu+\partial_\nu\xi_\mu$ be *proportional to* $\eta_{\mu\nu}$. This is the conformal Killing equation.

Definition 7.47 (Conformal Killing vector)**.** A vector field $\xi^\mu(x)$ is a *conformal Killing vector* of flat spacetime if

$$\partial_\mu\xi_\nu+\partial_\nu\xi_\mu=\frac{2}{d}\,(\partial_\rho\xi^\rho)\,\eta_{\mu\nu}, \tag{7.206}$$

i.e. if the infinitesimal coordinate change $x^\mu\to x^\mu+\xi^\mu$ alters the metric only by a local rescaling, $\eta_{\mu\nu}\to(1-\frac{2}{d}\,\partial\cdot\xi)\eta_{\mu\nu}$.

The form of Eq. (7.206) is fixed by tracing both sides: the trace of the left-hand side is $2\,\partial\cdot\xi$ and the trace of the right-hand side is $\frac{2}{d}(\partial\cdot\xi)\,d=2\,\partial\cdot\xi$, so

the coefficient $2/d$ is the unique one consistent with taking the trace. In $d > 2$ the solutions of Eq. (7.206) are finite in number, and they are precisely the four families

$$\begin{aligned} \text{translations:} &\quad \xi^\mu = a^\mu, && \partial\cdot\xi = 0, \\ \text{Lorentz:} &\quad \xi^\mu = \omega^\mu{}_\nu\, x^\nu \ (\omega_{\mu\nu} = -\omega_{\nu\mu}), && \partial\cdot\xi = 0, \\ \text{dilatation:} &\quad \xi^\mu = x^\mu, && \partial\cdot\xi = d, \\ \text{special conformal:} &\quad \xi^\mu = 2(b\cdot x)\, x^\mu - x^2\, b^\mu, && \partial\cdot\xi = 2d\,(b\cdot x), \end{aligned} \tag{7.207}$$

the last family parametrized by a constant vector b^μ. The first two have vanishing divergence (they are ordinary Killing vectors); the dilatation has constant divergence; the special conformal transformation (SCT) has divergence linear in x. Counting generators: d translations, $\frac{1}{2}d(d-1)$ Lorentz rotations, 1 dilatation, and d SCTs sum to

$$d + \tfrac{1}{2}d(d-1) + 1 + d = \tfrac{1}{2}(d+1)(d+2), \tag{7.208}$$

which in $d = 4$ is 15 — the dimension of the conformal algebra $\mathfrak{so}(4,2) \cong \mathfrak{su}(2,2)$, the same number of generators as the Poincaré algebra (10) plus dilatation (1) plus SCTs (4).

That the SCT field in Eq. (7.207) solves the conformal Killing equation is a short computation worth showing, since it also delivers the divergence of the SCT current. Differentiating $\xi_\nu = 2(b\cdot x)x_\nu - x^2 b_\nu$,

$$\partial_\mu \xi_\nu = 2\, b_\mu x_\nu + 2(b\cdot x)\eta_{\mu\nu} - 2x_\mu b_\nu, \tag{7.209}$$

whose symmetric part is

$$\partial_\mu\xi_\nu + \partial_\nu\xi_\mu = 2b_\mu x_\nu + 2(b\cdot x)\eta_{\mu\nu} - 2x_\mu b_\nu + 2b_\nu x_\mu + 2(b\cdot x)\eta_{\mu\nu} - 2x_\nu b_\mu = 4(b\cdot x)\,\eta_{\mu\nu}, \tag{7.210}$$

the cross terms cancelling in pairs, exactly $\frac{2}{d}\,(\partial\cdot\xi)\eta_{\mu\nu}$ with $\partial\cdot\xi = 2d\,(b\cdot x)$. Thus the SCT is conformal Killing, and substituting Eq. (7.210) into Eq. (7.205) the divergence of the special-conformal current $K^\mu_{(b)} = \Theta^{\mu\nu}_{\mathrm{c}}\xi_\nu$ is

$$\partial_\mu K^\mu_{(b)} = \tfrac{1}{2}\,\Theta^{\mu\nu}_{\mathrm{c}} \cdot 4(b\cdot x)\eta_{\mu\nu} = 2(b\cdot x)\,\Theta^\mu_{\mathrm{c}\,\mu}. \tag{7.211}$$

Stripping the arbitrary constant b_ρ, the d special-conformal currents and their divergences are

$$K^{\mu\rho} = 2\,x^\rho x_\nu\,\Theta^{\mu\nu}_{\mathrm{c}} - x^2\,\Theta^{\mu\rho}_{\mathrm{c}}, \qquad \partial_\mu K^{\mu\rho} = 2\,x^\rho\,\Theta^\mu_{\mathrm{c}\,\mu}. \tag{7.212}$$

We can now state the general result the construction has proved.

Theorem 7.48 (Tracelessness generates the conformal algebra)**.** *Let a Poincaré-invariant theory possess a symmetric, conserved stress tensor* $\Theta^{\mu\nu}_{\mathrm{c}}$ *that is* traceless

on shell, $\Theta^{\mu}_{\mathrm{c}\,\mu} = 0$. *Then for every conformal Killing vector* ξ *of Eq. (7.207) the current* $J^{\mu}_{\xi} = \Theta^{\mu\nu}_{\mathrm{c}}\xi_{\nu}$ *is conserved on shell,* $\partial_{\mu}J^{\mu}_{\xi} = 0$. *The resulting* $\frac{1}{2}(d+1)(d+2)$ *conserved charges close into the conformal algebra* $\mathfrak{so}(d,2)$ *(for* $d > 2$*): translations and Lorentz rotations give the Poincaré subalgebra, the dilatation gives the grading generator* D *with* $[D, P^{\mu}] = iP^{\mu}$ *and* $[D, K^{\mu}] = -iK^{\mu}$*, and the SCTs give* K^{μ} *with* $[K^{\mu}, P^{\nu}] = 2i(\eta^{\mu\nu}D - M^{\mu\nu})$*. Conversely, in a Poincaré-invariant theory whose virial current is a total derivative, the stress tensor can be improved to a traceless* $\Theta^{\mu\nu}_{\mathrm{c}}$*, and scale invariance is promoted to full conformal invariance.*

Proof. Conservation of each J^{μ}_{ξ} is Eq. (7.205) evaluated on a conformal Killing vector: the symmetric derivative is $\frac{2}{d}(\partial\cdot\xi)\eta_{\mu\nu}$ by Eq. (7.206), so $\partial_{\mu}J^{\mu}_{\xi} = \frac{1}{d}(\partial\cdot\xi)\,\Theta^{\mu}_{\mathrm{c}\,\mu} = 0$ when the tensor is traceless. The counting Eq. (7.208) gives the number of charges. The algebra relations follow from computing the charges $Q_{\xi} = \int d^3x\, J^0_{\xi}$ and their Poisson brackets (equivalently, commutators after quantization, Chapter 9); the brackets reproduce the action of the corresponding conformal Killing vectors on fields, which is the defining representation of $\mathfrak{so}(d,2)$. The converse is the improvement construction of Section 7.7.3: when $V^{\mu} = \partial_{\nu}\sigma^{\nu\mu}$ as in Eq. (7.190), the symmetric improvement Eq. (7.194) can be chosen to set the on-shell trace to zero, after which Eq. (7.211) shows the SCT currents are conserved, not merely the dilatation current. □

The converse deserves emphasis because it is a genuine theorem and a frequent source of confusion: scale invariance does *not* automatically imply conformal invariance. The extra input is that the virial current V^{μ} be a total derivative, equivalently that the trace of the stress tensor be improvable to zero rather than merely to a total derivative. In essentially all relevant local field theories — and in particular for the scalar, by Eq. (7.190) — the condition holds, so the distinction rarely bites; but it is logically real, and theories with a conserved virial that is not a total derivative are scale- but not conformally invariant. For the massless scalar the virial is the gradient of $\frac{\Delta}{2}\phi^2$, the condition is met, and classical scale invariance is automatically classical conformal invariance.

7.7.5 Scalar ϕ^4 theory: the classical scale symmetry of the massless theory

We now collect what the machinery has delivered for ϕ^4 theory, continuing the thread from its $\mathbb{Z}_2$ stage earlier in this chapter and from the classical stress tensor of Eq. (6.178). The carried Lagrangian is Eq. (6.56), and the trace identity Eq. (7.201) reads off three facts at a glance.

Massless ϕ^4 *in* $d = 4$ *is classically scale and conformally invariant.* Setting $m = 0$ in four dimensions, Eq. (7.202) gives $\Theta^{\mu}_{\mathrm{c}\,\mu} = 0$ identically on shell. By Theorem 7.43 the dilatation current is conserved, and by Theorem 7.48 — the

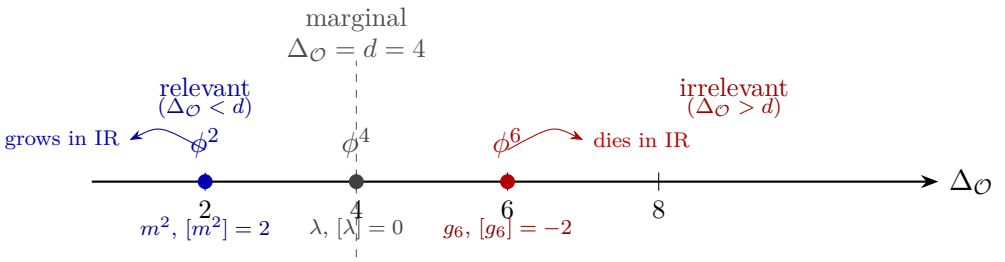

Figure 7.6: The classical relevance ladder for the $\mathbb{Z}_2$-even scalar operators in $d = 4$, placed by their scaling dimension $\Delta_{\mathcal{O}}$. An operator is relevant, marginal, or irrelevant according as $\Delta_{\mathcal{O}}$ is less than, equal to, or greater than the spacetime dimension $d = 4$; equivalently, its coupling has positive, zero, or negative mass dimension. The trace identity Eq. (7.202) confirms that only ϕ^2 (with coupling m^2, $[m^2] = 2$) contributes to $\Theta^{\mu}_{\mathrm{c}\,\mu}$ classically; the marginal ϕ^4 contributes nothing, and higher operators such as ϕ^6 are irrelevant. The arrows anticipate the renormalization-group flow of Chapter 23.

virial being a total derivative Eq. (7.190) — the full set of 15 conformal currents is conserved. The massless quartic scalar is a classical conformal field theory, with the scalar carrying the conformal weight $\Delta = 1$ fixed in Eq. (7.185). This is the classical seed of the fixed-point description that Part XIV will quantize.

The mass term is the unique relevant operator that breaks scale invariance. With $m \neq 0$, the trace is $\Theta^{\mu}_{\mathrm{c}\,\mu} = m^2\phi^2 \neq 0$, and the dilatation current is no longer conserved:

$$\partial_\mu D^\mu = \Theta^{\mu}_{\mathrm{c}\,\mu} = m^2\phi^2. \tag{7.213}$$

The breaking is proportional to m^2, a coupling of positive mass dimension $[m^2] = 2$. In the language of Eq. (7.203) and Eq. (7.204), ϕ^2 is the operator of lowest dimension ($\Delta_{\phi^2} = 2 < d = 4$) consistent with the $\mathbb{Z}_2$ symmetry $\phi \to -\phi$, hence the unique *relevant* deformation; a ϕ^2 term grows in importance toward long distances and is the one operator that must be tuned to reach the scale-invariant point. This is the precise classical statement behind the statement, made repeatedly downstream, that "the mass is the relevant coupling of ϕ^4 theory."

The quartic coupling is classically marginal. In $d = 4$ the coupling λ is dimensionless, $[\lambda] = 4 - d = 0$ by Eq. (7.203), and its operator ϕ^4 has dimension $\Delta_{\phi^4} = 4 = d$ exactly. It therefore contributes nothing to the trace Eq. (7.202): the quartic interaction respects classical scale invariance. This is what "marginal" means — a coupling that neither grows nor shrinks under rescaling at the classical level, sitting exactly on the boundary between relevant and irrelevant. Figure 7.6 places the three lowest $\mathbb{Z}_2$-even operators on the dimension axis and reads off their classical relevance.

These three facts — scale invariance of the massless theory, the mass as the

unique relevant breaking, the marginality of λ — are exact *classically*. They are also, every one of them, modified by quantization, and honesty requires the modification be named here even though it is discharged far downstream.

Caution

Classical scale invariance is generically destroyed by quantization. Regularizing the quantum theory requires a mass scale μ (the renormalization scale, Chapter 22), and physical couplings acquire a dependence on it: the dimensionless λ becomes a running $\lambda(\mu)$. The trace identity Eq. (7.202) is then corrected to

$$\Theta^{\mu}_{\mathrm{c}\,\mu} = m^2(1+\gamma_m)\,\phi^2 + \frac{\beta(\lambda)}{4!}\,\phi^4 + \cdots , \tag{7.214}$$

where $\beta(\lambda) = \mu\, d\lambda/d\mu$ is the beta function — nonzero even in $d = 4$, where classically $[\lambda] = 0$ — and γ_m is the mass anomalous dimension. The non-vanishing of $\Theta^{\mu}_{\mathrm{c}\,\mu}$ in the massless quantum theory, with the classical $\frac{4-d}{24}\lambda$ replaced by $\frac{\beta(\lambda)}{4!}$, is the *trace (or conformal) anomaly*: the marginal coupling becomes "marginally relevant or irrelevant" depending on the sign of β. Equation Eq. (7.214) is stated here only to make the connection explicit; it is derived in Chapter 24 (the one-loop $\beta_\lambda = 3\lambda^2/16\pi^2$) and given its anomaly interpretation in Chapter 36.

Looking ahead

The classical conformal data assembled here — the traceless improved tensor $\Theta^{\mu\nu}_{\mathrm{c}}$, the fixed scaling dimension $\Delta = 1$ of the scalar, the trace identity $\Theta^{\mu}_{\mathrm{c}\,\mu} = m^2\phi^2$, and the marginality of λ — is exactly the input the quantum theory will deform. The renormalization group of Chapter 23 and the explicit beta function of Chapter 24 turn the classical dimensions into anomalous ones and convert the clean trace Eq. (7.202) into the trace anomaly Eq. (7.214); the conformal-field-theory technology of Chapter 47 organizes the resulting fixed-point physics; and the Wilson–Fisher fixed point of Chapter 52, found by tuning the marginal λ against the small dimensionful $\frac{4-d}{24}\lambda$ term of Eq. (7.201) in $d = 4-\epsilon$, realizes a genuinely interacting conformal field theory — the quantum completion of the classical scale symmetry this chapter has just laid bare, and the handoff that closes ϕ^4 theory's classical chapter.

Further reading

Noether's correspondence is treated in every serious field-theory text; the accounts closest to this chapter in convention and emphasis are [396, 432, 454], with [500]

the most careful on the relation between Poincaré invariance, the stress tensor, and the field content, and [129] the most lucid on the physical meaning of the global/local distinction and the role of symmetry as an organizing principle. The reader who wants the source should consult Noether's original 1918 paper [369], which proves both the first and the (less often quoted) second theorem in a single framework; the symmetric improvement of the stress tensor is due independently to [57] and [419]. The scale and conformal material previewed in the final section is developed in full, in the language used here, in [147] and [532].

Chapter 8

Gauge Invariance: Classical Electromagnetism

This chapter asks one question and follows its consequences to the end of classical electrodynamics: *what does it cost to demand that a symmetry hold not rigidly but locally?* Chapter 7 taught us to read a continuous symmetry through Noether's first theorem (Theorem 7.10), but every symmetry considered there was rigid – the transformation parameter a single constant applied identically everywhere. Yet if a symmetry is genuinely a statement about description rather than about nature, it ought to be choosable independently at each point of spacetime, just as two distant laboratories may fix their coordinate axes without consulting one another. The phase of the complex matter field of Chapter 6 is exactly such a convention. Demanding the freedom to fix it point by point – making the global U(1) of Chapter 2 *local* – turns out not to be free: it collides with the one piece of structure every Lagrangian carries, the derivative. Diagnosing that collision and paying its price reconstructs, with nothing else assumed, the whole of Maxwell's electrodynamics. This is the *gauge principle*, and it is the organizing idea not only of this chapter but of Parts V and VII; here it is carried out in full for the abelian group, and Chapter 25 will repeat the identical program for a non-abelian one.

The chapter imports its raw material from the two preceding chapters of Part II and from Part I. The complex-scalar and Dirac Lagrangians on which the construction acts, and the independent treatment of ψ and $\bar{\psi}$, are those built in Chapter 6; the Euler–Lagrange machinery and the canonical-momentum bookkeeping are likewise from there. The conserved current that turns out to be the obstruction's coefficient – and, in the end, the source of the field – is the global U(1) Noether current of Chapter 7. The tensor and index conventions, the Levi-Civita symbol, and the classification of antisymmetric tensors are from Chapter 3; the group U(1) itself, its compactness, and the fact that $\pi_1(\mathrm{U}(1)) = \mathbb{Z}$ are from Chapter 2; and the retarded Green's function used to fix the gauge

is the one constructed in Chapter 5. Throughout we use the book-wide canon: the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units $\hbar = c = 1$, the covariant derivative $D_\mu = \partial_\mu - iqA_\mu$ with the electron carrying $q = -e < 0$, and the gamma-matrix conventions of Chapter C.

The development runs as a single chain, each section handing the next its open problem. Section 8.1 promotes the global phase to a local one and isolates the obstruction precisely: the ordinary derivative of a covariantly transforming field is not itself covariant, and the failure is governed, term for term, by the Noether current. Section 8.2 repairs it by the only available means – a new vector field A_μ whose inhomogeneous transformation is rigged to absorb the offending gradient – assembling the gauge-covariant derivative and deriving minimal coupling, the unique leading interaction of matter with the gauge field. Section 8.3 confronts the fact that A_μ has arrived with a transformation law but no dynamics and is not itself gauge invariant; it extracts the gauge-invariant residue of the connection as the field strength $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$, built from the commutator of covariant derivatives, proves its invariance and the Bianchi identity, identifies its components as $\mathbf{E}$ and $\mathbf{B}$, and reveals it – through parallel transport and holonomy – as the curvature of the connection. Section 8.4 writes the unique gauge-invariant, Lorentz-invariant, parity-even, two-derivative action $-\frac{1}{4}F_{\mu\nu}F^{\mu\nu}$, derives the inhomogeneous Maxwell equations as its Euler–Lagrange equations while the Bianchi identity supplies the homogeneous pair, and shows that coupling to matter *forces* the source to be conserved. Section 8.5 faces the gauge redundancy head-on: it exhibits configuration space as a quotient, fixes the gauge in the Lorenz, Coulomb, temporal, and axial ways, counts the photon's two physical polarizations, and constructs them explicitly as transverse plane waves. Section 8.6 assembles the full classical QED Lagrangian, identifies the electromagnetic current as the U(1) Noether current and as the very Maxwell source, verifies exact local gauge invariance, and recovers the Lorentz force – launching QED at its classical layer. Finally Section 8.7 shows that the connection carries gauge-invariant information the field strength cannot: the Aharonov–Bohm holonomy, physical even where $F_{\mu\nu} = 0$, and – run in reverse against a magnetic monopole – Dirac's quantization of electric charge, exhibiting the connection, not its curvature, as the fundamental object.

A brief word on scope and rigor. Everything load-bearing is proved here in full: the obstruction and its tie to Noether, the covariance of D_μ and the uniqueness of the gauge transformation that secures it, the gauge invariance of $F_{\mu\nu}$ and the Bianchi identity (twice, directly and via Jacobi), the uniqueness of the Maxwell kinetic term, all four Maxwell equations component by component, the degree-of-freedom count, the explicit transverse polarizations, the conservation of the electromagnetic current on shell, the Lorentz force from the eikonal limit, and the Aharonov–Bohm phase and Dirac condition. no earlier model is imported here – QED begins in this chapter – and what later chapters call "the QED Lagrangian" is the frozen Eq. (8.143) fixed in Section 8.6. The two quantizations

the classical theory demands – of the photon and of the electron – are flagged as they arise and deferred to Chapter 13 and Chapter 11 respectively.

8.1 From Global to Local: The Gauge Principle

The chapter introduction posed a single question, and the rest of the book is in one sense an extended answer to it: *what does it cost to demand that a symmetry hold not rigidly but locally?* Chapter 7 taught us to read a continuous symmetry as a source of conserved quantities through Noether's first theorem, but every symmetry it considered was rigid — the transformation parameter was a single constant, applied identically at every point of spacetime. There is something physically uncomfortable about that. A symmetry asserts that a certain change of description leaves all physics unchanged; if that is genuinely a statement about *description* rather than about nature, it ought to be possible to make the change of description differently in different places, just as one is free to choose a different set of coordinate axes in two distant laboratories without any global authority synchronizing them. The phase of a complex matter field, as we are about to see, is exactly such a conventional choice. The demand that we be allowed to fix it independently at each point — to make the internal symmetry *local* — turns out not to be free. It collides with the one piece of structure every Lagrangian in this book contains: the derivative. Diagnosing that collision precisely, and naming the structure needed to resolve it, is the business of this section; resolving it is the business of the next.

8.1.1 The global $U(1)$ symmetry, recalled

We take as our cleanest carrier the free complex scalar field already assembled in Chapter 6. Recall its Lagrangian (6.62),

$$\mathcal{L} \;=\; (\partial_\mu \phi^*)(\partial^\mu \phi) \;-\; m^2\, \phi^* \phi, \tag{8.1}$$

with $\phi(x)$ a single complex Lorentz scalar (the index conventions are those of Chapter 3) and m its mass. Throughout this section ϕ is the complex field of Chapter 6; the presence of ϕ^* always signals the complex case, exactly as agreed there. We choose the complex scalar rather than the Dirac field only because its phase structure is uncluttered by spinor indices; the entire argument below transcribes verbatim to the electron field ψ of QED, where the phase multiplies the spinor as a whole and the γ-matrices are mere spectators. We note that case explicitly at the end of the subsection.

Chapter 2 identified the group of phases $e^{i\theta}$, $\theta \in [0, 2\pi)$, as the abelian Lie group U(1), parametrized by a single angle and with the trivial commutation law $e^{i\theta_1} e^{i\theta_2} = e^{i(\theta_1+\theta_2)}$. Acting on ϕ it generates the transformation, recall (6.66),

$$\phi \;\longmapsto\; \phi' \;=\; e^{\,iq\,\alpha}\,\phi, \qquad \phi^* \;\longmapsto\; \phi'^* \;=\; e^{-\,iq\,\alpha}\,\phi^*, \tag{8.2}$$

where α is a real constant and we have introduced a real number q, the *charge*, in the exponent. This is no new freedom: (8.2) is precisely the symmetry (6.66) of Chapter 6 with its group parameter written as $q\alpha$ rather than as a single angle. We split it this way deliberately. The factor α will shortly be promoted to a function of spacetime and will play the role of the transformation *parameter*; the factor q is a fixed attribute of the field ϕ, measuring how strongly it responds to the phase rotation, and it is this q that will become the electric charge of the matter when the symmetry is gauged. That (8.2) leaves (8.1) invariant is immediate and worth seeing once more: every term pairs one ϕ with one ϕ^*, so the phases cancel, $\phi'^*\phi' = e^{-iq\alpha}e^{iq\alpha}\phi^*\phi = \phi^*\phi$, and because α is constant it passes through ∂_μ untouched, $\partial_\mu\phi' = e^{iq\alpha}\partial_\mu\phi$, so the kinetic term is invariant for exactly the same reason. The invariance rests squarely on the constancy of α.

By Noether's first theorem (Theorem 7.10) this rigid symmetry yields a conserved current. Applying the theorem to (8.2) — a computation carried out in full in Chapter 7, which we import rather than repeat — gives

$$j^\mu \;=\; iq\,(\phi^*\,\partial^\mu\phi \;-\; \phi\,\partial^\mu\phi^*), \qquad \partial_\mu j^\mu = 0 \;\text{ on-shell}, \tag{8.3}$$

the conserved charge being $Q = \int \mathrm{d}^3x\, j^0$ (this is Eq. (7.70) with the charge factor q restored). When the symmetry is eventually gauged, j^μ will turn out to be nothing other than the electromagnetic current that sources Maxwell's equations; for the moment it is just the Noether current of a rigid phase rotation, and we record it because the obstruction we are about to compute will turn out to be governed by precisely this object.

For the Dirac field the situation is identical at the level that concerns us. The free Dirac Lagrangian $\bar\psi(i\partial\!\!\!/ - m)\psi$ of Chapter 6 is invariant under $\psi \mapsto e^{iq\alpha}\psi$, $\bar\psi \mapsto e^{-iq\alpha}\bar\psi$ with α constant, since $\bar\psi = \psi^\dagger\gamma^0$ supplies the conjugate phase and the spinor indices on which $\partial\!\!\!/$ acts are untouched by the scalar phase $e^{iq\alpha}$. Everything we say below about $\partial_\mu\phi$ holds word for word for $\partial_\mu\psi$.

8.1.2 Localizing the phase: the obstruction

We now make the move the whole chapter turns on.

Definition 8.1 (Local $U(1)$ transformation)**.** A *local* (or *gauge*) U(1) transformation is the replacement

$$\phi(x) \;\longmapsto\; \phi'(x) \;=\; e^{\,iq\,\alpha(x)}\,\phi(x), \qquad \phi^*(x) \;\longmapsto\; \phi'^*(x) \;=\; e^{-\,iq\,\alpha(x)}\,\phi^*(x), \tag{8.4}$$

in which the parameter $\alpha = \alpha(x)$ is now an arbitrary smooth real-valued function on spacetime rather than a constant. The global transformation (8.2) is the special case $\alpha(x) = \text{const}$.

Pointwise, (8.4) is still an element of U(1) acting on ϕ; what has changed is that the group element is allowed to differ from point to point. The mass

term does not notice: at each point the phases still cancel, $\phi'^*(x)\phi'(x) = e^{-iq\alpha(x)}e^{iq\alpha(x)}\phi^*(x)\phi(x) = \phi^*(x)\phi(x)$, because conjugation is a local operation and $\alpha(x)$ is the same real number for ϕ and ϕ^* at the given x. The kinetic term is another matter entirely, because the derivative is *not* a local operation: $\partial_\mu\phi(x)$ depends on the values of ϕ in an infinitesimal neighbourhood of x, where the local phase α takes slightly different values.

The source of all the trouble is the single line that follows from the product rule. Differentiating the transformed field,

$$\partial_\mu\phi'(x) \;=\; \partial_\mu\Big(e^{\,iq\,\alpha(x)}\,\phi(x)\Big) \;=\; e^{\,iq\,\alpha(x)}\,\partial_\mu\phi(x) \;+\; \big(iq\,\partial_\mu\alpha(x)\big)\,e^{\,iq\,\alpha(x)}\,\phi(x), \tag{8.5}$$

and factoring out the common phase,

$$\boxed{\partial_\mu\phi' \;=\; e^{\,iq\,\alpha}(\partial_\mu + iq\,\partial_\mu\alpha)\phi} \tag{8.6}$$

Compare this with how ϕ itself transforms, $\phi' = e^{iq\alpha}\phi$. The field picks up the phase $e^{iq\alpha}$ and *nothing else*; we say it transforms *homogeneously*, or *covariantly*, under the local group. Its derivative does not. Instead of the clean homogeneous law $\partial_\mu\phi \mapsto e^{iq\alpha}\partial_\mu\phi$ that held in the global case, (8.6) carries an extra, *inhomogeneous* term $iq(\partial_\mu\alpha)\phi$ inside the parentheses. The ordinary derivative of a covariantly transforming field is not itself covariant. When $\partial_\mu\alpha = 0$ — the global case — the offending term vanishes and homogeneity is restored; when α varies in space or time, it does not. This single mismatch is the obstruction, and the rest of the chapter is its resolution.

It is worth watching the obstruction propagate all the way into the Lagrangian, with every step shown, both to confirm that nothing cancels it and to identify exactly what survives. The transformed conjugate derivative is the complex conjugate of (8.6),

$$\partial_\mu\phi'^* \;=\; e^{-\,iq\,\alpha}(\partial_\mu - iq\,\partial_\mu\alpha)\phi^*. \tag{8.7}$$

The kinetic term of (8.1) therefore transforms as

$$\begin{aligned}(\partial_\mu\phi'^*)(\partial^\mu\phi') &= \Big[e^{-iq\alpha}(\partial_\mu - iq\,\partial_\mu\alpha)\phi^*\Big]\Big[e^{+iq\alpha}(\partial^\mu + iq\,\partial^\mu\alpha)\phi\Big] \\ &= \big(\partial_\mu\phi^* - iq(\partial_\mu\alpha)\phi^*\big)\big(\partial^\mu\phi + iq(\partial^\mu\alpha)\phi\big),\end{aligned} \tag{8.8}$$

where in the second line the two phases $e^{-iq\alpha}e^{+iq\alpha} = 1$ have cancelled — this is the only cancellation available, and it removes the phase but not its derivative. Multiplying out the four terms,

$$\begin{aligned}(\partial_\mu\phi'^*)(\partial^\mu\phi') &= (\partial_\mu\phi^*)(\partial^\mu\phi) \;+\; iq(\partial^\mu\alpha)\,\phi\,(\partial_\mu\phi^*) \;-\; iq(\partial_\mu\alpha)\,\phi^*\,(\partial^\mu\phi) \\ &\qquad -\; (iq)(iq)\,(\partial_\mu\alpha)(\partial^\mu\alpha)\,\phi^*\phi \\ &= (\partial_\mu\phi^*)(\partial^\mu\phi) \;+\; iq\,(\partial_\mu\alpha)\big(\phi\,\partial^\mu\phi^* - \phi^*\,\partial^\mu\phi\big) \;+\; q^2\,(\partial_\mu\alpha)(\partial^\mu\alpha)\,\phi^*\phi,\end{aligned} \tag{8.9}$$

where in passing to the last line we relabelled the dummy index in the second term ($\mu \leftrightarrow$ itself, simply grouping the two linear-in-$\partial\alpha$ contributions) and used $-(iq)(iq) = -i^2q^2 = +q^2$. Now recognize the middle term. Comparing the bracket with the Noether current (8.3), $j^\mu = iq(\phi^*\partial^\mu\phi - \phi\,\partial^\mu\phi^*)$, we have $iq(\phi\,\partial^\mu\phi^* - \phi^*\,\partial^\mu\phi) = -\,j^\mu$, so the linear term is exactly $-(\partial_\mu\alpha)\,j^\mu$. Since the mass term is unchanged, the full Lagrangian transforms as

$$\mathcal{L} \;\longmapsto\; \mathcal{L}' \;=\; \mathcal{L} \;-\; (\partial_\mu\alpha)\,j^\mu \;+\; q^2\,(\partial_\mu\alpha)(\partial^\mu\alpha)\,\phi^*\phi, \tag{8.10}$$

that is, the change in the Lagrangian density under a local phase rotation is

$$\delta\mathcal{L} \;\equiv\; \mathcal{L}' - \mathcal{L} \;=\; -\,(\partial_\mu\alpha)\,j^\mu \;+\; q^2\,(\partial_\mu\alpha)(\partial^\mu\alpha)\,\phi^*\phi. \tag{8.11}$$

Equation (8.11) is the central result of this section, the obstruction the chapter must overcome. Every term on its right-hand side is proportional to a derivative of α, so $\delta\mathcal{L} = 0$ if and only if $\partial_\mu\alpha = 0$ everywhere, i.e. precisely for the rigid transformations already known to be symmetries. For any genuinely local $\alpha(x)$ the Lagrangian changes, the action $S = \int \mathrm{d}^4x\,\mathcal{L}$ changes with it, and the theory (8.1) is *not* invariant under Theorem 8.1. The leading piece of the obstruction, linear in $\partial_\mu\alpha$, is $-(\partial_\mu\alpha)\,j^\mu$: the Noether current of the global symmetry is exactly the coefficient with which the local transformation fails. This is not a coincidence, and the worked example below makes the connection precise.

Worked Example 8.2 (The infinitesimal obstruction and its tie to Noether)**.** It pays to see (8.11) at infinitesimal order, both because the algebra is cleaner there and because it exposes why the Noether current had to appear. Take $\alpha(x)$ infinitesimal and work to first order, dropping all terms of order α^2. To this order the finite transformation (8.4) linearizes to

$$\delta\phi = iq\,\alpha\,\phi, \qquad \delta\phi^* = -iq\,\alpha\,\phi^*, \tag{8.12}$$

and the quadratic term $q^2(\partial_\mu\alpha)(\partial^\mu\alpha)\phi^*\phi$ in (8.11), being second order in α, drops out. What remains is

$$\delta\mathcal{L} \;=\; -\,(\partial_\mu\alpha)\,j^\mu \qquad \text{(to first order in } \alpha\text{)}. \tag{8.13}$$

Let us re-derive (8.13) directly from (8.12), as an independent check that no sign slipped in the finite computation. Varying (8.1) term by term,

$$\delta\mathcal{L} = (\partial_\mu\delta\phi^*)(\partial^\mu\phi) + (\partial_\mu\phi^*)(\partial^\mu\delta\phi) - m^2(\delta\phi^*\,\phi + \phi^*\,\delta\phi). \tag{8.14}$$

The mass piece vanishes identically: $\delta\phi^*\phi + \phi^*\delta\phi = -iq\alpha\,\phi^*\phi + iq\alpha\,\phi^*\phi = 0$, which is just the statement that $\phi^*\phi$ is pointwise invariant. For the kinetic

piece we need $\partial_\mu \delta\phi = \partial_\mu(iq\alpha\phi) = iq(\partial_\mu\alpha)\phi + iq\alpha\,\partial_\mu\phi$ and its conjugate $\partial_\mu\delta\phi^* = -iq(\partial_\mu\alpha)\phi^* - iq\alpha\,\partial_\mu\phi^*$. Substituting,

$$\begin{aligned}\delta\mathcal{L} &= \big[-iq(\partial_\mu\alpha)\phi^* - iq\alpha\,\partial_\mu\phi^*\big]\partial^\mu\phi + (\partial_\mu\phi^*)\big[iq(\partial^\mu\alpha)\phi + iq\alpha\,\partial^\mu\phi\big] \\ &= \underbrace{iq\,\alpha\big[(\partial_\mu\phi^*)(\partial^\mu\phi) - (\partial_\mu\phi^*)(\partial^\mu\phi)\big]}_{=0} + iq(\partial_\mu\alpha)(\phi\,\partial^\mu\phi^* - \phi^*\,\partial^\mu\phi) \\ &= -(\partial_\mu\alpha)\,j^\mu, \end{aligned} \tag{8.15}$$

where the terms proportional to α (not its derivative) cancel between the two contributions — exactly as they must, since for constant α we must recover the global invariance $\delta\mathcal{L} = 0$ — and the surviving derivative term is identified through (8.3) as $-(\partial_\mu\alpha)j^\mu$. This reproduces (8.13).

The form (8.13) also illuminates Noether's theorem itself. Integrating $\delta\mathcal{L}$ over spacetime and discarding a surface term,

$$\delta S = \int \mathrm{d}^4x\,\big[-(\partial_\mu\alpha)\,j^\mu\big] = \int \mathrm{d}^4x\,\alpha\,(\partial_\mu j^\mu) \;-\; \int \mathrm{d}^4x\,\partial_\mu(\alpha\,j^\mu). \tag{8.16}$$

For *constant* α the left side is zero (global symmetry) and the surface term vanishes, giving nothing new. But (8.16) holds for *any* $\alpha(x)$, and on a field configuration that solves the equations of motion the action is stationary against all variations, so $\delta S = 0$ for arbitrary α of compact support; the boundary term then drops and arbitrariness of α forces $\partial_\mu j^\mu = 0$. This is the "Noether trick": promoting a global parameter to a local one and reading off the current's conservation from the coefficient of $\partial_\mu\alpha$. We will not lean on it — Chapter 7 proved current conservation independently — but it shows that the obstruction (8.11) is not an accident peculiar to this Lagrangian. *Any* theory with a global continuous symmetry fails local invariance at precisely the rate set by its Noether current. The obstruction and the conservation law are two readings of the same equation.

8.1.3 What the obstruction means: comparing fields in different internal frames

Before repairing the obstruction it is worth understanding what it is telling us, because the understanding dictates the cure. The deep statement hidden in (8.6) is geometric, and grasping it now will make the covariant derivative of the next section feel inevitable rather than invented.

A complex field $\phi(x)$ has, at each spacetime point x, a magnitude $|\phi(x)|$ and a phase $\arg\phi(x)$. The magnitude is unambiguous, but the phase is meaningful only relative to a convention — a choice of what counts as "real and positive" in the internal complex plane attached to the point x. Call that choice the *internal frame* at x. A global U(1) transformation (8.2) rotates every internal frame by

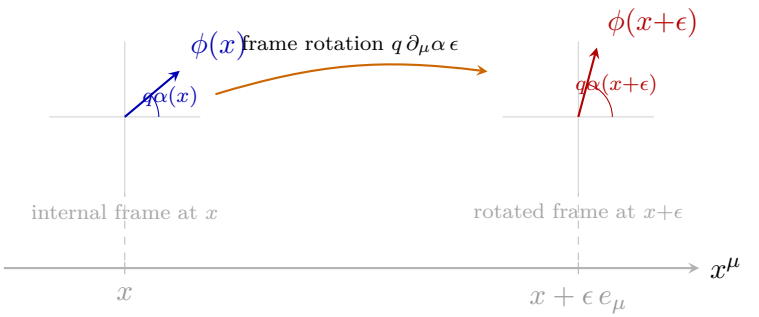

Figure 8.1: The geometric content of the obstruction. The phase of ϕ is defined only relative to an internal frame (a choice of phase-zero in the complex plane) attached to each spacetime point. A local U(1) transformation rotates that frame independently at each point. The ordinary derivative subtracts $\phi(x+\epsilon\,e_\mu)$ from $\phi(x)$ as if the two frames coincided; when they do not, the difference includes the spurious frame rotation $q\,\partial_\mu\alpha\,\epsilon$, which is exactly the inhomogeneous term $iq(\partial_\mu\alpha)\phi$ of (8.6).

the same angle $q\alpha$; this is a harmless relabelling, like agreeing to measure all phases from a different zero, and nothing physical can depend on it. A *local* transformation (8.4) rotates the internal frame at each point by its own angle $q\alpha(x)$: it allows the zero of phase to be chosen independently at every point of spacetime.

Now ask what the derivative does. By definition $\partial_\mu\phi$ measures the rate of change of ϕ along the direction μ, built from the difference $\phi(x+\epsilon\,e_\mu)-\phi(x)$ of the field at two neighbouring points divided by ϵ. But $\phi(x+\epsilon\,e_\mu)$ and $\phi(x)$ live in *different* internal frames once the frame is allowed to vary in space: the subtraction compares a complex number measured against the convention at $x+\epsilon\,e_\mu$ with one measured against the convention at x. If those two conventions are rotated relative to each other — which is exactly what $\partial_\mu\alpha\neq 0$ means — then part of the "difference" the derivative reports is not a change in the field at all, but a change in the yardstick. That spurious, frame-rotation contribution is precisely the inhomogeneous term $iq(\partial_\mu\alpha)\phi$ in (8.6). Figure 8.1 draws the picture: when the internal frames at neighbouring points are misaligned, the naive difference of field values double-counts the misalignment.

Physical Insight

The obstruction is not a defect of the complex scalar; it is a defect of the *derivative*. The ordinary derivative is built to compare field values at neighbouring points, and it does so by naive subtraction — which silently assumes that the internal frames at those points are the same.

That assumption is exactly what a local symmetry forbids us to make. The cure cannot be to abandon comparison; physics needs derivatives. The cure must be to teach the derivative how to undo the relative frame rotation before it subtracts — to supply a rule for "parallel transporting" the internal frame from one point to the next so that like is compared with like. Such a rule is precisely a *connection*, and the field that encodes it will be the gauge potential A_μ. This is the same idea that, in spacetime geometry, turns the ordinary derivative into the covariant derivative of general relativity; here the geometry is internal rather than spacetime, but the logic is identical. The gauge potential is the connection on an internal U(1) bundle, a point we return to geometrically in Chapter 25.

This reframing tells us exactly what to demand. We do not want to give up local invariance — the whole motivation was that an internal phase is a pure convention that ought to be choosable point by point. Nor can we give up derivatives. So we must modify the derivative. We seek an operator D_μ, to replace ∂_μ in the kinetic term, with the defining property that it turns a covariantly transforming field into another covariantly transforming object:

$$D_\mu\phi \;\longmapsto\; (D_\mu\phi)' \;=\; e^{\,iq\,\alpha(x)}\,(D_\mu\phi), \tag{8.17}$$

homogeneously, with no leftover $\partial_\mu\alpha$ term, for every $\alpha(x)$. If such a D_μ exists, then $(D_\mu\phi)^*(D^\mu\phi)$ transforms exactly as the original $\phi^*\phi$ did — the phases cancel and nothing survives — and replacing $\partial_\mu \to D_\mu$ in (8.1) produces a Lagrangian invariant under the full local group.

Definition 8.3 (The gauge principle, as a program)**.** The *gauge principle* is the demand that a theory be invariant under *local* transformations of an internal symmetry group, together with the constructive program this demand forces:

1. Replace every ordinary derivative ∂_μ acting on a charged field by a *gauge-covariant derivative* D_μ obeying the homogeneous transformation law (8.17).
2. Discover what new field-theoretic structure D_μ must contain in order to satisfy that law; for an internal U(1) this will force the existence of a vector field A_μ, the gauge potential, with its own prescribed transformation.
3. Build the gauge-invariant dynamics of A_μ itself from the object that measures the failure of D_μ to commute with itself — the field strength, or curvature.

In this chapter the program, carried out for U(1), reconstructs all of classical electrodynamics; in Chapter 25 the identical program for a non-abelian group reconstructs Yang–Mills theory.

Notation Watch

We have written the local rotation as $e^{iq\alpha(x)}$ with a charge q kept explicit and have not yet committed to its sign or to the sign convention relating D_μ to A_μ. Both are fixed precisely in the next section, in agreement with the standing conventions of QED: the covariant derivative will be $D_\mu = \partial_\mu - iqA_\mu$, the electron will carry $q = -e$ with $e > 0$, so that $D_\mu = \partial_\mu + ieA_\mu$ on the electron field. Until then q is simply a fixed real charge labelling how strongly ϕ responds to the phase rotation. We flag this because the sign of the gauge coupling is the most error-prone convention in the subject; here it is merely staged, in the next section it is nailed down.

We have now isolated the enemy with complete precision. Promoting the global U(1) phase symmetry of charged matter to a local one breaks the kinetic term by the obstruction (8.11), whose origin is the single inhomogeneous term in $\partial_\mu(e^{iq\alpha}\phi) = e^{iq\alpha}(\partial_\mu + iq\,\partial_\mu\alpha)\phi$ of (8.6): the ordinary derivative compares fields living in differently rotated internal frames and so cannot transform homogeneously. The next section meets this head-on. It introduces a vector field A_μ whose transformation is engineered to absorb the unwanted $iq(\partial_\mu\alpha)\phi$, assembles the covariant derivative D_μ satisfying (8.17), and shows that this single requirement *forces* the matter to couple to A_μ in the unique combination known as minimal coupling — the first concrete result of the gauge principle, and the opening move of classical QED.

8.2 The Covariant Derivative and Minimal Coupling

The previous section left us holding an obstruction. When the rigid internal phase symmetry of a charged matter field is promoted to a *local* one — a phase α that varies from spacetime point to spacetime point — the matter Lagrangian fails to be invariant, and the failure can be traced to a single offending object: the ordinary derivative. Under the local transformation $\psi(x) \to \psi'(x) = e^{iq\alpha(x)}\psi(x)$ the field itself rotates rigidly at each point, but its derivative does not, because differentiation compares the field at x with the field at the neighbouring point $x + \mathrm{d}x$, and those two points now carry *different* phase conventions. Concretely, the computation of Section 8.1 gave (8.6), which for the field ψ reads

$$\partial_\mu\psi(x) \;\longrightarrow\; \partial_\mu\big(e^{iq\alpha(x)}\psi(x)\big) \;=\; e^{iq\alpha(x)}\Big(\partial_\mu\psi(x) + i\,q\,(\partial_\mu\alpha(x))\,\psi(x)\Big). \tag{8.18}$$

The first term inside the bracket is what we want: the derivative dressed by the same phase $e^{iq\alpha}$ as the field, exactly as a covariant object should be. The second term, $iq(\partial_\mu\alpha)\psi$, is the obstruction. It is inhomogeneous — it involves $\partial_\mu\alpha$ rather than α — and it is precisely the fingerprint of the fact that α is now

allowed to change from point to point. A globally constant α has $\partial_\mu \alpha = 0$ and the obstruction vanishes, recovering the rigid symmetry of Chapter 7; a genuinely local α does not, and Eq. (8.18) says the naive kinetic term $\bar{\psi}\, i\gamma^\mu \partial_\mu \psi$ cannot survive.

This section resolves the obstruction. The strategy is not to abandon the demand for local invariance but to take it seriously and ask what the theory must contain in order to meet it. The answer is forced, and it is the central construction of the whole book: we must introduce a new field, the *gauge potential* A_μ, whose sole job is to compensate the inhomogeneous term, and we must replace the ordinary derivative by a modified *covariant derivative* D_μ that differentiates and compensates in one stroke. Demanding that $D_\mu \psi$ transform like ψ then fixes both the form of D_μ and the transformation law of A_μ uniquely, and feeding D_μ back into the matter Lagrangian — the rule called *minimal coupling* — manufactures the entire interaction between matter and the electromagnetic field out of nothing but the requirement of local symmetry. This is the gauge principle in action, and it is how this book launches QED at its classical layer.

8.2.1 The derivative as a comparator, and why it fails

To see what to do, it helps to recall what a derivative *is*. The directional derivative of ψ along a unit vector n^μ is the limit

$$n^\mu \partial_\mu \psi(x) \;=\; \lim_{\varepsilon \to 0} \frac{\psi(x + \varepsilon n) - \psi(x)}{\varepsilon}, \tag{8.19}$$

a comparison between the value of the field at two infinitesimally separated points. For an ordinary function this comparison is unambiguous because the values $\psi(x + \varepsilon n)$ and $\psi(x)$ live in the same space and can simply be subtracted. But ψ is a charged field: it carries an internal U(1) phase, and under a local transformation the phase convention used at x is $e^{iq\alpha(x)}$ while the one used at $x + \varepsilon n$ is $e^{iq\alpha(x+\varepsilon n)}$ — *different* conventions. Subtracting $\psi(x + \varepsilon n)$ from $\psi(x)$ is then like subtracting two vectors expressed in two different bases: the result is meaningless because the two terms do not transform the same way. This is the geometric content of the obstruction in Eq. (8.18).

The cure is to supply a rule for carrying the internal phase from one point to its neighbour before comparing — a *comparator*, or in the geometric language of Section 8.3 a *connection*. We posit a quantity $U(x + \varepsilon n, x)$, a U(1) phase factor (the parallel transporter studied in Section 8.3), whose job is to translate the phase convention at x into the phase convention at $x + \varepsilon n$, transforming by construction as $U(y, x) \to e^{iq\alpha(y)}\, U(y, x)\, e^{-iq\alpha(x)}$ so that the transported field $U(x+\varepsilon n, x)\, \psi(x)$ rotates with the same phase $e^{iq\alpha(x+\varepsilon n)}$ as the genuine field $\psi(x + \varepsilon n)$ sitting at the destination. Their difference is then a legitimate comparison. Writing the comparator for an infinitesimal step as $U(x + \varepsilon n, x) = 1 + i\varepsilon q\, n^\mu A_\mu(x) + O(\varepsilon^2)$ introduces a vector field $A_\mu(x)$ — the gauge potential — whose coefficient, the

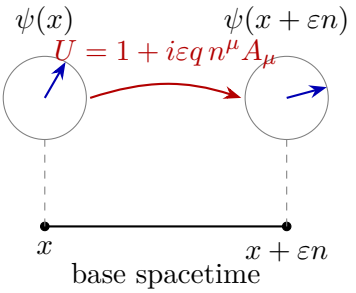

Figure 8.2: The covariant derivative as a comparator. The charged field ψ carries an internal U(1) phase (the arrow in each circle). Because a local transformation rotates the phase by a *different* amount at x and at $x+\varepsilon n$, the two values cannot be compared directly. The connection A_μ supplies the parallel-transport rule U that carries the phase from x to its neighbour before the comparison; the covariant derivative D_μ is the resulting transport-corrected difference.

real constant q, we will identify as the coupling strength (the charge). The comparator construction is taken up systematically in the next section, where the same A_μ reappears as the connection of a fibre bundle. For the present purpose its value is to tell us the form of the corrected derivative, which we now simply adopt as a definition and justify directly; the equivalence of this definition with the infinitesimal limit of the comparator is shown in Section 8.3.

8.2.2 The gauge potential and the covariant derivative

We now make the construction precise. Both objects below carry the chapter's sign and charge conventions, fixed once here and used unchanged for the rest of QED.

Definition 8.4 (Gauge potential and covariant derivative)**.** Let ψ be a matter field of charge q transforming under the local internal U(1) as $\psi(x) \to \psi'(x) = e^{iq\alpha(x)}\psi(x)$ with $\alpha : \mathbb{R}^{1,3} \to \mathbb{R}$ a smooth real function and q a real constant, the *coupling* (the charge carried by ψ). Introduce a real vector field $A_\mu(x)$, the *gauge potential*, transforming as a Lorentz four-vector (Chapter 3). The *gauge-covariant derivative* acting on ψ is

$$D_\mu\psi \;\equiv\; (\partial_\mu - i\,q\,A_\mu)\psi. \tag{8.20}$$

The gauge potential is declared to transform under the same local U(1) by the *inhomogeneous* (affine) rule

$$A_\mu(x) \;\longrightarrow\; A'_\mu(x) \;=\; A_\mu(x) + \partial_\mu\alpha(x). \tag{8.21}$$

Three features of Theorem 8.4 deserve emphasis before we prove that it works. First, Eq. (8.20) adopts the global sign convention of the book, $D_\mu = \partial_\mu - iqA_\mu$

(STYLE convention; see Section 8.2.4 below for the reconciliation with the electron's positive charge magnitude). Second, the charge q appears in two places at once — inside the phase $e^{iq\alpha}$ that rotates the matter field and inside the coupling $-iqA_\mu$ of the covariant derivative — and it is the *same* q in both. That this single constant does double duty is the seed of charge universality, developed below. Third, the transformation law Eq. (8.21) is not an independent postulate we are free to choose; it is forced. The whole point of A_μ is to cancel the inhomogeneous term in Eq. (8.18), and as the next theorem shows, Eq. (8.21) is the unique law that accomplishes this. The transformation is *inhomogeneous* because it shifts A_μ by a gradient, $\partial_\mu\alpha$, rather than merely rephasing it; this gradient shift is exactly the gauge freedom of the electromagnetic potential familiar from undergraduate electromagnetism, here *derived* rather than assumed. That A'_μ remains a real four-vector is automatic: α is a real scalar, so $\partial_\mu\alpha$ is a real four-vector (Chapter 3), and the sum of two real four-vectors is one. Note also that Eq. (8.21) carries no factor of the charge: a single gauge potential A_μ shifts the same way no matter which charged field it is being compared against, so one A_μ can serve fields of *different* charges $q_1, q_2, \ldots$ simultaneously, each with its own covariant derivative $\partial_\mu - iq_iA_\mu$ — exactly as the one electromagnetic field couples to electrons, protons and muons at once.

Theorem 8.5 (Covariance of the gauge-covariant derivative)**.** *With D_μ defined by Eq. (8.20) and A_μ transforming by Eq. (8.21), the covariant derivative of a charge-q field transforms homogeneously, with exactly the same phase as the field itself:*

$$D_\mu\psi \;\longrightarrow\; D'_\mu\psi' \;=\; e^{iq\alpha(x)}\,(D_\mu\psi). \tag{8.22}$$

Equivalently, $D_\mu\psi$ lies in the same internal frame as ψ: the combination $D_\mu\psi$ rotates rigidly under the local symmetry, so any expression built from ψ, $\bar\psi$ and their covariant derivatives by contracting all internal phases to zero is locally U(1)*-invariant.*

Proof. We substitute the two transformation laws — the matter law $\psi \to e^{iq\alpha}\psi$ and the potential law Eq. (8.21) — into the primed covariant derivative and carry every term. By definition,

$$D'_\mu\psi' \;=\; (\partial_\mu - i\,q\,A'_\mu)\,\psi' \;=\; \partial_\mu(e^{iq\alpha}\psi) \;-\; i\,q\,A'_\mu\,e^{iq\alpha}\psi. \tag{8.23}$$

The first term we already expanded in Eq. (8.18):

$$\partial_\mu(e^{iq\alpha}\psi) \;=\; e^{iq\alpha}\,\partial_\mu\psi \;+\; i\,q\,(\partial_\mu\alpha)\,e^{iq\alpha}\psi. \tag{8.24}$$

For the second term we insert the potential's transformation law Eq. (8.21), $A'_\mu = A_\mu + \partial_\mu\alpha$:

$$-i\,q\,A'_\mu\,e^{iq\alpha}\psi \;=\; -i\,q(A_\mu + \partial_\mu\alpha)e^{iq\alpha}\psi \;=\; -i\,q\,A_\mu\,e^{iq\alpha}\psi \;-\; i\,q\,(\partial_\mu\alpha)\,e^{iq\alpha}\psi, \tag{8.25}$$

where the gradient shift of A_μ has produced a term $-iq(\partial_\mu\alpha)e^{iq\alpha}\psi$ carrying the *same* factor iq as the obstruction, but with the opposite sign — this matched sign and magnitude is the reason the gradient shift in the transformation law was chosen as it was. Adding Eq. (8.24) and Eq. (8.25),

$$D'_\mu\psi' = e^{iq\alpha}\,\partial_\mu\psi \;+\; \underbrace{i\,q\,(\partial_\mu\alpha)\,e^{iq\alpha}\psi}_{\text{from }\partial_\mu\psi'} \;-\; i\,q\,A_\mu\,e^{iq\alpha}\psi \;\underbrace{-\,i\,q\,(\partial_\mu\alpha)\,e^{iq\alpha}\psi}_{\text{from }A'_\mu}$$
$$= e^{iq\alpha}\,\partial_\mu\psi \;-\; i\,q\,A_\mu\,e^{iq\alpha}\psi \;=\; e^{iq\alpha}(\partial_\mu - i\,q\,A_\mu)\psi \;=\; e^{iq\alpha}\,D_\mu\psi. \qquad (8.26)$$

The two inhomogeneous pieces $\pm\,iq(\partial_\mu\alpha)e^{iq\alpha}\psi$ — one produced by differentiating the field's phase, the other produced by the gradient shift of the potential — are equal and opposite, and they cancel identically. What survives is the field's covariant derivative dressed by the single overall phase $e^{iq\alpha}$, which is Eq. (8.22). This proves the theorem. □

The cancellation in Eq. (8.26) is the entire mechanism of gauge theory in miniature, and it is worth naming what each piece did. The matter field's phase rotation generated $+iq(\partial_\mu\alpha)\psi$; this is the obstruction. The gauge potential's gradient shift generated $-iq(\partial_\mu\alpha)\psi$; this is the compensation. They are forced to be equal and opposite because the charge q in the phase $e^{iq\alpha}$ is the very same q that multiplies A_μ in D_μ, and that is no accident — it is the content of the demand that A_μ be a comparator for the phase carried by ψ. The gauge potential is, in this precise sense, the field whose transformation is rigged to absorb the inhomogeneity of a local phase.

Physical Insight

The covariant derivative is the operation "differentiate, then undo the local phase slip you just introduced." The field A_μ stores, at every point, the infinitesimal rotation needed to compare the internal phase at x with the phase an instant away; D_μ subtracts that rotation off. Where an ordinary $\partial_\mu\psi$ measures both the genuine change of ψ and the spurious change in the phase convention, $D_\mu\psi$ measures only the genuine change. This is why $D_\mu\psi$ transforms like ψ while $\partial_\mu\psi$ does not: the connection has removed the part of the derivative that was merely bookkeeping.

8.2.3 Minimal coupling: the matter–photon interaction, derived

Theorem 8.5 hands us a recipe. Any matter Lagrangian that was invariant under the *global* U(1) of Chapter 7 was built so that every internal phase cancels — a ψ always paired with a $\bar\psi$, an $e^{iq\alpha}$ with an $e^{-iq\alpha}$. The only obstruction to promoting that global invariance to a local one was the derivative, whose transformation Eq. (8.18) spoiled the cancellation. But $D_\mu\psi$ transforms exactly

as ψ does. Therefore, if we take the globally invariant matter Lagrangian and replace every ordinary derivative by a covariant one, the resulting Lagrangian is invariant under the *local* U(1), because now even the derivative terms carry the field's phase and cancel against their conjugates. This is the rule of *minimal coupling*.

Definition 8.6 (Minimal coupling)**.** Given a matter Lagrangian $\mathcal{L}_{\text{matter}}(\psi, \partial_\mu \psi)$ invariant under the global U(1), the *minimally coupled* Lagrangian is obtained by the substitution

$$\partial_\mu \;\longrightarrow\; D_\mu = \partial_\mu - i\, q\, A_\mu \tag{8.27}$$

applied to the matter field (Chapter 6 supplies the scalar, Dirac and Maxwell Lagrangians on which the substitution acts). The result $\mathcal{L}_{\text{matter}}(\psi, D_\mu \psi)$ is invariant under the local U(1) of Theorem 8.4.

The local invariance is immediate from Theorem 8.5: wherever $\partial_\mu \psi$ stood, the substitution puts $D_\mu \psi$, which transforms as $e^{iq\alpha} D_\mu \psi$ exactly as $\psi \to e^{iq\alpha}\psi$; the Lagrangian was already arranged so that each ψ-phase meets a compensating $\bar{\psi}$-phase, and the substitution preserves that pairing. We verify this explicitly, term by term, in Theorem 8.7 below.

The name "minimal" signals that this is the simplest coupling that does the job: it introduces no new free parameters beyond the single coupling q already present in D_μ, and it adds the fewest possible derivatives. One could imagine non-minimal gauge-invariant couplings — for instance a Pauli term $\bar{\psi}\sigma^{\mu\nu}\psi\, F_{\mu\nu}$ built from the field strength of the next section — and such terms are perfectly consistent with local U(1) invariance; what minimal coupling asserts is that the *leading* interaction, the one forced on us merely by gauging the derivative, is Eq. (8.27). That the leading interaction of light with charged matter should be dictated by symmetry alone, with no freedom left except the value of the charge, is the gauge principle's most striking classical claim.

8.2.4 The electron, and the interaction current

We now specialize to the carried example of QED: a single Dirac field ψ describing the electron. Its Lagrangian, introduced in Chapter 6, is the free Dirac Lagrangian $\mathcal{L}_{\text{Dirac}} = \bar{\psi}(i\gamma^\mu \partial_\mu - m)\psi$. Minimal coupling, Eq. (8.27), turns it into

$$\mathcal{L} \;=\; \bar{\psi}(i\gamma^\mu D_\mu - m)\psi \;=\; \bar{\psi}(i\not{D} - m)\psi, \tag{8.28}$$

where $\not{D} = \gamma^\mu D_\mu$ in the slash notation of Chapter 3. This is the matter sector of the classical QED Lagrangian; the photon's own kinetic term, built from the curvature of Section 8.3, completes it.

The electron's charge fixes q. With the global convention $D_\mu = \partial_\mu - iqA_\mu$ and the physical fact that the electron carries charge $-e$ with $e > 0$ the elementary

charge, we set $q = -e$, so that the electron field rotates by $\psi \to e^{-ie\alpha}\psi$ and

$$D_\mu\psi \;=\; (\partial_\mu + i\,e\,A_\mu)\psi \qquad (\text{electron},\; q=-e,\; e>0). \tag{8.29}$$

The gauge law Eq. (8.21) carries no charge, so it is unchanged for the electron, $A_\mu \to A_\mu + \partial_\mu\alpha$. Equation (8.29) is the electron covariant derivative used throughout the rest of QED.

Notation Watch

The book's global convention (STYLE) is $D_\mu = \partial_\mu - iqA_\mu$, with the *signed* charge q inserted directly. The electron has $q = -e$ where $e > 0$ is the magnitude of the elementary charge, so on the electron field the two minus signs combine to give the manifestly positive-looking $D_\mu = \partial_\mu + ieA_\mu$ of Eq. (8.29). There is no contradiction: $\partial_\mu - iqA_\mu$ and $\partial_\mu + ieA_\mu$ are the same operator once $q = -e$ is substituted. When in doubt, use the signed form $D_\mu = \partial_\mu - iqA_\mu$ and let the sign of q take care of itself.

A second, independent convention choice concerns where the charge is carried in the transformation law. We have placed the charge in *both* the matter phase $\psi \to e^{iq\alpha}\psi$ and the coupling $-iqA_\mu$ of D_μ, with the potential shifting by the charge-free gradient $A_\mu \to A_\mu + \partial_\mu\alpha$. This is the convention used uniformly across Section 8.1 and Section 8.3, and its virtue is that a single A_μ serves all charges at once. Some texts (e.g. Peskin–Schroeder) instead strip the charge from the phase, writing $\psi \to e^{i\alpha}\psi$ with the potential shifting by $A_\mu \to A_\mu + \frac{1}{q}\partial_\mu\alpha$; the obstruction then reads $i(\partial_\mu\alpha)\psi$ and the covariance statement Eq. (8.22) becomes $D_\mu\psi \to e^{i\alpha}D_\mu\psi$. The two are related by the harmless rescaling $\alpha \to q\alpha$ of the gauge parameter and describe identical physics. The non-Abelian rule generalized in Chapter 25, $D_\mu = \partial_\mu - igA^a_\mu T^a$ with $\psi \to U\psi = e^{i\alpha^a T^a}\psi$ and $A_\mu \to UA_\mu U^{-1} - \frac{i}{g}(\partial_\mu U)U^{-1}$, sits between the two Abelian conventions: there the coupling g lives only in D_μ and the gauge law, while the group element U carries none. Our Abelian convention is recovered from the non-Abelian one by the field-dependent identification $g\alpha^a T^a \to q\alpha$, after which the matter phase $e^{iq\alpha}$ and the gradient shift $\partial_\mu\alpha$ emerge as stated; the apparent $\frac{1}{g}$ in the non-Abelian shift is the artefact of keeping g out of the exponent, exactly the choice we declined to make in the Abelian case.

Expanding Eq. (8.28) exposes the physics minimal coupling has manufactured. Writing $i\not{D} = i\gamma^\mu\partial_\mu + q\gamma^\mu A_\mu$ (general q, using $iD_\mu = i\partial_\mu + qA_\mu$),

$$\mathcal{L} \;=\; \bar\psi(i\gamma^\mu\partial_\mu - m)\psi \;+\; q\,\bar\psi\gamma^\mu\psi\,A_\mu, \tag{8.30}$$

the first group being the free Dirac Lagrangian of Chapter 6 and the second a genuine *interaction* term coupling the matter to the gauge field. It has a structure that will recur at every later stage of QED: the gauge field A_μ is contracted

against a matter current. Recall from Chapter 7 that the global U(1) symmetry $\psi \to e^{i\alpha}\psi$ of the free Dirac theory has, by Noether's first theorem, the conserved *number* current

$$j^\mu \;=\; \bar{\psi}\gamma^\mu\psi, \qquad \partial_\mu j^\mu = 0, \tag{8.31}$$

the same current whose charge counts electrons minus positrons. The interaction term in Eq. (8.30) is precisely this current, weighted by the coupling, dotted into the potential:

$$\mathcal{L}_{\text{int}} \;=\; q\,\bar{\psi}\gamma^\mu\psi\,A_\mu \;=\; q\,j^\mu A_\mu \;\equiv\; J^\mu A_\mu, \qquad J^\mu \equiv q\,j^\mu = q\,\bar{\psi}\gamma^\mu\psi. \tag{8.32}$$

Here J^μ is the *electromagnetic* (electric) current: the Noether number current of Chapter 7 multiplied by the charge q. For the electron, $q = -e$, so $J^\mu = -e\,\bar{\psi}\gamma^\mu\psi$ — carrying the physical sign of the electron's charge. (The charge-weighted current J^μ is the Dirac counterpart of the already-charge-weighted scalar current of (8.3), where the factor q was carried inside j^μ from the outset; the two conventions agree on the physically meaningful object J^μ that couples to A_μ.) The appearance of the coupling–current combination $J^\mu A_\mu$ is the first sighting of the structure that locks symmetry to dynamics: the very current whose conservation expressed the global symmetry of Chapter 7 is, after gauging, the source to which the gauge field couples. We will see in the next sections that this same J^μ turns out to be the source term in the Maxwell equations, so that the conserved charge of the symmetry and the charge that sources the electromagnetic field are one and the same object — the deepest classical consequence of the gauge principle.

Physical Insight

Minimal coupling explains, in one line, why all particles of a given charge couple to the electromagnetic field with the *same* strength: the coupling is the single constant q in D_μ, and it is fixed by how the field transforms under U(1) — it is the very integer (in units of e) that appears in the phase $e^{iq\alpha}$ — not by any independent choice. Universality of the electromagnetic coupling — that the proton and positron couple to the photon with charge exactly $+e$, the electron with exactly $-e$ — is the gauge principle's prediction, not an experimental coincidence.

8.2.5 Worked verification of local invariance

The claim that minimal coupling yields a locally invariant action is the load-bearing assertion of this section. Theorem 8.5 already proves it in the abstract; we now discharge it concretely, carrying the gauge transformation of every term in the minimally coupled Dirac Lagrangian Eq. (8.28) and exhibiting the cancellation explicitly. We do it twice: once the short way, using covariance directly, and once the long way, expanding into a free piece plus an interaction

and watching the inhomogeneous gradient terms cancel between them. The two routes must — and do — agree.

Worked Example 8.7 (Local U(1) invariance of the coupled Dirac Lagrangian)**.** Consider $\mathcal{L} = \bar{\psi}(i\gamma^\mu D_\mu - m)\psi$ with $D_\mu = \partial_\mu - iqA_\mu$ and the local transformations

$$\psi \to \psi' = e^{iq\alpha}\psi, \qquad \bar{\psi} \to \bar{\psi}' = e^{-iq\alpha}\bar{\psi}, \qquad A_\mu \to A'_\mu = A_\mu + \partial_\mu \alpha, \tag{8.33}$$

where $\alpha = \alpha(x)$ is a smooth real function. The transformation of $\bar{\psi}$ follows from that of ψ together with $\bar{\psi} = \psi^\dagger\gamma^0$ and the reality of α: $\bar{\psi}' = (e^{iq\alpha}\psi)^\dagger\gamma^0 = e^{-iq\alpha}\psi^\dagger\gamma^0 = e^{-iq\alpha}\bar{\psi}$. We show $\mathcal{L} \to \mathcal{L}$, i.e. $\mathcal{L}$ is locally invariant.

Short route (via covariance). The mass term involves no derivative and is invariant on its own:

$$m\,\bar{\psi}'\psi' \;=\; m\,e^{-iq\alpha}\bar{\psi}\,e^{iq\alpha}\psi \;=\; m\,\bar{\psi}\psi, \tag{8.34}$$

the two phases meeting and cancelling because α is a real scalar and so commutes through the Dirac matrices and spinors. For the kinetic term we invoke Theorem 8.5, $D_\mu\psi \to e^{iq\alpha}D_\mu\psi$, together with $\bar{\psi} \to e^{-iq\alpha}\bar{\psi}$:

$$\bar{\psi}'\,i\gamma^\mu D'_\mu\psi' \;=\; (e^{-iq\alpha}\bar{\psi})\,i\gamma^\mu\,(e^{iq\alpha}D_\mu\psi) \;=\; e^{-iq\alpha}e^{iq\alpha}\,\bar{\psi}\,i\gamma^\mu D_\mu\psi \;=\; \bar{\psi}\,i\gamma^\mu D_\mu\psi. \tag{8.35}$$

Adding Eq. (8.35) and $-$Eq. (8.34) gives $\mathcal{L} \to \mathcal{L}$. The decisive step is that $D'_\mu\psi'$ carries the *same* phase $e^{iq\alpha}$ as ψ', so that it cancels against the conjugate phase of $\bar{\psi}'$ just as the undifferentiated ψ' would — which is exactly what covariance was constructed to guarantee.

Long route (term by term). To see the cancellation without invoking the theorem, expand the Lagrangian as in Eq. (8.30) into a free part and an interaction part, and transform each separately. The free part is $\mathcal{L}_0 = \bar{\psi}(i\gamma^\mu\partial_\mu - m)\psi$ and the interaction is $\mathcal{L}_{\text{int}} = q\,\bar{\psi}\gamma^\mu\psi\,A_\mu$. Under Eq. (8.33), the free kinetic term transforms as

$$\begin{aligned}\bar{\psi}'\,i\gamma^\mu\partial_\mu\psi' &= e^{-iq\alpha}\bar{\psi}\,i\gamma^\mu\,\partial_\mu(e^{iq\alpha}\psi) = e^{-iq\alpha}\bar{\psi}\,i\gamma^\mu\,e^{iq\alpha}(\partial_\mu\psi + iq(\partial_\mu\alpha)\psi)\\ &= \bar{\psi}\,i\gamma^\mu\partial_\mu\psi \;+\; \bar{\psi}\,i\gamma^\mu\,iq(\partial_\mu\alpha)\psi \;=\; \bar{\psi}\,i\gamma^\mu\partial_\mu\psi \;-\; q\,(\partial_\mu\alpha)\,\bar{\psi}\gamma^\mu\psi,\end{aligned} \tag{8.36}$$

using $\partial_\mu(e^{iq\alpha}\psi) = e^{iq\alpha}(\partial_\mu\psi + iq(\partial_\mu\alpha)\psi)$ from Eq. (8.18) and $i\cdot i = -1$. The free kinetic term is therefore *not* invariant on its own: it picks up the spurious gradient term $-q(\partial_\mu\alpha)\,\bar{\psi}\gamma^\mu\psi = -(\partial_\mu\alpha)J^\mu$, which is the obstruction made manifest. The mass term is invariant exactly as in Eq. (8.34), so $\mathcal{L}_0$ shifts by $\delta\mathcal{L}_0 = -q(\partial_\mu\alpha)\,\bar{\psi}\gamma^\mu\psi$.

The interaction term transforms by combining the invariance of the bilinear $\bar{\psi}\gamma^\mu\psi$ (its two phases cancel, as in the mass term) with the inhomogeneous shift of A_μ:

$$q\,\bar{\psi}'\gamma^\mu\psi'\,A'_\mu = q\,(e^{-iq\alpha}\bar{\psi})\gamma^\mu(e^{iq\alpha}\psi)\,(A_\mu + \partial_\mu\alpha) = q\,\bar{\psi}\gamma^\mu\psi(A_\mu + \partial_\mu\alpha)$$

$$= q\,\bar{\psi}\gamma^{\mu}\psi\,A_{\mu} \;+\; q\,(\partial_{\mu}\alpha)\,\bar{\psi}\gamma^{\mu}\psi. \tag{8.37}$$

The interaction term thus shifts by $\delta\mathcal{L}_{\text{int}} = +q(\partial_{\mu}\alpha)\,\bar{\psi}\gamma^{\mu}\psi$. Adding the two shifts,

$$\delta\mathcal{L} \;=\; \delta\mathcal{L}_0 + \delta\mathcal{L}_{\text{int}} \;=\; -q(\partial_{\mu}\alpha)\,\bar{\psi}\gamma^{\mu}\psi \;+\; q(\partial_{\mu}\alpha)\,\bar{\psi}\gamma^{\mu}\psi \;=\; 0, \tag{8.38}$$

the obstruction from the free derivative is cancelled exactly by the inhomogeneous shift of the gauge potential. The Lagrangian is locally U(1)-invariant, $\mathcal{L} \to \mathcal{L}$, in agreement with the short route.

Equation (8.38) is the long route's payoff and it teaches the mechanism better than the theorem alone: the offending gradient term $-(\partial_{\mu}\alpha)J^{\mu}$ produced by the free kinetic term is precisely the source-coupling $+(\partial_{\mu}\alpha)J^{\mu}$ produced by the gauge variation of the interaction. Minimal coupling works because the interaction term $J^{\mu}A_{\mu}$ was built from the same current $J^{\mu} = q\,j^{\mu}$ whose non-invariance it must cancel — a self-consistency that the gauge principle enforces automatically. The identical computation goes through verbatim for a charged scalar with $\mathcal{L} = (D_{\mu}\phi)^{\dagger}(D^{\mu}\phi) - m^2\phi^{\dagger}\phi$: the two covariant factors each contribute a phase $e^{\pm iq\alpha}$ that cancel by Theorem 8.5, so minimal coupling renders the charged-scalar kinetic term locally invariant by the same token. Local U(1) invariance is thus not special to the Dirac field; it is a property of the covariant derivative, and any matter field that carries a U(1) charge inherits it.

We have, then, accomplished the section's task. The obstruction of Section 8.1 is resolved: a new vector field A_{μ} with the inhomogeneous transformation law Eq. (8.21) compensates the local phase slip, the covariant derivative $D_{\mu} = \partial_{\mu} - iqA_{\mu}$ transforms charged fields covariantly (Theorem 8.5), and minimal coupling Eq. (8.27) delivers a locally U(1)-invariant matter action whose interaction term $J^{\mu}A_{\mu}$ is the gauge field coupled to the conserved current of Chapter 7. Yet the field we were forced to introduce remains curiously incomplete: it has arrived equipped with a transformation law but with no dynamics of its own — no kinetic term, no equation of motion, nothing in the Lagrangian that lets A_{μ} propagate. Worse, the transformation law Eq. (8.21) shows that A_{μ} itself is not gauge invariant; it shifts by a gradient, so A_{μ} cannot appear bare in any invariant action. To give the gauge potential dynamics we must first build a gauge-invariant object out of it, and the only invariant combination of derivatives of A_{μ} turns out to be the antisymmetrized one — the curvature of the connection. Constructing that object, the field strength $F_{\mu\nu}$, from the commutator of covariant derivatives, and reading off from it the geometry of the gauge field, is the work of Section 8.3.

8.3 The Field Strength as Curvature

The previous section handed us a new object and an embarrassment. Demanding that the global U(1) phase symmetry of the matter Lagrangian survive when the

phase is allowed to vary from point to point forced into existence a vector field A_μ and a modified derivative, the gauge-covariant derivative $D_\mu = \partial_\mu - iqA_\mu$ of Theorem 8.4, whose defining virtue is that it transforms homogeneously: under a local gauge transformation $\psi \to e^{iq\alpha(x)}\psi$, $A_\mu \to A_\mu + \partial_\mu\alpha$, the combination $D_\mu\psi$ rotates by the same phase as ψ itself (Theorem 8.5). That is exactly enough to build a gauge-invariant matter action by minimal coupling. But A_μ entered as pure bookkeeping: it has, as yet, no dynamics, no equation of motion, no Lagrangian of its own. It is a field that does things to matter but is not itself a thing. The embarrassment is that we cannot simply write down a kinetic term for it, because the naive candidates—$\partial_\mu A_\nu\,\partial^\mu A^\nu$, $A_\mu A^\mu$, and the like—are not gauge invariant: the gauge freedom $A_\mu \to A_\mu + \partial_\mu\alpha$ that made D_μ work now obstructs any term built directly from A_μ and its bare derivatives.

To give A_μ dynamics we must first extract from it the gauge-invariant information it carries. The potential A_μ is partly physical and partly redundant: the gradient $\partial_\mu\alpha$ can be added at will, so any single component of A_μ can be set to anything at a point by a suitable choice of gauge. What is the gauge-invariant residue? The covariant derivative itself supplies the answer. We built D_μ to compare the field at infinitesimally separated points in a gauge-respecting way; the gauge-invariant content of A_μ is precisely the *failure of that comparison to be path-independent*. Quantified, that failure is a single antisymmetric tensor, the field strength $F_{\mu\nu}$, and it is—in the most literal differential-geometric sense the chapter will make good on—the *curvature* of the gauge connection A_μ. This section constructs $F_{\mu\nu}$ from the commutator of covariant derivatives, proves it gauge invariant, derives the identity it satisfies for free (the Bianchi identity), reads off its components as the electric and magnetic fields, and gives the geometric picture—parallel transport and holonomy around a loop—that both explains the word "curvature" and sets up the non-abelian generalization of Chapter 25.

8.3.1 The commutator of covariant derivatives

A single covariant derivative is gauge covariant, but it is not, by itself, gauge invariant: it carries a free index and transforms as $D_\mu\psi \to e^{iq\alpha}D_\mu\psi$. To manufacture something gauge *invariant* we need to compare derivatives, and the cleanest comparison is to ask whether covariant differentiation in two different directions commutes. For ordinary partial derivatives the answer is always yes, $[\partial_\mu, \partial_\nu] = 0$, because mixed partials of a smooth function are symmetric. Covariant derivatives are different: each carries a copy of the potential A_μ, and the potentials at the two stages of the double derivative need not cancel. The amount by which they fail to cancel is the object we are after.

We compute the commutator $[D_\mu, D_\nu]$ acting on a charged field ψ, carrying every term. With $D_\mu = \partial_\mu - iqA_\mu$,

$$D_\mu D_\nu\psi = (\partial_\mu - iqA_\mu)(\partial_\nu\psi - iqA_\nu\psi)$$

$$= \partial_\mu \partial_\nu \psi - iq\,\partial_\mu(A_\nu \psi) - iq A_\mu\,\partial_\nu \psi + (-iq)(-iq) A_\mu A_\nu \psi$$
$$= \partial_\mu \partial_\nu \psi - iq\,(\partial_\mu A_\nu)\,\psi - iq\,A_\nu\,\partial_\mu \psi - iq\,A_\mu\,\partial_\nu \psi - q^2 A_\mu A_\nu\,\psi. \quad (8.39)$$

The commutator is the antisymmetrization of (8.39) in $\mu \leftrightarrow \nu$. Take the difference term by term. The pure second-derivative term is symmetric and cancels,

$$\partial_\mu \partial_\nu \psi - \partial_\nu \partial_\mu \psi = 0, \quad (8.40)$$

this being the equality of mixed partials for the smooth field ψ. The two terms in which a single A multiplies a first derivative of ψ also cancel: the pair $-iq\,A_\nu\,\partial_\mu \psi - iq\,A_\mu\,\partial_\nu \psi$ is already symmetric under $\mu \leftrightarrow \nu$, so subtracting its swap gives zero. The quadratic term $-q^2 A_\mu A_\nu \psi$ is symmetric as well—A_μ and A_ν are ordinary commuting functions in the abelian theory—and cancels in the same way. The only survivor is the term in which the derivative lands on the potential:

$$[D_\mu, D_\nu]\,\psi = -iq(\partial_\mu A_\nu - \partial_\nu A_\mu)\psi. \quad (8.41)$$

Three features of (8.41) deserve emphasis before we name the result. First, all derivatives of ψ have dropped out: the right-hand side is ψ multiplied by a function of A_μ alone. The commutator $[D_\mu, D_\nu]$ is therefore not a differential operator at all but an ordinary (multiplicative) function—an algebraic object built purely from the potential. Second, that function is manifestly antisymmetric in $\mu\nu$. Third, the ψ on which we acted has disappeared from the structure of the answer; the operator identity

$$[D_\mu, D_\nu] = -iq\,F_{\mu\nu} \quad (8.42)$$

holds on every charged field, whatever its charge q. This last point is what makes (8.42) a clean *definition*.

Definition 8.8 (Field strength)**.** The *electromagnetic field strength* $F_{\mu\nu}$ is the antisymmetric two-tensor defined by the commutator of covariant derivatives,

$$[D_\mu, D_\nu] = -iq\,F_{\mu\nu}. \quad (8.43)$$

In the abelian (U(1)) theory the computation (8.41) evaluates this to

$$F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu, \quad (8.44)$$

an antisymmetric tensor of the kind catalogued in Chapter 3, with $F_{\nu\mu} = -F_{\mu\nu}$ and hence six independent components in four spacetime dimensions.

The defining relation (8.43) is more fundamental than the explicit formula (8.44), because it is the relation that survives generalization. Nothing in the derivation of (8.41) used that the gauge group was U(1) until the very last step, where we cancelled the quadratic term $-q^2 A_\mu A_\nu \psi$ against its swap on the grounds that

the potentials commute. In a non-abelian theory the potential is matrix-valued, $A_\mu = A_\mu^a T^a$ with non-commuting generators $\left[T^a, T^b\right] = i f^{abc} T^c$ (Chapter 2), and the quadratic term does *not* cancel; it leaves behind a commutator $[A_\mu, A_\nu]$ that adds a term $g f^{abc} A_\mu^b A_\nu^c$ to the field strength. That self-interaction term—the structural origin of everything that makes Yang–Mills theory harder and richer than electrodynamics—is the subject of Chapter 25. Here the gauge group is abelian, the generators are a single number, $f^{abc} \equiv 0$, and the term is simply absent. We flag its provenance now so that the appearance of $F_{\mu\nu}$ as a commutator reads, in hindsight, as the abelian shadow of a general construction.

Physical Insight

The field strength is not an extra postulate bolted onto the gauge field; it is forced. Once we accept that comparing a charged field at neighbouring points requires the covariant derivative D_μ, the question "does the order of comparison matter?" is unavoidable, and its answer *is* $F_{\mu\nu}$. The potential A_μ tells you how to parallel-transport a phase along a path; the field strength tells you that transport around a closed loop need not return you to where you started. Everything physical about the electromagnetic field lives in that discrepancy, and the discrepancy is gauge invariant precisely because it is a statement about the geometry of transport, not about the arbitrary phase convention you adopt at each point.

8.3.2 Gauge invariance of the field strength

The commutator construction already strongly suggests that $F_{\mu\nu}$ is gauge invariant. The operator $[D_\mu, D_\nu]$ acts on a charged field by simple multiplication, and under a gauge transformation it conjugates the way a covariant operator must: since $D_\mu \to e^{iq\alpha} D_\mu e^{-iq\alpha}$ (this is the content of covariance, Theorem 8.5), the commutator goes to $e^{iq\alpha}\,[D_\mu, D_\nu]\,e^{-iq\alpha}$, and because $[D_\mu, D_\nu] = -iqF_{\mu\nu}$ is mere multiplication by a function, the two phase factors—which are themselves just multiplication by $e^{\pm iq\alpha}$—cancel, leaving $-iqF_{\mu\nu}$ unchanged. It is worth seeing the same conclusion fall directly out of the explicit transformation law of A_μ, with all the algebra on the page, because that computation pinpoints exactly which cancellation is doing the work.

Theorem 8.9 (Gauge invariance of $F_{\mu\nu}$)**.** *In the abelian theory the field strength $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ is invariant under the gauge transformation $A_\mu \to A'_\mu = A_\mu + \partial_\mu \alpha$ for every smooth gauge function $\alpha(x)$:*

$$F'_{\mu\nu} = F_{\mu\nu}. \tag{8.45}$$

Proof. Substitute the transformed potential $A'_\mu = A_\mu + \partial_\mu \alpha$ directly into the

definition (8.44):

$$\begin{aligned} F'_{\mu\nu} &= \partial_\mu A'_\nu - \partial_\nu A'_\mu \\ &= \partial_\mu(A_\nu + \partial_\nu\alpha) - \partial_\nu(A_\mu + \partial_\mu\alpha) \\ &= (\partial_\mu A_\nu - \partial_\nu A_\mu) + (\partial_\mu\partial_\nu\alpha - \partial_\nu\partial_\mu\alpha) \\ &= F_{\mu\nu} + 0. \end{aligned} \tag{8.46}$$

The first bracket is $F_{\mu\nu}$ by definition. The second bracket vanishes identically: it is the antisymmetrization of $\partial_\mu\partial_\nu\alpha$, and for a smooth scalar function α the mixed second partials are symmetric, $\partial_\mu\partial_\nu\alpha = \partial_\nu\partial_\mu\alpha$, so the two terms cancel. Hence $F'_{\mu\nu} = F_{\mu\nu}$. □

The proof is a single line of algebra, but it carries the central physical message of the chapter, so it is worth restating in words. The gauge redundancy of the potential is exactly the freedom to add a pure gradient $\partial_\mu\alpha$. A gradient is curl-free; the antisymmetrized derivative $\partial_{[\mu}\partial_{\nu]}\alpha$ that $F_{\mu\nu}$ would see is therefore zero. The field strength is built to be blind to precisely the part of A_μ that gauge transformations can change. This is why $F_{\mu\nu}$, and not A_μ, is the carrier of physical, observable information about the electromagnetic field, and it is why the gauge-invariant kinetic term of the next section will be assembled out of $F_{\mu\nu}$ rather than out of A_μ directly.

Caution

Gauge invariance of $F_{\mu\nu}$ does not mean A_μ is unphysical scaffolding to be discarded. The potential carries information that the local field strength does not: the Aharonov–Bohm effect shows that a charged particle's quantum phase responds to $\oint A_\mu \, \mathrm{d}x^\mu$ around a loop even through regions where $F_{\mu\nu} = 0$. What is true is that only the gauge-invariant combinations of A_μ are observable, and around a closed loop that combination is precisely $\oint A_\mu \, \mathrm{d}x^\mu = \frac{1}{2}\int F_{\mu\nu} \, \mathrm{d}\sigma^{\mu\nu}$ by Stokes' theorem—the flux of the curvature, as we make explicit in Theorem 8.12.

8.3.3 The Bianchi identity

Because $F_{\mu\nu}$ is the antisymmetrized derivative of a potential, it is not an arbitrary antisymmetric tensor field: it satisfies an identity, automatically and independently of any equation of motion. This is the homogeneous, or Bianchi, identity. It is a *kinematic* constraint—true for any A_μ whatsoever, before dynamics are imposed—and we will see in the next section that it already encodes two of the four Maxwell equations, the two that have no source on their right-hand side.

Theorem 8.10 (Homogeneous Bianchi identity)**.** *The abelian field strength satisfies the cyclic identity*

$$\partial_\lambda F_{\mu\nu} + \partial_\mu F_{\nu\lambda} + \partial_\nu F_{\lambda\mu} = 0, \tag{8.47}$$

equivalently written $\partial_{[\lambda} F_{\mu\nu]} = 0$ *with square brackets denoting total antisymmetrization over the enclosed indices.*

We give two proofs. The first is direct and elementary; the second runs through the Jacobi identity of the covariant derivatives and is the form that survives the non-abelian generalization.

Proof by direct substitution. Insert $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ into each of the three terms of (8.47) and expand:

$$\begin{aligned} \partial_\lambda F_{\mu\nu} &= \partial_\lambda \partial_\mu A_\nu - \partial_\lambda \partial_\nu A_\mu, \\ \partial_\mu F_{\nu\lambda} &= \partial_\mu \partial_\nu A_\lambda - \partial_\mu \partial_\lambda A_\nu, \\ \partial_\nu F_{\lambda\mu} &= \partial_\nu \partial_\lambda A_\mu - \partial_\nu \partial_\mu A_\lambda. \end{aligned} \tag{8.48}$$

Add the three lines. Group the six terms into three pairs, each pair containing the same field component differentiated by the same two derivative operators in opposite order. The term $+\partial_\lambda \partial_\mu A_\nu$ cancels $-\partial_\mu \partial_\lambda A_\nu$; the term $-\partial_\lambda \partial_\nu A_\mu$ cancels $+\partial_\nu \partial_\lambda A_\mu$; and the term $+\partial_\mu \partial_\nu A_\lambda$ cancels $-\partial_\nu \partial_\mu A_\lambda$. Every cancellation is an instance of the symmetry of mixed partials, $\partial_\rho \partial_\sigma = \partial_\sigma \partial_\rho$, applied to the smooth potential. The sum vanishes, which is (8.47). □

Proof via the Jacobi identity. For any three linear operators X, Y, Z the Jacobi identity

$$[X, [Y, Z]] + [Y, [Z, X]] + [Z, [X, Y]] = 0 \tag{8.49}$$

holds identically, by expanding each double commutator and observing that all twelve resulting products cancel in pairs. Apply it to the three covariant derivatives $X = D_\lambda$, $Y = D_\mu$, $Z = D_\nu$. By the definition (8.43), each inner commutator is $[D_\mu, D_\nu] = -iqF_{\mu\nu}$, so

$$[D_\lambda, -iqF_{\mu\nu}] + [D_\mu, -iqF_{\nu\lambda}] + [D_\nu, -iqF_{\lambda\mu}] = 0. \tag{8.50}$$

It remains to evaluate $[D_\lambda, F_{\mu\nu}]$. Since $F_{\mu\nu}$ is a gauge-invariant (neutral) function, it acts on a charged field ψ by ordinary multiplication, and

$$[D_\lambda, F_{\mu\nu}]\,\psi = D_\lambda(F_{\mu\nu}\psi) - F_{\mu\nu}\, D_\lambda\psi = (\partial_\lambda F_{\mu\nu})\,\psi, \tag{8.51}$$

where the gauge-potential pieces $-iqA_\lambda F_{\mu\nu}\psi$ from the first term and $-F_{\mu\nu}(iqA_\lambda)\psi$ from the second cancel, leaving only the derivative landing on $F_{\mu\nu}$. (Geometrically, (8.51) says that on a neutral field the covariant derivative reduces to the ordinary one; in the non-abelian theory $F_{\mu\nu}$ is charged under the adjoint and this

step instead produces the *covariant* derivative $D_\lambda F_{\mu\nu}$, which is why the general Bianchi identity reads $D_{[\lambda}F_{\mu\nu]} = 0$—see Chapter 25.) Substituting (8.51) into (8.50) and dividing by the common factor $-iq$ gives exactly (8.47). □

The Jacobi route exposes why (8.47) is an *identity* and not a field equation: it descends from the associativity of operator composition, which holds for any A_μ whatsoever. No variational principle, no Lagrangian, no choice of dynamics is involved. Of Maxwell's four equations, two will turn out to be this kinematic identity in disguise, owed to nothing more than the existence of a potential; the other two are genuine dynamics, derived in Section 8.4 from the Maxwell action of the next section.

8.3.4 Electric and magnetic fields as components of $F_{\mu\nu}$

We have an antisymmetric two-tensor with six independent components and a claim that it contains all the gauge-invariant physics of the electromagnetic field. The reader's undergraduate electromagnetism also packaged that physics into six numbers—the three components of the electric field $\mathbf{E}$ and the three of the magnetic field $\mathbf{B}$. They are the same six numbers. Making the identification explicit both grounds the abstract construction and lets us read the Bianchi identity as physics.

Write the potential in terms of the scalar and vector potentials of undergraduate electromagnetism, $A^\mu = (\phi, \mathbf{A})$, so that with the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$ the lower-index components are $A_\mu = (\phi, -\mathbf{A})$ and $\partial_\mu = (\partial_t, \boldsymbol{\nabla})$, $\partial^\mu = (\partial_t, -\boldsymbol{\nabla})$. The electric field is defined to be

$$E^i \equiv F^{i0}, \tag{8.52}$$

and we check this reproduces the textbook formula. Raising indices with the metric, $F^{i0} = \eta^{i\alpha}\eta^{0\beta}F_{\alpha\beta} = (-1)(+1)F_{i0} = -F_{i0}$, and from the definition $F_{i0} = \partial_i A_0 - \partial_0 A_i = \partial_i\phi - \partial_t(-A^i) = \partial_i\phi + \partial_t A^i$. Hence

$$E^i = -F_{i0} = -\partial_i\phi - \partial_t A^i, \qquad \text{i.e.} \qquad \mathbf{E} = -\boldsymbol{\nabla}\phi - \partial_t\mathbf{A}, \tag{8.53}$$

which is exactly the standard expression for the electric field in terms of the potentials. The magnetic field is defined through the spatial–spatial components by

$$B^i \equiv -\tfrac{1}{2}\,\epsilon^{ijk}F_{jk}, \tag{8.54}$$

with ϵ^{ijk} the three-dimensional Levi-Civita symbol of Chapter 3 ($\epsilon^{123} = +1$). Using $F_{jk} = \partial_j A_k - \partial_k A_j = -\partial_j A^k + \partial_k A^j = -(\partial_j A^k - \partial_k A^j)$,

$$B^i = -\tfrac{1}{2}\,\epsilon^{ijk}\big[-(\partial_j A^k - \partial_k A^j)\big] = \tfrac{1}{2}\,\epsilon^{ijk}(\partial_j A^k - \partial_k A^j) = \epsilon^{ijk}\partial_j A^k, \tag{8.55}$$

the last step using the antisymmetry of ϵ^{ijk} to combine the two equal contributions. This is $\mathbf{B} = \boldsymbol{\nabla} \times \mathbf{A}$. Collecting the components into the matrix of $F_{\mu\nu}$ (rows and columns ordered $\mu, \nu = 0, 1, 2, 3$),

$$F_{\mu\nu} = \begin{pmatrix} 0 & E^1 & E^2 & E^3 \\ -E^1 & 0 & -B^3 & B^2 \\ -E^2 & B^3 & 0 & -B^1 \\ -E^3 & -B^2 & B^1 & 0 \end{pmatrix}, \tag{8.56}$$

where the top row follows from $F_{0i} = -F_{i0} = E^i$ and the spatial block from inverting (8.54), $F_{jk} = -\epsilon_{jki} B^i$. The six independent entries of the antisymmetric tensor are the three electric and three magnetic field components, exactly as promised. The Lorentz tensor $F_{\mu\nu}$ has thus unified $\mathbf{E}$ and $\mathbf{B}$ into a single geometric object whose transformation under boosts—mixing the electric and magnetic blocks—is the relativistic statement that electric and magnetic fields are frame-dependent shadows of one curvature.

Worked Example 8.11 (The Bianchi identity is the homogeneous Maxwell pair)**.** We show that the four independent components of the Bianchi identity (8.47) are precisely the two source-free Maxwell equations, $\boldsymbol{\nabla} \cdot \mathbf{B} = 0$ and Faraday's law $\boldsymbol{\nabla} \times \mathbf{E} = -\partial_t \mathbf{B}$. Because $\partial_{[\lambda} F_{\mu\nu]}$ is totally antisymmetric in its three indices, it has only $\binom{4}{3} = 4$ independent components, labelled by which index is *omitted*.

All-spatial component $(\lambda\mu\nu) = (1, 2, 3)$. Equation (8.47) reads

$$\partial_1 F_{23} + \partial_2 F_{31} + \partial_3 F_{12} = 0. \tag{8.57}$$

From (8.56), $F_{23} = -B^1$, $F_{31} = -B^2$, $F_{12} = -B^3$, so (8.57) becomes $-(\partial_1 B^1 + \partial_2 B^2 + \partial_3 B^3) = 0$, that is

$$\boldsymbol{\nabla} \cdot \mathbf{B} = 0. \tag{8.58}$$

The absence of magnetic monopoles is the statement that F is a curl: it has no all-spatial "divergence" because it is built antisymmetrically from a potential.

Components with one time index, e.g. $(\lambda\mu\nu) = (0, 1, 2)$:

$$\partial_0 F_{12} + \partial_1 F_{20} + \partial_2 F_{01} = 0. \tag{8.59}$$

Using $F_{12} = -B^3$, $F_{20} = -F_{02} = -E^2$, $F_{01} = E^1$ and $\partial_0 = \partial_t$, (8.59) reads $-\partial_t B^3 - \partial_1 E^2 + \partial_2 E^1 = 0$, i.e. $\partial_1 E^2 - \partial_2 E^1 = -\partial_t B^3$. The left side is the third component of $\boldsymbol{\nabla} \times \mathbf{E}$, so this is the 3-component of Faraday's law. The choices $(0, 2, 3)$ and $(0, 3, 1)$ give the 1- and 2-components by the same steps, assembling into

$$\boldsymbol{\nabla} \times \mathbf{E} = -\partial_t \mathbf{B}. \tag{8.60}$$

The two homogeneous Maxwell equations are thus not dynamical laws to be derived from an action; they are the kinematic identity that any field strength built from a potential must obey. This is the payoff promised after Theorem 8.10: half of Maxwell's equations is geometry, true the moment one writes $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$.

It is occasionally convenient to package (8.47) in dual form. Define the dual field strength $\widetilde{F}^{\mu\nu} \equiv \frac{1}{2}\,\epsilon^{\mu\nu\rho\sigma}F_{\rho\sigma}$ with $\epsilon^{0123} = +1$ (Chapter 3); then the totally antisymmetric Bianchi identity (8.47) is equivalent to the compact statement

$$\partial_\mu \widetilde{F}^{\mu\nu} = 0, \tag{8.61}$$

because contracting (8.47) with $\epsilon^{\kappa\lambda\mu\nu}$ and using the antisymmetry of the ϵ-symbol reproduces the four components worked out in Theorem 8.11. The dual form makes the parallel with the inhomogeneous equations $\partial_\mu F^{\mu\nu} = J^\nu$ of the next section visually plain: the homogeneous pair is the same divergence taken on the dual.

8.3.5 Curvature, parallel transport, and holonomy

We now justify the word that has been doing rhetorical work throughout: *curvature*. The claim is not an analogy. The covariant derivative D_μ is, in the precise vocabulary of differential geometry, a *connection* on a complex line bundle over spacetime, and $F_{\mu\nu}$ is its *curvature*—the same object that, for the Levi-Civita connection on a Riemannian manifold, is the Riemann tensor. The dictionary is exact, and laying it out now both explains why the commutator construction was inevitable and prepares the bundle picture that the non-abelian theory of Chapter 25 will make essential.

The geometric content is encoded in *parallel transport*. A charged field ψ at a point x carries a phase whose absolute value is a matter of gauge convention; to compare the phase at x with the phase at a neighbouring point y we must specify a rule for carrying the phase from one to the other—a rule for parallel transport. The covariant derivative *is* that rule in infinitesimal form: a field is said to be parallel-transported, or covariantly constant, along a path if its covariant derivative along the path's tangent vanishes. For a displacement $\mathrm{d}x^\mu$, demanding $\mathrm{d}x^\mu D_\mu \psi = 0$ means

$$\mathrm{d}x^\mu(\partial_\mu - iqA_\mu)\psi = 0 \quad\Longrightarrow\quad \mathrm{d}\psi = iq\,A_\mu\,\mathrm{d}x^\mu\,\psi. \tag{8.62}$$

Integrating (8.62) along a path γ from x to y gives the finite transport law $\psi(y) = U_\gamma(y,x)\,\psi(x)$ with the *comparator* (or Wilson line)

$$U_\gamma(y,x) = \exp\!\left(iq\int_\gamma A_\mu\,\mathrm{d}x^\mu\right), \tag{8.63}$$

the exponential being ordinary in the abelian case where the integrand at different points commutes (in the non-abelian case it becomes a path-ordered exponential, Chapter 25). The comparator transforms under a gauge change so as to cancel the phases at its endpoints, $U_\gamma(y,x) \to e^{iq\alpha(y)}U_\gamma(y,x)e^{-iq\alpha(x)}$, which is exactly the property that lets it carry a phase from x to y in a gauge-covariant way.

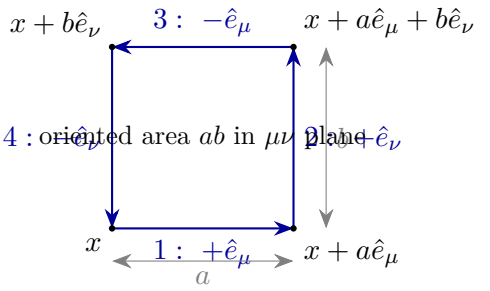

Figure 8.3: The infinitesimal rectangular loop in the μ–ν plane used to compute the holonomy in Theorem 8.12. Parallel transport once around the loop multiplies a charged field by $U(C) \approx 1 + iq\,F_{\mu\nu}\,ab$: the curvature $qF_{\mu\nu}$ is the holonomy per unit oriented area.

Now the decisive question: does the result of parallel transport depend on the path? If two paths from x to y give the same answer, the connection is "flat" and the phase difference between x and y is a well-defined, path-independent quantity—there is no physical field. If different paths disagree, transport is path-dependent, and the disagreement around a closed loop is the physical content of the field. The disagreement is measured by the *holonomy*, the comparator around a closed loop C,

$$U(C) = \exp\!\left(iq \oint_C A_\mu \, \mathrm{d}x^\mu \right), \tag{8.64}$$

and the claim is that for an infinitesimal loop the holonomy is governed by $F_{\mu\nu}$. The next worked example computes it explicitly; Fig. 8.3 fixes the geometry.

Worked Example 8.12 (Holonomy around an infinitesimal loop equals the curvature)**.** Take the small rectangular loop C of Fig. 8.3, lying in the μ–ν coordinate plane with one corner at x, side a along $\hat{e}_\mu$ and side b along $\hat{e}_\nu$ (no sum on the fixed directions μ, ν). We evaluate $\oint_C A_\rho \, \mathrm{d}x^\rho$ to leading nonvanishing order in the side lengths by summing the four straight segments, approximating each segment integral by its midpoint value (the midpoint rule is accurate to the order we need).

Segment 1 ($x \to x + a\hat{e}_\mu$, direction $+\mu$, midpoint $x + \frac{a}{2}\hat{e}_\mu$): contributes $+a\,A_\mu\big(x + \frac{a}{2}\hat{e}_\mu\big)$.

Segment 2 ($x + a\hat{e}_\mu \to x + a\hat{e}_\mu + b\hat{e}_\nu$, direction $+\nu$, midpoint $x + a\hat{e}_\mu + \frac{b}{2}\hat{e}_\nu$): contributes $+b\,A_\nu\big(x + a\hat{e}_\mu + \frac{b}{2}\hat{e}_\nu\big)$.

Segment 3 ($x + a\hat{e}_\mu + b\hat{e}_\nu \to x + b\hat{e}_\nu$, direction $-\mu$, midpoint $x + \frac{a}{2}\hat{e}_\mu + b\hat{e}_\nu$): contributes $-a\,A_\mu\big(x + \frac{a}{2}\hat{e}_\mu + b\hat{e}_\nu\big)$.

Segment 4 ($x + b\hat{e}_\nu \to x$, direction $-\nu$, midpoint $x + \frac{b}{2}\hat{e}_\nu$): contributes $-b\,A_\nu\big(x + \frac{b}{2}\hat{e}_\nu\big)$.

Group segments 1 and 3 (both along μ). They differ only in that segment 3 is displaced by $b\hat{e}_\nu$, so a first-order Taylor expansion gives

$$a\Big[A_\mu(x+\tfrac{a}{2}\hat{e}_\mu)-A_\mu(x+\tfrac{a}{2}\hat{e}_\mu+b\hat{e}_\nu)\Big]=-a\,b\,\partial_\nu A_\mu+O(\text{cubic}). \tag{8.65}$$

Likewise group segments 2 and 4 (both along ν); segment 2 is displaced from segment 4 by $a\hat{e}_\mu$, giving

$$b\Big[A_\nu(x+a\hat{e}_\mu+\tfrac{b}{2}\hat{e}_\nu)-A_\nu(x+\tfrac{b}{2}\hat{e}_\nu)\Big]=+a\,b\,\partial_\mu A_\nu+O(\text{cubic}). \tag{8.66}$$

Adding (8.65) and (8.66), the line integral is

$$\oint_C A_\rho\,\mathrm{d}x^\rho=a\,b\,(\partial_\mu A_\nu-\partial_\nu A_\mu)=F_{\mu\nu}\,a\,b, \tag{8.67}$$

the flux of $F_{\mu\nu}$ through the loop—a special case of Stokes' theorem, $\oint A_\rho\,\mathrm{d}x^\rho=\frac{1}{2}\int F_{\rho\sigma}\,\mathrm{d}\sigma^{\rho\sigma}$, for the oriented area element ab. The holonomy is therefore

$$U(C)=\exp\!\big(iq\,F_{\mu\nu}\,ab\big)=1+iq\,F_{\mu\nu}\,ab+O((ab)^2). \tag{8.68}$$

Parallel transport around an infinitesimal loop fails to be the identity, and the failure, per unit oriented area, is exactly $iq\,F_{\mu\nu}$. This is the geometric meaning of the field strength: *$qF_{\mu\nu}$ is the curvature of the gauge connection*, the holonomy density of the loop. It is also, read physically, the infinitesimal Aharonov–Bohm phase—the gauge field makes itself felt on a charged field only through the curvature it produces, which is why $F_{\mu\nu}$ and not A_μ is the locally observable field.

The infinitesimal holonomy (8.68) also gives a third, geometric derivation of the commutator formula (8.42) and closes the circle of the section. Parallel transport of ψ around the loop and the double covariant derivative are the same operation: a short computation shows that transporting around the infinitesimal rectangle and comparing with the untransported field reproduces $\psi(x)\to\psi(x)+[D_\mu,D_\nu]\,\psi\,ab$ to leading order, so that the holonomy generator $iqF_{\mu\nu}$ of (8.68) is identical to $-[D_\mu,D_\nu]$ of (8.42). The commutator of covariant derivatives *is* the failure of parallel transport to commute; that is why we were entitled, from the first line of Section 8.3.1, to call $F_{\mu\nu}$ a curvature.

Physical Insight

The connection/curvature dictionary that this section has built quietly is the entire conceptual content of gauge theory, and it is worth stating once in its general form, because Part VII will do nothing but generalize the group:

- the gauge potential A_μ is a *connection*—a rule for parallel transport,

i.e. for comparing the internal (phase) space of the matter field at neighbouring points;

- the covariant derivative D_μ is that connection in infinitesimal form;
- the field strength $F_{\mu\nu} = \frac{i}{q}[D_\mu, D_\nu]$ is the *curvature*— the holonomy of an infinitesimal loop, the obstruction to path-independent comparison;
- gauge transformations are changes of phase convention (local frame) fibre by fibre; A_μ transforms inhomogeneously (it is not a tensor), while $F_{\mu\nu}$ transforms homogeneously (here, trivially: it is gauge invariant);
- the Bianchi identity $\partial_{[\lambda}F_{\mu\nu]} = 0$ is the geometric identity obeyed by any curvature, the differential-form statement $\mathrm{d}F = 0$ that F is closed.

Replacing the abelian phase $e^{iq\alpha}$ by a non-abelian group element $e^{i\alpha^a T^a}$ turns this into Yang–Mills theory; replacing the internal space by the tangent space of spacetime turns it into general relativity, with A_μ the Christoffel connection and $F_{\mu\nu}$ the Riemann curvature. The fact that electromagnetism, the strong and weak interactions, and gravity are all theories of a connection and its curvature is the deepest structural unity in physics, and this section is where the reader first meets it.

We now have the gauge-invariant residue of the potential in hand: the field strength $F_{\mu\nu}$, gauge invariant (Theorem 8.9), constrained by the Bianchi identity (Theorem 8.10), and equal to the electromagnetic fields $\mathbf{E}, \mathbf{B}$ packaged as the curvature of the gauge connection. The one ingredient still missing for a dynamical theory of A_μ is a Lagrangian, and gauge invariance has all but written it for us: the kinetic term must be a Lorentz scalar built from $F_{\mu\nu}$, and the unique such scalar with the right number of derivatives is the contraction $F_{\mu\nu}F^{\mu\nu}$. Constructing the Maxwell action from this invariant, adding a conserved source, and extracting the inhomogeneous Maxwell equations as its Euler–Lagrange equations is the task of the next section.

8.4 The Maxwell Action and Field Equations

The previous section handed up a single, geometrically privileged object: the field strength $F_{\mu\nu}$, constructed as the curvature of the gauge connection through the commutator of covariant derivatives, shown to be gauge invariant (Theorem 8.9), and obeying the Bianchi identity (Eq. (8.47)) as an off-shell consequence of being

a curvature. We now have the raw material for a dynamical theory but not yet the theory itself. A field acquires dynamics from an action; the action determines, through the variational principle of Chapter 6, which configurations of A_μ are physically realized. The task of this section is to write down that action. We will not guess it and check it after the fact. We will instead *derive* it from a short list of principles — Lorentz invariance, gauge invariance, parity, and a ceiling of two derivatives — and find that these requirements are so constraining that the answer is essentially forced: up to an overall normalization and additive total derivatives, there is exactly one candidate. Out of that unique Lagrangian, the Euler–Lagrange equations deliver the inhomogeneous Maxwell equations; the Bianchi identity supplies the homogeneous ones for free; and the demand that a coupling to matter respect gauge invariance forces the matter current to be conserved. By the end we will have assembled the photon sector $-\frac{1}{4}F_{\mu\nu}F^{\mu\nu}$ of the frozen classical QED Lagrangian of QED, with all four of Maxwell's equations recovered in their familiar three-vector form.

8.4.1 What may appear in the Lagrangian

The Lagrangian density $\mathcal{L}$ is a function of the gauge potential A_μ and its derivatives, and we constrain it by four requirements, each of which is physically motivated rather than imposed for convenience.

Lorentz invariance. $\mathcal{L}$ must be a Lorentz scalar, so that the action $S = \int \mathrm{d}^4x\, \mathcal{L}$ is frame-independent and the resulting dynamics respects special relativity. Every index must be contracted.

Gauge invariance. The physics is invariant under $A_\mu \to A_\mu + \partial_\mu \alpha(x)$ for arbitrary smooth α, as established in the construction of the connection. For the *equations of motion* to be gauge invariant it suffices that the action change by at most a boundary term — a quasi-symmetry in the sense of Theorem 7.4. The cleanest way to guarantee this, and the one we adopt and then justify, is to build $\mathcal{L}$ out of the manifestly gauge-invariant curvature $F_{\mu\nu}$ alone.

Locality and a derivative ceiling. $\mathcal{L}$ is a polynomial in the fields and their derivatives evaluated at a single spacetime point (locality), and we demand at most two derivatives in total. The derivative count is not arbitrary: a Lagrangian with more than two derivatives generically yields field equations of higher than second order, which carry extra initial data and, upon quantization, ghostlike negative-norm states (the Ostrogradsky problem). Restricting to two derivatives is the statement that we want the leading, renormalizable, healthy theory; higher-derivative corrections are irrelevant operators in the sense made precise by the renormalization group in Chapter 23.

Parity. We require invariance under spatial reflection $\mathbf{x} \to -\mathbf{x}$. This is a property of classical electromagnetism (and of QED), and dropping it admits exactly one extra term, which we will identify and dispose of.

The building blocks are therefore Lorentz scalars, built from A_μ and ∂_μ, gauge invariant, with at most two derivatives. Let us enumerate them.

No-derivative terms. The only Lorentz scalar with no derivatives that can be built from A_μ is $A_\mu A^\mu$. It is *not* gauge invariant:

$$A_\mu A^\mu \;\longrightarrow\; (A_\mu + \partial_\mu\alpha)(A^\mu + \partial^\mu\alpha) = A_\mu A^\mu + 2A_\mu\partial^\mu\alpha + (\partial_\mu\alpha)(\partial^\mu\alpha), \quad (8.69)$$

and the extra pieces do not assemble into a total derivative for arbitrary α. A term $\frac{1}{2}m^2 A_\mu A^\mu$ in the Lagrangian is precisely a *photon mass term*, and (8.69) shows that gauge invariance forbids it. This is a sharp and physical conclusion: *the gauge principle forces the photon to be massless.* A massive vector field is described instead by the Proca Lagrangian

$$\mathcal{L}_{\text{Proca}} = -\tfrac{1}{4}F_{\mu\nu}F^{\mu\nu} + \tfrac{1}{2}m^2 A_\mu A^\mu, \quad (8.70)$$

which is Lorentz invariant and yields a perfectly sensible classical theory of a spin-1 particle of mass m, but which is *not* gauge invariant precisely because of the mass term. The contrast is instructive and we will return to it.

Physical Insight

The masslessness of the photon is not an experimental input fitted by hand; it is a *consequence* of demanding local $U(1)$ invariance. The same logic, applied to the non-abelian case in Chapter 25, forbids tree-level masses for the gluon and the electroweak gauge bosons — which is why giving mass to the W and Z requires the Higgs mechanism (Chapter 33), a way of generating an effective m^2A^2 without ever writing one in the Lagrangian. The photon mass bound is experimentally extraordinary: $m_\gamma \lesssim 10^{-18}\,\text{eV}$, fully consistent with the exact zero the gauge principle predicts.

Two-derivative terms. With two derivatives and quadratic in A (the leading order; higher powers of A with two derivatives are not available for an abelian field because F is linear in A), gauge invariance restricts us to scalars built from two factors of $F_{\mu\nu}$, since F already carries one derivative each. There are exactly two Lorentz scalars of this type:

$$F_{\mu\nu}F^{\mu\nu} \qquad \text{and} \qquad F_{\mu\nu}\widetilde{F}^{\mu\nu}, \quad \widetilde{F}^{\mu\nu} \equiv \tfrac{1}{2}\,\epsilon^{\mu\nu\rho\sigma}F_{\rho\sigma}, \quad (8.71)$$

where $\widetilde{F}^{\mu\nu}$ is the *dual* field strength and $\epsilon^{\mu\nu\rho\sigma}$ is the Levi-Civita symbol with $\epsilon^{0123} = +1$. (One might also try $\partial_\mu F^{\mu\nu}\,A_\nu$ or $A_\mu\partial^2 A^\mu$, but the first is, after integration by parts, $-\frac{1}{2}F_{\mu\nu}F^{\mu\nu}$ up to a boundary term, and the second is not gauge invariant; gauge-invariant non-redundant two-derivative scalars are

exhausted by (8.71), a point we prove below.) We must dispose of the second invariant on two independent grounds.

First, $F_{\mu\nu}\widetilde{F}^{\mu\nu}$ is *parity odd*. Under spatial reflection the electric field is a polar vector ($\mathbf{E} \to -\mathbf{E}$) while the magnetic field is an axial vector ($\mathbf{B} \to +\mathbf{B}$); we will see momentarily that $F_{\mu\nu}\widetilde{F}^{\mu\nu} \propto \mathbf{E}\cdot\mathbf{B}$, which is therefore a pseudoscalar, odd under parity. Requiring parity invariance excludes it outright.

Second — and this holds even without invoking parity — $F_{\mu\nu}\widetilde{F}^{\mu\nu}$ is a *total derivative* and so contributes nothing to the classical field equations. We verify this explicitly. Using $F_{\rho\sigma} = \partial_\rho A_\sigma - \partial_\sigma A_\rho$,

$$\begin{aligned} F_{\mu\nu}\widetilde{F}^{\mu\nu} &= \tfrac{1}{2}\,\epsilon^{\mu\nu\rho\sigma} F_{\mu\nu}F_{\rho\sigma} = \tfrac{1}{2}\,\epsilon^{\mu\nu\rho\sigma}\,(\partial_\mu A_\nu - \partial_\nu A_\mu)(\partial_\rho A_\sigma - \partial_\sigma A_\rho) \\ &= 2\,\epsilon^{\mu\nu\rho\sigma}\,(\partial_\mu A_\nu)(\partial_\rho A_\sigma), \end{aligned} \tag{8.72}$$

where the four cross terms collapsed to one because $\epsilon^{\mu\nu\rho\sigma}$ is totally antisymmetric: relabelling indices, each of the four products equals $\epsilon^{\mu\nu\rho\sigma}(\partial_\mu A_\nu)(\partial_\rho A_\sigma)$. Now $\epsilon^{\mu\nu\rho\sigma}$ is constant, so we may pull the leading derivative outside,

$$\epsilon^{\mu\nu\rho\sigma}(\partial_\mu A_\nu)(\partial_\rho A_\sigma) = \partial_\mu(\epsilon^{\mu\nu\rho\sigma} A_\nu\,\partial_\rho A_\sigma) - \epsilon^{\mu\nu\rho\sigma} A_\nu\,\partial_\mu\partial_\rho A_\sigma, \tag{8.73}$$

and the last term vanishes identically because $\partial_\mu\partial_\rho A_\sigma$ is symmetric in (μ,ρ) while $\epsilon^{\mu\nu\rho\sigma}$ is antisymmetric in (μ,ρ). Hence

$$F_{\mu\nu}\widetilde{F}^{\mu\nu} = 2\,\partial_\mu(\epsilon^{\mu\nu\rho\sigma} A_\nu\,\partial_\rho A_\sigma) \;\equiv\; \partial_\mu K^\mu, \tag{8.74}$$

a pure four-divergence. Added to the action it contributes only $\int \mathrm{d}^4x\,\partial_\mu K^\mu = \oint_\partial K^\mu\,\mathrm{d}S_\mu$, a boundary term that does not affect the local equations of motion. In the classical abelian theory it is therefore completely inert. It is not, however, meaningless: integrated over Euclidean spacetime it computes a topological invariant (the instanton number) and multiplies a physical parameter θ in the path integral, the θ-term, whose consequences — the strong-CP problem in QCD — are the business of Chapter 41. We flag it here and set it aside.

We are left with a single admissible structure, $F_{\mu\nu}F^{\mu\nu}$. We will fix its normalization below by matching to the canonical kinetic term and the conventional Maxwell equations. First we make the enumeration claim airtight.

Proposition 8.13 (Uniqueness of the Maxwell kinetic term)**.** *Among local Lagrangian densities for an abelian gauge potential A_μ that are (i) Lorentz scalars, (ii) invariant under $A_\mu \to A_\mu + \partial_\mu\alpha$ up to a total derivative, (iii) of at most second order in derivatives, and (iv) parity even, the only one that produces nontrivial dynamics is, up to an overall multiplicative constant and additive total derivatives,*

$$\mathcal{L} = -\tfrac{1}{4}\,F_{\mu\nu}F^{\mu\nu}. \tag{8.75}$$

Proof. We argue directly, not by appeal to the building-block heuristic. A Lagrangian quadratic in A_μ and of second order in derivatives is, up to total

derivatives, a linear combination of the three independent Lorentz scalars

$$\mathcal{T}_1 = (\partial_\mu A_\nu)(\partial^\mu A^\nu), \qquad \mathcal{T}_2 = (\partial_\mu A^\mu)(\partial_\nu A^\nu), \qquad \mathcal{T}_3 = (\partial_\mu A_\nu)(\partial^\nu A^\mu). \tag{8.76}$$

Indeed any two-derivative quadratic scalar contracts two factors of ∂A, and there are exactly three ways to route the four indices into Lorentz-invariant pairs; terms with a $\Box$ acting on one A reduce to these by integration by parts. Moreover $\mathcal{T}_2$ and $\mathcal{T}_3$ are equal up to a total derivative,

$$\mathcal{T}_3 - \mathcal{T}_2 = (\partial_\mu A_\nu)(\partial^\nu A^\mu) - (\partial_\mu A^\mu)(\partial_\nu A^\nu) = \partial_\mu\big[A_\nu \partial^\nu A^\mu - A^\mu \partial_\nu A^\nu\big], \tag{8.77}$$

as one checks by expanding the divergence and using $\partial_\mu \partial^\nu A^\mu = \partial^\nu \partial_\mu A^\mu$. So modulo total derivatives only two structures are independent, say $\mathcal{T}_1$ and $\mathcal{T}_3$, and we write $\mathcal{L} = a\,\mathcal{T}_1 + b\,\mathcal{T}_3$. Impose gauge invariance: under $\delta A_\mu = \partial_\mu \alpha$,

$$\delta\mathcal{T}_1 = 2(\partial_\mu\partial_\nu\alpha)(\partial^\mu A^\nu), \quad \delta\mathcal{T}_3 = 2(\partial_\mu\partial_\nu\alpha)(\partial^\nu A^\mu) = 2(\partial_\mu\partial_\nu\alpha)(\partial^\mu A^\nu), \tag{8.78}$$

where in $\delta\mathcal{T}_3$ we relabelled the dummy indices $\mu \leftrightarrow \nu$ and used the symmetry of $\partial_\mu\partial_\nu\alpha$. Thus $\delta\mathcal{T}_1 = \delta\mathcal{T}_3$, and

$$\delta\mathcal{L} = (a+b)\cdot 2(\partial_\mu\partial_\nu\alpha)(\partial^\mu A^\nu). \tag{8.79}$$

For this to be a total derivative for *arbitrary* α we need $a + b = 0$; otherwise, integrating by parts, $\delta S = -(a+b)\int \mathrm{d}^4x\, 2\,\alpha\,\partial_\mu\partial_\nu\partial^\mu A^\nu + (\text{bdy})$, and the bulk term $\propto \alpha\,\Box\,\partial_\nu A^\nu$ does not vanish for general field configurations. Hence $b = -a$, and

$$\mathcal{L} = a\,(\mathcal{T}_1 - \mathcal{T}_3) = a\big[(\partial_\mu A_\nu)(\partial^\mu A^\nu) - (\partial_\mu A_\nu)(\partial^\nu A^\mu)\big] = \tfrac{a}{2}\,F_{\mu\nu}F^{\mu\nu}, \tag{8.80}$$

the last equality being the identity $F_{\mu\nu}F^{\mu\nu} = 2[(\partial_\mu A_\nu)(\partial^\mu A^\nu) - (\partial_\mu A_\nu)(\partial^\nu A^\mu)]$, verified by expanding $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$. So gauge invariance alone collapses the two-parameter family to a single structure $\propto F^2$. The parity-odd partner $F\widetilde{F}$ is excluded by (iv) and in any case is a total derivative (8.74); no-derivative terms are excluded by gauge invariance (8.69). Choosing the constant $a = -\frac{1}{2}$ gives (8.75). $\square$

The normalization $-\frac{1}{4}$ is the standard one, and its two factors deserve a word, since the chapter's later sign-sensitive results depend on it. Write out $F_{\mu\nu}F^{\mu\nu}$ in terms of fields. With the identifications fixed in Chapter 6 and Appendix A,

$$F^{0i} = -E^i, \qquad F^{ij} = -\epsilon^{ijk}B^k, \tag{8.81}$$

which follow from $\mathbf{E} = -\nabla A^0 - \partial_t \mathbf{A}$ and $\mathbf{B} = \nabla \times \mathbf{A}$, one finds (lowering indices flips the sign of each electric component but not the magnetic ones)

$$F_{\mu\nu}F^{\mu\nu} = 2\big(F_{0i}F^{0i} + \tfrac{1}{2}F_{ij}F^{ij}\big) = 2\big(-\mathbf{E}^2 + \mathbf{B}^2\big), \qquad \text{so} \qquad -\tfrac{1}{4}F_{\mu\nu}F^{\mu\nu} = \tfrac{1}{2}(\mathbf{E}^2 - \mathbf{B}^2). \tag{8.82}$$

The $-\frac{1}{4}$ thus produces the textbook Lagrangian density $\frac{1}{2}(\mathbf{E}^2 - \mathbf{B}^2)$: the sign makes the time-derivative "kinetic" part $\frac{1}{2}\mathbf{E}^2 = \frac{1}{2}\dot{\mathbf{A}}^2 + \cdots$ enter with a positive coefficient, so that the field energy is bounded below, and the overall scale gives the canonically normalized propagating modes (the two photon polarizations counted in Section 8.5.2). For completeness, the same components give the parity-odd invariant

$$F_{\mu\nu}\widetilde{F}^{\mu\nu} = -4\,\mathbf{E}\cdot\mathbf{B}, \tag{8.83}$$

confirming that it is the pseudoscalar $\mathbf{E}\cdot\mathbf{B}$ announced above, and explaining geometrically why it could only ever be a boundary term: $\mathbf{E}\cdot\mathbf{B} = \frac{1}{2}\partial_t(\mathbf{A}\cdot\mathbf{B}) + \cdots$ is a total derivative on shell and, as (8.74) shows, off shell as well.

Notation Watch

The split of the index sum in (8.82) uses $F_{0i}F^{0i} = -(F^{0i})^2 = -\mathbf{E}^2$ and $\frac{1}{2}F_{ij}F^{ij} = \frac{1}{2}(\epsilon^{ijk}B^k)(\epsilon^{ijl}B^l) = \mathbf{B}^2$, where the factor $\frac{1}{2}$ corrects for double-counting the antisymmetric spatial pair (i,j), and $\epsilon^{ijk}\epsilon^{ijl} = 2\delta^{kl}$. The relative sign of $\mathbf{E}^2$ and $\mathbf{B}^2$ is a direct fingerprint of the mostly-minus metric; in the mostly-plus convention $F_{\mu\nu}F^{\mu\nu}$ would carry the opposite overall sign and the Lagrangian would still be $\frac{1}{2}(\mathbf{E}^2 - \mathbf{B}^2)$, but only because the $-\frac{1}{4}$ would be quoted as $+\frac{1}{4}$. We use mostly-minus throughout (Chapter 8 chapter introduction); the combination $-\frac{1}{4}F^2$ is the invariant statement.

8.4.2 Coupling to a source: conservation forced by gauge invariance

A pure-radiation theory is not yet electrodynamics; the field must couple to charges. The simplest Lorentz-invariant, local coupling between the potential A_μ and an external four-current J^μ is the contraction $J^\mu A_\mu$, linear in the potential. We add it to the action with a sign chosen to reproduce the conventional field equations:

$$S[A] = \int \mathrm{d}^4x \,\Big(-\tfrac{1}{4}F_{\mu\nu}F^{\mu\nu} - J^\mu A_\mu \Big). \tag{8.84}$$

Here $J^\mu = (\rho, \mathbf{J})$ collects the charge density and the current density; for the moment it is a prescribed external function of spacetime (the dynamical, matter-field origin of J^μ as the $U(1)$ Noether current of Chapter 7 is identified in Section 8.6, completing QED's classical layer).

The coupling $J^\mu A_\mu$ involves the bare potential, not the gauge-invariant $F_{\mu\nu}$, so it is *not* manifestly gauge invariant, and we must check that it does not spoil the gauge symmetry on which the whole construction rests. Under $A_\mu \to A_\mu + \partial_\mu\alpha$ the field-strength term is untouched (Theorem 8.9), while the source term changes by

$$-\int \mathrm{d}^4x\, J^\mu(A_\mu + \partial_\mu\alpha) = -\int \mathrm{d}^4x\, J^\mu A_\mu \;-\; \int \mathrm{d}^4x\, J^\mu\partial_\mu\alpha. \tag{8.85}$$

Integrate the last term by parts:

$$-\int \mathrm{d}^4x\, J^\mu \partial_\mu \alpha = -\oint_\partial \mathrm{d}S_\mu\, J^\mu \alpha \;+\; \int \mathrm{d}^4x\, (\partial_\mu J^\mu)\, \alpha. \tag{8.86}$$

Assuming, as always, that the gauge parameter α and the current fall off at the boundary so that the surface integral vanishes, the change in the action is

$$\delta S = \int \mathrm{d}^4x\, (\partial_\mu J^\mu)\, \alpha. \tag{8.87}$$

For the action (8.84) to be gauge invariant — so that the gauge redundancy persists in the presence of matter and the field equations remain consistent — this must vanish for *every* gauge function $\alpha(x)$. By the fundamental lemma of the calculus of variations, $\delta S = 0$ for all α if and only if

$$\partial_\mu J^\mu = 0. \tag{8.88}$$

This is a striking inversion of the logic of Chapter 7. There, a continuous symmetry of the action *implied* a conserved current via Noether's first theorem (Theorem 7.10). Here the implication runs the other way: *gauge invariance of the action does not merely permit but requires the source to be a conserved current.* Current conservation is not an extra physical assumption layered on top of electromagnetism; it is the price of admission for coupling matter to a gauge field at all. A non-conserved source is mathematically inconsistent with gauge invariance, and we will see in a moment that it is equally inconsistent with the field equation itself.

Physical Insight

The two facts — Noether's theorem (global symmetry ⇒ conserved current) and the present result (gauge invariance ⇒ conserved source) — are two faces of the same coin, and their meeting point is the gauge principle. A global $U(1)$ symmetry of charged matter gives, by Noether, a conserved current J^μ. Promoting that symmetry to a *local* one forces a gauge field A_μ into existence and couples it precisely to that same J^μ through $-J^\mu A_\mu$. Gauge invariance of the coupling then *re-derives* $\partial_\mu J^\mu = 0$ — now as a consistency condition rather than a Noether output. Symmetry and dynamics are locked together: the same current that the global symmetry conserves is the source that sources the field. This circle of ideas is the structural heart of Chapter 8 and the seed of the Ward–Takahashi identities of Chapter 19, which are its quantum echo.

8.4.3 The inhomogeneous Maxwell equations

We now extract the dynamics. The action (8.84) is varied with respect to the dynamical field A_μ using the field-theoretic Euler–Lagrange equation derived in

Chapter 6, namely (Eq. (6.61))

$$\partial_\alpha\left(\frac{\partial\mathcal{L}}{\partial(\partial_\alpha A_\beta)}\right)-\frac{\partial\mathcal{L}}{\partial A_\beta}=0, \tag{8.89}$$

with β the free index. The decisive computation is $\partial\mathcal{L}/\partial(\partial_\alpha A_\beta)$, and because that is exactly the place where the antisymmetry of F conspires with the $\frac{1}{4}$ to produce a clean result — and exactly where factor-of-two and sign errors breed — we carry it out in full. This computation was previewed in Theorem 6.12; we repeat it here, with the source coupling included from the start, because the resulting field equation (8.95) is the central dynamical statement of this chapter and the gauge-theoretic reading of its source is new.

Worked Example 8.14 (The field equation $\partial_\mu F^{\mu\nu}=J^\nu$ from $\mathcal{L}=-\frac{1}{4}F^2-J\cdot A$)**.** The Lagrangian is $\mathcal{L}=-\frac{1}{4}F_{\mu\nu}F^{\mu\nu}-J^\mu A_\mu$. We compute the two pieces of (8.89) in turn.

Step 1: the undifferentiated derivative. The field A_β appears undifferentiated only in the source term, $-J^\mu A_\mu$, with J^μ an external (field-independent) function. Hence

$$\frac{\partial\mathcal{L}}{\partial A_\beta}=-J^\beta. \tag{8.90}$$

Step 2: open up the kinetic term. Write the kinetic term with all indices explicit and lower them with the metric so that the dependence on $\partial_\alpha A_\beta$ is exposed:

$$-\tfrac{1}{4}F_{\mu\nu}F^{\mu\nu}=-\tfrac{1}{4}\,\eta^{\mu\rho}\eta^{\nu\sigma}\,F_{\mu\nu}F_{\rho\sigma},\qquad F_{\mu\nu}=\partial_\mu A_\nu-\partial_\nu A_\mu. \tag{8.91}$$

We need the derivative of $F_{\mu\nu}$ with respect to the independent variable $\partial_\alpha A_\beta$. Treating each component $\partial_\alpha A_\beta$ as independent,

$$\frac{\partial(\partial_\mu A_\nu)}{\partial(\partial_\alpha A_\beta)}=\delta_\mu{}^\alpha\delta_\nu{}^\beta,\quad\Longrightarrow\quad\frac{\partial F_{\mu\nu}}{\partial(\partial_\alpha A_\beta)}=\delta_\mu{}^\alpha\delta_\nu{}^\beta-\delta_\nu{}^\alpha\delta_\mu{}^\beta, \tag{8.92}$$

the antisymmetrized pair of Kronecker deltas being the signature of the antisymmetry of F in (μ,ν).

Step 3: differentiate and contract. Differentiating the product $F_{\mu\nu}F^{\mu\nu}$ gives two equal contributions (one from each factor), so

$$\begin{aligned}\frac{\partial\mathcal{L}}{\partial(\partial_\alpha A_\beta)}&=-\tfrac{1}{4}\cdot 2\,F^{\mu\nu}\,\frac{\partial F_{\mu\nu}}{\partial(\partial_\alpha A_\beta)}=-\tfrac{1}{2}\,F^{\mu\nu}(\delta_\mu{}^\alpha\delta_\nu{}^\beta-\delta_\nu{}^\alpha\delta_\mu{}^\beta)\\&=-\tfrac{1}{2}(F^{\alpha\beta}-F^{\beta\alpha})=-\tfrac{1}{2}(F^{\alpha\beta}+F^{\alpha\beta})=-F^{\alpha\beta},\end{aligned} \tag{8.93}$$

where the second line contracted the deltas against $F^{\mu\nu}$ and the last step used the antisymmetry $F^{\beta\alpha}=-F^{\alpha\beta}$. The factor $\frac{1}{2}$ and the two terms of the antisymmetrization conspire exactly: the result is the clean $-F^{\alpha\beta}$.

Step 4: assemble. Insert (8.93) and (8.90) into the Euler–Lagrange equation (8.89):

$$\partial_\alpha\big(-F^{\alpha\beta}\big)-\big(-J^\beta\big)=0 \quad\Longrightarrow\quad \partial_\alpha F^{\alpha\beta}=J^\beta. \tag{8.94}$$

Renaming the free index $\beta\to\nu$ and the dummy $\alpha\to\mu$, we obtain the inhomogeneous Maxwell equations,

$$\boxed{\partial_\mu F^{\mu\nu}=J^\nu}. \tag{8.95}$$

The field equation (8.95) carries the conservation law (8.88) inside it, and this is the second, independent route to current conservation promised above. Contract (8.95) with ∂_ν:

$$\partial_\nu J^\nu=\partial_\nu\partial_\mu F^{\mu\nu}=0, \tag{8.96}$$

which vanishes identically because $\partial_\nu\partial_\mu$ is symmetric under $\mu\leftrightarrow\nu$ while $F^{\mu\nu}$ is antisymmetric, so their full contraction is zero before any equation of motion is imposed. Thus the field equation is consistent *only* for a conserved current — and we have now seen $\partial_\mu J^\mu=0$ emerge twice, once from gauge invariance of the action (8.88) and once from the structure of the field equation (8.96). The two are the same statement viewed from the action and from its extremum, which is exactly as it must be.

8.4.4 The homogeneous equations from the Bianchi identity

Equation (8.95) is only half of Maxwell's system: it is the pair $\nabla\cdot\mathbf{E}=\rho$ and $\nabla\times\mathbf{B}-\partial_t\mathbf{E}=\mathbf{J}$, as we verify component by component below. The other half — $\nabla\cdot\mathbf{B}=0$ and $\nabla\times\mathbf{E}+\partial_t\mathbf{B}=0$ — are not equations of motion and do not come from the action at all. They are the off-shell identity satisfied by any field strength that is the curvature of a potential, the Bianchi identity established in the previous section (Eq. (8.47)),

$$\partial_\lambda F_{\mu\nu}+\partial_\mu F_{\nu\lambda}+\partial_\nu F_{\lambda\mu}=0. \tag{8.97}$$

This holds identically once $F=\mathrm{d}A$, independently of any Lagrangian, which is why the homogeneous Maxwell equations are sometimes said to be "kinematic" rather than dynamical. The identity (8.97) is equivalent to the compact dual form

$$\partial_\mu\widetilde{F}^{\mu\nu}=0, \qquad \widetilde{F}^{\mu\nu}=\tfrac{1}{2}\epsilon^{\mu\nu\rho\sigma}F_{\rho\sigma}, \tag{8.98}$$

the equivalence being immediate: $\partial_\mu\widetilde{F}^{\mu\nu}=\frac{1}{2}\epsilon^{\mu\nu\rho\sigma}\partial_\mu F_{\rho\sigma}$, and the totally antisymmetric contraction of ϵ with $\partial_\mu F_{\rho\sigma}$ reproduces, up to a numerical factor, the cyclic sum in (8.97). The striking near-symmetry between $\partial_\mu F^{\mu\nu}=J^\nu$ and $\partial_\mu\widetilde{F}^{\mu\nu}=0$ is the statement that, in the absence of magnetic monopoles, the magnetic "current" on the right of the dual equation is zero; the deep reason is geometric (F is a curvature, hence closed as a two-form), and it is the cleanest preview of the holonomy/bundle viewpoint set up in the previous section.

8.4.5 Recovering the four three-vector Maxwell equations

We now make the contact with the familiar Maxwell equations completely explicit, translating the two covariant statements (8.95) and (8.98) into the four three-vector equations of Gauss, Ampère–Maxwell, no-monopoles, and Faraday. The dictionary is (8.81), which we record once more together with the lowered-index and dual components needed below. From $F^{0i} = -E^i$ and $F^{ij} = -\epsilon^{ijk}B^k$, lowering indices with $\eta = \mathrm{diag}(+,-,-,-)$ gives

$$F_{0i} = +E^i, \qquad F_{ij} = -\epsilon^{ijk}B^k, \tag{8.99}$$

and a short computation with $\epsilon^{0123} = +1$ (carried out in Theorem 8.15 below) gives the dual components

$$\widetilde{F}^{0i} = -B^i, \qquad \widetilde{F}^{ij} = \epsilon^{ijk}E^k. \tag{8.100}$$

It is convenient to display $F^{\mu\nu}$ as an explicit matrix; the rows and columns run $\mu,\nu = 0,1,2,3$:

$$F^{\mu\nu} = \begin{pmatrix} 0 & -E^1 & -E^2 & -E^3 \\ E^1 & 0 & -B^3 & B^2 \\ E^2 & B^3 & 0 & -B^1 \\ E^3 & -B^2 & B^1 & 0 \end{pmatrix}, \tag{8.101}$$

where the lower block uses $F^{12} = -\epsilon^{123}B^3 = -B^3$ and cyclically, and $F^{i0} = -F^{0i} = E^i$. With these in hand the reduction is mechanical.

Worked Example 8.15 (The four Maxwell equations, component by component)**.** We take the four covariant components of (8.95) and (8.98) in turn, with $J^\mu = (\rho, \mathbf{J})$.

(1) Gauss's law (the $\nu = 0$ inhomogeneous equation). Set $\nu = 0$ in $\partial_\mu F^{\mu 0} = J^0$. Since $F^{00} = 0$, only spatial $\mu = i$ contributes:

$$\partial_i F^{i0} = J^0 \implies \partial_i E^i = \rho \implies \nabla\cdot\mathbf{E} = \rho, \tag{8.102}$$

using $F^{i0} = E^i$ from (8.101) and $J^0 = \rho$. This is Gauss's law.

(2) Ampère–Maxwell law (the $\nu = j$ inhomogeneous equation). Set $\nu = j$ in $\partial_\mu F^{\mu j} = J^j$, splitting the sum into $\mu = 0$ and $\mu = i$:

$$\partial_0 F^{0j} + \partial_i F^{ij} = J^j. \tag{8.103}$$

The first term is $\partial_0 F^{0j} = -\partial_t E^j$ (using $F^{0j} = -E^j$). For the second, $F^{ij} = -\epsilon^{ijk}B^k$, so

$$\partial_i F^{ij} = -\epsilon^{ijk}\partial_i B^k = +\epsilon^{jik}\partial_i B^k = (\nabla\times\mathbf{B})^j, \tag{8.104}$$

where the sign flip used $\epsilon^{ijk} = -\epsilon^{jik}$ and the last equality is the definition $(\nabla\times\mathbf{B})^j = \epsilon^{jik}\partial_i B^k$. Assembling,

$$-\partial_t E^j + (\nabla\times\mathbf{B})^j = J^j \implies \nabla\times\mathbf{B} - \partial_t\mathbf{E} = \mathbf{J}, \tag{8.105}$$

the Ampère–Maxwell law, complete with Maxwell's displacement current $-\partial_t \mathbf{E}$.

(3) No magnetic monopoles (the $\nu = 0$ homogeneous equation). First we establish the dual components (8.100). From $\widetilde{F}^{0i} = \frac{1}{2}\epsilon^{0ijk}F_{jk} = \frac{1}{2}\epsilon^{ijk}F_{jk}$ (the spatial Levi-Civita symbol), and $F_{jk} = -\epsilon^{jkl}B^l$,

$$\widetilde{F}^{0i} = \tfrac{1}{2}\epsilon^{ijk}(-\epsilon^{jkl}B^l) = -\tfrac{1}{2}\,\epsilon^{ijk}\epsilon^{ljk}\,B^l = -\tfrac{1}{2}\cdot 2\delta^{il}\,B^l = -B^i, \tag{8.106}$$

using $\epsilon^{ijk}\epsilon^{ljk} = 2\delta^{il}$. Now set $\nu = 0$ in $\partial_\mu \widetilde{F}^{\mu 0} = 0$; since $\widetilde{F}^{00} = 0$, only $\mu = i$ survives, and $\widetilde{F}^{i0} = -\widetilde{F}^{0i} = B^i$:

$$\partial_i \widetilde{F}^{i0} = 0 \implies \partial_i B^i = 0 \implies \nabla \cdot \mathbf{B} = 0, \tag{8.107}$$

the statement that there are no magnetic monopoles.

(4) Faraday's law (the $\nu = j$ homogeneous equation). We need $\widetilde{F}^{ij} = \frac{1}{2}\epsilon^{ij\rho\sigma}F_{\rho\sigma}$; the nonzero contributions have one temporal and one spatial index, giving $\widetilde{F}^{ij} = \epsilon^{ij0k}F_{0k} = \epsilon^{ijk}F_{0k} = \epsilon^{ijk}E^k$ (here $\epsilon^{ij0k} = \epsilon^{0ijk} = \epsilon^{ijk}$ after moving the 0 to the front through two transpositions, and $F_{0k} = E^k$ from (8.99)). Set $\nu = j$ in $\partial_\mu \widetilde{F}^{\mu j} = 0$:

$$\partial_0 \widetilde{F}^{0j} + \partial_i \widetilde{F}^{ij} = 0. \tag{8.108}$$

The first term is $\partial_0 \widetilde{F}^{0j} = -\partial_t B^j$. The second is

$$\partial_i \widetilde{F}^{ij} = \epsilon^{ijk}\partial_i E^k = -\epsilon^{jik}\partial_i E^k = -(\nabla \times \mathbf{E})^j. \tag{8.109}$$

Together,

$$-\partial_t B^j - (\nabla \times \mathbf{E})^j = 0 \implies \nabla \times \mathbf{E} + \partial_t \mathbf{B} = 0, \tag{8.110}$$

Faraday's law of induction. The four three-vector Maxwell equations are recovered in full.

The accounting is worth pausing on. Two of Maxwell's equations — Gauss and Ampère–Maxwell — are *dynamical*: they are the Euler–Lagrange equations of the action (8.84), they involve the source J^μ, and they would be different for a different Lagrangian. The other two — no-monopoles and Faraday — are *kinematic*: they hold identically for any F derived from a potential, are sourceless, and follow from the Bianchi identity (8.98) without reference to the action. This clean split is invisible in the three-vector formulation, where all four equations sit on an equal footing; it is one of the things the covariant, gauge-theoretic formulation makes manifest. It also explains, retroactively, why electromagnetism is naturally written in terms of a potential A_μ rather than the fields $\mathbf{E}, \mathbf{B}$ directly: introducing A_μ solves the homogeneous pair automatically, leaving only the inhomogeneous pair as genuine dynamics.

Historical Note

That two of the four equations are identities of the potential, and only two are dynamical, was not clear to Maxwell, who worked with the fields and the vector potential on a roughly equal footing and regarded all of his equations as physical laws. The recognition that the potential is the more fundamental object — forced on physics first by the Aharonov–Bohm effect (Chapter 8 closing sections) and then decisively by the gauge principle — is a twentieth-century reframing. The covariant tensor form (8.95), with its automatic conservation law (8.96), is due to Minkowski (1908), who first wrote electromagnetism as a single antisymmetric tensor equation in spacetime.

8.4.6 The Maxwell sector of classical QED

With (8.75) established we have, for the first time in the book, the gauge field's own dynamics in hand, and we can record the contribution this section makes to QED. The classical QED Lagrangian, the carried model of QED, is

$$\mathcal{L}_{\text{QED}} = \bar{\psi}\,(i\not{D} - m)\,\psi \;-\; \tfrac{1}{4}F_{\mu\nu}F^{\mu\nu}, \qquad D_\mu = \partial_\mu + ieA_\mu, \tag{8.111}$$

and the present section has built the second term and shown it to be the unique gauge-invariant, Lorentz-invariant, parity-even, two-derivative kinetic term for the photon. The matter sector $\bar{\psi}(i\not{D} - m)\psi$ and the identification of the source $J^\mu = -e\bar{\psi}\gamma^\mu\psi$ as the electron's $U(1)$ Noether current — so that varying (8.111) with respect to A_μ returns exactly $\partial_\mu F^{\mu\nu} = J^\nu$ with this J^ν — is the work of Section 8.6. There the conservation law (8.88) that gauge invariance demanded of the source will be seen to be guaranteed automatically, because J^μ is the Noether current of the very symmetry that was gauged. The circle closes: the global $U(1)$ symmetry of Chapters 6 and 7 produces a conserved current; gauging it produces the photon and couples it to that current; and the photon's own dynamics is the Maxwell Lagrangian derived here.

We have constructed the unique gauge-invariant action for the electromagnetic field, derived all of Maxwell's equations from it, and seen current conservation forced by gauge symmetry. But the very gauge freedom that selected this action has not gone away: distinct potentials A_μ and $A_\mu + \partial_\mu\alpha$ yield the same fields and the same physics, so the field equations cannot determine A_μ uniquely from initial data — the Euler–Lagrange operator $\partial_\mu F^{\mu\nu}$ has $\partial^\nu\alpha$ in its kernel. The next section confronts this redundancy head-on: it fixes the gauge in the standard ways, exposes what is left after the redundancy is removed, and counts the two genuine physical polarizations of the photon, planting the seed of the quantization subtlety that Chapters 13 and 26 will discharge.

8.5 Gauge Redundancy, Gauge Fixing, and Physical Degrees of Freedom

The previous section closed with the inhomogeneous field equations $\partial_\mu F^{\mu\nu} = J^\nu$ (Eq. (8.95)) and a result that, read carefully, is more unsettling than it first appears: the dynamics depends on the potential A_μ *only* through the field strength $F_{\mu\nu}$ (Theorem 8.9). Two potentials that differ by the gradient of a scalar produce the same $F_{\mu\nu}$, hence the same equations of motion, the same forces, the same everything measurable. The theory therefore does not determine A_μ; it determines at most an equivalence class of A_μ's. This is not a defect to be patched but the central structural feature of the field, and learning to live with it — to count what is real, to remove what is not, and to do so without spoiling the symmetries we prize — is the business of this section. The redundancy we expose here is the classical shadow of the difficulty that will dominate the quantization of the photon in Chapter 13 and of non-abelian gauge fields in Chapter 26; getting the classical bookkeeping exactly right now is what makes those later chapters tractable.

We carry the conventions fixed for the chapter: mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units, $A^\mu = (\phi, \mathbf{A})$ with $A_\mu = (\phi, -\mathbf{A})$, field strength $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$, and the Maxwell Lagrangian with a conserved external source,

$$\mathcal{L} = -\tfrac{1}{4} F_{\mu\nu}F^{\mu\nu} - J_\mu A^\mu, \tag{8.112}$$

recalled from Eq. (8.75), whose Euler–Lagrange equation is Eq. (8.95). The electric and magnetic fields are $E^i = F^{i0}$ and $B^i = -\tfrac{1}{2}\epsilon^{ijk}F_{jk}$, so that $\mathbf{E} = -\nabla\phi - \partial_t \mathbf{A}$ and $\mathbf{B} = \nabla \times \mathbf{A}$.

8.5.1 Gauge redundancy: the configuration space is a quotient

We begin by naming the transformation precisely and stating exactly what it does and does not change.

Definition 8.16 (Gauge transformation)**.** Let $\alpha : \mathbb{R}^{1,3} \to \mathbb{R}$ be a smooth function on spacetime. The associated *gauge transformation* of the electromagnetic potential is

$$A_\mu(x) \;\longmapsto\; A^{(\alpha)}_\mu(x) = A_\mu(x) + \partial_\mu \alpha(x). \tag{8.113}$$

Two potentials are said to be *gauge equivalent* if they are related by Eq. (8.113) for some α; the set of all potentials gauge equivalent to a given A_μ is its *gauge orbit*.

Three facts make this an equivalence relation and a redundancy of the description rather than a physical operation. They are elementary, but stating them is what licenses every later manipulation.

Proposition 8.17 (Gauge redundancy)**.** *The map Eq. (8.113) has the following properties.*

(i) It leaves the field strength invariant: $F^{(\alpha)}_{\mu\nu} = F_{\mu\nu}$ *for every* α*.*

(ii) It is an equivalence relation: *gauge equivalence is reflexive, symmetric, and transitive, so the space of potentials is partitioned into disjoint gauge orbits.*

(iii) It leaves the physics invariant: A_μ *and* $A^{(\alpha)}_\mu$ *solve Eq. (8.95) for the same source* J^ν*, produce the same* $\mathbf{E}, \mathbf{B}$*, and (when matter is coupled minimally, as in the next section) the same equations of motion for the matter, provided the source is conserved,* $\partial_\nu J^\nu = 0$*.*

Proof. (i) Substituting Eq. (8.113) into the field strength,

$$F^{(\alpha)}_{\mu\nu} = \partial_\mu(A_\nu + \partial_\nu\alpha) - \partial_\nu(A_\mu + \partial_\mu\alpha) = F_{\mu\nu} + (\partial_\mu\partial_\nu - \partial_\nu\partial_\mu)\alpha = F_{\mu\nu}, \quad (8.114)$$

the added term vanishing because partial derivatives commute on the smooth function α. This is the same cancellation already recorded in Theorem 8.9; we repeat it because it is the engine of everything below.

(ii) Reflexivity is $\alpha = 0$. Symmetry follows because the inverse of Eq. (8.113) is the gauge transformation with parameter $-\alpha$: if $A' = A + \partial\alpha$ then $A = A' + \partial(-\alpha)$. Transitivity follows because the composition of two gauge transformations is a third: $(A + \partial\alpha) + \partial\beta = A + \partial(\alpha + \beta)$. The parameters thus form an abelian group under addition — the abelian character of U(1) electromagnetism — and the orbits, as equivalence classes, are disjoint and cover the whole space of potentials.

(iii) Since the field equation Eq. (8.95) is written entirely in terms of $F_{\mu\nu}$, and $F_{\mu\nu}$ is unchanged by (i), any solution remains a solution. Equivalently, at the level of the action: under Eq. (8.113) the kinetic term $-\frac{1}{4}F_{\mu\nu}F^{\mu\nu}$ is strictly invariant by (i), while the source term changes by

$$-J_\mu A^{(\alpha)\,\mu} = -J_\mu A^\mu - J_\mu\partial^\mu\alpha = -J_\mu A^\mu - \partial^\mu(J_\mu\alpha) + (\partial^\mu J_\mu)\,\alpha. \quad (8.115)$$

The middle term is a total divergence, integrating to a boundary contribution that does not affect the equations of motion; the last term vanishes by current conservation $\partial_\mu J^\mu = 0$. Hence the action changes at most by a boundary term, $S[A^{(\alpha)}] = S[A] + \oint \mathrm{d}\Sigma_\mu(-J^\mu\alpha)$, and the dynamics is untouched. The measurable fields $\mathbf{E}, \mathbf{B}$ are components of $F_{\mu\nu}$ and so are invariant by (i). □

Equation (8.115) repays a moment's attention: gauge invariance of the matter-coupled action is *equivalent* to conservation of the source. We derived current conservation from gauge invariance in the previous section; Eq. (8.115) is the same coin viewed from the other face — if J^μ were not conserved, Eq. (8.113) would change the physics, and the would-be gauge symmetry would be illusory. The two statements are locked together, and this lock is the classical seed of the Ward–Takahashi identities of the quantum theory.

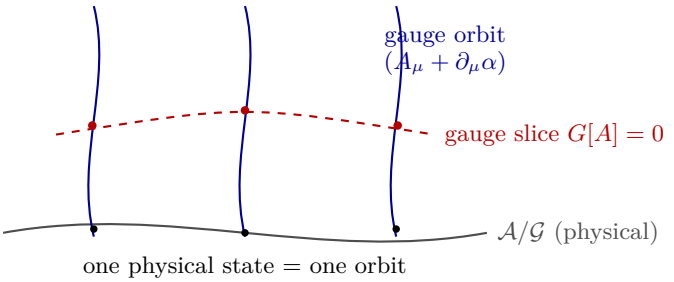

Figure 8.4: The configuration space of electromagnetism as a quotient. Vertical fibers are gauge orbits (all A_μ related by Eq. (8.113)); each projects to a single physical configuration in the base $\mathcal{A}/\mathcal{G}$. A gauge condition $G[A] = 0$ is a slice (dashed) chosen to meet each orbit exactly once, selecting one representative per physical state. *Reachability* of the gauge is the statement that the slice meets every orbit; *residual freedom* is the statement that it meets some orbits more than once.

Physical Insight

The lesson of Theorem 8.17 is geometric. The true arena of electromagnetism is not the space $\mathcal{A}$ of potentials but the quotient $\mathcal{A}/\mathcal{G}$ by the group $\mathcal{G}$ of gauge transformations — the space of *orbits*. Physical configurations are points of this quotient; a single potential A_μ is a particular, arbitrary representative of a point, like a particular set of coordinates on a manifold. Every physical quantity is a function on the quotient, i.e. a gauge-invariant functional of A_μ. The redundancy is the price of describing this quotient with the linearly-transforming, manifestly Lorentz-covariant object A_μ rather than with the gauge-invariant but cumbersome $F_{\mu\nu}$ (which carries its own redundancy through the Bianchi identity and cannot be coupled minimally to charged matter). Holding a covariant description and a clean count of physical data at the same time is exactly the tension that gauge fixing manages.

8.5.2 Counting the physical degrees of freedom

The potential A_μ has four components per spacetime point, but Theorem 8.17 shows that not all four are physical. We now make the count precise. The naive bookkeeping is

$$\underbrace{4}_{\text{components of } A_\mu} - \underbrace{1}_{\text{gauge freedom}} - \underbrace{1}_{\text{non-dynamical } A_0 \,/\, \text{Gauss constraint}} = \underbrace{2}_{\text{physical polarizations}}, \tag{8.116}$$

and the rest of this subsection earns each subtraction. The first is immediate: Eq. (8.113) lets us adjust one function $\alpha(x)$ freely, so one combination of the four components carries no information. The second subtraction is subtler and deserves a full argument, because it is where the constrained, non-propagating nature of A_0 enters — and that is precisely the feature that complicates canonical quantization in Chapter 13.

A_0 is non-dynamical. A field component is *dynamical* only if the Lagrangian contains its time derivative, for only then does it carry a canonical momentum and an evolution equation second-order in time. Examine the time derivatives in Eq. (8.112). The kinetic term is built from $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$, whose components split into

$$F_{0i} = \partial_0 A_i - \partial_i A_0, \qquad F_{ij} = \partial_i A_j - \partial_j A_i, \tag{8.117}$$

with $F_{00} \equiv 0$ by antisymmetry. Time derivatives appear *only* in F_{0i}, and there only as $\partial_0 A_i$ — the time derivative of the *spatial* components. The time derivative $\partial_0 A_0$ never occurs anywhere, because the would-be carrier F_{00} vanishes identically. Concretely, the canonical momentum conjugate to A_μ is

$$\pi^\mu \equiv \frac{\partial \mathcal{L}}{\partial(\partial_0 A_\mu)} = -F^{0\mu}, \tag{8.118}$$

as one reads off by differentiating $-\frac{1}{4}F_{\alpha\beta}F^{\alpha\beta}$ (the source term has no field-derivatives). Its time component is a *primary constraint*,

$$\pi^0 = -F^{00} = 0, \tag{8.119}$$

holding identically and not as an equation of motion. The spatial components are the physical electric field, $\pi^i = -F^{0i} = F^{i0} = E^i$. Thus A_0 has vanishing conjugate momentum: it is not a dynamical variable but a Lagrange multiplier.

Proposition 8.18 (The $\nu = 0$ Maxwell equation is the Gauss-law constraint)**.** *The time component ($\nu = 0$) of the field equation Eq. (8.95) contains no second time derivative of any field and is therefore a constraint on initial data rather than an evolution equation. Explicitly it reads*

$$\nabla\cdot\mathbf{E} = J^0 = \rho, \tag{8.120}$$

Gauss's law, which determines (the non-dynamical) A_0 in terms of the instantaneous configuration of the dynamical fields and the charge density.

Proof. Set $\nu = 0$ in $\partial_\mu F^{\mu 0} = J^0$. Since $F^{00} = 0$, the $\mu = 0$ term drops and only the spatial divergence survives,

$$\partial_\mu F^{\mu 0} = \partial_i F^{i0} = \partial_i E^i = \nabla\cdot\mathbf{E} = J^0. \tag{8.121}$$

No ∂_0^2 appears: the highest time derivative present is the single one inside $E^i = F^{i0} = -\partial_i A^0 - \partial_0 A^i$, namely $\partial_0 A^i$, which enters Eq. (8.120) as a *first* time derivative. A relation among the fields and their first time derivatives at a single instant, with no second time derivative to integrate forward, is a constraint on the Cauchy data, not a law of evolution. The other three equations ($\nu = i$) do contain $\partial_0^2 A^i$ and are the genuine evolution equations for the dynamical A^i. □

The two subtractions in Eq. (8.116) are now justified, and it is worth seeing them once more in the cleaner phase-space language, because that is the form the quantization chapters use. The phase space carries the eight functions (A_μ, π^μ). The primary constraint Eq. (8.119), $\pi^0 \approx 0$, and the secondary (Gauss) constraint Eq. (8.120), $\partial_i \pi^i - \rho \approx 0$ — which arises by demanding that $\pi^0 \approx 0$ be preserved in time — are two *first-class* constraints (their Poisson bracket vanishes, reflecting the abelian gauge group). A standard result of constrained Hamiltonian dynamics is that each first-class constraint removes two phase-space functions: one because the constraint surface is lower-dimensional, one because it generates a gauge transformation along which physics is constant. Two first-class constraints thus remove $2 \times 2 = 4$ of the eight phase-space functions, leaving $8 - 4 = 4$ physical phase-space functions, i.e. $4/2 = 2$ configuration-space degrees of freedom per point — the same two as Eq. (8.116). The configuration-space heuristic and the phase-space count agree, and both deliver the answer we will confirm explicitly with plane waves below: *the electromagnetic field has two physical, transverse polarizations.*

Caution

The count "$4 - 1 - 1 = 2$" is not "4 minus 2 arbitrary subtractions." The two subtracted units are physically distinct and are removed by distinct mechanisms. One unit is pure redundancy — the gauge function α — and is removed by a *choice* (gauge fixing). The other is a genuine equation, Gauss's law, that the data must satisfy; it is removed by a *constraint*, not a choice. Conflating them is the source of much confusion in canonical quantization, where the gauge must be fixed (a choice) *and* the Gauss constraint imposed (a law) before the physical Hilbert space is correctly identified — the subject of Chapter 13.

8.5.3 Lorenz gauge: covariant fixing

Gauge fixing means choosing, for each orbit, a single representative — a slice through the orbits, as in Fig. 8.4. A good gauge condition must be (a) *reachable*: every orbit contains at least one representative obeying it; and ideally (b) *complete*: it picks exactly one. We treat in turn the gauge that keeps Lorentz covariance manifest and the gauge that keeps the physical content manifest, signposting the

trade-off that the quantization chapters inherit.

Definition 8.19 (Lorenz gauge)**.** A potential is said to be in *Lorenz gauge* if it satisfies the Lorentz-invariant condition

$$\partial_\mu A^\mu = 0. \tag{8.122}$$

Because the left side $\partial_\mu A^\mu$ is a Lorentz scalar, the condition Eq. (8.122) has the same form in every inertial frame: a potential that is in Lorenz gauge for one observer is in Lorenz gauge for all. This is the property that makes the gauge indispensable for relativistic calculations, and it is exactly the property the alternatives below surrender.

Proposition 8.20 (Lorenz gauge is reachable, and reduces Maxwell to the wave equation)**.** *Given any potential A_μ, there exists a gauge transformation Eq. (8.113) bringing it into Lorenz gauge. In that gauge the field equation Eq. (8.95) becomes the inhomogeneous wave equation*

$$\Box A^\nu = J^\nu, \qquad \Box \equiv \partial_\mu \partial^\mu = \partial_t^2 - \nabla^2. \tag{8.123}$$

Proof. Let A_μ be arbitrary, with $\partial_\mu A^\mu = f(x)$ some function not necessarily zero. Seek α so that the transformed potential $A_\mu^{(\alpha)} = A_\mu + \partial_\mu \alpha$ is in Lorenz gauge:

$$0 \overset{!}{=} \partial_\mu A^{(\alpha)\,\mu} = \partial_\mu A^\mu + \partial_\mu \partial^\mu \alpha = f + \Box \alpha. \tag{8.124}$$

This requires α to solve the inhomogeneous wave equation $\Box \alpha = -f$. The d'Alembertian $\Box$ admits a Green's function — the retarded propagator constructed in Chapter 5 — so a solution exists for any (suitably decaying) source f:

$$\alpha(x) = -\int \mathrm{d}^4 y \; G_{\mathrm{ret}}(x-y)\, f(y), \qquad \Box_x G_{\mathrm{ret}}(x-y) = \delta^{(4)}(x-y). \tag{8.125}$$

Hence Lorenz gauge is reachable from any starting potential. Once Eq. (8.122) holds, expand the field equation. Writing $F^{\mu\nu} = \partial^\mu A^\nu - \partial^\nu A^\mu$,

$$\partial_\mu F^{\mu\nu} = \partial_\mu \partial^\mu A^\nu - \partial^\nu (\partial_\mu A^\mu) = \Box A^\nu - \partial^\nu (\partial_\mu A^\mu). \tag{8.126}$$

The second term is $-\partial^\nu(\partial_\mu A^\mu) = 0$ in Lorenz gauge, and $\partial_\mu F^{\mu\nu} = J^\nu$ collapses to Eq. (8.123). □

What Theorem 8.20 buys is decisive: in Lorenz gauge each of the four components of A^ν obeys an independent, manifestly covariant wave equation sourced by the corresponding component of the conserved current. The price — visible already in Eq. (8.116) — is that four components obey a two-degree-of-freedom theory, so Lorenz gauge cannot be complete. There must be leftover gauge freedom. There is, and identifying it precisely is what allows the explicit polarization count.

Proposition 8.21 (Residual gauge freedom in Lorenz gauge)**.** *The Lorenz condition Eq. (8.122) does not fix the gauge completely. A further gauge transformation $A_\mu \mapsto A_\mu + \partial_\mu \alpha$ preserves Lorenz gauge if and only if the parameter is a solution of the homogeneous wave equation,*

$$\Box \alpha = 0. \tag{8.127}$$

The space of such α is infinite-dimensional, so a one-function residual freedom remains.

Proof. Suppose A_μ already satisfies $\partial_\mu A^\mu = 0$. After a further transformation with parameter α, the new divergence is $\partial_\mu(A^\mu + \partial^\mu \alpha) = 0 + \Box\alpha$. This vanishes — keeping us in Lorenz gauge — precisely when $\Box\alpha = 0$. The homogeneous wave equation has a vast solution space (every superposition of null plane waves $e^{-ik\cdot x}$ with $k^2 = 0$ solves it), so the residual freedom is genuine and infinite-dimensional, exactly one undetermined function's worth, matching the one excess unit that Eq. (8.116) says must still be removable after Lorenz fixing. □

8.5.4 Coulomb, temporal, and axial gauges: the trade-off

Lorenz gauge keeps covariance manifest at the cost of carrying unphysical components (the timelike and longitudinal photons of Chapter 13). The opposite philosophy fixes the gauge so that only physical degrees of freedom remain, at the cost of manifest covariance. The cleanest such choice is the Coulomb gauge.

Definition 8.22 (Coulomb gauge)**.** A potential is in *Coulomb* (or *radiation*, or *transverse*) gauge if its spatial part is divergence-free,

$$\nabla\cdot\mathbf{A} = \partial_i A^i = 0. \tag{8.128}$$

The reachability argument parallels Theorem 8.20 but uses the Poisson rather than the wave operator, which is the technical signature of the lost covariance. Given A_μ with $\nabla\cdot\mathbf{A} = g(x)$, a gauge transformation shifts $\mathbf{A} \mapsto \mathbf{A} + \nabla\alpha$ (since $A_i^{(\alpha)} = A_i + \partial_i\alpha$ and $A^i = -A_i$), so

$$\nabla\cdot\mathbf{A}^{(\alpha)} = \nabla\cdot\mathbf{A} + \nabla^2\alpha = g + \nabla^2\alpha \overset{!}{=} 0 \implies \nabla^2\alpha = -g, \tag{8.129}$$

a Poisson equation solved at each instant by $\alpha(t,\mathbf{x}) = \frac{1}{4\pi}\int \mathrm{d}^3y\, g(t,\mathbf{y})/|\mathbf{x}-\mathbf{y}|$. Coulomb gauge is thus reachable. The residual freedom is the set of α with $\nabla^2\alpha = 0$ at each time, i.e. spatially harmonic functions; with the physical boundary condition that fields vanish at spatial infinity these are at most spatially constant, so Coulomb gauge is essentially complete (only a global, physically inert constant survives). The structural payoff appears in Gauss's law: Eq. (8.120) becomes

$$\nabla\cdot\mathbf{E} = -\nabla^2 A^0 - \partial_0(\nabla\cdot\mathbf{A}) = -\nabla^2 A^0 = \rho \implies \nabla^2\phi = -\rho, \tag{8.130}$$

using Eq. (8.128) to kill the second term. The scalar potential $\phi = A^0$ is therefore not an independent field at all but the *instantaneous* Coulomb potential of the charge distribution, $\phi(t,\mathbf{x}) = \frac{1}{4\pi}\int \mathrm{d}^3y\, \rho(t,\mathbf{y})/|\mathbf{x}-\mathbf{y}|$ — hence the name. Both non-physical components (A^0 and the longitudinal part of $\mathbf{A}$) are eliminated explicitly, leaving the two transverse components of $\mathbf{A}$ as the only dynamical fields. Manifest unitarity (only physical, positive-norm degrees survive) is bought by sacrificing manifest covariance: Eq. (8.130) is an instantaneous, frame-dependent relation, and a Lorentz boost takes one out of Coulomb gauge.

Notation Watch

The condition $\partial_\mu A^\mu = 0$ is the *Lorenz* gauge, named for the Danish physicist Ludvig Lorenz, and is *not* the Lorentz (Hendrik Lorentz) transformation, despite the near-homograph and the fact that the gauge happens to be Lorentz-invariant. We follow the now-standard spelling "Lorenz gauge" throughout. "Coulomb," "radiation," and "transverse" gauge all denote the same condition Eq. (8.128).

Two further gauges round out the standard toolkit; we state them and their use, since they recur in Chapter 13 and Chapter 26.

Temporal gauge $A^0 = 0$ uses the gauge function $\alpha(t,\mathbf{x}) = -\int_0^t A^0(t',\mathbf{x})\,\mathrm{d}t'$ to set the scalar potential to zero; it is reachable but leaves a large residual freedom (any time-independent $\alpha(\mathbf{x})$), so it must be supplemented by imposing Gauss's law by hand on the initial data. It is convenient in canonical and lattice formulations because it removes the constrained variable outright. *Axial gauge* $n_\mu A^\mu = 0$ for a fixed reference four-vector n_μ (light-cone gauge when $n^2 = 0$) likewise eliminates one component algebraically; it is prized in perturbative gauge theory because the unphysical polarizations decouple without ghosts, at the cost of a frame-dependent, n-dependent propagator. The common thread is the trade governing every gauge choice:

> *a gauge that keeps Lorentz covariance manifest (Lorenz, axial-covariant) retains unphysical components whose unphysical nature must be enforced separately; a gauge that keeps only physical components (Coulomb, temporal) breaks manifest covariance.*

No gauge does both. This irreducible tension is benign classically — one simply picks the convenient gauge for the problem at hand — but becomes the defining difficulty of quantizing the photon, where covariance is needed to keep calculations tractable yet a positive-norm Hilbert space is needed for probabilities to make sense. The resolution, the Gupta–Bleuler construction and its modern descendant the BRST cohomology, is the business of Chapter 13 and Chapter 26; the present section's job is to have made the problem precise.

8.5.5 Plane waves and the two physical polarizations

We now make the abstract count of Eq. (8.116) completely explicit by solving the free field equations and exhibiting the two physical polarization vectors. This is the classical photon, and the polarization vectors constructed here are exactly those that will be promoted to creation operators in Chapter 13.

Worked Example 8.23 (The free plane wave and its two transverse polarizations)**.** We solve the source-free Maxwell equations in Lorenz gauge, impose the gauge and residual conditions, and read off the physical polarizations.

Step 1: the wave equation and the dispersion relation. With $J^\nu = 0$, Theorem 8.20 reduces Maxwell's equations in Lorenz gauge to $\Box A^\nu = 0$ together with $\partial_\mu A^\mu = 0$. Following the Fourier methods of Chapter 5, seek a complex plane-wave solution (the physical field is its real part),

$$A^\mu(x) = \varepsilon^\mu(k)\, e^{-ik\cdot x} + \text{c.c.}, \qquad k\cdot x = k^0 t - \mathbf{k}\cdot\mathbf{x}, \tag{8.131}$$

with constant *polarization vector* $\varepsilon^\mu(k)$. Acting with the d'Alembertian,

$$\Box A^\mu = \partial_\nu\partial^\nu\big(\varepsilon^\mu e^{-ik\cdot x}\big) = (-ik_\nu)(-ik^\nu)\,\varepsilon^\mu e^{-ik\cdot x} = -k^2\,\varepsilon^\mu e^{-ik\cdot x}, \tag{8.132}$$

so $\Box A^\mu = 0$ forces the *massless dispersion relation*

$$k^2 = (k^0)^2 - |\mathbf{k}|^2 = 0, \qquad k^0 = |\mathbf{k}| \equiv \omega. \tag{8.133}$$

The wave is null — the photon is massless — and propagates at the speed of light, as a classical electromagnetic wave must.

Step 2: the Lorenz condition removes one component. Imposing Eq. (8.122) on the ansatz,

$$\partial_\mu A^\mu = -ik_\mu\varepsilon^\mu\, e^{-ik\cdot x} + \text{c.c.} = 0 \implies k_\mu\varepsilon^\mu = 0. \tag{8.134}$$

This is one complex linear condition on the four components of ε^μ, leaving three. We have used the gauge *condition*; we have not yet used the residual gauge *freedom*.

Step 3: the residual freedom removes a second component. By Theorem 8.21 we may still shift the potential by $\partial_\mu\alpha$ with $\Box\alpha = 0$. Choose a residual parameter of the same wave-vector,

$$\alpha(x) = i\,a\,e^{-ik\cdot x} + \text{c.c.}, \qquad \Box\alpha = -k^2\alpha = 0 \text{ (by Eq. (8.133))}, \tag{8.135}$$

with a a complex constant. Then $\partial_\mu\alpha = ia(-ik_\mu)e^{-ik\cdot x} + \text{c.c.} = a\,k_\mu e^{-ik\cdot x} + \text{c.c.}$, so the polarization vector shifts by a multiple of k^μ,

$$\varepsilon^\mu \;\longmapsto\; \varepsilon^\mu + a\,k^\mu. \tag{8.136}$$

Two polarization vectors differing by a multiple of k^μ describe the same physical wave. Note this shift is consistent with Step 2: it changes $k_\mu \varepsilon^\mu$ by $a\, k_\mu k^\mu = ak^2 = 0$, so it preserves the Lorenz condition, exactly as Theorem 8.21 guarantees. The four components of ε^μ, minus one from Eq. (8.134), minus one from the freedom Eq. (8.136), leave $4 - 1 - 1 = 2$ — the count Eq. (8.116), now realized componentwise.

Step 4: choose a frame and exhibit the polarizations. Orient the spatial axes so the wave travels along z:

$$k^\mu = (\omega, 0, 0, \omega), \qquad k_\mu = (\omega, 0, 0, -\omega). \tag{8.137}$$

With $k_\mu = (\omega, 0, 0, -\omega)$ and $\varepsilon^\mu = (\varepsilon^0, \varepsilon^1, \varepsilon^2, \varepsilon^3)$, the Lorenz condition Eq. (8.134) reads $k_\mu \varepsilon^\mu = \omega\varepsilon^0 + 0 + 0 + (-\omega)\varepsilon^3 = \omega(\varepsilon^0 - \varepsilon^3) = 0$, hence

$$\varepsilon^0 = \varepsilon^3. \tag{8.138}$$

Now spend the residual freedom Eq. (8.136) to set the time component to zero. With $k^\mu = (\omega, 0, 0, \omega)$, choosing $a = -\varepsilon^0/\omega$ gives a new time component $\varepsilon^0 + a\, k^0 = \varepsilon^0 - \varepsilon^0 = 0$, and simultaneously a new third component $\varepsilon^3 + a\, k^3 = \varepsilon^3 - \varepsilon^0 = 0$ by Eq. (8.138). Both the timelike and the longitudinal (along $\mathbf{k}$) components are thereby removed:

$$\varepsilon^0 = \varepsilon^3 = 0, \qquad \varepsilon^\mu = (0, \varepsilon^1, \varepsilon^2, 0). \tag{8.139}$$

The surviving polarization is purely *transverse* — perpendicular to the direction of propagation $\mathbf{k}$. (This frame choice has, in effect, brought the free field into Coulomb gauge: Eq. (8.139) gives $\varepsilon^0 = 0$ and $\mathbf{k}\cdot\boldsymbol{\varepsilon} = \omega\varepsilon^3 = 0$, i.e. Eq. (8.128), confirming that Lorenz-plus-residual lands on the same two physical states the manifestly-physical gauge isolates.) A convenient real orthonormal basis for the two-dimensional space of transverse polarizations is

$$\varepsilon^\mu_{(1)} = (0, 1, 0, 0), \qquad \varepsilon^\mu_{(2)} = (0, 0, 1, 0), \tag{8.140}$$

normalized in the mostly-minus metric to $\varepsilon_{(\lambda)} \cdot \varepsilon_{(\lambda')} = \eta_{\mu\nu}\varepsilon^\mu_{(\lambda)}\varepsilon^\nu_{(\lambda')} = -\delta_{\lambda\lambda'}$ (spacelike, hence the minus sign). Equivalently, the circular (helicity) basis diagonalizes rotations about $\mathbf{k}$,

$$\varepsilon^\mu_\pm = \mp\tfrac{1}{\sqrt{2}}(0, 1, \pm i, 0), \qquad \varepsilon_\pm \cdot \varepsilon^*_\pm = -1, \quad \varepsilon_\pm \cdot \varepsilon^*_\mp = 0, \tag{8.141}$$

corresponding to the two helicities ± 1 of the photon. The general free solution is the superposition over all null k of these two polarizations, $A^\mu(x) = \sum_{\lambda=1,2} \int \frac{\mathrm{d}^3k}{(2\pi)^3} \left[\varepsilon^\mu_{(\lambda)}(k)\, c_\lambda(k)\, e^{-ik\cdot x} + \text{c.c.}\right]$ — precisely the expansion that becomes the photon mode expansion when the coefficients $c_\lambda(k)$ are promoted to operators in Chapter 13.

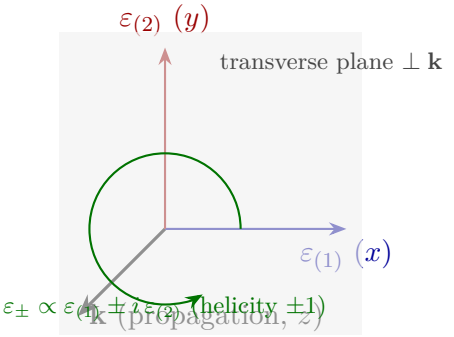

Figure 8.5: The two physical polarizations of a free electromagnetic plane wave (Theorem 8.23). After imposing the Lorenz condition Eq. (8.134) and spending the residual freedom Eq. (8.136), the polarization vector lies in the plane transverse to the propagation direction $\mathbf{k}$. The real basis $\varepsilon_{(1)}, \varepsilon_{(2)}$ describes linear polarization; the complex combinations $\varepsilon_\pm$ describe the two circular (helicity ± 1) states.

The worked example closes the loop opened by Eq. (8.116): the abstract assertion that two of the four components of A_μ are physical has become the concrete pair of transverse polarization vectors Eq. (8.140), with the gauge redundancy realized step by step as the removal first of the timelike and then of the longitudinal direction. We now possess a complete classical field: a gauge potential A_μ whose redundancy is understood and fixable, whose physical content is exactly two propagating, transverse, helicity-± 1 polarizations, and whose equations of motion are sourced by a conserved current. This clean object is ready to be coupled to charged matter. In the next section we assemble the full classical QED Lagrangian, identify the electromagnetic current as the global U(1) Noether current of Chapter 7, and watch it appear as the very source J^μ of the Maxwell field — launching QED at its classical layer and locking symmetry to dynamics.

8.6 The Classical QED Lagrangian

The previous sections built, piece by piece, every ingredient of classical electrodynamics from a single demand: that the global $U(1)$ phase symmetry of the matter field be promoted to a local one. Requiring invariance under $\psi \to e^{ie\alpha(x)}\psi$ forced into existence a connection A_μ, a covariant derivative that compares the field at neighbouring points, and a curvature $F_{\mu\nu}$ measuring the failure of that comparison to be path-independent. We then gave the connection its own gauge-invariant dynamics — the Maxwell Lagrangian $\mathcal{L}_{\text{Max}} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu}$ of Eq. (8.75), whose field equation is Eq. (8.95) — and, in the preceding section, exposed its gauge redundancy and counted the two physical polarizations of the radiation field. What remains is to put the two halves together: the minimally coupled electron

handed up through Eq. (8.29), and the photon. The result is the complete *classical* theory of electrons and photons, and it is the launching point of QED, the running example that will carry us — through quantization, scattering, loops, and the anomalous magnetic moment — to the precision frontier of the book.

The assembly is more than bookkeeping. When we write down the coupled Lagrangian and turn the variational crank, a remarkable thing happens: the conserved current that Noether's theorem (Chapter 7) extracts from the global $U(1)$ symmetry of the matter sector turns out to be *exactly* the source term that the electromagnetic field equations demand. The symmetry current and the field source are one and the same object. This is the deepest payoff of the gauge principle at the classical level — symmetry and dynamics are welded together — and it is the structural fact that makes the quantized theory consistent. The present section assembles the Lagrangian, derives the current as the Noether current, identifies it as the Maxwell source, writes down the coupled equations of motion, verifies the full gauge invariance of the action, and recovers the Lorentz force law in the point-particle limit. By its end the symbols ψ, m, e, α, A_μ, and $F_{\mu\nu}$ that every later QED chapter uses will be fixed once and for all.

8.6.1 Assembling the Lagrangian

The matter sector is the free Dirac Lagrangian of Eq. (6.68), $\mathcal{L}_D = \bar{\psi}(i\partial\!\!\!/ - m)\psi$, built in Chapter 6 for a spin-$\frac{1}{2}$ field ψ of mass m with the Dirac adjoint $\bar{\psi} = \psi^\dagger\gamma^0$; the gamma-matrix conventions are those of Chapter C, with $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$ and the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$. The gauge principle instructs us to replace the ordinary derivative by the covariant derivative of the electron field, Eq. (8.29),

$$D_\mu \;=\; \partial_\mu + ieA_\mu, \tag{8.142}$$

in which $e > 0$ is the elementary charge and the electron carries charge $q = -e$, so that the general rule $D_\mu = \partial_\mu - iqA_\mu$ of Chapter A specializes to the $+ie$ appearing here. Adding to the minimally coupled matter the gauge-invariant kinetic term for the connection gives the complete classical Lagrangian density of quantum electrodynamics:

$$\boxed{\mathcal{L}_{\mathrm{QED}} \;=\; \bar{\psi}\,(iD\!\!\!/ - m)\,\psi \;-\; \tfrac{1}{4}\,F_{\mu\nu}F^{\mu\nu}, \qquad D_\mu = \partial_\mu + ieA_\mu, \quad F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu.} \tag{8.143}$$

This is the frozen QED model. From here onward, whenever a later chapter says "the QED Lagrangian" it means exactly Eq. (8.143), with these symbols and this sign convention.

It is worth seeing the interaction laid bare. Expanding the covariant derivative in $D\!\!\!/ = \gamma^\mu D_\mu = \gamma^\mu(\partial_\mu + ieA_\mu)$ and using $i\gamma^\mu(ieA_\mu) = -e\gamma^\mu A_\mu$,

$$\mathcal{L}_{\mathrm{QED}} \;=\; \underbrace{\bar{\psi}\,(i\partial\!\!\!/ - m)\,\psi}_{\text{free electron}} \;\underbrace{-\,\tfrac{1}{4}F_{\mu\nu}F^{\mu\nu}}_{\text{free photon}} \;\underbrace{-\,e\,\bar{\psi}\gamma^\mu\psi\,A_\mu}_{\text{interaction}}. \tag{8.144}$$

The entire coupling between matter and radiation is the single trilinear term $-e\,\bar{\psi}\gamma^{\mu}\psi\,A_{\mu}$: one photon line A_{μ} attached to the bilinear $\bar{\psi}\gamma^{\mu}\psi$. The strength of that coupling is governed by e, and it is conventional — and, once $\hbar$ and c are restored, dimensionally natural — to package it as the dimensionless *fine-structure constant*

$$\alpha \;=\; \frac{e^{2}}{4\pi} \;\approx\; \frac{1}{137}, \tag{8.145}$$

in the Heaviside–Lorentz, natural units used throughout (the 4π is absent from the Lagrangian because those units push it into the definition of charge). Every perturbative QED amplitude in the chapters to come is an expansion in powers of α, and the smallness of α is why that expansion is so spectacularly accurate.

Physical Insight

The interaction term in Eq. (8.144) was not posited; it was *forced*. We did not choose to couple the electron to the photon through $\bar{\psi}\gamma^{\mu}\psi A_{\mu}$ — demanding local $U(1)$ invariance left no other option for a renormalizable, gauge-invariant coupling at lowest order. The vector nature of the coupling (a γ^{μ}, hence a current), its universality (every charged field couples through the same A_{μ} with strength set by its charge), and even the masslessness of the photon (a mass term $\frac{1}{2}m_{\gamma}^{2}A_{\mu}A^{\mu}$ is not gauge invariant) are all consequences of the principle, not inputs. This is why the gauge principle is the organizing idea of the book: it converts a symmetry requirement into a unique dynamics.

The structure of the trilinear vertex is the object the Feynman rules of Chapter 17 will encode; it is worth drawing now, while it is still purely classical, so the diagrammatic language has a referent (Fig. 8.6).

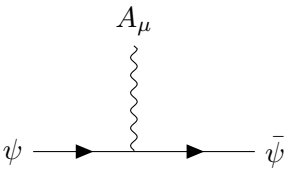

Figure 8.6: The classical QED interaction vertex read off from $-e\,\bar{\psi}\gamma^{\mu}\psi\,A_{\mu}$ in Eq. (8.144): an electron line (the conserved current $\bar{\psi}\gamma^{\mu}\psi$) meets the photon A_{μ} with coupling proportional to e. The same vertex, promoted to operators, is the single building block of all QED Feynman diagrams (Chapter 17).

8.6.2 The electromagnetic current as the $U(1)$ Noether current

The matter Lagrangian, with or without the coupling to A_{μ}, is invariant under the global phase rotation $\psi \to e^{ie\alpha}\psi$ with α a constant — the rigid remnant

of the local symmetry that drove the whole construction. By Noether's first theorem (Theorem 7.10) this continuous internal symmetry produces a conserved current. We now compute it, because it is the central object of QED: it is what couples to the photon, what sources Maxwell's equations, and what becomes, on quantization, the conserved electric charge.

Definition 8.24 (Electromagnetic four-current)**.** The *electromagnetic current* of the Dirac field is the Noether current of the global $U(1)$ symmetry $\psi \to e^{ie\alpha}\psi$, namely

$$\boxed{J^\mu \;=\; -\,e\,\bar\psi\,\gamma^\mu\,\psi} \tag{8.146}$$

Its time component $J^0 = -e\,\psi^\dagger\psi$ is the electric charge density, carrying the electron's negative sign through the factor $-e$; the spatial part $\mathbf{J} = -e\,\psi^\dagger\boldsymbol{\gamma}^0\boldsymbol{\gamma}\psi$ is the electric current density.

We derive Eq. (8.146) from the Lagrangian Eq. (8.143) and verify its conservation in full, as the first stage of QED's central computations.

Worked Example 8.25 (The electromagnetic current from Noether's theorem)**.** We continue QED by extracting Eq. (8.146) from Eq. (8.143) using the apparatus of Chapter 7, then checking $\partial_\mu J^\mu = 0$ on the equations of motion.

Step 1: the transformation and its generators. The global $U(1)$ acts only on the matter fields and leaves the coordinates and the gauge field fixed:

$$\psi \;\to\; e^{ie\alpha}\psi, \qquad \bar\psi \;\to\; e^{-ie\alpha}\bar\psi, \qquad A_\mu \to A_\mu, \qquad \delta x^\mu = 0, \tag{8.147}$$

with α a real constant. Because this is an internal symmetry, the coordinate variation vanishes and the intrinsic variation equals the total variation. To first order in α,

$$\delta_0\psi = ie\alpha\,\psi, \qquad \delta_0\bar\psi = -ie\alpha\,\bar\psi. \tag{8.148}$$

The action is strictly invariant (not merely up to a boundary term): every term in Eq. (8.144) pairs one ψ with one $\bar\psi$, so the phases $e^{ie\alpha}e^{-ie\alpha} = 1$ cancel identically, and the constant α passes through every derivative. Hence the boundary current K^μ of Eq. (7.32) vanishes.

Step 2: the conjugate momenta. The Noether current Eq. (7.32) for an internal symmetry reduces to $J^\mu = \Pi^\mu_a\,\delta_0\phi_a$ summed over the fields, where $\Pi^\mu_a = \partial\mathcal{L}/\partial(\partial_\mu\phi_a)$ is the conjugate-momentum density of Eq. (7.17). Only the derivative of ψ appears in Eq. (8.143) — the kinetic term is $\bar\psi\,i\gamma^\mu\partial_\mu\psi$, while $\bar\psi$ enters undifferentiated and A_μ does not transform — so

$$\Pi^\mu_\psi \;=\; \frac{\partial\mathcal{L}_{\text{QED}}}{\partial(\partial_\mu\psi)} \;=\; \bar\psi\,i\gamma^\mu, \qquad \Pi^\mu_{\bar\psi} = 0. \tag{8.149}$$

The covariant derivative does not change this: $D_\mu\psi = \partial_\mu\psi + ieA_\mu\psi$ depends on $\partial_\mu\psi$ exactly as $\partial_\mu\psi$ does, so the coefficient of $\partial_\mu\psi$ is still $\bar\psi\,i\gamma^\mu$.

Step 3: assemble the current. Stripping the parameter α (the conserved current is the coefficient of the infinitesimal parameter),

$$J^\mu \;=\; \Pi^\mu_\psi \frac{\delta_0 \psi}{\alpha} \;=\; (\bar\psi\, i\gamma^\mu)\,(ie\,\psi) \;=\; i^2 e\,\bar\psi\gamma^\mu\psi \;=\; -\,e\,\bar\psi\gamma^\mu\psi, \tag{8.150}$$

which is exactly Eq. (8.146). The sign is not a convention we imposed: it is produced by the two factors of i — one from the i in the Dirac kinetic term, one from the generator ie of the phase rotation — and it correctly assigns negative charge density to the electron field.

Step 4: verify conservation on shell. Noether's theorem guarantees $\partial_\mu J^\mu = 0$ on solutions, but it is instructive — and a sharp test of the gamma-matrix conventions — to see the cancellation explicitly. Write $\partial_\mu J^\mu = -e\,\partial_\mu(\bar\psi\gamma^\mu\psi) = -e\big[(\partial_\mu\bar\psi)\gamma^\mu\psi + \bar\psi\gamma^\mu(\partial_\mu\psi)\big]$. We need the two coupled equations of motion in the gauge field, derived in Section 8.6.4 below; we quote them here. The Dirac equation $(i\not{D} - m)\psi = 0$, written out with $D_\mu = \partial_\mu + ieA_\mu$, gives

$$i\gamma^\mu\partial_\mu\psi \;=\; m\psi + e\not{A}\,\psi \quad\Longrightarrow\quad \bar\psi\gamma^\mu\partial_\mu\psi \;=\; \frac{1}{i}(m\,\bar\psi\psi + e\,\bar\psi\not{A}\psi) \;=\; -i(m\,\bar\psi\psi + e\,\bar\psi\not{A}\psi), \tag{8.151}$$

where $\not{A} = \gamma^\mu A_\mu$. The adjoint Dirac equation $\bar\psi(i\overleftarrow{\not{D}} + m) = 0$, with the adjoint covariant derivative $\bar\psi\overleftarrow{D}_\mu = \partial_\mu\bar\psi - ieA_\mu\bar\psi$ (opposite sign because $\bar\psi$ rotates as $e^{-ie\alpha}$), gives

$$i(\partial_\mu\bar\psi)\gamma^\mu \;=\; -\,m\,\bar\psi - e\,\bar\psi\not{A} \quad\Longrightarrow\quad (\partial_\mu\bar\psi)\gamma^\mu \;=\; +\,i(m\,\bar\psi + e\,\bar\psi\not{A}), \tag{8.152}$$

so that, right-multiplying by ψ, $(\partial_\mu\bar\psi)\gamma^\mu\psi = +i(m\,\bar\psi\psi + e\,\bar\psi\not{A}\psi)$. Adding the two contributions,

$$(\partial_\mu\bar\psi)\gamma^\mu\psi + \bar\psi\gamma^\mu\partial_\mu\psi \;=\; +i(m\,\bar\psi\psi + e\,\bar\psi\not{A}\psi) \;-\; i(m\,\bar\psi\psi + e\,\bar\psi\not{A}\psi) \;=\; 0. \tag{8.153}$$

The mass terms cancel and — crucially — so do the gauge-field terms $e\,\bar\psi\not{A}\psi$: the coupling to A_μ enters the two Dirac equations with opposite signs, exactly as required for the current to remain conserved in the presence of the field. Therefore

$$\partial_\mu J^\mu \;=\; -e\,\partial_\mu(\bar\psi\gamma^\mu\psi) \;=\; 0, \tag{8.154}$$

the conservation of electric charge, valid in any external or dynamical electromagnetic field.

The conserved charge associated with Eq. (8.146) through Theorem 7.12 is

$$Q \;=\; \int d^3x\, J^0 \;=\; -e\int d^3x\,\psi^\dagger\psi, \tag{8.155}$$

the total electric charge of the field configuration, time-independent by Eq. (8.154). At the classical, c-number level $\psi^\dagger\psi > 0$ is a positive number density, so Q has

a definite sign fixed by the $-e$; the full reconciliation of this with the existence of both negatively charged electrons and positively charged positrons must wait for the quantization of the Dirac field in Chapter 11, where Q becomes a normal-ordered operator counting the difference of particle and antiparticle numbers.

8.6.3 The current is the Maxwell source

We now reach the structural climax of the chapter. The current Eq. (8.146) was extracted from a *symmetry* of the matter sector. We will see that the very same current is the *source* of the electromagnetic field — the right-hand side of the inhomogeneous Maxwell equation. Symmetry current and field source coincide. This is not an accident of electromagnetism; it is the inevitable consequence of having built the coupling by gauging the symmetry whose current we computed.

Vary Eq. (8.143) with respect to the gauge field A_ν. The only A-dependence is in the Maxwell term and in the interaction $-e\,\bar\psi\gamma^\mu\psi\,A_\mu$ of Eq. (8.144). From the Maxwell sector we recorded in Eq. (6.190) that $\partial\mathcal{L}_{\rm Max}/\partial(\partial_\mu A_\nu) = -F^{\mu\nu}$, while the interaction contributes $\partial\mathcal{L}_{\rm int}/\partial A_\nu = -e\,\bar\psi\gamma^\nu\psi$ and has no ∂A dependence. The Euler–Lagrange equation Eq. (6.30) for A_ν reads $\partial_\mu[\partial\mathcal{L}/\partial(\partial_\mu A_\nu)] - \partial\mathcal{L}/\partial A_\nu = 0$, that is

$$\partial_\mu(-F^{\mu\nu}) - (-e\,\bar\psi\gamma^\nu\psi) = 0 \quad\Longrightarrow\quad \boxed{\partial_\mu F^{\mu\nu} \;=\; e\,\bar\psi\gamma^\nu\psi \;=\; -J^\nu.} \tag{8.156}$$

The inhomogeneous Maxwell equation Eq. (8.95), whose source J^ν was a prescribed external current in Section 8.4, now has that source supplied entirely by the matter fields: it is the conserved $U(1)$ current $\bar\psi\gamma^\nu\psi$. Up to the overall sign that fixes the electron's charge as negative, the source is precisely the electromagnetic current Eq. (8.146). The two italicized objects of this section — the Noether current of the matter symmetry and the source of the Maxwell field — are the same current. This is the gauge principle's payoff made concrete.

Notation Watch

Three closely related currents appear in QED and it is worth keeping them straight, because their signs are the most-checked feature of the whole subject.

- The *number current* $n^\mu = \bar\psi\gamma^\mu\psi$, conserved by Eq. (8.154), with $n^0 = \psi^\dagger\psi > 0$. It carries no charge factor.
- The *electromagnetic (electric) current* $J^\mu = -e\,n^\mu = -e\,\bar\psi\gamma^\mu\psi$ of Eq. (8.146), the Noether current of $\psi \to e^{ie\alpha}\psi$, whose charge $Q = \int J^0$ is negative for the electron.
- The *Maxwell source* $\partial_\mu F^{\mu\nu} = e\,\bar\psi\gamma^\nu\psi = -J^\nu$.

All three are the same conserved current up to a constant; the relative sign between J^μ and the source $-J^\mu$ in Eq. (8.156) is the bookkeeping of the negative electron charge in the frozen convention $D_\mu = \partial_\mu + ieA_\mu$. Once $\hbar, c$ are restored, J^μ has units of (charge)×(probability flux), and Eq. (8.156) reads $\partial_\mu F^{\mu\nu} = -J^\nu$ in Heaviside–Lorentz units. We will write the field equation in the manifestly derived form $\partial_\mu F^{\mu\nu} = e\,\bar\psi\gamma^\nu\psi$ when the matter content is explicit, and as $\partial_\mu F^{\mu\nu} = -J^\nu$ when emphasizing the current.

Physical Insight

Why must the source be the symmetry current? Because the coupling was *defined* to be $\mathcal{L}_{\text{int}} = -e\,\bar\psi\gamma^\mu\psi\,A_\mu$, i.e. the gauge field contracted with the matter current. Varying such a coupling with respect to A_μ can return nothing but that current. And the current that appears in a minimal coupling $J^\mu A_\mu$ is, by Noether's construction, exactly the conserved current of the global symmetry one gauged. So the identity "source = symmetry current" is forced the moment one builds the interaction by minimal coupling. Conversely, the conservation of the source, $\partial_\mu(\partial_\nu F^{\nu\mu}) = 0$ (automatic from the antisymmetry of F), *requires* the source to be a conserved current — the field equations are inconsistent otherwise. Gauge invariance, current conservation, and the masslessness of the photon are three faces of one fact.

A direct corollary deserves emphasis. The antisymmetry $F^{\mu\nu} = -F^{\nu\mu}$ makes $\partial_\nu\partial_\mu F^{\mu\nu} \equiv 0$ identically. Taking ∂_ν of Eq. (8.156) therefore gives $\partial_\nu J^\nu = 0$ *as a consistency condition of the field equations themselves* — independently of the Dirac dynamics. The matter equations of motion must deliver a conserved current, or Maxwell's equations have no solution. We verified in Theorem 8.25 that they do. This interlocking is the classical seed of the Ward–Takahashi identities that protect the quantum theory (Chapter 19).

8.6.4 The coupled equations of motion

We collect the full set of classical field equations of QED, derived by varying Eq. (8.143) independently with respect to $\bar\psi$, ψ, and A_μ. As in Chapter 6 we treat ψ and $\bar\psi$ as independent fields, the legitimate invertible relabelling justified at Eq. (6.66).

Proposition 8.26 (Classical QED field equations)**.** *The Euler–Lagrange equations of* $\mathcal{L}_{\text{QED}}$ *are the coupled Dirac–Maxwell system*

$$(i\not{D} - m)\psi = 0, \qquad\qquad D_\mu = \partial_\mu + ieA_\mu, \tag{8.157}$$

$$\bar{\psi}(i\overleftarrow{\not{D}} + m) = 0, \qquad \bar{\psi}\overleftarrow{D}_\mu = \partial_\mu\bar{\psi} - ieA_\mu\bar{\psi}, \tag{8.158}$$

$$\partial_\mu F^{\mu\nu} = e\,\bar{\psi}\gamma^\nu\psi = -J^\nu. \tag{8.159}$$

Proof. Variation with respect to $\bar{\psi}$. In Eq. (8.143) the adjoint field appears undifferentiated — every derivative falls on ψ — so $\partial\mathcal{L}/\partial(\partial_\mu\bar{\psi}) = 0$ and $\partial\mathcal{L}/\partial\bar{\psi} = (i\not{\partial} - m)\psi$. The Euler–Lagrange equation Eq. (6.30) for $\bar{\psi}$ collapses to its undifferentiated term, giving the gauged Dirac equation Eq. (8.157) algebraically, with no integration by parts. This is the free Dirac equation Eq. (6.70) with $\partial_\mu \to D_\mu$: minimal coupling, made dynamical.

Variation with respect to ψ. Now ψ is the differentiated field. Writing the kinetic piece as $\bar{\psi}i\gamma^\mu D_\mu\psi = \bar{\psi}i\gamma^\mu\partial_\mu\psi - e\bar{\psi}\not{A}\psi$, we have $\partial\mathcal{L}/\partial(\partial_\mu\psi) = \bar{\psi}i\gamma^\mu$ and $\partial\mathcal{L}/\partial\psi = -e\,\bar{\psi}\not{A} - m\bar{\psi}$. The Euler–Lagrange equation $\partial_\mu(\bar{\psi}i\gamma^\mu) - (-e\bar{\psi}\not{A} - m\bar{\psi}) = 0$ becomes

$$i(\partial_\mu\bar{\psi})\gamma^\mu + e\,\bar{\psi}\not{A} + m\bar{\psi} = 0, \tag{8.160}$$

which is the adjoint Dirac equation Eq. (8.158): collecting the derivative and the gauge term into $\bar{\psi}\overleftarrow{D}_\mu = \partial_\mu\bar{\psi} - ieA_\mu\bar{\psi}$ gives $i\bar{\psi}\overleftarrow{\not{D}} = i(\partial_\mu\bar{\psi})\gamma^\mu + e\bar{\psi}\not{A}$, so Eq. (8.160) reads $\bar{\psi}(i\overleftarrow{\not{D}} + m) = 0$. Equations Eq. (8.157) and Eq. (8.158) are Dirac conjugates of one another, as one verifies by taking the Hermitian conjugate of Eq. (8.157) and multiplying by γ^0, using $(\gamma^\mu)^\dagger = \gamma^0\gamma^\mu\gamma^0$ from Chapter C; the relative sign of the eA term flips precisely because $i \to -i$ under conjugation, which is the algebraic origin of the cancellation in Eq. (8.153).

Variation with respect to A_ν. This is the computation of Section 8.6.3, reproduced here for completeness. With $\partial\mathcal{L}/\partial(\partial_\mu A_\nu) = -F^{\mu\nu}$ from Eq. (6.190) and $\partial\mathcal{L}/\partial A_\nu = -e\,\bar{\psi}\gamma^\nu\psi$, the Euler–Lagrange equation gives $\partial_\mu F^{\mu\nu} = e\,\bar{\psi}\gamma^\nu\psi$, which is Eq. (8.159). □

The system Eq. (8.157)–Eq. (8.159) is the complete classical theory of electrons and photons. It is genuinely coupled and nonlinear: the electron moves in the field A_μ it itself helps to create, because the field equation Eq. (8.159) is sourced by the very ψ whose evolution Eq. (8.157) depends on A_μ. The two free theories of Chapter 6 — a Dirac field obeying $(i\not{\partial} - m)\psi = 0$ and a Maxwell field obeying $\partial_\mu F^{\mu\nu} = 0$ — are recovered in the limit $e \to 0$, in which the coupling, the source, and the back-reaction all switch off simultaneously. The single parameter e controls all three, which is again the gauge principle at work: there is only one coupling constant because there is only one way the symmetry permits matter and radiation to interact.

Historical Note

That a single gauge coupling governs both how charges source fields and how fields push charges was, historically, an empirical input to Maxwell's and Lorentz's electrodynamics — two separate postulates, the field equa-

tions and the force law. The gauge principle unifies them: both follow from the one interaction term $-e\,\bar{\psi}\gamma^{\mu}\psi A_{\mu}$. The same logic, applied to the non-abelian groups of Chapter 25, would later predict the existence and self-interactions of the W, Z, and gluons before any were observed — the most striking vindication of taking the principle seriously as a law of nature rather than a bookkeeping device.

8.6.5 Gauge invariance of the full action

We have built $\mathcal{L}_{\text{QED}}$ to be invariant under local $U(1)$ transformations, but it is worth verifying the invariance of the assembled theory in one explicit calculation, since the cancellation of the offending $\partial_{\mu}\alpha$ terms is exactly what the covariant derivative was engineered to achieve.

Proposition 8.27 (Local gauge invariance of $\mathcal{L}_{\text{QED}}$)**.** *The Lagrangian Eq. (8.143) is invariant under the simultaneous local transformation*

$$\psi(x) \to e^{ie\alpha(x)}\psi(x), \qquad \bar{\psi}(x) \to e^{-ie\alpha(x)}\bar{\psi}(x), \qquad A_{\mu}(x) \to A_{\mu}(x) - \partial_{\mu}\alpha(x), \tag{8.161}$$

for any smooth function $\alpha(x)$.

Proof. The proof rests on the single property that defines the covariant derivative: under Eq. (8.161), $D_{\mu}\psi$ transforms exactly as ψ does. Compute directly, with $\psi' = e^{ie\alpha}\psi$ and $A'_{\mu} = A_{\mu} - \partial_{\mu}\alpha$,

$$\begin{aligned} D'_{\mu}\psi' &= (\partial_{\mu} + ieA'_{\mu})(e^{ie\alpha}\psi) \\ &= e^{ie\alpha}\Big[\partial_{\mu}\psi + ie(\partial_{\mu}\alpha)\psi + ie(A_{\mu} - \partial_{\mu}\alpha)\psi\Big] \\ &= e^{ie\alpha}(\partial_{\mu} + ieA_{\mu})\psi \;=\; e^{ie\alpha}\,D_{\mu}\psi. \end{aligned} \tag{8.162}$$

The $ie(\partial_{\mu}\alpha)\psi$ produced by differentiating the phase is cancelled exactly by the $-ie(\partial_{\mu}\alpha)\psi$ from the gauge shift of A_{μ}: this cancellation is the whole point of the construction. Consequently the bilinear that makes up the matter kinetic term is pointwise invariant: using Eq. (8.162) for $\not{D}'\psi' = e^{ie\alpha}\not{D}\psi$,

$$\bar{\psi}'\, i\not{D}'\psi' = (e^{-ie\alpha}\bar{\psi})\, i\,(e^{ie\alpha}\not{D}\psi) = e^{-ie\alpha}e^{ie\alpha}\,\bar{\psi}\, i\not{D}\psi = \bar{\psi}\, i\not{D}\psi, \tag{8.163}$$

the factor $e^{ie\alpha}$ on $\not{D}'\psi'$ being annihilated by the $e^{-ie\alpha}$ on $\bar{\psi}'$. The mass term is invariant by the same phase cancellation, $\bar{\psi}'\psi' = e^{-ie\alpha}e^{ie\alpha}\bar{\psi}\psi = \bar{\psi}\psi$, this time without even needing the covariant derivative. Finally the field-strength tensor is invariant on its own, because the gauge shift is a gradient:

$$F'_{\mu\nu} = \partial_{\mu}A'_{\nu} - \partial_{\nu}A'_{\mu} = \partial_{\mu}(A_{\nu} - \partial_{\nu}\alpha) - \partial_{\nu}(A_{\mu} - \partial_{\mu}\alpha) = F_{\mu\nu} - (\partial_{\mu}\partial_{\nu} - \partial_{\nu}\partial_{\mu})\alpha = F_{\mu\nu}, \tag{8.164}$$

since partial derivatives commute. Each of the three terms in Eq. (8.143) is therefore separately invariant, and so is $\mathcal{L}_{\text{QED}}$ and the action $S = \int d^4x\,\mathcal{L}_{\text{QED}}$. □

The invariance is exact and local, holding term by term and point by point — no integration by parts, no boundary terms. This is the hallmark of a theory built by gauging: the symmetry is not a property the dynamics happens to possess but the principle from which the dynamics was deduced. Note that it was the masslessness of the photon that survived: a putative term $\frac{1}{2}m_\gamma^2 A_\mu A^\mu$ would transform into $\frac{1}{2}m_\gamma^2(A_\mu - \partial_\mu\alpha)(A^\mu - \partial^\mu\alpha) \neq \frac{1}{2}m_\gamma^2 A_\mu A^\mu$ and is forbidden. The photon is massless because gauge invariance forbids its mass — a classical statement whose quantum protection (the photon stays massless to all orders) is one of the triumphs of the Ward identity in Chapter 19.

8.6.6 Recovering the Lorentz force

The coupled equations Eq. (8.157)–Eq. (8.159) contain all of classical electrodynamics, including the force a field exerts on a charge. To see this we take the *eikonal* (geometrical-optics) limit of the matter sector, in which the Dirac field describes a sharply localized wave packet whose centre traces a classical worldline. In that limit the field-theoretic coupling $-e\,\bar\psi\gamma^\mu\psi A_\mu$ reduces to the coupling of a point charge to the potential, and the Dirac equation reduces to a classical equation of motion. We carry the reduction at the level of the point-particle action, which is the standard and cleanest route, and recover the relativistic Lorentz force.

A relativistic point particle of mass m and charge q tracing a worldline $x^\mu(\tau)$, with four-velocity $u^\mu = dx^\mu/d\tau$ and proper time τ, has the action

$$S_{\rm pp} \;=\; -\,m\int d\tau \;-\; q\int A_\mu\,dx^\mu \;=\; \int d\tau\,\Big[-m\sqrt{u_\nu u^\nu} \;-\; q\,A_\mu(x)\,u^\mu\Big]. \tag{8.165}$$

The first term is the free relativistic kinetic action, whose nonrelativistic limit $-m\sqrt{1-\mathbf{v}^2} \to -m + \frac{1}{2}m\mathbf{v}^2$ reproduces ordinary kinetic energy; the second is the minimal coupling of the charge to the potential, the point-particle image of the field-theory current–potential coupling $\int d^4x\, J^\mu A_\mu$ with $J^\mu(x) = q\int d\tau\, u^\mu \delta^4(x - x(\tau))$. The charge of the electron is $q = -e$.

Worked Example 8.28 (The Lorentz force from the eikonal limit)**.** We derive the equation of motion from Eq. (8.165) and identify the Lorentz force. Vary $x^\mu(\tau)$ and use the Euler–Lagrange equation $\dfrac{d}{d\tau}\dfrac{\partial L}{\partial u^\mu} - \dfrac{\partial L}{\partial x^\mu} = 0$, with $L = -m\sqrt{u_\nu u^\nu} - qA_\mu u^\mu$. We parametrize by proper time, so $\sqrt{u_\nu u^\nu} = 1$ on the solution and the kinetic term contributes cleanly.

Kinetic term. $\dfrac{\partial}{\partial u^\mu}\big(-m\sqrt{u_\nu u^\nu}\big) = -m\dfrac{u_\mu}{\sqrt{u_\nu u^\nu}} = -m\,u_\mu$ (setting the root to unity after differentiating), so $\dfrac{d}{d\tau}\big(-mu_\mu\big) = -m\,\dfrac{du_\mu}{d\tau}$. The kinetic term has no explicit x-dependence, so it contributes nothing to $\partial L/\partial x^\mu$.

Interaction term. $\dfrac{\partial}{\partial u^\mu}\big(-qA_\nu u^\nu\big) = -qA_\mu$, whence $\dfrac{d}{d\tau}\big(-qA_\mu\big) = -q\,(\partial_\nu A_\mu)\,u^\nu$ along the worldline. The explicit x-dependence gives $\dfrac{\partial}{\partial x^\mu}(-qA_\nu u^\nu) = -q\,(\partial_\mu A_\nu)\,u^\nu$.

Assemble. The Euler–Lagrange equation is

$$\underbrace{-m\frac{du_\mu}{d\tau} - q(\partial_\nu A_\mu)u^\nu}_{\frac{d}{d\tau}\partial L/\partial u^\mu} \;-\; \underbrace{\big(-q(\partial_\mu A_\nu)u^\nu\big)}_{\partial L/\partial x^\mu} \;=\; 0, \tag{8.166}$$

that is, $-m\,\dfrac{du_\mu}{d\tau} = q(\partial_\nu A_\mu)u^\nu - q(\partial_\mu A_\nu)u^\nu = -q(\partial_\mu A_\nu - \partial_\nu A_\mu)u^\nu = -q\,F_{\mu\nu}u^\nu$. Cancelling the sign,

$$m\frac{du_\mu}{d\tau} = q\,F_{\mu\nu}u^\nu \quad\Longleftrightarrow\quad \boxed{f^\mu \;=\; m\frac{du^\mu}{d\tau} \;=\; q\,F^{\mu\nu}u_\nu.} \tag{8.167}$$

This is the covariant Lorentz force law. (Had we used a quadratic auxiliary kinetic term $\frac{1}{2}m\,u_\nu u^\nu$ in place of $-m\sqrt{u_\nu u^\nu}$, the spatial part of $u_\nu u^\nu$ would carry the wrong sign in the mostly-minus metric and flip the force; the relativistic square root is essential to get the sign right.)

Check the components. With $u^\mu = \gamma(1,\mathbf{v})$, $u_\nu = \gamma(1,-\mathbf{v})$, and the standard identifications $F^{i0} = E^i$, $F^{ij} = -\epsilon^{ijk}B^k$ of the field strength, the spatial part of Eq. (8.167) is

$$f^i = q\,F^{i\nu}u_\nu = q\big(F^{i0}u_0 + F^{ij}u_j\big) = q\big(E^i\gamma + (-\epsilon^{ijk}B^k)(-\gamma v^j)\big) = q\gamma\big(\mathbf{E}+\mathbf{v}\times\mathbf{B}\big)^i. \tag{8.168}$$

Dividing by γ to convert $d/d\tau$ to d/dt recovers $\dfrac{d\mathbf{p}}{dt} = q(\mathbf{E}+\mathbf{v}\times\mathbf{B})$, the familiar three-dimensional Lorentz force. For the electron, $q = -e$.

The Lorentz force closes the classical circle. The same current $J^\mu = -e\,\bar\psi\gamma^\mu\psi$ that is the Noether current of the global $U(1)$ (Section 8.6.2) and the source of Maxwell's equations (Section 8.6.3) is also, in the eikonal limit, the agent of the Lorentz force: matter couples to the field through $J^\mu A_\mu$, and that one coupling produces the field's source, the symmetry's conserved charge, and the force on the charge. A single trilinear term in Eq. (8.144) does all of this work. That economy — one coupling, one current, three classical consequences — is the signature of a gauge theory.

8.6.7 The classical structure of QED

We have assembled the complete classical theory. To state precisely what is now in hand for the chapters to come: the standard Lagrangian Eq. (8.143) with its symbols $\psi, m, e, \alpha, A_\mu, F_{\mu\nu}$; the conserved electromagnetic current Eq. (8.146),

identified both as the $U(1)$ Noether current and as the Maxwell source; the coupled Dirac–Maxwell equations of Theorem 8.26; the exact local gauge invariance of the action (Theorem 8.27); and the Lorentz force Eq. (8.167) as the eikonal limit of the coupling. Everything is classical: the fields are c-numbers (with ψ anticommuting, as flagged in Chapter 6), there is no Hilbert space, and there are no quanta.

The two outstanding tasks are both quantizations, and the gauge structure uncovered here is precisely what makes each delicate. The photon's gauge redundancy — the freedom Eq. (8.161) that left A_μ ambiguous and forced the constraint structure noted in the previous section — obstructs a naive canonical quantization and must be handled by gauge fixing and the physical-state conditions of Chapter 13. The electron, a first-order constrained field, is quantized as the Dirac field in Chapter 11, where the classical charge Eq. (8.155) becomes the operator that counts electrons minus positrons and the sign subtlety noted there is resolved. With both quantized, the trilinear vertex of Fig. 8.6 becomes the engine of every QED process, and QED proceeds to its first scattering amplitude.

With the classical theory complete and gauge-invariant, one question remains before quantization: is the potential A_μ merely a convenient bookkeeping device for the gauge-invariant field strength $F_{\mu\nu}$, or does it carry physical information of its own? The next section answers this through the holonomy of A_μ around closed loops — the Aharonov–Bohm phase — showing that the connection, not merely its curvature, is the fundamental object, and using this to derive Dirac's quantization of electric charge.

8.7 Holonomy, the Aharonov–Bohm Effect, and Charge Quantization

The previous sections of this chapter built the gauge potential A_μ from the demand of local U(1) invariance, identified its curvature $F_{\mu\nu}$ (Theorem 8.8), and proved that $F_{\mu\nu}$ is the gauge-invariant content of the connection (Theorem 8.9). It is tempting to conclude that $F_{\mu\nu}$ is therefore the whole physical story and that A_μ is mere bookkeeping — a redundant potential whose only invariant residue is the field strength. That conclusion is false, and the way it fails is one of the deepest lessons in the book. The potential carries gauge-invariant information that $F_{\mu\nu}$ does *not* capture: information that is global rather than local, attached to closed loops rather than to points. The object that extracts it is the *holonomy* of the connection, already glimpsed in the comparator construction of Section 8.2.1. This section makes the holonomy precise as the Wilson line and the Wilson loop, shows by the Aharonov–Bohm effect that it is physical even where $F_{\mu\nu} = 0$, and then turns it around: requiring the holonomy to be consistent in the presence of a magnetic monopole forces electric charge to be

quantized. The conclusion that will carry into the rest of the book is that the connection A_μ, not the field strength alone, is the fundamental object.

Notation Watch

Throughout this section we adopt the *charge-stripped* parametrization of the gauge freedom recorded as the alternative in Section 8.2.4: the matter phase is written $\psi \to e^{i\alpha}\psi$ (the charge absent from the exponent) and the potential shifts by $A_\mu \to A_\mu + \frac{1}{q}\partial_\mu\alpha$. This is the harmless rescaling $\alpha \to q\alpha$ of the chapter's default convention $\psi \to e^{iq\alpha}\psi$, $A_\mu \to A_\mu + \partial_\mu\alpha$ (Eq. (8.21)); we use it here only because it makes the topological winding arguments below — in which α is literally the U(1) phase angle, so that its winding is directly an integer — read most cleanly. The gauge-invariant holonomy $W[C] = \exp\!\left(iq \oint_C A\right)$ is, of course, independent of which parametrization is used.

8.7.1 Parallel transport and the Wilson line

Recall the comparator $U(y,x)$ introduced in Section 8.2.1: the U(1) phase factor that translates the internal phase convention at x into the convention at a neighbouring point y, transforming as $U(y,x) \to e^{i\alpha(y)}\,U(y,x)\,e^{-i\alpha(x)}$ — the charge-stripped form (Section 8.7) of the comparator law $U \to e^{iq\alpha(y)}Ue^{-iq\alpha(x)}$ established in Section 8.2.1, the two related by $\alpha \to q\alpha$ — so that the transported field $U(y,x)\psi(x)$ rotates with the destination's phase. For an infinitesimal step the comparator was $U(x+\varepsilon n, x) = 1 + i\varepsilon q\, n^\mu A_\mu(x) + O(\varepsilon^2)$. We now build the comparator for a *finite* separation by composing infinitesimal ones along a path. This is parallel transport, and the result is the central object of the section.

Let Γ be a smooth oriented path from x to y, parametrised by $\xi^\mu(s)$ with $s \in [0,1]$, $\xi(0) = x$, $\xi(1) = y$. Discretise Γ into N steps of size $\Delta s = 1/N$ and compose the infinitesimal comparators in order:

$$W_\Gamma(y,x) \;=\; \lim_{N\to\infty} \prod_{k=N}^{1} \Big[\, 1 + i\,q\,\dot\xi^\mu(s_k)\,A_\mu(\xi(s_k))\,\Delta s \,\Big], \tag{8.169}$$

where $\dot\xi^\mu = d\xi^\mu/ds$ and the product is path-ordered (later points on the left). Because the U(1) phase factors are numbers — they commute — the ordering is immaterial here, and the limit Eq. (8.169) is the exponential of the sum of the exponents, i.e. the path integral of A_μ along Γ. (In the non-abelian generalisation of Chapter 25 the comparators are matrices that do not commute, the ordering survives, and one must keep the path-ordering symbol; the abelian case is the one in which it collapses.) We record the result as a definition.

Definition 8.29 (Wilson line)**.** For a charge-q field and an oriented path Γ from x to y, the *Wilson line* (the finite parallel-transport comparator) is

$$W_\Gamma(y,x) \;=\; \exp\!\Big(\, i\,q \int_\Gamma A_\mu \, dx^\mu \Big), \tag{8.170}$$

where $\int_\Gamma A_\mu\,dx^\mu = \int_0^1 A_\mu(\xi(s))\,\dot\xi^\mu(s)\,ds$ is the integral of the one-form $A = A_\mu\,dx^\mu$ along Γ.

The Wilson line inherits the transformation law of the comparator it was assembled from, and this is the first thing to verify. Under a local gauge transformation, A_μ shifts by a gradient, $A_\mu \to A_\mu + \frac{1}{q}\partial_\mu\alpha$ (Section 8.7), so the line integral changes by the integral of a total derivative:

$$\int_\Gamma A'_\mu\,dx^\mu \;=\; \int_\Gamma A_\mu\,dx^\mu \;+\; \frac{1}{q}\int_\Gamma \partial_\mu\alpha\,dx^\mu \;=\; \int_\Gamma A_\mu\,dx^\mu \;+\; \frac{1}{q}\big[\alpha(y)-\alpha(x)\big], \tag{8.171}$$

where we used $\int_\Gamma \partial_\mu\alpha\,dx^\mu = \int_0^1 \frac{d}{ds}\alpha(\xi(s))\,ds = \alpha(y)-\alpha(x)$, the fundamental theorem of calculus applied to the pullback of $d\alpha$. Exponentiating,

$$W_\Gamma(y,x) \;\longrightarrow\; e^{\,i\alpha(y)}\, W_\Gamma(y,x)\, e^{-i\alpha(x)}, \tag{8.172}$$

exactly the comparator law. The transported field then behaves correctly: under the gauge transformation $W_\Gamma(y,x)\,\psi(x) \to e^{i\alpha(y)}W_\Gamma(y,x)e^{-i\alpha(x)}\,e^{i\alpha(x)}\psi(x) = e^{i\alpha(y)}\,[W_\Gamma(y,x)\psi(x)]$, i.e. it acquires the phase of the destination point y, just like the genuine field $\psi(y)$. The Wilson line is the device that lets us compare charged fields at finite separation.

It is worth checking that Theorem 8.29 reproduces the covariant derivative in the infinitesimal limit, closing the loop with Section 8.2.1. For a step $y = x + \varepsilon n$ along a straight segment, $\int_\Gamma A_\mu\,dx^\mu = \varepsilon\, n^\mu A_\mu(x) + O(\varepsilon^2)$, so $W = 1 + i\varepsilon q\, n^\mu A_\mu + O(\varepsilon^2)$, and the transport-corrected difference is

$$\begin{aligned}\psi(x+\varepsilon n) - W(x+\varepsilon n, x)\,\psi(x) &= \big[\psi + \varepsilon n^\mu\partial_\mu\psi\big] - \big[1 + i\varepsilon q\, n^\mu A_\mu\big]\psi + O(\varepsilon^2)\\ &= \varepsilon\, n^\mu(\partial_\mu - iqA_\mu)\psi + O(\varepsilon^2) \;=\; \varepsilon\, n^\mu(D_\mu\psi) + O(\varepsilon^2).\end{aligned} \tag{8.173}$$

The covariant derivative is exactly the leading rate at which the field fails to be parallel along the path — the infinitesimal holonomy. The connection A_μ is the generator of parallel transport; D_μ and W_Γ are the same geometric idea read at two scales.

8.7.2 The Wilson loop and its flux

The Wilson line $W_\Gamma(y,x)$ is not by itself gauge invariant: its endpoints carry the phases $e^{i\alpha(y)}$ and $e^{-i\alpha(x)}$. Those phases cancel precisely when the path closes on itself, $y = x$. The resulting closed-loop holonomy is gauge invariant and physical, and it is the abelian *Wilson loop*.

Theorem 8.30 (Gauge invariance of the Wilson loop and its flux)**.** *Let $C = \partial S$ be a closed oriented loop bounding a surface S. The Wilson loop*

$$W[C] \;=\; \exp\!\Big(i\,q \oint_C A_\mu \, dx^\mu \Big) \tag{8.174}$$

is invariant under any local gauge transformation $A_\mu \to A_\mu + \frac{1}{q}\partial_\mu \alpha$, and it equals the exponential of the charge times the flux of the field strength through S,

$$\boxed{\; W[C] \;=\; \exp\!\Big(i\,q \oint_{\partial S} A_\mu \, dx^\mu \Big) \;=\; \exp\!\Big(\frac{i\,q}{2} \int_S F_{\mu\nu}\, dS^{\mu\nu} \Big) \;} \tag{8.175}$$

where $dS^{\mu\nu}$ is the antisymmetric area element of S.

Proof. Gauge invariance. Setting $y = x$ in Eq. (8.171), the boundary term is $\frac{1}{q}[\alpha(x) - \alpha(x)] = 0$ for a single-valued α, so $\oint_C A_\mu\, dx^\mu$ is unchanged and $W[C] \to W[C]$. The argument is in fact more robust than this. Suppose α is permitted to be *multivalued* around C — as it must be allowed to be, since the only object required to be single-valued is the physical phase factor $e^{i\alpha}$, not α itself. Then $\oint_C \partial_\mu \alpha\, dx^\mu = \oint_C d\alpha = 2\pi k$ for some integer k (the winding number of the map $C \to \mathrm{U}(1)$, $x \mapsto e^{i\alpha(x)}$; the value must be a multiple of 2π precisely so that $e^{i\alpha}$ returns to itself). The loop integral then shifts by $\frac{1}{q}\cdot 2\pi k$, and

$$W[C] \;\longrightarrow\; W[C]\, \exp\!\Big(iq \cdot \tfrac{1}{q}\, 2\pi k \Big) \;=\; W[C]\, e^{\,2\pi i k} \;=\; W[C]. \tag{8.176}$$

The Wilson loop is invariant even under these *large* gauge transformations, which cannot be reached continuously from the identity. This is the first appearance of the integer winding of $\mathrm{U}(1)$ — of $\pi_1(\mathrm{U}(1)) = \mathbb{Z}$ from Chapter 2 — and we shall see it again, decisively, in the charge-quantization argument below.

Equality to the flux. The one-form $A = A_\mu\, dx^\mu$ has exterior derivative

$$dA \;=\; \partial_\mu A_\nu \, dx^\mu \wedge dx^\nu \;=\; \tfrac{1}{2}(\partial_\mu A_\nu - \partial_\nu A_\mu)\, dx^\mu \wedge dx^\nu \;=\; \tfrac{1}{2} F_{\mu\nu}\, dx^\mu \wedge dx^\nu, \tag{8.177}$$

where the second equality uses the antisymmetry of the wedge product $dx^\mu \wedge dx^\nu = -dx^\nu \wedge dx^\mu$ to antisymmetrise the coefficient, and the third is the definition of the curvature $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ (Theorem 8.8). The field strength is literally the curvature two-form of the connection. Stokes' theorem for differential forms, $\oint_{\partial S} A = \int_S dA$, then gives

$$\oint_{\partial S} A_\mu\, dx^\mu \;=\; \int_S dA \;=\; \frac{1}{2}\int_S F_{\mu\nu}\, dx^\mu \wedge dx^\nu \;\equiv\; \frac{1}{2}\int_S F_{\mu\nu}\, dS^{\mu\nu}. \tag{8.178}$$

Multiplying by iq and exponentiating yields Eq. (8.175). □

Two readings of Eq. (8.175) matter. First, it says the holonomy of the connection around C is controlled by the flux of F through *any* surface spanning C — the right-hand side is independent of the choice of S, as it must be, because changing S to S' with the same boundary changes the integral by $\frac{1}{2}\oint_{\partial(S-S')} A$ over a *closed* surface $S - S'$, which by the homogeneous Maxwell/Bianchi identity $\partial_{[\lambda} F_{\mu\nu]} = 0$ (Section 8.3) measures the magnetic charge enclosed and vanishes whenever that charge is zero. (When it does *not* vanish — a monopole inside — the surface-independence fails by a multiple of 2π, and that failure is the whole content of Section 8.7.4.) Second, in the magnetostatic situation the right-hand side is just the ordinary magnetic flux. To see this cleanly, take C to be a spatial loop traversed at a fixed instant, so $dx^0 = 0$ along C and only the spatial components contribute. With $A^\mu = (\phi, \vec{A})$ the lowered spatial component is $A_i = \eta_{ij} A^j = -A^i = -(\vec{A})_i$, hence

$$\oint_C A_\mu \, dx^\mu \;=\; \oint_C A_i \, dx^i \;=\; -\oint_C \vec{A}\cdot d\vec{\ell} \;=\; -\int_S (\nabla\times\vec{A})\cdot d\vec{S} \;=\; -\int_S \vec{B}\cdot d\vec{S} \;=\; -\,\Phi_B, \tag{8.179}$$

using ordinary three-dimensional Stokes in the middle and $\vec{B} = \nabla \times \vec{A}$. Thus $W[C] = e^{-iq\Phi_B}$: the Wilson loop of a static magnetic field is the exponential of (minus) the charge times the enclosed flux. The overall sign is a convention artefact of the index placement and the loop orientation; the gauge-invariant physical content is q times the flux Φ_B enclosed, defined modulo 2π.

8.7.3 The Aharonov–Bohm effect

We can now exhibit the promised phenomenon: a region in which $F_{\mu\nu} = 0$ identically, so that classically "nothing is there," and yet the connection has a nontrivial, observable holonomy. The field strength vanishes locally but the gauge potential is not globally pure gauge — there is no single-valued α with $A_\mu = \frac{1}{q}\partial_\mu \alpha$ throughout the region — and the obstruction is detected by the Wilson loop.

The experimental geometry (Fig. 8.7) is the standard two-path interference experiment with a long thin solenoid placed in the shadow between the paths. A coherent beam of charged particles is split, the two partial waves ψ_1, ψ_2 travel along paths Γ_1 and Γ_2 that pass on opposite sides of the solenoid, and they recombine on a screen. The magnetic field is confined inside the solenoid; the particles move only through the field-free exterior. Each partial wave is parallel-transported by the Wilson line along its path, picking up a phase $\exp(iq\int_{\Gamma_a} A_\mu \, dx^\mu)$ relative to the field-free amplitude (this is the statement, made quantitative in nonrelativistic quantum mechanics, that minimal coupling attaches the comparator phase to a propagating charged particle; we are using here only the classical, kinematic content of the connection). The interference pattern depends on the

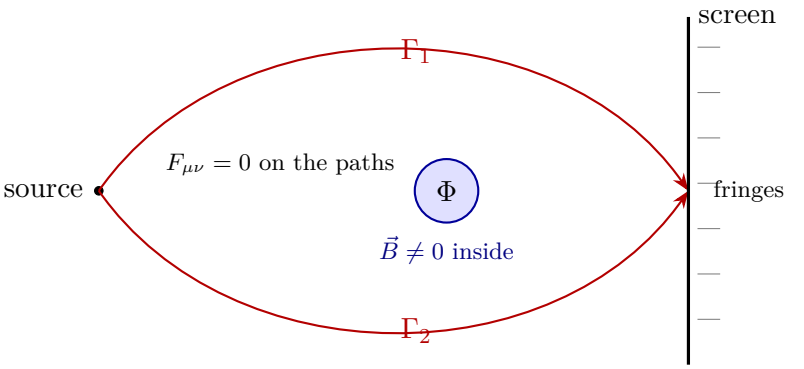

Figure 8.7: The Aharonov–Bohm setup. An idealised infinite solenoid (seen end-on) confines a magnetic flux Φ to its interior; outside, $\vec{B} = 0$ and the electron paths Γ_1, Γ_2 never touch any field. Yet the relative phase of the two partial waves is $q \oint_C A_\mu \, dx^\mu = -q\Phi$, shifting the interference fringes on the screen. The connection is observable where the field strength is not.

relative phase

$$\Delta\varphi \;=\; q\int_{\Gamma_1} A_\mu \, dx^\mu - q\int_{\Gamma_2} A_\mu \, dx^\mu \;=\; q\oint_C A_\mu \, dx^\mu, \qquad C = \Gamma_1 - \Gamma_2, \tag{8.180}$$

the holonomy around the closed loop C formed by going out along Γ_1 and back along Γ_2, a loop that encircles the solenoid. By Theorem 8.30 and Eq. (8.179) this relative phase is $\Delta\varphi = -q\Phi$, controlled entirely by the enclosed flux. It is nonzero even though $F_{\mu\nu} = 0$ all along both paths. The following worked example computes the potential explicitly, verifies that it is field-free yet non-pure-gauge in the exterior, and confirms the phase.

Worked Example 8.31 (Aharonov–Bohm phase of an idealised solenoid)**.** Model the solenoid as an infinite cylinder of radius a along the z-axis, carrying a uniform internal field $\vec{B} = B\,\hat{z}$ for $r < a$ and $\vec{B} = 0$ for $r > a$, with total enclosed flux $\Phi = \pi a^2 B$. Work in cylindrical coordinates (r, φ, z).

Step 1: the exterior potential. Symmetry dictates $\vec{A} = A_\varphi(r)\,\hat{\varphi}$. Demand that it reproduce the flux through every circle of radius $r > a$ centred on the axis. Three-dimensional Stokes gives

$$\oint_r \vec{A}\cdot d\vec{\ell} \;=\; A_\varphi(r)\,(2\pi r) \;=\; \int_{\text{disc}} \vec{B}\cdot d\vec{S} \;=\; \Phi \qquad (r > a), \tag{8.181}$$

since the disc bounded by the circle catches the entire flux once $r > a$. Hence

$$\vec{A} \;=\; \frac{\Phi}{2\pi r}\,\hat{\varphi} \qquad (r > a). \tag{8.182}$$

Step 2: the exterior field vanishes. Using the curl in cylindrical coordinates for a purely azimuthal $\vec{A} = A_\varphi(r)\hat{\varphi}$,

$$\vec{B} = \nabla \times \vec{A} \;=\; \frac{1}{r}\frac{\partial (r A_\varphi)}{\partial r}\,\hat{z} \;=\; \frac{1}{r}\frac{\partial}{\partial r}\Big(r \cdot \frac{\Phi}{2\pi r}\Big)\hat{z} \;=\; \frac{1}{r}\frac{\partial}{\partial r}\Big(\frac{\Phi}{2\pi}\Big)\hat{z} \;=\; 0 \qquad (r > a), \tag{8.183}$$

confirming $F_{\mu\nu} = 0$ throughout the region the particles traverse.

Step 3: the exterior potential is not (globally) pure gauge. Locally one can write $\vec{A} = \nabla\chi$ with $\chi = \frac{\Phi}{2\pi}\varphi$, since $\nabla\chi = \frac{1}{r}\partial_\varphi \chi\,\hat{\varphi} = \frac{\Phi}{2\pi r}\hat{\varphi}$. But χ is the multivalued angle, increasing by Φ each time one circles the axis; there is no single-valued function on the punctured exterior whose gradient is $\vec{A}$. This is the precise sense in which A_μ is not pure gauge: $F = 0$ guarantees A is *locally* exact (closed forms are locally exact, Poincaré's lemma), but the exterior is not simply connected, so it need not be *globally* exact. The failure is measured by the loop integral.

Step 4: the phase. For a loop C encircling the solenoid once,

$$\oint_C \vec{A}\cdot d\vec{\ell} \;=\; \int_0^{2\pi} \frac{\Phi}{2\pi r}\,(r\,d\varphi) \;=\; \Phi, \tag{8.184}$$

independent of the loop's radius or shape, depending only on the enclosed flux. By Eq. (8.179), $\oint_C A_\mu\,dx^\mu = -\Phi$, so the Aharonov–Bohm phase is

$$\Delta\varphi \;=\; q\oint_C A_\mu\,dx^\mu \;=\; -\,q\,\Phi, \qquad W[C] \;=\; e^{-iq\Phi}. \tag{8.185}$$

Step 5: gauge invariance and observability. Any other potential differs from Eq. (8.182) by $\frac{1}{q}\nabla\alpha$ for a single-valued α, which adds $\frac{1}{q}[\alpha]_C = 0$ to the loop integral; the phase Eq. (8.185) is gauge invariant. It is observable: shifting the flux Φ rigidly displaces the interference fringes on the screen, and the pattern repeats whenever $q\Phi$ advances by 2π, i.e. whenever Φ advances by the *flux quantum*

$$\Phi_0 \;=\; \frac{2\pi}{|q|} \;=\; \frac{2\pi\hbar}{|q|} \;=\; \frac{h}{|q|} \qquad \text{(restoring } \hbar\text{)}, \tag{8.186}$$

which for $|q| = e$ is h/e. (In a superconductor the carriers are charge-$2e$ Cooper pairs and the observed flux quantum is correspondingly $h/2e$ — an experimental confirmation that the relevant charge is the carrier's, exactly as Eq. (8.186) demands.) The point is established: the gauge potential carries gauge-invariant physical information through its holonomy in a region where the field strength is identically zero.

Physical Insight

The Aharonov–Bohm effect forces a revision of what is "physically real" in electromagnetism. The field strength $F_{\mu\nu}$ is local but incomplete: it does not determine the holonomies, hence does not determine the physics, on a topologically nontrivial region. The potential A_μ is complete but redundant: it overdetermines the physics by the gauge freedom. The genuinely physical, gauge-invariant data is neither — it is the set of holonomies $W[C] = \exp(iq \oint_C A)$ for all closed loops C, the connection "integrated up." On a simply connected region every loop bounds and $W[C]$ is fixed by F via Eq. (8.175), so F suffices; on a region with noncontractible loops the holonomies around them are independent new data. The connection, read through its holonomy, is the fundamental object. This is the classical seed of the statement, central to Chapter 25, that gauge theory is the theory of a connection on a fibre bundle, and that Wilson loops are its natural gauge-invariant observables.

8.7.4 Dirac's charge-quantization condition

The Wilson loop turned a field-free region into an observable. We now run the logic in reverse. Suppose a magnetic monopole exists. The Wilson loop then constrains the allowed electric charges, and the constraint is Dirac's celebrated quantization condition: the mere consistent coexistence of one monopole with charged matter forces every electric charge to be an integer multiple of a fixed unit.

A magnetic monopole of magnetic charge g is a point source of $\vec{B}$,

$$\vec{B}(\vec{r}) \;=\; \frac{g}{4\pi}\,\frac{\hat{r}}{r^2}, \qquad \oint_{S^2} \vec{B}\cdot d\vec{S} \;=\; g, \tag{8.187}$$

the flux through any sphere enclosing it being g (the field is the magnetic analogue of the Coulomb field). This immediately conflicts with $\vec{B} = \nabla \times \vec{A}$: if a globally smooth $\vec{A}$ existed, the flux through the closed sphere S^2 would be $\oint_{S^2}(\nabla \times \vec{A})\cdot d\vec{S} = 0$ by the divergence theorem (a curl has no sources), contradicting Eq. (8.187). Equivalently, $\nabla \cdot \vec{B} = g\,\delta^3(\vec{r}) \neq 0$ violates the Bianchi identity $\nabla \cdot \vec{B} = 0$ that $\vec{B} = \nabla \times \vec{A}$ would enforce. A monopole cannot be described by a single globally defined potential.

Dirac's resolution: the string. Dirac's device is to keep a potential almost everywhere by importing the missing flux along an infinitely thin solenoid — a *Dirac string* — running from infinity to the monopole, say along the negative z-axis. The string delivers flux $+g$ *into* the monopole, so that $\nabla \cdot \vec{B} = 0$ holds everywhere (the outgoing radial flux g is balanced by the incoming string flux g),

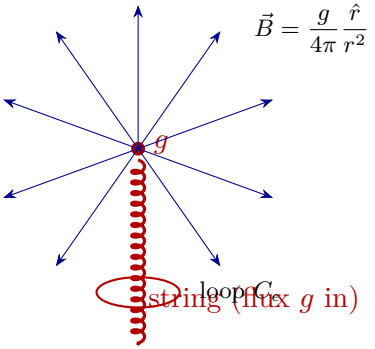

Figure 8.8: The Dirac monopole. Radial magnetic field of charge g emanates from the source; the return flux is carried in along an unphysical string (here down the $-z$ axis), so that $\nabla \cdot \vec{B} = 0$ and a potential exists off the string. A small loop C_ϵ encircling the string sees the full flux g and gives a Wilson loop e^{iqg}; demanding that the string be invisible forces $qg = 2\pi n$.

and a vector potential $\vec{A}$ exists everywhere *except on the string*. The monopole's radial field is then $\nabla \times \vec{A}$ off the string. An explicit such potential is

$$\vec{A}^N \;=\; \frac{g}{4\pi}\,\frac{1-\cos\theta}{r\sin\theta}\,\hat{\varphi}, \tag{8.188}$$

singular along $\theta = \pi$ (the negative z-axis, where the string lies) but smooth elsewhere. The string is an artefact of the description, not a physical object: its location can be moved by a gauge transformation (e.g. to the positive z-axis, giving a second potential $\vec{A}^S = -\frac{g}{4\pi}\frac{1+\cos\theta}{r\sin\theta}\hat{\varphi}$ regular near the south pole instead). Physics must not depend on where we put it. That single demand is the quantization condition.

Theorem 8.32 (Dirac quantization condition)**.** *If a magnetic monopole of magnetic charge g coexists with a particle of electric charge q, then*

$$\boxed{\,q\,g \;=\; 2\pi n, \qquad n \in \mathbb{Z}.\,} \tag{8.189}$$

Proof. Wilson loop around the string. Consider a small closed loop C_ϵ that encircles the Dirac string once, at a point away from the monopole (Fig. 8.8). The string is an idealised thin solenoid carrying flux g, so C_ϵ encloses exactly the flux g. By Theorem 8.30 (in the magnetostatic form Eq. (8.179), with $\Phi = g$) the holonomy around it is

$$W[C_\epsilon] \;=\; \exp\!\Big(iq \oint_{C_\epsilon} A_\mu\, dx^\mu\Big) \;=\; e^{\mp iqg}, \tag{8.190}$$

the sign depending only on the loop's orientation relative to the string. The string, however, is pure gauge artefact: it is invisible, carries no field on C_ϵ in any

physical sense (we may relocate it by a gauge transformation), and therefore the holonomy that detects it *must be trivial*. Were $W[C_\epsilon] \neq 1$, an Aharonov–Bohm experiment of exactly the kind in Theorem 8.31 would reveal the string's position, making the unphysical artefact observable — a contradiction. Hence

$$e^{iqg} = 1 \qquad \Longrightarrow \qquad q\,g = 2\pi n, \quad n \in \mathbb{Z}, \tag{8.191}$$

which is Eq. (8.189). □

Remark 8.33 (The two-patch derivation). The same condition arises without ever invoking an idealised solenoid, in a form that makes its topological character manifest — the form taken up systematically for non-abelian connections in Chapters 25 and 41. Cover the sphere S^2 surrounding the monopole with two overlapping patches: a northern patch (all of S^2 except the south pole) using $\vec{A}^N$ of Eq. (8.188), and a southern patch (all but the north pole) using $\vec{A}^S$. Each is smooth on its own patch; neither is global. On the overlap, the equatorial band, they differ by

$$\vec{A}^N - \vec{A}^S = \frac{g}{4\pi}\,\frac{(1-\cos\theta)+(1+\cos\theta)}{r\sin\theta}\,\hat{\varphi} = \frac{g}{2\pi}\,\frac{1}{r\sin\theta}\,\hat{\varphi} = \nabla\Big(\frac{g}{2\pi}\,\varphi\Big), \tag{8.192}$$

using $\nabla(\,f(\varphi)\,) = \frac{1}{r\sin\theta}\partial_\varphi f\,\hat{\varphi}$ in spherical coordinates. The two potentials are thus related by a gauge transformation $\vec{A}^N = \vec{A}^S + \frac{1}{q}\nabla\alpha$ with transition function

$$\alpha(\varphi) = \frac{q\,g}{2\pi}\,\varphi, \qquad e^{i\alpha} = \exp\Big(\frac{i\,q\,g}{2\pi}\,\varphi\Big). \tag{8.193}$$

The transition function $e^{i\alpha}$ is the U(1)-valued gluing map that relates the charged field's phase convention in the two patches; for the field to be well defined it must be single-valued as we go once around the equator, $\varphi \to \varphi + 2\pi$. That requires α to advance by a multiple of 2π, i.e. $\frac{qg}{2\pi}\cdot 2\pi = qg = 2\pi n$ — once more Eq. (8.189). In this language the integer n is the winding number of the transition function around the equator, an element of $\pi_1(\mathrm{U}(1)) = \mathbb{Z}$ (Chapter 2); it is the first Chern number of the U(1) bundle over S^2, and it counts the magnetic charge in units of $2\pi/q$. Charge quantization is the statement that this winding is an integer.

8.7.5 The connection is fundamental

Dirac's condition Eq. (8.189) is the most economical argument known for a fact the world obeys with extraordinary precision: electric charge is quantized. Every observed charge is an integer multiple of $e/3$ (quarks) or e (leptons), to a part in 10^{21} for the electron–proton charge difference, yet the Standard Model *as a Lagrangian* does not require it — the U(1) hypercharges could a priori be any real numbers. Dirac's argument supplies a sufficient reason: if even a single magnetic monopole exists *anywhere* in the universe, then $qg = 2\pi n$ forces every electric

charge to be a multiple of $2\pi/g$. The quantization of one charge propagates to all. Grand unified theories (Chapter 35) make this concrete — they predict monopoles as smooth solitons and thereby *derive* charge quantization — and the non-perturbative methods of Chapter 41 construct such monopoles explicitly.

The structural lesson is sharper than the phenomenology, and it is the lesson this whole chapter has been driving toward. The integer n in Eq. (8.189) is topological: it is the winding of a U(1)-valued map, an element of $\pi_1(\mathrm{U}(1)) = \mathbb{Z}$ (Chapter 2). It exists, and is an integer, precisely because the gauge group is the *compact* circle U(1) rather than the non-compact line $\mathbb{R}$. Had the internal symmetry been $\mathbb{R}$ — the same Lie algebra, the same $F_{\mu\nu}$, the same Maxwell equations locally — the group would be simply connected, $\pi_1(\mathbb{R}) = 0$, there would be no winding, no quantization, and no flux quantum. Charge quantization is therefore not a fact about the field strength at all; it is a fact about the *global* structure of the gauge group and the bundle the connection lives on. The local data $F_{\mu\nu}$ is blind to it. Only the connection, read globally through its holonomies and transition functions, knows.

This is the verdict the chapter hands to the rest of the book: the gauge potential is not redundant scaffolding around a physical $F_{\mu\nu}$; it is the primary object, a connection whose curvature is F and whose holonomy carries information F cannot. The classical Wilson loop $W[C]$ introduced here in the abelian setting is promoted in Chapter 25 to the non-abelian, path-ordered Wilson loop that serves as the order parameter for confinement in Yang–Mills theory, and the winding integers that quantized charge here reappear in Chapter 41 as the instanton number and the magnetic charge of 't Hooft–Polyakov monopoles. With the connection established as fundamental, and its global content made visible, the classical theory of the gauge field is complete; what remains is the gauge redundancy whose quantization becomes the central problem of Chapter 13 and Chapter 26.

Further reading

The gauge principle and its reconstruction of electrodynamics are developed, at complementary levels, in Peskin and Schroeder [396] and Schwartz [432], and – with the deepest insistence that the principle is a derivation rather than a convenience – in Weinberg [500]. The covariant, tensorial formulation of Maxwell's equations and the classical material on potentials, gauge fixing, and radiation is treated thoroughly in Jackson [279]. The geometric reading of A_μ as a connection and $F_{\mu\nu}$ as a curvature, including the fibre-bundle language that Chapter 25 will need, is laid out in Nakahara [355]; the foundational statement that the nonintegrable phase factor (the holonomy), not the field strength, is the complete gauge-invariant description is the classic paper by Wu and Yang [527]. The observability of the potential in a field-free region is Aharonov and

Bohm [8], and the quantization of electric charge from the consistency of a single magnetic monopole is Dirac [151].

Part III

Free Quantum Fields

Chapter 9

Quantization of the Scalar Field

This is the chapter in which the book first builds a genuine quantum field theory. Everything before it has been preparation of one of two kinds. The mathematical chapters of Part I assembled tools – the representation theory of the Lorentz and Poincaré groups in Chapter 3, the functional and analytic machinery of Chapter 5 – and the field-theory chapters of Part II treated fields as *classical* dynamical systems: the action principle and canonical formalism in Chapter 6, the symmetry-and-current calculus of Noether in Chapter 7, the gauge principle in Chapter 8. In each of those the field $\phi(x)$ was a number-valued function on spacetime, a configuration to be varied. Here that changes once and for all. We promote $\phi(x)$ to an *operator* on a Hilbert space, impose canonical commutation relations as the field-theoretic image of $[\hat{x}, \hat{p}] = i$, and follow the consequences. The classical scalar of ϕ^4 theory becomes a quantum field; this is the free ($\lambda = 0$) sector of that thread, and the interactions are switched back on only in Part IV.

We import rather than rebuild the classical input. The free real scalar Lagrangian $\mathcal{L} = \frac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) - \frac{1}{2}m^2\phi^2$, its canonical momentum $\pi = \dot{\phi}$, the Hamiltonian, and the Klein–Gordon equation $(\Box + m^2)\phi = 0$ are taken as established in Chapter 6. The conserved energy–momentum tensor and four-momentum P^μ, together with the internal U(1) current and charge of the complex scalar, are taken as Noether output from Chapter 7. The theory of distributions, the residue calculus, the contour deformations, and the $i\varepsilon$ prescription that we lean on to make sense of the propagator are taken from Chapter 5. None of these is reproved; each is invoked by Chapter 5 and its siblings where it is used.

The strategy is best stated in words before any formula. Expand the classical field in spatial Fourier modes; the Klein–Gordon equation then says that each mode $\phi(\mathbf{p}, t)$ obeys the equation of a harmonic oscillator with frequency $E_{\mathbf{p}} = \sqrt{\mathbf{p}^2 + m^2}$. A free field is therefore nothing but a continuum of decoupled harmonic oscillators, one for each momentum. The whole quantum content of the chapter is then the Sakurai-level ladder-operator solution of the single oscillator – which we assume as a quantum-mechanics prerequisite – applied to all of these

oscillators at once, with the bookkeeping arranged so that Lorentz invariance is manifest at every step. The art is entirely in the covariant bookkeeping: the Lorentz-invariant measure, the relativistic single-particle normalization, and the $i\varepsilon$ contour that ties the time ordering of operators to the analytic structure of a function of momentum.

Four payoffs follow, and the rest of the book leans on all four. First, *particles are not assumed; they emerge.* Acting on the ground state with a raising operator produces a one-quantum state, and we will see directly that this excitation carries the energy, momentum, and Lorentz transformation law of a relativistic particle of mass m and spin 0 – exactly the irreducible one-particle representation classified in Chapter 3. Second, the *vacuum is nontrivial*: summing the oscillator zero-point energies gives a (divergent) vacuum energy, and although its absolute value is unobservable, *differences* of it are physically real, as the worked Casimir computation shows. Third, the field is *causal* in a precise, checkable sense – field operators at spacelike separation commute (microcausality) – and we will see that demanding this is precisely what forces a spin-0 field to be quantized with commutators rather than anticommutators, the spin-statistics connection in its simplest form. Fourth, the central dynamical object the chapter delivers is the *Feynman propagator*: the time-ordered two-point function whose $i\varepsilon$-deformed contour encodes time ordering as analyticity, and which becomes the internal line of every Feynman diagram from Chapter 10 onward.

We fix conventions once, in force for the whole chapter, matching the book-wide canon of Appendix A: the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$ so that $p^2 = m^2$ on shell; natural units $\hbar = c = 1$; the relativistic single-particle normalization and the Lorentz-invariant measure $\widetilde{dp} = d^3p/[(2\pi)^3\, 2E_{\mathbf{p}}]$ used throughout the book; and the Feynman $(i\varepsilon)$ prescription for the propagator. A closing honesty is owed up front, because the cleanliness of this construction is deceptive. It works *because the theory is free.* The moment interactions are present the interaction picture itself becomes mathematically delicate – this is the content of Haag's theorem – and a genuinely interacting scalar field in four dimensions is believed to be *trivial*, that is, free in disguise. What we build in this chapter is therefore not a toy: it is the rigorous bedrock on which the perturbative edifice of Chapters 10, 14 and 15 is erected, and the place to which every later subtlety about interacting fields must ultimately be referred.

9.1 From Oscillators to Fields: Canonical Quantization

Every preceding chapter has either sharpened a tool or treated a field as a classical object. We now cross the line that gives the subject its name. The free real scalar arrived at the door of this chapter as a purely classical system: in Chapter 6 we wrote its Lagrangian, read off its canonical momentum, Legendre-transformed to

a Hamiltonian, and derived its equation of motion; in Chapter 7 we extracted its conserved energy–momentum and internal charges as Noether output. None of that knew anything about $\hbar$. The task of the present section is to make the field an *operator*, and to do so in the one way that the reader already trusts completely: by repeating, infinitely many times, the quantization of the harmonic oscillator. The whole construction of free quantum field theory is the statement that a free field is a continuum of decoupled oscillators labelled by momentum, and that each is quantized by the Sakurai-level ladder algebra assumed as prerequisite. This section installs the foundation of that program — the operator field and the canonical commutation relations it must obey — and checks that the foundation is internally sound before the next section builds on it.

This is the free, $\lambda = 0$, sector of ϕ^4 theory, continued directly from its classical stage in Chapter 6.

9.1.1 The classical free theory, imported

We take the free real scalar field exactly as Chapter 6 left it, in the conventions fixed there and in Chapter 5: mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$ and natural units $\hbar = c = 1$. The Lagrangian density of the free theory is the $\lambda \to 0$ limit of the ϕ^4 Lagrangian,

$$\mathcal{L} = \tfrac{1}{2}\,(\partial_\mu\phi)(\partial^\mu\phi) - \tfrac{1}{2}m^2\phi^2, \tag{9.1}$$

imported from Eq. (6.21). Treating $\phi(t,\mathbf{x})$ as the generalized coordinate at each spatial point $\mathbf{x}$, the canonically conjugate momentum density is

$$\pi(x) = \frac{\partial\mathcal{L}}{\partial(\partial_0\phi)} = \partial_0\phi(x) \equiv \dot\phi(x), \tag{9.2}$$

which is Eq. (6.120). The Legendre transform to the Hamiltonian, performed in Chapter 6, gave Eq. (6.122),

$$H = \int d^3x\,\left[\tfrac{1}{2}\,\pi^2 + \tfrac{1}{2}\,(\nabla\phi)^2 + \tfrac{1}{2}m^2\phi^2\right], \tag{9.3}$$

a manifestly positive functional of the field and its momentum. Finally, the Euler–Lagrange equation of Eq. (9.1) is the Klein–Gordon equation Eq. (6.55),

$$(\Box + m^2)\,\phi = 0, \qquad \Box \equiv \partial_\mu\partial^\mu = \partial_0^2 - \nabla^2. \tag{9.4}$$

These four equations are the entire classical input. We do not rederive them; the rest of the section is about what happens when ϕ and π stop being numbers.

9.1.2 The oscillator template

Before quantizing the field we recall precisely which feature of the classical system we intend to carry over, because the field commutation relations are not a new postulate so much as the obvious continuum analogue of an old one.

A single nonrelativistic particle has a coordinate q and a conjugate momentum p with classical Poisson bracket $\{q,p\}=1$. Dirac's canonical quantization promotes these to operators obeying $[q,p]=i$ (with $\hbar=1$). A system of N decoupled degrees of freedom has coordinates q_i and momenta p_j, $i,j=1,\dots,N$, with

$$[q_i,p_j]=i\,\delta_{ij},\qquad [q_i,q_j]=[p_i,p_j]=0. \tag{9.5}$$

The Kronecker delta encodes the physical statement that distinct degrees of freedom are independent: measuring the position of oscillator i does not disturb the momentum of oscillator $j\neq i$.

A field is the limit of Eq. (9.5) in which the discrete label i becomes a continuous spatial point $\mathbf{x}$. Concretely, imagine discretizing space into a cubic lattice of spacing a, so that the field is replaced by a coordinate $q_{\mathbf{n}}=\phi(\mathbf{x_n})$ at each lattice site $\mathbf{x_n}=a\mathbf{n}$, with conjugate momentum $p_{\mathbf{n}}=a^3\,\pi(\mathbf{x_n})$ (the cell volume a^3 converts the momentum *density* π into the momentum of the site degree of freedom). The Hamiltonian Eq. (9.3) becomes a sum over sites of oscillator energies coupled to their neighbours through the discretized gradient $(\nabla\phi)^2$; it is a lattice of masses joined by springs (Fig. 9.1). Imposing Eq. (9.5) on these site variables gives $[q_{\mathbf{m}},p_{\mathbf{n}}]=i\,\delta_{\mathbf{mn}}$, i.e.

$$\Big[\phi(\mathbf{x_m}),a^3\,\pi(\mathbf{x_n})\Big]=i\,\delta_{\mathbf{mn}}\quad\Longrightarrow\quad[\phi(\mathbf{x_m}),\pi(\mathbf{x_n})]=i\,\frac{\delta_{\mathbf{mn}}}{a^3}. \tag{9.6}$$

As $a\to 0$ the combination $\delta_{\mathbf{mn}}/a^3$ is exactly the lattice representation of the three-dimensional Dirac delta: it vanishes for $\mathbf{m}\neq\mathbf{n}$, diverges at coincidence, and integrates to one over space, $\sum_{\mathbf{n}}a^3\,(\delta_{\mathbf{mn}}/a^3)=1$. The continuum limit of Eq. (9.6) is therefore the equal-time commutator $[\phi(\mathbf{x}),\pi(\mathbf{y})]=i\,\delta^{(3)}(\mathbf{x}-\mathbf{y})$. This is not a derivation of quantum mechanics; it is the demonstration that the canonical quantization of a field is the same postulate the reader already accepts for finitely many oscillators, read in the continuum.

9.1.3 The canonical quantization postulate

We now state the postulate that defines the quantum theory. From here on ϕ and π are operators on a Hilbert space, with all the classical relations of Section 9.1.1 reinterpreted as operator equations.

Definition 9.1 (Equal-time canonical commutation relations)**.** The quantum free scalar field is the operator-valued field $\phi(t,\mathbf{x})$ with conjugate momentum operator

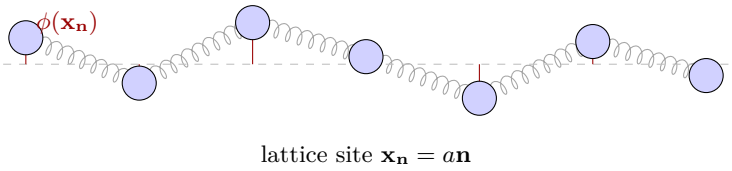

Figure 9.1: The mechanical picture behind canonical quantization. Discretizing space turns the free scalar into a lattice of point masses (sites), each carrying a coordinate $q_{\mathbf{n}} = \phi(\mathbf{x_n})$ (its displacement from equilibrium, red arrows) and coupled to its neighbours by springs encoding the gradient energy $\frac{1}{2}(\nabla\phi)^2$. Quantizing each site by the oscillator rule Eq. (9.5) and taking $a \to 0$ produces the field commutation relations. The mass term $\frac{1}{2}m^2\phi^2$ adds an on-site restoring force; in the next section the normal modes of this lattice become the relativistic plane waves.

$\pi(t, \mathbf{x})$, subject to the *equal-time canonical commutation relations* (ETCR)

$$[\phi(t, \mathbf{x}), \pi(t, \mathbf{y})] = i\,\delta^{(3)}(\mathbf{x} - \mathbf{y}), \tag{9.7}$$

$$[\phi(t, \mathbf{x}), \phi(t, \mathbf{y})] = [\pi(t, \mathbf{x}), \pi(t, \mathbf{y})] = 0, \tag{9.8}$$

in which both operators are evaluated at the *same time* t, and $\delta^{(3)}$ is the three-dimensional Dirac delta distribution of Theorem 5.5.

Three points of interpretation deserve emphasis, because they recur for every field quantized in this book.

First, Eq. (9.7) is the continuum image of Eq. (9.5): the Kronecker δ_{ij} that made discrete oscillators independent has become the Dirac $\delta^{(3)}(\mathbf{x} - \mathbf{y})$ that makes field values at distinct points independent. The factor of i and the units are inherited unchanged from the oscillator.

Second, the relations are imposed at *equal time*. The classical Poisson-bracket structure that canonical quantization promotes is the equal-time symplectic form on phase space; there is no canonical statement about $[\phi(x), \phi(y)]$ at *timelike or spacelike separated* points until we have solved the dynamics. Computing that unequal-time commutator — and discovering that it vanishes outside the light cone — is the content of microcausality, taken up later in this chapter. For now the commutators are anchored to a single time slice.

Third, $\phi(t, \mathbf{x})$ is not literally an operator attached to a point. The right-hand side of Eq. (9.7) is a distribution, so the left-hand side is too: ϕ is an *operator-valued distribution*, and acquires a well-defined operator meaning only after smearing against a test function, $\phi(f) \equiv \int d^3x\, f(\mathbf{x})\, \phi(t, \mathbf{x})$. We will write point-localized expressions throughout, as is universal in physics, but every such expression is shorthand for its smeared version, and the distributional machinery of Chapter 5 is what makes the shorthand safe. Products like $\pi(x)^2$ in the

Hamiltonian Eq. (9.3) are products of distributions at coincident points and will require care (normal ordering, the vacuum energy) later in the chapter; for the commutator algebra of this section no such product appears unprotected, and the manipulations are exact.

Caution

The ETCR are postulated, not derived from the classical theory — quantization is genuinely new physical input, the choice of a noncommutative operator algebra over a commutative one. What the oscillator analogy of Section 9.1.2 establishes is only that this input is the *same* input already accepted in nonrelativistic quantum mechanics, transcribed to a continuum of degrees of freedom. It is not a theorem that the continuum limit exists or is unique; for the free field it does, and that is what the explicit construction of the next section verifies. For interacting fields in four dimensions the very existence of such an operator field is a deep and partly open question (Haag's theorem, triviality), revisited in Part VI.

9.1.4 Why the Heisenberg picture is mandatory

In nonrelativistic quantum mechanics one may freely choose between the Schrödinger picture (states evolve, operators are fixed) and the Heisenberg picture (operators evolve, states are fixed); the two are related by a time-dependent unitary and give identical physics. In a relativistic field theory the choice is not free: only the Heisenberg picture makes Lorentz covariance manifest, and we adopt it from the outset.

The reason is structural. The object we are quantizing is a field $\phi(x)$ on spacetime, a function of the four-vector $x^\mu = (t, \mathbf{x})$. A Lorentz transformation mixes t and $\mathbf{x}$, so if the theory is to wear its covariance openly, the central operator must depend on all four coordinates on the same footing. The Schrödinger picture singles out time: operators are functions of $\mathbf{x}$ alone, evaluated on a privileged time slice, while the time dependence is exiled into the state. That is a legitimate but frame-dependent bookkeeping, and it obscures exactly the symmetry we most want to keep visible. The Heisenberg picture keeps the full $\phi(t, \mathbf{x})$ as a single spacetime operator and is the natural — in practice the only sane — language for covariant field theory.

In the Heisenberg picture the time dependence of the field is generated by the Hamiltonian Eq. (9.3),

$$\phi(t, \mathbf{x}) = e^{iHt}\, \phi(0, \mathbf{x})\, e^{-iHt}, \qquad \pi(t, \mathbf{x}) = e^{iHt}\, \pi(0, \mathbf{x})\, e^{-iHt}, \tag{9.9}$$

where $\phi(0, \mathbf{x})$ and $\pi(0, \mathbf{x})$ are the Schrödinger-picture operators on the $t = 0$ slice, and H is time-independent because the Lagrangian Eq. (9.1) has no explicit time dependence. Because H commutes with itself, H is the same operator in

both pictures, and the ETCR of Theorem 9.1, imposed on the $t = 0$ slice, are propagated to other times by Eq. (9.9); we verify this propagation explicitly in Theorem 9.3 below.

Differentiating Eq. (9.9) in t gives the Heisenberg equation of motion. For any Heisenberg operator $A(t) = e^{iHt}A(0)e^{-iHt}$,

$$\frac{dA}{dt} = iHe^{iHt}A(0)e^{-iHt} - e^{iHt}A(0)e^{-iHt}\,iH = i\,e^{iHt}\,[H, A(0)]\,e^{-iHt} = i\,[H, A(t)]\,, \tag{9.10}$$

using that H commutes through the unitaries it generates. Written for the field and its momentum, with the commutator in the order we will use,

$$i\,\frac{d\phi}{dt} = [\phi, H]\,, \qquad i\,\frac{d\pi}{dt} = [\pi, H]\,. \tag{9.11}$$

The dynamics is now entirely encoded in commutators with H. Everything the classical equations of motion did is reproduced by evaluating the right-hand sides of Eq. (9.11) using only the ETCR.

9.1.5 The Heisenberg equations reproduce Klein–Gordon

We are now in a position to check the central internal consistency of the construction: that the quantum dynamics generated by H is the same dynamics as the classical Klein–Gordon equation, now read as an operator statement. This is the field-theoretic counterpart of the familiar oscillator fact that $[q, H]$ and $[p, H]$ reproduce $\dot{q} = p/m$ and $\dot{p} = -m\omega^2 q$. We carry every step.

The only inputs are the ETCR Eq. (9.7)–Eq. (9.8), the Hamiltonian Eq. (9.3), and two elementary commutator identities valid for any operators,

$$[A, BC] = [A, B]\,C + B\,[A, C]\,, \qquad [AB, C] = A\,[B, C] + [A, C]\,B. \tag{9.12}$$

Throughout, all operators sit on the common time slice t (the slice on which H is evaluated as a spatial integral), so the ETCR apply directly; we suppress the common time argument and write $\phi(\mathbf{x})$, $\pi(\mathbf{y})$, etc. The momentum-conjugate combination of the ETCR we will need repeatedly is, equivalently to Eq. (9.7),

$$[\pi(\mathbf{x}), \phi(\mathbf{y})] = -i\,\delta^{(3)}(\mathbf{x} - \mathbf{y}). \tag{9.13}$$

The first equation: $\dot{\phi} = \pi$. We compute $[\phi(\mathbf{x}), H]$ with $H = \int d^3y\,[\frac{1}{2}\pi(\mathbf{y})^2 + \frac{1}{2}(\nabla\phi(\mathbf{y}))^2 + \frac{1}{2}m^2\phi(\mathbf{y})^2]$. Since ϕ commutes with ϕ at equal times by Eq. (9.8), the gradient and mass terms — built solely from ϕ — contribute nothing, and only the kinetic term survives:

$$[\phi(\mathbf{x}), H] = \int d^3y\;\tfrac{1}{2}\,\Big[\phi(\mathbf{x}), \pi(\mathbf{y})^2\Big]\,. \tag{9.14}$$

Apply the first identity of Eq. (9.12) with $A = \phi(\mathbf{x})$, $B = C = \pi(\mathbf{y})$:

$$\left[\phi(\mathbf{x}), \pi(\mathbf{y})^2\right] = [\phi(\mathbf{x}), \pi(\mathbf{y})]\ \pi(\mathbf{y}) + \pi(\mathbf{y})\ [\phi(\mathbf{x}), \pi(\mathbf{y})] = 2i\,\delta^{(3)}(\mathbf{x}-\mathbf{y})\,\pi(\mathbf{y}), \tag{9.15}$$

where the c-number $\delta^{(3)}(\mathbf{x}-\mathbf{y})$ from Eq. (9.7) commutes freely through $\pi(\mathbf{y})$ and the two terms add. Hence

$$[\phi(\mathbf{x}), H] = \int d^3y\; i\,\delta^{(3)}(\mathbf{x}-\mathbf{y})\,\pi(\mathbf{y}) = i\,\pi(\mathbf{x}). \tag{9.16}$$

Insert this into the first Heisenberg equation Eq. (9.11), $i\,\dot\phi = [\phi, H] = i\pi$, giving

$$\dot\phi(\mathbf{x}) = \pi(\mathbf{x}). \tag{9.17}$$

The quantum equation of motion has reproduced the defining relation Eq. (9.2) between the field and its conjugate momentum — now as an operator identity rather than a definition. This is the first nontrivial consistency check: the Hamiltonian flow is compatible with the Legendre transform that produced it.

The second equation: $\dot\pi = (\nabla^2 - m^2)\phi$. Now we compute $[\pi(\mathbf{x}), H]$. The kinetic term of H is built from π alone and commutes with $\pi(\mathbf{x})$ by Eq. (9.8); the surviving contributions are the gradient and mass terms,

$$[\pi(\mathbf{x}), H] = \int d^3y\ \left[\tfrac{1}{2}\ \left[\pi(\mathbf{x}), (\nabla\phi(\mathbf{y}))^2\right] + \tfrac{1}{2}m^2\ \left[\pi(\mathbf{x}), \phi(\mathbf{y})^2\right]\ \right]. \tag{9.18}$$

Take the mass term first. By the same Leibniz step as above, now using Eq. (9.13),

$$\tfrac{1}{2}m^2\ \left[\pi(\mathbf{x}), \phi(\mathbf{y})^2\right] = \tfrac{1}{2}m^2(\,[\pi(\mathbf{x}), \phi(\mathbf{y})]\,\phi(\mathbf{y}) + \phi(\mathbf{y})\,[\pi(\mathbf{x}), \phi(\mathbf{y})]\,) = -i\,m^2\,\delta^{(3)}(\mathbf{x}-\mathbf{y})\,\phi(\mathbf{y}), \tag{9.19}$$

whose y-integral is $-i\,m^2\,\phi(\mathbf{x})$.

The gradient term needs one extra step because $\pi(\mathbf{x})$ must be commuted past a *spatial derivative* of ϕ. Write $(\nabla\phi)^2 = \sum_i (\partial_i^{\mathbf{y}}\phi(\mathbf{y}))(\partial_i^{\mathbf{y}}\phi(\mathbf{y}))$, where $\partial_i^{\mathbf{y}}$ acts on the argument $\mathbf{y}$. The derivative is a linear operation that the commutator passes through,

$$[\pi(\mathbf{x}), \partial_i^{\mathbf{y}}\phi(\mathbf{y})] = \partial_i^{\mathbf{y}}\,[\pi(\mathbf{x}), \phi(\mathbf{y})] = -i\,\partial_i^{\mathbf{y}}\delta^{(3)}(\mathbf{x}-\mathbf{y}), \tag{9.20}$$

again using Eq. (9.13). Then, by the Leibniz identity applied to the product of the two factors $\partial_i^{\mathbf{y}}\phi(\mathbf{y})$,

$$\tfrac{1}{2}\ [\pi(\mathbf{x}), (\partial_i^{\mathbf{y}}\phi)(\partial_i^{\mathbf{y}}\phi)] = (\partial_i^{\mathbf{y}}\phi(\mathbf{y}))\ [\pi(\mathbf{x}), \partial_i^{\mathbf{y}}\phi(\mathbf{y})] = -i\,(\partial_i^{\mathbf{y}}\phi(\mathbf{y}))\,\partial_i^{\mathbf{y}}\delta^{(3)}(\mathbf{x}-\mathbf{y}), \tag{9.21}$$

the c-number derivative-of-delta again commuting through. Integrating over $\mathbf{y}$ and summing on i,

$$\int d^3y\ (-i)\,(\partial_i^{\mathbf{y}}\phi(\mathbf{y}))\,\partial_i^{\mathbf{y}}\delta^{(3)}(\mathbf{x}-\mathbf{y}). \tag{9.22}$$

Integrate by parts in $\mathbf{y}$, the boundary term vanishing because fields fall off at spatial infinity (equivalently because the delta has compact support):

$$\int d^3y\,(-i)\,(\partial_i^{\mathbf{y}}\phi)\,\partial_i^{\mathbf{y}}\delta^{(3)}(\mathbf{x}-\mathbf{y}) = \int d^3y\,(+i)\,(\partial_i^{\mathbf{y}}\partial_i^{\mathbf{y}}\phi(\mathbf{y}))\,\delta^{(3)}(\mathbf{x}-\mathbf{y}) = i\,\nabla^2\phi(\mathbf{x}). \tag{9.23}$$

Collecting the gradient and mass contributions in Eq. (9.18),

$$[\pi(\mathbf{x}), H] = i\,\nabla^2\phi(\mathbf{x}) - i\,m^2\phi(\mathbf{x}) = i\,(\nabla^2 - m^2)\,\phi(\mathbf{x}). \tag{9.24}$$

Insert this into the second Heisenberg equation Eq. (9.11), $i\,\dot\pi = [\pi, H]$:

$$\dot\pi(\mathbf{x}) = (\nabla^2 - m^2)\,\phi(\mathbf{x}). \tag{9.25}$$

Assembling Klein–Gordon. Differentiate Eq. (9.17) once more in time and substitute Eq. (9.25):

$$\ddot\phi = \dot\pi = (\nabla^2 - m^2)\,\phi \quad\Longrightarrow\quad \ddot\phi - \nabla^2\phi + m^2\phi = 0. \tag{9.26}$$

With $\Box = \partial_0^2 - \nabla^2$ in the mostly-minus metric, this is precisely

$$(\Box + m^2)\,\phi(x) = 0, \tag{9.27}$$

the operator Klein–Gordon equation. We record the result.

Proposition 9.2 (Heisenberg dynamics reproduces Klein–Gordon)**.** *Let ϕ and π be operators satisfying the equal-time canonical commutation relations of Theorem 9.1 and evolving in the Heisenberg picture under the free Hamiltonian Eq. (9.3). Then the Heisenberg equations of motion Eq. (9.11) are equivalent to the pair*

$$\dot\phi = \pi, \qquad \dot\pi = (\nabla^2 - m^2)\,\phi, \tag{9.28}$$

which together imply the operator Klein–Gordon equation $(\Box + m^2)\phi = 0$ of Eq. (9.27). The quantum field obeys, as an operator identity, the same dynamical equation Eq. (9.4) as the classical field.

The significance is worth stating plainly. We did not assume the operator field satisfies Klein–Gordon; we assumed only the ETCR and the form of H, and the dynamics followed. Conversely, the operator equation Eq. (9.27) is the bridge to the next section: it is a linear wave equation for an operator, and its general solution is a superposition of plane-wave modes whose coefficients are the operators we will identify as ladder operators. The classical solution method survives quantization wholesale; only the Fourier coefficients are promoted to operators.

Physical Insight

The harmonic oscillator's $[q, H] \propto p$ and $[p, H] \propto q$ closed back on Newton's second law; here $[\phi, H] \propto \pi$ and $[\pi, H] \propto (\nabla^2 - m^2)\phi$ close back on Klein–Gordon. Nothing in the field case is conceptually new — it is the oscillator computation done at every point of space at once, with the spatial coupling $(\nabla\phi)^2$ supplying the ∇^2 that ties neighbouring degrees of freedom together into a wave rather than leaving them as independent oscillations. This is the precise sense in which a free field "is" a continuum of oscillators.

9.1.6 Consistency: the canonical structure is conserved

One loose end remains. The ETCR of Theorem 9.1 were imposed on a single time slice. The Heisenberg evolution Eq. (9.9) then defines ϕ and π at every other time. For the construction to be consistent, the same canonical relations must hold on every slice — otherwise the algebra would depend on an arbitrary choice of initial time, and "equal-time commutator" would be ambiguous. We verify that the canonical structure is preserved, in two complementary ways.

Worked Example 9.3 (The ETCR are conserved by time evolution)**.** *Argument 1 (unitarity).* Time evolution acts by conjugation with the unitary $U(t) = e^{-iHt}$, and conjugation by a fixed unitary is an automorphism of the operator algebra: for any operators A, B,

$$\left[U^\dagger A\, U,\, U^\dagger B\, U\right] = U^\dagger\, [A, B]\, U, \tag{9.29}$$

since the intermediate $UU^\dagger = \mathbf{1}$ cancels. Applying this to Eq. (9.9) with $A = \phi(0, \mathbf{x})$, $B = \pi(0, \mathbf{y})$, and using that the $t = 0$ ETCR give $[\phi(0, \mathbf{x}), \pi(0, \mathbf{y})] = i\,\delta^{(3)}(\mathbf{x} - \mathbf{y})$,

$$[\phi(t, \mathbf{x}), \pi(t, \mathbf{y})] = e^{iHt}\, [\phi(0, \mathbf{x}), \pi(0, \mathbf{y})]\, e^{-iHt} = e^{iHt}\, \left(i\,\delta^{(3)}(\mathbf{x}-\mathbf{y})\right) e^{-iHt} = i\,\delta^{(3)}(\mathbf{x}-\mathbf{y}), \tag{9.30}$$

because the c-number $\delta^{(3)}$ passes through the unitaries and $e^{iHt}e^{-iHt} = \mathbf{1}$. The same step applied to Eq. (9.8) gives $[\phi(t, \mathbf{x}), \phi(t, \mathbf{y})] = [\pi(t, \mathbf{x}), \pi(t, \mathbf{y})] = 0$ on every slice. The equal-time canonical algebra is therefore independent of the slice on which it is imposed.

Argument 2 (infinitesimal, using the equations of motion). It is instructive to see the same conservation differentially, as a check that it is consistent with the dynamics derived in Theorem 9.2 rather than an independent assumption. Differentiate the equal-time commutator and use the product rule together with $\dot\phi = \pi$ from Eq. (9.17) and $\dot\pi = (\nabla^2 - m^2)\phi$ from Eq. (9.25):

$$\frac{d}{dt}\, [\phi(t, \mathbf{x}), \pi(t, \mathbf{y})] = \left[\dot\phi(t, \mathbf{x}), \pi(t, \mathbf{y})\right] + [\phi(t, \mathbf{x}), \dot\pi(t, \mathbf{y})]$$

$$= [\pi(t,\mathbf{x}),\pi(t,\mathbf{y})] + \left[\phi(t,\mathbf{x}),(\nabla^2_{\mathbf{y}}-m^2)\phi(t,\mathbf{y})\right]$$
$$= 0 + (\nabla^2_{\mathbf{y}}-m^2)\,[\phi(t,\mathbf{x}),\phi(t,\mathbf{y})] = 0, \tag{9.31}$$

where the first commutator vanishes by Eq. (9.8) and the second because $(\nabla^2_{\mathbf{y}}-m^2)$ acts on $\mathbf{y}$ and pulls outside the commutator, which is itself zero by Eq. (9.8). The right-hand side $i\,\delta^{(3)}(\mathbf{x}-\mathbf{y})$ is time-independent, consistent with its derivative vanishing. The identical computation gives $\frac{d}{dt}\,[\phi,\phi] = [\pi,\phi] + [\phi,\pi] = 0$ and $\frac{d}{dt}\,[\pi,\pi] = (\nabla^2 - m^2)([\phi,\pi]+[\pi,\phi]) = 0$, so all three ETCR are stationary. The canonical structure is a constant of the motion.

Both arguments deliver the same conclusion, and they reinforce each other: unitarity guarantees the preservation abstractly, while the infinitesimal check confirms that the specific equations of motion derived from H are exactly the ones consistent with that preservation. With this, Theorem 9.1 is a self-consistent definition: the equal-time commutators may be imposed on any one slice, and the dynamics distributes them faithfully to all others.

We have now built the object the rest of the chapter studies: a Heisenberg-picture operator field $\phi(x)$, obeying the operator Klein–Gordon equation Eq. (9.27) together with the equal-time canonical commutators Eq. (9.7)–Eq. (9.8). This is an operator equation we have not yet solved. The next section solves it the only way a linear wave equation can be solved — by expanding ϕ in plane-wave modes — and discovers that the Fourier coefficients are creation and annihilation operators whose algebra is fixed, mode by mode, by the canonical relations established here.

9.2 The Mode Expansion and Ladder Operators

The previous section handed us a Heisenberg-picture operator field $\phi(x)$, its conjugate momentum $\pi(x) = \partial_0\phi(x)$, the equal-time canonical commutation relations (ETCR)

$$[\phi(t,\mathbf{x}),\pi(t,\mathbf{y})] = i\,\delta^3(\mathbf{x}-\mathbf{y}), \qquad [\phi(t,\mathbf{x}),\phi(t,\mathbf{y})] = [\pi(t,\mathbf{x}),\pi(t,\mathbf{y})] = 0, \tag{9.32}$$

and the operator Klein–Gordon equation $(\Box+m^2)\phi = 0$, established in Section 9.1. We now have an operator-valued equation of motion and an algebra, but no solution and no Hilbert space yet. This section produces the solution. The strategy was announced in the chapter introduction and is worth restating in one sentence: a free field is a continuum of decoupled harmonic oscillators labelled by spatial momentum, so we Fourier-decompose ϕ into plane-wave modes, recognise each Fourier coefficient as a ladder operator of one such oscillator, and read off its algebra from Eq. (9.32). The only genuinely new ingredient beyond the Sakurai-level oscillator is relativistic bookkeeping: we must integrate over on-shell momenta with a measure that respects Lorentz invariance, and we must normalise

the ladder operators so that this covariance stays manifest. We deal with that measure first, because every formula in the rest of the chapter is written against it.

9.2.1 The Lorentz-invariant measure

A real classical solution of $(\Box + m^2)\phi = 0$ is a superposition of plane waves $e^{\mp ip\cdot x}$ whose four-momentum lies on the positive-energy mass shell

$$p^2 = m^2, \qquad p^0 = E_{\mathbf{p}} \equiv \sqrt{\mathbf{p}^2 + m^2} > 0. \tag{9.33}$$

The set of such p is the forward sheet of the two-sheeted hyperboloid $p^2 = m^2$ (Fig. 9.2). Summing over modes therefore means integrating a function $f(\mathbf{p})$ over this sheet. The naive choice $\int d^3p\, f(\mathbf{p})$ is *not* Lorentz invariant: a boost mixes p^0 into the spatial components and distorts the volume element d^3p. The correct, invariant prescription is

Definition 9.4 (Lorentz-invariant measure)**.** The *Lorentz-invariant measure* on the positive mass shell (9.33) is

$$\int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}}\,, \qquad E_{\mathbf{p}} = \sqrt{\mathbf{p}^2 + m^2}. \tag{9.34}$$

The factor $(2\pi)^3$ is bookkeeping matched to the Fourier convention of Chapter 5; the dynamically meaningful factor is the $1/2E_{\mathbf{p}}$.

The cleanest proof that (9.34) is invariant builds it out of a manifestly invariant four-dimensional integral and an on-shell delta function. This is the device the book will reuse whenever a three-dimensional phase-space integral must be shown to be covariant.

Theorem 9.5 (Invariance of the on-shell measure)**.** *Under a proper orthochronous Lorentz transformation $p \mapsto p' = \Lambda p$ (with $\Lambda \in SO^+(1,3)$, the connected component identified in Theorem 3.6), the measure (9.34) is unchanged: for any test function f on the mass shell,*

$$\int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}}\, f(p)\Big|_{p^0 = E_{\mathbf{p}}} = \int \frac{d^3p'}{(2\pi)^3\, 2E_{\mathbf{p}'}}\, f(\Lambda^{-1}p')\Big|_{p'^0 = E_{\mathbf{p}'}}. \tag{9.35}$$

Proof. Consider the four-dimensional integral

$$I[f] = \int \frac{d^4p}{(2\pi)^4}\, (2\pi)\, \delta(p^2 - m^2)\, \theta(p^0)\, f(p), \tag{9.36}$$

where now p^0 is an *independent* integration variable, not yet set to $E_{\mathbf{p}}$. We show two things: (i) $I[f]$ equals the left-hand side of (9.35); (ii) $I[f]$ is invariant under $SO^+(1,3)$. Together these give the claim.

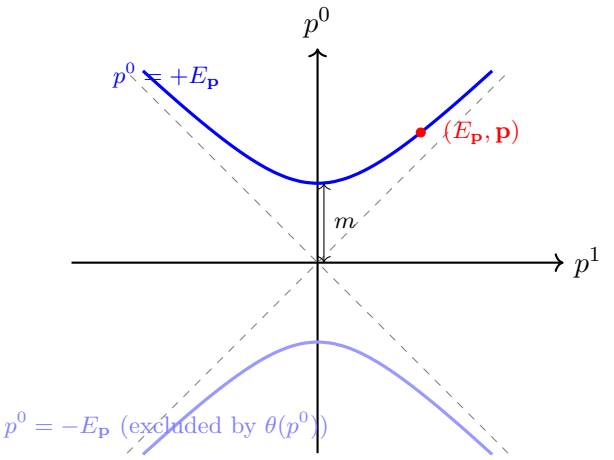

Figure 9.2: The mass shell $p^2 = m^2$ in the (p^0, p^1) plane. The step function $\theta(p^0)$ selects the upper (forward) sheet $p^0 = +E_{\mathbf{p}}$. A proper orthochronous Lorentz transformation slides points along a sheet without ever crossing the light cone (dashed), so it never moves a forward vector onto the backward sheet; this is why $\theta(p^0)$, and hence the measure (9.34), is invariant.

(i) Doing the p^0 integral. Hold $\mathbf{p}$ fixed and write the argument of the delta function as a function of p^0:

$$p^2 - m^2 = (p^0)^2 - \mathbf{p}^2 - m^2 = (p^0)^2 - E_{\mathbf{p}}^2. \tag{9.37}$$

This vanishes at the two simple roots $p^0 = \pm E_{\mathbf{p}}$. The composition rule for the delta distribution proved in Theorem 5.5,

$$\delta(g(p^0)) = \sum_{i:\, g(p_i^0)=0} \frac{\delta(p^0 - p_i^0)}{|g'(p_i^0)|}, \tag{9.38}$$

applies with $g(p^0) = (p^0)^2 - E_{\mathbf{p}}^2$, so that $g'(p^0) = 2p^0$ and $|g'(\pm E_{\mathbf{p}})| = 2E_{\mathbf{p}}$. Hence

$$\delta(p^2 - m^2) = \frac{1}{2E_{\mathbf{p}}}\Big[\,\delta(p^0 - E_{\mathbf{p}}) + \delta(p^0 + E_{\mathbf{p}})\,\Big]. \tag{9.39}$$

The step function $\theta(p^0)$ kills the second term, which has support at the negative root. Performing the p^0 integral against the surviving $\delta(p^0 - E_{\mathbf{p}})$ collapses the (2π) against one power of $(2\pi)^{-4}$ and sets $p^0 = E_{\mathbf{p}}$ inside f:

$$I[f] = \int \frac{d^3p}{(2\pi)^3}\,\frac{1}{2E_{\mathbf{p}}}\,f(E_{\mathbf{p}}, \mathbf{p}), \tag{9.40}$$

which is exactly the left-hand side of (9.35).

(ii) Invariance of (9.36). We check each factor of the integrand in turn. The four-volume d^4p transforms with the Jacobian $|\det(\partial p'/\partial p)| = |\det \Lambda|$. Every

$\Lambda \in O(1,3)$ satisfies $\Lambda^{\mathsf{T}}\eta\Lambda = \eta$, whence $(\det\Lambda)^2 = 1$ and $\det\Lambda = \pm 1$; the proper subgroup is precisely the one with $\det\Lambda = +1$, so $d^4p' = d^4p$. The argument $p^2 = \eta_{\mu\nu}p^\mu p^\nu$ of the delta function is a Lorentz scalar, so $\delta(p^2 - m^2)$ is invariant. The mass parameter m^2 is a fixed number. There remains $\theta(p^0)$. Its invariance is the one place the words "proper" and "orthochronous" actually earn their keep. The support of $\delta(p^2 - m^2)$ is the set $p^2 = m^2 \geq 0$, i.e. timelike (or, in the $m \to 0$ limit, null) four-vectors. For any such vector with $p^0 > 0$ — a *future-pointing* vector — an orthochronous transformation, defined in Theorem 3.3 by ${\Lambda^0}_0 \geq 1$, keeps $p'^0 > 0$. Concretely, for a timelike p one has the reverse Cauchy–Schwarz inequality $\left|\sum_i {\Lambda^0}_i\, p^i\right| < {\Lambda^0}_0\, p^0$ on the forward cone, so the sign of $p'^0 = {\Lambda^0}_0 p^0 + {\Lambda^0}_i p^i$ is fixed by the dominant term ${\Lambda^0}_0 p^0 > 0$. Thus a future-pointing on-shell vector maps to a future-pointing on-shell vector, and $\theta(p^0)$ is invariant on the support of the delta function. Every factor of (9.36) is therefore invariant, so $I[f] = I[f \circ \Lambda^{-1}]$; combined with (9.40) this is (9.35). $\square$

The identity (9.39) is worth recording on its own, because it is the covariant statement that the measure equals an integral over the forward cone:

$$\frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}} \;=\; \frac{d^4p}{(2\pi)^4}\,(2\pi)\,\delta(p^2 - m^2)\,\theta(p^0). \tag{9.41}$$

We will reuse this in the next section to write the conserved four-momentum covariantly, and again in the construction of the propagator later in the chapter.

9.2.2 The mode expansion of the field

We now solve the operator Klein–Gordon equation. Classically, the general real solution of $(\Box + m^2)\phi = 0$ is a superposition of the plane-wave solutions $e^{-ip\cdot x}$ and $e^{+ip\cdot x}$ with p on the positive mass shell (9.33); reality pairs the coefficient of $e^{+ip\cdot x}$ as the complex conjugate of the coefficient of $e^{-ip\cdot x}$. Quantization promotes these two coefficients to operators, mutually adjoint rather than complex-conjugate, since ϕ is now a Hermitian operator. Integrating over modes with the invariant measure (9.34), we are led to the following ansatz, which we will then verify solves the equation and is consistent with the ETCR.

Definition 9.6 (Mode expansion)**.** The free Hermitian scalar field and its conjugate momentum are expanded as

$$\phi(x) = \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}} \Big(a_{\mathbf{p}}\, e^{-ip\cdot x} + a^\dagger_{\mathbf{p}}\, e^{+ip\cdot x} \Big)\Big|_{p^0 = E_{\mathbf{p}}}, \tag{9.42}$$

$$\pi(x) = \partial_0\phi(x) = \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}}\, (-iE_{\mathbf{p}}) \Big(a_{\mathbf{p}}\, e^{-ip\cdot x} - a^\dagger_{\mathbf{p}}\, e^{+ip\cdot x} \Big)\Big|_{p^0 = E_{\mathbf{p}}}, \tag{9.43}$$

with $p \cdot x = E_{\mathbf{p}} x^0 - \mathbf{p} \cdot \mathbf{x}$ on shell. The operators $a_{\mathbf{p}}$ (annihilation) and $a^\dagger_{\mathbf{p}}$ (creation) are the unknowns; the relativistic normalization is fixed by the choice of measure in (9.42).

Three points justify each part of this ansatz before we extract the algebra.

It solves the equation. Acting with $\Box + m^2$ on (9.42), the derivatives hit only the exponentials. On the mass shell $\Box\, e^{\mp ip\cdot x} = -p^2\, e^{\mp ip\cdot x} = -m^2\, e^{\mp ip\cdot x}$, so $(\Box + m^2) e^{\mp ip\cdot x} = 0$ mode by mode and the whole integral vanishes. Thus (9.42) is a solution of the operator Klein–Gordon equation for *any* operators $a_{\mathbf{p}}, a^\dagger_{\mathbf{p}}$; the equation of motion fixes the kinematics (which exponentials appear) but says nothing yet about the algebra. The algebra will come from the ETCR.

It is manifestly Hermitian. The second term of (9.42) is the adjoint of the first, integrated against the same real measure, so $\phi^\dagger = \phi$. This is the operator analogue of the classical reality condition.

The momentum expansion is consistent. Differentiating (9.42) with respect to x^0 brings down $-iE_{\mathbf{p}}$ from $e^{-ip\cdot x}$ and $+iE_{\mathbf{p}}$ from $e^{+ip\cdot x}$, giving exactly (9.43). We use $\pi = \partial_0 \phi$, the canonical momentum of the free scalar established in Section 9.1.

9.2.3 Inversion: extracting the ladder operators

To read off the algebra of $a_{\mathbf{p}}$ from (9.32) we first invert the expansion, expressing $a_{\mathbf{p}}$ and $a^\dagger_{\mathbf{p}}$ as integrals of ϕ and π over a single constant-time slice. The idea is the standard Fourier projection: integrate the field against a conjugate plane wave over all space at fixed time, picking out one momentum component.

Proposition 9.7 (Inversion formulae)**.** *For each* $\mathbf{p}$ *the operators in* (9.42) *are given, at any fixed time* $x^0 = t$*, by*

$$a_{\mathbf{p}} = \int d^3x\, e^{+ip\cdot x} \big(E_{\mathbf{p}}\, \phi(x) + i\, \pi(x)\big)\Big|_{p^0 = E_{\mathbf{p}}} = i \int d^3x\, e^{+ip\cdot x} \overset{\leftrightarrow}{\partial_0}\, \phi(x), \tag{9.44}$$

$$a^\dagger_{\mathbf{p}} = \int d^3x\, e^{-ip\cdot x} \big(E_{\mathbf{p}}\, \phi(x) - i\, \pi(x)\big)\Big|_{p^0 = E_{\mathbf{p}}} = -\, i \int d^3x\, e^{-ip\cdot x} \overset{\leftrightarrow}{\partial_0}\, \phi(x), \tag{9.45}$$

where $f \overset{\leftrightarrow}{\partial_0} g \equiv f\,(\partial_0 g) - (\partial_0 f)\, g$*. The right-hand sides are independent of the time* t *at which the slice is taken.*

Proof. Insert the expansions (9.42)–(9.43) into the first form of (9.44). Two spatial Fourier integrals appear. Writing q for the integration momentum of the field and p for the fixed external momentum, and keeping the on-shell time factors explicit,

$$\int d^3x\, e^{+ip\cdot x}\, \phi(x) = \int \frac{d^3q}{(2\pi)^3\, 2E_{\mathbf{q}}} \int d^3x \Big(a_{\mathbf{q}}\, e^{i(p-q)\cdot x} + a^\dagger_{\mathbf{q}}\, e^{i(p+q)\cdot x} \Big)$$

$$= \int \frac{d^3q}{(2\pi)^3\,2E_{\mathbf{q}}}\Big(a_{\mathbf{q}}\,e^{i(E_{\mathbf{p}}-E_{\mathbf{q}})t}(2\pi)^3\delta^3(\mathbf{p}-\mathbf{q}) + a^\dagger_{\mathbf{q}}\,e^{i(E_{\mathbf{p}}+E_{\mathbf{q}})t}(2\pi)^3\delta^3(\mathbf{p}+\mathbf{q})\Big). \tag{9.46}$$

Here the spatial integral $\int d^3x\, e^{-i(\mathbf{p}\mp\mathbf{q})\cdot\mathbf{x}} = (2\pi)^3\delta^3(\mathbf{p}\mp\mathbf{q})$ is the standard Fourier representation of the delta distribution from Theorem 5.18. The first delta sets $\mathbf{q}=\mathbf{p}$ (so $E_{\mathbf{q}}=E_{\mathbf{p}}$ and the time factor becomes 1); the second sets $\mathbf{q}=-\mathbf{p}$ (so again $E_{\mathbf{q}}=E_{\mathbf{p}}$, leaving a factor $e^{2iE_{\mathbf{p}}t}$). Doing the q-integral and cancelling $(2\pi)^3/[(2\pi)^3 2E_{\mathbf{p}}] = 1/2E_{\mathbf{p}}$,

$$\int d^3x\; e^{+ip\cdot x}\,\phi(x) = \frac{1}{2E_{\mathbf{p}}}\Big(a_{\mathbf{p}} + a^\dagger_{-\mathbf{p}}\,e^{2iE_{\mathbf{p}}t}\Big). \tag{9.47}$$

The identical manipulation on the momentum expansion (9.43), where the integrand carries the extra factor $-iE_{\mathbf{q}}$ with a relative minus sign between the two terms, gives

$$\int d^3x\; e^{+ip\cdot x}\,\pi(x) = \frac{-iE_{\mathbf{p}}}{2E_{\mathbf{p}}}\Big(a_{\mathbf{p}} - a^\dagger_{-\mathbf{p}}\,e^{2iE_{\mathbf{p}}t}\Big) = -\frac{i}{2}\Big(a_{\mathbf{p}} - a^\dagger_{-\mathbf{p}}\,e^{2iE_{\mathbf{p}}t}\Big). \tag{9.48}$$

Now form the combination $E_{\mathbf{p}}\,(9.47) + i\,(9.48)$:

$$E_{\mathbf{p}}\int d^3x\, e^{ip\cdot x}\phi + i\int d^3x\, e^{ip\cdot x}\pi = \frac{1}{2}\Big(a_{\mathbf{p}} + a^\dagger_{-\mathbf{p}}e^{2iE_{\mathbf{p}}t}\Big) + \frac{1}{2}\Big(a_{\mathbf{p}} - a^\dagger_{-\mathbf{p}}e^{2iE_{\mathbf{p}}t}\Big) = a_{\mathbf{p}}. \tag{9.49}$$

The creation-operator pieces, with their $e^{2iE_{\mathbf{p}}t}$ time factors, cancel identically, leaving $a_{\mathbf{p}}$ alone — and with no residual dependence on t. This is the first form of (9.44). The compact form follows by recognising the combination: with $f = e^{+ip\cdot x}$ one has $\partial_0 f = iE_{\mathbf{p}} f$, so

$$i\,f\overleftrightarrow{\partial_0}\,\phi = i(f\,\partial_0\phi - (\partial_0 f)\,\phi) = i\,f\,\pi + E_{\mathbf{p}}\,f\,\phi, \tag{9.50}$$

whose space integral is precisely (9.49). Taking the Hermitian adjoint of (9.44), using $\phi^\dagger=\phi$, $\pi^\dagger=\pi$ and $(e^{ip\cdot x})^* = e^{-ip\cdot x}$, gives (9.45).

Time-independence, asserted in passing above, deserves an explicit verification rather than reliance on the cancellation in (9.49); we discharge it in Theorem 9.8. □

Worked Example 9.8 (The inversion is time-independent)**.** We show directly that $\partial_t a_{\mathbf{p}} = 0$, so that the slice in Theorem 9.7 may be taken at any time. Differentiate the first form of (9.44) under the integral sign:

$$\partial_t a_{\mathbf{p}} = \int d^3x\;\partial_t\Big[e^{ip\cdot x}(E_{\mathbf{p}}\,\phi + i\,\pi)\Big] = \int d^3x\; e^{ip\cdot x}\Big(iE_{\mathbf{p}}(E_{\mathbf{p}}\phi + i\pi) + E_{\mathbf{p}}\,\partial_t\phi + i\,\partial_t\pi\Big), \tag{9.51}$$

where we used $\partial_t e^{ip\cdot x} = iE_{\mathbf{p}} e^{ip\cdot x}$. Now substitute the operator equations of motion established in Section 9.1: $\partial_t \phi = \pi$ (definition of the conjugate momentum) and $\partial_t \pi = \partial_t^2 \phi = (\nabla^2 - m^2)\phi$ (the Heisenberg equation, equivalent to the Klein–Gordon equation). The bracket becomes

$$iE_{\mathbf{p}}^2\phi - E_{\mathbf{p}}\pi + E_{\mathbf{p}}\pi + i(\nabla^2 - m^2)\phi = i(E_{\mathbf{p}}^2 - m^2)\phi + i\,\nabla^2\phi = i\,\mathbf{p}^2\,\phi + i\,\nabla^2\phi, \tag{9.52}$$

using $E_{\mathbf{p}}^2 - m^2 = \mathbf{p}^2$. The two π-terms have cancelled. It remains to integrate against $e^{ip\cdot x}$. Twice integrating by parts in $\mathbf{x}$ (boundary terms vanish for the smeared, normalizable configurations of Chapter 5) trades ∇^2 acting on ϕ for ∇^2 acting on the exponential: $\int d^3x\, e^{ip\cdot x}\nabla^2\phi = \int d^3x\,(\nabla^2 e^{ip\cdot x})\phi = -\mathbf{p}^2 \int d^3x\, e^{ip\cdot x}\phi$, since $\nabla^2 e^{-i\mathbf{p}\cdot\mathbf{x}} = -\mathbf{p}^2 e^{-i\mathbf{p}\cdot\mathbf{x}}$. Hence

$$\partial_t a_{\mathbf{p}} = i\int d^3x\, e^{ip\cdot x}(\mathbf{p}^2\phi + \nabla^2\phi) = i(\mathbf{p}^2 - \mathbf{p}^2)\int d^3x\, e^{ip\cdot x}\phi = 0. \tag{9.53}$$

The annihilation operator is genuinely constant in time, as the Heisenberg picture of a *free* field demands: $a_{\mathbf{p}}$ is a constant of the motion, the operator amplitude of a single eternal mode. The same computation with $e^{-ip\cdot x}$ shows $\partial_t a_{\mathbf{p}}^\dagger = 0$.

9.2.4 The ladder algebra

With the inversion formulae in hand the algebra of $a_{\mathbf{p}}$ follows from the ETCR by a single double integral. This is the central computation of the section: it converts the canonical commutators of the fields into the oscillator algebra of the modes.

Theorem 9.9 (Ladder algebra)**.** *The operators defined by* (9.44)–(9.45) *satisfy*

$$\left[a_{\mathbf{p}}, a_{\mathbf{q}}^\dagger\right] = (2\pi)^3\, 2E_{\mathbf{p}}\,\delta^3(\mathbf{p}-\mathbf{q}), \qquad [a_{\mathbf{p}}, a_{\mathbf{q}}] = \left[a_{\mathbf{p}}^\dagger, a_{\mathbf{q}}^\dagger\right] = 0. \tag{9.54}$$

Proof. Because each of $a_{\mathbf{p}}$, $a_{\mathbf{q}}^\dagger$ is time-independent (Theorem 9.8), we may evaluate both on the *same* time slice $x^0 = y^0 = t$ and use the equal-time relations (9.32). Write $\phi_x \equiv \phi(t,\mathbf{x})$, $\pi_x \equiv \pi(t,\mathbf{x})$. From the first forms of (9.44) and (9.45),

$$\left[a_{\mathbf{p}}, a_{\mathbf{q}}^\dagger\right] = \int d^3x\, d^3y\; e^{ip\cdot x}\, e^{-iq\cdot y}\,\left[E_{\mathbf{p}}\phi_x + i\pi_x,\; E_{\mathbf{q}}\phi_y - i\pi_y\right]. \tag{9.55}$$

Expand the commutator bilinearly. The four terms are

$$E_{\mathbf{p}}E_{\mathbf{q}}\,[\phi_x,\phi_y] - iE_{\mathbf{p}}\,[\phi_x,\pi_y] + iE_{\mathbf{q}}\,[\pi_x,\phi_y] + [\pi_x,\pi_y]\,. \tag{9.56}$$

By the ETCR (9.32) the first and last vanish, while $[\phi_x,\pi_y] = i\delta^3(\mathbf{x}-\mathbf{y})$ and $[\pi_x,\phi_y] = -i\delta^3(\mathbf{x}-\mathbf{y})$. Hence the bracket equals

$$-iE_{\mathbf{p}}\cdot i\,\delta^3(\mathbf{x}-\mathbf{y}) + iE_{\mathbf{q}}\cdot(-i)\,\delta^3(\mathbf{x}-\mathbf{y}) = (E_{\mathbf{p}} + E_{\mathbf{q}})\,\delta^3(\mathbf{x}-\mathbf{y}). \tag{9.57}$$

Insert this into (9.55) and use $\delta^3(\mathbf{x}-\mathbf{y})$ to do the $\mathbf{y}$-integral, setting $\mathbf{y}=\mathbf{x}$ and $y^0 = x^0 = t$:

$$\left[a_{\mathbf{p}}, a_{\mathbf{q}}^\dagger\right] = (E_{\mathbf{p}}+E_{\mathbf{q}}) \int d^3x\; e^{i(E_{\mathbf{p}}-E_{\mathbf{q}})t}\, e^{-i(\mathbf{p}-\mathbf{q})\cdot\mathbf{x}} = (E_{\mathbf{p}}+E_{\mathbf{q}})\, e^{i(E_{\mathbf{p}}-E_{\mathbf{q}})t}\, (2\pi)^3\delta^3(\mathbf{p}-\mathbf{q}). \tag{9.58}$$

The remaining delta sets $\mathbf{q}=\mathbf{p}$, whereupon $E_{\mathbf{q}} = E_{\mathbf{p}}$, the time factor $e^{i(E_{\mathbf{p}}-E_{\mathbf{q}})t} = 1$, and $E_{\mathbf{p}} + E_{\mathbf{q}} = 2E_{\mathbf{p}}$. This yields the advertised

$$\left[a_{\mathbf{p}}, a_{\mathbf{q}}^\dagger\right] = (2\pi)^3\, 2E_{\mathbf{p}}\, \delta^3(\mathbf{p}-\mathbf{q}). \tag{9.59}$$

For the second relation, repeat the computation with $a_{\mathbf{q}}$ in place of $a_{\mathbf{q}}^\dagger$. The only change is the sign of the π_y term:

$$[a_{\mathbf{p}}, a_{\mathbf{q}}] = \int d^3x\, d^3y\; e^{ip\cdot x}\, e^{iq\cdot y}\; \left[E_{\mathbf{p}}\phi_x + i\pi_x,\; E_{\mathbf{q}}\phi_y + i\pi_y\right]. \tag{9.60}$$

The surviving terms now give $iE_{\mathbf{p}}\,[\phi_x, \pi_y] + iE_{\mathbf{q}}\,[\pi_x, \phi_y] = iE_{\mathbf{p}}(i\delta) + iE_{\mathbf{q}}(-i\delta) = (E_{\mathbf{q}} - E_{\mathbf{p}})\,\delta^3(\mathbf{x}-\mathbf{y})$. The $\mathbf{y}$-integral then produces $(2\pi)^3\delta^3(\mathbf{p}+\mathbf{q})$, which forces $\mathbf{q} = -\mathbf{p}$, hence $E_{\mathbf{q}} = E_{\mathbf{p}}$ and the prefactor $E_{\mathbf{q}} - E_{\mathbf{p}} = 0$. Therefore $[a_{\mathbf{p}}, a_{\mathbf{q}}] = 0$, and taking the adjoint, $\left[a_{\mathbf{p}}^\dagger, a_{\mathbf{q}}^\dagger\right] = 0$. □

The structure of (9.54) is exactly that of an infinite family of independent harmonic oscillators, one for each momentum $\mathbf{p}$: distinct momenta commute, and a creation operator fails to commute with its own annihilation operator by a c-number. The continuum delta function $\delta^3(\mathbf{p}-\mathbf{q})$ replaces the Kronecker delta of the discrete oscillator, and the factor $(2\pi)^3 2E_{\mathbf{p}}$ is the relativistic normalization carried by our choice of measure. The whole engine of Chapter 9 is now the Sakurai-level oscillator solution applied to this family — but with the bookkeeping fixed so that Lorentz covariance never has to be re-checked.

It is reassuring, and a good consistency test of the whole construction, that the algebra (9.54) reproduces the ETCR we started from when fed back through the mode expansion. We verify this closure explicitly.

Worked Example 9.10 (The algebra reproduces the ETCR)**.** We compute $[\phi(t,\mathbf{x}), \pi(t,\mathbf{y})]$ from (9.42)–(9.43) and the algebra (9.54), and recover $i\delta^3(\mathbf{x}-\mathbf{y})$. Substituting the expansions,

$$\begin{aligned}[\phi(x), \pi(y)] = \int \frac{d^3p}{(2\pi)^3 2E_{\mathbf{p}}} \frac{d^3q}{(2\pi)^3 2E_{\mathbf{q}}}\, (-iE_{\mathbf{q}}) \\ \times \left[a_{\mathbf{p}}e^{-ip\cdot x} + a_{\mathbf{p}}^\dagger e^{ip\cdot x},\; a_{\mathbf{q}}e^{-iq\cdot y} - a_{\mathbf{q}}^\dagger e^{iq\cdot y}\right].\end{aligned} \tag{9.61}$$

Only the two cross commutators survive,

$$\left[a_{\mathbf{p}}, a_{\mathbf{q}}^\dagger\right] = (2\pi)^3 2E_{\mathbf{p}}\, \delta^3(\mathbf{p}-\mathbf{q}), \qquad \left[a_{\mathbf{p}}^\dagger, a_{\mathbf{q}}\right] = -(2\pi)^3 2E_{\mathbf{p}}\, \delta^3(\mathbf{p}-\mathbf{q}), \tag{9.62}$$

the like–like commutators being zero by (9.54). Each delta function collapses the $\mathbf{q}$-integral onto $\mathbf{q}=\mathbf{p}$, sending $E_{\mathbf{q}}\to E_{\mathbf{p}}$ and cancelling the measure factor $1/[(2\pi)^3 2E_{\mathbf{q}}]$ against the $(2\pi)^3 2E_{\mathbf{p}}$ from the commutator. Collecting the two surviving pieces,

$$[\phi(x),\pi(y)] = \int \frac{d^3p}{(2\pi)^3 2E_{\mathbf{p}}}\,(-iE_{\mathbf{p}})\Big[(-1)\,e^{-ip\cdot(x-y)} + (-1)\,e^{+ip\cdot(x-y)}\Big], \tag{9.63}$$

where the first bracketed term comes from $a_{\mathbf{p}}e^{-ip\cdot x}$ paired with $-a^\dagger_{\mathbf{q}}e^{iq\cdot y}$ and the second from $a^\dagger_{\mathbf{p}}e^{ip\cdot x}$ paired with $a_{\mathbf{q}}e^{-iq\cdot y}$. At equal time $x^0=y^0=t$ the energy phases drop out, $p\cdot(x-y)\to-\mathbf{p}\cdot(\mathbf{x}-\mathbf{y})$, and the prefactor $(-iE_{\mathbf{p}})(-1)/(2E_{\mathbf{p}}) = i/2$ is independent of $\mathbf{p}$, so

$$[\phi(x),\pi(y)] = \frac{i}{2}\int\frac{d^3p}{(2\pi)^3}\Big(e^{+i\mathbf{p}\cdot(\mathbf{x}-\mathbf{y})}+e^{-i\mathbf{p}\cdot(\mathbf{x}-\mathbf{y})}\Big) = i\int\frac{d^3p}{(2\pi)^3}\,e^{i\mathbf{p}\cdot(\mathbf{x}-\mathbf{y})} = i\,\delta^3(\mathbf{x}-\mathbf{y}), \tag{9.64}$$

where the two exponentials give the same integral (relabel $\mathbf{p}\to-\mathbf{p}$ in the second) and Theorem 5.18 identifies the result as the delta function. The factors of $E_{\mathbf{p}}$ cancel exactly because the $2E_{\mathbf{p}}$ in the algebra matches the $2E_{\mathbf{p}}$ in the measure — the relativistic normalization is self-consistent. An identical computation gives $[\phi(x),\phi(y)]=[\pi(x),\pi(y)]=0$ at equal times, since there the surviving prefactor is $E_{\mathbf{p}}-E_{\mathbf{p}}=0$ (for ϕ–ϕ) or carries an odd power of $E_{\mathbf{p}}$ that integrates to zero by parity. The mode construction and the canonical construction are thus two views of the same theory.

9.2.5 Two normalizations, one physics

The factor $2E_{\mathbf{p}}$ in (9.54) is the single most common source of convention confusion in the subject, because it clashes with the normalization a reader brings from nonrelativistic quantum mechanics. The clash is purely one of bookkeeping — no physics depends on it — but every later formula in the book (states, propagators, cross-section flux factors) inherits the choice, so we fix it once and flag it loudly.

Notation Watch

In nonrelativistic QM the oscillator ladder operators obey $\big[\hat a_{\mathbf{p}},\hat a^\dagger_{\mathbf{q}}\big] = \delta^3(\mathbf{p}-\mathbf{q})$ — the "δ-normalization." This book instead uses the *relativistic* (or *covariant*) normalization

$$\big[a_{\mathbf{p}},a^\dagger_{\mathbf{q}}\big] = (2\pi)^3\,2E_{\mathbf{p}}\,\delta^3(\mathbf{p}-\mathbf{q}). \tag{9.65}$$

The two are related by a momentum-dependent rescaling,

$$a_{\mathbf{p}} = \sqrt{(2\pi)^3\,2E_{\mathbf{p}}}\;\hat a_{\mathbf{p}}, \qquad \big[\hat a_{\mathbf{p}},\hat a^\dagger_{\mathbf{q}}\big] = \delta^3(\mathbf{p}-\mathbf{q}), \tag{9.66}$$

which one can verify by substituting into (9.65). Why pay the price of the extra $2E_{\mathbf{p}}$? Because it is exactly the factor that makes the measure (9.34), the mode expansion (9.42), and (in the next section) the one-particle states $|\mathbf{p}\rangle \propto a^\dagger_{\mathbf{p}}|0\rangle$ all transform covariantly under boosts *without* stray Jacobians. With the δ-normalized $\hat{a}_{\mathbf{p}}$ a boost would drag an awkward $\sqrt{E_{\mathbf{p}'}/E_{\mathbf{p}}}$ through every equation. The relativistic normalization buys manifest Lorentz covariance at the cost of a $2E_{\mathbf{p}}$ one must simply remember. Throughout this book the bare symbols $a_{\mathbf{p}}, a^\dagger_{\mathbf{p}}$ *always* mean the relativistically normalized operators of (9.65); the hatted $\hat{a}_{\mathbf{p}}$ appears only when an explicit comparison to QM is being made.

Physical Insight

The reason the free quantum field is tractable at all is encoded in (9.54): different momentum modes commute. The field is not one complicated quantum system but an infinite collection of *independent* simple ones, each an oscillator that the reader already solved as an undergraduate. Interactions — the $\frac{\lambda}{4!}\phi^4$ term of ϕ^4 theory, switched off here — are precisely what couple these oscillators to one another, turning a soluble problem into the perturbative expansion of Chapter 14. Everything clean in this chapter is clean because we set $\lambda = 0$.

Handoff

We have solved the operator Klein–Gordon equation in closed form: the field is the mode sum (9.42), and its Fourier coefficients are creation and annihilation operators obeying the relativistic oscillator algebra (9.54), with the covariant measure (9.34) as the connective tissue. These mode operators $a_{\mathbf{p}}, a^\dagger_{\mathbf{p}}$ are the objects from which every later ϕ^4 amplitude in ϕ^4 theory will be built. The commutator $\left[a_{\mathbf{p}}, a^\dagger_{\mathbf{p}}\right] > 0$ also tells us that $a^\dagger_{\mathbf{p}}$ raises and $a_{\mathbf{p}}$ lowers a not-yet-identified energy: the algebra demands a state of lowest energy annihilated by every $a_{\mathbf{p}}$. Constructing that vacuum, building the Fock space on top of it, and showing that its excitations are relativistic spin-0 particles of mass m is the work of the next section.

9.3 Fock Space, the Vacuum, and the Particle Interpretation

The previous section handed us a family of operators. Solving the operator Klein–Gordon equation by a plane-wave expansion produced, for each spatial momentum

$\boldsymbol{p}$, a lowering operator $a_{\boldsymbol{p}}$ and a raising operator $a^\dagger_{\boldsymbol{p}}$, and the equal-time canonical relations collapsed into the algebra

$$\left[a_{\boldsymbol{p}}, a^\dagger_{\boldsymbol{q}}\right] = (2\pi)^3\, 2E_{\boldsymbol{p}}\, \delta^3(\boldsymbol{p}-\boldsymbol{q}), \qquad [a_{\boldsymbol{p}}, a_{\boldsymbol{q}}] = \left[a^\dagger_{\boldsymbol{p}}, a^\dagger_{\boldsymbol{q}}\right] = 0. \tag{9.67}$$

This is the import we work from; it is established in Eq. (9.54) and we shall not rederive it. What we have so far, however, is only an *algebra*: a set of formal symbols with commutation rules. We have no Hilbert space on which they act, no states, no energies, no particles. Building that Hilbert space, and reading off its physics, is the entire business of this section.

The logic is the one every reader already knows from the single harmonic oscillator. There, $[a, a^\dagger] = 1$ together with a Hamiltonian $H = \omega(a^\dagger a + \frac{1}{2})$ generates the whole spectrum from a single normalizable state annihilated by a. The free scalar field is a continuum of decoupled oscillators, one per momentum mode, so the construction is the same applied infinitely many times, with the bookkeeping made Lorentz covariant. We will (i) postulate a unique vacuum killed by every $a_{\boldsymbol{p}}$ and argue why it is forced on us; (ii) build one-particle states with a relativistically invariant normalization and prove the corresponding completeness relation; (iii) stack creation operators to build the multiparticle sectors, reading off Bose statistics directly from Eq. (9.67); (iv) substitute the mode expansion into the energy and momentum operators inherited from Chapter 7 and diagonalize them, term by term, keeping every cross-term; and (v) prove that a single excitation of momentum $\boldsymbol{p}$ is an eigenstate of the four-momentum with eigenvalue $p^\mu = (E_{\boldsymbol{p}}, \boldsymbol{p})$ on the mass shell $p^2 = m^2$, carrying exactly the Poincaré quantum numbers of the mass-m, spin-0 irreducible representation classified in Chapter 3. The single blemish that survives — a divergent c-number E_0 in the Hamiltonian — is precisely the loose thread the next section must tie off.

Throughout we use the relativistic single-particle normalization fixed in Section 9.2, and it will be convenient to name the Lorentz-invariant measure once and for all:

$$\int \widetilde{dp} \;\equiv\; \int \frac{d^3p}{(2\pi)^3}\,\frac{1}{2E_{\boldsymbol{p}}}, \qquad E_{\boldsymbol{p}} \equiv \sqrt{\boldsymbol{p}^2 + m^2} > 0. \tag{9.68}$$

That Eq. (9.68) is genuinely Lorentz invariant — the property that makes it the natural measure for relativistic states — is shown in Theorem 9.14 below.

9.3.1 The vacuum

A Hilbert space built from lowering and raising operators must have a floor: a state that cannot be lowered further. If it did not, repeated application of the $a_{\boldsymbol{p}}$ would manufacture states of ever-decreasing energy without bound, and no quantum theory with a stable ground state could survive. We therefore *define* the floor and then check that the definition is consistent and, for the free theory, essentially forced.

Definition 9.11 (The vacuum)**.** The *vacuum* $|0\rangle$ is the state annihilated by every lowering operator,

$$a_{\boldsymbol{p}}\,|0\rangle = 0 \qquad \text{for all } \boldsymbol{p}, \tag{9.69}$$

normalized to unity,

$$\langle 0|0\rangle = 1. \tag{9.70}$$

Two remarks fix its status. First, $|0\rangle$ is not "empty space" in any naive sense; it is the state with no quanta, but as we shall see in Section 9.3.4 it carries a nonzero (indeed divergent) zero-point energy and, as a quantum state, has nontrivial fluctuations of the field. The physical insight box below states the picture; the mathematics that follows does not depend on it. Second, Eq. (9.70) is a genuine normalization, in contrast to the continuum-normalized momentum states we build next: $|0\rangle$ is an honest unit vector of the Hilbert space.

Physical Insight

The free vacuum is the quietest the field can be, not the absence of the field. Every mode $\boldsymbol{p}$ is an oscillator pinned in its ground state, and a quantum oscillator in its ground state still jitters: $\langle 0|\phi(\boldsymbol{x})^2|0\rangle \neq 0$. "Particles" are the discrete excitations of these oscillators above the floor. Nothing is "created from nothing"; a creation operator promotes one mode from its ground state to its first excited state, and we agree to call that lump of localized energy and momentum a particle.

Uniqueness for the free theory. Theorem 9.11 asserts existence of *a* state with the stated property; we must argue it is the *only* one (up to phase), since otherwise "the vacuum" would be ambiguous and the particle interpretation would not be well defined. For the free field the argument is clean. Suppose $|\Omega\rangle$ also satisfies $a_{\boldsymbol{p}}\,|\Omega\rangle = 0$ for all $\boldsymbol{p}$. The Fock construction of Section 9.3.3 shows that the states obtained by applying strings of creation operators to $|0\rangle$ span the entire Hilbert space $\mathcal{F}$; in particular any vector, $|\Omega\rangle$ included, can be written as a (possibly continuous) superposition

$$|\Omega\rangle = c_0\,|0\rangle + \int \widetilde{dp}\, c_1(\boldsymbol{p})\, a^\dagger_{\boldsymbol{p}}\,|0\rangle + \tfrac{1}{2}\int \widetilde{dp}\,\widetilde{dq}\, c_2(\boldsymbol{p},\boldsymbol{q})\, a^\dagger_{\boldsymbol{p}} a^\dagger_{\boldsymbol{q}}\,|0\rangle + \cdots . \tag{9.71}$$

Apply $a_{\boldsymbol{k}}$ to both sides. On the left it gives zero by hypothesis. On the right, $a_{\boldsymbol{k}}$ commuted through the creation operators using Eq. (9.67) lowers the n-creation term to an $(n-1)$-creation term whose coefficient is built from c_n; for instance the one-particle term yields $\int \widetilde{dp}\, c_1(\boldsymbol{p})(2\pi)^3 2E_{\boldsymbol{p}}\delta^3(\boldsymbol{k}-\boldsymbol{p})\,|0\rangle = c_1(\boldsymbol{k})\,|0\rangle$ (the $2E_{\boldsymbol{p}}$ from the commutator cancelling the $1/2E_{\boldsymbol{p}}$ of the invariant measure), and the two-particle term yields $\int \widetilde{dq}\, c_2(\boldsymbol{k},\boldsymbol{q})\, a^\dagger_{\boldsymbol{q}}\,|0\rangle$, and so on. Setting the result to zero

sector by sector forces $c_1 \equiv 0$, then $c_2 \equiv 0$, and inductively every coefficient with $n \geq 1$ vanishes. Hence $|\Omega\rangle = c_0\,|0\rangle$: the only states killed by all annihilation operators are multiples of $|0\rangle$. Imposing Eq. (9.70) fixes $|c_0| = 1$, so $|0\rangle$ is unique up to an irrelevant overall phase.

Caution

This uniqueness argument is honest only because the theory is free: the operators $a_{\boldsymbol{p}}$ are exactly the ladder operators of the full Hamiltonian, and "no quanta" is an exact, dynamically stable notion. In an *interacting* theory the would-be free vacuum is not an eigenstate of the true Hamiltonian, the interaction-picture Fock space is mathematically delicate (Haag's theorem), and the physical vacuum must be characterized differently — as the unique Poincaré-invariant ground state, with its uniqueness a nontrivial theorem (Reeh–Schlieder territory). The construction in this chapter is the rigorous free bedrock on which the perturbative expansion of Chapters 14 and 15 is then erected.

9.3.2 One-particle states and covariant normalization

The first excited sector is obtained by acting once with a creation operator. The inner product of the bare object $a^\dagger_{\boldsymbol{p}}\,|0\rangle$ is, directly from the algebra,

$$\langle 0|\,a_{\boldsymbol{p}}\,a^\dagger_{\boldsymbol{q}}\,|0\rangle = \langle 0|\Big(\Big[a_{\boldsymbol{p}}, a^\dagger_{\boldsymbol{q}}\Big] + a^\dagger_{\boldsymbol{q}} a_{\boldsymbol{p}}\Big)|0\rangle = (2\pi)^3 2E_{\boldsymbol{p}}\,\delta^3(\boldsymbol{p}-\boldsymbol{q})\;\langle 0|0\rangle = (2\pi)^3 2E_{\boldsymbol{p}}\,\delta^3(\boldsymbol{p}-\boldsymbol{q}), \tag{9.72}$$

and the combination $2E_{\boldsymbol{p}}\,(2\pi)^3\delta^3(\boldsymbol{p}-\boldsymbol{q})$ is already a Lorentz scalar: under a boost the bare three-dimensional delta function $\delta^3(\boldsymbol{p}-\boldsymbol{q})$ picks up a Jacobian, and the factor $2E_{\boldsymbol{p}}$ supplied by the relativistic normalization Eq. (9.67) is exactly what cancels it (see Theorem 9.14). This is the whole reason the measure was chosen to carry the $2E_{\boldsymbol{p}}$ into the commutator in the first place: it makes the natural one-particle norm frame-independent, so that statements like "$\langle p|q\rangle$" mean the same thing in every frame. No extra rescaling is needed, and we take the bare state itself as the covariantly normalized one.

Definition 9.12 (Covariantly normalized one-particle state)**.** For each on-shell momentum $p^\mu = (E_{\boldsymbol{p}}, \boldsymbol{p})$ define

$$|p\rangle \;\equiv\; a^\dagger_{\boldsymbol{p}}\,|0\rangle\,. \tag{9.73}$$

Proposition 9.13 (Covariant normalization)**.** *The states Eq. (9.73) satisfy*

$$\langle p|q\rangle = 2E_{\boldsymbol{p}}\,(2\pi)^3\delta^3(\boldsymbol{p}-\boldsymbol{q}), \tag{9.74}$$

and the right-hand side is Lorentz invariant.

Proof. Directly from Eq. (9.73) and Eq. (9.72),

$$\langle p|q\rangle = \langle 0|\, a_{\boldsymbol{p}} a^\dagger_{\boldsymbol{q}}\, |0\rangle = 2E_{\boldsymbol{p}}\,(2\pi)^3\delta^3(\boldsymbol{p}-\boldsymbol{q}). \tag{9.75}$$

Invariance of the combination $2E_{\boldsymbol{p}}\,\delta^3(\boldsymbol{p}-\boldsymbol{q})$ is shown in Theorem 9.14. □

Worked Example 9.14 (The Lorentz-invariant measure and normalization)**.** We verify that both $\int\widetilde{dp}$ in Eq. (9.68) and the normalization Eq. (9.74) are Lorentz invariant. Start from the manifestly invariant four-dimensional integral over the positive-energy mass shell,

$$\int \frac{d^4p}{(2\pi)^4}\,(2\pi)\,\delta(p^2-m^2)\,\theta(p^0), \qquad p^2=(p^0)^2-\boldsymbol{p}^2. \tag{9.76}$$

Both factors are invariant: $\delta(p^2-m^2)$ depends only on the scalar p^2, and $\theta(p^0)$ is invariant because an orthochronous Lorentz transformation cannot flip the sign of the energy of a timelike or lightlike momentum. Do the p^0 integral. Writing $p^2-m^2=(p^0)^2-(\boldsymbol{p}^2+m^2)=(p^0-E_{\boldsymbol{p}})(p^0+E_{\boldsymbol{p}})$ and using $\delta(f(p^0))=\sum_i \delta(p^0-p^0_i)/|f'(p^0_i)|$, only the root $p^0=+E_{\boldsymbol{p}}$ survives the $\theta(p^0)$, with $|f'(E_{\boldsymbol{p}})|=2E_{\boldsymbol{p}}$. Hence

$$\int \frac{d^4p}{(2\pi)^4}\,(2\pi)\,\delta(p^2-m^2)\,\theta(p^0) = \int \frac{d^3p}{(2\pi)^3}\,\frac{1}{2E_{\boldsymbol{p}}} = \int\widetilde{dp}. \tag{9.77}$$

The left side is invariant, so the right side is too: Eq. (9.68) is a Lorentz scalar measure. The same computation read backwards shows that $2E_{\boldsymbol{p}}\,\delta^3(\boldsymbol{p}-\boldsymbol{q})$ is invariant. Indeed, demanding $\int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\boldsymbol{p}}}\left[2E_{\boldsymbol{p}}(2\pi)^3\delta^3(\boldsymbol{p}-\boldsymbol{q})\right]=1$ identifies $2E_{\boldsymbol{p}}(2\pi)^3\delta^3(\boldsymbol{p}-\boldsymbol{q})$ as the delta function *dual to the invariant measure*, and a quantity dual to an invariant measure is itself invariant. Concretely, under a boost $\boldsymbol{p}\to\boldsymbol{p}'$ with $E_{\boldsymbol{p}'}=\gamma(E_{\boldsymbol{p}}-\beta p^3)$ one has $d^3p'/E_{\boldsymbol{p}'}=d^3p/E_{\boldsymbol{p}}$ (the Jacobian of the boost on the mass shell equals $E_{\boldsymbol{p}'}/E_{\boldsymbol{p}}$), so $\delta^3(\boldsymbol{p}-\boldsymbol{q})$ alone scales by $E_{\boldsymbol{p}}/E_{\boldsymbol{p}'}$ — precisely the non-invariance Eq. (9.72) suffered — while the factor $2E_{\boldsymbol{p}}$ in Eq. (9.74) cancels it. This is the whole reason the relativistic normalization Eq. (9.67) carries the $2E_{\boldsymbol{p}}$ in the commutator.

With the normalization Eq. (9.74) settled, the completeness relation on the one-particle sector takes a form matched to the invariant measure.

Proposition 9.15 (Resolution of the identity on the one-particle sector)**.** *Let $\mathcal{H}_1$ be the closed span of the states $|p\rangle$. The operator*

$$\mathbf{1}_1 = \int\widetilde{dp}\;\,|p\rangle\langle p| = \int \frac{d^3p}{(2\pi)^3}\,\frac{1}{2E_{\boldsymbol{p}}}\,|p\rangle\langle p| \tag{9.78}$$

is the identity on $\mathcal{H}_1$.

Proof. Act on an arbitrary one-particle state $|q\rangle$ and use Eq. (9.74):

$$\mathbf{1}_1\,|q\rangle = \int \frac{d^3p}{(2\pi)^3}\,\frac{1}{2E_{\boldsymbol{p}}}\;|p\rangle\;\left[2E_{\boldsymbol{p}}(2\pi)^3\delta^3(\boldsymbol{p}-\boldsymbol{q})\right] = \int d^3p\;\delta^3(\boldsymbol{p}-\boldsymbol{q})\;|p\rangle = |q\rangle\,. \tag{9.79}$$

Since the $|q\rangle$ span $\mathcal{H}_1$, $\mathbf{1}_1$ is the identity there. The cancellation of the two factors of $2E_{\boldsymbol{p}}$ is exactly why the invariant measure pairs with the covariant normalization. □

9.3.3 Multiparticle states, Bose symmetry, and Fock space

Higher sectors are built by acting with more creation operators. Define the (covariantly normalized) n-particle state

$$|p_1,\dots,p_n\rangle \;\equiv\; a^\dagger_{\boldsymbol{p}_1}\cdots a^\dagger_{\boldsymbol{p}_n}\,|0\rangle\,. \tag{9.80}$$

The single most important structural fact follows for free from the last line of Eq. (9.67): because $\left[a^\dagger_{\boldsymbol{p}}, a^\dagger_{\boldsymbol{q}}\right] = 0$, the creation operators commute, and the state Eq. (9.80) is *totally symmetric* under exchange of any two of its labels,

$$|\dots,p_i,\dots,p_j,\dots\rangle = |\dots,p_j,\dots,p_i,\dots\rangle\,. \tag{9.81}$$

This is Bose statistics, and it is not an extra postulate: it is forced by the commutator (as opposed to anticommutator) algebra that the canonical *commutation* relations of the scalar field handed us. (The deeper question of *why* a spin-0 field must be quantized with commutators rather than anticommutators — the spin–statistics connection — is settled by microcausality in a later section of this chapter.) Physically, Eq. (9.81) says the particles are indistinguishable and that any number of them may occupy the same mode.

Worked Example 9.16 (Two-particle inner product and manifest symmetry)**.** We compute $\langle p_1\,p_2|q_1\,q_2\rangle$ directly from the algebra, exhibiting the symmetric ("permanent") structure. Using Eq. (9.80),

$$\langle p_1\,p_2|q_1\,q_2\rangle = \langle 0|\,a_{\boldsymbol{p}_2}a_{\boldsymbol{p}_1}\,a^\dagger_{\boldsymbol{q}_1}a^\dagger_{\boldsymbol{q}_2}\,|0\rangle\,. \tag{9.82}$$

Evaluate the vacuum expectation value by commuting annihilation operators to the right until they hit $|0\rangle$. First move $a_{\boldsymbol{p}_1}$ past the two creation operators:

$$\begin{aligned} a_{\boldsymbol{p}_1}a^\dagger_{\boldsymbol{q}_1}a^\dagger_{\boldsymbol{q}_2} &= \left(\left[a_{\boldsymbol{p}_1}, a^\dagger_{\boldsymbol{q}_1}\right] + a^\dagger_{\boldsymbol{q}_1}a_{\boldsymbol{p}_1}\right)a^\dagger_{\boldsymbol{q}_2} \\ &= (2\pi)^3 2E_{\boldsymbol{p}_1}\delta^3(\boldsymbol{p}_1-\boldsymbol{q}_1)\,a^\dagger_{\boldsymbol{q}_2} + a^\dagger_{\boldsymbol{q}_1}\left(\left[a_{\boldsymbol{p}_1}, a^\dagger_{\boldsymbol{q}_2}\right] + a^\dagger_{\boldsymbol{q}_2}a_{\boldsymbol{p}_1}\right) \\ &= (2\pi)^3 2E_{\boldsymbol{p}_1}\delta^3(\boldsymbol{p}_1-\boldsymbol{q}_1)\,a^\dagger_{\boldsymbol{q}_2} + (2\pi)^3 2E_{\boldsymbol{p}_1}\delta^3(\boldsymbol{p}_1-\boldsymbol{q}_2)\,a^\dagger_{\boldsymbol{q}_1} + a^\dagger_{\boldsymbol{q}_1}a^\dagger_{\boldsymbol{q}_2}a_{\boldsymbol{p}_1}. \end{aligned} \tag{9.83}$$

The last term annihilates $|0\rangle$ on the right of Eq. (9.82). Now apply $a_{\boldsymbol{p}_2}$ to what remains and use $a_{\boldsymbol{p}_2}a^\dagger_{\boldsymbol{q}}\,|0\rangle = (2\pi)^3 2E_{\boldsymbol{p}_2}\delta^3(\boldsymbol{p}_2-\boldsymbol{q})\,|0\rangle$:

$$\langle 0|\, a_{\boldsymbol{p}_2}a_{\boldsymbol{p}_1}a^\dagger_{\boldsymbol{q}_1}a^\dagger_{\boldsymbol{q}_2}\,|0\rangle = (2\pi)^6\, 2E_{\boldsymbol{p}_1}2E_{\boldsymbol{p}_2}\big[\delta^3(\boldsymbol{p}_1-\boldsymbol{q}_1)\delta^3(\boldsymbol{p}_2-\boldsymbol{q}_2)+\delta^3(\boldsymbol{p}_1-\boldsymbol{q}_2)\delta^3(\boldsymbol{p}_2-\boldsymbol{q}_1)\big]. \tag{9.84}$$

The covariant $2E$ factors carried by the relativistic commutators are already in place — with each delta one may write $2E_{\boldsymbol{p}_1} = 2E_{\boldsymbol{q}_1}$ etc. — giving the manifestly exchange-symmetric result

$$\langle p_1\, p_2|q_1\, q_2\rangle = \big[2E_{\boldsymbol{p}_1}(2\pi)^3\delta^3(\boldsymbol{p}_1-\boldsymbol{q}_1)\big]\big[2E_{\boldsymbol{p}_2}(2\pi)^3\delta^3(\boldsymbol{p}_2-\boldsymbol{q}_2)\big]+(\boldsymbol{q}_1\leftrightarrow\boldsymbol{q}_2). \tag{9.85}$$

The two terms are the two ways of pairing incoming with outgoing labels; the symmetry under $\boldsymbol{q}_1\leftrightarrow\boldsymbol{q}_2$ (and equally $\boldsymbol{p}_1\leftrightarrow\boldsymbol{p}_2$) is the inner-product expression of Eq. (9.81). This pairing structure is the seed of Wick's theorem, derived from the generating functional in Chapter 10.

Occupation-number basis and the Fock space. For a system in a finite box (momenta discretized, $a^\dagger_{\boldsymbol{p}}\to a^\dagger_k$ with $\left[a_k, a^\dagger_{k'}\right] = \delta_{kk'}$), the states

$$|\{n_k\}\rangle = \prod_k \frac{(a^\dagger_k)^{n_k}}{\sqrt{n_k!}}\,|0\rangle\,, \qquad n_k\in\{0,1,2,\dots\}, \tag{9.86}$$

are orthonormal eigenstates labelled by the *occupation numbers* n_k — exactly as for a collection of independent harmonic oscillators, one per mode. Each mode is an oscillator; the field's Hilbert space is the (restricted) tensor product of these oscillator Hilbert spaces. Taking the continuum limit, the abstract statement is:

Definition 9.17 (Fock space)**.** The *Fock space* of the free real scalar is the Hilbert-space direct sum

$$\mathcal{F} = \bigoplus_{n=0}^{\infty}\mathcal{H}_n, \qquad \mathcal{H}_0 = \mathbb{C}\,|0\rangle\,, \quad \mathcal{H}_n = \mathrm{Sym}^n(\mathcal{H}_1), \tag{9.87}$$

where $\mathcal{H}_n$ is the symmetric (n-fold) tensor power of the one-particle space $\mathcal{H}_1$, spanned by the states Eq. (9.80). The symmetrization Sym^n implements the Bose symmetry Eq. (9.81) at the level of the space itself.

The completeness relation on all of $\mathcal{F}$ is the sum of the sector resolutions,

$$\mathbf{1}_{\mathcal{F}} = |0\rangle\langle 0| + \int\widetilde{dp}\;|p\rangle\langle p| + \frac{1}{2!}\int\widetilde{dp}\,\widetilde{dq}\;|p\,q\rangle\langle p\,q| + \cdots\,, \tag{9.88}$$

where the $1/n!$ in the n-particle term corrects for the overcounting introduced by integrating independently over labels that Eq. (9.81) identifies. That the strings of creation operators acting on $|0\rangle$ exhaust $\mathcal{F}$ is what we used in proving vacuum uniqueness in Section 9.3.1; Eq. (9.88) is the precise statement that they do.

9.3.4 Diagonalizing the energy and momentum

We now make contact with dynamics. The energy and momentum operators are not new postulates: they are the conserved charges of spacetime translations, the components of the Noether four-momentum

$$P^\mu = \int d^3x\, T^{0\mu}, \qquad P^0 = H = \int d^3x \left[\tfrac{1}{2}\pi^2 + \tfrac{1}{2}(\nabla\phi)^2 + \tfrac{1}{2}m^2\phi^2\right], \qquad \boldsymbol{P} = -\int d^3x\, \pi\, \nabla\phi, \tag{9.89}$$

established as classical Noether output in Eq. (7.97) and promoted to operators here. Our task is to substitute the mode expansion, recalled from Eq. (9.42), and reduce these to the ladder operators. Evaluated at $t = 0$ (the operators are time independent, so any time will do) the field and its conjugate momentum read

$$\phi(\boldsymbol{x}) = \int \frac{d^3p}{(2\pi)^3}\,\frac{1}{2E_{\boldsymbol{p}}}\,(a_{\boldsymbol{p}} + a^\dagger_{-\boldsymbol{p}})\,e^{i\boldsymbol{p}\cdot\boldsymbol{x}}, \tag{9.90}$$

$$\pi(\boldsymbol{x}) = \int \frac{d^3p}{(2\pi)^3}\left(-\frac{i}{2}\right)(a_{\boldsymbol{p}} - a^\dagger_{-\boldsymbol{p}})\,e^{i\boldsymbol{p}\cdot\boldsymbol{x}}, \tag{9.91}$$

where the single-exponential form is obtained by relabelling $\boldsymbol{p} \to -\boldsymbol{p}$ in the creation pieces of Eq. (9.42), whose measure $d^3p/[(2\pi)^3\,2E_{\boldsymbol{p}}]$ is carried over intact (for π, the relabelling acts on Eq. (9.43) and the $-iE_{\boldsymbol{p}}$ there combines with the $1/2E_{\boldsymbol{p}}$ of the measure to leave the constant $-i/2$).

The Hamiltonian. We treat the three terms of H in turn, using $\int d^3x\, e^{i(\boldsymbol{p}+\boldsymbol{q})\cdot\boldsymbol{x}} = (2\pi)^3\delta^3(\boldsymbol{p}+\boldsymbol{q})$, which sets $\boldsymbol{q} = -\boldsymbol{p}$ (hence $E_{\boldsymbol{q}} = E_{\boldsymbol{p}}$) in every product. For the kinetic term,

$$\begin{aligned}\int d^3x\,\tfrac{1}{2}\pi^2 &= \tfrac{1}{2}\int \frac{d^3p\,d^3q}{(2\pi)^6}\left(-\frac{i}{2}\right)^2 (a_{\boldsymbol{p}} - a^\dagger_{-\boldsymbol{p}})(a_{\boldsymbol{q}} - a^\dagger_{-\boldsymbol{q}})\,(2\pi)^3\delta^3(\boldsymbol{p}+\boldsymbol{q}) \\ &= \int \frac{d^3p}{(2\pi)^3}\left(-\frac{1}{8}\right)(a_{\boldsymbol{p}} - a^\dagger_{-\boldsymbol{p}})(a_{-\boldsymbol{p}} - a^\dagger_{\boldsymbol{p}}).\end{aligned} \tag{9.92}$$

For the gradient term each ∇ brings down a factor $i\boldsymbol{p}$ and $i\boldsymbol{q}$, and after $\boldsymbol{q} = -\boldsymbol{p}$ the product is $(i\boldsymbol{p})\cdot(-i\boldsymbol{p}) = \boldsymbol{p}^2$; for the mass term there is no derivative. Together,

$$\int d^3x \left[\tfrac{1}{2}(\nabla\phi)^2 + \tfrac{1}{2}m^2\phi^2\right] = \int \frac{d^3p}{(2\pi)^3}\,\frac{\boldsymbol{p}^2 + m^2}{8E_{\boldsymbol{p}}^2}\,(a_{\boldsymbol{p}} + a^\dagger_{-\boldsymbol{p}})(a_{-\boldsymbol{p}} + a^\dagger_{\boldsymbol{p}}). \tag{9.93}$$

Now $\boldsymbol{p}^2 + m^2 = E_{\boldsymbol{p}}^2$, so the coefficient in Eq. (9.93) is $\frac{1}{8}$. Adding Eq. (9.92) and Eq. (9.93), the two products combine as

$$H = \int \frac{d^3p}{(2\pi)^3}\,\frac{1}{8}\Big[-(a_{\boldsymbol{p}} - a^\dagger_{-\boldsymbol{p}})(a_{-\boldsymbol{p}} - a^\dagger_{\boldsymbol{p}}) + (a_{\boldsymbol{p}} + a^\dagger_{-\boldsymbol{p}})(a_{-\boldsymbol{p}} + a^\dagger_{\boldsymbol{p}})\Big]. \tag{9.94}$$

Expanding both products and keeping every cross-term,

$$(a_{\boldsymbol{p}} + a^\dagger_{-\boldsymbol{p}})(a_{-\boldsymbol{p}} + a^\dagger_{\boldsymbol{p}}) = a_{\boldsymbol{p}}a_{-\boldsymbol{p}} + a_{\boldsymbol{p}}a^\dagger_{\boldsymbol{p}} + a^\dagger_{-\boldsymbol{p}}a_{-\boldsymbol{p}} + a^\dagger_{-\boldsymbol{p}}a^\dagger_{\boldsymbol{p}}, \tag{9.95}$$

$$(a_{\boldsymbol{p}} - a^\dagger_{-\boldsymbol{p}})(a_{-\boldsymbol{p}} - a^\dagger_{\boldsymbol{p}}) = a_{\boldsymbol{p}}a_{-\boldsymbol{p}} - a_{\boldsymbol{p}}a^\dagger_{\boldsymbol{p}} - a^\dagger_{-\boldsymbol{p}}a_{-\boldsymbol{p}} + a^\dagger_{-\boldsymbol{p}}a^\dagger_{\boldsymbol{p}}, \tag{9.96}$$

so the cross-terms $a_{\boldsymbol{p}}a_{-\boldsymbol{p}}$ and $a^\dagger_{-\boldsymbol{p}}a^\dagger_{\boldsymbol{p}}$ cancel in the difference, leaving

$$H = \int \frac{d^3p}{(2\pi)^3}\,\frac{1}{8}\,(2\,a_{\boldsymbol{p}}a^\dagger_{\boldsymbol{p}} + 2\,a^\dagger_{-\boldsymbol{p}}a_{-\boldsymbol{p}}) = \int \frac{d^3p}{(2\pi)^3}\,\frac{1}{4}\,(a_{\boldsymbol{p}}a^\dagger_{\boldsymbol{p}} + a^\dagger_{-\boldsymbol{p}}a_{-\boldsymbol{p}}). \tag{9.97}$$

In the second term substitute $\boldsymbol{p} \to -\boldsymbol{p}$ (legitimate since $E_{\boldsymbol{p}}$ is even and the measure invariant): it becomes $\int \frac{d^3p}{(2\pi)^3}\frac{1}{4}a^\dagger_{\boldsymbol{p}}a_{\boldsymbol{p}}$. In the first term use Eq. (9.67) to normal-order, $a_{\boldsymbol{p}}a^\dagger_{\boldsymbol{p}} = a^\dagger_{\boldsymbol{p}}a_{\boldsymbol{p}} + (2\pi)^3 2E_{\boldsymbol{p}}\delta^3(0)$. Collecting,

$$\boxed{H = \int \frac{d^3p}{(2\pi)^3}\,\frac{1}{2}\,a^\dagger_{\boldsymbol{p}}a_{\boldsymbol{p}} \;+\; E_0 \;=\; \int \widetilde{dp}\;E_{\boldsymbol{p}}\,a^\dagger_{\boldsymbol{p}}a_{\boldsymbol{p}} \;+\; E_0}, \qquad E_0 = \frac{1}{2}\,(2\pi)^3\delta^3(0)\int \frac{d^3p}{(2\pi)^3}\,E_{\boldsymbol{p}} = \frac{V}{2} \tag{9.98}$$

We have used the standard identification $(2\pi)^3\delta^3(0) = \int d^3x = V$, the (infinite) volume of space. The structure is exactly that of the single oscillator $\omega(a^\dagger a + \frac{1}{2})$, summed over modes: the first term counts the energy $E_{\boldsymbol{p}}$ of each quantum, the second is the sum of the zero-point energies $\frac{1}{2}E_{\boldsymbol{p}}$ of all the oscillators. That E_0 is doubly divergent — an infinite spatial volume times an ultraviolet-divergent momentum integral — is the blemish announced in the introduction; Section 9.3.1 guaranteed $|0\rangle$ is unique, but said nothing about its energy being finite. Taming E_0 is the entire subject of the next section.

The momentum. The same computation for $\boldsymbol{P}$ in Eq. (9.89) is more economical because there is no mass term and, as we will see, the c-number piece is killed by parity rather than merely subtracted. Inserting Eq. (9.91) and $\nabla\phi = \int \frac{d^3p}{(2\pi)^3}\frac{i\boldsymbol{p}}{2E_{\boldsymbol{p}}}(a_{\boldsymbol{p}} + a^\dagger_{-\boldsymbol{p}})e^{i\boldsymbol{p}\cdot\boldsymbol{x}}$,

$$\begin{aligned}\boldsymbol{P} &= -\int d^3x\,\pi\,\nabla\phi = -\int \frac{d^3p\,d^3q}{(2\pi)^6}\Big(-\frac{i}{2}\Big)\frac{i\boldsymbol{p}}{2E_{\boldsymbol{p}}}(a_{\boldsymbol{q}} - a^\dagger_{-\boldsymbol{q}})(a_{\boldsymbol{p}} + a^\dagger_{-\boldsymbol{p}})(2\pi)^3\delta^3(\boldsymbol{p}+\boldsymbol{q}) \\ &= -\int \frac{d^3p}{(2\pi)^3}\,\frac{\boldsymbol{p}}{4E_{\boldsymbol{p}}}(a_{-\boldsymbol{p}} - a^\dagger_{\boldsymbol{p}})(a_{\boldsymbol{p}} + a^\dagger_{-\boldsymbol{p}}),\end{aligned} \tag{9.99}$$

where again $\boldsymbol{q} = -\boldsymbol{p}$, $E_{\boldsymbol{q}} = E_{\boldsymbol{p}}$, and $(-i)(i) = 1$. Expanding,

$$(a_{-\boldsymbol{p}} - a^\dagger_{\boldsymbol{p}})(a_{\boldsymbol{p}} + a^\dagger_{-\boldsymbol{p}}) = a_{-\boldsymbol{p}}a_{\boldsymbol{p}} + a_{-\boldsymbol{p}}a^\dagger_{-\boldsymbol{p}} - a^\dagger_{\boldsymbol{p}}a_{\boldsymbol{p}} - a^\dagger_{\boldsymbol{p}}a^\dagger_{-\boldsymbol{p}}. \tag{9.100}$$

The terms $a_{-\boldsymbol{p}}a_{\boldsymbol{p}}$ and $a^\dagger_{\boldsymbol{p}}a^\dagger_{-\boldsymbol{p}}$ are even under $\boldsymbol{p} \to -\boldsymbol{p}$ (the operators commute, so each is invariant under the relabelling), while they multiply the odd factor $\boldsymbol{p}$; their integrals therefore vanish by parity. We are left with

$$\boldsymbol{P} = -\int \frac{d^3p}{(2\pi)^3}\,\frac{\boldsymbol{p}}{4E_{\boldsymbol{p}}}(a_{-\boldsymbol{p}}a^\dagger_{-\boldsymbol{p}} - a^\dagger_{\boldsymbol{p}}a_{\boldsymbol{p}}). \tag{9.101}$$

In the first surviving term substitute $\boldsymbol{p} \to -\boldsymbol{p}$, which flips the sign of the prefactor $\boldsymbol{p}$ and turns $a_{-\boldsymbol{p}} a^\dagger_{-\boldsymbol{p}}$ into $a_{\boldsymbol{p}} a^\dagger_{\boldsymbol{p}}$:

$$\boldsymbol{P} = \int \frac{d^3p}{(2\pi)^3} \frac{\boldsymbol{p}}{4E_{\boldsymbol{p}}} (a_{\boldsymbol{p}} a^\dagger_{\boldsymbol{p}} + a^\dagger_{\boldsymbol{p}} a_{\boldsymbol{p}}) = \int \frac{d^3p}{(2\pi)^3} \frac{\boldsymbol{p}}{2E_{\boldsymbol{p}}} a^\dagger_{\boldsymbol{p}} a_{\boldsymbol{p}} + \frac{(2\pi)^3 \delta^3(0)}{2} \int \frac{d^3p}{(2\pi)^3} \boldsymbol{p}, \tag{9.102}$$

having used $a_{\boldsymbol{p}} a^\dagger_{\boldsymbol{p}} = a^\dagger_{\boldsymbol{p}} a_{\boldsymbol{p}} + (2\pi)^3 2E_{\boldsymbol{p}} \delta^3(0)$. The final integral $\int d^3p\, \boldsymbol{p}$ vanishes identically: its integrand is odd. Thus the c-number contribution to the momentum cancels on its own — there is no "zero-point momentum" — and

$$\boxed{\boldsymbol{P} = \int \widetilde{dp}\, \boldsymbol{p}\, a^\dagger_{\boldsymbol{p}} a_{\boldsymbol{p}} = \int \frac{d^3p}{(2\pi)^3} \frac{\boldsymbol{p}}{2E_{\boldsymbol{p}}} a^\dagger_{\boldsymbol{p}} a_{\boldsymbol{p}}}. \tag{9.103}$$

The asymmetry between H and $\boldsymbol{P}$ is instructive: $E_{\boldsymbol{p}} > 0$ is even in $\boldsymbol{p}$, so its zero-point sum survives, whereas $\boldsymbol{p}$ is odd, so opposite modes cancel. The divergence problem afflicts only the energy.

9.3.5 The spectrum and the particle interpretation

We can now read the physics off the normal-mode forms Eq. (9.98) and Eq. (9.103). The key technical input is the commutator of these operators with a creation operator, which we compute once and reuse. From Eq. (9.67),

$$\left[H, a^\dagger_{\boldsymbol{q}}\right] = \int \widetilde{dp}\, E_{\boldsymbol{p}} \left[a^\dagger_{\boldsymbol{p}} a_{\boldsymbol{p}}, a^\dagger_{\boldsymbol{q}}\right] = \int \widetilde{dp}\, E_{\boldsymbol{p}}\, a^\dagger_{\boldsymbol{p}} \left[a_{\boldsymbol{p}}, a^\dagger_{\boldsymbol{q}}\right] = E_{\boldsymbol{q}}\, a^\dagger_{\boldsymbol{q}}, \tag{9.104}$$

where we used $\left[a^\dagger_{\boldsymbol{p}} a_{\boldsymbol{p}}, a^\dagger_{\boldsymbol{q}}\right] = a^\dagger_{\boldsymbol{p}} \left[a_{\boldsymbol{p}}, a^\dagger_{\boldsymbol{q}}\right]$ (the c-number E_0 commutes with everything). Identically,

$$\left[\boldsymbol{P}, a^\dagger_{\boldsymbol{q}}\right] = \boldsymbol{q}\, a^\dagger_{\boldsymbol{q}}. \tag{9.105}$$

A creation operator raises the energy of any state by $E_{\boldsymbol{q}}$ and its momentum by $\boldsymbol{q}$. Acting on the vacuum, with $H|0\rangle = E_0|0\rangle$ and $\boldsymbol{P}|0\rangle = 0$ (the latter because $a_{\boldsymbol{p}}|0\rangle = 0$),

$$H|p\rangle = H a^\dagger_{\boldsymbol{p}}|0\rangle = \left(\left[H, a^\dagger_{\boldsymbol{p}}\right] + a^\dagger_{\boldsymbol{p}} H\right)|0\rangle = (E_{\boldsymbol{p}} + E_0)|p\rangle\,, \tag{9.106}$$

$$\boldsymbol{P}|p\rangle = \left(\left[\boldsymbol{P}, a^\dagger_{\boldsymbol{p}}\right] + a^\dagger_{\boldsymbol{p}} \boldsymbol{P}\right)|0\rangle = \boldsymbol{p}\,|p\rangle\,. \tag{9.107}$$

Measuring energies relative to the vacuum — equivalently, after the normal-ordering subtraction of E_0 carried out in the next section — the one-particle state is a simultaneous eigenstate of energy and momentum,

$$H|p\rangle = E_{\boldsymbol{p}}|p\rangle\,, \qquad \boldsymbol{P}|p\rangle = \boldsymbol{p}\,|p\rangle\,, \qquad E_{\boldsymbol{p}} = \sqrt{\boldsymbol{p}^2 + m^2}. \tag{9.108}$$

The eigenvalues obey the relativistic dispersion relation $E^2_{\boldsymbol{p}} - \boldsymbol{p}^2 = m^2$, i.e. $p^\mu p_\mu = m^2$: the excitation propagates on the mass shell of a particle of mass m.

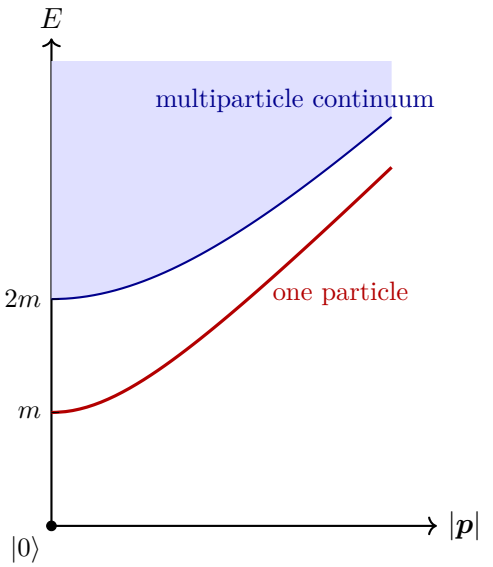

Figure 9.3: Spectrum of the free real scalar field. The vacuum $|0\rangle$ sits at the origin (energies measured relative to it). One-particle states fill the isolated hyperboloid $E = \sqrt{\boldsymbol{p}^2 + m^2}$, gapped from the vacuum by the rest mass m. Two- and higher-particle states fill the shaded continuum, whose lower boundary at fixed total momentum is $E = \sqrt{\boldsymbol{p}^2 + (2m)^2}$, attained when the two quanta share the momentum equally; at $\boldsymbol{p} = 0$ this is the threshold $2m$. The isolation of the one-particle shell from the continuum is what makes "a particle" a sharp notion.

This is the punchline of canonical quantization. We did not put particles into the theory; we quantized a field and discovered that its elementary excitations are discrete, indivisible lumps carrying momentum $\boldsymbol{p}$, energy $\sqrt{\boldsymbol{p}^2 + m^2}$, and rest mass m. The parameter m in the Lagrangian Chapter 6, hitherto just a coefficient, is now physically interpreted as the mass of the particle the field describes.

The same reasoning iterates. An n-particle state Eq. (9.80) satisfies

$$H\,|p_1,\dots,p_n\rangle = \Big(\sum_{i=1}^{n} E_{\boldsymbol{p}_i}\Big)\,|p_1,\dots,p_n\rangle\,, \qquad \boldsymbol{P}\,|p_1,\dots,p_n\rangle = \Big(\sum_{i=1}^{n} \boldsymbol{p}_i\Big)\,|p_1,\dots,p_n\rangle\,, \tag{9.109}$$

again up to the single common shift E_0 in the energy, obtained by commuting H and $\boldsymbol{P}$ past each of the n creation operators in turn using Eq. (9.104) and Eq. (9.105). The energies simply add, as they must for free, non-interacting quanta. Figure 9.3 shows the resulting spectrum: an isolated one-particle hyperboloid $E = \sqrt{\boldsymbol{p}^2 + m^2}$ separated from the vacuum by the mass gap m, and above it the multiparticle continuum.

The number operator and conservation of particle number. The counting structure is made precise by the *number operator*

$$N = \int \widetilde{dp}\, a_{\boldsymbol{p}}^\dagger a_{\boldsymbol{p}}. \tag{9.110}$$

Its commutator with a creation operator is, by the identical manipulation as Eq. (9.104) but with $E_{\boldsymbol{p}} \to 1$,

$$\left[N, a_{\boldsymbol{q}}^\dagger\right] = a_{\boldsymbol{q}}^\dagger, \tag{9.111}$$

so N counts creation operators: applied to the n-particle state Eq. (9.80) it returns $N\,|p_1,\dots,p_n\rangle = n\,|p_1,\dots,p_n\rangle$, and $N\,|0\rangle = 0$. The Fock decomposition Eq. (9.87) is precisely the eigenspace decomposition of N, with $\mathcal{H}_n$ the eigenspace of eigenvalue n. Comparing Eq. (9.98) and Eq. (9.110), the Hamiltonian is built entirely from the mode number densities $a_{\boldsymbol{p}}^\dagger a_{\boldsymbol{p}}$, which all commute with N; hence

$$[H, N] = 0. \tag{9.112}$$

In the free theory the Hamiltonian *conserves particle number*: a state of n quanta evolves into a state of n quanta, never creating or destroying any. This is exactly what one expects of decoupled oscillators, and it is exactly what interactions will spoil — the ϕ^4 term we switch on in Chapter 14 fails to commute with N, which is what allows the scattering and particle-number-changing processes that make the interacting theory interesting.

9.3.6 The Poincaré content: a relativistic spin-0 particle

We have shown the excitations carry energy $E_{\boldsymbol{p}}$ and momentum $\boldsymbol{p}$ on the mass shell. To certify that they are *particles* in the precise sense of relativistic quantum mechanics, we must show that the one-particle states furnish an irreducible representation of the Poincaré group, and identify *which* one. Wigner's classification (Theorem 3.44) tells us that positive-energy irreducible representations of the Poincaré group are labelled by a mass $m \geq 0$ and, for $m > 0$, by a spin $s \in \{0, \tfrac{1}{2}, 1, \dots\}$ — the latter being a representation of the little group, the subgroup $SO(3)$ that fixes a chosen rest-frame momentum (Theorem 3.43). We now verify that the scalar's one-particle space is the $(m, s{=}0)$ representation.

Lorentz action on one-particle states. Let $U(\Lambda)$ be the unitary implementing a Lorentz transformation Λ on the Hilbert space; under spacetime translations and Lorentz rotations the generators close into the Poincaré algebra of Eqs. (3.147) to (3.149), with P^μ the very four-momentum we diagonalized above. Because ϕ is a *scalar* field, $U(\Lambda)\phi(x)U(\Lambda)^{-1} = \phi(\Lambda x)$; feeding this into the mode expansion Eq. (9.42) and matching coefficients determines how $U(\Lambda)$

acts on the ladder operators. Because the invariant measure $\widetilde{dp}$ is preserved under the change of variables $\boldsymbol{p} \to \boldsymbol{\Lambda p}$, the relativistically normalized creation operator transforms with *no* stray Jacobian — exactly what the $2E_{\boldsymbol{p}}$ in the commutator Eq. (9.67) was arranged to buy:

$$U(\Lambda)\, a^\dagger_{\boldsymbol{p}}\, U(\Lambda)^{-1} = a^\dagger_{\boldsymbol{\Lambda p}}, \qquad \Longrightarrow \qquad U(\Lambda)\,|p\rangle = |\Lambda p\rangle\,. \tag{9.113}$$

Worked Example 9.18 (The boost factor and the invariance of $|p\rangle \to |\Lambda p\rangle$)**.** We check that the two halves of Eq. (9.113) are consistent and that they preserve the inner product. Take the first relation as given (it follows from $U(\Lambda)\phi U(\Lambda)^{-1} = \phi(\Lambda x)$ together with invariance of $\int\widetilde{dp}$). Apply $U(\Lambda)$ to Eq. (9.73), using $U(\Lambda)\,|0\rangle = |0\rangle$ (the vacuum is Poincaré invariant, being the unique state of Theorem 9.11 and annihilated by $\boldsymbol{P}$):

$$U(\Lambda)\,|p\rangle = U(\Lambda) a^\dagger_{\boldsymbol{p}} U(\Lambda)^{-1}\,|0\rangle = a^\dagger_{\boldsymbol{\Lambda p}}\,|0\rangle = |\Lambda p\rangle\,, \tag{9.114}$$

which is the second relation. The transformation carries no boost factor precisely because the relativistic normalization has already absorbed the $2E_{\boldsymbol{p}}$ into the commutator and the invariant measure; the covariant inner product Eq. (9.74) is what lets the bare state $|p\rangle = a^\dagger_{\boldsymbol{p}}\,|0\rangle$ transform as cleanly as its Lorentz-scalar label suggests. As a consistency check, unitarity of $U(\Lambda)$ demands $\langle \Lambda p|\Lambda q\rangle = \langle p|q\rangle$, and indeed

$$\langle \Lambda p|\Lambda q\rangle = 2E_{\boldsymbol{\Lambda p}}(2\pi)^3\delta^3(\boldsymbol{\Lambda p} - \boldsymbol{\Lambda q}) = 2E_{\boldsymbol{p}}(2\pi)^3\delta^3(\boldsymbol{p}-\boldsymbol{q}) = \langle p|q\rangle\,, \tag{9.115}$$

where the middle equality is the invariance of $2E_{\boldsymbol{p}}\delta^3(\boldsymbol{p}-\boldsymbol{q})$ established in Theorem 9.14. The normalization, the measure, and the Lorentz action are mutually consistent: this is the whole point of the covariant bookkeeping.

The Casimirs: mass m and spin 0. The Poincaré group has two Casimir invariants, $P^2 = P^\mu P_\mu$ and $W^2 = W^\mu W_\mu$, where

$$W^\mu = -\tfrac{1}{2}\,\epsilon^{\mu\nu\rho\sigma} P_\nu M_{\rho\sigma} \tag{9.116}$$

is the Pauli–Lubański vector built from the translation generators P_ν and the Lorentz generators $M_{\rho\sigma}$ of Eqs. (3.147) to (3.149). On an irreducible representation these take the constant values $P^2 = m^2$ and $W^2 = -m^2 s(s+1)$ (Theorem 3.44). We evaluate both on our one-particle states.

For the first Casimir, Eq. (9.108) gives $P^\mu\,|p\rangle = p^\mu\,|p\rangle$ with $p^0 = E_{\boldsymbol{p}}$, so

$$P^2\,|p\rangle = p^\mu p_\mu\,|p\rangle = (E_{\boldsymbol{p}}^2 - \boldsymbol{p}^2)\,|p\rangle = m^2\,|p\rangle\,. \tag{9.117}$$

Every one-particle state has the same eigenvalue m^2: the representation has a single, sharp mass $m > 0$.

For the second Casimir, the cleanest evaluation is in the rest frame, possible precisely because $m > 0$. Pick the rest-frame momentum $k^\mu = (m, \mathbf{0})$; the state $|k\rangle$ is a representative of the one-particle space, and by Eq. (9.113) the full space is generated from it by boosts. In this frame $P_\nu \to (m, \mathbf{0})$, so only $\nu = 0$ contributes to Eq. (9.116):

$$W^\mu |k\rangle = -\tfrac{1}{2}\, \epsilon^{\mu 0 \rho\sigma}\, m\, M_{\rho\sigma} |k\rangle \,. \tag{9.118}$$

Since $\epsilon^{00\rho\sigma} = 0$, the $\mu = 0$ component vanishes, while for spatial $\mu = i$ the antisymmetric symbol ϵ^{i0jk} selects the spatial rotation generators $M_{jk} = \epsilon_{jk\ell} J^\ell$, giving $W^i |k\rangle = m\, J^i |k\rangle$ — the Pauli–Lubański vector reduces, in the rest frame, to the angular momentum, which is the generator of the little group $SO(3)$ (Theorem 3.43). Now the decisive point: the scalar field carries *no internal index*. The rest-frame one-particle state $|k\rangle$ is labelled by nothing but its momentum, so the little group, which fixes k, has nothing to rotate and acts trivially,

$$J^i |k\rangle = 0, \qquad \text{hence} \qquad W^\mu |k\rangle = 0, \qquad W^2 |k\rangle = 0. \tag{9.119}$$

Because W^2 is a Lorentz scalar, its eigenvalue is frame independent: $W^2 |p\rangle = 0$ for every one-particle state. Comparing with $W^2 = -m^2 s(s+1)$ and $m > 0$ forces $s(s+1) = 0$, i.e.

$$s = 0. \tag{9.120}$$

The little group $SO(3)$ acts in its trivial (one-dimensional) representation, which is the defining feature of spin 0.

Physical Insight

Spin is the little-group label, and the little group is "what is left of Lorentz after you have used up the boosts to go to the rest frame." For a massive particle that residue is the rotation group $SO(3)$, and the spin records which $SO(3)$ representation the rest-frame states form. A single, index-free state forms the trivial representation: it just sits there under rotations. That is what it *means* for the scalar's quantum to be spinless, and it is why a real scalar field describes exactly one species of spin-0 particle — no polarizations, no internal multiplet.

Combining Eqs. (9.113), (9.117) and (9.119): the one-particle space carries the action $U(\Lambda) |p\rangle = |\Lambda p\rangle$ of the Poincaré group, it is irreducible (the boosts connect every momentum to every other, and the rest-frame fibre is one-dimensional so there is no proper invariant subspace), and its Casimirs are $P^2 = m^2$, $W^2 = 0$. By Theorem 3.44 it *is* the mass-m, spin-0 irreducible representation of the Poincaré group. The abstract "what can a relativistic particle be" of Chapter 3 and the concrete excitations of the quantized field have met: the quantum of the free real scalar is the simplest relativistic particle there is.

This fixes the particle content of the free ϕ^4 theory once and for all. We continue ϕ^4 theory from its classical and symmetry stages (Chapters 6 and 7): at $\lambda = 0$ the theory describes a *single neutral spin-0 species* of mass m, with the multiparticle Fock space Eq. (9.87) as its state space. Because the field is real (Hermitian, $\phi = \phi^\dagger$), there is a single kind of $a_{\boldsymbol{p}}^\dagger$ and hence a single particle that is its own antiparticle, carrying no conserved internal charge — the $\mathbb{Z}_2$ symmetry $\phi \to -\phi$ of Chapter 7 acts as $(-1)^N$ on Fock space, assigning each quantum charge -1 under the $\mathbb{Z}_2$. These are the asymptotic states that the interaction of Chapter 14 will scatter.

We have built a physically interpreted Hilbert space: a unique vacuum, relativistic spin-0 particles as its excitations, a Bose-symmetric Fock space, and energy and momentum operators diagonalized on it. The construction is complete but for one scar — the divergent c-number E_0 in Eq. (9.98), the summed zero-point energy of infinitely many oscillators. The next section confronts that divergence head-on: it introduces normal ordering as the prescription that removes E_0, separates what is mere convention from what is physical, and shows through the Casimir effect that, although the absolute vacuum energy is unobservable, *differences* of vacuum energies are measurable and real.

9.4 The Vacuum Energy and Normal Ordering

The diagonalization of the previous section delivered the Hamiltonian of the free real scalar field in the form

$$H = \int \frac{\mathrm{d}^3 p}{(2\pi)^3\, 2\omega_{\mathbf{p}}}\, \omega_{\mathbf{p}} \left(a_{\mathbf{p}}^\dagger a_{\mathbf{p}} + \tfrac{1}{2} \left[a_{\mathbf{p}}, a_{\mathbf{p}}^\dagger \right] \right), \qquad \omega_{\mathbf{p}} = \sqrt{\mathbf{p}^2 + m^2}, \tag{9.121}$$

together with the relativistically normalized ladder algebra $\left[a_{\mathbf{p}}, a_{\mathbf{q}}^\dagger \right] = (2\pi)^3\, 2\omega_{\mathbf{p}}\, \delta^{(3)}(\mathbf{p}-\mathbf{q})$, all other commutators vanishing (recall Eqs. (9.54) and (9.98)). The first term in Eq. (9.121) is the number operator weighted by energy: it counts the quanta built on the vacuum and assigns each its relativistic energy $\omega_{\mathbf{p}}$. That part is exactly what a sensible energy operator should be, and it annihilates the vacuum. The second term does not: $\frac{1}{2}\left[a_{\mathbf{p}}, a_{\mathbf{p}}^\dagger \right] = (2\pi)^3 \omega_{\mathbf{p}} \delta^{(3)}(0)$ is a c-number, and an infinite one. Before we can call Eq. (9.121) the energy of a quantum field we must confront this term: understand exactly how badly it diverges, decide what part of it is physics and what part is bookkeeping, and produce a finite, well-defined generator of time translations. That is the business of this section. The reward is a clean vacuum with $H\,|0\rangle = 0$ and, as a bonus that is anything but trivial, the discovery that while the *absolute* value of the vacuum energy is a convention, its *response to boundaries* is a measurable force.

9.4.1 The zero-point energy and its divergences

Isolate the c-number piece of Eq. (9.121). Acting on the vacuum, $a_{\mathbf{p}}\,|0\rangle = 0$, so only the commutator term survives:

$$E_0 \;\equiv\; \langle 0|H|0\rangle = \int \frac{\mathrm{d}^3p}{(2\pi)^3\,2\omega_{\mathbf{p}}}\,\omega_{\mathbf{p}}\,\tfrac{1}{2}\,\left[a_{\mathbf{p}},a_{\mathbf{p}}^\dagger\right] = \frac{1}{2}\,(2\pi)^3\delta^{(3)}(0)\int\frac{\mathrm{d}^3p}{(2\pi)^3}\,\omega_{\mathbf{p}}. \tag{9.122}$$

Each momentum mode contributes $\frac{1}{2}\omega_{\mathbf{p}}$: the field is a continuum of decoupled oscillators, and every oscillator carries the irreducible ground-state energy $\frac{1}{2}\hbar\omega$ familiar from elementary quantum mechanics. The total E_0 is the sum of these zero-point energies, and it is doubly divergent. We disentangle the two divergences.

The volume (infrared) factor. The symbol $\delta^{(3)}(0)$ is the value of a delta function at coincident argument, which is meaningless until regulated. Quantize instead in a large cubic box of side L and volume $V = L^3$ with periodic boundary conditions, so that momenta are discrete, $\mathbf{p} = \frac{2\pi}{L}\mathbf{n}$ with $\mathbf{n}\in\mathbb{Z}^3$. In a finite box the Dirac delta of the continuum is the limit of a Kronecker delta times the density of states, and the standard dictionary reads

$$(2\pi)^3\delta^{(3)}(\mathbf{p}-\mathbf{q}) \;\longleftrightarrow\; V\,\delta_{\mathbf{p},\mathbf{q}}, \qquad \text{so} \qquad (2\pi)^3\delta^{(3)}(0) \;\longleftrightarrow\; V. \tag{9.123}$$

The infinity hiding in $\delta^{(3)}(0)$ is therefore just the spatial volume: $E_0 \propto V$. This is an *extensive* divergence, an infrared effect tied to the infinite extent of space, and it is entirely benign. It tells us that the sensible object is not the total vacuum energy but the vacuum energy *density*

$$\rho_0 \;=\; \frac{E_0}{V} = \frac{1}{2}\int\frac{\mathrm{d}^3p}{(2\pi)^3}\,\omega_{\mathbf{p}} = \frac{1}{2}\int\frac{\mathrm{d}^3p}{(2\pi)^3}\,\sqrt{\mathbf{p}^2+m^2}. \tag{9.124}$$

The ultraviolet divergence. The remaining integral in Eq. (9.124) diverges at large momentum. Doing the angular integration, $\int \mathrm{d}^3p = 4\pi\int_0^\infty p^2\,\mathrm{d}p$, and inserting a sharp cutoff $|\mathbf{p}|\le\Lambda$ to make the statement precise,

$$\rho_0(\Lambda) = \frac{1}{4\pi^2}\int_0^\Lambda \mathrm{d}p\;p^2\sqrt{p^2+m^2}. \tag{9.125}$$

For $p \gg m$ the integrand is $p^2\sqrt{p^2+m^2} = p^3\sqrt{1+m^2/p^2} = p^3 + \frac{1}{2}m^2p + O(1/p)$, so

$$\rho_0(\Lambda) = \frac{1}{4\pi^2}\left(\frac{\Lambda^4}{4}+\frac{m^2\Lambda^2}{4}+\cdots\right) = \frac{\Lambda^4}{16\pi^2}+\frac{m^2\Lambda^2}{16\pi^2}+\cdots. \tag{9.126}$$

The leading divergence is *quartic* in the cutoff. This is the worst divergence anywhere in the free theory, and it is a direct expression of the infinite number

of high-momentum oscillators each contributing $\frac{1}{2}\omega_{\mathbf{p}} \sim \frac{1}{2}|\mathbf{p}|$. It is independent of any interaction: a free field, with nothing to scatter off anything, already has an infinite ground-state energy.

Physical Insight

The two divergences have opposite physical character and must not be conflated. The volume factor V is infrared — it would be finite in a finite universe and signals that only densities are intensive, physical quantities. The Λ^4 growth is ultraviolet — it reflects our pretence that the free-field mode expansion is valid up to arbitrarily short distances. Quantum field theory does not claim to know the physics at $p \to \infty$; the cutoff Λ is an honest admission of ignorance, and every physical conclusion below will be arranged so that Λ drops out.

9.4.2 Operator ordering and the origin of the ambiguity

It is worth asking where the offending $\frac{1}{2}\omega_{\mathbf{p}}$ came from, because the answer shows it to be partly a matter of convention. The Hamiltonian density of the classical scalar field, established in Chapter 6, is $\mathcal{H} = \frac{1}{2}\pi^2 + \frac{1}{2}(\nabla\phi)^2 + \frac{1}{2}m^2\phi^2$, a sum of products of the classical fields ϕ and π. Classically these are numbers and their product is unambiguous. Upon quantization ϕ and π become operators that do not commute, and a classical monomial like π^2 or ϕ^2 does not determine a unique operator: in terms of ladder operators it contains pieces such as $a_{\mathbf{p}}a_{\mathbf{p}}^\dagger$ and $a_{\mathbf{p}}^\dagger a_{\mathbf{p}}$, which differ by the c-number $(2\pi)^3 2\omega_{\mathbf{p}}\delta^{(3)}(0)$. The passage from the classical Hamiltonian to Eq. (9.121) therefore carries an *ordering ambiguity*.

Different ordering prescriptions of the same classical H differ only by c-numbers. Concretely, write the symmetric (Weyl) ordering that the naive substitution produces,

$$H_{\text{Weyl}} = \int \frac{\mathrm{d}^3p}{(2\pi)^3\,2\omega_{\mathbf{p}}}\,\omega_{\mathbf{p}}\,\tfrac{1}{2}\big(a_{\mathbf{p}}^\dagger a_{\mathbf{p}} + a_{\mathbf{p}}a_{\mathbf{p}}^\dagger\big) = \int \frac{\mathrm{d}^3p}{(2\pi)^3\,2\omega_{\mathbf{p}}}\,\omega_{\mathbf{p}}\,a_{\mathbf{p}}^\dagger a_{\mathbf{p}} \;+\; E_0, \tag{9.127}$$

where the last equality used the commutator and Eq. (9.122). Any other ordering — all $a^\dagger$ to the left, all to the right, or anything in between — yields the same operator $a_{\mathbf{p}}^\dagger a_{\mathbf{p}}$ piece and a *different* additive constant. The dynamically nontrivial content of the Hamiltonian, the part that has nonzero commutators with the fields and hence generates the equations of motion, is fixed; only a scalar shift of the energy zero is left undetermined by the classical theory. This is precisely the freedom we are entitled to exploit, and the prescription that exploits it cleanly is normal ordering.

9.4.3 Normal ordering

Definition 9.19 (Normal ordering)**.** Let $:\cdots:$ denote the operation that reorders any product of creation and annihilation operators so that every annihilation operator stands to the right of every creation operator, treating the ladder operators as though they commuted in the process (no commutator terms are generated). For a single product of fields, $:\mathcal{O}:$ is obtained by writing each field through its mode expansion, expanding the product, and in every resulting monomial moving all $a^\dagger$ to the left of all a.

By construction a normal-ordered product has all annihilation operators acting first, so its vacuum expectation value vanishes unless the product is a pure c-number: $\langle 0|:\mathcal{O}:|0\rangle = 0$ for any $\mathcal{O}$ that is a nontrivial product of fields. Applying the prescription to the Hamiltonian and using Eq. (9.127),

$$:H: \;= \int \frac{\mathrm{d}^3p}{(2\pi)^3\,2\omega_{\mathbf{p}}}\,\omega_{\mathbf{p}}\,a^\dagger_{\mathbf{p}}a_{\mathbf{p}} = H - E_0. \tag{9.128}$$

The normal-ordered Hamiltonian is the original Hamiltonian with the zero-point energy subtracted. It is manifestly finite and positive (it is $\omega_{\mathbf{p}}$ times a number operator), it annihilates the vacuum, $:H:\,|0\rangle = 0$, and it assigns to the one-particle state $a^\dagger_{\mathbf{p}}|0\rangle$ exactly the energy $\omega_{\mathbf{p}}$ that the spectrum of the previous section demanded. We adopt $:H:$ as *the* Hamiltonian of the free scalar field; from here on, "H" in ϕ^4 theory means the normal-ordered generator, and every later Wick contraction in the interacting theory inherits this convention.

It is essential to verify that subtracting E_0 has cost us nothing physical. The following proposition makes this precise and is the formal justification for the whole prescription.

Proposition 9.20 (Normal ordering is a c-number subtraction)**.** *The normal-ordered Hamiltonian differs from H by the c-number $E_0 = \langle 0|H|0\rangle$ times the identity. Consequently $:H:$ has the same commutators with every operator as H does, generates the same Heisenberg equations of motion, and defines the same dynamics; the only change is a uniform downward shift of the entire energy spectrum by E_0, chosen so that the vacuum sits at zero.*

Proof. From Eq. (9.128), $:H: \;= H - E_0\,\mathbf{1}$ with E_0 a complex (here real) number, not an operator. For any operator $\mathcal{O}$,

$$[:H:,\mathcal{O}] = [H - E_0\mathbf{1},\mathcal{O}] = [H,\mathcal{O}] - E_0\,[\mathbf{1},\mathcal{O}] = [H,\mathcal{O}]\,, \tag{9.129}$$

because the identity commutes with everything. In particular the Heisenberg equation of motion for the field, $\dot\phi = i\,[H,\phi]$, is unchanged when H is replaced by $:H:$, and likewise for $\dot\pi$; the Klein–Gordon equation that follows is identical. The energy eigenvalues shift uniformly: if $H\,|\Psi\rangle = E\,|\Psi\rangle$ then $:H:\,|\Psi\rangle = (E - E_0)\,|\Psi\rangle$,

so all gaps $E_i - E_j$ — the only spectral data that enter transition frequencies and the S-matrix — are preserved. Thus normal ordering is exactly the statement "measure energy relative to the vacuum," and it changes no commutator, no equation of motion, and no physical energy difference. □

Caution

Proposition 9.20 licences dropping E_0 *only* because E_0 is a constant independent of the dynamical variables. Normal ordering is not a general license to discard divergences. In the interacting theory the analogous subtractions are field- and momentum-dependent and constitute genuine renormalization (Chapter 22); there the removed pieces are operators, not c-numbers, and the argument above does not apply. Here, and only here, the subtraction is free.

9.4.4 Is the vacuum energy physical?

We have just discarded an infinite constant with a clear conscience, so we owe the reader an honest account of what survives. In any theory whose dynamics is generated by commutators with H — which is to say, all of quantum mechanics in the absence of gravity — the absolute value of the energy is unobservable. A spectrometer measures frequencies $\omega_{ij} = E_i - E_j$; a calorimeter measures energy released, again a difference; an S-matrix depends on energy *differences* between in- and out-states. Adding a constant to H shifts every level together and cancels from every such quantity. The number E_0, and indeed its quartic cutoff dependence, is therefore not something the non-gravitational theory can ever be asked to predict. Setting it to zero by normal ordering is not a swindle; it is the correct response to a quantity that no experiment in flat space can access.

Two caveats sharpen this statement, and they are the substance of the rest of the section.

First, the indifference to constants fails the moment gravity is switched on. General relativity couples to the full stress–energy tensor, and a constant vacuum energy density ρ_0 acts as a cosmological constant: it gravitates, curving spacetime in a way that an absolute energy could never do in flat space. The convention-dependence of E_0 then collides with the convention-independence of geometry, and the collision is the cosmological-constant problem, to which we return in Section 9.4.6.

Second — and this is measurable already without gravity — although the *absolute* vacuum energy is a convention, the *difference* in vacuum energy between two configurations of the boundaries or background is not. If we change the boundary conditions imposed on the field, we change which modes are available, and the sum of their zero-point energies changes by a finite, cutoff-independent amount. That finite change is a real energy, and its gradient with respect to

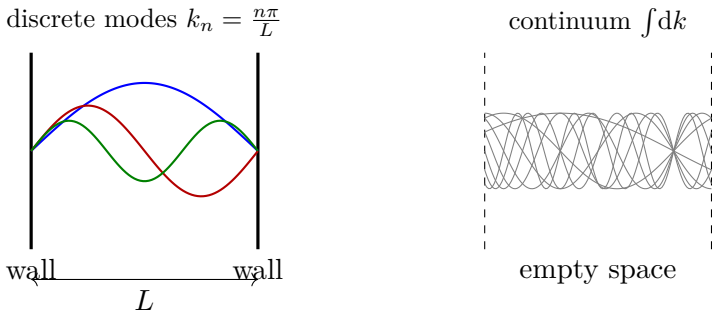

Figure 9.4: The Casimir setup in one dimension. Imposing Dirichlet conditions at two walls a distance L apart (left) selects the discrete standing-wave modes $k_n = n\pi/L$; the same region of empty space (right) supports a continuum of modes. Both vacuum energies are ultraviolet divergent, but their difference — the Casimir energy — is finite because the short-wavelength modes are common to both and cancel.

the boundary position is a real force. This is the Casimir effect, and we now compute it from first principles.

9.4.5 The Casimir effect: zero-point energy made visible

Place the field in a region bounded by walls and demand that the field vanish on the walls (Dirichlet boundary conditions; for a scalar this models, e.g., a field forced to a node at an ideal conductor). The allowed standing waves now form a discrete set whose wavelengths are fixed by the geometry, and the vacuum energy becomes a discrete sum of zero-point energies rather than an integral. As the wall separation changes, the sum changes, and the difference from the empty-space value is the Casimir energy. The decisive feature is that, although both the bounded-region sum and the empty-space integral are ultraviolet divergent, their difference is finite: the highest-momentum modes do not feel the walls and cancel between the two configurations. We exhibit this first in one spatial dimension, where every step can be shown in full, and then in the physical three-dimensional parallel-plate geometry.

Worked Example 9.21 (The 1+1-dimensional Casimir energy)**.** Consider a massless real scalar field in one spatial dimension, confined to the interval $0 \le x \le L$ with Dirichlet conditions $\phi(0) = \phi(L) = 0$. The normal modes that satisfy these conditions are $\sin(k_n x)$ with

$$k_n = \frac{n\pi}{L}, \qquad n = 1, 2, 3, \ldots, \tag{9.130}$$

and, since the field is massless, each has angular frequency $\omega_n = |k_n| = n\pi/L$. Each mode is an independent oscillator contributing $\frac{1}{2}\omega_n$ to the ground-state

energy, so the vacuum energy between the walls is

$$E(L) = \frac{1}{2}\sum_{n=1}^{\infty}\omega_n = \frac{\pi}{2L}\sum_{n=1}^{\infty} n. \tag{9.131}$$

The sum $\sum_{n\geq 1} n$ is wildly divergent. We extract its finite physical content in two independent ways and check that they agree.

Method 1: zeta-function continuation. The Riemann zeta function $\zeta(s) = \sum_{n\geq 1} n^{-s}$ converges for $\operatorname{Re} s > 1$ and continues analytically to a meromorphic function on the whole s-plane, with the special value $\zeta(-1) = -\frac{1}{12}$ established in Section E.3. The divergent series $\sum_{n\geq 1} n = \sum_{n\geq 1} n^{-(-1)}$ is the value of $\zeta(s)$ at $s = -1$ *read off the analytic continuation*, which is the canonical way to assign a finite value to such an asymptotic/divergent series (Section 5.6.1). Hence

$$\sum_{n=1}^{\infty} n \;\xrightarrow{\text{reg}}\; \zeta(-1) = -\frac{1}{12}, \qquad E(L) = \frac{\pi}{2L}\left(-\frac{1}{12}\right) = -\frac{\pi}{24L}. \tag{9.132}$$

The energy is finite and *negative*. The minus sign and the factor will be justified by the second, regulator-explicit method, which shows where the divergence went.

Method 2: exponential cutoff with explicit cancellation. Zeta continuation is rigorous but it hides the divergent piece; we now keep it visible. Damp each mode by $e^{-a\omega_n}$, with $a > 0$ a short-distance cutoff length (high-frequency modes, $\omega_n \gtrsim 1/a$, are suppressed because no real wall is perfectly reflecting at arbitrarily high frequency), and take $a \to 0$ at the end. Define $\varepsilon \equiv a\pi/L$ and $x \equiv e^{-\varepsilon}$. Then

$$E(L,a) = \frac{\pi}{2L}\sum_{n=1}^{\infty} n\, e^{-a\omega_n} = \frac{\pi}{2L}\sum_{n=1}^{\infty} n\, x^n = \frac{\pi}{2L}\,\frac{x}{(1-x)^2}, \tag{9.133}$$

where we summed the geometric-type series via $\sum_{n\geq 1} n x^n = x\,\frac{d}{dx}\sum_{n\geq 1} x^n = x\,\frac{d}{dx}\frac{x}{1-x} = \frac{x}{(1-x)^2}$, valid for $|x| < 1$. To expose the $a \to 0$ behaviour, expand in ε. It is cleanest to differentiate the small-ε expansion of $\sum_{n\geq 1} e^{-n\varepsilon} = 1/(e^{\varepsilon} - 1)$, whose Laurent series is

$$\frac{1}{e^{\varepsilon}-1} = \frac{1}{\varepsilon} - \frac{1}{2} + \frac{\varepsilon}{12} - \frac{\varepsilon^3}{720} + \cdots. \tag{9.134}$$

Since $\sum_{n\geq 1} n\, e^{-n\varepsilon} = -\frac{d}{d\varepsilon}\sum_{n\geq 1} e^{-n\varepsilon}$, we differentiate Eq. (9.134) term by term:

$$\sum_{n=1}^{\infty} n\, e^{-n\varepsilon} = -\frac{d}{d\varepsilon}\left(\frac{1}{\varepsilon} - \frac{1}{2} + \frac{\varepsilon}{12} - \frac{\varepsilon^3}{720} + \cdots\right) = \frac{1}{\varepsilon^2} - \frac{1}{12} + \frac{\varepsilon^2}{240} - \cdots. \tag{9.135}$$

Substituting $\varepsilon = a\pi/L$, so that $1/\varepsilon^2 = L^2/(\pi^2 a^2)$, and using Eq. (9.133),

$$E(L,a) = \frac{\pi}{2L}\left(\frac{L^2}{\pi^2 a^2} - \frac{1}{12} + O(a^2)\right) = \underbrace{\frac{L}{2\pi a^2}}_{\text{divergent}} - \underbrace{\frac{\pi}{24L}}_{\text{finite}} + O(a^2). \tag{9.136}$$

The divergence is the first term, $L/(2\pi a^2)$. Crucially it is *extensive*: it is proportional to the length L of the region, exactly as a bulk energy density should be. It is, in fact, nothing but the empty-space zero-point energy of the same length. To see this, compute the vacuum energy of an unbounded line of length L directly, with the *same* cutoff, using the continuum of modes $\int_{-\infty}^{\infty} \mathrm{d}k/(2\pi)$ at density L per unit k (this is Eq. (9.123) in one dimension):

$$E_{\text{free}}(L,a) = L\int_{-\infty}^{\infty} \frac{\mathrm{d}k}{2\pi}\,\frac{1}{2}\,|k|\; e^{-a|k|} = \frac{L}{2\pi}\int_0^{\infty} \mathrm{d}k\; k\, e^{-ak} = \frac{L}{2\pi}\,\frac{1}{a^2}. \tag{9.137}$$

This is precisely the divergent term in Eq. (9.136). The Casimir energy is the difference between the energy with walls and the energy of the same region of empty space,

$$E_{\text{Cas}}(L) \equiv \lim_{a\to 0}\big[E(L,a) - E_{\text{free}}(L,a)\big] = -\frac{\pi}{24L}, \tag{9.138}$$

finite, cutoff-independent, and in exact agreement with the zeta-function value Eq. (9.132). The two regulators agree because they compute the same physical quantity — the shift in vacuum energy caused by the walls — and that shift never depended on the unphysical short-distance details that the divergent term absorbed.

The force. The walls feel a force equal to minus the gradient of the energy:

$$F = -\frac{dE_{\text{Cas}}}{dL} = -\frac{d}{dL}\left(-\frac{\pi}{24L}\right) = -\frac{\pi}{24L^2}. \tag{9.139}$$

The force is negative, meaning it pulls the walls together: the Casimir force is *attractive*. The vacuum, by carrying less zero-point energy when the walls are closer, exerts a real pull on them. Nothing in this conclusion depended on the regulator; only the finite difference Eq. (9.138) entered.

Physical Insight

Reread the cancellation in Eq. (9.136)–Eq. (9.137): the infinity that we discarded by normal ordering in Eq. (9.128) is the same infinity that cancels here. The bulk zero-point energy density is a constant shift and drops out of every difference; what remains, the boundary-induced $-\pi/24L$, is genuinely there. This is the precise sense in which "the vacuum energy

is unobservable but its differences are real." The Casimir effect does not measure E_0; it measures how E_0 *responds* to a change of geometry.

The one-dimensional result is the cleanest possible demonstration, but the historically and experimentally decisive case is two parallel plates in three dimensions. We carry that computation out as well, since it produces the number that experiment confirms.

Worked Example 9.22 (Parallel-plate Casimir energy in 3+1 dimensions)**.** Take a massless scalar field between two parallel plates of area A separated by a distance a along z, with Dirichlet conditions on each plate. The transverse momentum $\mathbf{k}_\perp = (k_x, k_y)$ is continuous; the longitudinal momentum is quantized as $k_n = n\pi/a$, $n = 1, 2, \dots$. The mode frequencies are $\omega_{n,\mathbf{k}_\perp} = \sqrt{\mathbf{k}_\perp^2 + (n\pi/a)^2}$, and the vacuum energy per unit plate area is

$$\frac{E(a)}{A} = \frac{1}{2}\sum_{n=1}^{\infty} \int \frac{\mathrm{d}^2 k_\perp}{(2\pi)^2} \sqrt{\mathbf{k}_\perp^2 + \left(\frac{n\pi}{a}\right)^2}. \tag{9.140}$$

The transverse integral is ultraviolet divergent; we regulate and continue it by treating the transverse dimension as $d_\perp = 2 - 2\varepsilon$ and analytically continuing, exactly the dimensional-continuation logic of Section E.3. We need the standard continued integral — the Euclidean form of the master one-loop integral derived in full in Theorem D.22 — valid for the analytic continuation in d and in the exponent,

$$\int \frac{\mathrm{d}^d k}{(2\pi)^d} \, (\mathbf{k}^2 + M^2)^{-s} = \frac{1}{(4\pi)^{d/2}} \, \frac{\Gamma\!\left(s - \frac{d}{2}\right)}{\Gamma(s)} \, (M^2)^{\,d/2 - s}, \tag{9.141}$$

which we apply at $s = -\frac{1}{2}$ (so that $(\mathbf{k}^2 + M^2)^{1/2}$ appears) with $d = 2$ and $M = n\pi/a$. Using $\Gamma(-\frac{3}{2}) = \frac{4}{3}\sqrt{\pi}$ and $\Gamma(-\frac{1}{2}) = -2\sqrt{\pi}$,

$$\int \frac{\mathrm{d}^2 k_\perp}{(2\pi)^2} \sqrt{\mathbf{k}_\perp^2 + M^2} \;=\; \frac{1}{4\pi} \, \frac{\Gamma(-\frac{3}{2})}{\Gamma(-\frac{1}{2})} \, M^3 = \frac{1}{4\pi} \cdot \frac{\frac{4}{3}\sqrt{\pi}}{-2\sqrt{\pi}} \, M^3 = -\frac{M^3}{6\pi}. \tag{9.142}$$

The (power-law) ultraviolet divergence of the transverse integral has been discarded by the continuation, exactly as the extensive divergence was discarded in one dimension; what it leaves is the analytic remainder $-M^3/6\pi$. Inserting $M = n\pi/a$ into Eq. (9.140),

$$\frac{E(a)}{A} = \frac{1}{2}\sum_{n=1}^{\infty} \left(-\frac{1}{6\pi} \left(\frac{n\pi}{a}\right)^3 \right) = -\frac{\pi^2}{12\,a^3} \sum_{n=1}^{\infty} n^3 = -\frac{\pi^2}{12\,a^3}\,\zeta(-3). \tag{9.143}$$

The remaining sum over n is again assigned its zeta value, and $\zeta(-3) = \frac{1}{120}$ (Section E.3). Therefore

$$\boxed{\frac{E(a)}{A} = -\frac{\pi^2}{1440\,a^3}} \qquad \Longrightarrow \qquad \frac{F}{A} = -\frac{d}{da}\frac{E(a)}{A} = -\frac{\pi^2}{480\,a^4}. \tag{9.144}$$

The pressure is negative: the plates are pulled together. For the electromagnetic field the same computation with two physical photon polarizations (and Neumann as well as Dirichlet modes) gives the celebrated $E/A = -\pi^2/(720\,a^3)$ and force per area $-\pi^2\hbar c/(240\,a^4)$, which is the quantity measured in the laboratory. The single-scalar result Eq. (9.144) is exactly one half of it — the electromagnetic field contributes two physical polarizations, hence twice the energy of a single Dirichlet scalar — and it is the version that belongs to ϕ^4 theory.

Historical Note

Casimir derived the electromagnetic plate force in 1948 while studying colloidal suspensions; the prediction of an attractive force from nothing but vacuum fluctuations was for decades regarded as marginal, but it has since been confirmed with $\sim 1\%$ precision in modern force-microscopy experiments. The effect is the sharpest demonstration that the zero-point energy of a quantum field, while not itself an observable, has observable consequences whenever a boundary or background breaks the translation invariance that would otherwise make it an irrelevant constant.

9.4.6 Frontier flag: the cosmological-constant problem

We close with the one place where the absolute vacuum energy refuses to be a convention. As noted above, gravity couples to the total stress–energy, and a Lorentz-invariant vacuum has $\langle T_{\mu\nu}\rangle = \rho_{\rm vac}\,\eta_{\mu\nu}$, so the constant $\rho_{\rm vac}$ enters Einstein's equations as a cosmological constant Λ and curves spacetime. Now the shift we so cheerfully removed by normal ordering becomes physical, and its natural size is a catastrophe. If the free-field mode expansion were trusted up to a cutoff Λ, the vacuum energy density Eq. (9.126) would be of order

$$\rho_{\rm vac} \sim \frac{\Lambda^4}{16\pi^2}. \tag{9.145}$$

Taking Λ at the Planck scale $M_{\rm Pl} \sim 10^{19}$ GeV, where quantum gravity certainly intervenes, gives $\rho_{\rm vac} \sim 10^{74}$ GeV^4. The value inferred from the observed accelerating expansion of the universe is $\rho_\Lambda \sim 10^{-47}$ GeV^4 — a meV-scale energy density. The naive estimate exceeds the measured value by roughly

$$\frac{\rho_{\rm vac}}{\rho_\Lambda} \sim 10^{121}, \tag{9.146}$$

and even the most conservative choice of cutoff (say the electroweak or QCD scale) leaves a discrepancy of dozens of orders of magnitude. Why the gravitating vacuum energy is so many orders of magnitude smaller than every field-theoretic estimate — and why it is small but not exactly zero — is the *cosmological-constant problem*. As of the mid-2020s it has no accepted solution: it is not

resolved by supersymmetry (which is broken), nor by known anthropic, dynamical, or symmetry-based mechanisms in any way that the community regards as compelling. It stands as the most quantitatively severe known clash between quantum field theory and gravitation, and the reader should keep it in mind as the honest limit of the clean construction of this chapter: normal ordering disposes of the vacuum energy perfectly as long as gravity is switched off, and not at all once it is switched on.

With a finite, normal-ordered Hamiltonian in hand and a vacuum pinned at zero energy, the spectrum of the free theory is fully under control. We may now turn from *states* to *dynamics*: the next section computes the free two-point functions of the field and assembles them into the Feynman propagator, the object whose time-ordered structure and $i\epsilon$ contour will become the single line in every diagram of the interacting theory.

9.5 Correlation Functions and the Feynman Propagator

We have arrived at the dynamical heart of the free theory. The preceding sections handed us a complete quantum kinematics: a vacuum $|0\rangle$ annihilated by every lowering operator, a field operator $\phi(x)$ written as a Lorentz-covariant superposition of creation and annihilation operators, and a Hamiltonian rendered finite by normal ordering. What we do *not* yet have is a single object that packages the dynamics — the propagation of a disturbance of the field from one spacetime point to another — in a form ready for perturbation theory. That object is the two-point correlation function, and its time-ordered version, the Feynman propagator, is the most important quantity in this chapter. It is the amplitude for the field to "create a quantum at y and absorb it at x," it is the Green's function of the Klein–Gordon operator, and from Chapters 14 and 15 onward it is the internal line of every Feynman diagram. The path-integral chapter (Chapter 10) will rederive this very object from the generating functional $Z[J]$; the two derivations must agree, and they do.

Our strategy is to compute the vacuum expectation value of a product of two fields directly from the mode expansion, study its analytic structure, and then show that the time-ordered product — the combination that perturbation theory actually demands — is reproduced with magical economy by a single covariant four-momentum integral whose only subtlety is an $i\varepsilon$ in the denominator. That $i\varepsilon$, far from being a regulator we tolerate, turns out to *be* the instruction "time-order the operators." Establishing this equivalence, in full, is the work of the section.

Throughout we use the mode expansion and canonical structure fixed earlier in this chapter. We recall them in the form we need: with $E_{\mathbf{p}} \equiv \sqrt{\mathbf{p}^2 + m^2} > 0$

the on-shell energy and $p^0 = E_{\mathbf{p}}$ understood inside on-shell exponentials,

$$\phi(x) = \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}} \left(a_{\mathbf{p}}\, e^{-ip\cdot x} + a^\dagger_{\mathbf{p}}\, e^{+ip\cdot x} \right), \qquad \left[a_{\mathbf{p}}, a^\dagger_{\mathbf{p}'} \right] = (2\pi)^3\, 2E_{\mathbf{p}}\, \delta^3(\mathbf{p}-\mathbf{p}'), \tag{9.147}$$

all other commutators vanishing, $a_{\mathbf{p}}\,|0\rangle = 0$, and the canonical momentum is $\pi(x) = \dot\phi(x)$ with the equal-time relation $[\phi(x^0,\mathbf{x}), \pi(x^0,\mathbf{y})] = i\,\delta^3(\mathbf{x}-\mathbf{y})$ (Eqs. (9.7) and (9.42)). We also use the Lorentz invariance of the measure $d^3p/(2\pi)^3 2E_{\mathbf{p}}$ established when we built the one-particle states (Eq. (9.68)); it is what makes the manifestly noncovariant-looking integrals below covariant after all.

9.5.1 The Wightman two-point function

The simplest correlator is the vacuum expectation value of the unordered product of two fields.

Definition 9.23 (Wightman two-point function)**.** The *(positive-frequency) Wightman function* of the free real scalar field is

$$D(x-y) \;\equiv\; \langle 0|\, \phi(x)\, \phi(y)\, |0\rangle\,. \tag{9.148}$$

That it depends only on the difference $x-y$ is not assumed but computed; it follows from translation invariance of the vacuum, which we now see explicitly. Insert the mode expansion Eq. (9.147) for both fields:

$$\phi(x)\phi(y) = \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}} \frac{d^3q}{(2\pi)^3\, 2E_{\mathbf{q}}} \left(a_{\mathbf{p}} e^{-ip\cdot x} + a^\dagger_{\mathbf{p}} e^{+ip\cdot x} \right) \left(a_{\mathbf{q}} e^{-iq\cdot y} + a^\dagger_{\mathbf{q}} e^{+iq\cdot y} \right). \tag{9.149}$$

Of the four operator products aa, $aa^\dagger$, $a^\dagger a$, $a^\dagger a^\dagger$, only $a_{\mathbf{p}} a^\dagger_{\mathbf{q}}$ survives between vacua: any term with an annihilator on the right kills $|0\rangle$, and any term with a creator on the left is killed by $\langle 0|$. Using $\langle 0|\, a_{\mathbf{p}} a^\dagger_{\mathbf{q}}\, |0\rangle = \langle 0| \left[a_{\mathbf{p}}, a^\dagger_{\mathbf{q}} \right] |0\rangle = (2\pi)^3\, 2E_{\mathbf{p}}\, \delta^3(\mathbf{p}-\mathbf{q})$, the $\mathbf{q}$ integral collapses, the commutator's $2E_{\mathbf{p}}$ cancelling the measure factor $1/2E_{\mathbf{q}}$:

$$\boxed{D(x-y) = \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}}\, e^{-ip\cdot(x-y)}} \qquad (p^0 = E_{\mathbf{p}}). \tag{9.150}$$

This is the first key result. Several of its properties are worth recording, because they control everything that follows.

(i) Positive frequency. Every term carries $e^{-iE_{\mathbf{p}}(x^0-y^0)}$ with $E_{\mathbf{p}} > 0$: as a function of the time difference the Wightman function contains only positive-frequency Fourier components. This is the operator statement that $\phi(y)\,|0\rangle$ is a

superposition of one-particle states of positive energy — the field, acting on the vacuum, can only *create*, never destroy negative energy.

(ii) Lorentz invariance. Written with the invariant measure $d^3p/(2\pi)^3 2E_{\mathbf{p}}$ and the invariant exponent $p\cdot(x-y)$ at $p^0 = E_{\mathbf{p}}$, the integral Eq. (9.150) is manifestly invariant under the orthochronous Lorentz group: $D(x-y)$ is a Lorentz scalar function of $x-y$. For spacelike separation it can therefore depend only on the invariant $(x-y)^2 < 0$, and by choosing a frame in which $x^0 = y^0$ one sees it does *not* vanish there — a point we return to when we analyze causality.

(iii) Distributional nature. The integrand decays only as the inverse of $E_{\mathbf{p}} \sim |\mathbf{p}|$ at large momentum, so $\int d^3p/2E_{\mathbf{p}}$ is badly divergent for $x = y$. Thus $D(x-y)$ is not an ordinary function: it is a tempered distribution, finite only when smeared against test functions, exactly the kind of object the distribution theory of Theorem 5.18 was built to handle. We will always treat it as such; in particular the manipulations below (interchanging integrals, closing contours) are justified at the level of tempered distributions reviewed there.

(iv) Conjugation. Since ϕ is Hermitian, $D(x-y)^* = \langle 0|\,\phi(y)\phi(x)\,|0\rangle = D(y-x)$, which from Eq. (9.150) is the same integral with $e^{+ip\cdot(x-y)}$. The two orderings $D(x-y)$ and $D(y-x)$ are complex conjugates, not equal; their difference is the commutator function $\langle 0|\,[\phi(x),\phi(y)]\,|0\rangle = D(x-y) - D(y-x)$, the central object of Section 9.6.

9.5.2 Time ordering and the Feynman propagator

Perturbation theory, as we will see in Chapter 14, is built from the Dyson series, and every term in that series is a vacuum expectation value of a *time-ordered* product of fields. We therefore need the correlator with the operators arranged in order of increasing time from right to left. Recall the time-ordering symbol $\mathcal{T}$, defined on two bosonic fields by

$$\mathcal{T}\,\phi(x)\phi(y) \;\equiv\; \theta(x^0-y^0)\,\phi(x)\phi(y) + \theta(y^0-x^0)\,\phi(y)\phi(x), \tag{9.151}$$

i.e. the later field stands to the left. (For bosons the two terms commute at equal time up to the equal-time commutator, which vanishes for the fields themselves, so the symbol is unambiguous at $x^0 = y^0$.)

Definition 9.24 (Feynman propagator)**.** The *Feynman propagator* of the free real scalar field is the time-ordered two-point function

$$D_F(x-y) \;\equiv\; \langle 0|\mathcal{T}\phi(x)\phi(y)|0\rangle. \tag{9.152}$$

Taking the vacuum expectation value of Eq. (9.151) and using Eq. (9.148) for each ordering gives immediately the position-space form

$$D_F(x-y) = \theta(x^0-y^0)\,D(x-y) + \theta(y^0-x^0)\,D(y-x). \tag{9.153}$$

In words: for x later than y a quantum is created at y and absorbed at x; for y later than x the roles are reversed. The same positive-energy quantum always propagates *forward* in time, which is the physical content the $i\varepsilon$ prescription below will encode. Equation Eq. (9.153) is exact and will serve as the target that the covariant momentum integral must reproduce.

9.5.3 The covariant momentum-space form via the p^0 contour

The position-space expression Eq. (9.153) is correct but ungainly: it is built from on-shell three-dimensional integrals glued together with step functions, and it hides Lorentz covariance behind the explicit time-ordering. The remarkable fact — the technical centerpiece of the section — is that the *same* distribution is produced by a single, manifestly covariant integral over *all four* components of an off-shell momentum, with the time-ordering smuggled in entirely through an infinitesimal imaginary part of the mass.

Theorem 9.25 (Contour representation of the Feynman propagator)**.** *The Feynman propagator Eq. (9.152) admits the four-dimensional integral representation*

$$\boxed{D_F(x-y) = \int \frac{d^4p}{(2\pi)^4}\, \frac{i\, e^{-ip\cdot(x-y)}}{p^2 - m^2 + i\varepsilon}} \tag{9.154}$$

where now p^0 ranges over all of $\mathbb{R}$ independently of $\mathbf{p}$ (the momentum is off shell, $p^2 \neq m^2$ in general), $\varepsilon \to 0^+$, and the equality holds as tempered distributions.

Proof. The strategy is to perform the p^0 integral in Eq. (9.154) by contour methods, leaving the three-dimensional $\mathbf{p}$ integral untouched, and to show that the result is exactly Eq. (9.153). Write $t \equiv x^0 - y^0$ for the time difference and factor the denominator. Since $p^2 - m^2 = (p^0)^2 - \mathbf{p}^2 - m^2 = (p^0)^2 - E_{\mathbf{p}}^2$, we have

$$p^2 - m^2 + i\varepsilon = (p^0)^2 - E_{\mathbf{p}}^2 + i\varepsilon = \big(p^0 - (E_{\mathbf{p}} - i\varepsilon')\big)\big(p^0 + (E_{\mathbf{p}} - i\varepsilon')\big), \tag{9.155}$$

where the second equality holds to first order in the infinitesimal because

$$(p^0 - E_{\mathbf{p}} + i\varepsilon')(p^0 + E_{\mathbf{p}} - i\varepsilon') = (p^0)^2 - (E_{\mathbf{p}} - i\varepsilon')^2 = (p^0)^2 - E_{\mathbf{p}}^2 + 2iE_{\mathbf{p}}\varepsilon' + O(\varepsilon'^2), \tag{9.156}$$

so the choices match with $\varepsilon = 2E_{\mathbf{p}}\,\varepsilon'$. Because $E_{\mathbf{p}} > 0$, ε and ε' have the same (positive) sign, and we may take $\varepsilon' \to 0^+$ at the end. The displaced poles in the complex p^0 plane therefore sit at

$$p^0 = +E_{\mathbf{p}} - i\varepsilon' \quad \text{(just } \textit{below} \text{ the positive real axis)}, \qquad p^0 = -E_{\mathbf{p}} + i\varepsilon' \quad \text{(just } \textit{above} \text{ the neg} \tag{9.157}$$

This staggered placement — one pole nudged down, one nudged up — is the entire content of the $i\varepsilon$; it is what distinguishes the Feynman propagator from

its retarded and advanced cousins (Section 9.5.5). The configuration and the two ways of closing the contour are drawn in Fig. 9.5.

Now consider the inner integral

$$I(\mathbf{p},t) \equiv \int_{-\infty}^{\infty} \frac{dp^0}{2\pi} \, \frac{i\, e^{-ip^0 t}}{(p^0 - E_{\mathbf{p}} + i\varepsilon')(p^0 + E_{\mathbf{p}} - i\varepsilon')}. \tag{9.158}$$

To use the residue theorem (Theorem 5.23) we must close the open contour along $\mathbb{R}$ with a large semicircle on which the integrand vanishes, and the choice of half-plane is forced by the convergence of the exponential. Parametrize the semicircle as $p^0 = Re^{i\theta}$; then

$$\left| e^{-ip^0 t} \right| = \left| e^{-iRt(\cos\theta + i\sin\theta)} \right| = e^{\,Rt\,\sin\theta}. \tag{9.159}$$

For this to decay as $R \to \infty$ we need $t \sin\theta < 0$. Two cases arise.

Case $t > 0$ (so $x^0 > y^0$). We need $\sin\theta < 0$, i.e. $\theta \in (-\pi, 0)$: the contour must be closed in the *lower* half-plane. By Jordan's lemma the semicircle contributes nothing and the closed contour encircles only the pole at $p^0 = E_{\mathbf{p}} - i\varepsilon'$, traversed *clockwise*, so the residue theorem gives a factor $-2\pi i$. The residue of the integrand at that pole is obtained by deleting the vanishing factor and setting $p^0 = E_{\mathbf{p}}$ in the rest:

$$\mathrm{Res}_{p^0 = E_{\mathbf{p}} - i\varepsilon'} = \left. \frac{i\, e^{-iE_{\mathbf{p}} t}}{p^0 + E_{\mathbf{p}}} \right|_{p^0 = E_{\mathbf{p}}} = \frac{i\, e^{-iE_{\mathbf{p}} t}}{2E_{\mathbf{p}}}. \tag{9.160}$$

Hence

$$I(\mathbf{p},t) = \frac{1}{2\pi}\,(-2\pi i)\,\frac{i\, e^{-iE_{\mathbf{p}} t}}{2E_{\mathbf{p}}} = \frac{e^{-iE_{\mathbf{p}} t}}{2E_{\mathbf{p}}} \qquad (t > 0), \tag{9.161}$$

using $(-i)(i) = 1$. Reinstating the three-dimensional integral and the spatial exponential $e^{+i\mathbf{p}\cdot(\mathbf{x}-\mathbf{y})}$ carried along from Eq. (9.154),

$$D_F(x-y)\big|_{t>0} = \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}}\, e^{-iE_{\mathbf{p}} t}\, e^{+i\mathbf{p}\cdot(\mathbf{x}-\mathbf{y})} = \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}}\, e^{-ip\cdot(x-y)} = D(x-y), \tag{9.162}$$

because $E_{\mathbf{p}} t - \mathbf{p}\cdot(\mathbf{x}-\mathbf{y}) = p\cdot(x-y)$ at $p^0 = E_{\mathbf{p}}$. We have recovered the first piece of Eq. (9.153).

Case $t < 0$ (so $y^0 > x^0$). Now $\sin\theta > 0$ is required, so we close in the *upper* half-plane, encircling only the pole at $p^0 = -E_{\mathbf{p}} + i\varepsilon'$, traversed *counterclockwise*: a factor $+2\pi i$. The residue is

$$\mathrm{Res}_{p^0 = -E_{\mathbf{p}} + i\varepsilon'} = \left. \frac{i\, e^{-ip^0 t}}{p^0 - E_{\mathbf{p}}} \right|_{p^0 = -E_{\mathbf{p}}} = \frac{i\, e^{+iE_{\mathbf{p}} t}}{-2E_{\mathbf{p}}}, \tag{9.163}$$

so that

$$I(\mathbf{p},t) = \frac{1}{2\pi}\,(+2\pi i)\,\frac{i\, e^{+iE_{\mathbf{p}} t}}{-2E_{\mathbf{p}}} = \frac{e^{+iE_{\mathbf{p}} t}}{2E_{\mathbf{p}}} \qquad (t < 0), \tag{9.164}$$

using $(i)(i)/(-1) = 1$. Therefore

$$D_F(x-y)\big|_{t<0} = \int \frac{d^3p}{(2\pi)^3\,2E_{\mathbf{p}}}\, e^{+iE_{\mathbf{p}}t}\, e^{+i\mathbf{p}\cdot(\mathbf{x}-\mathbf{y})}. \tag{9.165}$$

Because $E_{\mathbf{p}}$ and the measure are even in $\mathbf{p}$, we may substitute $\mathbf{p} \to -\mathbf{p}$ to flip the sign of the spatial exponential without changing anything else:

$$D_F(x-y)\big|_{t<0} = \int \frac{d^3p}{(2\pi)^3\,2E_{\mathbf{p}}}\, e^{+iE_{\mathbf{p}}t - i\mathbf{p}\cdot(\mathbf{x}-\mathbf{y})} = \int \frac{d^3p}{(2\pi)^3\,2E_{\mathbf{p}}}\, e^{+ip\cdot(x-y)} = D(y-x), \tag{9.166}$$

recognizing the conjugate Wightman function from property (iv) above. We have recovered the second piece of Eq. (9.153).

Combining the two cases reproduces exactly

$$D_F(x-y) = \theta(x^0-y^0)\,D(x-y) + \theta(y^0-x^0)\,D(y-x), \tag{9.167}$$

which is Eq. (9.153), the operator time-ordered product. This establishes Eq. (9.154). □

The proof makes the slogan precise: *the $i\varepsilon$ is time ordering.* The displacement of the poles is not a computational convenience that we remove at the end — it is the part of the formula that knows which field is later. Pushing the positive-energy pole below the axis guarantees that when x is the later point ($t > 0$) the contour, forced downward by convergence, captures precisely the positive-frequency propagation $D(x-y)$; pushing the negative-energy pole above the axis does the symmetric job for $t < 0$.

Physical Insight

The Feynman propagator describes a single physical process viewed two ways. Read forward in time it is a particle created at the earlier point and absorbed at the later one; read with $t < 0$ it is the antiparticle (here, for the neutral scalar, the particle is its own antiparticle) running the other way. The $i\varepsilon$ is the bookkeeping that sends positive-energy quanta forward and negative-energy quanta backward in time, so that only physical, forward-in-time, positive-energy propagation ever occurs. This is Stueckelberg and Feynman's reinterpretation of antiparticles, here visible already in the free theory.

9.5.4 Independent check: the operator time-ordered product

The contour theorem was proved by *assuming* the momentum integral Eq. (9.154) and reducing it to the operator expression Eq. (9.153). It is worth confirming the operator expression itself directly from the mode expansion, with no contour

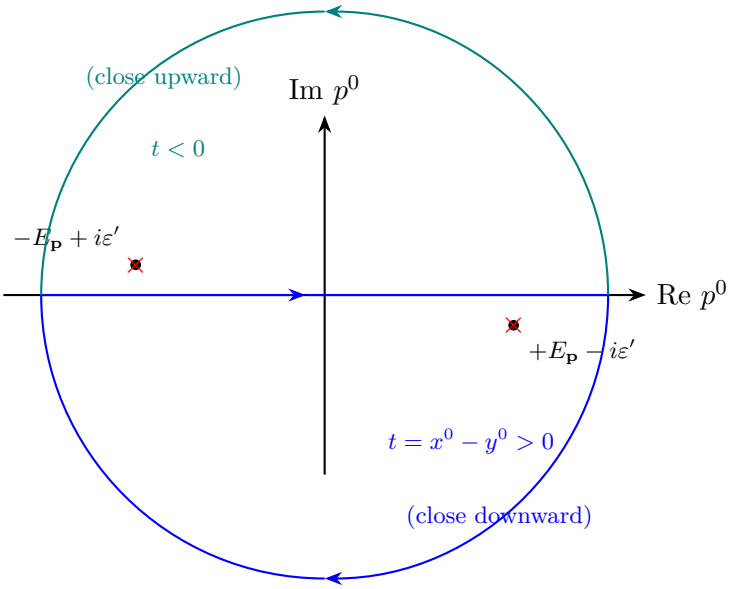

Figure 9.5: The $i\varepsilon$ prescription as a contour routing. The Feynman denominator $p^2 - m^2 + i\varepsilon$ places the pole at $p^0 = +E_{\mathbf{p}}$ just below the real axis and the pole at $p^0 = -E_{\mathbf{p}}$ just above it. For $x^0 > y^0$ the exponential $e^{-ip^0(x^0-y^0)}$ forces the contour closed in the lower half-plane (blue, clockwise), picking up only the positive-energy pole and yielding $D(x-y)$; for $x^0 < y^0$ it is closed in the upper half-plane (teal, counterclockwise), picking up the negative-energy pole and yielding $D(y-x)$. The single analytic prescription thus encodes the two-piece time-ordered product.

at all, so that the two starting points are seen to be genuinely the same object rather than one defined in terms of the other.

Worked Example 9.26 (The time-ordered product from the modes)**.** Compute $\langle 0|\,\mathcal{T}\,\phi(x)\phi(y)\,|0\rangle$ directly from Eq. (9.147).

For $x^0 > y^0$ the time-ordering symbol Eq. (9.151) returns $\phi(x)\phi(y)$, whose vacuum expectation value is, by definition, $D(x-y)$. The computation of $D(x-y)$ from the modes was already carried out in full in Eqs. (9.149) and (9.150): only the $a_{\mathbf{p}}a^\dagger_{\mathbf{q}}$ term survives, and

$$\langle 0|\,\phi(x)\phi(y)\,|0\rangle = \int \frac{d^3p}{(2\pi)^3\,2E_{\mathbf{p}}}\,e^{-ip\cdot(x-y)} = D(x-y). \tag{9.168}$$

For $y^0 > x^0$ the symbol returns $\phi(y)\phi(x)$; the identical computation with $x \leftrightarrow y$ gives $\langle 0|\,\phi(y)\phi(x)\,|0\rangle = D(y-x)$. Assembling the two cases with their step functions reproduces Eq. (9.153) on the nose:

$$\langle 0|\,\mathcal{T}\,\phi(x)\phi(y)\,|0\rangle = \theta(x^0-y^0)D(x-y)+\theta(y^0-x^0)D(y-x) = D_F(x-y). \tag{9.169}$$

No analyticity, no contour, and no $i\varepsilon$ entered: the operator definition and the covariant integral Eq. (9.154) are two faces of the same distribution, and Theorem 9.25 is the bridge between them.

9.5.5 Locating the Feynman choice: retarded and advanced Green's functions

The denominator $1/(p^2-m^2)$ has poles on the real p^0 axis at $p^0=\pm E_{\mathbf{p}}$, and the integral Eq. (9.154) is ill-defined until we say how the contour avoids them. The $i\varepsilon$ is one such prescription; it is not the only one. The full set of inequivalent prescriptions corresponds to the four ways of routing the contour around the two poles, and the physically distinguished ones — besides Feynman's — are the retarded and advanced Green's functions. Comparing them locates the Feynman choice and prepares the causal analysis of the next section.

The retarded prescription pushes *both* poles below the real axis, which is achieved by the replacement $p^0\to p^0+i\varepsilon$ everywhere, i.e.

$$G_R(x-y)=\int\frac{d^4p}{(2\pi)^4}\,\frac{i\,e^{-ip\cdot(x-y)}}{(p^0+i\varepsilon)^2-E_{\mathbf{p}}^2}=\int\frac{d^4p}{(2\pi)^4}\,\frac{i\,e^{-ip\cdot(x-y)}}{(p^0+i\varepsilon-E_{\mathbf{p}})(p^0+i\varepsilon+E_{\mathbf{p}})}, \tag{9.170}$$

with poles at $p^0=\pm E_{\mathbf{p}}-i\varepsilon$, both in the lower half-plane. For $t<0$ we close upward and enclose nothing, so G_R vanishes for $x^0<y^0$ — it is *retarded*, supported on the future. For $t>0$ we close downward (clockwise) and pick up both residues. Their sum is

$$\mathrm{Res}_{p^0=E_{\mathbf{p}}}+\mathrm{Res}_{p^0=-E_{\mathbf{p}}}=\frac{i\,e^{-iE_{\mathbf{p}}t}}{2E_{\mathbf{p}}}+\frac{i\,e^{+iE_{\mathbf{p}}t}}{-2E_{\mathbf{p}}}=\frac{i}{2E_{\mathbf{p}}}\big(e^{-iE_{\mathbf{p}}t}-e^{+iE_{\mathbf{p}}t}\big)=\frac{\sin E_{\mathbf{p}}t}{E_{\mathbf{p}}}, \tag{9.171}$$

so that $\int dp^0/(2\pi)=\frac{1}{2\pi}(-2\pi i)\cdot(\sin E_{\mathbf{p}}t)/E_{\mathbf{p}}=-i\,(\sin E_{\mathbf{p}}t)/E_{\mathbf{p}}$, and

$$G_R(x-y)=-\,i\,\theta(x^0-y^0)\int\frac{d^3p}{(2\pi)^3}\,\frac{\sin E_{\mathbf{p}}t}{E_{\mathbf{p}}}\,e^{+i\mathbf{p}\cdot(\mathbf{x}-\mathbf{y})}=\theta(x^0-y^0)\,\langle0|\,[\phi(x),\phi(y)]\,|0\rangle\,. \tag{9.172}$$

The last equality follows because the commutator function is, from properties (i) and (iv),

$$\langle0|\,[\phi(x),\phi(y)]\,|0\rangle=D(x-y)-D(y-x)=\int\frac{d^3p}{(2\pi)^3\,2E_{\mathbf{p}}}\big(e^{-iE_{\mathbf{p}}t}-e^{+iE_{\mathbf{p}}t}\big)e^{+i\mathbf{p}\cdot(\mathbf{x}-\mathbf{y})}=-\,i\int\frac{d^3$$

(9.173)

The advanced function is obtained by the mirror choice $p^0\to p^0-i\varepsilon$, placing both poles above the axis; it is supported on the past, $G_A(x-y)=-\theta(y^0-x^0)\,\langle0|\,[\phi(x),\phi(y)]\,|0\rangle$.

Two observations close the comparison. First, all three are *Green's functions* of the same Klein–Gordon operator (proved next), differing only by which homogeneous solution one adds: $G_R-G_A=D(x-y)-D(y-x)=\langle0|\,[\phi(x),\phi(y)]\,|0\rangle$

Prescription	Pole routing in p^0	Support / interpretation
Feynman D_F	$+E_{\mathbf{p}}$ below, $-E_{\mathbf{p}}$ above	all t; time-ordered product
Retarded G_R	both poles below	$t > 0$; response after the source
Advanced G_A	both poles above	$t < 0$; support in the past

Table 9.1: The three physically distinguished pole prescriptions for $1/(p^2 - m^2)$. All three are Green's functions of the Klein–Gordon operator (Theorem 9.27); they differ only by solutions of the homogeneous equation, and the difference is built from the on-shell commutator function Eq. (9.173).

is annihilated by $(\Box + m^2)$ because each Wightman piece is on shell. Second, the Feynman choice is the only one of the three that is neither purely retarded nor purely advanced; it propagates positive frequencies forward and negative frequencies backward, which is exactly why it, and not G_R or G_A, is the object generated by the time-ordered perturbation series. The classical theory of Chapter 6 naturally selects G_R (a field responds to its sources after they act); the quantum amplitude selects D_F.

Notation Watch

Conventions for the scalar Green's function differ across the literature by an overall factor of i and by a sign, because some authors define the propagator as the Green's function of $(\Box + m^2)$ with unit source while we define it as the time-ordered correlator. With the canon of this book — numerator i in Eq. (9.154), mostly-minus metric, $\Box = \partial^\mu \partial_\mu = \partial_t^2 - \nabla^2$ — the normalization is fixed once and for all by Theorem 9.27 below, $(\Box + m^2) D_F = -i\delta^4$. When importing a formula from another source, check its metric and its i before trusting a sign.

9.5.6 The propagator is the Green's function of the Klein–Gordon operator

We have called D_F a propagator and a Green's function; we now prove the second name. The Klein–Gordon operator is $(\Box_x + m^2)$ with $\Box_x = \partial_\mu^x \partial_x^\mu$, the operator whose vanishing is the free equation of motion Eq. (6.55).

Theorem 9.27 (Klein–Gordon Green's function)**.** *The Feynman propagator satisfies*

$$\boxed{(\Box_x + m^2)\, D_F(x - y) = -\, i\, \delta^4(x - y)} \tag{9.174}$$

and is therefore (up to the conventional factor $-i$) the Green's function of the Klein–Gordon operator. The same identity holds for G_R and G_A.

Proof, momentum space. Act with $(\Box_x+m^2)$ under the integral sign in Eq. (9.154). Since $\partial_\mu^x e^{-ip\cdot(x-y)} = -ip_\mu\, e^{-ip\cdot(x-y)}$,

$$(\Box_x+m^2)\, e^{-ip\cdot(x-y)} = \big((-ip)^\mu(-ip)_\mu+m^2\big)e^{-ip\cdot(x-y)} = (-p^2+m^2)\, e^{-ip\cdot(x-y)} = -(p^2-m^2)\, e^{-} \tag{9.175}$$

Therefore

$$(\Box_x+m^2)\, D_F(x-y) = \int \frac{d^4p}{(2\pi)^4}\, \frac{i\,\big(-(p^2-m^2)\big)}{p^2-m^2+i\varepsilon}\, e^{-ip\cdot(x-y)} = -\,i\int \frac{d^4p}{(2\pi)^4}\, \frac{p^2-m^2}{p^2-m^2+i\varepsilon}\, e^{-ip\cdot(x-} \tag{9.176}$$

Write the ratio as $\dfrac{p^2-m^2}{p^2-m^2+i\varepsilon} = 1 - \dfrac{i\varepsilon}{p^2-m^2+i\varepsilon}$. The second term vanishes as a tempered distribution when $\varepsilon \to 0^+$ (its only support is an infinitesimal neighborhood of the mass shell, which has measure zero against test functions; this is the statement of Section 5.1.5). The first term gives the complete momentum-space delta function (Theorem 5.18),

$$\int \frac{d^4p}{(2\pi)^4}\, e^{-ip\cdot(x-y)} = \delta^4(x-y), \tag{9.177}$$

so that $(\Box_x + m^2)D_F(x-y) = -i\,\delta^4(x-y)$, as claimed. For G_R and G_A the numerator and the leading denominator are identical; only the routing of the poles differs, and that affects Eq. (9.176) only through the vanishing $i\varepsilon$ term. Hence all three prescriptions are Green's functions with the same right-hand side. □

The momentum-space proof is the quickest, but it conceals the physical origin of the delta function, which is the canonical equal-time commutator. The following independent derivation in position space makes that origin explicit and ties the result directly back to the quantization conditions of the chapter's opening.

Worked Example 9.28 (Position-space derivation of the Green's-function identity)**.** We verify Eq. (9.174) starting from the operator form Eq. (9.153), differentiating the step functions and using the canonical commutation relations. Write $t = x^0 - y^0$ and recall $\partial_{x^0}\theta(t) = \delta(t) = -\partial_{x^0}\theta(-t)$.

First time derivative. Differentiating Eq. (9.153),

$$\partial_{x^0} D_F = \delta(t)\big[D(x-y)-D(y-x)\big]+\theta(t)\,\partial_{x^0}D(x-y)+\theta(-t)\,\partial_{x^0}D(y-x). \tag{9.178}$$

The $\delta(t)$ bracket is evaluated at equal times $x^0 = y^0$, where $D(x-y)-D(y-x) = \langle 0|\,[\phi(x),\phi(y)]\,|0\rangle$ vanishes: the equal-time commutator of two fields is zero (Eq. (9.7)). The first term drops, leaving

$$\partial_{x^0} D_F = \theta(t)\,\partial_{x^0}D(x-y) + \theta(-t)\,\partial_{x^0}D(y-x). \tag{9.179}$$

Second time derivative. Differentiating again,

$$\partial_{x^0}^2 D_F = \delta(t)\,[\partial_{x^0} D(x-y) - \partial_{x^0} D(y-x)] + \theta(t)\,\partial_{x^0}^2 D(x-y) + \theta(-t)\,\partial_{x^0}^2 D(y-x). \tag{9.180}$$

The $\delta(t)$ bracket is now nontrivial. Using $\partial_{x^0} D(x-y) = \langle 0|\,\dot\phi(x)\phi(y)\,|0\rangle$ and $\partial_{x^0} D(y-x) = \langle 0|\,\phi(y)\dot\phi(x)\,|0\rangle$, the bracket at equal times is the vacuum expectation of the equal-time commutator of $\dot\phi$ with ϕ. Since $\pi = \dot\phi$ for the free real scalar, the canonical relation $[\phi(\mathbf{x}), \pi(\mathbf{y})] = i\delta^3(\mathbf{x}-\mathbf{y})$ gives $\left[\dot\phi(x), \phi(y)\right]\big|_{\text{ET}} = [\pi(\mathbf{x}), \phi(\mathbf{y})] = -i\delta^3(\mathbf{x}-\mathbf{y})$. Therefore

$$\delta(t)\,[\partial_{x^0} D(x-y) - \partial_{x^0} D(y-x)] = \delta(t)\,\big(-\,i\,\delta^3(\mathbf{x}-\mathbf{y})\big) = -\,i\,\delta^4(x-y). \tag{9.181}$$

Assembling the Klein–Gordon operator. The spatial and mass terms act only on the smooth Wightman functions and pass through the step functions untouched:

$$(-\nabla^2 + m^2) D_F = \theta(t)(-\nabla^2 + m^2) D(x-y) + \theta(-t)(-\nabla^2 + m^2) D(y-x). \tag{9.182}$$

Adding Eq. (9.180) and Eq. (9.182), and using $\Box = \partial_{x^0}^2 - \nabla^2$,

$$(\Box_x + m^2) D_F = -\,i\,\delta^4(x-y) + \theta(t)\,(\Box + m^2) D(x-y) + \theta(-t)\,(\Box + m^2) D(y-x). \tag{9.183}$$

But each Wightman piece is built from on-shell modes $e^{\mp ip\cdot(x-y)}$ with $p^2 = m^2$, so $(\Box + m^2)$ annihilates it: $(\Box + m^2)D = 0$, as in Eq. (9.175) with $p^2 = m^2$. The two θ-terms vanish identically, leaving

$$(\Box_x + m^2)\, D_F(x-y) = -\,i\,\delta^4(x-y), \tag{9.184}$$

in agreement with Eq. (9.174). The delta function is seen here to be *nothing but* the canonical equal-time commutator, propagated forward by the second time derivative of the time-ordering step functions — the dynamical content of quantization made visible in the propagator.

This completes the construction of the central dynamical object of the free scalar theory. The Feynman propagator Eq. (9.154) is simultaneously the time-ordered vacuum correlator, the inverse of the Klein–Gordon operator with Feynman boundary conditions, and the carrier of the $\lambda = 0$ sector of ϕ^4 theory that Chapter 10 will reproduce from $Z[J]$ and that becomes the internal line of every diagram from Chapters 14 and 15 onward. The comparison with the retarded and advanced functions has already isolated the on-shell commutator function $\langle 0|\,[\phi(x), \phi(y)]\,|0\rangle$ of Eq. (9.173); whether *that* object vanishes outside the light cone — the precise statement of relativistic causality, and the requirement that will force Bose statistics on the scalar — is the question taken up in Section 9.6.

9.6 Microcausality, the Commutator Function, and Spin-Statistics

The previous section handed us the field's two-point structure: the Wightman functions and, assembled from them through the time-ordered product, the Feynman propagator $D_F(x-y)$. Those objects answer the question *what amplitude connects two spacetime points*. We now ask a sharper question, the one on which the whole edifice of relativistic quantum theory either stands or falls: *can a measurement made here and now disturb a measurement made simultaneously a light-year away*? In ordinary quantum mechanics there is no obstruction in principle—the formalism is built on a single absolute time and says nothing about how fast influences propagate. In a relativistic theory there must be an obstruction, because a superluminal influence is, in some other inertial frame, an influence that runs backwards in time, and that way lie closed causal loops and the collapse of physical prediction.

The remarkable fact this section establishes is that the free scalar field, quantized exactly as the earlier sections prescribed, already encodes the prohibition. The carrier of the answer is a single c-number distribution, the *Pauli–Jordan commutator function* $\Delta(x-y)$, and the entire content of relativistic causality at the level of free fields is the statement that Δ vanishes outside the light cone. We will compute Δ from the mode expansion, prove its vanishing at spacelike separation by an argument that uses nothing more than the connectedness of the proper orthochronous Lorentz group, and read off the physical meaning: spacelike-separated local observables commute, so no measurement can signal faster than light. The same computation then pays an unexpected dividend. If we had stubbornly quantized the scalar with anticommutators instead of commutators, the object forced to vanish for causality would have been the wrong kind of function—an *even* one rather than an *odd* one—and explicit calculation shows it does not vanish at spacelike separation. Causality therefore *selects* Bose statistics for the spin-0 field. This is the spin-statistics connection in the one instance where this chapter can establish it honestly and completely.

9.6.1 The commutator is a c-number

We work throughout in the Heisenberg picture, where the free field carries its full spacetime dependence in the mode expansion established earlier in this chapter,

$$\phi(x) = \int \frac{d^3p}{(2\pi)^3\, 2\omega_{\mathbf{p}}} \Big(a_{\mathbf{p}}\, e^{-ip\cdot x} + a^\dagger_{\mathbf{p}}\, e^{+ip\cdot x} \Big), \qquad p^0 = \omega_{\mathbf{p}} = \sqrt{\mathbf{p}^2 + m^2}, \tag{9.185}$$

with the ladder algebra

$$\Big[a_{\mathbf{p}}, a^\dagger_{\mathbf{q}} \Big] = (2\pi)^3\, 2\omega_{\mathbf{p}}\, \delta^{(3)}(\mathbf{p}-\mathbf{q}), \qquad [a_{\mathbf{p}}, a_{\mathbf{q}}] = \Big[a^\dagger_{\mathbf{p}}, a^\dagger_{\mathbf{q}} \Big] = 0 \tag{9.186}$$

fixed in Eq. (9.54). Here $p\cdot x = \omega_{\mathbf{p}} x^0 - \mathbf{p}\cdot\mathbf{x}$ is the on-shell Minkowski product in the mostly-minus metric, and the relativistically normalized measure $d^3p/[(2\pi)^3\,2\omega_{\mathbf{p}}]$ is the one used book-wide.

Consider the equal-or-unequal-time commutator $[\phi(x),\phi(y)]$ of two fields at arbitrary spacetime points. Insert Eq. (9.147) for each field. A commutator of sums is the sum of commutators, and the only surviving terms are those pairing one annihilation with one creation operator, since by Eq. (9.67) the aa and $a^\dagger a^\dagger$ pieces commute:

$$\begin{aligned}[\phi(x),\phi(y)] &= \int \frac{d^3p}{(2\pi)^3\,2\omega_{\mathbf{p}}}\frac{d^3q}{(2\pi)^3\,2\omega_{\mathbf{q}}}\Big(\left[a_{\mathbf{p}},a^\dagger_{\mathbf{q}}\right]e^{-ip\cdot x+iq\cdot y}+\left[a^\dagger_{\mathbf{p}},a_{\mathbf{q}}\right]e^{+ip\cdot x-iq\cdot y}\Big)\\ &= \int \frac{d^3p}{(2\pi)^3\,2\omega_{\mathbf{p}}}\frac{d^3q}{(2\pi)^3\,2\omega_{\mathbf{q}}}(2\pi)^3\,2\omega_{\mathbf{p}}\,\delta^{(3)}(\mathbf{p}-\mathbf{q})\Big(e^{-ip\cdot x+iq\cdot y}-e^{+ip\cdot x-iq\cdot y}\Big),\end{aligned} \tag{9.187}$$

where in the second line we used $\left[a^\dagger_{\mathbf{p}},a_{\mathbf{q}}\right] = -\left[a_{\mathbf{q}},a^\dagger_{\mathbf{p}}\right] = -(2\pi)^3\,2\omega_{\mathbf{p}}\,\delta^{(3)}(\mathbf{p}-\mathbf{q})$. The delta function collapses the $\mathbf{q}$ integral, setting $\mathbf{q}=\mathbf{p}$ and hence $\omega_{\mathbf{q}}=\omega_{\mathbf{p}}$, so that the commutator's $2\omega_{\mathbf{p}}$ cancels the measure factor $1/2\omega_{\mathbf{q}}$ and leaves the single invariant measure $1/(2\omega_{\mathbf{p}})$:

$$\boxed{[\phi(x),\phi(y)] = \int \frac{d^3p}{(2\pi)^3}\,\frac{1}{2\omega_{\mathbf{p}}}\Big(e^{-ip\cdot(x-y)}-e^{+ip\cdot(x-y)}\Big) \equiv i\,\Delta(x-y).} \tag{9.188}$$

Two features deserve emphasis at once. First, the right-hand side is a *c-number*: the operator-valued ladder operators have cancelled, leaving an ordinary distribution multiplying the identity. Equivalently, $[\phi(x),\phi(y)]$ commutes with every operator in the theory; the commutator of two free fields is not itself a dynamical quantity. Second, the result depends only on the difference $x-y$, as translation invariance demands. The factor i in the definition is conventional and makes Δ real, as we now confirm.

Definition 9.29 (Pauli–Jordan function)**.** The *Pauli–Jordan (or commutator) function* of the free scalar field of mass m is the c-number distribution

$$\Delta(x) \;=\; -\,i\int \frac{d^3p}{(2\pi)^3}\,\frac{1}{2\omega_{\mathbf{p}}}\Big(e^{-ip\cdot x}-e^{+ip\cdot x}\Big), \qquad p^0=\omega_{\mathbf{p}}, \tag{9.189}$$

so that $[\phi(x),\phi(y)] = i\,\Delta(x-y)$.

It is useful to record three elementary properties directly from Eq. (9.189), each obtained by a relabelling of the integration variable.

Reality. Complex conjugation sends $e^{\mp ip\cdot x}\to e^{\pm ip\cdot x}$ and $-i\to+i$, which together reproduce Eq. (9.189) unchanged; thus $\Delta(x)^* = \Delta(x)$, and Δ is real. Consistently, $[\phi(x),\phi(y)]^\dagger = [\phi(y),\phi(x)] = -\,[\phi(x),\phi(y)]$ is anti-Hermitian, matching the explicit factor i.

Oddness. Sending $x \to -x$ in Eq. (9.189) interchanges the two exponentials and so flips the overall sign,

$$\Delta(-x) = -\,\Delta(x). \tag{9.190}$$

This single fact will do almost all the work in the microcausality proof.

Equal-time values. Setting $x^0 = 0$ in Eq. (9.189), the two exponentials become $e^{\pm i\mathbf{p}\cdot\mathbf{x}}$, which map into one another under $\mathbf{p} \to -\mathbf{p}$; the integral therefore vanishes,

$$\Delta(0, \mathbf{x}) = 0. \tag{9.191}$$

This is exactly the canonical statement $[\phi(\mathbf{x}, t), \phi(\mathbf{y}, t)] = 0$ at equal times. Differentiating Eq. (9.189) once with respect to x^0 and then setting $x^0 = 0$ brings down a factor $\mp i\omega_{\mathbf{p}}$ from each exponential; the surviving combination is $e^{+i\mathbf{p}\cdot\mathbf{x}} + e^{-i\mathbf{p}\cdot\mathbf{x}}$ with the $\omega_{\mathbf{p}}$ cancelling the measure, giving

$$\partial_0 \Delta(x)\big|_{x^0=0} = -\int \frac{d^3p}{(2\pi)^3}\, e^{i\mathbf{p}\cdot\mathbf{x}} = -\,\delta^{(3)}(\mathbf{x}), \tag{9.192}$$

where the last step is the Fourier representation of the delta distribution recalled in Theorem 5.5. Since $\pi(y) = \partial_{y^0}\phi(y)$, applying ∂_{y^0} to $[\phi(x), \phi(y)] = i\Delta(x - y)$ and evaluating at $x^0 = y^0$ reproduces the canonical relation $[\phi(\mathbf{x}, t), \pi(\mathbf{y}, t)] = i\,\delta^{(3)}(\mathbf{x} - \mathbf{y})$. The Pauli–Jordan function thus packages the entire equal-time canonical structure together with its covariant evolution off equal times into one Lorentz object.

9.6.2 Covariant form and Lorentz invariance

The expression Eq. (9.189) singles out a frame through the choice $p^0 = \omega_{\mathbf{p}} > 0$, yet the result should not. To make the invariance manifest we rewrite the three-dimensional on-shell measure as a four-dimensional integral over an unconstrained p restricted to the mass shell. The identity

$$\int \frac{d^4p}{(2\pi)^4}\, 2\pi\,\delta(p^2 - m^2)\,\theta(p^0)\; f(p) = \int \frac{d^3p}{(2\pi)^3}\,\frac{1}{2\omega_{\mathbf{p}}}\; f(\omega_{\mathbf{p}}, \mathbf{p}) \tag{9.193}$$

follows from $\delta(p^2 - m^2) = \delta((p^0)^2 - \omega_{\mathbf{p}}^2) = \frac{1}{2\omega_{\mathbf{p}}}\big[\delta(p^0 - \omega_{\mathbf{p}}) + \delta(p^0 + \omega_{\mathbf{p}})\big]$ and the step function $\theta(p^0)$ keeping only the positive root; it is the Lorentz-invariant measure used throughout the book. Applying Eq. (9.193) to the first exponential in Eq. (9.189), and to the second after the substitution $p \to -p$ (which turns $e^{+ip\cdot x}$ into $e^{-ip\cdot x}$ supported on $p^0 = -\omega_{\mathbf{p}}$, i.e. the lower mass-shell branch carried by $\theta(-p^0)$), the two terms combine into a single integral over both branches weighted by the sign of the energy:

$$\boxed{\Delta(x) = -\,i\int \frac{d^4p}{(2\pi)^4}\, 2\pi\,\delta(p^2 - m^2)\;\mathrm{sgn}(p^0)\, e^{-ip\cdot x}.} \tag{9.194}$$

Every ingredient of Eq. (9.194) is now under Lorentz control. The measure d^4p is invariant; the on-shell delta $\delta(p^2 - m^2)$ is invariant because p^2 is; the plane wave $e^{-ip\cdot x}$ is invariant. The only factor whose invariance requires comment is $\mathrm{sgn}(p^0)$.

Proposition 9.30 (Invariance and oddness of Δ)**.** *For every proper orthochronous Lorentz transformation $\Lambda \in L_+^\uparrow$,*

$$\Delta(\Lambda x) = \Delta(x), \tag{9.195}$$

and Δ is odd, $\Delta(-x) = -\Delta(x)$.

Proof. Oddness is Eq. (9.190). For the invariance, apply the change of variables $p \to \Lambda p$ in Eq. (9.194). The measure and the on-shell delta are unchanged, and $e^{-i(\Lambda p)\cdot x} = e^{-ip\cdot(\Lambda^{-1}x)}$ since the Minkowski product is invariant. It remains to check that $\mathrm{sgn}(p^0)$ is preserved. On the mass shell $p^2 = m^2 > 0$ the four-vector p is timelike, and an orthochronous transformation is precisely one that does not reverse the time-orientation of timelike vectors: it maps the forward light cone to itself, so $\theta(p^0)$ and $\theta(-p^0)$ are individually preserved and hence so is $\mathrm{sgn}(p^0)$. Therefore the integrand is invariant and $\Delta(\Lambda^{-1}x) = \Delta(x)$ for all $\Lambda \in L_+^\uparrow$; renaming $\Lambda^{-1} \to \Lambda$ gives Eq. (9.195). (That $L_+^\uparrow$ is exactly the time-orientation-preserving, parity-and-time-reversal-free component is the content of Theorem 3.6.) □

The restriction to $L_+^\uparrow$ in Theorem 9.30 is essential and not a technicality: time reversal would flip $\mathrm{sgn}(p^0)$ and send $\Delta \to -\Delta$, and it is the interplay between this restriction and the invariance that makes the next theorem possible.

9.6.3 The microcausality theorem

We can now prove the central result. Recall (Section 3.1.1) that the separation $x - y$ is *spacelike* when $(x-y)^2 < 0$, *timelike* when $(x-y)^2 > 0$, and *lightlike* when $(x-y)^2 = 0$; spacelike-separated points lie outside each other's light cones and admit no causal influence between them.

Theorem 9.31 (Microcausality of the free scalar)**.** *The Pauli–Jordan function vanishes at spacelike separation:*

$$\Delta(x) = 0 \qquad \textit{whenever} \qquad x^2 < 0, \tag{9.196}$$

and consequently

$$[\phi(x), \phi(y)] = 0 \qquad \textit{whenever} \qquad (x-y)^2 < 0. \tag{9.197}$$

Proof. The argument turns on a single geometric fact about spacelike vectors: *there exists* $\Lambda \in L_+^\uparrow$ *with* $\Lambda x = -x$. Grant this for a moment. Then by invariance Eq. (9.195), $\Delta(x) = \Delta(\Lambda x) = \Delta(-x)$; but by oddness Eq. (9.190), $\Delta(-x) = -\Delta(x)$. The two equalities give $\Delta(x) = -\Delta(x)$, hence $2\Delta(x) = 0$, hence $\Delta(x) = 0$. Equation Eq. (9.197) then follows from $[\phi(x), \phi(y)] = i\Delta(x-y)$ because $(x-y)^2 < 0$.

It remains to exhibit the transformation. Let x be spacelike, $x^2 = -a^2$ with $a > 0$. By the orbit structure of $L_+^\uparrow$ (Theorem 3.6), any spacelike vector can be brought to a standard purely spatial form by a proper orthochronous transformation: first apply a boost in the plane spanned by the time axis and $\mathbf{x}$ to set the time component to zero—this is possible precisely because $|\mathbf{x}| > |x^0|$ for a spacelike vector, so the requisite rapidity is real—and then a rotation to align the result with the third spatial axis. The net transformation $R \in L_+^\uparrow$ achieves $Rx = (0, 0, 0, a)$. Now perform a rotation by angle π about the *first* spatial axis; call it $\mathcal{R}_\pi$. It acts as $(x^1, x^2, x^3) \mapsto (x^1, -x^2, -x^3)$ on spatial components and fixes time, so $\mathcal{R}_\pi(0, 0, 0, a) = (0, 0, 0, -a) = -Rx$. Rotations are rotations: $\mathcal{R}_\pi \in L_+^\uparrow$ (determinant $+1$, time-orientation preserving). Therefore

$$\Lambda \;\equiv\; R^{-1}\,\mathcal{R}_\pi\,R \;\in\; L_+^\uparrow \qquad \text{satisfies} \qquad \Lambda x = R^{-1}\mathcal{R}_\pi(Rx) = R^{-1}(-Rx) = -x, \tag{9.198}$$

which is the claim. □

Physical Insight

The proof reduces a deep physical principle to one picture (Fig. 9.6). A spacelike separation has no invariant time-ordering: in one frame x happens before y, in another after, and there is even a frame in which the labels are swapped. Mathematically, the Lorentz orbit of a spacelike vector is the *single-sheeted* hyperboloid $x^2 = -a^2$, which is connected and contains both x and $-x$; the connectedness of $L_+^\uparrow$ lets us slide continuously from x to $-x$ inside it. A timelike vector, by contrast, lives on a *two-sheeted* hyperboloid $x^2 = +a^2$, and $L_+^\uparrow$—preserving the sign of the time component—can never carry the future sheet to the past sheet. There is no $\Lambda \in L_+^\uparrow$ with $\Lambda x = -x$ for timelike x, the proof's mechanism fails, and indeed $\Delta(x) \neq 0$ inside the light cone: a causal influence between timelike-separated points is allowed, as it must be.

9.6.4 Causality as the commuting of local observables

What Theorem 9.31 establishes about the elementary field propagates immediately to every *local observable*. A local observable supported near a spacetime point x is built as a (Hermitian, normal-ordered) polynomial in the field and its derivatives

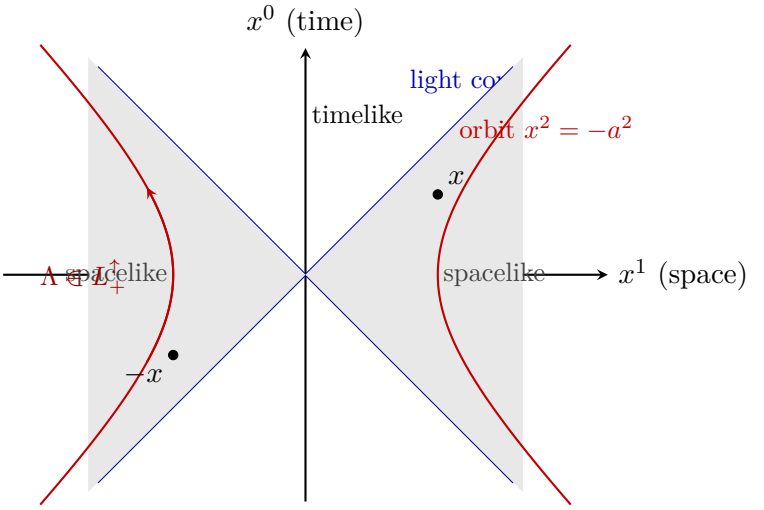

Figure 9.6: Microcausality geometry. For a spacelike separation x (with $x^2 = -a^2 < 0$) the Lorentz orbit is the single-sheeted hyperbola $x^2 = -a^2$ (red), a connected curve that contains both x and its reflection $-x$. A proper orthochronous transformation $\Lambda \in L_+^\uparrow$ slides x to $-x$ along this orbit. Since Δ is invariant under Λ and odd under $x \to -x$, it must vanish on the shaded spacelike region. A timelike x lies on a two-sheeted hyperbola whose future and past branches $L_+^\uparrow$ cannot interchange, so no such Λ exists and $\Delta \neq 0$ inside the cone.

evaluated there—the energy density $\frac{1}{2}{:}\pi^2{:} + \frac{1}{2}{:}(\nabla\phi)^2{:} + \frac{1}{2}m^2{:}\phi^2{:}$, the number-density-like ${:}\phi^2{:}$, and so on. Let $\mathcal{O}_A(x)$ and $\mathcal{O}_B(y)$ be two such observables. Each is a polynomial in fields at x and at y respectively. Expanding the commutator $[\mathcal{O}_A(x), \mathcal{O}_B(y)]$ by the Leibniz rule produces a sum of terms, each of which is a product of fields multiplied by at least one elementary commutator $[\phi(x), \phi(y)]$ (derivatives of the field commute through to act on Δ, since $\partial_\mu^x [\phi(x), \phi(y)] = i\,\partial_\mu \Delta(x-y)$). Because that elementary commutator is the c-number $i\Delta(x-y)$, and because Δ and all its derivatives vanish for $(x-y)^2 < 0$ (differentiating the identically-zero function on the open spacelike region leaves zero), every term vanishes. Hence

$$[\mathcal{O}_A(x), \mathcal{O}_B(y)] = 0 \qquad \text{for} \qquad (x-y)^2 < 0. \tag{9.199}$$

This is the field-theoretic statement of causality, and it is worth saying plainly why it is exactly the right statement. In quantum mechanics, two observables can be measured without one disturbing the other—can be measured *simultaneously* and *independently*—if and only if they commute. Equation Eq. (9.199) asserts that any two observables localized at spacelike separation commute. Therefore a measurement carried out in one laboratory cannot influence the statistics

of any measurement carried out, at that instant, outside its light cone. No expectation value, no probability distribution, nothing an experimenter could detect, responds to a spacelike-separated intervention. Whatever correlations exist between spacelike regions—and entangled states have plenty—they cannot be used to transmit a signal, because the local measurement operators simply commute. A relativistic quantum field theory is, by construction, a no-signalling theory. We elevate Eq. (9.199) to a defining axiom of any local relativistic quantum theory, and call it *microcausality* or *local commutativity*; the free scalar is our first concrete model in which it is a theorem rather than a postulate.

Caution

Microcausality forbids *signalling*, not *correlation*. The two-point Wightman function $\langle\phi(x)\phi(y)\rangle$ does not vanish at spacelike separation—it falls off as e^{-mr} over distances $r \gtrsim 1/m$, as the worked example below makes quantitative. Spacelike correlations are real and physical. What vanishes is the *commutator*, and with it any possibility of using those correlations to send information faster than light. Confusing the non-vanishing of the correlator with a violation of causality is a perennial error; the propagator's spacelike tail and microcausality are perfectly compatible precisely because $D_F = \langle \mathcal{T}\phi\phi\rangle$ is symmetric while the causal content lives in the antisymmetric part Δ.

9.6.5 Spin and statistics: why the scalar must be Bose

We arrived at microcausality having quantized with *commutators*, Eq. (9.67). Suppose, perversely, that we had not—that we had tried to build the scalar's Fock space on *anticommutators*, declaring

$$\left\{a_{\mathbf{p}}, a^{\dagger}_{\mathbf{q}}\right\} = (2\pi)^3\, 2\omega_{\mathbf{p}}\, \delta^{(3)}(\mathbf{p}-\mathbf{q}), \qquad \{a_{\mathbf{p}}, a_{\mathbf{q}}\} = \left\{a^{\dagger}_{\mathbf{p}}, a^{\dagger}_{\mathbf{q}}\right\} = 0, \tag{9.200}$$

which is the Fermi–Dirac choice that, for half-integer spin, will turn out to be mandatory in Chapter 11. Does it produce a causal theory for the scalar? The test is whether observables built from ϕ commute at spacelike separation. Repeat the computation of Section 9.6.1, but now the object that collapses to a c-number is the *anticommutator* of the fields, because it is $\left\{a, a^{\dagger}\right\}$ that is a number under Eq. (9.200). Pairing annihilation with creation operators exactly as in Eq. (9.187),

$$\begin{aligned}\{\phi(x),\phi(y)\} &= \int \frac{d^3p}{(2\pi)^3\,2\omega_{\mathbf{p}}}\frac{d^3q}{(2\pi)^3\,2\omega_{\mathbf{q}}}(2\pi)^3\,2\omega_{\mathbf{p}}\,\delta^{(3)}(\mathbf{p}-\mathbf{q})\Big(e^{-ip\cdot x+iq\cdot y}+e^{+ip\cdot x-iq\cdot y}\Big)\\ &= \int \frac{d^3p}{(2\pi)^3}\,\frac{1}{2\omega_{\mathbf{p}}}\Big(e^{-ip\cdot(x-y)}+e^{+ip\cdot(x-y)}\Big) \;\equiv\; \Delta_+(x-y)+\Delta_+(y-x),\end{aligned} \tag{9.201}$$

where the relative sign is now + because $\left\{a^\dagger_{\mathbf{p}}, a_{\mathbf{q}}\right\} = +\left\{a_{\mathbf{q}}, a^\dagger_{\mathbf{p}}\right\} = +(2\pi)^3\, 2\omega_{\mathbf{p}}\, \delta^{(3)}(\mathbf{p}-\mathbf{q})$, and we have abbreviated the positive-frequency Wightman function

$$\Delta_+(x) \;\equiv\; \int \frac{d^3p}{(2\pi)^3}\,\frac{1}{2\omega_{\mathbf{p}}}\, e^{-ip\cdot x} \;=\; \langle \phi(x)\phi(0)\rangle\,, \tag{9.202}$$

the object computed in the previous section. The contrast with Eq. (9.188) is the entire story. There the relative sign was $-$, producing the *odd* function Δ; here it is $+$, producing the manifestly *even* function $\Delta_+(x-y)+\Delta_+(y-x)$, symmetric under $x \leftrightarrow y$.

Oddness was the linchpin of Theorem 9.31: the Lorentz orbit argument forced Δ to equal both $+\Delta$ and $-\Delta$ at spacelike separation, killing it. Run the same argument on the anticommutator and it gives nothing. For spacelike $x-y$ we still have a $\Lambda \in L^\uparrow_+$ with $\Lambda(x-y) = -(x-y)$, and Δ_+ is Lorentz invariant, so the function maps to itself—but, being even, it was already invariant under the reflection, and we learn only $0=0$. No constraint. To find out whether it actually vanishes we must compute, and the computation (carried out in full in Theorem 9.34) returns a strictly positive answer:

$$\{\phi(x),\phi(y)\}\Big|_{(x-y)^2<0} = 2\,\Delta_+(x-y) = \frac{m}{2\pi^2 r}\,K_1(mr) \;>\; 0, \qquad r \equiv \sqrt{-(x-y)^2}, \tag{9.203}$$

where K_1 is a modified Bessel function and we used that Δ_+ is symmetric, $\Delta_+(x) = \Delta_+(-x)$, for spacelike x (its argument and reflection are related by $L^\uparrow_+$). The anticommutator does *not* vanish outside the light cone.

Why this dooms causality is now immediate. Under the Fermi assumption the anticommutator $\{\phi(x),\phi(y)\}$ is the c-number Eq. (9.203), while the *commutator*—the object that controls whether observables built from ϕ can be measured independently—is no longer a c-number at all. Solving $\left\{a_{\mathbf{p}}, a^\dagger_{\mathbf{q}}\right\} = (2\pi)^3 2\omega_{\mathbf{p}}\delta^{(3)}$ for the commutator gives $\left[a_{\mathbf{p}}, a^\dagger_{\mathbf{q}}\right] = (2\pi)^3\, 2\omega_{\mathbf{p}}\, \delta^{(3)}(\mathbf{p}-\mathbf{q}) - 2\, a^\dagger_{\mathbf{q}} a_{\mathbf{p}}$, an operator; assembled into $[\phi(x),\phi(y)]$ it remains operator-valued and does not vanish for spacelike $x-y$. The Hermitian observable $\phi(x)$ would then fail to commute with $\phi(y)$ at spacelike separation, in flat contradiction with the no-signalling requirement Eq. (9.199). There is no escape by redefining observables: the symmetric, strictly positive c-number Eq. (9.203) is forced, and a non-zero symmetric two-point structure with operator-valued commutator cannot satisfy local commutativity. We conclude:

Theorem 9.32 (Spin-statistics for the scalar field)**.** *The free spin-0 field cannot be consistently quantized with anticommutators: the Fermi algebra Eq. (9.200) yields a non-vanishing anticommutator Eq. (9.203) and an operator-valued, non-vanishing commutator at spacelike separation, violating microcausality Eq. (9.199).*

Causality therefore forces *Bose–Einstein quantization, the commutator algebra Eq. (9.67), for which* $[\phi(x), \phi(y)] = i\Delta(x-y) = 0$ *outside the light cone. A spin-0 field is necessarily a boson.*

Physical Insight

The decisive quantity is the *sign* that the field commutator/anticommutator carries between its two exponentials, and that sign is fixed by the rotational (Lorentz) transformation property of the field—i.e. by its spin. For the scalar, which is rotationally inert, microcausality wants the *odd* combination, and the odd combination is the commutator: Bose. The deep version of the theorem (below) shows that a field in a representation of half-integer spin carries an extra minus sign under the 2π rotation hidden in the analytic continuation relating $\Delta_+(x)$ to $\Delta_+(-x)$, which flips precisely this preference: for half-integer spin it is the *anticommutator* that microcausality selects. Spin dictates statistics through the geometry of the rotation group.

9.6.6 The general spin-statistics theorem: statement and scope

What we have proved is the spin-0 instance of a sweeping structural result. It is worth stating the general theorem precisely, together with an honest account of which of its hypotheses this chapter has actually used and which await later machinery.

Theorem 9.33 (Spin-statistics connection, general form—stated)**.** *Let a quantum field theory satisfy: (i) invariance under the proper orthochronous Poincaré group, with fields transforming in finite-dimensional representations of the Lorentz group labelled by their spin j; (ii) a Hilbert space with positive-definite inner product (no negative-norm physical states) and a unique Poincaré-invariant vacuum of lowest energy (positivity of the energy spectrum); (iii) microcausality, i.e. local commutativity Eq. (9.199) of observables at spacelike separation. Then fields of integer spin $j \in \mathbb{Z}$ must be quantized with* commutators *(Bose–Einstein statistics), and fields of half-integer spin $j \in \mathbb{Z} + \frac{1}{2}$ with* anticommutators *(Fermi–Dirac statistics). The opposite choice in either case is inconsistent: it produces either a violation of microcausality or a Hamiltonian unbounded below / a state space with negative norms.*

The proof of Theorem 9.33 in full generality rests on the analytic structure of the vacuum expectation values $\langle \phi(x_1) \cdots \phi(x_n) \rangle$—specifically on the fact that positivity of the energy (hypothesis (ii)) makes the Wightman functions boundary values of functions analytic in a forward tube, so that the spacelike continuation relating $\Delta_+(x)$ to $\Delta_+(-x)$ can be performed, and on the careful bookkeeping of the $(-1)^{2j}$ that a spin-j field's Lorentz indices accumulate under that continuation.

This is the content of the Wightman axioms and the analytic-continuation argument; it is genuinely a Part-of-the-book-level result and we do not reproduce its complete machinery here, because the analyticity it needs has not yet been developed. What this chapter *has* delivered, in full and without gaps, is the $j = 0$ case: there the Lorentz representation is trivial, the $(-1)^{2j} = +1$ bookkeeping is invisible, and the whole argument collapses to the elementary even-versus-odd dichotomy of Section 9.6.5. The reader has therefore seen the real mechanism—causality choosing a sign, spin fixing which sign is allowed—in its cleanest example.

The complementary half-integer case is exhibited in Chapter 11, where the Dirac field is quantized. There the logic runs in reverse: attempting to impose *commutators* on the spin-$\frac{1}{2}$ field produces a Hamiltonian with no lower bound (and, equivalently, a spacelike-non-vanishing object of the wrong symmetry), and only *anticommutators* restore both positivity of the energy and microcausality. Reading Theorem 9.32 alongside the Dirac result is reading the two faces of one theorem: for the boson, commutators are forced; for the fermion, anticommutators are forced; in each case it is the marriage of relativity (Lorentz invariance plus causality) with quantum mechanics (positivity of the spectrum) that does the forcing, and neither half is optional.

Historical Note

The connection was discovered piecemeal. Fierz (1939) and Pauli (1940) gave the first general arguments tying statistics to spin via the requirement of a positive energy and (for bosons) the vanishing of spacelike commutators; the modern axiomatic proof, resting on the analyticity of Wightman functions, is due to Lüders and Zumino and to Burgoyne in the 1950s, and is set out in the monograph of Streater and Wightman. The spin-0 calculation of this section is essentially Pauli and Jordan's original 1928 computation of the function that now bears their names, repurposed to make the statistics argument transparent.

We close the formal development with the worked computation promised above, which both supplies the number quoted in Eq. (9.203) and makes the propagator's spacelike behaviour concrete.

Worked Example 9.34 (The spacelike Wightman function and the non-vanishing anticommutator)**.** We evaluate $\Delta_+(x)$ of Eq. (9.202) for a spacelike separation and confirm Eq. (9.203). By Lorentz invariance of Δ_+ (it is built from the invariant measure and depends on x only through invariants, with the energy sign fixed) we may choose the frame in which the separation is purely spatial, $x = (0, \mathbf{r})$ with $|\mathbf{r}| = r = \sqrt{-x^2}$. Then $p \cdot x = -\mathbf{p} \cdot \mathbf{r}$ and

$$\Delta_+(0, \mathbf{r}) = \int \frac{d^3p}{(2\pi)^3} \frac{1}{2\omega_{\mathbf{p}}} e^{i\mathbf{p}\cdot\mathbf{r}}. \tag{9.204}$$

Carry out the angular integration. Writing $d^3p = p^2\,dp\,d\Omega$ with $p = |\mathbf{p}|$ and aligning the polar axis with $\mathbf{r}$,

$$\int d\Omega\, e^{i\mathbf{p}\cdot\mathbf{r}} = 2\pi \int_{-1}^{1} d(\cos\theta)\, e^{ipr\cos\theta} = \frac{4\pi}{pr}\sin(pr), \tag{9.205}$$

so that, with $\omega_{\mathbf{p}} = \sqrt{p^2+m^2}$,

$$\Delta_+(0,\mathbf{r}) = \frac{1}{(2\pi)^3}\cdot\frac{4\pi}{r}\int_0^\infty dp\,\frac{p^2}{2\sqrt{p^2+m^2}}\,\frac{\sin(pr)}{p} = \frac{1}{4\pi^2 r}\int_0^\infty dp\,\frac{p\,\sin(pr)}{\sqrt{p^2+m^2}}. \tag{9.206}$$

The radial integral is evaluated by relating it to a standard integral representation of the modified Bessel function K_0, namely

$$\int_0^\infty dp\,\frac{\cos(pr)}{\sqrt{p^2+m^2}} = K_0(mr), \tag{9.207}$$

valid for $m, r > 0$. Differentiating Eq. (9.207) with respect to r brings down $-p\sin(pr)$ on the left and uses $K_0'(z) = -K_1(z)$ on the right:

$$\int_0^\infty dp\,\frac{p\,\sin(pr)}{\sqrt{p^2+m^2}} = -\frac{d}{dr}\int_0^\infty dp\,\frac{\cos(pr)}{\sqrt{p^2+m^2}} = -\frac{d}{dr}K_0(mr) = m\,K_1(mr). \tag{9.208}$$

Substituting into Eq. (9.206),

$$\boxed{\Delta_+(0,\mathbf{r}) = \frac{m}{4\pi^2 r}\,K_1(mr).} \tag{9.209}$$

Since $K_1(z) > 0$ for all $z > 0$, the Wightman function is strictly positive at every spacelike separation. The anticommutator Eq. (9.201) at spacelike separation is $\Delta_+(x-y) + \Delta_+(y-x) = 2\Delta_+(0,\mathbf{r}) = \dfrac{m}{2\pi^2 r}K_1(mr) > 0$, which is Eq. (9.203).

The asymptotics make the physics vivid. Using $K_1(z) \sim \sqrt{\pi/2z}\,e^{-z}$ as $z \to \infty$,

$$\Delta_+(0,\mathbf{r}) \xrightarrow{mr\gg 1} \frac{m}{4\pi^2 r}\sqrt{\frac{\pi}{2mr}}\,e^{-mr} = \frac{1}{4\pi^2}\sqrt{\frac{\pi m}{2}}\,\frac{e^{-mr}}{r^{3/2}}. \tag{9.210}$$

Spacelike correlations are non-zero but Yukawa-suppressed over the Compton wavelength $1/m$: a particle can be "found" a spacelike distance away only with an amplitude that dies exponentially beyond $r \sim 1/m$. This is the same e^{-mr} falloff noted for the propagator's spacelike tail in the previous section, and it is the quantitative companion to the caution above—the correlator is non-zero, yet, because the commutator Δ vanishes identically there, no signal rides on it.

With Theorems 9.31 and 9.32 the free real scalar is now a fully solved, demonstrably causal relativistic quantum theory: its excitations are bosons, its

observables respect the light cone, and its propagator is the Green's function established in the previous section. These are precisely the consistency facts that all later ϕ^4 perturbation theory will assume in silence. The construction so far has used only the field's reality; lifting that restriction to a *complex* scalar will, in the next section, expose a conserved U(1) charge and split the single boson into a particle and a distinct antiparticle—the structure on which the charge of the QED and gauge threads is built.

9.7 The Charged Scalar: Antiparticles and Conserved Charge

Every construction in this chapter so far has rested on a single real field. A real field is the simplest possible relativistic quantum field, and it taught us the whole machine: the mode expansion as a continuum of oscillators, the Fock space built on a vacuum, the propagator with its $i\varepsilon$ contour, and the microcausality that the previous section showed forces Bose statistics. But a real field describes only one kind of quantum. To make contact with the world of electrons, pions, and the gauge charges that organize the Standard Model, we need a field that distinguishes a quantum from its mirror image – a *particle* from an *antiparticle* – and that carries a conserved internal quantum number. The minimal such object is the complex (charged) scalar field. Quantizing it is almost no extra work: a complex field is two real fields in a trench coat, so the oscillator engine runs unchanged. The payoff is large and structural. Two independent species of quantum emerge from one field; they have rigorously equal mass and exactly opposite charge; and the global U(1) symmetry whose Noether current we constructed classically in Chapter 7 reappears as a self-adjoint operator Q whose eigenvalues label those species. This is the section in which "charge" first becomes a quantum-mechanical observable, and in which antiparticles – glimpsed already in the negative-frequency half of the real field's mode expansion – acquire an independent operational identity.

We continue ϕ^4 theory at its free ($\lambda = 0$) level and place the carried real scalar in its proper context: it is the special, self-conjugate case of the construction below. The standing conventions are those of the rest of the chapter – mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units $\hbar = c = 1$, on-shell energy $E_{\mathbf{p}} = +\sqrt{\mathbf{p}^2 + m^2}$, four-momentum $p^0 = E_{\mathbf{p}}$ with $p \cdot x = E_{\mathbf{p}} x^0 - \mathbf{p} \cdot \mathbf{x}$ – and we use throughout the Lorentz-invariant single-particle normalization fixed earlier in this chapter, abbreviating the invariant measure as

$$\widetilde{dp} \equiv \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}}. \tag{9.211}$$

9.7.1 The complex scalar as two real fields

The classical complex scalar was introduced as part of the recurring cast in Chapter 6, and its global phase symmetry and Noether current were derived in Chapter 7. We restate the Lagrangian for readability:

$$\mathcal{L} \;=\; (\partial_\mu \phi)^\dagger (\partial^\mu \phi) \;-\; m^2\, \phi^\dagger \phi, \tag{9.212}$$

where ϕ is now a complex field and $\phi^\dagger$ its Hermitian conjugate (in the classical theory, its complex conjugate ϕ^*; we write $\dagger$ in anticipation of operators). Varying $\phi^\dagger$ and ϕ independently gives two Klein–Gordon equations,

$$(\Box + m^2)\, \phi = 0, \qquad (\Box + m^2)\, \phi^\dagger = 0, \tag{9.213}$$

so both ϕ and $\phi^\dagger$ are on-shell at mass m. There is no second mass scale: whatever quanta the theory contains, they are degenerate. This degeneracy, which will become the statement that particle and antiparticle have equal mass, is built in from the start by the single coefficient m^2 in Eq. (9.212).

That a complex field is two real fields is not a metaphor. Write

$$\phi \;=\; \frac{1}{\sqrt{2}}(\phi_1 + i\,\phi_2), \qquad \phi^\dagger \;=\; \frac{1}{\sqrt{2}}(\phi_1 - i\,\phi_2), \tag{9.214}$$

with ϕ_1, ϕ_2 real (Hermitian). Substituting into Eq. (9.212) and using $\phi^\dagger\phi = \frac{1}{2}(\phi_1^2 + \phi_2^2)$ and the analogous identity for the kinetic term,

$$\mathcal{L} \;=\; \tfrac{1}{2}(\partial_\mu\phi_1)(\partial^\mu\phi_1) - \tfrac{1}{2}m^2\phi_1^2 \;+\; \tfrac{1}{2}(\partial_\mu\phi_2)(\partial^\mu\phi_2) - \tfrac{1}{2}m^2\phi_2^2. \tag{9.215}$$

The cross terms cancel because $(\partial\phi_1)(\partial\phi_2)$ enters $\phi^\dagger\phi$ and the kinetic piece with opposite signs from the $\pm i\phi_2$. So the complex theory is exactly two decoupled real Klein–Gordon fields of equal mass m. We *could* therefore quantize ϕ_1 and ϕ_2 separately by the construction already in hand and be done. We will instead quantize ϕ directly, because the natural ladder operators of the complex field – not those of ϕ_1, ϕ_2 – are the ones that diagonalize the charge, and it is the charge eigenstates that deserve the name "particle" and "antiparticle." Theorem 9.37 ties the two bookkeepings together explicitly.

Canonical structure. Treating ϕ and $\phi^\dagger$ as independent, the momenta conjugate to them are

$$\pi \;=\; \frac{\partial \mathcal{L}}{\partial \dot\phi} \;=\; \dot\phi^\dagger, \qquad \pi^\dagger \;=\; \frac{\partial \mathcal{L}}{\partial \dot\phi^\dagger} \;=\; \dot\phi. \tag{9.216}$$

Promoting fields to operators, we impose the equal-time commutation relations (ETCR), the complex-field analogue of the real-field relations established earlier in this chapter:

$$[\phi(\mathbf{x},t), \pi(\mathbf{y},t)] = i\,\delta^{(3)}(\mathbf{x}-\mathbf{y}), \qquad \left[\phi^\dagger(\mathbf{x},t), \pi^\dagger(\mathbf{y},t)\right] = i\,\delta^{(3)}(\mathbf{x}-\mathbf{y}), \tag{9.217}$$

with all other equal-time commutators among $\{\phi, \phi^\dagger, \pi, \pi^\dagger\}$ vanishing. In particular $\left[\phi, \phi^\dagger\right] = 0$ and $\left[\phi, \pi^\dagger\right] = 0$ at equal times: ϕ commutes with its own conjugate field and with the momentum $\pi^\dagger = \dot{\phi}$ conjugate to that conjugate. These are exactly the relations Eq. (9.215) would give for two independent real fields, repackaged.

9.7.2 Mode expansion and the two ladder sets

The operator solution of Eq. (9.213) is a superposition of positive- and negative-frequency plane waves, just as for the real field; the new feature is that the field is no longer Hermitian, so the coefficient of $e^{+ip\cdot x}$ need not be the conjugate of the coefficient of $e^{-ip\cdot x}$. We are free to introduce a *second, independent* set of operators there. Write

$$\phi(x) = \int \widetilde{dp}\left(a_{\mathbf{p}}\, e^{-ip\cdot x} + b^\dagger_{\mathbf{p}}\, e^{+ip\cdot x}\right), \tag{9.218}$$

$$\phi^\dagger(x) = \int \widetilde{dp}\left(a^\dagger_{\mathbf{p}}\, e^{+ip\cdot x} + b_{\mathbf{p}}\, e^{-ip\cdot x}\right), \tag{9.219}$$

with $p^0 = E_{\mathbf{p}}$ understood on shell. This is the central structural statement of the section, so read off what it says. The field ϕ *annihilates an a-quantum* (coefficient $a_{\mathbf{p}}$ of the positive-frequency wave) and *creates a b-quantum* (coefficient $b^\dagger_{\mathbf{p}}$ of the negative-frequency wave). The conjugate field $\phi^\dagger$ does the reverse: it creates an a-quantum and annihilates a b-quantum. The two species are not interchangeable – ϕ and $\phi^\dagger$ treat them oppositely – and this manifest asymmetry between ϕ and $\phi^\dagger$ is precisely what a single real field, with $b = a$, cannot exhibit. For the real field the reality condition $\phi = \phi^\dagger$ forces the negative-frequency coefficient to be the conjugate of the positive-frequency one; relaxing reality is exactly what opens up the second ladder set.

To pin down the algebra of $a_{\mathbf{p}}, b_{\mathbf{p}}$ we need the inversion formulas. Define the time-symmetric bilinear $f \overleftrightarrow{\partial}_0 g \equiv f\,\dot{g} - \dot{f}\,g$. Then, for any on-shell wave with $p^0 = E_{\mathbf{p}}$,

$$a_{\mathbf{p}} = \int d^3x\; e^{+ip\cdot x}\, i\overleftrightarrow{\partial}_0\, \phi(x), \qquad b_{\mathbf{p}} = \int d^3x\; e^{+ip\cdot x}\, i\overleftrightarrow{\partial}_0\, \phi^\dagger(x), \tag{9.220}$$

together with the Hermitian conjugates for $a^\dagger_{\mathbf{p}}, b^\dagger_{\mathbf{p}}$. We verify the first relation; the second is identical with $\phi \to \phi^\dagger$, i.e. $a \leftrightarrow b$. Using $i\, e^{ipx} \overleftrightarrow{\partial}_0\, \phi = i\, e^{ipx}\dot{\phi} + E_{\mathbf{p}}\, e^{ipx}\phi$ and inserting Eq. (9.218), the $a_{\mathbf{q}} e^{-iq\cdot x}$ term contributes a factor $(E_{\mathbf{q}} + E_{\mathbf{p}})\, e^{i(p-q)\cdot x}$, whose spatial integral $\int d^3x\, e^{-i(\mathbf{p}-\mathbf{q})\cdot\mathbf{x}} = (2\pi)^3\delta^{(3)}(\mathbf{p}-\mathbf{q})$ sets $\mathbf{q} = \mathbf{p}$, $E_{\mathbf{q}} = E_{\mathbf{p}}$, the time exponential to unity, and the factor to $2E_{\mathbf{p}}$; against the measure $\widetilde{dq}$ this collapses to $a_{\mathbf{p}}$. The $b^\dagger_{\mathbf{q}} e^{+iq\cdot x}$ term instead contributes $(E_{\mathbf{p}} - E_{\mathbf{q}})\, e^{i(p+q)\cdot x}$, and the spatial integral now forces $\mathbf{q} = -\mathbf{p}$, hence $E_{\mathbf{q}} = E_{\mathbf{p}}$ and the prefactor

$(E_{\mathbf{p}} - E_{\mathbf{q}}) = 0$: the antiparticle piece drops out. This is the algebraic content of "ϕ annihilates an a, not a b."

We can now derive the ladder algebra from the ETCR, rather than postulating it – exactly the discipline the real-field section followed.

Proposition 9.35 (Two independent ladder algebras from the complex ETCR)**.** *The ETCR Eq. (9.217) are equivalent to the commutation relations*

$$\left[a_{\mathbf{p}}, a^{\dagger}_{\mathbf{q}}\right] = \left[b_{\mathbf{p}}, b^{\dagger}_{\mathbf{q}}\right] = (2\pi)^3\, 2E_{\mathbf{p}}\, \delta^{(3)}(\mathbf{p}-\mathbf{q}), \tag{9.221}$$

with all other commutators among $\{a_{\mathbf{p}}, a^{\dagger}_{\mathbf{p}}, b_{\mathbf{p}}, b^{\dagger}_{\mathbf{p}}\}$ *– in particular the mixed ones* $[a_{\mathbf{p}}, b_{\mathbf{q}}]$, $\left[a_{\mathbf{p}}, b^{\dagger}_{\mathbf{q}}\right]$ *– vanishing.*

Proof. From Eq. (9.220) and $\pi^{\dagger} = \dot{\phi}$, $\pi = \dot{\phi}^{\dagger}$, the inversion formulas read, at the common time t,

$$a_{\mathbf{p}} = \int d^3x\; e^{ip\cdot x}(E_{\mathbf{p}}\,\phi + i\,\pi^{\dagger}), \qquad a^{\dagger}_{\mathbf{q}} = \int d^3y\; e^{-iq\cdot y}(E_{\mathbf{q}}\,\phi^{\dagger} - i\,\pi). \tag{9.222}$$

Their commutator receives contributions only from $[\phi, \pi]$ and $\left[\pi^{\dagger}, \phi^{\dagger}\right]$, since $\left[\phi, \phi^{\dagger}\right] = \left[\pi^{\dagger}, \pi\right] = 0$:

$$\begin{aligned}
\left[a_{\mathbf{p}}, a^{\dagger}_{\mathbf{q}}\right] &= \int d^3x\, d^3y\; e^{ip\cdot x} e^{-iq\cdot y}\left(-iE_{\mathbf{p}}\;[\phi(x), \pi(y)] + iE_{\mathbf{q}}\;\left[\pi^{\dagger}(x), \phi^{\dagger}(y)\right]\right) \\
&= \int d^3x\, d^3y\; e^{ip\cdot x} e^{-iq\cdot y}\;(E_{\mathbf{p}} + E_{\mathbf{q}})\;\delta^{(3)}(\mathbf{x}-\mathbf{y}) \\
&= \int d^3x\; e^{i(p-q)\cdot x}\;(E_{\mathbf{p}} + E_{\mathbf{q}}) \;=\; (2\pi)^3\, 2E_{\mathbf{p}}\,\delta^{(3)}(\mathbf{p}-\mathbf{q}),
\end{aligned} \tag{9.223}$$

where we used $[\phi, \pi] = i\delta^{(3)}$ and $\left[\pi^{\dagger}, \phi^{\dagger}\right] = -\left[\phi^{\dagger}, \pi^{\dagger}\right] = -i\delta^{(3)}$, and in the last step the spatial integral set $\mathbf{q} = \mathbf{p}$. The same computation with $\phi \to \phi^{\dagger}$ gives $\left[b_{\mathbf{p}}, b^{\dagger}_{\mathbf{q}}\right] = (2\pi)^3 2E_{\mathbf{p}}\delta^{(3)}(\mathbf{p}-\mathbf{q})$. For the mixed commutator, write $b^{\dagger}_{\mathbf{q}} = \int d^3y\, e^{-iq\cdot y}(E_{\mathbf{q}}\phi - i\pi^{\dagger})$; then $\left[a_{\mathbf{p}}, b^{\dagger}_{\mathbf{q}}\right]$ involves only $[\phi, \phi]$, $\left[\phi, \pi^{\dagger}\right]$, $\left[\pi^{\dagger}, \phi\right]$ and $\left[\pi^{\dagger}, \pi^{\dagger}\right]$, every one of which vanishes by Eq. (9.217). Hence $\left[a_{\mathbf{p}}, b^{\dagger}_{\mathbf{q}}\right] = 0$, and likewise $[a_{\mathbf{p}}, b_{\mathbf{q}}] = 0$. The converse – that Eq. (9.221) reproduces Eq. (9.217) when substituted back into Eqs. (9.218) and (9.219) – follows by the identical Fourier manipulation run in reverse, exactly as for the real field. □

The two ladder sets are therefore genuinely independent: they commute with one another and each obeys the standard relativistically normalized oscillator algebra. The Fock construction now proceeds in duplicate. There is a single vacuum $|0\rangle$, annihilated by *both* families,

$$a_{\mathbf{p}}\,|0\rangle = b_{\mathbf{p}}\,|0\rangle = 0 \quad \forall\,\mathbf{p}, \qquad \langle 0|0\rangle = 1, \tag{9.224}$$

and two towers of excitations built on it. We call the a-quanta *particles* and the b-quanta *antiparticles*; the relativistically normalized one-quantum states are

$$|\mathbf{p}\rangle_a = a^\dagger_{\mathbf{p}}\,|0\rangle\,, \qquad |\mathbf{p}\rangle_b = b^\dagger_{\mathbf{p}}\,|0\rangle\,, \qquad {}_a\langle\mathbf{p}|\mathbf{q}\rangle_a = {}_b\langle\mathbf{p}|\mathbf{q}\rangle_b = (2\pi)^3 2E_{\mathbf{p}}\,\delta^{(3)}(\mathbf{p}-\mathbf{q}). \tag{9.225}$$

Both species carry the mass-m, spin-0 Poincaré quantum numbers classified in Chapter 3, because both are excitations of the same mass-m field; what distinguishes them is not a spacetime label but the internal charge to which we now turn. The two corresponding number operators are

$$N_a = \int \widetilde{dp}\; a^\dagger_{\mathbf{p}} a_{\mathbf{p}}, \qquad N_b = \int \widetilde{dp}\; b^\dagger_{\mathbf{p}} b_{\mathbf{p}}. \tag{9.226}$$

Physical Insight

The names "particle" and "antiparticle" are at this stage simply labels for the two commuting oscillator families. They earn physical meaning only once we exhibit a measurable quantity – the conserved charge – that takes opposite values on them. Until then, nothing distinguishes a from b: the Hamiltonian, which one obtains by the same substitution as in the real case and which reads $H = \int \widetilde{dp}\, E_{\mathbf{p}}\,(a^\dagger_{\mathbf{p}} a_{\mathbf{p}} + b^\dagger_{\mathbf{p}} b_{\mathbf{p}})$ after normal ordering, treats them symmetrically and assigns them equal energy. Mass and spin cannot tell a particle from its antiparticle; only charge can.

9.7.3 The conserved U(1) charge as an operator

The Lagrangian Eq. (9.212) is invariant under the global phase rotation $\phi \to e^{-i\alpha}\phi$, $\phi^\dagger \to e^{+i\alpha}\phi^\dagger$. By Noether's theorem (Theorem 7.10) this symmetry carries a conserved current, derived in Chapter 7 and recorded there as Eq. (7.70),

$$j^\mu \;=\; i(\phi^\dagger\,\partial^\mu\phi - (\partial^\mu\phi^\dagger)\,\phi), \qquad \partial_\mu j^\mu = 0, \tag{9.227}$$

the four-divergence vanishing on shell by Eq. (9.213). The associated conserved charge is the spatial integral of the time component, which we now promote to an operator:

$$Q \;=\; \int d^3x\; j^0(x) \;=\; i\int d^3x\;(\phi^\dagger\dot\phi - \dot\phi^\dagger\,\phi) \;=\; i\int d^3x\;\phi^\dagger \overleftrightarrow{\partial}_0\,\phi. \tag{9.228}$$

Classically Q is time independent; as an operator it will commute with H. Our task is to express it in the ladder basis, where its action is transparent.

Theorem 9.36 (The charge operator)**.** *With the normal-ordering prescription that places all annihilation operators to the right (which fixes the additive constant by demanding $Q\,|0\rangle = 0$), the charge Eq. (9.228) is*

$$Q \;=\; \int \widetilde{dp}\;(a^\dagger_{\mathbf{p}} a_{\mathbf{p}} - b^\dagger_{\mathbf{p}} b_{\mathbf{p}}) \;=\; N_a - N_b. \tag{9.229}$$

It generates the U(1) *symmetry and assigns the ladder operators definite charges,*

$$\left[Q, a_{\mathbf{p}}^\dagger\right] = +a_{\mathbf{p}}^\dagger, \quad \left[Q, b_{\mathbf{p}}^\dagger\right] = -b_{\mathbf{p}}^\dagger, \quad [Q, a_{\mathbf{p}}] = -a_{\mathbf{p}}, \quad [Q, b_{\mathbf{p}}] = +b_{\mathbf{p}}, \tag{9.230}$$

so that a particle carries charge $+1$ *and an antiparticle charge* -1*, in units of the coupling.*

Proof. Insert the mode expansions Eqs. (9.218) and (9.219) and their time derivatives,

$$\dot\phi = \int \widetilde{dp}\,(-iE_{\mathbf{p}})(a_{\mathbf{p}}e^{-ip\cdot x} - b_{\mathbf{p}}^\dagger e^{+ip\cdot x}), \qquad \dot\phi^\dagger = \int \widetilde{dq}\,(+iE_{\mathbf{q}})(a_{\mathbf{q}}^\dagger e^{+iq\cdot x} - b_{\mathbf{q}}e^{-iq\cdot x}), \tag{9.231}$$

into $\int d^3x\,(\phi^\dagger\dot\phi - \dot\phi^\dagger\phi)$. Each $\int d^3x$ produces $(2\pi)^3$ times either $\delta^{(3)}(\mathbf{p}-\mathbf{q})$ (from terms whose spatial exponentials are $e^{\pm i(\mathbf{p}-\mathbf{q})\cdot\mathbf{x}}$) or $\delta^{(3)}(\mathbf{p}+\mathbf{q})$ (from $e^{\pm i(\mathbf{p}+\mathbf{q})\cdot\mathbf{x}}$). Carrying out the $\widetilde{dq}$ integral against these deltas and tracking the phases, $\int d^3x\,\phi^\dagger\dot\phi$ evaluates to

$$\int \widetilde{dp}\left[\tfrac{-i}{2}\,a_{\mathbf{p}}^\dagger a_{\mathbf{p}} + \tfrac{i}{2}\,b_{\mathbf{p}}b_{\mathbf{p}}^\dagger + \tfrac{i}{2}\,e^{+2iE_{\mathbf{p}}t}\,a_{-\mathbf{p}}^\dagger b_{\mathbf{p}}^\dagger - \tfrac{i}{2}\,e^{-2iE_{\mathbf{p}}t}\,b_{-\mathbf{p}}a_{\mathbf{p}}\right], \tag{9.232}$$

where $a_{-\mathbf{p}} \equiv a_{\mathbf{q}}\big|_{\mathbf{q}=-\mathbf{p}}$ and we used $E_{-\mathbf{p}} = E_{\mathbf{p}}$. The companion piece $\int d^3x\,\dot\phi^\dagger\phi$ gives

$$\int \widetilde{dp}\left[\tfrac{+i}{2}\,a_{\mathbf{p}}^\dagger a_{\mathbf{p}} - \tfrac{i}{2}\,b_{\mathbf{p}}b_{\mathbf{p}}^\dagger + \tfrac{i}{2}\,e^{+2iE_{\mathbf{p}}t}\,a_{-\mathbf{p}}^\dagger b_{\mathbf{p}}^\dagger - \tfrac{i}{2}\,e^{-2iE_{\mathbf{p}}t}\,b_{-\mathbf{p}}a_{\mathbf{p}}\right]. \tag{9.233}$$

The two time-dependent off-diagonal structures – $a^\dagger b^\dagger$ and ba – appear with identical coefficients in both, so they *cancel* in the difference $\phi^\dagger\dot\phi - \dot\phi^\dagger\phi$. This cancellation is the operator statement that Q is conserved: had they survived, Q would carry the explicit time dependence $e^{\pm 2iE_{\mathbf{p}}t}$. What remains is purely diagonal,

$$\int d^3x\,(\phi^\dagger\dot\phi - \dot\phi^\dagger\phi) = \int \widetilde{dp}\,(-i\,a_{\mathbf{p}}^\dagger a_{\mathbf{p}} + i\,b_{\mathbf{p}}b_{\mathbf{p}}^\dagger), \tag{9.234}$$

and multiplying by the prefactor i from Eq. (9.228),

$$Q = \int \widetilde{dp}\,(a_{\mathbf{p}}^\dagger a_{\mathbf{p}} - b_{\mathbf{p}}b_{\mathbf{p}}^\dagger). \tag{9.235}$$

The antiparticle term is in the "wrong" order. Using $b_{\mathbf{p}}b_{\mathbf{p}}^\dagger = b_{\mathbf{p}}^\dagger b_{\mathbf{p}} + \left[b_{\mathbf{p}}, b_{\mathbf{p}}^\dagger\right]$ and Eq. (9.221),

$$Q = \int \widetilde{dp}\,(a_{\mathbf{p}}^\dagger a_{\mathbf{p}} - b_{\mathbf{p}}^\dagger b_{\mathbf{p}}) - \int \widetilde{dp}\,(2\pi)^3 2E_{\mathbf{p}}\,\delta^{(3)}(0) = \int \widetilde{dp}\,(a_{\mathbf{p}}^\dagger a_{\mathbf{p}} - b_{\mathbf{p}}^\dagger b_{\mathbf{p}}) - \int d^3p\,\delta^{(3)}(0). \tag{9.236}$$

The subtracted term is a (divergent) c-number, the charge analogue of the zero-point energy. Unlike the vacuum energy it is naturally zero rather than merely

irrelevant: normal ordering, defined here as moving all annihilation operators to the right, discards it and enforces $Q\,|0\rangle = 0$, the physically obvious statement that the vacuum is neutral. This gives Eq. (9.229).

The commutators Eq. (9.230) now follow from Eq. (9.221). Since $\left[a^\dagger_{\mathbf{q}} a_{\mathbf{q}}, a^\dagger_{\mathbf{p}}\right] = a^\dagger_{\mathbf{q}}\left[a_{\mathbf{q}}, a^\dagger_{\mathbf{p}}\right] = a^\dagger_{\mathbf{q}}(2\pi)^3 2E_{\mathbf{q}}\delta^{(3)}(\mathbf{q}-\mathbf{p})$, and b commutes with a,

$$\left[Q, a^\dagger_{\mathbf{p}}\right] = \int \widetilde{dq}\; a^\dagger_{\mathbf{q}}\,(2\pi)^3 2E_{\mathbf{q}}\,\delta^{(3)}(\mathbf{q}-\mathbf{p}) = a^\dagger_{\mathbf{p}}. \tag{9.237}$$

The minus sign in $-b^\dagger b$ flips the result for b, giving $\left[Q, b^\dagger_{\mathbf{p}}\right] = -b^\dagger_{\mathbf{p}}$; the annihilation-operator relations are the Hermitian conjugates. Finally, applying Eq. (9.230) to the field, $[Q,\phi] = \int \widetilde{dp}([Q, a_{\mathbf{p}}]\, e^{-ipx} + \left[Q, b^\dagger_{\mathbf{p}}\right] e^{ipx}) = -\phi$, so $e^{i\alpha Q}\phi\, e^{-i\alpha Q} = e^{-i\alpha}\phi$: Q is the generator of the U(1) rotation it was built from, closing the loop with Noether. □

The reading of Eq. (9.229) is the whole point. The charge counts particles minus antiparticles. Acting on the one-quantum states Eq. (9.225),

$$Q\;|\mathbf{p}\rangle_a = +\,|\mathbf{p}\rangle_a\,, \qquad Q\;|\mathbf{p}\rangle_b = -\,|\mathbf{p}\rangle_b\,, \tag{9.238}$$

exhibiting two species of equal mass m (both on the shell $E_{\mathbf{p}} = \sqrt{\mathbf{p}^2 + m^2}$ of the single field) and opposite charge ± 1. This is the rigorous form of the statement that to every charged particle there corresponds an antiparticle of the same mass and opposite charge – here not a postulate or an appeal to the Dirac sea, but a theorem about the spectrum of Q on the Fock space of one complex field. Because $[Q, H] = 0$ (both are diagonal in the number operators), charge is conserved under time evolution, and because Q generates the symmetry, charge superselects: states of different Q never mix.

Caution

The overall sign and the unit of Q are conventions, inherited from the choice of phase direction in the U(1) rotation and from any coupling constant one factors out of the current Eq. (9.227). What is convention-independent, and physical, is that the two species carry *opposite* charge of *equal* magnitude, and that the vacuum and the Hamiltonian are neutral. When this scalar is later gauged in QED, the unit of Q becomes the electric charge q in the covariant derivative $D_\mu = \partial_\mu - iqA_\mu$, and the sign convention here must be matched to the gauge-coupling sign convention fixed book-wide.

Worked Example 9.37 (The two real fields, the charge as a rotation, and charge eigenstates)**.** We reconcile the complex ladder operators with the two-real-field picture of Eq. (9.214), and see the charge as the generator of rotations

in the (ϕ_1, ϕ_2) plane. Quantize ϕ_1, ϕ_2 as two independent real scalars with ladder operators $a_{1,\mathbf{p}}, a_{2,\mathbf{p}}$ obeying $\left[a_{i,\mathbf{p}}, a^\dagger_{j,\mathbf{q}}\right] = \delta_{ij}(2\pi)^3 2E_{\mathbf{p}}\delta^{(3)}(\mathbf{p}-\mathbf{q})$, all cross-commutators zero. Substituting the real-field mode expansions into Eq. (9.214) and matching to Eq. (9.218), the coefficient of $e^{-ip\cdot x}$ is $a_{\mathbf{p}}$ and that of $e^{+ip\cdot x}$ is $b^\dagger_{\mathbf{p}}$, giving

$$a_{\mathbf{p}} = \frac{1}{\sqrt{2}}(a_{1,\mathbf{p}} + i\, a_{2,\mathbf{p}}), \qquad b_{\mathbf{p}} = \frac{1}{\sqrt{2}}(a_{1,\mathbf{p}} - i\, a_{2,\mathbf{p}}). \tag{9.239}$$

This is a change of basis on the pair of oscillators at each $\mathbf{p}$. One checks the algebra directly:

$$\left[a_{\mathbf{p}}, a^\dagger_{\mathbf{q}}\right] = \tfrac{1}{2}\left[a_{1,\mathbf{p}} + ia_{2,\mathbf{p}}, a^\dagger_{1,\mathbf{q}} - ia^\dagger_{2,\mathbf{q}}\right] = \tfrac{1}{2}\left(\left[a_{1,\mathbf{p}}, a^\dagger_{1,\mathbf{q}}\right] + \left[a_{2,\mathbf{p}}, a^\dagger_{2,\mathbf{q}}\right]\right) = (2\pi)^3 2E_{\mathbf{p}}\delta^{(3)}(\mathbf{p}-\mathbf{q}) \tag{9.240}$$

$$\left[a_{\mathbf{p}}, b^\dagger_{\mathbf{q}}\right] = \tfrac{1}{2}\left[a_{1,\mathbf{p}} + ia_{2,\mathbf{p}}, a^\dagger_{1,\mathbf{q}} + ia^\dagger_{2,\mathbf{q}}\right] = \tfrac{1}{2}\left(\left[a_{1,\mathbf{p}}, a^\dagger_{1,\mathbf{q}}\right] - \left[a_{2,\mathbf{p}}, a^\dagger_{2,\mathbf{q}}\right]\right) = 0, \tag{9.241}$$

recovering Eq. (9.221) and the independence of a and b. Substituting Eq. (9.239) into $N_a - N_b$ and simplifying, the diagonal pieces cancel and the charge becomes

$$Q = \int \widetilde{dp}\; (a^\dagger_{\mathbf{p}} a_{\mathbf{p}} - b^\dagger_{\mathbf{p}} b_{\mathbf{p}}) = \int \widetilde{dp}\; (-i\, a^\dagger_{1,\mathbf{p}} a_{2,\mathbf{p}} + i\, a^\dagger_{2,\mathbf{p}} a_{1,\mathbf{p}}), \tag{9.242}$$

the generator that rotates $a_1 \leftrightarrow a_2$: this is the $\mathrm{SO}(2) \cong \mathrm{U}(1)$ realized on the two real fields. Neither $a^\dagger_{1,\mathbf{p}}|0\rangle$ nor $a^\dagger_{2,\mathbf{p}}|0\rangle$ is a charge eigenstate; the eigenstates are the complex combinations $a^\dagger_{\mathbf{p}}|0\rangle$ and $b^\dagger_{\mathbf{p}}|0\rangle$, with $Q = \pm 1$. This is why the complex basis is the physical one: a quantum of definite charge is a specific superposition of a ϕ_1-quantum and a ϕ_2-quantum, and only that superposition has a definite value of the conserved observable.

9.7.4 The charged propagator and the flow of charge

The dynamical object that will become the internal line of every Feynman diagram is again the time-ordered two-point function. For the charged field the relevant ordering pairs ϕ with $\phi^\dagger$, because – as the mode content of Eqs. (9.218) and (9.219) makes clear – only that pairing can connect the vacuum to itself. Consider first the two Wightman orderings. For $x^0 > y^0$, only the particle term contributes,

$$\left\langle 0|\phi(x)\phi^\dagger(y)|0\right\rangle = \int \widetilde{dp}\,\widetilde{dq}\; e^{-ip\cdot x} e^{+iq\cdot y}\left\langle 0|a_{\mathbf{p}} a^\dagger_{\mathbf{q}}|0\right\rangle = \int \widetilde{dp}\; e^{-ip\cdot(x-y)} \;\equiv\; D(x-y), \tag{9.243}$$

using $\left\langle 0|a_{\mathbf{p}} a^\dagger_{\mathbf{q}}|0\right\rangle = (2\pi)^3 2E_{\mathbf{p}}\delta^{(3)}(\mathbf{p}-\mathbf{q})$ and the invariant measure to collapse the $\widetilde{dq}$ integral; D is the same positive-frequency Wightman function met for the

real field. For $y^0 > x^0$, only the antiparticle term survives, because now we need an annihilation acting first on the right vacuum:

$$\Big\langle 0|\phi^\dagger(y)\phi(x)|0\Big\rangle = \int \widetilde{dp}\,\widetilde{dq}\; e^{-iq\cdot y}e^{+ip\cdot x}\,\Big\langle 0|b_{\mathbf{q}}b^\dagger_{\mathbf{p}}|0\Big\rangle = \int \widetilde{dp}\; e^{+ip\cdot(x-y)} \;=\; D(y-x). \tag{9.244}$$

The Feynman propagator is the time-ordered combination,

$$D_F(x-y) \;=\; \Big\langle 0|\mathcal{T}\,\phi(x)\phi^\dagger(y)|0\Big\rangle \;=\; \theta(x^0-y^0)\,D(x-y) + \theta(y^0-x^0)\,D(y-x). \tag{9.245}$$

Structurally this is identical to the real-scalar time-ordered function: the same two Wightman pieces glued by step functions. The physics packed into it, however, is now sharper. When $x^0 > y^0$ a *particle* of charge $+1$ is created at y by $\phi^\dagger(y)$ and annihilated at x by $\phi(x)$; when $y^0 > x^0$ an *antiparticle* of charge -1 is created at x and annihilated at y. In both orderings the net charge transported from y to x is $+1$: a particle going forward, or an antiparticle going backward, move one unit of charge the same way. This is the precise content of the slogan that an antiparticle is a particle propagating backward in time, and it is why the charged propagator carries an *arrow*: the line has an orientation, from the $\phi^\dagger$ end (charge in) to the ϕ end (charge out). Figure 9.7 records this.

Because Eq. (9.245) is the same step-function combination of the same Wightman functions as in the neutral case, the contour representation derived earlier in this chapter applies verbatim, and we may quote it:

$$D_F(x-y) = \int \frac{d^4p}{(2\pi)^4}\,\frac{i\,e^{-ip\cdot(x-y)}}{p^2-m^2+i\varepsilon}, \tag{9.246}$$

with the Feynman $i\varepsilon$ routing the positive-frequency pole below and the negative-frequency pole above the real p^0 axis, exactly as in Eq. (9.154). The charged scalar propagator is, in momentum space, indistinguishable from the neutral one; all the new information lives in the orientation of the line, not in the analytic form.

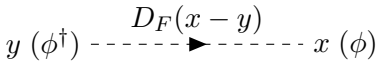

Figure 9.7: The charged scalar propagator as an oriented internal line. The arrow points from the $\phi^\dagger$ insertion at y to the ϕ insertion at x, recording the flow of one unit of U(1) charge from y to x. A particle propagating forward in time and an antiparticle propagating backward carry this charge identically, which is why a single oriented line suffices. A neutral scalar line, by contrast, carries no arrow.
